Staging and Treatment of Hodgkin's Disease

J. L. AMIEL and J. P. DROZ
Service de Medecine A, Institut Gustave-Roussy, 94800–Villejuif, France

THE FIGHT against illness is like any other kind of warfare, inasmuch as it comprises a period of open conflict, with spear-head thrusts and sweeping advances, followed by a phase during which control over conquered territory has to be consolidated.

We believe this phase has now been reached for Hodgkin's disease. Recent years have seen revolutionary progress in the approach of the illness and its treatment: noteworthy developments include the use of lymphography [1], the use of new histological classifications [2, 3] and the practice of laparotomy accompanied by splenectomy and ovary transposition [1, 4, 5]. In the field of radiotherapy, new irradiation techniques have been introduced with more penetrating sources, higher doses, for wider targets with lymphnode areas anatomically or physiologically adjacent, to the lesions [6, 7]. Progress in chemotherapy includes new effective drugs such as periwinkle alcaloids and procarbazine, as well as new methods of administering and combining drugs, and combination of radio and chemotherapy [7–9]. All this has radically changed the picture as regards Hodgkin's disease and its treatment.

A feeling of uneasiness, however, is beginning to mar the general satisfaction at these successes, for which no cancerologist of the preceding generation would have dared to hope. For some people consider that the accumulation of procedures, improvements, and even minor trimmings, are beginning to give the clinical picture of Hodgkin's disease a somewhat over-elaborated and overloaded look that does not simply detract from its elegance but undermines its soundness. Patients are cured twice over (by radiotherapy and chemotherapy) which may sometimes be once too much. For chemotherapy aplasias, unpleasant after effects and serious complications of radiotherapy may even prove fatal, and such patients, who are supposed to have been cured, may be left with extensive sclerosis, mediastinitis, pericarditis, post-radial myelopathia, castration in women, azospermia in men, secondary malignant diseases, epithelioma, sarcoma and even leukemia [7, 9]. All this calls for a more appropriate economy of means in effecting cures and for more comfort for the patients once they have been completed.

Some of the practices used to combat Hodgkin's disease are necessary, but others are questionable, either on account of their gravity or because their interest is uncertain.

The necessary medical acts need only to be listed here briefly: they include histological biopsy, indispensable for diagnosis, anamnesis and an effort to ascertain whether the patient is suffering or has suffered from fever, noteworthy loss of weight or intensive sweating. Clinical and radiological surveys are also necessary, including X-rays of the thorax, inclined frontal tomographies and bilateral lymphography, as biological test, no more sophisticated test has yet been able to replace the sedimentation rate.

The decision considered controversial on account of its gravity is laparotomy with splenectomy [1, 4, 5, 7, 10].

Few problems appear to have been tackled in a more irrational manner, yet the motives for such action are simple and logical: lymphography cannot explore the entire lymphnode regions in the abdomen, the interpretation of liver and spleen scintigraphy is problematical and there is not even any correlation between the size of the spleen and its penetration by the disease. For all these reasons, exploratory laparotomy and splenectomy, with all the successive lymphnode liver and bone biopsies they imply, are necessary to obtain a complete picture of the subdiaphragmatic stage of Hodgkin's disease [7]. Yet laparotomy involves delaying essential

therapy, as well as a certain rate of morbidity or even mortality (a mortality rate, however low, is inevitable in abdominal surgery) and systematic removal of so-called normal spleens, all this in relation to patients whose immunological balance is already disturbed. Some people believe preliminary laparotomy has such obvious advantages that they can no longer conceive of treating Hodgkin's disease without it, whatever the clinical stage of the case (Kaplan thinks this even holds for Stage IV, which seems a little extreme); others feel the drawbacks and risks of laparotomy so keenly that they refuse to perform it at all.

Such confusion is normal during the years of trials that follow the introduction of a new technique, but practical experience usually clarifies the situation. Unfortunately this has not been the case for laparotomy in Hodgkin's disease and the position is still confused. The practice of laparotomy has chiefly led to negative conclusions, making it clear, for instance, that spleen size and splenic scintigraphy do little to make prediction of its Hodgkin infiltration, that the spleen may simply be large for "reactional" reasons and that, in particular, the clinical and histological staging do not permit reliable forecasts of splenic conditions [4, 5, 7]. True, the more advanced the prelaparotomy staging the more likely the spleen is to be positive, and in Stages I and II splenic infiltration does indeed seem more common where histological type is bad (mixed cellularity and lymphocyte depletion). All the same, in Stages I and II and therefore, in prelaparotomy staging with only upper diaphragmatic lesions, about 20% of spleens are positive even when histological type is good (lymphocyte predominance or nodular sclerosis [1, 4, 5, 7]. Many consider that this solves the problem, since such a high spleen lesion rate, unexpected, under what appear to be the most favourable conditions, makes it imperative to take systematic action with regard to the spleen, and, if it is not removed, it will have to be irradiated. But the problem is not so simple: to disregard spleen lesions in 20 out of 100 patients during the initial treatment does not mean that they are lost cases. One does not know how microscopic lesions would develop. Let us assume that they would all tend to become "visible". In such cases a second course of treatment, centred on splenectomy, ensures a high percentage of long remissions and probable cures, for cases with "good histology". What are the effects of splenectomy or spleen irradiation on the other 80 patients whose spleen is "negative"? The basic problem is in fact to know, for Stages I and II, if systematic initial laparotomy and splenectomy lead, in the "short run" (roughly the duration of the first remission) and, even more, in the "long run" (duration of survival) to better, comparable or worse results than those obtained if laparotomy is not systematic (splenectomy being performed later, should any splenic lesions develop). Although it is generally acknowledged that initial laparotomy and splenectomy helped to improve our understanding of Hodgkin's disease [1, 4, 5, 7], it is not certain that they improve patients' life expectancy.

The results of a trial conducted along these lines might vary according to the presentations of the disease. Oddly enough, however, in this era of randomized, cooperative and international trials, such a trial has never been carried out, or even initiated. The only choice left to the therapist is removal of the spleen or irradiation of the splenic region, with the obvious drawbacks this involves for the left kidney and left costal diaphragmatic sinus. Systematic laparotomy accompanied by splenectomy is therefore tending to become generalized for Stages I, II and IIIA, regardless of histological types, which is reasonable in the light of present results. But the matter is unlikely to end there, and a greater variety of indications will no doubt gradually come to light. However, as long as no trials are conducted of the kind described above, this regrettable deficiency will make the process long and difficult.

On top of all this, case histories of Hodgkin's disease have generally been enriched or encumbered by investigations the practical contribution of which to progress has not always been obvious. For instance, the illness seems to attract all the new techniques in radiology. The various kinds of arteriography and cavography are not to be used in this disease, liver and spleen scintigraphy can be useful, provided one remembers that they lead to extremely uncertain conclusions. As regards the radiological aspects of the illness, we believe that in recent years technetium pyrophosphate bone scintigraphy, a remarkably sound technique, is the most outstanding progress.

Biologists, and above all immunologists, seem even more fascinated by Hodgkin's disease than radiologists. No research group that has initiated work on immunological tests has failed to start off by initiating a programme for the study of Hodgkin's disease. At one time, it seemed probable that immunologists, like clinicians and histologists, would succeed in establishing a classification system for Hodgkin's disease which would lead to a prognosis and help to determine the treatment prescribed. However this hope has

not materialized [11] and it cannot be said that even the most sophisticated immunological surveys have added much to our understanding of Hodgkin's disease, over and above the initial observation of frequent tuberculin anergy.

The immunologists have certainly not said their last word and will, no doubt, succeed in working out more instructive tests than those currently in use. However, even though this type of research should continue, nothing, if the patients' interests alone are considered, can, at the present time, justify any delay whatever in initiating the treatment to perfect the immunological survey.

In our present knowledge of Hodgkin's disease, a good staging [1, 5] can be simple, and even sparing of investigations.

Although the procedures involved in drawing up staging of Hodgkin's disease sometimes seem cluttered up with superfluous investigations, that this is even truer as regards treatment, which is positively inflationary, with radio and chemotherapists jostling each other in their eagerness to look after these patients, who are actually curable.

Despite the progress in this sphere during the past 20 yr, complete agreement has never been reached on any one form of the illness. Nevertheless a few well-established facts are now formally recognized and we believe they ought to guide our present choices. In Stages I, II and IIIA of Hodgkin's disease, permanent cures can be obtained by radiotherapy [6, 7]. The doses are well codified—4000 rad in 4 weeks; treatment should be directed at a large field that takes in affected lymph node areas and the areas adjoining them. Upper diaphragmatic lesions require mantle irradiation.

More recent trials showed that either splenectomy or irradiation of the splenic region, as well as systematic irradiation of the lumbaraortic lymph nodes, one month after mantle irradiation, considerably improve longterm results for upper diaphragmatic lesions of Stages I and II. Where the histology of such cases is poor (mixed cellularity and lymphocyte depletion) the results of irradiation alone can be improved by a second treatment comprising systematic chemotherapy, provided it extends over a prolonged period of 18 months to 2 yr and is well tolerated, as is the case for prolonged vinblastine chemotherapy [6]. IIIA stages require mantle irradiation, followed by inversed γ-irradiation after a month's interval; there again, secondary extended chemotherapy seems helpful.

Discussion regarding treatment of these stages centres on the possible interest of applying chemotherapy before radiotherapy. Encouraging results have been reported by this method [8] but there is of course the risk that such chemotherapy, designed to improve the essential means of treatment—radiotherapy—may jeopardize the latter's effect by imposing limitation of dosage; there is also the danger that even when the treatment is well tolerated it may exceed what is necessary to effect a cure, and this might have long term consequences which are still difficult to assess, such as azoospermia or malignant secondary disease.

Another established fact is the remarkable effectiveness of combined chemotherapy in Stage IV cases: thus, 80% complete remissions were obtained using the MOPP Protocol (nitrogen mustard, vincristine, procarbazine and prednisone) or its derivatives [9, 10]. Long term results are not perhaps as good as expected, since delayed relapses were frequent.

The problem is to find out what can be done after the conclusion of MOPP treatment, which in principle lasts only 6 months. It would be possible to continue courses of MOPP and lengthen the intervals between them but in practice this could involve a risk of lasting aplasia, perhaps due in the main to the repeated doses of nitrogen mustard. Often, the only possible treatment after MOPP is chemotherapy with one compound having little myelotoxicity, such as the administration of vinblastine over a prolonged period.

Stage IIIB cases ("B" signs are fever, 10% loss of wt and sweating at night) are probably those that involve the largest number of poorly solved problems; moreover it is in this field that chemo- and radiotherapists find it most difficult to delineate their respective spheres of action.

In practice, some IIIB cases are "big" IIIB cases, with high fever, drastic loss of wt and alarming general condition. Some are "little or minor" IIIB cases with a light and passing fever or occasional night sweating.

It seems clear to us that treatment of "big" IIIB cases should start with chemotherapy. Indeed it would take an extremely unrelenting radiotherapist to push a patient shivering with fever under high-powered irradiation devices [7]. The results of MOPP-type chemotherapy, or its derivatives, have proved excellent [8, 9, 10]. However it remains to be seen whether chemotherapy alone can be relied on to cure such cases.

Some use only chemotherapy, full course of MOPP followed by whatever long term chemotherapy remains possible. Some after a chemotherapy, for instance 3 courses of MOPP, will attempt eradication radiotherapy, followed by a second course of chemotherapy, according to the

hematological tolerance of the patient, 3 courses of MOPP if it is good, vinblastine only if it is poor.

In the case of so-called minor IIIBs there will obviously be a tendency to use the second method of successive chemo- and radiotherapy; one might even start with eradication radiotherapy and follow it up systematically with chemotherapy over a prolonged period.

Trials provide the only means of elucidating these questions, although this will not be easy because the concept of IIIB is so much clearer in theory than in practice.

To sum up the present position, it seems reasonable to suggest the following clinical procedures for treating Hodgkin's disease: for Stages I, II and IIIA—laparotomy accompanied by splenectomy; after that, cases remaining in Stages I and II may be treated by mantle field radiotherapy followed by lumbar-aortic radiotherapy; "bad" forms of such cases (poor histology or over 40 yr old) should then be subjected to extended chemotherapy, for instance one and a half or two yr vinblastine treatment. Stage IV should be given MOPP-type chemotherapy followed by extended chemotherapy, the most effective and easiest form to handle being vinblastine treatment. A major IIIB case should either be treated like a Stage IV or be given several courses of chemotherapy (for instance, 3 series of MOPP) followed by eradication radiotherapy and extended vinblastine chemotherapy. This procedure could also be applied to minor IIIB cases, the very slight IIIBs being treated like IIIAs.

Hodgkin's disease has occupied the limelight for 20 yr now in the cancer field and has perhaps suffered from being in the forefront for so long. Some patients seem positively overburdened by all the different protocols controlled by immunologists, surgeons, radiotherapists and chemotherapists. However, since much has now been done for this disease, a great deal of attention and enthusiasm will now be switched to other malignant diseases, and this will create a calmer climate in which to effect the painstaking adjustments still necessary to bring Hodgkin's disease under more complete control.

Biochemical and Clinical Studies of Chronic Lymphocytic Leukemia*

YOUCEF M. RUSTUM and DONALD J. HIGBY

Departments of Medicine A and Grace Cancer Drug Center, Roswell Park Memorial Institute, Buffalo, NY 14263, *U.S.A.*

Abstract—*Attempts were made to identify biochemical parameters that would characterize leukemic cells obtained from patients with chronic lymphocytic leukemia at early stages of the disease and with more aggressive phases. These studies included (a) the quantitative estimation of the ribonucleotide pool and of the ability of the cells to utilize* de novo *vs salvage metabolites; and (b) the measurement of the extent of metabolic activation of selected antimetabolites such as ara-C and 6-MP. Cells obtained from the peripheral blood of six male patients with chronic lymphocytic leukemia were shown to possess a reduced ability to utilize* de novo *pathways of purine and pyrimidine biosynthesis as indicated by the lack of ATP and UTP formation from glycine and orotic acid, respectively. In one of these patients, however, although the cells initially lacked the ability of utilizing glycine and orotate, a progressive increase in TdR and glycine incorporation into nucleic acid was observed, and was found to reach a plateau within two months prior to death. In another patient, the ability of cells to utilize glycine for the formation of ATP was found to be coincident with the appearance of advanced and aggressive disease. Concurrent with these shifts from total reliance of cells on salvage pathways for nucleic acid synthesis, to at least partial dependence on* de novo *pathways, a change in the ribonucleotide profile was observed with a shift from lower to higher ATP/IMP ratios. In the four other patients studied, the clinical and the biochemical profiles were both stable and unchanged to date.*

INTRODUCTION

CHRONIC lymphocytic leukemia (CLL) is a disease which frequently evolves from a benign lymphocytosis to a clinically serious disorder, characterized by problems such as obstructive lymphadenopathy and anemia, thrombocytopenia, granulocytopenia, cutaneous disorders and defects in humoral immunity [1]. Since the disease usually runs a protracted course, it is not uncommon for patients to become refractory to conventional therapy at a time when they remain in otherwise relatively good clinical condition. The inability to offer further effective therapy at this stage results in the gradual deterioration and eventual death of the patient from disease or intercurrent complications.

At various times after diagnosis, most patients with CLL develop increasingly aggressive disease. Various staging systems have shown some correlation with survival [2, 3]. Whether these different stages represent points in the natural history of the disease or subtly different disease types has not yet been clearly determined.

As a first step towards the rational management of patients refractory to conventional therapy, biochemical parameters possibly relevant to drug action, may be measured and therapeutic agents may be logically chosen on the basis of measurements of biochemical parameters *in vitro*. For example, recently a study by Scholar and Calabresi showed that the enzymes necessary for the *de novo* synthesis of purines were low in lymphocytes from both normal donors and patients with CLL [4]. Thus, inhibitors of *de novo* purine biosynthesis would not represent a logical choice in such cases.

This report describes a detailed biochemical and clinical study of 6 patients with CLL at various stages of their disease, including 2 patients who underwent clinical and biochemical alterations of the disease.

MATERIAL AND METHODS

Material

Ribonucleoside mono-, di- and tri-phosphate standards and Ficoll (mol. wt approx. 400,000)

Accepted 9 May 1977.

*This work was supported in part by USPHS grants CA-13038, CA-2599 abd CA-18420 from the National Cancer Institute.

were obtained from Sigma Chemical Co. (St. Louis, MO). All phosphorylated compounds were the disodium salts of the 5′ derivatives and were dissolved in 2 mM ammonium formate buffer, pH 4.4. Sodium diatrizoate was obtained from Winthrop Laboratories (New York, NY). Glycine-2-^{14}C, 36.7 mc/mmole; adenosine-8-^{14}C, 52 mc/mmole; and arabinosyl cytosine-5-^{3}H, 10–16 C/mmole were obtained from Schwarz/Mann (Orangeburg, NY). Thymidine-2-^{14}C, 56 mc/mmole was from Amersham and Searle (Arlington Heights, Ill.). 6-MP-8-^{14}C, 0.25 mc/16.7 mg was obtained from New England Nuclear (Boston, Mass.). Orotic acid-5-^{3}H, 7 C/mmole was from Nuclear Dynamics, potassium phosphate reagent was obtained from Baker Chemical Co., (Philipsburg, NJ).

Cell separation

(a) *Leukapheresis.* Continuous flow leukapheresis with an IBM–NCI cell centrifuge was used on several occasions to obtain lymphocyte blood fractions for study. Patients were premedicated with 5000 heparin i.v. after outflow and return catheters had been introduced into the antecubital veins. ACD solution, formula A, American Instrument Co., 1 ml/40 ml of blood was infused into the extracorporeal circuit before centrifugation. The centrifuge bowl was run at 800 rev/min. In normal individuals this procedure yields approximately $5–10 \times 10^9$ white blood cells (80–90% lymphocytes) in 2–3 hr [5]. In leukemic patients, the actual yield depends on the composition and quantity of the leukocyte fraction in the peripheral blood.

(b) *Density gradient cell separation.* Hypaque–Ficoll solutions were prepared as follows: (34%), w/v sodium diatrizoate (10 parts) and 9% w/v Ficoll (24 parts) were mixed. Solutions were kept in the dark, frozen and thawed out prior to use [6].

The first 10–15 ml of white cell enriched blood separated by leukapheresis was overlaid on 8 ml of a Hypaque–Ficoll gradient in a 15 ml conical centrifuge tube with 8 ml of cell suspension. Tubes were then centrifuged at $600 \times g$ for 25 min at room temperature. Three distinctly separate areas were observed. Uppermost was plasma; in the middle, lymphocytes; and at the bottom of the tube, granulocytes and red blood cells. Lymphocytes were removed, washed with RPMI-1640 and counted. The entire procedure required about 45 min. Differential counts were made on the cell suspension, after leukapheresis and Hypaque–Ficoll separation fractions using Wright–Giemsa stained slides.

Ribonucleotide separation

Lymphocytes obtained from CLL patients were extracted with 6% perchloric acid (10^7 cells/0.2 ml) and centrifuged at $2000 \times g$ for 1 min. The acid soluble fraction was then immediately adjusted to pH 7.0 with 2 N potassium hydroxide and the precipitate was removed by centrifugation. The acid-soluble fraction was immediately analyzed for its ribonucleotide content using either a DEAE cellulose column [7] or a high pressure liquid chromatograph.

A Dupont high pressure liquid chromatograph, Model 830, fitted with an ABX column (2 m × 2 mm, U-shaped) and with a dual cell detector was used for high pressure liquid chromatography (HPLC) separation of the ribonucleotides. Separation was carried out using a concave gradient No. 2. The initial buffer concentration was 2 mM potassium phosphate (pH 3.0) and the final was 0.5 M (pH 4.4), with a gradient of 3% per min. This method was used for the separation of ribonucleoside mono-, di- and tri-phosphates as well as the various ara-C metabolites, ara-CMP ara-UMP, ara-CDP and ara-CTP. HPLC separation was carried out at room temperature under a pressure of 1000 psi resulting in a flow rate of about 1 ml/min. The effluent was monitored simultaneously at 254 and 280 nm with absorption recorded on a 2-pen Hewlett–Packard recorder. Areas under each peak were automatically integrated using an Autolab Minigrator. In experiments in which drug metabolism was investigated, the effluents representing individual absorption peaks were collected directly into counting vials. Radioactivity in each vial was determined using a Packard Model 330 liquid scintillation spectrophotometer.

Metabolism of metabolites and antimetabolites

Separated and purified lymphocytes (5.0×10^7 cells/7 ml) were incubated at 37°C for 30 min with labeled agents (20 uCi of ara-C-5-^{3}H, 5 uCi each of 6-mercaptopurine (6-MP), adenosine ribonucleotide (AR), thymidine deoxyribonucleotide (TdR) and glycine. At the end of the incubation period, tubes were centrifuged at $600 \times g$ for 2 min, washed twice with a 0.9% sodium NaCl and a semi-dry pellet was either taken up directly into a counting vial for the measurement of total uptake of the labeled agent or extracted with 6% perchloric acid (PCA) for the analysis of acid-soluble fraction by HPLC. Incorporation of labeled agents into RNA and DNA was determined as described previously. Each vial was counted at least twice for 10 min each time.

Patients

All patients studied were considered to have classical chronic lymphocytic leukemia based on standard clinical and cytologic criteria. The clinical characteristics of the patients are summarized in Table 1. At the time of study, all patients except PM were under chemotherapeutic treatment and all were stage III or IV.*

Two patients, VL and GF, presented with uremia and hyperuricemia [3] while the other 4 patients had minimal symptoms at presentation. One patient, PM, had been under observation for a period of 11 yr during which time the disease evolved from stage II to stage IV.

One patient, PM, is described in detail. This 56-yr-old Caucasian male was incidentally discovered to have CLL during a routine yearly examination in 1962. In 1963 he developed adenopathy, primarily in the central region, and increasing lymphocyte counts. When the count was 70,000, he was treated initially with chlorambucil and then with tetraethylmelamine (TEM) intermittently for 8 yr until he became refractory to this agent. For an additional yr he was treated with very modest success but with progressive problems of anemia, using chlorambucil and high doses of prednisone. Increasing adenopathy and rising lymphocyte counts together with worsening thrombocytopenia occurred and he was referred to this Institute. In the early part of 1974, the patient was treated with various regimens utilizing cyclophosphamide, streptonigrin and prednisone. These agents resulted in stabilization of the lymphocyte count, but did not correct either the thrombocytopenia nor the adenopathy. In August 1974, the patient had a rapidly increasing lymphocyte count, massive adenopathy in the neck, chronic low grade fever, progressive weight loss and other signs of hypermetabolism. He was treated with total nodal radiotherapy, approximately 2000 rad to all regions, but while this resulted in regression of the node masses in the neck, there was little effect on other symptoms and signs of the disease.

In December 1974, an arteriovenous fistula was created in the right arm. The patient was then leukapheresed using the IBM–NCI cell separator a total of 18 times in a 30-day period, removing a total of 5.6×10^{12} cells. At the beginning of leukapheresis, the patient's peripheral white blood cell count was 210,000. There was a rapid drop in his counts to approximately 10,000. During the ensuing 3 months, the patient maintained his absolute blood lymphocyte count between 15–25,000/mm^3, showed regression of neck adenopathy, a loss of fever, a gain in weight and a partial correction of both thrombocytopenia and anemia. Bone marrow samples obtained during this period showed gradual increase in myeloid and erythropoiesis with reduction of lymphocytosis. One further leukapheresis procedure was done in late March for biochemical studies. Because the disease appeared stable and the patient seemed to be in better clinical condition than he had been in the previous 2 yr, no further therapy was given.

*Stage O, bone marrow and blood lymphocytosis only; Stage I, lymphocytosis with enlarged nodes; Stage II, lymphocytosis with enlarged spleen or liver or both; Stage III, lymphocytosis with anemia; Stage IV, with thrombocytopenia [3].

RESULTS

Ribonucleotide profiles

The ribonucleotide profiles of cells obtained at different stages of the disease in patient PM are shown in Fig. 1. Figure 1(a) is a typical HPLC chromatogram showing the complete ribonucleotide contents of CLL cells and is representative of profiles obtained on 5 different occasions between April 1974 and May 1975.

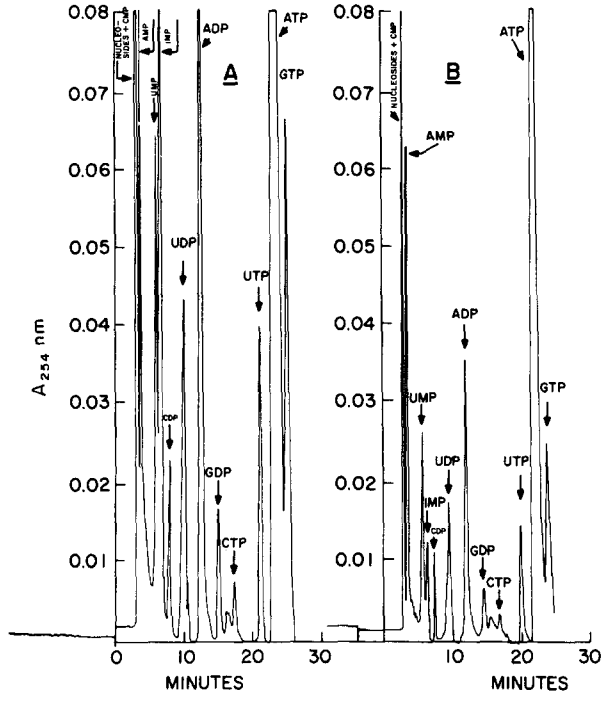

Fig. 1. High pressure liquid chromatography of acid soluble extracts of cells obtained from patient (PM) with chronic lymphocytic leukemia. A represents a typical chromatogram of cell extracts of the patient before "transformation" (6/74–6/75) and B after "transformation" (7/75–11/75). Cells (1.0×10^8) were extracted with 1.0 ml of 6% PCA and the supernatant was then neutralized to pH 7.0 with 2N KOH. Ten microliters (about 10^6 cells) of such an extract was analyzed on an HPLC (see Methods).

									Radiation therapy	Disease

Striking features are in the area of the monophosphates, especially IMP, and in the area of the triphosphates, in particular ATP. The ratio of ATP to IMP in Fig. 1(a) is about two. Similar findings were observed when the acid soluble fraction of the cells was analyzed using a DEAE column chromatographic method [7]. Figure 1(b) shows the ribonucleotide profiles of cells obtained from the same patient in June 1975. This chromatogram differs from that shown in Fig. 1(a) in that the pools of IMP are sharply reduced with concomitant increase in the pools of triphosphate, especially those of ATP and GTP. Progressive increase in the ribonucleotide triphosphates were observed with time, reaching a maximum in August 1975 (data not shown).

The ribonucleotide profile of the cells obtained from the other 5 patients were also analyzed and the data are summarized in Table 2. In one patient (JA) a ribonucleotide profile, reproducible on 2 occasions, similar to that shown in Fig. 1(a) was obtained. At a later date, however, (February 1975) the IMP peak was reduced drastically with a concomitant increase in the ATP pool. These biochemical changes in the ribonucleotide profile were observed simultaneously with the ability of cells to utilize glycine and thymidine (see below). Thus, in 2 of 6 patients (PM and JA, Table 2) a shift from a low ATP/IMP ratio (1.4 and 1.3 respectively) to a higher ratio (14 and 30 respectively) was observed. In the other 4 patients, the profiles consistently resembled that of Fig. 1(b).

In vitro *precursor activation and incorporation into nucleic acids*

The uptake of glycine and orotic acid into cells and their incorporation into ATP and UTP, respectively, was measured as an indicator for determining the ability of cells from patients with CLL to utilize *de novo* purine and pyrimidine synthetic pathways. Incorporation of AR into ATP and of TdR into nucleic acids was measured as a parameter for evaluating the ability of CLL cells to utilize salvage pathways of purines and pyrimidines, respectively.

The ability of CLL cells to utilize salvage and *de novo* metabolites were further investigated in the other five patients. The data are summarized in Table 3. In one of these five patients (JA) a significant and reproducible increase in glycine utilization was observed at later stages. The data also show that the cells obtained from the 2 patients (PM and JA), at their initial presentation, possessed a lower profile in their ability to utilize glycine and TdR than these cells obtained from the other 4 patients. In contrast, GF cells utilized salvage and *de novo* metabolites relatively better than cells obtained from the 5 other patients. These cells were characterized as typical T type while the cells of the 5 other patients were typical B type (J. Minowada, Personal Communication).

The results of the studies carried out on the cells from one CLL patient (PM) at various stages of the disease are shown in Fig. 2. In the early stage of the disease (July 1974–May 1975) when the patient was clinically stable and for several months thereafter, these cells possessed a limited capacity to use glycine and thymidine for nucleic acid synthesis. The incorporation of AR was, however, rapid. From July onward the ability of these cells to utilize glycine and TdR increased progressively while the incorporation of AR into nucleic acids was not significantly altered. These biochemical changes preceded

any distinct change in the clinical status of the patient. At the time of the appearance of a large tumor mass in the right groin, tissue biopsy and bone marrow cells were also analyzed for their ribonucleotide profile and for the ability of the cells to utilize *de novo* and salvage metabolites. The material obtained from the solid tumor mass utilized glycine and thymidine considerably more efficiently than cells obtained from peripheral blood. In addition, the ribonucleotide triphosphate pools of cells obtained from the solid mass were over two fold greater than those found in cells obtained from the peripheral blood of the same patient (data not shown).

Relationship between nucleotide pool ratios and tumor cell reliance on de novo *and salvage pathways*

Differences in the ability of L-1210, P-288, Taper hepatoma and CLL cells to utilize *de novo* and salvage metabolites for nucleic acid synthesis are shown in Table 4. The data indicate that there is a direct relationship between the ATP/IMP ratios and the ability of cells to utilize *de novo* metabolites. The larger the ratio (e.g., Taper hepatoma), the greater the dependency of these cells to utilize metabolites for *de novo* nucleic acid synthesis. Conversely, the smaller the ratio (CLL cells) the greater the dependence of these cells on salvage pathways. The data in Table 4 also show that 6-MP, a known inhibitor of *de novo* pathways of purine biosynthesis produced a significant increase in the life span of mice bearing Taper hepatoma, while it produced only a marginal increase in the life span of mice bearing L-1210 cells.

In vitro *metabolism of selected antimetabolites*

Cells obtained from the peripheral blood of patients with CLL were incubated *in vitro* with ara-C-^{3}H. Thirty minutes thereafter, the acid soluble fractions were prepared and analyzed for their content of labeled ara-C and its known anabolic and catabolic products. Results of these studies are summarized in Table 5. The results

Table 4. *Relationship between reliance of tumor cells on salvage and* de novo *pathways for nucleic acid synthesis and drug sensitivity**

	Salvage†	*De novo*	ATP/IMP	Increase in survivors‡ 6-MP (%)

indicate that these cells transport and activate ara-C to the triphosphate level. The amount of ara-CTP formed after 30 min incubation with ara-C varied from patient to patient. Furthermore, the amount of ara-UMP formed was found to be high in two patients (JA and CB) while in the others it was quite low.

Clinical diagnosis and treatment

On 29 July, 1975 the patient (PM) presented with no changes in his hematologic parameters but with a sensation of weakness and the appearance of a large node in the right groin. Aspiration of this node was consistent with CLL. A marrow sample obtained at this time showed that the percentage of lymphoblasts had increased from 6 to 12%. Biochemical measurements showed that the DNA and RNA content per cell had doubled and the average cell size of lymphocytes (measured by ocular micrometry) was nearly doubled.

The patient was treated with 3 hr infusions of 6-MP, 600 mg/m^2 i.v. daily for 5 days. At the beginning of treatment the patient's total lymphocyte count was 224,000 and the patient had a serum calcium of 12.5 mg %. The treatment did not result in a significant change in the calcium level nor in the size or firmness of the lymph nodes in the neck but the white count gradually dropped to an absolute lymphocyte count of 85,000 with marked thrombocytopenia (7500/ml). Upon recovery of the platelets to pretreatment levels of 65,000/ml the patient was placed on ara-C 100 mg/m^2 by continuous daily infusion for 5 days. This treatment resulted in a drop of the total white count from 99,000 to 70,000 in a 7 day period. In addition, the calcium dropped from 12.5 to 9.5 mg % and the

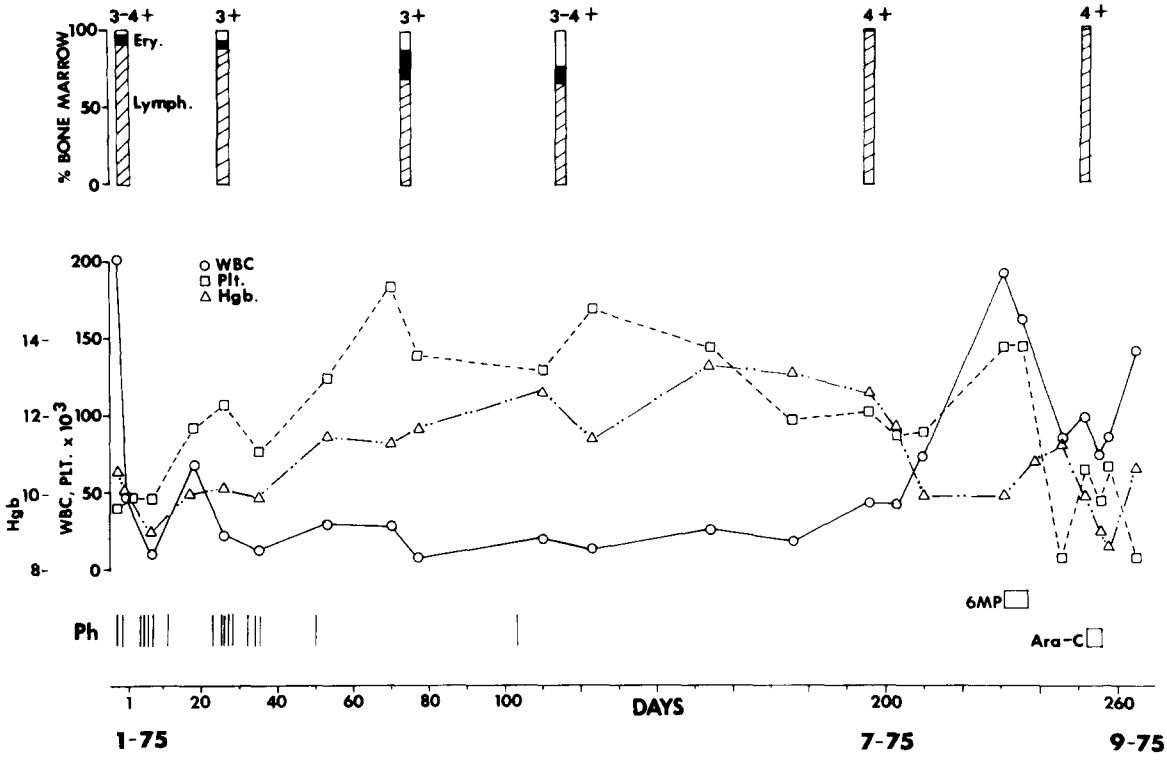

Fig. 3. Clinical course following remission induction with leukapheresis (PM). Biochemical and clinical changes in the character of the disease were noted at day 200. *6-Mercaptopurine and cytosine arabinoside were given as indicated (see text).*

lymph nodes regressed in volume by 25% with marked softening. The patient's appetite improved although low grade fever continued to be present. Seven days layer, the patient developed marked absolute granulocytopenia together with pneumonia and septicemia and expired, this being 13 yr after diagnosis. Figure 3 is a summary of this patient's course from the time of leukapheresis treatment through the period of transformation and the treatment with 6-MP and ara-C.

DISCUSSION

Chronic lymphocytic leukemia (CLL) is a disease in which the abnormal lymphocytes resemble their normal counterparts morphologically, but show significant alterations of functional integrity. The disease is characterized by a variable course, ranging from a benign lymphocytosis to an aggressive disease characterized by ever-increasing numbers of cells, infiltration of hematopoietic lymphoid and other organs, associated defects in immune system, defects in the production of normal marrow elements, hemolytic anemia and susceptibility to severe viral infections. Therapy may not be necessary in the early stages, while in the more advanced phases control is often achieved with alkylating agents and prednisone. As the disease progresses, however, current therapeutic modalities are usually unsatisfactory and disease-related death ultimately occurs.

The management of CLL, chronic myeloblastic leukemia and so-called "prolymphocytic leukemia," with intensive leukapheresis has been described [8–10]. This study documents the temporary effectiveness of this mode of therapy in one of the patients studied. Following short-term intensive leukapheresis, the patient showed progressive improvement in all the parameters of his disease, including repopulation of the marrow with normal elements. Leukapheresis may have altered the characteristics of the disease more fundamentally, perhaps by creating a more favorable ratio between normal marrow stem cell elements to the leukemic precursors. Whether the terminal "aggressive" phase of the disease in this patient may have been influenced by leukapheresis is not known. The experience of others would suggest that this type of intervention is at least not harmful.

Attempts have been made to characterize the disease by *in vitro* phytohemagglutinin (PHA) stimulation [11], chromosomal markers [12, 13] and serum protein levels [7]. More recently, Scholar and Calabresi [4] have shown that some CLL cases are characterized by the inability of

the leukemic cells to utilize glycine as a *de novo* precursor for nucleic acid synthesis. These cells thus appear to rely predominantly on salvage pathways for maintaining cell function.

In this report, attempts were made to characterize biochemically CLL patients at various clinical stages of their diseases. These studies included the quantitative estimation of ribonucleotide pools in particular, the ratios of ATP/IMP, the ability of the cells to utilize *de novo* vs salvage metabolites, and the measurement of the extent of metabolic activation of selected antimetabolites such as ara-C. These studies were carried out simultaneously on cells obtained from each patient at various visits to the hospital. Such studies might be of value in (a) the establishment of baselines for the biochemical profiles of CLL cells during early ("benign") stages of the disease; (b) determining whether or not changes in the biochemical profiles can be used to predict impending clinical changes in the disease; and (c) evaluation of the use of these tests to predict the sensitivity of CLL cells to selected antineoplastic agents. This report is a preliminary study summarizing the results of such investigations in 6 patients.

The data reported here confirms the studies of Scholar and Calabresi [4]. Cells from 6 patients with CLL were shown to possess a reduced ability to utilize purine and pyrimidine *de novo* metabolites, as indicated by the lack of formation of ATP and UTP formation from glycine and orotic acid respectively. However, in one of our patients (PM) although the CLL cells initially lacked the ability of utilizing glycine and orotate, TdR and glycine incorporation into nucleic acid progressively increased, preceding the accelerated phase of his disease. This increase reached a plateau within 2 months prior to death. In another patient, JA, the ability of cells to utilize glycine for the formation of ATP developed coincidentally with the occurrence of advanced and aggressive disease. Coincident with these shifts from a major reliance of cells on salvage pathways for nucleic acid synthesis, to at least partial dependence on *de novo* pathways, a corresponding change in the ribonucleotide profile was observed. Table 2 illustrates the shift from lower to higher ATP/IMP ratios. Prior to the shifts, repeated observations on different occasions had remained relatively constant.

However, in the 4 other CLL patients, there was no correlation between high ATP/IMP ratios and the ability of these cells to utilize *de novo* metabolites. Although nucleoside triphosphate pools in the cells of these latter patients were relatively high, their CLL cells maintained predominantly salvage pathways for providing precursors for nucleic acid synthesis.

It is thus conceivable that the dependence on salvage pathways represents a homeostatic mechanism for the control of proliferation of CLL cells, corresponding to the rather indolent "accumulative" phase of the disease, and that more aggressive disease may be a consequence of the development of clones of cells with capabilities for *de novo* synthesis of DNA. This hypothesis remains to be tested.

In 3 animal tumor cell lines the antitumor activity of 6-MP seems to correlate with the ability of these cells to utilize salvage and *de novo* (glycine) metabolites. The uptake of AR in CLL was of the order of magnitude of Taper hepatoma and P-288. In contrast, the uptake of a *de novo* metabolite was found to be lowest in L-1210, next in P-288, and the greatest in Taper hepatoma. In these animal tumor systems, the ATP/IMP ratio was inversely correlated with the ability of these cells to utilize salvage metabolites. In tumors with an active *de novo* pathway, antimetabolites capable of inhibiting these pathways may be most effective. Indeed, the results show that treatment of mice bearing Taper hepatoma with 6-MP produced long term survival. In contrast, in L-1210, a tumor with a relatively marked dependence on salvage pathways, 6-MP produced only a 25% increase in survival time.

In summary, although the results of this investigation do not allow us to draw a definite conclusion at this time, they point out the need for determining in more patients whether or not fluctuation in the ribonucleotide pools and their ratio and changes in the balance between *de novo* and salvage pathways may be used as an early warning sign for an impending change in the clinical status of CLL patients. If it turns out that the changes in the ATP/IMP ratios and the dependence on salvage vs *de novo* pathways do not correlate with impending clinical crisis in every CLL patient, in those patients with positive correlation measurement of these parameters may have some value in the early management of the diseases with chemotherapy.

‡Istituto di Anatomia e Istologia Patologica dell'Università de Padova, Italy

Abstract—*A peculiar tumour of children, similar for certain histological and biological features to Burkitt's lymphoma has been recognized in Italy, probably a B lymphoma.*

The serological data are not consistent with the same aetiology of African cases, except for one of 8 patients (5 tested appropriately). "Maxicure with minitreatment" after cyclophosphamide has been reported for African cases; similar results have been achieved in 3/8 patients of this series with the adriamycin + vincristine combination; this combination probably deserves larger testing also in African cases. Four out of eight patients are faring well, at the time of reporting.

INTRODUCTION

THE PECULIAR lymphoma recognized in African children by Burkitt§ was earlier regarded as a nosological entity confined to certain geographical areas. Later on, a similar condition began to be recognized in Europe and the States [1, 2].

Pathological (and cytological) features of these 2 clinical entities are identical [3] while the serology and pattern of distribution of the tumour deposits seem to be at variance from country to country [1–4]. Furthermore only occasionally EBV (Epstein–Barr virus) infection can be found responsible or correlated in cases described outside Africa.

In the last years, we have observed 8 patients with immunological, morphological and clinical features resembling, more or less, the African cases. The possible leukemic evolution and the low titres of EBV antibodies, however, suggest the existence of an autonomous form of the disease in Europe or, at least, in Italy.

MATERIAL AND METHODS

The age of our patients varies between 3 and 19 yr; illness duration at admission had been very short (4–8 weeks). Regarding *presentation*, 1 girl at the admission was already leukemic‖; 1 boy progressed in 4 months to a leukemic picture; 4/8 patients, however, were thrombocytopenic and anemic since the beginning; Table 1 shows an outline of epidemiological and presentation data. Tumours were clinically staged as follows: stage I—localized facial tumour; stage II—two or more facial tumours; stage III—intrathoracic, intra-abdominal, or osseous tumour (excluding jaws) and paraplegia; stage IV—meningeal or generalized bone marrow metastases, according to I. T. Magrath (1975).

Two patients had a maxillary tumour, and 2 paraplegia from spinal involvement. Two patients presented with fever and weight loss (systemic signs) from the start.

Histopathology

Paraffin sections after formol fixation and hematoxylin + eosine stain have been the basic diagnostic tool.

Cytological studies

Bone marrow aspirates and imprints from biopsy specimens have been obtained for all patients. All these preparations were stained

Accepted 2 June 1977.

§African lymphoma; Burkitt's tumour are synonyms; for cases described outside the endemic area, Burkitt-like tumour has been the commonly adopted eponym.

‖She was earlier admitted to another hospital and it is difficult from reported data to know if she was leukemic on the first admission.

EA = early antigen—VCA = virus capside antigen—EBNA = Epstein–Barr nuclear antigen.
*Under 'living area' heading – NIC means Northern Italy, country; SIT means Southern Italy, town.
In 4/5 patients the serology was retested when in remission without any change in EA, VCA, EBNA titre.

according to the May Grünwald Giemsa method. Node aspirates were performed when possible. In some patients these studies have been repeated on spinal fluid and other specimens (e.g. pleural fluid).

For cytochemistry, Methyl Green Pyronine, P.A.S. peroxidase and Oil Red O have been also used. Cell markers have been detected by *immunological methods* on marrow or biopsy specimens using Hyland antisera tagged with fluorescein and monospecific anti gamma, alpha, mu, K and lambda activity [6]. Cell suspensions were observed after this preparation through an Orthoplan Leitz microscope for immunofluorescence. Jondal method [7] has been used to study spontaneous rosette formation with sheep erithrocytes.

Serology and virology

Studies for early antigen; membrane antigen and viral capside antigen and for Epstein–Barr nuclear antigen (EA; MA; VCR; EBNA) have been made at presentation and in several other occasions according to the standard techniques [8–10]. In the last patient nuclear hybridization studies for EBV components in the tumour cell genoma has also been performed [11].*

RESULTS

Epidemiology

Previous infectious mononucleosis was not reported in our patients on careful questioning; one patient came from an area of endemic malaria; social status varied from low to middle class (manual worker to school teacher); geographic distribution was haphazard from all Italy; no clustering of tumours of the lymphocytic system or tumours affecting young patients was discovered on enquiry.

Pathology

A starry sky appearance with large lymphocytic sheets and scattered non-malignant macrophages was the common feature of 8/8 patients (Figs. 1 and 2).

Cytomorphology

The blast-like cells found in the tumour imprint in some patients invaded the circulation and bone marrow; they were poorly differentiated with a moderately expanded basophylic cytoplasm showing many vacuoles of 1–2μ dia. Rounded or slightly oval nuclei with a delicate chromatine net-work and one prominent nucleolum were usually seen (Fig. 2). MGP stain as well as Oil Red O were positive in the cytoplasms. Negative reactions from peroxidase and PAS stains were obtained in all specimens.

Lymphocyte markers

Only two cases, 4 and 7, have been studied for surface markers (1) of the malignant cells; both had on the cell membrane distinctive spots of a monoclonal surface marker (Sm. Ig.) of IgM type with lambda light chains. Fluorescence was relatively strong. No spontaneous rosette formation was observed.

Serological studies

Table 1 shows that only two patients had titres similar to African lymphoma; one with only VCA and one with both VCA and EBNA. These patients had not suffered from infectious mononucleosis and gave a negative Paul Bunnel reaction. An attempt to molecular hybridization gave negative results in one patient (serologically negative) and no study of this type has been performed on the other patients.

Response to treatment

The first patient was treated with a loading dose of cyclophosphamide with only transient improvement. Then radiotherapy to bulky disease and combined chemotherapy as for acute lymphoid leukemia (ALL) proved slightly effective; this boy died after a 12 month course. One patient failed to respond to the ABVD scheme [12] and is now in full remission at 20 months after treatment according to the L10 protocol [13]. Four patients began the treatment with one 24 hr course of adriamycin (65 mg/m^2) followed at 48 hr by vincristine 1 mg/m^2; 3 of these patients are now living and well at 18, 36 and 54 months (one of them received further adriamycin as maintenance treatment for 6 months). The fourth of these 4 patients, despite adriamycin maintenance relapsed and died at 3 months. Adriamycin + vincristine, according to the above-mentioned schedule, was also applied as second treatment of choice after radiation failure in a 5th patient, who nevertheless died at 12 months. Of 3 patients treated for relapse according to the L10 scheme, 1, No. 7 in Table 1, is now free of evidence of disease at 20 months, and 2 died (1 at 44 and 1 at 12 months from the beginning). Table 2 summarizes these data.

*Sera and tumour specimens for these studies have been mailed with dry ice in RPMI with 20% FCS and antibiotics to the Lyon International Cancer Agency, France. We acknowledge here the friendly cooperation of Dr. G. Blaubin De Thé to this work and of Dr. N. Munoz for revision of the slides.

The syncronic disappearance of mediastinal and lung involvement suggested discontinuation of adriamycin from March. The patient is symptom free at* 14 months *from treatment discontinuation.*

DISCUSSION

In 6 yr, 8 patients (among ~ 10,000 admissions) suggested a Burkitt-like diagnosis to our pathologist (N.P.) on paraffin sections and on cytological examination. Four out of eight patients are now in full unmaintained remission, 3 of them after a brief course of adriamycin + vincristine.

The bone involvement, often initially observed, appeared earlier or later in 7/8 patients and should be considered a prominent feature. The tumour cells appeared to behave as monoclonal B cells [1] in the 2 cases subjected to full immunocytological studies, in good agreement also with Binder [14] and Epstein's data [15] for sporadic cases of non-African Burkitt-like lymphoma. Tumour sites included twice the maxillary bone (lower incidence than in true BL (Fig. 3), and twice also the central nervous system + lymph nodes (higher incidence).

Two out of eight cases became frankly leukemic (1 of them had a leukemic picture since the beginning), while in Africa the bone marrow infiltration usually appears unaccompanied by peripheral blood invasion [16]. This feature however may be prominent [3] in American cases (50%) and has been repeatedly reported in Europe and in the United States of America [1, 17].

Table 3. Clinical evolution in dying patients

Death modality	Patients (No./total)	(%)
Leukemic transformation	2/8	25
Progression of tumour masses	2/8	25

The serology of only 1 patient was in full agreement with the African cases; the prominent features of this case were abdominal localization and unmaintained remission at 3 yr after ileal resection and a short course of adriamycin + vincristine. The cyclophosphamide "maxicure with minitreatment" policy, sometimes effective for African cases, has been tried only once and with a poor outcome in our patient, No. 1, while it has proved successful with adriamycin + vincristine in cases 5, 6 and 8.

A good outcome seems possible (although not warranted for the moment) also in case 7, treated as ALL with the L10 protocol followed by radiotherapy on the mediastinum and is now off treatment since 4 months [13]. Radiation treatment and prolonged multiple chemotherapy have not proved to be successful in 4 patients.

Our feeling is that the cases described pertain to a separate entity among the B lymphomas, non-Hodgkin type, of children. This entity has pathology, pathogenesis, clinical behaviour, tumour-host relationships similar to African lymphoma, but is probably related to aethiological or triggering factors different from EB virus and, possibly, different from patient to patient.

Tumor Growth Inhibition Mediated by Trypsin Inhibitor or Urokinase Inhibitors*

RENÉ VERLOES,† GHANEM ATASSI,§ PATRICK DUMONT‡ and LOUIS KANAREK†¶

†*Laboratorium voor Chemie der Proteïnen, Vrije Universiteit Brussel*, 65, *Paardenstraat*, *B*-1640 *Sint-Genesius-Rode*, *Belgium* and ‡*Service de Médecine Interne et Laboratoire d'Investigation Clinique Henri Tagnon, Université Libre de Bruxelles, Centre des Tumeurs*, 1, *Rue Héger-Bordet*, B-1000 *Bruxelles*, *Belgium*

Abstract—*When testing* in vitro, *we often observed that erythrocytes taken from Ehrlich ascites tumor bearing mice displayed enhanced agglutinability by the lectin Concanavalin A, suggesting that protease activity operates* in vivo.

In several studies, we were able to inhibit Ehrlich ascites tumor growth by the repeated administration of soya bean trypsin inhibitor. Studies of dosages and schedules of treatment showed that for 20,000 *initially grafted cells, treatment resulted in* 0–70% *of long-term survivors and induced a significant increase in mean survival time of treated mice over control mice. For* 200,000 *grafted tumor cells,* 0–40% *of long-term survivors were recorded.*

In a comparative study, we found that different inhibitors of urokinase displayed a similar chemotherapeutic effect against 200,000 *inoculated cells. Our results corroborate the idea that a plasminogen activator monitored chain of fibrinolytic and proteolytic activity controls tumor growth and metastasis enzymatically.*

INTRODUCTION

THERE is growing evidence that proteolytic and fibrinolytic enzymes are involved in tumor growth and metastasis: *in vitro* studies of cell line cultures have shown that normal cells grow to monolayer cultures, reach reproducible cell saturation densities and obey growth inhibition by cell–cell contact [1]. Resting cells can be triggered into mitosis if some hormones (insulin), lectins (Concanavalin A) or protease (trypsin) are added to the cultures [2]. Tumor cells, however, pile up each other, attain higher cell saturation densities and die if they are not transferred to fresh culture medium [3].

So, it was proposed that tumor cells, unlike normal cells, carry or secrete their own mitotic protease [4]. Since 1915 it is known that mammalian tumor cells lyse clotted plasma substrates [5]. Whereas normal fibroblasts and cultures of normal tissues release little if any fibrinolytic enzymes, it was reported that mammalian fibroblasts transformed by DNA or RNA viruses, chemically or virally induced carcinomas and human malignant tumors in culture release substantial quantities of fibrinolytic enzymes [6]. Reich *et al.* clearly demonstrated that this fibrinolytic activity is generated by the interaction of serum plasminogen [7] with a cellular activator of plasminogen (PA) found in the supernatants of tumor cell cultures [8]. Further studies revealed that PA is also associated with untransformed cells, such as macrophages [9] and human fibroblasts [10] and that PA is to be induced in those cells.

Very likely, this PA, after its induction by the coagulation enzymes and inflammatory agents [11], may physiologically monitor the migration (such as macrophage diapedesis) of those particular cell types active in wound healing processes and enable those cells to transect the structural barriers encountered during migration [12]. Tumor cells continuously produce PA and are capable of migrating in wounds [13]. Furthermore, it is clearly established now that patients with advanced cancer and lymphoid malignancies often show impaired cellular and humoral immune responses [14]. Micromolecular circulating fibrin and degradation products of plasminolytic activity, have shown to induce a

time-dependent and dose-dependent immunosuppressive action in the early phase of clonal proliferation of immunocompetent cells *in vitro* and *in vivo* [15] and were claimed to be responsible for immunosuppression. PA activity was found to be associated with the plasma membrane in Rous sarcoma virus transformed chick embryo fibroblasts [16] and Funahara *et al.* demonstrated the presence of PA in extracts of Ehrlich ascites tumor cells [17].

Recently, Astedt and Holmberg were able to demonstrate an immunological identity of urokinase and ovarian human carcinoma PA released in tissue culture [18]. Possibly, this enzyme, after its secretion by the tumor cell, may activate serum plasminogen and initiate a chain of proteolytic activities on neighbouring cells, tissues or serum proteins in the microenvironment of the tumor cell. In this study, we investigated if the administration of trypsin inhibitor of soya bean or urokinase inhibitors could influence the growth of murine ascites tumors.

Soya bean trypsin inhibitor is the naturally occurring macromolecular inhibitor of trypsin, plasmin, kallikreins, chymotrypsin and prothrombin convertase [19]. Urokinase is a 31,000 or 54,700 dalton molecule with proteolytic specificity for plasminogen [210].

Enzymatic activity can be inhibited by inhibitors of serine proteases such as para-amino-benzamidine and epsilon-amino-*n*-caproic acid [21].

MATERIALS AND METHODS

Material

Concanavalin A was a 10% protein powder obtained from Sigma (lot No. 94C5015) with specific ultraviolet absorption of 1.37 (1 mg/ml) at 280 nanometer and pH = 7.0 (Carl Zeiss spectrophotometer). Soya bean trypsin inhibitor was obtained from Wortington (lot no. 56B449), Sigma (lot No. 85C8057) and the British Drug Houses (lot No. 2985980). The purity was checked by amino acid analysis (Durrum) and continuous ultraviolet spectrum (230–350 nm range) and compared to literature data [22]. Inhibitor protein content was estimated, assuming specific optical density of 1.0 for a 1 mg/ml solution at 280 nm. Either the Wortington preparation (0.6 mg inhibitor/mg product) or the Sigma vial (0.72 mg inhibitor/mg product) was used. ε-amino-*n*-caproic acid (lot No. 124C0056), para-amino-benzamidine (lot No. 15C0015) and imidazole (lot No. 53C5500) were supplied by the Sigma Corporation.

U shaped wells containing agglutination plates were obtained from Linbro Chemicals, New Haven (Code IS-MCR-96).

Enzymes and buffers

Trypsinolysis was performed in (0.01 M Kaliumphosphate–0.15 M NaCl; pH = 7.3) (PBS), using Sigma trypsin (lot no. F 8253) with 11,400 B.A.E.E. units/mg. α-Chymotrypsin treatment was done in PBS using a Wortington vial (lot no. 540404) with 50.1 units/mg. Proteolytic activity of pronase (Calbiochem- lot no. 10118-units non-specified) was tested in (0.1 M Borate–0.05 M HCl–2 mM $CaCl_2$; pH = 7.5) buffer. Pepsinolysis was done in (1 mM glycin-0.15 M NaCl; pH = 3.2) buffer (Sigma, lot no. P 7012–4100 units/mg).

Urokinase (Warner–Lambert Research Institute, Wa-13,497-1, lot No. 1) was obtained as a lyophilized material containing 300,000 CTA units, kept frozen and diluted in phosphate buffered saline just before use. Assuming that 200,000 CTA units correspond to 1.5 mg active protein [23], we expressed the enzyme concentration in mg/ml quantities.

Concanavalin A agglutination assay

In Linbro plates, 0.05 ml PBS was pipetted and twofold consecutive dilutions were made by adding 0.05 ml from an original 1 mg/ml Con A solution in PBS buffer. After an incubation period of 30 min, 0.05 ml of the target cell suspension was added at a concentration of 10^8 erythrocytes/ml and agglutinations were scored after 1 hr at 37°C. Every experiment was performed in triplicate.

Experimental animals and tumors

Mice and tumors. For all studies, two strains of mice and three tumors were used. We chose to work with lymphoid L1210 leukemia because it offers an experimental model that is well documented in literature and allows activity prediction against leukemia [24]. We also worked with the lymphocytic P388 leukemia and the well known Ehrlich ascites carcinoma.

For each experiment, 10–20 mice were used. Mean survival time ± the standard deviation (S.D.) of the treated mice and the control mice, as well as the dosage and timing of each experiment are specified in the tables.

Survivors on day 90 after tumor graft were considered as long-term survivors, killed and were not used in the final evaluation of the mean survival time. A 25% increase in mean survival time of treated mice over controls was considered significant and supported by a single tailed Fisher *t*-test.

CDF_1 mice. Inbred (BALB/c × DBA/2) F_1 animals were supplied by Charles River Breeding Laboratories. Those mice were stored at least for 3 weeks in an isolation room before we started experimenting. Female CDF_1 mice (BALB/c female × DBA/2) F_1 animals weighing 19–23 g were used. L1210 lymphoid leukemia and P388 lymphocytic leukemia were originally obtained from Mr. I. Wodinsky (Arthur D. Little, Inc., Cambridge, Mass.).

Those tumors are maintained in DBA/2 mice by weekly intraperitoneal (i.p.) inoculation.

L1210 or P388 ascites were aspirated from DBA/2 mice and a suspension was made in Hank's balanced salt solution; 10^4 cells in 0.1 ml solution were injected intraperitoneally to obtain the ascitic form of leukemia. Animals were randomized into test groups and control groups.

BALB/c mice. An hyperdiploid line of the Ehrlich ascites tumor was originally obtained from Dr. Maisin. This tumor has been transplanted for years by Mr. A. Cordier in inbred BALB/c mice by weekly passage of 10^7 tumor cells to intact mice. Either male mice weighing minimum 19 g or female mice weighing at least 18 g were used.

Ehrlich ascites tumor cells were aspirated from BALB/c mice and diluted in phosphate buffered saline, 0.1 ml of the suspension was injected i.p. to obtain the ascitic form of the carcinoma. Animals were randomized into test groups and control groups.

RESULTS

1. *Effect of proteolysis on the agglutinability of rabbit erythrocytes by Concanavalin A*

Rabbits were obtained from a local breeder and blood from the ear vein was collected and pooled vol/vol in heparin containing Alsever solution. After repeated washings and centrifugations at 3015 × ***g*** for 20 min, at 4°C, the erythrocyte pellet was resuspended in the appropriate buffer ten times the original blood volume. Under frequent shaking, the cell suspensions were incubated at 37°C and an aliquot of the enzyme stock solution was added to a final 0.1 % enzyme concentration. At 10, 20, 40, 60, 90 and 120 min of incubation, samples were removed from the reaction mixture, centrifuged and resuspended in PBS buffer.

In Linbro plates, cells (10^8 erythrocytes/ml) were assayed for agglutination by 1 ml/ml Con A solution.

In Table 1, mean values of the Con A agglutination titer are expressed in $\log_2$ units as a function of the incubation period with the different enzyme solutions. We observed that, for each enzyme tested, long incubation periods (60–120 min) yield comparable agglutination patterns, increased over untreated controls. Agglutinability of cells exposed to trypsin was comparable to chymotrypsin treated erythrocytes. Incubation with pepsin was less effective and prolonged incubation with pronase resulted in lysis of many cells after 90 min.

2. *Effect of trypsin or urokinase on the agglutinability of mouse erythrocytes by Con A*

BALB/c mice were bled in the retro-orbital plexus and blood was collected in heparin containing Alsever solution..

After repeated washings and centrifugations at 297 × ***g*** for 10 min, at 4°C, the erythrocyte pellet was resuspended at 2.10^9 cells/ml in PBS buffer. One twentieth of a millilitre of the suspension was incubated for 30–60 min with 0.1 ml of trypsin (final concentration: 0, 0.02, 0.2, 2.0 mg/ml) or urokinase concentrations (final concentration: 0, 0.02, 0.2 mg/ml) to which

Table 1. *Effect of protease on the agglutinability of rabbit red blood cells by Concanavalin A*

	$\log_2$ agglutination titer as a function of the incubation time (min)					
Enzyme	0	20	40	60	90	120
Trypsin	9.5	14	15	15.5	16	15.5
Pepsin	9.5	9.5	9.5	11.5	11.5	12

Rabbit erythrocytes were treated by 0.1 % enzyme solutions and samples were removed at different incubation times.

Agglutinability by 1 mg/ml Con A were scored after 1 hr at 37°C.

NT = not tested.

Table 2. Effect of incubation or effect of a single administration of SBTI on Ehrlich ascites tumor growth

Schedule number	Trypsin inhibitor concentration	Treatment (day)	MST ± S.D. (days)
A1	0.2 mg/ml	0	21.0 ± 1.94
A2	0.050 mg/ml	0	25.0 ± 1.99
A3	0.010 mg/ml	0	23.5 ± 0.6
A4	0	–	21.6 ± 0.4
B1	50 mg/kg	1 hr before transplant	22.33 ± 1.29
B2	50 mg/kg	24 hr after transplant	22.0 ± 1.32
B3	0		22.0 ± 0.70

In schedules A1–A4, 4.10^6 Ehrlich cells were incubated vol/vol (30 min—0°C) with different solutions of SBTI and 2.10^5 cells were grafted to BALB/c mice intraperitoneally on day 0.

In schedules B1–B3, BALB/c mice were inoculated intraperitoneally with 2.10^5 Ehrlich cells on day 0 and treated as indicated.

MST ± S.D. = Mean survival time ± standard deviation.

0.2 ml of pooled BALB/c plasma was added. After the incubation, the cells were washed, centrifuged at 297 × *g* for 10 min at 4°C, adjusted to 10^8 cells/ml and tested for Con A agglutinability. As seen in Table 2, agglutinability was shown to be dependent on the enzyme concentration. Very likely, enzyme activity at low doses could be inhibited by earlier described serum protease inhibitors, such as the α_1 antitrypsin protein [25].

3. *Agglutinability of blood taken from Ehrlich ascites tumor bearing mice*

Eleven intact male BALB/c mice were inoculated intraperitoneally with 2.10^5 Ehrlich ascites cells on day 0.

On days 0, 5, 9, 15 and 18, blood from the retro-orbital plexus was collected and stored at 4°C in heparin containing Alsever solution and 0.25 ml blood was added to an aliquot of 0.15 ml heparin containing Alsever solution. After extensive washings and centrifugations at 297 × *g* for 10 min, 4°C, erythrocytes were adjusted to 2.5 × 10^8 cells/ml in PBS buffer.

In Linbro plates, target erythrocytes were tested for agglutinability by 2 mg/ml Con A solution. Mean values and the standard deviation were recorded as indicated in Fig. 1. Erythrocytes of intact BALB/c mice (2.5 × 10^8/ml) were treated with 0.1% trypsin in PBS for 1 hr, washed twice and centrifuged at 297 × *g* for 10 min at 4°C. They were assayed in parallel with untreated erythrocytes for Con A agglutinability. As seen in Fig. 1, we observed that agglutinability increases with tumor age and reaches agglutination titers comparable to those of *in vitro* enzyme treated cells, suggesting a similar *in vivo* proteolytic activity in Ehrlich ascites tumor bearing mice. We also found that after grafting intraperitoneally 10^4 L1210 or P388 tumor cells in CDF_1 mice on day 0, $\log_2$ agglutination titers increased from 8.63 ± 0.61 (day 0) to 9.19 ± 0.44 on day 10. We assume that the tumor grew too quickly and did not persist long enough to show good detectable effects.

4. *Influence of incubation or administration of SBTI on Ehrlich ascites tumor growth*

First, we looked for a direct interaction of SBTI with non-malignant cells. We observed that high dose of trypsin inhibitor (10 mg/ml) could agglutinate mouse splenocytes (Sigma vial: $\log_2 = 2.0$; BDH vial: $\log_2 = 9.0$) or mouse erythrocytes (Sigma vial: $\log_2 = 0.0$; BDH vial: $\log_2 = 7.5$) irrespective of the incubation temperature (4°C and 37°C). Since we found that

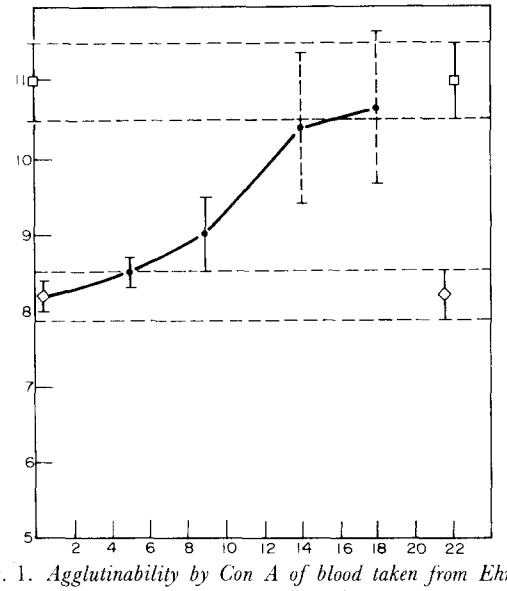

Fig. 1. *Agglutinability by Con A of blood taken from Ehrlich ascites tumor bearing mice. Intact BALB/c mice were inoculated intraperitoneally with* 2.10^5 *Ehrlich cells on day* 0. *On days* 0, 5, 9, 15 *and* 18, *blood from the retro-orbital sinus was collected and agglutinability of erythrocytes by Concanavalin A was scored* (○) *and compared to trypsin treated* (□) *or untreated erythrocytes of intact mice* (◇). (*Agglutination titer* ± *the standard deviation.*) *Abscis* = $\log_2$ *haemagglutination titer Ordinate = tumor age* (*days*).

those commercial trypsin inhibitors are pure at 60–72%, it seems logic to ascribe this property at least to a contaminating agent in the preparation. This has led us to choose the Sigma product for further experiments.

Then, we investigated if there was a direct (passive) cytotoxic effect of SBTI on 4.10^6 Ehrlich cells in PBS buffer in a vol/vol ratio at low temperature (0°C) with SBTI preparations of 0.4 mg/ml, 0.1 mg/ml or 0.02 mg/ml and a blank (control).

We assumed that a 30-min incubation period is sufficiently long to allow interaction of inhibitor with cell membrane proteins even in the presence of reduced metabolic activity (0°C). Grafting those incubated cells to intact mice did not extend mean survival time of those mice as indicated in Table 3. We also observed that a 50 mg/kg-single administration dosage of SBTI was ineffective against 2.10^5 implanted Ehrlich ascites cells. Then we applied a chemotherapeutic trial after an initial tumor graft on day 0. For 2.10^4 grafted cells, we found that a 20 mg/kg inhibitor dose resulted in 70% of long-term survivors, when given on days 1–5 the mean survival time of treated, but tumor bearing mice, was significantly prolonged, as recorded in Table 4. For 2.10^5 grafted cells, the percentage of long-term survivors varied from 40–0% of the mice and depended on the treatment schedule when 50 mg/kg were administered repeatedly as indicated in Table 4. Other treatment schedules were also therapeutically effective but a treatment started on day 7 after tumor grafting was ineffective.

Finally, we tried to improve chemotherapeutic effects by a combination with immunotherapy. Assuming an interaction of the inhibitor with a membrane protease, we hoped to kill SBTI coated tumor cells immunologically. Antibodies to trypsin inhibitor were elicited in rabbits by subcutaneous injection of 0.5 mg of protein in PBS buffer emulsified in complete Freund adjuvans. Animals were boosted after one month with three injections of 0.5 mg within two days interval and bled 14 days later.

Table 3. Con A agglutinability of mouse erythrocytes incubated with urokinase or trypsin

Enzyme + concentration		Log_2 haemaggl. at 30 min	Log_2 haemaggl. at 60 min

All BALB/c mice received a transplant of Ehrlich ascites cells intraperitoneally on day 0.
Significant (*t*-test) at $P<0.01$ *level* (+).

Analysis of the rabbit sera revealed the presence of antibodies precipitating with SBTI in 1% agar supplemented with 4% polyethyleneglycol. Those heterologous sera were repeatedly absorbed with pooled mouse blood cells to remove cytotoxic and agglutinating antibodies, following the technique of Boyse *et al.* [26]. Intact randomized BALB/c mice received a tumor graft of 2.10^5 cells on day 0 and they were treated on days 1, 4, 7, 11 and 16 with low doses of inhibitor (5 mg/kg).

Untreated control mice died with a mean survival time of 21.5 ± 1.93 days. Mice treated intraperitoneally died after 19.37 ± 1.92 days (11% of long-term survivors), whereas all mice treated intravenously died after 21.7 ± 1.37 days. Mice which received i.p. treatment followed by intraperitoneal inoculation of 0.2 ml antiserum lived $26.9 + 4.57$ days (11% long-term survivors), whereas all mice treated i.v. and inoculated intraperitoneally with 0.2 ml of antiserum died after 18.75 ± 4.59 days. In a subsequent approach, mice were directly vaccinated with SBTI in complete Freund adjuvans, but this immunochemotherapeutic experimentation did not yield any improved outcome.

5. *Comparison between antitumor activity of trypsin inhibitor and urokinase inhibitors on murine ascites tumor growth*

In a last trial, we tested, with equal pharmacological dosages, different inhibitors of urokinase as well as SBTI for activity against L1210 and P388 leukemia and Ehrlich carcinoma.

All tumor grafted mice received intraperitoneal treatment on days 1–5 with 20 mg/kg doses. Under the present conditions, it was observed that neither inhibitor affected L1210 or P388 growth, whereas Ehrlich ascites carcinoma was inhibited by ε-amino-*n*-caproic acid (70% of long-term survivors), para-aminobenzamidine (30% of long-term survivors) and by SBTI (10% of long-term survivors), as seen in Table 5.

DISCUSSION

The conceptual ideas dealing with the correlation of tumor growth, metastasis and proteolytic activity are complex. It is established now that tumor cells, unlike their parent normal cells, lyse clotted plasma substrates [5]. This fibrinolytic activity is generated by the interaction of serum plasminogen (PA) [7] found in the supernatants of tumor cell cultures [8]. We hypothesize that PA may play a crucial role in monitoring invasiveness in other tissues and organs, a mechanism in common with PA of some non-malignant cell lines, such as macrophages. Therefore, we tried to determine the biological effects of inhibiting PA activity in tumor bearing mice. Very little is known about PA activity of P388 or L1210 cells but Funahara *et al.* found that PA could be extracted from Ehrlich cells [17]. Leblanc and Bach were

All mice received a tumour transplant on day 0, intraperitoneally.
On days 1, 2, 3, 4, 5 mice were treated intraperitoneally with a 20 mg/kg dosage.
Mean survival time ± the standard deviation (MST ± S.D.) and the percentage (%C) of long-term survivors (day 90) are indicated.

unable to detect any PA activity in Ehrlich ascites fluid but observed that Ehrlich ascites tumor growth *in vivo* is accompanied by a kinin forming protease system that closely interrelates with both the fibrinolysin and blood coagulation systems [27]. Working with a standardized agglutination technique, we found that agglutinability of erythrocytes by Con A was increased after exposure to protease but with quantitative differences among the enzymes studied. Similarly, agglutinability of mouse erythrocytes was increased when incubated with trypsin or urokinase in the presence of mouse plasma. Taking advantage of this test, we observed that erythrocytes taken from Ehrlich tumor bearing mice display higher agglutinability by Con A, increasing with tumor age and suggesting the presence of a similar proteolytic activity *in vivo*. Agglutination patterns of P388 or L1210 tumor bearing animals were not considerably elevated.

Search for a direct cytotoxic effect of SBTI (passive absorption) by a short time incubation with Ehrlich cells and grafting those incubated cells to intact mice, revealed that mean survival time of treated mice was not prolonged over control mice.

However, those *in vivo* results require to be extended by *in vitro* SBTI coculture studies. Applying chemotherapy to tumor bearing mice clearly shows that for 20,000 initially grafted tumor cells, inoculation of 20 mg/kg SBTI exerts a chemotherapeutic effect, up to 70%, for different treatment schedules and significantly increases mean survival time over control mice. For 200,000 tumor grafted cells, treatment by a 50 mg/kg dose still resulted in 40% of long-term survivors. Time spaced schedules proved to be most efficient. In a comparative study, we tried to inhibit growth of different murine ascites tumors by SBTI and inhibitors of urokinase. On an equally pharmacological basis, we found that treatment of Ehrlich ascites carcinoma by ε-amino-*n*-caproic acid, para-aminobenzamidine and SBTI resulted respectively in 70, 30 and 10% of long-term survivors, whereas neither product affected L1210 or P388 leukemia growth. The fact that SBTI did not inhibit murine leukemia growth does not exclude prognosis for human leukemia. It is known that human lymphoblastic leukemic cells are often coated by tumor specific IgG fragments, which suggests that protease activity operates *in vivo* [28].

We believe that we can attribute our results to a direct inhibition of PA activity *in vivo*. However, we do not exclude the possibility that inhibition of degradation of fibrinogen by plasmin may favor specific anti-tumor responses in the weakly immunogenic Ehrlich tumor bearing mice (inhibition of formation of immunosuppressive fibrin microparticulates) and not in the poorly immunogenic L1210 or P388 tumor bearing mice.

Clinical as well as laboratory studies show that leukemic cells and solid tumor cells tend to form clumps of two or more cells formed on fibrin substratum, which are important in metastasis [29]. A solid tumor needs a network of blood capillaries to grow beyond a certain size [30]. Some reports indicate that a fibrin substrate is essential for capillaries to grow in the tumor tissue, whereas others indicate that fibrin is found at early metastatic sites [31–33]. Further studies can determine the effects of administration of those trypsin and urokinase inhibitors on metastatic leukemia and solid tumor growth. We hypothesize that PA may play a crucial role in monitoring invasiveness in other tissues and organs. We also hypothesize that the administration of SBTI may favor specific immunotherapeutic trials, when given intratumorily.

Studies on the Selective Toxicity of Guanazole in Mice*

C. DAVE, M. A. PAUL and Y. M. RUSTUM

Department of Experimental Therapeutics, Grace Cancer Drug Center, Roswell Park Memorial Institute, New York State Department of Health, 666 Elm Street, Buffalo, NY 14263, U.S.A.

Abstract—*Guanazole (3,5-diamino-1,2,4-triazole (GZ), an antileukemic agent effective against acute myelocytic leukemia, seems to exert its action through inhibition of ribonucleoside diphosphate reductase. Using recently developed technique for drug infusion in unrestricted mice, 5–30 mg/ml guanazole was infused at a rate of 0.2–0.3 ml/hr in normal mice and mice bearing leukemia L1210 or a subline resistant to guanazole (L1210/GZ). Incorporation of ^{14}C-uridine (UR) into DNA was considerably reduced in spleen, thymus and bone marrow; incorporation of ^{3}H-thymidine was reduced to a much greater extent in these tissues. The inhibition of precursor incorporation was dependent on the concentration of guanazole used and was somewhat correlated to the intracellular drug concentration in different tissues. This inhibition was in the following order: L1210 spleen > normal spleen > L1210/GZ spleen. Analysis of free intracellular ribonucleotide pools indicated the presence of a high IMP and a low ATP pool in normal spleen, and a moderate IMP and a high ATP pool in spleen infiltrated by cells from either leukemia; this profile resembled that observed in intraperitoneally growing L1210 cells. Guanazole infusion resulted in the reversion of pools profile from that characteristic of L1210 spleen to that of normal spleens. The morphological form and microscopic characteristics of L1210 spleen from mice treated with GZ also resemble those of spleen from non-leukemic mice.*

Study of in vitro uptake of guanazole in leukemia L1210, indicated that the transport occurred by a passive diffusion process. In the subline, L1210/GZ, the initial rate of uptake was 1/3rd to 1/4th of that in the parent line. This suggested that a generalized change in membrane architecture is likely to have accurred in L1210/GZ.

The results of this study are consistent with the idea that in different tissues in mice, the mechanism of action of guanazole is dependent upon inhibition of ribonucleotide reductase, whereas its selectivity of action is dependent upon differences in uptake.

INTRODUCTION

GUANAZOLE (3,5-diamino-1,2,4-triazole, NSC 1895) (GZ) is an agent having activity against mouse leukemia L1210 [1]. It has also been found to be effective against acute myelocytic leukemia [2, 3]. The complete remission was obtained with the drug in phase I and II clinical trials in between 10 and 20% of the cases.

The major limitation in therapy with GZ[2] is its hematologic toxicity [2, 3]. However, in a limited number of cases, the response to GZ was remarkably selective [2]. Since the drug is not metabolized by mouse [4], rat [5], or human [6] and since the differences in response between target host and tumor cells were quantitative, the selectivity of action may reside in a differential drug distribution between host and tumor cells or in differential sensitivities of cellular target sites. The only known biochemical mechanism of action of GZ is the inhibition of ribonucleoside diphosphate reductase [7]. The accumulation of cells in the G_1/S boundary of the cell cycle observed after *in vitro* treatment with GZ [8] is consistent with the above-mentioned mechanism.

After methodology of continuous i.v. infusion of drugs into unrestrained mice was developed in this laboratory [9], it became feasible to study the basis for the selective toxicity of GZ *in vivo* under treatment conditions similar to those employed for treatment of patients [3]. Correlations between drug concentration, ribonucleotides pool sizes and incorporation of nucleic

acid precursor into RNA and DNA in different mouse tissues were drawn based on the results of this investigation.

MATERIAL AND METHODS

Animals and tumor in vivo

DBA/2J female mice weighing between 18–20 g were obtained from Jackson Laboratories, Bar Harbor, Maine. Since the last 10 yr, leukemia L1210 has been maintained in these mice in this laboratory by weekly i.p. transplantation (1×10^6 cells/mouse).

During the course of these studies, a subline of leukemia L1210 resistant to GZ (L1210/GZ) was developed over a period of 6 months by treating tumor-bearing mice from day 1 through day 5 with gradually increasing doses of GZ (200–1000 mg/kg, i.p.) and utilizing the surviving ascites tumor cells for subsequent transplantation. Treatment of mice bearing the L1210/GZ with GZ did not result in an increase in survival time greater than 5% of the controls.

For studies involving continuous infusions of GZ into leukemic mice, 10^6 L1210 cells were inoculated i.v., rather than i.p. and at specified times thereafter, the drug was infused continuously as described below.

In vitro *drug uptake*

Leukemia L1210 or L1210/GZ cells were obtained from the peritoneal cavity of DBA/2J mice inoculated i.p. with 2×10^6 cells/mouse, 4 days prior to cell collection. Harvested cells were washed with RPMI 1640 medium to remove the contaminating ascites fluid and red cells. The cells (1×10^7/ml, 5 ml/tube), were then suspended in RPMI medium containing 10% dialyzed fetal calf serum and incubated at 37°C with different concentration of ^{14}C-GZ for varying time. Total uptake by the cells in wet pellet was determined as the amount of radioactivity in the wet pellet minus that in fluid present in the extracellular space. The corrections for the extracellular space volume and radioactivity were determined by standard ^{3}H-inulin methods. The details of the procedures used have been described elsewhere in detail [10].

Intravenous infusion procedure

Mice were temporarily restrained and the tail vein was cannulated with saline-filled polyethylene tubing (Intramedic PE No. 10, Clay Adams Co.) through a cut made with a surgical suture needle (Ethicon, Type B No. 682). Proper positioning of the cannula was routinely verified by the backflow of blood. The other end of the tube was connected to a Luer Lock syringe by means of a No. 27 gauge hypodermic needle. The cannula was protected by a 75×12 mm polystyrene tube and the mouse was released in the cage with the infusion assembly connected to a Harvard infusion pump [9]. In this way, it was possible to infuse drug for several days without visible trauma to the animals. Groups of mice were infused with saline or GZ solution for varying periods of time at a flow rate of 0.3 ml/hr.

Incorporation of radiolabeled nucleosides

At the termination of infusion, ^{14}C-uridine of a specific activity of 2.5 μCi/0.4 μmole/0.2 ml and ^{3}H-thymidine of a specific activity of 25 μCi/0.1 μmole/0.2 ml were immediately injected through the polyethylene cannula and the mice were sacrificed 15 min thereafter. In some experiments, ^{3}H-uridine (UR) and ^{14}C-thymidine (TdR) were used without any change in the quantities injected. Tissues were rapidly removed and frozen in liquid nitrogen. Tissue homogenates were then prepared in cold 6% perchloric acid (PCA) by 10 strokes with a Ten-Broeck homogenizer. Bone marrow cells were recovered from both femurs by rinsing the marrow cavities with 1 ml saline per femur. These cells were also treated with 6% PCA.

The homogenates were centrifuged at 1000 ***g*** for 10 min at 4°C. The PCA-soluble supernatant fraction containing nucleosides and nucleotides, as well as GZ, was assayed for total radioactivity and for GZ.

To remove residual soluble matter, the PCA pellet containing nucleic acids and other macromolecules was washed 3 times with 5 ml of cold 6% PCA. DNA and RNA were separated by the method of Schneider [11]. This procedure involved alkaline hydrolysis of RNA with 1 ml of 1N NaOH at 37°C for 1 hr followed by neutralization and extraction of RNA nucleotides with cold PCA. DNA nucleotides were extracted from the residue by treatment with PCA at 70°C for 15 min. Aliquots of RNA and DNA were counted for radioactivity. RNA content was determined by the orcinol reaction [11] and DNA by a modification of Burton's method [12] using 0.6 mM paraldehyde instead of acetaldehyde [9].

Guanazole was determined colorimetrically by a procedure involving diazotization and coupling with diphenylamine [13].

Determination of ribonucleotide pool sizes

Purine and pyrimidine ribonucleotides in spleen and in L1210 cells obtained from i.p. ascites tumor were separated by diethylamino-

ethyl (DEAE)-cellulose column chromatography and quantitated as described previously [14]. Identification of components was based on their elution position on the calibrated column, and by absorbance ratio at 280/254 nm at pH 4.4 and 12. Spleens were removed under minimum anesthesia and placed into liquid nitrogen. A high speed of tissue removal was essential to minimize the breakdown of nucleoside triphosphates [15, 16]. Labeled ATP added to tissues as a marker prior to extraction with PCA was recovered quantitatively indicating that no breakdown of triphosphates occurred during tissue processing.

Measurement of radioactivity

Radioactivity was determined in a Packard liquid scintillation counter by counting up to 1 ml aliquot of the aqueous samples in 1 ml of a scintillation counting fluid containing 0.6% w/v PPO, 0.06% dimethyl POPOP and 15% Beckman Biosolv 3 in toluene. The counts were corrected for quenching using the external standard ratio method [17].

RESULTS

Differential effect of GZ on the incorporation of nucleic acid precursors in different tissues in mice

The effects of GZ on the incorporation of TdR and UR into nucleic acids of mouse tissues are summarized in Table 1. Following 18 hr of continuous infusion, the drug produced greater inhibition of ^{14}C-UR incorporation into DNA than into RNA. The maximum inhibition occurred in spleen, thymus and bone marrow cells. No inhibition occurred in kidney and liver tissues. In the liver, a stimulation of incorporation into nucleic acids was apparent. Furthermore, GZ was more inhibitory to the incorporation of ^{3}H-TdR into DNA than that of UR into the DNA of lymphoid and hemopoietic tissues. In other tissues either no effect or a stimulation of incorporation was observed. In the experiments involving both UR and TdR, no noticeable differences were observed between total acid-soluble pools of corresponding tissues from control and GZ-treated mice. This suggested that GZ has no effect on the transport of nucleotides *per se*.

The GZ effect on thymidine incorporation could not be reversed when an equimolar mixture of the other three unlabeled deoxyribonucleosides was injected together with thymidine.

The inhibition of UR and TdR incorporations into DNA of lymphoid and hemopoietic tissues appeared to be somewhat related to the intracellular GZ concentrations (Table 1). Consistent results were obtained when 5 and 30 ml/mg GZ solutions were infused for 1 hr at which time, steady-state level of GZ was presumably reached in plasma [9]. Thus incorporation of uridine into DNA of spleen and thymus decreased respectively from about 25 to 12 and 43 to 22% of the control on increasing GZ concentration from 5 to 30 mg/ml. Under the same conditions, incorporation of uridine into

Table 1. *Distribution of GZ in non-leukemic DBA/2J mice following* 18 hr *i.v. infusion and effects on the incorporation of uridine and thymidine into nucleic acids of various tissues*

Tissue	Guanazole μg/g tissue	Uridine incorporated into DNA (% of the control)	Uridine incorporated into RNA (% of the control)	Thymidine incorporated into DNA (% of the control)

Guanazole (5 mg/ml) was infused i.v. for 18 hr at the rate of 0.3 ml/hr. Control animals received infusion of normal saline. Specific incorporation of ^{14}C-uridine into DNA and RNA was determined and expressed as % of control values. Incorporation ^{3}H-thymidine into DNA was also expressed as % of control. The average values for incorporation of uridine into DNA (dpm/mg DNA) of spleen, thymus, bone marrow, heart, brain, kidney and liver from saline-treated mice were: 28,654; 1,475; 37,142; 6,931; 1,218; 6,325 and 13,230, respectively and those into RNA (dpm/mg RNA) were: 12,291; 9,311; 4.574; 23,149; 8,939; 12,245 and 13,191, respectively.

*†Each value is an average based upon either (*) 6 control and 6 drug-treated animals or (†) 4 control and 4-drug-treated animals ± standard deviation.

RNA did not change in the case of thymus and decreased from 52 to 41% of control in the case of spleen. With this treatment, intracellular concentration of GZ increased from 60 ± 10 to 331 ± 20 mg/g wet weight of the spleen respectively (2 mice/group).

Drug uptake in L1210 and L1210/GZ in vitro

Since the data obtained with GZ infusion (Table 1) suggested that the tissue-selective effects of GZ is related to differential GZ uptake,

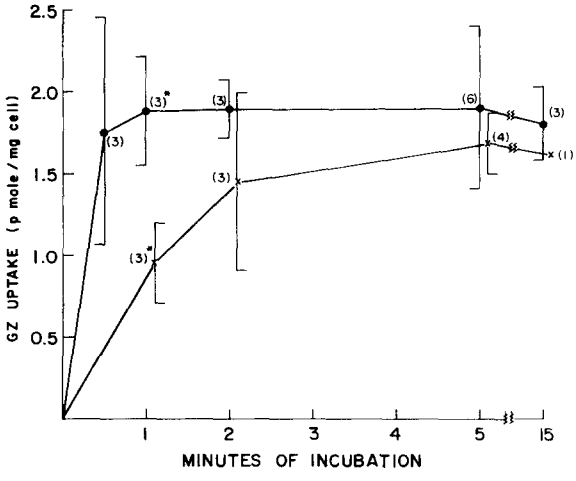

Fig. 1. In vitro *uptake of* ^{14}*C-GZ at varying periods of time. L1210 (●) or L1210/GZ (×) cells obtained from the i.p. cavity of DBA/2J female mice on the* 4th *day after transplantation of* 2 × 10^6 *cells, were incubated with* ^{14}*C-GZ* (4.0 μM) *at* 37°C *as described in the text. Incubation with GZ was carried out for varying periods of time up to* 15 min *and the drug uptake per mg net cell weight was determined.*

Each point is an average of the number of experiments indicated in parenthesis; vertical bars indicate standard deviation. All the uptake values for the L1210/GZ cells, have been shifted to the right by 0.1 min *in order to accommodate the vertical bars. *Values significantly different at* $P = 0.002$ *using Student's t-test.*

it was of interest to compare the GZ uptake in L1210/GZ cells. The course of uptake of GZ in both cell lines is shown in Fig. 1. The initial rate of GZ uptake was very rapid in both cell lines although in L1210 cells, it was about 2–3 times greater than in L1210/GZ cells. Differences between the two lines in the total amount of GZ taken up decreased considerably within 5 min and the uptake seemed to remain constant thereafter up to 15 min. At that time point, the intracellular concentration in L1210 cells was about 75% of that in the extracellular water, assuming that all the GZ was distributed in intracellular water [about 60% net weight of the cells [6]. In the case of L1210 cells, the initial rate of uptake determined at 1 min after drug addition did not show any saturation over a 250-fold range of extracellular drug concentration (Table 2). It may be mentioned that throughout

Table 2. Effect of drug concentration on the in vitro *uptake of* ^{14}*C-GZ by mouse leukemia L-1210*

GZ concentration (μM)	Uptake (pmole/mg cell/min)	I/E ratio
4.0	1.9 ± 0.5 (6)	0.79
14.0	7.5 ± 0.1 (2)	0.92
100.0	59.6 ± 7.1 (2)	0.99
1000.0	514.5 ± 62.7 (2)	0.86

DBA/2J female mice were inoculated i.p. with 2 × 10^6 L-1210 per mouse on day 0. On day 4, the mice were sacrificed and the leukemic cells were harvested, washed and incubated at 37°C with varying concentrations of ^{14}C-GZ as described in Materials and Methods, for 1 min. The uptake was determined as described and I/E was calculated assuming 60% of cell volume as total intracellular water and the specific gravity of the cells as 1.0.

Each value is an average of the number of observations ± S.D. or 0.5 range in the case of two observations. Number of observations are shown in parentheses.

the time-course of this study, the cell viability as determined by trypan blue exclusion remained 98–100% for both the cell lines.

Effect of GZ in mice bearing leukemia L1210

A comparison of the effect of GZ on the survival of DBA/2J-female mice given L1210 and L1210/GZ leukemia i.p., is shown in Table 3. The growth of L1210/GZ appeared to be somewhat slower than that of L1210 as inferred from the increased survival of the corresponding untreated mice. This is consistent with the marked increase in immunogenicity of this tumor [18]. Drug treatment did not have any significant effect on the survival of mice bearing the resistant leukemia.

When DBA/2J female mice were injected i.v. with 10^6 L1210 cells, their average survival was 4–5 days. On autopsy, the spleen of these mice was found to be enlarged and increased in weight from 60–70 mg to 250–300 mg, and leukemia cell colonies could be seen. No ascites fluid

Table 3. Effect of guanazole treatment on survival of leukemia-bearing mice

Dose of GZ (mkg × 5)	Average survival (days) ± S.D. L-1210	L-1210/GZ
Control	8.6 ± 0.4	9.2 ± 0.5
450	11.0 ± 1.2	9.6 ± 0.5

DBA/2J female mice were inoculated i.p. with L-1210 or L-1210/GZ cells (1 × 10^6/mouse).

Groups of 10 mice were either treated with saline (control) or GZ once daily for 5 days from day 1 onwards and their survival was observed.

Table 4. Effects of guanazole infusion for 1 hr *on incorporation of* ^{14}C*-thymidine and* ^{3}H*-uridine into spleen DNA of leukemic and non-leukemic mice*

Tumor in spleen	Infused guanazole (mg/ml)	Guanazole (μg GZ/μg DNA)	TdR incorporation into DNA (% of the control)	UR incorporation into DNA (% of the control)
None	5	27± 3	44.0± 3.5	78.1±1.9
	30	85± 6	10.1± 3.2	35.3±2.0
L1210	5	36± 6	19.1± 1.0	75.8±9.7
	30	103± 7	7.2± 4.1	31.9±6.1

	30	41±15	66.3±10.2	72.9±1.5

GZ (5 or 30 mg/ml) was infused for 1 hr at rate of 0.2 ml/hr (control mice were infused with saline). A mixture (0.2 ml) containing 2.08 μCi/0.1 μmole (U-^{14}C)-TdR or 20.1 μCi/0.4 μmole ^{3}H-uridine was injected through the cannula 15 min before sacrifice and removal of tissues. GZ in tissues was determined in the neutralized, PCA-soluble extracts as described in the text and expressed as μg per g frozen weight of tissues. Specific incorporations of TdR and UR into DNA were determined in the PCA-insoluble pellet and the results are expressed as percent of the corresponding saline-treated controls. The average saline-treated control values for TdR incorporation into DNA (dpm/mg DNA) were 23, 100; 22, 500 and 23, 800; and for UR incorporation into DNA (dpm/mg DNA) were 8, 460; 7, 690 and 9, 210 in the cases of spleen from normal, L1210-bearing and L1210/GZ-bearing mice respectively. The individual control values ranged between 93 and 107% of their means. Each number is an average of two experimental values ±0.5 range.

was, however, detected. Both non-leukemic and leukemic spleens showed a similar ability to incorporate uridine or thymidine into RNA and DNA (see legend of Table 4).

As shown in Table 4 and consistent with the data on GZ uptake in L1210 and L1210/GZ cells, the inhibition of incorporation of thymidine was higher in "L1210 spleen" than in "L1210/GZ spleen". In normal spleen cells, the inhibition was intermediate. Incorporation of uridine into DNA was similarly affected by the drug although the inhibition was less marked than that of thymidine into DNA.

Ribonucleotide profile of normal and leukemic spleen

A typical column chromatographic separation of the free ribonucleoside mono, di- and triphosphates found in normal and leukemic spleens is shown in Fig. 2. Figure 2(A) represents the ribonucleotide profile of normal mouse spleens (average 67 mg each). In this chromatograph IMP is the major component while ATP as well as other triphosphate pools were present at a considerably lower level. This chromatograph was reproduced in 6 separate experiments using the DBA/2J mice. The results of other experiments, not reported here, indicated that the NTP pools vary depending on the strain of mice. For example, high ATP pools were isolated from normal spleens obtained from Swiss and C57Bl/6J mice. Figures 2B and 2D represent the chromatographic separation of the ribonucleoside mono, di- and triphosphates found in leukemic spleen at 2 and 4 days, respectively after an i.v. administration of 10^6 L1210 cells. These chromatographs show a progressive increase in the ATP pool with time after L1210 inoculation. The increase was in parallel with the increase in spleen weight (160–240 mg), indicating progressive infiltration of the spleen by L1210 cells. Figure 2C shows the ribonucleotide profile of L1210 cells obtained from the peritoneal cavity of mice, which is similar to those obtained from L1210 containing spleens (Figs. 2B and SD).

The effect of continuous 48-hr infusion of GZ (30 mg/ml, 0.3 ml/hr) was investigated. The results show that treatment with GZ reduced the average spleen weight almost to control levels. Histopathological examination revealed the absence of leukemic cells in the spleen from drug-treated mice. Although under this schedule, GZ infusion did not prolong survival of leukemia bearing animals, the ribonucleotide profile returned to the non-leukemic pattern.

DISCUSSION

Administration of GZ by continuous i.v. infusion resulted in a substantial inhibition of incorporation of uridine and thymidine into DNA, particularly of hemopoietic tissues. The inhibition was quite marked within 1 hr even at concentrations of GZ in the infusion fluid as low as 5 mg/ml and when only a 1.5 mg of GZ was administered. In contrast, a single i.v. push of 1.5 mg GZ has no such effect on precursor incorporation. This demonstrates the usefulness of this infusion system for studying agents of very short half-life in unrestricted mice. The in-

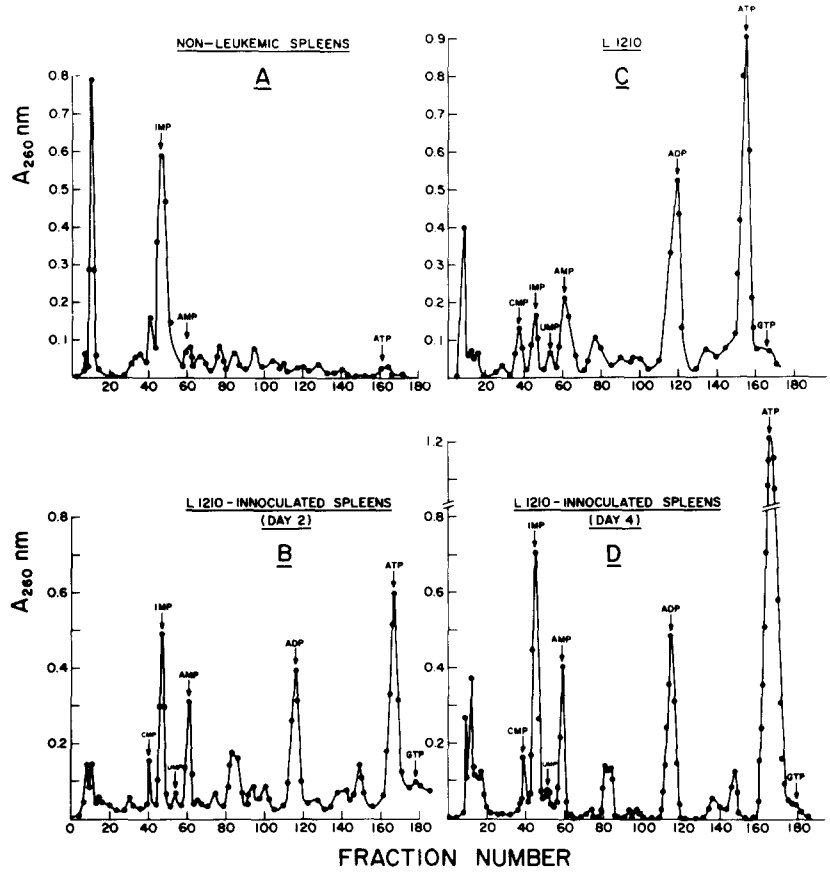

Fig. 2. DEAE-cellulose column chromatographic separation of free ribonucleotides found in normal DBA/2J mouse spleen (A) in leukemic spleen 2 days (B) and 4 days (D) after i.v. administration of 10^6 *L1210 cells. Ribonucleotide profile of ascites form of L1210 is shown in (C). Each chromatograph in A, B and D represents pooled extract of 4 spleens from which 20* A_{260} *absorbance units were absorbed on each column and eluted with an ammonium formate gradient* pH 4.4 (3 mM–0.3 M). *Similarly, 20* A_{260} *absorbance units were also used in the case of extract from ascitic L1210 cells.*

hibition of uridine incorporation into RNA and DNA of various tissues is consistent with the inhibition of ribonucleotide reductase by GZ as a primary mechanism of drug action [7]. The observed lack of inhibition of uptake of precursors or of the DNA polymerase reaction (C. Dave, unpublished data), are consistent with the contention that the reductase is probably the major site of drug action. The basis for the inhibition of incorporation of thymidine found in this study is not clear. Such an inhibition could occur due to possible changes in the pool sizes of deoxynucleotides, such as increase in dTTP or decreases in purine dNTP's. Alternately, it may represent another site of action of GZ.

Correlation of the inhibition of precursor incorporation with concentration of GZ in various tissues suggest that the differential sensitivity of tissues to the drug may be primarily related to drug uptake rather than to differential sensitivities of cellular ribonucleotide reductase(s). The transport data of GZ in L1210 cells suggest that the drug uptake occurs by a passive diffusion process. A decrease in uptake rate in L1210/GZ may therefore be related to plasma membrane changes in the resistant line. Indeed, enhanced antigenicity indicating possible membrane changes has been found to occur in L1210/GZ [18]. Similar membrane changes have also been postulated to occur in the case of L1210 cells resistant to 4,4′-diacetyldiphenyldiphenylurea-bis(guanylhydrazone)—a drug known to be taken up by a passive diffusion process [10, 19]. Thus membranes of different tissues may offer a different degree of resistance to entry of GZ and this may be the basis for its tissue-specificity.

It should, however, be pointed out that in a Chinese hamster ovary cell line, resistant to hydroxyurea, another ribonucleotide reductase inhibitor, the occurrence of an isoenzyme was found to be the basis for drug resistance [20]. Thus, in analogy with hydroxyurea, both altered

uptake of GZ and altered sensitivity of the reductase to the drug could be determinant of sensitivity to GZ. Based upon this premise, the determination of uptake of GZ and of incorporation of uridine into DNA would possibly indicate the likelihood that target cells are sensitive to GZ. Peripheral or bone marrow lymphoblasts from leukemic patients may be considered as potential target cells in this respect.

Low concentrations of triphosphate pools in normal spleen may be a unique occurrence in these mice since the corresponding profiles in two other strains of mice was akin to that seen in liver [14, 15]. Since we are determining steady-state concentrations of nucleotide pools the low concentrations may represent very rapid turnover. Alternately, these may represent high activity of phosphates in normal DBA/2J spleens. The data obtained on the ribonucleotide pools of spleen in non-leukemic versus leukemic mice demonstrate that qualitative and quantitative differences exist in spleen as a result of infiltration by leukemic cells. After infusion with GZ, a dramatic decrease occurred in the leukemic spleen size and also in the profile of ribonucleotides which reverted to the non-leukemic pattern. Such differences in the pool sizes may be indicative of differences existing in the regulation and biosynthetic needs of the cell types involved. Whether such differences could be exploited to diagnose potential or existing malignancy or to predict sensitivity towards a particular therapeutic regimen requires further investigation.

In conclusion, the results reported herein are in agreement with the earlier finding by Brockman *et al.* [7] indicating that the mechanism of action of guanazole is mediated through inhibition of ribonucleoside diphosphate reductase in different normal and tumor tissues in mice. The mechanism of selectivity of action, however, seems to be primarily dependent upon drug uptake.

Biochemical and Karyological Properties of Cells Resistant to the Quinazoline Antifolate, Methasquin*

JUNE L. BIEDLER,† ALBERTA M. ALBRECHT‡ and BARBARA A. SPENGLER†
†*Laboratories of Cellular and Biochemical Genetics and* ‡*Drug Resistance and Cyto-Regulation, Memorial Sloan-Kettering Cancer Center, New York, New York* 10021, *U.S.A.*

Abstract—*Eleven methasquin-resistant sublines were selected* in vitro *from a Chinese hamster cell line and maintained at drug concentrations of* 0.01–50.0 μg/ml. *Dose–response data showed that increases in resistance ranged from* 6- *to* 6500-*fold and that all sublines were cross-resistant to methotrexate. Dihydrofolate reductase activity was elevated* 3- *to* 165-*fold in the* 11 *methasquin-resistant lines. Relationships between drug response and enzyme activity suggested that for* 6 *sublines increased dihydrofolate reductase may be the primary determinant of response, whereas additional factors such as quantitative change in other tetrahydrofolate enzymes may influence resistance to antifolate in the other* 5. *Karyotype analysis of conventionally stained metaphase cells revealed the presence of nonuniformly altered chromosomes. Strikingly long chromosome segments were found on* 1 *homologue of chromosome* 2 *or* 4 *as a consistent feature of most, but not all, of the* 11 *methasquin-resistant sublines. The similarity of these findings to those previously reported for methotrexate sublines and more recent results obtained by trypsin-Giemsa banding analysis provide evidence of specific chromosomal alteration associated with increased intracellular dihydrofolate reductase.*

INTRODUCTION

BIOLOGICAL and biochemical studies of a series of Chinese hamster sublines selected with and resistant to methotrexate (MTX) and cross-resistant to the quinazoline antifolate, methasquin (MQ), demonstrated that an increased amount of dihydrofolate reductase (5,6,7,8-tetrahydrofolate: $NADP^+$-oxidoreductase, EC 1.5.1.3) was a primary but not the only determinant of drug response in these cells [1]. Although dihydrofolate reductase activity was elevated in all of the 9 resistant sublines, the disproportionate relationships between enzyme activity and antifolate resistance, as well as the differential response of the various sublines to MTX and MQ, suggested more than one mode of resistance. Further, the resistant sublines could be classified into 2 groups, with respect to each antifolate, when degree of resistance was correlated with enzyme increase. Partial purification and characterization of dihydrofolate reductase from drug-sensitive parent cells and the 4 MTX-resistant sublines chosen for further investigation revealed the presence, in 2 of the 4 lines, of enzyme with decreased affinity for MTX but not for MQ [2]. Those cells which synthesized the novel enzyme were relatively more sensitive to the quinazoline antifolate than to MTX. The various observations prompted a similar study of a series of resistant sublines derived by direct exposure to MQ.

Prior chromosomal studies of MTX-resistant Chinese hamster lines suggested specificity of chromosome alteration associated with elevated levels of dihydrofolate reductase [1]. Furthermore, we earlier described specific karyotypic alteration of a marker chromosome in MTX-resistant sublines of mouse leukemia L1210 [3]. This report describes drug resistance patterns and dihydrofolate reductase activity of 11 Chinese hamster sublines selected by MQ and provides further evidence of specific cytogenetic abnormalities.

MATERIAL AND METHODS

The 11 MQ-resistant sublines included in this study were selected from mass cultures of parent

DC-3F cells [4] by stepwise increases in concentration of MQ. Six sublines were derived independently of any other. Subline DC-3F/MQ8 (Table 1) was separated from DC-3F/MQ2 after 15 days of exposure to a low concentration of MQ. DC-3F/MQ19 was separated from DC-3F/MQ11, and DC-3F/MQ39 from DC-3F/MQ19, after drug exposure for 47 and 314 days, respectively. Eagle's minimum essential medium supplemented with 10% fetal calf serum was used throughout.

growth phase at time of enzyme assay. Protein was determined by the method of Lowry [7].

MQ was prepared in the laboratories of Dr. John Davoll and Dr. John Dice of Parke, Davis and Company, Ann Arbor, Mich. and supplied by Dr. Harry B. Wood of the Cancer Chemotherapy National Service Center. Its biological activities have been detailed [8]. MTX was obtained from Lederle Laboratories, Pearl River, N.Y. The 2 antifolates have similar mol. wt, 438.4 and 454.4, respectively.

*ED_{50} value (50% inhibitory concentration) is based on 2–3 experimental determinations.
†Resistance is expressed as ratio of ED_{50} values for resistant to parental line; ratios were calculated as antilog of difference between log ED_{50} values obtained by computer.
‡ED_{50} of methasquin: ED_{50} of methotrexate, as calculated from molar equivalents of calculated values.

Response of resistant sublines to MQ and MTX was determined in a 3-day assay procedure based on relative cell counts in control and drug-treated cultures. Resistant cells were grown for 12–15 days in drug-free medium, with 2 transfers, prior to assay. Details of experiments and data analysis are essentially as previously described [1, 4], except that a thymidine supplement was not used. The dose effective in inhibiting and/or killing 50% of the cell population by the end of the 3-day period is reported as an ED_{50} value.

Dihydrofolate reductase activity was determined by previously described procedures [1,2,5]. Methods described earlier were also followed for measuring 5, 10-methylenetetrahydrofolate dehydrogenase activity either singly in reaction mixtures containing the formaldehyde adduct of dl,L-tetrahydrofolate as substrate, or coupled to serine hydroxymethyltransferase in reactions containing serine in place of formaldehyde [6]. Cells were grown for 13–14 days in absence of drug and were in exponential

Karyotype analysis and determination of chromosome numbers were made on conventional acetic orcein stained preparations, as for the MTX-resistant sublines [1]. In the present study, chromosomes were identified and classified with aid of recent results obtained by trypsin-Giemsa banding analysis [9, 10]. Modal chromosome number was derived from counts of 20–50 cells per subline. Ploidy estimates are based on surveys of 200 consecutive metaphase cells per line. Karyological determinations were carried out within 4–6 months after maintenance level of drug had been reached and were concurrent with drug response and enzyme activity determinations.

RESULTS

Resistance and cross-resistance

Response of drug-sensitive DC-3F cells and of each of the resistant sublines to both MQ and MTX is indicated by the ED_{50} values listed in Table 1. There was close correspondence be-

tween selective concentration of MQ and response to that agent for all resistant lines. Further, all sublines were similarly cross-resistant to MTX, as reflected in the calculated ED_{50} ratios (Table 1).

Correlation of dihydrofolate reductase activity with response to antifolates

All sublines had more dihydrofolate reductase activity than DC-3F (Table 2). Sublines with the greatest degree of resistance, viz. DC-3F/MQ8, DC-3F/MQ19 and DC-3F/MQ39, had the highest enzyme activity levels. However, when enzyme activity values are plotted against ED_{50} values (Fig. 1), the 11 MQ selected sublines appear to fall into 2 groups differing in the relationship between enzyme level and drug response. The 5 sublines in Group 2 demonstrate comparatively higher levels of resistance in relation to dihydrofolate activity than do the 6 sublines and parental DC-3F cells in Group 1. All cell lines responded similarly to the 2 antifolates (Table 1). Therefore, differential sensitivity to MQ by the dihydrofolate reductases of each group of sublines, as previously observed for MTX-resistant lines [2], does not apparently account for the disparity between enzyme and resistance levels; a study of the inhibition by MTX and MQ of the dihydrofolate reductase activity of representative sublines DC-3F/MQ19 (Group 2) and DC-3F/MQ25 (Group 1) demonstrated similar drug-titration patterns (Fig. 2).

Table 2. Dihydrofolate reductase activity of drug-sensitive parent line and methasquin-resistant sublines. The value for DC-3F line ± S.D. is based on 5 independent enzyme assays and was previously reported [3]. All other values were obtained in 2–3 independent determinations

DC-3F/MQ39	67.83	165

*μmole of dihydrofolate reduced/hr/mg protein.
†Ratio of specific activities of resistant to parent cell line.

Activity of other enzymes

Low levels of serine hydroxymethyltransferase and 5,10-methylenetetrahydrofolate dehydrogenase activity were detected in cell extracts of the parent line, DC-3F and 4 representative resistant sublines (Table 3). Both enzyme activities in the 2 sublines from Group 2 resembled those determined for DC-3F with the greatest difference, a 30% lower level of dehydrogenase, displayed by DC-3F/MQ19. In contrast, dehydrogenase levels, when assayed separately, were 50–60% lower for the resistant sublines of Group 1. When coupled to serine hydroxymethyltransferase, the dehydrogenase activity of DC-3F/MQ29 was similarly low. The combined serine hydroxymethyltransferase and dehydrogenase activity of DC-3F/MQ11, also in Group 1, was somewhat higher than that of DC-3F/MQ29, but was, nonetheless, lower than the parental value.

Chromosome studies

Seven of the 11 MQ-resistant sublines had chromosome numbers predominantly in the diploid range, while 3 sublines were near-tetraploid (Table 4). In the 11th subline, DC-3F/MQ29, the frequency of "tetraploid" metaphases was consistently 20–25%. Of the 3 independently-derived hypotetraploid lines, DC-3F/MQ10 and DC-3F/MQ31 had low levels of dihydrofolate reductase relative to degree of resistance (thereby placing them in Group 2), while DC-3F/MQ20 had considerably higher enzyme activity. The effect of tetraploidy *per se* on drug response and enzyme activity is not immediately apparent.

Karyotype analysis of the 8 "diploid" sublines revealed seemingly nonuniform chromosomal alterations similar to those previously observed in MTX-resistant cells [1]. As before, unusually long chromosome segments consistently were found on the long of arms of chromosomes 2 and 4, particularly. Representative karyotypes are presented (Fig. 3) for parent DC-3F cells and 3 of the 5 MQ-resistant sublines with very high dihydrofolate reductase activity (Table 2). The abnormal chromosome arms are strikingly longer than those of any of the normal chromosomes of the Chinese hamster. DC-3F/MQ39 was derived from DC-3F/MQ19 and is karyotypically similar to it. The only other MQ-resistant subline with a greater than 100-fold increase in enzyme activity is DC-3F/MQ25 (Table 2). It was found to have an abnormally long chromosome 9, a less frequent alteration observed also in MTX-resistant cells [1]. In these MQ-resistant sublines the only other consistent

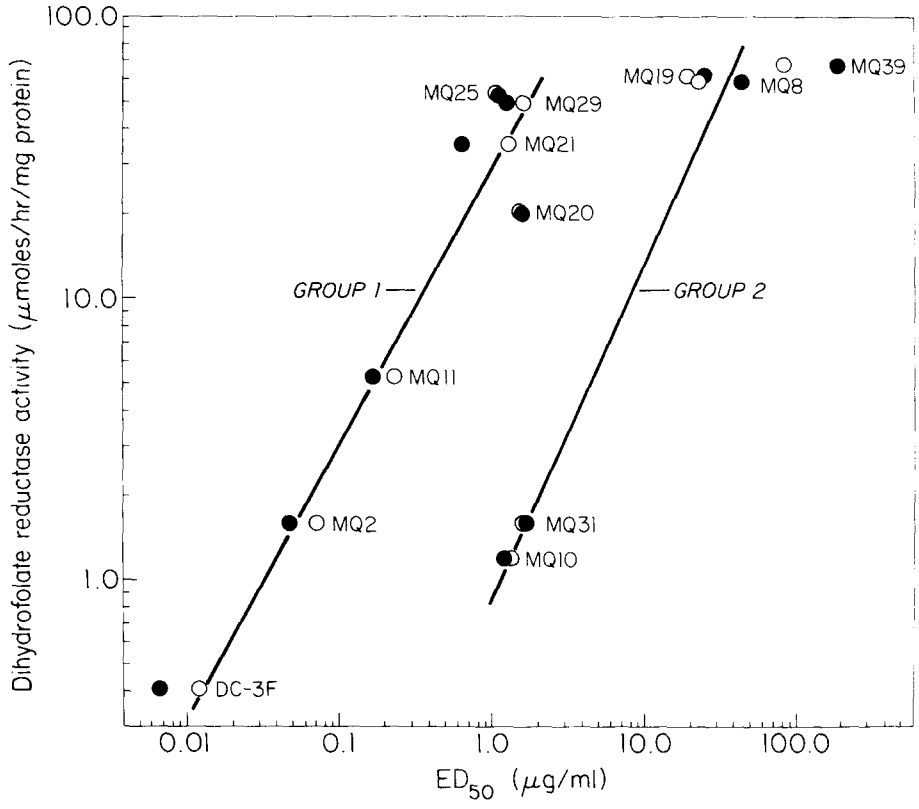

Fig. 1. Relationship between dihydrofolate reductase activity and response to MQ and MTX in terms of ED_{50} *for drug-sensitive DC-3F line and MQ-resistant sublines. Sublines are designated by abbreviated form of line name (Table 1). Methasquin response, ○; methotrexate response ●.*

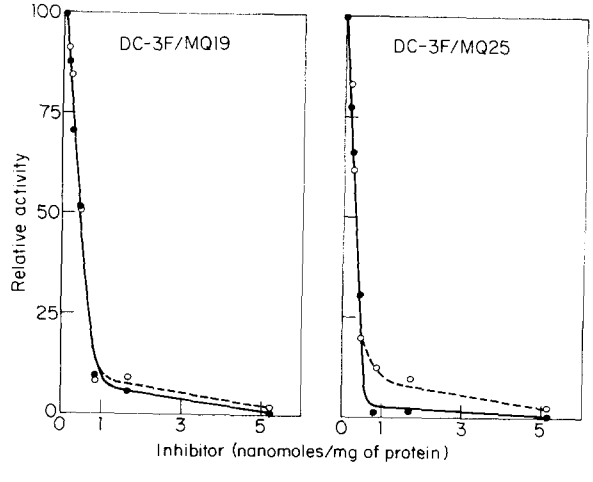

Fig. 2. Inhibition of the reduction of dihydrofolate by MTX (●) and MQ (○). Enzyme activity was determined following preincubation of cell extracts with different amounts of the inhibitors at pH 6.5. Reaction mixtures contained equivalent amounts of dihydrofolate reductase activity of either DC-3F/MQ19 or DC-3F/MQ25. Inhibitor is described in terms of the amount used/mg of protein and enzyme activity is expressed relative to uninhibited activity taken as 100.

karyotypic abnormalities characterized parent DC-3F cells as well: long arm translocation of chromosome 5, short arm translocation of chromosome 6, long arm deletion of chromosome 7 and missing or deleted X chromosomes.

Another cytologic feature of MQ-resistant cells which also characterized cells selected by MTX was the unstable configuration of a No. 2 chromosome [1]. During the course of development of resistance, examination of metaphase cells of sublines DC-3F/MQ8 and DC-3F/MQ11 revealed that usually one chromosome 2 showed either a deletion, a break, or, more commonly, a translocation to it of another centromere-containing chromosome or chromosomal segment (Fig. 4). Thus, the structural abnormality was of several different types and involved several chromosomes in addition to the No. 2. Usually only one of the homologues and only one arm of a chromosome 2 appeared affected. It is obvious even from conventionally stained chromosomes (Fig. 4) that the presumed

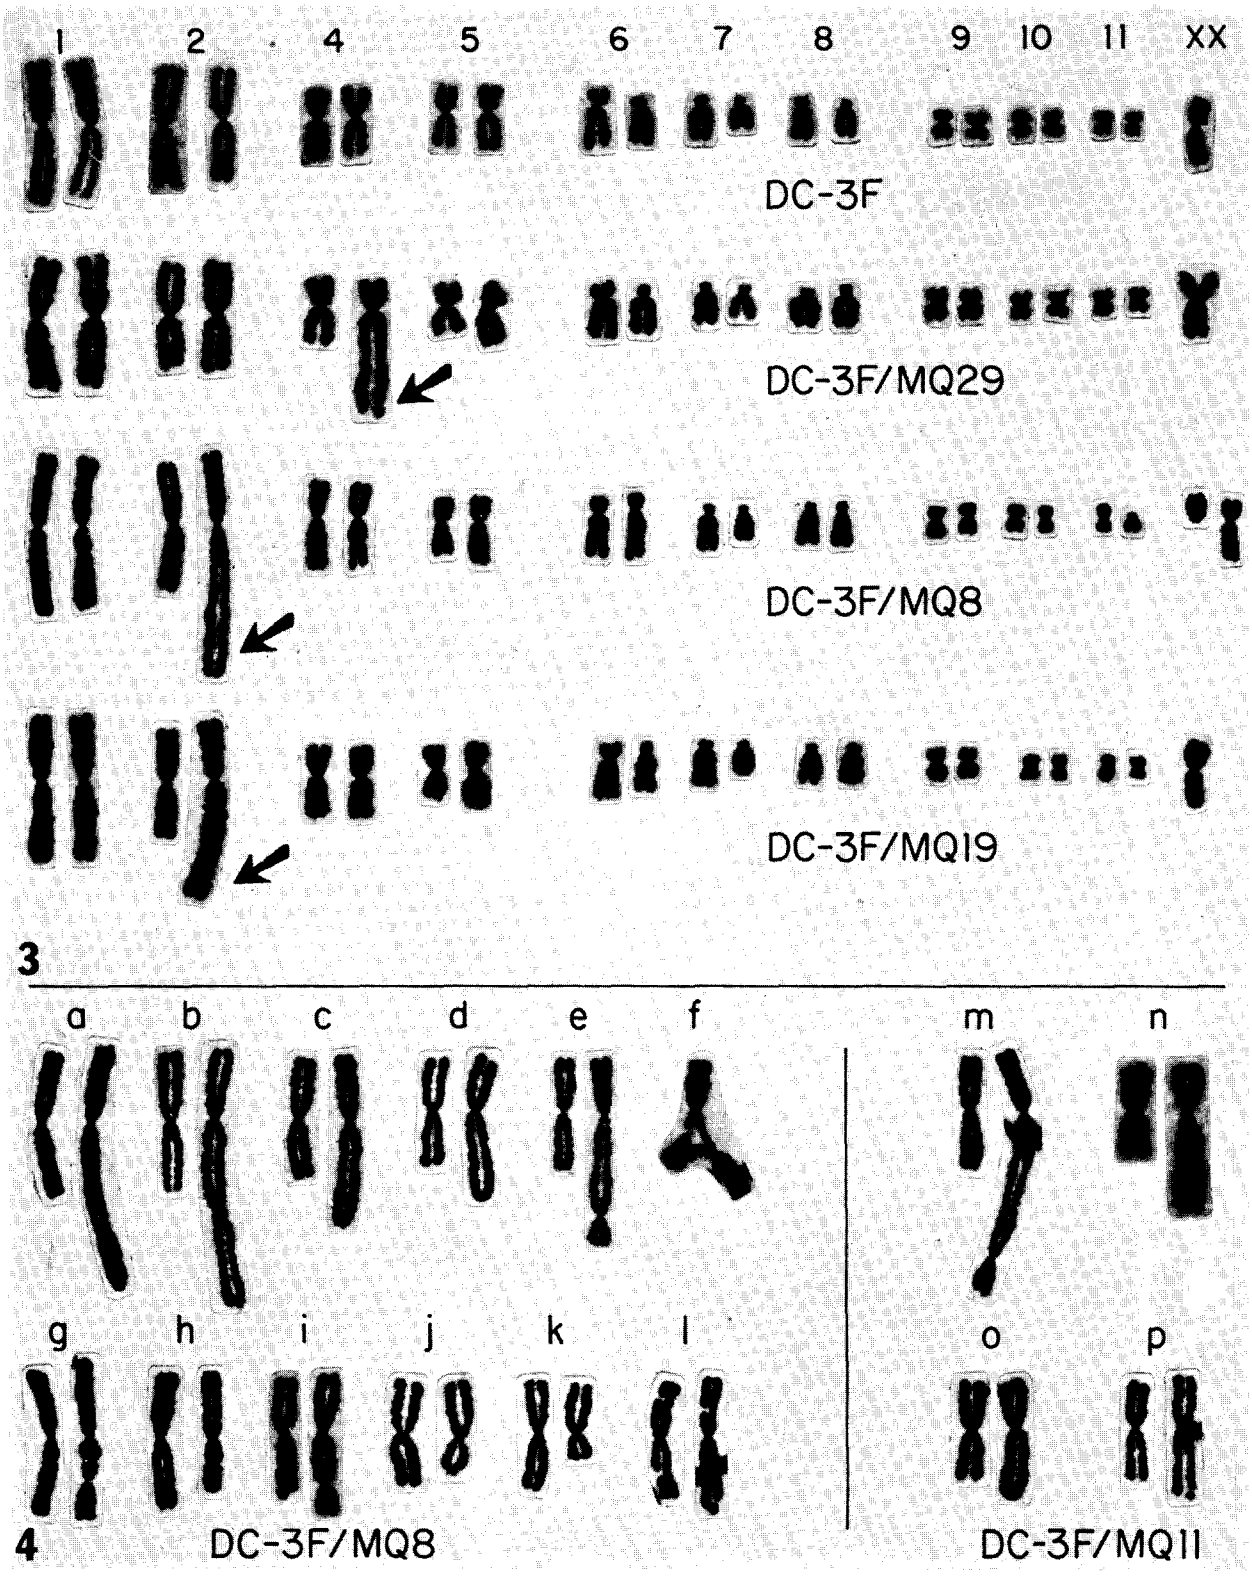

Fig. 3. Karyotypes of parent DC-3F line and 3 methasquin-resistant sublines with greater than 100-fold increases in dihydrofolate reductase activity. Abnormally long chromosome segments are indicated by arrows.

Fig. 4. Sets of No. 2 chromosomes from metaphase cells of sublines DC-3F/MQ8 and DC-3F/MQ11 karyotyped during course of development of resistance. Normal chromosome 2 is at left, for each pair. Note translocated acrocentric chromosomes with distal centromeres (sets a, c, d, h, j, o). The abnormal No. 2 of Set a has a long segment in addition to the distally translocated acrocentric, while the abnormal No. 2 of Sets h and j show partial deletions of the abnormal arm. Some abnormal No. 2 chromosomes had strikingly long arms apparently without an additional centromere (Sets b, n, p). In some cells a probable No. 5 chromosome was translocated to a No. 2 (Sets e, m and possibly g and i). Sometimes a chromosome 2 was deleted without an apparent translocation (Set k). Chromosome breaks or gaps were observed frequently (Sets f, l and p). Set f is a quadriradial resulting from a reciprocal translocation between both No. 2 chromosomes.

breakpoint in the No. 2 was not always at the same site, in whichever arm was involved. By the time that the sublines were fully resistant (i.e. no evidence of toxicity) to their final selective concentration, cells were karyotypically stable, and the configuration of the No. 2 or other altered chromosome was consistent (Fig. 3).

DISCUSSION

All of the MQ-resistant sublines had elevated levels of dihydrofolate reductase even when selected with very low concentrations of antifolate (0.01 and 0.1 μg/ml), thus implicating this enzyme activity as a primary determinant of drug response in this system. Moreover, for the 6 MQ-resistant sublines of Group 1, there is close correspondence between degree of increase in target enzyme activity and resistance (Tables 1 and 2). As previously discerned for resistant sublines directly selected with MTX [1], an additional factor appears operative for some of the antifolate-resistant populations; the 5 sublines of Group 2 are considerably more resistant than would be expected solely on the basis of enzyme activity (Fig. 1). Two highly resistant Group 2 sublines, DC-3F/MQ8 and DC-3F/MQ19, derived from the less resistant Group 1 sublines, DC-3F/MQ2 and DC-3F/MQ11, sometime after the selection process was begun (see Material and Methods) apparently developed greater resistance relative to target enzyme activity as a result of higher selection pressure (Fig. 1). This observation suggests that

an additional contributory determinant is expressed at high selective concentrations of antifolate.

In the earlier studies of Chinese hamster cells selected with MTX [2], we found, in several of the sublines, a dihydrofolate reductase structurally different from parent DC-3F type. In drug titration studies, the altered enzyme showed a decreased affinity for MTX but an unchanged sensitivity to MQ. The presence of the mutant enzyme form was reflected in the observed differential response of the resistant cells to the two antifolates; sublines with altered enzyme were relatively more resistant to MTX than to the quinazoline analogue. All of the MQ-resistant sublines, however, responded similarly to the two drugs. Furthermore, kinetic analysis of the inhibition by the two antifolates of the enzymic reduction of dihydrofolate demonstrated similar drug titration patterns. Therefore, the greater resistance of Group 2 sublines does not appear to be the result of an altered dihydrofolate reductase similar to that detected and characterized in MTX-resistant cells.

Nevertheless, two clearly distinguishable groups of sublines differ in the relationship of resistance level to level of dihydrofolate reductase activity. Several explanations are possible. Sublines of Group 2 (Fig. 1), with relatively high resistance in relation to enzyme level, might synthesize a dihydrofolate reductase that is structurally different from that in Group 1 sublines and from the mutant enzyme form found in MTX-selected cells [2]. Such an alteration could influence the kinetics of intracellular enzyme activity in the presence of drug. Alternatively, other enzymes of folate metabolism [11] may quantitatively or qualitatively differ in the two subline groups. As suggested by the values for the serine hydroxymethyltransferase and 5,10-methylenetetrahydrofolate dehydrogenase activities of selected sublines of Groups 1 and 2 (Table 3), decreased levels of enzymes needed for efficient utilization of tetrahydrofolate, below the parental cell type level, might prevent the full expression of increased dihydrofolate reductase activity. In addition to enzyme differences, dissimilarities in active transport of MQ could contribute to the basis for the two groups.

Cytogenetic analysis of MQ-resistant cells strengthened previous observations of specific chromosome abnormalities in antifolate-resistant cells with increased levels of dihydrofolate reductase [1, 3, 12, 13]. In drug-resistant Chinese hamster cells the abnormalities are manifested as strikingly long chromosome segments most frequently marking chromosomes 2 and 4. Recently we extended these observations by examination of 13 of the "diploid" sublines independently selected with either MTX or MQ by means of trypsin-Giemsa banding methods [9, 10]. As briefly described elsewhere [14, 15], in those 7 sublines with greater than 100-fold increases in dihydrofolate reductase activity, a long, homogeneously staining region ("HSR") was consistently present, usually on the long arm of a chromosome 2 or otherwise on a chromosome 4 or 9 and, in one instance, on an unidentified marker chromosome. Further evidence of the relationship between the anomalous chromosome region and resistance to MTX or MQ associated with increased target enzyme activity was provided by another preliminary investigation [16]. When highly resistant, cloned cell populations were maintained in drug-free medium, there was a parallel decrease in antifolate resistance and average HSR length. In addition, we have found that in cell lines with high target enzyme activity as much as 2% of the total protein is dihydrofolate reductase [2], while in parent DC-3F cells the enzyme comprises approximately 0.012% of cell protein (A. M. Albrecht, unpublished observation). It thus appears that the strikingly long (HSR) chromosome segments are associated with overproduction of target enzyme. We are currently studying this phenomenon in an attempt to elucidate the functional significance of the anomalous chromosome region. Detailed karyotype analysis by chromosome banding techniques of the antifolate-resistant Chinese hamster sublines will be reported.

Comparisons of these MQ-selected sublines and the previously described MTX-selected sublines [2] reveal both similarities and dissimilarities. The apparently specific chromosome abnormalities are qualitatively similar. All of the 17 antifolate-resistant sublines derived from DC-3F exhibited elevated dihydrofolate reductase activity. Nevertheless, there was indication of an additional, though probably differing, determinant(s) of resistance for some sublines in each drug category. Increases in resistance and cross-resistance to MQ, as compared to MTX, were consistently of lesser magnitude. Should these various differences be reflected at the clinical level, MQ would be a useful adjunctive chemotherapeutic agent to MTX.

Geographic and Time Trends of Coffee Imports and Bladder Cancer*

ALAN S. MORRISON
Department of Epidemiology, Harvard School of Public Health,
677 *Huntington Avenue, Boston, Massachusetts* 02115, *U.S.A.*

Abstract—*Bladder cancer incidence rates were related to* per capita *coffee imports for ten countries and time trends in these variables were analyzed for the United States and Denmark. Among the ten countries, there was a weak positive association between coffee and bladder cancer for both men and women. There was a weak positive correlation of the time trends of coffee imports and bladder cancer incidence for men, but not women, in the United States. The trend of coffee imports for Denmark was dissimilar to both male and female trends in bladder cancer incidence. Because the relationships observed are neither strong nor consistent in direction, these results provide little support for an association of coffee drinking with the development of bladder cancer.*

INTRODUCTION

THE RELATIONSHIP between coffee drinking and development of bladder cancer has been the subject of several case-control studies [1–5]. These studies suggest a positive association [6]. Stocks [7] and Takahashi [8] reported that national rates of coffee importation were not related to bladder cancer mortality rates. However, an association between coffee consumption and incidence of bladder cancer might not be clearly reflected in mortality rates. Therefore geographic and temporal correlations of coffee consumption with incidence rate of bladder cancer were examined.

MATERIAL AND METHODS

This analysis was based on countries for which coffee and cigarette consumption figures and bladder cancer incidence rates were available. "The World Coffee Economy" presents national data on coffee imports for 1929 through 1960 [9]. National data on cigarette consumption also have been published [10]. The consumption figures in the present report are averages of annual data related to the population age 15 or greater. Incidence rates age-standardized to the European population were obtained from "Cancer Incidence in Five Continents" [11]. The rates for Canada and the United Kingdom are means of rates from the individual registries. Incidence rates for the "European" population were used for New Zealand. Data for South Africa have not been included as coffee and cigarette consumption were not linked with the specific racial groups for which incidence rates were published. For Denmark and Connecticut, incidence rates have been measured over extended periods [12–14], permitting study of time trends.

Trends presented in this report are based on age-standardized annual incidence rates per 100,000. However, trends in rates for men and women age 65–74 also were examined. In all regression analyses, the two independent variables were the measures of coffee and cigarette consumption. The latter was included because cigarette smoking is a well established risk indicator for bladder cancer [15], and ignoring cigarette consumption might lead to the appearance of erroneous relationships between coffee and bladder cancer. Thus, regression coefficients presented for coffee imports have been adjusted for the effect of cigarette consumption. In each analysis the independent variable was the annual incidence rate.

RESULTS

The basic information for the international comparisons is presented in Table 1. Exposure data were taken from the period about 25 yr before the incidence data were collected in order to allow for the probable long induction period of bladder cancer [1]. The rate of coffee

1965–1968	——	3808	23.4	6.4

§For 1960.
‖For Connecticut.

importation has a range of about 100-fold, from 0.11 in Japan to 10.91 in Denmark. Regular coffee-bladder cancer trends are not apparent, but some of this irregularity seems attributable to differences in cigarette consumption. In two countries with low or moderate incidence rates but relatively high coffee consumption—Norway and Sweden—cigarette consumption was quite low. In the United Kingdom, where bladder cancer rates were high but there was little coffee consumption, the annual number of cigarettes smoked per adult was high.

The age-adjusted annual bladder cancer incidence rate for men was estimated to increase 0.45 per 100,000 for each kilogram of coffee imported per person per year. The corresponding rate of increase for women was estimated as 0.23. Two-sided *P*-values for these regression coefficients are 0.59 and 0.17, respectively. However, a *protective* effect of coffee drinking on bladder cancer seems most unlikely, judging from previous studies, so one-sided *P*-values of 0.30 and 0.08 might be more appropriate.

Data on time trends in the U.S. and Denmark are presented in Tables 2 and 3. In both countries, bladder cancer rates for both men and women have increased, this increase being somewhat greater in Denmark than in the U.S. In Denmark, a uniform trend in coffee imports is not apparent; there was a marked decrease around the time of World War II. There has been a slow increase in coffee imports in the U.S. In each area, cigarette consumption has risen sharply during the period of observation, the increase from the earliest time period to the most recent being about threefold.

Table 3. Coffee and cigarette consumption and age-standardized bladder cancer incidence rates by time period, Denmark

	Coffee (kg imported per adult per yr)	Cigarettes (number per adult per yr)	Bladder cancer (annual incidence per 100,000)	
			Male	Female
1929–1932	10.44	470	—	—
1933–1937	9.72	476	—	—
1938–1942	5.73	570	—	—
1943–1947	1.95	530	8.7	3.4
1948–1952	5.15	1116	11.9	3.9
1953–1957	8.76	1196	16.1	5.2
1958–1962	11.61*	1430	18.7	5.8
1963–1967	—	1522	23.8	6.4

*For 1958–1960.

Regression coefficients were computed for descriptive purposes, although the coefficients were based on only six observations for the U.S. and five for Denmark. Incidence rates for time periods beginning in the 1940s and after were related to exposure data for the period 10 yr earlier. There was a weak positive association of coffee imports with the bladder cancer rate for U.S. men (regression coefficient, 0.31) but not for U.S. women (regression coefficient, −0.19). In Denmark, the trend in coffee imports was dissimilar to the trends of both male and female rates of bladder cancer. The regression coefficients were −0.51 for men and −0.15 for women.

The geographic and temporal relationships of coffee imports to incidence rates for men and women age 65–74 were similar to the associations presented for the age-standardized rates.

DISCUSSION

Observations from case-control studies have not been consistent, but have suggested a positive association between coffee drinking and risk of bladder cancer. Cole reported relative risks of 1.3 in men and 2.5 in women for drinkers of one or more cups per day, compared to those who drank less [1]. Positive associations were found by Fraumeni *et al.* [2] in three of four sex-race groups, and Bross and Tidings [3] in five of six age-sex groups, although the over-all association was weakly negative for women in the latter study. A positive association also was observed in a study limited to women that was reported by Simon *et al.* [4]. However, dose–response relationships have not been observed in these studies and bladder cancer did not appear associated with coffee drinking in a study done in Canada [5].

Bladder cancer mortality rates have not been found to be correlated with rates of coffee importation [7, 8]. In the mortality studies the effects of cigarette smoking and induction period were not taken into account, but these factors were accommodated in the present analysis of incidence rates. Positive associations of coffee and bladder cancer were observed for the international comparisons, although these relationships are weak. The increasing bladder cancer rate for Connecticut men does follow the increase in U.S. coffee imports, but a similar trend was not observed for men in Denmark.

The bladder cancer rate increases for women in Connecticut and Denmark were less than those for men in the respective areas. These relatively small increases for women are consistent with the comparatively low exposure rates of women to the major known bladder cancer risk factors, cigarette smoking and occupation [6]. With tobacco consumption taken into account, there was no evidence that coffee contributed to the female rate increase in either area. Thus, on balance, the observed geographic and temporal trends provide little support for a coffee–bladder cancer association.

The irregularities in the results of the case-control studies suggest that observed positive associations of coffee and bladder cancer are not the result of a causal link [4]. The apparent lack of consistent geographic and temporal correlations also suggests this point of view. However, the present results have some important limitations. First, the analyses were, of necessity, based on only a small amount of information. Second, the measure of "exposure" is rather indirect; that is, the amount of coffee imported annually per adult over 15 may not be a good indicator of potentially relevant long-term coffee drinking patterns of individuals. Therefore, consistent changes of incidence rates in relation to coffee imports might not have been observed readily.

Comparison of the Cytotoxicity of Methotrexate and Aminopterin on Methotrexate Resistant Murine Lymphoma Cells *in Vitro*

J. H. GOLDIE* and S. I. HARRISON

Departments of Medicine, University of Toronto and University of British Columbia, Canada

Abstract—*The cytotoxicity of equivalent concentrations of methotrexate and aminopterin were compared on two methotrexate resistant sublines of murine lymphoma cells. At all concentrations of drug and for all durations of exposure the effects of the two agents were equivalent. Under the experimental conditions employed the superior transport properties of aminopterin failed to produce enhanced cytotoxicity as compared with methotrexate.*

INTRODUCTION

METHOTREXATE (MTX) superceded aminopterin in clinical use in the early 1950's and has remained to this date the most important and widely used folic acid antagonist in clinical cancer chemotherapy. Early toxicological studies in animals and in man indicated a somewhat superior therapeutic index for MTX, though for equivalent therapeutic effect it was suggested that the dose of MTX must be five to ten times higher than aminopterin. [1–3].

Recent studies by Goldman would suggest that at equivalent concentrations aminopterin is transported more efficiently into cells and hence on an equimolar basis may be a more effective cytotoxic agent than MTX [4]. With current protocols utilizing very high doses of MTX this biochemical advantage might be translated into both a better anti-tumour effect as well as a possible economic saving in terms of less drug being required. To test this hypothesis we compared the effect of very high concentrations of MTX and aminopterin on the viability of two lines of murine lymphoma cells, each relatively resistant to MTX, but by differing mechanisms. Under the experimental conditions employed we could discern no differences in effect between aminopterin and methotrexate when time and dose were varied.

MATERIAL AND METHODS

Cells and cell culture

A subline of L5178Y lymphoma cells (L5178Y-MRT) which are capable of growing continuously in suspension culture at concentrations of methotrexate of 5×10^{-6}M was employed. The cells were grown in Fischer's medium for leukemic mouse cells (Grand Island Biologicals, New York, U.S.A.) supplemented with 10% foetal calf serum (Flow Laboratories Ltd., U.S.A.). Resistance in this cell line has been found previously to be related to impaired MTX transport [5, 6].

L1210 cells designated R3U (a gift from Dr. R. C. Jackson, Laboratory of Experimental Oncology, Indiana University) were grown in RPMI 1640 medium (Grand Island Biologicals, New York, U.S.A.) supplemented with 10% foetal calf serum. This cell line was capable of sustained growth at concentrations of methotrexate up to 10^{-6}M. Resistance in this cell line associated with an elevated level of dihydrofolate reductase, but normal MTX transport [7].

Cell viability assays were performed according to the method of Chu and Fischer [8] and with modifications previously described [9]. The method for the L1210 cells was essentially identical to that for the L5178Y cells. Under these conditions the cloning efficiency for the L5178Y cells was between 65–75% and for the L1210 cells between 60–70%. The data expressed in the survival curves represents the mean and standard deviation of the colony counts of five replicate cultures with each point expressed as a percentage of the non-treated

control cultures, which were given the value of 100%. Survival was determined under conditions where duration of exposure was kept constant at 24 hr and dose was progressively increased. In the time course survival curve the concentration of drug was set at 10^{-4}M and the survival at 6, 24 and 48 hr was measured.

Reagents

MTX was obtained as the sodium salt from Lederle Laboratories, Montreal, Canada. Aminopterin was obtained from Sigma Biochemicals, St. Louis, U.S.A.

RESULTS

Figure 1(a) and (b) shows the survival curves of the L5178Y and L1210 cells with percent

drug concentration on the survival of the two cell lines with the duration of exposure extended to 48 hr. In both cell lines increasing exposure beyond 24 hr resulted in significant increase in fractional cell kill, but again no large differences between MTX and aminopterin were observed.

DISCUSSION

It is disappointing to observe that in our system aminopterin showed no advantage over methotrexate. The cell lines employed were deliberately selected because they were moderately resistant to methotrexate and by what appears to be the two principle mechanisms of resistance for mammalian cells [7]. No sweeping generalization from these negative results ought to be made. The superior transport properties of aminopterin noted by Goldman [4] may not be manifest in all tumour types or under all experimental conditions. Furthermore the pharmacokinetics of the two drugs in the patient may provide an advantage of one drug over the other which is not apparent in an *in vitro* system. In this connection, however, the pharmacokinetic differences between MTX and aminopterin that have been demonstrated in the mouse [10] seem to result in enhanced toxicity for aminopterin. The demonstration of a clear cut biological superiority of aminopterin over methotrexate in some tumour systems would lend encouragement for the search for human malignancies where the substitution of one antifolate for the other would offer significant advantages in terms of treatment.

CONCLUSION

In the two cell lines employed in these experiments each resistant to methotrexate by differing mechanisms, no evidence of superiority of aminopterin over methotrexate could be found in cell viability assays. Though there are theoretical considerations for believing aminopterin might be superior to methotrexate, this was not apparent in the *in vitro* conditions described in this report.

Studies of the Growth of an Ascitic Tumour. I. Cellular and Subcellular Changes During the Tumour Growth

L. KOPPER, A. JENEY, J. TAKÁCS, I. BENEDECZKY, E. DZURILLAY and K. LAPIS

Ist Institute of Pathology, Semmelweis Medical University, 1085 Budapest, Üllői u. 26, Hungary

Abstract—*The growth rate of the NK/Ly ascitic tumour decreases continuously but reversibly with the enlargement of the tumour mass. The increase in duration and distribution of cell cycle times is accompanied by structural alteration of nuclei and cell membranes, a reduced level of precursor incorporation into biopolymers and a decreased RNA polymerase activity. Besides the similarity in the nuclear proteins different types of non-histones are preferentially synthesized in the fast and slowly proliferating cell population. Furthermore, differences are observed in the decomposition rate of nuclear protein fractions. The more extensive binding of proteins to DNA is in harmony with these observations and all suggested that gene-expression decreases during tumour growth.*

INTRODUCTION

SINCE ascitic tumours are relatively homogeneous cell populations, they are widely used as test systems for experiments designed to obtain data on the characteristics and regulatory mechanisms of tumour growth. Numerous studies have provided evidences on the various changes both at the cellular and subcellular level during tumour growth [1–13] but very few were concerned with a comprehensive analysis of the same tumour. We have felt that detailed studies of the tumour growth using cell kinetic, biochemical and morphological approaches and concentrating mainly on the nuclear changes might help us not only to know more about the important steps involved in the steadily decreasing rate of cell proliferation but also to plan experiments on drug sensitivity at different stages of the tumour. The latter issue is based on several observations indicating the role of growth rate in the effectiveness of cancer chemotherapy [14–18].

MATERIAL AND METHODS

The NK/Ly ascitic tumor employed for these studies is a more or less diploid transplantable lymphoma [19] maintained in non-inbred CFLP mice by i.p. injection of 5×10^6 tumour cells weekly. The tumour has a tetraploid subline (5–10% of cells) and two marker chromosomes [20–22]. The animals were housed in plastic cages and fed with LATI pellet mouse diet and drinking water *ad libitum* (Laboratory Animals Breeding Center, LATI, Gödöllő, Hungary).

To determine growth curves, tumour-bearing mice were killed at various intervals after transplantation by cervical dislocation and the total number of ascitic tumour cells per mouse was counted in a haematocytometer. The doubling time of tumours was estimated from the computed growth curve fitting a Gompertzian equation to the experimental data.

In the labelling index experiments ^{3}H-thymidine (1 μCi/g body weight) was injected i.p. and the mice were killed 60 min later. For repeated labelling ^{3}H-thymidine was administered at 8 hr intervals. In the labelled-mitoses experiment, mice were killed at intervals of 2–4 hr after a single ^{3}H-thymidine injection. In each case the ascitic fluid was withdrawn with 0.6% sodium citrate in physiological saline. Smears were made on clean slides and fixed in methanol:glacial acid (3:1 v/v).

For preparation of autoradiographs, slides were dipped into an Ilford K5 emulsion, exposed for 1–2 weeks and developed in Microdol X. The number of labelled mitoses was determined on 250 mitoses and the data were analysed by the method of Steel and Hanes [23]. The fraction of labelled cells was counted from 1000 tumour cells.

The smears derived from single and repeated

Accepted 13 July 1977.

labelling experiments were used for cytophotometric studies. Feulgen staining was performed before autoradiography as follows: hydrolysis with 1 N hydrochloric acid at 60°C to ensure maximal dye binding and incubation for 1 hr in Schiff's reagent. Single cell DNA content was determined at 550 nm by Barr and Stroud microdensitometer type GN 2.

For electronmicroscopic study 0.25–0.25 ml of ascitic tumour was fixed in 2% OsO_4 according to the method of Palade [24]. In the case of double fixation the cells were fixed in phosphate buffered (pH 7.4) 2.5% glutaraldehyde and postfixed in OsO_4. For cytochemistry the tumour was fixed only with glutaraldehyde. The RNP "staining" was carried out according to Bernhard [25]. The ruthenium-red "staining" was performed in cacodylate buffered (pH 7.4) 2.5% glutaraldehyde for 1 hr. The fixative contained 500 μg/ml ruthenium red. The tumour cells were rinsed in sucrose (7.5%) containing cacodylate buffer and postfixed in ruthenium red containing OsO_4 for 3 hr in the dark. The specimens were dehydrated in a graded series of ethanol and propylene oxide solutions and embedded in Durcupan ACM. Ultrathin sections were stained for 30 min in saturated aqueous uranyl acetate and/or in lead citrate for 2 min [26]. Sections were examined with a JEM 7 A electron microscope.

For biochemical studies the tumour cells harvested at various times after the *in vivo* administration of labelled precursors were extracted twice with ice-cold 0.5 N perchloric acid (PCA). The pellet was treated with hot (70°C) 0.5 N PCA to release nucleic acids. The residue was solubilized in 0.1 N sodium hydroxide for protein measurements. The nucleotides were measured at 260 nm, while RNA, DNA and protein content were determined by the method described by Brown [27], Burton [28] and Lowry *et al.* [29] respectively.

For measuring RNA polymerase activity, nuclei were isolated in a hypotonic medium containing 0.3% Triton X-100 [30]. Magnesium and manganese activated RNA polymerase activity was assayed as described by Pogo [31].

Chromatin proteins were studied at 1, 6 and 24 hr after i.p. administration of 30 μCi ^{3}H-lysine and in some experiments of ^{3}H-arginine to 3–10 day-old ascitic tumours. In these experiments nuclei were purified according to Perry *et al.* [32]. Nuclear protein fractions were prepared by a sequential extraction procedure as follows: 0.15 M NaCl, 0.35 M NaCl, 0.2 N HCl and finally nuclear residual acidic proteins solubilized in 0.01 M sodium phosphate buffer (pH 6.8) containing 1% SDS. Proteins were separated according to their molecular weight by SDS-polyacrylamide gel electrophoresis as described by Webern and Osborne [33]. The gels stained with Coomassie-Brilliant-Blue were scanned in Joyce-Loebl "Chromoscan" densitometer at 575 nm, frozen at −20°C and mechanically sliced. The gel-slices were placed into scintillation vials, dissolved in 0.5 ml of 30% H_2O_2 at 50°C for 24 hr.

To estimate DNA-protein interactions, chromatin was isolated at low ionic strength [34] and binding of ethidium bromide to DNA was measured in a Farrand spectrofluorimeter at 335 nm excitation and at 593 nm fluorescent wavelength [35].

All radioactivity measurements were performed in a toluene-2-ethoxyethanol based scintillation fluid by using a Beckman LS-100 C spectrometer.

The following isotopes and fine chemicals were used: thymidine-6-^{3}H (s.a.*: 5 Ci/mM), uridine-5-^{3}H (s.a.: 5 Ci/mM), L-leucine-4,5-^{3}H (s.a.: 54 Ci/mM), L-arginine-5-^{3}H (s.a.: 16 Ci/mM), uridine-5-^{3}H-5'-triphosphate (s.a.: 1 Ci/mM). They were purchased from the Radiochemical Centre, Amersham. L-Lysine-6-^{3}H (s.a.: 291 mCi/mM) was purchased from the MTA Institute for Isotopes, Budapest. Ethidiumbromide (2,7-diamino-10-ethyl-9-phenylphenatridium) was produced by Calbiochem.

RESULTS

Cell kinetic studies

After transplantation of 5×10^6 NK/Ly ascitic tumour cells the growth rate decreased continuously. The experimental growth data were well fitted by a Gompertzian function (Fig. 1a). The proliferation rate of the tumour was influenced by the number of transplanted cells (Fig. 1b), but it was independent of tumour age (Fig. 1c). Among the main factors influencing the growth rate an increase of median cell cycle time was demonstrated with the labelled mitosis technique (Fig. 2, Table 1). In addition to this, the heterogeneity of the cell cycle time also increased as is indicated by the computed distributions (Fig. 3). The growth fraction at various stages of tumour growth was calculated from the data on the duration of cell cycle phases assuming an exponential distribution of cells in the cycle (Table 1). Repeated labelling experiments gave slightly higher values of growth

fraction possibly because of the transition of cells from the proliferative to the non-proliferative stage and vice versa. Both the calculated and measured values of the growth fraction indicated a decreasing tendency in the ratio of proliferating cells (Fig. 4, Table 1). There was no appreciable change in cell loss factor with increasing tumour age up to 7 days (Table 1).

The cytophotometry was combined with autoradiography to establish the DNA content of the cells existing in the G_1 and G_2 phases. After a pulse ^{3}H-thymidine labelling the ratio of G_1 and G_2 cells was 71.5–27.5% in 7-day-old and 62.0–32.5% in 14-day-old tumours (Fig. 5a and b) indicating a slight increase of G_2 cells with the aging of the ascites tumour. Furthermore, the DNA content was measured in the non-labelled cells observed at the plateau of the labelling index in the repeated labelling experiment (i.e. non-proliferating cells) of 14-day-old

tumours. In this case the ratio of G_1 and G_2 cells was 75.0–19% (Fig. 5c).

Biochemical studies

Both the percentage of the labelled cells (Table 1) and the number of the silver grains observed above the nuclei decreased with the tumour age. These two parameters showed a change of DNA synthesis both at the population and cell levels. In harmony with these data a decrease in the specific activity of DNA was measured in the PCA-insoluble fraction of tumour cells (Table 2).

Simultaneously with the decreasing rate of DNA labelling the same tendency for RNA and protein synthesis could be observed (Table 2). The question arises as to whether differences in the labelling of the macromolecules reflect differences in the synthesis. However, the data demonstrating a slower decrease in the labelling

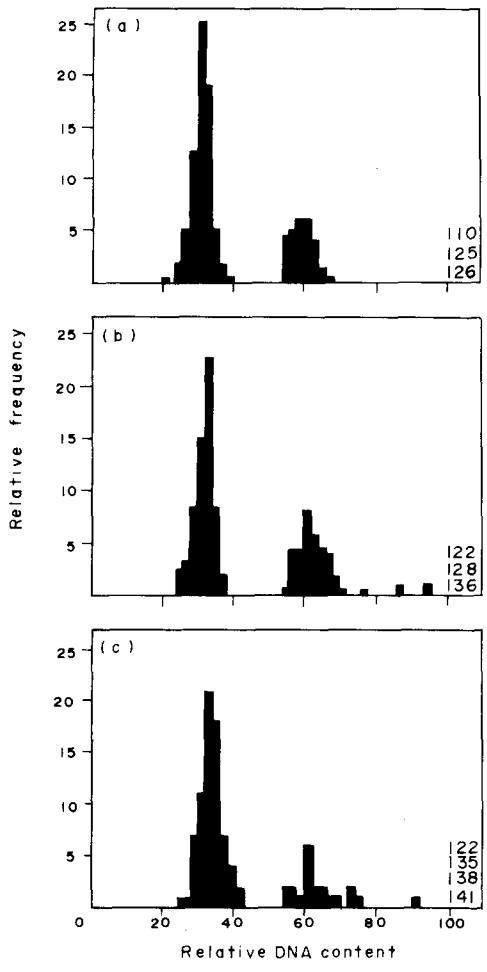

Fig. 5. Cytophotometric study on the relative DNA content of non-labelled NK/Ly ascites tumour cells after single (a—7-day-old, b—14-day-old tumour) and repeated (c—14-day-old tumour) ^{3}H-thymidine injections.

of the acid soluble fraction (nucleotide and aminoacid pool) than in that of the biopolymers seem to suggest that precursors are present in sufficient amount (Table 2). In contrast with the steady DNA content (13–15 pg/cell) the RNA and protein content per cell gradually increased after transplantation.

Measurements on RNA polymerase activity at various days after tumour transplantation give evidence that during enlargement of the tumour mass the RNA synthesis decreases at the transcriptional level (Fig. 6). In the presence of magnesium the incorporation of ^{3}H-UTP was three fold higher in the 3-day-old tumour cell nuclei than in the 8–14-day-old one. Manganese activated RNA polymerase also operated at a lower level in the slowly proliferating tumours.

Since gene functions are controlled by chromatin proteins it was presumed that chromatin proteins show differences in their synthetic rate at various days after tumour transplantation where cells revealed decreasing rate of nucleic acid synthesis. Table 3 shows the specific activity of various protein fractions after 1 hr labelling with ^{3}H-lysine in the 3 and 10-day-old tumours. The lower incorporation into the 10-day-old tumours might be brought about by factors other than synthetic capacity (differences in precursor uptake, etc.). Therefore, specific activity of the nuclear protein fractions were related to the specific activity of proteins in whole cells as has been proposed by Cholon and Studzinski [36]. The figures of the relative specific activity show

that labelling of nuclear proteins is definitely lower than whole cell proteins, however, after 24 hr they tend to increase—except chromatin proteins extracted with 0.35 M NaCl from 3-day-old tumour—indicating a slower turnover for chromatin proteins as for other cellular proteins.

Histones and residual acidic proteins were separated on SDS-polyacrylamide gel electrophoresis. The residual acidic proteins isolated from the 3-day-old tumours showed a high level of labelling in protein fractions with a mol. wt of about 40–50,000. On the contrary, in the 10-day-old tumours, the predominant incorporation of ^{3}H-lysine was observed in a much lower mol. wt region (Fig. 7a and b). Studies on histones isolated from 3-day-old tumour demonstrated that labelling in F_3 and F_{2b} surpassed all other fractions, however, in the case of the 10-day-old tumour F_{2a_1} and F_{2a_2} fractions were equally labelled as well (Fig. 8a and b).

Since binding of ethidiumbromide to DNA is prevented by chromatin proteins—mainly by F_1 histone—the interaction between DNA and protein could be estimated by measuring fluorescence intensity of ethidiumbromide which had been complexed to chromatin [34]. The lower ethidiumbromide fluorescency observed in the chromatin of 10-day-old tumour compared to the one isolated from the 3-day-old tumour (Table 4) may be regarded as an indication that in the slowly proliferating cells the chromatin proteins are more extensively bound to DNA i.e. the size of the available free segments in the DNA has been decreased at advanced growth stages of the tumour.

Electronmicroscopic study

The NK/Ly ascitic tumour cells are usually spherical with few microvilli on their surface. The karyoplasm of oval or bean-shaped nuclei is medium electron dense. Using OsO_4 fixation some tumour cells of 2–4-day-old tumours showed an even distribution of chromatin without condensation either around the nucleolus or along the nuclear membrane (Fig. 9). In addition to the great number of free ribosomes only few rough surfaced endoplasmic reticulum (rEr) could be observed. The Golgi area was usually broader and the cytoplasm contained some lysosomes and lipid droplets in the advanced age of the tumour. The double fixation maintained the structure better than the OsO_4 and the marginised chromatin was unanimously present in all cells. The electronmicroscopic cytochemical studies revealed further differences in the ultrastructural organization of cell nucleus and cell surface. The EDTA "staining" of 10–14-

day-old tumour was quite regular showing the RNP containing structures (e.g. nucleolus) with high density, and the DNP structures (chromatin) appeared with medium density—as grey fields (Fig. 10). On the contrary, in the 2–4-day-old cells the RNP and DNP structures were equally stained as electron dense areas. The presence of a regularly stained young leukocyte rules out the possibility of a methodical error (Fig. 11).

The cell surface was studied by ruthenium red staining. The cell coat of 2-day-old tumour cells proved to be continuous while with the tumour age it became more and more discontinuous. The thickness of the cell coat at 2-day-old tumour was 470 Å ± 188 Å (extreme values: 163 Å–920 Å) and at 10-day-old tumour it was 160 Å ± 46Å (extreme values: 105 Å–290 Å) (Figs. 12 and 13).

DISCUSSION

The cell kinetic data revealed a tendency of the growth rate of NK/Ly ascitic tumour to slow down from the time of transplantation, as has been found in other ascitic tumours [1–13, 37]. The growth rate was modified by the number but not by the age of the inoculated cells. This may suggest that despite the decreasing rate of cell proliferation during the tumour growth, the

cells regained their growth capacity in a new environment. The main reason for growth retardation was a remarkable increase both in the length and the distribution of cell cycle time and its phases. The rate of cell loss increased slightly between 7 and 10 days.

The growth fraction decreased with tumour age indicating that some cells are blocked in the interphase. The relative amount of DNA at 14 days indicated that most of these cells had the G_1 DNA content, but 19% of them had a DNA content of the G_2 state. It may be concluded that cells were able to interrupt their cycle both in G_1 and G_2. The G_1 arrest of normal and tumour

cells is well known [38] and date confirming the possibility of G_2 arrest in ascites tumours is also available [39]. However, owing to the presence of tetraploid cells in the NK/Ly ascitic tumour, it is uncertain whether the unlabelled cells having a G_2 DNA content after repeated ^{3}H-thymidine injections are tetraploid cells in G_1 phase or diploid cells in G_2.

The RNA and protein content per cell showed steady increase after the transplantation as a result either of the enhanced rate of RNA and protein synthesis or the declining rate of their catabolic processes compared to synthetic ones. The latter explanation seems to be more plausible since a gradually decreasing rate of both RNA and protein synthesis during tumour growth could be demonstrated. Similar changes in RNA and protein synthesis have been observed by Harris *et al.* [40], using Ehrlich ascites tumour. The decrease in ^{3}H-thymidine labelled cells studied by autoradiography at population level served further evidence to the alteration of DNA metabolism. Decreasing activity of DNA polymerase has also been detected autoradiographically [41].

These events accompanying tumour growth may be regulated at the chromatin level. Studies on chromatin proteins demonstrated differences in the nuclear metabolism between "fast" and "slowly" proliferating cell populations of NK/Ly ascites tumour.

These differences appeared in the various labelling patterns of the chromatin proteins separated on polyacrylamid gel electrophoresis. In agreement with the report of Wisenthal and Ruddon [42] the "fast" proliferating cells could be characterized by preferential labelling in the high mol. wt region of the nuclear residual acidic proteins. However, at later stages when cell proliferation decreased significantly in the same tumour, the preferential labelling took place in a residual acidic protein fraction with a much lower molecular weight. These data seem to indicate the implication of high molecular weight proteins in maintaining the fast proliferating state of the cell population. Since certain histones (F2a2 and F2a1) showed a relatively higher labelling in 10-day-old than in 3-day-old tumours it may be presumed that these histones play a critical role in the slow proliferating property of these ascitic tumour cells. As a further conclusion to the present studies based on the decreased RNA polymerase activity and the lower ethidiumbromide binding to DNA in the 10-day-old tumour than in the 3-day-old one may suggest an increasingly repressed state of chromatin during tumour growth.

According to the electronmicroscopic studies on the ascitic tumour cells at different growth stage changes in the density of cytoplasm, in the appearance of mitochondria, rough surfaced endoplasmic reticulum and lipid droplets were observed [43–46]. In the case of NK/Ly ascites tumour one of the most striking findings was the lack of preferential RNP staining, i.e. the staining of chromatin besides the RNP containing structures using Bernhard's method [25] in the cells of 2–4 days old ascites tumour. A likely explanation for this phenomenon would be a change in the structure of chromatin or in the relationship between the nucleolus and associated chromatin with tumour age. Another important alteration was observed on the cell surface. The trypsin-sensitive cell coat stained by ruthenium red seemed to be more discontinuous and thin with the age of the tumour.

In this study the NK/Ly ascites tumour served as a tool to obtain more data on tumour growth. It is widely known that the deceleration of growth rate occurs in growing cell populations both *in vitro* and *in vivo*. Different changes involved in this process could be detected but an order of events may be suggested only hypothetically. It seems to us that the morphological and biochemical observed alterations of chromatin may be responsible for the decreased synthetic rate of macromolecules and for the cell kinetic changes. However, it may be presumed that before the modification of chromatin, other cell components may be altered e.g. the cell surface, which results in the suppression of the genetic material [47].

Studies of the Growth of an Ascitic Tumour. II. A System to Study the Tumour-Age Dependent Effect of Antitumour Agents

L. KOPPER, A. JENEY, K. LAPIS and M. TÖRÖK
First Institute of Pathology, Semmelweis Medical University,
1085 *Budapest Üllői u.* 26, *Hungary*

Abstract—*Tumour-age dependent activity of an antimetabolite and some alkylating agents was studied using a newly described* in vivo *system. Treatment was performed at different growth stages (i.e. on the* 4th *and* 10th *day after transplantation) on NK/Ly ascites tumour, characterized by different rates of proliferation. The tumour growth inhibitory effect of the drugs was measured on the* 7th *day after the retransplantation of the treated cells. According to the data, the cytostatic agents could be classified into three categories: (a) those having the same effect on the two populations: cyclophosphamide, Lycurim, DMDAI, CCNU; (b) those having greater effect on the fast proliferating* 4*-day-old tumour:* 5*-FU, DBD. DAD, MeCCNU; (c) those having greater effect on the slowly proliferating* 10 *day-old tumour: BCNU.*

INTRODUCTION

THE STUDY of the correlation between the tumour growth rate and therapeutic sensitivity is one of the broadly investigated and discussed approaches in cancer chemotherapy. Series of experiments have been carried out in this field applying various *in vivo* and *in vitro* test-systems [1–12].

Our previous investigations on the growth of an ascites tumour allowed us to design a new model for studying the tumour-age dependent activity of various antitumour agents under *in vivo* circumstances. It has been described that the growth rate of NK/Ly ascites tumour decreased with the age of the tumour which was accompanied by cell kinetic, morphological and biochemical alterations such as the increase of duration and distribution of cell cycle time, the decrease of the ratio of proliferating cells, elevated RNA and protein content of tumour cells, decreased synthetic rate of biopolymers and changes in the structure and function of chromatin [13]. All of these data suggest a progressively but reversibly repressed genetic activity during the tumour growth. According to the results the 4 and 10 days old tumours were regarded as "fast" and "slowly" proliferating populations respectively (Table 1). The purpose of recent investigations was to compare the drug sensitivity of the 4 and 10 days old tumours using mainly alkylating agents.

Accepted 13 July 1977.

Table 1. *Cell kinetic and biochemical parameters of NK/Ly ascites tumour at* 4 *and* 10 *days after transplantation*

	4-day-old	10-day-old
Doubling time (hr)	33.12	132.58
Median cell cycle time (hr)	30.6	56.7
Growth fraction	0.88	0.68
Thymidin index (%)	55.0	36.5
Cell loss factor	0.02	0.45
dpm/mg DNA $\times 10^{-3}$	11000	1760
dpm/mg RNA $\times 10^{-3}$	7663	1387
dpm/mg protein $\times 10^{-3}$	210450	58982

MATERIAL AND METHODS

The *NK/Ly ascites tumour* was used throughout this study. The serial transplantation was performed by the injection of 5×10^6 tumour cells into the peritoneal cavity of noninbred CFLP mice (Laboratory Animals Breeding Center, Gödöllö, Hungary).

The tumour-bearing mice were treated by various drugs intraperitoneally on the 4th and 10th days following transplantation. One hour later their abdomen was opened, the ascites tumour was removed, the cells were counted by haematocytometer and the cell concentration was adjusted to 2×10^7/ml, 10^7 cells (0.5 ml) were retransplanted into healthy mice i.p. and the total number of cells was registered at different intervals thereafter. Four to six mice were used on days 2 and 4, while 6–8 mice were killed on day 7 after transplantation.

The *growth inhibitory effect* was estimated from the value of the total number of cells obtained on the 7th day after retransplantation. To evaluate the differential effect of a drug on "fast" and "slowly" proliferating cells, an index called *tumour-age factor* was introduced and calculated as follows:

$$\text{Tumour-age factor} = \frac{\text{percentage of growth inhibition of 10-day-old tumour}}{\text{percentage of growth inhibition of 4-day-old tumour}}$$

The *following drugs* were used:

Cyclophosphamide (NSC 26271)
2-bis(2-chloroethyl)amino tetrahydro-2H-1,3,2-oxaphosphorine 2 oxide.
VEB, Jenapharm, Ankerwerk, Rudolstadt, DDR.

BCNU (NSC 409962)*
1,3-bis(2-chloroethyl-)-1-nitrosourea.

MeCCNU (NSC 95441)*
1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea.

CCNU (NSC 79037)*
1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea
Division of Cancer Treatment, NCI, U.S.A.
*(Supplied by Dr. Goldin).

5-Fluorouracil (NSC 19893)
Roche Products Ltd., Welwyn Garden City, England

Dibromodulcitol, DBD (NSC 104800)†
1,6-dibromo-1,6-dideoxy-D-dulcitol.

Dianhydrodulcitol, DAD (NSC 132313)†
1,2-5,6-dianhydro-dulcitol.
†Chinoin Chemical and Pharmaceutical Works Ltd., Budapest, Hungary.

DMDAI‡
1,6-dimesyl-2,3-4,5-dianhydro-L-iditol.

Zitostop‡
1,2-5,6-tetra-O-methylsulphonyl-D-mannitol.

Lycurim‡
1,4-di-mesyl-oxiethylamino-1,4-dideoxy-m-erythritol.
‡Institute of Drug Research, Budapest, Hungary.

Cyclophosphamide, 5-fluorouracil and DAD were solved in physiological saline; DBD, DMDAI, Zitostop and Lycurim were suspended in 5% Tween-80 and the nitrosoureas in DMSO-5% Tween 80 (1:9 v/v). The controls were injected with the appropriate solvent.

RESULTS

Figures 1 and 2 demonstrate the regrowth curves of treated and retransplanted cells. The effect of 5-fluorouracil—the only non-alkylating agent among the drugs examined—could be regarded as a control in this system. According to

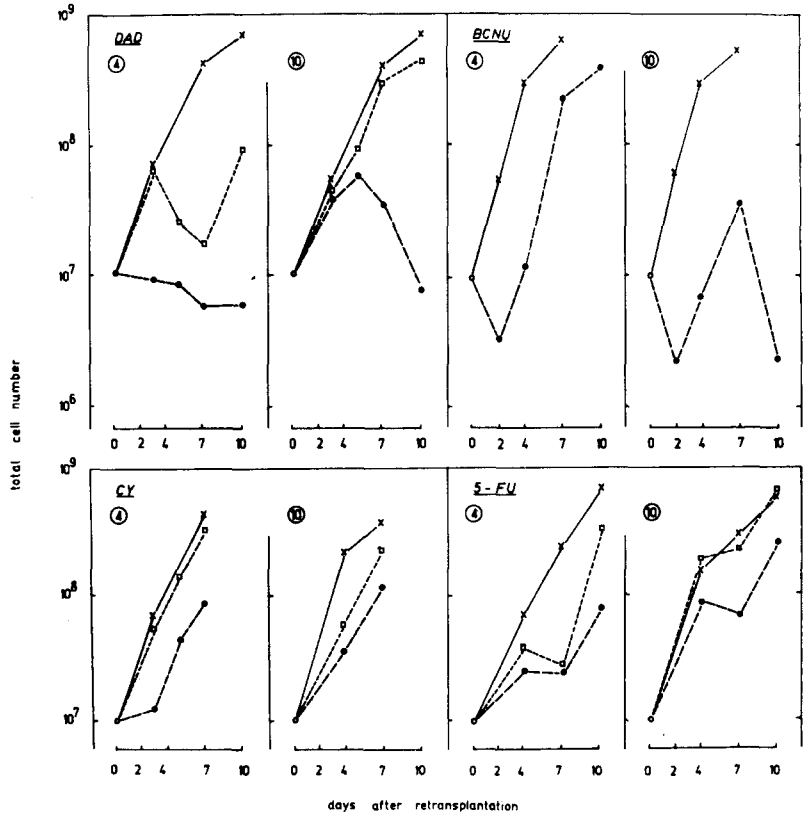

Fig. 1

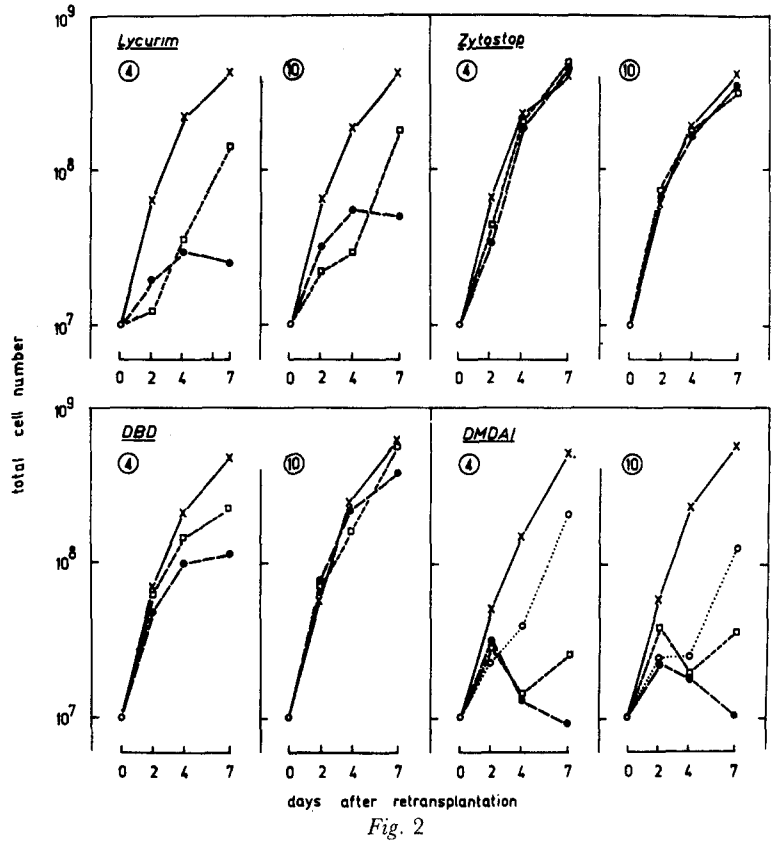

Fig. 2

Figs. 1 *and* 2. *The regrowth curves of treated and untreated NK/Ly ascites tumours. The treatment was performed on the* 4th *and* 10th *days (marks in circles) for* 1 *hr and* 10^7 *cells were retransplanted into healthy mice i.p.*

Control	×-----× ○----○	□·····□	●-----●
DAD		3.5 mg/kg	7.5 mg/kg
BCNU			20 mg/kg
CY		40 mg/kg	80 mg/kg
5-FU		100 mg/kg	500 mg/kg
Lycurim		8 mg/kg	20 mg/kg
Zytostop		500 mg/kg	1250 mg/kg
DBD		140 mg/kg	350 mg/kg
DMDAI	70 mg/kg	140 mg/kg	350 mg/kg

expectation, the "fast" proliferating 4-day-old tumour showed a more pronounced sensitivity against 5-fluorouracil than the 10-day-old one. The shapes of the curves indicate that the cells are still able to complete at least one division after treatment. DBD did not influence the proliferation of the 10-day-old tumour, but the 4-day-old one was affected, showing a dose-dependent inhibition after a temporary control-like growth. The inhibiting effect of DAD, an epoxid derivative of DBD, appeared both on the 4 and 10 days old tumours, but it appeared earlier and lasted longer on the former one. There were no obvious differences in the shape of regrowth curves after cyclophosphamide, DMDAI and Lycurim treatments indicating a similar degree of inhibition of the two cell populations. Higher sensitivity of the 10-day-old tumour was observed only in the case of BCNU.

The result of the BCNU treatment prompted us to get more data not only on the effect of BCNU, but also on the other nitrosoureas, such as CCNU and MeCCNU. Different doses of the drugs were used and the ratio of the total cell number of treated to controls on the 7th day after retransplantation was plotted against the doses. Figure 3 shows the dose–response curves. The MeCCNU was slightly more effective against the 4-day-old tumour as compared to the 10-day-old one. On the contrary the BCNU was much more effective against the slowly proliferating 10-day-old tumour. The CCNU had almost the same effect on the two cell populations. Drawing the curves with regard to tumour age (Fig. 4) it is obvious that real differences could only be seen in the sensitivity of the 4-day-old tumour.

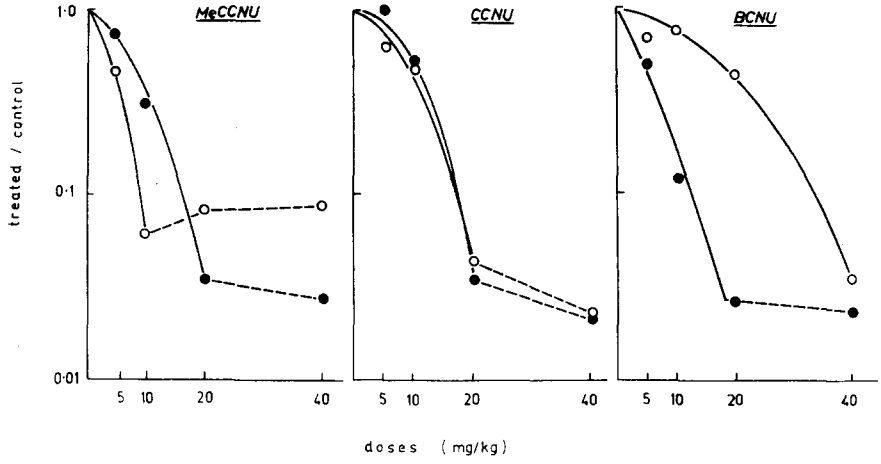

Fig. 3. Dose–response curves of nitrosoureas. The growth inhibiting effect was calculated from the total cell number counted at 7th day after retransplantation. 4-day-old tumour ○----○ 10-day-old tumour ●----● (The values of 4 and 10 days tumours were significantly different— $P<0.05$—at 5–10 mg/kg of MeCCNU and 10–20 mg/kg of BCNU).

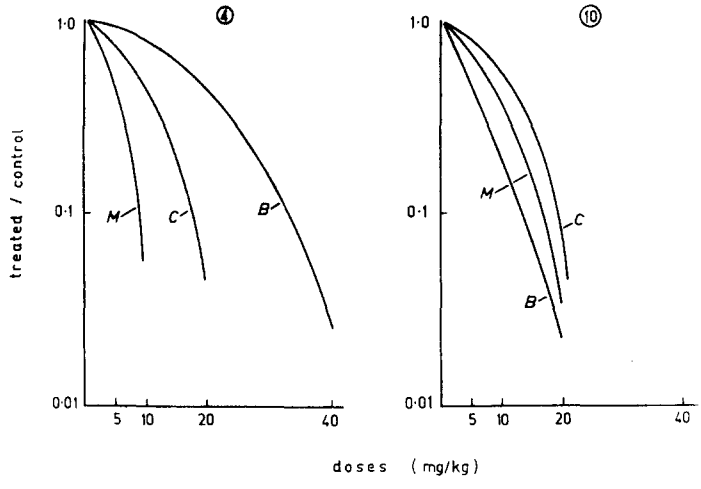

Fig. 4. Dose–response curves of nitrosoureas grouped according to tumour age. (M = MeCCNU, C = CCNU, B = BCNU).

DISCUSSION

There are some observations which stimulate the study of the correlation between tumour growth and therapeutic sensitivity. In this respect one of the important clinical data is the relatively good response of rapidly proliferating human tumours against chemotherapeutic agents [14, 15]. Unfortunately, these highly responsive tumours represent only a small fraction of cancer incidences. It is believed that the presence of a large fraction of proliferating cells, i.e. the high growth fraction, may explain their responsiveness. Another stream of clinical and experimental studies emphasized that the speed of cell proliferation is fairly varied not only in different kinds of tumours, but at different stages of growth of the same tumour [16–19]. It was also proved that the cell kinetic status may play an important role in the therapeutic sensitivity of tumours [1, 20]. Finally, we must mention the kinetic differences between normal and malignant tissues serving a possibility to enhance the selectivity of our treatment [21].

*CFU = colony forming unit; PFU = plaque forming unit.

As it has been pointed out, various systems were applied to study the correlation between the growth rate and therapeutic sensitivity of tumours. A few of them were compiled on a table to demonstrate not only the variety of the systems but also the different treatment times and the types of evaluation (Table 2). Our system differs from most of these because we compared the sensitivity of the same tumour at different stages of growth. Previously we described some cell kinetic, morphological and biochemical properties of the two (4 and 10 days old) tumour cell populations [13]. It should be emphasized that besides the marked differences most of the cells were in proliferating state in both populations.

Our tumour-age dependent system was based on the observation that the ascites tumour cells derived from tumours of different age retained their proliferative capacity and putting them into a new environment (retransplantation), they are able to grow with the same speed. It means that 10^7 retransplanted cells from 4 and 10 days old tumours produce the same growth curve. The effect of drugs on the two cell populations with different size seems to be easy to compare, since it had been demonstrated that the cell killing effect of the cytostatic drugs follows the primary kinetic order [15]. The tumour inhibiting effect of the cytostatic agents may vary depending on the duration of treatment as it has been shown by Hahn *et al.* [22]. In our case, the one hour treatment time was applied partly to avoid the repair of the drug-caused damage before the retransplantation and partly it was based on our previous data suggesting maximal or near maximal uptake of DBD and DAD after the 1hr treatment [23].

Table 3 summarizes the growth inhibitory effect of the different antitumour agents and the calculated tumour-age factor. These data allowed us to classify the effect of drugs studied into three categories:

1. Those which had no substantially different effect on the fast and slowly proliferating populations—cyclophosphamide, Lycurim, DMDAI, CCNU;
2. Those which were more effective against the fast proliferating tumour cell population—5-FU, DBD, DAD, MeCCNU;
3. The only drug inhibiting the growth of the slowly proliferating 10 days old tumour better than that of the 4 days old one was BCNU.

5-FU produced the expected result regarding its inhibitory effect on thymidilate synthetase to be essential for DNA synthesis. The primary targets of DBD and DAD are the chromosomal proteins [24, 25]. It is interesting to recall our observation that the metabolic state of chromosomal proteins is changing during the tumour growth [13]. These data also suggest that there is a correlation between the proliferation de-

*Growth inhibition $= 1 - \frac{\text{total cell number of treated}}{\text{total cell number of control}} \times 100.$

†Tumour-age factor $= \frac{\text{growth inhibition (10 day)}}{\text{growth inhibition (4 day)}}.$

‡Variation in the growth inhibition—expressed as the percentage of the growth inhibition—has been estimated according to the equation:

$$\text{Variation} = \pm \sqrt{\frac{A_1^2}{n_1^2} + \frac{A_2^2}{n_1^2}}.$$

where A_1 and A_2 are the ratio of standard deviation to mean value of total cell number in control and treated groups; n_1 and n_2 are the number of mice in respective groups.

pendent activity of DBD and DAD and their intracellular effect.

Cyclophosphamide is known to be more effective against proliferative cells [1, 4]. This information has derived from studies using two "sharply" different populations: proliferating and non-proliferating ones. But in our system both populations were mainly composed of proliferating cells and there was no substantial difference in their sensitivity against Cyclophosphamide. Lycurim was proved to be an effective antineoplastic and immunosuppressive agent in clinical practice as well [26–28]. DMDAI, having both mezil and epoxy groups in its chemical structure, showed a strong antitumour effect experimentally [29, 30]. Neither Lycurim nor DMDAI showed proliferation-dependent effect in our system.

The nitrosoureas behaved quite differently in our tumour-age dependent system—basically against the 4-day-old tumour—which could be the result of the different repair capacity of the damaged cells. From the therapeutic point of view the "preferential" effect of BCNU on a slowly proliferating population seems to be very important because of the shortage of such drugs in our therapeutic regimen. Theoretically, it may mean that with the help of BCNU we could influence the tumours with low growth fractions and perhaps increase the more selective cell-killing between the tumour and the critical (usually rapidly proliferating) normal tissues. Concerning the proliferation dependent effect of BCNU our data is supporting the results of others [6–9], but there are also contradictory data [4, 31]. The advantage of the dose–response curve is clearly seen from data of Table 3, since the value of tumour-age factor approached 1.0 with elevating doses.

From these data it could be concluded that the

tumour inhibitory effect of certain alkylating agents is different, while that of others is similar at various stages of tumour growth. It is felt that if the growth stage of a human tumour to be treated could be judged, the use of the tumour-age factor may be a help in selecting the most promising drug or drug-combination. There is no need to emphasize that the cell kinetic status is an important—but only one of the important—aspects of cancer treatment. We are still far from the causative therapy of cancer, but our increasing knowledge on the correlation between drug effect and tumour growth rate, the cell kinetic complexity of a cell population, the mechanisms operating behind the change of growth rate, and the mechanisms regulating the tumour growth are a hopeful way of keeping cancer under our control.

Acknowledgements—We are thankful for the supply of nitrosoureas to Dr. A. Goldin, National Cancer Institute, Bethesda, Maryland, U.S.A.

Oestrogen Receptors in Transplantable Ovary-Independent, Mammary Tumours of the Rat

R. A. HAWKINS, A. HILL, B. FREEDMAN, ENID KILLEN and W. R. MILLER

Department of Clinical Surgery, University of Edinburgh, Edinburgh, United Kingdom

Abstract— *Oestrogen receptor activity (available cytoplasmic binding sites) has been determined in three lines of transplantable rat mammary tumours. At sacrifice, the plasma concentrations of oestradiol-17B and prolactin were determined by radioimmunoassay.*

Low levels of receptor activity were detected in two tumour lines but none was detected in the third line.

Receptor levels in these transplantable tumours, which exhibit ovary-independent growth, were compared with those found in ovary-dependent tumours induced by DMBA in random-bred rats. The comparison was performed in (a) intact animals (b) ovariectomised animals and (c) ovariectomised animals subsequently treated with replacement oestrogen. Irrespective of endocrine status, the mean tumour receptor level was significantly higher in the DMBA-induced tumours. However, considerable overlap between the groups occurred, suggesting that there is no clear division in receptor levels between ovary-dependent and ovary-independent tumours.

INTRODUCTION

PREVIOUS studies have shown that amongst rat mammary tumours induced by DMBA (7,12 dimethyl benz(a)anthracene), ovary-dependent tumours contain higher levels of oestrogen-binding activity than do ovary-independent tumours [1–5]. It is our experience that very few DMBA-induced tumours can be shown to be truly ovary-independent. We have, however, been able to study three lines of transplantable mammary tumours which are clearly ovary-independent.

Since the level of oestrogen receptor activity is markedly affected by the endocrine status of the host [6], we have measured receptor levels in these transplantable tumours and compared the values for two tumour lines with those found for DMBA-induced tumours, in various endocrine states.

MATERIAL AND METHODS

Tumours

Three lines (TG3, TG5, TG6) of transplantable tumours were originally set up by Mr. I. W. J. Wallace, F.R.C.S. and Mr. D. Drewitt, B.Sc. of this department, by subcutaneous implantation of explants from each of three DMBA-induced mammary tumours into hosts of an inbred strain of Sprague–Dawley rat ('ADRA' obtained from the Animal Disease Research Association, Moredun, Edinburgh). Histologically, all three parent tumours were adenocarcinomata, but whilst the TG3 and TG5 lines maintained this morphological characteristic, the TG6 line showed a progressive change with the appearance of some fibrosarcomatous elements over the time of study. At the time of use in the present work, the growth of all three tumour lines was ovary-independent. The growth patterns for typical tumours of each type are shown in Fig. 1. Tumours were selected for study over several generations, the average generation being approximately 20 for the TG3 line, 6 for the TG5 line and 4 for the TG6 line.

DMBA-induced tumours were induced by intragastric instillation of DMBA (30 mg) in a random-bred strain of rats (Oxford Laboratories Ltd.). All tumours were allowed to grow until at least 1.5 × 1.5 cm before use for receptor assay or ovariectomy.

Accepted 20 July 1977.

Endocrine manipulation and assessment of ovary-dependence

In order to assess ovary-dependence/independence, the tumours in one group of animals (group a) were measured at intervals with calipers before and after bilateral ovariectomy under ether anaesthesia. Tumour size was expressed as the product of measurements in two dimensions.

For a second group of animals (group b) tumours were measured before and during sequential manipulation by ovariectomy, no treatment for 10 days and oestradiol-17B administration for 6 days (1–5 μg/day s.c. in oil).

Ovary-independent tumours were defined as those tumours which continued to increase in size for the period of study following ovariectomy (usually by >30% over 9–14 days).

Ovary-dependent tumours were classified either as those tumours showing a continuous decrease in size for the period following ovariectomy (usually ≧50% over 9–14 days)—group (a), or where animals were subsequently further treated by oestrogen administration, as those tumours regressing upon ovariectomy and clearly regrowing upon oestrogen administration—group (b).

Tumours showing extensive necrosis, changes due to a large cystic fluid content, or equivocal growth patterns were regarded as unassessable and were excluded.

Tumour receptor concentration in intact and ovariectomised rats bearing transplantable tumours

In an initial experiment, receptor concentrations were determined in the tumours from 23 intact, cycling animals (7 TG3, 10 TG5 and 6 TG6). A further 17 rats bearing 23 transplantable tumours (11 TG3, 11 TG5 and 1 TG6) were ovariectomised and left for 14 days prior to sacrifice and determination of tumour receptor concentration.

Comparison of receptor concentrations in transplantable tumours and DMBA-induced tumours

In a second study, receptor concentrations in 2 lines of transplantable tumours (TG3 and TG5) were compared with those in DMBA-induced tumours in each of 3 endocrine states.

For receptor assay, tumours were excised from:

(a) 21 ovariectomised rats (6 regressing, DMBA-induced tumours and 15 growing, transplantable tumours, 8 TG3, 7 TG5);

(b) 21 rats treated by ovariectomy and subsequent administration of oestradiol-17B (15 DMBA-induced tumours showing regression followed by regrowth, and 6 transplantable tumours showing continuous growth i.e. 1TG3, 5TG5);

(c) 22 intact, cycling rats (10 DMBA-induced tumours, 12 transplantable tumours i.e. 10 TG3, 2 TG5).

Thus in groups (a) and (b), only animals showing clearly ovary-independent growth for a DMBA-induced tumour, or clearly ovary-independent growth for a transplantable tumour were examined. In group (c) the tumour specimen for assay was removed by biopsy (in oestrus, metoestrus or dioestrus, but not proestrus) under ether anaesthesia and the animals were then left approximately 14 days and ovariectomised. However, it was not possible to determine the ovary-dependence/independence of these tumours since the biopsy procedure alone frequently disturbed the growth of the tumour.

Measurement of plasma oestradiol-17B and prolactin concentrations

At sacrifice, the animals were bled through the abdominal aorta under ether anaesthesia. In all rats except group (c), bleeding preceded tumour excision, but in group (c), biopsy specimens of tumour were taken and animals were not sacrificed until approximately 4 weeks later.

Plasma was separated by centrifugation at 4°C and stored at −20°C for radioimmunoassay by methods previously described [7]. The sensitivities of these assays were calculated to be 3 ng prolactin/ml plasma and 0.13 ng oestradiol-17B/100 ml plasma when analyses were conducted on duplicate, 0.1 ml and single, 4.0 ml samples of plasma respectively.

Determination of oestrogen receptor concentration

Tumour tissue, removed either by biopsy under ether anaesthesia [group (c) only] or after killing by exsanguination, was placed in Tris buffer containing dithiothreitol (0.25 M sucrose 10 mM Tris, 1 mM ethylene diamine tetraacetate, 0.5 mM dithiothreitol, pH 8.0) and stored on ice for 1 hr. The concentration of oestrogen receptors in each tumour was measured by a method described previously [6].

Briefly, 600–800 mg tumour was trimmed free of adhering tissue and capsule at 4°C, cut up finely with scissors and homogenized in an ice-cooled tube at the rate of 300 mg/ml buffer, using a Silverson homogenizer (1 × 20 sec, 1 × 15 sec at maximum speed with a 45 sec interval for cooling between bursts). The resulting homogenate was centrifuged at 105,000 × ***g*** for 50 min to yield a clear cytosol. Portions (0.1 ml) of cytosol were incubated, in duplicate, at 4°C with 10 pg [^{3}H]oestradiol-17B (5060 counts/min) and varying quantities of non-radioactive oestradiol-17B (0, 10, 30, 50, 70, 90 and 20,000 pg) in a total volume of 1.2 ml Tris buffer (composition as

Results are mean values ± 1 standard error.
K_d = dissociation constant of oestradiol-17β binding, P_0 = concentration of oestrogen receptor sites. *Sensitivity defined as described under Materials and Methods.
†$P<0.01$, ‡$P<0.10$ when OVX and intact values compared for same tumour line.

above except that dithiothreitol was omitted). After overnight equilibrium, free oestradiol-17B was removed by the addition of 0.5 ml charcoal suspension (0.15% charcoal, 0.0015% dextran in Tris buffer w/v), further incubation at 4°C for 15 min and centrifugation for 10 min at 4°C.

The protein-bound fraction was decanted into 5 ml organic scintillator solution for determination of ^{3}H activity. After correction for non-specific binding using the mean value for the 20,000 pg tubes, the data was analysed according to Scatchard [8] to derive the dissociation constant of binding (K_d) and the concentration of receptor sites (P_c). The latter was expressed both as fmole binding sites/mg wet tumour and as fmole binding sites/mg cytosol protein, using the protein concentration of the cytosol found on measurement by the method of Lowry, Rosebrough, Farr and Randall [9].

The sensitivity of the method was empirically defined as 0.05 fmole/mg wet tumour or 1 fmole/mg cytosol protein, since a clearly increasing displacement of [^{3}H] oestradiol-17B with increasing mass of non-radioactive oestradiol-17B present was generally observed above this receptor level.

Statistics

The significance of differences in receptor concentrations was evaluated by the Wilcoxon rank test.

RESULTS

Tumour receptor concentrations in intact rats

Low, but detectable levels of oestrogen receptor activity were found in two of the three lines of transplantable tumours, i.e. the TG3 and TG5 lines (Table 1). The dissociation constant of binding was of the order of 0.4×10^{-10} molar in each tumour line and no significant difference in receptor levels was apparent between the two tumour lines. In the third tumour line, (TG6), receptor activity was found in only 2 of 6 tumours examined and the levels detected were extremely low.

Effect of ovariectomy

The efficacy of ovariectomy was confirmed by the reduction of plasma oestradiol-17B concentrations to the level of the sensitivity of the assay (Table 1). Prolactin concentrations were also significantly reduced in 2 of the groups of rats bearing tumours (TG3 and TG5) and the apparent rise in prolactin level in the one rat bearing a TG6 tumour which was examined after ovariectomy is probably a spurious result (Table 1).

Despite these changes in plasma hormone concentrations following ovariectomy, no significant change in receptor level was observed in either TG3 or TG5 lines of tumours (Table 1, Fig. 2).

Comparison of receptor levels in transplantable tumours (ovary-independent) with levels in ovary-dependent, DMBA-induced tumours

Receptor levels in the transplantable tumours were compared with those in DMBA-induced tumours obtained from animals in each of three endocrine states. Firstly, 14 days after ovariectomy, (Fig. 3a), receptor concentrations were significantly ($P<0.05$) higher in DMBA-induced tumours which regressed than in the tumours (non-regressed) of either TG3 or TG5 transplanted line, though there was a considerable overlap between groups. Secondly, when tumour-bearing animals were subjected to ovariectomy and subsequent administration of oestrogen (Fig. 3b), the receptor concentrations in ovary-dependent, DMBA-induced tumours were clearly higher than the concentrations in the ovary-independent, transplantable tumours ($P<0.01$).

Thirdly, receptor concentrations in biopsy specimens from uncharacterised, DMBA-induced tumours were also significantly higher than the values found in transplantable tumours of either TG3 or TG5 line, though again there was a considerable overlap between the two types of tumour. Attempts to separate the biopsied, DMBA-induced tumours into ovary-dependent and independent types by their response to subsequent ovariectomy were unsuccessful: The biopsy procedure alone generally interfered with tumour growth.

DISCUSSION

Oestrogen receptor activity has been detected in low but significant amounts in 2 out of 3 lines of transplantable rat mammary tumours. The two lines containing low receptor levels maintained the morphological appearance of adenocarcinomata whilst the other tumour line without detectable activity showed some tendency to progress towards a sarcoma by the time of the study. Gala and Peck [10] have described two transplantable, mammary tumours, of which one was an adenoma with "high" levels of oestrogen receptor activity, whilst the other was a sarcoma devoid of receptor activity.

At the time of study, all three transplantable tumour lines exhibited ovary-independent growth. Prior to this work, however, at least one of these lines (TG3) had passed through an ovary-

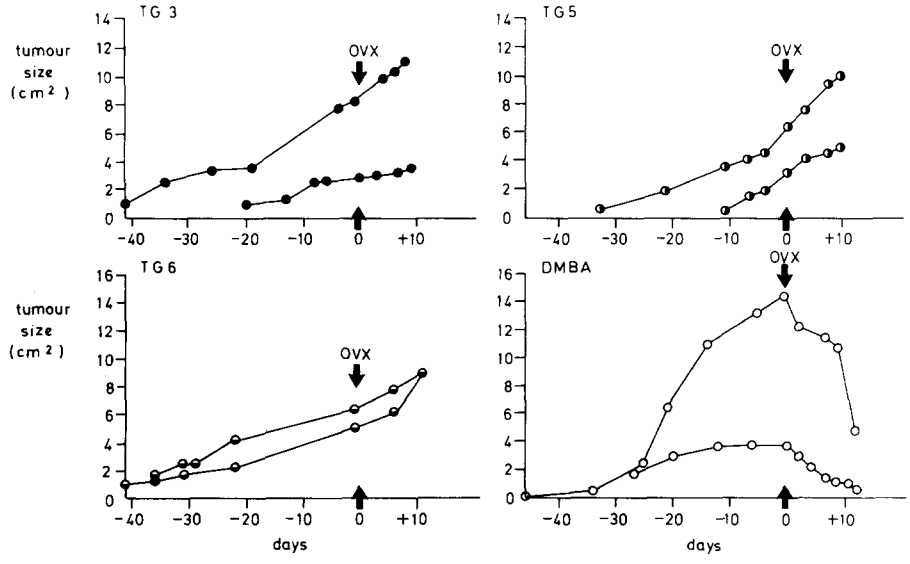

Fig. 1. *The ovary-independent growth of 3 lines of transplantable mammary tumours. Tumour sizes were measured before and after bilateral ovariectomy of 2 rats bearing transplantable tumours, for each tumour line. For comparison, the effect of ovariectomy of the host upon the growth of two typical DMBA-induced tumours is also illustrated. OVX indicates the time of ovariectomy, and measurements are plotted against days pre (−) or post (+) ovariectomy.*

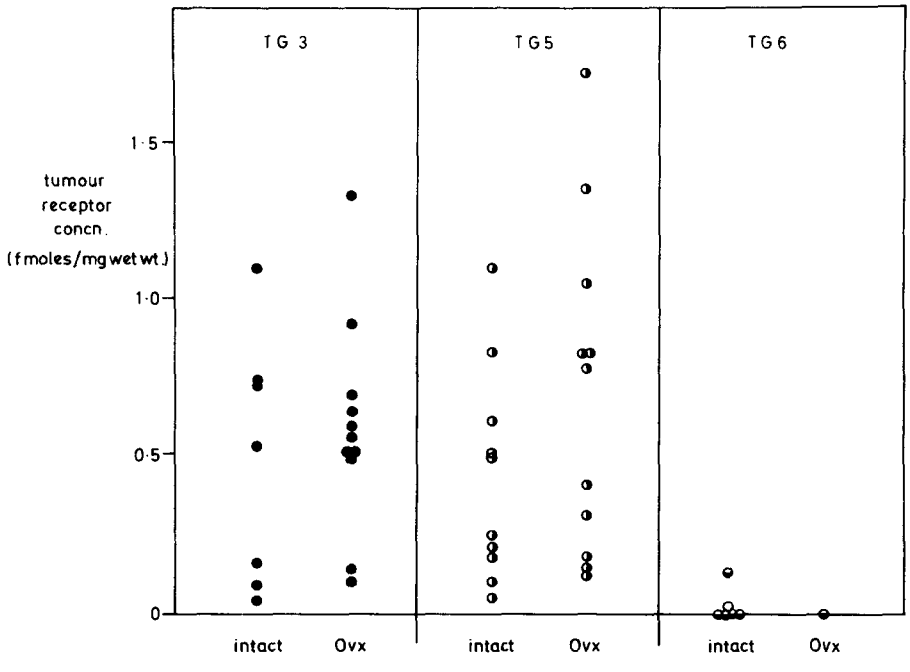

Fig. 2. *Oestrogen receptor concentrations in each of 3 lines of transplantable mammary tumour. For each tumour line, receptor concentrations are shown in the tumours from intact and ovariectomised hosts. Each circle represents the value for a single tumour.*

dependent phase in the very early generations. A similar progression from dependence to independence has been reported for certain strains of transplantable mouse tumour [11] and for other transplantable rat mammary tumours [12, 13].

The mere *presence* of oestrogen receptor activity in a tumour is thus not an indication of ovary-dependence, in agreement with the findings of others [11, 14–16] though as we have previously reported [17], the growth of at least some of these

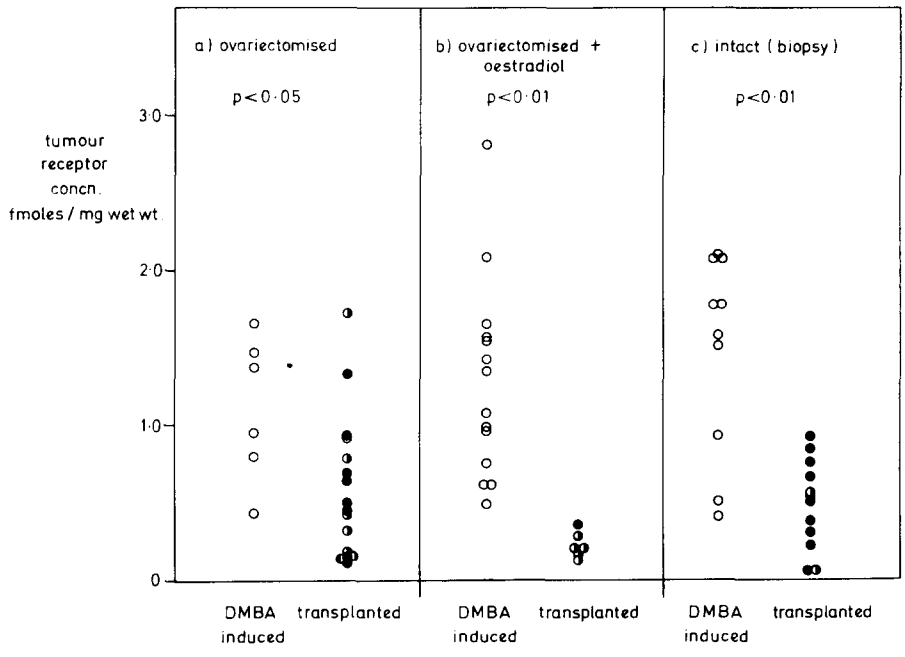

Fig. 3. Oestrogen receptor concentrations in ovary-independent, transplantable tumours were compared with values found in DMBA-induced tumours in each of 3 endocrine states. In (a), ovariectomised rats and (b), rats treated sequentially by ovariectomy and oestradiol administration, open circles denote receptor concentrations from ovary-dependent, *DMBA-induced tumours; in (c), intact animals, open circles represent receptor concentrations in uncharacterised DMBA-induced tumours. Solid circles represent receptor concentrations in transplantable tumours of the TG3 line, and half-solid circles those in transplantable tumours of the TG5 line.*

tumours is increased following oestrogen administration, i.e. is oestrogen-*sensitive*.

The R3230AC transplantable mammary tumour is also not *ovary-dependent* yet is sensitive to oestrogen [18] and similarly contains low levels of oestrogen receptor activity [14]. According to Sluyser and Van Nie [11] transplantable mammary tumours may change from "dependent" to "responsive" to "independent" tumours, in association with diminishing receptor levels upon successive transplantations. Although the data presented here was too small to show such significant differences in receptor levels between generations, it is our impression that the receptor levels in our TG3 and TG5 lines are also gradually diminishing with succeeding transplantations.

In the transplantable tumours studied here (Table 1), as in the R3230AC tumour [19] available receptor levels were undiminished by ovariectomy, though this finding could be the resultant of a decrease in *total* receptor sites and an increase in the number of available sites, upon removal of endogenous hormones. In contrast, the level of available receptor activity falls significantly after ovariectomy in most DMBA-induced tumours [6, 20, 21] where both receptor synthesis and general anabolism may depend on the presence of the ovary. This fall in available receptor level in DMBA-induced tumours after ovariectomy, which we [6] and others (20, 21) have previously reported, was not seen in present work [Fig. 3, group (a) vs group (c)], probably because the receptor levels were measured in tumours from exsanguinated, ovariectomised rats (group a) but non-exsanguinated, intact rats (group c). The presence of a higher blood content in the latter type of tumour may account for our finding of receptor levels lower than those which we found previously [6] for DMBA-induced tumours from intact rats, and for the lack of difference between the values for tumours from intact and ovariectomised rats, since blood plasma can markedly suppress the level of receptor activity detected [22].

Early work with DMBA-induced mammary tumours implied very clear differences in magnitude of receptor levels between dependent and independent tumours of the rat [1–5]. More recently, Costlow, Buschow, Reichert and McGuire [23] also found clearly higher levels of both oestrogen and prolactin receptor activity in an ovary-dependent subline (MD) of a transplantable mammary tumour (MTW9) than in an ovary-independent subline (MA). In the present work, significantly lower *mean* receptor concentrations were found in the TG3 and TG5 tumour lines (ovary-independent) than in

DMBA-induced tumours (80–100% ovary-dependent) in each of three endocrine states. However, there was a considerable overlap in receptor values between the two types of tumour in intact animals, or in animals treated by ovariectomy only.

This finding of a less striking difference than was first proposed is in line with the views of Mobbs and Johnson [15], Boylan and Wittliff [16] and DeSombre, Kledzik, Marshall and Meites [13]. In the latter work, in particular, for both oestrogen receptors and prolactin receptors, there was a clear overlap between the concentrations found in dependent and independent mammary tumours. It is to be noted, however, that strictly only measurements on *biopsy* specimens taken prior to endocrine manipulation relate to the hormonal sensitivity at that time, and are comparable to the usual clinical situation where for prognostic use, biopsy material is taken *before* endocrine therapy.

For technical reasons (low incidence of DMBA-induced tumours in inbred rats, low transplant-acceptance rate in random-bred rats), the comparisons made here between DMBA-induced and transplantable tumours are complicated by the fact that the tumours were generated in rats of different strains. These strains of rat have different basal levels of prolactin (24, 25 and c.f. values in Table 1 with those in reference [6]), a hormone which has previously been shown to modulate tumour receptor levels [20, 21]. Thus it is possible that the lower receptor levels detected in transplanted tumours may be related to the lower levels of this hormone which circulate in our inbred rats, rather than to a lesser degree of hormonal sensitivity. This possibility is currently being investigated.

Irrespective of the origin of this overlap in receptor concentrations between dependent and independent rat mammary tumours (e.g. effect of strain, hormonal levels or variation in degree of hormonal sensitivity) extrapolation of these findings to the clinical situation would suggest that predictions based on oestrogen receptor concentrations should be made with caution. Thus at the present time, only "receptor-negative" tumours, (i.e. those with receptor levels clearly below the overlap range) can be accurately predicted to fail to respond to endocrine therapy.

Acknowledgements—We are grateful to Professor A. P. M. Forrest for his interest and advice and to the Cancer Research Campaign for Grant no. SP1256. We thank Dr. A. A. Shivas, Department of Pathology, University of Edinburgh, for examining the histology of the transplanted tumours, and Mrs. Dorothy Gray for her expert help in producing and measuring both carcinogen-induced and transplanted tumours.

Radioimmunoassay reagents were kindly donated by the NIAMDD rat pituitary distribution program, U.S.A. (prolactin reagents) and Drs. A. E. Bolton and W. Hunter of the Radioimmunoassay Team, Forrest Road, Edinburgh (anti-oestradiol-17B serum).

The Gross and Cellular Response of a Rat Mammary Tumour to Single Doses of Cyclophosphamide*

J. V. MOORE† and B. DIXON

Department of Radiotherapy, University of Leeds, Cookridge Hospital, Leeds LS16 6QB, United Kingdom

Abstract—*The response of a transplanted mammary carcinoma of Wistar rats, to single intraperitoneal doses of cyclophosphamide* (25–250 mg kg^{-1}) *has been assayed by measurement of; delay in growth of the tumour between* 9 *and* 25 mm; *cell survival* in vitro, 3 *and* 24 hr *after* in situ *treatment; tritiated thymidine autoradiography and Feulgen microdensitometry of histological material. All three methods of assay indicate that at* 9 mm *diameter the tumour contains a subpopulation of malignant cells relatively resistant to cyclophosphamide doses in excess of* 50 mg kg^{-1}. *The* in vitro *cell survival assay suggests that these cells comprise* 40–50% *of the clonogenic population and are capable of considerable* in situ *repair of potentially lethal damage within* 24 hr *of treatment. Cellular repopulation from this resistant component, after* 150 mg kg^{-1} *of drug, is delayed for* 6 *or more days and restoration to near pre-treatment status only achieved by* 10 days, *in this rapidly-growing tumour.*

INTRODUCTION

MOST drugs used routinely in cancer chemotherapy function by interfering with processes of cell multiplication [1]. Thus in comparing drug effects on e.g. a lymphoma cell population in rapid exponential growth with an unstimulated normal renewal tissue with relatively few cells in the replication cycle, the therapeutic advantage may be marked [2]. However, solid tumours in animals and humans can have 85% or more of their cells out of cycle [3] and these may be less susceptible to the action of cytotoxic drugs. If such cells are preferentially spared, then their therapeutic importance depends upon their number and capacity to re-enter cycle. This is known to occur in irradiated tumours [4], although the transition may not be rapid [5].

We have examined the response of an experimental solid tumour, known to contain a population of non-cycling cells [6], to cyclophosphamide (CP) whose cytotoxicity is held to be proliferation-dependent, but whose action is not markedly cell-cycle-phase specific [1]. In this study, the gross response to single doses of the agent has been defined and related to cellular survival and changes in cellular kinetics of the treated tumour.

Accepted 27 July 1977.

MATERIAL AND METHODS

1. *Animals and tumour*

Male and female John's strain Wistar rats were used, at a body weight of 150–200 g. Animals were kept under a 12 hr light (06.00–18.00), 12 hr dark (18.00–06.00) regimen and provided with food and water *ad lib.* Subcutaneous experimental tumours were prepared by implantation in the flank with an isogeneic mammary carcinoma (LMC_1) of spontaneous origin. Details of methods of transplantation and subsequent macroscopic and cellular growth have been reported elsewhere [7]. The present study employed tumours of the 37th to 40th transplant generations, rats being assigned randomly to treatment groups when the tumour reached a mean diameter of 9 ± 1 mm. Thereupon CP ("Endoxana"; Ward Blenkinsop, Bracknell) was injected intraperitoneally (i.p.) in 0.9% saline, as single doses of 25–250 mg kg^{-1} of body-weight. All injections were given between 11.00 and 12.00 hr.

2. *Assays*

The gross response of the tumour to CP was measured in terms of changes in tumour volume with time after treatment. These were computed from daily, caliper measurements of three mutually perpendicular diameters of each tumour. From these data, tumour response was de-

termined by the method of Thomlinson and Craddock [8] i.e. by plotting the delay in growth of the tumour between 9 mm (370 mm^3) and 25 mm (8000 mm^3) relative to untreated controls, as a function of CP dose.

The survival of clonogenic LMC_1 tumour cells *in situ* after exposure of 9 mm diameter tumour to CP was assayed *in vitro* by a method modified after that of Reinhold [9], as described by Moore [7]. Clonogenic cells were defined as those which, after 10 days' incubation at 37°C, had given rise to colonies of 50 or more cells.

The kinetic status of the overall cell population of LMC_1 tumours treated with CP was measured by tritiated thymidine (^{3}H-TdR) autoradiography and Feulgen microdensitometry; details of both methods have been reported elsewhere [6, 10]. Tumour-bearing rats, which had received doses of CP 1 hr to 10 days earlier, were injected i.p. with ^{3}H-TdR (0.5 μCi g^{-1} of body-weight) at 12.00–13.00 hr and killed 1 hr later. Autoradiographs of equatorial sections of tumours were prepared for determination of Labelling Index (LI), Mitotic Index (MI) and Cellular Density (CD; i.e. the number of cytologically-intact tumour nuclei per 100 × 100 μm microscope field). A minimum of 2000 nuclei were scored in each section and 4–5 sections, from different tumours, in each treatment group. For Feulgen microdensitometry, an imprint was made onto a microscope slide of the freshly-cut faces of the bisected tumours later used in preparing autoradiographs. A smear was also made of peripheral blood of the tumour host. After fixation and staining, measurements were made on a Vickers M85 integrating microdensitometer, small lymphocytes of the peripheral blood being used to determine the DNA content of normal diploid, non-proliferative cell nuclei. For each treatment group, 600 tumour nuclei and 50 lymphocytes were scanned at random, the material being taken from 2 tumours/hosts.

RESULTS

1. *Tumour growth delay*

Inhibition of the growth of LMC_1 tumours in treated rats was CP-dose dependent (Fig. 1). Only for the largest dose tolerated by female rats (250 mg kg^{-1}) did regression below treatment size occur. For tumours regrowing after treatment, the overall volume doubling time was not significantly higher than in untreated controls and did not vary with dose of CP. The time taken for the tumour to reach a mean diameter of 25 mm (14.1 ± 0.1 days) was the same in untreated male and female rats and overall this was true for the tumours in CP-treated rats. Therefore, tumour data from both sexes of host were used to establish the CP dose, tumour response curve. Delay in growth of the tumour was not a linear function of dose (Fig. 2). Between 25 and 75 mg kg^{-1}, an additional delay of 1 day was attained with each 5 mg kg^{-1} increment in dose. Between 75 mg kg^{-1} and the maximally-tolerated dose, a 25 mg kg^{-1} increment was required for the same effect.

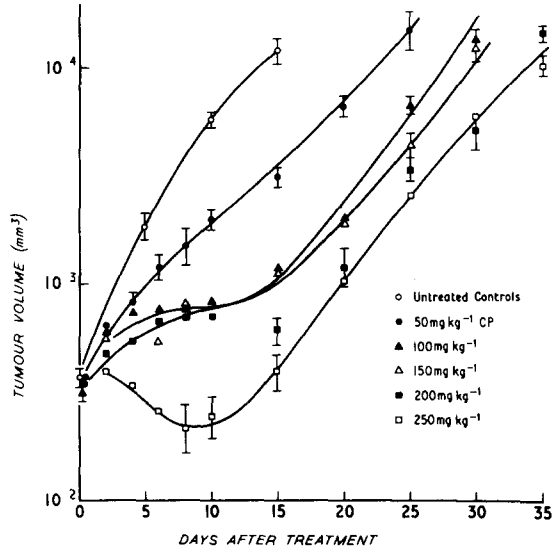

Fig. 1. Growth response of LMC_1 to CP. Mean ± 1 S.E. of data for 4–21 female rats per treatment group. Mean volume doubling time of untreated controls 4 ± 1 days.

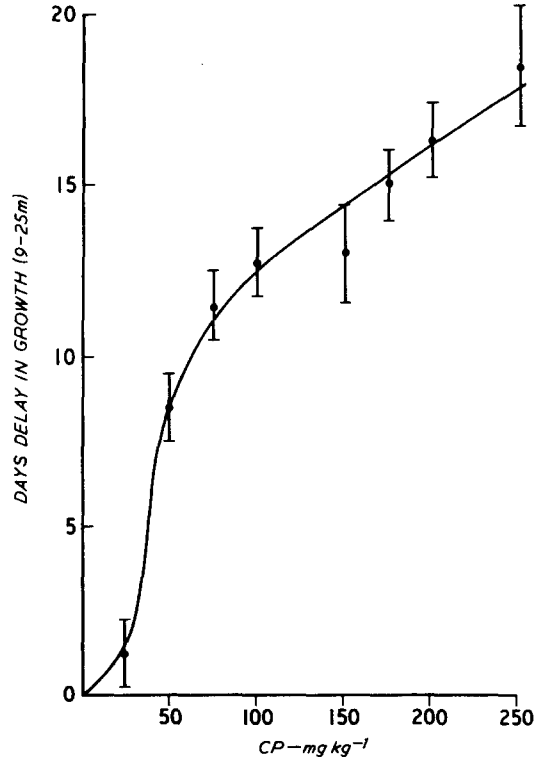

Fig. 2. Growth delay of LMC_1 after CP. Pooled data for male and female rats, 13–30 per dose-point. Mean delays ± 2 S.E.

2. *Survival of clonogenic cells*

The biological half-life of CP and its toxic metabolites in rats has been estimated to be 1–2 hr [11]. Assay for survival of LMC_1 cells was therefore carried out 3 hr after injection of the drug, when the cells should have been subjected to much of the integrated dose. However, cells *in situ* may be able to repair potentially lethal damage (PLD) due to CP [12]. A second assay was therefore carried out 24 hr after treatment, since if LMC_1 cells did so repair, results might be expected to be more closely comparable with those for the *in situ* end-point of growth delay. Within the range of CP doses used, 50–250 mg kg^{-1}, survival of clonogenic cells decreased as a logarithmic function of dose for both intervals (Fig. 3). However, a dose-dependent recovery of clonogenic capacity occurred between the two times, giving D_0 values for curves fitted to the two sets of data of 40 ± 5 mg kg^{-1} at 3 hr, 58 ± 3 mg kg^{-1} at 24 hr. In neither case did the best fit to the experimental data extrapolate to 100 % survival at zero dose, the intercept at 3 hr being 0.18 ± 0.06 and that for 24 hr, 0.44 ± 0.05. In both cases, the difference from unity was highly significant ($P < 0.001$).

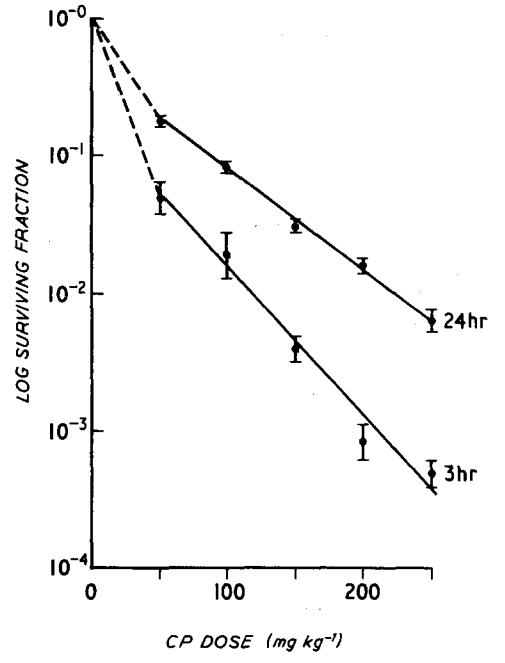

Fig. 3. In vitro *survival of* LMC_1 *cells after CP* in situ. *Mean surviving fractions* $\pm$ 1 *S.E. for replicate platings of cells from single tumours. It is assumed that the dose–response curves have no threshold* [12] *and are exponential for doses* < 50 mg kg^{-1}.

3. *Cellular kinetics after CP treatment*

The time dependence of kinetic changes in tumours of treated rats was examined following a dose of 150 mg kg^{-1}, this dose being approximately at the mid-point of the "resistant" component of the curve for growth delay (Fig. 2). It is evident from both the microdensitometric and ^{3}H-TdR data that cellular kinetics were perturbed for several days (Fig. 4, a and b). The frequency distribution of nuclear DNA content indicates that, in the first two days after treatment of this predominantly tetraploid tumour, the G_1 components were markedly depleted with a commensurate increase in the frequency of S and/or G_2 nuclei. Thus LI remained high during this time, but MI fell almost to zero. Although tumour volume increased by about 50% in these first two days (Fig. 1), the cellularity of the tumour fell by approximately 40% (Fig. 4, b). It is likely then, in the presence of the mitotic block, that the gross volume increase was largely due to changes in cell volume associated with the higher modal DNA content of the cell nuclei. Over the succeeding 4 days, LI was depressed, suggesting that a large proportion of the cells present at treatment had by now accumulated in G_2. Only at 10 days did the microdensitometric and ^{3}H-TdR data indicate that the tumour was regaining a kinetic state characteristic of the untreated condition.

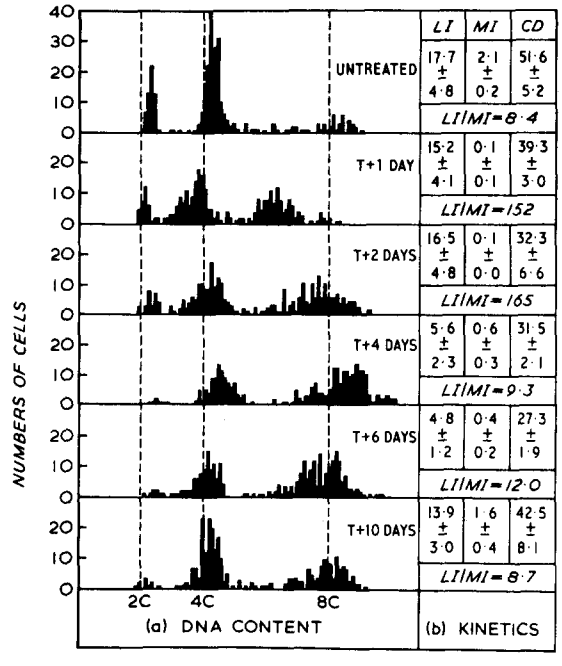

Fig. 4.a. *Nuclear DNA content of* LMC_1 *cells after* 150 mg kg^{-1} *of CP* in situ. *2c and higher integer values of DNA content established by comparison with small lymphocyte nuclei.*

b. *Corresponding values for LI, MI and CD measured from histological sections of* 9 mm LMC_1 *tumours treated with* 150 mg kg^{1} *CP. Mean values* (%) $\pm$ 1 *S.E. Median cell cycle time for untreated tumours* 18 hr [6].

To determine if the patterns of response to graded doses of CP revealed by growth delay and clonogenic cell survival were reflected in the kinetic behaviour of the cells, a further ^{3}H-TdR experiment was carried out. This assay was complicated by the early perturbations of phase relationships; the first time at which LI/MI ($\sim$Ts/Tm) was restored to pre-treatment value was 4 days (Fig. 4, b). Accordingly, rats bearing 9 mm tumours received single doses of 50–200 mg kg^{-1} CP and 4 days later were injected with ^{3}H-TdR and killed at 1 hr. From autoradiographs of tumour sections, LI, MI and CD were plotted as a logarithmic function of dose (Fig. 5). The values of the three parameters declined rapidly with increasing dose up to about 100 mg kg^{-1}. Doses greater than this had little additional effect on ^{3}H-TdR labelling or cellularity of the tumour and a reduced effect on the frequency of mitoses.

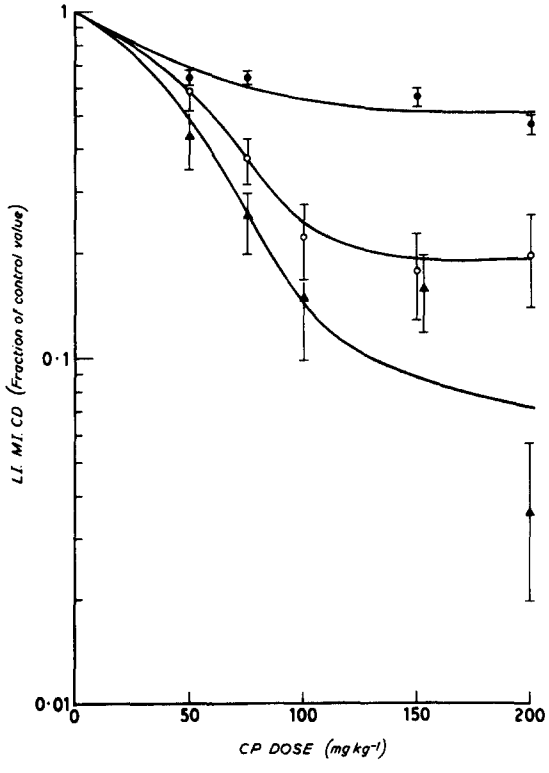

Fig. 5. Cell kinetic response of LMC$_1$ to graded doses of CP, measured 4 days after treatment. Values of LI ○, MI ▲, CD ●, relative to untreated controls, ± 1 S.E.

DISCUSSION

The gross response of the LMC$_1$ tumour to CP has been measured by tumour growth delay, an end-point with which much information has previously been obtained on the response of experimental tumours to irradiation [8, 13]. From such studies it is seen that where all the cells of a tumour are of equal apparent sensitivity to radiation, e.g. when the tumour is made "anoxic", the dose–delay curve rises smoothly with increasing slope. Conversely, where the aerobic tumour contains two subpopulations of different sensitivities, a biphasic delay curve results, with reduced slope at higher doses. This was the form of the delay curve for LMC$_1$ tumours treated with CP (Fig. 2), indicating by analogy that the tumour normally contains cells that are preferentially spared by GP.

The cells that are important in tumour regrowth following a period of delay are ultimately those capable of repeated division. The *in vitro* survival of clonogenic cells in LMC$_1$ after CP depended upon the time of assay (Fig. 3), in a manner consistent with the repair of PLD *in situ* [12]. It is usually held that in tumours such repair is predominantly of slowly-cycling or non-cycling cells [14]. If this is true for the CP-resistant component of cells in LMC$_1$, then extrapolation of the 24 hr-survival curve back to the ordinate (Fig. 3) indicates that these constitute 44 ± 5% of the cell population in 9 mm tumours. This value compares favourably with that for the non-cycling population of 40% estimated previously by ^{3}H-TdR analysis [6].

Any attempt to describe the subsequent fate of the therapeutically important, surviving clonogenic cells in terms of cellular kinetics of the treated tumour is complicated by the fact that kinetic analyses usually sample not only from a population of surviving clonogenic, but also proliferative though non-clonogenic cells [15]. Thus in the first 2 days after 150 mg kg^{-1} CP, LI remained high despite a mitotic block (Fig. 4, b). Our interpretation of the subsequent sharp fall in LI is that the majority of cells in S up to this time were "terminal" and by 4 days had accumulated as non-proliferative cells in G$_2$ (Fig. 4, a). The low LI and MI between 4 and 6 days would thus be characteristic of a surviving population in or entering cycle no less than 2 days after drug treatment, but which as yet represented only a small proportion of an overall population containing many terminal cells. For these surviving cells the ratio LI/MI was approximately that of the untreated tumour.

If at 4 days these labelled and mitotic cells represented the surviving "clonogenic" population, then the values of the kinetic parameters at this time following different doses of drug should indicate their relative survival *in situ*. These remained virtually unchanged with doses of CP in excess of 75–100 mg kg^{-1} (Fig. 5). In addition, the change in value with time after 4 days in LI, MI and CD would reflect the rate of cell repopulation within the tumour. After 150 mg kg^{-1} CP, little repopulation had occurred by 6

days, most thereafter (Fig. 4). In these circumstances it might be expected that a further dose of CP would be more effective at longer rather than shorter intervals, i.e. as cells re-enter cycle, particularly if this permitted a reduced response in therapeutically-limiting normal tissues. This hypothesis is being tested experimentally.

Efficacy of Combined Interferon Cyclophosphamide Therapy after Diagnosis of Lymphoma in AKR Mice*

ION GRESSER, CHANTAL MAURY and MICHEAL TOVEY
Laboratory of Viral Oncology, Institut de Recherches Scientifiques sur le Cancer,
94800 *Villejuif, France*

ALTHOUGH the spontaneous lymphoma of AKR mice has been considered a useful model for the evaluation of chemotherapeutic drugs [1–8], very few substances are effective in delaying death. Frei *et al.* reported that only 4 of 27 compounds useful in cancer chemotherapy increased by 100% or more the mean survival time of AKR mice after diagnosis of lymphoma [8]. Of these, cyclophosphamide was the most effective drug [3, 4, 8]. Interferon may also be considered an effective drug since daily treatment of AKR mice increased average survival time by approximately 100% after diagnosis of lymphoma [9]. Since experimental and clinical results have shown that combination drug therapy is often superior to single drug therapy, we have investigated the effect of combination interferon–cyclophosphamide therapy in this experimental system. Chirigos and Pearson reported the striking efficacy of interferon and BCNU in the treatment of mice injected with LSTRA leukemia cells [10]. To our knowledge this is the only published report of combined interferon-antitumor drug therapy in an experimental tumor system. In view of the increasing interest in the use of interferon in the treatment of patients with various forms of neoplasia [11–14] it would seem important to determine to what extent, based on animal experimentation, combined therapy can be envisaged in man.

*This work was supported in part by grants from the D.R.M.E. (contract no. 76–342) and from the Fondation pour la Recherche Médicale Française.

Female AKR mice more than 6 months of age were purchased from Jackson Laboratories, Bar Harbor, ME. All mice were examined daily for enlarged inguinal, axillary and submaxillary lymph nodes, enlarged spleen and signs of respiratory distress secondary to an enlarged thymus. Mice were included in the study only when they had definite peripheral lymphadenopathy *and* splenomegaly (+, on a scale of 0 to +++). A few of these mice also had signs of some respiratory distress. Mice were *not* included if they had only minimal adenopathy, only peripheral adenopathy, only splenomegaly, or only signs of respiratory distress. Upon diagnosis of lymphoma each mouse was marked and treated or left untreated according to a prearranged plan. Each mouse was then weighed daily and the evolution of clinical signs of disease was recorded. All dead mice were autopsied. There were 4 groups of mice: untreated; treated with one intraperitoneal (i.p.) injection of cyclophosphamide (Lucien-Collombes Laboratories, France) (150 mg/kg); one injection i.p. of cyclophosphamide followed 3 days later by daily administration i.p. of 0.25 ml of control preparation; one injection of cyclophosphamide followed 3 days later by daily administration of 0.25 ml i.p. of a mouse C-243 cell interferon preparation titering 3.2×10^{-6} (specific activity of approximately 2.8×10^6 to 1.2×10^7 units/mg protein). Techniques of production, semipurification and assay of interferon and control preparations have been previously reported [15]. (Interferon units refer to interferon reference units.) In all instances cyclophosphamide induced a rapid (1–3 days) decrease in

†: $P < 0.001$.
q.d.: Each day.
①: Cyclophosphamide 150 mg/kg.

signs of lymphoma (i.e. enlarged inguinal, axillary and submaxillary lymph nodes, enlarged spleen and thymus).

As can be seen from Fig. 1 and Table 1, a single injection of cyclophosphamide increased significantly the survival time of AKR mice after diagnosis of lymphoma from a mean of 17 days to 29 days. No significant difference was observed between mice injected with cyclophosphamide alone and those injected with cyclophosphamide followed by daily injections of a control preparation. In contrast, treatment of mice with one injection of cyclophosphamide followed by daily administration of mouse interferon increased survival time by approximately 200% (Fig. 1, Table 1).*

Because of the limited amount of potent interferon preparations available we did not include in this experiment a group of mice receiving interferon alone, but have plotted on Fig. 1 in dashed line (◇— — —◇) the results previously obtained in this system with interferon [9]. (Comparison of the survival time after diagnosis of lymphoma of untreated AKR mice in the previous published [9] and current experiments showed no significant difference.) The previously observed increase in survival time for interferon treated AKR mice [9] Fig. 1 and the increased survival time for cyclophosphamide treated mice in this experiment, suggest that the therapeutic effects of interferon and cyclophosphamide may be additive.

Although cyclophosphamide treatment considerably reduced the tumor burden, such

*Attempts in a subsequent experiment to investigate the effect of daily interferon treatment with repeated doses of cyclophosphamide [8] could not be pursued due to mortality in mice receiving several injections of cyclophosphamide.

treatment did not eliminate all tumor cells and mice eventually died with lymphoma. Our previous results [16–18] have shown that interferon treatment was most effective when the tumor burden was low. Thus the experiment reported above, although performed with relatively few mice, showed that after reduction of tumor load with cyclophosphamide interferon treatment increased survival time by approximately 200%. These results and those of Chirigos and Pearson [10] may have some relevance to the treatment of patients with neoplasia since they suggest that interferon therapy may be of particular benefit when administered in combination with anti-tumor chemotherapy.

Perspectives in Cancer Research

Increased Selectivity of Drugs by Linking to Carriers

ANDRÉ TROUET

Laboratoire de Chimie Physiologique, Université de Louvain, and International Institute of Cellular and Molecular Pathology, avenue Hippocrate, 75, B-1200 Bruxelles, Belgium

THE THERAPEUTIC effectiveness of antitumoral, and of antiprotozoal drugs is very much restricted by their lack of selectivity towards their respective targets. Since the biochemical and metabolic properties of the normal host cells and the pathological cells are very small if not inexistent, it is very difficult to modify the chemical structure of a drug in such a way that it acquires target recognition abilities while keeping its pharmacological properties. It is therefore not surprising that many efforts have been spent since several years to increase the selectivity of drugs by association or linkage to a carrier molecule that would carry the active compounds to the target cells and prevent their interaction with normal cells.

Without being exhaustive we can enumerate:

(a) the association of antitumoral drugs to, antibodies [1–9], proteins [10–14], DNA [15–16], liposomes [17–25] and to hormones [26, 27].

(b) the linking of antiviral compounds to dipeptides [27], proteins [28] and synthetic polymers [29].

(c) the binding of antiprotozoal drugs to DNA [30].

(d) the inclusion of antiinflammatory agents, antibodies, enzymes and toxins in liposomes [31].

In this paper we will review the "drug-carrier concept" with special emphasis on its implications at the cellular level. We will also try to draw some guidelines for further research in this field.

We will define a "carrier" as a molecule or an assembly of molecules, the major characteristic of which is that it is unable, as such or bound to a drug, to cross the plasma membrane of eukaryotic cells by permeation or active transport.

ADVANTAGES OF DRUG TO CARRIER LINKING

As mentioned above the major advantage sought for by the use of drug-carriers is a higher selectivity of action. The carrier can induce the drug to act selectively in two ways. The carrier–drug complex can, first of all, be selectively activated in the vicinity of the target cells by factors released from these cells or present at their surface. The carrier can on the other hand recognize selectively the target cell surface and allow the drug to act either at the surface or intracellularly after uptake of the carrier–drug complex.

The association of a drug with a carrier can also modify its mechanism of intracellular penetration and promote the cellular uptake of drugs that cannot enter cells because of a native or acquired membrane impermeability.

The rate and degree of excretion as well as the intratissular distribution of the carrier-linked drug will also be modified at a variable extent according to the size and the nature of the carrier. As a consequence the pharmacokinetic properties of the drug could be modified and result in higher as well as longer sustained plasma and extracellular levels of the active compound. This can induce secondarily a higher therapeutic effectiveness.

LIMITATIONS OF DRUG TO CARRIER-LINKING

Since the adsorption of a non-permeant carrier through the gastro intestinal tract, skin or mucosa, seems highly improbable, the use of carrier linked drugs will probably preclude any oral or topical administration.

Restriction will also be imposed on the parenteral use of drug–carrier combinations according to the anatomical and tissular localization of the target. The tissular distribution of the drug-carrier will indeed be restricted by the ability of the carrier to cross the various types of capillary membranes that separate the site of injection and the blood stream from the targets. This will depend very much on the physicochemical properties and the molecular size of the carrier as well as on the type of capillaries involved. It is indeed very well known that the structure of capillary membranes varies very much from one tissue and organ to another. Capillaries of liver, spleen and bone marrow will very probably not constitute a great obstacle even to the largest of the possible carriers that are liposomes. These capillaries are indeed characterized by an incomplete basal membrane and by non contiguous endothelial cells. If one considers however, other tissues like endocrine glands, intestine and muscle, the situation becomes more complex since the capillaries of these tissues are characterized by a complete basal membrane and a continuous lining of endothelial cells. Macromolecules and liposomes will certainly have great difficulties in crossing these membranes and in reaching targets localized across the capillary wall and the obstacle will of course be the greatest in the central nervous system. We have however to consider that in many pathological states, like tumours or infections, the capillaries can be modified and their structure as well as their permeability properties altered.

In preparing drug-carrier complexes, great care should be taken in order to avoid any direct or indirect toxic effects induced by the carrier itself. The carrier should be non toxic, non immunogenic (as such or in combination with the drug) and biodegradable. This latter property is important in order to avoid cellular overloading and its toxic consequences as already observed after clinical use of poorly or non degradable molecules like polyvvynylpyrrolidone.

CARRIERS AND DRUG-CARRIER LINKS

In order to discuss the different possible carriers as well as the requirements for the drug to carrier links we will have to distinguish first, drugs acting exatracellularly from those acting on the host cells. In this latter category we will then discuss in more detail the various possible interactions between cells and the drug-carrier complexes.

(1) *Extracellular site of action*

Amongst the drugs with an extracellular site of action, that are liable to benefit of a carrier linking we count: (a) drugs acting on extracellular protozoa, parasites and bacteria; (b) enzymes like asparaginase, uricase; (c) compounds that counteract the deleterious effects of enzymes released in the extracellular space during pathological processes like inflammation, rheumatoid arthritis or shock.

The carriers should in this case (a) have a molecular size that prevents them from crossing the endothelia and capillaries lining the various vascular spaces and body cavities; (b) not to be captured at a great extent by the macrophages and the reticulo endothelial system; (c) be small enough to be excreted by the kidney in order that all the compounds that do not reach the targets can be eliminated in an inactive form.

If the link with the carrier does not interfere with the activity of the drug the main advantage of the carrier complex will be to provide the drug with different pharmacokinetic properties. The drug could in this way be maintained for a longer time and at a higher concentration in the blood stream or various body compartments like the peritoneum, pleural cavity, joint cavity or cerebrospinal fluid. The inclusion in a suitable carrier like a liposome can also decrease the immunogenicity of the active compound and decrease its reactivity with free or cell-bound antibodies [19, 32].

Some degree of selectivity can be conferred to drugs of this category if the carrier linked drug is inactive and can be released from the carrier in an active form by, or in the vicinity of the extracellular target. Such a selectivity could for example be obtained in the treatment of extracellular infections by protozoa, or parasites, that secrete exoenzymes like collagenase, polysaccharidase or proteases. If the link between the drug and the carrier is susceptible to hydrolysis by one of these enzymes, the drug will be released and activated specifically in the vicinity of the extracellular targets. In the case of infections by protozoa or parasites the carrier drug complex can also be taken up by endocytosis or ingested and the drug released inside the lysosomal or digestive system of the parasite. The selectivity of the drug complex will depend in this case on the avidity of the infectious agent for the carrier molecule and on the digestibility of the carrier and the carrier drug link.

(2) *Intracellular site of action*

The selectivity of a carrier complex formed with a drug acting intracellularly can be modulated by: (a) a selective release in the

vicinity or at the surface of the target cell; (b) a selective uptake by the target cell.

(*a*) *Extracellular release.* A selective release of active compounds from suitable carriers could be achieved in at least two pathological situations involving the selective release of hydrolytic enzymes by cells involved in the pathological process (Fig. 1). In inflammatory and rheumatoid diseases, proteases and collagenases have indeed been shown to be secreted in the extracellular space. The same could be true in some types of cancer cells that have been shown to excrete or possess at their cell surface proteolytic enzymes. The ideal carrier in this situation should: (a) not be endocytized by the reticulo endothelial system; (b) be small enough to be excreted by the kidney; (c) the drug to carrier link should be sensitive to one of the enzymes excreted selectively by the target pathological cells.

(*b*) *Intracellular release.* In this category of carrier-drug combinations the selectivity will be

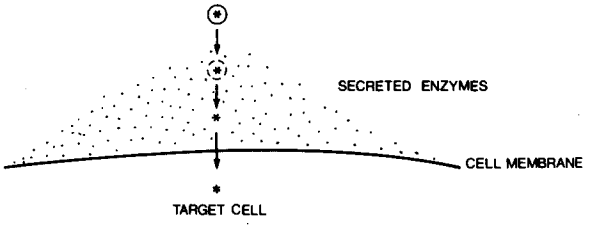

Fig. 1. *Drug-carrier complex activated in the extracellular space by enzymes released from the target cells. Symbols of Figs.* 1, 2 *and* 3: ⊛ *inactive drug-carrier complex;* ○ *carrier;* * *free and active drug.*

determined by a selective interaction between the carrier and the target cell surface. This interaction will then be followed by an intracellular penetration of the complex that can occur either by endocytosis or by transport through the cell membrane if the drug is included in a particular type of macromolecular vesicles.

UPTAKE BY ENDOCYTOSIS (LYSOSOMOTROPIC DRUG-CARRIER)

The most common mode of cellular penetration of a non-permeant carrier is endocytosis. During this process, the carrier-drug complex will reach the lysosomes after fusion of the endocytic vacuole with the lysosomes [33] (Fig. 2). Inside the lysosomes, the drug can be released and activated if the carrier or the link between the drug and the carrier is hydrolyzed by the enzymes or the acid pH prevailing inside the lysosomes. The drug itself should of course not be destroyed in the same conditions.

After release the drug can act inside the lysosomes themselves and in this category we find (1) antibiotics acting against intralysosomal bacteria or protozoa; (2) antiinflammatory or antirheumatoid compounds that are supposed to act on the lysosomal constituents themselves (chloroquine, gold salts, corticosteroids); (3) lysosomal enzymes that can be used in the treatment of lysosomal storage diseases; (4) agents that could destroy the lysosomal membrane, induce the intracytoplasmic release of lysosomal hydrolases and lead to the destruction of the cell.

A drug-carrier complex of this type will concentrate specifically the drug inside the cell compartment wherein it is supposed to act. It will also allow active compounds that are unable to cross the plasma membrane to reach the lysosomes.

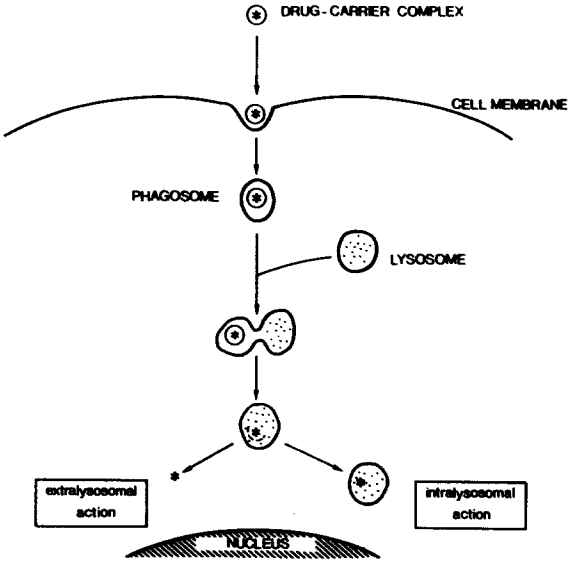

Fig. 2. *Mechanism of entry and mode of action of a drug-carrier complex taken up by endocytosis.*

The usefulness of a lysosomotropic carrier complex can be extended to drugs acting on extralysosomal compartments provided that the drugs are able to cross the lysosomal membranes.

Moreover, the selectivity of the lysosomotropic complexes will depend not only on the specific interaction of the carrier with the cells but also on the endocytic activity of the target cells.

UPTAKE THROUGH THE CELL MEMBRANE

It has been shown recently that unilamellar lipid vesicles can in some conditions, fuse with cellular membranes and release their content directly inside the cytoplasm [34, 35] (Fig. 3). This peculiar type of carrier could allow to introduce inside the cytoplasm (a) macromo-

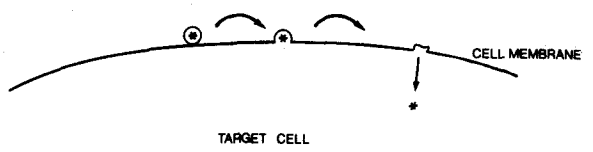

Fig. 3. Mechanism of entry of a drug included in a unilamellar lipid vesicle fusing with the cell membrane.

lecules that evade in this way the hydrolytic enzymes of lysosomes; (b) drugs that cannot permeate through the cellular or lysosomal membranes. When the technology of these vesicles will be mastered and their cell behaviour very clearly analyzed, the field of genetic engineering and enzyme replacement therapy will be wide open as well as the possibility of bypassing the cell membranes by any drug towards which these membranes are unpermeable.

CELL SELECTIVITY MEDIATED BY CARRIERS

If the ultimate goal of the carrier binding is to obtain drugs that recognize and interact specifically with the target cells it is important to consider that two intermediate levels of improved selectivity can be achieved by linking drugs to suitable if not optimal carriers.

All drugs, acting at the intracellular level, penetrate, after administration, into most of the cells of the body by permeation through the cell membrane. By linking these active compounds to a carrier, the tissular distribution and cell uptake will become more restricted than that of the free drug. Cells possessing low endocytic activities or separated from the site of administration by capillar membranes unpermeable to the carrier will remain out of reach. If the target cells do not fall in this category, the drug carrier will remain active and its side effects reduced.

A higher level of selectivity will be reached in the case of drugs linked to an endocytozable carrier if the target cells display a very high endocytic activity towards the carrier. In these conditions, the drug carrier will not only be less toxic but also more active if its rate of penetration and intracellular concentration is higher than if the active compound was given alone.

POSSIBLE CELL SELECTIVE CARRIERS

Except for the drug-carrier complexes acting or released extracellularly the selectivity of a carrier will depend on a specific interaction with the plasma membrane of the target cells. As possible cell selective carriers we can enumerate as follows:

(1) Antibodies directed against cell specific antigens.
(2) Peptidic hormones, that like insulin, vasopressin, thyrotropin, etc., interact with the surface membrane of some cell types.
(3) Viral envelopes or surface components responsible for the selective interaction of viruses and some cell types.
(4) Lectins.
(5) Selectively endocytized macromolecules like for example asialofetoproteins selectively taken up by hepatocytes.
(6) Polypeptidic fragments of toxin (diphtheria, ricin, abrin) responsible for the cellular fixation and penetration of the toxin.

The recognition and selectivity properties of carriers can on the other hand only come to their full expression if the carrier is not taken up in a random way by the cells with which the carrier comes in contact first after administration, namely endothelial cells and cells of the reticulo endothelial system.

In the case of lysosomotropic drug-carrier complexes, the carrier should, after reaction with the cell surface, induce its endocytosis by the cell. Very little is however known today about the factors that determine the fate of a macromolecule after its fixation to the cell surface. Using antibodies of various specificities and rat embryo fibroblasts in culture, we have shown in collaboration with Y. J. Schneider and P. Tulkens [36, 37] that the type of surface antigens with which antibodies react play an important role in determining the intracellular fate. Antibodies directed against lysosomal antigens react with the cell surface and are subsequently very quickly endocytized and concentrated inside the lysosomes. By contrast antibodies directed against plasma membrane antigens seem to remain associated for a very long period with the cell surface and are not accumulated at a great extent in the lysosomes. The fate of IgG molecules can also be modified by fixation of fluorescein isothiocyanate. While normal IgG are endocytized very slowly and at a very low extent by cells in culture, fluorescein labelled IgG are taken up very rapidly and specifically transferred inside the lysosomes.

A similar problem arises with regard to the unilamellar vesicles, the physicochemical properties of which probably determine their cellular uptake by endocytosis or their fusion with the cell membrane [35].

EXAMPLES OF DRUG-CARRIER COMPLEXES WITH INCREASED SELECTIVITY

To illustrate the modifications in selectivity that can be reached by linking drugs to carriers we will briefly summarize our results obtained in the field of cancer and trypanosomiasis chemotherapy by linking drugs to DNA.

Daunorubicin and adriamycin, very potent but very toxic antitumoral drugs, can be transformed into lysosomotropic drug-carrier complexes by linking to high molecular weight DNA. In experimental tumours it has been shown that daunorubicin-DNA and adriamycin-DNA are less toxic than the free drug. Heart [38], liver and kidney are protected at a very great extent against the toxic action of the drugs, this protection is lower in the case of bone marrow and absent with regard to the lymphoid tissues [39]. Although less toxic the DNA complexes are more active than the free drug in treatment of L1210 leukemia mice. Preliminary results in the treatment of human leukemia and various solid tumours indicate also that the cardiotoxicity of ADR and DNR could be reduced when given as DNA complexes while retaining their therapeutic effectiveness.

The lower toxicity of the DNA linked drugs is probably due to a decreased uptake of DNR and ADR by some normal cell types either because of their lower endocytic activity or because of their inaccessibility to macromolecules. The higher chemotherapeutic effectiveness can be explained by improved pharmacokinetic properties of the DNA complexes [40] and by the avidity and endocytic activity of the tumour cells towards DNA.

We have also shown that complexes formed between ethidium bromide and DNA have a lower toxicity than free ethidium bromide and a higher chemotherapic efficiency in the treatment of mice infected with Trypanosoma cruzi [30]. The increased efficiency of DNA-ethidium bromide can be due to a higher uptake of the complexes by the endocytizing parasites during their stay in the blood stream. It could also be explained by a selective concentration of the drug in the lysosomal system of the host cells that shelter the parasites during their intracellular stage. The first explanation is highly unlikely since DNA-ethidium bromide displays a lower chemotherapic efficiency against Trypanosoma brucei which are exclusively extracellular parasites.

CONCLUSIONS

A great deal of basic and applied research is still needed before the "drug-carrier" concept can be developed at the highest degree and provide highly selective drugs designed on the basis of their biochemical effects while making use of the enormous possibilities arising from the ever expanding field of cell biology.

Various molecules will have to be purified or synthetized in order to be screened as possible carriers.

(1) Plasma proteins.
(2) Cell specific antibodies.
(3) Nucleic acids.
(4) Peptidic hormones.
(5) Polysaccharides.
(6) Synthetic polypeptides (with various molecular weights and amino acid compositions).
(7) Lectins.
(8) Liposomes.
(9) Unilamellar lipid vesicles.
(10) Biodegradable microcapsules.

While screening these compounds special emphasis should be put on the analysis of the following properties: (1) cell selectivity; (2) interaction with cells; with special emphasis on their endocytosis or in the case of lipid vesicles on their fusion with plasma membrane; (3) uptake by the reticulo endothelial system; (4) passage through capillary barriers; (5) tissular distribution.

Finally techniques have to be developed that will allow drugs to be linked to macromolecules in such a way that they can be released from these carriers in an active form by hydrolysis of the drug-carrier link or by digestion of the carrier.

Although not new, the concept of vectoring drugs selectively to their target by carriers is becoming more and more liable to clinical application. The recent developments in cellular and molecular biology, as well as the progress achieved in organic chemistry will contribute decisively to the design of highly selective drug-carrier complexes so badly needed in the treatment of cancer, protozoal and degenerative diseases.

Neuraminidase-like Effect of Vitamin A on Cell Surface*

ANTOINETTE HOGAN-RYAN and J. J. FENNELLY

Department of Medicine and Therapeutics, University College, Woodview, Stillorgan Road, Dublin 4, Ireland

Abstract—*Control human lymphocytes and mouse Landscutz ascites tumour cells were treated* in vitro *with vitamin A alcohol. Vitamin A treatment produced changes in the cell wall which resulted in the release of sialic acid. This was similar to the effect observed when the cells were treated with the specific enzyme neuraminidase. Exposure of positive charges by vitamin A may lead to increased immunogenicity of allogeneic blast cells.*

INTRODUCTION

PRE-TREATMENT with vitamin A has been shown to enhance the therapeutic effectiveness of radiation and chemotherapeutic agents [1–3]. The vitamin exerts growth inhibitory effects on cultured murine leukaemic cells [4] and is associated with increased acid hydrolytic activities and increased tumour growth inhibition when given with cyclophosphamide [5].

Vitamin A can interact with and produce alterations of lysosomal membranes, resulting in the release of acid hydrolases [6–8] which may account for the increase in susceptibility of tumour cells to chemotherapeutic drugs [4]. However, changes in surface character of the cells, such as charge, antigenic properties and recognition by macrophages are produced by vitamin A [1–3] and these effects may account for the increased tumour cell susceptibility to chemotherapeutic drugs [4, 5]. It is known that vitamin A affects cells due to its penetration of lipoprotein membranes followed by formation of a micellar configuration of membrane lipids. The specific orientation of vitamin A within the membrane leads to the formation of a highly reactive moiety which is involved in electron transfer in or on the membrane of subcellular organelles [10].

Because of these actions of vitamin A on membrane structures, Brandes *et al.* [9] examined the cell surface of malignant cells exposed to vitamin A and under similar conditions compared this with neuraminidase treatment which removes negatively charged sialic acid from the glycoprotein surface. He noted the effects of vitamin A on Ruthenium Red staining and positive and negative colloidal particle binding and observed the similarities in the effects produced, i.e. loss of surface coat material, reduction in negative surface charge and exposure of positive charge.

We decided to investigate whether the cell surface changes induced by treatment of cells *in vitro* with vitamin A results in the release of free sialic acid due to neuraminidase activity or as peptide bound sialic acid due to non-specific hydrolytic activity.

MATERIAL AND METHODS

Vitamin A alcohol was obtained from Sgma Chemical Co., St. Louis, MO, U.S.A. and dissolved in 0.1% ethanol. *Vibrio cholera* neuraminidase (500 U/ml) was obtained from Calciochem. Cells used were (1) mouse Landscutz ascites tumour cells and (2) human lymphocytes from control subjects.

Treatment of cells

Seven day tumour cells were washed twice in Tris buffered saline pH 7.4 (TBS). They were resuspended in this medium at a concentration of 1×10^7 cells/ml before use.

Lymphocytes were obtained from whole blood (in preservative free heparin) by gradient centrifugation using Ficoll Triosil. The lymphocyte rich layer was washed twice in Tris buffered saline pH 7.4 and was resuspended in this medium at a concentration of 1×10^7 cells/ml.

Accepted 27 May 1977.

*This work was supported by the Irish Cancer Society.

Incubation

Cells were incubated with Vitamin A/ethanol in varying concentrations to give a final concentration of 10–200 μg vitamin A/0.1% of ethanol/10^7 cells/ml. Cells containing 0.1% ethanol were used as controls. *Vibrio cholera* neuraminidase (VCN) was added to the cells suspensions at a concentration of 20 U/1 $\times 10^7$ cells/ml. Cells containing an identical volume of TBS were used as controls. All incubations took place in a shaking water bath at 37°C for 3 hr.

Viability

Dead cell counts were carried out under phase constrast on cell suspension mixed with an equal volume of lissamine green. VCN treated cells were 80–85% viable and did not differ from TBS controls by more than 5%. Vitamin A/ethanol-treated cells were 70% viable as were control cells containing 0.1% ethanol. The cells were removed by centrifugation for 5 min, at 500 ***g*** and the supernatants retained for estimation of free and bound sialic acid. Free sialic acid was estimated using the method of Warren [11] on supernatants which had been dried by rotary evaporation at 60°C and redissolved in 0.2 ml distilled warer. Bound sialic acid was measured by estimating the increase in sialic acid release from supernatants after refluxing for 3 hr with equal volume 2N (HCl).

RESULTS

Results show that vitamin A had a marked effect on the cells as viewed under the microscope. After 3 hr incubation with vitamin A, the cell surface had become crenated and many intracellular black spots were visible. The mean amount of sialic acid released from control cells (TBS) was 59.6 ± 10.3 nM/10^9cells and from control cells (0.1% ethanol) was 58.28 ± 15.6 nM/10^9 cells. In both cases 15 samples were measured.

The minimum effective concentration of vitamin A was 50 μg/10^9 cells when the mean 83.1 ± 5.2 nM sialic acid/10^9 cells was obtained. However, optimum concentration was 100 μg vitamin A/10^9 cells, when 96.60 ± 10.53 nM sialic acid/10^9 was released. This shows that the mean sialic acid released by 100 μg vitamin A/10^9 cells is 38.3 nM ($P > 0.005$).

In comparison the mean sialic acid released in VCN-treated cells (20 U/ml) was 176 ± 30.9 nM/10^9 cells, so the mean sialic acid released by the enzyme was 116.4 nM/10^9 ($P < 0.005$). The amount of sialic acid released by vitamin A is therefore 33% of the possible release of free sialic acid as measured by the increase in sialic acid after acid hydrolysis averaged 12 nM/10^9 cells but is not a genuine value as hydrolysed control values were not significantly different so sialic acid released as a result of vitamin A treatment is free sialic acid.

When lymphocytes from pooled blood of 5 control subjects were incubated at 37°C with vitamin A or with VCN as in previous experiments the following results were obtained. The mean sialic acid released from control samples was 94.9 ± 44.07 nM/10^9 cells (42 samples). Addition of 100 μg vitamin A/10^9 cells resulted in sialic acid values of 160.1 ± 55.2 nM/10^9 cells (12 samples). Therefore, 100 μg vitamin A released an average sialic acid of 65.2 nM/10^9 cells. In comparison, addition of 20 U/ml of VCN resulted in mean sialic acid levels of 309 ± 99.2 nM/10^9 cells which gives an average release of 214.3 nM sialic acid/10^9 cells by VCN. In lymphocytes, vitamin A released 30% of the possible sialic acid released by VCN. The sialic acid released as a result of incubation of lymphocytes with vitamin A is unbound sialic acid, as no significant increase in sialic acid levels was apparent when the supernatant was hydrolysed by refluxing with equal volume 2N HCl.

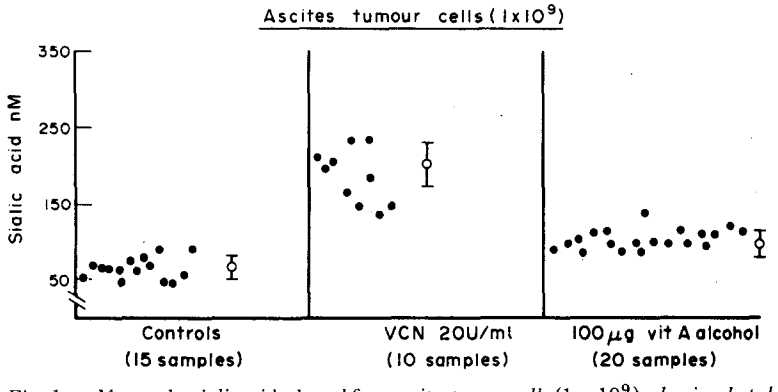

Fig. 1. Nanomoles sialic acid released from ascites tumour cells (1×10^9) *when incubated for* 3 hr *at* pH 7.6 *without additive (controls) and with VCN* (20 U/ml) *and vitamin A alcohol* (100 μg/ml) *respectively.*

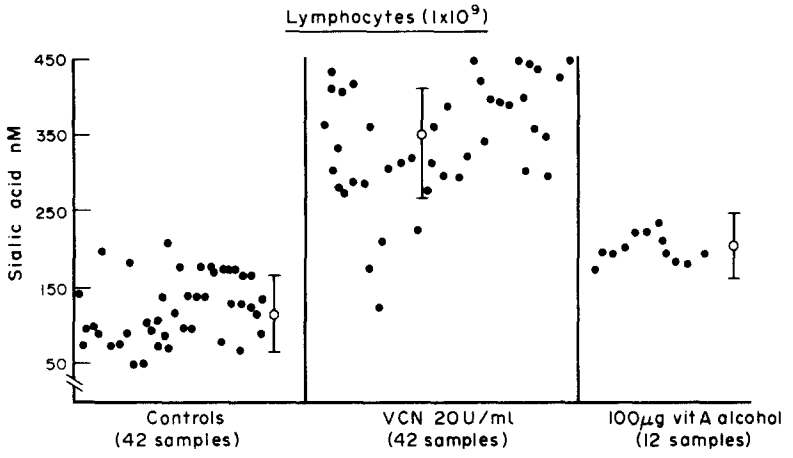

Fig. 2. Nanomoles sialic acid released from normal lymphocytes (1×10^9) *when incubated for* 3 hr *at* pH 7.6 *without additive (controls) and with VCN* (20 U/ml) *and vitamin A alcohol* (100 μg/ml) *respectively.*

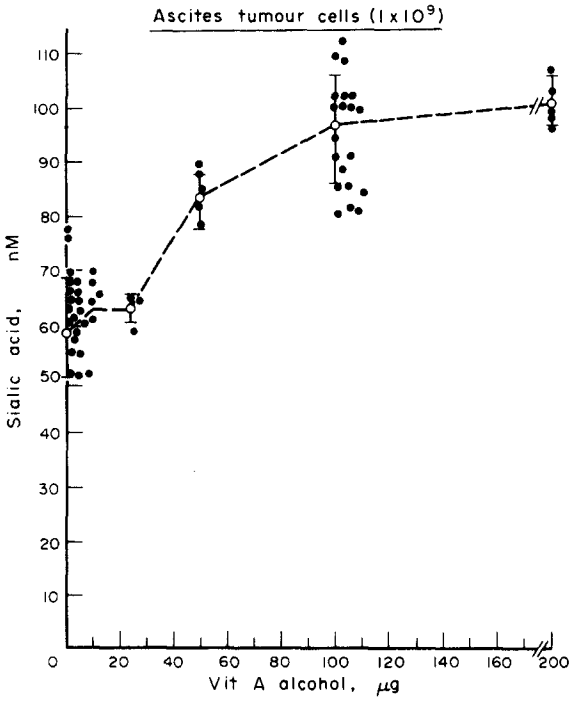

Fig. 3. Nanomoles sialic acid released from ascites tumour cells (1 $\times 10^9$) *when incubated for* 3 hr *at* pH 7.6 *with varying concentrations* (0–200 μg/ml) *vitamin A alcohol.*

DISCUSSION

The surface coat of the cells is affected by vitamin A [1–3] and the direct effect of vitamin A on the cell wall may account for the tumour cell increased susceptibility to chemotherapeutic drugs [4, 5]. These results show that cell surface changes induced by *in vitro* treatment with vitamin A result in the release of free sialic acid indicating an effect on cell surface similar to VCN which specifically cleaves the glycosidic link releasing terminal sialic acid.

Thus the reduction in negative surface change and exposure of positive charges on vitamin A treated malignant cells [4] is due at least in part to removal of negatively charged sialic acid from the cell surface. Holland and Bekesi [12] have shown strong evidence that pre-treatment of allogeneic myeloblasts with VCN increases the immunogenicity of these cells; VCN treated blasts when used in conjunction with chemotherapy have more than doubled the remission period in patients with acute myelogenous leukaemia. Whether vitamin A treated blasts would have a similar effect remains to be seen. Lundgren and Simmonds [13] using peripheral blood lymphocytes showed that VCN treated cells incubated with normal allogeneic lymphocytes in mixed lymphocyte culture (M.L.C.) more than doubled the rate of DNA synthesis compared to normal MLC response. We have found similar stimulation in MLC response when H^3 thymidine incorporation into 5-day-mixed cultures of lymphocutes and VCN-treated allogeneic blast cells. Work is now in progress to establish if immunogenicity of these blast cells is increased by incubation with Vitamin A.

Transformation of 5-Aza-2′-deoxycytidine-^{3}H and Its Incorporation in Different Systems of Rapidly Proliferating Cells

ALOIS ČIHÁK

Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Sciences, 166 10 *Prague* 6, *Czechoslovakia*

Abstract—*5-Aza-2′-deoxycytidine-*^{3}H *undergoes in Ehrlich ascitic cells phosphorylation and deamination resulting in the formation of new metabolites. In the acid-soluble pool of tetrahydrouridine-treated cells the level of deaminated analogue and of 5-azauracil formed by its phosphorolytic cleavage was substantially decreased. Both* in vivo *and in cell suspension* in vitro *5-aza-2′-deoxycytidine-*^{3}H *is incorporated into nucleic acids.*

In AKR mice with lymphatic leukemia the drug is preferentially incorporated into lymphatic tissues. While the blast infiltration of the liver results in a 3–4 fold increase of the uptake of the analogue the incorporation of thymidine-^{3}H *is enhanced 12–17 times to compare with the normal livers. Cytosine arabinoside depresses the incorporation of thymidine-*^{3}H *as well as 5-aza-2′-deoxycytidine-*^{3}H. *In regenerating rat livers thymidine, deoxycytidine but not 5-aza-2′-deoxycytidine are utilized with a greater efficiency than in the stationary liver. 5-Aza-2′-deoxycytidine is thus incorporated into rapidly proliferating cells while its uptake into lymphatic system is preferential.*

INTRODUCTION

5-AZAPYRIMIDINES represent a group of highly efficient cytostatics. Phase II and III studies have shown that 5-azacytidine is especially active in human acute myelogenous leukemia [1, 2] with an overall response rate of 36%. However, the clinical use of the drug is complicated by severe nausea and vomiting [1, 3]. Another compound of the group, 5-aza-2′-deoxycytidine, has also an impressive cytostatic activity [4, 5]. The drug is efficiently incorporated into nucleic acids in the lymphatic system [6, 7] and suppresses the cell growth in AKR mice with lymphatic leukemia, in P388 leukemia bearing mice and in L1210 leukemia [8].

The strong inhibitory effect of 5-aza-2′-deoxycytidine in microorganisms depends on its foregoing metabolic transformation, i.e. deamination and cleavage of deaminated nucleoside [9]. In higher organisms the analogue is also metabolized and several new compounds were detected in the urine of drug-treated mice [7]. 5-Aza-2′-deoxycytidine inhibits the phosphorylation of deoxycytidine and is incorporated into DNA [8]. Pretreatment of mice with the drug results in the inhibition of thymidine incorporation into spleen DNA in parallel with the decrease of thymidine and thymidylate kinase activities [7].

The aim of the present study was to follow the metabolic conversion of 5-aza-2′-deoxycytidine in tumor cells and to compare the incorporation and inhibitory effect of this antileukemic agent in different systems of rapidly proliferating cells.

Accepted 7 June 1977.

MATERIAL AND METHODS

Chemicals

5-Azacytidine, 5-aza-2′-deoxycytidine and cytosine arabinoside were prepared in the Department of Organic Synthesis of this Institute. Tritiated 5-aza-2′-deoxycytidine (19.5 Ci/mmole) was prepared by Dr. B. Černý, Isotope Laboratory, Prague-Krč. Thymidine (methyl-^{3}H) (8.1 Ci/mmole) and 2′-deoxycytidine-2-^{14}C (44 mCi/mmole) were provided by the Institute for Research, Production and Uses of Radioisotopes, Prague. Tetrahydrouridine was a gift from Dr. G. L. Neil, The Upjon Company, Kalamazoo.

Animals

Groups of 10 female mice (strain H, 25–28g) kept under standard laboratory conditions were transplanted i.p. 10^7 Ehrlich ascitic cells. The animals were used for the experiments 9 days later. Groups of 6 inbred AKR female mice were transplanted s.c. 2.10^7 leukemic cells and 7 days later were injected with the labelled compounds (maximal vol 0.2 ml, 2 hr pulse-labelling). Partial hepatectomy was carried out [10] between 8–9 a.m. under light ether narcosis using groups of 6 Wistar female rats (175g). The labelled compounds were injected i.p. in a maximal vol 0.3 ml 2 hr before killing. The details are given in legends to the corresponding figures and tables.

Metabolic conversion of 5-*aza*-2′-*deoxycytidine*-^{3}H

Transformation of the drug was followed both *in vivo* and *in vitro* using Ehrlich ascitic tumor cells. During *in vivo* experiments the drug was injected i.p. to groups of 4 mice (100 μCi/0.2 μmole per animal) 2 hr before killing. Ascitic cells were removed and extracted with 5 vol of cold 0.4M $HClO_4$. The acid soluble fractions were neutralized with 2M KOH, cooled and clear supernatant fractions after centrifugation (5000 × ***g***, 5 min, 2°C) containing the newly formed radioactive metabolites were analyzed chromatographically using Whatman No. 3 paper as indicated in Figs. 1 and 2. The suspension of washed ascitic cells was used to follow transformations of 5-aza-2′-deoxycytidine-^{3}H *in vitro*. Incubation was carried out at 37°C in 25 mM Tris–HCl buffer (pH 7.5) containing 25 mM KCl and 5 mM $MgCl_2$ in the presence of 0.1 mM 5-aza-2′-deoxycytidine-^{3}H. The extraction of radioactive metabolites from the cellular pool and separation procedures were the same as described above. The radioactive spots on chromatograms were localized with a Frieseke–Hoepfner scanner and identified according to the position of standards.

Incorporation of 5-*aza*-2′-*deoxycytidine*-^{3}H

The incorporation of the analogue and of pyrimidine precursors into the fraction of nucleic acids was followed in various tissues of mice and rats. 5-Aza-2′-deoxycytidine-^{3}H, thymidine(methyl-^{3}H) or deoxycytidine-2-^{14}C were injected i.p. 2 hr before killing to groups of 5–6 animals. The tissues under investigation were quickly removed and homogenized in a cooled glass homogenizer with a tight-fitting Teflon pestle in 10 vol of cold 0.25 mM KCl. One millilitre portions of the homogenates were mixed with 1 ml of 0.4M $HClO_4$, the suspensions centrifuged (5000 × ***g***, 5 min, 2°C) and sediments extracted 3 times under cooling with 4 ml of 0.2M $HClO_4$ to remove the acid soluble low-molecular-weight components. Resulting sediments were extracted with 5 ml of alcohol–ether (3 : 1), dried and dissolved at 80–100°C in 1 ml of formic acid. The radioactivity of aliquots was measured using liquid scintillation system Isocap/300 (Nuclear Chicago Division).

RESULTS

Metabolic transformation of 5-*aza*-2′-*deoxycytidine*-^{3}H *in Ehrlich ascitic cells*

After the administration of 5-aza-2′-deoxycytidine-^{3}H to mice with Ehrlich ascitic carcinoma the drug is rapidly metabolized giving rise to new metabolites in the tumour cells. Analyzing total acid soluble cellular pool of the labelled cells by paper chromatography in different solvent systems at least nine newly formed compounds was detected. Figure 1 shows the separation of radioactive material on Whatman No. 3 paper using isobutyric acid–ammonium hydroxide-water as the solvent system.

Individual spots (Fig. 1A) were identified in the following way. Spot 1 is supposed to contain higher 5′-phosphates of the analogue and of 5-aza-2′-deoxyuridine. The corresponding zone was eluted and rechromatographed as is shown in Fig. 1(B). According to their chromatographic characteristics spot 2 contains 5-aza-2′-deoxyuridine 5′-monophosphate, spot 3, 5-azauracil, spot 4, 5-aza-2′-deoxyuridine (or product of its degradation), spot 5, 5-aza-2′-deoxycytidine 5′-monophosphate, spot 6 unknown derivative of deoxyribose and spot 7 unreacted 5-aza-2′-deoxycytidine. Spots 8, 9 and 10 contain the products of degradation of 5-aza-2′-deoxycytidine which are presently studied by Dr. A. Piskala of this Institute who supplied also some of the necessary standards.

The incubation of Ehrlich ascitic cells in suspension in the presence of 5-aza-2′-deoxycytidine-^{3}H resulted in the formation of the same set of compounds (Fig. 2A) as above. The addition of tetrahydrouridine, an inhibitor of cytidine deaminase [11], modifies the pattern of the newly formed compounds (Fig. 2B). While the level of products of 5-aza-2′-deoxycytidine degradation is unchanged (spots 8, 9 and 10) there is almost no radioactivity in the area corresponding to 5-azauracil (spot 3) and 5-aza-2′-deoxyuridine (spot 4). The radioactivity is localized mainly in the zone of 5-aza-2′-deoxycytidine 5′-monophosphate (spot 5) and of

5-aza-2′-deoxyuridine 5′-monophosphate (spot 2).

The time course of the uptake of the label into the fraction of nucleic acids during the incubation of Ehrlich ascitic cells in suspension with 5-aza-2′-deoxyxytidine-^{3}H is shown in Fig. 3. Somewhat lower uptake of the label observed in the presence of tetrahydrouridine apparently indicates that both 5-azacytosine and 5-azauracil nucleotides are taken up into cellular nucleic acids. The low stability of 5-azapyrimidines [12, 13] complicates the isolation and chemical characterization of nucleic acids with incorporated 5-azauracil or 5-azacytosine [14].

Preferential incorporation of 5-aza-2′-deoxycytidine-^{3}H into DNA in the spleen and the thymus of AKR mice with lymphatic leukemia

In earlier studies on the distribution [6] and inhibitory mechanism [7, 8] of 5-aza-2′-deoxycytidine in mice an increased uptake of the drug into lymphatic tissues was observed. In this study we followed the drug uptake and its distribution in tissues of AKR mice with lymphatic leukemia during the terminal stage of the disease.

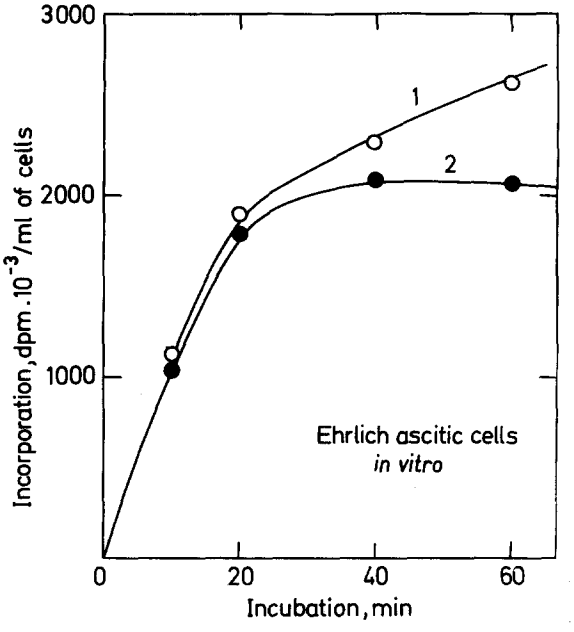

Fig. 3. In vitro *incorporation of 5-aza-2′-deoxycytidine-^{3}H into nucleic acids in Ehrlich ascitic cells.*

Ascitic cells from 10 animals (9 days after transplantation) free of erythrocytes and washed with cold 0.9% NaCl were suspended in 10 ml *of* 25 mM *Tris*–HCl buffer (*pH* 7.5) *containing* 25 mM KCl *and* 5 mM $MgCl_2$. *Incubation was carried out at* 37°C *in* 1 ml *portions after the addition of* 0.1 μmole *5-aza-2′-deoxycytidine-^{3}H* (200 μCi) *without* (1) *or with* (2) 3 *mM tetrahydrouridine. The incorporation of the label into the fraction of nucleic acids was measured as described in Material and Methods.*

From the data presented in Table 1 it is evident that thymidine-^{3}H is incorporated in control AKR mice about 11 times more effectively into nucleic acids in the spleen than in the liver. In leukemic animals the uptake of thymidine-^{3}H by the liver was 12 times (calculated per 1 g of the tissue) and 17 times (calculated per the liver) higher, respectively, than in the liver of intact animals. The labelling of nucleic acids, calculated per 1 g of the spleen and especially of the thymus of mice with lymphatic leukemia was lower than in the corresponding tissues of control AKR mice. However, the total uptake of thymidine-^{3}H into spleen nucleic acids was significantly increased (Table 1).

Using 5-aza-2′-deoxycytidine-^{3}H, the uptake of the radioactivity in the liver and kidney of intact AKR mice was about twice as high as that with thymidine-^{3}H. Nevertheless, the incorporation of the drug into nucleic acids in the spleen of intact animals was at least 25 times higher than in the liver (Table 2). While the uptake of thymidine-^{3}H was only about 4 times higher in the thymus than in the liver (Table 1) 5-aza-2′-deoxycytidine-^{3}H was taken up into thymus nucleic acids 12 times more effectively than in the liver (Table 2). In contrast to 12-17 fold enhancement of thymidine-^{3}H incorporation into leukemic liver the utilization of 5-aza-2′-deoxycytidine-^{3}H was enhanced 3–4 times only. Similarly as with thymidine-^{3}H the labelling of nucleic acids by the analogue in the spleen of mice with lymphatic leukemia was increased.

The ratio of the labelling of infiltrated livers, spleen and thymus with 5-aza-2′-deoxycytidine-^{3}H and thymidine-^{3}H, taking into account the labelling of the tissue and supposing the same radioactivity of administered compounds (see Tables 1 and 2) is 0.3–0.5, 4.2–5.5 and 8.0–11.5, respectively, indicating the preferential uptake of the analogue into lymphatic system.

To distinguish the uptake of 5-aza-2′-deoxycytidine into DNA and other molecules present in the acid-insoluble fraction the selective inhibitory effect of cytosine arabinoside on semiconservative replication of DNA [15, 16] was made use of. The data presented in Table 3 show that the incorporation of both thymidine and 5-aza-2′-deoxycytidine into the fraction of nucleic acids in the spleen and the thymus of leukemic mice is markedly depressed by the simultaneous administration of this drug. In the liver the inhibitory effect of cytosine arabinoside is much lower indicating the uptake of the label from both compounds into other molecules than only DNA. This is not surprising in view of the

Groups of 5 male AKR mice (25 g) 7 days after inoculation with 2.10^7 leukemic cells were injected i.p. with cytosine arabinoside (3 μmole) simultaneously with thymidine (methyl-^{3}H) (50 μCi/0.2 μmole per animal) or 5-aza-2'-deoxycytidine-^{3}H (150 μCi/0.2 μmole per animal) 2 hr before killing. Controls are taken as 100%.

known metabolic conversion of 5-aza-2'-deoxycytidine into 5-azauracil [7] which is transformed to 5-azauridine 5'-monophosphate [17] and incorporated (5% of the incorporation of 5-aza-2'-deoxycytidine-^{3}H) into RNA. It is also known that tritium from thymidine-^{3}H can appear in macromolecular species other than DNA, especially in the liver [18].

Low incorporation of 5-aza-2'-deoxycytidine-^{3}H by proliferating hepatocytes in regenerating rat livers

The changes taking place after partial hepatectomy are characterized by an early increase of template activity of proliferating hepatocytes [19] followed 18–24 hr later by a pronounced enhancement of the synthesis of DNA and mitotic activity [20]. The data presented in Table

4 show that while thymidine and deoxycytidine are incorporated into liver DNA 24 hr after partial hepatectomy 9 and 12 times more effectively, the uptake of 5-aza-2′-deoxycytidine is not increased. However, in intact rat livers the incorporation of tritium labelled analogue was much higher than that of thymidine-^{3}H. This is probably due to the uptake of the label from 5-aza-2′-deoxycytidine-^{3}H into some other classes of cellular macromolecules than DNA. In the thymus of rats 24 hr after partial hepatectomy the utilization of thymidine, deoxycytidine and especially of 5-aza-2′-deoxycytidine was significantly decreased.

The treatment of rats by 5-azacytidine prior to partial hepatectomy results in the enhancement of thymidine incorporation into DNA in 24 hr regenerating livers [21]. Under similar conditions the utilization of the label from 5-aza-2′-deoxycytidine-^{3}H remained unchanged (Table 5). 5-Azacytidine pretreatment results in a further depression of thymidine-^{3}H and especially of 5-aza-2′-deoxycytidine-^{3}H incorporation into nucleic acids in the spleen and thymus.

DISCUSSION

5-Aza-2′-deoxycytidine was prepared synthetically [22] in 1964. While the corresponding ribonucleoside, 5-azacytidine, has been intensively studied since 1964 (e.g. [23, 24]) and is presently used with success in the treatment of various forms of human leukemias [25–27], 5-aza-2′-deoxycytidine has not yet found an application in the clinic. This is partly due to a limited supply of the deoxy analogue and mainly to a limited knowledge of the inhibitory mechanism of its action.

In mammalian tissues 5-aza-2′-deoxycytidine inhibits the phosphorylation of deoxycytidine in the acid-soluble cellular pool and depresses the incorporation of this pyrimidine into DNA [8]. At the same time the incorporation of the analogue into DNA molecules in the lymphatic system was observed. It is of interest that deoxycytidine affects the uptake of the analogue into nucleic acids to a lesser degree than 5-aza-2′-deoxycytidine the incorporation of deoxycytidine [7]. Following the administration of 5-aza-2′-deoxycytidine to mice the spleen of the

Table 4. Differences in incorporation of thymidine-^{3}H, deoxycytidine-2-^{14}C and 5-aza-2′-deoxycytidine-^{3}H in the liver of intact and partially hepatectomized rats

Administered	Incorporation, dis/min 10^{-3}/g tissue ± S.E. (%)		
	Intact	Partially hepatectomized	
Thymidine-^{3}H	31.1 ± 5.2	289.6 ± 28.8	(930)
Deoxycytidine-2-^{14}C	6.0 ± 0.7	73.2 ± 9.4	(1220)
5-Aza-2′-deoxycytidine-^{3}H	207.0 ± 22.5	218.2 ± 22.5	(105)

Groups of 6 intact or partially hepatectomized female rats (175–180g) 24 hr after operation were given 2 hr before killing thymidine(methyl-^{3}H) (100 μCi/0.2 μmole per animal), deoxycytidine-2-^{14}C (6 μCi/0.2 μmole per animal) or 5-aza-2′-deoxycytidine-^{3}H (100 μCi/0.2 μmole per animal). Intact animals are taken as 100%.

Table 5. Changes in the incorporation of thymidine-^{3}H and 5-aza-2′-deoxycytidine-^{3}H in 5-azacytidine-treated rats subjected to partial hepatectomy

Tissue	5-Azacytidine treatment	Incorporation, dis/min 10^{-3}/organ ± S.E. (%)			
		Thymidine-^{3}H		5-Aza-2′-deoxycytidine-^{3}H	
Regenerating liver	−	452.5 ± 43.8	(100)	342.7 ± 27.2	(100)
	+	678.3 ± 41.9	(150)	360.0 ± 16.8	(105)
Spleen	−	76.3 ± 12.0	(100)	354.0 ± 42.6	(100)
	+	41.8 ± 4.9	(54.8)	75.7 ± 10.4	(21.4)

Groups of 5 female rats (175–185g) were given i.p. at 24 hr intervals two doses of 5-azacytidine (6 μmole per 100g) or 0.9% NaCl and 24 hr later partial hepatectomy was carried out. Incorporation of thymidine(methyl-^{3}H) (100 μCi/0.2 μmole per animal) or 5-aza-2′-deoxycytidine-^{3}H (100 μCi/0.2 μmole per animal) into the fraction of nucleic acids was measured 24 hr after operation during a 2 hr pulse.

treated animals had much lower capacity to incorporate thymidine and displayed lower activity of thymidine and thymidylate kinases [7].

There are several findings indicating that the mode of action of 5-aza-2′-deoxycytidine is different from that of 5-azacytidine [7, 8, 23]. Recently the compounds originating from the tritium labelled drug were detected in the urine of mice already 4 hr after its administration. Beside several unidentified components 5-aza-uracil and guanidine were isolated from the urine in pure state and identified [7]. The transformation of 5-aza-2′-deoxycytidine in mice as proposed on the basis of compounds detected in the urine involves the deamination and splitting of deaminated deoxynucleoside resulting in the formation of 5-azauracil.

In the present study we used Ehrlich ascitic cells to follow the conversion of 5-aza-2′-deoxycytidine-^{3}H. From the data presented in Figs. 1 and 2 it is evident that the analogue is partly deaminated to 5-aza-2′-deoxyuridine and both fraudulent deoxynucleosides are phosphorylated not only to 5′-monophosphates but also to higher 5′-phosphates (Fig. 1B). Since tetrahydrouridine depresses the deamination of 5-aza-2′-deoxycytidine (Fig. 2B) and since 5-aza-2′-deoxyuridine 5′-monophosphate is present in the acid-soluble pool of the treated cells the deamination at the nucleotide level is probable. Using partially purified enzyme extract from calf thymus the formation of both anomalous 5′-monophosphates was observed also in an *in vitro* system (unpublished).

5-Aza-2′-deoxycytidine is incorporated into the fraction of nucleic acids. However, there are tissue differences in the uptake of tritium labelled analogue and of thymidine (Tables 1 and 2). While thymidine is incorporated into the liver of AKR mice with lymphatic leukemia to a larger extent than 5-aza-2′-deoxycytidine the latter compound is preferentially incorporated into spleen and thymus nucleic acids. Cytosine arabinoside markedly depressed the incorporation of both compounds in the spleen and the thymus indicating the incorporation of the label into DNA (Table 3). The lower inhibitory effect of cytosine arabinoside on the uptake of the label in infiltrated livers suggests the labelling of other molecules than only DNA.

Lower incorporation of 5-aza-2′-deoxycytidine-^{3}H than that of thymidine-^{3}H was also observed in proliferating hepatocytes in regenerating rat livers (Tables 4 and 5). Again, the higher uptake of the analogue (but less pronounced than in mice) was observed in the spleen and the thymus of intact and partially hepatectomized rats (Table 5).

These findings speak in favour of the increased affinity of 5-aza-2′-deoxycytidine for the lymphatic system and the potential usefulness of the drug against malignancies of the lymphatic system. Up to now 5-aza-2′-deoxyxytidine has not been used in the clinic in distinction to 5-azacytidine which is effective in acute myelogenous leukemia [1, 2, 27]. It remains to be seen whether in lymphatic leukemia which is less responsive to 5-azacytidine the deoxy analogue will be more efficient.

Estradiol Binding by Human Breast Carcinoma Cytosols: The Influence of Commonly Used Reference Parameters on the Results

ROLAND HÄHNEL and ELLA TWADDLE
Department of Obstetrics and Gynaecology, University of Western Australia, King Edward Memorial Hospital for Women, Subiaco 6008, *Western Australia*

Abstract—*The estradiol binding by human breast carcinoma cytosols was measured by saturation analysis and antiestrogen inhibition. The results were related to the weight of the tissue, the total protein content of the cytosol, the tissue protein content of the cytosol and the DNA content of the tissue. Taking estrogen binding/*mg *total protein estimated by saturation analysis as reference, the tumors were classified into estrogen receptor positive, estrogen receptor negative or borderline cases. Comparison with the estrogen binding related to the other tissue parameters or obtained by antiestrogen inhibition showed identical tumor classification in about* 85% *of cases.*

INTRODUCTION

THE ESTIMATION of estrogen receptors in the tumor has become an important factor in determining the treatment of disseminated breast carcinoma. Only patients with receptor-positive tumors have a significant chance of responding to endocrine therapy. It is, therefore, necessary to be aware of the numerous problems that are encountered when the receptor proteins are estimated [1–3]. One of the variables that has not received any attention so far is the influence of the various reference parameters commonly used to express the estradiol binding results. While comparisons between tissue slice and tissue cytosol results have been reported [4, 5] correlations between estradiol binding results obtained by saturation analysis and those obtained by antiestrogen inhibition have not been studied nor has the estradiol binding expressed per mg protein been compared with the binding per g tissue wet weight or per mg DNA. Do all these different ways of calculating the results agree with regard to classifying a carcinoma as receptor-positive or receptor-negative, or as a borderline case?

In this report estradiol binding by breast carcinoma cytosols was studied by both estradiol saturation and by antiestrogen inhibition, and the binding results were related to total cytosol protein, to the cytosol protein proper (i.e. not including the protein contamination from blood plasma), to DNA and to the wet weight of the tissue.

Accepted 14 June 1977.
A preliminary account of this work was presented at the Fifth International Congress of Endocrinology, Hamburg, 1976, Abstract No. 133.

MATERIAL AND METHODS

Preparation of cytosol

Homogenization of the tissue and preparation of the high-speed supernatant has been described before [6]. The cytosol was used for binding studies and for the estimation of protein, while the pellet was used for DNA determinations.

Estradiol binding by saturation analysis

Binding of estradiol to the cytosol receptor was studied over a concentration range of 50 pg to 5050 pg per ml cytosol using a constant amount of 50 pg tritiated estradiol and increasing amounts of unlabelled estradiol as described before [7]. Incubation was at 25°C for 1 hr followed by treatment with dextran-coated charcoal to remove excess steroid and loosely bound steroid. Receptor-bound estradiol-17β was determined as the difference between estradiol binding (in fmole/mg protein) at the lowest and at saturating steroid concentrations. From the Scatchard plot of the results the association constant of the estradiol-receptor

interaction and the number of binding sites were also calculated.

Estradiol binding in the presence of antiestrogen

Cytosol was incubated in the same way with 50 pg tritiated estradiol-17β in the absence and presence of 23,000 pg CN 55945 (Parke-Davis Co.)[8]. Receptor bound estradiol-17β was calculated as the difference between estradiol binding in the absence and presence of the antiestrogen.

Protein estimation

Total protein in the cytosol was measured according to Lowry *et al.* [9]. Plasma albumin in the cytosol was determined by immunodiffusion [10] using LC (low concentration) Partigen Albumin plates (Behringwerke A.G., Marburg, Germany). Tissue protein was then calculated as total protein minus 1.666 × plasma albumin.

DNA-estimation

The pellet and the fat layer obtained after high-speed centrifugation of the tissue homogenate were weighed. A half a gram of the pellet (or less) was redispersed by vigorous shaking in 5 ml of 5% trichloroacetic acid. The suspension was heated at 80%C for 20 min, then cooled and centrifuged for 5 min at 3800 rev/min, 0.1–1.0 ml aliquots of the supernatant were used for the color reaction and made up to 2 ml with 5% trichloroacetic acid. The pellet was re-extracted twice with fresh 5 ml portions of 5% trichloroacetic acid. Calf thymus DNA (Calbiochem) dissolved in 0.001 N NaOH was used as standard over a concentration range of 4–400 μg/4 ml. For the color reaction [11] equal parts of 0.08% indole in distilled water and 4 N HCl were mixed and 2 ml of this mixture were added to the DNA standards or pellet extracts. The solution was mixed on a vortex and heated in a boiling water bath for 15 min, during which time the tubes were shaken twice. The tubes were then cooled in ice water and extracted several times with 1 ml chloroform to remove the non-specific pink color, until the chloroform layer remained colorless. The optical density of the aqueous phase was measured at 490 μm using a 1 cm cuvette.

RESULTS

1. *Comparison of estradiol binding estimated by estradiol saturation analysis or by antiestrogen inhibition*

Estradiol binding by human breast carcinoma cytosol was estimated by saturation analysis, the difference between binding (in fmole/mg protein) at the lowest (50 pg estradiol/ml cytosol) and the highest (5050 pg estradiol/ml cytosol) concentrations being the amount of receptor-bound estradiol. Estradiol binding obtained in this way was used as reference for all comparisons and was also used to calculate association constant and number of binding sites. This is schematically shown on Fig. 1.

In the antiestrogen method, receptor-bound

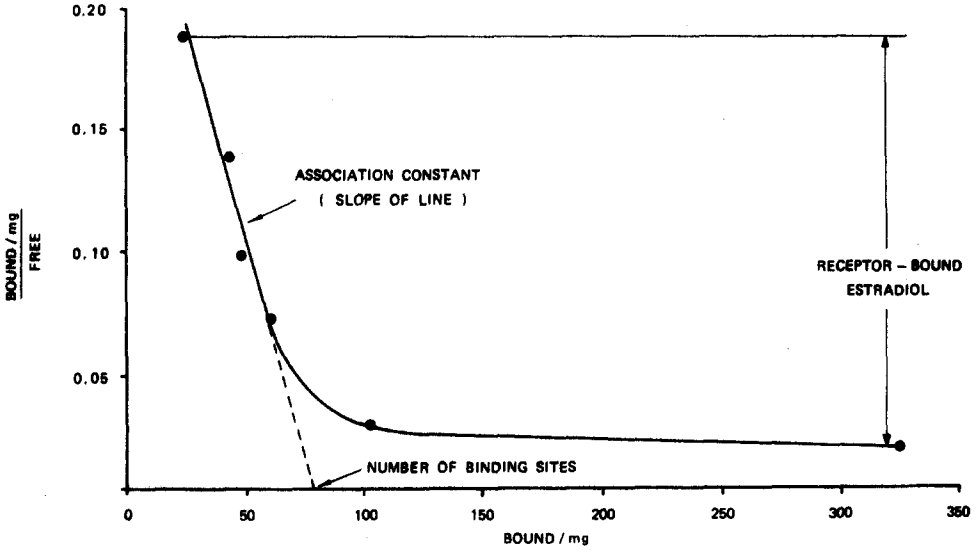

Fig. 1. Estimation of receptor bound estradiol, association constant and number of binding sites. The receptor-bound estradiol is calculated as the difference between the first and the last experimental points as shown schematically on the chart. The values used were not the derived figures of the ordinate (bound/mg)/free but the actual binding results in fmole estradiol bound/mg protein. The scale of the abscissa is in fmole.

estradiol was calculated as the difference between estradiol binding in the absence and in the presence of excess antiestrogen.

In Table 1, estradiol binding by human breast carcinoma cytosols, estimated by estradiol saturation (column A) and by antiestrogen inhibition (column B) is expressed per mg of total protein of the cytosol.

Breast carcinomas fall into 2 groups with regard to estradiol binding properties. One

Column A is fmole/mg total protein, by estradiol saturation. Column B is fmole/mg total protein, by antiestrogen inhibition. Column C is fmole/mg tissue protein. Column D is fmole/g tissue (wet weight). Column E is fmole/mg DNA of tissue.

category of carcinomas behaves like a typical target organ (e.g. uterus), binds considerable amounts of estradiol and the binding is achieved by a limited number of receptor sites. The other group binds little estradiol, the binding is not saturable and is in all other aspects like the non-specific binding by a non-target tissue (e.g. skeletal muscle) [4]. The actual binding values assigned to ER+, ER± and ER− depend on a number of variables [2] and are somewhat arbitrary. In spite of this various groups working independently have come to very similar figures and have concluded that this classification is helpful in predicting the results of endocrine therapy for metastatic breast cancer [3].

If one defines binding values (obtained by saturation analysis) greater than 8 fmole/mg as estrogen receptor positive (ER+), values between 4–8 fmole/mg as borderline cases (ER±) and values below 4 fmole/mg total protein as receptor negative (ER−), the following tumors in Table 1 would be estrogen-dependent: FR-1, MB-1, MG-1, MO-2, RA-1, RO-3, RU-1, SH-1, SM-1a, TA-1. In this group the mean estradiol binding was 27.19 with a standard deviation of ± 15.53 and a range from 10.75 to 56.20 fmole/mg. The group of ER± cases consists of: BI-1, CO-1, DA-1, LE-2, MI-1, PO-1, with estradiol binding ranging from 4.78 to 6.80 and a mean and standard deviation of 6.38± 0.91 fmole/mg. All the remaining breast carcinomas were ER−. The mean estradiol binding in this group of 30 carcinomas was 1.48 fmole/mg with a standard deviation of± 1.45 and a range from −0.42 to 3.85. Using this grouping of the individual tumors and then applying it to the results obtained with the same tumors by antiestrogen inhibition shows general agreement (39/46) but also a number of discrepancies. All the tumors found to be ER− by estradiol saturation analysis would also be ER− by the antiestrogen inhibition method. The mean binding and standard deviation in this group was 0.58± 1.33 fmole/mg with a range from −3.90 to 2.71. The mean binding was significantly lower than that obtained by estradiol saturation (t= 2.489, confidence limit> 98%). The same trend for lower results with the antiestrogen inhibition was observed in the ER± and the ER+ groups. Estradiol binding in the ER± group estimated by antiestrogen inhibition was 4.37± 0.62 fmole/mg (mean± standard deviation) which is significantly lower than the results for this group obtained by estradiol saturation (t= 4.451, confidence limit> 99.73%). The ER+ group bound 9.93± 8.44 fmole/mg (mean± standard deviation) estimated by antiestrogen inhibition, much less than obtained by estradiol saturation (t= 3.088, confidence limit> 99%).

Two results CO-1, DA-1 that were ER± by estradiol saturation, showed binding of less than 4 fmole/mg protein by antiestrogen inhibition and would have been classified ER−. In 5 more carcinomas estrogen receptors would have been underestimated (in relation to the classification obtained by estradiol saturation analysis). Three showed intermediary levels (FR-1, MB-1, SM-1a) which would have put them into the ER± group and in two (RA-1, RO-3) antiestrogen inhibition would have classed the tumor as ER−, while estradiol saturation analysis grouped them as ER+. These results are summarized in Table 2.

Table 2. Comparison of estradiol binding of 46 breast carcinoma cytosols estimated by estradiol saturation (reference) and by antiestrogen inhibition

	ER+ n=10	ER± n=6	ER− n=30	Total n=46
Agreement	5	4	30	39
Underestimation	5	2	0	7
Overestimation	0	0	0	0

Underestimation means that binding based on antiestrogen inhibition would have placed the tumor in a group with less ER content; overestimation indicates that binding based on antiestrogen inhibition would have placed the tumor into a group with higher ER content. "n" is the number of cases.

The correlation coefficient for the pairs of results in columns A and B, Table 1 was 0.624 (confidence limit>99.9%) and the regression, y=1.004+0.271 x.

2. *Comparison of results of estradiol binding (estimated by estradiol saturation) expressed per* mg *total protein, per* mg *tissue protein, and per* g *tissue wet weight*

In addition to using 2 different methods of estimating receptor binding (estradiol saturation and antiestrogen inhibition) the values thus obtained have also been related to different reference parameters. In the earlier stages of receptor research the wet weight of the tissue was most commonly used for this purpose, later also the total protein content of the cytosol, and more recently the tissue protein and the DNA content of the tissue. In Table 1 the results of estradiol binding calculated per mg total protein (column A) are compared with the same results expressed per mg tissue protein (column C) and per g tissue wet weight (column D).

Since the results of columns A and D (Table 1) have different units these figures cannot be compared directly as those of columns A and B. Rather, the binding results per g tissue wet weight were grouped into ER+, ER± and

ER − based on the classification derived from the estradiol binding per mg protein. When this was done, a mean estradiol binding per g tissue of 40.22 fmole with a standard deviation of 42.02 and a range from −24.11 to 138.84 was found for the ER− carcinomas. This is significantly different from the group of ER± tumors (confidence limit >99.9%) which showed a mean binding of 149.87± 58.79/g tissue. The lowest result in this group (DA-1), however, would fit better into the ER− class, and the highest (MI-1) could also be in the ER+ tumors. Three individual results from the ER− class (WH-2, WH-1, SC-1) could also belong to the ER± sample. The mean binding in the ER+ group was 666.55 ± 443.92 fmole/g tissue. While this is significantly different from the ER± class (confidence limit >98%), one individual result (SH-1) would also fit into the ER± class. These findings are summarized in Table 3. The correlation coefficient for the comparison of binding per g tissue with binding per mg total protein was 0.980 (confidence limit >99.9%) and the regression $y = -3.368 + 25.25$ x.

Table 3. Comparison of estradiol binding of 48 breast carcinoma cytosols calculated per mg *total protein (reference) and per* g *wet weight of tissue*

	ER+ $n=10$	ER± $n=6$	ER− $n=32$	Total $n=48$
Agreement	9	4	29	42
Underestimation	1	1	0	2
Overestimation	0	1	3	4

Again, the designation of the tumors as ER+, ER± and ER− would have been identical in most instances (42/48) no matter if the estradiol binding was related to the weight of the tumor or to the total protein content of the tissue cytosol. In the few cases where the two methods differed, no trend towards over or underestimation was evident.

Part of the total protein concentration in the tissue cytosol is not due to tissue protein but represents a contamination by plasma proteins. The proportions will vary according to the vascularity of the tissue involved and, therefore, relating estradiol binding to total cytosol protein may result in an erroneous classification of the tumor. By estimating serum albumin in the cytosol and assuming 60% albumin in serum, the contribution of blood protein to the total cytosol protein can be assessed [12]. In the present series of tissue proteins in the cytosol made up an average of 59.5% of the total protein with a standard deviation of ± 14.1%. There was no statistically significant difference between the tissue protein in the ER+, ER± or ER− cytosols, nor was there any difference in the total proteins. In other words, the classification of the tumors into one of the 3 groups was not influenced by relating the estradiol binding to either total protein or tissue protein. Since the tissue protein is always less than the total protein, estradiol binding expressed per mg tissue protein (Column C, Table 1) will always be higher than the estradiol binding per mg total protein (Column A, Table 1). Estradiol binding per mg tissue protein in the ER+ group was 40.28 ± 27.43 fmole/mg tissue protein (mean ± standard deviation) and was higher than in the reference group but the difference was not statistically significant ($t = 1.273$, confidence limit 95%, 2.12). Similarly, the results related to tissue protein were higher than those related to total protein for both the ER± and ER− groups (10.84 ± 1.91 fmole/mg tissue protein, and 3.01 ± 3.06 fmole/mg tissue protein, respectively, $t = 4.657$, confidence limit >99% and $t = 2.485$, confidence limit >95%, respectively). These results are summarized in Table 4.

Table 4. Comparison of estradiol binding of 45 breast carcinoma cytosols calculated per mg *total protein (reference) and per* mg *tissue protein*

	ER+ $n=9$	ER± $n=5$	ER− $n=31$	Total $n=45$
Agreement	9	0	21	30
Underestimation	0	0	0	0
Overestimation	0	5	10	15

The correlation between estradiol binding per mg tissue protein and estradiol binding per mg total protein was highly significant (correlation coefficient 0.991, regression $y = 0.462 + 1.536$ x).

Once more, in the majority of cases (30/45) the classification would have been identical, whether the estradiol binding was related to tissue protein or total protein. In one third of the cases, however, the use of the tissue protein values as a reference for the estradiol binding results would have put the tumors into a group with a higher receptor content.

3. *Comparison of estradiol binding per* mg *DNA and per* mg *total protein*

The pellet obtained after high-speed centrifugation of the tissue homogenate was assayed for DNA, and the estradiol-binding results estimated in the supernatant were related to the DNA values by calculating the amount of DNA

per g tissue and then expressing the amount of estradiol bound per mg DNA. The results are given in Table 1, column E.

If the tumors are classified as ER ± or ER − on the basis of the estradiol binding results per mg protein (column A), the estradiol binding per mg DNA (column E) in the ER − group is 28.70 ± 34.59 fmole/mg DNA and that of the ER + group 239.48 ± 129.13 fmole/mg DNA. The small ER ± group is not statistically different from the ER − group (38.60 ± 24.09 fmole/mg DNA). In most cases the classification of the tumors would have been identical no matter whether estradiol binding was calculated per mg DNA or per mg protein. But close inspection of the results shows that some individual tumors would not be in the same group. Tumor WH-2 clearly belongs to the ER + group according to the estradiol binding per mg DNA, but is in the ER − group by its estradiol binding per mg protein. Tumors WI-1 and CR-2 that are ER − based on the reference method, would have been classified as ER ± by its estradiol binding per mg DNA; and tumors LE-2 and DA-1, both ER ± by the reference method would have been ER − when mg DNA was used as the basis for calculating the results. These differences and agreements are summarized in Table 5.

Table 5. *Comparison of estradiol binding of* 34 *breast carcinomas calculated per* mg *protein (reference) or per* mg *DNA*

	ER + $n=8$	ER ± $n=3$	ER − $n=23$	Total $n=34$
Agreement	8	1	20	29
Underestimation	0	2	0	2
Overestimation	0	0	3	3

The correlation between the results expressed per mg DNA and those expressed per mg total protein was highly significant (correlation coefficient 0.899, confidence limit > 99.9%, regression $y = 12.442 + 9.264\,x$.

4. *Comparison of tumor classification based on estradiol binding per* mg *protein or association constant of estradiol-receptor interaction*

It was suggested in an earlier paper [7] that the characterization of the estradiol-receptor interaction by saturation assay and Scatchard plot provides the best discrimination between hormone-dependent and hormone-independent breast carcinomas. This was based on evidence that the association constant—unlike estradiol binding per mg protein—was not influenced by partial saturation of the receptors due to endogenous estradiol, nor by partial loss of receptors due to freezing or storage. The Scatchard plot also provides a visual aid which makes the distinction between ER + and ER − tumors easier, since ER − tissues give a straight line with a very small slope or, depending on the scale, a straight line apparently parallel to the abscissa and ER + tissues a nonlinear curve (Fig. 1). Since detailed results of a comparison between association constant and binding per mg protein, based on a much smaller sample, were presented before [7], the individual results of the 177 tumors (which include the earlier results, results of the patients listed in Table 1 and additional tumors) have not been tabled, but are summarized only (Table 6).

Table 6. *Comparison of tumor classification in* 177 *patients, based on estradiol binding per* mg *protein (reference) and association constant of estradiol-receptor interaction*

	ER + $n=82$	ER − $n=95$	Total $n=177$
Agreement	78	89	167
Underestimation	4	0	4
Overestimation	0	6	6

As before, estradiol binding below 4 fmole/mg protein indicates ER −, between 4 and 8 fmole/mg ER ± and above 8 fmole/mg ER +. Based on the Scatchard plot a tumor is ER + if there is evidence for saturable binding sites (nonlinear curve) and ER − if saturation cannot be demonstrated (line parallel to abscissa) [7]. In most cases both methods result in an identical classification of the tumor and over and underestimation occur with about the same frequency. Since a borderline classification has not been defined for the association constants, 25 ER ± results from the estradiol binding per mg protein have not been included in Table 6. Of these results, 6 would have been receptor negative and 19 receptor positive by the Scatchard plot method.

DISCUSSION

It is reassuring to know that the distinction between estrogen receptor positive and estrogen receptor negative human breast carcinomas based on the binding of estradiol is identical in the large majority of cases (about 85%) even when the tissue parameters to which the results are related, are as diverse as tissue wet weight, total or tissue protein content of the cytosol,

DNA content of the tissue, and even though different procedures like antiestrogen inhibition or estradiol saturation are used to obtain the results.

In relatively few cases the results differed sufficiently from one another to change the tumor classification in comparison to the estradiol binding per mg total protein, which was arbitrarily used as a reference method. It is not known at present which results most accurately describe the receptor status of the tumor and most reliably predict the patient's response to endocrine therapy in those cases in which the same estradiol binding by one particular tumor, related to different tissue properties (weight, protein, DNA etc.), put the tumor into different categories (ER+, ER± and ER−). The results of the present study indicate that at least in some comparisons the trends are obvious. Estradiol binding given per mg tissue protein would "overestimate" receptors in comparison with results expressed per mg total protein (Table 4) and antiestrogen inhibition tends to comparatively "underestimate" receptors (Table 2). To obtain comparable results the binding limits for the groups (> 8 fmole/mg total protein for ER+, 4–8 for ER±, < 4 for ER− in the reference method) could be redefined for the two other methods just mentioned. In the remaining comparisons (Tables 3, 5 and 6) where results led to both higher and lower classifications compared with the standard method such adjustments cannot be made and the reasons for the differences are obscure.

Abstract—*The authors report the clinical observation of a patient with radiological features of an IgA with light chains type lambda osteosclerotic myeloma, associated with progressive sensorimotor polyneuropathy. Attention is drawn to these rare sclerotic forms of myeloma and the high frequency of associated neuropathies.*

In this case, marked hypercalcitoninemia was discovered with no other abnormality of the phosphocalcic balance. The authors advance the hypothesis of an ectopic secretion of calcitonin by tumoral plasma cells and discuss the potential role of this hormone in the pathogenesis of myeloma osteosclerosis.

In addition, the fixation of the M-Component on the peripheral nerve trunks is demonstrated by means of immunofluorescence techniques, thus directly supporting the immunological conception of dysglobulinemic neuropathies.

INTRODUCTION

MALIGNANT plasmocyte proliferations most often induce osteolytic and/or osteoporotic radiological lesions and, far less frequently, sclerotic bone lesions [1, 2].

The secretion of an osteoclast inhibiting factor or of an osteoblast stimulating factor has been advanced to explain this osteocondensation [3].

Chronic sensorimotor polyneuropathies are frequently associated with these rare sclerotic myelomas [4]. The pathogenesis of these dysglobulinemic polyneuropathies is not clearly known. Recent observations suggest that nerve alterations may be due to immunological mechanisms [5, 6].

MATERIAL AND METHODS

Case report

Mr. Leonard C . . . was born in 1915. He suffered from chronic phlebopathy of the lower limbs and labile hypertension. Since 1967, he has been complaining of paroxysmal positional vertigo, transient visual disorders, and of intermittent weakness, either of the left leg, or on the right side of the body.

An X-ray picture of the cervical spine showed metastatic-like homogeneous osteocondensations, located in the vertebral body of C3, in the left pedicle and in the posterior apophysis of C7 (Fig. 1a and b). An additional osteosclerotic lesion was discovered in the left postero-lateral portion of the vertebral body of D9.

On examination, a few hard, mobile, painless adenopathies were felt in the right supraclavicular fossa. Cardiopulmonary condition was in the normal range. There was no hepatomegaly nor splenomegaly.

Neurological examination

Moderate weakness was noticed in the distal muscle groups of the lower extremities. The muscle strength reflexes were normal in the upper limbs but the rotular reflexes were sluggish and the Achilleus reflexes were absent. There was no Babinski sign. Sensory examination revealed decreased vibratory sense in the distal portions of both the upper and the lower extremities. There was sock-like hypo-algesia in the lower limbs.

RESULTS

General investigations

The blood cells count was normal. Erythrocyte sedimentation rate was 20 mm/1st hr. Fibrinogen was 4.5 g/l and blood proteins were 67 g/100 ml. Electrophoresis showed 60.4%of albumin, 2.8% of alpha 1-globulins, 19.2% of gamma-globulins. Serum electrolytes and a fasting blood sugar level were normal. Renal and hepatic tests were normal. Serological tests for syphilis were negative. Serum alkaline

Accepted 5 July 1977.

and acid phosphates, hydroxyprolinuria were in the normal range. Glucose tolerance test was normal.

Phosphocalcic values were in the normal range except for calcitonin (CT) which was highly increased to 3000 pg/ml. (In normal subjects, the basal levels of CT are between 0 and 600 pg/ml of serum with a mean of 180 pg ± 150 [7].)

Biopsy of the enlarged lymph nodes showed pseudonodular massive plasmocyte infiltration of the medullary cords, with peripheral compression of the lymphatic follicles (Fig. 2).

These histological findings suggested the diagnosis of an osteosclerotic form of Kahler's disease, which was confirmed by the following techniques.

Serum IgA was twice higher than the normal value: 800 mg%. The IgG and IgM were normal. Immunoelectrophoresis showed a pathological monoclonal immunoglobulin (M-Component), identified as an IgA with light chains type lambda. Urine examination for proteinuria was negative. Conventional tests for Bence–Jones proteins in concentrated urine (× 100) were negative.

Light microscope examination of the bone marrow showed a medullary plasmocytosis at 7%, with many abnormal cells. Bone biopsy of C7 posterior apophysis confirmed the lesion and showed marked thickening of the spongy bone structures, with reduced medullary spaces containing a large population of plasmocytes and plasmoblasts, often bi-nucleate as already seen in the lymph nodes (Fig. 3).

Neurological investigations

The cerebrospinal fluid (CSF) was normal, except for a total protein count of 55 mg/100 ml. Electrophoresis of CSF proteins was normal. Immunoelectrophoresis was not obtained.

Electrodiagnostic studies showed marked alterations of motor nerve conduction velocity with no motor responses in both anterior tibial nerve trunks. In most distal muscles, electromyography showed fibrillation potentials at rest and decreased interference pattern on voluntary contraction.

Biopsies of cutaneous branches of the sural nerve, were examined by light-, electron- and immunofluorescent microscopy. No morphological modification was observed by light microscopy. On transverse semi-thin sections, the nerves were almost normal (Fig. 4). However, moderate demyelinisation was already evident on some trunks (Fig. 5). Focalized alterations of myelin sheaths were confirmed by electron-microscopic examination (Fig. 6). The morphological modifications were slight in the nerve and very partial in each nerve trunk. The amyelinic nerves seemed normal and the Schwann cells were not modified. The conjunctive structure of the nerve was morphologically intact and no fibrillar material suggesting amyloid could be found. There was no inflammatory infiltrate. The wall of some small arteries however, was thickened by an "onion bulb" proliferation of basal membranes which included cytoplasmic ramifications of endothelial cells (Fig. 7).

Fresh longitudinally cut fragments of the same nerve trunk were studied with the usual two-layer immunofluorescent technique. Fluorescein-conjugated anti IgG and anti IgM antiserums stained the preparations in a non-specific way and only a diffuse basal fluorescence was observed. In contrast, application of the fluorescein-conjugated anti IgA antiserum revealed intense staining of the perineurium and of the central portion of the nerve (Fig. 8). No specific labelling was obtained with any of the antiserums when tested on fragments of peripheral nerve trunks of three controls with osteolytic myelomas (two IgG myelomas, one IgA myeloma), but without clinical or electrical signs of polyneuropathy.

Therapy and follow-up

The patient was treated with a daily dose of cyclophosphamide (100 mg per os) and high doses of vitamin B complex. This therapy was continued from May 1974 to June 1976 with gradual and marked improvement of the sensori-motor polyneuropathy. In May 1975, after one year of therapy, the motor nerve conduction velocities became subnormal and, a motor response was again elicited in the anterior tibial nerves. The radiological control showed no variations in size and aspect of the previous lesions, nor the development of any other ones. Although the patient experienced a clear improvement in his clinical state, chemotherapy did not appear to modify the serum levels either of CT or of immunoglobulins [Table 1] while repeated immunoelectrophoresis of serum proteins showed the abnormal IgA spike throughout the clinical course.

DISCUSSION

This unusual observation raises many questions but we shall discuss the two major ones only: the osteosclerotic myeloma and the myelomatous polyneuropathies.

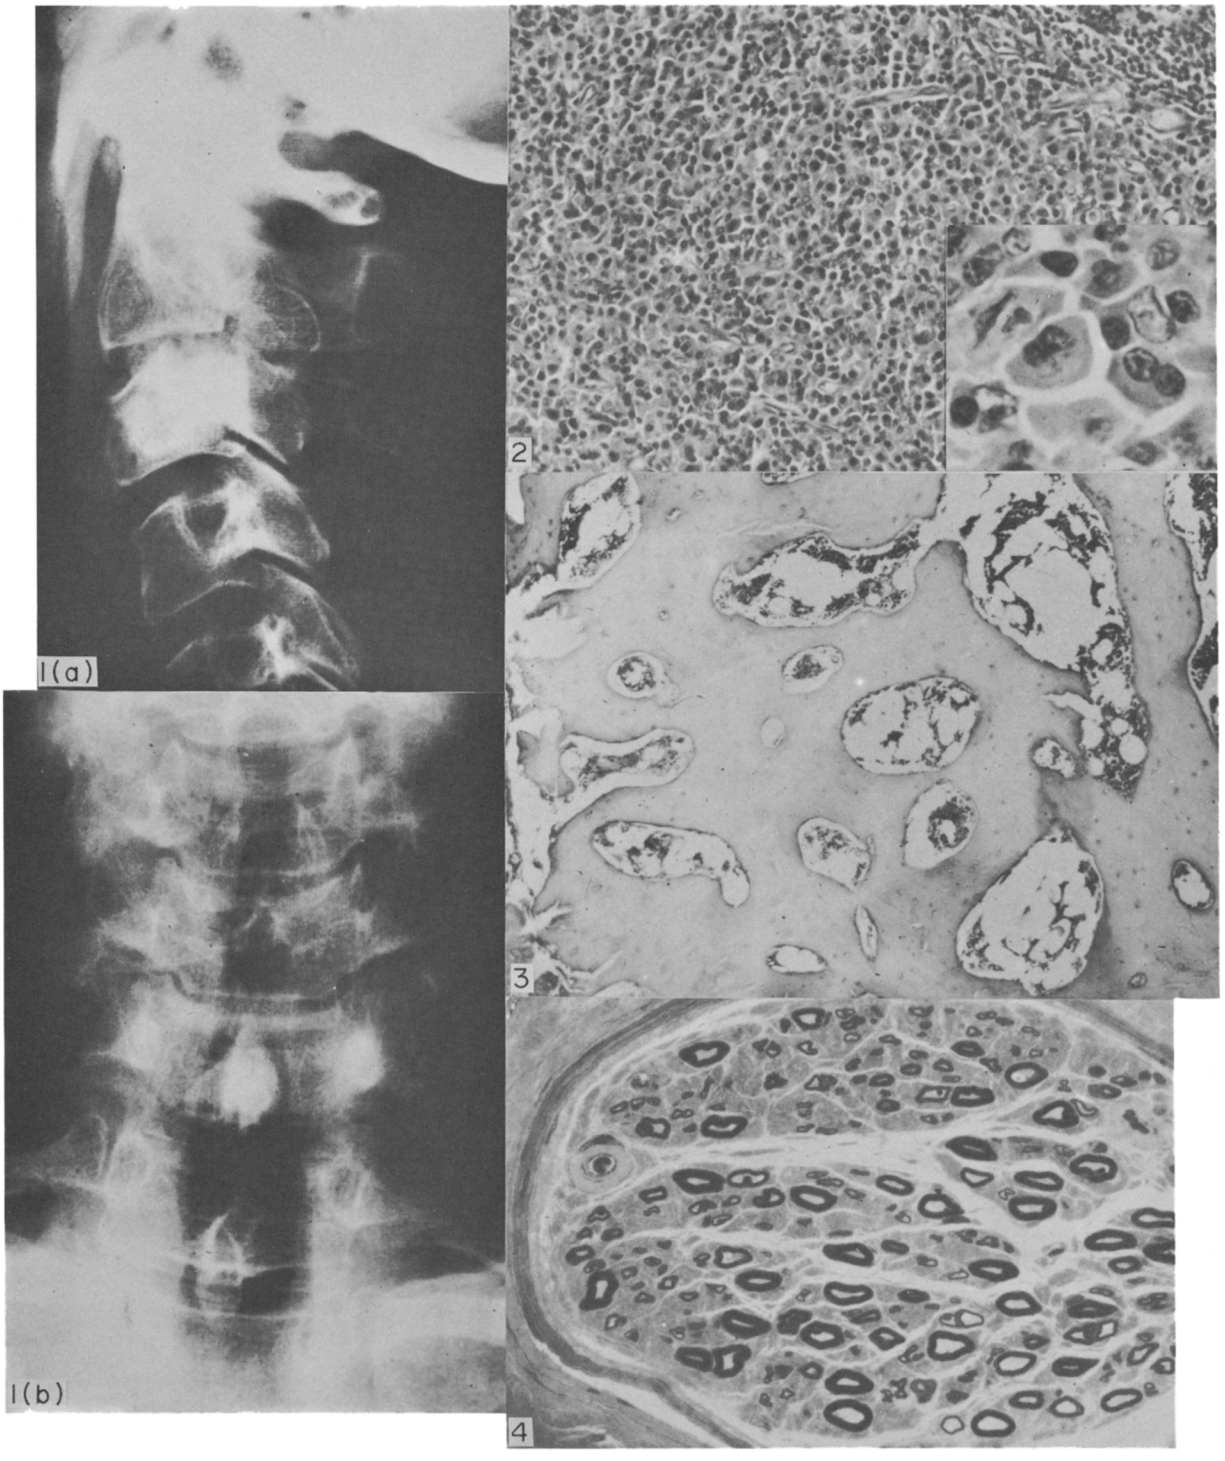

Fig. 1. *Radiograph of cervical spine revealing homogeneous osteocondensations at the level of: (a) C3 vertebral body, (b) C7 posterior apophysis and left pedicle.*

I. Osteosclerotic myeloma

(A) *Radiological and clinical aspects.* These osteosclerotic forms of myeloma are very infrequent. Only 50 cases have been reported in the literature (for a general review, see [8–11]). Their radiological features have been reviewed in 37 observations by Bismuth *et al.* [3]. Four main lesions are noted. The most frequent are pictures of diffuse osteosclerosis (37%) and of focal osteocondensation which give a "mottled" aspect of the bone (30%). Less often, there are bony spiculations on the surface of the bone (20%) and lytic images surrounded by a ring of osteosclerosis (13%). Occasionally, these various lesions may be observed in the same patient and be associated with lytic lesions. Osteosclerotic lesions mainly involve the axial skeleton and unlike osteolytic lesions, tend to spare the skull.

The pathology of osteosclerosis is linked to thickening of spongious bone structures surrounding the foci of plasmocyte tumoral proliferation [3, 4, 8, 12–14].

(B) *Pathogenesis of the bone sclerosis.* The mechanism of bone sclerosis in myeloma is not clear. It has been suggested that the osteocondensation might be induced either by inhibition of osteoclastic resorption, or by osteoblastic hyperactivity in the tumoral foci [15] and might occur indirectly through the action of a hormonal or pseudo-hormonal (?) substance secreted by tumoral cells [3]. The very high levels of CT found in this case suggest that CT might be this hormonal substance.

Although, to our knowledge, such a hypercalcitoninemia has not yet been described in osteosclerotic myelomas, it is tempting to advance that CT could be the inductive factor of osteosclerosis in some cases of myelomas. In fact, some authors have demonstrated that CT inhibits bone resorption by reducing osteolysis [16, 17] and that CT is produced in large amounts by tumoral cells in thyroid medullary carcinomas, a condition in which bone metastases are frequently osteosclerotic [18]. An ectopic secretion by tumoral cells, a phenomenon already described in other neoplastic affections [19, 20] seems to be the most likely hypothesis to account for high levels of CT. To support this assumption, we are now measuring levels of CT in extracts of various tissues, particularly of lymph nodes invaded by tumoral plasmocytes (Fig. 2). Our preliminary results which will be published elsewhere, seem to support this mechanism.

Thus, this production of an "osteogenic" factor by the tumoral plasmocyte could be the very reverse of the mechanism involved in the bone resorption of osteolytic myelomas, where secretion of an osteoclast stimulating factor has been proved by Mundy *et al.* [21].

II. *Myelomatous polyneuropathies*

(A) *Frequency.* The incidence of chronic polyneuropathy varies in relation to the radiological picture of the myeloma. In the classical osteolytic or osteoporotic forms, polyneuropathies are observed in 2.7% [22] to 3.2% [23] of the cases. But, in a survey of 36 osteosclerotic myelomas, Mangalik *et al.* [9] found these complications in 40% of the cases. The frequency of polyneuropathy is evaluated at 20% in the course of single plasmocytomas [24].

No common factor has been noted to account for this increased incidence of neuropathy in sclerotic forms of myeloma. Compression of numerous nerve roots by sclerotic bone is doubtful because deformation of involved bones has not been observed, even in generalized sclerotic forms [3].

(B) *Clinical aspects.* According to Davis *et al.*

[24], manifestations of sensorimotor polyneuropathies can precede the diagnosis of myelomatosis in 76% of the cases. The lapse of time between the onset of neurological symptoms and confirmation of the diagnosis varies from 2 to 24 months, the average being 9 months. The mean age of patients suffering premonitory polyneuropathic signs of myeloma is 52 yr.

The progression of this type of polyneuropathy is often slow, death occurring, on an average, after 2 yr [4]. As in our case, therapy may bring some improvement and even remission of neurological disturbances [24].

So far, no correlation has been established between the intensity of the neuropathy and the evolution of the myeloma.

(C) *Histological aspect.* According to Henson and Urich [25] histological modifications are similar to those observed in neoplastic sensorimotor polyneuropathies. As far as we know, only one ultrastructural study of myelomatous polyneuropathies has been published [26]. Recent electron microscope studies of dysglobulinemia neuropathies concern mainly Waldenström's macroglobulinemia [6, 27–29]. In these cases, authors report that morphological modifications were compatible with remyelinating processes and that axon alterations are slight. Vital *et al.* [29] also stress that pathological lesions are closely related and proportional to clinical manifestations.

Morphological alterations in our observation, although not severe, are more consistent with the pattern of a primary demyelinating disease than with an axonal degeneration. Alterations of the walls of small arteries that we described in the nerve do not appear to have been mentioned previously. Their pathological significance is still unknown.

(D) *Electrophysiological studies.* The few electrophysiological studies in this field have all clearly demonstrated a drastic decrease of velocity in sensitive and motor nerve conduction. However, this reduction of electrical conduction has also been observed by Walsh [26] in 25% of myelomas, with no clinical evidence of neuropathy. These results tend to suggest the existence of incipient forms of dysglobulinemic neuropathies.

(E) *Pathogenesis.* Among numerous theories proposed, the most favoured pathogenic concept is now related to immunological mechanisms. The initial hypotheses originated from research by Waldenström *et al.* [30] and Zettervall *et al.* [31], who have shown that the pathological immunoglobulin (M-component) secreted by tumoral plasmocytes, has both the structure and the function of a normal antibody. Morley *et al.* [4], Bigner *et al.* [27] and Davis *et al.* [24], suggested that myelomatous cells could occasionally produce a circulating substance acting as an "antibody" against some components of the peripheral nervous system, thus inducing progressive neuropathy. Other arguments supporting immunological mechanisms are based on similarities between clinical and histological aspects of dysglobulinemic polyneuropathies and those of paraneoplastic polyneuropathies, the pathogenesis of the latter being now explained by immunological factors [32–34]. Immunofluorescence technics now yield strong arguments for this immunological theory. Our preliminary results [35] confirmed and completed by Chazot *et al.* [5], then by Propp *et al.* [6], enable us to make further comments.

(1) *Fixation site of the M-Component.* On longitudinal sections, we observe a strong fixation on the nerve sheaths, a localization already indicated by Chazot *et al.* [5], and a dense linear fluorescence in the central portion of the nerve fibres. According to Luyten *et al.* [36], such a fluorescence linear "pattern" suggests that the "antigen-antibody" interreaction occurs in the proximity of the myelin sheath. Looking at transverse sections, Chazot *et al.* [5] suggested a deposit in contact with the myelin sheaths, while Iwashita *et al.* [28] considered that deposits were between the nerve fibres. Propp *et al.* [6] even wrote that the M-Component seems directly linked to the myelin membrane. According to these assertions, the M-Component might attach itself partially on the nerve sheath, but mainly on the myelin sheaths.

(2) *Fixation mechanisms of the M-Component.* This mechanism of fixation on the peripheral nerve trunks is not clear. By proving that the M-Component of a neuropathic patient could be attached to the nerve trunk of a healthy individual, Chazot *et al.* [5] suggested that the M-Component has a specific affinity for the peripheral nerve and eventually for the myelin sheaths. However, Propp *et al.* [6] have indicated that the fixation of the M-Component on the nerve fibres is an unspecific physico-chemical reaction with no proven immunological mechanisms.

(3) *Lesion mechanisms of the M-Component.* Among the main theories, the most interesting is that of an interrelation of immunoglobulins with membrane phospholipids [37]. Fixation of the M-Component to some structures of the myelin sheath would increase myelin permeability, with

swelling then its destruction. The cytotoxic role of the activated complement system should also be considered because the third component of complement (C'3) has been found to be attached on the nerve trunks [5].

A last but tempting hypothesis is based on recent advances on amyloidosis. Glenner *et al.* [38] have well established that amyloid substance results from an insoluble and fibrillar organization of some polypeptides which, in many cases, could be immunoglobulin fragments.

According to this theory, it may be considered that M-Component deposits, observed on nerve trunks by immunofluorescent techniques represent a kind of "precursors", for the amyloid substance. The fact that these "precursors" can play a pathogenic role and induce lesions of nerve fibres, is perfectly supported by recent publications on Portuguese amyloid neuropathies. Coimbra *et al.* [39], Jorge Carvalho *et al.* [40], have demonstrated that alterations of both Schwann's cells and myelin sheaths precede the onset of amyloid deposits, these deposits subsequently aggravating the previous lesions either directly through mechanical compression or indirectly through ischemia. Immunofluorescent studies on two cases of familial amyloid neuropathies showed that amyloid substance contained an IgG with light chains type kappa [41]. Whether the immunoglobulin was a "precursor" of amyloid, or was subsequently attached on the amyloid is still to be elucidated.

To reach a unified concept between recent immunological data and results of former observations, one may advance that fixation of the M-Component in the nerve trunks is an intermediary stage or a form of transition towards the final phase of the evolution amyloidosis neuropathy.

Importance of Schedule in Adriamycin/Cyclophosphamide Combination Chemotherapy*

D. W. YESAIR,† S. McNITT,† J. TOBIAS‡§ and I. WODINSKY†

†*Arthur D. Little, Inc., Cambridge, Massachusetts* 02140, *U.S.A.*

Abstract—*Use of the chemosensitive tumor* P388 *lymphocytic leukemia has facilitated the demonstration of small but perhaps important schedule-dependent therapeutic effects with adriamycin (ADR) and cyclophosphamide (CY) combination therapy. Administration of ADR at least* 3 days *pror to the administration of CY resulted in inhibition of DNA synthesis to a greater extent in tumor than in bone marrow. This preferential inhibition of thymidine incorporation into nucleic acid of tumor cells is in accord with the enhanced chemotherapeutic response observed when the agents were given in this sequence (ADR* day 5 *and CY on* day 8, 9 or 10). *This effect on response was more marked with lower doses of the drugs, which could be of clinical significance since the total dose of ADR is so restrictive.*

INTRODUCTION

IMPRESSIVE results have been obtained with the use of adriamycin (ADR) and cyclophosphamide (CY) combination chemotherapy in a number of human tumours [1–3]. In particular, the activity of this combination against carcinomas of the breast and ovary appears to be greater than expected from the single agent data available for each of these agents used alone, with responses in these malignancies at least as good as for any other drug combinations in current use [4, 5]. Previous work has demonstrated not only a definite therapeutic synergism between ADR and CY for a large number of transplantable animal tumors [6] but also a dramatic inhibition of DNA synthesis which greatly exceeded the inhibition of tumor-cell DNA synthesis caused by each agent when used alone [7]. Against the advanced murine L1210 leukemia, the activity of this combination was particularly surprising because of the relative ineffectiveness of one of the agents (ADR).

Since cumulative cardiotoxicity frequently limits continued use of ADR, often necessitating discontinuation of treatment in responsive patients, the optimal use of this valuable agent is particularly important. The present studies were designed to investigate dose and scheduling in ADR/CY combinations with a view to determining whether manipulation of either variable could improve therapeutic effect without necessarily increasing ADR dosage. Preliminary results of these studies have been reported [8].

MATERIAL AND METHODS

Adriamycin (NSC 123127) was supplied by Farmitalia, Milan, Italy and cyclophosphamide (NSC 26271) was the clinical dose form, Cytoxan®, obtained from Mead Johnson Laboratories, Evansville, Indiana. The thymidine (methyl-^{3}H) was purchased from New England Nuclear, Boston, Massachusetts and was diluted with cold thymidine (1 mg/ml) from Sigma Chemical Company, St. Louis, Missouri, yielding a specific activity of 0.45 Ci/mmole. All compounds were prepared in physiological saline and administered in a vol of 0.5 ml.

Accepted 12 September 1977.
*Supported by Contracts N01-CM-33727, N01-CM-53849 and N01-CM-53765 from the Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Department of Health, Education and Welfare. Dr. Tobias was supported by the Cancer Research Campaign (UK) and was Berkeley Travelling Fellow, Gonville and Caius College, University of Cambridge.
§Present address: Royal Marsden Hospital, Sutton, Surrey, England.

P388 lymphocytic leukemia was serially transplanted by intraperitoneal inoculation of 10^6 ascites tumor cells into CDF_1 mice weighing 20–25 g.

In the experimental therapeutic studies, groups of 10 tumor-bearing mice were treated on day 5 with CY, followed sequentially by ADR on day 5, 6, 7, 8, 9 or 10 and conversely on day 5 with ADR followed sequentially by CY on day 5, 6, 7, 8, 9 or 10. In additon, both drugs were administered as a single agent on day 5, 6, 7, 8, 9 or 10. All agents were administered by the intraperitoneal route.

A thymidine labelling technique was used to evaluate the inhibition of DNA synthesis of tumor and bone marrow cells following drug treatment. Mice received 25 μCi of tritiated thymidine by intraperitoneal injection 15 min prior to death by cervical dislocation. In pilot studies, it was demonstrated that thymidine incorporation into DNA of tumor cells and tissues was linear between 5 and 30 min. Tumor cells and femurs were pooled in groups of 3 mice and 2–3 groups were analyzed at each time period. Tumor cells in ascitic fluid were concentrated by centrifugation (1000 × ***g***), resuspended twice in saline and counted using a Model B Coulter counter. Femurs, initially frozen in liquid nitrogen at time of death, were thawed and bone marrow was obtained by gentle aspiration in ice-cold physiological saline as previously described [7]. Nucleic acid from tumor cells and from bone marrow was precipitated by 10 vol of cold 5% trichloroacetic acid (TCA) and extracted into 2 vol of hot (90°C) 5% TCA. The extracted nucleic acid was analyzed for radioactivity in a Nuclear-Chicago Mark I scintillation counter by means of external standard channel-ratio correction and quantitated spectrophotometrically at 260 nm in a Zeiss Model PMQ II spectrophotometer. Results were expressed as disintegrations per min per optical density unit of DNA.

RESULTS

DNA synthesis in untreated tumor-bearing animals

A fall in DNA synthesis was seen in the liver, heart and bone marrow of all tumor-bearing animals over the 5- to 10-day period following i.p. implantation of 10^6 P388 cells (Fig. 1). DNA synthesis also declined in P388 cells recovered from ascitic fluid. Although absolute DNA synthesis in ascitic P388 cells was 10 times greater than that of any host tissue (in dis/min per optical density unit at 260 nm of nucleic acid), DNA synthesis fell

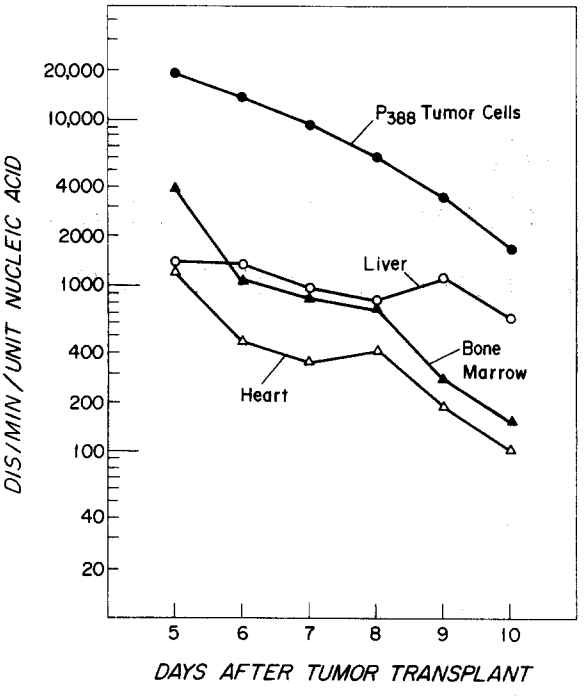

Fig. 1. Nucleic acid turnover in tissues from saline-treated, tumor-bearing mice. Tumor-bearing mice were administered 25 μCi *of tritiated thymidine* 15 min *prior to death. The DNA from tissues and P388 cells was extracted, quantitated and analyzed for radioactivity.*

equally for all tissues and P388 cells at approximately 1 log over days 5–10 (median day of death of untreated tumor-bearing animals was day 11).

Survival of tumor-bearing animals treated with ADR/CY combination

Treatment of P388 leukemia with ADR or CY in combination resulted in an increased life span (ILS) greater than that expected from the summation of each drug given individually in all treatment groups (Fig. 2). Maximal ILS with single-agent treatment was 50% for ADR (8 mg/kg given once on day 5 after tumor inoculation) and 120–140% for CY (200 mg/kg given once on day 5, 6 or 8). With combination treatment, several interesting trends were apparent. The administration of a high dose of cyclophosphamide with adriamycin resulted in maximum ILS of over 300% and in a significant number of long-term survivors (>60 days) when administered on day 5. This advantage was decreased progressively when adriamycin was withheld until day 6, 7 or 8. The administration of adriamycin followed by cyclophosphamide showed somewhat less increase in ILS as well as in long-term survivors on day 5 and decreased thereafter until day 8. The administration of adriamycin first followed by cyclophosphamide on day 8, 9 or 10 resulted in a rebound in both ILS %

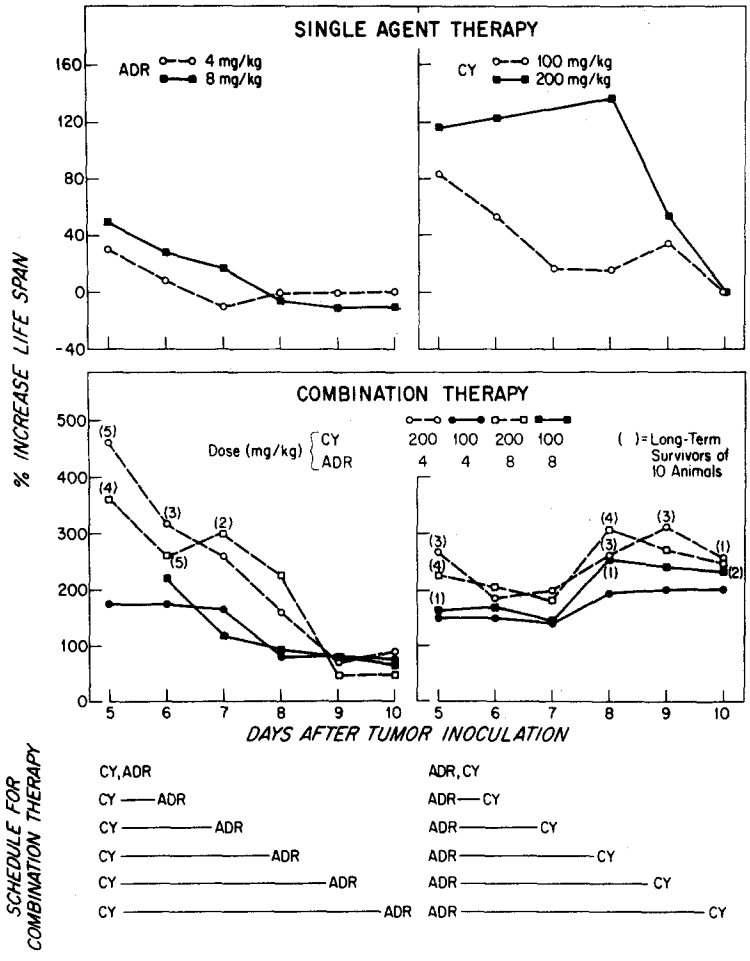

Fig. 2. Effectiveness of sequential therapy schedules with ADR and CY against P388 leukemia as opposed to each agent given singly. 10^6 *P388 cells were inoculated i.p. on* day 0 *and drugs were administered i.p. on* day 5 *through* 10 *according to schedule for combination therapy, or as a single dose for adriamycin or cyclophosphamide on* day 5, 6, 7, 8, 9 *or* 10. *Numbers in parentheses indicate number of long-term survivors* (>60 days) *out of* 10 *animals.*

and long-term survivors, which greatly contrasts with the results of administering cyclophosphamide first followed by adriamycin on day 8, 9 or 10.

The single agent therapy data indicated that cyclophosphamide was a better chemotherapeutic drug than adriamycin. This finding also appears to be true in combination therapy. Cyclophosphamide administered first, followed by adriamycin, showed maximum ILS % on day 5 but showed a progressive decrease thereafter. When adriamycin was administered first followed by cyclophosphamide, there was a marked effect of cyclophosphamide, especially on days 8 through 10. In the subsequent studies, we have tried to evaluate the relationship among schedules of administering the two agents, tumor burden and inhibition of DNA in both tumor cells and bone marrow.

Tumor cell burden following treatment with ADR/CY

Total ascitic cell counts fell rapidly after treatment with ADR or CY (Fig. 3). Sham injection with saline did not affect the exponential proliferation of i.p. implanted P388 cells (Fig. 3A), which increased by almost 1 log over days 5 through 10; CY at 250 mg/kg had a greater cytotoxic effect than ADR at 10 mg/kg when given as a single agent on day 5 after tumor implantation (2 log vs 1.5 log, respectively, Fig. 3B), but both agents were relatively less effective when given singly on day 8 (*ca.* 1 log, Fig. 3C). When ADR and CY were given in combination, they were not more cytotoxic than CY when given alone on day 5 (Fig. 3D). Similarly, when ADR and CY were given with a 3-day separation (irrespective of which was given first), they were at least as cytotoxic as when both agents were given on day 5, despite delaying one of the agents for an additional 3 days (Fig. 3D). Thus, the tumor burden did not appear to be decreased as a result of administering the two agents in combination.

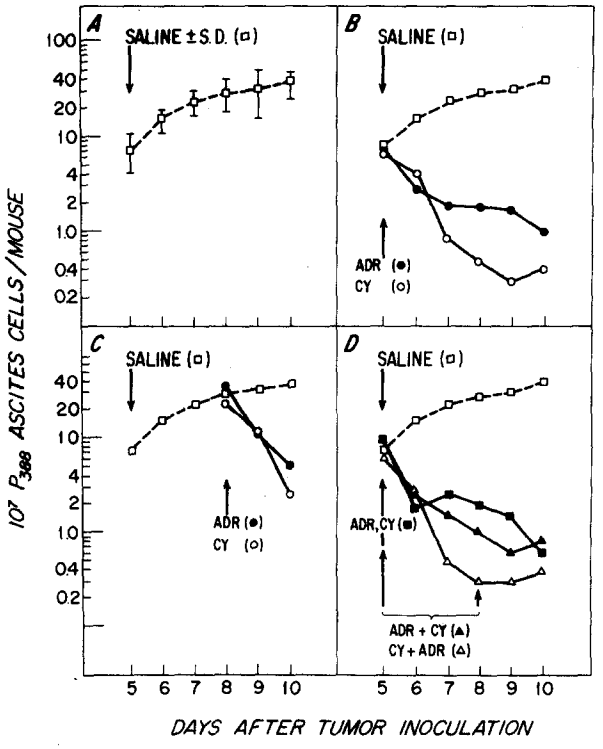

Fig. 3. Effect of ADR and CY on P388 cells growth. 10^6 *P388 cells were inoculated i.p. on* day 0 *and drugs (ADR,* 10 mg/kg; *CY,* 250 mg/kg) *or saline were administered i.p. according to the schedule shown in the figure.*

Inhibition of DNA synthesis in tumor cells and bone marrow

Both ADR and CY inhibited DNA synthesis in P388 tumor cells (Fig. 4A); extent and duration of this inhibition were greater for CY than for ADR and recovery from the CY-induced inhibition began later than recovery after ADR. Simultaneous administration (day 5) of ADR and CY did not inhibit DNA synthesis more effectively than CY alone (Fig. 4B). ADR given on day 8 (after CY on day 5) did not result in further effective inhibition of DNA synthesis (Fig. 4C); at 10 days, tumor cell DNA synthesis was 430% of control. However, when ADR was given *before* CY (Fig. 4D), the ADR-induced inhibition of DNA synthesis (day 5) was followed by an equally pronounced CY-induced inhibition (day 8). Subsequently, at day 10, tumor cell DNA synthesis had just recovered to 100% of control with no overshoot.

The effect of ADR and CY on DNA synthesis in bone marrow (Fig. 5) differed from that for P388 cells in the same animal (Fig. 4). Briefly, the depth and duration of this inhibition and the recovery time for both drugs were comparable (Fig. 5A). In comparing bone marrow with tumor cells, there is a marked difference in the duration of the inhibition as well as the magnitude of the overshoot depending upon whether the drug was used singly (Figs. 5A and 4A) or in combination on day 5 (Figs. 5B and 4B). When CY was administered on day 5 and ADR on day 8. ADR had little effect on the overshoot in the incorporation of ^{3}H-thymidine into DNA of bone marrow (Fig. 5C) being similar to that for P388 cells (Fig. 4C). The magnitude of the inhibition of DNA synthesis of bone marrow, compared to tumor cells, was most striking when ADR was given on day 5 and CY on day 8 (Figs. 5D and 4D). The inhibition of ADR-induced overshoot by CY in bone marrow did not decrease the ^{3}H-thymidine incorporation to less than 400% of control, whereas in P388 tumor cells the inhibition was decreased to about 20% of control. Further, the recovery of DNA synthesis in bone marrow was greater than 1000% of control on day 10, whereas in P388 cells, the recovery was equivalent to control with no overshoot at the same time period.

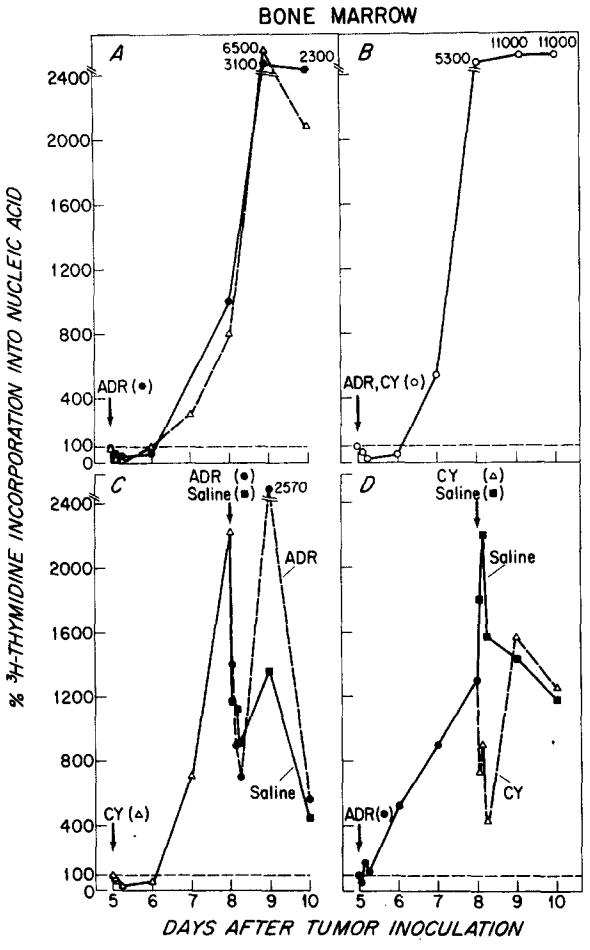

Fig. 5. Effect of ADR and CY on the percent incorporation of ^{3}H-thymidine into nucleic acid of bone marrow of P388 tumor-bearing mice. The 100% incorporation represents the nucleic acid turnover in bone marrow as seen in Fig. 1.

DISCUSSION

Encouraging preliminary results in the treatment of carcinoma of the breast (4), ovary (5) and uterine endometrium (3) with ADR/CY combination chemotherapy have been paralleled by the demonstration of therapeutic synergism in animal tumor systems. However, the optimal dose, timing and schedule of administration of this combination are not known. In L1210 leukemia, a steep dose–response curve was obtained for both agents in combination (7). Separation of the agents for periods up to 24 hr did not appear to exert a clear therapeutic advantage. In the present studies, use of a more chemosensitive tumor has facilitated the demonstration of small but perhaps important therapeutic differences with schedule alterations.

The most striking schedule-dependent effect appears to be the superiority of ADR→CY combinations over CY→ADR combinations. Even when sequential treatment with CY was delayed to day 10 (advanced disease, one day before death), long-term survivors were occasionally seen (Fig. 2). By contrast, treatment with CY on day 5 and delay of ADR until day 9 or 10 gave results no better than CY treatment only on day 5. Since ADR is a less effective agent than CY in P388 leukemia, this observation was particularly unexpected. The ability of CY to produce a real inhibition of tumor cell DNA synthesis on day 8 after ADR (given on day 5) further reflects the enhanced effectiveness of this sequence, since ADR given on day 8 (after CY on day 5) failed to inhibit further DNA synthesis in tumor cells. The observations of transient, reversible inhibition of bone marrow DNA synthesis are in accord with the known myelosuppressive effects of this combination in man.

The explanation for these observations is unclear. It has previously been postulated that the alkylating activity of CY may be enhanced by ADR due to increased receptivity of the ADR-damaged DNA molecule [7]. Intercalation of ADR into DNA appears to be an important mechanism of its action and it is possible that CY effectiveness is most pronounced when partial recovery from the DNA-intercalation action of ADR is taking place. Increased sensitivity to the effect of an alkylating agent might reasonably be expected during this period. It has been shown that ADR inhibits the hepatic mono-oxygenase system [9]. CY depends on hepatic enzymes for activation [10]. Phenobarbital, which increases the mono-oxygenase system, stimulates leukopenia rather than chemotherapy by CY, whereas SKF-525A, which inhibits the mono-oxygenase system, decreases leukopenia and enhances chemotherapy by CY [11]. ADR may act similarly to SKF-525A. The possibility of increased circulating levels of activated CY or of ADR, when the drugs are given in combination rather than singly, has been investigated and does not appear to be a likely explanation [7]. Finally, the liver may normally represent a protected compartment from the action of CY. If ADR acts directly on hepatocytes, influx of activated CY may be more effective in the presence of ADR, thus allowing for greater clearing of tumor-cell infiltration in the liver, itself a possible cause of death in experimental leukemias.

The importance of proper scheduling has been increasingly stressed since the emergence of more effective combination chemotherapy for human leukemias and solid tumors [12]. The combinations of vinblastine and bleomycin [13] and methotrexate and L-asparaginase [14] are good examples of schedule-dependent pairs

of drugs. Proper scheduling with ADR and CY is of crucial importance for clinical cancer chemotherapy not only in order to ensure maximal antitumor effect but also to conserve ADR for each patient as long as possible; 550 mg/m^2 is at present the total recommended cumulative dose [15]. Observations regarding schedule-dependency may also shed light on the mechanism of action of these agents and, in particular, on their unusual degree of therapeutic synergism.

A Fetal Antigen in a Mouse Fibrosarcoma with Possible Cross-reactivity with an Adult Mouse Skin Component*

CHARLES TONG,† ELLIOTT H. STONEHILL,‡ PAUL J. HIGGINS and AARON BENDICH

Laboratory of Cell Biochemistry, Memorial Sloan-Kettering Cancer Center, New York, NY 10021, *U.S.A.*

Abstract—*A late gestation–neonatal phase antigen has been found in a mouse fibrosarcoma. The cross-reacting antigen of tumor, fetal and neonatal mice possessed gamma-mobility upon immunoelectrophoresis in* 2% *agar at* pH 8.6 *and was undetectable in extracts of normal adult internal organs. A related, unstable, constituent was detected in normal adult mouse skin.*

INTRODUCTION

ONE OF the characteristics of cancer tissue is its frequent association with embryonal antigens [1–6]. In a continuation of the study of such antigens in our laboratory [3], rabbit antisera prepared to aqueous extracts of a 3-methylcholanthrene-induced mouse fibrosarcoma were found, after appropriate absorption, to precipitate an antigen common to the tumor, late gestation stage mouse fetuses and neonatal mice. This report describes these findings.

MATERIAL AND METHODS

The mouse tumor cell line "QUA", cloned from a 3-methylcholanthrene-induced C57 BL/6 mouse fibrosarcoma, was kindly furnished by Dr. June L. Biedler of the Memorial Sloan-Kettering Cancer Center [7]. Tumors arising in several C57 BL/6 mice after inoculation of QUA cells were pooled and extracted with phosphate-buffered saline (PBS) as described by Stonehill and Bendich [8]. Another 3-methylcholanthrene-induced mouse fibrosarcoma, MeTu, in second passage, was kindly furnished by Dr. Ellen Borenfreund of this laboratory. The age of C57 BL/6 mouse fetuses was determined by mean crown–rump length [9]. Fetal and neonate trunk portions (body, less skin and limbs) and fetal organs were also extracted with PBS. Antisera were prepared in New Zealand white rabbits by 3 weekly subcutaneous inoculations of 5 mg of lyophilized PBS extracts of QUA tumor tissue using the immunization procedure of Stonehill and Bendich [8]. Pooled antisera were absorbed with normal adult mouse serum and with lyophilized PBS extracts of adult mouse internal organs until all precipitin activity to adult serum and adult internal tissue extracts was eliminated. Immunoelectrophoresis was carried out for 45 min at 25 mA/200 V in 2% agar using barbiturate buffer, pH 8.6, of 0.075 ionic strength (Beckman B-2 buffer, Beckman Instruments, Inc., Palo Alto, CA). For single radial immunodiffusion assay [10], 2.5 ml of 1% agarose (w/v) in Beckman B-2 buffer, pH 8.6, was mixed with 100 μl of rabbit pre-immunization serum and 100 μl of adult internal tissue-absorbed anti-QUA tumor serum and layered on a 1 × 3 in. microscope slide. Antigen wells, 3.75 mm dia, were cut and filled with 10 μl of antigen solution previously adjusted to a concentration of 2–4 mg protein/ml [11]. Slides were incubated at 4°C for 14 days, stained [12] and the diameters of the precipitin discs measured. The radial immunodiffusion unit employed is the square of the diameter (in mm) of the precipitin disc minus the square of the antigen well diameter per microgram of protein assayed.

RESULTS

When adult internal tissue-absorbed anti-

QUA tumor antiserum was assayed by Ouchterlony double-diffusion, a precipitin line of identity was obtained when tumor and embryo extracts were in adjacent wells, Fig. 1(a). This line bent slightly away from an adjoining well when adult skin extracts were examined in the same plate indicating the possible occurrence of cross-reacting determinant(s) in adult mouse skin. This finding is reminiscent of the presence of a fetal-related antigen in normal adult human skin cell cultures which was detected by

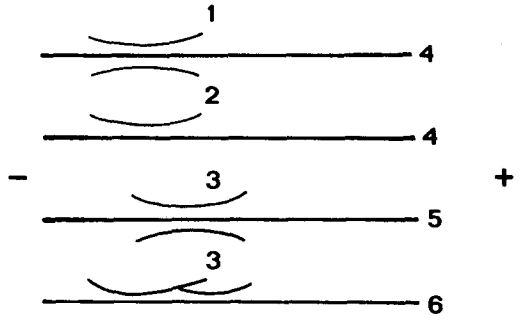

Fig. 2. Demonstration of a cross-reacting antigen in a mouse fibrosarcoma and mouse embryo employing agar immunoelectrophoresis; 25 mA/200V *for* 45 min, *barbitol buffer,* pH 8.6, *ionic strength* 0.075. immunofluoroscence techniques using serum from sarcoma-bearing patients [13]. Moreover, skin cells have been shown to afford immunoprotection against transplantation challenge with QUA [14], and cross-reactivity among mouse fetus, mouse tumor and adult mouse skin has been reported [3, 15]. These data suggest the presence of a fetal-type antigen in normal adult skin. The appearance of fetal antigen in fragments of normal skin after 9 days in culture [16] is consistent with this interpretation. A precipitin line of identity was produced when the following were tested with adult internal organ-absorbed anti-QUA tumor serum, Fig. 1(b): extracts of 15–19 day skinned fetuses or skinned postpartum mice, extracts of an independent 3-methylcholanthrene-induced fibrosarcoma, MeTu, pooled sera of QUA tumor-bearing mice, and sera of animals carrying the MeTu tumor. Adult serum and extracts of normal adult internal organs were negative, Fig. 1(a). Absorption of the anti-QUA tumor antiserum with lyophilized extracts of adult skin, 17-day skinned fetus, or QUA tumor completely removed precipitin activity to all three.

Immunoelectrophoresis disclosed a single precipitin arc with gamma mobility when embryo and tumor extracts were tested with adult internal organ-absorbed anti-QUA serum (Fig. 2). The cross-reacting antigen of normal skin was not seen in the usual 45 min immunoelectrophoretic analysis. However, a precipitin arc of apparent zero mobility was observed at much shorter times (5–10 min). Its absence after longer times of electrophoresis suggests an innate instability and further studies of

the skin antigen are in progress (P. J. Higgins, personal communication).

Quantitative evaluations of the concentration of gamma-antigen in various mouse tissues by radial immunodiffusion assay are shown in Table 1. The gamma-antigen appeared in fetal tissues after day 15 of gestation and persisted until 2 days postpartum. Since the concentration was somewhat higher at parturition, the distribution of the antigen at this stage was determined for several organs. A high concentration occurred in the spleen, while the levels in thymus and liver were similar to that in whole trunk extracts. The gamma-component was undetectable in extracts of brain, intestine and kidney. The significance of this unequal distribution is not apparent, although it may be that the fetal/neonatal spleen is the principal site of gamma-antigen biosynthesis.

DISCUSSION

The antigen described here appears to be analogous to the gamma-fetoprotein in human neoplasms described by Edynak *et al.* [2] who used sera from cancer patients for its detection in their studies. However, these authors [2] did not detect antigens with gamma mobility in fetal mouse serum nor in the 20 spontaneous mouse mammary tumors examined.

The presence of gamma-antigen could not be ascertained in extracts of QUA tumor cells which had been propagated *in vitro* with the immunological assays employed here. However, upon re-inoculation into animals, these cells grew into tumors from which the gamma-antigen could be extracted [17]. This loss and regain of antigen could represent the net result of an interaction of the tumor with its environment, further understanding of which may shed light on the general problem of tumor-host relationships. It may also imply perhaps a cessation of the synthesis of the fetal component when tumor cells are propagated in culture. Alternatively, the gamma-component may not be synthesized in the tumor *in vivo* but may be acquired from another tissue source via the blood and processed in the tumor.

The Relationship of Thymidine Metabolism to the Use of Fractional Incorporation as a Measure of DNA Synthesis and Tissue Proliferation

KENNETH D. TEW* and DAVID M. TAYLOR

Radiopharmacology Department, Division of Biophysics, Institute of Cancer Research, Royal Marsden Hospital, Sutton, Surrey, SM2 5PT, England

Abstract—*After* 1 hr, *metabolism of thymidine*-6-3*H* (*TdR*-3*H*) *in tumour-bearing August female rats yielded a number of radioactive products. Rapidly dividing tissues (tumour, gut and spleen) incorporated high levels of tritium into DNA as labelled thymine. Conversely, the excretory organs (liver and kidney) had high levels of labelled catabolites, which included, tritiated water* (^3H_2O), *beta-amino isobutyric acid* (*βAIB*) *and beta-ureidoisobutyric acid* (*βUIB*). *Other metabolites were incorporated irreversibly into cellular RNA, proteins and lipids and others were in a form still amenable for conversion to DNA-thymine.*

Fractional incorporation (*F.I.*) *reflects the rate of DNA synthesis within an individual tissue by expressing the DNA uptake of TdR-3H as a function of the total tissue tritium. In the spleen the F.I. response following a single dose of cyclophosphamide* (*CY*) *was shown to correlate with gross morphology and DNA content. Similarly the histological response of the jejunal mucosa after a single dose of methotrexate* (*MTX*) *correlated with F.I. data for TdR-3H and deoxyuridine*-6-3*H* (*UdR*-3*H*).

INTRODUCTION

THE INCORPORATION of tritiated thymidine (TdR-3H) into DNA has long been used as a measure of the rate of DNA synthesis. Possibly the most complete review of thymidine usage is by Cleaver [1]. In any labelled precursor study it is important that the molecule should reach the cell in a chemical form that still resembles the parent compound. Any metabolism may alter the chemical nature of the labelled compound and thus limit its availability. In this context, Wand *et al.* [2] have shown that self-radiolysis of TdR-3H can result in TdR breakdown and for this reason these studies have utilised only freshly prepared TdR-3H. Even so *in vivo* metabolism of TdR has been shown to give products which are available for the synthesis of macromolecules other than DNA (Fig. 1). In rat liver more than 30% of the tritium from TdR-methyl-3H was incorporated into protein, RNA and lipid material [3]. Although a tritium atom attached to the methyl group of TdR is probably more labile than a tritium atom on C 6, it was considered probable that levels of tritium from TdR-6-3H would become associated with extraneous macromolecules. Such extraneous incorporation is obviously important in consideration of the rate of DNA synthesis as measured by TdR-3H incorporation into DNA, since they may limit the availability of the precursor for DNA synthesis. Because of this, the catabolism of TdR-6-3H (Fig. 2) has been studied by measuring the activity associated with the various cellular fractions of a number of rat tissues, after a 1 hr pulse label of freshly obtained TdR-6-3H.

The parameter of Fractional Incorporation (F.I.) which we have made use of in previous studies [4–6], expresses the incorporation of TdR-3H into DNA as a fraction of total cellular tritium. This measure has been shown to be a valuable alternative to specific activity (DPM 3H/mg DNA) in correlating levels of DNA synthesis with tumour cell kinetics in mice

[7] especially after chemotherapy. This present study considers how the chemical state of the 3H label in the acid soluble fraction could affect F.I. measurements and also relates F.I. values to other modes of measuring tissue proliferation following cytotoxic drug therapy.

MATERIAL AND METHODS

The animals used were 5–6 month old inbred female August rats bearing s.c. A15 carcinomata. Cyclophosphamide (WB Pharmaceuticals Ltd., Bracknell, Berks) and

methotrexate (Lederle Laboratories Ltd.) were administered intraperitoneally to lightly anaesthetised rats. Thymidine-6-3H, 24 Ci/mmole, deoxyuridine-6-3H, 21 Ci/mmole (Radiochemical Centre, Amersham) were administered 1 hr prior to death by cervical dislocation. Excised tissues were treated biochemically and histologically as described previously [5]. DNA was estimated colourimetrically [8] after extraction using a modification of the Schmidt–Thannhauser procedure [9].

The following scheme was undertaken to further characterise the acid soluble constituents from tissue samples:

15 ml Acid Soluble Extract → Count 1 ml → A

5 ml lyophilise. Redissolve in 5 ml dH_2O. Count 1 ml. Calculate ^3H_2O. → B		5 ml mix with 100 mg acid washed, neutralised charcoal [10]. Leave 1 hr at room temperature with intermittent mixing. Centrifuge 2000 rev/min during 5 min.
	C ←	Decant supernatant and count aliquot. Wash precipitate with 2 × 5 ml dH_2O. Count resultant washings to check for residual 3H. Add 10 ml ethanol/NH_3/dH_2O solution (2 : 1 : 2) to charcoal and mix. Leave overnight at 37°C. Centrifuge to clarify, 2500 rev/min during 15 min. Decant and evaporate to dryness in stream of warm air. Redissolve in 0.5 ml dH_2O.
	D ←	Count an aliquot and carry out thin layer chromatography.
Count from RNA fraction		E
Count from DNA fraction		F
Count from protein fraction		G
Total 3H in fraction		A + E + F + G = H

The metabolic fate of the tritium from TdR-3H may be calculated thus:

% of DNA incorporated thymine	= F/H × 100
% of ribothymine in RNA	= E/H × 100
% of amino acid 3H	= G/H × 100
% of ^3H_2O	= B/H × 100
% of non-nucleotide 3H	= C/H × 100
% of acid soluble 3H	= A/H × 100

Thin layer chromatography of thymidine breakdown products

For all chromatographic separation procedures TLC, Ready Plastic Sheets F1140 PEI/LS 254 PEI cellulose with luminescer (254 nm), 20 × 20 (Schleicher and Schull, Dassel, West Germany) were used.

The method used was similar to that of Randerath and Randerath [11]. Ten microlitres of each sample, together with prepared standard solutions, were applied to a thin pencil line drawn horizontally 2 cm from the base of the plate. Duplicate plates were run in the following solvent systems:

1. 1 N acetic acid run to 2 cm above the origin, then immediate transfer without intermediate drying to 1 N acetic acid and 3 M lithium chloride (9 : 1). Results obtained using

standard solutions gave the following R_F values:

TdR	0.74
T	0.68
TMP	0.42
TDP	0.12
TTP	0.099

These values were in accord with the theory that separation is dependent upon the phosphate moieties of the nucleotides.

2. Fink [12] has outlined a number of the less common catabolites of thymine-14C. To test for the presence of these after TdR-3H, a solvent of tertiary-butyl alcohol, methylethyl ketone, water and ammonium hydroxide (40:30:20:10) was employed using Whatman No. 3 chromatography paper. A few of the possible thymidine catabolites are listed below with their R_F values [12]:

Thymidine	0.58
Thymine	0.55
βAIB	0.33
βUIB	0.34
Dihydrothymine	0.78

After development chromatograms were dried in a stream of warm air and cut horizontally into 1 cm strips, so that with a solvent front 15 cm above the origin, 17 strips were cut (allowing overlap at both ends).

These strips were placed in glass scintillation vials and eluted with 1 ml of 1 N PCA at room temperature for 1 hr. After this, 10 ml of scintillant [7 vol of butyl-PBD (0.6% w/v) in toluene plus 3 vol tergitol TP9] was added and counting was carried out as previously described [5].

Preliminary experiments were undertaken to check the possibility of loss of counts through quenching by either the cellulose or paper strips. A known amount of tritium was counted in the presence and absence of both PEI cellulose and paper. Counts for all samples were comparable, suggesting no loss in efficiency through particle adsorption of radioactivity. In addition, total recovery of the original spotted radioactivity was achieved.

Estimation of fractional incorporation

Values for F.I. of 3H-TdR and 3H-UdR were calculated from the following formula:

$$\text{F.I.} = \frac{^3\text{H dis/min in DNA}}{^3\text{H dis/min in total tissue}}.$$

RESULTS AND DISCUSSION

Products of thymidine-3H metabolism

The proportions of the total tritium fractions isolated from liver, kidney, tumour, gut and spleen at 1 hr after injection of TdR-3H are shown in Table 1.

The TLC method used did not allow identification of all catabolites, thus there is a line in Table 1 which represents unknown compounds. The suggestion by Steel and Lamerton [13] that after 1 hr all tritium from TdR-3H was localised either in DNA or in tritiated water (^3H_2O) was shown not to be the case in these tissues. Certainly in the rapidly dividing tissues (tumour, jejunal mucosa and spleen) much of the label was localised as thymine-3H in DNA. However, substantial amounts of label were also associated with other macromolecules and metabolites. The proportion of label in the various metabolites was variable and dependent upon the tissue. The highest proportions of labelled β-amino isobutyric (βAIB) and β-ureido iso-

butyric acids (βUIB) were found in the liver and kidney. In the liver of male Lewis strain rats, Chang and Looney [14] found that up to 66% of the 3H from TdR-3H was present in βAIB. The results presented here show a slightly lower, approximately 54%, incorporation of 3H from TdR. The high levels of these non-protein amino acids in the liver and kidney were not surprising in view of the excretory function of the organs. The tumour showed significant amounts of βAIB. Similarly, patients suffering from various types of lymphoma have been shown to excrete quantities of these acids after administration of nitrogen mustard [15]. Also, patients fed diets rich in DNA have been shown to excrete large amounts of βAIB [16]. These facts when considered in relation to the catabolic pathway of thymidine would suggest strongly that the non-protein amino acids play no role in the anabolic synthesis of cell macromolecules. Therefore the label localised in such metabolites will no longer be available for DNA synthesis.

Tritiated water contributed between 10 and 20% of the total tissue 3H in the liver, tumour, intestinal mucosa and spleen. Again, not unexpectedly, the kidney had the highest level, 35%. Presumably the tritiated water reaches equilibrium with the other tissue fluids and plays little significant part in the anabolic synthesis of DNA.

Localization of label in RNA, protein and lipids was not as high as that found with Me-3H-thymidine [3]. Liver, kidney and jejunal mucosa had approximately 10% of the label associated with these molecules whereas tumour and spleen had only 2%. This tritium, once again, is presumably not available for DNA synthesis.

Contrary to the results discussed so far, the tritium associated with nucleotides may well be utilizable for DNA synthesis. Acid soluble dTDP has been shown to be a direct progenitor of DNA thymidylate [17], hence the low levels of nucleotide-associated tritium may well be involved in the DNA synthetic pathway.

Two pathways of thymine utilisation, one synthetic and the other degradative, are known to be functional in all tissues, their relative activities depending upon the physiologic state of the tissues. In the synthetic pathway, thymine is converted to thymidine by attachment of a deoxyribose moiety and this is phosphorylated by thymidine kinase to form thymidylic acid. Thymidylic acid is then further phosphorylated to dTTP which is utilised for DNA synthesis. Studies in bacterial cells in cultivated Novikoff hepatoma cells have suggested a compartmentalisation of thymine and thymidine with both being used as direct DNA precursors [18–20]. In addition, it has been suggested that thymine incorporation into the DNA of various rat liver hepatomas may be the result of either the deamination of 5-methylcytosines or the recycling of thymine from RNA turnover [21]. Judging from these findings it appears possible that the thymine found in these tissues may be available for DNA synthesis.

Thus there appears to be a balance between labelled molecules, some of which are only catabolites e.g. ^3H_2O, βAIB, βUIB, some of which cannot be incorporated into DNA since they are irreversibly associated with RNA, proteins and lipids and finally those which may still be metabolised to DNA-thymidylate; e.g. unchanged thymidine, nucleotides and possibly thymine.

In general these results indicate that after a 1 hr pulse label little of the TdR-3H remains in an unaltered form. In the fast-dividing tissues, spleen, gut and tumour the majority is incorporated into DNA via dTTP. In these tissues very low levels of tritiated metabolites are in a form amenable for further metabolism to DNA. The liver and kidney have low levels of incorporation into DNA and high levels of labelled catabolic products.

Comparison of specific activity and fractional incorporation at variable thymidine doses

By increasing the radioactive dosage of TdR-3H, theoretically more labelled TdR should enter the *in vivo* pool and eventually become incorporated into DNA. Figure 3 shows that using a radioactive dose range of 0.5–2.5 mCi/kg the increase in tissue acid soluble and total tritium was linear after a 1 hr pulse label. No attempt was made to dilute the TdR-3H with unlabelled TdR to give a standard injected mass, since the dilution of a "labelled-bolus" of TdR-3H when injected is considerable. For the dose range of TdR used, every molecule of TdR-3H is diluted by 10^7–10^8 unlabelled molecules in the animal. This linear increase in the cellular pools will continue until a saturation-state is reached. The acid soluble pool levels of TdR-3H in liver are the highest. The major part of this tritium is in catabolite form, as is the acid soluble tritium from the other tissues. The differences between acid soluble and total levels of tritium represent uptake into macromolecules (DNA, RNA and protein). A plot of the specific activity (counts/min/mg DNA) for the same samples as shown in Fig. 3 revealed a linear increase similar to that of the acid soluble and total cell pools. Figure 4(a) shows that the actively dividing tissues, gut, spleen and tumour have the steepest gradients.

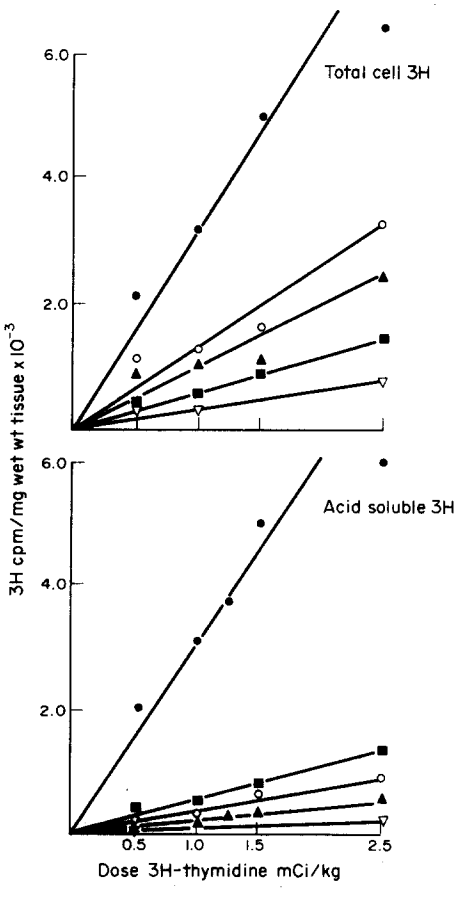

Fig. 3. Total and acid soluble 3H levels in tissues 1 hr *after variable doses of thymidine-6-3H.*

The fact that no shoulders were observed on the curves suggested that the precursor pools did not contain sufficient labelled molecules to saturate the thymidylate pool at the dose-range used.

The F.I. data, Fig. 4(b), shows a different pattern over the same dose range. There was no such linear increase as with specific activity. Instead the fractional incorporation values remained more or less similar. This would agree with the predicted pattern for the fractional incorporation values, since unlike specific activity, this measure is independent of the total TdR-3H reaching the tissue. The critical factor is the incorporation of TdR-3H into the DNA from the tissue pool. Once again the more actively proliferating tissues have the higher fractional incorporation values.

Thus the use of F.I. as a measure of DNA synthesis obviates the necessity to attain steady intracellular pool levels of TdR-3H. Nor is it necessary to attain the minimal TdR-3H pool levels to ensure a linear uptake of label into DNA [22]. It also has the effect of ensuring independence from the amount of tritium reaching the tissues and therefore allows for variation in blood flow to large solid tumours, as well as subsequent absorption variations. The need for accurate injection volumes (on a mg/kg basis) is reduced and the effect of environmental variation, which may affect the distribution of this label, is nullified.

Application of F.I. to tissue proliferation

The following data relate the responses of

spleen and intestinal mucosa (jejunal) to treatment with CY and MTX respectively and attempt to correlate F.I. measurements with non-biochemical parameters of tissue proliferation. Correlation of F.I. with tumour volume response [5, 7] and bone marrow cellularity [23] after cytotoxic drug treatment have been illustrated previously.

Spleen

The effect of a single dose of 100 mg/kg CY (LD5) upon spleen weight, DNA content and DNA synthesis is shown in Table 2. Table 2 shows that the CY caused a decrease in all three parameters within the first 24 hr, recovery ensued between 7 and 10 days. The weight and volume (Fig. 5) were double the pre-treatment value by 10 days. The DNA content was 50% increased. The F.I. value was much increased, the 98.9 value signifying that all but 1% of the TdR reaching the spleen was incorporated into DNA. The total levels of 3H reaching the spleen were also significantly increased as compared with control.

Figure 5 illustrates the difference in volume between a control and treated spleen. As well as the difference in size, white nodules were present in the treated spleen. These were pyorrhoeic inflammations containing dead cells and mucus (Fig. 6). Whilst the increase in size after treatment was highly reproducible, the formation of these inflammatory foci was a rare occurrence. An autoradiograph of the red pulp region of the treated spleen is also shown. The lymphocyte and macrophage populations incorporated high levels of TdR-3H so presumably these cells were the most actively dividing and would account, at least in part, for the observed increase in F.I. Consideration of spleen function would suggest that the increased splenic activity after treatment was caused by a "rebound-effect" either as a direct result of drug treatment or indirectly due to infection. Since a similar effect was found using methotrexate [5] this spleen reaction was not a specific CY mediated response.

Intestinal mucosa

Table 3 summarises the effect of 5 mg/kg MTX on parameters of jejunal cell proliferation. Evidence of lymphocyte involvement (as well as crypt and villus structure) was gained by studying stained cross sections of jejunum. Representative examples of these sections are shown in Figs. 7–14.

DNA synthesis measurements are complicated by the balance of supply of thymidylate from salvage and *de novo* sources. Methotrexate restricts the supply of *de novo* thymidylate (measured by 3H-UdR) and the concomitant toxicity to the intestinal mucosa results in reduction in 3H-TdR incorporation. The F.I. value for 3H-TdR had recovered between 72 and 120 hr after MTX treatment and although 3H-UdR took longer to recover it is likely that the 3H-TdR incorporation is a better parameter for judging tissue recovery, since it is independent of MTX induced changes in endogenous dUMP pools [24]. The depression and recovery pattern of the 3H-TdR F.I. data was mirrored by animal weight and mucosal DNA content. Maximal DNA loss occurred at 24 hr and this was followed by a period of recovery. DNA synthesis began to recover between 48 and 72 hr and this corresponded with microscopic recovery since some regeneration was visible by 72 hr. The crypt hypertrophy observed at 144 hr was not reflected in an overshoot in F.I. values. This was probably because the total number of crypts was less than control. The smaller number were longer and contained two to three layers of dividing cells, as opposed to the control thickness

of one cell layer. In general there was good correlation between the F.I. values and the morphological appearance of the jejunum.

The gut recovery data may assist in providing an explanation for the findings of Harding *et al.* [25] who showed that the body weight of their rats was depressed if a second dose of MTX was administered 2–6 days after a first, but not if given later. Our temporal scheduling method for two alkylating agents [23] makes use of the recovery of F.I. in host target tissues. We have shown that the most animal-sparing combination occurs when these target tissues are allowed to recover before administration of a second insult. Thus, in the above example, F.I. in the jejunum has recovered by days 7–8 and administration of a second MTX dose at this time should cause minimal gut toxicity.

BCG-Immunotherapy of L_2C-Guinea Pig Leukemia

H. D. DOPATKA, M. MAJER and H. FREUDENSTEIN
Behringwerke AG, D-3550 Marburg, Federal Republic of Germany

Abstract—*Guinea pigs of inbred strain 2 were treated by an intradermal injection with a lethal dose of* 10^5 *gelatine purified leukemic blood leukocytes in mixture with* 10^7 *colony-forming units (CFU) of BCG strain Copenhagen* 1331. *Of* 56 *animals inoculated in this manner* 66% *showed a significantly* ($P=0.05$) *improved life expectation in comparison to* 48 *guinea pigs not BCG-treated, all perishing of leukemia within an average of* 22.4 days (±3.9 *S.D.*) *after tumor cell application. BCG enabled* 19% *of the animals to survive* L_2C*-inoculation more than* 15 *weeks. Eighteen of these survivors were challenged with* 10^5 L_2C*-leukocytes,* 15 *of them remained healthy demonstrating an acquired resistance against this leukemia. Positive tuberculin reaction converted to negative in the three susceptible, challenged animals and was transiently missing in two resistant guinea pigs with a spontaneous remission of histologically apparent leukemia. BCG was useless when injected separately from* L_2C*-leukocytes or brought into contact with tumor cells* 15 days *after implantation. Antitumor activity of* L_2C*-cells adjoining BCG was furthermore hindered by BCG-vaccination six to seven weeks before immunotherapy. Increase of bacterial mass from* 1×10^7 *to* 2×10^8 *CFU for immunotherapy did not restore the antileukemic effect. BCG-induced ulceration at the site of injection of* L_2C*-leukocytes occurred in pre-sensitized animals much earlier than in unvaccinated guinea pigs. These results are discussed with respect to the presumably restricted possibilities of BCG acting against leukemia in animal models.*

INTRODUCTION

THE EFFICACY of immunotherapy with Bacillus Calmette-Guérin (BCG) to prolong the chemotherapy induced remission in leukemia patients is not definitively clarified yet. Early results from the BCG-treatment of acute myelocytic leukemia (AML) were hopeful, [1–4] but not conclusive because inappropriate control groups had been chosen. The same restrictions must be noted for the studies concerning the immunotherapy of chronic myeloid leukemia (CML) [4, 5]. Encouraging work has been done to prolong the remission of patients with acute lymphoblastic leukemia (ALL) by BCG [4, 6] but follow-up studies have failed to confirm these results. [7, 8].

All these clinical trials were based exclusively on findings derived from different experimental murine leukemias as the Rauscher leukemia [9], the Gross leukemias E♀K1 [9] and E♂G2 [10], the Moloney leukemia LSTRA [11, 12], the L1210 leukemia [13, 14] and especially the spontaneous leukemia of the AKR-mouse [15–17]. To obtain additional information we investigated a new model in BCG-research, the L_2C-guinea pig leukemia.

This leukemia, having spontaneously appeared in 1954, was isolated from an animal of inbred strain 2 and transmitted further by serial transplantations [18]. The advantages of the model are: firstly, unlike many chemically induced tumors, the guinea pig leukemia is weakly immunogenic [19]; secondly, and more importantly, cellular immunity appears to be the predominant, if not exclusive, factor in immunoprotection against this disease [20]. This resembles the situation in human leukemias where cellular immunity appears to be of decisive importance against ALL [21–24], AML [21, 22, 24, 25] and CML [5, 26]. As opposed to the mouse, the guinea pig exhibits a tuberculin reaction [27, 28] nearly identical to that in man [29, 30]. This is a further advantage of the L_2C-system because the tuberculin reaction reflects changes in cellular immunity in leukemic patients very simply [5, 21, 23]. In addition, the L_2C-leukemia is attractive because of its similarity to the ALL of childhood with regard to pathology [31] and to the meningeal form after chemotherapy [32]. Sensitivity to this leukemia is not age dependent [33] and the thymus of leukemic animals is not

Accepted 14 September 1977.

affected [33, 34]. Terminal stages of the illness show a severe thrombocytopenia [35]. With respect to these characteristics the L_2C-leukemia may prove to be the most valuable model for the study of ALL [33].

In the same inbred strain of guinea pigs a hepatocarcinoma was described. It was often used as a model for BCG-imuunotherapy [36–40], and therefore it was possible to compare susceptibilities of a leukemia and a solid tumor to BCG in a genetically identical environment.

The following experiments reveal some features concerning the sensitivity of the L_2C-leukemia to BCG-treatment and the effect of BCG-vaccination prior to immunotherapy. Subsequently, we will discuss the differences which possibly exist between solid and leukemic neoplasias to enforce optimum anti-tumor efficacy of BCG.

MATERIAL AND METHODS

Guinea pigs of inbred strain 2 [41] were obtained directly from Altick Ass. Hudson (Wisc. 54016) by air carriage. Inbred status of the animals was checked by skin transplantation between three pairs of males selected from different litters. The technique employed has been described by others in detail [42], but we anaesthetized by inhalation of Penthrane (Deutsche Abbott GmbH, Ingelheim). We kept the guinea pigs free of endoparasites in groups of three to four in stainless steel grid cages at room temperatures of 295K with a relative air humidity of 55%. Animals were fed with dry pellets of guinea pig chow (Intermast, Soest, Ger.) and water continuously available. They got carrots twice a week. Only males were used for BCG experiments.

L_2C-leukemia cells were obtained from D. Gericke (Hoechst AG, Ger.), who got the material in an unknown passage generation from L. Gross. Leukemic spleen cell preparations in Hanks' solution, pH 7.0, with 10% DMSO were frozen and stored in liquid nitrogen in the usual manner [43]. Sterility controls of cell suspension for freezing or for experiments were done with samples in thioglycolate medium at 293 and 310K, in Sabouraud medium at 293K and on blood agar plates at 310K. Only in the first experiment did we use these frozen spleen cells as leukemic inoculum. It turned out to be too risky to use fresh cells as there was frequent contaminations of the spleen during preparation. For this technical reason all other experiments were begun with a fresh leukocyte preparation.

Citrated blood was taken from an anaesthetized terminal leukemic animal by cardiac puncture and leukocytes were purified in gelatine [44]. We centrifuged the leukocyte suspension at $200 \times g$ for 20 min and then after washing once more, for 10 min. Cells were counted and viability assessed with use of trypan blue exclusion. The proportion of undifferentiated blast cells did not change markedly during purification procedure as estimated by Pappenheim staining. Samples were separated just before use to test sterility as described above. Leukemic leukocytes were applied in disposable plastic syringes. White blood cells of L_2C-inoculated animals were estimated three times a week by using a cell-counter (TOA Medical Electronics, Kobe, Jap.). Measurement of the hemoglobin content was done optically with a Hb-meter (American Optical Corporation, Buffalo).

Frozen BCG (Strain Copenhagen 1331) was employed only in the first experiment using leukemic spleen cells as tumor inoculum. The bacteria were harvested from a dispersed culture in Sauton-medium with 0.2% tween at 310K. The yield was washed, resuspended in stabilizer and stored at 243K. Before use, BCG was thawed quickly and an equal volume of *aqua bidest.* was added. *Fresh BCG* of the same strain was used in the second experiment in mixture with L_2C-leukocytes. These bacteria were grown in a dispersed culture as described before but used immediately after harvesting. *Lyophilized BCG*, a commercial product of the Behringwerke AG (Marburg, Ger.), was used in the majority of the experiments. To prepare this vaccine (K.-Nr. 240-1) BCG of strain Copenhagen 1331 was cultured for 7 days in Sauton-medium at 310K. Subsequently, pellicle grown bacterial mass was grounded with steel balls, centrifuged and resuspended in a stabilizer fluid consisting of 3.5% Haemaccel® (registered trade mark of Hoechst AG), a degraded gelatine and 5% glucose before lyophilization. *Colony forming units* (CFU) were estimated by spreading appropriate dilutions of the BCG-suspension on Dubos-agar plates enriched with 5% horse blood. Colonies were counted after 4 weeks of incubation at 310K. *Dry weights* were determined by using 0.45 μm filters (Sartorius, Göttingen, Germany) 50 mm dia and dried at 378K for 24 hr before and after loading with bacteria. Dilutions of BCG were done in stabilizer after addition of an equal volume of *aqua bidest* to keep an isotonic environment.

Immunotherapy was done for the most part by adding BCG to a lethal dose of L_2C-material and injecting the mixture intradermally. Exact concentration applied, body weights of guinea

pigs and modifications of the experimental procedure are described in detail in figure legends. All control groups without BCG were inoculated at the end of each test to exclude a possible loss of activity during injection procedure.

Tuberculin tests were carried out with old tuberculin (Behringwerke AG, Marburg) containing 100,000 i.u./ml. After a dilution of 1:100 with physiological NaCl, 0.1 ml of this solution was injected intradermally in the shaved dorsal region of the guinea pig. Largest diameter of induration, not erythema, was measured 24 hr later; a diameter of 5 mm or more was accepted as a positive skin reaction [28]. All injections and readings were done by the same person.

Statistical analysis of survival times of guinea pigs in different groups after implantation of leukemic material with or without BCG was adapted to the observation that in BCG-treated groups some animals survived, and therefore the distribution of life times possesses an open flank, which was never observed in control groups, where animals died without any exception. Thus, we calculated the distribution of life duration with its different probabilities only for control groups according to Student's *t*-values. The number of animals with life prolongation in a BCG-treated group was expressed as the percentage beyond the upper confidence limit of $P=0.05$ in the corresponding control group. In the experiments 6 and 7 we compared animals life data in the two pre-sensitized groups using the one-tailed test of Mann and Whitney.

RESULTS

One of the limitations of a successful immunotherapy in animals as well as in man is a high number of tumor cells in the organism. In murine systems for example the critical concentrations are 10^4 for the E♂G2 [10] and 10^5 for the L1210 leukemia [13]. More than 10^5 leukemic cells may overwhelm the possible benefit of BCG in the guinea pig system too. On the other hand, application of a reduced cell number would allow some guinea pigs to survive without support of BCG because 10^5 L_2C-leukocytes injected intradermally are necessary to cause 100% deaths [20]. For all the following experiments we therefore used a transplantation dose of 10^5 tumor cells.

Experiment 1: *BCG in mixture with L_2C-spleen cells*

In the first experiment spleen cells were used as tumor inoculum. One group of guinea pigs received leukemic cells alone, the other one got the same dose in combination with BCG. Details of the procedure are exemplified in the legend to Fig. 1. To consider possible toxic effects of BCG suspending medium against spleen cells, the amount of viable L_2C-cells was determined after finishing all injections, but a distinct decrease was not observable. About one week after inoculation all animals developed a small intradermal nodule at the side of L_2C-injection. The BCG-group was

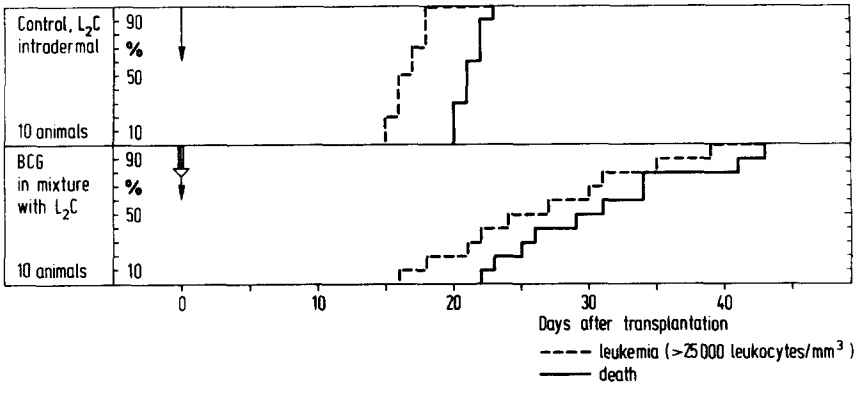

Fig. 1. Cumulative mortality of guinea pigs inoculated with a mixture of L_2C-spleen cells and BCG.

A frozen L_2C-spleen cell suspension from a female with 224,000 *leukocytes/*mm^3 *and an amount of* 91% *leukemic blast cells in the peripheral blood was thawed rapidly in a* 310*K water bath. Each guinea pig of the test group got intradermally* 0.5 ml *BCG suspension (broad arrow) containing* 1.4×10^6 *CFU (determined after thawing) and a dry weight of* 0.032g *in mixture with* 0.5 ml *of a* 1:100 *dilution of the spleen cell suspension. Control animals were inoculated with* 0.5 ml *spleen cells in mixture with* 0.5 ml *stabilizer* 1:2 *diluted with* aqua dest. *Each animal got* 1.3×10^5 *viable and* 3.0×10^4 *dead spleen cells or a better ratio of this (thin arrows). Median animal weights were* 581g *for the test and* 580g *for the control group at the beginning of the experiment.*

totally tuberculin positive on day 9. In this skin test the other group, which had received spleen cells alone but remained healthy during the test, served as a negative control. Beginning with day 20 an inflammatory reaction characterized by induration, ulceration and necrosis developed in the BCG group in all animals but with individually different degrees. As shown in Fig. 1 all guinea pigs subsequently succumbed to leukemia. The onset of disease was however considerably delayed in the BCG-group. Herein 80% of the animals have a significant ($P=0.05$) extension of life span although 0.05% DMSO present in the spleen cell suspension at the time of injection might hinder activity of BCG.

Experiment 2: *BCG added to L_2C-leukocytes at different times*

In the next experiment fresh leukemic leukocytes from the blood were purified. Using the procedure described in Material and Methods only viable cells were obtained. Results of this BCG-experiment are presented in Fig. 2. The first group of guinea pigs which served as a control received only the tumor cells. These animals developed moderate, intradermal nodules. The onset of leukemia and occurrence of death took place in the same period after transplantation as observed for the control group in experiment 1. The second group of guinea pigs got L_2C-leukocytes and BCG in mixture. Ulcerations were observed two weeks after transplantation. An antitumor activity of BCG was noted in this group by a significant ($P=0.05$) life-prolongation of seven animals. Of these, two guinea pigs were still alive 15 weeks after tumor implantation. And these will be referred to later as long-term survivors. Animals of the third group were inoculated with tumor material at the beginning of the experiment and received BCG 15 days later by injection into intradermal tumor nodules. As can be seen in the graph, two animals of this group were leukemic at this time, but neither these guinea pigs nor the rest of the group showed an improvement of life-expectation or duration of disease by BCG-treatment although ulceration of the nodules were noticed. Therefore, time of BCG-employment and not ulceration of tumor nodules was crucial in antileukemic activity of BCG.

Experiment 3: *measurement of BCG-antitumor activity in the L_2C-system*

In the preceding experiment the number

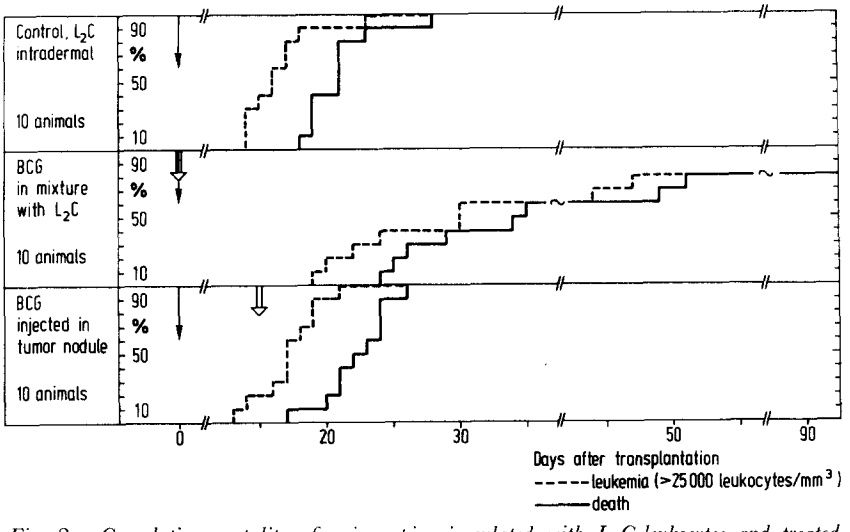

Fig. 2. Cumulative mortality of guinea pigs inoculated with L_2C-leukocytes and treated with BCG at different times.

Leukocytes were prepared from a male with a white cell blood count of 310,000/mm^3 *and a portion of* 60% *blast cells in peripheral blood. Each animal got* 0.5 ml 1.1×10^5 *viable tumor cells intradermally (thin arrows). Guinea pigs of the second group received in mixture with these leukocytes* 0.5 ml *BCG with* 7.8×10^7 *CFU and* 1.3 mg *dry weight (broad arrow in the middle panel). Despite washing BCG twice with physiological* NaCl, *traces of detergent derived from culture medium might have been present and toxic for leukocytes. To exclude this possibility,* 0.5 ml *of the* 0.45 μm *filtered (Millex, Millipore) first BCG-washing were added to the leukocytes of the control group. When tumors were palpable at the injection site in all animals of the third group,* 0.2 ml *BCG with* 5.2×10^6 *CFU and* 0.07 mg *dry weight from a fresh liquid culture was applied locally (broad arrow in the lowest panel). Median animal weights were* 488g *in the first,* 489g *in the second and* 490g *in the third group as estimated just before start.*

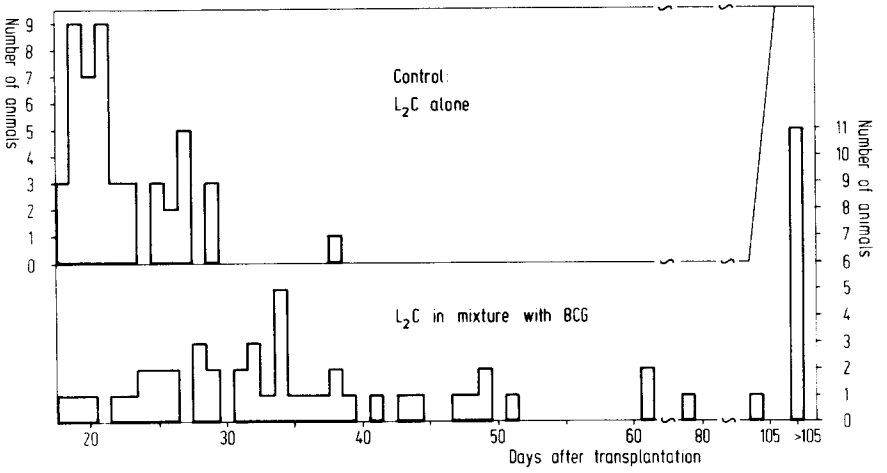

Fig. 3. Life time-histogram of guinea pigs after intradermal inoculation of L_2C-leukocytes. In the immunotherapy group each animal received 0.5 ml *L_2C-leukocytes with about* 1.0×10^5 *cells in mixture with* 0.5 ml *BCG strain Copenhagen containing nearly* 1.0×10^7 *CFU. Control guinea pigs got* 0.5 ml *of the same leukemic material after addition of* 0.5 ml 1:2 *diluted stabilizer to obtain an environment for leukocytes comparable to that in the immunotherapy group.*

of guinea pigs was not sufficient to calculate percentages of animals with BCG-induced life prolongation or ability to survive. For technical reasons it was not possible to enlarge the basis for this calculation in one extensive experiment. Therefore, three unrelated tests were done in an identical manner as experiment 2 but omitting the third group. Combining experiment 2 and the three tests of experiment 3 a total of 56 guinea pigs were inoculated with a mixture of L_2C-leukocytes and BCG; as a control 48 animals were not BCG-treated. As shown in Fig. 3 all control animals died between day 18 and 38 after transplantation with an average of 22.4 ± 3.9 S.D. (standard deviation). As demonstrated in the same graph BCG improved life expectation considerably for many guinea pigs. In comparison to the corresponding controls of each test a total number of 37 BCG-treated animals (66%) possessed a significant ($P = 0.05$) extension of life including 11 animals (19%) which survived L_2C-transplantation for more than fifteen weeks.

Experiment 4: rechallenge of animals surviving by BCG-immunotherapy

Eighteen guinea pigs, which survived L_2C-transplantation in the experiments described before and in an accompanying study comparing the antitumor activities of different BCG-vaccines, were challenged with 10^5 L_2C-leukocytes applied intradermally as described above but now without adding BCG. All these survivors were tuberculin positive as tested some days before the experiment. The challenge was carried out 92–184 days after the first L_2C-inoculation.

Since a positive tuberculin reactivity might influence the course of leukemia by itself, animals of the challenge control group were sensitized with BCG 4–17 weeks before use. These control animals, 33 in total number, all died of leukemia within an average of 25.6 days (± 4.7 S.D.) after L_2C-inoculation.

Reaction types observed in the rechallenged group are summarized in Table 1. Out of

Table 1. Observed reactions of eighteen long-term survivors after rechallenge with L_2C-leukocytes

Reaction types	Number of guinea pigs	Animals with reduced hemoglobin content in the blood	Disappearance of tuberculin reactivity
Leukemia	3	3	Yes
One or two attacks of leukemia with remission	2	1	Transient
L_2C-resistent	13	1	No

Results are explained in detail in the running text.

the 18 survivors challenged only three animals died of leukemia 34, 59 and 74 days after tumor cell application respectively. For all these animals a loss of positive tuberculin reaction was observed accompanying the neoplastic disease.

Forty-four and 90 days after beginning of the challenge another guinea pig showed elevated leukocyte concentrations in the peripheral blood up to 34,000 cells/mm^3, 1–2% in typical leukemic forms. Both events were in parallel with a transient conversion from tuberculin positive to negative. Very surprisingly, this leukemic animal recuperated each time in parallel with a slow restoration of the capability to react in the skin test. A self limiting disease was observed in a second animal too, in which 121 days after start of challenge leukocytes increased to 33,000/mm^3 with typical blast cells in the peripheral blood and a simultaneous loss of delayed hypersensitivity against tuberculin. As in the case described above, a spontaneous remission of leukemia occurred for some days accompanied by a restoration of tuberculin reactivity.

The majority of the challenge group, thirteen animals, remained continously healthy for several months demonstrating a strong acquired resistance against L_2C-leukemia. These guinea pigs were tuberculin positive during challenge and served as a positive control for the skin tests with negative results as mentioned above.

Two challenged animals, one of the L_2C-resistant and one of the guinea pigs with the single spontaneous remission, exhibited a decline of erythrocytes concentration to 2.9×10^6/mm^3 and 3.3×10^6/mm^3 three months after challenge. At this time erythrocytes concentrations tested in other animals of the challenge group were normal with a mean value of 5.5×10^6/mm^3, very similar to that of untreated guinea pigs of inbred strain 2. Against a normal content of 15g hemoglobin per 100 ml, blood concentration of this substance was strongly reduced in both animals to 10g and 8.5 g/100 ml respectively, a level normally measured only in leukemic guinea pigs. Additionally, these animals showed loss of body weight. Illness, presumably of the hematopoetic system, disappeared very slowly after some weeks.

Experiment 5: *BCG-vaccination before BCG-immunotherapy*

Since a positive tuberculin reaction is very common in humans [30], we investigated in the following experiments the influence of this immunologic state on antitumor activity of BCG in the L_2C-system. Guinea pigs were sensitized by intradermal injections with BCG. Six weeks thereafter animals received the usual dose of L_2C-leukocytes plus BCG. One control

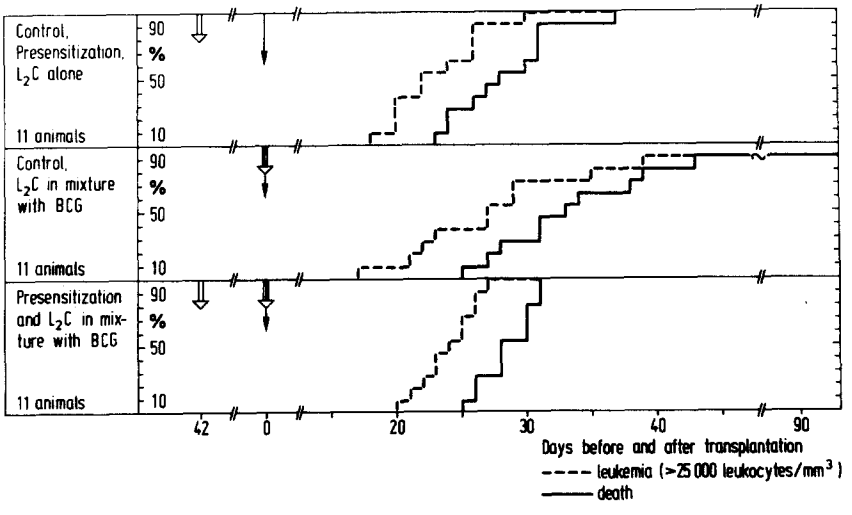

Fig. 4. Cumulative mortality of guinea pigs inoculated with a mixture of L_2C-leukocytes and BCG. Effect of intradermal pre-sensitization with BCG.

Animals of two groups were sensitized by injecting 0.1 ml *with* 4.3×10^6 *CFU BCG in each flank intradermally (broad arrows on day* 42 *before transplantation). A guinea pig with a leukocyte count of* 177,000/mm^3 *and a portion of* 84% *leukemic cells in the peripheral blood was sacrificed for leukocyte preparation. From this, all animals in the experiment received* 0.5 ml *with* 0.8×10^5 *L_2C-cells (thin arrows), two groups in mixture with BCG containing* 1.0×10^7 *CFU and* 0.065 mg *dry weight (broad arrows on day* 0), *one group with* 0.5 ml 1:2 *diluted stabilizer instead of BCG (upper panel). Median animals weights were* 574g *for the first,* 599g *for the second control and* 587g *for the actual test group.*

group got this mixture without pre-sensitization in a manner identical to the tests mentioned in experiment 3, a second control group was vaccinated with BCG, but inoculated with L_2C-leukocytes alone. As shown in Fig. 4 in this experiment pre-sensitization with BCG abolished the antitumor activity of BCG totally, because both BCG-vaccinated groups have exactly the same mean of death-time, that is within 28.4 days after L_2C-inoculation regardless of adding BCG to leukemic material or not. Antitumor activity of BCG was reduced by pre-sensitization to such an extent that this group resembles the usual negative control groups receiving L_2C-cells alone. It was not possible to decide if BCG-vaccination itself has a weak benefit against L_2C-leukemia because a suitable control was missing here.

Experiment 6: *BCG in L_2C-prophylaxis and BCG injected simultaneously but separately to the tumor cells*

Since a possible prophylatic effect of BCG-vaccination against human leukemias is now under discussion [45] a comparable situation was tested in the L_2C-system. Hereto the first group of guinea pigs was vaccinated with BCG and inoculated with L_2C-leukocytes seven weeks later. Another question to be answered was the possible requirement of contact between BCG and tumor cells for successful immunotherapy. Therefore animals of the second group received BCG and L_2C-leukocytes by contralateral intradermal injection. In addition, to confirm the results of experiment, 5 guinea pigs of the third group were pre-sensitized with BCG and treated with the BCG–L_2C-mixture later. The fourth and fifth group which consisted of non-vaccinated animals received L_2C alone as a negative control or submitted to usual immunotherapy as a positive control. Results of the experiment are depicted in Fig. 5. Since in our experiments an extension of leukemia, that means the duration of the neoplastic disease, by BCG was never observed, only the lines for cumulative death are entered in Fig. 5. Nevertheless, each animal enumerated died of leukemia.

Three main types of reaction were observed for the five different groups. The group receiving BCG and L_2C-material at different sites was not statistically distinguished from the animals inoculated with only L_2C-leukocytes. This was also observed in the case of BCG-vaccinated animals inoculated with the L_2C-cells some weeks later. But here there was a remarkable exception: one animal survived 102 days after L_2C-implantation. Since this guinea pig was tuberculin positive after vaccination, it might be possible that in rare cases BCG-vaccination alone has an effect against L_2C-leukemia.

Another type of reaction in the positive control group was the antitumor activity of BCG against accompanying tumor material as expressed in animals with improved life expectation and the occurrence of survivors. This was expected for successful immunotherapy.

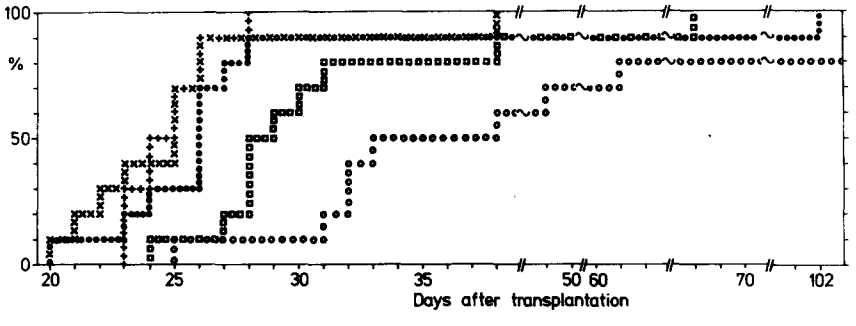

Fig. 5. Cumulative mortality of guinea pigs inoculated intradermally with L_2C-leukocytes and treated with BCG in different ways.
×—*L_2C alone;* ●—*sensitized with BCG* (−49 days), *L_2C alone;* □—*sensitized with BCG* (−49 days), *L_2C in mixture with BCG;* ○—*L_2C in mixture with BCG:* +—*L_2C and BCG at different sites.*

Each group consisted of 10 *animals. Guinea pigs of two groups were sensitized by injecting* 0.1 ml *with* 7.3×10^5 *CFU of BCG intradermally in each flank* 49 days *before starting transplantation. For this, leukemic material was prepared from an animal with* 290,000 *leukocytes*/mm^3 *and a portion of* 88% *blast cells in the peripheral blood. On day* 0 *all animals received* 1 ml *of* 0.5 ml *with* 1.2×10^5 *L_2C-leukocytes supplemented with* 1.0×10^7 *CFU and* 0.065 mg *dry weight of BCG or with* 1:2 *diluted stabilizer. Animals of one group got leukocytes and BCG separately, but both in doses equal to those applied in the other groups. Median animals weights ranged from* 589 *to* 622 g *for the five different groups.*

The last type of reaction was intermediate between the two described above and was measured for the pre-sensitized group inoculated with a mixture of L_2C-cells and BCG. A slight life prolongation of some guinea pigs was recognizable, but survivors were absent. Pre-sensitization with BCG reduced antitumor activity of this *Mycobacteria* applied later, but not to the same extent as observed in the foregoing experiment. This becomes clear by calculating the differences between both pre-sensitized groups; mixing BCG with leukemic material improved life expectation ($P=0.01$) in opposition to the experiment outlined in Fig. 4.

To investigate the state of cellular immunity in this experiment delayed hypersensitivity was measured repeatedly. Guinea pigs pre-sensitized with BCG were checked four days before L_2C-implantation by tuberculin test and found to be all positive. Here some animals from the groups not BCG-vaccinated served as a negative control. Ten days after L_2C-inoculation the tuberculin test was repeated. All animals were tested except those which had received BCG and L_2C separately. Guinea pigs without any BCG-treatment but injected with L_2C-leukocytes remained negative; the immunotherapy group became positive and both BCG-vaccinated groups remained positive but generally with a stronger skin reaction than measured in the first test or as compared to that in the immunotherapy group. This enhancement in skin reactivity was expected in repeated tuberculin tests. Some BCG-vaccinated guinea pigs, which received L_2C-leukocytes without BCG, were examined during the whole incubation period until death. These animals were strongly positive all the time. This includes leukemia up to nine weeks after BCG-vaccination. This is in remarkable contrast to the tuberculin conversions observed in leukemic animals during rechallenge tests mentioned above.

Experiment 7: BCG-immunotherapy with enhanced BCG-mass to counteract detrimental effect of preceding BCG-vaccination

In the following approach we tried to restore the antitumor activity of BCG in pre-sensitized guinea pigs by raising BCG concentration mixed with L_2C-leukocytes. The test performed was very similar to that outlined in Fig. 4. The same kind of controls were chosen. Guinea pigs of two groups, ten animals each, were vaccinated by injection 5.0×10^6 CFU of BCG intradermally. One group of 10 animals determined for the positive control of immunotherapy was not vaccinated. Some weeks later 1.3×10^5 L_2C-leukocytes were injected at the beginning of the experiment, two groups in mixture with 2.0×10^8 CFU of BCG. This elevated BCG dose did not improve life expectation of the pre-sensitized group to the level of that of the unvaccinated immunotherapy (data not shown). Comparing both vaccinated groups, addition of the large amount of BCG to unaltered leukemic load brought only a slight advantage ($P=0.025$) in life duration, fewer than noticed in Fig. 5 illustrating an experiment with a normal BCG-concentration of 1.0×10^7 CFU. So an elevated BCG-mass is not able to compensate for the reduction of antitumor activity by pre-sensitization with the same *Mycobacteria*.

In the last three experiments we observed that ulceration of an intradermal leukemic nodule developing during L_2C-incubation period occurred earlier in animals pre-sensitized with BCG than in controls not vaccinated. Intensity of ulceration or number of animals affected did not change with pre-sensitization. Possessing values in three experiments at the same point in time, 12 days after L_2C-inoculation, it was possible to quantify our observation knowing that three weeks after injection of BCG-L_2C-mixture an open ulceration develops in nearly all animals with or without pre-sensitization. The percentages listed in Table 2 clearly show that the development of ulceration is terminated first in pre-sensitized animals. This means that the speed of the local BCG-induced attack against leukemic tumor nodules is accelerated by BCG-vaccination some weeks before. As expected, increase of BCG-mass added to tumor cells injected also accelerate ulceration in guinea pigs not pre-sensitized.

DISCUSSION

BCG-vaccination as a prophylaxis against human leukemia has recently been discussed, but it seems difficult to prove its efficacy statistically [45]. In animals the spontaneously developing leukemia of AKR-mice was somewhat retarded in age-distribution but not reduced in incidence by prophylactic application of BCG [16, 17]. In our study vaccination of guinea pigs with BCG seven weeks before injecting a lethal dose of L_2C-leukocytes did not confer statistically significant protection (Fig. 5). One vaccinated animal, however, survived 102 days after inoculation of tumor cells. Such a long survival time has never before been observed in unvaccinated guinea pigs among a total number of nearly 100

Table 2. Portions of guinea pigs with open ulceration 12 days *after intradermal injection of L_2C-leukocytes plus BCG. Enhancing effect of pre-sensitization with BCG*

Data derived from	CFU of BCG injected i.d. together with L_2C-Leukoc.	Animals with ulceration/ Animals L_2C-inoculated	
		Without pre-sensitization	Pre-sensitized with BCG
Expt. 5	1×10^7	0/11	7/11
Expt. 6		3/10	10/10
Expt. 7	2×10^8	6/10	10/10

Data listed stem from the experiments described in detail above. In all three cases animals got nearly the same load of 1.0×10^5 L_2C- leukocytes in mixture with different quantities of BCG as indicated.

animals. This observation is similar to that described for infection of BCG-vaccinated marmosets with *Herpesvirus saimiri* [46]: again no statistically significant difference from the unvaccinated group was detectable but one animal showed a remarkable delay in development of malignant lymphoma and another one survived infection unaccountably.

A general theory about the mechanism of action of BCG in immunotherapy of malignancies has recently been discussed [47, 48]. In a very concise form the main points are: the initial step is a lymphocyte mediated local macrophage activation by BCG resulting in a non-specific killing of tumor cells. This event was called the "innocent bystander" effect of BCG [49]. In the following phase a release of tumor antigens from destroyed cells occurs enabling the induction of a systemic specific antitumor immunity. Close contact between BCG and tumor cells seems to be essential for the initiation of this sequence of events as demonstrated by using different sarcomas of rat [50, 51], a hepatocarcinoma of guinea pig [36], a murine leukemia [12] and our cavian leukemia as shown in Fig. 5 where BCG injected separately from tumor cells was ineffective.

For some solid tumors the "innocent bystander" effect of BCG is sufficient to eliminate neoplastic disease without the help of systemic immunity. In certain experimental models antitumor immunity was not induced by BCG for unknown reasons or because of a deficiency of the immunologic apparatus. This was demonstrated with six different tumors in mice [49, 52] and with one, P8, out of three tumors in rats [53]. As far as tested, artificial blocking of immunoresponsiveness does not prevent successful abolition of these tumors by BCG [49, 53]. Furthermore, the athymic "nude" mouse suppressed rat sarcoma cells after local employment of BCG [54] proving that systemic immunity is not involved in this process. In one case, the P7 osteosarcoma of rats, BCG has induced antitumor immunity after destruction of neoplastic cells [51], but this immunity was a superfluous, secondary effect because the local effectivity did not require an immunocompetent organism [53]. Exceptions were the CC5-rat osteosarcoma and the cavian hepatocarcinoma where BCG must induce antitumor immunity to be efficient in immunotherapy [37, 51]. However, it seems that antitumor immunity is generally of minor importance in the rejection of most localized solid tumors by BCG.

This is not the case for experimental leukemias although most investigators did not check the immunological state of their "cured" animals after immunotherapy. BCG-induced antitumor immunity was observed for the LSTRA-leukemia of mice [12] and in our experiments for the L_2C-leukemia by demonstrating a resistance against tumor challenge in 83% of animals, which survived by BCG-immunotherapy. Furthermore, these results and several other reports suggest that in leukemia systems BCG acts by establishing systemic antitumor immunity exclusively. During the incubation period, after intradermal application of L_2C-leukocytes until outbreak of leukemia, a nodule develops at the site of injection very similar to a localized tumor. Excision of this

nodule did not prevent the animal from break out of leukemia [19] or alter the course of the disease [20]. These earlier findings were confirmed by the fact that elimimation of the intradermal tumor nodule by BCG-induced ulceration has no effect on following L_2C-leukemia (conclusion of experiment 2). Both experiments, surgical excision and ulcerous destruction, demonstate that the determination for leukemia must occur before the development of a tumor nodule. To evaluate the duration of this decisive stage, which we will call "latency period" in the following, it is important to know that the time required for completion of tumor killing by BCG is seven days or more in a murine sarcoma system [55]. BCG admixed to L_2C-leukocytes and injected intradermally should possess similar restrictions to destroy the malignant cells locally. To build up immunity against L_2C-leukemia by application of irradiated leukocytes requires a minimum of eight days [20]. If systemic immunity is the only weapon against leukemia, BCG very probably acts during latency by killing tumor cells without any possibility of preventing leukemia by this kind of activity. For protection from leukemia a systemic immunity is required, which develops slowly as a consequence of the indolence of BCG to stimulate the immunologic apparatus. Therefore, it is difficult to block induction of leukemia because a sufficient level of systemic immunity has been reached during latency. Only in this case will animals survive with an acquired systemic immunity against leukemia. At present, the mechanism of leukemia induction during latency is unknown. Since tumor viruses were discussed in the L_2C-system [56], it is possible that these agents are introduced or derepressed by the transplanted L_2C-leukocytes causing the disturbance of the hematopoetic system in the recipient. This idea is in agreement with the observation made by others for the E♂G2 murine leukemia [10], namely that an early leukemia related unknown event determines in an almost absolute fashion the efficacy of the BCG-immunotherapy. This fundamental difference between the BCG-immunotherapy of solid tumors and that of leukemias is supported by further results.

Firstly, injecting a mixture of leukemic cells and BCG we got a continuous spectrum ranging from animals which died at the same time as control animals without BCG to guinea pigs with an extremely long delay in onset of the illness or animals resistant against leukemias (Fig. 2). We have never had survivors without observing at the same time a broad gradation of this type. This would be the consequence expected for a competition between BCG and leukemia in individual animals.

Secondly, BCG injected in leukemic nodules just before onset of the disease or in early stages of neoplasia was useless (lowest panel of Fig. 2). Determination for leukemia during latency had expired before BCG was employed. In a solid tumor of the same guinea pig inbred strain, however, injection of BCG into the intracutaneous tumor nodules caused a definite tumor remission in 69% of animals treated [38].

Thirdly, pre-sensitization of guinea pigs with BCG interfered with the immunotherapy of BCG some weeks later (experiments 5 and 6). It is unlikely that in tuberculin positive guinea pigs an immunologic defense mechanism hinders BCG in its "innocent bystander" effect, for example by killing most *Mycobacteria*, because improvement of bacterial mass from 1.0×10^7 to 2.0×10^7 CFU injected did not restore immunotherapeutic effects to a level comparable to that observed in animals not vaccinated with BCG before (experiment 7). Since the local attack of macrophages against adjoining tumor cells seems to be of the same kind in solid tumors as in leukemic nodules, it is informative that pre-sensitization with BCG has no effect upon the successful treatment of solid tumors in mice [52] or guinea pigs [38, 39]. Therefore, in our system BCG-vaccination might interfere in some way with the establishment of systemic antitumor immunity during immunotherapy. In this phase ulceration of the intradermal nodules of leukemic cells appeared earlier in pre-sensitized animals than in guinea pigs not BCG-vaccinated (Table 2). Therefore. one may hypothesize that destruction of immunobilized L_2C-leukocytes and hence, the antigenic stimulus was achieved too early in relation to BCG-stimulation of the reticuloendothelial system.

An additional result of the challenge of guinea pigs surviving by BCG-immunotherapy was the observation that a close relationship exists between the outbreak of neoplastic disease and the alteration of skin reactivity against tuberculin from positive to negative (Table 1). Three of these animals were not resistant against strong L_2C-challenge and died of leukemia with simultaneous loss of delayed hypersensitivity reactivity. A limited systemic immunity against leukemia was nevertheless present in these animals as indicated by prolonged survival times in comparison to those of challenge control animals. Two L_2C-resistant guinea pigs showed a transient leukemia with spontaneous remission

never found in L_2C-susceptible guinea pigs [34]. In both cases leukemia was accompanied again by a temporal but total loss of tuberculin reactivity which was constantly present in all other L_2C-resistant guinea pigs receiving the same tumor inoculum. This conversion of delayed hypersensitivity would not have been caused by an immunosuppressing exogenous infection, repeated skin testing or ageing of reactivity against tuberculin as supported by appropriate controls and maintained by known literature [27, 57]. This disappearance of delayed hypersensitivity reaction is a further distinction from the hepatocarcinoma system in guinea pigs where progressive growth of BCG-adjoining tumor cells was not preceded by a loss of skin reactivity to tuberculin [40]. Therefore, in the guinea pig leukemia system loss of skin reactivity reflects at least partially break down of immunologic surveillance against L_2C-leukemia. The mechanism of this strong connection between tuberculin reaction and immunologic surveillance against leukemia must remain unclarified.

Another question left unanswered is the self-restriction of leukemia by a BCG-initiated immunological defense mechanism. This is the central problem in immunotherapy of leukemia, namely to strengthen the biologic barrier of the host against tumor recurrence. The availability of the L_2C-leukemia for BCG-experiments may now help investigators understand the process preceding the relapse of patients free of detectable leukemia after chemotherapy.

Abstract—*The activities of seven enzymes associated with carbohydrate metabolism were measured in tumours from patients with primary carcinomas and the results were analysed in three different ways, i.e. according to tissue weight and enzyme/6PGDH and enzyme/PFK ratios. The tumours were then grouped together according to the number of nodes found to contain metastases and the following significant differences were observed. 1. Significantly lower activity of α-GPDH was observed in tumours from patients in whom four or more lymph nodes were found to contain metastatic deposits than in those with no nodal involvement. 2. Enzyme/6PGDH and enzyme/PFK ratios were significantly lower in tumours from patients with four or more nodes involved than in those with no nodal involvement. Possible prognostic significance of these enzymes is discussed.*

INTRODUCTION

IT IS generally accepted than an early indication of the clinical course of any carcinoma will greatly assist clinicians in deciding on a suitable treatment. A considerable effort therefore is being made to devise biochemical parameters for this purpose. It is hoped that carcinomas will either secrete specific factor(s) which are not present in non-cancerous women or alter the body pool concentrations of parameter(s) normally present so that there are significant differences between the two categories. These hypotheses are then extended in clinical studies to test whether such parameter(s) can correlate with the prognosis. In no field is this more relevant than in carcinoma of the breast. Although the ideal factor(s) for this purpose has not been observed, several workers have attempted to investigate hormones, tumour antigens, proteins and enzymes as likely candidates and found some abnormalities in patients with breast carcinoma [1–4]. In recent studies activities of enzymes associated with carbohydrate metabolism in primary breast carcinomas have been measured to test the hypothesis that the energy requirements of a rapidly growing carcinoma may be related to the rate of glycolysis and therefore by measuring the activities of certain enzymes it might be possible to predict the clinical course of the disease [5–7]. If so, they should correlate with the recurrence and survival rates. It is well known that in women with primary breast cancer, the disease-free interval and 5 yr survival is greatly reduced if lymph nodes are found to contain metastatic deposits at the time of mastectomy [8, 9]. Therefore, analysis of the results obtained on enzyme activities in the primary carcinomas related to the presence or absence of nodal involvement at the time of mastectomy might give some insight into the usefulness of these measurements in prognosis. This paper reports the findings after such an analysis.

Accepted 15 September 1977.

MATERIAL AND METHODS

All the chemicals used in the study were purchased from British Drug Houses Ltd. and were of analytical grade. α-GPDH, TPI, G6PDH, aldolase, NADH, $NADP^+$, ATP, F-6-P, G-6-P, 6PG and pyruvate were purchased from Boehringer Mannheim. G-1-P was purchased from Koch-Light Ltd. DHAP was prepared from the dicyclohexylammonium salt of the dimethylketal according to the manufacturer's (Boehringer Mannheim)

instructions.* Primary tumours were obtained from patients with carcinoma of the breast undergoing mastectomy. The malignancy of the tumours was confirmed by histological examination. The tissues were wrapped in aluminium foil, frozen on solid carbon dioxide and transferred to the laboratory where they remained frozen (−20°C) until further processing. All the tissues taken for histology were processed routinely and section from two levels of each lymph node block examined in order to increase the chances of finding small deposits of metastatic tumour. In this series an average of 23 axillary lymph nodes (range 8–58) were found in radical mastectomy specimens.

The tissues were cleared of any surrounding fat, weighed and cut into small pieces. The semi-frozen tissues were then homogenised in a Silverson homogeniser according to the procedure of Shonk and Boxer [10]. The homogenates were centrifuged (800 ***g*** for 15 min) at 4°C, the cytosol fraction was decanted off and used as a source of enzymes. A 5% solution of tumours was used in these estimations. The activities of PFK, G6PDH, 6PGDH, PGM, LDH, α-GPDH and PHI were measured. Enzyme assays were performed in a Beckman recording spectrophotometer according to the procedure of Shonk and Boxer [10], with the exception that one minute readings were recorded automatically for five minutes and a mean of the last four was taken as an average change in optical density (O.D.).

The results were calculated on the basis of units (U) of enzyme activity per gram wet weight of tissue. A unit is defined as that amount of enzyme which will catalyse the transformation of 1 μmole of substrate per minute. The results were analysed in three different ways: as units of enzyme activity/g and as enzyme/6PGDH and enzyme/PFK ratios. They are presented as mean ± S.D. The means were tested for significance by a Student's '*t*'-test.

*The following abbreviations are used in this paper.
Enzymes—α-GPDH, α-glycerolphosphate dehydrogenase; TPI, triosephosphate isomerase; G6PDH, glucose-6-phosphate dehydrogenase; PFK, phosphofructo kinase; 6PGDH, 6-phosphogluconate dehydrogenase; PGM, phosphogluco mutase; LDH, lactate dehydrogenase; PHI, phosphohexose isomerase.
Co-enzymes—NADH, reduced nicotinamide adenine dinucleotide; $NADP^+$, nicotinamide adenine dinucleotide phosphate; ATP, adenosine triphosphate.
Substrates—F-6-P, fructose-6-phosphate; G-6-P, glucose-6-phosphate; 6PG, 6-phosphogluconate; G-1-P, glucose-1-phosphate; DHAP, dihydroxyacetone phosphate.

RESULTS

This study is based on a total of 95 patients, 47 of these were free of nodal involvement. Of the remainder there were 10 patients with only one involved lymph node, 8 with two, 3 with three and 27 in whom four or more nodes were involved. For the purpose of analysis, patients with two or three involved nodes were grouped together.

The values (U/g) obtained in these four categories are shown in Table 1.

There were no statistically significant differences in the activities of G6PDH, 6PGDH, PGM, LDH and PHI between patients with no node involvement and those in the one, 2+3 or 4+ categories. α-GPDH activities were significantly lower in patients in the 4+ category than in those in whom no nodes were found to contain metastases.

Further analyses of the results on the basis of enzyme/6PGDH and enzyme /PFK ratios are shown in Tables 2 and 3, respectively.

In both cases significantly higher α-GPDH/6PGDH and α--GPDH/PFK ratios were observed in tumours from patients with no nodal involvement than those in whom four or more nodes were found to contain metastatic deposits. Furthermore, α-GPDH/PFK ratios in tumours from patients who had two or three involved nodes were higher than those with four or more involved nodes.

DISCUSSION

Recurrence and survival after mastectomy are usually considered to be dependent on certain clinical factors such as size of carcinoma, histology, anatomic type, grade of malignancy and lymph node involvement. The most closely related amongst these variables was the spread of the disease to the surrounding lymph nodes. Fisher and his colleagues [8] have shown that after surgical removal of the breast the 5 yr survival rate in patients with localised disease and absence of nodal involvement is 76% which drops to 45% when up to three nodes are involved and 31% when four or more are found to contain metastatic deposits. The same also applies to recurrence rates. In the absence of axillary metastases the 5 yr recurrence rate is 21%, which rises to 81% if four or more nodes are involved. Similar findings have been reported by others [11, 12]. However, these are gross classifications and as has been pointed out by Cutler and Myers [11] the patients falling into the same prognostic class show marked variation in clinical characteristics. Therefore, further classification

Table 1. *Enzyme activities* (μmole *of pyridine nucleotide reduced or oxidised*/min/g *tissue*) *in human breast carcinomas. The tumours were separated according to the number of lymph nodes found to contain metastatic deposits*

Enzyme ↓ / Nodes →	0	1	2+3	4+

on other indices is desirable. It is possible that biochemical parameters, in conjunction with clinical variables, may find a role in further separation of likely candidates who might require early adjuvant therapy.

Although a large number of parameters have been investigated in the hope that they could be used as prognostic aids, none is known to be in routine clinical use and with two exceptions they have not been found to correlate with recurrence rates [13, 14]. In this study we have attempted to ascertain whether enzyme patterns in these tumours correlate with other factors related to prognosis. To correlate with prognosis, the para-

meter must show significant differences between known clinical variables. In this respect the results are showing some promise in that lymph node involvement which is associated with poor prognosis, shows differences in both enzyme activities and ratios. In particular α-GPDH activities and α-GPDH/6PGDH and α-GPDH/PFK ratios show significant differences between tumours from patients in whom no nodes were found to contain metastatic deposits and those in whom four or more nodes were involved. It remains to be seen whether these patients with low α-GPDH activity will develop recurrences sooner irrespective of nodal involvement. If so, the α-GPDH activity or α-GPDH/6PGDH ratio might prove to be a useful parameter in predicting the clinical course of the disease.

Low levels of α-GPDH have been noted in all the neoplastic tissues [15]. However, the results reported here indicate that the activity of the enzyme is significantly different between tumours from patients with no nodal involvement and those in whom four or more nodes were involved. Although it is known that in some animal tumours growth rates correlate with the activity of glycolytic enzymes, it is not clearly understood what regulates the relative activities of enzymes within tissues [16]. In hormone responsive tissues such as carcinogen-induced rat mammary tumours or epididymis, oophorectomy and testosterone treatment appear to alter enzyme levels respectively [17, 18]. But these are hormone dependent tissues and withdrawal of or treatment with the hormone is bound to induce major changes in growth which are reflected in enzymic activities. Whether the enzyme values reported here correlate with the endocrine status of these patients remains to be explored.

In conclusion, certain enzyme activities in primary carcinomas appear to correlate with known clinical parameters involved in prognosis. In particular α-GPDH/6PGDH and α-GPDH/PFK ratios show significant differences between tumours from patients with no nodal involvement and those in whom four or more nodes were found to contain metastatic deposits.

Abstract—*The activities and isoenzyme distributions of soluble hexokinase were investigated spectrophotometrically and by cellulose acetate membrane electrophoresis in extracts of normal human brain, a series of fetal brains ranging in gestational age between* 6 *and* 42 *weeks and in* 27 *gliomas. The enzyme was first detected at* 14 *weeks gestational age, at a level approximately half of the normal adult level. Only one isoenzyme (type* I*) was present. The activity gradually increased until similar levels to those found in the adult were reached at term. The rise in enzyme levels was particularly rapid between* 35 *and* 40 *weeks. This rapid rise was associated with the appearance of a second isoenzyme of hexokinase (type* II*), first detected at the age of* 36 *weeks gestation. Normal adult brain contained type* I *hexokinase only. Further work needs to be done to determine when the type* II *enzyme disappears.*

Types I *and* II *isoenzymes were detected in fourteen of the gliomas studied, with a high incidence in the poorly differentiated tumours.*

INTRODUCTION

HEXOKINASE (ATP: D-Hexose-6-phosphotransferase. EC 2.7.1.1.) has been shown to exist in multiple molecular forms in mammalian tissues. Four isoenzymes have been identified by chromatographic [1] and electrophoretic [2] techniques. They have been numbered from I–IV in order of increasing mobility towards the anode. The distribution of types I–III has been shown to vary from tissue to tissue, at different ages and with the nutritional status of the animal [3–7]. Type IV hexokinase is the specific glucokinase [8, 9] and has been found only in liver and kidney [3–7, 10]. Mammalian brain has been shown to contain mainly type I hexokinase with a trace of the type II enzyme [5–7].

Studies of hexokinase in neoplasia have been mainly confined to experimental rat hepatomas. Several groups have demonstrated a progressive loss of glucokinase and an increase in hexokinase with increasing tumour malignancy [11–16]. Recently variations in the isoenzyme pattern have been observed in human uterine tumours [17, 18].

The present paper is a study of the activities and isoenzyme patterns of soluble hexokinase in normal adult human brain, in a series of 31 fetal brains ranging in gestational age from 6 to 42 weeks and in 27 gliomas.

MATERIAL AND METHODS

Glucose-6-phosphate dehydrogenase (G-6-PDH) and disodium nicotinamide adenine dinucleotide phosphate (NADP) were purchased from Boehringer Mannheim, West Germany; dithiothreitol (DTT), and phenazine methosulphate (PMS) from the Sigma Chemical Company, London; and all other reagents from British Drug Houses, United Kingdom. All reagents were of the purest grade available. "Celagram" cellulose acetate membranes (78 × 150 mm) were obtained from Shandon Scientific Company, United Kingdom.

Normal human cerebral tissues were either obtained at autopsy within 15 hr of death, or directly after surgical removal. The cases analysed ranged in age from 17 to 50 yr.

Fetal brains up to 28 weeks gestation were obtained from spontaneous or induced abortions and fetal brains between 28 and 42 weeks

gestation were obtained from post mortem specimens. None of these post mortems showed any evidence of cerebral abnormalities.

Samples of tumours of the nervous system were obtained directly after surgical removal.

All tissues were either used immediately or stored at −20°C until used. No changes were observed in enzyme activity or in isoenzyme patterns after storage of whole tissues or soluble cell fractions at −20°C for up to one month.

Samples were homogenised over ice in a bench homogeniser (Silverson U.K.) for two periods of 30 sec with a 1 min interval. The tissues were homogenised in 100 mM potassium phosphate buffer pH 7.4 containing 2 mM EDTA and 0.2 mM DTT. The crude homogenates were centrifuged at 20,000 × *g* for 45 min and the clear supernatant containing the soluble cell fraction filtered through gauze. Part of this fraction was made up to a final dilution of 1 in 10 with homogenizing buffer for enzyme assay. The remainder was made up to a final dilution of 1 in 4 prior to electrophoresis.

Hexokinase was assayed by coupling the enzyme reaction to the reduction of NADP by the G-6-PDH reaction and following the change in absorption at 340 nm in an SP1800A recording spectrophotometer (Pye Unicam, U.K.) with a constant cell temperature of 37°C. The assay system was essentially that of Beutler [19] and consisted of a 10 min preincubation of the enzyme preparations in 0.1 M Tris/HCl buffer pH 8.0 containing 2.0 mM D-glucose, 0.2 mM NADP, 0.2 units/ml of G-6-PDH and 3.0 mM magnesium chloride. The reaction was initiated by the addition of ATP at a final concentration of 3.0 mM. Addition of 0.2 units per ml of 6-phospho-gluconate dehydrogenase caused no further increase in enzyme activity.

Total protein concentrations were measured by the automated modification of the biuret reaction [20].

A unit of enzyme activity is defined as the amount of enzyme which will convert 1 μmole of D-glucose to glucose-6-phosphate/min/mg protein under the assay conditions at 37°C.

Electrophoretic procedure was adapted from a previously reported method [18]. Eight samples of approximately 0.1–0.2 munits of enzyme activity were run side by side on each cellulose acetate membrane using a buffer concentration of 50 mM barbitone, 5.0 mM EDTA, 1.0 mM DTT and 10.0 mM D-glucose at pH 8.6. A total potential of 28.2 V/cm was applied for 1 hr by which time a marker of albumen-bound bromophenol blue had migrated 4.8 cm towards the anode. The isoenzymes were localised *in situ* by placing the membrane in contact with a 0.5% agarose gel containing 50 mM Tris, 5.0 mM ATP, 5.0 mM $MgCl_2$, 2.0 mM KCN, 0.5 mM NADP, 25 μg/ml PMS, 0.4 mg/ml nitro blue tetrazolium, 0.2 units/ml G-6-PDH and 10.0 mM D-glucose at a final pH of 8.2. Incubation was carried out at 37°C for 1 hr in the dark after which time the insoluble blue bands associated with enzyme activity could be seen. The membranes were fixed in 5% acetic acid for 15 min and scanned at 578 nm with a vitatron densitometer (Fisons, U.K.).

Controls were set up using identical electrophoretic conditions but in this case the membranes were stained in a medium lacking substrate (D-glucose) and no bands of enzyme activity were seen on any of these membranes.

RESULTS

The pattern of development of hexokinase activity in fetal brain is shown in Fig. 1. The enzyme was first detected at the gestational age of 14 weeks and at this time the level was approximately half that found in the normal human adult brain. This level showed a gradual increase throughout gestation reaching the adult level at term.

There was no significant difference in the activity of hexokinase in adult grey and white matter in material obtained at autopsy, but the activity in grey and white matter was slightly higher in fresh surgical specimens than in grey and white matter obtained at autopsy. Mean hexokinase activity in autopsy specimens was 0.0030 μmole/min/mg protein ($N=10$, S.D. $=0.0018$) whilst that for surgically removed specimens was 0.0038 μmole/min/mg protein ($N=28$, S.D. $=0.0016$). This indicates a slight loss of activity during autolysis.

Electrophoresis of fetal and adult brain homogenates showed that during the first 36

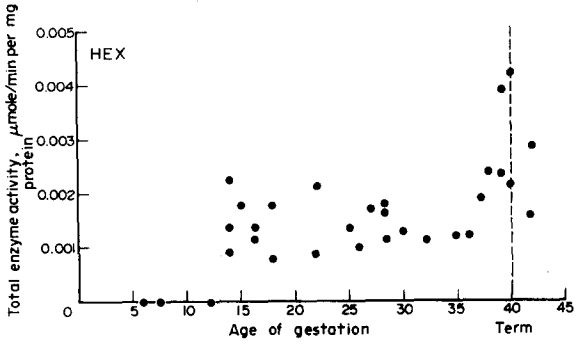

Fig. 1. The development of hexokinase activity in fetal human brain. Extracts of fetal brain were prepared and assayed spectrophotometrically by the method described in the text. The corresponding adult mean values are 0.0030 μmole/min/mg *protein* (units/min/mg *protein*) *for autopsy specimens and* 0.0038 μmole/min/mg *protein for surgical specimens. The horizontal axis is gestational age in weeks.*

*Standard deviation.

weeks of gestation and in adult specimens, only one band of hexokinase, type I, was present, whilst during the last 4–6 weeks of gestation two isoenzymes, types I and II, were consistently observed (Fig. 2).

In an electrophoretic survey of 25 astrocytomas (15 grade IV, 6 grade III and 4 grade II), type II hexokinase was seen in 10 of the grade IV astrocytomas, in one of the grade III astrocytomas and in 2 of the grade II astrocytomas. The more benign gliomas, including two of the grade II tumours, a single ganglioglioma, and a well-differentiated ependymoma, showed an identical pattern to that of normal adult brain. Electrophoresis was carried out on samples showing approximately similar activities of enzyme and the relative proportions of each isoenzyme present were calculated by integration of the respective peak areas after scanning (Table 1).

DISCUSSION

Between 15 and 44% of hexokinase in the mammalian brain has been shown to be mitochondrial-bound [21, 22]. It has also been suggested that the soluble hexokinase in brain is largely of glial cell origin and that the particulate fraction is neuronal [23]. In the present study only soluble hexokinase was measured and the results obtained could bear a direct relationship to the glial cell content. All tumours studied were glial cell in origin.

The study has shown that the soluble fraction of hexokinase, the major glycolytic rate limiting enzyme in brain [24] appeared in significant quantities at about 14 weeks gestational age. Other glycolytic enzymes including aldolase, pyruvate kinase, phosphofructokinase and phosphoglucomutase have also been shown to appear at this age in man [25]. Since soluble hexokinase may be a marker of glial cells in brain this period may coincide with an important period of glial cell development.

Electrophoretic studies show that only type I hexokinase was present in fetal brain up to 36 weeks gestational age when the type II isoenzyme appeared. This enzyme is not present in the normal adult human brain and the significance of its appearance late in fetal development is unclear. There is clearly a need for further work on this enzyme.

Type II hexokinase was also found in many of the gliomas studied. The highest incidence was seen in the more malignant tumours (grade IV). The presence of this enzyme in neoplastic and fetal brain and its absence in adult brain implies that the isoenzyme is a carcino-embryonic antigen, one of a large number that have now been described [26, 27]. The appearance of the enzyme does not signify a dedifferentiation towards primitive undifferentiated forms since the isoenzyme was only observed in the later stages of development when the tissues are showing evidence of differentiation. It seems that this reversion is towards a highly specialised period of cerebral development implying an ordered alteration in genetic activity in this particular case. The fact that the isoenzyme form appeared predominantly in the more malignant tumours implies that this particular misprogramming of genetical information is a consequence of neoplasia and not a cause of it.

Abstract—*AAFC is a fluorinated anhydride analog of cytosine arabinoside, partially hydrolysed* in vivo *into ara-FC and ara-FU. Antitumor activity has been observed during phase* I *studies in acute leukemia and solid tumors.*

A hundred and sixty six patients with advanced tumors belonging to selected histological types received AAFC, 15–20 mg/kg *daily* × 5 *q3w, or* 33–40 mg/kg *weekly i.v. during* 3 *weeks or longer. One hundred and thirty-two observations were fully evaluable including* 67 *without and* 65 *with prior chemotherapy. Responses were observed in adenocarcinoma of stomach* (7/14), *pancreas* (2/3) *and colon and rectum* (2/32), *epidermoid carcinoma of head and neck* (4/30), *breast carcinoma* (1/17) *and small cell carcinoma of lung* (1/9), *but not in epidermoid carcinoma of lung* (0/27). *Both treatment schedules were active. There were* 8/67 *responders among not pretreated and* 9/65 *among pretreated patients.*

Toxicity was more pronounced after daily × 5 *application. The limiting toxicity consisted in anemia, leucopenia, thrombopenia, nausea and vomiting. Parotid pain or postural hypotension were not observed.*

INTRODUCTION

ANHYDRO-ARA-5-FLUOROCYTIDINE (2,2′-anhydro-arabino-5-fluorocytosine, AAFC, NSC-166641) is a new arabinosylcytosine (ara-C) derivative with pharmacological features suggesting a possible superiority to ara-C as an antineoplastic agent. Like other similar cyclo- or halogenated compounds it is more resistant to deamination than ara-C resulting in a longer half life in blood [1]. This point is of clinical importance, considering the S-phase specific properties of ara-C and ara-C derivatives. The physiological disposition of AAFC is characterized by a conversion to arabinosyl-fluorocytosine (ara-FC) and arabinosyl-fluorouracil (ara-FU), two active antitumor substances [2]. Moreover, it has been postulated that AAFC could be active on its own, being mainly excreted unconverted and more active than ara-C in ara-C resistant leukemia-cell lines [3]. Finally, it has been demonstrated that, contrary to ara-C, AAFC can be given at a therapeutically

Accepted 10 October 1977.

active dose by single weekly i.v. injections and that its use is not limited, as for cyclocytidine [4], by parotid pains or postural hypotension.

AAFC has been shown to be active in human acute myeloblastic leukemia, either alone or in combination [5]. The present report constitutes the first large clinical investigation of the use of AAFC in adult patients with solid tumors. A progress report on 105 cases has already been presented in abstracted form elsewhere [6].

MATERIAL AND METHODS

Selection of patients

The eligibility was restricted to a limited number of tumors. Epidermoid carcinoma of head and neck and of lung and adenocarcinoma of stomach, colon, rectum and pancreas were considered tumor types of first priority because of their poor responsiveness to available agents. Carcinoma of the breast and anaplastic small cell carcinoma of the lung were also considered eligible because of their frequency and of the great number of patients surviving with tumors primarily or secondarily resistant to other available treatments. All other tumor types were rejected, not because they were judged less important, but as a consequence of practical considerations concerning the number of observations statistically required for each tumor type studied. The criteria for inclusion were a histologically confirmed tumor diagnosis corresponding to one of the selected tumor types, measurable and evolutive disease not suitable for surgery or radiation therapy, a Karnofsky performance >40, age >15, granulocytes $>2500/mm^3$, thrombocytes $>100{,}000/mm^3$, blood creatinine $<1.5/100$ ml. Patients with a second tumor, or with overt psychosis, senility or central nervous system lesions were excluded. Pleural effusions, bone and brain metastases were not considered measurable lesions. Patients were not eligible during or immediately after other chemo- or radiation therapy as well as during the first three weeks after the last day of the previous treatment. The only exception was a palliative radiation on a limited bone lesion outside the location of measurable tumor masses.

Treatment schedules

The treatment schedules compared correspond to the ones used in two Phase I studies in solid tumors [7, 8]:

1. AAFC 15 mg/kg body weight daily for five consecutive days by rapid i.v. injections in one daily dose to be repeated every three weeks;
2. AAFC 33 mg/kg body weight in one weekly rapid i.v. injection to be repeated weekly.

The dose was modified according to toxicity or a weekly dose omitted. Anti-emetics were largely used to counteract nausea and vomiting. Whenever possible, the treatment was pursued for 6 weeks or more, unless it was considered in the interest of the patient to stop it earlier. The dose originally scheduled in regimen 1 was 20 mg/kg/day. A severe haematologic toxicity encountered in the first patients in regimen 1 required a downward modification to 15 mg/kg/day. Later during the study, it appeared that even after this dose modification regimen 2 was less toxic and apparently as active as regimen 1 so that this latter was dropped and the dose for regimen 2 raised to 40 mg/kg/week.

Mechanics of the study

Principal investigators and institutions participating in this study as members of the Group are mentioned in Table 1. The study was activated in February 1975 and closed in May 1976. The final analysis was made on follow-up data available as of December 1976. Patients registration and randomization were centralized at EORTC Data Center in Brussels. Patients were randomly allocated to one of the two treatment schedules defined in the above section on a 1:1 rate. Randomization was stratified with regard to institution, tumor type and previous treatment with chemotherapic agents. Treatment results quoted as objective response by local investigators were presented with all available documents at Group meetings and the final assessment of the therapeutic result for each of these cases was made by general agreement of all Group members. All protocol documents were finally reviewed for eligibility, quality of data recording, protocol violations and treatment results by the chairman and the secretary of the Group.

Tumor measurements, drug toxicity, tumor symptoms, weight, temperature, analgesics and other treatments and a complete blood count were registered before treatment and at weekly intervals. Blood creatinine, alkaline phosphatase and transaminases were registered every three weeks.

Evaluation of response

Patients records were considered inevaluable whenever one or more of following reasons were present: ineligibility, incomplete data,

Anaplastic small cell carcinoma of lung	3	6	0	1	1	2	1	14
Total	45	87	1	2	8	8	15	166

T.R.: Treatment refused.
L.F.: Lost to follow-up within first 2 weeks of treatment.
I. : Ineligible.
P.V.: Protocol violation.
I.D.: Incomplete data.

improper randomization, major protocol violation, early loss to follow-up (first two weeks of treatment) and treatment refusal. Evaluable observations were classified in five response categories. Complete response corresponds to a complete disappearance of all measurable

tumor lesions. Partial response corresponds to a decrease of more than 50% of the product of the two largest perpendicular diameters of all measurable lesions without appearance of other tumors. In case of metastatic liver enlargement or other deep abdominal tumor masses, a reduction by 75% of the evaluated tumor mass was required. Stable disease corresponds to minor variations within upper and lower 50% limits. Progression corresponds to a 50% or more increase of the product of perpendicular diameters of measurable lesions, or a 75% increase of evaluable tumor masses. Early death corresponds to patients dying within the first three weeks of treatment. In this category, an attempt was made to distinguish between tumor related and treatment related death.

RESULTS

Antitumor effect

One hundred and sixty-six patients were registered and randomized. Thirty-four patients were rejected as being not evaluable: 8 were ineligible, 15 for incomplete data, 8 for major protocol violation, 2 were lost to follow-up and 1 for treatment refusal. Among 132 evaluable patients, 6 were treated at 20 mg/kg × 5 days every 3 weeks, 39 at 15 mg/kg × 5 days every 3 weeks, 53 at 33 mg/kg weekly and 34 at 40 mg/kg weekly. The distribution of patients by cell type is seen in Tables 2 and 3.

AAFC was found to be ineffective in epidermoid carcinoma of lung. A low grade activity was observed in epidermoid cancer of head and neck, with 4 responses in 30 patients, corresponding to a response rate of 13.3% (95% confidence limits of 3.8% and 30.7%) and in adenocarcinoma of colon and rectum with 2 responses in 32 patients or 6.3% (95% confidence limits of 0.8% and 20.8%). AAFC was found active in the group of adenocarcinoma of stomach and pancreas with 9 responses in 17 patients, or a response rate of 52.9% (95% confidence limits of 27.8% and 77.0%). For anaplastic small cell carcinoma of lung, 1 response was observed in 9 patients and for breast carcinoma 1 response in 17 patients (Table 3).

Comparing the treatment schedules, the overall response rate was 3/45, or 6.7% for regimen 1 and 14/87, or 16.1% for regimen 2. Focusing on adenocarcinoma of the stomach and pancreas, the corresponding response rates are 1/5, or 20% for regimen 1 and 8/12, or 66.7% for regimen 2. These differences are not significant at the level of probability $P = 0.05$ (chi square test corrected). There is no difference

‡Censored observation.

in response rate for patients previously treated (9/65, or 13.8%) with other antitumor agents and for untreated patients, (8/67 or 11.9%). For G.I. tract and pancreas tumor patients responses were observed in 4/22 or 18.2% and 7/27 or 25.9% respectively. Patients with G.I. tumors previously treated did receive FU and were probably resistant to it at the time they entered the AAFC trial.

Duration of response

The median length of remission for responders, defined as the time elapsed between the first evidence of tumor regression and tumor relapse, was 9 weeks (2–55 weeks). Responses were obtained after 2–12 weeks. The median duration of treatment for responders was 8 weeks (3–42 weeks). Because of the great heterogeneity of the patients treated the survival from treatment day 1 varies considerably from 4 weeks to more than 71 weeks, among treatment responders (Table 4).

Toxicity, tolerable dose

The dose limiting toxicity of AAFC consisted of myelosuppression and gastric intolerance. Besides leucopenia and thrombocytopenia anemia was frequent and severe with a loss of hemoglobin concentration reaching 25–35% of the initial figure. Red cell transfusions were required in many cases during and after AAFC treatment. The hematologic toxicity was proportional to the dose (Table 5). Treatment regimens in 5 days were more toxic than weekly injections. Myelosuppression was observed at the time of 5 deaths, caused by sepsis, hemorrage or acute cardiac failure. Nausea and vomiting appeared frequently during the first few hours after injection. Their intensity appeared not to be significantly modified during treatments with a constant dose. In many cases, they were accompanied by general malaise and profound weakness, part of which possibly explained by anemia. Stomatitis was another frequently observed side effect, usually mild and never requiring interruption or modification of the treatment. Skin rashes, jaw pains or postural hypotension or alopecia were never observed.

The percentage of the theoretical dose actually received and the median duration of treatment are given in Table 6 for each treatment schedule. At 15 mg/kg and 33 mg/kg the actual dose is close to 100% of the theoretical figure. At 40 mg/kg weekly, the actual dose, corresponding to 84% of the theoretical one, is not significantly greater than the dose received at 33 mg/kg.

DISCUSSION

The most striking result of this study has been the antitumor activity observed in adenocarcinoma of stomach and pancreas. In a previously published Phase I study of AAFC, one objective response was also observed in three patients with pancreas carcinoma [6]. As AAFC is partially transformed *in vivo* to

ara-FU. it could be questioned whether the observed antitumor activity in digestive adenocarcinomas must be related to FU-like effect. There are serious arguments against this hypothesis. The fraction of AAFC converted to ara-FU is very small [1]. Moreover, the absence of activity of AAFC in colorectal tumors and of difference in response for patients previously treated or not is hardly compatible with AAFC acting as an analog of FU.

AAFC seems thus more probably to act as an analog of ara-C, either after transformation in ara-FC, or as AAFC itself. The antitumor effect of ara-C in gastric and pancreatic carcinoma has not yet been completely demonstrated, although tumor responses have been reported [9–11].

Epidermoid carcinoma of head and neck is the only other tumor where a low grade activity has been documented. This finding is in concordance with observations made in Phase I study, where two responses have been noticed for the same tumor type [6].

Comparing the two treatment schedules used here, the first observation is that the majority of responses have been obtained after weekly i.v. injections. Given the limited number of responses obtained no clear conclusion can be drawn from this fact, except that AAFC is active when injected once weekly thus allowing for long term out-patient treatment. The total dose tolerated in 3 or 6 weeks is smaller when AAFC is given in 5 days every 3 weeks than once weekly. At 15 mg/kg/day, in regimen 1, the total dose in 6 weeks is 150 mg for a toxicity close to the upper tolerable limit. At 33 mg/kg weekly in regimen 2, the total dose in 6 weeks is 200 mg with a lower toxicity than in regimen 1. This schedule dependence of tolerable dose resembles that observed with other pyrimidine nucleotide analogs like ara-C [9] or 5-fluoro-2′-deoxyuridine [12].

In conclusion AAFC can be considered as a new depot form of ara-C with increased resistance to deamination. It can be safely and efficiently used by single weekly rapid intravenous injections during 3–6 weeks or even more. The foregoing data suggest that AAFC is active in various solid tumor types, particularly adenocarcinoma of the stomach and pancreas. The results of this early Phase II study obtained on a limited number of patients support the view that the antitumor activity of AAFC deserves a further clinical investigation, particularly for solid tumor types where ara-C has shown some activity.

Acknowledgements—The authors wish to thank Hoffman-La Roche for supplying the AAFC (RO 21-0702) used in this study.

Letter to the Editor

New E.O.R.T.C. Trial on Early Hodgkin's Disease (HV)

J. M. V. BURGERS

President, Radiotherapy–Chemotherapy Group, Antoni van Leeuwenhoekhuis, Plesmanlaan 121, *Amsterdam, The Netherlands*

ONE OF a number of working parties and cooperative groups of the European Organisation for Research on Treatment of Cancer (EORTC), is the Radiotherapy–Chemotherapy group.

Under the presidencies of Professor Tubiana, Professor Breur, Professor van der Werf-Messing and Professor Abbatucci, this group is conducting a number of clinical trials on early stages of Hodgkin's disease (H I, H II), on non Hodgkin lymphomas (L-R I, L-R II), on Ewing sarcoma (E I) and on osteosarcoma (O II).

The early results on the H I trial have been published [1]. Reports on the other trials are being prepared and will be submitted to the *European Journal of Cancer* [3]. New trials, on Hodgkin's disease stage III B, osteosarcoma and ovarian tumors are in progress of formulation.

A new trial on early stages of Hodgkin's disease (clinical stage I and II above diaphragm) (H V), has started in January 1977. The final protocol was decided by Burgers (Amsterdam), Hayat (Paris), Lebourgeois (Paris), Rosenburg (Stanford), Sizoo (Rotterdam) and Tubiana (Paris). The aim of this trial is to compare intensive initial treatment with a high chance of cure but certain risks with less intensive initial treatment, and in case of relapse, second treatment with curative intent. The patient material will be stratified into two groups, one with favourable prognostic signs, the other with less favourable prognostic signs. The subgroup with favourable prognostic signs includes patients who have LP or NS histology and stage I, or stage II with positive mediastinum and age below 40 yr and have ESR below 70 mm and a negative spleen.

This group comprises about 25% of the patient material and for them splenectomy is obligatory. The treatment comparison is between mantlefield irradiation, 4000 rad in 4 weeks, and mantlefield + paraaortic bar irradiation, 4000 rad in twice 4 weeks.

The remaining patients have less favourable prognostic signs. Splenectomy is not done in these patients. Their treatment consists of either total nodal and spleen irradiation, 4000 rad in 2 or 3 periods of 4 weeks, or 3 courses of MOPP followed by mantlefield irradiation to 3500 rad in 4 weeks followed by 3 further courses of MOPP. The endpoints to be studied are:

(a) Length of disease free survival in first, and second remission, and survival.
(b) Complication rate (including sterility), and performance status.
(c) Development of secondary malignant disease.

Some of the reasons for setting up this trial are as follows:

1. In the H I study (mantlefield irradiation only, no splenectomy), in the favourable group the disease free survival is 72 % (mean FU 8 yr). In the H II study (mantlefield + paraaortic bar irradiation and negative splenectomy), the disease free survival is 94% (mean FU $2\frac{1}{2}$ yr). As a number of relapsing patients in this part of the H I study could be cured with a second treatment, there may be some overtreatment in this H II subgroup.
2. In the H II study, there is no difference in disease free survival with splenectomy or spleen irradiation. No kidney damage has as yet come to light. In the patients with less favourable prognostic signs, and NS histology, where no chemotherapy was added, the recurrence rate was high (50%) mainly in iliac glands or in irradiated areas.
3. According to a British lymphoma study [2] for patients in stage IIIA (pathological), total nodal irradiation gave a higher

remission rate than MOPP (6 courses), namely 70% vs 50% (mean FU 2 yr). Recently it was proposed to combine MOPP with "iceberg" irradiation.

4. MOPP induces sterility in males and some females. Total nodal irradiation induces no sterility in males. Females below 40 yr are rare in the "less favourable" group. The ovaries can be transposed but it is also permitted to omit iliac irradiation in this group. Fewer secondary malignancies are expected in the TNI group than in the MOPP + RT group (from several as yet unpublished sources: ± 1%).

We expect the following rates of disease free survival in the respective groups:

(a) Favourable signs, mantlefield irradiation only: >70%. High chance of cure in relapsing patients with second treatment.

(b) Favourable signs, mantlefield + paraaortic bar irradiation: 95%.

(c) Less favourable signs, total nodal irradiation: >70%. Second treatment (eg MOPP) possible in relapsing patients.

(d) Less favourable signs, MOPP + RT: >70%.

European Centres desiring more information, or desirous of participation in this trial, are invited to write to the secretariat of the EORTC Radiotherapy–Chemotherapy Group.

Preliminary Trial of 9-Hydroxy-2-Methyl Ellipticinium (NSC 264–137) in Advanced Human Cancers

P. JURET,* A. TANGUY,* A. GIRARD,* J. Y. LE TALAER,* J. S. ABBATUCCI,* N. DAT-XUONG,† J. B. LE PECQ‡ and C. PAOLETTI‡

**Centre François Baclesse, 14018, Caen, France, †Institut de Chimie des Substances Naturelles du CNRS 91190 Gif-sur-Yvette, France, ‡Laboratoire de Chimiothérapie Expérimentale de l'Institut Gustave-Roussy, 94800 Villejuif, France*

ELLIPTICINE and some of its derivatives are endowed with antitumor properties in animal [1–3]. 9-Methoxy-ellipticine has been used with some success in human myeloblastic leukemia [4–5]. The effects of these compounds could be related to their ability to bind and intercalate into DNA [6]. According to this hypothesis, a search for new ellipticines was carried out with an *in vitro* screen. Before being tested in standard conditions on experimental tumors, the compounds were first assayed for their affinity to DNA. Along these lines, we have selected a new compound, 9-hydroxy-2-methyl ellipticinium (9H2ME in this paper), carrying a quaternarized nitrogen, which displays a very favorable chemotherapeutic index on leukemia L 1210 [7]. This drug is submitted to a clinical trial on solid human tumors: the preliminary results concerning the first 18 patients are reported in this paper.

All the patients had advanced solid cancers which could not be treated longer with other usual chemical drugs, either owing to the fact that they were inefficacious or as a consequence of a severe impairment of the leucocyte or platelet blood count.

Table 1. *Preliminary results obtained with 9-hydroxy-2-methyl ellipticinium in* 18 *advanced cancers*

Number of patients	18 (14 ♀; 4 ♂)
Weekly doses	from 4 mg/m^2 to 110 mg/m^2
Number of injections in each patient	from 2 to 26
Total dose in each patient	from 10 to 1800 mg
Number of remissions	8: breast 5 (bone metastases—local recurrences) bronchus 1 (small cell anapl.) thyroid 1 (anaplastic) colon 1 (lung metastases)
Duration of effect	from 1.5 month to > 7 months
Failures	8 (7 breasts—1 larynx)
Not evaluable	2

The drug was administered intravenously at weekly intervals. The first patients were given 4 mg/m^2 in each injection as this weekly dose seemed to be reasonable according to previous toxicological studies on animals [7]. Yet in the face of the unexpected good tolerance of 9H2ME by patients, these injections were progressively increased up to 110 mg/m^2. As a matter of fact, one did not usually exceed 70–80 mg/m^2 as digestive troubles occurred more frequently and intensively beyond this dose.

Accepted 12 September 1977.

The results of this trial are summarized in Table 1. In this table, "objective remission" is defined as an obvious objective clinical, radiological or scintigraphic improvement lasting longer than 1 month, whatever the importance of this improvement.

In the 16 patients who could be evaluated, administration of 9H2ME resulted in objective remissions whose length at the present time reaches from 1 month to > 7 months.

Leucocytes and platelets counts were non affected by this treatment even in patients who were given high doses. No enzymatic trouble, no renal disturbance were found. In the matter of side effects, one has only noted nausea or vomiting for a short time in about half of the patients, transient variation of blood pressure (increase in 3 cases, decrease in 2 cases) and transient rise of temperature (6 cases). The only serious accident which was noted concerns an anaplastic carcinoma of the thyroid. Paradoxically this accident underlines the efficiency of 9H2ME. The patient's lesions which surrounded the neck shrank rapidly. Feeding *per os* could be resumed. The patient died suddenly from a jugular-carotid haemorrhage as a result of the tumor regression.

These preliminary data demonstrate that a new ellipticine derivative, characterized by a low hematologic, hepatic, nervous or renal toxicity, is able to induce objective remissions in solid human cancers, mainly breast tumors and its metastases. It is submitted to further clinical studies in order to determine the optimal indications, dosages and schedules.

Announcement

E.O.R.T.C. SYMPOSIUM ON CONTROVERSIES IN CANCER TREATMENT

To be held in Brussels on 26–29 April, 1978, the first day of which will be devoted to controversies on design and analysis of clinical trials.

Abstracts (in English) of free communications on cancer therapy must be submitted by 15 February, 1978 (to be presented on 29 April).

For details and registration, write to: Dr. M. Staquet, E.O.R.T.C. Data Center, Institut Jules Bordet, rue Héger-Bordet 1, 1000 Bruxelles.

This symposium will be held 2 rue Evers, 1000 Bruxelles (1st floor). Attendance will be limited to the first 200 registrations. Registration fee: 3000 Belgian francs.

Perspectives in Cancer Research

Expression of Hormone Receptors in Cancer Cells: A Hypothesis

M. CIKES

Ludwig Institute for Cancer Research, CH-1066 Epalinges-sur-Lausanne, Switzerland

Abstract—*It is postulated that the quantitative and qualitative changes of hormone receptors observed in cancer cells are a consequence of retrogenic expression resulting in appearance of cellular properties characteristic of certain developmental stages of the normal parental cells. As an example, the high levels of hormone receptors found in some human breast cancers may reflect a transition to normal developmental stages of the mammary gland. The occurrence of "ectopic" hormone receptors in cancer cells may be regarded as a paradigm of "ectopic" hormone production observed in a variety of human tumors. The altered expression of hormone receptors may be responsible for excessive hormonal stimulation of cancer cells.*

INTRODUCTION

MALIGNANT transformation of cells is not infrequently accompanied by quantitative and qualitative changes in responsiveness to hormonal stimulation. Since hormones exert their effects on target tissues via specific receptors located either on the cell surface or in the cytoplasm, it seems probable that the changes in hormone responsiveness in neoplasia are a result of variations in the number of functionally active hormone receptors.

The hypothesis advanced here postulates that the changes of hormone receptors in cancer cells reflect the transition of cellular properties to certain developmental stages of their normal counterparts.

Conceptually, the idea of reversion in cancer cells to more immature developmental stages can be traced back to 1874 and since then it has been revived in various forms [1]. The occurrence in cancer cells of fetal enzymes and antigens is well documented (for review see ref. [2]). For the purpose of this discussion, it is of secondary importance whether the transition to more immature stages has been affected by blockade of the normal ontogenetic process or by dedifferentiation of normal adult fully differentiated cells. However, it is clear that neoplastic tissues frequently demonstrate properties characteristic of fetal cells and tissues.

Accepted 27 April 1977.

QUANTITATIVE CHANGES OF HORMONE RECEPTORS IN CANCER CELLS

The best known example of quantitative changes of hormone receptors is human breast cancer. The determination of hormone receptors in human breast tumors has been widely used to predict tumor response to hormonal treatment [3]. These studies have revealed a wide range of estrogen receptor (ER) content in extracts from breast cancer tissues [4, 5]. Although the ratio of parenchymal to connective tissue components can account for some of the many fold differences in the concentration of ER found in the malignant breast tissues, it is insufficient to explain the wide range [6]. Moreover, normal resting mammary gland tissue, a target organ for estrogen, contains comparatively low or undetectable amounts of ER [7–10].

The levels of ER found in some human breast cancers are comparable to those found in the mammary gland during lactation. It is interesting to mention that as early as 1896 Sir George Thomas Beatson, who inaugurated ovariectomy for palliation of advanced human breast cancer, noticed a similarity between breast cancer in young women and the lactating mammary gland. "It was clear to me that the changes that take place in the mammary gland in the process of lactation are almost identical, to a certain point, with what takes place in a cancerous mamma [11]."

In agreement with Beatson's original observation are the more recent findings showing a similarity in hormone receptor content in breast tumors and the lactating mammary gland. Beers and Wittliff [12] found that ER content in infiltrating ductal carcinoma of human breast was similar to that of the lactating mammary gland. Prolactin receptor content in R3230AC rat mammary carcinoma was similar to that of the normal rat lactating mammary gland [13], while the levels of prolactin receptors in DMBA-induced rat mammary tumors may even exceed that in lactating mammary gland [14]. addition, Hilf *et al.* [15] showed that transplantable rat mammary carcinoma R3230AC responded to estrogen with enzyme changes associated with lactation. The same rat mammary tumor had similar RNA-ase and RNA-ase inhibitor levels as the lactating rat mammary gland [16].

Alterations of hormonal responsiveness in neoplastic tissues have frequently been observed in animal models. Rat mammary tumors induced by dimethylaminobiphenyl had about 5 times higher levels of cyclic AMP and responded stronger to epinephrin stimulation than normal breast tissue [17]. It seems probable that the responsiveness of tumor tissues to hormonal stimulation, as measured by changes in adenyl cyclase activity reflects, at least in part, the quantitative changes of specific hormone receptors. Machia *et al.* [18] and Mandato *et al.* [19] showed that the reduced activation of the adenyl cyclase activity in a transplantable rat hepatoma after stimulation with TSH was due to a decrease in binding of the hormone to the tumor plasma membranes. Prostaglandin caused a greater augmentation of cyclic AMP in malignant hepatomas than in uninvolved liver and benign hyperplastic nodules of ethionine treated rats [20]. An increase of the isoprotenol responsiveness and the decrease of the glucagon responsiveness was observed in the preneoplastic livers of rats fed a diet containing 3'methyl-4-dimethyl-aminoazobenzene [21]. These changes in hormone responsiveness were similar to those found in fetal and perinatal rat liver [22, 23]. A comparison of cyclic AMP response to glucagon stimulation in a series of Morris hepatomas with various degrees of differentiation showed that the response of highly differentiated hepatomas was similar to mature rat liver, whereas the response of the less differentiated tumors resembled that of fetal or newborn rat liver [24]. Kelly *et al.* [25] reported that the increase of cyclic AMP after stimulation with catecholamines and prostaglandins was much higher in SV40-transformed WI-38 cells than in the normal untransformed cells. Mammary tumors induced by estrogen and progesterone in spayed GR mice had ten times higher levels of estrogen receptor than normal mammary gland tissues from the same animals [26].

These findings suggest that the alterations of responsiveness to hormonal stimulation and the changes of the levels of hormone receptors observed in tumorous tissues might reflect a transition in tumor cells to certain developmental stages of the normal fully differentiated parental tissues.

QUALITATIVE CHANGES OF HORMONE RESPONSIVENESS IN CANCER CELLS

The first indication of tumor stimulation by "inappropriate" hormones was obtained in a corticosterone producing rat adrenortical carcinoma [27]. ACTH stimulated the adenyl cyclase activity both in the tumor and normal rat adrenal tissue. However, the tumor adenyl cyclase activity was stimulated by epinephrine, norepinephrine and thyroid-stimulating hormone (TSH) while the normal rat adrenal tissue was unresponsive to these hormones. The tumor possessed also receptors for luteinizing hormone (LH) and follicle stimulating hormone (FSH) as well as the beta adrenergic receptor. The tumor enzyme failed to respond to glucagon, vasopressin, parathyroid hormone or thyrocalcitonin. The same authors later examined a series of human tumors for the response to hormone stimulation [28]. Two parathyroid adenomas composed of chief cells were stimulated by glucagon while an oxyphil parathyroid adenoma failed to respond to any hormone tested. These investigators did not examine normal human parathyroid tissue for stimulation with glucagon. However, the cyclase activity of dog parathyroid has been reported to respond to glucagon stimulation [29]. Schorr *et al.* [28] found that the cyclase activity of a thyroid follicular carcinoma was stimulated by TSH and LH. The TSH stimulation was more intensive in the tumor than in the colloid goiter. However, the posssibility of contamination of LH preparations with TSH was not excluded. ACTH stimulated the adenyl cyclase activity of a chromophobe hypophyseal adenoma. Normal dog pituitary was not stimulated with ACTH. A pheochromocytoma from a patient with bilateral localization of the tumor responded to glucagon, ACTH and TSH stimulation. Pheochromocytomas from another two patients were unresponsive to any hormone tested. The cyclase activity of the normal bovine adrenal medulla

was reported to be unresponsive to glucagon [30]. In a later study Hinshaw and Ney [31] reported that 3 of 9 human pheochromocytomas were stimulated by glucagon while the normal human adrenal medulla did not respond to this hormone. Two of four human adrenocortical tumors were responsive to both ACTH and LH and one of them responded with a 40% decrease in 17-hydroxy-steroid excretion after administration of triiodothyronine in doses sufficient to suppress the endogenous TSH. The other two adrenocortical tumors were not stimulated with any of the hormones tested.

More recently, Lacombe *et al.* [32] observed a qualitative change of adrenoreceptors in Zajdela hepatoma of rat. Normal rat liver possesses the β_2 adrenoreceptor characterized by stimulation with catecholamines in the following order of potency: proctokylol > isoproterenol > adrenalin > noradrenalin. The adrenoreceptor found in Zajdela hepatoma was of the β_1 type with catecholamines in the following order lamine stimulation: isoproterenol > proctokylol > noradrenalin > adrenalin.

EXPRESSION OF HORMONE RECEPTORS AND GROWTH CONTROL

Cellular changes relevant to malignant behaviour of cells will be those that will enable the cells to survive and multiply in an environment that imposes an efficient growth control on normal tissue components. Generally, 2 ways can be envisaged of how cells could escape the growth control signals. One is the acquisition by the cells of receptors for growth promoting stimuli; the other is a loss of receptors responsible for mediation of growth restricting influences. The hypothesis advanced here is primarily concerned with the former escape mechanism. The high levels of hormone receptors frequently found in cancer cells is a prerequisite for the stimulating effect of circulating hormones on cancer cells. The concentrations of hormone receptors in a proportion of human and animal tumors were higher than in the normal parental tissues and comparable to that of the parental tissues during the fetal stage or the physiologic periods characterized by high susceptibility to hormonal influences. These findings make it likely that the quantitative and qualitative changes observed in cancer cells are a consequence of the acquisition by cancer cells of hormone receptor properties characteristic of stages in the normal differentiation of the cell of origin.

It is conceivable that the presence in neoplastic cells of high amounts of hormone receptors will enable these cells to proliferate in an environment with relatively low concentration of circulating hormones, while normal cells will be less stimulated in the same environment. A significant correlation has indeed been found between the degree of prolactin binding activity in rat mammary tumors and prolactin-induced growth response of these tumors [33]. Consistent with these observations is a report demonstrating a direct correlation between ER concentration in human breast tumors and their response to hormonal treatment [4].

The appearance in cancer cells of "ectopic" hormone receptors promotes autonomy of the tumor since the tumor cells may be stimulated by hormones other than the ones which stimulate the normal parental tissue. "Ectopic" hormone receptors may be regarded as a paradigm of ectopic hormone production, a phenomenon frequently encountered in a variety of human tumors [34]. The production of ectopic hormones by tumor tissues is not a chaotic process; it is regarded as an ontogenic phase-specific event whose appearance is determined by the embryological origin of the normal parental tissue [34]. The same might apply for "ectopic" hormone receptors.

Early Events During C1300 Neuroblastoma Cell Interaction with Syngeneic Lymphocytes

M. FIORANI, R. BUTLER, L. BERTOLINI and R. REVOLTELLA

Laboratory of Cell Biology, C.N.R., v. Romagnosi 18*A*, *Rome, Italy*

Abstract—*Rosette formation leading to specific target cell lysis has been shown between spleen lymphocytes and syngeneic cloned C1300 neuroblastoma cells. These two phases of cell interaction could be separated by low temperature, EDTA or cytochalasin-B, which permitted the formation of rosettes but inhibited lysis. Significant differences were also seen between the various clones of neuroblastoma tested. Additon of EDTA or cytochalasin-B shortly after rosette formation prevented target cell lysis, but addition later than* 5–10 min *from rosette formation was ineffective, indicating a triggering of lysis and/or critical damage shortly after cell adherence.*

INTRODUCTION

EVIDENCE has been recently provided that autogenous immunity to C1300 neuroblastoma (NB) cells exists in syngeneic A/J mice [1]. Spleen cells of unsensitized mice or mice with a growing NB tumor recognize antigenic differences on the membrane surface of syngeneic NB cells in a one way mixed lymphocyte-tumor blastogenic assay system [2] or by chromium release from prelabeled NB target cells [3]. Morphologically, the first event of such cell recognition reactions consisted of adherence of lymphocytes to NB cells [4]. The purpose of this study was the characterization and analysis of the early phases which follow first cell contact and lead to target cell lysis.

Cell adherence was documented by an *in vitro* rosette formation between attacking lymphocytes and NB cells. After binding lymphocytes were observed for a potential cytotoxic effect on target cells. This was measured by dye-exclusion or chromium release assays.

MATERIAL AND METHODS

1. *Reagents*

The following drugs were used: cytochalasin-B (I.C.I. Research Lab., Cheshire, England), colchicine, (Sigma Chemical Co., St. Louis, Mo), vinblastine (Velbe, Eli Lilly and Co., Indianapolis, Ind.). All solutions of drugs were freshly prepared and used immediately. Ethylen-di-amino-tetracetic acid (EDTA) was from Sigma.

2. *C1300 neuroblastoma (NB) cells*

Cloned neuroblastoma cells (Clone NB1R, NB6R, NB9R and NB10R) were isolated in our laboratory from a C1300 NB line originally supplied 5 yr ago by Dr. F. Jacob (Institut Pasteur, Paris). These cells are maintained in suspension culture as anaplastic cells in 20% Fetal Bovine Serum (FBS) in Dulbecco's modified Eagle's medium in 12% CO_2 and air atmosphere. When the cells are allowed to adhere to tissue culture vessels in the absence or in low concentration of FBS, they transform, rapidly emit cytoplasmic processes and acquire several biochemical and morphological characteristics of mature neurons [5]. Evidence has been recently provided that different clones derived from the same C1300 NB cell line share a common set of tumor-associated antigenic determinants which are mainly responsible for tumor cell recognition by syngeneic lymphocytes *in vitro*. A different quantitative expression of such antigenic determinants was seen, however, among the clones and in respect to the original line. Clone NB6R appeared to be the most stimulatory for syngeneic spleen cells and exhi-

bited high expression of such common NB-associated antigen(s) [2].

3. *Mice*

Normal 2 month male A/J mice (The Jackson Laboratories, Bar Harbor, Maine) were inoculated sub-cutaneously with 2×10^6 NB6R per mouse and spleens were dissected 7 days thereafter, at a time when the growing tumor mass at the site of cell injection was 2 × 2 mm in size.

4. *Lymphocyte suspension*

Lymphocytes were obtained from spleens by the Metrizoate–Ficoll method (Lymphoprep, Nyegaard and Co, AS, Oslo) [6]. Defibrinated non adherent-spleen cell preparations were centrifuged at room temperature (300 × ***g*** for 30 min) and the white cells at the interface between medium and Lymphoprep consisted mainly of lymphocytes (over 90%), monocytes and few granulocytes (1–2%).

5. *Rosette technique*

NB cells in suspension culture were washed twice and resuspended before the test in serum-free Earle's balanced salt solution (EBSS) to a concentration of 10^5 viable cells ml^{-1}. Five hundred microliters of spleen lymphoid cells were mixed with 0.1 ml of neuroblastoma cells at various cell ratios in round-bottomed plastic test tubes, centrifuged (300 ***g***) for 5 min at room temperature and gently resuspended. The cells were examined for rosette formation in a haemocytometer and Giemsa stained cytocentrifuge preparations, using a Shandon Elliott Cytospin cytocentrifuge. In some time course kinetic studies of rosette formation, cells in pellet were resuspended in their own medium and immediately fixed in equal vol of 0.1% paraformaldehyde in the same diluent to "freeze" the reaction at each desired time. NB cells with four or more lymphocytes attached were counted as rosettes. Rosettes were kept at desired temperature and examined for cell viability. Aldehyde (2.0% paraformaldehyde, 2.0% glutaraldehyde, v/v 1:1) fixed rosettes were also prepared for electron microscopy [7].

6. *Assay for cell cytotoxicity*

Labeled neuroblastoma cells [8] (5×10^4 ^{51}Cr) were pipetted into round-bottom glass tubes (100 × 7.5). Varying concentrations of spleen lymphocytes were added at a lymphocyte to target (L/T) ratios ranging from 2:1 to 200:1 in a final vol of 0.5 ml RPMI-1640 medium containing 2% heat decomplemented and filtered FBS. The cells were centrifuged (300 ***g***) for 5 min. The pellets were then gently resuspended before incubation at 37°C in 5% CO_2 in 95% air. After 1 hr the tubes were centrifuged and 0.5 ml of medium were aspirated for gamma counting. Per cent specific cytotoxicity was expressed as:

$$\frac{\begin{array}{l}{}^{51}Cr \text{ release in experimental} - \\ {}^{51}Cr \text{ release in controls (NB cells alone)}\end{array}}{\begin{array}{l}\text{maximum } {}^{51}Cr \text{ release } (+5\% \text{ SDS}) - \\ {}^{51}Cr \text{ release in controls (NB cells alone)}\end{array}} \times 100$$

Target cell killing *in vitro* was also demonstrated by the erythrosin-B method after resuspending the cells in their own medium.

7. *Inhibitors*

Tumor membrane antigens. A soluble, crude cell extract was prepared by stirring $2–5 \times 10^8$ NB6R cells for 16 hr at 4°C in 3 M KCl, pH 7.4 Tris-buffered saline followed by dialysis and high speed centrifugation (105,000 ***g*** for 2 hr at 4°C). This cell product, named crude soluble antigen (CSA), was shown to be immunogenic when added *in vitro* to syngeneic spleen cells from unprimed A/J mice; it also induced a significantly increased incorporation of ^3H-Th by spleen lymphoid cells from neuroblastoma bearing mice inoculated 7 days before with 2×10^6 viable tumor cells [2]. A second tumor cell extract was obtained by a mild papain digestion of crude membrane preparations of NB6R cells followed by Sephadex G-150 fractionation. A soluble product, named crude membrane antigen (CMA, mol. wt below 30,000) was recovered in peak III as elsewhere described [2]. CMA was a very effective and specific inhibitor of blastogenesis of syngeneic A/J spleen lymphoid cells against NB cells in a unidirectional mixed cell culture system. On the contrary, it proved to be poor stimulatory when challenged *in vitro* with lymphocytes from normal A/J mice or from mice bearing neuroblastoma tumours. Soluble cell products from spleen, liver and kidney cells of normal A/J mice were prepared in a similar manner and were used as a source of negative controls.

Antibodies. The 7S fractions from 2 rabbits injected subcutaneously 15 days previously with 2×10^7 aldehyde fixed (0.07% formaldehyde and 0.02% glutaraldehyde) NB6R cells were obtained by recycling Sephadex-G-200 and DE-52 (Whatman) column chromatography (0.005 M ionic strength pH 7.8 phosphate buffer) and was free of active complement or 19S antibody. This globulin fraction was then absorbed on spleen, liver and kidney of normal

A/J mice. In the presence of guinea pig complement (1:10) this 7S fraction was effective in killing *in vitro* 100% NB6R cells at 1:30 dilution after 60 min at 37°C. In the absence of added complement no cell killing was obtained. The 7S immunoglobulin fraction from a rabbit hyperimmune serum against human serum albumin absorbed on normal A/J cells was used as a source of negative control. Fab preparations of 7S immunoglobulins were obtained by papain digestion [9]. Anti-theta serum was prepared by giving C3H mice a course of seven injections of A/J thymus cells, at weekly intervals. All the sera were pooled and absorbed on normal liver and kidney A/J cells. The cytotoxic effect of anti-theta serum was tested on A/J mouse spleen cells by a chromium release assay or the erythrosin-B dye method: more than 70% of normal spleen lymphocytes were killed by this antiserum at a dilution of 1:10 in the presence of complement. Sepharose 4B beads (Bio-Rad, Richmond. Cal.) were covalently coated with rabbit anti mouse gamma globulin 7S immunoglobulins (MGG) as described by Wigzell *et al.* [10]; by sensitive radioimmunoassay, using ^{125}I-labeled 7S-MGG [11], it was calculated that 1 μg of beads (dry weight) bound at saturation about 10^7 molecules of ^{125}I-MGG.

RESULTS

1. *Rosette technique*

Firm adherence of syngeneic spleen lymphocytes to C1300 neuroblastoma cells in suspension was demonstrated by the rosette technique. Lymphocytes bound to NB target cells at sites distributed at random on their surface (Fig. 1). When, however, the cells in the pellet were left to incubate for longer than 5–10 min at 24°C or higher temperature, there was a tendency for lymphocytes (usually less than 10 per target cell) to bind at a restricted polar area on the target cell and blebs from the cytoplasm of NB cells rapidly formed firstly in the proximity of the areas of contact of adhering lymphocytes and then over the whole cell surface (Fig. 2).

Increasing numbers of dead NB cells were then counted; dead cells did not form rosettes. When different NB clones were compared for rosette-forming capacity with lymphocytes, all clones were capable of forming rosettes. However, significant differences were shown among the clones. For example, cells of clone NB10R, even when they were incubated with a large number of lymphocytes, formed few rosettes (but many cells with 1–3 lymphocytes attached). In contrast, the majority of cells from clone NB1R and NB6R formed rosettes with usually 10–20 lymphocytes bound per cell, even if they were exposed to few lymphocytes in the test (Fig. 3). Using T-lymphocytes enriched spleen cell population (after filtration through Sepharose-beads covalently coated with anti-mouse immunoglobulins antibody) almost 100% NB6R cells formed rosettes with 10–20 lymphocytes firmly bound per cell (lymphocyte to target cell ratio 32:1). Under the same experimental conditions, using a B-lymphocyte enriched cell population (after treatment with anti-theta antibody and 1:10 fresh guinea pig serum as a source of complement, at 37°C for 60 min) few (5–6%) rosettes were obtained with the majority of NB6R cells binding a maximum of 1–2 lymphocytes per cell. Preincubation of NB cells with anti-NB6R Fab-antibody consistently inhibited rosette formation. Cell adherence was prevented by pre-exposing A/J lymphocytes to soluble NB cell extracts (CSA) or to a solubilized crude membrane antigen (CMA) from NB6R cells before exposure to NB cells. If similarly made preparations from normal A/J mouse cells or cell membrane were tested, no inhibition of rosette formation was obtained. These results are reported in Table 1.

2. *Target cell lysis*

After binding, the lymphocytes were observed to kill rosette forming NB target cells *in vitro* in the absence of added serum complement, as demonstrated by the erythrosin-B dye method. The kinetic of target cell lysis in experiment performed at 37°C followed an S-shaped curve. Using NB6R cells, an initial lag phase of less than 10 min was seen until 50% cell lysis took place within 15 min. In the chromium release assay, the cytotoxic effect of lymphocytes on these target cells was detected after an initial lag time of less than 15 min at room temperature (less than 5 min at 37°C), increasing rapidly and reaching 50% cell lysis in less than 20 min at room temperature (in about 15 min at 37°C). Using 30 min of incubation at room temperature as a standard procedure, it was shown that maximal target cell lysis was observed at an optimal lymphocyte to target cell ratio 16–32:1. The results of a typical experiment are reported in Fig. 4. When in these experimental conditions different NB clones were compared as target cells in the chromium release assay, following rosette formation with syngeneic normal lymphocytes, significantly different ratios of lymphocytes were required to induce a maximum release of chromium by a fixed number of pre-labeled cells, with the different clones. As a general observation, clones which more easily formed rosettes

Table 1. Effects of previous treatments of attacking A/J spleen lymphocytes or syngeneic cloned (NB6R) C1300 neuroblastoma cells, on rosette formation and target cell lysis. Lymphocytes from mice inoculated 7 days before with NB6R cells, were incubated, after treatment, with ^{51}Cr labeled NB6R cells at 32:1 lymphocyte to target cell ratio. Rosette formation and ^{51}Cr release from target cells were measured as described in Material and Methods. Data are reported as mean values (±S.D.) on triplicate experiments

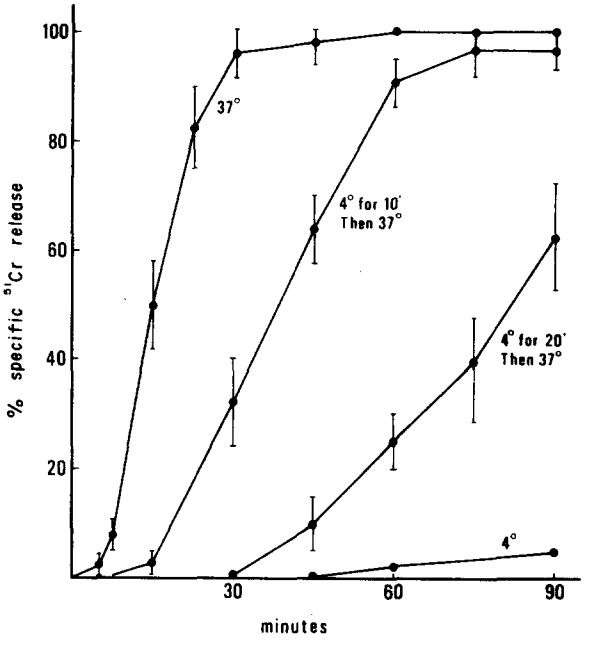

Fig. 4. Kinetic of NB6R cell lysis by syngeneic spleen lymphocytes from A/J mice with a growing C1300 neuroblastoma as detected by release of ^{51}Cr from pre-labeled target cells: Lymphocytes and target cells (32:1 ratio) were mixed at 37°C or at 4°C, then centrifuged and incubated at 37°C. Data which are reported are expressed as mean values of five experiments ± S.D. Cell-cultures which were kept at 4°C at all times, gave less than 5% cytotoxicity after 90 min.

also required a lower effector to target cell ratio for being lysed (Table 2).

CMA from NB6R cells specifically prevented chromium release from pre-labeled NB target cells. Clones which more easily formed rosettes required higher concentrations of CMA for inhibition of lysis (Fig. 5). However CMA had to be given to effector cells at an optimum interval of time before their exposure to target cells. When CMA was added to lymphocytes at the same time or after the effector cells less or no inhibition was induced (Fig. 6). Preincubation of NB target cells with Fab fragments of anti-NB6R antibody (which specifically prevented rosette formation) also inhibited cell lysis from lymphocytes. When Fab fragments were added to rosettes already formed, no inhibition of chromium release was induced. The results of these experiments are summarized in Table 1.

Table 2. Effect of different lymphocyte to target cell (L/T) ratio in ^{51}Cr *release by pre-labeled NB6R cells forming rosettes with sensitized syngeneic spleen lymphocytes. Rosette formation and* ^{51}Cr *release were measured at* 37°C *as described in Material and Methods*

3. *Dissociation of tumor-lymphocyte adherence and cytotoxic phases*

(a) *Effect of temperature.* Temperature significantly affected NB cell cytotoxicity by attacking lymphocytes. Lysis of target cells did not occur at 4°C but rapidly occurred at higher temperature reaching a maximum at 37–40°C (Fig. 7). When cells were pre-cooled for 10 min at 4°C, spun to a cell pellet (350 ***g***) 5 min at 4°C), resuspended and then transferred into a water bath at 37°C, the initial lag phase was prolonged as compared to cells always maintained at high temperature and the maximal rate of lysis took place within 2–3 hr (Fig. 4). Cells pre-cooled for 20–30 min before centrifugation, formed rosettes which could be easily detached simply by pipetting the cell suspension (2–3 times). Dead NB6R cells were shown only after 1–2 hr after the temperature was raised to 37°C.

(b) *Effects of EDTA.* The adhesion of lymphocytes to rosette-forming NB cells could be reversed with EDTA (0.01 M) (Fig. 8). EDTA added shortly after cell centrifugation (less than 5 min at room temperature) separated lymphocytes from NB6R cells and target cells released significantly less chromium than did EDTA-untreated controls. If EDTA was given after 10 min from rosette formation, detachment of NB6R cells from lymphocytes was still obtained but target cell lysis was not prevented. At room temperature, separation of cells forming a rosette by EDTA took about 5–10 min to be completed: at 37°C the reaction was significantly shorter (2–3 min). In absence of EDTA, mechanical shaking or pipetting and/or low temperature were usually ineffective in separating the attached cells.

(c) *Effect of plant alkaloids and cytochalasin-B.* Colchicine and vinblastine, two drugs which induce irreversible disaggregation of microtubular proteins, had no effect in preventing rosette formation and chromium release from rosette-forming NB cells at any concentration tested which permitted cell viability (Table 3). Cytochalasin-B, a drug which has been shown to affect a variety of cellular functions involving microfilament protein organization, did not affect rosette formation but strongly inhibited NB cell lysis by attacking lymphocytes (Table 3). In the presence of cytochalasin-B, uniform binding by lymphocytes onto the target cell surface was seen, even at 37°C, without tendency of lymphocytes to gather on a polar region of the target cell.

The effect of the drug was dose dependent with an optimum at 10 μg/ml (Fig. 9). The effect was reversible since washing and replacing of medium immediately induced target cell lysis. Cytochalasin-B inhibited cell lysis if given before or immediately after (less than 5 min) cell adhesion. If given 10 min after rosette formation cytochalasin-B did not prevent target cell lysis (Fig. 9).

DISCUSSION

Our findings clearly indicate that spleen lymphocytes from A/J mice with a growing C1300 neuroblastoma tumor bind to and induce lysis of syngeneic C1300 NB cells *in vitro*. The effector cells have been identified mainly as T (thymus derived) lymphocytes and the specificity of the reaction was shown by the ability of Fab fragments of anti-NB antibodies and of solubilized NB membrane antigens to inhibit the rosette formation and cytotoxic tests. Significant differences in their ability to form rosettes and in the effector/target cell ratios necessary for optimal lysis were observed among the different clones of the same NB line. The quantity of rosette formation also varied significantly among the

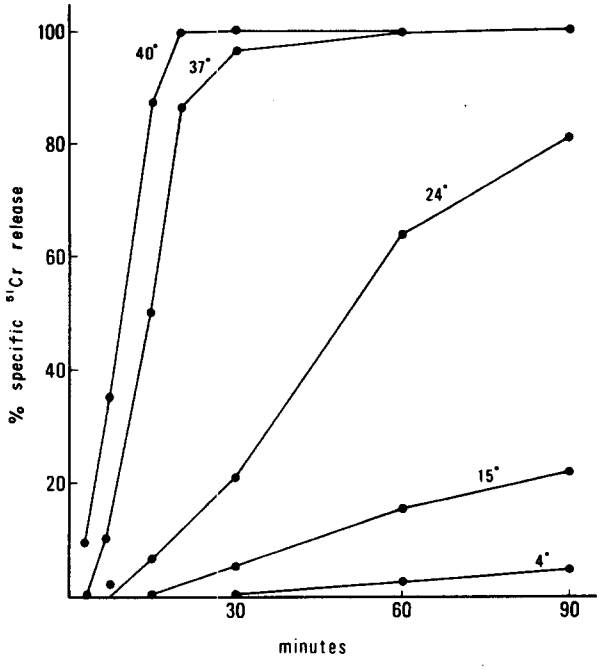

Fig. 7. Effect of temperature on target cell lysis by lymphocytes. Cultures containing sensitized A/J lymphocytes and NB6R cells were incubated at a cell ratio of 32:1 at the temperature indicated.

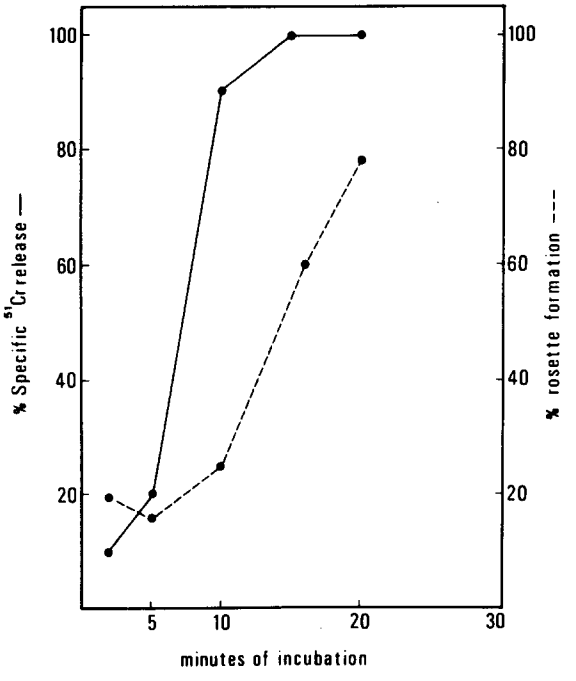

Fig. 8. Inhibition of rosette formation and cytotoxicity by EDTA. Sensitized A/J spleen lymphocytes and ^{51}Cr-labeled NB6R cells (32:1 cell ratio) were placed in culture and prepared for rosette formation. EDTA (0.01M) was added at the indicated intervals. Tubes which did not receive EDTA were used as controls. Cytotoxicity was measured after 1 hr at 37°C. The values obtained on duplicate cultures varied less than 5%.

clones (which had previously been shown [2] to vary quantitatively in the expression of NB-associated antigens), indicating a requirement for the presence and/or optimal presentation of antigenic sites on the target cells. Dead NB cells did not form rosettes, possibly due to denaturation or an altered presentation of antigenic sites.

The nature of these NB-associated antigens is as yet unknown. NB cells are known to contain cross-reacting tumor-associated transplantation antigens. Crude membrane antigens have been solubilized and some of these soluble components, at least CMA from clone NB6R, were shown not to be viral structural antigens [12]. NB cells, however, can contain RNA viral structural protein and glycoprotein antigens on their cell surface [12], and modification of histocompatibility antigens during cell transformation and differentiation *in vitro*, under conditions of cell culture in low serum concentration, has been recently observed (Invernizzi, G. and Revoltella, R., manuscript in preparation). The

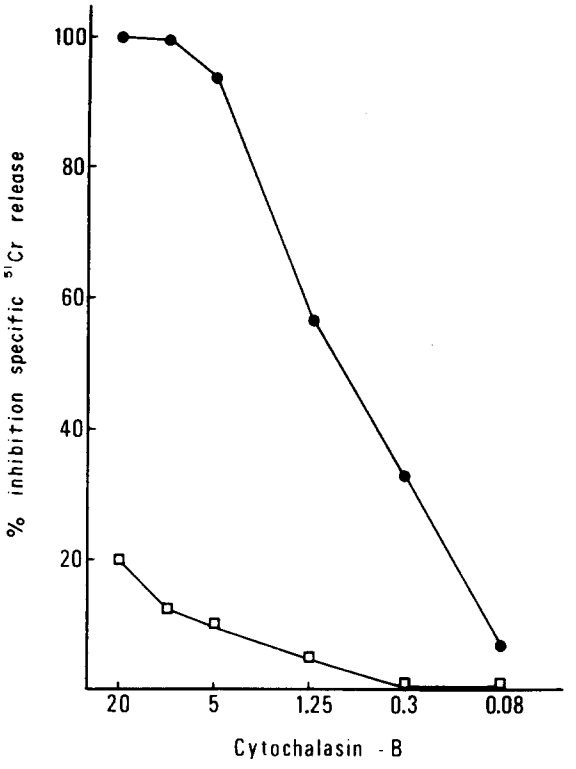

Fig. 9. Inhibition of target cell lysis by cytochalasin-B. Cultures containing sensitized A/J lymphocytes and NB6R cells were incubated at a ratio of 32:1 *at* 37°C *for* 60 min. *Cytochalasin-B was added along with effector and target cells* (●) *or,* 10 min *after rosette formation* (□).

activity of these membrane antigens has been characterized only insofar as they stimulate syngeneic lymphocytes *in vitro* [2], induce rosette formation and release ^{51}Cr in the presence of sensitized lymphocytes. The relationship between the expression of these membrane-associated tumor antigens on NB cells cultured *in vitro* to antigens of tumors growing in syngeneic recipients *in vivo* remains to be clarified.

The lytic reaction which follows rosette formation was strongly dependent on temperature, showing a sigmoidal curve with a sharp inflection at about 24°C. Rosette formation, however, was not affected quantitatively by low temperature, but rosettes formed at 4°C tended to be more fragile and to have a uniform binding of lymphocytes over the target cell surface, whereas at higher temperatures the rosettes were more stable and lymphocytes were frequently seen limited to polar regions. Cytochalasin-B showed a similar effect, i.e. inhibition of lysis but not of rosette formation and uniform lymphocyte binding even at 37°C. Cytochalasin-B has been described to interfere with the contractile microfilament system in the cell membrane [13–15] although this hypothesis is disputed since it is not clear whether the reported interference of this drug is a direct effect or results from the inhibition of other cellular functions such as phospholipid metabolism [16], oxidative phosphorylation [17], etc. Microtubular-associated functions do not seem to play a significant role in target cell lysis by lymphocytes since colchicine and vinblastine, despite being at adequate concentrations for disrupting microtubules or preventing cell growth (for review, see ref. [18]) were without effect. At concentrations at which inhibitory effects were obtained, effector cells were in fact killed by the drugs.

The inhibition of lysis by cytochalasin-B appeared to be at an early stage of the lytic process since addition after 10 min of the rosette formation reduced the degree of inhibition of target cell lysis.

CMA, which inhibited both rosette formation and target cell lysis if added initially, was ineffective at inhibiting lysis if added shortly after the beginning of the incubation.

In the presence of EDTA, the rosettes were more fragile and were easily disrupted. Significant differences were seen among the clones. When EDTA was added within 5–10 min of rosette formation, significantly less chromium release was obtained, but EDTA added later did not inhibit the cytotoxic reaction, even when the rosettes were disrupted.

These data, in conclusion, indicate that the cytotoxic reaction developed shortly after specific cell adherence. Once linkage between attacking and target cells had been established, free tumor antigen could no longer separate effector from target cells. Triggering of the cytotoxic reaction, which may involve changes in topography and/or conformation of membrane interacting sites leading to activation of the attacking cells could be prevented within 5–10 min with EDTA or by cytochalasin-B. Once triggered, the reaction became irreversible, probably because of critical damage to the target cells and lysis eventually occurred.

Recent evidence from several laboratories indicate many analogies in describing a reaction of antibody-dependent cell-mediated cytotoxicity [19, 20]. In these systems, an induced phase for lysis occurred within minutes and was followed by a lytic phase requiring several hours. These and other data involving a variey of target and effector allogeneic cell systems [21–24] all suggest at least two phases of effector mechanisms.

Macrophage-Mediated Cytostatic Activity on Tumour Cells after Treatment with Triton WR 1339*

ALBERTO MANTOVANI, NADIA POLENTARUTTI, MARINA SIRONI, ANNUNCIATA VECCHI, FEDERICO SPREAFICO and SILVIO GARATTINI

Istituto di Ricerche Farmacologiche "Mario Negri", Via Eritrea, 62–20157 Milan, Italy

Abstract—*Peritoneal macrophages collected from mice treated with schedules of Triton WR 1339 previously shown to inhibit metastasis formation in experimental tumour models were found to nonspecifically inhibit growth and DNA synthesis of tumour cells* in vitro. *No significant lysis of* ^{51}Cr-*labelled target cells could be detected. It is suggested that activation of macrophage-mediated cytostasis may contribute to the antimetastatic activity of Triton WR 1339.*

INTRODUCTION

THE NONIONIC detergent Triton WR 1339 (TWR), chemically a formaldehyde polymer of the polyoxyethylene ether of octylphenol, has been previously reported to inhibit metastasis formation in a number of animal models of cancer cell dissemination [1].

The mechanisms responsible for this anti-disseminative activity are still unclear and possibly complex, involving effects both on the cancer cell and the host [2]. In view of previous observations that treatment with this compound resulted in increased RES activity in tumour-bearing mice [3] and that TWR-treated macrophages could efficiently inhibit bacterial proliferation *in vitro* [4], it was considered of interest to investigate the possible effects of TWR on macrophage cytotoxic capacity towards tumour cells.

MATERIAL AND METHODS

Mice

Female (BALB/c × DBA2)F_1 (CD_2F_1) mice, weighing 20–22 g, obtained from Charles River, Calco, Italy, were employed throughout.

Drugs

TWR, obtained from Winthrop Co., U.S.A., was injected i.p. in 0.2 ml of 0.9% NaCl solution at a dose of 500 mg/kg for 6 consecutive days, unless otherwise stated. In most experiments, tests were performed 24 hr after the last drug injection. *Corynebacterium parvum* (*C. parvum*, lot 086P, Wellcome Research Laboratories, Beckenham, England), employed as a reference macrophage activator [5], was injected i.p. at a dose of 1.4 mg/mouse and macrophage cytotoxicity was assessed 8–12 days after this treatment.

Macrophage monolayers

Macrophage monolayers consisting of approximately 10^6 mononuclear phagocytes, were prepared as previously described [6]. Briefly, peritoneal exudate cells suspended in minimal essential medium (MEM) were seeded in the wells of Costar trays (Costar, Cambridge, Mass., USA). After 2 hr incubation at 37°C, the monolayers were washed with jets of MEM to remove nonadherent cells. Examination of Giemsa-stained preparations revealed that >95% of the adherent cells were mononuclear phagocytes.

^{3}H-*TdR uptake test*

The SL_2 lymphoma of DBA/2 origin was obtained from Dr. R. Evans, Chester Beatty Research Institute, Sutton, Surrey, England. Tumour cell DNA synthesis was evaluated as previously described [6] except that tritiated thymidine (^{3}H-TdR) was employed as a radiolabelled precursor instead of [^{125}I] Iododeoxyuridine. Briefly, 5×10^4 tumour cells were cultivated in 1 ml RPMI 1640 medium supplemented with 10% foetal bovine serum (growth medium) for 48 hr on macrophage monolayers. At the end of the incubation lymphoma cells were transferred to plastic tubes, washed twice with MEM and incubated 3 hr at

Table 1. *Inhibition of tumour cell DNA synthesis by TWR-treated macrophages*

Macrophages	% Inhibition of ^{3}H-TdR uptake*		
	24 hr	48 hr	72 hr
Normal	7±0·5	10±1.8	−15±1
TWR	79±0.7†	73±1.2†	66±0.7†
C. parvum	82±1†	91±0.5†	75±0.4†

* Cytotoxicity was assessed after different incubation times.
†$P<0.01$ compared to normal group.

37°C with 1 μCi ^{3}H-TdR (specific activity 5Ci/mmole, Amersham, England) in 1 ml growth medium. Acid precipitable radioactivity was then determined as previously described [7] and the percentage of inhibition of ^{3}H-TdR uptake was calculated according to the formula:

$$\left(1-\frac{A}{B}\right)\times 100,$$

where A is the isotope uptake in the test group and B is the radioactivity incorporated in the presence of normal macrophages. Under these conditions normal CD_2F_1 peritoneal macrophages did not affect growth and DNA synthesis of SL_2 lymphoma cells.

^{51}Cr-*release assay*

The cytolysis assay employed in this study has previously been described [8]: 5×10^4 ^{51}Cr-labelled SL_2 lymphoma cells were incubated for different times on macrophage monolayers. Percent ^{51}Cr release was calculated as:

$$\frac{\text{isotope release in supernatant}}{\text{total releasable radioactivity per sample}}\times 100.$$

Maximal isotope release from SL_2 target cells determined by osmotic lysis averaged 75%.

Statistical analysis

Results presented are means ±S.E. of 3 replicates per experimental group. Statistical significance was assessed by Dunnet's test.

RESULTS

As shown in Fig. 1, morphologically TWR-treated peritoneal macrophages were clearly different from normal mononuclear phagocytes. In fact after 2 hr incubation at 37°C and repeated washing to remove non-adherent cells, virtually all normal macrophages were still rounded up whereas TWR treated phagocytes were completely spread out. Moreover, TWR macrophages appeared larger and markedly more vacuolated than controls. No significant differences could be detected in the number of mononuclear phagocytes recoverable from the peritoneal cavity of normal or drug-treated mice.

Table 1 shows a typical experiment in which SL_2 lymphoma DNA synthesis was evaluated after different times of *in vitro* culture in the

presence of macrophages collected from TWR-treated animals. TWR treated mononuclear phagocytes markedly suppressed tumour cell DNA synthesis, peak inhibition being observed at 24 hr, cytotoxicity values slightly declining thereafter. Similar results were obtained when the TLX9 lymphoma or the FS6 fibrosarcoma of C57Bl origin were employed as targets (unpublished observations). Table 1 also shows that *C. parvum* treated monolayers caused greater inhibition of ^{3}H-TdR incorporation by tumour cells than macrophages collected from TWR-injected animals.

It has been shown that tumour cell DNA synthesis assays similar to that employed in these studies present a number of pitfalls [9]. Therefore in a series of experiments, macrophage cytotoxicity was evaluated either by visual counting of the number of lymphoma cells or by ^{51}Cr-release assay. As illustrated in Fig. 2, in the presence of TWR-treated monolayers significant inhibition of target cell proliferation was observed whereas no lysis of tumour cells occurred over a 24 hr observation period. Macrophages activated by *C. parvum*, employed as a reference compound in these studies, also inhibited tumour cell proliferation and in addition caused slight (4–8%) though significant lysis of target cells (Fig. 2).

In vitro cultivation of peritoneal macrophages in growth medium for different times prior to challenge with lymphoma cells resulted in rapid loss of the cytostatic activity of TWR-treated monolayers, significant stimulation of tumour cell DNA synthesis (33%) being observed after 48 hr *in vitro* (Fig. 3).

Cytotoxity disappeared similarly with *C. parvum*-treated macrophage preparations but the loss of cytostasis occurred significantly later (48 hr) than in TWR treated-monolayers (24 hr).

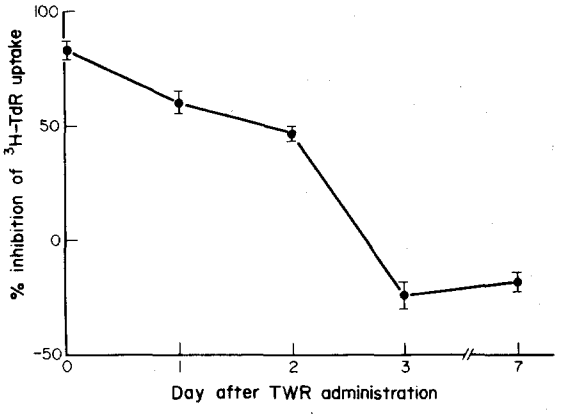

Fig. 4. Time course of the growth inhibitory capacity of TWR-treated macrophages. Macrophages were obtained from the peritoneal cavity at different times after interruption of drug administration (TWR 500 mg/kg *i.p.* × 6 days).

Table 2. Macrophage activation by TWR: effect of different drug schedules

TWR (mg/kg)	% Inhibition of ^{3}H-TdR uptake
None	2
500 × 12 days	75*
500 × 6 days	68*
500 × 2 days	−15
500	−20
250 × 12 days	52*
50 × 6 days	25

CD_2F_1 mice were treated with TWR i.p., and macrophage cytotoxicity was assessed 24 hr after the last drug injection.
* $P<0.01$ compared to controls.

A similar decay of cytostatic capacity in TWR-treated macrophages was observed *in vivo* after interruption of drug administration (Fig. 4). In fact as early as 3 days after stopping treatment with this agent, no significant phagocyte-mediated cytostasis was observed.

In a series of experiments the capacity of different TWR schedules to activate macrophages was examined.

As shown in Table 2, while significant cytotoxicity was detected following injections of 500 mg/kg for at least 6 days or of 250 mg/kg for 12 days, lower drug doses or shorter treatments resulted in a complete lack of cytotoxicity.

DISCUSSION

The results presented demonstrate that TWR administered *in vivo* renders murine macrophages cytotoxic for tumour cells *in vitro*. Cytotoxicity

under these conditions appears to be the expression of a cytostatic reaction and does not involve lysis of target cells. Thus TWR joins the now relatively long list of compounds, such as endotoxin, double stranded RNA, *C. parvum*, etc. which have been proved able to activate macrophages (see for review ref. [10]).

The mechanism by which TWR renders macrophages cytotoxic is not clear. The tuberculostatic activity of TWR-treated macrophages has been attributed to the drug interacting with lysosomes [11]. Since morphological studies have indicated that lysosomes are involved in the cytotoxic activity displayed by activated macrophages towards tumour cells [12, 13], it is tempting to speculate that phagocyte-mediated cytostasis induced by TWR may be related to this agent having some effect on lysosomes. Evidence of various types is now available to support the concept that mononuclear phagocytes play an important role in the regulation of metastatic spread [14–16]. Thus macrophage activation by TWR might contribute to the antimetastatic activity of this drug. This conclusion is supported by the observation that TWR treatments capable of activating macrophages (e.g. 500 mg/kg administered for 6 days or 250 mg/kg for 12 days, see Table 2) were previously reported to inhibit cancer cell dissemination, whereas drug schedules which did not render mononuclear phagocytes cytotoxic (e.g. 50 mg/kg for 6 days), had no effect on metastatizing tumour models [1–3].

However other pharmacological properties, such as interference with tumour cell adhesiveness, could play a role in giving this compound its antidisseminative activity [2].

The cytotoxic capacity of TWR-treated macrophages is rapidly lost following interruption of drug treatment. This could account for the need for prolonged administration of high doses of the compound in order to obtain significant antimetastatic effects [1].

Patterns of Vasculature in Two Pairs of Related Fibrosarcomas in the Rat and their Relation to Tumour Responses to Single Large Doses of Radiation

P. FALK
Medical Research Council Cyclotron Unit, Hammersmith Hospital, Ducane Road, London, W.12

Abstract—*Two pairs of related lines of rat fibrosarcoma, whose responses to radiation had already been the subject of much investigation, were chosen for a study of vascular patterns. The vascular pattern in each of these four types of tumour is described and illustrated. One member of each pair has central vascular supply and drainage, the other peripheral. In one of the latter it is suggested that the pattern of vasculature results from the pressure of cell multiplication transmitted and modified by collagen at the tumour edge and investing the radial vessels. In the other line with peripheral supply and drainage, where no such distribution of collagen occurs, the pattern seems to be connected with venous infarction.*

The patterns suggest that oxygenated blood is more evenly distributed in tumours where the supply is central than in those where it is external and this conclusion is in agreement with the radiation responses.

INTRODUCTION

MANY factors affecting the growth of tumours and their response to treatment are determined by the nutrition of their cells and hence by their blood supply. Whilst the final operative portion of the vascular system in the distribution and clearance of metabolites to and from the tissues is the capillary bed, the flow of blood through it is dependent on the size and arrangement of the larger vessels, that is the arteries and veins. It has been possible to study the arrangement of these vessels in two pairs of related lines of fibrosarcoma in rats chosen because their responses to radiation had already been intensively investigated [1–10]. All four tumours arose in the same strain of pure inbred rat (John's strain of Wistar rat), all had been maintained by transplantation within this strain and the radiation responses were investigated in tumours grown at the same site. Yet in spite of the similarity between the tumours, the responses to radiation had been found to be rather different in each, especially in relation to oxygenation. For this reason, the tumours seemed particularly suitable for the study of vascular patterns, the aim being to determine how far, if at all, the vascular pattern could explain the varying responses to radiation. Details of the characteristics of the tumours are given in Table 1.

MATERIAL AND METHODS

A detailed account of the experimental procedure has been published [11]. The tumours were implanted beneath the skin on the right flank of the abdomen where they had maximum room for expansion. When the tumours had reached the appropriate size, the rats were killed by cardiac injection of disodium edetate. Fixation for six weeks in neutral buffered formalin followed and at the end of this time the treatment varied. Some tumours were bisected and after staining the two halves were mounted in Resin 4116, produced by B.I.P. Chemicals Ltd., Warley, Worcs., U.K. This is a highly transparent polyester, which acts both as a clearing agent and mountant. Material for use with it is first dehydrated in successive ethanols and then transferred to ethyl acetate before immersion in the resin. After the addition of a catalyst the specimen is blocked in a glass mould.

Accepted 13 September 1977.

Table 1. *Data from* [8] *except where otherwise acknowledged*

	SSB1A	SSB1B	RIB_5	RIB_5C
Origin	A single spontaneous fibrosarcoma in breast tissue in a breeding rat. On transplantation into several animals, the two lines were isolated and distinguished by their different growth rates.		RIB_5 was induced in 1945 by subcutaneous injection of benzopyrene. RIB_5C was derived from RIB_5 by McNally in 1966 by culturing the cells *in vitro* over a period of 12 months, during which time the plating efficiency rose from 15 to 80%.	
Histology	Spindle-celled, the cells lying with a common orientation in small interlacing bundles with collagen bundles between	Resembles SSB1A, but has more collagen between bundles.	Originally spindle-celled, but now polygonal-celled and more anaplastic.	Polygonal-celled; marginally better differentiated than RIB_5.
Volume doubling time at 9 mm dia (days).	$1\frac{1}{2}$	$4\frac{1}{2}$	1	2
Time taken to grow from 9 to 25 mm dia (days).	11.9	30	7	12.7
Necrosis	Up to 9 mm diameter no regions of coagulative necrosis and only occasional scattered partly autolysed cells. Central necrosis appears at about 18–20 mm dia.	At first as SSB1A, but no mass necrosis at later stages.	Necrosis develops in microscopic areas at maximal distance from capillary blood vessels. At 9 mm dia these constitute about 15% of tumour volume. Between 11 and 14 mm dia, these areas coalesce to form a central necrotic mass, which then increases as the tumour grows.*	Resembles RIB_5, but at later stages only scattered islands of necrosis which remain discrete.

*Thomlinson (personal communication).

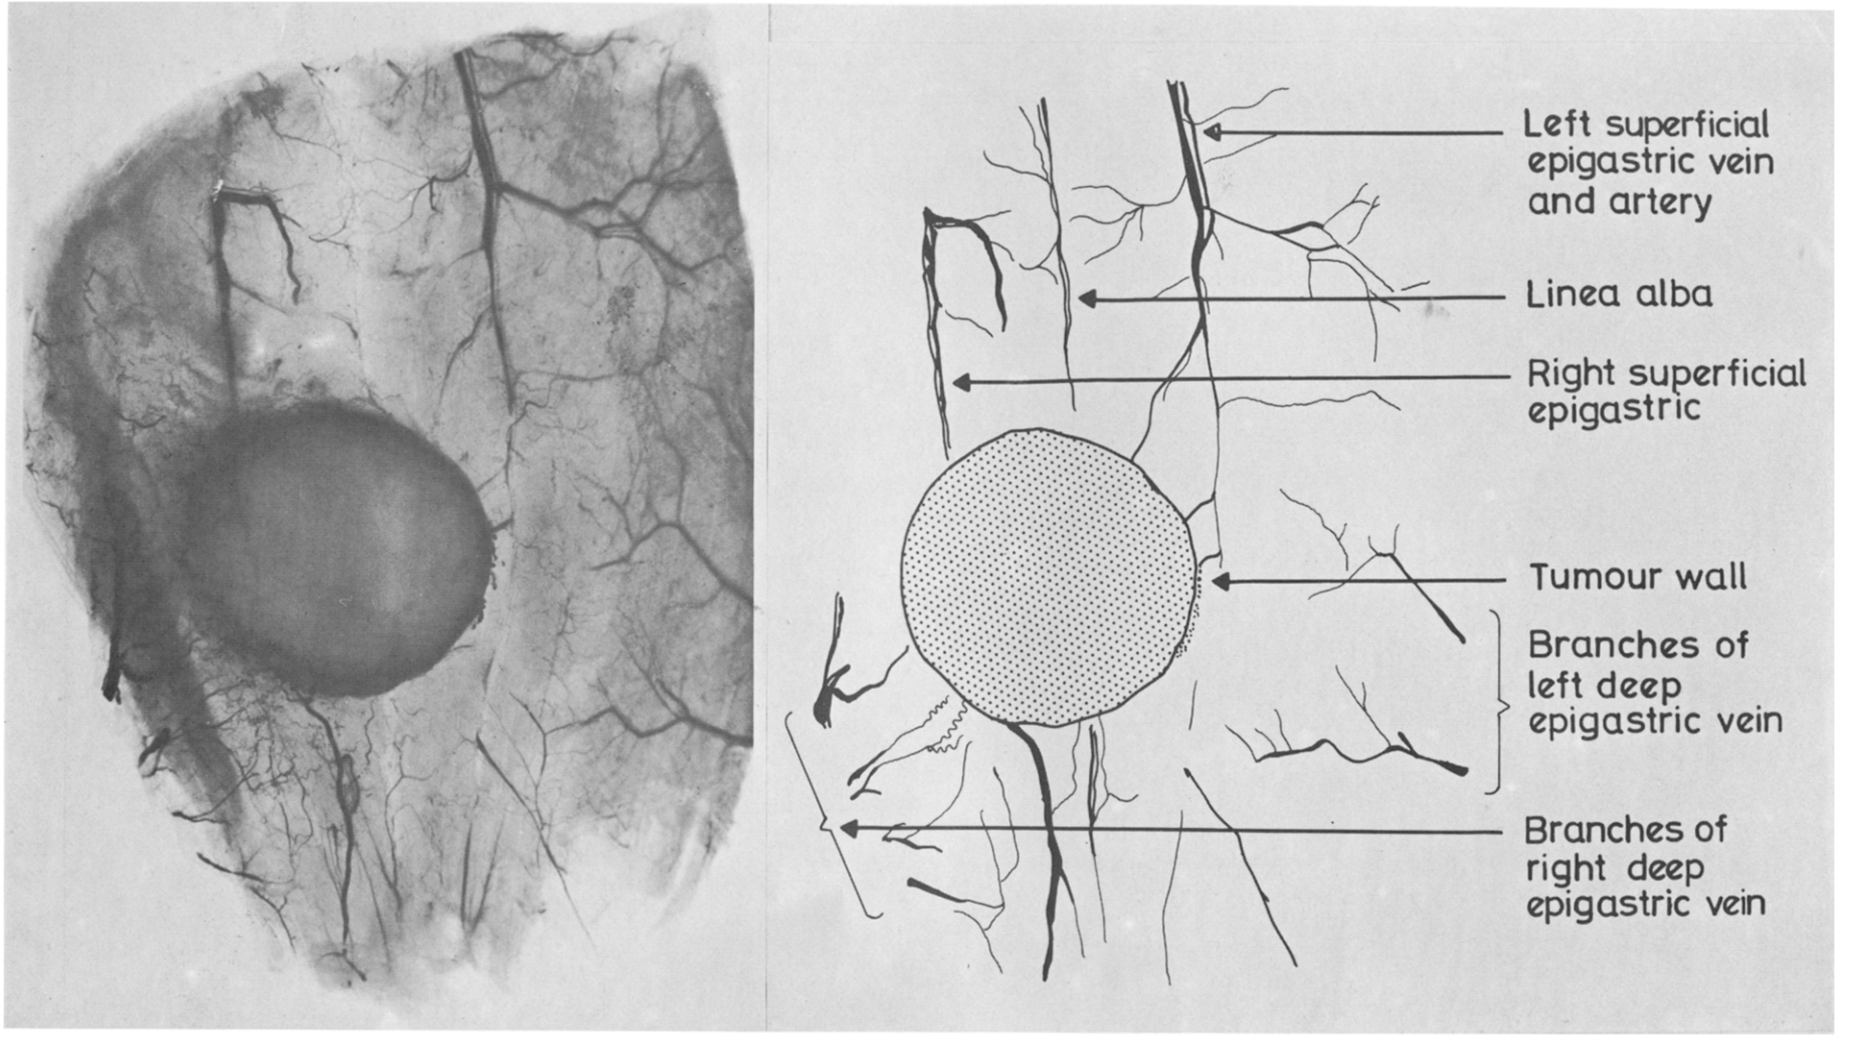

Fig. 1. *The inner half of tumour SSB1A and the surrounding abdominal wall, stained in benzidine and embedded in resin. The tumour measured* 13 × 14 × 9 mm. *The vascular supply is provided by the right superficial and deep epigastric systems with a slight contribution from the left superficial artery and vein. The centre of the tumour contains only microscopic vessels.*

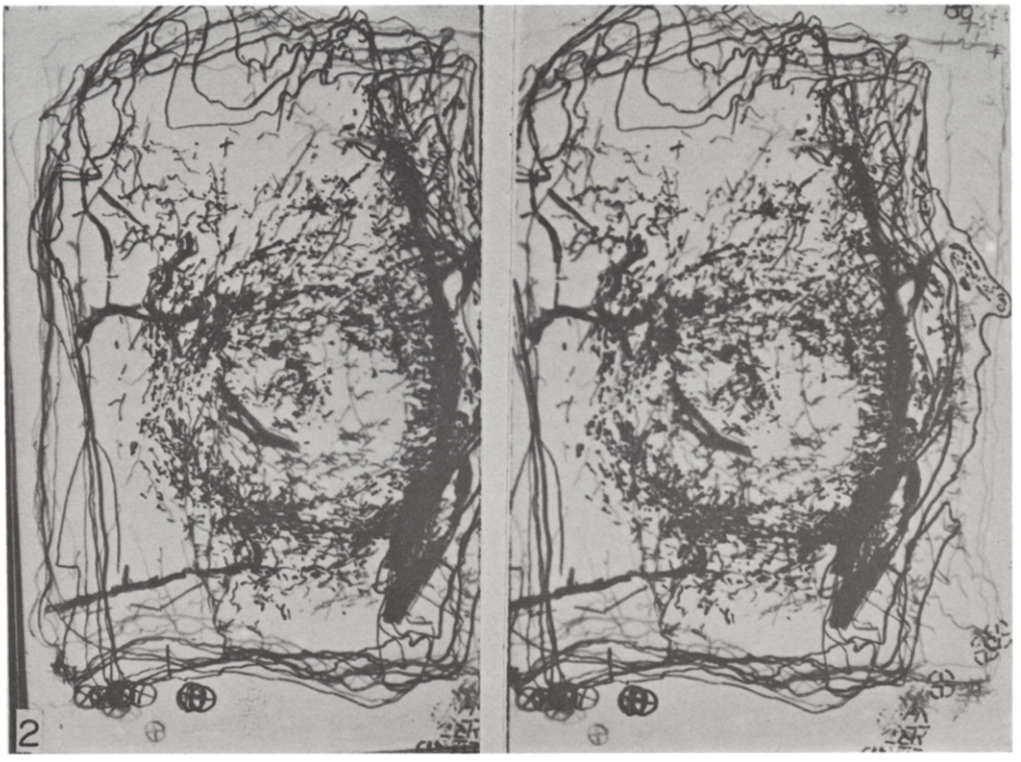

Fig. 2. Reconstruction of the vasculature of the inner half of tumour SSB1A and of the surrounding abdominal wall. The tumour measured 9.5 × 7 × 6.5 mm *and the reconstruction was made on a scale of* 20 : 1. *The wavy, superimposed lines round the edge are the outlines of successive sections. The halved tumour is hemispherical. A branch of the superficial epigastric vein lies to the right. Two small branches from the deep epigastric vein leave the tumour on the left (at* 7 *and* 10 *o'clock). The interior of the tumour is almost without blood vessels, but its walls are heavily invested. On this scale, no distinction is visible between afferent and efferent vessels. Figs.* 2, 4 *and* 5 *are stereoscopic pairs.*

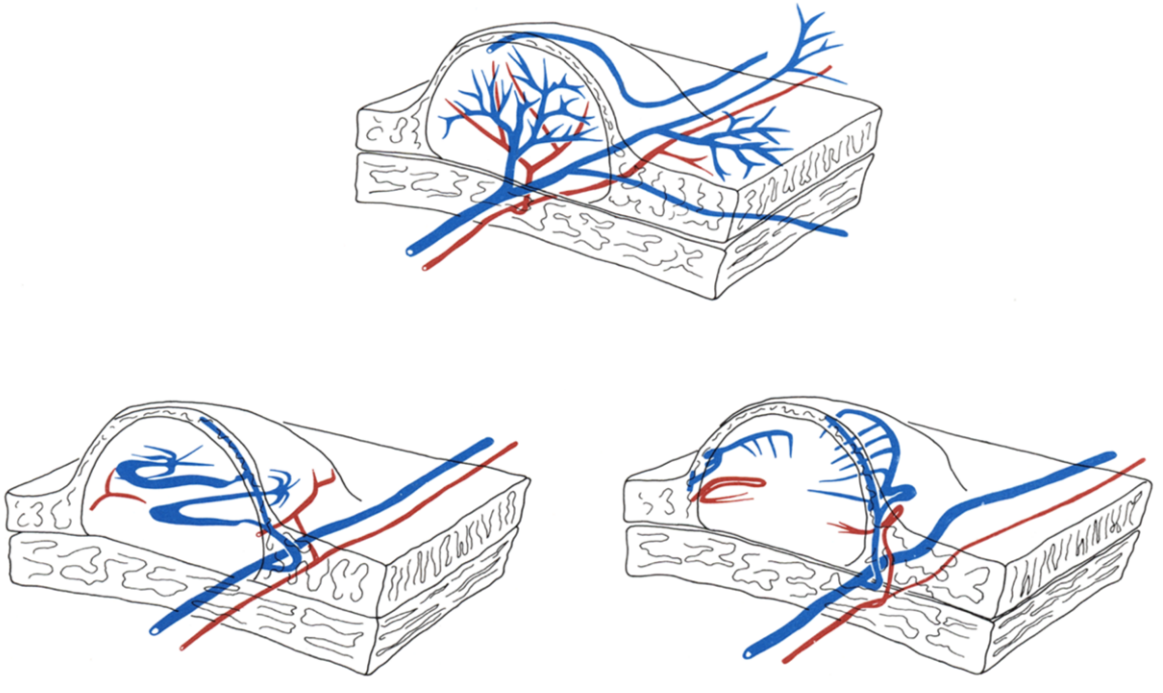

Fig. 3. The three types of pattern exhibited by the four tumour lines. Above, the internal supply and drainage pattern of SSB1B and RIB_5C; *below left, external supply and drainage exhibited by* RIB_5 *with marked constriction of the veins just before leaving the tumour and restriction of arteries to the area of venous constriction; below right, external supply and drainage exhibited by SSB1A, with highly modified veins restricted to the periphery of the tumour and arteries running over the tumour surface.*

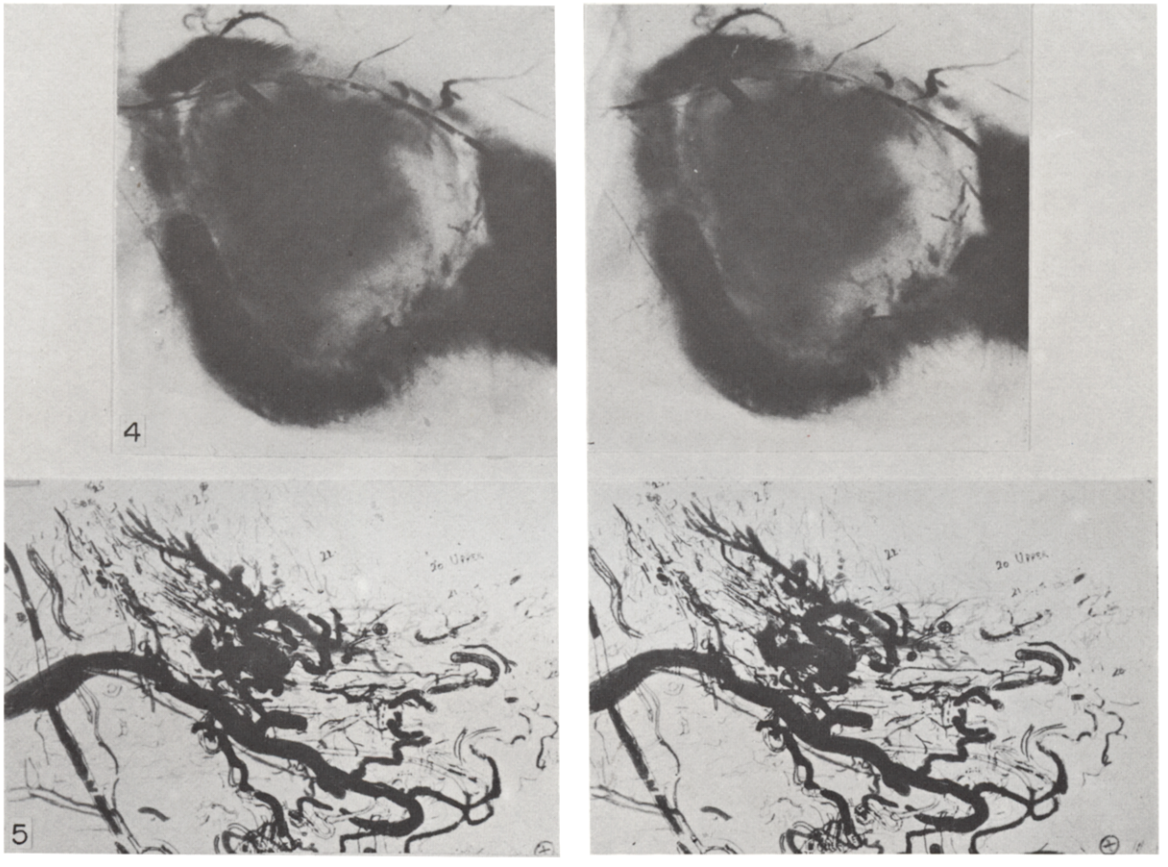

Fig. 4. The inner half of tumour SSB1B stained in benzidine and embedded in resin. The tumour is seen through the abdominal wall. The superficial epigastric vein is seen as a discontinuous line across the upper half of the picture, the vessel being constricted by the pressure of the tumour on it. The vasculature of the tumour has a shrub-like appearance and the single vein draining it can be seen entering the superficial epigastric vein. The outlines of the tumour are defined approximately by the three incidental haemorrhages which enclose it.

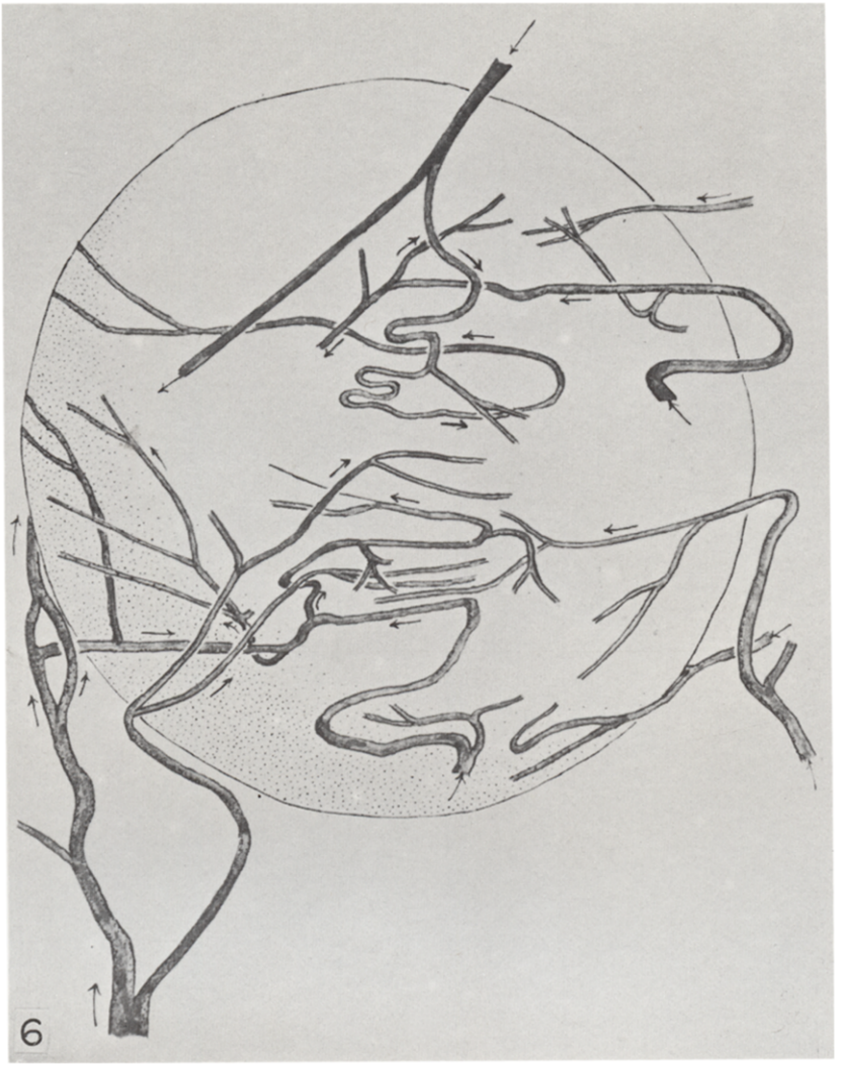
Fig. 5. Reconstruction of a portion of the same SSB1A tumour as in Fig. 2, the original made on a scale of × 120. *The tumour lies in the right upper portion of the photograph and the edge runs as an arc of a circle from the upper left corner to half way down the right margin. A broad vein outside the tumour ascends from the lower centre of the photograph to half way up on the left. The bases of three of its branches to the tumour are shown, but the course of the left one only is fully visible. Its base is sinuous and within the tumour it spreads circumferentially. Slightly nearer than the main vein is an artery appearing grey. An anastomosis is visible before the artery runs under the main vein (lower centre).*



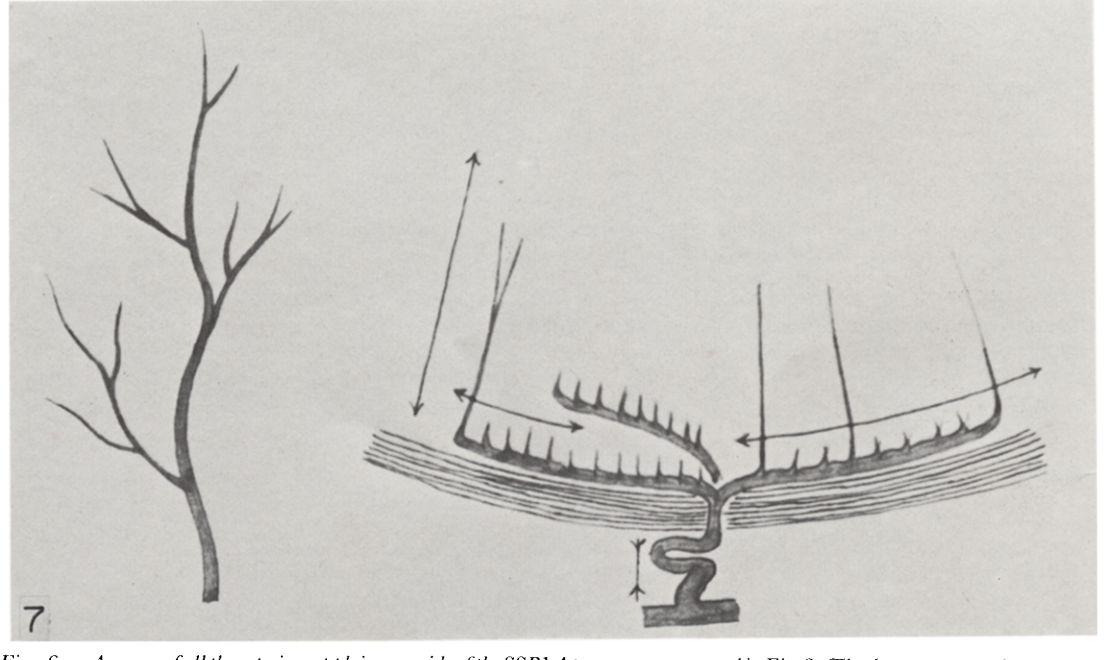


Fig. 6. *A survey of all the arteries supplying one side of the SSB1A tumour reconstructed in Fig.* 2. *The three upper arteries enter from the skin, the four lower from the abdominal wall. The arteries run over the tumour surface for a considerable distance before branching and entering it. The course of their branches within the tumour is not shown. The survey shows the uneven distribution of the arterial supply. The arrows reveal one anastomosis (lower left centre).*

Fig. 7. *A normal riverine vein on the left and the highly modified vein of tumour SSB1A on the right. Arrows represent the forces resulting from tumour growth which act on the vein. The parallel lines represent the collagen at the tumour surface. The tumour lies above these. The base of the vein is supported by loose connective tissue.*

In this method the surrounding tissues were left in place round the half tumour so that both the vascular supply to the tumour and the vessels within it were visible (Fig. 1). Tumours not treated in this way were cut with a cryostat into sections 200 μm thick. To standardize their treatment, a special technique was used for mounting the sections on glass slides. The vasculature of each section was next traced onto an acetate sheet, each sheet was supported on a pane of glass and the glass panes stacked one above another with spacers between. Placed on an X-ray viewer, the stack gave a 3-dimensional representation of the vasculature when viewed from above (Fig. 2). The blood vessels gave the alignment of adjacent sections and at a magnification of × 125 these conformed to within 2 mm.

In both methods staining was carried out by benzidine and hydrogen peroxide, which colour the blood an intense blue-black. Sections were normally counterstained with Eosin, but if it was necessary to identify collagen, Fast Green F.C.F. was used instead. The latter stain was also used for the same purpose with resin-embedded specimens. Benzidine staining was used in preference to injection methods because of its ability to reveal the state of constriction or of filling of a vessel. The methods used have the advantage that they can be employed with biopsy or post mortem material.

RESULTS

A difference that became apparent on sectioning the tumours or even when bisecting them for mounting in resin was that the sections or cut surfaces of the slow-growing member of each pair of tumours, SSB1B and RIB_5C, remained flat, whereas the sections and cut surfaces of the fast-growing members, SSB1A and RIB_5, curved in a saucer-shaped fashion. The centres of the latter thereby revealed a tendency to expand in relation to the peripheral zone. No such tendency was seen in the former tumours. For this reason the former were regarded as *lax* tumours, the latter as *tense*. Within the four tumour lines studied, this distinction coincides with a fundamental difference in the vascular patterns. This difference is illustrated in Fig. 3. In the upper figure, illustrating the vascular pattern of the two lax tumours, SSB1B and RIB_5C, an artery and a vein enter the tumour together at its base and branch together for some time. The general direction of flow of blood is therefore centrifugal in the arteries and centripetal in the veins. In contrast, in the tense tumours afferent and efferent vessels, even if they enter together, soon separate and since the main vessels are peripheral, not central, the direction of the flow of blood is centripetal in the afferent vessels and centrifugal in the efferent. For convenience throughout this paper the lax type is described as possessing central supply and drainage, while the tense type is described as having external supply and drainage. These descriptions are applicable only when the tumour is considered as an isolated unit. They are clearly inapplicable when the tumour is considered as part of the body of its host.

Although the two tense types of tumour agree in possessing external supply and drainage of blood, their patterns otherwise differ markedly (Fig. 3). In SSB1A, arteries are confined to the surface of the tumour, whereas in RIB_5 they penetrate into it, but after running not more than 200 μm turn through a right angle and continue their course just within its boundary. The form of the veins, too, is in sharp contrast, those of SSB1A running circumferentially just within the tumour before entering a main drainage vessel through a short, dilated and usually reflexed base, while those of RIB_5, which lie within the tumour and usually extend right across it, are characterized by their extreme degree of dilatation and their marked constriction immediately before leaving it.

The arrangement of the vascular supply to the tumour from the host, illustrated in Fig. 1, is in general typical of that obtaining in all four tumour lines, though the details vary both with the tumour line and with the exact point of implantation. In Fig. 1 the vascular supply comes from both the deep and superficial epigastric systems and it is noticeable that the left superficial epigastric vein and artery as well as the right contribute to the tumour's vasculature. In tumours implanted further to the rat's right, the left superficial epigastric system makes no contribution, and in the extreme case, the whole abdominal supply may come from the deep epigastrics. With tumour RIB_5, the position is similar, but for the two lax tumours, the more distant sources of supply do not occur. The kinking of two small branches of the deep epigastric vein in Fig. 1 is typical of the tense tumours and a kinking of small branches of the superficial epigastric vein may also occur in them. In the lax tumours kinking does not occur. In both tense tumours branches from the cutaneous artery and vein are present in addition to the abdominal supply.

Detailed description of the patterns of vasculature

SSB1B

Six tumours were investigated ranging in size from 14 × 11 × 10 to 24 × 19 × 14 mm.

This tumour possesses the simplest pattern of vasculature found in the four lines. An afferent and efferent vessel enter the tumour together from its abdominal side (Fig. 4) and then with frequent branching climb towards the skin. Since the afferent vessel even within the tumour retains its muscular investiture, it is clearly distinguishable from the efferent. Its branches are evenly but sparsely distributed to all parts of the tumour. The density is such that the distance between the termination of one branch and that of its nearest neighbour may be as much as 500 μm. There is no marked dilatation of the efferent vessels and the density of their fine branches is high. Intervals between their terminations seldom exceed 25 μm. No vessels filled by blood could be seen uniting the finest afferents with the finest efferents, though a faint grey network connecting the two systems could be seen in some areas. Occasional flattened erythrocytes lay on the strands of this network. A similar structure occurs in the other three tumour lines, suggesting that an extensive capillary network is present in all four tumour lines, but that it closes with the fall in arterial pressure at death. The evidence for this suggestion is considered later.

RIB_5C

Five tumours were examined ranging from 10 $\times$ 5.5 $\times$ 5 to 26 $\times$ 17 $\times$ 16 mm dia.

The vascular pattern of this tumour line resembles that of SSB1B, a vein and an artery entering the tumour together at its base and climbing together towards the skin. The artery in this case also has a well-marked muscular investiture. The pattern differs, however, in that the supply and drainage of blood afforded by these vessels is supplemented by three or four further pairs of arteries and veins which ascend the walls of the tumour and enter through its side. Within the tumour, the vessels soon cease to run side by side, but the artery retains its muscular investiture. There is no marked dilatation of the veins.

SSB1A

Fifteen tumours were investigated ranging in size from 8 $\times$ 7 $\times$ 6 to 20 $\times$ 13 $\times$ 16 mm.

The vasculature of this tumour line is strongly peripheral (Figs. 2 and 5). On reaching the tumour, arteries and veins cease to run together in pairs. The arteries run circumferentially over the surface of the tumour, many extending as much as quarter of the way round (Fig. 6). Some retrace their original course after a hairpin bend. Ultimately each divides into 2–6 branches and it is these which penetrate into the tumour. Each is only 6 μm in diameter and lacks a muscular investiture. Some penetrate as much as half way across the tumour; most end nearer the periphery. These afferent vessels tend to run straighter, to have a more uniform bore and to branch less often than efferent vessels of the same diameter, but the two can only be distinguished from each other with certainty by tracing them back to the vessel from which they were derived.

In tumours less than 9 mm in diameter, the veins as well as the arteries run circumferentially over the tumour, branching frequently with a normal riverine course. In older tumours, however, the form of their branches is highly modified (Fig. 5) and those draining the tumour acquire a characteristic pattern, though branches draining the adjacent tissues retain their riverine form. The pattern of the branch draining the tumour is most easily followed if it is traced from outside the tumour into it, i.e. against the flow of blood. Following it in this direction, the branch has a short, dilated and serpentine base which penetrates the tumour wall and immediately divides into about six arms, each running circumferentially just within the tumour. These arms are well spaced out, so that seen from outside the tumour they constitute the spokes of a wheel. There is, however, a considerable overlap between system and system. Each arm gives rise to further short branches, which again run circumferentially just within the tumour. Both the arms and their branches are dilated, but retain a muscular investiture. Along their whole length they give off efferent capillaries which run radially into the tumour.

The efferent capillaries branch very little and usually have a diameter of about 7 μm. A few are considerably broader with diameters up to 50 μm; these latter branch more often. There is a tendency for the 7 μm vessels to run in bundles, particularly in younger tumours (dia less than 10 mm). In tumours up to this size, both the coarse (50 μm diameter) and fine (7 μm diameter) vessels can be traced as much as two thirds of the way across the tumour before they disappear. In older tumours they travel for a much shorter distance before disappearing, and comparisons of vertical and horizontal sections shows that vessels running at right angles to the abdominal wall persist longer than those running parallel with it.

Staining with Fast Green F.C.F. indicates that both the 50 μm and the 7 μm efferent capillaries, though lacking a muscular coat, are invested with collagen and that the collagenous covering is continuous round the dilated circumferential

vessels and from them to a layer of collagen 5–10 fibres thick which surrounds the periphery of the tumour. Afferent capillaries are similarly invested with collagen and they too are anchored to the collagen surrounding the tumour. This distribution of collagen was not found in the other three tumour lines.

A further feature of interest seen in the two tense tumour lines, but not in the lax, is the occurrence of occasional arterial anastomoses. One occurs in Fig. 6, where it has the form of a T-junction, the two blood streams represented by the arms of the T meeting and running together down its vertical limb. Such anastomoses occur in Reinhold's sandwich preparations [12] and are of particular interest since they are starting points for vaso-constriction, which usually spreads from the junction along one horizontal limb or the other, reducing the flow along the vertical limb and eliminating the collisions that occur at the junction. Occasionally both horizontal limbs are constricted simultaneously with the cessation of flow along the vertical limb. A similar phenomenon seems to occur in the arterial anastomoses of SSB1A, since in two cases explored, the equivalent vessel to a horizontal arm of the T contained no blood, though the other two elements were well filled.

Necrosis was seen only in the largest of the SSB1A tumours. The necrotic area was almost central and measured 3 × 2 mm. No cell structure was visible and the necrosis was presumably coagulative. A ring of well filled blood vessels surrounded it extending 1–2 mm from it. These blood vessels closely resembled the efferent vessels seen leaving much younger tumours. They branched slightly more often and varied in diameter from 25 to 5 μm. They showed no connection with the vessels at the tumour's edge.

RIB$_5$

Three tumours were examined ranging in size from 10 × 9 × 7 to 12 × 9 × 8 mm.

In this tumour, as in SSB1A, supply and drainage of blood are external, but the pattern of its vasculature otherwise is quite different from that of SSB1A. After running over the surface of a tumour for a short distance, veins and arteries enter the tumour together in pairs and at once proceed on different courses. The artery, which retains its muscular investiture and branches occasionally, turns through a right angle and, though it may run quarter of the way round the tumour, neither it, nor any of its branches, departs more than 250 μm from the tumour edge. Later branches, lacking a muscular investiture, doubtless penetrate further into the tumour, but the large vessels of the efferent system make it impossible to trace them. When the veins are traced into the tumour, all but the smallest are found to constrict abruptly on entering so that for a distance of about 250 μm their channel is either bloodless and apparently closed, or at least very narrow. Further in the vessel broadens into a long, straight sinusoid, which extends more than half way across the tumour before constricting once more at its distal end. Here it is fed by a mop-like bundle of branches, and similar, but less dense, branches enter it along its sides. Towards the centre of the tumour some of these sinusoidal structures which lack a visible connection with the veins outside the tumour contain blood which seems stagnant, giving an uncharacteristic colour on staining.

DISCUSSION

(a) *The patterns of vasculature*

According to Rubin and Casarett [13], the earliest study of patterns of tumour vasculature was made just over a hundred years ago by C. Thiersch (1865) and the first investigator to work with transplantable tumours in rats was W. H. Lewis [14] whose forcible conclusion written 50 yr ago fits perfectly the four lines of tumour described here: "Each type of tumour has its own particular type of vascular pattern." Earlier in his paper he had suggested the possibility of "the continued multiplication of tumour cells exerting undue pressure on the capillaries" and his final conclusion was that "the blood vessels do not determine the growth of the tumour, but the tumour determines the growth and pattern of the vessels". Rubin and Casarett [13] were in complete agreement and stressed the importance of the stretching of vessels, as did Thomlinson [15], who pointed out the implications for radiotherapy, since stretching may lead to a hypoxic and therefore radio-resistant fraction of cells. The only modification that needs to be made to Lewis's first conclusion is that the pattern of vasculature is not static, but changes progressively with growth, each tumour having its characteristic pattern of development.

Since the publication of Lewis's paper, there have been two main lines of attack on the problem of tumour vasculature, one based on the study of fixed material, the other on living preparations. The first includes the works of: Margulis, Carlsson and McAlister [16], who examined seven tumour types in mice and showed that each has its characteristic vascular pattern, irrespective of the site of implantation, the stage of development or the strain of host;

Milne, Margulis, Noonan and Stoughton [17, 18], who showed that secondaries share the pattern of the primary neoplasm, providing that they are fully vascularized; and Rubin and Casarett [13, 19], who distinguished between internal and external supply and drainage patterns and were the first to associate vascular pattern with radiation response. The second line of investigation, employing sandwich techniques, because of the limitation on depth and because of the short life of the preparations, is not intended to disclose patterns of vasculature, but instead reveals the blood vessels alive and functioning, as well as the development of the vasculature in its early stages.

The most striking distinction between the patterns of the four lines described here is the possession by the two tense tumour lines of external supply and drainage, as opposed to the internal supply and drainage pattern of the two lax tumours. Such a distinction had already been described by Rubin and Casarett [19]. Their Murphy lymphosarcoma had central arborescent vascularisation and their Walker carcinosarcoma rich peripheral vascularisation with central necrosis. It is particularly interesting that though both tumours are fast growing, the lymphosarcoma is the faster. Extrapolated approximate volume doubling times at 10 mm diameter are: the lymphosarcoma, 24 hr, the carcinosarcoma, 36 hr. This shows that growth rate alone cannot be the factor determining the distinction in vascular pattern, since in the four types described here, the two faster have *external* and the two slower *internal* supply and drainage.

Of these two main types of pattern, internal and external supply and drainage, internal is clearly the simpler as demonstrated by the veins and arteries running together in pairs, the more normal pattern of branching of the vascular tree and the lesser degree of hypertrophy of the veins. The suggestion here is that the pattern of the tense tumours diverges from the simple type illustrated by the lax tumours for two distinct reasons. In SSB1A the pressures set up by tumour growth and the collagenous investiture of the blood vessels which anchors them to the collagen surrounding the tumour, modify the vascular pattern. In RIB_5 the pressure imposed by the actively dividing cells at the tumour's edge, seems to be responsible. Figure 7 contrasts the pattern of a normal riverine vein with that of the highly modified branch draining SSB1A. The forces on the vein resulting from the growth of the tumour are indicated by arrows. These forces are: radial stretching, resulting from increased diameter; circumferential stretching, resulting from the expanding circumference; and compression at the base of the branch, resulting from the advance of the periphery of the tumour. Providing that the vein and its branches are attached to the tumour at their proximal and distal ends and that the main vein is secured to the tumour edge, the three forces together would convert the riverine structure into approximately the pattern found in the tumour. It seems certain that the collagen which encircles the tumour and invests all the efferent vessels would inevitably provide just such an attachment and it is significant that this arrangement of collagen is found in this tumour, but not in the other three. The form of the afferent vessels may be explained in the same way. On their arrival at the tumour, they run over its surface for a considerable distance before dividing and entering it. A number turn on their original course after a hairpin bend (Fig. 6). Such courses are most easily explained by the assumption that an artery at its point of entry into the tumour, where it is anchored to the edge by collagen, is pushed back by the advancing tumour front.

In contrast, in RIB_5 there is no indication of stretching of either the afferent or the efferent vessels, nor is there any collagenous investiture of the vessels. Instead the narrowing or closure of the efferent vessels immediately within the tumour seems to indicate a compressional force operating in that zone and resulting indirectly from the pattern of the afferent vessels. Since the main branches of the afferent vessels are confined to the outermost shell of the tumour, the nutritional status of the cells in that zone is presumably maintained at a higher level than that of the cells in the centre of the tumour. Tannock [20] has shown that for a tumour with well marked tumour cords, the number of cells dividing at any time increases with higher nutritional status. In RIB_5 it is therefore reasonable to suppose that the rate of cell division is greater in the outer shell than in the centre of the tumour. In addition, according to Thomlinson (personal communication), RIB_5 causes some compression of the connective tissue round it forming a thin pseudo-capsule, which is infiltrated by tumour, so that the process advances as a wave. This pseudo-capsule would assist in maintaining the compressional force in the outer shell of the tumour. The pattern of necrosis in tumour RIB_5 is further confirmation of the explanation advanced here. Necrosis develops in many parts of the central zone of tumours once they have attained a diameter of 7 mm, but none is evident at the periphery. At a later stage in growth, massive central coagulative necrosis occurs and the scattered areas of necrosis are

limited to a transitional zone outside the necrotic centre and within the well vascularised outer shell (Thomlinson [1] and personal communication). Thus unlike SSB1A, tumour RIB_5 seems to confirm with John's hypothesis [1]: "massive necrosis in tumours is due to venous infarction following slowly progressive venous obstruction consequent upon the expansion of the tumour in a limited space."

(b) *The capillary network*

The suggestion that a capillary network exists uniting the visible afferent and efferent vessels, but closing at death, was made in the description of the vascular pattern of tumour SSB1B and it was further suggested that such a network exists in all four tumour types. Without some such system it is clearly impossible for blood from the afferent vessels to reach the efferent. That such an important structure should function in life and become almost invisible at death is not surprising in view of the behaviour of the blood vessels revealed in a sandwich preparation, e.g. [12]. There, erythrocytes may be seen to pass through a capillary one at a time, but suddenly the flow may increase, only later to cease as suddenly leaving no indication of the vessel's existence. Groups of corpuscles may remain motionless together and then resume movement in a capillary that has suddenly become patent. Eddy and Casarett [21] reported that in their sandwich preparations of a rat neurilemmoma preliminary data showed that a negative pressure on the cover of as little as three inches of water (5.6 mm Hg) could restore the flow in an occluded preparation and as much as 12 in. of water (22.5 mm Hg) positive pressure on the cover was needed to occlude an actively circulating tumour.

In SSB1B and the other types of tumour, the visible evidence in favour of a capillary network is the existence of a faint grey reticulum, the clarity of which varies in different parts of the tumour, but which in the most favourable areas seems to unite afferent and efferent vessel endings. Erythrocytes, often flattened, are irregularly present on it. The reticulum could alternatively be interpreted as a pattern of cell membranes, but since it is sometimes continuous across partial breaks in a section, this seems unlikely and it is more probable that with the drop of arterial pressure at death, the network has almost completely closed, the erythrocytes being either forced into the efferent vessels, or trapped or broken within the network. If broken, their contents would escape and when stained with benzidine and hydrogen peroxide, give a weak positive response.

In spite of the doubt about its existence, it is possible to visualize the network sufficiently well to estimate its density. In all four tumour lines, this was found to be about 3000 capillaries per sq mm in fixed preparations, equivalent allowing for shrinkage to 2400 in fresh. The pattern seemed always to be related to cell shape and so varied little in different areas of the same tumour.

The distance for which the capillary network appears to be the sole channel for the transport of oxygen varies considerably in the four tumour lines. In the lax tumours, in the size range of tumours investigated, the distance from the apparent endings of the afferent vessels to the apparent start of the efferent does not exceed 250 μm and is usually less. Marked hypoxia therefore would not be expected and this conclusion is in agreement with the finding that massive central necrosis does not occur even in tumours of 50 mm dia (Howlett, personal communication). The occurrence of scattered islands of necrosis in both types of lax tumour suggests, however, that not all cells are fully oxic, and the response to radiation described later, shows that RIB_5C in particular contains a significant hypoxic cell fraction. This may in some way be connected with its partially peripheral vascular supply.

In the two tense tumours, the situation is altogether different since in them the capillary network provides the sole channel of transport from the periphery of the tumour to its centre, a distance of 4 mm in the size range of tumour investigated. Hypoxia seems certain to occur and this conclusion agrees with the finding that massive central necrosis occurs in both.

(c) *Hypertrophy of the venous system*

A characteristic of all four tumour lines, already commented on, is the extreme preponderance of venous blood. This hypertrophy of the efferent system affects the number of vessels as well as their diameters and is considerably greater in the tense tumours than in the lax. As a result, a superficial examination often suggests that a tumour is an exceptionally well vascularized structure compared with the tissue around it. It is only when the arteries are identified with certainty, either from the thickness of their muscular investiture if such exists, or by tracing them back to their origin, that it becomes apparent that the supply of oxygenated blood to some parts of the tumour is relatively less than to the adjacent skin, muscle or connective tissue. It seems likely that the cause of the disparity between afferent and efferent vessels is

the exceptional mode of origin of the tumour vasculature. There seems to be general agreement that, apart from the host vessels incorporated into the tumour as it expands, tumour vasculature arises by venous budding of the host vessels, followed by branching and anastomosis with the consequent formation of a network, which becomes connected with the afferent system only at a later stage. The weight of evidence in favour of Folkman's tumour angiogenesis factor [22] in evoking this venous budding is considerable. If this explanation is accepted, the first step in inducing the venous hypertrophy is the action of the T.A.F. on the endothelial lining of the veins surrounding the tumour. The disparity is then increased further in the tense tumours by the forces already described, i.e. differential stretching in SSB1A leading to the development of the greatly expanded circumferential veins and venous constriction in RIB_5 leading to the development of the central sinusoids.

Two structural features which might possibly be interpreted as measures of T.A.F. effectiveness are: (a) the spiralling of veins adjacent to the tumour and (b) the distance from the tumour of the point where a vein is deflected towards it from its original course. The resin embedded preparations show that for tumours of equal volume, both effects are more marked with tense tumours than with lax. It may, therefore, be that a further basic difference between the two types is that the former produces more T.A.F. than the latter.

An important deduction to be made from the existence of the marked venous hypertrophy is that an estimate of the total blood volume of the tumour, e.g. in assessing the extent of neovascularisation following irradiation, is not an effective measure of the oxygen supply, since a large, but variable, proportion of the blood is stagnant. For reliable assessment of oxygen supply, the essential requirement is a knowledge of the size and pattern of the afferent vessels.

(d) *The relation between vascular pattern and radiation response*

If the vascular pattern of a tumour is such that some of its cells are inadequately supplied with oxygen, since the hypoxic fraction is more resistant to radiation than the remaining neoplastic cells, radiation will be less effective than in a tumour where the pattern has given rise to a uniformly oxic population. "The response of... tumours to irradiation appears to be a sensitive indicator of the proportion of the cell population that is protected from radiation injury because of hypoxia" [15]. Detailed descriptions of the methods for determining the hypoxic fraction from the results of radiation treatment have been given by Thomlinson [3, 4, 5, 15], McNally [6, 7] and Howlett *et al.* [8]. Figure 8 has been redrawn from [8] plotting to the same scale the response of the four tumour lines considered here. The graph shows the relative delay in tumour growth produced by varying doses of 250 kV X-rays, relative delay being defined as the time taken for treated tumours to grow from 9 to 25 mm dia expressed as a multiple of that taken by untreated tumours. From earlier work using rats irradiated (a) while breathing air, (b)

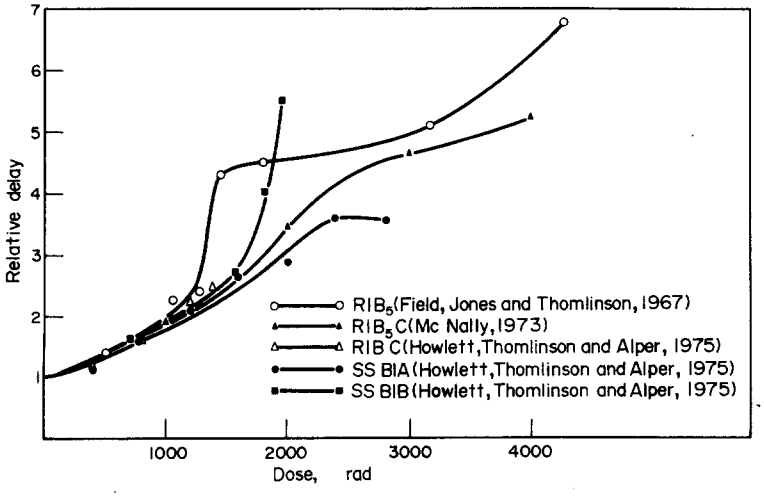

Fig. 8. The relative delay imposed on the four tumour lines by varying doses of 250 kV *X-rays, relative delay being defined as the time taken by treated tumours to grow from* 9 *to* 25 mm *dia expressed as a multiple of that taken by untreated tumours.*

while breathing oxygen at three times atmospheric pressure, and (c) while breathing normal air, but with the circulation to their tumours clamped so that all cells were effectively anoxic, and measuring either relative delay or survival of cells from tumours excised immediately after irradiation and cultured *in vitro*, it has been found that those tumours possessing a mixed cell population, both oxic and hypoxic, give a biphasic curve, when the results are plotted as in Fig. 8, while those with a uniform population give a monophasic curve. Of the four tumours considered here, the curves for RIB_5 and RIB_5C are clearly biphasic, while over the dose range employed, SSB1A appears biphasic and SSB1B monophasic, but in their cases high enough doses to justify a firm conclusion were not employed. In the case of SSB1B, however, Howlett *et al.* [8] quote additional earlier evidence and from it and from their own results conclude that no hypoxic fraction exists. For SSB1A no additional evidence of this kind is forthcoming, but recently Constable [10] has determined the pattern of oxygen removal rate in this particular tumour and reports that it was uniformly low throughout the core of the pre-irradiated tumour and more normal values were only found in a thin shell at the edge of the tumour. Though the oxygen removal rate of an excised portion of tumour outside the body of the host need have no exact relationship with the oxygen supply to the cells of the tumour *in situ*, this pattern agrees precisely with what has already been concluded from the study of the vascular pattern of the tumour.

To summarize, when the results of the available radiation experiments are compared with the expectations based on the patterns of vasculature, it is found that:

(a) there is complete agreement in the case of RIB_5 and SSB1B, the former having an hypoxic cell fraction, the latter not;

(b) RIB_5C, though having mainly internal supply and drainage, has an hypoxic cell fraction;

(c) the evidence from the radiation experiments is too incomplete for a firm conclusion to be drawn in the case of SSB1A, but if oxygen uptake rate is considered in its place, there is again agreement.

It can be concluded therefore, that in the four tumour lines considered, the pattern of vasculature is of greater significance than the relationship between tumour lines in determining response to radiation.

Acknowledgements—Dr. R. H. Thomlinson, now of the Regional Radiotherapy Centre, Mount Vernon Hospital, Northwood, introduced me to this work, suggested this investigation and constantly helped me with advice and encouragement during the work and during the preparation of this paper; I am most grateful to him. Dr. H. S. Reinhold, of T. N. O., Rijswijk, demonstrated living tumour circulation to me in his sandwich preparations and gave me much useful advice; Dr. B. Dixon, of the Regional Radiotherapy Centre, Cookridge Hospital, Leeds, supplied me with the material for the study of tumour RIB_5; I am deeply grateful to both and to the late Dr. Roland John of St. Thomas's Hospital for an introduction to the subject based on his unique knowledge and experience.

Many members of this Unit have helped in providing the tumours or by advice and discussion and in particular I am grateful to Mr. K. Finding, the artist of Fig. 3, and to the photographer, Mr. F. Paice, for his 3-dimensional photographs of the reconstructions and of the resin blocks.

Characterisation of Mammary Tumour Virus of Strain ICRC Mouse

K. A. KARANDE, B. J. JOSHI, V. R. TALAGERI, R. U. DUMASWALA and KAMAL J. RANADIVE

Biology Division, Cancer Research Institute, Tata Memorial Centre, Bombay 400012, *India*

Abstract—*The mouse mammary tumour virus (MuMTV) isolated and purified from the milk of strain ICRC mice, susceptible to spontaneous development of mammary cancer and leukemia, was investigated for its morphological, biophysical, immunological and structural characters.*

The purified virions banded at the density of 1.17 g/ml *in* 0–55% *linear sucrose gradient and contain mature B type particles along with few C type particles when studied under the electron microscope. The polyacrylamide gel electrophoresis of strain ICRC MuMTV reproducibly resolved at least ten polypeptides. The mol. wt of the three major polypeptides are* 49,000 (*p* 49), 34,000 (*p* 34) *and* 24,000 (*p* 24). *Two of these polypeptides p* 49 *and p* 34 *have been characterised as glycoproteins on the basis of staining with periodic acid Schiff's reagent. High titers of MuMTV antigens were noted in the milk plasma of strain ICRC mice. The anti MTV-S serum could detect common antigens in disrupted virions of strains ICRC and C3H(Jax) by immunodiffusion test.*

Strain ICRC was a high cancer strain in the earlier generations of inbreeding (the average tumour incidence in the breeders of first ten generations was 81.3%) *however, the tumour incidence in the* 45th *generation has gone down considerably. The parameters studied in the present investigations have indicated that the MuMTV of strain ICRC exhibit characters comparable to those of high cancer strain C3H(Jax), in spite of a significant decrease in the mammary tumour incidence.*

INTRODUCTION

STRAIN ICRC developed at the Biology Division of Cancer Research Institute, Bombay, is susceptible to the spontaneous development of mammary cancer and leukemia, both the lesions having viral etiology. Twenty-five per cent of animals invariably develop both the lesions, breast cancer and leukemia together. Extensive investigations carried out on this strain for biological characteristics including hormonal factors and spontaneous tumour incidence have been published in series of papers [1–7]. The thin section electron microscopy of mammary tumours of females from early generations of inbreeding has shown presence of potent MuMTV in strain ICRC [8]. This strain was a high cancer strain during the initial generations of inbreeding. The average tumour incidence of mammary cancer and leukemia in the breeders of first 10 generations was as high as 83.9 and 38.2% respectively [3]. However, with continuous inbreeding, consistent steady decrease in the incidence of both the lesions was noticed, although the electron micrographs evinced the same amount of mature B particles [9]. At present the strain is in its 47th generation of brother sister matings and the tumour incidence for mammary cancer and leukemia in breeders of generations 45th are reported to be 20 and 16% respectively. On force breeding, however, the breast tumour incidence positively increases to 70%. Besides spontaneous leukemia, development of leukemias have been reported on innoculation of cell suspensions as well as cell free filtrates of mammary tumours of strain ICRC [10]. Such unique features about the strain and its changing tumour incidence warranted further studies on characterisation of its viral agents—MuMTV and MULV. The present communication reports studies on morphological, immunological and structural characters of MuMTV of strain ICRC. Since sufficient quantities of B particles can be obtained from the milk, it was of interest to carry out these

Accepted 14 September 1977.

studies on MuMTV isolated and purified from the milk.

MATERIAL AND METHODS

Isolation of virus

Milk from strain ICRC breeders (7th and 12th day after parturition) was obtained by vaccum suction. The virus was isolated and purified from the milk according to the method described by Sarkar and Dion [11]. The method is as follows:

To a pool of 4 ml ICRC mouse milk, 16 ml 0.15 M EDTA, pH 7.4 and 10 ml phosphate buffered saline (PBS), pH 7.4 were added and thoroughly mixed. The mixture was centrifuged for 10 min at 5000 rev/min. After discarding the cream fraction and the pellet, the skimmed milk was centrifuged for 1 hr at 21,000 rev/min in SW 25.1 rotor. The supernatant was slowly removed and the pellet was allowed to soak in 0.5 ml PBS overnight at 4°C. The resuspended pellet was then layered on to a preformed linear sucrose gradient (0–55%) in a 14 ml tube and centrifuged for 1 hr at 113,000 ***g*** in SW 40 rotor. In most cases two distinct bands were visible in the gradient tubes. The bands were either collected separately or together by the downward displacement, diluted with PBS and pelleted for 30 min at 160,000 ***g***. The resuspended pellets were applied to a 2nd preformed sucrose gradient as mentioned above. The visible bands were collected, diluted with PBS, pelleted, suspended in PBS and were then used for further studies.

The MuMTV, isolated and purified in the similar manner, from strain C3H(Jax) milk (MTV-S) was used for the comparative studies.

Negative staining

A drop of either milk or purified virus preparation was applied to a carbon film on a 200 mesh grid and allowed to sit for 15 min for the virions to adhere. The excess fluid was drawn off with filter paper and a drop of 2% phosphotungstic acid (PTA, pH 7.4) was applied to the grid for 30 sec and removed. Fixation of the virus was performed prior to staining by floating the grid with absorbed virus on a drop of 2.5% glutaraldehyde for 3–5 min. After 3–4 washings in buffer, the grids were stained as above.

Thin sectioning

The viral pellets were fixed in 6.25% glutaraldehyde for 1–1½ hr, post fixed in 1% osmium tetroxide in cacodylate buffer, dehydrated in ethanol solutions and embedded in araldite. The sections were cut on a Porter-5-Blum MT2 sorval ultramicrotome, stained in uranyl acetate followed by lead citrate and examined in a Philips 300 electron microscope.

Antisera

Standard anti-MTV-S serum (rabbit antiserum against DBA/2 MTV) was kindly provided by Dr. H. Tanaka, Virus Research Institute, Kyoto, Japan. The antiserum was absorbed with 2 vol of whole milk from C57BL mice for 1 vol of serum by incubation at 37°C for 30 min, storage at 4°C overnight and finally clarification at 200,000 ***g*** for 30 min [12]. The serum was also absorbed with 50 mg/ml of lyophilized tissue extract from C57BL mice incubation at 37°C for 1 hr and finally clarification at 200,000 ***g*** for 30 min.

Immunodiffusion tests

Double diffusion tests [13] using 0.7% agar in normal physiological saline containing 0.001% thiomersal was employed to test the ICRC MuMTV. Slides were incubated at room temperature in a humidified chamber for 72 hr. After the development of precipitin lines, the slides were washed in PBS or normal saline and were photographed.

Immunoelectrophoresis

Immunoelectrophoresis was performed in 1% Noble agar in barbitol buffer, pH 8.6. After the addition of antigens, the electrophoresis was performed at 5 mA/slide for 90 min. After adding the antiserum, slides were kept in a humidified chamber till lines developed and treated as above.

Hemagglutination-inhibition assay (HAI) for viral antigens

HAI test of Sibal *et al.* [14] with slight modifications was employed for the detection of MTV antigens in the milk plasma of strains ICRC and C3H(Jax). Rabbit anti-MTV serum prepared by immunization with purified B particles from ICRC milk according to the method of Daams *et al.* [15] was used. The procedure for the absorption of the antiserum was the same as for standard anti-MTV-S serum, already mentioned. Sensitization of the sheep erythrocytes (SRBC) was done by coating purified virus (2 mg/ml) isolated from strain ICRC milk on to 2.5% suspension of tannic acid coated SRBC in PBS, pH 6.4, at room temperature for 10 min [16]. The milk plasma of low cancer strains ICRC/fC57, C3H/Mect and L(P) were used as controls.

Chemical analysis

The relative proportion of protein and RNA was ascertained by the measurement of O.D. at 280 and 260 nm [17]. The protein content was also measured by the method of Oyama and Eagle [18]—a modification of Lowry's method [19]. The RNA was estimated by the method of De Deken–Grenson and De Deken [20].

Polyacrylamide gel electrophoresis

Sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis was performed by method of Shapiro *et al.* [21]. Proteins were precipitated in 10% trichloroacetic acid (TCA) at room temperature for 15 min and then centrifuged at low speed for 15 min. The pellets were thoroughly drained, washed with 5.0% TCA and resuspended in 100 μl of 0.01 M sodium phosphate buffer (pH 7.8) containing 1% SDS and 1% β-mercaptoethanol and incubated at 37°C for 2 hr. After complete denaturation of the proteins the samples were mixed with 100 μl of 50% sucrose and 5–10 μl tracking dye (pyronin 0.25%), mixed thoroughly and applied on the gels. The gels contained 7.5% acrylamide, 0.25% bis acrylamide, 0.1% SDS and 0.1 M sodium phosphate (pH 7.8). Electrophoresis was performed at 3 mA/gel for 30 min followed by 3–3½ hr at 7 mA/gel. The gels were stained for 3–4 hr in 0.25% Coomassie brilliant blue in 40% methanol and 10% glacial acetic acid and destained by diffusion in 7% acetic acid and 5% methanol. The stained gels were scanned at 580 nm on a Densicord–Photovolt corporation, NY.

Glycoproteins were detected by periodic acid Schiff's staining [22]. Molecular weights of the viral polypeptides were estimated from their relative migration in gels compared to standard proteins electrophoresed in parallel gels. The molecular weight standards used were bovine serum albumin, mol. wt 68,000; ovalbumin, mol. wt 43,000, pepsin, mol. wt 35,000; trypsin, mol. wt 23,000; haemoglobin (Bovine) mol. wt, 15,000; lysozyme, mol. wt 14,400 and cytochrome C, mol. wt 11,700.

RESULTS

Buoyant density

Two light scattering bands were consistently observed when the ICRC milk pellet was applied to the 0–55% linear source gradient and spun at 113,000 ***g*** for 1 hr. The two bands were usually 3–5 mm apart, the lower band being broader than the upper band (Fig. 1). The upper and the lower bands when collected separately and layered on two separate gradients were found to band at the densities of 1.15 g/ml and 1.17 g/ml respectively. The milk from strain C3H(Jax) breeders, when run simultaneously with ICRC milk, consistently showed only one light scattering band at the density of 1.17 g/ml. When the spinning time was extended to 3 hr one single light scattering band was noticed in case of ICRC MuMTV (Fig. 2).

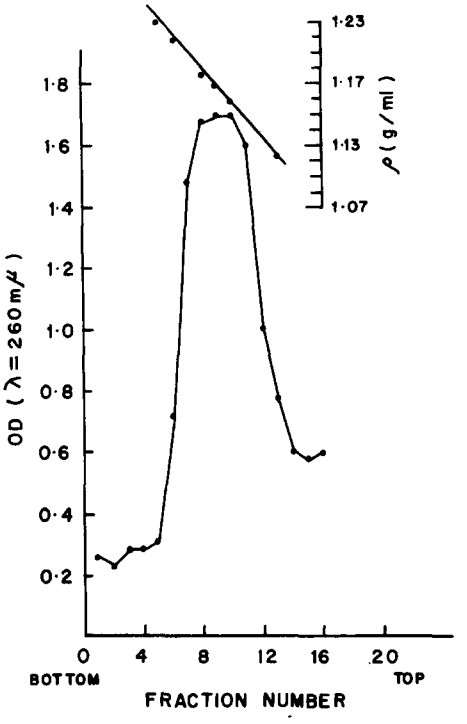

Fig. 2. Density gradient centrifugation of MuMTV from strain ICRC. The centrifugation was carried out for 3 hr *at* 30,000 rev/min *in Spinco SW* 40 *over* 14 ml *preformed sucrose gradient* (0–55%).

Virus morphology

In the negatively stained preparations of MuMTV, the virions showed striking morphological feature of the head and tail configuration (Fig. 3). When the virions were fixed with glutaraldehyde prior to PTA straining, practically all the particles became spherical and many of them were penetrated by stain revealing the core components of the virion. The characteristic surface projections were observed on most of the virions (Fig. 4).

In the thin sections, the purified viral pellet showed numerous mature B particles with occasional mature C type particles (Fig. 5). C type particles were noticed in the thin sections of lower as well as upper viral bands.

Immunodiffusion and immunoelectrophoresis tests

Standard anti-MTV S (DBA) serum was employed to test intact and disrupted B particles isolated from ICRC and C3H(Jax) milk. The serum produced one single line very near to antigen well with intact B particles from both the strains (Fig. 6). With ether disrupted B particles of both the strains, three precipitating lines appeared half way between the wells. All the antigens showed lines of identity in the immunodiffusion tests and β electrophoretic characteristics of B particle antigens in immunoelectrophoretic test.

HAI for viral antigens

It is evident from Table 1 that strains ICRC and C3H(Jax) had high antigen titers in their milk whereas the low cancer strains ICRC/fC57, C3H(Mect) and L(P) showed very low levels of MTV antigens.

Table 1. *Presence of MuMTV antigens in the milk of various strains of mice*

Mouse strain	Tumour incidence	HAI titer (Reciprocal)
ICRC	20%	1:256
C3H(Jax)	90%	1:1024
ICRC/f C57*	Nil	1:8
C3H/Mect†	Nil	1:32
L(P)	Nil	<1:8

*ICRC foster nursed on C57BL.
†C3H subline derived from C3H mammectomised females [47].

Chemical composition

On an average purified viral pellet obtained from 4 ml of strain ICRC milk was found to contain 3500 μg of proteins and 115 μg of RNA. Thus the total RNA content of virions was found to be 3.3% of the total proteins.

Polypeptide composition

The purified MuMTV from ICRC and C3H strains of mice was dissociated and electrophoresed as described before. Examination of the electrophoretic pattern after staining with coomassie blue revealed at least 12–14 polypeptide bands, 10 of which were detected reproducibly. The molecular weights of these as estimated from their relative migrations compared to standard proteins electrophoresed simultaneously were 100,000; 90,000; 81,000; 72,000; 62,000; 49,000; 34,000; 24,000; 15,000 and 12,000 (Table 2). Judging from the intensity of the stain polypeptides 49,000; 34,000 and 24,000 were considered as the major structural proteins of the virion (Fig. 7). The gels were

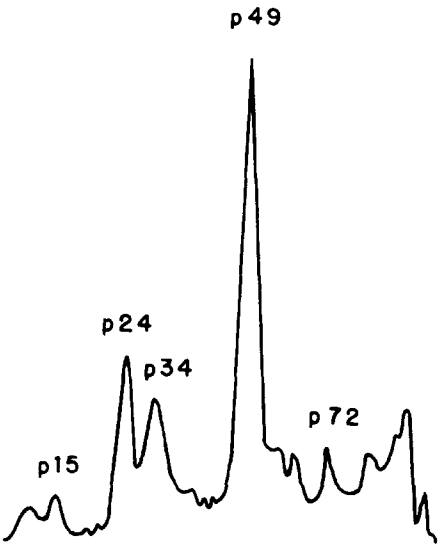

Fig. 8. *SDS-PAGE electrophoretic pattern of purified MuMTV from strain ICRC and the densitometric tracing of the gel stained with coomassie blue.*

scanned in densitometer and the relative percentage of each protein band estimated. Six gels were scanned for this purpose and average values were taken as representative of the relative amounts of individual polypeptides (Fig. 8). The same polypeptides were major or minor in each run but precise proportion varied among runs and strains. The three major polypeptides of mol. wt 49,000; 34,000 and 24,000 contained about 62.0% of the total protein. It should be mentioned here that we observed three more bands in the coomassie blue stained gels corresponding to the mol. wt greater than 100,000.

Six dye bands could be detected after staining of virus containing gels for glycoproteins with PAS (Fig. 9). These corresponded to polypeptides of mol. wt 100,000; 90,000; 62,000; 49,000 and 34,000. One additional band of glycoprotein was detected which corresponded to the polypeptide of the mol. wt more than 100,000. Thus it appears that the two major polypeptides of mol. wt 49,000 and 34,000 of MuMTV contain polysaccharides.

The relative proportions of carbohydrate in polypeptides of mol. wt 49,000 and 34,000 was observed to be more or less similar though the protein content of polypeptide of mol. wt 49,000 was found to be 1.8 times more than that of polypeptide of mol. wt 34,000.

DISCUSSION

MuMTV purified from milk or from mammary tumours have a characteristic buoyant

density in aqueous solutions which varies with the composition of the gradient [23, 24]. In sucrose gradient, the B particles band at the density of 1.17 g/ml. In the present study, where Sarkar and Dion method [11] was employed, two light scattering bands were consistently observed, one at the density of 1.17 g/ml and the other at 1.15 g/ml. In a simultaneous run with sucrose gradient, B particles from strain C3H(Jax) milk showed a single light scattering band at the density of 1.17 g/ml. The electron microscope studies in strain ICRC revealed the presence of B particles in predominance and a few C particles in each of the viral bands examined independently. This observation rules out the possibility of the upper band at the 1.15 g/ml. density being solely comprised of C particles though the presence of these particles in strain ICRC is of interest.

In a recent report by Sarkar, Manthey and Sheffield [25], on the effect of different preparative procedures for electron microscopy on the size and shape of both MuMTV and MuLV virions, a possibility of small particles present in MuMTV preparation which is intact and can carry virus infectivity has been suggested. Moore *et al.* [26] on the basis of a number of physical measurements also suggested that tumourigenic activity could be carried by a particle that was smaller than the usual B particles. In the present study the separation of B particles into two independent bands might be due to a difference in size of the virions resulting in a difference in sedimentation velocity and in the time needed to reach their density equilibrium. That this could be so is further strengthened by the fact when the gradient is subjected to extended spinning of three hours, the two bands merge into a single light scattering band. Further studies on the size differences of B particles in relation to their infectivity are underway.

The presence of C type particles besides B particles, in the milk of certain high mammary cancer strains of mice [27, 28] and in the culture medium of mouse mammary tumours has been reported by many [29–32]. Dmochowski *et al.* [27] have done the thin section electron microscopy of high speed centrifugal pellets of milk from different strains of mice with high or low incidence of mammary cancer and high or low incidence of leukemia. The presence of large numbers of B particles with few C particles in the milk of strain ICRC corroborates the findings reported by Dmochowski *et al.* [27] in the milk of strains of mice susceptible to mammary cancer with a medium incidence of leukemia.

MuMTV isolated from milk of strain ICRC was found to contain at least 10 polypeptides by polyacrylamide gel electrophoresis, with mol. wt ranging from 12,000 to 100,000 (Table 2). Three of these proteins, mol. wt 49,000 (p 49), 34,000 (p 34) and 24,000 (p 24) can be considered as the major structural proteins of the virions judging from the intensity of coomassie blue staining. Our identification of major polypeptides of MuMTV from ICRC milk agrees in general with those reported by others [11, 33–36]. However, certain differences are noted between their results and those obtained by us. The mol. wt of the major polypeptide according to our estimation and those reported by Dickson *et al.* [12] and Dickson and Skehel [37] is 49,000 whereas others have estimated values as 52,000 [35, 38, 39] and 55,000 [11, 40]. The same polypeptides are consistently major or minor though variations are observed in the precise proportions of different polypeptides reported by different workers in spite of a similar technique being used. These apparent discrepancies are

attributed to the differences in the sources of the virus [11]. In the present study, although certain minor differences are observed in the relative amounts of different mol. wt proteins of MuMTV from ICRC and C3H strains, both the strains contain p 49, p 34 and p 24 as the major polypeptides.

Polypeptide p 49 is the most prominent protein common to MuMTV isolated from strains R III, C3H, GR, A and BALB/c [11, 36, 37] and therefore considered to be a major group specific antigen (gs-1). It was shown to be a glycoprotein by PAS staining, glucosamine incorporation and lactoperoxidase iodination of intact virions [34, 35]. Further, Sarkar and Dion [11] on the basis of their immunodiffusion and immunoelectronmicroscopic studies convincingly established p 49 as a group specific antigen present on the virion surface and p 28 as the major group specific internal antigen (gs-2). In the present study we detected the presence of carbohydrate moieties in p 49 and p 34 by PAS staining in viral isolates of the both strains ICRC and C3H(Jax) suggestive of their locations on the virion membrane.

Since the MuMTV isolated from ICRC milk exhibited presence of few C type particles under the electron microscope, a comparison was made of the polypeptide pattern of MuMTV from strains ICRC and C3H(Jax) with a view to examining if some of the polypeptides attributed to ICRC MuMTV are derived from contaminating C type of viruses. In the polyacrylamide gels, the polypeptide pattern of MuLV (C type particles) isolated from strain ICRC leukemia lesions showed a major polypeptide of mol. wt 30,000 (Fig. 7) which was also reported by Oroszlan *et al.* [41] in MSV/MuLV viral preparations and was found to be a major group specific antigen. No protein corresponding to this major protein of MuLV was observed in the MuMTV of strain ICRC. This observation is further supported by the report of Kimball *et al.* [36], who observed the characteristic pattern of polypeptides of MuMTV only, in viral isolates from tissue culture fluid of primary cell cultures of BALB/c mice mammary tumours contaminated with MuLV to the extent of 3%.

The standard anti MTV-S serum could detect common antigens in the MuMTV isolated from ICRC and C3H(Jax) milk, in double immunodiffusion. The intact virions of both the strains produced a single strongly curved line very close to the antigen well indicating the particles to be of very large size [15, 42]. Blair [43] and Daams *et al.* [15] have reported complete B particles in this line when seen under the electron microscope. The anti MTV-S serum could produce 3–4 precipitating lines with ether disrupted B particles from ICRC as well as C3H(Jax) strains. All these lines show lines of identity. In immunoelectrophoresis experiments, these lines have β electrophoretic characteristics. Daams *et al.* [15] have done elaborate studies on antigenic structure of murine mammary tumour viruses in double immunodiffusion. These authors were able to show about three precipitating lines with disrupted MTV-S in LKB ouchterlony plates when tested against anti MTV-S serum. The effect of trypsin, pepsin, HCl, RNase, phospholipase C and acridine orange on the appearance of precipitation lines of MTV-S antigens was investigated. On the basis of these results, it was concluded by these authors that the lines towards the antiserum well represent the antigens of the membrane whereas the lines towards the antigen well represent the antigens of the nucleoid [44]. In the present studies, since the lines representing nucleoid and the membrane antigens show lines of identity in strains C3H(Jax) and ICRC, they indicate group specific antigens. Further work on the purification of subviral components of strain ICRC MuMTV for the antigenic studies is in progress.

In the present studies, we have employed HAI test of Sibal *et al.* [14] for the detection of MuMTV antigens in the milk plasma of strains ICRC and C3H(Jax). Using this method, these authors [14] have shown correlation between the mammary tumour incidence, presence of B type particles and the hemagglutination inhibition titer. Their findings were confirmed by Parks *et al.* [45]. By using more precise method like radioimmunoassay Verstraeten *et al.* [46] have studied the expression of MuMTV antigens in milk of female mice of several strains and substrains. It was concluded by these workers that the viral antigen levels were always more in the milk of high mammary cancer strains like C3H, GR and R III as compared to those of moderate mammary cancer strains like C3Hf, DBAf and low mammary cancer strains Af, DDf, 020 etc. In the present studies, both the strains C3H(Jax) and ICRC have shown comparable expression of viral antigens in their milk plasma. Although the mammary tumour incidence in breeders of strain ICRC has gone down to 20%, the parameters studied in the present investigations have indicated that the MuMTV of strain ICRC exhibit characters comparable to those of the high cancer strain C3H(Jax). Experiments are in progress to estimate the MTV antigens in the milk plasma by using

more precise methods to confirm these findings.

The strain ICRC is rather unique in having a large amount of MTV and still a low mammary tumour incidence. The decrease in the mammary tumour incidence in this strain can be therefore attributed to some other factors. The rise is the tumour incidence from 20 to 70% on force breeding is a point worth noting. Essentially it is the potency of hormonal stimulus that seems to determine the mammary tumour incidence.

Effect of Methotrexate and Aminopterin on Tritiated Nucleoside Suicide of Colony Forming Cells, *in Vitro**

EDWIN M. UYEKI, TOMOO NISHIMURA, TODD N. MILLER and TERESA U. BISEL

Department of Pharmacology, University of Kansas Medical Center, College of Health Sciences and Hospital, Kansas City, Kansas 66103, *U.S.A.*

Abstract—*The effects of methotrexate (MTX) and aminopterin (AMN) on the incorporation of deoxyuridine (dUrd), deoxythymidine (dThd) and uridine (Urd) into granulocytic/monocytic and lymphocytic colony forming cells (CFG-GM and CFC-L) from BDF_1 mice is demonstrated by the alteration of the tritiated nucleoside suicide of precursor cells. The proportion of colonies that survived suicide effects, i.e. self-irradiation, from a specific tritiated precursor reflects the number of CFC not incorporating the precursor. Preincubation of CFC-GM with MTX and AMN (10^{-5} M or 10^{-6} M) completely prevented* 6- ^{3}H-*dUrd* (5μCi) *suicide, partly reduced* ^{3}H-*dThd* (5 μCi) *suicide, and did not affect* ^{3}H-*Urd suicide when cells were pulsed for* 2–3 *hr. When cells were exposed to drugs and tritiated compounds for the duration of the culture period* (7 days), *the reduction in* 6- ^{3}H-*dUrd suicide by the folate antagonists* (10^{-7} *M*–10^{-8} *M*) *differed between CFC-GM and CFC-L. Results are discussed with respect to the suicide technique as a novel biochemical probe in the analysis of drug effects on colony forming cells*, in vitro.

INTRODUCTION

THERE has been much recent information on the mechanism of action of methotrexate (MTX), a folate inhibitor, *in vivo*, [1, 2] and *in vitro*, in many cell lines [1, 3–8]. Because this agent's hemopoietic toxicity is a major consideration in chemotherapy, we examined how MTX and aminopterin (AMN), an analog of MTX, alter the incorporation of various nucleosides into hemopoietic precursor cells. Our investigative approach combined colony forming cell (CFC) assays for the granulocytic/monocytic (CFC-GM) and B-lymphocytic (CFC-L) precursor cell lineages with the suicide technique, i.e. the lethal irradiation of a cell resulting from incorporation of a radioactive nucleic acid precursor. Our use of several tritiated precursors expands the scope of the suicide technique, which in the past was mainly associated with incorporation of radioactive deoxythymidine only [8].

Many [3–6] have directly determined radioactive nucleoside levels in cells after MTX treatment, but this direct analysis is not feasible in hemopoietic precursor cells for the following reasons: (1) physical isolation of a precursor cell population is not yet possible and (2) assuming that morphological identification could be established (for discussion, see [9]), the infrequency of these cells within the entire hemopoietic cell pool (about 2–5 precursor cells per 10^3 nucleated cells, according to our clonal assays [10]) adds to the impracticality of this direct approach. Hence, in our system, if MTX or AMN interferes with the incorporation of a specific radioactive nucleoside into a precursor cell, this effect would be reflected in the enhanced number of surviving colonies, i.e. progeny of precursor cells that did *not* undergo suicide. Thus, we studied how various dose regimens and drug incubation periods of MTX and AMN reduced the suicide effects of the following tritiated nucleosides: deoxythymidine, deoxyuridine and uridine, on CFC-GM and CFC-L development.

MATERIAL AND METHODS

BDF_1 female mice (Jackson Laboratory, Bar Harbor, Maine) were used as sources of bone

marrow and spleen cells for the clonal cultures. Administration of methotrexate (MTX) (donated by Lederle Laboratories, Pearl River, New York) or aminopterin (AMN) (Sigma, St. Louis, Missouri) preceded doses of radioactive compounds (expressed as μCi per ml) by 1–2 hr in washed out drug studies or by 10 min in unwashed studies. Nonradioactive cytidine (Cyd) (Sigma) was also administered with MTX as a pretreatment. The following tritiated precursors were purchased from New England Nuclear (Boston, Massachusetts): methyl tritiated deoxythymidine (^{3}H-dThd) (sp. act. = 20 Ci/mM), 6-tritiated deoxyuridine (6-^{3}H-dUrd) (sp. act. = 30 Ci/mM), 5- and 6-tritiated uridine (5-^{3}H-Urd and 6-^{3}H-Urd) (sp. act. = 25 Ci/mM). 5-tritiated deoxyuridine (5-^{3}H-dUrd) (sp. act. = 16 ci/mM) and 5,6-tritiated uridine (5,6-^{3}H-Urd) (sp. act. = 16 Ci/mM) were both obtained from ICN (Irvine, California).

Unwashed drug studies

Bone marrow cells (1×10^5 cells) were plated in 0.5 ml McCoy's 5A media (modified) with 10% fetal calf serum (FCS) and 5% horse serum in 35 mm tissue culture dishes; spleen cells (1×10^5 cells) were plated in 0.5 ml minimum Eagle's medium with 20% FCS + 1% sheep red blood cells. Then drugs and radioactive agents were added to these cell suspensions. An agar-media admixture was then added to make 1.0 ml semi-solid media, such that the final concentration was 0.3% of Bactoagar. Bone marrow cells were cultured for CFC-GM according to our modification [10] of the technique of Metcalf and Moore [11]. Spleen cells were cultured for B-lymphocytic CFC, using the method of Metcalf *et al.* [12]. Cultures were examined for clonal growth after 7 days incubation at 37°C.

Washed out drug studies

Higher concentrations of the drugs and radioactive agents were used in washed out studies than in unwashed experiments, due to the duration of drug exposure, i.e. 4 hr and 7 days, respectively. Bone marrow and spleen cells were plated at 1 or 2×10^5 cells per well in 1.0 ml media + serum (as described for unwashed studies). Preliminary tests showed that the presence of serum during drug exposure did not significantly alter drug or suiciding effects, yet was optimal for maintaining cell viability (not shown). Cells were incubated with drugs and nonradioactive agents at 37°C, washed out and cultured in the same Costar 6-well cluster tissue culture dishes in order to eliminate cell suspension transfer steps and to reduce interference by density inhibition conditions during drug pulse. These culture dishes consisted of six 35 mm wells per cluster dish. After a designated drug preincubation period, cells were pulsed with radioactive nucleic acid precursors for 2–3 hr. A mixture of nonradioactive deoxynucleosides (10^{-5} M) was added to cultures to terminate the radioactive pulse; this chase consisted of equal parts of deoxyguanosine, deoxyadenosine, deoxythymidine and deoxycytidine (Sigma). After the chase cells were washed twice with Hanks' Balanced Salt Solution + 5% calf serum; cells were centrifuged at 300 $\times$ ***g*** in between washes, using a Cooke carrier to hold each Costar cluster dish in the centrifuge. After the final wash cells were resuspended in 1.0 ml semi-solid media and cultured as was described for unwashed cultures.

RESULTS

Table 1 shows the reduction by MTX (10^{-5} M or 10^{-6} M) and AMN (10^{-5} M) of the suicide effects of 5 μCi ^{3}H-dThd or 6-^{3}H-dUrd on CFC-GM formation in a washed out experiment. Bone marrow cells were preincubated with one of the folate inhibitors for 2 hr before exposure to a tritiated deoxynucleoside for an additional 2 hr; cells were then washed out and prepared for culture. Because MTX and AMN block the conversion of deoxythymidylate from deoxyuridylate through an inhibition of the folate reductase, we predicted that MTX and AMN would block the metabolism of exogenous 6-^{3}H-dUrd. On the other hand, since dThd can be incorporated via the salvage pathway, ^{3}H-dThd suicide would not be directly affected by the metabolic interference of MTX or AMN. Results generally supported these notions; they are expressed as CFC per dish, percent of control and as a suicide ratio (radioactive treatment/nonradioactive treatment). The suicide ratio indicated the efficacy of drug prevention of suicide effects. For example, AMN treatment reduced 6-^{3}H-dUrd suicide, giving CFC values that were 79% of control; when comparing this CFC value to its corresponding nonradioactive value (AMN treatment alone), a suicide ratio of 0.96 is obtained. If the CFC value observed when cells were pretreated with MTX or AMN before the radioactive pulse (Columns B or C, Table 1) was *not* significantly different from the CFC value derived from the corresponding nonradioactive counterpart (Column A, Table 1), this indicated a dramatic reduction in the tritium suicide resulting from drug interference with the incorporation of a radioactive precursor. In other words, we are measuring if there is any significant difference between the CFC growth obtained with or without pulse, relative to drug

effects. The highest degree of suicide prevention by a drug would, then, occur when there is no difference between drug-treated cultures and drug-pretreated pulsed cultures.

MTX (10^{-5} M) caused the greatest reduction in 6-^{3}H-dUrd suicide of CFC-GM, raising the suicide ratio from 0.38 to 0.99; however, all drug treatments considerably reduced 6-^{3}H-dUrd toxicity, such that CFC values (Column B, Table 1) were *not* significantly different from their non-radioactive counterparts (Column A, Table 1). Although there was a greater inhibition of ^{3}H-dThd suicide when cells were pretreated with MTX, rather than AMN, these drug-pretreated cultures (Column C, Table 1) *were* significantly different from corresponding cultures exposed to the drug only (Column A, Table 1). Hence, the folate antagonists were more effective in blocking the effects of 6-^{3}H-dUrd suicide, than the effects of ^{3}H-dThd suicide, in CFC-GM.

To determine if MTX could similarly inhibit the intracellular metabolism of exogenous uridine, bone marrow cells were exposed to MTX (10^{-5} M) for 1 hr before a 3 hr pulse with 5 μCi 5,6-^{3}H-Urd, 6-^{3}H-Urd or 5-^{3}H-Urd. Cyd (10^{-4} M) was administered with MTX to one set of cultures to determine its role as a metabolic intermediate in the Urd pathway in CFC-GM, i.e., how Cyd altered ^{3}H-Urd suicide. Cultures were washed out and the resulting CFC-GM formation 7 days later, shown in Table 2, revealed that ^{3}H-Urd suiciding was relatively the same (>90% inhibition), regardless of the position(s) at which the tritium label was located. MTX, by itself, did not affect this ^{3}H-Urd suicide, but when cells were pretreated with Cyd in addition to MTX, a marked prevention of ^{3}H-Urd suicide was observed in the number of surviving colonies.

Data shown in Table 3 indicates that the metabolic fate of dUrd *is* reflected by differences in suicide effects when the tritium label occurs at the 5- or 6-position; one would expect 6-^{3}H-dUrd

Table 1. *MTX and AMN reduction of suicide effects of* 6-^{3}H-*dUrd and* ^{3}H-*dThd on CFC-GM*

Cyd 10^{-4} M	320	81						

Legend as for Table 1 except bone marrow cells were exposed to MTX (10^{-5} M) and/or Cyd (10^{-4} M) for 1 hr, followed by a 3 hr pulse with 5 μCi ^{3}H-Urd labeled in the 5-, 6- or 5,6-position. Agents were washed out. Values represent the mean of 3 cultures.

Cyd = cytidine, ^{3}H-Urd = tritiated uridine.

suicide to be greater than 5-^{3}H-dUrd suicide, since the nonradioactive methyl group replaces tritium at the 5-position. A 2 hr pulse of bone marrow cells with 5 μCi 6-^{3}H-dUrd reduced CFC-GM formation by greater than two-thirds; an equivalent dose of 5-^{3}H-dUrd did not affect clonal growth (suicide ratio = 1.08). Even at four-fold higher doses, 5-^{3}H-dUrd reduced colony formation by only a third. For this reason, 6-^{3}H-dUrd was always used for our suicide studies. Borsa and Whitmore [4] previously demonstrated higher levels of radioactivity in DNA when ^{3}H-dUrd was labeled at the 6-position, compared to the 5-position.

Tables 4 and 5 represent unwashed experiments, i.e. studies in which drugs and radioactive compounds were present for the entire culture period. Table 4 shows results of 6-^{3}H-dUrd suicide (0.5 μCi) on CFC-GM and the inhibition of suicide effects by low doses of MTX (10^{-8} M) or AMN (10^{-7} M and 10^{-8} M). Although the toxicity of MTX (10^{-8} M) and AMN (10^{-7} M) was similar (77 and 70% of control, respectively), AMN caused a greater reduction in 6-^{3}H-dUrd suicide than did MTX, i.e. 1.07 and 0.31 suicide ratios, respectively. The prevention of suicide effects by 10^{-8} M AMN was also more effective than MTX, lowering 6-^{3}H-dUrd toxicity to a suicide ratio of 0.66.

CFC-L formation demonstrated a greater sensitivity to the effects of AMN and MTX than did CFC-GM cultures when drugs were not washed out (Table 5). For example, CFC-GM cultures treated with 10^{-8} M concentrations of MTX or AMN were 77 and 111% of control, respectively (Table 4), compared to CFC-values, i.e. 40 and 39% of control, respectively (Table 5). In addition, MTX and AMN were equally toxic to CFC-L formation.

MTX and AMN (10^{-7} M and 10^{-8} M) effectively reduced 6-^{3}H-dUrd suicide (0.5 μCi) in lymphocytic colonies, such that suicide ratios ranged from 0.71 to 1.10. Cultures exposed to AMN (10^{-7} M and 10^{-8} M) or MTX (10^{-7} M) before the radioactive pulse (Column B, Table 5) were not significantly different from cultures given the corresponding drug treatment without pulse (Column A, Table 5), indicating a high degree of suicide prevention. Although some reduction in 6-^{3}H-dUrd suicide occurred with 10^{-8} M MTX pretreatment (i.e. 0.03 suicide ratio altered to 0.71 suicide ratio), the suicide prevention was not as marked as with the aforementioned drug treatments; that is, pulsed (Column B, Table 5) vs "no pulse" (Column A, Table 5) CFC values were significantly different from each other, relative to the 10^{-8} M MTX treatment. AMN also did not significantly alter suicide effects when administered at a 10^{-9} M concentration (see Column B vs Column A, Table 5). Hence, although variations in the toxic effects of or in the inhibition of 6-^{3}H-dUrd suicide by MTX and AMN were observed between unwashed CFC-GM and CFC-L cultures, both assays for hemopoietic precursor cells demonstrated sensitivity to the block on 6-^{3}H-dUrd metabolism by MTX or AMN at low physiologic concentrations.

Table 3. 6-^{3}H-*dUrd or* 5-^{3}H-*dUrd suicide of CFC-GM*

CFC-L = lymphocytic colony forming cells.
*Values (Column B) are significantly different ($P < 0.05$) from corresponding nonradioactive values (Column A) according to Duncan's new multiple range test, preceded by analysis of variance.

DISCUSSION

By combining suicide techniques with clonal assays, we can measure the ability of methotrexate or aminopterin to block the incorporation of specific nucleic acid precursors into hemopoietic precursor cells. The proportion of colonies that survive when either folate antagonist interferes with the process of tritiated nucleoside suicide indicates the proportion of precursor cells that are sensitive to the toxic effects of these agents, i.e. their inhibition of (nonradioactive) nucleoside incorporation into DNA or RNA. To our knowledge, this study represents the first attempt to determine the extent of MTX or AMN damage to hemopoietic precursor cell as it relates to a specific nucleoside's incorporation.

To examine how a short (4 hr) pulse with MTX and AMN altered dUrd and dThd incorporation into CFC-GM, bone marrow cells were exposed to different concentrations of the drugs before receiving 5 μCi 6-^{3}H-dUrd or ^{3}H-dThd. These doses (10^{-5} M and 10^{-6} M) were in the range of serum levels (10^{-8} M–10^{-4} M) found in patients on a high-dose MTX schedule [13] and thus, were clinically relevant. Others [1, 4, 7] have shown MTX inhibition of 6-^{3}H-dUrd incorporation into mature cell lines from normal and transformed tissues. Results in Table 1 similarly show that MTX and AMN block the conversion of dUrd to dThd in granulocytic/monocytic precursor cells, for both agents reduced 6-^{3}H-dUrd suicide. However, because dThd can bypass the MTX and AMN block by means of the salvage pathway, we did not expect any significant inhibition in ^{3}H-dThd suicide by the folate antagonists. Tew and Taylor [14] noted that bone marrow tissue of rats was capable of circumventing the MTX block *in vivo* by means of the salvage pathway. Although a 2 hr pretreatment with MTX (10^{-5} M and 10^{-6} M) resulted in a greater reduction of ^{3}H-dThd suicide than with AMN (10^{-5} M) pretreatment, these differences were not statistically significant. Hryniuk [6, 7] attributed a decrease in ^{3}H-dThd incorporation in L5178Y cells to early MTX obstruction of *de novo* purine synthesis; the early "purineless" death was reversed with hypoxanthine. The mechanism for MTX inhibition of dThd incorporation was suggested to be due to an indirect impairment of the reductase through a block of RNA synthesis [6]. We are presently investigating the role of purines in conjunction with dThd in alleviating MTX toxicity to CFC-GM and CFC-L, using the suicide technique.

Results of Table 2 show that the suicide of CFC-GM was the same, whether labeled at the 5-, 6- or 5,6-positions; MTX by itself did not alter these suicide effects, but MTX + Cyd did markedly reduce ^{3}H-Urd suicide. On the other hand, others [4, 6, 7] reported a decrease in 5-^{3}H-Urd incorporation into RNA of passaged cells after MTX treatment and suggested that the MTX-induced purineless state was a factor in this reduction (see above Discussion). Taken together, these results suggest the following possibilities: (1) ^{3}H-Urd is incorporated into RNA of granulocytic/monocytic progenitor cells and causes their suicide, but MTX does not affect this incorporation as seen in other cell types [4, 6, 7]; or (2) ^{3}H-Urd suicide is due to its incorporation into DNA, which is not blocked by MTX. Some preliminary findings (unpublished) that cytidine, but not deoxycytidine, reduces ^{3}H-Urd suicide support the first interpretation; however, further studies are required. The observation that 5-^{3}H-Urd suicide was blocked when Cyd (10^{-4} M) was added with the MTX pretreatment (Table 2) suggests that the observed suicide reduction was most likely due to the effects of Cyd alone.

The greater effect of ^{3}H-dUrd suicide of CFC-GM that occurred when the isotope was labeled at the 6-position, rather than the 5-position, points out the sensitivity of the suicide technique to detect the metabolic substitution of tritium with a nonradioactive methyl group at the 5-position of the dUrd compound. The fact that 5-^{3}H-dUrd suicide *did* occur at all could be explained by the radioactive (as opposed to the chemical) impurity of the isotope, i.e. 25% of tritium label occurred at the 6-position (confirmed by ICN).

CFC-L formation was generally more sensitive to MTX and especially, to AMN toxicity than was CFC-GM when drug exposure lasted for 7 days (Tables 4 and 5); e.g. with 10^{-8} M MTX, CFC-GM and CFC-L values were 77 and 40% of controls, respectively. Although Pinedo *et al.* [5] reported an enhanced toxicity of MTX (10^{-8} M) to CFC, i.e. 50% inhibition, when dialyzed FCS was used (vs undialyzed), it should be pointed out that our assay employing undialyzed FCS was more sensitive to MTX toxicity than their assay using undialyzed FCS. Moreover, in our assay system, clonal cultures of P815 mastocytoma cells were completely inhibited by 10^{-8} M MTX (unpublished). It has also been shown that serum levels of $2–5 \times 10^{-8}$ M MTX were not clinically toxic 72 hr after MTX administration [13]. It is of interest that at 10^{-8} M concentrations, MTX alone slightly reduced CFC-GM values (77% of control), yet did not markedly affect 6-^{3}H-dUrd suicide (as was also observed in L5178Y cells [7]); whereas, AMN was not toxic to CFC-GM (111% of control) and decreased 6-^{3}H-dUrd incorpo-

ration, raising the suicide ratio from 0.11 to 0.66. Hence, the clinical implications are that, at 10^{-8} M concentrations (over 7 days), AMN was more effective in blocking methylation of dUrd in bone marrow precursor cells than MTX. However, 10^{-8} M MTX did reduce 6-^{3}H-dUrd suicide in CFC-L; others [1, 5] have observed a similar reduction in 6-^{3}H-dUrd incorporation into various cell lines after the same MTX dose. Thus, MTX and AMN prevention of 6-^{3}H-dUrd suicide of CFC-GM was similar when cells were exposed to either drug for a short period (Table 1), but when drugs were not washed out (Table 4), 6-^{3}H-dUrd suicide was decreased to greater extent by AMN than MTX.

The 10^{-7} M and 10^{-8} M concentrations of MTX and AMN decreased 6-^{3}H-dUrd suicide in CFC-L (no wash study), such that the suicide ratios ranged from 0.71 to 1.10 (Table 5). Only the 10^{-9} M dose of AMN failed to alter 6-^{3}H-dUrd suicide (suicide ratio of 0.08). AMN (10^{-8} M) appeared to be more effective in preventing 6-^{3}H-dUrd suicide than MTX (10^{-8} M), although this difference was less marked than was seen in CFC-GM cultures; this may be related to the fact that MTX and AMN were equally toxic to CFC-L.

In conclusion, we have shown how the suicide technique can be used to determine the biochemical status of hemopoietic precursor cells, especially as it relates to drug mechanisms. Unique advantages of the suicide technique as a biochemical probe are: (1) It is possible to employ tracer concentrations of nucleosides (because they are tritiated*) to detect the biological response, viz. suicide, to drug alteration of nucleoside incorporation into major cellular macromolecules involved with replication mechanisms (DNA). (2) The short drug pulses (terminated by washing procedures), by temporal definition, specifically affect the precursor cell population when measured by clonal assays. (3) Although the number of CFC's that were irradiated from ^{3}H-nucleoside suicide is indirectly determined (relative to controls), the suicide technique is the only practical means at present of measuring such biochemical properties of hemopoietic (or even tumor) precursor cells. Finally, the clinical applications of the suicide technique could be done with little, or no revisions of the existing technique. We have already conducted preliminary studies on tritiated nucleoside suicide in human lymphoblastic CFC (in preparation). Also, we have found that this technique has wide applications; similar concentrations of other folate reductase inhibitors, trimethoprim and pyrimethamine, as well as other anti-tumor agents, e.g. 6-mercaptopurine and 5-fluorodeoxyuridine, will prevent the suicide effects of appropriate tritiated nucleosides in clonal cultures (in preparation).

*2 μCi of ^{3}H-dThd (sp. act. = 20 Ci/mM) is approximately equivalent to 10^{-10} moles labeled compound.

Kinetic Features of a Lymphoid Population in the Blastic Crisis of Chronic Granulocytic Leukaemia

MINOU D. FOADI, ANGELA M. SLATER and G. D. PEGRUM

Department of Haematology, Charing Cross Hospital Medical School, St. Dunstan's Road, London, W6 8RF, United Kingdom

Abstract—*Kinetic and chromosome studies were performed on the primitive cells from a patient in the blastic phase of chronic granulocytic leukaemia who had two distinct cell populations. Lymphoblastic cells predominated and stained with fluorescent labelled anti-acute lymphoblastic leukaemic sera. There was variation in the proliferative activity of the myeloid population but the lymphoid cells remained essentially quiescent.*

A Ph^1 chromosome was identified in the myeloid but not found in the lymphoid cells.

The findings suggest the presence of a population unlike those of acute lymphoblastic leukaemia with limited metabolic capacity.

INTRODUCTION

THE PRESENCE of immature cells with characteristics similar to lymphoblasts has been described in patients during blastic crisis of chronic granulocytic leukaemia (CGL) [1–7]. Such cells can now be recognised not only morphologically but they have the membrane markers recognized by anti-ALL serum [8].

The kinetics of these cells have not been studied previously. In this paper we present some analyses of the proliferative behaviour of the leukemic cells in a patient with CGL in blastic crisis whose peripheral blood and bone marrow contained a mixture of primitive myeloid and lymphoid cells.

Clinical details

A 37-yr old man was found to have CGL while in hospital for the repair of an inguinal hernia. The white blood count was 385×10^9/l, platelets 414×10^9/l and haemoglobin 14.7 g/dl. The Philadelphia chromosome was seen in direct bone marrow examination. He was treated with busulphan intermittently. There was a marked improvement in the clinical and haematological condition and he remained well for 17 months. He then developed thrombocytosis in which the platelets were increased to over 1000×10^9/l, followed by an increased white blood count and the appearance of blast cells in the peripheral blood. Bone marrow and blood findings were consistent with a blastic crisis. There was a predominance (80%) of primitive cells morphologically resembling lymphoblasts which reacted with anti-ALL serum. As a result of the treatment which included vincristine and L-asparaginase there was a reduction in the total blast cell count together with an improvement in the patient's general condition. He then developed an infection which was accompanied by neutropenia. The bone marrow at this time showed persistence of both primitive lymphoid and myeloid cells. He remained relatively well for a period of five months. Eight months later blast cells reappeared in large numbers in the peripheral circulation and despite intensive chemotherapy he died 27 months after the original diagnosis.

Accepted 14 September 1977.

MATERIAL AND METHODS

Kinetic and chromosome studies on the bone marrow and peripheral blood specimens were performed at the beginning of and repeated throughout the blastic crisis.

Methods

Aliquots of bone marrow and peripheral blood samples were incubated separately at 37°C with 2.5 μCi/ml of 3H-TdR (specific activity 5 Ci/mmole) for half an hour, 5 μCi/ml of 3H-UR (specific activity 5 Ci/mmole) and 10 μCi/ml of ^{14}C-leucine (specific activity 348

mCi/mmole) for one hour and smears were made of each buffy layer.

The DNA content of the cells was measured by microdensitometry of Feulgen stained nuclei [9] and this was combined with autoradiography [10].

Chromosomes were studied on direct bone marrow specimens and in peripheral blood cells stimulated with and without phytohaemagglutinin according to the method of Moorhead *et al.* 1960 [11]. During the terminal crisis, primitive myeloid and lymphoid cells in the bone marrow were separated using a cell sorter by means of an anti-ALL serum [12, 13] and the nuclear DNA content of both populations of cells was examined by microdensitometry using a Vickers M85 Microdensitometer.

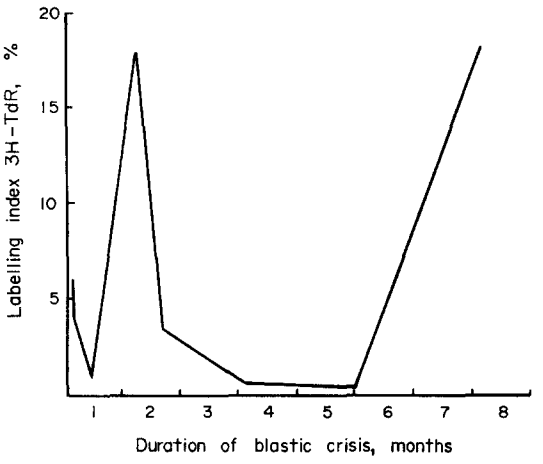

Fig. 2. Labelling index of large "myeloblasts" cells in the bone marrow during blastic crisis.

RESULTS

At the beginning of the blastic crisis, 80% of the nucleated cells in the peripheral blood and bone marrow were lymphoid (Fig. 1) and about 10% were myeblasts. There was a variation in the proportion of these cells throughout the course of crisis but lymphoid cells remained predominant. The majority of lymphoid cells were small (7–9 μ dia), with scanty cytoplasm and seldom had obvious nucleoli. They did not give a non-specific esterase reaction and some had periodic acid schiff (PAS) positive granules. The degree of PAS positivity did not change throughout the course of blastic phase. Some immature cells with a high cytoplasmic:nuclear ration were Sudan Black positive, along with the more clearly differentiated myeloid cells. It was not always easy to determine the origin of the medium sized blast cells. Although there were blocks of PAS positivity in some, others had the characteristics of myeloblasts. The peripheral blood LAP score was 17 (Normal control 15–95).

Labelling index (LI)

3H-*TdR*. At the beginning of malignant transformation the 3H-TdR uptake of the myeloblasts in the bone marrow was 4.5% increasing to 18% three weeks later. The number of cells in DNA synthesis fell to 4% in the next month and remained very low until the terminal stage when the LI of the myeloblasts rose to 18.4% again (Fig. 2). The LI of the lymphoid cells was $<1\%$ and remained low throughout the blastic crisis. Cells in mitosis were sparse (0.03%) and their number remained very low throughout the course of the blastic crisis.

3H-*UR*. The incorporation of 3H-UR was to measure the RNA synthetic activity. The myeloblasts had a high LI (80–86%) while only 5% of the small lymphoid cells had incorporated 3H-UR. The intensity of labelling examined by grain count was considerably higher in the myeloblasts (grain count 50–100) than in the small lymphoid cells (grain count 10–25). When size is taken into consideration the difference in grain count is unchanged.

^{14}C-*leucine*

At the onset of blastic crisis 88% of the myeloblasts incorporated ^{14}C-leucine while the LI of the small lymphoid cells was only 20%. A similar result was obtained at the terminal stage of the blastic crisis.

Lymphocyte transformation. No response to PHA occurred in the three day cultures of peripheral blood.

Chromosomes. The Philadelphia chromosome (Ph^1) was present in dividing myeloid cells on direct analysis of the bone marrow at diagnosis, in the beginning and throughout the blastic crisis. Lymphoblasts recognised by anti-ALL serum showed very few mitoses and we were unable to demonstrate the Ph^1 chromosome in any clearly recognisable lymphoid cells. Polyploidy and endoreduplication were seen in both direct bone marrow preparations and peripheral blood cultures during the blastic crises.

DNA content

Figure 3 shows the distribution of nuclear DNA content of lymphoid and myeloid cells in the bone marrow during the first month of blastic crisis. The lymphoid cells have a 2n DNA content with no cells in S while the myeloblasts

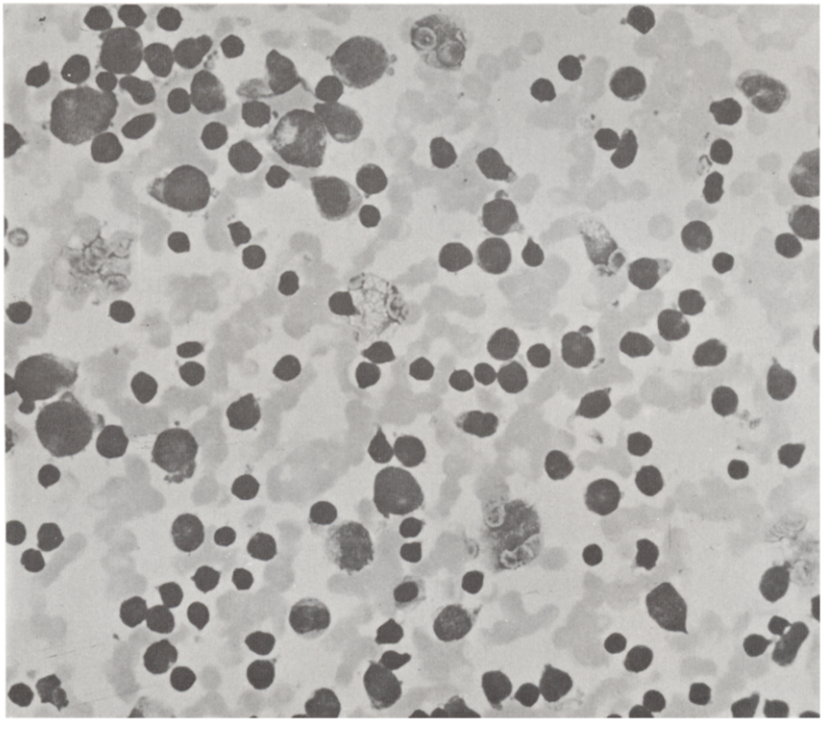

Fig. 1. Bone marrow stained with Jenner Giemsa demonstrating the presence of small "lymphoid" type cells.

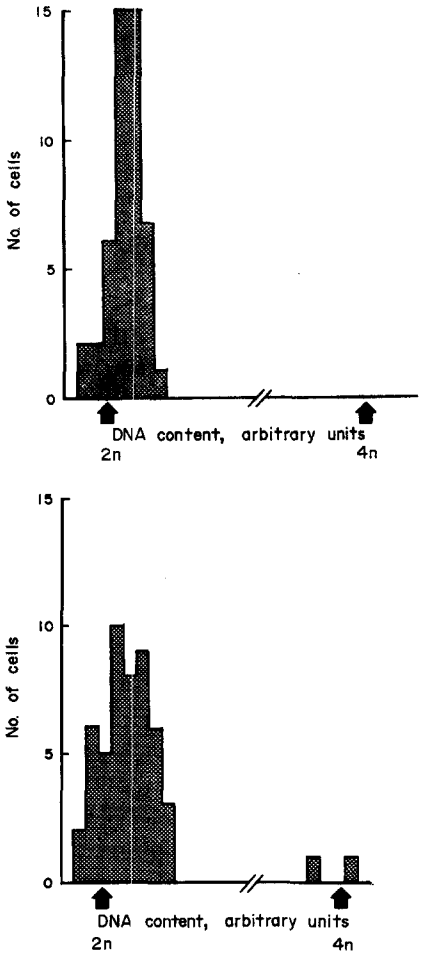

Fig. 3. Distribution of nuclear DNA content. Above small "lymphoid" cells and below large "myeloid" cells in the bone marrow.

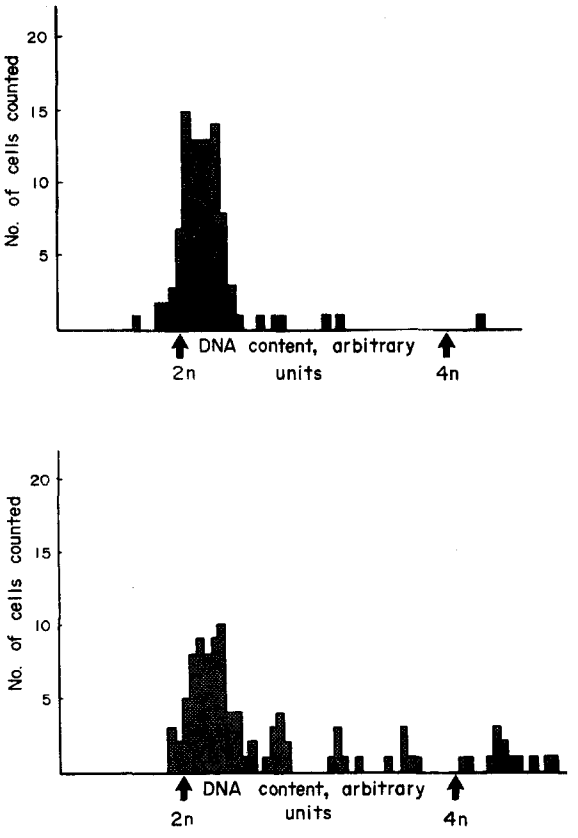

Fig. 4. DNA content of bone marrow cells separated by FACS (Fluorescence activated cell sorter). The upper histogram denoting ALL +ve and the lower ALL −ve cells.

have a wider distribution of unlabelled myeloblasts around G_1 with some in S phase.

When cells were separated on the cell sorter, according to their surface characteristics, there was no significant difference in the G_1 population between the ALL positive and ALL negative cells. However, in the myeloid cells not reacting with anti-ALL serum there were 18% of cells in S, G_2 and 8% with a DNA content above 4n (Fig. 4). The LI of myeloblasts at the same time was 18% while that of lymphoid cells was 1%.

Rosetting

The percentage of "T" "B" and "M" rosette forming lymphocytes was calculated in the peripheral blood. At the beginning of the blastic crisis, T and B cells were detected in reduced numbers and no M cells were present. A subsequent examination done one month later showed persistently low T and B rosettes.

DISCUSSION

It is well known that blasts from some cases of CGL in blastic crisis can morphologically resemble lymphoblasts [4, 6, 7]. The responsiveness of these cells to vincristine and prednisolone has been indirect evidence of their lymphoid origin. Recognition of such cells by anti-ALL serum [8] and the presence of the Ph^1 chromosome in some cases [7] supports this idea. It has been suggested that these blast cells arise from a pleuri-potential stem cell having the capacity not only to form erythrocytes, megakaryocytes and granulocytes but also the lymphoid population. This possibility was the subject of much argument among biologists around the turn of the century.

In the reports of cellular kinetics of bone marrow and peripheral blood from patients in blastic crisis of CGL, the emphasis has been on the study of the myeloid population, but the proliferative activity of lymphoid cells has not been investigated. Killmann *et al.* (1972) [14] found myeloblasts had a low 3H-TdR uptake during blastic transformation. A reduction in the number of cells synthesising DNA was observed in the bone marrow of CGL patients during blastic crisis [15, 16,

17]. The findings in our patient differ from others as there was a marked variation in the LI of myeloblasts during blastic crisis.

The blastic crisis of CGL has been compared with acute leukaemia [18], and the chronic phase of the disease considered as a preleukaemic state [14, 19, 20]. The kinetic behaviour of myeloblasts in our patient as demonstrated by 3H-TdR uptake and distribution of DNA content was shown to be similar to results obtained in acute leukaemia [15].

The fall in LI following chemotherapy and the rise terminally is similar to relapse of acute leukaemia [21] as are the variations in the distribution of nuclear DNA content [22] suggesting the presence of an aneuploid population of cells [23]. The latter was confirmed by chromosome studies.

The LI of the lymphoid population was low at the beginning of the crisis and remained so throughout the disease. The ability of the small lymphoid cells to synthesise RNA and protein was significantly less than the myeloid. The lymphoid cells had a 2n DNA content and none appeared in S or G_2. In repeated studies during the first two months the distribution of their DNA contents remained the same. In the terminal state the distribution of DNA content of anti-ALL +ve cells continued to differ from anti-ALL −ve (myeloid) cells. A few of the latter were in S or had a DNA content >4n. Theoretically the small lymphoid cells could either be in prolonged G_1 or out of cycle (G_0) with the potential to resume division once stimulated. The low RNA and protein synthetic activity is unlike the majority of blast cells in ALL in which the LI with 3H-UR is very high [24]. Certain points of dissimilarity between lymphoid cells in this patient and those of ALL are apparent:

(i) persistently low LI of blast cells with 3H-TdR throughout the course of the disease;
(ii) the lack of change in the distribution of DNA content usually seen in patients with ALL treated with chemotherapy;
(iii) very low RNA and protein synthetic activity.

We were unable to define a Ph^1 chromosome in the lymphoid cells on both direct bone marrow examination and peripheral blood, but the lack of sufficient chromosome spreads leaves this possibility unanswered. The kinetic pattern of the lymphoid cells containing Ph^1 has yet to be investigated.

The findings of different kinetic behaviour between the lymphoblasts in acute leukaemia and those presented here in blastic crisis indicate dissimilarity between the two populations. The lymphoid cells in this patient may be stem cells which fail to differentiate and accumulate in the bone marrow and peripheral blood [3]. It is suggested that in ALL the stem cells are amongst the circulating smaller lymphoblasts and the population is self-maintained [21]. The lymphoblasts described here appear to behave more like the stem cell in ALL and the explanation for their presence is unclear. Recent reports have shown that a small number of acute lymphoblastic leukaemias are in fact blastic crisis of chronic myeloid leukaemia [7]. If this is true then chemotherapy cannot be responsible for the emergence of this abnormal clone, although it may have been a contributory factor in this case. In view of the limited proliferative capacity of these primitive cells, it seems to us most likely that these cells have been present for some time and possibly from the beginning of the disease process.

Acknowledgements—We are grateful to Professor K. D. Bagshawe for allowing us to study this patient under his care. We thank Dr. George Janossy for making available cells separated by the cell sorter.

The Correlation of the Ongoing Proliferative Response to Tumour in Lymphoid Organs with the Anti-tumour Activity of the Lymphoid Cells

K. D. CHANDRADASA and R. M. R. BARNES
Department of Immunology, University of Liverpool, England

Abstract—*Anti-tumour activity of washed lymph node (LN) and spleen cells of mice bearing a transplanted methylcholanthrene-induced tumour (MC1) for* 10–14 *or* 25–28 days *was compared and correlated with the stimulation of deoxyribonucleic acid (DNA) synthesis in the lymphoid organs. While the anti-tumour effect per lymph node cell (LNC) changed little if at all during this period, the stimulation of DNA synthesis in the total cell population of the nodes diminished significantly by the* 25–28 day *stage of tumour-bearing in contrast to the markedly high level seen at* 10–14 days. *In the spleen, however, stimulation of DNA synthesis in the total cell population increased throughout the period of study while the anti-tumour activity per cell significantly decreased. Depressed effector activity of spleen cells was shown to be associated with a decrease in anti-tumour activity of the T cell population. These observations provide evidence for a suppression of the immune response to tumour antigens operating at the level of sensitization of the immunocompetent cells and further suggest that proliferation in the tumour-bearing host of a cell clone(s) with suppressor function may have a direct or indirect role in controlling the specific response to tumours.*

INTRODUCTION

THE FUNCTIONAL roles of the various lymphoid cell types involved in the immune response to tumours and tissue grafts are complex. Thymus derived (T) cells, essential for the development of immunocompetence, are also involved in the regulation or suppression of the immune response. Thus it has been shown that spleen localising T cells can suppress the response in lymph nodes [1, 2]. *In vitro* studies have shown that splenic T cells suppress the mixed lymphocyte reaction (MLR) whereas lymph node T cells from the same donors enhanced the MLR [3]. In the experimental animal it has been repeatedly shown that splenectomy improves the immune response in favour of the tumour host [4, 5]. Furthermore, treatment of the host with tumour bearer spleen cells can enhance tumour growth [6–8]. These and other similar observations support the view that the immune response to tumours can become suppressed, although the exact mechanism of this is far from clear. It was observed previously [9] that stimulation of DNA synthesis in lymph node cells became markedly impaired during tumour bearing, suggesting suppression of sensitization and effector cell production in lymph nodes. It was further suggested that suppressor factor(s) liberated during the course of the immune response to the tumour could be responsible for this impairment. In the present investigation we have examined the progess of anti-tumour activity of the lymph node and spleen cell populations in relation to the stimulation of DNA synthesis in these organs to gain further insight into the nature of the suppressor mechanism.

Accepted 15 September 1977.

MATERIAL AND METHODS

The materials and methods have been described previously in detail [6, 9] and only variations or new techniques are described here.

Mice

Inbred BALB/c mice of MRC origin were obtained from Bantin & Kingman Limited, Hull.

Tumour

MCl was induced in a female mouse by subcutaneous (s.c.) injection of 3-methylcholanthrene (3MC) and the tumour, a fibrosarcoma was kept biofrozen in liquid nitrogen until use. The tumour which was passaged in the same strain up to ten transplant generations during experimentation, was found to be moderately immunogenic and tumour hosts are capable of rejecting up to 2×10^5 cells when reinoculated s.c. following excision of an implanted tumour.

Transfer assays

These were conducted essentially as previously described with the following modifications of splenic and LNC suspensions. Cells were incubated in a 5% CO_2 in air atmosphere in 6 in.-dia plastic Petri dishes in Eagles Minimum Essential Medium (MEM) containing 100 μg streptomycin and 100 i.u. benzylpenicillin/ml together with 10% heat-inactivated foetal Calf serum (FCS-MEM) at 37°C for 2 hr prior to further treatment. At this stage the splenic, but not LNC, were treated with 0.8% NH_4Cl solution for 5 min. They were diluted 20 times with FCS-MEM and spun at $250 \times g$ for 7 min. Both LNC and spleen cells were subjected to a total of five washes during which the cell suspensions were gently drawn in and forced out through a Pasteur pipette 20 times at each washing. This procedure was found to be essential in order to restore the effector cells from tumour bearing individuals to maximal reactive state as Currie and Basham [10] have demonstrated for *in vitro* cytotoxic assays. We have also found this to be equally relevant for *in vivo* assays using the transfer test which is shown in Table 1. Finally, lymphoid cells were suspended in MEM, without FCS, and diluted to the required concentration. Tumour cell suspensions were prepared as previously described and the two cell preparations mixed together in ratios of 5×10^4 tumour cells and 50–400 times as many lymphoid cells in a vol of 0.1 ml of MEM. A cell mixture sufficient for 5–10 inoculations was usually prepared and injections were given s.c. into the flank. Mice were observed and the appearance of tumours was assessed by palpation over a period of 30 days from the time of inoculation.

Assessment of DNA synthesis in lymphoid organs and in tumours

DNA synthesis in the lymphoid organs was taken as a measure of the stimiluation of cell proliferation assessed by the uptake of ^{125}I-deoxyuridine (IUDR) and described previously by Pelc, Harris and Galdwell [11] and by Asherson and Barnes [12]. Ten to twelve micro-

*2/5 mice did not develop tumours.

LNC = lymph node cells obtained from mice bearing MCl tumours for 10 and 25 days.

S.E.M. = standard error of the mean (exp. 1—10 mice per group: exp. 2—5 mice per group).

Each cell transfer inoculum contained 5×10^4 tumour cells together with 2.5×10^6 LNC and the mixture was injected s.c. into the flank in 0.1 ml MEM.

In exp. 1 group (a) differs significantly ($0.001 < P < 0.1$) from group (b) at 13 days. In exp. 2 group (a) differs significantly ($0.01 < P < 0.05$) from group (a) 20/21 days.

curie of IUDR (specific activity 108 mCi/mg; Radiochemical Centre Amersham) were injected i.p. into mice and after 17 hr the axillary and inguinal lymph nodes (ipsilateral and contralateral), spleen, thymus and tumour were carefully removed and the radioactivity counted in a well-type Packard γ counter without further processing of the tissues. Results were expressed as mean counts per minute corrected for background.

Enrichment of T cells

The method used was that described by Trizio and Cudkowsky [13] with the following modifications. Cells in FCS–MEM were incubated for 2 hr in plastic Petri dishes in 5% CO_2 in air following which they were recovered readily by gentle shaking leaving phagocytic cells attached. The cell suspension was concentrated and packed into nylon wool columns which were then incubated at 37°C in 5% CO_2 in air for 45 min. Eluted cells were concentrated and treated with 0.8% NH_4Cl for 5 min, diluted 20 times in FCS–MEM, and centrifuged. The washing procedure was repeated five times as described above. Enrichment of suspensions for T cells was demonstrated by indirect immunofluorescence using anti-θ serum followed by fluorescein conjugated swine anti-mouse γ globulin (SWAM–FITC) (Fraburg Limited, Maidenhead) when, around 90% of the cells were found to be labelled whereas over 90% of the cells did not label with SWAM–FITC) alone indicating the near absence of B cells in the preparations.

Statistical evaluation of results

The Students' *t*-test was performed to determine the statistical significance of the results in experiments on stimulation of DNA synthesis and also those on the assessment of tumour growth suppressive activity of lymphoid cells shown in Fig. 1 and in Table 1. Chi square test was utilized to determine the signficance of the difference between proportions of mice not developing tumours following cell transfer shown in Tables 2 and 3.

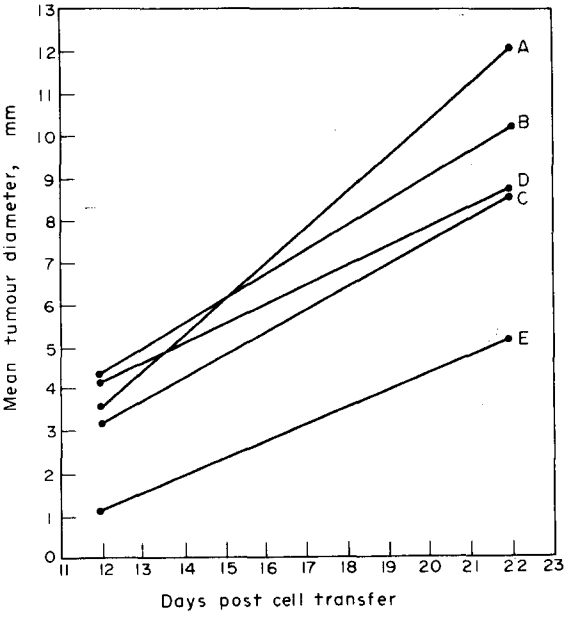

Fig. 1. Anti-tumour effect of tumour-bearer splenic T cell fraction in transfer assays. The rate of tumour growth in recipient mice following cell transfers is shown; 5×10^4 *MCl cells plus* 100–300 *times the number of splenic cells were inoculated into groups of* 5–6 *mice s.c. on the flank as follows:*

A—200 × *normal spleen cells.*
B—300 × *normal spleen cells.*
C—100 × 25 day *tumour bearer splenic T cells.*
D—200 × 25 day *tumour bearer splenic T cells.*
E—100 × 10 day *tumour bearer splenic T cells.*

Following differences between groups were significant: 12 days *after cell transfer, E vs C,* $0.01 < P < 0.02$; *(E vs D,* $0.05 < P < 0.1$*); 22 days after transfer, A vs E,* $0.001 < P < 0.01$.

RESULTS

Transfer assays

The following differences between 10–14 day and 25–28 day groups are significant, exp. 1 (a) ($\chi^2 = 8.87$, $0.001 < P < 0.01$); totals of exp. 1 (a) and exp. 2 ($\chi^2 = 11.9$, $0.001 < P < 0.01$).

allowed to grow for a period of 10–14 or 25–28 days. Nodes and spleens obtained from three or more mice were brought into single cell suspensions and were washed ×5 in MEM. Tumour cell suspensions were prepared from 10–14 day old tumours by trypsin disaggregation. The tumour and lymphoid cells were mixed together in the ratios of 1:50–1:400 and the mixtures were inoculated s.c. into groups of 5–10 normal mice so that each mouse received 5×10^4 tumour cells plus the appropriate number of lymphoid cells in 0.1 ml of MEM. The appearance of tumours was observed over a period of 30 days.

Comparison of the anti-tumour activity of the lymph node lymphocytes at different stages of tumour bearing

Table 2 shows that LNC taken from 10–14 day tumour bearers were markedly suppressive to the tumour cells. In two transfer assays, a total of 13/22 mice remained tumour free following transfer of cells at a LNC to tumour cell ratio of 50:1 compared with 2/17 of the control group inoculated with tumour cells alone. When the cell ratio was increased to 100:1 total suppression of tumour formation was observed in the cell transfer recipients of the test group whereas all 10 controls inoculated with tumour cells alone, developed tumours. The addition of 200 or 300 times as many normal spleen cells into the tumour cell inoculum had no influence on the outgrowth of tumours (Fig. 1).

Comparison of the tumour suppressive activity of LNC from the 10–14 day stage of tumour bearing with those at 25–28 days showed no significant difference when the LNC to tumour cell ratio utilized in transfer assays was 100:1. Total suppression of tumour outgrowth was obtained under these conditions. However, this cell ratio may not be sensitive enough to detect more subtle differences. Thus in one of two transfer assays conducted with a LNC to tumour cell ratio of 50:1, 7/9 mice did not develop tumours when the LNC were derived from the 10–14 day tumour bearers in contrast to 2/10 when the cells were taken from 25–28 day tumour-bearing mice. This difference was found to be significant ($0.01 < P < 0.02$). However, in a second transfer assay, tumour rejection was observed in 6/13 and 6/12 mice, respectively, in the two groups. This variability of results obtained at this lower cell ratio may indicate the limit of sensitivity for the technique under these experimental conditions. Nevertheless, the results obtained from the first experiment indicate that some loss of anti-tumour activity has taken place in the LNC population at the 25–28 day stage of tumour bearing.

Comparison of anti-tumour activity of splenic lymphocytes at different stages of tumour bearing

In experiments using 10–14 day old tumour bearer spleens, tumour suppression was very significant when the spleen cell to tumour cell ratio was 200:1, as compared with either the effects of 25–28 day spleen cells or with normal controls inoculated with tumour cells alone. In two transfer assays, 8/9 and 7/9 mice receiving the cells from the 10–14 day stage, as compared

to 1/10 and 3/9 mice receiving cells from the 25–28 day stage of tumour bearing, respectively, did not develop tumours following cell transfer. The difference 8/9 vs 1/10 in the first assay was found to be significant by the Chi-square test ($0.01 < P < 0.001$) as was the difference between the totals 15/18 vs 4/19 from the two experiments ($P = 0.001$). Controls which received the same number of tumour cells as were present in the cell transfers did not develop tumour only in 1/18 of the inoculated mice. Cell transfers using a spleen to tumour cell ratio of 400:1 led to total suppression of tumour outgrowth in both the 10–14 and 25–28 day tumour-bearer spleen cell recipients. Inoculation of as many as 20×10^6 spleen cells from 28 day tumour-bearers produced no tumours in any of five inoculated mice demonstrating the absence of metastatic cells capable of tumour formation.

Effector cell activity of column-enriched spleen (T) cells from tumour-bearing mice

Cell transfer assays were carried out using 10 and 25 day tumour-bearer splenic T cells with tumour to spleen cell ratios ranging from 1:100 to 1:300. These column purified suspensions contained less than 10% B cells as detected by SWAM-FITC. Each recipient was inoculated s.c. with 5×10^4 tumour cells together with the appropriate number of splenic T cells and the cell mixtures transferred into groups of 5–6 mice. Figure 1 shows that when $\times 100$ as many splenic T cells as tumour cells were used 2/5 recipients of the 10 day tumour bearer splenic T cells did not develop tumours compared with 0/5 after 12 days and 1/5 after 22 days in the recipients of 25 day splenic T cells. There was also a significant difference ($0.01 < P < 0.02$) in the growth rates of the resulting tumours in the two groups detected as tumour volume, 12 days after cell transfers, the 10 day spleen T cell recipient groups showing a marked reduction in tumour growth compared to the 25 day T cell recipients. The use of $\times 200$ the 25 day splenic T cells as tumour cells did not cause a significant difference. Control groups which received $\times 200$ or $\times 300$ the normal spleen cells as tumour cells did not lead to suppression of tumour formation and there was no significant difference in their growth rates compared to the 25 day spleen cell recipients.

Stimulation of DNA synthesis in lymphoid organs of tumour-bearing mice

A comparison was made of the rate of stimulation of DNA synthesis in the lymphoid organs of mice bearing tumours for 14 or 25 days. Two groups of four mice were injected s.c. with 10^6 MC1 cells, 11 days apart, so that at the time of testing they had borne tumours for 14 or 25 days. Both groups of mice and a third group of four normal controls, were injected i.p. with 12 μCi of IUDR and 17 hr later the ipsilateral and contralateral lymph nodes, spleen, thymus and tumours were removed and the radioactivity measured. Results were expressed as counts/min (cpm or as a stimulation index (SI).

Table 4 shows that DNA synthesis in the lymph nodes of mice bearing tumours for 25 days

Table 4. *Stimulation of DNA synthesis in lymphoid organs of mice* 14 *and* 25 days *after tumour initiation*

No. of days following s.c. implantation of 10^6 MCl cells	ILN		CLN		Spleen		Thymus		Tumour	
	Counts/min ±S.E.M.	SI	Counts/min ±S.E.M.	SI	counts/min ±S.E.M.	SI	counts/min ±S.E.M.	SI	counts/min ±S.E.M.	
14	3179±529	12.2	3789±1408	14.6	34318±2971	2.7	2525±326	1.4	25657±3629	
25	566±73.5	2.2	363±25.6	1.4	48519±3747	3.8	1147±157.7	0.6	47074±5533	
Normal Controls	*261±26.8		*259±23		12765±3927		1800±193		—	

The mice were injected i.p. with 12 μCi IUDR and the tissues removed 17 hr later. The activity incorporated is indicated as counts/min ± standard error of the mean (S.E.M.).

$$\text{SI} = \text{Stimulation Index} = \frac{\text{Mean counts/min in test group}}{\text{Mean counts/min in normal controls}}.$$

ILN = ipsilateral lymph nodes = (axillary and inguinal nodes on the same side as the tumour).

CLN = contralateral lymph nodes = (axillary and inguinal nodes on the opposite side to the tumour).

*These figures were obtained from axillary and inguinal lymph nodes from either the right or left flank.

The differences in counts/min between 14 and 25 day experimental groups are significant for following tissues, ILN ($0.001 < P < 0.01$); CLN ($P = 0.05$); spleen ($0.02 < P < 0.05$); thymus ($0.001 < P < 0.01$); tumour ($0.001 < P < 0.01$).

Table 5. Resistance to subsequent growth of tumour in mice pre-immunized to the same or different tumour

Immunizing tumour	Challenge tumour	Proportion of mice rejecting challenge tumour
MC1	MC1	*4/4
	MC5	0/4
MC5	MC1	0/4
	MC5	3/4
EAT	MC1	0/4

*Number of mice rejecting tumour / Total number of mice in the group

was markedly depressed compared to the level at 14 days. Significant differences were seen between the cpm and SI of the ipsilateral nodes ($0.001 < P < 0.01$) and between that of contralateral nodes ($P = 0.05$). These are also shown in their stimulation indices. In the thymus the decrease of DNA synthesis at 25 days was signficantly below the level of 14 days ($0.001 < P < 0.01$). In contrast DNA synthesis in the spleen was signficantly elevated at 25 days ($0.02 < P < 0.05$) as compared to that at 14 days and similarly DNA synthesis in the tumour was also markedly increased reflecting an increase in tumour mass ($0.001 < P < 0.01$).

The role of "specific" tumour associated antigens

Tumours were initiated in groups of mice as follows: 8 mice implanted s.c. with MC1, 8 mice with MC5 and another 5 with Ehrlic ascites tumour (EAT). When the tumours reached 0.5–1 cm dia by 10–14 days, they were surgically excised and all groups were given a rest period of 14–18 days, prior to tumour challenge as follows. Four mice immunized with MC1 were challenged with 5×10^4 MC1 cells and four were challenged with 5×10^4 MC5 cells. The group immunized with the MC5 was again split into two further groups and these were challenged as above with either MC1 or MC5. The mice immunized to the EAT were challenged with 5×10^4 MC1 cells only.

Table 5 shows that mice immunized to MC1 rejected MC1 cells while those immunized to MC5 or EAT developed tumours. Conversely, mice immunized to MC5 failed to suppress MC1 although MC5 immune mice rejected that tumour.

These results indicate clearly that the MC1 tumour contains specific tumour associated antigens which are neither shared with MC5, another syngeneic tumour, nor with the EAT, which probably contains several alloantigenic specificities.

DISCUSSION

The experiments described here show that the total anti-tumour activity generated by the lymph nodes and spleen at 10–14 days following tumour initiation was markedly stronger than at 25–28 days.

Proportionally, the detected tumour suppressive activity in the washed LNC population changed but little, under the experimental conditions employed, despite the very significant decrease of DNA synthesis and cell proliferation in nodes at the latter stage. This finding contrasts with the observations in the spleen. In the latter the very significant increase of stimulation of DNA synthesis observed at 25 days was also accompanied by a hyperplasia and a marked increase in the total number of cells in these lymphoid organs whilst the anti-tumour activity per cell decreased significantly. The decreased tumour suppressive activity of the spleen cells could have been the result of dilution of the effector cell population by the increased proliferation of non-specific cell clones, or cell clones having functions other than tumour suppressive activity. It is interesting to note in this context that Konda, Nakao and Smith [14] showed that both T and B splenic cell populations increased numerically as well as in their functional capacity to respond to a variety of non-tumour antigens during tumour-bearing. It appears therefore, that increase of cell clones with different functional capabilities can occur during the "suppression" of stimulation of cells with anti-tumour activity in lymph nodes and in the spleen. The decrease in anti-tumour activity of the spleen cell population was associated with T cells since transfer assays conducted with a nylon wool column-enriched T cell fraction was markedly less effective in tumour suppression at the latter stage of tumour bearing. This suggests a retarded proliferation of T cells with anti-tumour activity and an increase in the ratio of non-cytotoxic to cytotoxic T cells.

The findings reported here support our previous observations of the suppression of the immune response to MC-induced tumours [6, 7, 9] which showed that the anti-tumour response is suppressed or modulated by factors acting at the level of sensitization of the lymphocytes in addition to those factors involved in the blocking mechanisms. There is increasing evidence that suppressor mechanisms are in-

volved in the modulation of the immune response to non-neoplastic tissues [15, 16] as well as to tumours. Treves, Cohen and Feldman [17] reported a suppressed ability of tumour rejection or enhancement of tumour growth in animals treated with tumour-bearer spleen cell culture filtrates. In an interesting recent report Fujimoto, Greene and Sehon [18, 19] observed that suppressor cells can be found in spleen, nodes, thymus and bone marrow of tumour-bearers and that treatment of tumour transplant recipients with appropriate doses of such cells caused suppression of tumour rejection. Chandradasa [6, 7] had previously observed that intraperitonial inoculation of 200×10^6 spleen cells from tumour-bearing mice to other mice, at the time of tumour implantation, caused tumour enhancement and an increase of metastatic growths in the recipients. The observations reported here provide further evidence for the involvement of a defect of sensitization and proliferation of effector cells and the possible association of suppressor mechanisms in the modulation of the immune response in tumour-bearers and the facilitation of tumour growth.

Amputation and Doxorubicin for Treatment of Canine and Feline Osteogenic Sarcoma*

B. R. MADEWELL, R. L. LEIGHTON and G. H. THEILEN

Section of Clinical Oncology, Department of Veterinary Surgery, University of California, Davis, California 95616, *U.S.A.*

Abstract—*Fourteen dogs and* 3 *cats with naturally occurring oesteogenic sarcoma of the appendicular skeleton were treated with adjuvant chemotherapy using doxorubican* HCl *following treatment of the primary tumor by amputation or disarticulation. Doxorubican* HCl *was given intravenously every* 21 days *at a dosage of* 30 mg/m^2 *body surface area commencing* 3 *weeks after amputation, and continuing for* 6 *months or until metastatic disease was recognized radiographically. The median duration of clinical signs prior to surgical treatment for* 14 *dogs was* 51 days (*mean,* 54 days; *range,* 7–127 days). *The median time interval between surgery and onset of radiographically evident metastatic disease for* 9 *dogs was* 73 days (*range* 50–160 days). *Median post-operative survival for* 14 *dogs was* 104 days (*range* 52–368 days); 35% *were alive* 6 *months post-operatively,* 21% *were still alive at* 9 *months and* 14% *survived more than one year. Times to onset of metastatic disease and survival times were calculated from day of surgical treatment.*

For 3 *cats duration of preoperative clinical signs were* 24, 70 *and* 95 days; *intervals prior to metastatic disease for* 2 *cats were* 133 *and* 274 days; *and survival times were* 143, 180 *and* 414 days.

INTRODUCTION

With the possible exception of acute leukemia, most of the screening and secondary evaluation of potential anticancer agents is done in animal tumor systems that lack an objectively demonstrated correlation with the drug response of any specific type of human neoplasm. The search for better animal tumor models continues and the Ridgway osteogenic sarcoma is a valuable addition for the experimental chemotherapist [1]. The clinical, radiologic and pathologic features of spontaneous canine and feline osteosarcoma have been previously described [2–5], and it has been suggested that the dog is a useful model for study of osteosarcoma in man [6].

Despite the advances made in surgical and radiotherapeutic techniques, the treatment of dogs with osteogenic sarcoma results in relatively few survivors. Because pet owners frequently request euthanasia for their animal upon recognition of malignant disease, survival times for untreated (control) dogs with osteogenic sarcoma are not available. However, an historical control population of 65 dogs with naturally occurring oesteogenic sarcoma of the appendicular skeleton treated by surgery alone was reported [2]. In that study, end-results were as follows: the median post-operative survival was 18 weeks, with a range of 3 to greater than 578 weeks. Twenty-six percent were alive 6 months post-operatively, 13.8% were still alive at 9 months and 10.7% survived more than one year. The common cause for therapeutic failures was pulmonary metastasis.

Other methods used to control primary or metastatic disease in the dog have included irradiation, chemotherapy, immunotherapy, or combinations of those treatment modalities. Response of canine osteogenic sarcoma to irradiation has been discouraging. In one study, 18 animals were treated with conventional radiotherapy (X-rays or ^{60}Co) or fast neutrons (^{2}N). While cessation of tumor growth was apparent in some cases, osteogenic sarcoma was considered non-responsive to irradiation [7]. Thirty-one small animals in another study with osteogenic sarcoma were treated to an average of 5000 rad by various forms of irradiation; the percentage cure was zero [8]. Prophylactic X-irradiation of lungs did not inhibit pulmonary metastasis in 22 other dogs with osteogenic sarcoma when combined with primary therapy using amputation or X-irradiation [9].

Few chemotherapeutic studies for management of osteogenic sarcoma in the dog have been

Accepted 16 September 1977.

*This study was supported in part by Earl C. Anthony Grant No. D-1070.

reported [10–13]. Small numbers of animals treated and wide range of treatment modalities used makes comparison of data difficult. The use of combinations of anticancer drugs following amputation in 8 dogs reported in one study, however, resulted in median post-operative survival time of 10.5 months (mean, 12.3 months: range, 3–23 months) suggesting possible therapeutic advantage of systemic (adjuvant) chemotherapy following primary (surgical) therapy [13].

Immune therapy has been investigated preliminarily for treatment of canine osteogenic sarcoma [14]. Freeze-dried BCG vaccine was given intravenously to 6 dogs following amputation; median survival time was 52 weeks (mean, 46 weeks; range, 16–65 weeks) compared to 5 non-matched control dogs treated by amputation alone surviving 6–17 weeks (mean, 11 weeks).

Primary bone cancer has been reported infrequently in the cat. In a report of 15 cats with osteogenic sarcoma, the neoplasm tended to occur in the hind limbs of aged, female, domestic, short-hair cats [3]. For 5 cats treated by amputation of the affected limb, one cat developed metastatic disease 5 months post-operatively, while the other 4 cats were alive and non-metastatic 26 months after surgery.

MATERIAL AND METHODS

Animals and treatment

Fourteen privately owned dogs and 3 cats with spontaneously occurring osteogenic sarcoma of the appendicular skeleton were referred to the University of California, Veterinary Medical Teaching Hospital. Presumptive diagnosis of osteogenic sarcoma was based on clinical and radiographic examinations; definitive diagnosis was made in all cases by histopathology. As in man [15], osteosarcoma in the dog [4] is a tumor composed of malignant cells that produce osteoid.

Primary therapy used in all cases was amputation—a scapulohumeral disarticulation for neoplasms of the radius, ulna and distal humerus; mid-shaft femoral amputation for neoplasms of the distal tibia; coxofemoral disarticulation for neoplasms of the proximal tibial or femur. Block ostectomy was used in one dog (No. 4) for a neoplasm of the distal ulna. Prior to the therapy, the following studies were performed: radiographic examination of the tumor site and of the thorax for metastatic disease, complete blood count, urinalysis and a 12- channel biochemical profile. Excluded from study were animals with radiographically demonstrable metastatic disease, animals with concurrent medical problems which would preclude use of anticancer drugs, and those giant breed dogs which could not tolerate amputation because of severe concurrent orthopedic problems (e.g. hip dysplasia). Animals studied received chemotherapy using doxorubicin HCl (adriamycin) at a dosage of 30 mg/m^2 of body surface area starting 3 weeks post-operatively to allow surgical wound healing. Drug therapy was given intravenously every 21 days for 24 weeks. During the course of therapy, thoracic radiographs were obtained at 6 week intervals and hematologic and biochemical tests were monitored at 2–6 week intervals. Drug therapy was discontinued upon radiographic recognition of metastatic disease.

RESULTS

Table 1 lists breed, age, sex, site of primary neoplasm, duration of presurgical signs, time to onset of radiographically demonstrable pulmonary metastasis, total survival time and cause of death in 14 dogs and 3 cats with osteogenic sarcoma of the appendicular skeleton treated by surgery followed by systemic adjuvant chemotherapy. The 14 dogs were all large or giant breeds, known to be subject to excess risk of primary bone sarcoma [16]. Times given for onset of metastatic disease and survival are calculated from the day of amputation or disarticulation. The median duration of clinical signs prior to definitive therapy for the 14 dogs was 51 days (mean, 54 days; range, 7–127 days). The median time to onset of radiographically apparent metastatic disease for 9 dogs that developed metastasis was 73 days (range, 50–160 days). Two of the 3 cats developed pulmonary metastasis 133 and 274 days post-operatively; prolonged survival for one cat (No. 17) following recognition of metastatic disease appears inordinate. The third cat did not have post-mortem evidence of metastatic disease 180 days post-operatively when euthanatized because of intercurrent gastro-intestinal disease.

Median post-operative survival for 14 dogs was 104 days (range, 52–368 days). Two of the 14 dogs are still alive at time of writing. As in other clinical veterinary trials, survival is often compromised by elective euthanasia by pet owners. Two dogs in this study (Nos. 6 and 8), euthanatized soon after recognition of pulmonary metastasis were not clinically ill at time of death; all other dogs showed signs of systemic illness at the time of euthanasia. Excluding those 2 dogs from the survival data provides median post-operative survival time of 117 days.

Survival times for 3 cats were 143, 180 and 414 days post-operatively.

Causes for death are listed; 13 of the 14 animals that died during the study were necropsied. Unusual metastatic patterns were observed in several dogs. Dog No. 2 had metastasis to the right atrioventricular valve in addition to pulmonary metastasis; dogs No. 5 and 11 developed renal metastases in addition to pulmonary lesions. Dog No. 14 developed severe clinically apparent multiple skeletal metastases accompanied by few small pulmonary lesions that were not visualized radiographically.

Other lesions observed at post-mortem examinations were as follows: dogs No. 1 and 12 had histological evidence of myofibrillar atrophy and acute tubular nephrosis was identified in dogs 1, 4 and 5. Dog No. 2 had hypertrophic osteopathy. Dog No. 7 had diffuse interstitial pneumonitis and fibrosis. Cat No. 16 had both metastatic osteogenic sarcoma and malignant melanoma in lungs at necropsy. The primary site for the melanoma was not determined, but was presumably related to an ocular lesion treated two years earlier by enucleation.

DISCUSSION

The results which have been achieved in the treatment of osteogenic sarcoma by immediate surgery have been disappointing in man and dogs. Although local control can generally be achieved in primary lesions of the extremity, pulmonary metastasis and death within 12–18 months occur in over 80% of human patients with osteogenic sarcoma [17], and 90% of dogs with osteogenic sarcoma are dead 12 months post-operatively [2]. In dogs, less than 10% show radiographic evidence of pulmonary metastasis at the time of initial examination [9]. However, the subsequent "natural" course of the disease indicates that hematogenous pulmonary micrometastases are present in the majority of dogs at the time of diagnosis, or that tumor cells are released into the circulation during amputation. The problem of how to inhibit division of these malignant cells in the lung before they become apparent radiographically or clinically is a major goal in cancer therapy research; dogs with osteogenic sarcoma must be considered as having systemic disease when the diagnosis is first made and the treatment program planned accordingly.

During the past few years, several publications have indicated that the prognosis in osteogenic sarcoma in man is improving significantly as the result of adjuvant chemotherapy [18–20]. Early 1970's, a relatively new drug known as doxorubicin became available for clinical studies, and the effectiveness of doxorubicin in the treatment of metastatic osteosarcoma was soon apparent. Subsequent activity of the drug demonstrated in an adjuvant (prophylactic) setting prompted our interest in doxorubicin for treatment of canine and feline osteogenic sarcoma. For adjuvant chemotherapy to be effective, the primary lesion must be controlled [21]. Disarticulation or transmedullary amputation will usually insure ablation of the primary tumor in canine osteogenic sarcoma [2]; the only dog (No. 4) that developed local recurrence in this study was treated by block ostectomy of the distal ulna instead of radical amputation. While surgical resection will control primary disease, it appears unlikely from published data [7, 8] that radiotherapy alone will be similarly effective.

Dosage of doxorubicin and route of administration for dogs and cats in this study was based on published toxicity data in the dog [22, 23] and cat [24] and experience treating animals in our clinic [13]. As in man, doxorubicin in the dog and cat behaves as an inhibitor of cellular reproduction; damage to actively proliferating tissues is most prevalent and toxic manifestations reported and encountered in our experience include enterocolitis, alopecia, melanosis, hyperesthesia, shock-like syndrome and depression of hematopoiesis. Functional or morphologic damage to the heart was not encountered in the drug toxicity study [22]; however, focal myofibrillar atrophy diagnosed histologically in two dogs in this study may have resulted from doxorubicin toxicity. Similarly, nephrosis has not been reported in dogs or man as a manifestation of doxorubicin toxicity and development of nephrosis in 3 dogs reported herein was unexpected. While the possibility of pre-existing renal disease cannot be excluded, normal blood urea nitrogen values and urinalyses were obtained in all dogs prior to doxorubicin chemotherapy. Severe tubular nephrosis has been demonstrated in rabbits following doxorubicin treatment [22].

While the prognosis for a dog with osteogenic sarcoma is poor, the disease is not uniformly fatal following surgery alone for treatment of primary disease [2]. Prospective adjuvant chemotherapy trials using small numbers of animals is compromised by the contention that animals cured may have received unnecessary adjuvant chemotherapy. Additional difficulties encountered in a clinical veterinary setting include reluctance of pet owners to allow aggressive chemotherapy because of toxic side effects and costs of treatment. Clinical benefit from doxorubicin in man is correlated with the consistency of

Table 1. *Results of surgical treatment and adjuvant chemotherapy using doxorubicin in* 14 *dogs and* 3 *cats with osteogenic sarcoma*

Dog No.	Breed	Age (yr)	Sex	Site	Duration of presurgical clinical signs (days)	Time to onset of metastatic disease (days)	Survival time (days)	Cause of death
1.	Saint Bernard	6	F	Right distal tibia	14	160	230	Euthanatized because of cachexia. Post-mortem evidence of nephrosis and myofibrillar atrophy
2.	Irish Setter	2	M	Right proximal tibia	25	73	73	Euthanatized because of hypertrophic osteopathy. Metastasis to lungs, and right atrioventricular valve
3.	Irish Wolfhound	7	M	Left proximal tibia	7	NM*	365†	No evidence of metastatic disease
4.	German Shepherd	10	F	Left distal ulna	77	NM	386	Died from acute tubular nephrosis. No evidence of metastasis at post-mortem. Local recurrence at ostectomy site
5.	Great Pyrenees	7	F	Right proximal humerus	60	67	75	Euthanatized because of cachexia. Metastasis to lung and kidney. Tubular nephrosis evident histologically
6.	Saint Bernard	8	M	Right distal radius	24	106	106	Euthanatized at recognition of metastasis. Dog not systemically ill
7.	Irish Setter	4	M	Left distal ulna	43	NM	265	Died from diffuse interstitial pneumonitis and fibrosis

8.	Rhodesian Ridgeback	5	M	Left proximal humerus	58	60	83	Euthanatized at recognition of metastasis. Dog not systemically ill
9.	Great Dane	5	M	Right distal radius	26	NM	300†	No evidence of metastatic disease
10.	Great Pyrenees	5	M	Right distal tibia	48	109	131	Euthanatized because of cachexia. No post-mortem examination
11.	Doberman Pinscher	9	M	Right proximal humerus	127	50	52	Euthanatized because of metastasis and intercurrent cervical disc prolapse. Metastasis to lung, liver, kidney
12.	Great Pyrenees	3	M	Left distal radius	75	NM	80	Died acutely; focal myofibrillar atrophy demonstrated histologically
13.	Airedale Terrier	9	M	Left distal radius	120	60	102	Euthanatized because of cachexia. Metastasis to lungs
14.	German Shepherd	9	M	Right proximal humerus	54	92	92	Euthanatized because of multiple metastases to bone and lungs
15.	Domestic Short-haired cat	10	F	Left distal femur	95	NM	180	Euthanatized because of intercurrent gastrointestinal disease
16.	Domestic Long-haired cat	7	M	Right proximal tibia	70	133	143	Euthanatized because of cachexia. Metastasis to lungs

myelosuppression following administration of drug [25] and neoplasms such as osteogenic sarcoma treated with inadequate doses are likely to remain resistant to treatment [26]. Dose-limiting myelosuppression was infrequently encountered in dogs treated in this study, suggesting that the dosage of drug used may have been clinically ineffectual.

End-results obtained for treatment of osteogenic sarcoma using amputation and doxorubicin in this study is unimpressive. Using survival as a measure of response to therapy, the median post-operative survival times are less than those reported for surgery alone [2] and less than those reported for surgery followed by combination chemotherapy [13]. However, 5/14 dogs (35%) were alive 6 months post-operatively, 3/14 (21%) were still alive at 9 months and 2/14 (14%) survived for more than one year which is not worse than the historical group treated by surgery alone. Risks of doxorubicin treatment, however, may be disproportionate to the expected benefits and unexpected toxicoses suggest that additional drug evaluation in normal dogs is warranted.

Relevant criteria for evaluating end-results of treatment of the animal cancer patient include time to onset of metastatic disease (disease-free interval), and total survival time. Elective euthanasia at recognition of metastatic disease in some cases jeopardizes survival data and suggests that disease-free interval following primary treatment is the most relevant criteria of response to therapy in clinical veterinary oncology.

Serum Alpha-fetoprotein in Experimental Hepatocellular Carcinomas in Rats*

N. R. GOPAL NAIDU,† B. K. AIKAT,† R. J. DASH‡ and S. SEHGAL†

†*Department of Immunopathology*, ‡*Department of Endocrinology, Postgraduate Institute of Medical Education and Research, Chandigarh, India*

Abstract—*The present study has been carried out mainly to study the sequential changes of serum alpha-fetoprotein (AFP) levels with the evolution of experimental hepatocellular carcinoma (HCC) and to correlate with the histology of the tumors. Rats fed with* 0.06% *of azodyes developed HCC by* 8–24 *months and on the basis of their capacity to synthesize AFP, the animals can be divided into two distinct major groups– "quick responders" and "slow responders". In the first group the animals developed tumors by* 8–10 *months and mostly of poorly differentiated type with high serum AFP levels. The slow responders developed tumors only after* 16 *months and they were mostly of well differentiated with comparatively low AFP values. Both the groups showed biphasic response of AFP during the evolution of HCC. The animals in aflatoxin B*1 *group did not show AFP levels more than* 2μg/ml.

INTRODUCTION

ALPHA-FETOPROTEIN is a feto specific serum globulin synthesised by fetal liver and secreted into the serum during embryonal life of mammalian species. Abelev *et al.* [1], for the first time reported the presence of AFP in blood of mice bearing transplantable hepatomas. Reappearance of fetal antigens is now recognised as common phenomenon during oncogenesis. Elevated levels of serum AFP during hepatic carcinogenesis has subsequently been reported in different species of animals including man [2, 3]. Besides its appearance in rats with chemically-induced HCC its early elevation has also been demonstrated within weeks after the administration of chemical carcinogens [4]. However, certain chemical carcinogens like aflatoxin induced HCC which are not associated with significant rise of AFP [5].

The technique of agar gel immunodiffusion has been used for the estimation of serum AFP, but the sensitivity is relatively low. Among the more sophisticated methods for the early detection of HCC, radioimmunoassay (RIA) happens to be most sensitive one. In fact the use of RIA has revealed that even normal individuals and animals have a minimum quantity of AFP in circulation [6].

The present investigation was undertaken to study the serum AFP levels using RIA during the evolution of liver cancer using different types of chemical carcinogens and to correlate the morphological type of lesions with AFP synthesis.

MATERIAL AND METHODS

Wistar strain rats of both sexes weighing 90–120 g were kept in groups of four in wire mesh cages and maintained on laboratory diet. The carcinogens used were as follows:
Batch 1: (50 animals) was fed with 0.06% of 4-dimethyl-aminoazobenzene (DAB). Batch 2 (52 animals) with same dose of 3-methyl-4-dimethylaminoazobenzene (3-Me-DAB) and batch 3 (10 animals) was administered aflaxtoxin B1 (gift from E. K. Weisburger, National Cancer Institute, Bethesda, Maryland, U.S.A.) orally 25 μg in normal saline for 5 consecutive days for 8 weeks [7]. Control animals were maintained for each group. The azodye containing diet was fed to the rats for 6 months and then they were kept on normal diet. Due to lack of azodyes during the experimental period for some time, feeding with the experimental diet was discontinued after 10 weeks in 15 animals in each group and they were observed for 24 months for the development of HCC. The animals were sacrificed after the end of the experiment.

The animals were either sacrificed or biopsied at monthly intervals and tissues processed after

fixing in fresh Carnoy's fluid for 24 hr. Sections were cut at 4 μm, stained by H&E and Toluidine blue. Blood was collected at monthly interval by puncturing the occular sinus, serum was separated and stored at −20°C until further use.

Radioimmunoassay. Quantitative estimation of serum AFP was done by RIA using double antibody technique [8]. Pure rat AFP was kindly supplied by International Agency for Research on Cancer, Lyon, France. Monospecific antibody raised in sheep was kindly supplied by Dr. Helena Phiko.* Antisheep gamma-globulin was raised in rabbit in our laboratory. Purified rat AFP was iodinated by chloramine-T method [9]. The radioimmunoassay was carried out as shown below:—

PBS, 0.05M, p.H. 7.0 (0.1% gel)	0.4 ml
Serum or standard	0.1 ml
Labeled AFP (10,000 counts per 100 sec)	0.1 ml
Sheep antirat AFP (1 in 4000 dilution)	0.1 ml
Normal sheep serum (1 in 100 dilution)	0.1 ml
Mixed, incubated at 4°C for 24 hr	
Rabbit antisheep gamma-globulin (1 in 3 dilution)	0.1 ml
Mixed, incubated at 4°C for 24 hr	
2000 rev/min for 30 min	
Counted the precipitate	

The antibody dilution binding at least 20% of the precipitable counts was selected for the inhibition test. Standard inhibition curve was obtained by diluting pure AFP by two fold dilution ranging from 1000 to 1 ng and standard curve was plotted. Serum samples were tested in duplicate and the values were read against the standard curve (Fig. 1).

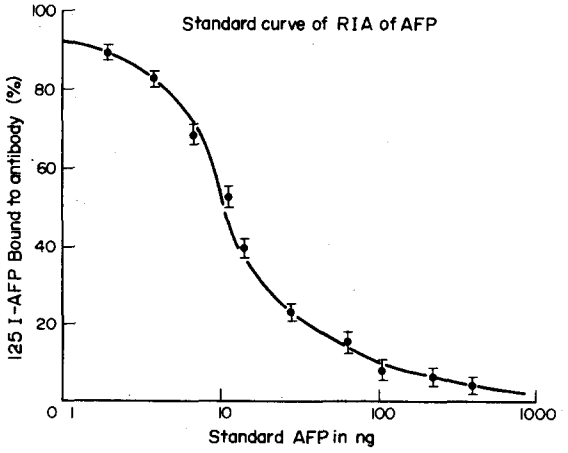

Fig. 1. Standard curve of radioimmunoassay of rat AFP.

*Department of Serology and Bacteriology, University of Helsinki, Finland.

From the standard curve obtained under the condition of the assay used, quantitation of purified rat AFP above 1 ng/0.1 ml could be reproducibly demonstrated. Hence a quantity of 10 ng of AFP per ml of serum sample could be detected with confidence. A set of dilution of known serum sample containing AFP and a set of standard AFP were used for calibration. The curves plotted on the same graph showed parallelism indicating specificity. The assay precision as determined by the coefficient of variation of inter and intra assay of reference sample did not exceed 10%.

Synthesis of AFP in the tumor tissue was demonstrated by immunoperoxidase technique [10] and the tissues were processed according to the Sainte-Marie's method [11].

RESULTS

The serum AFP levels of normal rats were 10–80 ng/ml, the average being 49 ng/ml. Males showed higher values (57 ± 9.4 ng/ml) than females (41 ± 14.1 ng/ml) and also the incidence of HCC in males was significantly higher.

A biphasic reaction of serum AFP levels was observed in most of the animals during the evolution of HCC with azodye carcinogens. The rats that were fed with diet containing 0.06% of azodyes for 6 months developed HCC during 8–24 months of observation. The serum AFP levels began to rise in the first month and increased to attain a peak between second and third month with the mean of 4 μg/ml. By the third month a clear suppression of AFP synthesis could be appreciated. From the fourth month onwards a majority of the animals showed subsequent progressive rise in AFP with the appearance of HCC. The sequential changes in AFP levels are depicted in Fig. 2.

Animals that showed the maximum AFP levels during the first 3 months were the earliest to develop HCC by 8–10 months (Group A). The subsequent serum AFP levels of these animals ranged from 250 to 1100 μg/ml. Two animals, which showed the serum AFP levels 7 μg/ml. during the first peak period, developed HCC as early as 8th month, showing a maximum AFP levels of 1100 μg/ml. Animals which showed gradual rise of AFP levels from fifth month onwards developed HCC by 16–24 months and the levels were less than 15 μg/ml (Group B). Three animals (Group C) which failed to show any rise of serum AFP during the first peak period, yet developed HCC by 16–24 months and the AFP levels were low as

Fig. 5. (*a*) *Tumor showing lack of AFP in highly ill differentiated cells (Top right). The adjoining poorly differentiated cells show intense reaction. Immunoperoxidase* × 440.
(*b*) *Random distribution of AFP synthesis by tumor cells lying singly or in clusters with intermixing AFP negative cells. Immunoperoxidase* × 440.

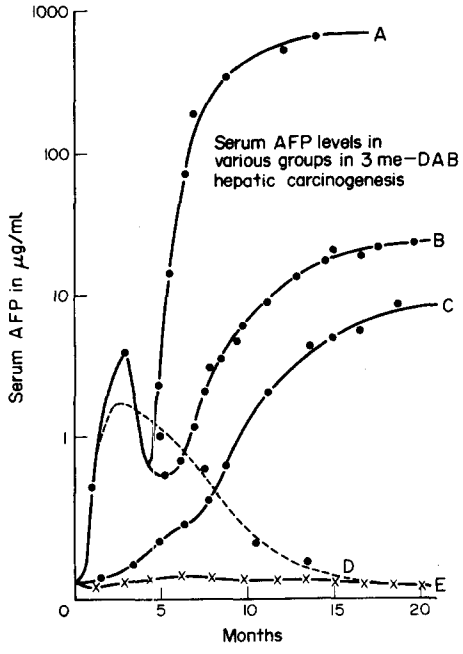

Fig. 2. Serum AFP levels in 3-Me-DAB carcinogenesis. Group A quick responders: groups B and C slow responders. Group D showed only primary reaction and group E no rise of serum AFP levels. No tumors developed in groups D and E.

compared to animals which showed biphasic response. Four animals (Group D) which showed initial rise of AFP during the first three months did not develop HCC and there was no subsequent rise of AFP. Four animals (Group E) did not show any rise of AFP during the whole period of experiments. Since the animals were being sacrificed at regular intervals to study sequential changes, it was not possible to document either the percentage of animals that developed HCC nor the precise percentage of animals showing absence of a second peak of AFP synthesis. However, the results of AFP levels of some of the animals have been depicted in the graph. Fig. 2.

Twelve animals (7 in 3-Me-DAB and 5 in 4-DAB group), which were fed with experimental diet for $2\frac{1}{2}$ months only, also developed HCC after 20 months. None of the animals in aflatoxin B1 group showed rise of AFP levels more than 1–2 μg/ml and 2 animals developed tumors after 26 months.

Histology

Tumors were classified into four grades. Grade I, well differentiated; grade II (Fig. 3), moderately differentiated; grade III, poorly differentiated and grade IV, undifferentiated (Fig. 4) according to Edmonson [12]. Animals which developed HCC by 8–10 months were mostly of grade III and some of grade IV. High incidence of AFP levels were observed in grade III where the values were 250–1110 μg/ml. Grade II HCC showed levels between 7 and 15 μg/ml. The synthesis of AFP was comparatively less marked in grades I and IV. Two tumors were recorded in aflatoxin B1 group: one is HCC of grade III with serum AFP levels less than 2 μg/ml and the other is a cholangiocarcinoma with no rise of AFP levels.

The findings were correlated using immunoperoxidase staining for AFP synthesis in these tumor tissues (Fig. 5). The poorly differentiated HCC showed intensive staining reaction indicating that all the cells synthesize AFP. Whereas in the tumors of grades I and II the AFP cells were distributed either singly or in clusters with intermixing AFP negative cells.

DISCUSSION

Early appearance of serum AFP in experimental rats has been designated as "Primary reaction" [13]. This is characterized by proliferation of the controversial "oval cells" and small hepatocytes in the liver [14]. The sequential changes observed in the rat liver during oncogenesis are as follows: injury, regeneration, proliferation of neoplastic nodule and ultimately to frank HCC [15]. In this study the synthesis of AFP started from first month onwards ranging 1–4 μg/ml (Fig. 2) presumably associated with the onset of regeneration. Sell *et al.* [16] observed a marked rise of AFP synthesis after partial hepatectomy in rats during the period of regeneration and serum AFP levels were six times the normal values. The observed rise in AFP during the "primary reaction" is most likely due to regeneration. In the present study 12/30 animals were fed the carcinogenic diet for 10 weeks only yet developed HCC. These observations are in accordance with those made by Hirai *et al.* [13], in which the DAB containing diet was replaced by a normal diet before the 7th week: none of the animals developed HCC; however, when DAB feed was replaced on the 12th week, HCC developed in most of the animals. It possibly indicated that the carcinogen has to act on the regenerating cells to cause malignant changes. Mice given 0.15% thioacetamide (TAA) after partial hepatectomy developed HCC earlier than those with TAA diet alone [17]. It may thus be speculated that the transitory AFP elevation in patients with liver cirrhosis or hepatitis indicate a "primary reaction". These patients may eventually develop HCC under the influence of some unknown carcinogenic factors

Table 1. *Showing the serum AFP levels, time of appearance of HCC and histological grading in various groups of animals in azodye carcinogenesis*

Group	AFP response Biphasic or monophasic	Maximum AFP levels (μg/ml)	Time of appearance of HCC (months)	Histological grading
A.	Biphasic	250–1110	8–10	Grades III and IV
B.	Biphasic	7–15	16–24	Grades I and II
C.	Monophasic	7–15	16–24	Grades I and II
D.	Monophasic	2–4	—	—
E.	None	<0.1	—	—

like naturally occurring aflatoxin or nitrosamine.

In the present study it is possible to divide the tumor-bearing animals into two distinct groups- "quick" and "slow" responders on the basis of their capacity to synthesize AFP. In "quick responders" the tumors developed by 8–10 months with high AFP values ranging from 250 to 1110 μg/ml (Group A). Majority of the tumors in this group were poorly differentiated HCC. The slow responders on the other hand developed HCC after 16 months and they were better differentiated and the serum AFP levels were significantly lower (15 μg/ml) than the other group. Relatively poorly differentiated (grade III) are able to synthesize AFP in larger-quantity. Highly anaplastic HCC behaving as quick responders, yet could not attain very high levels of AFP. (Table 1). These observations are consistent with those of Takahashi [18] who reported similar findings in human HCC. There were no tumors in groups D and E, though some of the animals did show transient initial rise of AFP.

There is an apparent discrepancy regarding AFP levels in aflatoxin induced hepatoma. Kroes and his coworkers [7] for first time demonstrated the rise of serum AFP in aflatoxin induced HCC in young Fischer strain rats and the reported levels ranged from as low as 1 μg to as high as 100 μg [19]. In our study 1/10 rats developed HCC only at the end of 26 months and the serum AFP levels did not exceed 2 μg/ml. This difference could possibly be attributed to the strain used, lower dose of aflatoxin B1, higher age of the animal in our study as well as tempo of carcinogenesis during aflatoxin B1 therapy.

Abstract—*In a study of* 128 *human primary breast cancers, a significant association has been shown between tumour cellularity and the level of oestrogen receptor activity (ORA) in tumours in which ORA was present, although cellularity was not related to the presence or absence of detectable ORA. In contrast, there was no association between the grade of elastosis and the level of ORA, but a highly significant association was observed between the grade of elastosis and the presence or absence of detectable ORA. Tumours containing large amounts of elastosis were more common in postmenopausal* (22/84) *than in premenopausal* (1/35) *women.*

INTRODUCTION

Two FEATURES of human breast cancer correlated with response to endocrine therapy, oestrogen receptors [1, 2] and elastosis [3], have themselves been shown to be associated [4]. The present report further examines elastosis and oestrogen receptor activity in relation to cellularity and menstrual status.

MATERIAL AND METHODS

One hundred and twenty-eight primary breast tumours were examined, 84 from postmenopausal patients, 35 from premenopausal and menopausal patients (patients whose last period was within 2 yr of the biopsy) and 9 from patients whose menstrual status could not be accurately classified.

Oestrogen receptor activity (ORA) was measured by saturation analysis of free and bound hormones with dextran-coated charcoal using methods previously described [5], and elastosis was demonstrated using a modified Gomori aldehyde-fuchsin stain [4]. The ORA was categorized as plus (detectable, concentration of oestrogen receptor binding sites, Po, greater than 0.1 fmole/mg wet wt of tissue) or minus (non-detectable, Po less than 0.1 fmole/mg wet wt of tissue). The tumours were graded according to the amount of elastosis into categories 0, 1 and 2, where 0 indicates that elastosis was not demonstrable, 1 indicates that elastosis was present in small or moderate amounts and 2 indicates the presence of a gross amount of elastosis. Elastosis was independently assessed blind by three observers, agreement between all three observers being 81% and between two of three observers 100%. A majority decision was accepted. Tumour cellularity was assessed using three categories: 1, 2 and 3, where 1 indicates a low, 2 a moderate and 3 a high tumour: normal tissue ratio. Cellularity was independently assessed blind by two observers, the agreement being 74%. Where disagreement occurred, the slides were re-read blind and classified by agreement.

The relationships between the presence or absence of detectable ORA and the grades of (a) cellularity and (b) elastosis were examined using chi-squared tests (see Tables 1 and 2). In addition, the relationships between the oestrogen receptor concentration in the ORA plus group and the grades of (a) cellularity and (b) elastosis, were analysed statistically. Because the receptor concentrations were not distributed symmetrically, the common median was regarded as a useful measure of the centre of distribution. The null hypothesis that the observations were derived from three distributions (the three grades of cellularity or elastosis) with a common median was examined using a chi-squared test (see Tables 3 and 4 and Figs. 1 and

‡Association between grade of elastosis and presence of receptors significant at $P < 0.001$ by χ^2 test.

2), a statistical procedure known as the extension of the median test [6].

The results for the tumours from postmenopausal women alone as well as those for all tumours were analysed statistically, but the number of specimens in the premenopausal/menopausal groups was too small to be thus analysed.

Table 3. Relationship between concentration *of oestrogen receptors and cellularity in 95 receptor-positive primary breast cancers*

Oestrogen receptor concentration (fmole/mg tumour)	Grade of cellularity		
	1	2	3
Postmenopausal			
≦3.12*	16 (9)	16 (17)	4 (9)
>3.12	2 (9)	17 (16)	14 (9)
All menstrual groups			
≦2.5*	16 (11)	26 (27)	6 (11)
>2.5	5 (10)	27 (26)	15 (10)

Tumours have been classified to show the frequency of occurrence of receptor concentrations greater or smaller than the common median (denoted by *) within each grade of cellularity. The figures in parenthesis show the expected numbers in each cell if the level of receptor activity is independent of the grade of cellularity. Deviations from the expected distribution are significant at the $P < 0.001$ and $P < 0.01$ levels for "postmenopausal" and "all menstrual" groups respectively.

Table 4. Relationship between concentration *of oestrogen receptors and grade of elastosis in 95 receptor-positive primary breast cancers*

Oestrogen receptor concentration (fmole/mg tumour)	Grade of elastosis		
	0	1	2
Postmenopausal			
≦3.12*	2 (4)	22 (22)	12 (10)
>3.12	5 (3)	20 (20)	8 (10)
All menstrual groups			
≦2.5*	4 (5)	35 (32)	9 (11)
>2.5	6 (5)	28 (31)	13 (11)

Tumours have been classified to show the frequency of occurrence of receptor concentrations greater or smaller than the common median (denoted by*) within each grade of elastosis. The figures in parenthesis show the expected numbers in each cell if the level of receptor activity is independent of the grade of elastosis.

RESULTS

(A) *Oestrogen receptor activity and cellularity*

The results are summarized in Tables 1 and 3. No association was observed between the presence or absence of detectable ORA and the grade of cellularity for either the postmenopausal group ($\chi^2 = 0.97$) or for all the tumours examined ($\chi^2 = 0.94$). In contrast, in the ORA plus group, the level of activity was positively correlated with the grade of cellularity (see Table 3 and Fig. 1) in both the postmenopausal group ($P < 0.001$) and all the tumours examined ($P < 0.01$).

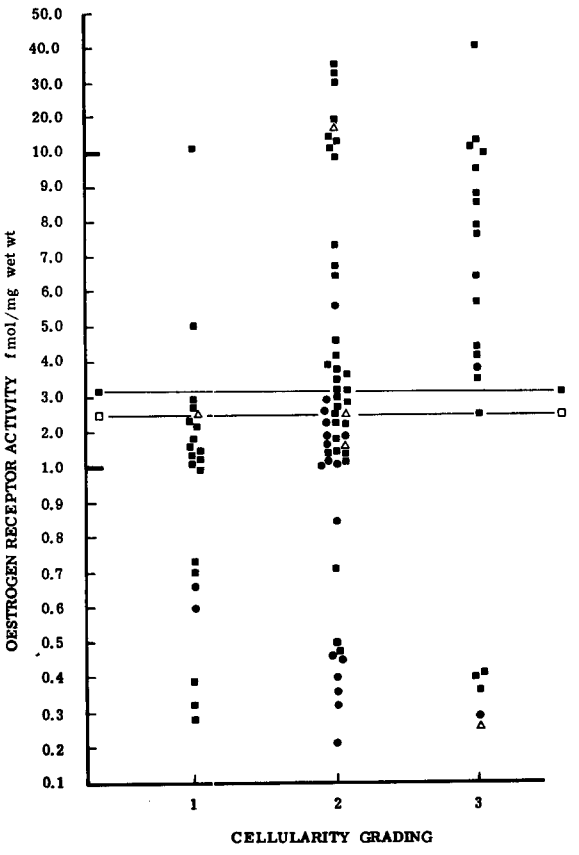

Fig. 1. Scatter plot showing the distribution of ORA for receptor-positive tumours in the three grades of cellularity. The common median P_0 value for the postmenopausal group (■———■) and all tumours (□———□) is shown. The number of tumours in each grade with a P_0 value greater or smaller than the common median is shown in Table 3. The tumours are categorized by the following symbols: (■) postmenopausal, (●) premenopausal, (△) menstrual status not determined.

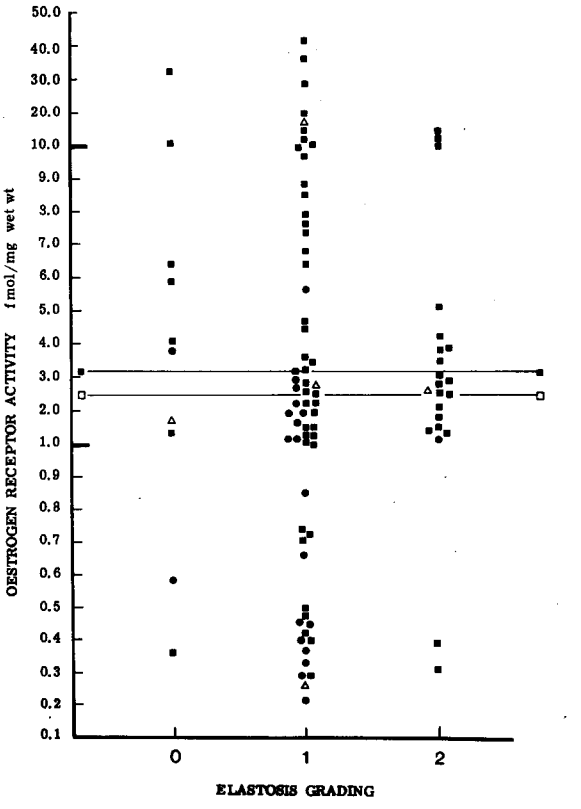

Fig. 2. Scatter plot showing the distribution of ORA for receptor-positive tumours in the three grades of elastosis. The common median P_0 value for the postmenopausal group (■———■) and all tumours (□———□) is shown. The number of tumours in each grade with a P_0 value greater or smaller than the common median is shown in Table 4. The tumours are categorized by the following symbols: (■) postmenopausal, (●) premenopausal, (△) menstrual status not determined.

(B) *Oestrogen receptor activity and elastosis*

The results are summarized in Table 2, and show a definite association between the presence or absence of detectable ORA and the grade of elastosis in all the tumours examined ($P<0.001$), although this did not attain statistical significance in the postmenopausal group alone ($P<0.1$, >0.5). In contrast, there was no association (see Table 4 and Fig. 2) between the level of activity in the ORA plus group and the grade of elastosis in either the postmenopausal group ($\chi^2=2.05$) or the total ($\chi^2=1.89$).

(C) *Elastosis and cellularity*

The results are summarised in Table 5, and there is no apparent correlation between the grades of cellularity and elastosis. According with the definition of the gradings, it was not possible to observe both high cellularity (grade 3) and gross elastosis (grade 2) in the same tumour.

Table 5. The frequency of concurrence of each grade of elastosis and cellularity in 128 human primary breast tumours

DISCUSSION

The purpose of this study was to investigate the interrelationships between oestrogen receptor activity, menstrual status, elastosis and cellularity in human primary breast cancer. ORA was measured quantitatively and objectively, whereas elastosis and cellularity were assessed subjectively. While subjective assessments can be biased, in the present study each feature was classified into three categories and assessed blind. The only apparent source of bias was a tendency to "play safe", giving a preponderance of results in the middle category for each feature.

The results show that the grade of cellularity does not influence the classification of ORA as plus or minus, concurring with previous findings [7–9]. However, in the present study, in tumours in which ORA was detectable, a highly significant association was observed between tumour cellularity and the level of ORA, confirming an earlier observation in multiple sections from 11 large primary tumours [10]. This finding is, however, in contrast to two previous reports [7, 8], while Rosen *et al.* [11] observed a trend but did not consider it significant, agreeing in general with these two previous reports. Terenius *et al.* [9] found a statistically significant difference in the level of ORA between tumours of high and moderate cellularity, but not between tumours of high and low cellularity (possibly because of the small numbers in the low cellularity group). Thus, the present study shows that although cellularity does not affect the rate for detection of receptor-positive tumours, it does influence the level of ORA when present. The findings are important if patients are to be selected for endocrine therapy on the basis of the concentration of oestrogen receptors, rather than the presence or absence of detectable ORA. The importance of relating clinical response to receptor concentration rather than presence or absence of detectable receptor has already been demonstrated [12, 13].

In contrast to cellularity, a significant association was shown between the grade of elastosis and the presence or absence of detectable ORA, but not with the level of ORA. Since the majority of this group of tumours has been described in our previous report [4], this observation simply extends our previous findings. One new finding was made on the relationship between elastosis and menstrual status. It was observed (Table 2) that 22/84 (26%) of the postmenopausal, in contrast to 1/35 (3%) of the premenopausal/menopausal group, contained a gross amount (grade 2) of elastosis. This finding provides further indirect evidence that there is a relationship between elastosis and the hormonal environment in human breast tumours. No satisfactory explanation can be given at present for these findings.

The Effect of Bleomycin and its Combined Effect with Radiation on Cultured Chinese Hamster Cells V-79

KIYOHIKO SAKAMOTO

Department of Radiation Biophysics, School of Medicine, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, *Japan*

Abstract—*The effect of bleomycin and combined effect of it with radiation on Chinese hamster cells V-79-BlM was studied.*

The survival curve of cells exposed to bleomycin showed slightly upwards-concaved firstly, then followed by exponential portion from a surviving fraction of 0.2, *and* D_0 *of terminal slope is* 185 μg/ml. *The result of two fractional exposure of bleomycin in the interval of* 1 *or* 5 hr *demonstrated less cell survivals than in single exposure. In combined treatment of bleomycin with radiation the decrease of* D_0 *was recognized, however* D_0 *was not changed compared with X-ray survival curve.*

INTRODUCTION

BLEOMYCIN is an anti-tumour drug isolated by Umezawa [1, 2] from cultures of *Streptomyces verticillus*. This antibiotic, a complex glycopeptide, has strong anti-tumour activities to human squamous carcinoma. Bleehen *et al.* demonstrated the interaction on *E. coli* B/r, however, they failed to show interactions on four of mammalian cells tested [3]. Radiation-drug interaction is of considerable interest because of a clear interaction between drug and radiation may show the way to enhance the possibility of curing certain cancers. Elkind and Sakamoto [4] suggested that interaction between radiation and drugs was unlikely when drug gave an exponential dose–response curve [4, 5] e.g. the survival curve of Chinese hamster cells treated with nitrogen mustard is exponential and this system does not show the drug-radiation interaction, but the survival curve of Chinese hamster cells exposed to actinomycin D is the threshold type, actinomycin D has shown strong interaction with radiation on the cells.

To study the relation between the mode of survival curve and the interaction is of interest. In the present paper, the effect of another drug, namely bleomycin, and its combined effect with 200 kVp X-ray on cultured Chinese hamster cells V-79 will be shown.

Accepted 27 September 1977.

MATERIAL AND METHODS

The experimental system used in this experiment is essentially the same as described by Elkind *et al.* [6, 7] therefore it will only be presented briefly.

Cells and their cultivation

A number of subclones of Chinese hamster cells designated originally V-79-1 by Elkind has been used. The doubling time of these cells when grown on glass dishes is 11–12 hr. They have a fibroblast-like morphology and produce colonies of about 2 or 3 mm dia in 9–10 days. Colony-forming ability was used as a measure of the cell's survival *in vitro*. Using a modified Eagle's medium [8] to which 15% fetal calf serum was added (EM-15), cells plated in appropriate numbers in 6 cm Petri dishes were grown overnight in a CO_2 incubator at 37°C before an experiment was started. This procedure was used to help insure that the distribution of cells throughout their growth cycle (i.e. the age density distribution) was close to that resulting from asynchronous, log-phase growth and hence fairly reproducible from experiment to experiment. During this overnight growth period, initially single cells formed micro-colonies, on average about three cells; consequently the experiments started with populations of micro-colonies rather than single cells.

Following a given treatment sequence, cells were incubated long enough for a maximum yield of colonies. They were then stained with

methylene blue and counted. Results are expressed as the fraction of cells surviving a given treatment relative to the number in the initial suspension plated, which were able to form colonies. (The percentage of colony formers in the starting suspension is designated the plating efficiency, P.E.)

Bleomycin treatment

The stock solution of bleomycin was prepared at a concentration of 5.0 mg/ml in saline and kept frozen between experiments. For use, stock solution was diluted in Eagle's medium with 15% fetal calf serum to 10 times higher than the final concentrations required. They were kept on ice and bleomycin treatment was made by adding 0.5 ml aliquots of appropriate drug solution to 4.5 ml of medium at 37°C for 3 hr. The reason why 3 hr was adapted as a treating time is that three hours was the minimum time to bring the survival to an exponential portion in the dose–response curve (Fig. 1). At the end of the treatment, bleomycin containing medium was sucked off, the cells were rinsed once with buffer containing 5% EM-15 and supplied with fresh medium at 37°C and incubated to observe eventual colony formation.

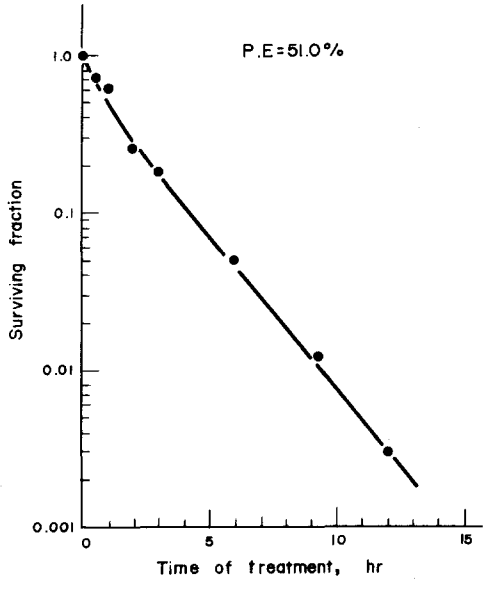

Fig. 1. Survivals of Chinese hamster cells treated with bleomycin in various treating time. The surviving fraction was the ratio of plating efficiency of a treated cell over that of the non-treated control. The survival curves were always constructed by plotting survival against total dose of the drug used. (Standard errors are shown where the means of several points are plotted.)

X-irradiation

The cells in Petri dishes with EM-15 medium were irradiated at 37°C. X-rays were generated by a therapy machine operated at 200 kVp and 20 mA and were filtrated through 0.5 mm Cu and 1.0 ml Al. The exposure dose rate, measured with a Victoreen Radocon II Integrating Ratemeter (Model 555), was 60 rad/min; the FSD was 50 cm. Immediately after exposure at room temperature, medium was sucked off and fresh medium kept at 37°C was applied to the dish for final incubation.

In the case of combined treatment of X-ray with bleomycin, if the first treatment was X-irradiation, medium was removed immediately after irradiation, fresh medium was put into the dish and bleomycin was added, 3 hr later bleomycin containing medium was taken away, cells were rinsed once with buffer and supplied with fresh medium and incubated for colony formation.

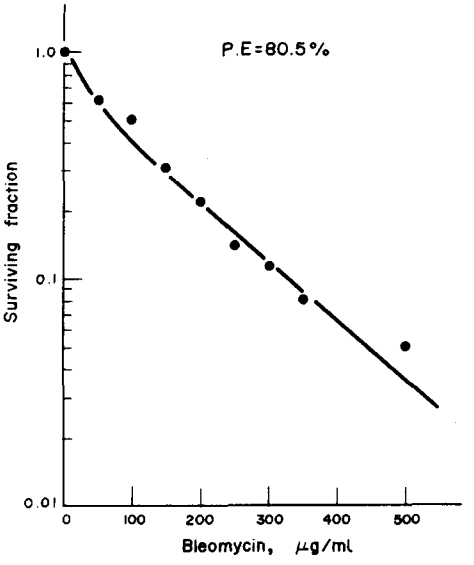

Fig. 2. Dose–survival curve of Chinese hamster cells treated with bleomycin for 3 hr.

In the experiment that bleomycin was used as the first treatment, medium was sucked off from dish containing bleomycin after 3 hr treatment, cells were rinsed once, then fresh medium was refed. The medium was replaced again with fresh medium for final incubation after X-ray exposure.

RESULTS

Survivals after bleomycin treatment

In Fig. 1, the survival of Chinese hamster cells V-79-BIM treated with bleomycin of 200 μg/ml is plotted against the time of treatment (time-inactivation curve). The curve begins with a slightly upward-concave curve, followed with an exponential declining line from a surviving fraction of 0.2. Figure 2 demonstrates

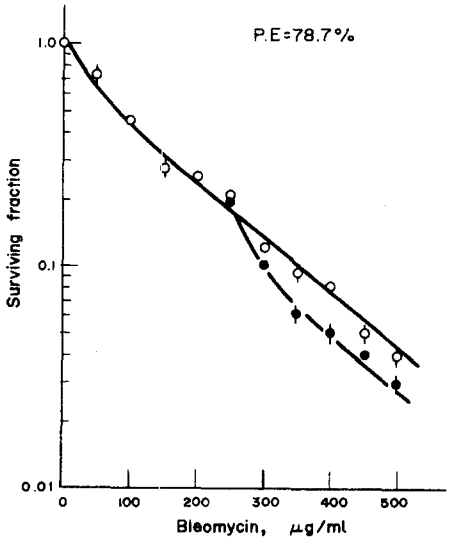

Fig. 3. Survival curve of Chinese hamster cells V-79-BlM after single and double treatment with bleomycin.
○: *Survival of cells treated with the drug at various concentrations for* 3 hr.
●: *Survivals of the cells which were treated first with the drug at* 250 μg/ml *for* 1.5 hr *and followed by a second treatment for* 1.5 hr *with the drug of various concentrations* 1 hr *after the first treatment.*

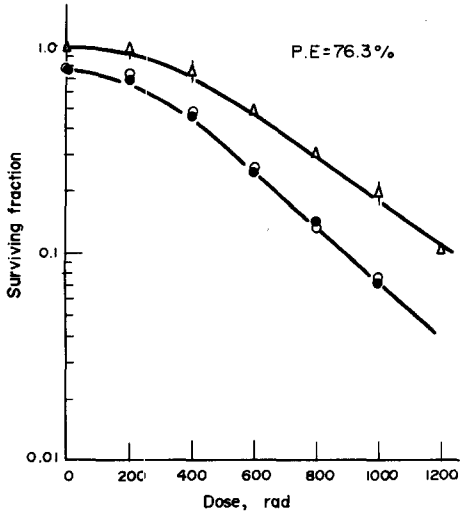

Fig. 4. Survival of Chinese hamster cells V-79-BlM after combined treatment of bleomycin and X-ray.
△: *Survivals of cells exposed to* 200 kVp *X-rays of various doses.*
○: *Survivals of cells exposed to various doses of X-rays immediately after treatment with bleomycin of* 100 μg/ml *for* 3 hr.
●: *Survivals of cells treated with bleomycin of* 100 μg/ml *for* 3 hr *immediately after X-ray exposure of various doses.*

the survival curve of cells to single dose of bleomycin for a fixed treatment time of 3 hr. The curve is similar to the time–inactivation curve of Fig. 1. The D_0 of the exponential portion of Fig. 2 is 185 μg/ml. Since these survival curves are quite different from a sigmoid type of a survival of X-irradiated Chinese hamster cells, it is difficult to assume the existence of Elkind-type recovery (an increased survival from recovery of X-ray induced sublethal type of damages). In order to confirm whether or not Elkind-type recovery is in bleomycin induced damage, split dose experiments were performed. In Fig. 3, the open circles are the survivals of cells treated with single doses of bleomycin for 3 hr and the closed circles are the survivals of cells, which were firstly treated with 250 μg/ml of bleomycin for 1.5 hr, rinsed and maintained in drug-free medium for 3 hr, and exposed second time with graded doses of bleomycin for 1.5 hr. The closed circle at 250 μg/ml bleomycin in Fig. 3 is that received the first 250 μg/ml bleomycin for 3 hr, followed by 3 hr of the non-treatment and by 1.5 hr of another non-treatment (0 μg/ml bleomycin). The results of split dose experiments are opposite to what

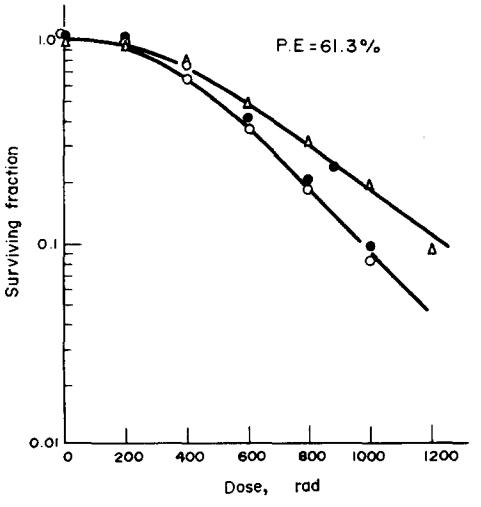

Fig. 5. Survival of Chinese hamster cells V-79-BlM after combined treatment of bleomycin and X-ray.
▲: *Survivals of cells exposed with X-rays of various doses.*
○: *Survivals of cells exposed to various doses of X-rays immediately after treatment with bleomycin of* 30 μg/ml *for* 3 hr.
●: *Survivals of cells treated with bleomycin of* 30 μg/ml *for* 3 hr *immediately after X-ray exposure of various doses.*

one sees in split dose experiments with X-rays. The reasons why the cell survival rate is less in two-fractionated than in single exposure of bleomycin are not clear. The residual damage in cells by first treatment may relate to the low survival ratio in the fractionated treatment.

Combined treatment

In Fig. 4, open triangles indicate the survivals of cells irradiated with 200 kVp X-rays, closed circles are those of the cells irradiated with X-rays first and treated with bleomycin of 100 μg/ml for 3 hr after X-irradiation, and open circles are those of the cells treated with 100 μg/ml bleomycin for 3 hr and followed with graded doses of X-rays.

Figure 5 is another set of experiments, where 30 μg/ml of bleomycin were used instead of

100 μg/ml. D_0s of X-rays survival curves in Figs. 4 and 5 are 390 and 370 rad respectively, these values are almost three times as large compared with the value obtained on the same cell line by Elkind and Sakamoto [4]. However, D_0 values in present paper are reproducible, Chinese hamster cells which are cultivated in my laboratory may become radio-resistant compared to the original cells.

In Figs. 4 and 5, bleomycin treatments before X-irradiation were not significantly distinguishable from the effects of bleomycin treatment after X-irradiation. The effect of the post- and pre-X-irradiation treatment of bleomycin was apparent in the D_0 values of the survival curves in Fig. 4, D_0 of 390 rad for X-irradiation alone was decreased to 308 rad with bleomycin treatment, while in Fig. 5, D_0 of 370 rad for X-rays alone was decreased to 270 rad with bleomycin treated group. However, bleomycin treatments affected little on the D_q values of X-irradiated cells.

DISCUSSION

The survival curves of Chinese hamster V-79 cells are made up of an initial rapid decline (upward-concaved), followed by an exponential decline. This type of survival curves is observed not only in the relation to a fixed bleomycin with various treatment times (Fig. 1), but also in the relation to various bleomycin concentration with a fixed treatment time (Fig. 2). Two curves indicated a shift to an exponential decline at around survival fractions of 0.2–0.3. Previously, Terasima *et al.* [9] obtained this type of survival curve in mouse L cells from varied treatment times, Sakamoto in a murine squamous cell carcinoma *in vivo* [10], and Barranco *et al.* in CHO cells *in vitro* [11].

It is noted that no such survival curves were found in other drugs with Chinese hamster cells (e.g. actinomycin D [3], nitrogen [4] mustard, neocarzinostatin [12] and daunomycin [13].

Since this type of survival curve seemed to be quite opposite to what one sees in the survival curve of X-rays (e.g. Figs. 4 and 5), where there is a shoulder, followed by a rapid exponential decline in their survival curves. Figure 3 shows that introduction of a time interval between two doses did produce an initial rapid decline portion. This seems to deny the existence of "sublethal damage (recoverable) of Elkind type" with bleomycin. Its outcome is a suggestion that bleomycin treatment of cancer patients (if cancer cells has similar survival curves) should be made the most effectively if treating the cells with small doses (say, sufficient to bring them to the exponential portion of the survival curve) in intervals of 3–6 hr.

The next question is what would be the bleomycin resistant component in the survival curve? Terasima *et al.*, noting the similar type of the survival curve in L cells, suggested several possibilities: a population made up of bleomycin sensitive and resistant cells, an existence of a saturation dose level, over which bleomycin affects cells ineffectively, and an induction of bleomycin-resistancy in the treated cell population. Humphrey *et al.* found that bleomycin treatment inducement blockage of cell progress at S and G_2 stages [11]. However, our results are not sufficient to support any hypothesis at this stage.

Since survival curve with bleomycin was different from actinomycin D, nitrogen mustard and neocarzinostatin and daunomycin, the combined effects with X-ray were carried out. In the previous works of Matsuzawa *et al.*, bleomycin had potentiating effect on X-rays especially in the post-irradiation treatment. While Terasima found little potentiating effects in mouse L cells, Bleehen *et al.*, reported no potentiating effects in HeLa cells, and *E. coli.* Sakamoto *et al.* [12] were unable to demonstrate a potentiating effect on a murine squamous cells carcinoma *in vivo*. In the present experiments, two concentrations bleomycin were used. One is a very low concentration of 30 μg/ml, which hardly kills the cells and the other is 100 μg/ml, which killed most of bleomycin sensitive cells, leaving bleomycin-resistant cells. Under these conditions, post- and pre-irradiation treatments with bleomycin showed no effects on D_q values of X-irradiated cells, and some 20–29% decrease in the D_0 portions of the X-irradiated cells. In other words, no effects of bleomycin on D_q seemed to suggest that bleomycin did not interfere "sublethal type of X-ray damages" and that it potentiates lethal type of X-ray damages. Or X-ray sensitivity of two bleomycin treated populations (one with bleomycin sensitivity and the other with decreased sensitivity and mostly resistant population) was similar. It is however, noted that the extent of bleomycin potentiation was only 20–29% in reduction of D_0 values.

Acknowledgements—I am grateful to Mrs. Yukiko Matsunaga and Miss Mariko Inoue for their technical assistance and to Nippon Kayaku Co. Ltd. for supplying bleomycin.

Letter to the Editor

Fibrinolysis in Lung Cancer

P. WHUR,* C. M. URQUHART,* D. C. WILLIAMS,* D. DONALDSON† and A. SAKULA†

**Marie Curie Memorial Foundation, Oxted, Surrey and †Redhill General Hospital, Redhill, Surrey, United Kingdom*

IT IS a feature of many malignant cells that they produce elevated levels of a urokinase-like plasminogen activator which converts serum plasminogen to plasmin *in vitro* [1, 2]. Since a prominent physiological function of plasmin is the cleavage of fibrin into fibrin degradation products (FDP), elevated FDP levels might be expected to occur in association with malignancy. In fact, there is considerable evidence of elevated fibrinolytic activity in some types of cancer, as well as in human tumour cell lines in culture [3]. For example, the majority of breast carcinomas and a substantial proportion of gastrointestinal adenocarcinomas were found to have plasminogen activator properties when tested *in vitro* [4]. However, this may not be a feature of all types of cancer. Thus, in acute leukaemia there was wide variation in fibrinolytic status [5], while sarcomas have been reported to exhibit only spontaneous fibrinolytic activity unassociated with plasminogen activation [4]. The levels of FDP in serum and urine are also substantially elevated in a variety of non-cancerous conditions, including disseminated intravascular coagulation [6], pulmonary embolism [7], deep vein thrombosis and myocardial infarction [8]. Since the urine contains urokinase, and the prostate exhibits direct fibrinolytic activity [9, 10], kidney or urinary tract disease may cause elevation of urinary, but not serum FDP [11, 12]. Consequently elevated FDP levels might be predicted in patients with some types of cancer, the relation between the two being dependent upon the elimination of other potential causes.

FDP assay systems are already being used in clinical cancer studies, for example, to evaluate the success of urokinase injection following tumour resection [13]. We have investigated the potential use of FDP assay as a diagnostic aid prior to confirmation of malignant disease. Our initial investigation has been carried out on patients with suspected bronchial carcinoma, referred for bronchoscopy. Samples of blood and urine were obtained from resting patients admitted to hospital a few hours previously. The samples were immediately mixed with soybean trypsin inhibitor to prevent further plasmin-dependent fibrinolysis; it may not, however, completely inhibit fibrinolysis by other enzymes [10]. Serum was then prepared, and stored at −20°C for up to a week before assay. The results are given in Table 1 and show that 78% of patients with subsequently confirmed bronchial carcinoma had normal FDP levels. Of the remaining 22% with bronchial carcinoma who showed elevated levels of FDP in urine and/or serum, only one individual was apparently free from concurrent nonmalignant disease likely to cause elevated FDP.

We conclude that elevated FDP levels are not a feature of primary carcinoma of the bronchus in newly referred patients and that the assay has no value as a diagnostic aid in such cases. However, in view of a report of 5 epidermoid carcinomas of the lung without associated fibrinolytic properties *in vitro* [4], together with the negative findings in our series, it seems that bronchial carcinomas may not be a potent source of plasminogen activator and may differ in this respect from some other forms of cancer. An alternative possibility is that tumour-associated fibrinolytic activity is present, but restricted to the tumour site in our patients; becoming generalized only at a later stage in the disease process. This alternative possibility is supported by preliminary observations, carried out in collaboration with Mr. John D. Griffiths and Mr. Harvey White, Royal Marsden Hospital, London, on patients with colorectal carcinomas. Tumours examined so far in this series have shown high plasminogen activator activity in fibrin–agar plate assays despite the fact that neither peripheral blood nor blood drained from the venous circulation of the tumour during operation contained elevated FDP. Thus, tumour-associated elevation of vascular FDP in cancer patients may be more characteristic of relatively gross and

Accepted 27 September 1977.

generalised pathological changes than of localised fibrinolytic activity at the tumour site. This former type of change has been described by Brassinne *et al.*, who have suggested that the hypofibrinogenaemia associated with prostatic adenocarcinoma may be due to disseminated intravascular coagulation [14], possibly associated with disseminated fibrinolysis.

Table 1. *FDP Levels* of* 31 *bronchoscopy patients*

No. of patients	Lung abnormality	Urine FDP (μg/ml)	Serum FDP (μg/ml)	Other possible causes of elevated FDP
20	bronchial carcinoma	normal	—	—
2	bronchial carcinoma	normal	normal	—
1	bronchial carcinoma	20	normal	none found
1	bronchial carcinoma	—	10	trauma
1	bronchial carcinoma	2.5	—	phlebitis
1	bronchial carcinoma	10	—	renal calculi
1	bronchial carcinoma	2.5	—	cardiac failure
1	bronchial carcinoma	1.25	—	cardiomegaly, dyspnoea
2	nonmalignant condition	normal	—	—
1	nonmalignant condition	normal	normal	—

*FDP levels were measured by haemagglutination—inhibition assay using the Wellcome FDP kit HA14. Normal levels were taken to be 5 ± 3 μg/ml (serum) and 1.25 μg/ml (urine). The normal urine levels of 0.25 μg/ml exceeds test sensitivity.

Role of Particle Size in the Formation of Respiratory Tract Tumors Induced by Benzo(a)pyrene*

FREJ STENBÄCK and JESUDOSS ROWLAND

Eppley Institute for Research in Cancer, University of Nebraska Medical Center, 42nd and Dewey Avenue, Omaha, NB 68105, U.S.A.

Abstract —*The role of particle size in experimental respiratory tumor formation was studied by intratracheal instillation of two different particle sizes of benzo(a)pyrene into Syrian golden hamsters. One group of hamsters received large particles* (64% *above* 10 μm), *the second group was treated with smaller-sized particles* (98% *less than* 10 μm). *Otherwise, treatment was similar. Only* 5 *respiratory tumor-bearing animals of* 48 *were found in the group receiving small particles, whereas* 31 *respiratory tumor-bearing animals of* 48 *were found in the group which received the larger particles. Analysis of the retention rate of instilled B(a)P showed that small particles cleared much more rapidly from the lungs than did the larger particles.*

INTRODUCTION

ADDITION of a carrier dust to a suspension of a polycyclic hydrocarbon in the experimental induction of respiratory tumors by intratracheal (i.t.) instillation using Saffiotti's methods [1] repeatedly was shown to significantly affect neoplastic progression [2]. For example, only large doses of benzo(a)pyrene [B(a)P] were effective without carrier dust and the tumor incidence was low [3], while when instilled as fine particles, B(a)P failed to induce any tumors [4]. Weekly instillation of much larger B(a)P particles in small doses induced mainly tracheal tumors [5]. The penetration and retention of carcinogen in lung tissue have been associated closely with subsequent tumor formation [6, 7]. The retention time of the carcinogen was related to the total dose instilled [3], as well as to the mode of particle preparation [8].

The present study describes the method of respiratory tumor induction and the tumor types found, in relation to retention rates, when B(a)P was given in different particle sizes and evaluates the role of particle size in experimental tumor induction.

Accepted 26 May 1977.

*Supported by Public Health Service contracts PHS-43-68-959 and NO1 CP33278 from the Division of Cancer Cause and Prevention, the National Cancer Institute, NIH, PHS.

MATERIAL AND METHODS

Animals and chemicals

Randomly bred, 6–7-week-old male and female Syrian golden hamsters from the Eppley Colony were used. They were housed by sex in groups of 6 in plastic cages on sterilized San-i-cel bedding and given Wayne diet (Allied Mills, Chicago, IL) and tap water *ad libitum*. B(a)P was obtained from Aldrich Chemical Company, Milwaukee, WI (batch no. 111237) and found 99.4% pure by thin layer chromatography. The saline solution, consisting of 0.9% NaCl, sterile and nonpyrogenic, was obtained from Baxter Laboratories, Inc. (Morton Grove, IL) and brevital sodium [sodium-α-1-methyl-5-allyl-5-(1-methyl-2-pentynyl)barbiturate] from Eli Lilly & Co. (Indianapolis, IN).

Preparation of B(a)P suspensions

Two suspensions of B(a)P in saline were prepared to obtain different particle size ranges. For group 1, B(a)P was ground in a mullite grinder 8 hr, suspended in saline and ballmilled 17 hr. For group 2, B(a)P was ground for 24 hr, suspended in saline and ballmilled 7 days. The containers, stainless steel balls and covers, were steam-autoclaved and the suspensions stored at 4°C for 2–3 weeks. Prior to each treatment they were vibrated ultrasonically for 3–4 min.

Particle sizes were determined by Coulter

Table 1. *Particle size distribution (by weight) of benzo(a)pyrene suspensions*

Group	Size (% below)					
	40 μm	30 μm	20 μm	10 μm	5 μm	1 μm
1	100	98	90	36	10	0
2	100	100	100	98	79	5

Electronics, Inc. (Hialeah, FL.). The samples were dispersed with 3–5 min of ultrasonication and run on a Coulter Counter Model TA using a biaperture technique. They pertained to individual particles rather than agglomerates. The particle size distribution for the two B(a)P suspensions is shown in Table 1.

Experimental design and conduct

The 144 hamsters were divided into 3 groups and received i.t. instillation, as described by Saffiotti *et al.* [1]. Group I received 3 mg B(a)P (large particles suspended in 0.2 ml saline) once weekly for 18 weeks. Group 2 was administered 3 mg B(a)P (small particles) suspended in 0.2 ml saline. As the solvent control, group 3 received 0.2 ml saline once weekly for 18 weeks.

The animals were weighed once weekly and checked twice daily, at which time gross observations were recorded. The animals were allowed to die spontaneously or were killed when moribund. For morphological studies at autopsy, tracheas were ligated and lungs removed *en bloc*, still fully expanded by air, and then fixed by immersion in 10% neutral buffered formalin. Histologic sections were prepared from each lobe of the lungs, larynx, trachea, stem bronchi and other organs showing gross pathologic changes. Sections were stained with hematoxylin and eosin. Other stains were used when needed.

Lung retention of B(a)P

To study the effect of different particle sizes of B(a)P on the retention rate, hamsters that received a single B(a)P instillation were serially sacrificed. The same suspension used for tumor induction was also employed in the retention rate study. For the 0 hr time determination, 3 hamsters were killed with sodium brevital within 30 sec after instillation and the lungs were placed in methylene chloride. Hamsters were also sacrificed in groups of 3 at intervals of 6 and 18 hr and 3 days. The respiratory tract, including the larynx, trachea and all lung lobes, was removed *en bloc* and placed in a "Virtis" homogenizer with 20 ml methylene chloride and homogenized for 5 min at full speed. The homogenate was then centrifuged for 15 min at 300 rev/min in a Fisher Scientific Centrifuge. The pellet which formed at the top was separated from the supernatant liquid and washed. The washings were combined with the supernatant, dried with magnesium sulfate and filtered, after which the volume was recorded. After appropriate dilution, the ultraviolet spectrum was determined and absorption at 387 nm used to calculate the B(a)P concentration. Further extraction of the pellet with methylene chloride produced no additional product. Recovery of B(a)P from the hamster respiratory tract at 0 hr consistently produced >95% of the instilled dose. Subsequent values are expressed as percent of the 0-hr recovery.

RESULTS

The survival rates of hamsters are given in Table 2. Those treated with the small particle size of B(a)P (group 2) had a median lifespan of 55 weeks, compared to 36 weeks in hamsters treated with the large particle size (group 1). The most common cause of death in group 2 was nephropathy, unrelated to treatment. Occasionally, pneumonia was seen in the solvent-treated animals. Suffocation due to neoplastic involvement of the respiratory system was occasionally encountered in group 1 and neoplastic alterations were found in many animals (Table 3).

Intratracheal instillation of large B(a)P particles induced laryngeal tumors, consisting of squamous cell papillomas in 5 animals. The trachea was the most common location for tumors and there were 12 papillomas, which were villous structures covered by squamous epithelium. There were also 20 squamous cell carcinomas, mostly well-differentiated with large keratin sheaths and 2 undifferentiated sarcomatoid tumors. Bronchial epithelial alterations, desquamation, squamous metaplasia and hyperplasia were seldom seen. The number of lung tumors was lower compared to tracheal tumors and consisted of 9 squamous cell carcinomas, similar to those of the trachea, 2 papillomas, 2 anaplastic carcinomas and 3 adenomas. Adenomatoid alveolar proliferation was frequently encountered. Adenosquamous lesions, composed of squamoid cells in a glandular pattern reminiscent of that seen in the tracheal papillomas, were observed in 2 animals.

Table 2. Number of survivals in weeks (% between brackets) of Syrian golden hamsters, treated with B(a)P/saline control

Group	Total No. of animals	Effective No. of animals	% of survivals in weeks									
			0	10	20	30	40	50	60	70	80	90

1	Large particles of B(a)P	47	31	55	5	—	12	20	2	2	9	3	2	16†
2	Small particles of B(a)P	46	5	6	1	1	4	—	—	—	—	—	—	17†
3	Saline	—	—	—	—	—	—	—	—	—	—	—	—	—

*TBA = tumour bearing animals.
†Forestomach papillomas.

Interstitial fibrosis was minimal, with infrequent accumulation of alveolar macrophages and pulmonary edema. In addition to the respiratory tumors, there were 16 forestomach papillomas.

Administration of small B(a)P particles (group 2) induced (in only 5 animals) neoplastic alterations, consisting of 1 papilloma, 1 squamous cell laryngeal carcinoma and 4 tracheal papillomas, in addition to an adenosquamous lesion similar to that seen in the previous group. No squamous cell carcinomas were observed in either the trachea or lungs. The pulmonary response in group 2 was otherwise minimal, and fibrosis or granulomas were not observed. Terminal alveolar congestion and edema were encountered occasionally. In addition to the lung tumors, there were 17 forestomach papillomas. The saline control (group 3) presented no respiratory tumors or lesions. Nephropathy with glomerular cellular proliferation and scarring was a common cause of death. Pulmonary congestion and infectious changes were infrequent.

The results of the retention rate study show a definite correlation between particle size and the rate of carcinogen clearance from the lungs,

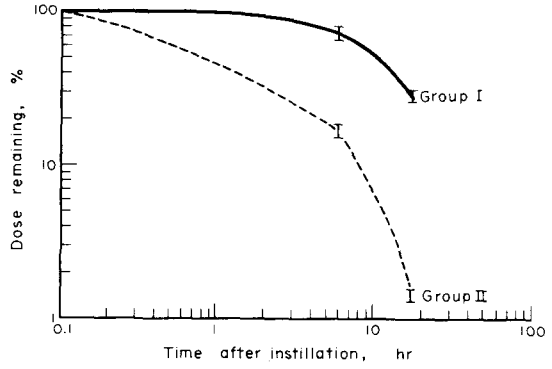

Fig. 1 Retention rate of B(a)P. Group 1—large particle size. Group 2—small particle size.

as shown in Fig. 1. A single dose, consisting of 2.96 mg of small particles of B(a)P in suspension, was cleared rapidly from the lungs; 17% was recovered after 6 hr and 1% after 18 hr. In contrast, the large particle B(a)P suspension was retained in the lungs for a longer period, with 75% recovered after 6 hr and 25% after 18 hr. No B(a)P of either particle size was recovered after 3 days. Thus, the large particles retarded the clearance of the carcinogen from the hamster lungs. Morphologically detectable alterations, specifically associated with particle size in the retention rate study, were not observed. Tracheobronchial epithelial desquamation, ciliacytophtoria, slit formation and alveolar cellular proliferation were seen in both carcinogen-treated groups. Saline instillation failed to produce any changes in the respiratory system.

DISCUSSION

Our results clearly indicate a decisive influence of particle size in experimental respiratory tumor induction. In early studies B(a)P failed to induce tumors when the carcinogen was instilled either alone [1] or in fine particles [4]. In the latter case when B(a)P was instilled in gelatin–saline suspension without a carrier dust, tumors occurred only at higher dose levels (about 100 mg) [3]. The first report on tumor induction by B(a)P alone dealt with instillation of large particles of the carcinogen (only 19% less than 10 μm and as much as 28% above 30 μm) in saline suspension [5]; here, the large B(a)P particles may have acted both as "carrier" particles and as a carcinogen. A positive dose–response relationship was demonstrated when low B(a)P doses were instilled for a longer time period [9].

Morphologically, the tumors in the present study were similar to those in man [10], consisting of mostly tracheobronchial surface papillomas and squamous cell carcinomas, preceded by epithelial metaplastic and dysplastic changes. The glandular tumor incidence was small: 5.5% in group 1, or nonexistent in group 2. The results are similar to those previously described [5, 9], pointing to a role of squamous metaplasia in respiratory tumor formation, and an association between polycyclic hydrocarbon inhalation and an increase in squamous cell carcinoma in man [11]. Morphological analysis of early B(a)P-induced lesions have also shown squamous metaplasia and atypia to be closely associated with subsequent tumor formation [10]. B(a)P-induced tumors occurred in a high incidence in the trachea (62%), compared to the larynx (9%) and lungs (29%) (group 1). A possible explanation is that the large particles (group 1) (64% above 10 μm) are propelled by the tracheobronchial surface mucociliary mechanisms in a proximal direction, which has less effect on smaller particles (group 2) (98% less than 10 μm). The lack of fibrogenic and granulomatous response in this study also may be due partially to the particle size.

An increased tumor incidence caused by adding carrier dust has been considered as being due to increased B(a)P retention [1, 12]. This aspect was also studied using the same B(a)P suspension. Large B(a)P particles were retained in the lungs for a longer time (25% recovered

after 18 hr) (Fig. 1), while the smaller particles cleared at a much faster rate (1% recovered after 18 hr). This tends to agree with previous reports that smaller particles are removed up to 95% in 5 hr [3], while larger particles are cleared only up to 50% in 24 hr [5]. These results, along with those in previous reports, suggest that large particles of B(a)P are retained longer in the lungs, acting both as carcinogen and "carrier" particles, while small B(a)P particles act only as a carcinogen and clear faster from the lungs, thus exhibiting only a very low level of carcinogenicity.

Previous studies have indicated an association between particle size, retention rate and subsequent respiratory tumor formation [13–19]. Saffiotti [20] reported results from a study using 3 different B(a)P samples, one prepared by grinding (particles up to 8.2 μm), one by precipitation (particles up to 17.5 μm) and one similarly prepared by ultrasonic treatment (particles up to 8.2 μm). The results indicated that the percentage of B(a)P retention decreased with decreasing particle size, as shown in this study. These results must be considered when comparing respiratory tumorigenesis studies, and the significance of different etiological agents. The particle size must also be considered in evaluating environmental and occupational hazards from respiratory cancer-inducing agents.

The Current Causes of Death in Patients with Malignant Melanoma

DANIEL R. BUDMAN, ELBER CAMACHO and ROBERT E. WITTES

Department of Medicine, Memorial Slaon-Kettering Cancer Center, New York, New York 10021, *U.S.A.*

Abstract—*The immediate cause of death was determined for all patients dying at Memorial Hospital from* 1973 *to* 1976 *with biopsy-proven malignant melanoma. One-third of patients died of a central nervous system involvement. Pulmonary involvement and infections were the next most common causes of death. The addition of chemotherapy or chemoimmunotherapy to surgery did not change the causes of death. The incidence of postmortem, documented CNS metastases has also increased since prior studies* 10 yr *ago.*

INTRODUCTION

MALIGNANT melanoma is a tumor of interest as its incidence is increasing at a rate greater than any other tumor except lung cancer [1, 2]. Recent studies have suggested that both chemotherapy and chemoimmunotherapy have at most limited effects in this neoplasm [3–5]. As the immediate cause of death in melanoma patients has not been carefully examined since the advent of chemotherapy and chemoimmunotherapy, this study examined the effect of current therapeutic modalities on the cause of death in these patients.

MATERIAL AND METHODS

The immediate cause of death in all patients with biopsy-proven malignant melanoma dying at Memorial Hospital between 1973 and 1976 were examined. Patients treated at Memorial but dying elsewhere were excluded from study to ensure uniformity of both medical care and pathologic findings during the final admission. Approximately 50% of patients followed for malignant melanoma at Memorial Hospital were included in this study. A total of 139 patients were evaluated. The clinical cause of death was determined by using the criteria of a previous study on the causes of death in cancer patients [6]. A CNS catastrophe was defined as a primary neurologic event due to tumor leading directly to the patient's demise. Intracranial hemorrhage, herniation and/or progressive metastatic disease with irreversible neurologic signs leading to death were included under this category. Infectious causes required cultures and/or evidence of an infection such as fever with leukocytosis and/or a pulmonary infiltrate which led to respiratory and/or vasomotor collapse not explainable by other causes. Respiratory causes of death only included pulmonary insufficiency directly caused by the metastatic process and not by superimposed infection. A hemorrhagic cause of death was defined as uncontrollable bleeding leading to vaso-motor collapse and/or leading to irreversible damage of a vital organ. Supportive autopsy evidence was available in 73 patients. When the immediate cause of death was clinically or pathologically uncertain the patient was scored as having "other" cause of death.

The age at time of death, sex and stage of disease at first diagnosis were determined. Final laboratory values, if within two days of death, were noted. The patients were then placed into one of three groups (Table 1) according to the type of treatment they received:

(1) Surgery and/or irradiation.
(2) Chemotherapy in addition to surgery and/or radiation therapy. Chemotherapy usually involved treatment with nitrosurea and DTIC initially, followed by multiple other experimental agents.
(3) Immunotherapy, in addition to surgery and/or radiation therapy plus chemotherapy. Thirty-five patients received only BCG, 10 *C. parvum*, 5 mixed bacterial vaccine (a variant of Coley's toxins), 3 allogeneic tumor vaccine and 2 transfer factor.

Accepted 30 June 1977.

Medain age	63	48	50	52
(range)	(32–92)	(20–76)	(16–73)	(16–92)
Stage, at time of diagnosis of melanoma				
Localized (skin ± nodes)				
Number of patients	19	51	41	111
Disseminated	5	14	4	23
Not determined		4	1	5
Second malignancies in patients	4	2	3	
	1. Breast cancer 2. Cervical carcinoma 3. Adenocarcinoma of the sigmoid colon 4. Adenocarcinoma of the sigmoid colon, lymphoma	1. Breast cancer 2. Adenocarcinoma of the sigmoid colon	1. Thyroid papillary adenocarcinoma 2. Adenocarcinoma of the colon 3. Lymphoma, Basal cell carcinoma of the skin	

The causes of death were then examined as indicated above and statistical analysis was done by chi square analysis with Yates' correction.

RESULTS

Table 1 indicates the composition of the patients studied. No significant differences among the three groups were found. Males predominated in all groups. Approximately 80% of patients in each group had localized skin or localized skin with proximal node metastases at the time of initial presentation.

Table 2 indicates the final hematologic values at time of death. Patients treated with either chemotherapy or chemoimmunotherapy tended to be more anemic, have a higher BUN and lower platelet count than patients treated solely with surgery and/or radiation. These differences were not of statistical significance. Hypercalcemia, defined as a serum calcium greater than 11.0 mg per deciliter, was noted in three of the chemotherapy and three of the chemoimmunotherapy patients.

Table 2. *Laboratory values of study patients*

	Percentage of abnormal values at time of death		
	Group 1	Group 2	Group 3
Hemoglobin < 10.0	35	45	54
White blood cell count < 2.0	5	6	5
Platelets < 100,000	15	21	25
BUN > 25	29	49	54

The most common causes of death (Fig. 1) were (1) central nervous system involvement by tumor ($P < 0.03$ compared to pulmonary involvement), (2) metastatic pulmonary involvement with respiratory insufficiency and (3) infections. One-half of the infectious processes in each group were pneumonias. Therapy did not change the relative frequency of the various causes of death in any of the groups (Fig. 1).

The extent of metastatic disease found on autopsy is shown in Table 3. Patients dying without evidence of melanoma (2 patients) or in the immediate postoperative period (3 patients) were excluded from analysis. Except for central

*Different from historical control, $P < 0.05$.

nervous system (CNS) involvement, the sites of involvement at time of death has not changed compared to historical controls at Memorial Hospital [7]. Approximately three-quarters of all study patients had CNS involvement at time of death (Table 3) which is almost twice the frequency previously reported from this Institution. CNS involvement usually demonstrated multiple mass lesions in the brain.

The total percentage of second malignant tumors in the patients studied was 6%. Four patients in the Group 1, two in Group 2, and three in Group 3 had at least one other malignancy (Table 1). No predominance of specific pathologic type of neoplasm was noted.

DISCUSSION

Several recent reviews have stressed the importance of infection in causing the demise of patients with cancer [6, 8]. However, these studies contained a heterogenous group of malignancies. Based upon these findings we have examined the immediate cause of death in one specific neoplasm and have noted that infection is not the major cause of death.

Approximately one-third of all patients with malignant melanoma die of CNS involvement independent of the modalities of treatment used. A previous report has emphasized that all patients with pathologic evidence of CNS involvement at autopsy died of CNS involvement [3]. This study did not confirm this finding as 73% of patients had pathologic proof of CNS metastases (Table 3), but slightly less than one-half that number died as a result. Since the last review of autopsy material from this Institution, however, the incidence of CNS involvement seems to have markedly increased. Patients in the current study had almost twice the frequency of involvement as did patients examined a decade ago at Memorial Hospital (Table 3). The reasons for this apparent increase are obscure, but may reflect more aggresive supportive care of other organ system involvement thus allowing a longer survival time to make neurologic disease evident. There is no change in the method of pathologic examination of the central nervous system since the last study to account for this finding.

Pulmonary insufficiency caused by metastatic disease in the lungs was the second most common cause of death in the total group of patients. This cause of death has not been previously stressed. Infection was the third most common cause of death. As pneumonia accounted for one-half of infectious causes of death, a pulmonary demise whether secondary to metastatic disease or infection was very frequent. Heightened awareness of possible infectious complications and early use of antibiotics may account for the lowered incidence of infections seen in this study compared to previous reports. In addition, we did not find the severe neutropenia seen in a previous study [8]. Whether this difference represents less aggresive cytotoxic therapy or heightened supportive care to maintain the patient over his leukopenic episode remains uncertain.

Effects of Ehrlich Ascites Tumor Transplantation in Mice on the Distribution of Cells Capable of Forming Hemopoietic Colonies *in vitro*

G. KEEB and P. K. LALA*

Department of Anatomy, McGill University,
3640 *University Street, Montreal, Canada*

Abstract—*The effects of intraperitoneal Ehrlich ascites tumor development in CBA/H-T_6 mice on the distribution of hemopoietic colony forming cells in the host bone marrow and spleen were studied using soft agar culture techniques. Cell suspensions of hemopoietic tissues obtained from mice at various days after i.p. transplantation of* 10^6 *tumor cells as well as from control mice were cultured for* 7 days *to grow granulocyte/macrophage colonies (CFU-C) in the presence of standard colony stimulating activity (CSA) provided by serum of endotoxin-treated mice and B lymphoid colonies in the presence of 2-mercaptoethanol. The CFU-C level in the femoral marrow of tumor-bearing mice declined rapidly both in concentration and absolute number to* 36 *and* 17% *of control values, respectively, between* 3–5 days, *followed by a gradual recovery to normal by* day 9. *In contrast, these values increased continuously in the spleen to* 27- *and* 75-*fold normal, respectively, by* 9 days. *B lymphoid colony-forming cells increased in concentration and absolute number in the spleen to* 5- *and* 10-*fold normal values, respectively, at* 7 days. *High levels of CSA, which promoted CFU-C development when added to normal marrow cells, were detected in the cell-free Ehrlich ascites serum. When either tumor cells or host-derived leukocytes fractionated from the tumor were used as feeder layers, major stimulation of CFU-C growth in normal marrow was seen with the former, and some minor stimulation with the latter. These* in vitro *studies, combined with our previous studies* in vivo *on spleen colony forming units (CFU-S), suggest that Ehrlich ascites tumor transplanted in mice stimulates a rapid redistribution of hemopoietic stem cells at various levels of differentiation from marrow to spleen, where they may undergo further growth; the stimulus is possibly mediated by factors liberated from the tumor.*

INTRODUCTION

A SERIES of investigations was undertaken in this laboratory to elucidate the overall response of the host lympho-myeloid system to heterotopic tumor transplantation in mice. These included an evaluation of the life history of host leukocytes migrating into the tumors [1, 2], an examination of the surface markers of lymphocytes accumulating in the tumors and host lymphoid organs [3, 4] and hemopoietic changes in the tumor bearing animals [5, 6]. The last named study revealed that intraperitoneal transplantation of Ehrlich ascites tumor (EAT) or TA-3(St) tumor in mice caused a rapid decline in the incidence as well as absolute number of pluripotent hemopoietic stem cells (spleen colony forming units, CFU-S) in the femoral marrow, associated with a rapid rise of these values in the spleen, and to a small extent in the blood. This suggested an accelerated CFU-S traffic from the host marrow to the spleen, where an active proliferation of this cell class was identified from ^{3}H-thymidine suicide experiments. However, one could not exclude the remote possibility that the observed changes in the spleen colony-forming potentials of the marrow and the spleen reflected a differential alteration in the homing properties of stem cells in these organs rather than a redistribution phenomenon. It was felt that *in vitro* colony assays could resolve this issue and in addition, reveal (1) whether tumor transplantation affected the distribution of "committed" stem cells, and (2) whether the tumors elaborated materials capable of stimula-

ting hemopoiesis. The study using soft agar cultures was therefore designed to examine (1) the effects of EAT transplantation on the organ distribution of cells capable of developing into granulocyte-macrophage colonies (CFU-C, considered as partially differentiated progeny of CFU-S) and (2) the possible elaboration of colony (CFU-C) stimulating activity (CSA) by the EAT. The presence of CSA was examined in the cell free Ehrlich ascites serum or blood serum of tumor bearing animals when added directly to cultures of normal bone marrow, as well as in the various cellular fractions of EAT when provided as feeder layers. Furthermore, since the spleens of these tumor bearing hosts showed an increased incidence of newly-formed, marrow-derived small lymphocytes [5, 6], the present study also evaluated in these spleens the incidence of cells capable of producing B lymphocyte colonies on agar in the presence of 2-mercaptoethanol [7]. These investigations revealed a major redistribution of CFU-C from the host marrow to the spleen—a finding which reinforced the conclusion of CFU-S redistribution, an elaboration of high levels of CSA by the tumor cells and an increase in the number of B lymphocyte colony forming cells within the host spleens.

MATERIAL AND METHODS

Tumor-host system

Ehrlich ascites tumor (EAT) used in the present study was maintained in inbred CBA/H-T_6 female mice (Jackson Laboratories, Bar Harbor, Maine) at 12–16 weeks of age by a weekly intraperitoneal transplantation of 10^6 tumor cells in 0.1 ml isotonic saline. This tumor was started as a subline 4 yr ago by transferring 10^6 tumor cells from our conventional EAT line maintained in CF_1 female mice into CBA/H-T_6 strain mice. The modal chromosome number of tumor cells is 68, and post-mitotic tumor cells contain a near tetraploid amount of DNA. Following an i.p. transplantation of 10^6 cells, tumor growth is exponential during the first 3 days, and a plateau population size of approximately 400 million tumor cells is attained by 7 days. The median survival time of tumor bearing animals is approximately 2 weeks.

Sampling of hemopoietic tissues for culture on soft agar

Groups of animals were killed by cervical dislocation, and the femora and spleens removed under aseptic conditions both from normal and tumor bearing hosts at various intervals after tumor transplantation. Femora were cleaned with gauze pads and the epiphyseal ends were carefully removed to expose medullary cavities which were then flushed out with bone marrow collecting fluid described by Metcalf and Moore [8] using a 23 gauge needle fitted to a sterile syringe. The extruded marrow was dispersed by gentle aspiration with a syringe through an 18 gauge needle. Spleens were minced in bone marrow collecting fluid with a pair of deWecker's iris scissors and gently aspirated with a sterile syringe through an 18 gauge needle. Marrow and splenic cell suspensions were freed of stroma and vessels by passage through a stainless steel sieve (80 mesh, 0.005 gauge) followed by 2 washes in bone marrow collecting fluid by centrifugation at 400 ***g*** for 10 min. The final pellets were resuspended, mixed well with a vortex mixer and the numbers of nucleated cells in the resulting single cell suspensions were determined using a particle counter (Coulter Electronics, Model B). Cells were kept on ice at 4°C until used for plating shortly after collection.

Soft agar culture

Aliquots of 1 ml 0.3% agar-medium containing the appropriate cell concentrations were pipetted into 35 mm plastic Petri dishes [8], allowed to gel at room temperature, and placed in a specially designed plexiglass incubating chamber. Colony stimulation was provided by a number of sources, to be described.

Incubation and scoring of cultures

Cultures were all incubated for 7 days in a humidified atmosphere of 10% CO_2 in air maintained at 37°C. Colonies (aggregates of 40 or more cells) and when feasible, clusters (small, 10–19 cells and large, 20–39 cells) were counted with a dissecting microscope (Zeiss) at 40 × magnification with indirect lighting. Squash preparations of agar cultures were prepared and stained with aceto-orcein for closer morphological examination. In addition, selected individual colonies from 2-mercaptoethanol stimulated cultures were transferred with fine-tipped Pasteur pipettes to microscope slides, air dried, methanol fixed and stained with Giemsa (pH 5.75).

Preparation of colony stimulating activity (CSA) sources for promoting CFU-C growth

(a) Post-endotoxin serum was prepared as a standard source of CSA [9] to evaluate changes in the number of CFU-C in bone marrow and spleen during tumor development. Adult female A/HeJ mice (Jackson Lab) were injected i.p. with 5 μg (in 0.1 ml vol) of *Salmonella typhosa* endotoxin (Difco) and after 2–4 hr their blood

was collected by cardiac puncture under light ether anesthesia and allowed to clot. Following centrifugation at 600 ***g*** for 20 min, the cell-free serum was treated by dialysis and centrifugation [10] to remove lipoproteins and dialyzable inhibitors of colony formation. The serum was then Millipore filtered (0.2 μm pore size) and stored in 1 ml aliquots at $-20°C$ until used.

(b) Cell-free Ehrlich ascites serum (from 7 day old tumors) and peripheral blood serum from mice bearing 7 day old tumors were collected and similarly treated prior to storage, as described for post-endotoxin serum. These sera were assayed for their CSA content as compared to that in the post-endotoxin serum on cultures of 10^5 nucleated marrow cells.

(c) Serum-free 7 day old ascites tumor and its various cellular fractions were tested as possible CSA-sources when provided as feeder layers. Ascites tumors were harvested without anticoagulant treatment and treated briefly with 0.83% ammonium chloride solution for lysis of erythrocytes [11]. This provided total nucleated cells which were washed and resuspended in bone marrow collecting fluid. To obtain leukocyte-rich or tumor cell-rich fractions from this nucleated cell population, modification of a sucrose density gradient technique [12] was employed. Briefly, suspensions of 60×10^6 nucleated cells/ml of Hanks' balanced salt solution (BSS) were layered in 1 ml vol onto 14 ml linear gradients of sucrose (5–15% in Hanks' BSS containing 20% fetal calf serum throughout). After gentle centrifugation (100 ***g*** for 10 min) the supernatants containing mostly leukocytes and pellets containing mostly tumor cells, were collected separately, washed twice in an excess of Hanks' BSS and then washed and resuspended in bone marrow collecting fluid.

Feeder layers containing 5×10^5 nucleated cells (from sources described above) in 1 ml 0.5% agar-medium were added to culture plates and allowed to gel prior to the addition of 1 ml 0.3% agar medium containing 10^5 nucleated marrow cells. After plating, smears were made from the remaining cell suspensions, stained with MacNeal's tetrachrome blood stain and differential counts were performed.

Determination of optimal concentration of post-endotoxin serum used as standard source of CSA

The following volumes of post-endotoxin serum were added to culture dishes prior to the addition of 1 ml aliquots of 0.3% agar medium containing a standard number of 10^5 nucleated marrow cells: 0.05 ml; 0.10 ml; 0.15 ml. Triplicates were made of each plate and colonies were scored after 7 days incubation. The increase in the number of colonies was nearly proportional to the concentration of post-endotoxin serum. Thus, 0.05 ml, 1.0 ml and 1.5 ml of this serum stimulated the production of 39.6 ± 1.5 (mean $\pm$ S.E.), 69.0 ± 2.6 and 100 ± 3.6 colonies, respectively. Since there was some colony confluence in the last case, 0.1 ml of post-endotoxin serum was selected as the optimal dose for providing CSA throughout this present study.

Determination of optimal cell numbers for plating in CFU-C studies

In pilot studies, a 0.1 ml vol of post-endotoxin serum was included in culture plates containing graded numbers of nucleated marrow and splenic cells. Triplicates were made of each plate and colonies were scored after 7 days incubation. As shown in Table 1, colony numbers increased in a linear fashion with increasing cell concentrations in culture. However, normal splenic cells produced poor colony numbers even at very high doses. In contrast, at comparably high doses of splenic cells from tumor bearing animals, colony-confluence led to scoring difficulties. To avoid this problem, optimal nucleated cell number for plating was considered as 2.5×10^5 for spleens and 10^5 for bone marrow.

Table 1. Colony (CFU-C) numbers (mean $\pm$ S.E.) produced by different doses of marrow and spleen cells in the presence of 0.1 ml *post-endotoxin serum*

Control bone marrow Nucleated cell dose ($\times 10^5$)	Spleen	
	Control mice	7 day EAT host
0.5	34 ± 3	—	—
1.0	69 ± 2.6	—	—
2.5	280 ± 25	2.0 ± 0.6	45 ± 5
5	—	4.5 ± 1	105 ± 4
10	—	10 ± 1.6	223 ± 9

2-mercaptoethanol stimulation of splenic cultures for B lymphocyte colony formation

Splenic cell suspensions from normal and tumor bearing mice were prepared and added to 0.3% agar medium, as described previously. One ml aliquots containing 10^6 splenic cells were pipetted into Petri dishes containing 2-mercaptoethanol at a final concentration of 5×10^{-5} M[7]. Cultures were scored for B lymphocyte colonies and clusters after 7 days of incubation.

RESULTS

Marrow and splenic CFU-C levels during tumor development

Bone marrow. Table 2 shows the number of colonies and clusters per 10^5 nucleated marrow cells at various intervals after tumor transplantation. Data on colonies are plotted in Fig. 1, expressed also as fractions of the incidence in the control marrow. The CFU-C concentration in marrow declined drastically after tumor transplantation, reaching levels 35–42% of control values between days 3 and 7, followed by a rapid recovery to control level by day 9. Since bone marrow cellularity also declined during the early intervals of tumor development (Table 3), the changes in the absolute number of CFU-C per femur were found to be more dramatic (Fig. 2). For example, this value declined rapidly from 5980 at 0 day to a minimal level of 1011 (approximately 17% of control) by day 3, followed by a gradual recovery to near normal level by day 9 (5,228 CFU-C, 87% of control).

Spleen. Colony and cluster numbers per 2.5×10^5 nucleated splenic cells are presented in Table 2. Following a short lag of 3 days, the CFU-C concentration in the spleen increased rapidly and by day 9 there was some 27 fold magnification compared to the control level (Fig. 3). These data became even more significant when the splenic enlargement after tumor transplantation (Table 3) was considered. The splenic CFU-C content (Fig. 4) appeared to increase without any lag; however, the rise was steepest between days 3 and 5, giving a doubling

Table 2. Mean (±S.E.) incidences of clusters (20–39 cells) and colonies (≧40 cells) in the femoral marrow (per 10^5 nucleated cells) and spleen (per 2.5×10^5 nucleated cells) at different days of tumor development, when cultured in the presence of post-endotoxin serum*

Day	Clusters		Colonies

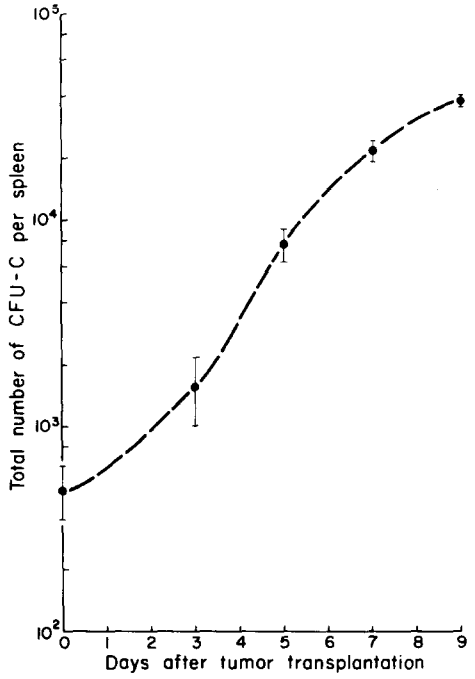

Fig. 4. Absolute number of CFU-C per spleen at different days of tumor development.

time of approximately 1 day during this interval. By day 9, the CFU-C number increased to approximately 75 fold of control values.

CFU-C morphology. Colonies were either compact or dispersed in appearance. Compact colonies were predominantly granulocytic in nature, often showing the whole range of maturation sequence starting from the center to the periphery (Fig. 5A). Dispersed colonies contained either granulocytes, or macrophages or a mixture of both cell classes. The presence of a tumor did not seem to influence the composition of colonies derived from any organ. However, cultures of spleens showed a preponderance of granulocytic colonies compared to the bone marrow cultures. For example, the average incidences ($\pm$S.E.) of colony types in normal splenic cell cultures were: granulocytic $83 \pm 8.3\%$, macrophage $8 \pm 2.5\%$ and mixed $9 \pm 2.8\%$; for normal bone marrow they were $45 \pm 7\%$, $37 \pm 6.1\%$, and $18 \pm 3\%$ respectively.

Evaluation of colony-stimulating activity (CSA) in sera from ascites tumors and peripheral blood of tumor bearing hosts

The CSA of various sera, in 0.1 ml vol, was assayed on 10^5 nucleated marrow cells and the results are presented in Fig. 6. Sera from the

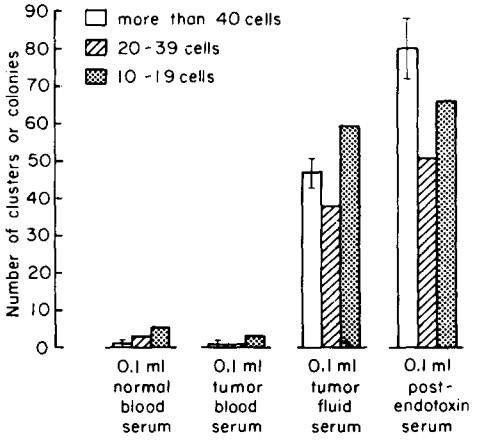

Fig. 6. Comparison of cluster or colony (CFU-C) numbers produced by 10^5 *normal bone marrow cells in the presence of various sera.*

peripheral blood of both normal and 7 day ascites tumor bearing mice exhibited no significant CSA, producing only 1.0 ± 0.6 and 0.3 ± 0.3 colonies. However, 7 day Ehrlich ascites exhibited significant CSA, producing 47 ± 3 colonies, compared to post endotoxin serum which stimulated the production of 80 ± 8 colonies. In addition, both these latter sera resulted in the production of many clusters. Since no activity was detectable in the blood sera of tumor-bearing animals, local production of CSA within the tumor was indicated.

Colony morphology was similar to that described in the previous section, with no significant differences observed in the colony types produced by stimulation with various sera.

Evaluation of various cellular fractions of Ehrlich ascites tumor as possible sources of CSA when used as feeder layers

The composition of various cellular fractions of the 7-day ascites tumors used in this assay is shown in Table 4. The degree of colony stimulation provided by these fractions to cultures of 10^5 nucleated marrow cells is indicated in Fig. 7. Feeder layers containing 5×10^5 cells of the leukocyte rich fraction

Table 4. Incidence (percent) of various cell types in the 7 day old ascites tumor and its various cellular fractions used in feeder layers as possible sources of CSA

	Tumor cells	Total leukocytes	Lymphocytes	Granulocytes	Monocytes and macrophages
Unfractionated tumor	88.8	11.2	4.3	2.8	4.1
Tumor cell-rich fraction	95.5	4.5	0.6	1.7	2.2
Leukocyte-rich fraction	4.2	95.8	31.4	18.3	46.1

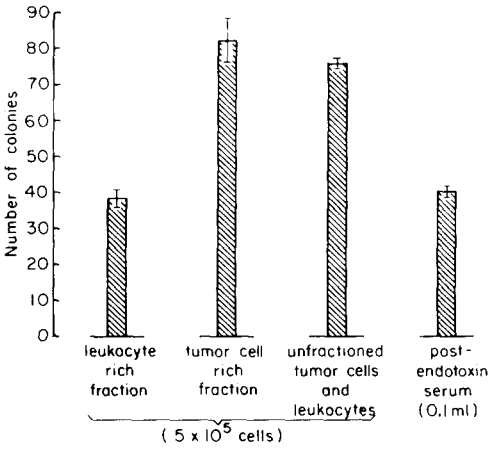

Fig. 7. Comparison of colony (CFU-C) numbers produced by 10^5 normal bone marrow cells grown in the presence of feeder layers containing various cellular fractions of 7 day old EAT.

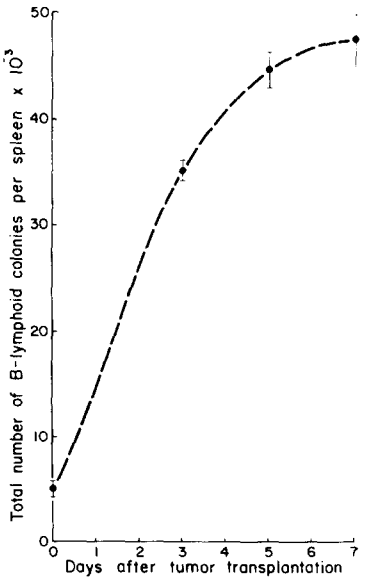

Fig. 8. Absolute number of B lymphocyte colonies per spleen at different days of tumor development.

stimulated the production of 39 ± 2 colonies, comparable to the 40 ± 1 colonies produced by 0.1 ml of post endotoxin serum within the same experiment. The tumor cell-rich fraction as well as the unfractionated tumor cells with their associated leukocytes provided a higher stimulation, producing 82 ± 6 and 75 ± 1 colonies, respectively. The difference between the latter two cases was not statistically significant at the 0.05 level.

Colony morphology. Colonies produced by stimulation with all three types of feeder layers were predominantly granulocytic in morphology, whether compact or diffuse in form, outnumbering macrophage colonies approximately 8–1. Mitoses were frequently seen in these colonies. Furthermore, in cultures stimulated by cells of the unfractionated tumor (11.2% leukocytes) or the tumor cell-rich fraction (4.5% leukocytes), a small percentage of the granulocytic colonies (approximately 10%) appeared more immature than those usually seen throughout this study after 7 days of incubation (Fig. 5B). Most of the cells in these colonies contained nuclei that were round or oval, and only the most peripheral cells showed certain degrees of nuclear lobulation characteristic of more mature forms. This colony type was not seen in cultures stimulated either by feeder layers of the leukocyte-rich fraction or by post-endotoxin serum.

Cells within the feeder layers themselves at 7 days of culture consisted of viable as well as dying cells, but no evidence of active proliferation was observed amongst these cells at this interval.

Changes in B lymphocyte colony forming potential of spleens during tumor growth

Table 5 shows the numbers of clusters and colonies produced by 10^6 nucleated splenic cells from mice at various intervals after tumor transplantation, using 2-mercaptoethanol stimulation of cultures. Colony incidence sharply increased to approximately 5 fold of control level by day 3, with no further significant change up to 7 days. When translated into absolute number of colony forming cells in the spleen (Fig. 8), the increase was 7 fold by day 3, followed by some further rise to a near plateau of approximately 10 fold normal level by 7 days.

Table 5. Number (mean of 4 replicate cultures ± S.E.) of lymphoid clusters (3–39 cells) and colonies (≧40 cells) produced in the presence of 2-mercaptoethanol by 10^6 splenic cells at various days of tumor growth

Days	Clusters	Colonies
0	565.3±24.7	81.5±12.4
3	203.5±41.2	392.0±10.7
5	239.8± 5.5	359.5±15.4
7	383.8±34.0	373.5±20.2

Colony morphology. Normal splenic cells formed colonies which were generally dispersed in nature and the cellular background was extremely dense. These cultures also contained a very large number of clusters. In contrast, spleens from mice either 3, 5 or 7 days after tumor transplantation produced large numbers of compact colonies (illustrated in Figs. 5C and D, ranging in size from 40 to several hundred cells. All colonies and clusters were composed of a wide variety of lymphoid cells: small, medium and large lymphocytes, blast cells and immature plasma cells. In addition to lymphoid colonies, mercaptoethanol stimulated cultures also showed small but significant numbers of megakaryocytic colonies. They were composed of 2–6 giant cells with multiple or multilobulated nuclei and abundant cytoplasm showing smooth rounded projections. Their incidences were not high enough for a statistical evaluation of possible differences between the normal and tumor-bearing mice.

DISCUSSION

Intraperitoneal transplantation of Ehrlich ascites tumor in CBA/H-T_6 was found to produce differential effects on the incidence of CFU-C in the host bone marrow and spleen, in a manner qualitatively similar to that recorded for CFU-S using the same tumor-host combination [6]. This similarity suggests that our previous findings on CFU-S reflected actual changes in the organ distribution of stem cells rather than a differential alteration of their homing properties detected by the assay system. Although blood CFU-C levels were not determined in the present study, the inverse relationship between the early changes in CFU-C numbers in the marrow and the spleen can be best explained, at least in part, by a redistribution phenomenon, as noted with CFU-S in the present [6] as well as other [13] tumor-host combinations.

In addition to CFU-C migration, a local production of CFU-C within the spleen by the process of multiplication and differentiation of CFU-S can best explain the pronounced and continued elevation of splenic CFU-C content at later intervals of tumor growth. For example, while the quantitative changes in the CFU-S and CFU-C contents were identical for marrow at all intervals, splenic CFU-C content continued to rise markedly (viz. to 75 fold at 9 days) even after the splenic CFU-S content reached a near plateau level (of 8–10 fold normal between 4–9 days). This suggestion is consistent with our earlier observations [6] of high proliferative activity in the splenic CFU-S, as evidenced by high ^{3}H-thymidine suicide rate, at 4–5 days of tumor growth when the near maximal CFU-S number had already been attained in the spleen. Thus, this proliferation appears to be a step in differentiation rather than self-amplification. Whether the stimulus for such proliferation is contained in the family of molecules identified as CSA, remains a matter of conjecture.

A significant level of CSA in the ascites serum appeared to result from local rather than systemic elaboration, since peripheral blood serum of the same tumor bearing hosts did not exhibit any detectable increase in CSA level. Results of the feeder layer experiments showed that tumor cells themselves represented a major cellular source of CSA and the leukocytes (possibly monocytes and macrophages) within the ascites tumor also elaborated CSA. The observed differences in the degree of stimulation provided by these two cellular constituents of the tumor could either reflect real differences in their CSA outputs or the effects of the presence of a higher proportion of colony inhibiting cells [14], viz. mature granulocytes in the leukocyte-rich fraction (Table 4). Observation of a significant proportion of immature granulocytic colonies growing on tumor cell feeder layers, but not in the presence of other CSA sources, may indicate that CSA released by the tumor cells is either deficient in some maturation factors or contaminated by factors that can cause "maturation-arrest". We favour the former possibility since similar colonies were not observed in the presence of Ehrlich ascites serum. This colony type is also found in the presence of supernatants from Ehrlich ascites tumor cell cultures (Eridani, personal communication). The absence of detectable CSA in the peripheral blood of the present tumor-bearing mice does not necessarily exclude possible *in vivo* effects of CSA elaborated by the tumor, since this may be rapidly utilized from the circulation. Relationship of CSA production *in vitro* to granulocytopoietic effects *in vivo* has been observed for some tumors [15].

A number of studies have reported changes in the CFU-S [13, 16–19] or CFU-C [20] contents

of mouse hemopoietic organs in other tumor-host combinations. Bone marrow generally showed a variable depletion [13, 16, 18] which may represent an acute effect of rapidly growing tumors. Possible reasons for this depletion are migration, death or growth inhibition. Although there is definite evidence for an enhanced migration [6, 13] other possibilities cannot be excluded completely. The marrow, in most cases, appears to show a quick recovery. In some cases with longstanding tumors, femoral stem cell content may show an actual rise, as reported for CFU-S in mice bearing transplanted fibrosarcoma [19] and spontaneous mammary tumors [6], or for CFU-C in mice bearing transplanted mammary tumors [20]. An increase in the splenic stem cell content appears to be an universal phenomenon for all tumor-host systems, applicable both to CFU-S [6, 13, 17] and CFU-C [20]. Although no work has been done on the erythropoietic progenitor cells (CFU-E) in tumor-bearing hosts, striking similarity of effects on the CFU-S and CFU-C in the present tumor-host system may suggest a common effect on all stem cells at various levels of differentiation. The significance of an elevation in the number of various stem cell classes within the spleen of tumor-bearing host is a matter of conjecture. This may fulfil the increased needs of a variety of functional cells: for example, there is an increase in the number of (i) newly-formed lymphocytes within the tumor site [1, 2] and the spleen [6], (ii) newly-formed monocyte-macrophage class of cells within the tumor [1, 2], (iii) granulocytes within the blood and the tumor at later intervals [6], (iv) erythroid and monocyte-macrophage class of cells in the spleen at later intervals of tumor growth [6]. However, the very early increase in the splenic stem cell numbers, which precedes all these phenomena, cannot be regarded as a kinetic consequence of an increased demand for functional cells. Similarly, this event is too early to be explained as effects of possible bacterial endotoxins released from the gut of tumor-bearing hosts. It appears to be a direct effect of tumor development, possibly mediated by antigenic and/or other products of tumor cells. We found that inoculation of tumor cell plasma membranes can produce a rapid increase in the splenic CFU-S content [6]. Various other antigenic materials including bacteria [21] or viruses [22–27] are known to produce similar effects on the distribution of hemopoietic stem cells, although their temporal patterns are somewhat different with different agents.

Tumor transplantation was found to cause a rapid increase in the incidence as well as the total number of splenic lymphocytes capable of producing B lymphocyte colonies in the presence of 2-mercaptoethanol. Macrophages, known to stimulate B lymphocyte colony formation [28] did not show an increase in their numbers within the spleen during the first 5 days of present tumor growth [6] and thus could not account for the above findings. Although the plating efficiency of our assay system was poorer compared to that reported by Metcalf *et al.* [7], present observations on the B lymphocyte colonies are significant in the light of our previous findings on the life history [5, 6] and surface markers [4] of splenic small lymphocytes in the same tumor-bearing hosts. Tumor transplantation caused an increase in the incidence of newly-formed, marrow-derived small lymphocytes within the spleen [5, 6] but no significant changes in the incidence of IgM-bearing B cells recognizable radio-autographically by their binding of ^{125}I-labeled anti-IgM [4]. On the other hand, there was a marked increase in the incidence of "double negative" small lymphocytes which had no detectable surface IgM or *0* antigen [4]; their incidence reached a maximum at 3 days after tumor transplantation followed by a plateau. This temporal pattern was very similar to that shown by the B lymphocyte colony forming cells in the present study. These sets of findings may be reconciled in 2 ways: (i) IgM-bearing B cells in the spleen of tumor transplanted animals had a higher colony forming ability because of a prior *in vivo* stimulation by some products released by the tumor, or (ii) the "double negative" small lymphocytes possessed the potentials to develop into B lymphocytes *in vitro*. Observations of B lymphocyte colony stimulating ability in sera from patients bearing some malignancies [29] may support the first possibility. On the other hand, B lymphocyte colony forming cells may represent a heterogeneous population and the relationship between the degree of differentiation and colony forming ability is unknown [28]. Furthermore, some "double negative" small lymphocytes in the normal mouse bone marrow [30] or human peripheral blood [31] are known to be capable of maturation into IgM-bearing B cells. Such a possibility is very likely also for some of the splenic "double negative" small lymphocytes in the present study. Experiments are in progress to test B lymphocyte colony forming abilities of various lymphocyte subpopulations fractionated from the spleen of tumor transplanted animals. Preliminary results have revealed high B lymphocyte colony forming ability of the "double negative" fraction (Lala and Jacobs, unpublished observations).

In conclusion, present studies combined with

our previous *in vivo* studies [6] on tumor transplanted mice demonstrate a rapid redistribution of pluripotent stem cells, stem cells committed to granulocyte/macrophage development, as well as lymphoid cells capable of producing B cell colonies *in vitro*, possibly initiated by an enhanced migration from the bone marrow to the spleen, where further amplification and differentiation of these cells take place. The precise significance of these responses, although seemingly immunological in nature, remains to be determined.

Growth and Metastasis of the Lewis Lung Carcinoma in Mice Defibrinated with Batroxobin*

M. B. DONATI, L. MUSSONI, A. POGGI, G. DE GAETANO and S. GARATTINI

Laboratory for Haemostasis and Thrombosis Research, Mario Negri Institute for Pharmacological Research, Via Eritrea, 62—20157 Milan, Italy

Abstract—*Lewis lung carcinoma (3LL) cells were implanted intramuscularly into $C_{57}B16J$ mice, rendered hypofibrinogenemic by daily intraperitoneal treatment with batroxobin (17.5 NIH u/kg body wt, twice per day). When this treatment was continued till spontaneous death of the animals, an increase in both metastasis number and weight was observed, but the primary tumor growth was unchanged. In contrast, both metastasis number and weight tended to decrease when defibrination was started from* day 11 *after tumor implantation, independently from surgical removal of the primary tumor.*

These data suggest that fibrinogen and/or its derivatives could play a different role in the various stages of the growth and dissemination of the same experimental tumor.

INTRODUCTION

IN ORDER to gather information on the possible role of fibrin in the processes of tumor growth and metastasis formation, we have previously studied the changes in hemostatic parameters occurring during development of a spontaneously metastasizing tumor, the Lewis lung carcinoma (3LL) [1]. Tumor-bearing animals were found to have higher blood fibrinogen levels, with a reduced plasma half-life of this protein and accumulation of radioactive fibrinogen both in the tumor and in the metastasis-bearing lungs. It was therefore felt of interest to study the growth and metastasis of this tumor in animals maintained on a very low level of circulating fibrinogen by intermittent treatment with batroxobin, a thrombin-like enzyme extracted from the venom of Botrops Moojeni, which converts fibrinogen to fibrin without activating platelets or other clotting factors [2, 3].

*This paper is the second of a series on Cancer and Haemostasis. This work was supported by Grants NIH PHRB-1R01 CA L2764-01 and CNR (Italian Research Council) 73.00400.04. Part of this work was presented at the Symposium on Thrombin-like enzymes, Trier, 15–17 July, 1975 and at the IV Meeting of the Metastasis Club of EORTC, Rÿswÿk, 27 March, 1976.

MATERIAL AND METHODS

Animals and tumor

The 3LL tumor was maintained and transplanted intramuscularly in $C_{57}B16$ mice as previously described [1, 4]. In some experiments, the tumor-bearing leg was amputated at day 11 after tumor implantation and the development of pulmonary metastases followed as in non-amputated animals. Metastasis number was evaluated visually by surface count; metastasis weight was estimated by the formula $4/3\ \pi\ r^3$ where r is the semiaxis of each nodule measured on a millimetric scale; the volume was then converted to weight assuming unit density.

Tumor and metastasis growth were measured at spontaneous death of the animals in some experiments; in other experiments, randomly allocated pairs of one control and one batroxobin-treated animal were followed and when either component of the pair died, the counterpart was also killed. These experimental conditions were chosen in order to rule out any differences in the mean survival time between the treated and control group which could interfere in the evaluation of the tumor and metastasis growth.

To study the growth curve of tumor and metastases in control and defibrinated animals,

groups of mice were killed at various intervals starting from day 14. A total of 300 mice was used for this study.

Blood studies

Blood fibrinogen, blood platelet and red cell counts were determined as previously described [1]. Blood was collected from non-anesthetized animals from the retroorbital plexus by means of Pedersen micropipettes and appropriately diluted for the various tests immediately thereafter.

Drugs

Batroxobin (Defibrase®) was kindly supplied by Pentapharm (Basel, Switzerland). Various drug dosages were preliminarly tested to achieve optimal defibrination of the mice. As indicated in Fig. 1, following an i.p. administration of 17.5 NIH units batroxobin per kg body wt,

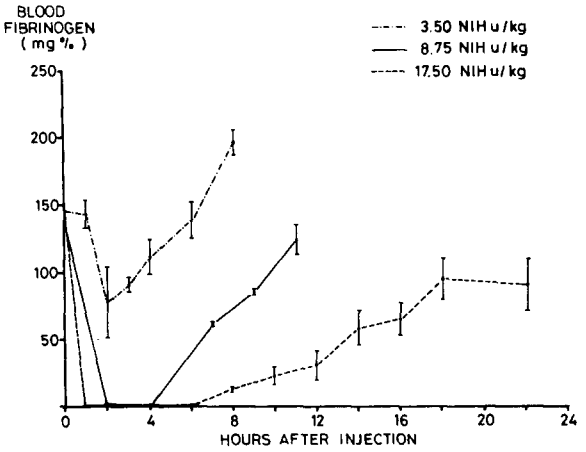

Fig. 1. Blood fibrinogen levels following a single i.p. injection of various dosages of batroxobin into normal mice. For each point, means ± S. E. of values obtained from 5 animals are indicated. The fibrinogen values lower than 8 mg% (sensitivity of the method used) have been arbitrarily reported on the abscissa at zero level. Fibrinogen levels in blood from control animals ranged between 158 and 230 mg%.

the fibrinogen level was lower than 40 mg% during 12 hr; a 12-hr intermittent administration schedule was therefore employed to maintain adequate hypo-fibrinogenemia throughout the experimental period (approximately one month). Batroxobin treatment was started 2 hr before either tumor implantation or amputation (at day 11) and continued till the animals died or were killed. During each experiment, groups of 5–10 animals were used for monitoring the level of defibrination achieved. At 2–3 day intervals, the fibrinogen level was measured immediately before the second daily administration of batroxobin; in 78% of the samples tested, the fibrinogen level was lower than 40 mg%. When the results obtained during the first 15 days of treatment were compared with those obtained in the second half of the observation period, the frequency of fibrinogen values lower than 40 mg% was not significantly different ($\chi^2 = 0.142$). This suggests that tachyphylaxis did not occur.

Control groups consisted of 3LL-bearing mice treated twice daily with i.p. injections of isotonic saline.

Statistical evaluation of the results was performed using Student's t-test or the χ^2 test.

RESULTS

In 3LL-bearing animals defibrinated since the day of tumor implantation, platelet and red cell counts dropped progressively as in control tumor-bearing mice (Fig. 2). The primary tumor weight was not modified by the treatment, whereas both the number and the weight of the pulmonary metastases were increased (Table 1 and Fig. 3).

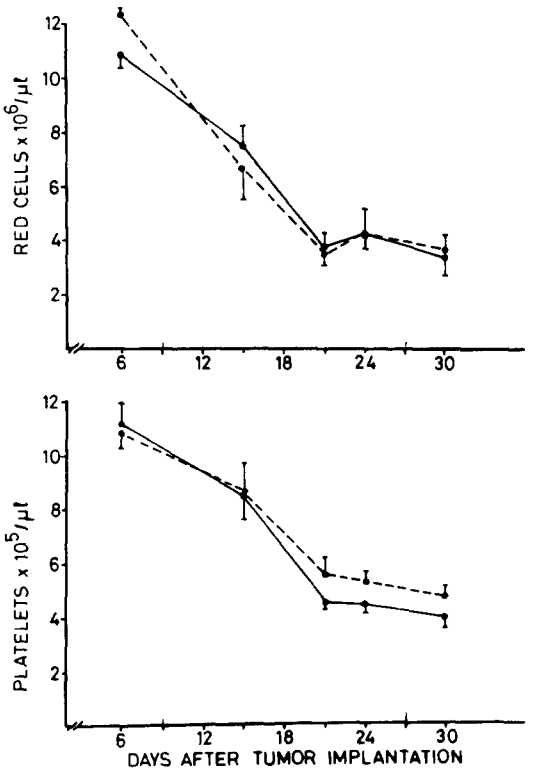

Fig. 2. Evolution of platelet and red cell count in control and batroxobin-treated (broken line) mice during development of the 3LL tumor. For each point, means and S. E. of the values obtained from 5 animals are indicated.

When treatment with batroxobin was associated with surgical removal of the primary tumor, the incidence of local tumor regrowth was significantly reduced ($P < 0.05$); moreover, in batroxobin-treated animals with recurrence of the primary tumor, this was slightly smaller than in control animals (Table 2). The weight and the number of lung metastases developing

in amputated mice with no recurrence of the primary tumor, were also slightly lower in batroxobin-treated animals (Table 3). Similar results were obtained when the mice were defibrinated starting from day 11, without removal of the primary tumor (Table 4).

DISCUSSION

Enhancement in fibrinogen metabolism was observed during the growth and spontaneous metastasis of the 3LL tumor [1]. To further investigate the possible pathogenetic role of fibrin(ogen) in the development of tumor and metastases in this experimental system, we followed 3LL growth in mice rendered hypofibrinogenemic by adminstration of batroxobin, a thrombin-like enzyme. In these conditions, 3LL-bearing mice developed thrombocytopenia and anemia similarly to untreated animals. This suggests that the drop in platelet count already observed in 3LL animals [4] is unlikely to be due to trapping of platelets within intravascular clots and further supports the hypothesis that a defect in platelet production is involved in its pathogenesis [1]. Similarly, the role of intravascular fibrin deposition in the pathogenesis of the hemolytic anemia observed in 3LL mice [1] could be questioned by this observation.

Neither the growth curve nor the weight at death of the primary tumor was modified in defibrinated mice. Similar negative results have been recently reported by De Wÿs *et al.* [5] in 3LL-bearing mice defibrinated by another thrombin-like enzyme, ancrod. However, the lack of effect of thrombin-like enzymes on the primary tumor does not rule out the possibility that fibrin may play some role in this experimental system, especially in relation

to the mechanism of metastasis formation. Indeed, the oral anticoagulant warfarin has a more marked inhibitory effect on metastasis formation than on primary 3LL-tumor growth [6, 7]. For this reason, we checked carefully for any possible effect of batroxobin on metastases.

Metastasis formation was enhanced when the mice were defibrinated during the whole tumor development period, whereas it appeared to decrease in mice defibrinated from the time of removal of the primary tumor. To assess whether this opposite trend could be related to the presence or absence of the primary tumor or to the different periods of defibrination, a group of mice was given batroxobin from day 11, but the primary tumor was not removed; in these animals too a tendency to decreased metastasis formation was noted. These observations suggest that fibrin(ogen) might play different roles in the various phases of metastatic spreading of the same tumor. Fibrin might possibly slow the release of cells from the primary mass but favor, as a guideline, their arrest and growth in the lungs.

These results on metastasis formation in batroxobin-treated mice are not easily comparable with data so far available in the literature [8–10].

In previous studies the effects of defibrinating enzymes have been followed applying short-term treatments to artificial "metastasis" systems. Tumor-cells were injected *intravenously* in animals defibrinated at most for 48 hr [8] and the development of either lung or extrapulmonary colonies (rather than metastases) was followed. The possibility of drawing conclusions from these systems on the role of fibrin in metastatic growth therefore seems questionable [1, 6].

Moreover, the studies mentioned were performed on different animal species (mouse, rabbit, rat); differences among the various species in sensitivity to defibrinating enzymes might explain some of the discrepancies between the results obtained with ancrod by Wood and Hilgard [9] in the rabbit and Hagmar [8] in mice. As a more general remark, it is also worth considering that removal of fibrin from the circulation by means of defibrinating enzymes may not necessarily result in altered deposition and/or clearing of fibrin from the tumor or from the metastatic foci; studies on the accumulation of fibrin within the tumor and metastases of batroxobin-treated animals could further elucidate the mechanism of tumor-cell fibrin interaction in the various phases of metastatic development.

Acknowledgements—We thank Nadia Polentarutti and Elisabetta Ballabio for their helpful assistance in performing some experiments reported in this paper. Judith Baggot, Anna Mancini and Vincenzo De Ceglie helped us in preparing the manuscript.

Batroxobin (Defibrase®) was kindly provided by Pentapharm Ltd., Basle, Switzerland, through the courtesy of Dr. K. Stocker. Thanks are also due to Roche, Milan for providing thrombin (Topostasine®).

Effects of 3′-Deoxy-3′-fluorothymidine on Proliferation Kinetics of Ehrlich Ascites Tumour Cells *In Vitro* (Comparison with Other Cytostatic Drugs)

P. LANGEN,* H. GRAETZ,* M. V. JANTA-LIPINSKI* and H. WEISS†

**Central Institute for Molecular Biology and †Central Institute for Cancer Research of the Academy of Sciences of the German Democratic Republic, Berlin, German Democratic Republic*

Abstract—*Treatment of Ehrlich ascites carcinoma cells* in vitro *with cytosine-arabinoside, 5-fluoro-2′-deoxyuridine and hydroxyurea in concentrations just completely inhibiting cell proliferation, results, in agreement with data published for other cells, in progressive loss of viability if the treatment exceeds a period of one generation time (about* 14 hr). *Pulse cytophotometric analysis of the treated cells showed them to be located mainly in the G_1-phase of the cell cycle. In contrast, cell proliferation can be inhibited for about* 32 hr *(more than 2 generation times), without loss of viability, if the treatment is done with 3′-deoxy-3′-fluorothymidine (3′-FTdR). Pulse cytophotometric analysis revealed a concentration-dependent delay of progression through the S-phase. At a concentration just completely inhibiting cell proliferation, discontinuation of proliferation was predominant in late S-phase at the G_2-boundary. These properties recommend 3′-FTdR for experiments aimed at improving cancer chemotherapy by a non-toxic accumulation of cells in the S-phase followed by treatment with a second, S-phase specific agent.*

INTRODUCTION

3′-Deoxy-3′-fluorothymidine (3′-FTdR; Fig. 1) is a selective inhibitor of DNA synthesis [1] with cytostatic [2] and virostatic [3] properties. It is

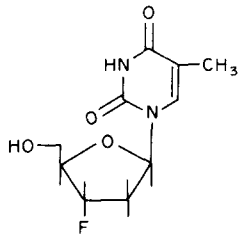

Fig. 1. Structure of 3′-FTdR.

fairly well phosphorylated by thymidine kinase; the resulting 5′-monophosphate is, though poorly, further phosphorylated to the 5′-triphosphate and, finally, incorporated into DNA [4]. Incorporation of 3′-FTdR into DNA will inevitably stop further chain growth, because there is no free 3′-hydorxyl group for the attachment of additional nucleotides.

In the following investigation we show that it is possible with 3′-FTdR to stop proliferation for more than two generations without killing the cells. Moreover, various aspects of inhibition by 3′-FTdR are analysed by pulse cytophotometry (PC).

MATERIAL AND METHODS

3′-FTdR was prepared by the method introduced by Kowollik *et al.* [5]; cytosine-arabinoside (CA), 5-fluoro-2′-deoxyuridine (FUdR) and hydroxyurea (HU) were of commercial origin. Ehrlich ascites tumour (EAT) cells obtained from AB mice about 5 days after transplantation were cultured in suspension as described by Negelein *et al.* [6], except that the sample volume was only 3 ml. The generation time of exponentially growing cells is about 14 hr. Due to a lag phase after transferring the cells to *in vitro* conditions there is only a 2–2.5-fold increase in the cell number during the first

Accepted 22 September 1977.

24 hr. However, results comparable to those described below were obtained with cells which were allowed to proliferate for 16 hr before use. In order to study all effects at comparable concentrations of the inhibitors, we generally used concentrations inhibiting cell proliferation between 80 and 100%. This means that the number of cells in the inhibited samples remained constant or even increased slightly. Such an increase is to be expected, since at the beginning of cultivation about 20% of the cells are always in the G_2-phase and are refractory to inhibition. Though it cannot be excluded that the balance in the cell number is a result of some cell deaths on one hand and some cell divisions on the other hand, we certainly have no major uncontrolled cell losses. The viability of the cells after treatment was determined from their ability to resume growth after removal of the inhibitors and further incubation (usually for 24 hr). During this incubation the medium contained compounds known to counteract the effects of the respective inhibitors (i.e. 2'-deoxycytidine for CA, thymidine for FUdR and a mixture of all four 2'-deoxyribonucleosides for HU; concentration of each nucleoside = 10 μM). Cells which divided during this time were considered to be viable (the surviving fraction). Though this method may not be as sensitive as the usual method of colony counting, its results seem to be comparable (at least for the purpose described in this paper) for the following reasons: (1) the loss of viability determined by this method for the treatment by CA, FUdR and HU is in agreement with published data [7–10] and (2) in all the cases where it was checked, prolonging the incubation for recovery did not alter the degree of recovery.

Cells were counted by an automatic counter TuR ZG2 from then "VEB Transformatoren- und Röntgenwerk Dresden". For PC analysis, cells were fixed in alcohol, treated with RNase and stained with ethidium bromide as described in [11].

For the quantitative evaluation of the histogramms the method of Barlogie *et al.* [12] was used.

RESULTS

1. *Effects on cell proliferation*

Figure 2 shows the effect of the cancerostatic agents investigated on cell proliferation during 24 hr. 3'-FTdR is less effective than CA but more so than HU. On the basis of these results the following concentrations were applied to obtain an 80–100% inhibition of cell proliferation (see Material and Methods): FUdR = 0.002 μM, CA = 1 μM, 3'-FTdR = 10 μM, HU = 200 μM.

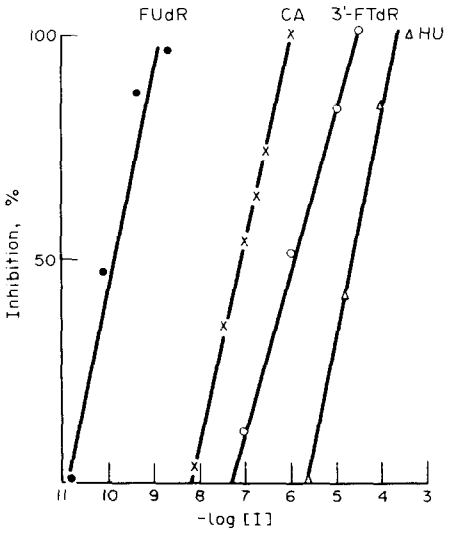

Fig. 2. Inhibition of cell proliferation as dependent on drug concentration. Concentrations are given at the abscissa in negative logarithms of molarity.

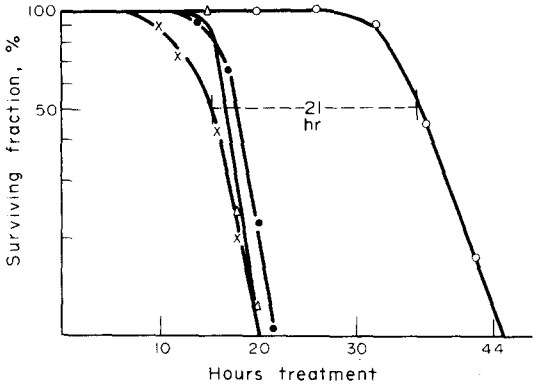

Fig. 3. Effect of drug concentrations inhibiting cell proliferation by 80–100% on cell survival as dependent on treatment time. ×——× 1 μM CA, ●——● 0.002 μM FUdR, △——△ 200 μM HU, ○——○ 10 μM 3'-FTdR.

Figure 3 demonstrates to what extent cells exposed to these inhibitory concentrations for various times recover after removal of the compounds. After treatment for about one generation with CA, FUdR and HU, a strong decrease of the surviving fraction was found. This is in agreement with data published in the literature. Therefore, despite the possible limitations for drawing conclusions from an outgrow assay under the described conditions, we consider the decrease of the growth potential to reflect the cell killing. In contrast, cells can be exposed to 3'-FTdR for a significantly longer period without affecting their growth potential. At higher concentrations, all inhibitors kill the cells more rapidly. With 3'-FTdR, concentrations 5 or 25-fold the dose mentioned above kills about 33 or 81% of the cells within 24 hr,

while in such concentrations the other inhibitors already cause a strong decrease in the cell number (cell loss by lysis). Thus, these results again demonstrate the lower cell killing potential of 3'-FTdR. Lowering the CA, FUdR or HU concentrations resulted in a decrease of both cell killing and inhibition of cell proliferation. It was impossible to find concentrations of these compounds which would inhibit cell proliferation without killing the cells. Approximately 9 hr after the removal of 3'-FTdR there is a burst of mitotic activity, indicating an apparent synchronization, which is lost after one cell division (Fig. 4). However, PC analysis (see below) shows that this is not a "true" synchronous passage through one round of replication, but only a progression from the late S-G_2-phase through mitosis. Thus, there is a rather long phase between removal of the drug and the burst of mitosis (see Discussion).

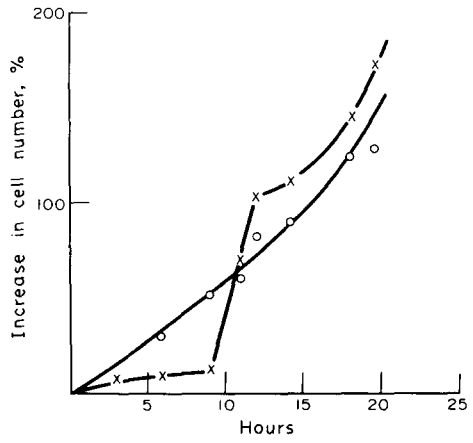

Fig. 4. Time course of cell division after release of a 24 hr *period of 3'-FTdR-inhibition.* O——O *controls,* ×——× *treated cells.*

2. *Effects on progression through the cell cycle*

Figure 5 demonstrates PC analysis of normal cells as well as of cells treated with CA, FUdR, HU or 3'-FTdR in concentrations inhibiting cell proliferation by 80–100%. The controls show the normal distribution of growing cell populations. Usually, with cells of this age we found about 30% cells in G_1, 50% in the S-phase and 20% in the G_2-phase or mitosis. Cells no longer viable after treatment with the killing agents FUdR, CA and HU are found predominantly in the G_1-phase, since there is a strong depletion of S-phase and G_2-phase cells. This is in agreement with recent data on *in vivo* treatment with CA of mice suffering from leukemia L1210 [13].

Quite in contrast, most cells treated with 3'-FTdR (and therefore still viable) are stopped in the late S-phase near the S/G_2-boundary (according to labelling indices, e.g. 84%; they are still mainly in the S-phase, which is also indicated by the PC distribution curves in Fig. 7).

Figure 6 compares the time course of progression through the cell cycle of control and 3'-FTdR treated cells over a period of 24 hr. It follows that progression through the S-phase is strongly delayed by 3'-FTdR (compare the 16 hr

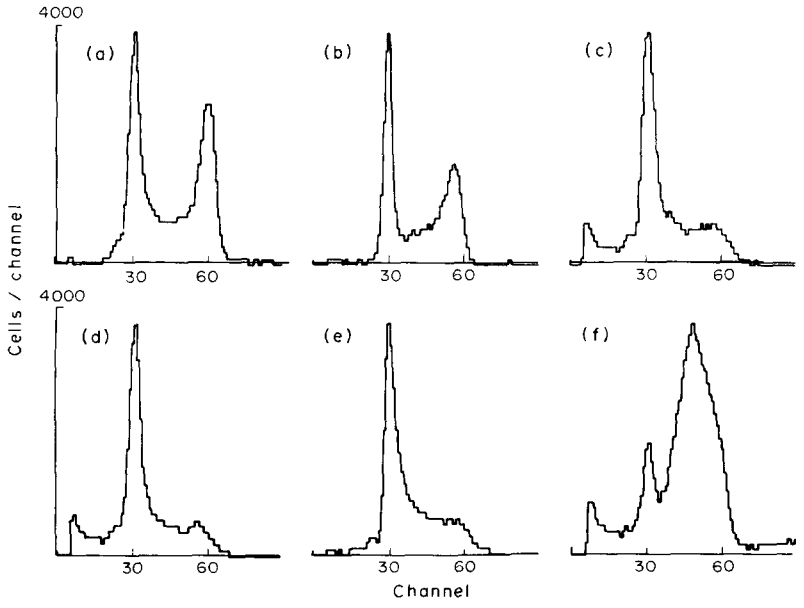

Fig. 5. PC analysis of cells treated for 24 hr *with the same concentrations as in Fig.* 3 *of (C) CA, (D) FUdR, (E) HU and (F) 3'-FTdR. (A) Controls at the beginning of cultivation, (B) controls after* 24 hr *in culture* (132% *increase in cell number).* % *Inhibition: CA* = 95, *HU* = 93, *FUdR* = 97, *3'-FTdR* = 91. *In this and the following figures some of the 3'-FTdR treated samples exhibit a minor peak in front of the* G_1*-peak. This peak consists of cell debris. However, such debris were not always seen and their amount is not correlated to the 3'-FTdR concentration.*

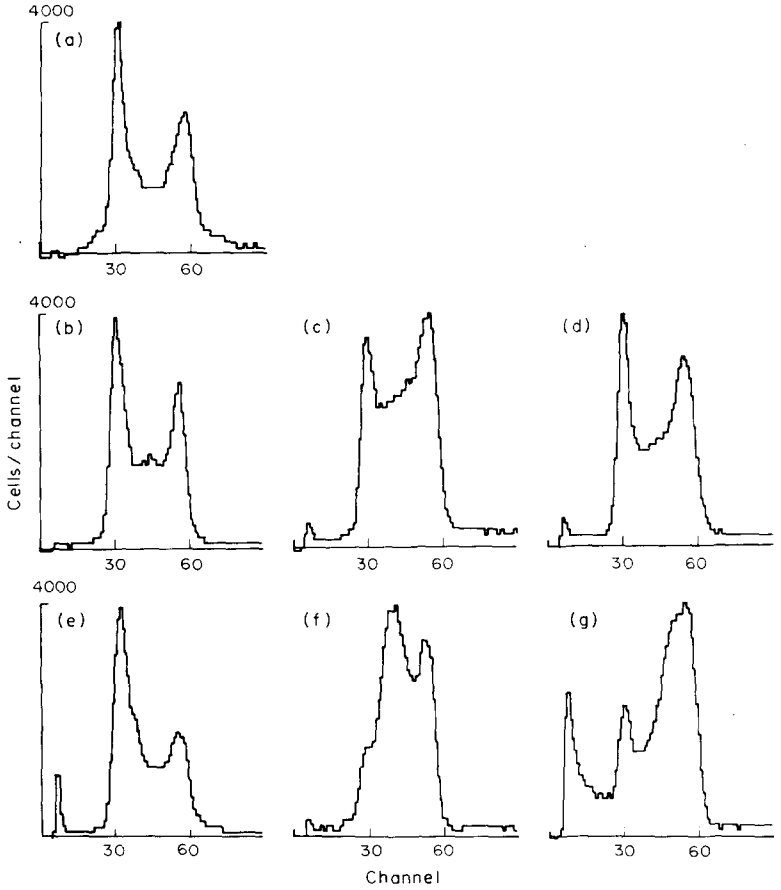

Fig. 6. Effect of 3′-FTdR (same concentration as in Fig. 3) on the progression of cells through the cell cycle over 24 hr. *A, B, C, D = controls at* 0, 8, 16 *and* 24 hr; *E, F, G = treated cells at* 8, 16 *and* 24 hr, 83% *inhibition after* 24 hr *of treatment.*

samples). The same is observed from Fig. 7 showing PC analysis of cells treated with various concentrations of 3′-FTdR (lower or higher than the 80–100% inhibitory concentration). Here with growing concentrations an increasing delay of cell progression through the S-phase is observed, the main cell peak being shifted from the late S-phase at lower concentrations to mid- or early S-phase at higher concentrations.

DISCUSSION

The presented data show that (a) cell killing with 3′-FTdR occurs at a much later time than with the other drugs studied and (b) that 3′-FTdR stops cell proliferation in the (late) S-phase (rather than in the G_1-phase as the other agents). To explain these differences, the respective modes of action have to be considered: FUdR and HU inhibit DNA synthesis by precursor starvation, CA inhibits (as its 5′-triphosphate) DNA polymerases and is incorporated into DNA (also into internal positions of the chain) [14–19]. With either of these compounds inhibition of DNA synthesis seems to be so stringent that further passage through the S-phase is completely prevented. PC analysis showed that in contrast to the other agents 3′-FTdR still permits the cells to pass very slowly through the main part of the S-phase. This effect may considerably delay the loss of viability. As to the mode of action of 3′-FTdR, experiments with intact cells indicated an incorporation of the compound into DNA [1] which was unambiguously demonstrated for cell-free conditions [4]. Since 3′-FTdR inhibition is reversible, the cell must be able to excise the compound or to bypass the blocked pieces. Excision may be facilitated by the terminal position of the analogue. Indeed, a 3′ to 5′-exonuclease activity has recently been demonstrated for a eukaryotic DNA polymerase [20]. As to bypassing, the results of Byars and Kidson [21] should be mentioned; they found that 2′, 3′-didexoythymidine (a very similar nucleoside, differing from 3′-FTdR only in a hydrogen instead of fluorine at the C-3′ position) is incorporated at the end of the growing DNA chain in mammalian cells. The incorporated nucleoside proved to remain in the DNA for many generations of unimpaired cell growth. However, the situation is not fully comparable to that seen with 3′-FTdR,

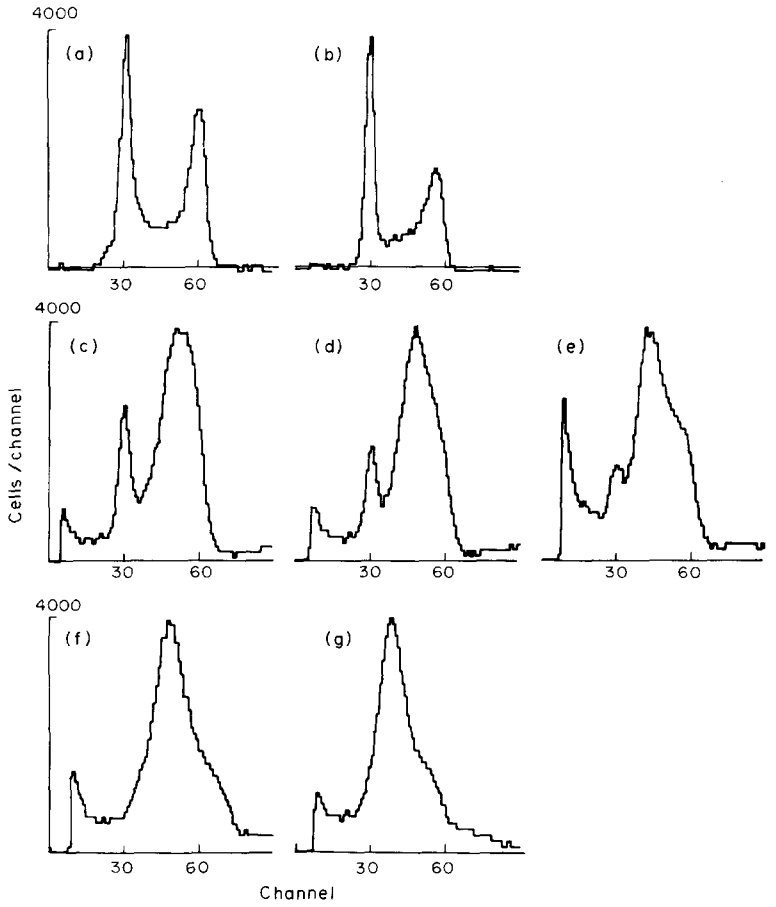

Fig. 7. PC analysis of cells treated for 24 hr *by various concentrations of 3'-FTdR. (A) controls at the beginning of the culture, (B) controls after* 24 hr *in culture* (106% *increase in cell number). Molarity of 3'-FTdR and* % *inhibition: (C)* 3×10^{-6}, 72, *(D)* 1×10^{-5} *(concentration used in Figs.* 3–6), 91, *(E)* 3×10^{-5}, 100, *(F)* 1×10^{-4}, 100 *(G)* 3×10^{-4}, 100.

because—at least in our EAT system—2', 3'-deoxythymidine, even in high doses, has negligible low cytostatic effects.

Wobus [22] found, also in EAT cells, that all of the few cells which undergo mitosis immediately after 3'-FTdR treatment show chromosomal aberrations. In contrast, cells entering mitosis 24–48 hr after removal of the drug showed less or even no aberrations. These results suggest that the lag phase between removal of the drug and the burst of mitosis observed in our experiments may be necessary for repairing at least the most severe lesions which otherwise would give rise to chromosomal aberrations. Preliminary results show that also under *in vivo* conditions (using mice) a dose-dependent arrest of EAT cells and leukemic cells in the late S-phase can be obtained after 24 hr of 3'-FTdR infusion. These results recommend 3'-FTdR as a most suitable agent for the nontoxic accumulation of cells in the S-phase. Usually, the range in cell cycle times is a serious obstacle for a successful chemotherapy with S-phase specific agents like CA [23]. Pretreatment with 3'-FTdR could considerably improve the action of such agents by shortening the necessary period of application. On the other hand, 3'-FTdR may also be used to limit tumour outgrowth during intervals of treatment with highly cytostatic agents.

The Antileukemic Effect of Systemic Non-specific BCG-immunostimulation vs Systemic Specific Immunostimulation with Irradiated Isogeneic Leukemic Cells*

L. OLSSON,† P. EBBESEN,† N. KIGER,‡ I. FLORENTIN‡ and G. MATHÉ‡

†*Department of Tumor Virus Research, Institute of Medical Microbiology, University of Copenhagen, Denmark and* ‡*Institute de Cancérologie et d'Immunogénétique, 94800 Villejuif, France*

Abstract—*The antitumoral effect of BCG has been compared to the antitumoral effect of injections of irradiated isogeneic leukemic cells in a transplantable, murine ascites leukemia. It was found that irradiated tumor cells in doses of* 10^7 *or* 10^9 *cells per injection (either s.c. or i.p.) induced prolongation of mean survival time and increased the percentage of cured mice.*

The effect of irradiated cells was highest with s.c. injections and an effect was observed only in mice inoculated with 10^2 *or* 10^3 *living leukemic cells. BCG had only beneficial effect when given i.v. and only in a dose of* 7×10^6 *viable units per injection. Lower doses of BCG had no effect compared to controls and higher doses given i.v. or i.p. enhanced tumor growth. BCG injected i.v. may induce a cure in mice inoculated with* 10^2–10^5 *living leukemic cells.*

Spontaneously cured mice were highly susceptible to a second tumor inoculum containing a tumor cell number only one decade higher than the first inoculum. In contrast, immunostimulated mice rejected inocula 2–3 decades above first inoculum.

Histologic examination of organs from mice cured either spontaneously or by immunostimulation revealed that BCG induced markedly histiocytic proliferation and infiltration in spleen, thymus, lymph nodes, liver, and lungs, whereas otherwise cured mice had no such lesions.

INTRODUCTION

IT IS well established that administration of immunoadjuvants may lead to tumor growth control in tumor-bearing mice [1, 2]. The adjuvants are classified as specific [3] when they stimulate immunological mechanisms that are supposed to be directed only against the actual tumor and classified as non-specific when they stimulate other activities of the immune system as well [3]. Bacille-Calmette-Guérin (BCG) has proven to be among the strongest non-specific immuno-adjuvants [4, 5], whereas it is more uncertain which specific immunoadjuvant is the most potent.

Most of these experiments have been performed with transplantable animals tumors, which are often rather strongly antigenic [6] and thus different from spontaneous human tumors that in many cases have shown no evidence of bearing specific tumor associated antigens. This obviously weakens the importance of the experimental results, especially as emphasis is often on immunologic mechanisms that have a neoantigen as prerequisite [7].

We have therfore used a transplantable murine leukemia that in its morphologic [8, 9], immunologic [9] and cytokinetic [8] properties are close to human lymphoid leukemia [10].

A systematic investigation into the effect of non-specific vs specific immunotherapy has not previously been performed in such a model.

In this paper we have concentrated on specific stimulation with isogenic irradiated tumor cells as compared to non-specific BCG-stimulation. We have studied the importance

of the route of administration, dose–response relationship, tumor load and susceptibility to a second inoculum after being cured of leukemia caused by a primary inoculum. Finally, the results of histologic examinations of organs from different groups of cured mice were compared.

MATERIAL AND METHODS

Mice and tumor

Female mice of an inbred $C_{57}Bl/6$ strain were used at 9–10 weeks of age. The mice were inoculated i.p. with various doses of leukemic cells from a transplantable leukemia that has been induced in the $C_{57}Bl/6$ strain by repeated injections of AKR leukemic cells. The tumor is isogeneic with the $C_{57}Bl/6$ mouse and its cytology, growth and various immunological characteristics have been described elsewhere [8, 9]. The tumor is maintained as an ascitic tumor by weekly i.p. injections of 5×10^6 tumor cells into healthy mice. Six-day-old tumor cells were used for inoculation in the various experiments. In each experiment, the mice were randomized into groups of 20 mice that were examined daily, the moribunds killed, and their ascites, liver, cor, kidney, lungs, lymph nodes, thymus, spleen and adrenals examined histologically.

The mice that were cured either spontaneously or by the various treatments were followed 90 days or more and then studied for their ability to reject a second inoculum of tumor cells. Each experimental group contained at least 5 mice. The mice were observed for another 90 days before it was stated whether the second tumor was rejected or not.

Adjuvants

Living BCG was produced at the Pasteur Institute (Paris, France), obtained from this source and comprised $7–10 \times 10^6$ viable units per mg. BCG was dosed according to the number of viable units and injected each week with start at day +1 after tumor cell inoculation. The injections were given either subcutaneously (s.c.), intravenously (i.v.) or intraperitoneally (i.p.) up to 8 times.

Tumor cells for irradiation were harvested from six-day-old ascites tumors. Normal lymphoid cells were obtained from mesenteric lymph nodes from healthy $C_{57}Bl/6$ mice. The cells were exposed to 10,000 rad from a ^{137}Cs-gamma source at a rate of 300 rad/min. The cells were injected immediately after irradiation either i.v., s.c. or i.p., with start at day +1 and given up to 8 times.

Statistics

Wilcoxon's non-parametric test has been used throughout.

RESULTS

I.v. adjuvant administration

Table 1 shows that 5–15% of non-treated mice reject tumor inocula on $10^2–10^3$ cells. 1.4×10^6 viable units of BCG did not alter the survival compared to controls, whereas 7×10^6 units of BCG induced an increase in the number of cured mice when the tumor inoculum was in the order of $10^2–10^5$ cells. The curative effect increases with decreasing number of inoculated tumor cells. In contrast, 21×10^6 units BCG decreased the mean survival time in the groups with $10^2–10^3$ tumor cell inoculum. No cured mice were observed in these groups.

Irradiated normal lymphoid cells as well as irradiated tumor cells had no effect on leukemic cell proliferation when given i.v.

I.p. adjuvant administration

BCG in a dose of 1.4×10^6 units had no effect on tumor growth (Table 3), 7×10^6 and 21×10^6 units of BCG are seen to shorten mean survival time in the 10^2 and 10^3 groups and no cured mice were observed in these groups. Furthermore, no effect of BCG was seen in the other groups with higher tumor cell inocula.

Irradiated tumor cells in a dose of 10^7 or 10^9 cells induced prolongation of mean survival time and increased the number of cured mice (Table 4). No difference was observed between the groups receiving 10^7 irradiated tumor cells or 10^9 cells. Irradiated normal lymphoid cells had no influence on tumor growth.

S.c. adjuvant administration

BCG had no effect on tumor growth (Table 5).

Equally, 10^5 irradiated tumor cells had no effect on tumor growth, in contrast to injections of both 10^7 and 10^9 irradiated tumor cells that highly significantly increased the mean survival time and incidence of cure of mice inoculated with either 10^2 or 10^3 tumor cells (Table 6). In fact, with these inocula the effect of irradiated tumor cells given s.c. is significantly ($P<0.01$) more beneficial than BCG given i.v. However, at 10^5-inoculum no effect was observed with

irradiated tumor cells. Irradiated normal cells had no effect on tumor growth.

Rejection of a second inoculum

Cured mice from repeated experiments of each group were randomized into subgroups of at least 5 mice that were inoculated with tenfold dilutions of a tumor cell suspension, starting one decade higher than the first inoculum.

Almost all spontaneously cured mice died of an inoculum only one decade higher than first inoculum and all mice in this group died with inocula two decades higher than the first inoculum.

Irradiated tumor cells administered i.p. induced resistance to a second inoculum that was 1–2 decades higher than the first one.

Mice cured by irradiated cells given s.c. had a complete resistance to tumor inocula even up to 10^5 tumor cells.

BCG did not induce the same high curability as irradiated tumor cells in the 10^2 and 10^3 groups, but mice cured by BCG however rejected a second inoculum to the same extent as mice cured by irradiated cells (Table 7).

Histologically, all dying mice revealed infiltration in parenchymal tissue. The natural structure of the organs was erased, some degree

of histiocytic proliferation was present, but there were no signs of severe BCGosis.

The spontaneously cured mice and mice with irradiated tumor cells revealed no histological lesions at autopsy. In contrast, mice cured by BCG showed histiocytic granulomas in the sinusoids and portal tracts of the liver, in spleen follicles and in peripheral lymph nodes. Infiltrates of histiocytes were also found around the small vessels in the lungs and around arterioli and paraglomerularily in the kidneys. Small histiocytic infiltrates were found between the medulla and cortex of some adrenals and among the myocardial fibrils. Additional findings were cells with abundant PAS positive cytoplasm in the perifollicular zone of the spleen and thymus alterations consisting of marked cortical atrophy and presence in the medulla of some cysts containing a PAS positive, mostly homogeneous material.

DISCUSSION

The present paper confirms and extends previous studies on the antitumoral effect of specific (irradiated tumor cells) vs non-specific (BCG) immunostimulation [11–14].

The effect of BCG and irradiated cells is highly dose-dependent [15, 16]. The present work permits a direct comparison between the effect of BCG and irradiated cells, showing that BCG is more efficient than irradiated cells with increasing tumor-inoculum, the reverse being true with decreasing tumor load. BCG could even enhance tumor growth, whereas such an effect was not observed in any case during treatment with irradiated tumor cells.

The benign histological reactions may be due solely to BCG, as non-tumor-bearing mice can show the same lesions after BCG-treatment.

The work of many groups has amply demonstrated that immunologic mechanisms may be cytotoxic to tumor cells *in vitro*. As argued previously, many of these results may not be relevant to human neoplasms due to differences in antigenicity, but even in appropriate models little evidence exists to support the hypothesis that the immunological mechanisms induced by immunoadjuvants play any important role in whatever tumor-regression is observed [17].

This implies that we consider both immunologic and non-immunologic mechanisms as possible candidates for the antitumoral effect [18].

In contrast to BCG, irradiated tumor cells in no case decreased the survival time or cure-expectancy. The best results were obtained with subcutaneous administration. The results were even superior to those induced by BCG in mice with small tumor inocula (10^2 or 10^3), whereas BCG was superior to irradiated cells in mice receiving large inocula (10^5).

The histiocytic reaction observed in mice cured after i.v. BCG treatment is in accordance with that described by Rappaport and Khalil [19], as is also the case with the cyst-like of the thymus from BCG treated animals. Such cysts containing PAS positive fluid may occur spontaneously in very old mice and may be induced in large numbers by estrogen treatment [20, 21]. The biological importance of this PAS positive fluid is unknown.

The efficiency of immunostimulation in human acute lymphoblastic leukemia is still debated as it has been postulated that the frequency of complete remissions is the same in patients receiving chemotherapy only as compared to a protocol combining chemotherapy and stimulation. Recently, it has however been claimed that whereas some patients treated with chemotherapy only, relapse after 3–4 yr in remission, no such late relapses are seen in patients receiving immunostimulation in addition to chemotherapy [1].

We think that our experiment concerning rejection of a second tumor cell inoculum is in favour of this argument for using immunostimulation as mice spontaneously cured were highly susceptible to a second inoculum and immunostimulated mice quite resistant to a second inoculum. The present work thus demonstrates that administration of immunoadjuvants may induce tumor regression and resistance to a second tumor inoculum. The results also suggest that the antitumoral mechanisms by BCG are different from those induced by irradiated cells. Further studies remain to elucidate these mechanisms, which must be known before immunostimulation can be applied optimally to the cancer patient.

Uptake and Subcellular Localization of Daunorubicin and Adriamycin in Cultured Fibroblasts*

G. NOËL,† C. PETERSON,‡ A. TROUET and P. TULKENS

International Institute of Cellular and Molecular Pathology, Université Catholique de Louvain, Avenue Hippocrate, 75, B-1200 Brussels, Belgium

Abstract—*Cellular uptake and subcellular localization of daunorubicin and adriamycin were studied in cultured rat embryo fibroblasts. Both drugs accumulated in the cells manifold above the extracellular concentration. The uptake of daunorubicin was 2–3 time higher than that of adriamycin. Cell fractionation techniques, including isopycnic centrifugation of cytoplasmic extracts, revealed that both drugs were exclusively localized in nuclei and lysosomes, but to quite different proportions. About 20% of accumulated daunorubicin was localized in the nuclei, as compared to 60% of adriamycin, which means that the nuclear concentrations of the drugs were very similar. In the lysosomes, on the other hand, the accumulation of daunorubicin was 4–5 times higher than that of adriamycin. The reason for this difference is so far not clear.*

The results give an explanation for observations of similar biologic effects of the drugs in spite of a marked difference in cellular accumulation.

INTRODUCTION

ALTHOUGH very similar in their chemical structures, daunorubicin (DNR) and adriamycin (ADR) are characterized by important but poorly understood differences in their pharmacological and therapeutic properties [1]. The antitumoral activity of these drugs is most probably related to their affinity for DNA, characterized by their intercalation between two successive DNA base pairs [2, 3].

The DNA binding properties of DNR and ADR are very similar *in vitro* [4], as could be expected by the evidence that the anthraquinone side chain, by which the drugs differ, does not take part in the intercalation process [3]. The accumulation of DNR has been shown to be consistently higher than ADR in L1210 and Ehrlich ascites cells [5–7]. While in the same cells, their effects on DNA and RNA synthesis are similar and cannot easily be correlated with the levels of intracellular drugs [5, 8].

We have tried to better understand the cellular pharmacology of DNR and ADR by studying their intracellular uptake and localization in cultured cells using the technique of cell fractionation. Our first studies, reported here, were performed on rat embryo fibroblasts, which have been extensively studied and characterized by this technique [9].

MATERIAL AND METHODS

Cell culture

Rat embryo fibroblasts were obtained and cultivated as described by Tulkens *et al.* [9]. For incubation with drugs, cells from the first or second subculture were used as soon as they reached confluency.

Uptake experiments

For the drug uptake experiments, cells were grown in Falcon®-T-flasks (25 cm^2 of growth

surface, which corresponds to ±1 mg of cell protein). After incubation, cells were washed three times with PBS (phosphate buffered saline, pH 7.4, NaCl 137 mM, KCl 2.7 mM, Na_2HPO_4 8 mM, KH_2PO_4 1.5 mM), harvested in this medium by scraping (with a rubber "policeman") and finally disrupted by ultrasonication (15 sec at 75 W, 20 kHz: Sonifier B-12, Branson Sonic Power Company, Conn. USA).

Cell fractionation procedures

After incubation with drugs, cells grown in Roux flasks (200 cm^2 growth surface) were washed three times with PBS and harvested by scraping after an incubation of 15–30 min with ice-cold EDTA (0.5 mM in PBS). For each fractionation experiment, 5 Roux flasks were used corresponding to ±50 mg of cell proteins. Cells were homogenized, fractionated and enzymes and proteins assayed as described earlier [9]. Cell fractionation involves the preparation of a cytoplasmic extract by differential centrifugation and the centrifugation of the various components of this extract to their equilibrium density in a sucrose gradient. The distribution of the various marker enzymes and of the drugs was plotted in the form of standardized histograms [10].

Drugs assays

ADR and DNR were assayed by fluorometry using excitation and emission wavelengths of 485 and 580 nm, respectively. In order to release the drugs from their association with cellular constituents, 1 ml aliquots of sonicated cell suspension or fractions were treated with 2 ml TCA (40%) and 0.1 ml BSA (10%) as coprecipitant. The drugs were then measured in the supernatant obtained after a low speed centrifugation. The drug concentration in each sample was calculated by comparison with identically treated standard solutions.

Metabolites of DNR and ADR were studied by thin layer chromatography of samples extracted from the cell suspensions with a mixture of chloroform-methanol (2:1). Silica gel plates and two different solvent systems were used: CH_2Cl_2–CH_3OH–HCOOH–H_2O (85:15:2:1) and $CHCl_3$–CH_3OH–H_2O (120:20:1).

Materials

All chemicals were of analytical grade. DNR-hydrochloride was kindly supplied by Rhône-Poulenc (Paris, France) and ADR-hydrochloride by Farmitalia (Milano, Italy).

RESULTS

Drug accumulation

The cellular uptake of DNR and ADR after various times of incubation at a 17.5 μM concentration is given in Fig. 1. The accumulation reaches a steady state level after 10–15 hr for both drugs, while the amount of DNR associated with the cells is about three times higher than that of ADR. The percentage of fluorescent drug recovered in the cells and the incubation medium at various times with respect to the starting fluorescence, is given in Table 1 and indicates that no loss of fluorescence occurs during incubation up to 6 hr. The absence of a major metabolic conversion of ADR or DNR by fibroblasts was confirmed by thin layer chromatography. Only trace amounts of daunorubicinol and adriamycinol were found after 14 hr of incubation.

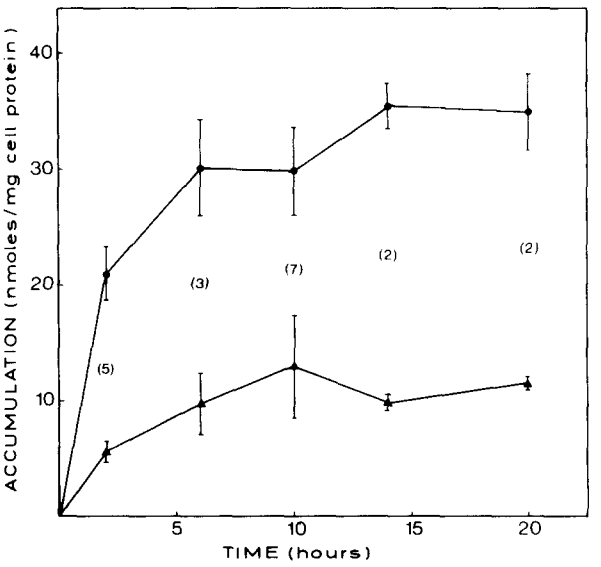

Fig. 1. Accumulation kinetics of DNR (circles) and ADR (triangles) in fibroblasts incubated at an extracellular drug concentration of 17.5 μM *(mean values ± S.D.). Figures within parentheses give numbers of experiments.*

Table 1. Drug fluorescence recovered in fibroblasts and incubation medium after incubation with DNR or ADR (17.5μM) *for different times*

Incubation time (hr)	Daunorubicin (% recovered)	Adriamycin (% recovered)
2	102 ± 3.0	98 ± 3.0
4	97 ± 3.5	97 ± 1.2
6	108 ± 2.3	103 ± 0.6

The table gives the percentage of drug fluorescence found after the incubation as compared to the starting medium (mean values ± S.D. of 3 experiments).

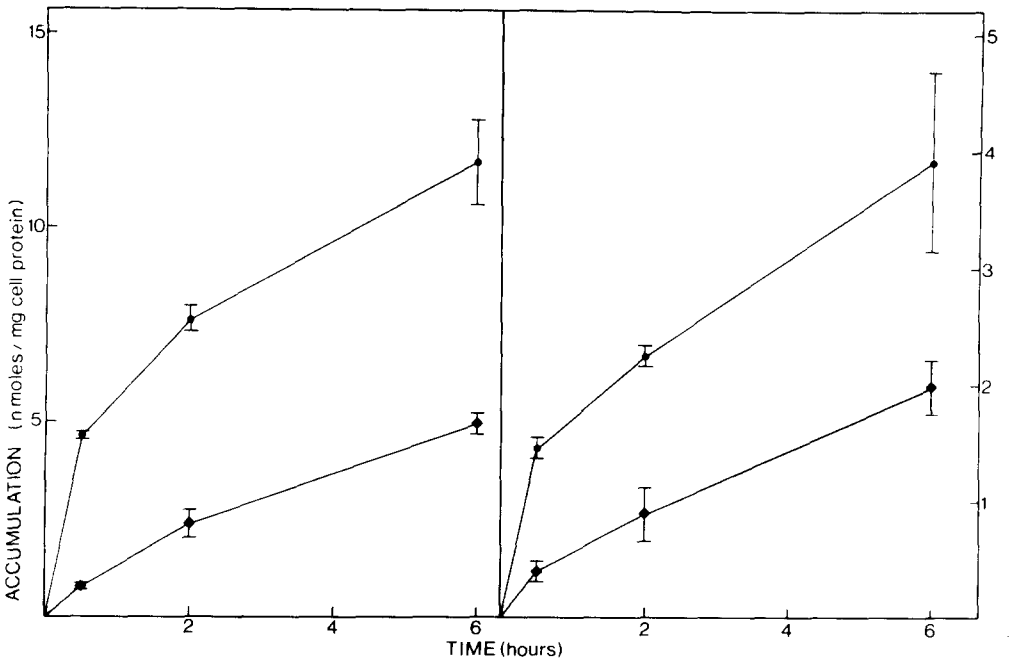

Fig. 2. Accumulation kinetics of DNR (circles) and ADR (squares) in fibroblasts incubated at an extracellular drug concentration of 5.25 μM *(left) and* 1.75 μM *(right). Mean values ± S.D. of 3 experiments are given.*

An about 2 fold difference in accumulation between DNR and ADR is also observed, as shown in Fig. 2, when the cells are incubated with the drugs at lower extracellular concentrations (5.25 μM and 1.75 μM).

In order to investigate whether ADR could affect the uptake of DNR, fibroblasts were incubated with a mixture of DNR and ADR at different proportions with a constant total drug concentration (17.5 μM). As shown in Fig. 3 the total drug uptake during 1 hr increases linearly with the percentage of DNR present in the mixture.

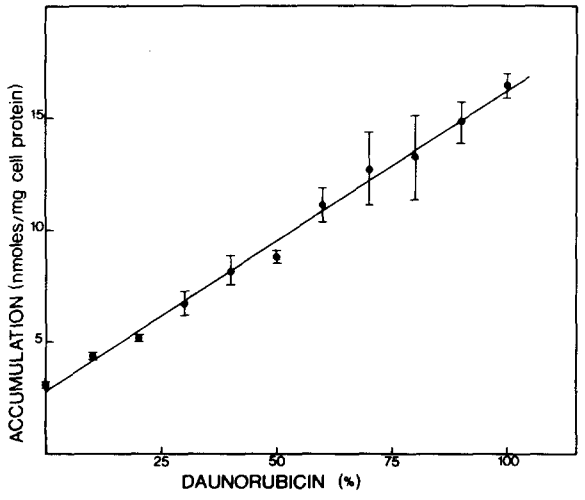

Fig. 3. Accumulation of fluorescent drugs in fibroblasts incubated for 1 hr *with a mixture of DNR and ADR in different proportions at a total concentration of* 17.5 μM. *Accumulation is presented as a function of the percentage of DNR in the mixture (mean values ± S.D. of 3 experiments).*

Subcellular localization of DNR and ADR

After incubation with DNR or ADR (17.5 μM) for 10 hr, fibroblasts were fractionated into a nuclear fraction and a cytoplasmic extract. The absence of nuclei in the cytoplasmic extract was verified by microscopy. The distribution of the drugs and of various marker enzymes in these two fractionations are given in Tables 2 and 3. The localization of DNR and ADR in the cytoplasmic extract was subsequently analyzed by equilibrium density centrifugation.

As shown in Figs. 4 and 5 the distribution patterns of DNR and ADR are clearly distinct from those of cytochrome oxidase (marker enzyme for mitochondria), NADPH: cytochrome c reductase (marker enzyme for endoplasmic reticulum) and 5′-nucleotidase (marker enzyme for plasma membrane). On the other hand, their distributions correspond closely to those of *N*-acetyl-β-glucosaminidase and cathepsin B, suggesting very strongly an association of both drugs with lysosomes.

Control experiments in which DNR was added to a fibroblast homogenate gave completely different results: the distribution of the drug in the cytoplasmic extract overlapped very

Table 2. Distribution of DNR, protein and marker enzymes between cytoplasmic extract and nuclear fraction in fibroblasts incubated with DNR (17.5 μM) for 10 hr

	Total value	Cytoplasmic extract(%)	Nuclear fraction (%)
DNR	40.34 nmole/mg cell protein	69.4	30.6
Protein	48.89 mg	80.0	20.0
Cytochrome oxidase	26.50 mU/mg cell protein	89.6	10.4
NADPH: cytochrome c reductase	7.32 mU/mg cell protein	84.1	15.9
N-acetyl-β-glucosaminidase	25.97 mU/mg cell protein	79.2	20.8
Cathepsin B	7.30 mU/mg cell protein	79.6	20.4
5′-nucleotidase	35.79 mU/mg cell protein	84.2	15.8

Table 3. Distribution of ADR, protein and marker enzymes between cytoplasmic extract and nuclear fraction in fibroblasts incubated with ADR (17.5 μM) for 10 hr

	Total value	Cytoplasmic extract (%)	Nuclear fraction (%)
ADR	6.22 nmole/mg cell protein	41.6	58.4
Protein	49.38 mg	73.7	26.3
Cytochrome oxidase	8.40 mU/mg cell protein	90.5	9.5
NADPH: cytochrome c reductase	4.12 mU/mg cell protein	85.9	14.1
N-acetyl-β-glucosaminidase	21.70 mU/mg cell protein	74.3	25.8
Cathepsin B	4.30 mU/mg cell protein	76.6	23.4
5′-nucleotidase	47.81 mU/mg cell protein	85.4	14.6

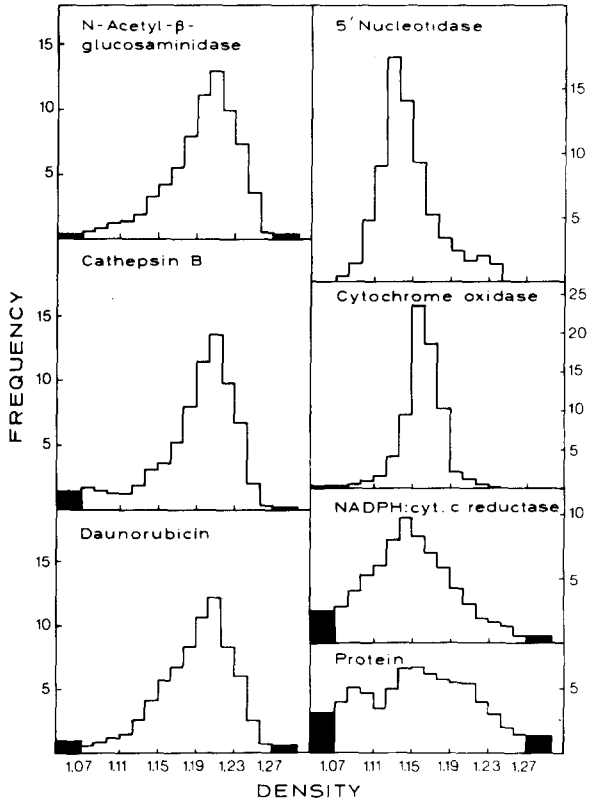

Fig. 4. Distribution of DNR, protein and marker enzymes in the cytoplasmic extract of fibroblasts incubated with the drug for 10 hr at an extracellular concentration of 17.5 μM. The frequency (ordinate) is $\Delta Q/(Q \times \Delta\rho)$, where ΔQ is the amount of constituent in the section. Q the total amount of the constituent in all sections and $\Delta\rho$ the density increment for each section (0.0133). Solid areas represent the amount of constituent recovered at densities below 1.07 and above 1.27.

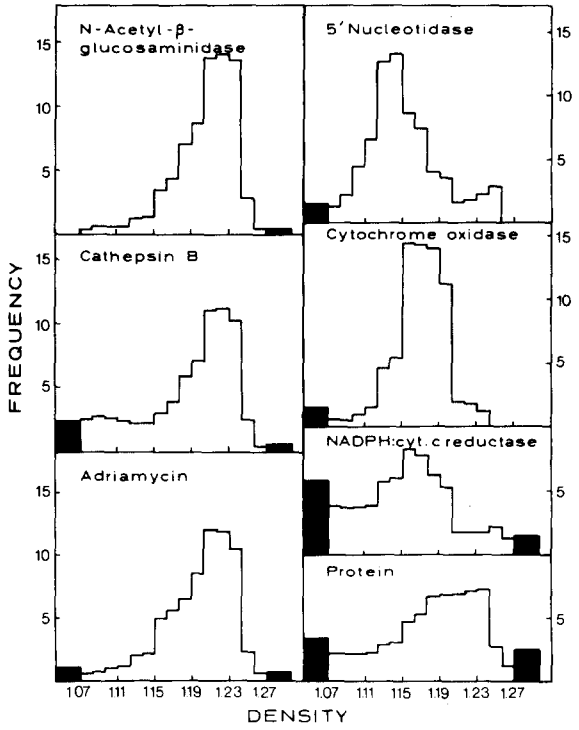

Fig. 5. Distribution of ADR, protein and marker enzymes in the cytoplasmic extract of fibroblasts incubated with the drug for 10 hr at an extracellular concentration of 17.5 μM.

closely the distribution of protein. This indicates that a redistribution of drug during the homogenization process cannot account for the results obtained with homogenates prepared from cells incubated with the drugs.

Since cytoplasmic DNR and ADR are exclusively localized in lysosomes, it becomes possible to estimate the nucleo-cytoplasmic distribution of the drugs on the basis of experiments reported in Tables 2 and 3. However, the nuclear fractions are contaminated with cytoplasmic components and therefore contain lysosomes. Taking into account the relative amount of *N*-acetyl-*β*- glucosaminidase and cathepsin B in the nuclear fraction, one can estimate the true distribution of DNR and ADR between the nuclei and the lysosomes. As illustrated in Fig. 6, these results indicate that for

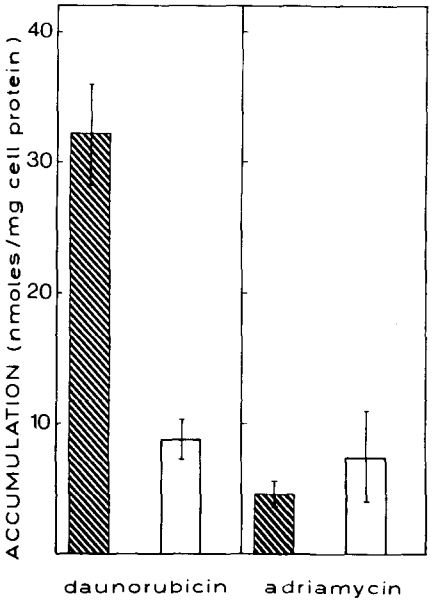

Fig. 6. Distribution of DNR and ADR between nuclei (open bars) and lysosomes (hatched bars) in fibroblasts incubated for 10 hr *with the drugs at an extracellular drug concentration od* 17.5 μM *(mean values ± S.D. of* 4 *experiments).*

the same extracellular concentration of drugs, the nuclear contents of DNR and ADR are very similar. The difference in intracellular concentration between the two drugs is exclusively accounted for by higher lysosomal concentration of DNR.

Similar nucleo-cytoplasmic distributions were obtained when cells were incubated for 8 hr at lower extracellular concentrations (5.25 and 1.75 μM).

DISCUSSION

As described earlier for other cell types [5, 6, 7] DNR and ADR are taken up in fibroblasts to a very high extent. We can evaluate from the data of Fig. 1 that DNR and ADR accumulate in the cells 800 and 150 times, respectively, as compared with the extracellular concentration. These results are obtained if we assume that 1 μg of fibroblast proteins corresponds to a cellular volume of 5 μl [11].

However, intracellular DNR and ADR do not distribute uniformly throughout the cells but accumulate in the nuclei and in the lysosomes. From Fig. 6 and Tables 2 and 3 we can calculate that after 10 hr of incubation at an external drug concentration of 17.5 μM, ±20% of intracellular DNR and ±60% of intracellular ADR are localized in nuclei. The concentrations of drug in the nuclei are very similar, while the lysosomal concentration of DNR is much higher than that of ADR. If we assume that the lysosomes occupy 4% of the total fibroblast volume [12], we can estimate that DNR is concentrated about 20,000 times and ADR about 3750 times inside the lysosomes as compared with the extracellular concentration.

The association of both drugs to nuclei is easy to explain by their affinity for DNA. The lysosomal accumulation can, on the other hand, be explained by the properties of weak bases of DNR and ADR. These drugs could indeed be able to permeate through cell membranes under their non-protonated form and become trapped inside the lysosomes, wherein the lower pH would increase very much the proportion of drugs existing under a protonated form, which would be unable to cross the lysosomal membrane [13]. We cannot however explain, on this basis, the difference in lysosomal accumulation observed between DNR and ADR, since these drugs have very similar pK_a-value [7, 14]. ADR does not interfere with the simultaneous accumulation of DNR since, as shown in Fig. 3, there is a linear relationship between total drug accumulation and the percentage of DNR in the mixture of DNR and ADR present in the incubation medium. This seems to rule out an effect of ADR on the storage capacity of the lysosomes e.g. by an effect on the intralysosomal pH.

An active outward transport for DNR at the plasma membrane level has been claimed by Danø *et al.* [15] and Skovsgaard [7] to exist in Ehrlich ascites cells. The differences in lysosomal accumulation observed between DNR and ADR could be explained by a higher affinity of such a transport system for ADR than for DNR as a consequence a higher extrusion rate for ADR from the cells. Since both drugs show similar nuclear concentrations, we have to postulate that ADR has a 7-fold larger affinity than DNR for nuclei. *In vitro*, R. Baurain (pers. comm.) has observed a significantly larger binding constant of ADR towards DNA, in comparison with DNR.

Our observations can also, if extended to other cell types, explain the higher specific inhibitory effect of ADR on nucleic acid synthesis and cell

growth, as compared to DNR, since a higher proportion of ADR is localized in the nuclei. The results could similarly explain, to some extent, the higher *in vivo* toxicity of ADR. Since after i.v. injections, DNR and ADR are cleared from the blood stream at the same rate [16], a greater proportion of DNR in the tissues should be stored in lysosomes wherein the drug is unable to exert its toxic action.

However, our results obtained with fibroblasts can only be extended to other cell types with great precautions. We have indeed to keep in mind that the amount of drug accumulated inside the lysosomal system of a given cell type will depend on the lysosomal volume of the cells. While the lysosomes occupy more or less 4% of the cellular volume of fibroblasts, other cells may have a smaller lysosomal volume, like for example hepatocytes (0.8%) [17] and rat hepatoma cells (1.9%) (P. Baudhuin, personal communication). On the other hand, the proportion of drug bound to the nuclei could be much higher in tumor cells if these cells are tetraploidal and contain a relatively higher amount of DNA. In fact, Skovsgaard [7] has claimed that less than 10% of DNR and ADR is localized in the lysosomes of Ehrlich ascites cells.

The Serum Immunoglobulins in Lymphoproliferative Malignancies*

GÉRALDINE ROSSET, JEAN-JÉRÔME FARQUET and ANDRÉ CRUCHAUD

Division of Immunology and Allergology (Wilsdorf Laboratory) and Division of Onco-Hematology, Department of Medicine, University of Geneva Medical School, Hôpital Cantonal, Geneva, Switzerland

Abstract—*Immune deficiency may be a prerequisite for or a consequence of the development of malignancies. This seems particularly true for lymphoproliferative disorders in which the proliferation of malignant cells and alterations of immunologic functions are closely connected. Our study was undertaken to determine whether the level of serum immunoglobulins is modified early and during the course of lymphoproliferative disorders. One hundred and thirty-two patients (38 Hodgkin's disease, 57 non-Hodgkin's lymphoma and 37 chronic lymphatic leukemia) were investigated at the time of diagnosis; 48 were reinvestigated after 6 months and 35 after 12 months. When mean values were considered, IgG was found to be higher (though not significantly) than in controls in the first stages of Hodgkin's disease; by contrast IgM was significantly lower from stage II to stage IV. No significant modification was found in lymphomas, while in CLL, IgG, IgA and IgM were definitely lower than in controls. CLL also disclosed the highest frequency of association of lowered immunoglobulins. Immunoglobulin levels did not show significant modifications during the course of the lymphoproliferative disorders studied. The scattering of individual values was the same in the three groups of malignancies and was not closely related to the stage of Hodgkin's disease and lymphoma.*

INTRODUCTION

LYMPHOCYTES belong to three main populations, T, B or null, characterized by different functions and various surface markers. Most non-Hodgkin's lymphomas, including chronic lymphocytic leukemia (CLL), are of B cell origin, while Hodgkin's disease probably results from a disorder of T lymphocytes [1, 2]. CLL and Hodgkin's disease are attended by well described immunologic deficiencies whereas such deficits are less well documented in solid non-Hodgkin's lymphomas [3–6].

The aim of the present study was to re-evaluate the problem of immunoglobulin levels in lymphoproliferative disorders with the prospect; (1) of detecting early isolated or associated modifications that could suggest the pre-existence of an immune deficiency, (2) of determining whether differences of either diagnostic or prognostic value can be established between Hodgkin's disease, CLL and the other non-Hodgkin's lymphomas, (3) of seeing whether significant modifications of immunoglobulin levels can be observed during the course of these disorders.

Although immunoglobulin level in CLL has been the subject of several publications [6–12], this problem has received little attention in the other non-Hodgkin's lymphomas [13] and in Hodgkin's disease [12–14].

Our results show that IgM in Hodgkin's disease, and IgG, IgA and IgM in CLL are significantly lower than in controls, that CLL has the highest rate of association of lowered immunoglobulins and that no significant modifications can be detected during the course of these diseases within a short period (12 months) of follow-up.

MATERIAL AND METHODS

Patients and controls

One hundred and nineteen normal subjects, 60 males and 59 females aged 20–80 yr and uniformly distributed throughout all age classes were used as controls.

One hundred and thirty-two patients (Table 1) who were seen in the Division of Onco-Hematology from 1968 to 1974 were investigated at the time of diagnosis and again after 6 and 12 months for 48 and 35 of

Accepted 30 Sepetember 1977.
*This study was supported by Grant 3.768.72 from the Swiss National Science Foundation.

them respectively. In all cases of Hodgkin's disease and of solid non-Hodgkin's lymphomas (the latter will be referred to as "lymphomas"), the diagnosis was established on clinical, radiological and histological examination. Patients with CLL were analyzed as a separate group and the diagnosis was based on bone marrow and peripheral blood examination.

Staging was done according to the Ann Arbor Conference [15]. Histological classification was established according to the Rye Conference [16] for Hodgkin's disease and according to Rappaport [17] and Lennert *et al.* [2] for non-Hodgkin's lymphomas.

None of the patients with CLL was treated during the study. All patients with Hodgkin's disease and lymphomas were treated with either radiotherapy or chemotherapy including one or several drugs and corticosteroids following initial determination of serum immunoglobulin levels. It must also be stressed that, except in one case, none of our patients complained of recurrent infections that could evoke an immunodeficiency during the years that preceded the diagnosis of lymphoproliferative disorder.

Determination of serum immunoglobulins

Blood was obtained by venipuncture and sera were stored at −20°C until used. Quantitative estimation of immunoglobulins was performed by radial diffusion in antibody-agar plates using 3 dilutions of each serum. Tripartigen plates (Behringwerke, Marburg, Germany) were used for IgG and IgA, and Immunoplates (Hyland Laboratory, Los Angeles, California) for IgM.

Immunoelectrophoresis

Immunoelectrophoresis was performed according to the micromethod of Scheidegger [18] using horse antiserum to whole human serum (Hyland) and rabbit antisera to IgG, IgA, IgM and kappa and lambda chains from our own stock that were rendered monospecific by appropriate absorptions.

Statistical analysis

The student's *t*-test was used to evaluate the significance of the results.

RESULTS

Immunoglobulin levels in controls and in lymphoproliferative disorders (Fig. 1, Tables 2 and 3)

From the data presented in Fig. 1, it appears that low values were more frequent than high values whatever the type of disorder studied and also that this frequency does not depend upon the stage of Hodgkin's disease or lymphoma. The average values of each group show that the IgG level was slightly higher in Hodgkin's disease and lymphoma than in controls though these differences were not significant. In Hodgkin's disease also, IgM was lower than in controls and in CLL all three immunoglobulins were significantly lower than in all other groups (Fig. 1, Table 2). When the different stages of Hodgkin's disease and of lymphoma were considered, significant differences were found in the former but not in the latter group. IgG was higher than in controls in stages I, II and III of Hodgkin's disease but only in stage II was this difference significant. IgG was lower than normal in stage IV. As for IgM, it was significantly lower than in controls in stages II, III and IV (Fig. 1, Table 3). Three patients, two with Hodgkin's disease and one with lymphoma, were striking for their low IgG level. The first patient had been treated for several years for recurrent respiratory infections before Hodgkin's disease developed. He was known to have very low IgG and IgA and normal IgM. When Hodgkin's disease stage I was diagnosed, immunoglobulin values were as follows: IgG 107, IgA 0 and IgM 185 mg/100 ml. He eventually died from septicemia following splenectomy. The second patient who had Hodgkin's disease stage III had essentially lowered IgG (IgG 123, IgA 133 and IgM 92 mg/100 ml). The third patient had lymphoma stage III and rheumatoid arthritis: immunoglobulin levels were IgG 150, IgA 140 and IgM 235 mg/100 ml.

Association of immunoglobulins with levels higher or lower than normal

Table 4 presents the frequency of abnormally high and low values as well as the frequency with which two or three immunoglobulins with abnormal values were associated in one patient. IgG was found to have elevated values in a relatively small number of cases

of Hodgkin's disease and in a greater number of lymphoma without relationship to the stage of the disease. Only the lymphoma group had a significantly higher frequency of at least one elevated immunoglobulin as compared to controls. By contrast, decreased values were found more frequently. The number of cases with low IgG and IgM was greater in all patients groups than in controls while, for IgA, this was the case only in CLL. The most striking group was CLL since 2 or 3 immunoglobulins were lowered in 13 patients, i.e. 35.1% of cases. It is remarkable that in none of our patients did we find divergent abnormalities with, for instance, the association of one immunoglobulin above and one below 2 standard deviations.

Differences in immunoglobulin levels during the course of disease

Forty-eight patients investigated at the time of diagnosis could be explored after 6 months of evolution and 35 were reinvestigated after 12 months. As shown in Table 5, the average value of the three immunoglobulins tested was not significantly modified in any of the three groups of patients. However, this type of investigation made sense only in the CLL

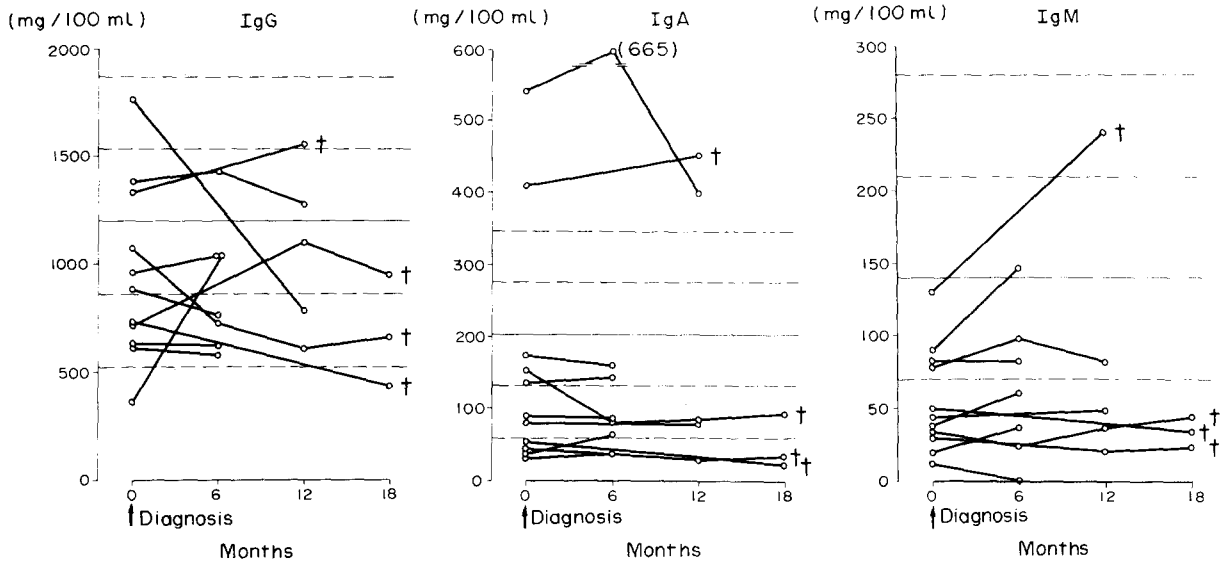

Fig. 2. Immunoglobulin levels during the course of chronic lymphocytic leukemia. —— mean value of 119 controls; --- one and two standard deviations from the mean.

group, since all patients with Hodgkin's disease and lymphoma were treated in the meantime while patients with CLL were not. Eleven of these patients were reinvestigated at least once after 6, 12 or 18 months. As shown in Fig. 2, an increase or decrease greater than one standard deviation was observed on 4 occasions for IgG and one occasion for IgA and IgM. No clear correlation could be established between these modifications and the course of the disease. It is, however, remarkable that among the four patients who died, three had low levels of immunoglobulins, particularly IgA and IgM. One died from heart failure at 73, one from miliary tuberculosis at 73 and one from severe anemia and gastrointestinal hemorrhage at 71. The patient with elevated immunoglobulins had alcoholic cirrhosis and died from hepatic failure at 68.

Presence of M-components

Immunoelectrophoresis did not reveal the presence of M-component in any of the patients investigated.

DISCUSSION

Our data show that the scattering of individual values was approximately the same in all three groups of lymphoproliferative disorders studied; however only in Hodgkin's disease and CLL were mean values significantly different from normal. In Hodgkin's disease, IgG was rather elevated in the first stages and lowered in stage IV, while IgM was constantly lowered from stages II to IV. Elevated IgG has been reported by other authors [12, 14], while some controversy exists as for data regarding IgM. Decreased IgM level has been reported by Waldmann *et al.* [12], while IgM was found mostly within normal limits by Gajl-Peczalska *et al.* [11] and elevated by Wagener *et al.* [14]. The reason for these discrepancies is not clear since our patients, as well as patients reported in the other studies, were not treated at the time of investigation.

Immunoglobulins were, on the average, little affected in lymphomas though individual high and low values were encountered. This is at variance with the observations of Gajl-Peczalska *et al.* [11] who reported low average values for IgM (if one excepts one case of Waldenström macroglobulinemia) and normal values for IgG and IgA. In our cases, no significant differences were noted depending on the stage of the tumor. It was not attempted to establish correlations between immunoglobulin levels and the histological type of lymphoma; these correlations were not evident in another study [11].

CLL was characterized by immunoglobulin levels lower than in controls and other lymphoproliferative disorders, as was already reported [7, 9, 10, 12]. In addition, the CLL group disclosed the most frequent association of lowered immunoglobulins. Although patients were investigated at the time of diagnosis, it could not be decided whether hypogammaglobulinemia was present at the beginning of the disease, since CLL gives usually few

clinical symptoms and is often overlooked in its early stage. However, it is known that the longer the duration of the disease, the more frequent the chances to discover hypogammaglobulinemia [6, 9]. In addition, decreased rate of IgG synthesis has been demonstrated in CLL [19].

The elevation of immunoglobulin levels, particularly IgG, that was observed in some patients, especially in the group of Hodgkin's disease and lymphoma may well represent a humoral response to tumor antigens. These antibodies might be cytotoxic and contribute to the destruction of the malignant cells; alternatively, they might be blocking and enhance the proliferation of the tumor. The hypothesis that patients with high immunoglobulin levels do better than those with normal or low immunoglobulin levels still awaits confirmation. Regarding the first question we asked ourselves before starting this investigation, it is evident that the decrease of one or more immunoglobulin(s), although present in some early stages of Hodgkin's disease and lymphoma, was not frequent enough to support the hypothesis of a pre-existing humoral immune deficiency. Also, the clinical history of our patients was not in favour of this possibility. Though decreased immunoglobulin levels were the most frequent in CLL, it could not be ascertained which disorder, hypogammaglobulinemia or proliferation of malignant cells, came first. The answer to the second question depends upon whether mean values or individual immunoglobulin levels are considered. On a statistical basis, a decrease of two or three immunoglobulins was significantly more frequent in CLL, and a decrease of IgM was more frequent in advanced stages of Hodgkin's disease than in controls and in lymphoma. However, cases with high or low immunoglobulin levels were found in all three groups of lymphoproliferative disorders and in all stages of Hodgkin's disease and of lymphoma. This makes it difficult to retain the determination of immunoglobulin levels as a convenient method of differential diagnosis of the various lymphoproliferative disorders. As for the third question, it could not be shown that immunoglobulin levels were significantly modified during the course of the lymphoproliferative disorders studied and three of the four CLL patients who died had low immunoglobulin levels already at the time of diagnosis. It must be stressed that our follow-up was relatively short for a disease which has usually a prolonged course.

Clearly, lymphoproliferative disorders affect immunologic functions in quite a different way than other malignancies do, although both types of tumors probably result from an initial deficit of immune surveillance or from immune escape mechanisms: severe alterations of immune reactions which may appear in late stages of non-lymphoid malignancies are often present early in lymphoproliferative disorders. It is also remarkable that different types of tumoral processes originating in the lymphoid tissue such as those we have studied modify to various extents such a simple parameter as immunoglobulin levels, even when two of these processes, CLL and solid non-Hodgkin's lymphoma, have in most cases the same B cell origin.

Melanogenuria in Hamsters with Transplantable Melanoma

S. PAVEL, B. MATOUŠ, J. DUCHOŇ and Z. SCHWIPPELOVÁ

Department of Biochemistry, Faculty of General Medicine, Charles University, 128 53 Prague 2, Czechoslovakia

Abstract—*Little has been known about the excretion of melanogens (melanogenuria) in animals with experimental melanoma. In this report the first information about melanogenuria in hamsters with transplantable melanotic and amelanotic melanoma is given. In hamsters with melanotic melanoma apparently increased concentration and excretion of so called Thormählen positive melanogens in urine was found in comparison with hamsters with amelanotic melanoma or hamsters without tumours. Similar results were obtained when the excretion of all diazo positive compounds in urine was measured.*

Thin-layer chromatography of ethyl acetate extracts of hamster urine proved the presence of at least 15 phenolic or indolic acids. Some of them remained unidentified. However, such compounds as p-hydroxyphenylacetic acid, homovanillic acid, vanilmandelic acid or 5-hydroxyindole-acetic acid were identified. Only in the urine of hamsters with melanotic melanoma were we able to detect the isomeric 5-hydroxy-6-methoxyindolyl-2-carboxylic and 6-hydroxy-5-methoxyindolyl-2-carboxylic acids.

INTRODUCTION

THE URINARY excretion of melanogens (melanogenuria) in human subjects suffering from malignant melanoma has been studied for many years [1–8] and two principal groups of melanogens have been distinguished, i.e. Thormählen positive and Thormählen negative melanogens [9]. While there was a lot of knowledge collected, practically nothing was known about melanogenuria in animals with experimental melanomas. Only in 1970 Procházková and Duchoň described the presence of homovanillic and vanillactic acids in the urine of mice with Harding–Passey melanoma [10] and in the same year Käser *et al.* described the presence of the aforesaid acids in the urine of hamsters with transplantable melanoma type V 15 [11]. The isolated reports refer to occurrence of 3,4-dihydroxyphenylalanine in the urine of animals with experimental melanoma [12–14].

In the present paper we want to report on the first information about melanogenuria in hamsters with transplantable melanotic and amelanotic melanoma.

MATERIAL AND METHODS

Animals and tumours

Golden Syrian male hamsters were used in all studies. The tumour source was melanotic and amelanotic melanoma supplied by the courtesy of Dr. Bomirski (Poland). The properties of both related tumour lines have been described by Bomirski and coworkers [15, 16].

Two or three hamsters were placed in each glass metabolic cage (Velaz—Prague) and 24 hr urine collection was carried out. Urine was collected in glass bottles of metabolic cages containing 0.2 ml of 10% $NaHSO_3$. Hamsters without tumours served as controls.

Photometric tests

The concentration of Thormählen positive melanogens was measured in daily urinary samples of hamster with melanotic and amelanotic melanoma and controls using a quantitative modification of the Thormählen reaction [17] as follows:

One fifth to a half of a millilitre of urine was mixed with 1 ml of 0.2% sodium nitroprusside. Two millilitres of 10% KOH was added to this mixture and contents of test tube was well mixed. Finally, the solution was acidified by 0.2 ml of concentrated HCl. The absorbance at 620 nm was determined in 20 min.

The amounts of Thormählen positive melanogens in urine were expressed in terms of mg equivalent of indole, calculated using the standard curve for indole.

The quantity of all phenolic compounds in

Accepted 30 September 1977.

urine able to react with diazotized *p*-nitroaniline was measured according to Gan *et al.* [18].

Ethyl acetate extraction and thin-layer chromatography

The Thormählen negative melanogens were also studied qualitatively. Fifty millilitres of urine were acidified to pH 1 by HCl (indicator paper) and extracted twice with the same volume of ethyl acetate. The pooled extracts were dried with anhydrous sodium sulphate and evaporated to dryness in vacuo. The extract was dissolved in 1 ml of methanol and an aliquot of 20 µl was applied to thin-layer of cellulose (20 × 20 cm, Lucefol—Kavalier, Votice) and subjected to two-dimensional chromatography in the following solvents: I. Isopropanol–ammonia–water (8:1:1), II. anisole–acetic acid–water (69:30:1) [19]. The time of development was 180 min (I.) and 30 min (II.) respectively. The detection was carried out by diazotized *p*-nitroaniline in alkaline medium, u.v. light, Ehrlich's reagent and "ammoniacal silver nitrate".

Statistics

The results were evaluated statistically by Student's *t*-test.

RESULTS

The results of total excretion of Thormählen positive melanogens were expressed either as concentration values (µg equivalents of indole/ml) or as mean excretion values of the quantity of melanogens excreted by 1 hamster for 1 day (µg equivalents of indole/24 hr). Figure 1 illustrates the values of concentration and Fig. 2 the excretion in a group of hamsters with melanotic melanoma, amelanotic melanoma and without tumours. The values are summarized in Tables 1 and 2.

The quantity of all phenolic compounds in urine of hamsters capable of reacting with diazotized *p*-nitroaniline was measured according to Gan *et al.* [18]. The results are given in Fig. 3 and in Table 3.

In all cases the difference between the group of hamsters with melanotic melanoma on the one hand and with amelanotic melanoma or the control group on the other hand were considered significant with the probability of 99%.

The Thormählen negative melanogens were studied by comparing two-dimensional thin-layer chromatograms of ethyl acetate extracts of urines in each group (Fig. 4).

As is shown in Fig. 4 we confirmed the presence of the previously described compound

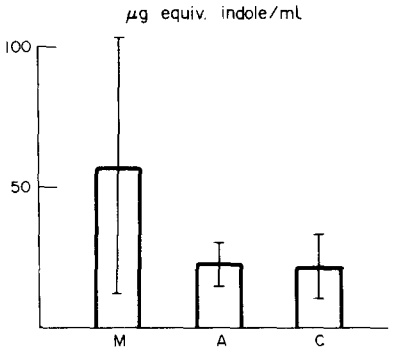

Fig. 1. Concentration of Thormählen positive melanogens in urine of hamsters. M—hamsters with melanotic melanoma; A—hamsters with amelanotic melanoma; C—hamsters without tumors (controls). The values are numerically summarized in Table 1.

—homovanillic acid—in the urine of hamsters with melanotic melanoma. Nevertheless, homovanillic acid was present in the urine of hamsters with amelanotic melanoma and hamsters without tumours, too. We turned our attention to the next Thormählen negative melanogen, whose chromatographic behaviour, and particularly the fluorescence in u.v. light, were strikingly similar to the melanogen described in 1967 by Duchoň and Matouš [3] in the urine of melanoma patients. These authors [3] identified the compound as a mixture of isomeric 5-hydroxy-6-methoxyindolyl-2-carboxylic and 6-hydroxy-5-methoxyindolyl-2-carboxylic acids. We were able to elucidate the identity of this Thormählen negative melanogen as a mixture of the isomeric acids above mentioned (to be published).

DISCUSSION

Figures 1 and 2 illustrate that the excretion

Table 1. Concentration of Thormählen positive melanogens in hamster urine

Experimental groups	No. of hamsters	Concentration (mean ± S.D.) (μg equiv. indole/ml)
Melanotic melanoma	148	57.0 ± 46.0
Amelanotic melanoma	32	22.6 ± 7.8
Controls	62	21.4 ± 10.8

Table 2. Excretion of Thormählen positive melanogens/24 hr

Experimental groups	No. of hamsters	Excretion (mean ± S.D.) (μg equiv. indole/24 hr)
Melanotic melanoma	148	89.7 ± 58.9
Amelanotic melanoma	29	51.5 ± 13.6
Controls	39	52.4 ± 21.2

Table 3. Excretion of diazo positive compounds/24 hr

Experimental groups	No. of hamsters	Excretion (mean ± S.D.) (μg equiv. tyrosine/24hr)
Melanotic melanoma	84	15.21 ± 6.60
Amelanotic melanoma	33	8.00 ± 3.14
Controls	51	5.98 ± 3.07

and concentration values of Thormählen positive melanogens of the melanotic group are clearly higher than in other groups. The group of hamsters with melanotic melanoma includes animals shortly after transplantation, when the tumour growth is macroscopically difficult to trace. This becomes evident when we plot the excretion of Thormählen positive melanogens versus days after transplantation (Fig. 5). This fact reduces the average values and has an unfavourable effect on other characteristics of the group.

Despite this, the values of excretion and/or concentration of Thormählen positive melano-

gens, as well as of the compounds which give a positive diazo test, are significantly higher in hamsters with transplantable melanotic melanom ($P<0.01$) when compared with the values of excretion and/or concentration of Thormählen positive melanogens in hamsters with amelanotic melanoma and in control animals.

Thin-layer chromatography of acid ethyl acetate extracts of hamster urine showed the presence of at least 15 compounds and only one qualitative difference was noted. It was the presence of 5-hydroxy-6-methoxyindolyl-2-carboxylic and 6-hydroxy-5-methoxyindolyl-2-carboxylic acid in the urine of melanotic melanoma hamsters. These compounds were not found in the urine of hamsters with amelanotic melanoma or control hamsters.

The presence of vanillactic acid was not observed in any of the urines. This, in our opinion, was due to the low levels of vanillactic acid in these urines. We had previously detected the presence of this acid in hamsters with melanotic melanoma (unpublished results). The presence of 3,4-dihydroxyphenylacetic acid in the urine of every hamster is a very interesting finding: this compound is very sensitive to alkaline media and for that reason was not found in paper chromatograms subjected to long development in an alkaline system. In addition, this catechol-acid is destroyed during the purification steps of extraction into ethyl acetate, re-extraction by an alkali solution followed by acidification and renewed extraction into ethyl acetate.

Our results suggest that the presence of melanotic melanoma in hamsters causes increased formation and excretion of some phenolic acids. As this increase was not found in animals with amelanotic melanoma, the quantitative differences in excretion could be due to the pigment melanin, in tumours.

The only qualitative difference between the groups was the presence of the isomeric 5-hydroxy-6-methoxyindolyl-2-carboxylic and 6-hydroxy-5-methoxyindolyl-2-carboxylic acids in the urines of hamsters with melanotic melanoma. We cannot, however, exclude the possibility that the above mentioned acids are formed in hamsters with amelanotic melanoma and controls, although in such small amounts that we were unable to detect them by the present methods.

Qualitative and quantitative differences could be caused either by different metabolic processes in tumour tissue or by different interaction of tumours with host organism. Hamsters with transplantable melanoma seems to be a good model for further study of melanogenuria.

Bacterial Infection and Acute Myeloblastic Leukaemia: An Analysis of Two Hundred Patients Undergoing Intensive Remission Induction Therapy

*JEFFREY S. TOBIAS, PETER F. M. WRIGLEY and †FRANCIS O'GRADY
Imperial Cancer Research Fund, Department of Medical Oncology, St. Bartholomew's Hospital, London, E.C.1., United Kingdom

Abstract—*A survey was undertaken to define the infectious problems which occurred during intensive treatment of acute myeloblastic leukaemia. Two-hundred patients, treated consecutively at a single hospital, were studied. Bacteraemia, pneumonia and wound infecions were the most common infectious problems; the most important bacterial pathogens were* Escherichia coli, Pseudomonas aeruginosa *and* Staphylococcus aureus. *The presence of severe neutropenia and/or falling granulocyte count were accompanied by a worse prognosis. Patients who had a temperature of at least 38°C at initial presentation had a significantly worse complete remission (CR) rate ($P<0.015$) and survival rate ($P<0.01$) than patients who were afebrile; this difference could not be explained by more frequent early death in the febrile group.*

Presence of fever at diagnosis, like age and platelet count, is thus an important prognostic factor. A scoring system, based on these diagnostic features, should help to identify those patients who, because of high probability of entering CR, should be aggressively treated. Conversely, the outlook for non-responding patients may be improved by the delivery of less intensive chemotherapy when probability of entering CR, based on criteria available within hours of admission, is very low.

INTRODUCTION

OVER the past decade a number of advances in the management of acute myelogenous leukaemia (AML) have been made as a result of more effective chemotherapy, better supportive care and the introduction of immunotherapy [1–3]. Despite small increases in survival, the disease remains almost universally fatal. Since the advent of fresh platelet transfusions has reduced the morbidity and mortality of haemorrhage [4], overwhelming infection during periods of neutropenia has become increasingly important as a cause of death [5]. It is well recognized that the risk of infection in patients with acute leukaemia is inversely proportional to the circulating granulocyte count at levels below 1000 cells/mm^3 and that delay in treating such infections may seriously hinder the likelihood of response [7]. Empirical treatment of febrile neutropenic patients with broad-spectrum antibiotics has therefore become more widely employed. Since the optimal design of empirical antibiotic regimes relies on a knowledge of common pathogens, documentation of the infectious problems during induction of first remission in AML is important. In this survey we have studied the pattern of bacterial infection seen during the initial intensive remission induction period, the importance of fever as a presenting feature, and the relative effectiveness of a variety of antibiotic combinations.

MATERIAL AND METHODS

The study population consisted of 200 consecutive patients with AML, all treated at a single hospital from 1971 to 1975. The age range was 14–74 yr (mean age 49.6). Only four patients

had received significant previous treatment (usually with 6-mercaptopurine or methotrexate). Unequivocal diagnosis of AML or a variant (including acute promyelocytic, acute myelomonoblastic, acute erythroblastic or acute monoblastic leukaemia) was confirmed in all cases by bone marrow puncture.

On admission to hospital, routine surveillance cultures were performed on all patients. These included swabbing of nose and throat; culture of urine and blood; and culture of stool specimens if diarrhoea was present. Infected lesions were always swabbed. Routine cultures for anaerobic organisms were not performed unless indicated clinically. As well as haematological and biochemical tests, a chest X-ray was always obtained. Almost all patients received intensive chemotherapy, either with one or more courses of cytosine arabinoside and daunorubicin, or with cytosine arabinoside, adriamycin, vincristine and prednisolone, in an attempt to achieve a complete remission (CR). Some patients later received other drugs in addition; these included vincristine, prednisolone, 6-thioguanine and cyclophosphamide. Most patients became severely neutropenic (<200 cells/mm^3) during the first few weeks after treatment was commenced. If the patient became febrile, all cultures were repeated and further chest X-rays were taken throughout the febrile period; at least one further set of blood cultures (2–3 bottles per set) was obtained before instituting antibiotic treatment.

The chief criterion for administration of antibiotics was the presence of fever of at least 38°C on two consecutive occasions, separated by a 2–4 hr interval. In patients who had fever which was thought to be due to administration of blood products or a drug allergy, antibiotic therapy was withheld until it seemed likely that the continued fever could no longer be ascribed to these factors. If bacteriological documentation of infection was obtained, these data dictated further therapy. If the organisms were sensitive to agents used in the empirical regime, these drugs were continued. In the absence of bacteriological proof, the antibiotics were continued if fever defervescence was judged to be satisfactory. Administration of antibiotics continued for 5 days after fever had returned to normal. If there had been no response to the fever at 5 days, the empirical antibiotic regime was discontinued and an alternative regime was commenced. Response to antibiotic therapy was considered successful if fever abated within five days of institution of antibiotic therapy and symptoms and signs of infection had cleared by this time. However, in some clinical situations, healing of infected lesions, such as large abscesses or radiologically evident pneumonias, though clearly occurring by five days, was not complete. If such lesions continued to improve and eventually showed complete resolution, these were also judged to be successful responses to the empirical antibiotic therapy. If fever defervescence was obtained but bacterial cultures were still positive, this was judged to be a failure. Other failures of therapy were judged to have occurred when there was no fever defervescence, when febrile patients died after an adequate trial (48 hr) of antibiotic therapy, or if cultures were positive even in the absence of the fever at any point during therapy. Equivocal responses were considered as treatment failures. Episodes of presumed infection were considered evaluable unless patients died within 24 hr of commencing antibiotic therapy.

Laminar airflow rooms were not employed and patients were almost always nursed on an open ward. In a small number of cases (34 courses of antibiotic therapy out of a total of 619), evaluation was not possible because of inadequate data.* All statistical analyses were performed using the chi-squared test with Yates' correction (1 degree of freedom), unless explicitly stated otherwise.

RESULTS

Frequency of infection during remission induction of AML

Only 5 of 200 patients remained afebrile throughout the entire period of remission induction. The average number of antibiotic treatment courses during this period was 3.1 patient. Positive bacteriological culture was obtained on 398 occasions (Table 1). The commonest bacterial species (all sites) were *E. coli*, *Staph. aureus* and *Ps. aeruginosa*. Although the frequency of infection with most organisms remained constant throughout the study period, there was an unusually high incidence of pseudomonas infections in 1972–1973.

Bacteraemia was encountered on 60 occasions; organisms causing bacteraemia were similar to those causing other infections (Table 2). *Staph. albus* bacteraemia was only considered significant in the 17 cases in which the organism was grown from all bottles of culture medium on two consecutive occasions within 48 hr. *Pseudomonas* and *Klebsiella* were equally frequent causes of Gram-negative bacteraemia as *E. coli* and *Staph. albus* was more commonly cultured from blood than expected from its incidence at

*Failure to evaluate these episodes was chiefly due to inadequate records of cause of fever (17 episodes) or outcome (12 episodes).

Table 1. Positive bacterial cultures (all sites included) in 200 patients with AML at St Barholomew's Hospital over a 5-yr period

**Staph. albus* bacteraemia was only considered significant in the 17 cases in which the organism was grown from all bottles of culture medium on two consecutive occasions within 48 hr.

Fever, remission and survival

The presence of fever on admission to hospital was an adverse prognostic sign (Table 3). A CR was obtained in 39/93 (42%) of patients who were afebrile (<37°C) on admission, whereas a CR was obtained only in 26/107 (24%) of patients who were febrile (>37°C) on admission ($0.012 < P < 0.015$). This was *not* chiefly due to more frequent early deaths in the febrile group, since the CR rate in patients surviving at least four weeks from diagnosis was 39/74 (53%) of initially afebrile patients and 26/74 (35%) of initially febrile patients ($P < 0.05$). Thus patients who were febrile on admission retained their poor prognosis *even if they survived their initial infection*. A slightly greater number of initially febrile patients succumbed, however, during the first four weeks (33/107 initially febrile patients compared to 17/93 in the afebrile group: $P > 0.05$).

Survival was also significantly different in the two groups. Initially afebrile patients had a mean survival of 8.6 months whilst initially febrile patients had a mean survival of only 5.0 months (all patients included, whether in remission or not: $P < 0.01$).

Patients who were febrile on admission to hospital also differed haematologically from afebrile patients, but not in the important prognostic variables of age and initial platelet count (Table 4). Mean initial white blood count (WBC) and absolute blast count (BC) were significantly lower for afebrile patients (WBC: $23.2 \pm 4.7 \times 10^3/mm^3$ vs $55.7 \pm 10.2 \times 10^3/mm^3$; BC: $15.9 \pm 4.2 \times 10^3/mm^3$ vs $37.7 \pm 6.9 + 10^3/mm^3$). However, despite this correlation, the influence of initial WBC and BC on probability of CR was not statistically significant (WBC: $P > 0.12$; BC: $P > 0.20$, log rank test). Initially febrile patients who achieved a CR had lower presenting WBC's than febrile patients who failed to achieve CR ($39.4 \pm 9.6 \times 10^3/mm^3$ vs $59.5 \pm 13.0 \times 10^3/mm^3$) but this trend was not statistically significant. The same trend was

Table 3. Prognostic importance of fever on first admission to St. Bartholomew's hospital with newly-diagnosed AML

observed for presentation BC ($29.6 \pm 9.2 \times 10^3$/mm^3 vs $37.4 \pm 8.6 \times 10^3$/mm^3).

Influence of age and initial platelet count

As noted elsewhere for substantially the same group of patients [8], both age and initial platelet counts were important predictors of response to antileukaemic therapy. Complete responses were obtained in 7/10 (70%) of patients under 20 yr, 29/61 (47.5%) of patients aged 20–40 yr, 23/76 (30%) of patients aged 41–60 yr and 12/53 (23%) of patients over 60 yr. Mean age of all complete responders was 39.8 yr, whilst that of non-responders was 46.8 yr, ($P < 0.01$, log rank test). *CR* was achieved in 42% of patients presenting with platelet counts above 20,000/mm^3 and only 27% of patients whose presenting platelet counts were below this figure ($P < 0.05$, log rank test). Age, probability of fever on admission and platelet count were independent; mean age of all initially afebrile patients was 48 yr, whilst that of all initially febrile patients was 45.5 yr ($P > 0.5$). Mean platelet counts were almost identical in the febrile and afebrile groups (Table 4).

Influence of granulocyte counts during therapy

Likelihood of successful response to antibiotic therapy was influenced both by the initial granulocyte count (at the onset of fever) and the change in granulocyte count during the febrile episode (Tables 5 and 6). Two hundred and fifty-four episodes of fever (in which absolute granulocyte counts were available on the first and last day of the febrile episode) were analysed. Overall response rate in this group was 61%, which was not significantly different from the response rate observed for the complete group. Of 20 episodes which proved fatal, 15 occurred in patients whose granulocyte count at the start of the fever was less than 100/mm^3. With initial granulocytopenia to less than 100 cells/mm^3, success rate was only 45%, whereas success rates of over 70% were seen if the initial granulocyte count was greater than 100 cells/mm^3. Favourable response was most likely if a rise in granulocyte count occurred during the course of the treatment. In 68/78 (88%) of such courses, there was a good response, regardless of the initial granulocyte count (Table 6). If granulocytes fell during therapy, only 64/109 (59%) of courses were successful. In 45 cases, febrile episodes occurred during periods in which granulocytes were totally undetectable throughout the course of treatment; 11 (24%) of these episodes proved fatal. Most infections occurred during extreme periods of marrow aplasia; the median granulocyte count at which fever was first noted to be present was 140 cells/mm^3 (standard error ± 24 cells/mm^3).

Table 5. Influence of initial granulocyte count on response to antibiotic therapy

Absolute granulocyte count (cells/mm^3)	Type of response: Success		Non-fatal failure		Fatal failure	
	No.	%	No.	%	No.	%

*Additional positive cultures of doubtful significance were obtained from throat and nose swabs, as follows: Haemolytic *Streptococci* (20 patients), *E. coli* (15 patients), *S. aureus* (31 patients), *Pseudomonas aeriginosa* (5 patients), *Enterococcus* (3 patients). *Mycoplasma pneumoniae* (1 patient), *Proteus* spp. (1 patient).

Site and prognosis of infection in AML

A total of 69 patients died during the study period; in 62 of these, infection was considered to be a significant contributing factor. Regardless of the empirical regime used, the probability of successful response was dependent on the site of infection (Table 7). The worst prognosis was seen in patients with Gram-negative septicaemias (fatal in 54% of 26 cases) and pneumonias (32% fatal in 105 cases). The presence of positive sputum-culture during the episode of pneumonia did not influence prognosis. Patients with documented Gram-positive bacteraemia had a significantly higher survival rate ($P<0.05$) than those with a Gram-negative bacteraemia. Failure of response to antibiotic therapy was usually fatal in pneumonia and invariably fatal in septicaemia. Failure of soft tissue or surface lesions to respond to antibiotic therapy was unusual (6/49 failures). All six soft-tissue failures were associated with perianal or anorectal abscess, fistula or fissure. Twelve such lesions were documented; six were successfully treated with antibiotics with or without surgical drainage.

Empirical antibiotic regimes

The choice of empirical antibiotic combinations reflected the availability of newer and more promising antibiotics over the past 5 yr (Table 8). All antibiotics were routinely given by the intravenous route, with the exception of the first two pairs of agents, which were usually

Table 8. Five yr empirical antibiotic therapy in febrile neutropenic patients with AML

		507	58

given by mouth. The overall response rate (all combinations, all evaluable treatment courses included) was 58%, with a gradual improvement in response rate during each year of the study period. Since fresh platelet transfusions and granulocyte transfusions have been available in this unit throughout the whole period, the improvement in response rate is unlikely to be due to better supportive care in recent years.

DISCUSSION

As with previous studies [5, 9, 10], infection during periods of neutropenia was the chief cause of death in our patients undergoing remission induction for AML. Although patients who were febrile on admission were at an increased risk of death during the first four weeks after diagnosis, this trend was not statistically significant, unlike the study of Yates and Holland [11]. In our patients, presence or absence of fever on admission was clearly of prognostic importance, even when all deaths within the first four weeks (usually the result of infection) were excluded from analysis. In the study by Carey *et al.*, patients who were febrile at presentation were less likely to enter CR, but the reasons were unclear [12]; in particular, it was not stated whether such patients failed to enter CR because of more frequent early death. In the present study, the better prognosis of the initially afebrile patients, both for remission ($P<0.015$) and survival ($P<0.01$), remain largely unexplained, and cannot be accounted for on the basis of lower mean age or higher initial platelet count.

Since initial blast count in the peripheral blood was lower in this group ($P<0.008$), such patients presumably had a smaller tumour burden; however, initial total blast count and total white blood count are not usually considered to be major risk factors [13] and their influence in the present study did not reach statistical significance. An alternative explanation is an increased likelihood of reinfection in patients who were initially febrile since such patients may harbour pathogenic organisms more frequently.

Particularly lethal were the Gram-negative septicaemias and pneumonias, although the death rate from pneumonia in this series was approximately half the mortality rate noted by Sickles *et al.* in a group of 68 patients with acute leukaemia [14], presumably reflecting the greater efficacy of prompt antibiotic treatment when given almost immediately a fever of 38°C was observed in any neutropenic patient. In the study by Viola [9], pneumonia constituted four of 33 leukaemia deaths, but pneumonia with bacteraemia was responsible for a further ten deaths. In a study of 22 cases of perianal or anorectal complications of leukaemia, Sehdev *et al.* reported a fatality rate of 7 deaths out of 18 episodes in patients with acute leukaemia [15]. Our experience was similar, with three fatalities amongst 12 patients.

Since bacteriological documentation of infection may require two or more days, the use of empirical antibiotic therapy for febrile episodes during periods of neutropenia is now widely accepted [16]. Many empirical combinations have been reported [17—19] and treatment has usually been instituted after 48 hr if fever persists. Our practice since 1971 has been to wait no longer than four hours, providing that obvious non-infectious causes of fever can be excluded. The potentially dangerous drawback of low bacteriological confirmation rate has probably been offset by the gradually improving response rates, especially since the more widespread use of high doses of carbenicillin. Other groups have also confirmed relatively good response rates in neutropenic patients treated with combinations which include this antibiotic [17, 20].

In this hospital the chief agents identified during the 5 yr study period were *E. coli* (108), *Staph. aureus* (80) and *Ps. aerguinosa* (47). *Pseudomonas* infections appeared to be particularly common in 1972–1973, and this changing trend of bacterial flora has been noted elsewhere [21]. It seems logical therefore to include an aminoglycoside antibiotic in any empirical regime. Because of the continuing and serious danger of pseudomonas infections, a combination of an aminoglycoside such as gentamicin or tobramycin with large doses of carbenicillin, should provide adequate antibacterial cover. Good evidence now exists for therapeutic synergism between gentamicin and carbenicillin [22]. Since tobramycin is superior to gentamicin for many strains of *pseudomonas in vivo* [23] (including many gentamicin-resistant strains) [24], it should perhaps be preferred. At present, there are no conclusive data in man which have confirmed that this theoretical advantage is clinically important in neutropenic patients. Concurrent administration of aminoglycosides and high doses of cephalosporins has been implicated as a potential cause of nephrotoxicity [25, 26] and the combination should be used with caution. A large randomised cooperative study has shown that the combination of cephalothin and gentamicin was significantly more nephrotoxic than other equally effective antibiotic regimes [27].

Although empirical antibiotic therapy in febrile neutropenic patients with AML and other malignant diseases has now been widely accepted as proper management, the ideal of a broad-spectrum, effective, non-toxic and cheap antibiotic regime has not yet been realised. Prophylaxis with gut sterilising antibiotic combinations may decrease the likelihood of infection [28], but fails to abolish it entirely. Likewise, the routine use of laminar airflow rooms remains controversial with regard to both cost and value [29]. For established infection, possible alternative measures include therapeutic granulocyte transfusions in patients who are failing to respond to antibiotic therapy [30, 31], the use of transfer factor [32], and the administration of more effective doses of antibiotics already known to be of value by computing dosage on the basis of age, weight, sex and renal function [33]. It is known that satisfactory response to gentamicin therapy in non-neutropenic patients depends on the achievement of appropriate circulating levels [34]; conventional doses may be insufficient to achieve such levels. Closer attention to early treatment of febrile episodes with adequate doses of appropriate antibiotics (with monitoring where necessary) should lead to a greater recovery rate in infected neutropenic patients with AML and therefore an increased likelihood of achieving a complete remission. Moreover, initial assessment of simple presentation characteristics such as age, platelet count and presence of fever may permit the development of a risk-factor scoring system in patients with AML. Since early death is often due to overtreatment of patients in whom achievement of a complete remission is highly unlikely, such a scoring system may allow such patients to be treated less aggressively without aiming for complete remission but with greater emphasis on supportive care. This approach should improve the median survival of non-remitting patients who still comprise approximately one-half of all patients with AML, whilst in no way compromising aggressive attempts to induce a more durable and complete remission in patients who are young, afebrile on admission and not grossly thrombocytopenic.

Acknowledgements—We are indebted to the medical and nursing staff of St. Bartholomew's Hospital, London for their devoted care of these patients. In particular, we wish to record our gratitude to the late Professor Hamilton Fairley, who was largely responsible for their management.

The Immunostimulatory Activity of 3-(*p*-Chlorophenyl)-2,3-Dihydro-3-Hydroxythiazole [3, 2-α]-Benzimidazole-2-Acetic Acid (NSC 208828)*

ALDO TAGLIABUE,† GIULIO ALLESANDRI, NADIA POLENTARUTTI, ALBERTO MANTOVANI, ELENA FALANTANO, ANNUNCIATA VECCHI, SILVIO GARATTINI and FEDERICO SPREAFICO‡

Istituto di Recerche Farmacologiche "Mario Negri". Via Eritrea, 62-20157 Milan, Italy

Abstract—*A preliminary characterization of* 3-(p-*chlorophenyl*)-2,3-*dihydro*-3-*hydroxythiazolo* [3,2-α]-*benzimidazole*-2-*acetic acid was conducted in mice employing tumorous and non-tumorous systems. Single doses of this chemical markedly increased the primary and secondary anti-SRBC response after optimal immunization and raised the GvH-inducing capacity of splenocytes whereas no effects were seen on the response to a T-independent antigen.*

Immunostimulatory doses of the drug did not modify colloidal carbon clearance, macrophage non-specific cytotoxicity towards lymphoma cells or K cell activity in the spleen. Single injections with this agent increased survival in L 1210*Ha leukemia-bearing mice when administered in conjunction with irradiated tumor cells and increased anti-leukemia resistance to subsequent tumor challenges in animals primed with inactivated leukemia cells. Single drug doses* 1 day *after tumor transplantation exerted also a potent antimetastatic effect in the Lewis lung carcinoma system.*

INTRODUCTION

MUCH interest is currently focused on non-specific immunomodulators in view of the favourable results obtained through their use in the treatment of experimental tumors and of at least a number of human malignancies. Attention towards this type of agents has additionally been spurred by preliminary indications of their potential in other conditions in which a disordered or insufficient immune reactivity is believed to be of pathogenic importance such as rheumatic diseases, recurrent or chronic infections, primary immunodeficiencies, etc. [1, 2]. The bacterial origin of the immunostimulants more widely employed in the clinic, i.e. BCG and *Corynebacterium parvum* (*C. parvum*), in addition to being responsible for a number of side effects [3–5], has also resulted in problems of standardization and in difficulties in the analysis of their mode of action. There is thus the need for a larger number of active compounds having defined chemical characteristics, greater ease of employ and different mechanisms of action at the immunocyte subpopulation levels.

This report describes the results obtained in the preliminary characterization of 3-(*p*-chlorophenyl)-2,3-dihydro-3-hydroxythiazole (3,2-α)-benzimidazole-2-acetic acid (NSC 208828, Fig. 1), a synthetic compound possessing definite immunomodulatory capacity.

Accepted 3 October 1977.

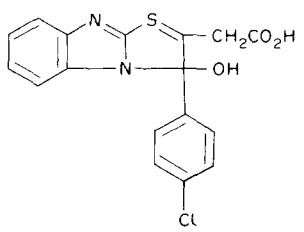
MATERIAL AND METHODS

Animals

Mice of both sexes of the following strains were used: C57Bl/6; C3H, B6D2F$_1$ (C57Bl/6 × DBA/2) and CD2F$_1$ (BALB/c × DBA/2). The animals were obtained from Charles River, Italy (Calco, Italy) and weighed 20–22 g at the start of the experiments.



NSC 208828

Fig. 1. Chemical structure of NSC 208828.

Drugs

NSC 208828, kindly provided by Dr. E. Alburn (Wyeth Laboratories, Philadelphia, Pa.) was freshly suspended in sterile 0.9% NaCl solution containing 1% Tween 80 and administered intraperitoneally (i.p.). Cyclophosphamide (Cy), supplied by Dr. H. J. Wood (DRD, NCI, Bethesda, Md) was freshly dissolved in saline. Suspensions of formalin-killed *C. parvum* (lot 086 P, Wellcome Research Laboratories, Beckenham, England) were diluted with saline and injected intravenously (i.v.) in the dose of 0.7 mg/mouse.

Tumors

The spontaneously metastasizing Lewis lung (3LL) carcinoma was maintained and transplanted intramuscularly (i.m.) in C57Bl/6 mice, its strain of origin, the standard inoculum being 2.10^5 viable cells; the extent of pulmonary metastatization was assessed as previously described [6]. The L1210 Ha Leukemia, i.e. a subline previously described as being immunogenic in compatible hosts [7], was maintained by weekly i.p. passages in syngeneic DBA/2 mice (H-2^d) whereas for experimental tests it was transplanted in compatible $CD2F_1$ (H-2^d/H-2^d) or allogeneic C3H (H-2^k) mice.

Response to sheep erythrocytes and type III pneumococcal polysaccharide

Conditions for the assay of primary spleen hemolytic plaque-forming cells (PFC) after the i.p. injection of 10^8 sheep erythrocytes (SRBC) were as previously described [6]; for secondary responsiveness mice were given two equal SRBC inocula 10 days apart and indirect PFC developed using optimal dilutions of commercially available rabbit antiserum to mouse gamma globulins. For type III pneumococcal polysaccharide (S III, a gift of Dr. P. J. Baker, NIAID, NIH, Bethesda, MD), the optimally immunizing dose of 0.5 μg was administered i.p. and specific anti-SIII PFC measured as detailed elsewhere [7].

Graft vs Host (GvH) assay

GvH was assessed by the popliteal lymphnode weight gain assay [8]. Recipient $B6D2F_1$ (H-2^b/H-2^d) female mice immunodepressed 24 hr before with 100 mg/kg i.p. Cy, were injected into the right hind footpad with a suboptimal number (3×10^6/0.05 ml) of splenocytes from control or drug-treated C3H mice of the same sex. Equal numbers of formol-inactivated cells were injected contralaterally. Both popliteal lymph nodes were collected 7 days later and the ratio between the weight of the right and left nodes (lymphnodal index) taken as a measure of the severity of GvH [9].

Clearance of colloidal carbon

The procedure of Biozzi *et al.* [10] was employed injecting $CD2F_1$ mice with 320 mg/kg i.v. of colbidal carbon (Pelikan ink, lot C11/1431/A).

Macrophage cytotoxicity

The cytotoxic capacity of purified peritoneal macrophages from $CD2F_1$ mice towards exponentially growing SL2 and TLX9 lymphoma cells was evaluated after 48 hr incubation by cell counting of the surviving lymphoma cells and by their uptake of tritiated thymidine following experimental conditions previously reported [11].

K cell activity assay

Technical conditions employed to evaluate in $CD2F_1$ mice spleen K cell activity against chicken erythrocytes as targets were as detailed previously [12].

Statistical analysis

Statistical significance of the differences in mean survival times (MST) was assessed by the Mann–Whitney U test, each experimental group consisting of at least 10 mice. Statistical significance for the other parameters was established by Duncan's new multiple range test with experimental groups consisting of at least 6 animals.

RESULTS

Effects of NSC 208828 on immune reactivity

The capacity of single i.p. injections of NSC 208828 (100 mg/kg) to influence the primary response of $CD2F_1$ mice to SRBC was firstly investigated, administering the drug on various days in relation to antigen and counting the PFC 4 days after SRBC, i.e. at the peak response in these conditions. Significant increases in PFC numbers were

Table 1. *Time-dependency of the effect of NSC* 208828 *on the primary anti-SRBC response*

Day of treatment	PFC/Spleen
—	24,230 (17,420–33,710)

Table 2. *Effect of different doses of NSC* 208828 *on the primary anti-SRBC and anti-S* III *responses*

Dose (mg/kg i.p.)	PFC/Spleen	
	anti-SRBC	anti-S III
—	24,500 (20,010–30,000)	8,700 (6,900–10,300)
25	30,700 (24,100–37,450)	8,230 (6,710–9,930)
50	62,900* (44,740–81,530)	8,460 (5,130–11,420)
100	77,270† (56,900–93,870)	9,275 (9,390–10,250)
150	63,050* (56,900–79,990)	9,550 (8,630–10,340)
200	19,960 (16,360–24,350)	N.T.

$CD2F_1$ mice (6 per experimental group) were injected i.p. with 10^8 SRBC or 0.5 μg S III on day 0, drug was given on day 2 and the assay performed on day 4 and 5 for SRBC and S III, respectively. Values shown are means of 3 experiments.

*$P<0.05$; †$P<0.01$.

observed (Table 1) only when the drug was given after immunization, pre or concomitant treatments being inactive in these conditions. Table 2 shows the dose–response relationship obtained with drug treatments performed 48 hr after SRBC; whereas doses of 25 or 200 mg/kg did not produce significant changes in PFC values, the injection of 50, 100 or 150 mg/kg resulted in a trebling of the PFC response. A similar increase in PFC values was present also when the assay was performed 7 days after SRBC and approximately a doubling in the total number of spleen direct and indirect PFC was seen when 100 mg/kg of the chemical was injected 48 hr after a second SRBC challenge and the test was performed after a further 2 days (data not shown). The effects of this compound on the primary response to a T-independent antigen such as S III was next investigated. As presented in Table 2, treatments with this agent capable of markedly augmenting the anti-SRBC response were not significantly effective in modifying the number of peak (day 5) anti-S III PFC in the spleen, and a follow-up of the response at later days also failed to evidentiate significant differences between control and drug-treated animals.

In order to obtain informations on the activity of NSC 208828 on cellular reactivities, its effect on the GvH-mounting capacity of lymphoid cells was studied. As shown in Table 3, whereas a single injection of 50 mg/kg one day before sacrifice of the cell donor resulted in a modest and not significant increase in the splenocyte capacity to induce a GvH, a clear activity was seen with 100 or 150 mg/kg, the percent increases in lymph-

nodal index over controls being in fact 63 and 81%, respectively. Studies were also conducted to investigate the effects of this chemical on allogeneic tumor growth. As illustrated in Table 4 by representative data, the treatment with this drug of C3H recipients 24 hr before the transplant of incompatible L1210 Ha leukemia cells was followed by an increase in the number of progressive tumor takes evident at all drug doses tested, although the effect reached statistical significance only after doses of 50 or 100 mg/kg. In view of the effects of various immunomodulators on macrophages, the functional capacity of these elements in animals treated with NSC 208828 was explored. No significant modifications in colloidal carbon clearance were however detected after the administration of otherwise active doses of the compound; for instance, values of 0.026 and 0.029 were calculated for the granulopectic index in control and $CD2F_1$ mice given 100 mg/kg i.p. of this agent 3 days before assay. In the same conditions a value of 0.043 ($P<0.05$) was measured in mice given 0.7 mg i.v. *C. parvum*, employed as positive control agent. Furthermore, purified peritoneal macrophages collected from $CD2F_1$ mice 7 or 15 days after the administration of 100 mg/kg NSC 208828 did not exhibit any significant cytotoxic activity towards cultured SL2 or TLX9 lymphoma cells as assessed either by tumor cell counts or by measuring the incorporation of radiolabelled thymidine in lymphoma cells. In the same testing conditions, the i.v. injection of 0.7 mg *C. parvum* resulted in 80–90% growth inhibition of the target tumor cells. Lastly, the effect of this drug on spleen K cell activity was investigated employing again

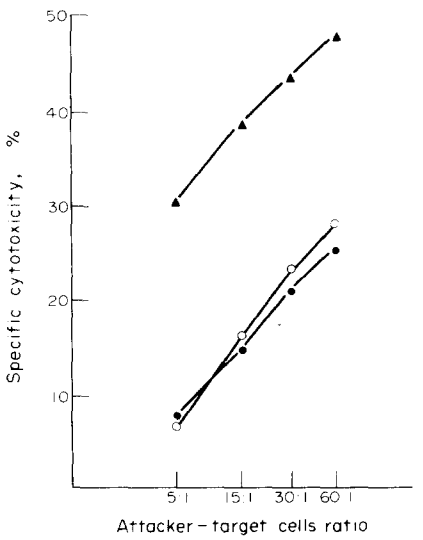

Fig. 2. *Spleen K cell activity in* $CD2F_1$ *mice* 7 days *after treatment with NSC* 208828 (100 mg/kg *i.p.*, ○———○), C. parvum (0.7 mg/*mouse i.v.*, ▲----▲) *or saline* (●———●).

C. parvum as a positive reference compound [1]. As shown in Fig. 2 where the data of one representative experiment performed testing the spleen cells 7 days after the injection of 100 mg/kg NSC 208828 are presented, no significant stimulation of K cell activity in respect to controls could be found. Similarly negative results were observed with drug doses ranging from 25 to 200 mg/kg and testing the splenocytes from 1 to 15 days after treatment.

Antitumoral effect of NSC 208828

The capacity of this agent in conjunction with a tumor cell vaccine to increase the survival of $CD2F_1$ mice subsequently challenged with graded numbers of the compatible L1210 Ha leukemia was firstly examined. Table 5 shows that single injections of 100 mg/kg of this drug could potentiate the protective effect exerted by the inactivated leukemia cells as evidenced by the significant extra increase in survival found when a challenge of 10^6 live leukemia cells was used and by the obtainment of a consistent proportion (30–50% in 4 such experiments) of cures (i.e. over 90 days survivors) when the challenge was of 10^5 L1210 cells. No significant increase in MST in respect to untreated controls was seen when 100 or 150 mg/kg of the drug was given on day 1 or on days 1–4 to $CD2F_1$ hosts transplanted with 10^4 or 10^3 L1210 cells i.p. or s.c. In contrast an antitumoral activity was seen when NSC 208828 was given together with 10^7 X-rayed leukemia cells i.p. 24 hr after the s.c. transplant of

10^4 cells of the immunogenic L1210 Ha subline (Table 6).

A clearer antineoplastic activity was on the other hand seen in the 3LL carcinoma system, in which single injections of the compound given 1 day after tumor transplant produced significant reductions in both the number and weight of the lung metastases although no detectable effects were exerted on the weight of the primary i.m. tumor (Table 7). In these conditions, the administration of 25 mg/kg of the compound showed a significant antimetastatic effect in only 1 of 2 experiments, whereas consistent results were observed with 50 or 100 mg/kg and the highest activity was found with a dose of 150 mg/kg, a treatment which also resulted in the absence of detectable lung metastases in 40–60% of the animals in 3 experiments. It may be noted that using the same treatment conditions, an optimal dose of 3 mg/kg i.p. of Levamisole, i.e. a dose previously shown to possess immunostimulant activity [6], was ineffective.

DISCUSSION

An immunostimulatory capacity for NSC 208828 has previously been advanced by Fenichel *et al.* [13] on the basis of its anti-metastatic activity in the 3LL system, which was absent in previously immunodepressed mice, and of its capacity to increase circulating T lymphocytes in rats. Our findings that single doses of this chemical can markedly stimulate in mice the primary and secondary response to SRBC and the capacity of lymphoid cells to mount a GvH reaction, provide direct evidence to support the conclusion of an activity of this agent on the immune system.

Moreover the data obtained in the L1210 Ha leukemia system showing that NSC 208828 increases the protective effect of X-rayed

leukemia cells towards subsequent live tumor challenges, further supports the conclusion that the antitumoral activity of this drug is attributable to its immunostimulatory capacity.

It may additionally be noted that the compound was not cytotoxic *in vitro* for L1210 Ha cells at a concentration of 200 μg/ml (unpublished data). The possibility of inducing allogeneic tumor enhancement by pretreatments with active doses of this agent parallels previous demonstrations of a similar effect with other well known immunomodulators, such as *C. parvum* [14], BCG [15], Levamisole [16] and Pyran copolymer [17]. Since the mechanism(s) responsible for this effect of NSC 208828 have not been investigated, the possibility of a production of blocking factors as seen for tumor enhancement after BCG or Levamisole [16, 18] is just one of the possible hypotheses which can be advanced.

In regard to immunocyte subpopulation(s) stimulated by this drug, in view of its activity on the T-B dependent anti-SRBC response and the absence of detectable effects when the T-independent S III antigen [19] was employed, it would appear that T-lymphocytes are among the targets for this compound. This tentative conclusion is supported by our finding of a stimulation of GvH, a reactivity known to be dependent on T cells for its expression [20]. The relative importance of an increase in the functional capacity of these cells and of an expansion in their numbers is still to be determined. We have in fact found that total spleen cellularity was approximately doubled 7 days after the injection of 100–150 mg/kg of NSC 208828 in mice (unpublished data), an observation which may parallel the finding of an increase in circulating T lymphocyte numbers in normal rats [13].

In the conditions employed, phagocytes did not appear to be significantly influenced by clearly immunostimulatory doses of this chemical as indicated by the absence of changes in the rates of colloidal carbon clearance and in the capacity of purified peritoneal macrophages to non specifically inhibit tumor cell growth. Also unchanged by this drug was the activity of K cells, i.e. of the elements mediating antibody-dependent cellular cytotoxicity, a mechanism currently credited with an important role in tumor control [21, 22], although the precise nature of its effector cell(s) is still matter of debate. In this respect, this agent appears similar to Levamisole a chemically related drug whose capacity to restore to normal levels depressed immune reactivities has been the object of much recent interest [1, 23, 24] and which has been shown to be inactive on K cells in the same system [1]. Levamisole is also believed to exert its effects mainly through T lymphocytes [1, 6] although activites on macrophage-monocytes and polymorphonuclears have also been described [1, 23]. A more definite comparative evaluation of these two chemicals must wait however further studies.

In these experimental conditions the active dose range was generally comprised between 50 and 150 mg/kg and indications were obtained

for best effectiveness at the latter dose level and for a disappearance of activity at still higher dosages, at least in the anti-SRBC system. If confirmed in a larger number of conditions, the latter finding would be an analogy to what seen with other immunomodulators for which the treatment conditions as regards, for instance, dose and timing of injection in respect to the stimulus, can often be critical. It is clear, therefore, that the therapeutically most effective conditions of treatment with this compound have still to be more firmly established through a more systematic analysis in a wider series of experimental models. In conclusion thus, although NSC 208828 has been shown to possess a number of interesting properties, (e.g. potent immunostimulatory activity after single treatments in both neoplastic and non neoplastic systems, capacity to synergize with chemotherapy and effectiveness after oral administration [13] a wide margin of safety between active and toxic doses), further experimentation is necessary before its therapeutic potential is fully assessed and its value relative to other immunomodulators established.

Abstract—*Microscopic alterations of canine bronchial epithelium were studied during the course of recurrent localized carcinogen exposure. Varying sequences and administrations of benzo(a)pyrene and/or* N-*methyl*-N-*nitrosourea were applied to* 5 *groups of dogs. After a period of study ranging from* 24 *to* 34 *months, a relatively orderly progression of epithelial alterations was appreciated, regardless of the type of treatment, based upon monthly biopsies of the site of carcinogen administration. The initial lesion was that of hyperplasia of the columnar cells with occasional intra-epithelial gland formation. Basal cell hyperplasia and squamous metaplasia ensued and were frequently coexistent. Atypical epithelial maturation was noted in all dogs, especially in those whose biopsies exhibited squamous metaplasia. Control sites revealed no epithelial abnormalities. These studies define the evolution of apparently pre-neoplastic bronchial epithelial lesions and also establish the dog as an ideal experimental model for studying the sequence of events during induction of bronchial carcinomas.*

INTRODUCTION

THE EXPERIMENTAL induction of pulmonary carcinoma by chemical means has been achieved by several groups of investigators, but the resulting cancers have not been analogous to the very common bronchogenic carcinomas in man. For example, multicentric carcinomas have been induced in the Syrian golden hamster by intratracheal administration of benzo(a)pyrene (BP) [1], *N*-methyl-*N*-nitrosourea (NMU) [2], or 7H-dibenzo(c,g)carbazole [3]. Schreiber and coworkers have induced circumscribed tracheal cancers with NMU in hamsters [4]. In dogs, Staub *et al.* [5] have caused bronchial carcinomas using 9, 10-dimethyl-1, 2 benzanthracene and Nakajima and co-workers [6] used 20-methyl-cholanthrene to induce cancers. These and other animal models do not usually allow for precise localization of carcinogens, and, therefore, for localized tumor production. In addition, the resulting neoplasms do not always allow for serial observations of oncogenesis. Because the tumors induced may not be similar to the human disease, we are working at producing and studying localized bronchial carcinomas in dogs utilizing a method of recurrent localized intrabronchial injections and/or applications of carcinogens [7]. Our microscopic morphologic observations made serially during a period ranging from 24 to 34 months, and following carcinogen exposure, constitute this report.

MATERIAL AND METHODS

Five groups of dogs were studied (Table 1). In Group I the carcinogen was BP (15 mg/ml) attached to a ferric oxide carrier as suggested by the work of Saffioti *et al.* [1]. For Group II, NMU freshly dissolved in saline at a concentration of 15 mg/ml was used. For Groups III, IV and V, sequential administration of the two carcinogens was employed. In Group III, BP was injected recurrently into the submucosa until squamous metaplasia was induced, and in Groups IV and V, BP was injected for 7 months;

Table 1. Summary of experimental design

	Test animal	No. dogs	Carcinogen	Volume (ml)	Concentration (mg)	Total dose (mg)	Method	Maximum duration (months)
Group I	Mongrel	7	BP-Fe_2O_3	3	15	810	Submucosal injection	32
Group II	Mongrel	8	NMU	3	10–15	810–945	Submucosal injection	28
Group III*	Mongrel	6	BP-Fe_2O_3	3	15	405–1620	Submucosal injection	11
			NMU	0.5	10	240–360	Mucosal application	16
Group IV*	Inbred Beagle	12	BP	0.5	30	315	Submucosal injection	7
			NMU	0.5	10	135	Mucosal application	17
Group V*†	Inbred Beagle	21	BP	0.5	30	315	Submocosal injection	7
			NMU	0.5	10	135	Mucosal application	17

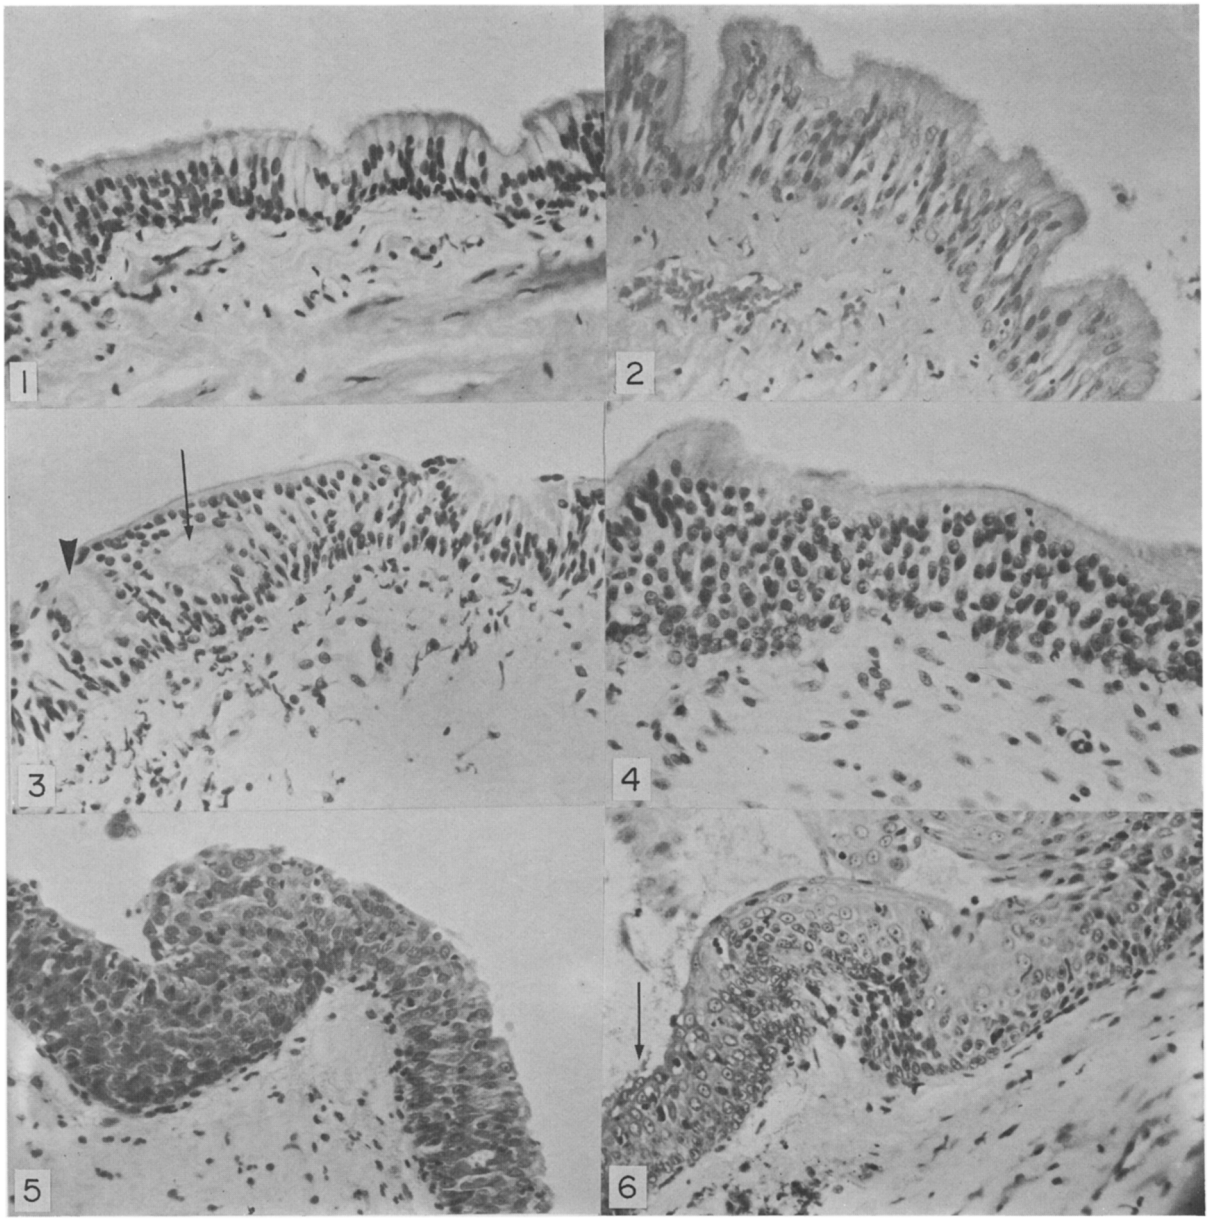
BP—3,4 benzo(a)pyrene.
NMU—*N*-methyl-*N*-nitrosourea.
*BP injections were continued until the appearance of squamous metaplasia at the site of administration; thereafter, NMU was applied locally and BP was discontinued.
† Group V dogs were treated with azathioprine and prednisolone to achieve chronic immunosuppression.

thereafter, the weekly BP injections were discontinued and replaced by topical NMU (5 mg) applications at that same site. This is a modified schedule of that found to be effective in hamsters by Kaufman and Madison [8]. Groups IV and V differed from Group III in that BP was not attached to Fe_2O_3 but injected in a steroid suspension medium. Groups IV and V differed from one another in that Group V dogs were given azathioprine (2.5 mg/kg) and prednisolone (1.0 mg/kg) daily in order to study the effects of immunosuppression on carcinogenesis. Serial monitoring of this regimen was performed after 2, 5 and 9 months of treatment. Antibody responses to bovine and rat red blood cells and chicken gamma globulin were determined to measure humoral immunity. Cell mediated immunity was assessed on the basis of split thickness skin allograft survival; a single mongrel dog served as the common donor for all allografts. Delayed cutaneous hypersensitivity responses to rabies vaccine, distemper–hepatitis–leptospirosis vaccine, and 3,5 dinitro chlorobenzene were determined. Dogs in Group IV served as controls [9].

The origin of the right intermediate (accessory) lobe bronchus served as the site of carcinogen administration. BP was injected into the submucosa in all instances and NMU was applied topically except in Group II dogs where it was also injected. Weekly bronchoscopies at the time of carcinogen administration, and monthly biopsies were performed in all animals. Bronchoscopies and biopsies were continued following cessation of carcinogen exposure. The origin of the left lobe bronchus served as the control site where the solvents for the corresponding carcinogens were administered in the same manner as the carcinogens. Biopsies of control sites were taken at the same intervals as those of the experimental site.

Exposure of the bronchial mucosa to carcinogen was accomplished using a modified esophageal varices needle. For the injection procedure, the tip of the needle was shortened to avoid deep penetration of the submucosa or lung parenchyma. For the topical application procedure, a small sponge was attached to the end of the needle through which soluble carcinogen could be quantitatively applied to the mucosal surface. Targetting of these procedures to the desired location was assisted by direct vision bronchoscopy. A more detailed description of instrumentation and techniques has been previously reported [10].

Fragments of tissue (2 mm) were obtained with biopsy forceps through the bronchoscope. The specimens were fixed in 10% neutral



Note: All sections are stained with hematoxylin and eosin. Number of weeks refers to time after onset of carcinogen application.

buffered formalin, dehydrated in alcohols, embedded in paraffin, sectioned at 4–5 μm and stained with hematoxylin and eosin.

In evaluating the microscopic findings, we established these criteria for defining the observed alterations:

Normal—The usual mucociliary pseudostratified respiratory epithelium prevails.

Columnar hyperplasia—The mucosa is thickened, there is an increase in layers of columnar cells.

Basal hyperplasia—The basal or reserve cells, which are small and inconspicuous, become enlarged, polygonal and prominent. Thereafter, they increase in number and add more strata of cells to the mucosa. Although the surface may be composed of ciliated respiratory epithelium, ultimately the basal cells replace the overlying columnar cell element. Mucous cells are usually absent. Other terms for basal cells are germinative [11] or transitional cells [12].

Squamous metaplasia—The mucosa is composed of nonkeratinizing stratified squamous epithelium; keratin is occasionally produced.

Atypia—There is abnormal cellular maturation and/or clusters of cells with an altered nucleocytoplasmic ratio, irregular hyperchromatic nuclei and loss of nuclear polarity. In this lesion, mitotic figures, sometimes of abnormal configuration, are present in various locations in the epithelial layers. Although atypia may be a feature of columnar and basal hyperplasia, it is most frequently associated with squamous metaplasia.

RESULTS

This report is based upon 943 histologic observations from 54 dogs in our study. Neither the various carcinogenic regimens nor the use of adjuvant immunosuppressives, altered the morphogenesis of the abnormalities during the period of this study.

All biopsies prior to the administration of carcinogens were normal (Fig. 1). Microscopic bronchial mucosal and submucosal abnormalities were induced in all dogs. They appeared an average of 7 weeks (range 4–16 weeks) after initial instillation of carcinogens. All dogs had mucosal abnormalities within 3 months.

Hyperplasia of the columnar epithelial cells was observed as the earliest alteration (Fig. 2). In its most pronounced form it was associated with adenomatous transformation of portions of the mucosa and with intramucosal gland formation ("adenomatosis") (Fig. 3). Although columnar hyperplasia was sporadically noted during the course of observation, it was most often present within the first 3–6 months. Proliferation of basal cells (Fig. 4), which was the most frequent change, occurred as the sole mucosal abnormality, or in conjunction with columnar hyperplasia or squamous metaplasia. It was noted as early as one month after carcinogen application and was a constant feature of almost all abnormal biopsies. When affected, the respiratory epithelium was thickened to a variable degree by proliferating basal cells. In the extreme degree, they constituted the entire thickness of the mucous membrane without clearcut surface differentiation (Fig. 5). Squamous metaplasia appeared as early as 4 weeks post-instillation and by 16 weeks nearly all biopsies showed this alteration (Figs. 6 and 7); it was usually non-keratinized. After a variable period of time following the appearance of squamous metaplasia, some degree of dysplastic maturation (atypia) was noted in 40 dogs or 76% of all the animals (Fig. 7). This change has been present on 3 or more biopsies in 20 dogs, or 38% of the animals. However, sequential biopsies have not regularly revealed the atypia shown on previous biopsy.

The evolution of these lesions as a function of time after instillation of carcinogen is presented in Fig. 8.

The mucosal alterations described above represent a summary of the lesions in all dogs. While these changes appear to proceed as described, for each individual animal the progression did not always adhere to the ideal situation and fluctuations from one abnormality to another were frequently noted in successive biopsy specimens. As a result, at any single interval, all biopsies did not show the abnormality expected from the progression proposed here. Hence, the chart in Fig. 8 indicates that at no time did 100% of the biopsies have a specific lesion at any given time. The chart is meant to represent a general summary of the progression

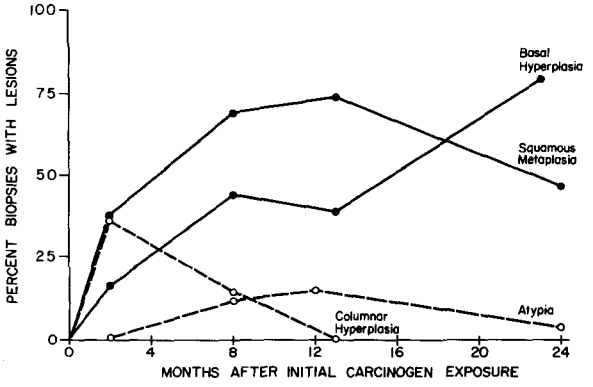

Fig. 8. Evolution of epithelial abnormalities as revealed by serial biopsies. This graph represents a summary of the lesions in all dogs at selected intervals.

of the epithelial changes induced by the carcinogens.

Abnormalities of the submucosa in the biopsies were as varied as those of the mucosa, and their appearance also was dependent upon the site sampled. Submucosal changes were induced by injection of both BP and NMU. The initial lesion was localized necrosis of the collagen, muscularis and cartilaginous plates (Fig. 9). This was associated with leakage of proteins and fibrin, edema and infiltration by variable numbers of polymorphonuclear leukocytes. In many instances, these cells extended into the mucosa (Fig. 10). In sites distant from repeated injections, or upon termination of the treatment, evidence of healing was noted. Fibroblastic proliferation with collagen deposition, proliferation and ingrowth of capillaries, and the presence of macrophages, lymphocytes and plasma cells were observed. In a few biopsy specimens, empty clefts of crystalline shape were noted in the submucosa (Fig. 11). These presumably represented remnants of carcinogen or carrier substance and were associated with extensive areas of necrosis, edema and inflammation. That the submocosal changes resulted from the carcinogens and not from the carriers, or from repetitive biopsies, was attested to in considering the biopsies from Group I. In this group, the presence of necrosis in close proximity to a mass of ferric oxide pigment in the specimen verified that the biopsy was from a site of injection (Fig. 12). There was no constant relationship between the submucosal alterations and those occurring in the overlying epithelium. After the cessation of carcinogen administration, healing by fibrosis was regularly evident in the submucosa. Abnormal fibroblasts or other connective tissue or lymphoid elements were not observed.

The technical and drug toxicity factors which led to the deaths of 31 dogs at various phases of these experiments have been reported in detail [13]. Briefly, 18 of the dogs (Group V) were immunosuppressed and expired either of infectious complications, bone marrow toxicity, and/or generalized debilitation. Four dogs in Group II died of local or systemic effects of excessive NMU; subsequent to these fatalities the dosage was diminished without evident toxicity. Deaths were also due to anesthesia [2] or massive hemorrhage during endoscopy [2]. One severely debilitated dog from Group I was sacrificed and found to have massive intestinal and pulmonary ascariasis. The remaining 4 dogs succumbed to causes which remain uncertain even after postmortem examination. Careful postmortem examination of all these dogs revealed that the spectrum of bronchial mucosal changes, as indicated above, was present in the same animal. Serial sectioning of the region of the orifice of the right intermediate lobe bronchus indicated that the various epithelial lesions could be either adjacent to and admixed with one another or widely separated. The degree or appearance of columnar hyperplasia was minimal or absent in the autopsy specimens, most likely because the deaths usually occurred after the sixth month of the experiment. One of the dogs which died at the time of the first monthly biopsy exhibited extensive columnar hyperplasia with adenomatosis at autopsy. Basal hyperplasia and squamous metaplasia were minimal. In all other dogs, columnar hyperplasia was minimal or absent in the autopsy specimens, most likely because the deaths occurred after the sixth month of the experiment. Squamous metaplasia and atypia were constant findings in all of the autopsy specimens. The metaplastic alterations were adjacent to either normal, or more frequently, hyperplastic epithelium. Additionally, the atypical features affected mainly the squamous epithelium, although dysplastic basal hyperplasia also occurred. Abnormal epithelium and occasionally normal epithelium, covered submucosa displaying the changes described above. However, the extent of fibrosis could be better appreciated in the autopsy specimens; vast areas of scarring responsible for considerable deformity of the bronchial contour were evident. As a result, many sites with severe epithelial abnormalities were apparently inaccessible to the biopsy forceps.

In all cases, biopsies from control sites revealed no mucosal alterations; occasional specimens showed submucosal edema and/or mild inflammation. As alluded to previously, it was readily possible to determine if the tissues sampled represented the location of the control injection because of the presence of Fe_2O_3 deposits (Fig. 13). Approximately 50% of the biopsies in Group I contained collections of red-black ferric oxide pigment which served to indicate a site of injection. Detailed observations on numerous sections of the left lower lobe bronchus taken at all autopsies also revealed an absence of significant mucosal and submucosal alterations.

Morphologic abnormalities associated with systemic manifestations of carcinogen administration, e.g. bone marrow hypoplasia, cellular atypia and/or neoplasia were not evident in any extrabronchial site examined in the dogs that died.

Although the microscopic alterations affecting

the bronchial wall are emphasized here, significant stenosis of the bronchial orifice, leading to complete obstruction in a small number of dogs from all groups, was evident by bronchoscopic examination. This finding extends our previous observations of stenosis affecting bronchi exposed to carcinogen [7, 13].

The results of the immunosuppression regimen indicated that antibody responses were depressed within two months, skin graft rejection was prolonged, and cutaneous responses to the injected antigens were suppressed, as compared to controls (Group IV) [9].

DISCUSSION

With the current clinical and experimental interest in respiratory tract oncogenesis, it is clear that pre-neoplastic changes of the tracheobronchial tree deserve attention [4, 14]. We have defined sequential morphologic alterations induced by recurrent carcinogen applications in the canine bronchus. Our study shows that the use of serial biopsies is a practical method with which to study the effects of substances such as carcinogens on the various bronchial tissues in large animals. Others have shown that chemical carcinogenesis in dog lungs is possible [5, 6], and we, therefore, feel that our dogs will also develop cancers. Our focus currently is upon pre-neoplastic lesions, partly because that is now the stage of our experiments and partly because that is the likely area for clinically significant diagnostic and therapeutic progress [14]. We have described the microscopic evolution of the canine bronchus exposed to non-carcinogenic recurrent trauma and to one or two carcinogens, and have noted that carcinogen-induced lesions progress through a relatively orderly sequence. Hyperplasia of columnar epithelium with or without adenomatosis, proliferation of the basal cells, squamous metaplasia and atypia represent to date the response of canine bronchial epithelium to carcinogen application. These changes seem to persist even after cessation of carcinogen exposure.

The events which occur in the submucosa in response to carcinogen exposure are likewise sequential and progressive. Deposition of chemicals, necrosis, inflammation and macrophage activity are followed by evidence of scarring and chronic inflammation with concomitant distortion of the architecture. Because the carcinogens have been introduced into the submucosa, we realize the possibility that malignancies other than carcinomas, e.g. fibrosarcoma, leiomyosarcoma, etc. may also be produced during the course of this study. Although BP and NMU have been effective in inducing pulmonary carcinomas [1, 2, 15], they have also been utilized in the production of soft tissue malignancies [1, 16]. As demonstrated by Shabad and Pylev [17], fibrosarcomas, angiosarcomas and reticulosarcomas may be induced in the course of bronchial epithelial carcinogenesis.

The effects of carcinogen injection on the bronchial submucosa were similar for both BP and NMU in our animals. This observation is not surprising in light of the work of Hoosen *et al.* [18] who evaluated the early reaction of subcutaneous tissue to repeated injections of different carcinogens. They found that these substances cause destruction of collagen, inhibition of cell multiplication and induction of cytomegaly. It appears that the bronchial submucosal effects observed by us are predominantly those of carcinogen exposure (i.e. destruction of collagen), although reparative and proliferative changes also occurred.

Our study has revealed that there is no basic difference in the evolution of lesions induced solely or primarily with BP as compared to NMU. Although our initial data [7] suggested that the epithelial changes seemed to appear more promptly with BP than with NMU, our current results do not support that impression. The use of a larger number of animals has permitted us to note the wider temporal variation in response to carcinogen application; hence, what appeared initially to be significant differences in rate of development of cellular changes actually represented individual variation among the animals.

Epithelial alterations similar to those described in this study on dogs have been noted in rodents whose respiratory tracts were exposed to various carcinogens. Harris *et al.* [15] studying the Syrian golden hamster treated with BP, described the earliest abnormality as epithelial hyperplasia which corresponded to the basal hyperplasia in our group of animals. Similarly, in animals exposed to NMU, basal hyperplasia of the tracheobronchial epithelium was consistently produced [15]. This type of change was considered to be the earliest abnormality. In contrast is our finding of a rather pronounced hyperplasia of cells that we identified to be of columnar origin. Following columnar hyperplasia, we observed basal hyperplasia usually in association with squamous metaplasia. Basal hyperplasia, on the other hand, was less commonly noted in conjunction with columnar hyperplasia. Columnar hyperplasia was instead frequently associated with "adenomatous" metaplasia or gland formation within the thickened mucosa, a lesion that has not been previously

emphasized either in experimental animals or in humans. Shabad and Pylev [17] described similar hyperplastic lesions of columnar epithelium in the bronchi of rats treated with intratracheal instillation of 7,12-dimethylbenz(a)anthracene. However, the proliferation of cells was frequently of a papillary nature and consisted of several layers of columnar or cuboidal cells extending into the bronchial lumen.

The fact that similar or progressive mucosal alterations did not appear on every biopsy, and that the sequence of events that we have described in detail was not necessarily reflected in every specimen sampled was initially disturbing to us. For example, the absence of cellular atypia on a biopsy after it was noted on a previous one was of concern. We felt that the lesions produced were "regressing" despite continued gross bronchoscopic changes, and in some cases the continued application of carcinogens. Our observations on autopsy tissue helped to resolve the questions posed by these observations. Postmortem examinations, with multiple sections of injection sites, on the dogs which were studied for greater than 3 months, revealed the frequent coexistence of normal and abnormal tissue. In fact, the entire spectrum of mucosal abnormalities occurred within a radius of 1 cm of the application sites. In addition, the degree of deformity and stenosis of the orifice of the right accessory lobe bronchus resulting from the submucosal alterations made it virtually impossible to sample many of the more affected areas during the bronchoscopic procedure. It is for these reasons that we feel that the inconstant biopsy findings in individual dogs do not represent a variability in the biologic process, but far more likely represent sampling errors. The importance of these observations in relation to human bronchial lesions cannot be overemphasized. In the face of convincing gross morphologic changes, a single negative bronchoscopic biopsy should not be taken to indicate the absence of significant disease. Multiple biopsy specimens are necessary.

The question of reversibility following carcinogen exposure is of basic importance. Griesemer *et al.* [12] noted that upon cessation of acute exposure of transplanted rat trachea to 7,12-dimethyl(a)anthracene or to BP, most of the hyperplastic-metaplastic lesions initially produced were replaced by normal or near-normal mucociliary epithelium. These investigators felt that this was evidence of regression of the changes. They also noted the appearance of pleomorphic-atrophic epithelium, the nature and significance of which was uncertain. Whether these abnormal cells are those which will ultimately be precursors of a malignant process, should it occur, is not clear. Our observations cannot yet contradict the conclusions of Griesemer *et al.* [12] conclusively, but the trend of our results is in that direction. So far, the bronchial epithelial lesions we have induced in dogs have not regressed even after the carcinogens were stopped.

On the basis of our results to date and those of others utilizing the same carcinogens in the respiratory tract of rodents [1, 2, 15], we expect that the mucosal alterations discussed here represent precursors of malignant tumors. Saffiotti *et al.* [1], Harris and others [15, 19] have shown that the progression of normal to malignant bronchial epithelium proceeds through a relatively orderly sequence of events, all of which have been achieved by us, save for the appearance of the final stage of cancer. In rodents, squamous and other carcinomas have developed generally within one year of carcinogen exposure. However, in the few models in which localized carcinomas were induced in dogs, the tumors did not appear as rapidly. The cancers resulting from weekly bronchial applications of 20-methylcholanthrene in dogs by Nakajima *et al.* [6] appeared from 2 yr 5 months to 3 yr 10 months after onset of the experiment. In a somewhat related setting, Howard [20] utilizing $^{239}PO_2$ particle inhalation carcinogenesis in dogs, induced lung cancers in beagles 38–110 months after initial exposure. It seems that in the canine model a considerably longer period of time is necessary for development of pulmonary malignancies than in other species exposed to similar conditions. We believe that the lack of tumorogenesis in our group of animals to date reflects this species variation. Alternatively, it may also be indicative that our carcinogen regimen in dogs is less rapid than that employed by others [5, 6]. Nevertheless, it is expected that carcinomas derived from bronchial mucosa will eventuate.

Interaction of Adriamycin and Radiation in Combined Treatment on Mouse L-Cells

M. BISTROVIĆ, B. NAGY, Ž, MARIČIĆ and K. KOLARIĆ
Central Institute for Tumors and Allied Diseases, Ilica 197, 41000 *Zagreb, Yugoslavia*

Abstract—*Using an established cell line, we have studied the survival properties after combined action of adriamycin and radiation. The results show that subtoxic concentration of adriamycin sensitizes the cells towards irradiation. This effect can be observed on the modified survival curve, showing a decrease in the extrapolation number. The cell survival after exposure to simultaneous action of both agents was essentially lower as compared with superposed survival after single treatment. If treatments were applied separately, cell survival increased. This equalled the superposed survival when the time interval between treatments was longer than* 3 hr. *The observed synergistic effect depended upon the concentration of acriamycin.*

INTRODUCTION

ADRIAMYCIN is a relatively new antibiotic of the anthracycline group which exhibits antitumor activity with a high therapeutic toxicity ratio [1, 2]. This antibiotic by binding to nucleic acids inhibits cellular DNA and RNA synthesis [3]. Although early S-phase cells are the most sensitive, progression delay was observed in all phases of the cell cycle [4]. In contrast to some cell cycle dependent drugs, adriamycin may have a killing effect on dividing and non-dividing cells [5]. Thereby, it has been suggested that this agent may be an effective drug on slow growing tumors.

Recently some authors have indicated that adriamycin also increases the radiosensitivity of tumor [6–8] and that combined therapy may prove to be useful. The results obtained with some *in vitro* studies [9] indicated that adriamycin, although affecting the radiation survival curve, did not inhibit split-dose repair. Investigations reported in this paper provide further data on the synergistic effect of adriamycin and irradiation.

MATERIAL AND METHODS

Mouse L-cells, clone 929-E, were cultivated on plastic Petri dishes in Dulbecco-modified minimal essential medium containing streptomycin and penicillin supplemented with 5% fetal calf serum (Gibco).

Cell survival was estimated by the clone forming ability of single cells after 12 days, according to the method of Puck and Marcus [10]. In order to gain the same number of clones in irradiated, treated and control dishes, the appropriate number of cells was inoculated. The control suspension was diluted to yield about 100 clones per dish. After plating, dishes were incubated at 37°C for 20 hr. At the end of the incubation period, the average cell multiplicity was about 1.2. For the data shown in Fig. 1, asynchronous cells were obtained by trypsinizing logarithmically growing cultures. Cell cultures were kept in 5% CO_2 in air and the temperature throughout was 37°C. Adriamycin was obtained from Farmitalia-Milano, Italy.

A stock solution of adriamycin was prepared in the medium immediately before each experiment. Certain volumes of this solution were added to each Petri dish so that the expected final concentrations were obtained. The drug was washed from the cultures with prewarmed medium after an indicated time and then incubated further for 12 days with 5 ml of complete medium without drug.

The irradiation was performed by 70 kVp X-ray machine (Phillips) with a dose rate of 100 R/min. In the experiments designed to investigate the synergism of adriamycin and irradiation the samples were exposed to 400 rad, and treated with certain concentrations of adriamycin for 3 hr.

Accepted 2 August 1977.

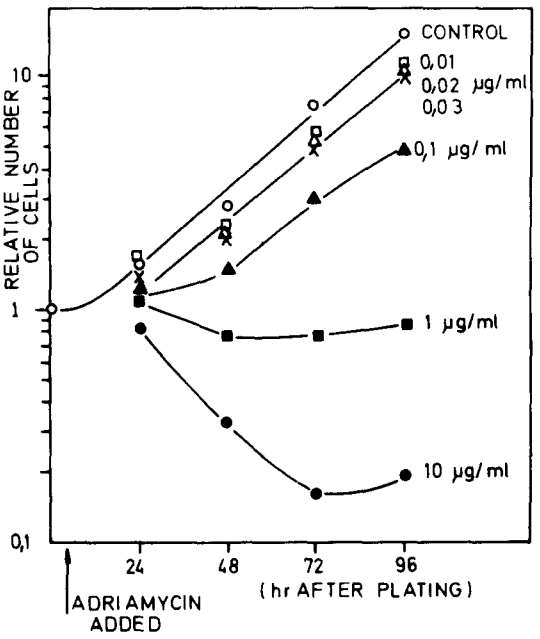

Fig. 1. Effect of adriamycin on cell division. Adriamycin was added 5 hr after plating. Open circles—untreated control, open squares—0.01 μg/ml, open triangles—0.02 μg/ml, crosses—0.03 μg/ml, solid triangles—0.1 μg/ml, solid squares—1 μg/ml, solid circle—10 μg/ml.

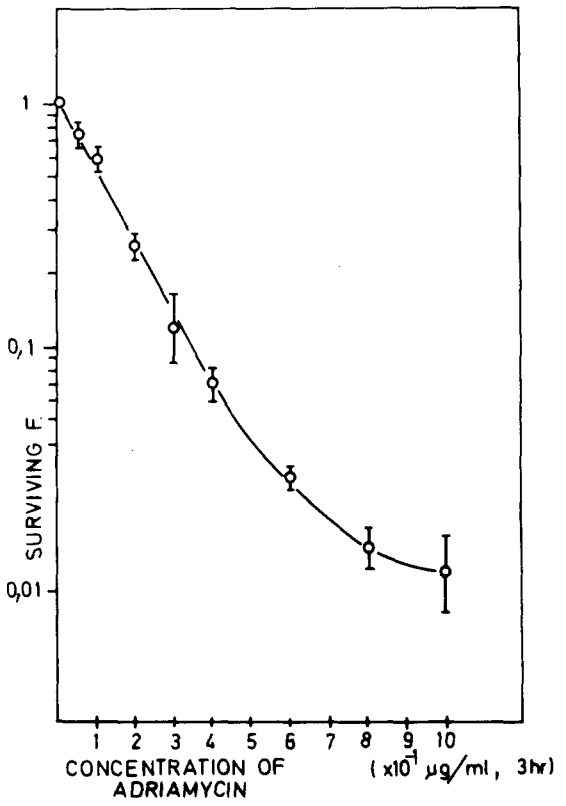

Fig. 2. Cell survival after treatment with adriamycin for 3 hr.

RESULTS

1. *Effects of adriamycin on cell division*

Asynchronous exponentially growing cells were exposed to various concentrations of adriamycin continuously. Nontreated control cells grew exponentially with doubling time 20 ± 1 hr. At concentrations 0.01–0.03 μg/ml cell division was delayed, however at higher concentrations the growth rate seemed to change significantly (Fig. 1).

2. *Effect of adriamycin on cell survival*

Exponentially growing cells were exposed to various concentrations of adriamycin for 3 hr. Survival rates after this treatment are shown on Fig. 2. The biphasic curve obtained is similar to the survival curve of some other antitumour-antibiotics (e.g. bleomycin) [11].

3. *Effect of nontoxic adriamycin concentration on cell survival after irradiation*

Before irradiation with various doses of 70 kVp X-rays, the cells were exposed to 0.02 μg/ml adriamycin for 3 hr. This concentration of adriamycin is nontoxic with a 100% survival rate (see Fig. 2). The survival curve became completely exponential. It is obvious that adriamycin caused a lower survival rate at the same dose exposition due to the decrease of extrapolation number.

4. *Synergism of adriamycin and irradiation*

Samples were exposed to 400 rad 1, 2, 3 and 4 hr before adriamycin (0.02, 0.2 and 1 μg/ml for 3 hr) was added. Next series of samples were irradiated immediately 0.5, 1, 2 and 3 hr after drug was added. Finally, the remaining samples were irradiated by the same dose 1, 2, 3 etc. hr after the removal of the drug. The control group of samples was treated simultaneously in the following way: the first samples were treated with adriamycin only, the second group was only irradiated and the third group of samples remained untreated control. Samples which were only treated with adriamycin gave the survival A. The irradiated control samples gave the survival B. Results are shown on Fig. 4. The zone inside the dotted lines represents the corresponding superposition level of survival obtained by multiplying A × B (see e.g. [12]) and accounting for s.e. of this product. All results have been calculated assuming survival 1 for untreated and unirradiated control. The data show that the highest killing effect was obtained when the radiation was given at the same time and up to 1 hr after adriamycin.

DISCUSSION

Results show that subtoxic concentration of adriamycin sensitized the cells towards irra-

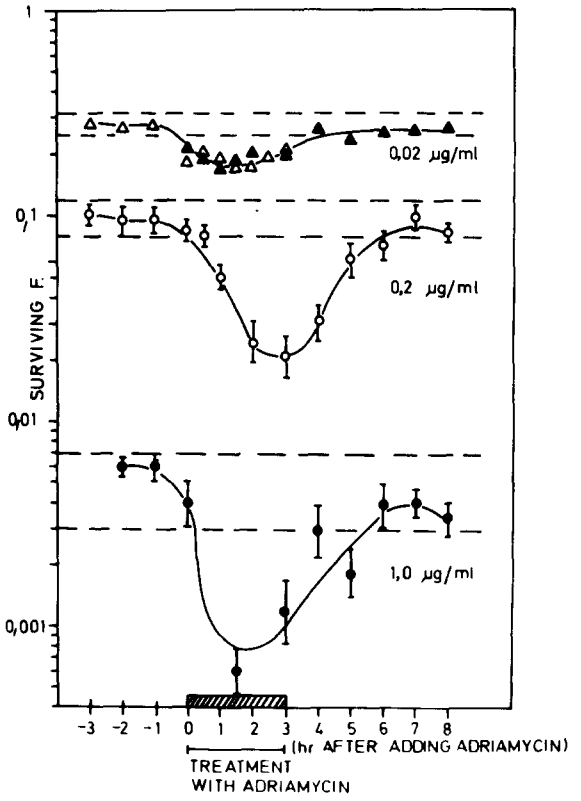

Fig. 4. Combined action of 400 rad *ionizing irradiation and adriamycin treatment for* 3 hr. *Open and solid triangles*—400 rad + 0.02 μg/ml, *open circles*—400 rad + 0.2 μg/ml, *solid circles*—400 rad + 1 μg/ml. *Dotted lines define the corresponding region of superposition.*

diation (see Fig. 3). This effect could be related to the modification of the survival curve, followed by decrease in the extrapolation number. An intensive synergistic effect was observed when a simultaneous action of adriamycin and irradiation occurred (Fig. 4). Synergistic effect increased progressively with time achieving its maximum value 1 hr after adriamycin was added and continued to last 1 hr after drug was removed. A high synergistic ratio (lowest survival/superposed survival) 1:7 was obtained by increasing the adriamycin concentration. When, however, adriamycin treatment and irradiation were separated by a time interval longer than 3 hr, only the superposing effect was observed.

Malignancy and Prognosis Evaluated by an Embryonic System

Grading of Breast Tumours*

G. V. SHERBET† and M. S. LAKSHMI

Department of Biochemical Pathology, University College Hospital Medical School, London, England

Abstract—*An embryological system for grading tumours with regard to their malignancy was described by the authors in earlier publications. This system is based on cellular responses induced by tumour cells on implantation into chick embryo blastoderms. In this communication the ectodermal cellular responses induced by human breast tumour cells are described. Carcinomas of the breast induce intense cellular responses, but those induced by the nonmalignant cells of cystic hyperplasia are feeble. The breast tumours and hyperplastic tissue have been embryologically graded, and an apparent correlation between embryological grade and histology is indicated.*

INTRODUCTION

TUMOUR tissues implanted into chick embryo blastoderms induce cellular responses from the embryonic tissues [1–3]. These responses appear to have histogenetic specificity. Tumours of endodermal origin, for example, most actively induce characteristic proliferative responses from the embryonic endoderm [4] but astrocytic tumours which are neuroectodermal in origin induce cellular responses from the embryonic ectoderm [5]. We describe here the induction of an ectodermal cellular response in embryos by human breast tumours. The cellular responses also appear to be related to the state of progression of the tumour and may be scored to provide a numerical grading which correlates with the degree of tumour malignancy [6]. In a series of human astrocytic tumours we have used embryological grading to determine malignancy and have observed that the grading correlates well with prognosis [5, 7]. In this communication we also examine the embryological grading of some human breast tumours in relation to their histology.

MATERIAL AND METHODS

The breast tumour cells tested were obtained from tissue cultures of breast biopsy specimens. They were donated by Dr. P. A. Riley and were derived from early stages of tissue cultures maintained as described by Riley *et al.* [8]. The cells were detached from culture flasks using a rubber "policeman", washed with Pannett–Compton saline, pelleted by centrifugation and implanted into 16–18 hr old chicken blastoderms [9, 10]. More than 15 implants were made of each tumour. The embryos with the implanted tumour tissue were incubated for a further 18 hr, when they were fixed and examined histologically. The cellular responses were scored and the tumours embryologically graded as described previously [6].

RESULTS AND DISCUSSION

1. *The ectodermal response*

The tumours were found to induce intense responses from the ectodermal cell layer of the blastoderm (Table 1, Figs. 1–6). The structures induced in the ectoderm bear much similarity to neural tissue in their characteristic palisaded cellular arrangement (Fig. 1). In some cases the induced structures were found to have undergone distinct morphogenesis into neural tube-like structures (Figs. 2 and 3). The tumour cells which produced the response illustrated in Fig. 3 may be seen in Fig. 4. The structure illustrated in Fig. 5

Table 1. Cellular response of chick embryo blastoderms to breast tumour implants

Patient	Host mesodermal response (%)	Ectodermal response (%)	Ectodermal response degree	Endodermal response (%)	Endodermal response degree	Morphogenetic displacement (%)
MCP	11.0	31.0	+	14.0	+	23.0
MCF	10.0	67.0	2+	50.0	+	27.0

BAS	42.0	100.0	2+	73.0	+	13.0
HOR	43.0	100.0	3+	70.0	2+	15.0
*Non-malignant**						
BAI (Cystic hyperplasia)	0.0	20.0	−	0.0	±	4.0
222 (meningioma)	80.0	66.0	+	0.0	−	0.0

*A meningioma has been included here only to provide comparison (and obviously is not a part of this series).
The tumors are graded according to the following method of scoring: Host mesodermal response 75–100% 0 pt, 50–74% 1 pt, 25–49% 2 pts, 0–24% 3 pts. Ectodermal and endodermal response (frequency) 75–100% 3 pts, 50–74% 2 pts, 25–49% 1 pt, 0–24% 0 pt. Ectodermal and endodermal response (degree) + 1pt, 2+ 2pts, 3+ 3pts. Morphogenetic displacement 75–100% 3 pts, 50–74% 2 pts, 30–49% 1 pt, 0–29% 0pt.

is reminiscent of a secondary embryonic axis induced by embryonic organisers in similar intrablastodermal implantation experiments.

2. *Nature of the histogenetic response*

There is now ample evidence which suggests that the induction of histogenetic responses in embryos may be a characteristic of neoplasms (Table 2). Human astrocytomas and breast tumours are the only neoplasms which have induced ectodermal response, in a series of tumours of various histological origin that we have investigated to date. Palayoor and Batra [2] observed that mammary carcinomas of C3H mice were able to induce neuroid reaction, using the chick embryonic system. Both astrocytomas and breast tumours are of ectodermal origin. Of the mesodermal tumours, Yoshida ascites sarcoma and leukemic bone marrow cells have been found able to induce a low level of proliferation of the ectoderm. On the other hand, tumours of endodermal origin appear to induce most actively a response in the embryonic endoderm, although in the present experiments carcinomas of the breast have been able to induce responses in the endoderm (Table 1).

One can only speculate as to the mechanisms by which these histogenetic responses may have been induced, from analogous tissue interactions in embryogenesis. The induction of differentiation of neural tissue by implantation of neural tissue [12, 13], the induction of limb bud by implanted limb buds [14, 15] are well known instances of "homogenetic inductions". The homogenetic inductions are in fact very closely associated with the state of differentiation of the implanted tissue. Competent embryonic ectoderm is capable of inducing neural tissue differentiation only when it has itself been induced to differentiate in that direction. The histogenetic response produced by astrocytomas and breast tumours may reflect the acquisition of embryonic characteristics by dedifferentiation accompanied by an acquisition of the ability to synthesise substances which can alter the path of differentiation of the ectoderm. Inappropriate synthesis of substances is not unusual in neoplasms. Tumours are known to be accompanied by paraneoplastic syndromes of endocrinopathy. Not only has ectopic production of hormones by some neoplasms been abundantly documented [16], but it has also become apparent that this ability may be closely related to the state of differentiation of the neoplasm [17].

3. *The embryological grading of breast tumour malignancy*

The tumours were found to belong to various embryological grades between 9 and 15 indicating increasing malignancy in that order. The histology of these tumours appears to confirm the differences in their malignancy predicted by the embryological grading (Table 3).

In comparison with the responses induced by the malignant carcinomas, those produced by nonmalignant hyperplastic tissue of the breast seem innocuous (Table 1). One such case examined was given embryological grade 4, as also was a nonmalignant meningioma. This is much higher than normal liver cells of rat which elicited a grade 1 response

in this system [6]. The embryonic system was able to distinguish between the experimentally induced minimum-deviation tumours of rat, which have a wide spectrum of differentiation and malignancy. Even the very slow growing minimum-deviation rat hepatoma 9633, which is a well-differentiated tumour and which has no metastatic ability, could be distinguished from normal liver implants from which the tumour may be said to differ in the main in its slightly more rapid rate of growth. This discriminatory ability of our system is presumably reflected in the production of low grade responses by cystic hyperplastic tissue of the breast and nonmalignant meningioma. In contrast, the more malignant astrocytic tumours [5] and mammary carcinomas produced much more intense responses from the embryonic tissues, and generally belonged to much higher embryological grades.

It appears therefore that the embryonic system possesses a fair degree of sensitivity

Table 2. Histogenetic specificities of embryonic responses

Tumour	Ectodermal response	Endodermal response	Reference

MCD	13	Poorly differentiated adenocarcinoma with poor lymphocyte response. Lymph nodes free of tumour
BAS	13	Poorly differentiated adenocarcinoma with lymphatic infiltration. Lymph nodes free of tumour
AME	14	Invasive carcinoma. Tumour with cellular area of anastomosing trabeculae of spheroidal cells with fibrous reaction of scirrhous adenocarcinoma. No lymphocytic response
HOR	15	Poorly differentiated finely trabecular carcinoma incompletely contained by fibrous reaction with lymphatic permeation.

*Determined as prescribed previously [6] (see footnote to Table 1).
†Histological data was obtained from the Department of Morbid Anatomy, University College Hospital Medical School.

which enables it to respond to discrete differences in the normality and of degree of malignancy of the implanted tissues.

Although the embryological grades of breast tumours investigated here appeared to correlate well with the histology, no follow-up studies have been made. This is because we recognise that selective pressures may operate in the tissue culture phase, and therefore the embryological grades obtained with cells grown in culture may not reflect prognosis accurately. We propose to investigate by direct implantation, i.e. without interposing a tissue culture phase, a large series of breast tumours, in conjunction with a follow-up study over a period of 5 yr.

We consider that the embryological system of grading may find its most rewarding application in the management of breast cancer where the form of treatment is closely linked with the clinical stage of the disease and, as Mansfield [18] has pointed out, one is posed with the dilemma of deciding whether to follow conservative forms of treatment or to adopt more radical procedures. It is hoped that our proposed future studies using the embryological malignancy grading system will be helpful in this respect.

‡*NCI, NIH, Bethesda, Md* 20014, *U.S.A.*

Abstract—*The uptake of* ^{125}*I-5-iodo-2′-deoxy-uridine* (^{125}*IUdR) by lymphoma cells is inhibited in lethally irradiated hosts incompatible for* Hh (*hemopoietic-histocompatibility*) *loci. In the course of attempts to reproduce this phenomenon* in vitro, *a soluble factor* (*uptake inhibiting factor, or UIF*) *was found in the supernatant of cultured* (16 hr, 37°C) *spleen cells. UIF was produced by non-stimulated splenocytes of various strains of conventional and athymic* (*nude*) *mice and rats and by various tumor lines as well. UIF was found to be non-strain, non-species and non-tissue specific, since it was capable of inhibiting the* ^{125}*IUdR uptake of mouse, hamster and human tumor cells of various tissue origins. Lethal irradiation, silica or IDF* (*immunodepressive factor*) *treatment of donor mice, or irradiation or treatment with actinomycin D of spleen cells* in vitro, *did not prevent UIF production by such cells. On the other hand* 5-*fluoro-2′-deoxy-uridine* (*FUdR*) *reduced UIF production by* 50%. *UIF was found to be relatively resistant to heat and proteolytic enzymes* in vitro. *In addition UIF was capable of cytostatic or cytotoxic effects on tumor cells in tissue culture. UIF-like activity was found also in the plasma of tumor bearing mice. The biological role of UIF seems to be uncertain. Nevertheless it could interfere markedly with* in vitro *assays involving cell proliferation monitored by DNA-precursor uptake.*

INTRODUCTION

NORMAL hematopoietic or lymphomatous cells do not proliferate in the spleen of lethally irradiated recipient mice incompatible for the *Hh* locus [1–8]. The uptake of 5-iodo-deoxy-uridine ^{125}I (^{125}IUdR), a non-physiological precursor incorporated into DNA in place of thymidine [9], has been used to monitor cell growth or proliferation inhibition in spleen, liver and lung of irradiated recipients [5–8].

Attempts were made in our laboratory to reproduce *in vitro* ^{125}IUdR uptake inhibition of lymphoma cells by coculturing them with spleen cells obtained from lethally irradiated, *Hh*-incompatible donor mice. The data of several experiments indicated that non-specific inhibition of ^{125}IUdR uptake occurred in lymphoma cells when cocultured *in vitro* with either syngeneic or allogeneic splenocytes.

Soluble factor(s) capable of inhibiting the ^{125}IUdR uptake by cancer cells was found in the supernatant of cultured spleen or tumor cells. The factor (hereafter called UIF, or uptake inhibiting factor) reduced or abolished not only ^{125}IUdR uptake but also tumor cell proliferation *in vitro*. UIF was found to be relatively resistant to heating and to treatment with proteolytic enzymes *in vitro*. It was produced in fairly constant amounts by splenocytes of various mouse strains, including nude (athymic) mice, whereas UIF production by cancer cells varied greatly with the type of tumor line used. In addition UIF-like activity was found in the plasma of tumor bearing mice.

MATERIAL AND METHODS

Animals

Inbred mice 2–4 months old of both sexes of C57Bl/6Cr(*H-2*^{b}), B10.129 (5M)Cr(*H-2*^{b}, *H-1*^{b}), C57Bl/10 ScSnCr (*H-2*^{b},*H-1*^{c}), BALB/c Cr (*H-2*^{d}), C_3H Cr (*H-2*^{k}), SJL (*H-2*^{s})

strain; hybrid male mice BALB/cCr × DBA/2Cr F_1 ($H\text{-}2^d/H\text{-}2^d$, hereafter called $CD2F_1$) 2–3 months old; male mice maintained in a close but not inbred colony of the strain BALB/c/A/BOM Cr($H\text{-}2^d$, nu/nu, genetically thymusless, "nude" strain on BALB/c background, originally obtained from Dr. Carl W. Friis, Ry, Denmark, hereafter referred to as BALB-Nu); and 5-month old male rats of Sprague–Dawley strain were used. All animals were obtained from the Animal Production Section, National Cancer Institute, National Institutes of Health, Bethesda, Md.

Tumors

Ascitic L1210, L1210/AraC (L1210 subline resistant to AraC), P388 and $6C_3HED$ lymphomas and sarcoma 180 (S-180), solid Lewis lung carcinoma (LLC) and B16 melanoma (B16M) were obtained at the National Cancer Institute. Radiation-induced lymphoma L5MF-22 of B10.129(5M) origin [10] was kindly supplied by Dr. G. Cudkowicz (Department of Pathology, State University of New York at Buffalo, Buffalo, N.Y.). ATPC+, a BALB/c mammary carcinoma [11], GPY, a Polyoma-induced sarcoma of hamster origin, and HeLa of human origin, have been maintained in tissue culture in our laboratory for several years.

Ascites L1210, L1210/AraC and P388 leukemias were passaged in $CD2F_1$ male mice, $6C_3HED$ in male C_3H recipients, and S-180 in male swiss mice, (10^5 cells i.p., suspended in 0.2 ml medium 199, weekly). LLC and B16M lines were maintained by injecting 10^6 viable cells (in medium 199) obtained from solid tumors, into the hind leg of female C57Bl/6 mice. Splenic lymphoma L5MF-22 was serially passaged using cell suspension obtained from grossly enlarged spleens, injected intravenously (10^5 cells/mouse i.v., in medium 199) into syngeneic B10.129(5M) or compatible C57Bl/10 male mice [10]. ATPC+, GPY and HeLa cells were serially passed in tissue culture (see below).

In vitro *incubation of normal or tumor cells for UIF production*

Normal spleen or splenic tumors were teased with a sterile flat-end forcep in order to obtain a cell suspension in chilled medium 199 (Difco Lab., Detroit, Michigan). Cell suspension was washed three times centrifuging at 250 × ***g*** for 10 min and resuspended in the same medium at the desired cell concentration. Since cell washing did not modify the results, in some experiments the entire washing procedure was omitted. Ascites tumors were collected from the peritoneal cavity of mice, diluted with medium 199, washed twice centrifuging at 250 × ***g***, and resuspended at the desired concentration in medium 199. Incubation of cell suspensions was carried out overnight for 16 hr at 37°C in a CO_2 incubator, 10% CO_2, in 50 mm dia sterile Petri dishes (Falcon Plastics, Oxnard, Ca.). After incubations the supernatant was collected, centrifuged at 400 × ***g***, dispensed into sterile vials and stored at −20°C until use. When supernatant of frozen-thawed cells were used, spleen cell suspension (20×10^6/ml) in medium 199 was frozen at −70°C and thawed at 39°C, three times and then centrifuged at 400 × ***g*** for 15 min and the supernatant stored at −20°C until use.

$^{125}IUdR$ uptake assay

Bone marrow cells obtained from femurs and tibias of donor mice, or splenic or ascites tumor cells were suspended in chilled medium 199, washed three times as previously described and resuspended at the concentration of 2.5×10^6 cells/ml of medium 199. Four tenths of a millilitre of cell suspension (10^6 cells) was incubated with 0.4 ml of medium 199 or of supernatant of overnight-incubated cells at various concentrations in plastic test tubes (12 × 75 mm, Falcon Plastics) for 1 hr at 37°C in a CO_2 incubator, in 10% CO_2. Then 0.2 ml of medium 199 containing 50% of heat-inactivated fetal calf serum (FCS, GIBCO, Grand Island, N.Y.), 0.1 μg of 5-fluoro-2′-deoxyuridine (FUdR) and 1 μCi of ^{125}IUdR, were added, and the tubes incubated further for 2 hr in the same conditions previously described. Cell suspension was then washed three times with chilled medium 199, centrifuging at 250 × ***g***. After the last centrifugation, the supernatant was discarded and the pellet read in a γ-scintillation counter (Packard, Gamma Scintillation Spectrometer, Model 3002).

When plasma of mice was tested, 0.4 ml of plasma from control or tumor-bearing mice was added to 0.4 ml of L1210 cell suspension and the test performed as previously described. Plasma from $CD2F_1$ mice challenged with 10^5 cells i.p. of L1210, L1210/AraC and P388 lines, from C_3H mice challenged with 10^5 cells i.p. of $6C_3HED$ line, and from B10.129(5M) inoculated with 10^5 cells i.v. of L5MF-22 lymphoma was collected 7 days after tumor transplantation. Plasma from C57Bl/6 mice inoculated with 10^5 cells i.m.

of Lewis lung carcinoma or B16 melanoma was collected 12 days after tumor challenge.

UIF determination

The inhibitory activity of supernatants of cells incubated overnight was assayed using L1210 leukemia cells, except when otherwise specified in the test.

Inhibition of ^{125}IUdR uptake by tumor cells mixed with splenocytes in vitro

Tumor cell suspension in 0.4 ml of medium 199 was added to plastic tubes (12 × 75 mm, Falcon Plastics) containing 0.4 ml of washed spleen cell suspension in medium 199 obtained from mice lethally irradiated (800R) 1 day before cell collection. After 1 hr and 45 min of incubation in a CO_2 incubator (37°C, 10% CO_2), 0.1 ml of heat-inactivated fetal calf serum (GIBCO) and 0.2 ml of medium 199 containing FUdR 0.1 μg and ^{125}IUdR 1 μCi were added. Following 16 hr of incubation as previously described, cell mixtures were washed three times and the pellet read in the γ-scintillation counter (Packard).

Tissue cultures of tumor cells

ATPC+, GPY and HeLa cells were cultivated either in plastic test tubes (12 × 75 mm, Falcon Plastics) or in Petri dishes (50 mm dia, Falcon Plastics) using Eagle medium (Difco Laboratories) containing 10% heat-inactivated calf serum and penicillin and streptomycin. The number of cultured cells was determined by detaching cells with a rubber policeman and counting them in a hemocytometer chamber in presence of trypan blue.

Irradiation procedures

Mice received a total-body irradiation of 800 rad using a Westinghouse "Quadrocondex" X-ray machine; 200 kV, 15 mA, at a distance of 54 cm, using 0.25 mm copper and 0.5 mm aluminum filters, at a dose rate of 137 rad/min. Cell suspensions in medium 199 were irradiated *in vitro* with 5000 rad in sealed glass vials at room temperature, using the same X-ray machine, at a distance of 25 cm, at a dose rate of 661 rad/min.

Reagents and drugs

Silica particles were obtained through the courtesy of Dr. G. Cudkowicz (Dept. of Pathology, School of Medicine, State University of New York at Buffalo, Buffalo, N.Y.). Actinomycin D and 5-fluoro-2′-deoxy-uridine were obtained from Drug Synthesis and Chemistry Branch, National Cancer Institute, NIH; ^{125}IUdR was obtained from Radiochemical Centre (Amersham, England); pepsin and papain were obtained from Sigma (St. Louis, Mo.) and pronase from Calbiochem (Lajolla, Calif.).

IDF [Immunodepressive factor(s)] preparation [12]

Cell suspension (10^8 cells/ml) in medium 199 of IDF-positive L5MF-22 lymphoma line, was frozen and thawed 3 times, centrifuged at 1000 × ***g*** for 20 min, the supernatant collected, diluted 1:10 with medium 199 and filtered through a 0.40 μ-millipore sterile membrane and stored at −20°C. Donor mice were treated with 0.2 ml/mouse i.p. of IDF preparation (final dilution = $1:10^4$) three days before the spleen collection.

RESULTS

Two lymphomas that originated in mice carrying the *H-2*^{b} (L5MF-22) or *H-2*^{d} (L1210) haplotypes respectively were cocultured *in vitro* for 16 hr with spleen cells collected from lethally-irradiated donors compatible or not for the *Hh-H-2* complex [1–8]. The data (Table 1) indicate that strong inhibition of ^{125}IUdR uptake occurred in tumor cells cocultivated either with compatible or allogeneic *Hh*-incompatible splenocytes. These data suggested the possibility that soluble, non-specific inhibitor(s) of ^{125}IUdR uptake could have been released by spleen cells, following short term culture *in vitro*. Therefore several viable or non-viable spleen cells were incubated either at 37°C or at 4°C, the supernatant collected and tested for inhibitory activity on ^{125}IUdR uptake by L1210 leukemic cells *in vitro*. The data illustrated in Fig. 1 show that the supernatant of viable mouse or rat spleen cells incubated at 37°C inhibited markedly the ^{125}IUdR uptake, whereas no inhibitory activity was found when heat-killed cells were incubated at 37°C or viable cells were incubated at 4°C. The supernatant of frozen–thawed cells incubated overnight at 37°C showed marginal activity, whereas no activity was found when medium 199 alone was used.

A dose–response assay was performed using serial dilutions of supernatant from incubated B10.129(5M) spleen cells (12×10^7 cells/ml), and L5MF-22 target cells. Inhibition of ^{125}IUdR uptake by tumor cells was proportional to the concentration of supernatant added, and an S-shaped curve was obtained. The data reported on probability chart gave a straight line, as evidenced in Fig. 2. Similar results, not reported here, were obtained when

L1210 leukemic target cells were used for the ^{125}IUdR uptake inhibition assay. On the basis of such data, it was possible to define the UIF unit as the amount of inhibitor(s) present in the supernatant, capable of inhibiting the ^{125}IUdR uptake of 10^6 normal or tumor cells by 50%. Under this definition, the preparation used in the assay reported in Fig. 2 contains approximately 40 UIF units/ml, against L5MF-22 lymphoma cells.

UIF production by normal or neoplastic cells of the same genetic origin, was determined using splenocytes pooled from ten B10.129(5M) male mice or L5MF-22 lymphoma cells (of B10.129(5M) origin) incubated for 16 hr at various cell concentrations as illustrated in Fig. 3. UIF was assayed against L1210 leukemia

cells and the results indicate that UIF production was proportional to cell concentration. The activity of normal spleen cells was slightly higher than that of tumor cells.

The production of UIF by splenocytes of various strains of mice and by a number of mouse tumor lines was determined. The results reported in Table 2 show that normal spleen cells of various conventional strains of mice or of athymic mice produced comparable amounts of UIF. On the other hand marked variation of UIF production was found in tumor lines, ranging from 2.83 to 46.39 units/ml. It is noteworthy that UIF was produced by splenic and ascitic tumors as well, and that a minimal amount of UIF was produced by parental L1210 line, whereas high levels of the inhibitor were produced by the Ara C-resistant leukemia subline.

The inhibitory activity of two UIF preparations on ^{125}IUdR uptake by normal bone marrow or various tumor lines was tested and the results are reported in Table 3. In general lymphoma and normal bone marrow cells were more sensitive to UIF than carcinoma, melanoma or sarcoma tumors. The only exception was the GPY line, a hamster sarcoma of Polyoma virus origin, maintained in tissue culture.

Preliminary studies were conducted in order to determine whether UIF would have any inhibitory effect on cell replication *in vitro*.

‖ 1 unit = amount of supernatant capable of inhibiting 50% of ^{125}IUdR uptake of test cells.

¶ % activity related to the inhibitory activity on ^{125}IUdR uptake by L1210 cells (= 100%).

The total number of ATPC+, GPY and HeLa cells was significantly lower in the cultures exposed to UIF in various experimental conditions as illustrated in Table 4. In particular UIF was more effective when added to the culture on the same day of cell seeding than 1 or 2 days later (group 1 vs 2, group 6 vs 7), with one exception (group 4 vs 5) where essentially total inhibition of tumor growth was found in both cultures.

Experiments were performed in order to test whether physical or chemical agents would have any influence *in vivo* or *in vitro* on UIF production by normal spleen cells. The results, illustrated in Table 5, show that immunosuppressive doses of X-rays, lethal for

the donor (800 rad), or lethal for lymphoid cells *in vitro* (5000 rad) did not prevent UIF production. An antimacrophage agent such as silica particles [13] and IDF, a virus capable of depressing T-dependent allograft reactions [10, 12], were not capable of impairing UIF production. On the other hand, treatment with FUdR, capable of inhibiting endogenous thymidine synthesis [14], decreased the UIF production by approximately 50%. Moreover a slight inhibitory effect seemed to have been induced by *in vitro* treatment with actinomycin D.

The sensitivity of UIF to heating or to treatment with proteolytic enzymes *in vitro* was studied, using a UIF preparation obtained from $CD2F_1$ spleen cells and tested against L1210 leukemic cells for ^{125}IUdR uptake inhibition (Table 6). The data show that UIF was relatively resistant to heating: almost 50% of UIF activity remained after 30 min exposure to 100°C. A limited reduction (23–30%) of UIF titer was induced by enzymatic treatment *in vitro*, with all three proteolytic enzymes tested.

Since considerable amounts of UIF were produced by tumor cells *in vitro*, preliminary studies were performed in order to test whether plasma of tumor-bearing mice would contain appreciable amounts of UIF. Plasma of control or tumor-bearing mice was added to L1210 leukemic cells and incubated with ^{125}IUdR. UIF activity was calculated taking into account the ^{125}IUdR uptake of L1210 cells incubated with normal mouse plasma (100% of precursor uptake). The results of the experiment (Table 7) showed that appreciable levels of UIF activity were detectable in tumor-bearing mice and ascitic fluid.

DISCUSSION

In the course of studies on anti-*Hh* reactions *in vitro*, using lethally-irradiated spleen cells, soluble, non-specific inhibitor(s) (UIF) of ^{125}IUdR uptake by normal and cancer cells has been detected. A number of biological properties of UIF has been studied and they can be outlined as follows:

(a) UIF is produced by non-stimulated normal spleen as well as cancer cells;
(b) UIF is non-strain, non-species or tissue specific, since it was produced by tumors and spleens of various strains of mice (Table 2) as well as by rat spleen cells (Fig. 1) and was found to be active on normal or tumor cells of various origin (Table 3);
(c) UIF production is not conditioned by mature T cells activity, being synthesized actively by spleen cells of nude mice (Table 2);

(d) at high concentration UIF seems to be cytotoxic or cytostatic for various tumor lines in tissue culture (Table 4);
(e) lethal irradiation both *in vivo* and *in vitro*, silica or IDF treatment *in vivo*, capable of interfering with macrophage functions or with antilymphoma allograft reactions respectively [12, 13] did not prevent UIF production (Table 5);
(f) inhibition of endogenous thymidine synthesis by FUdR reduced but did not abolish UIF production (Table 5);
(g) protein-synthesis inhibition, induced by treatment with actinomycin D *in vitro*, did not prevent UIF production (Table 5);
(h) UIF is relatively stable to heat and proteolitic enzyme treatment *in vitro* (Table 6);
(i) UIF-like activity can be detected in the blood of tumor-bearing mice (Table 7).

A number of factors released by human [15–18], mouse [19–25], hamster [26], rat [27, 28] and calf [27, 29] normal or stimulated lymphoid cells have been described in the literature. Some of them were found to be active in inhibiting thymidine incorporation or proliferation of cancer cells [15, 19, 21, 23, 24] as well as of normal lymphocytes [15, 17, 19, 21–29]. Immunosuppression and cytotoxic activity was demonstrated for extracts of calf thymus and spleen [29] and for a factor obtained from Con A-stimulated splenocytes of $C_{57}Bl/6$ mice (SIRS, 22). Nonstimulated, or Con A, LPS, PHA-stimulated cultures of splenocytes of various strains of mice produce a proliferation inhibiting factor (PIF) which is T-dependent and species-specific [23]. Hersh *et al.* [18] suggested that cell "crowding" in culture would result in release of soluble "signals" of proteinaceous nature capable of inhibiting DNA synthesis. More recently Opitz *et al.* [30], Fernbach *et al.* [25] and Evans and Booth [31] pointed out that a number of inhibitors described in the literature should not be considered to be true inhibitors of DNA synthesis, but as small molecules capable of interfering with the uptake of the labeled thymidine or ^{125}IUdR used for the assay. A good candidate was considered to be thymidine itself [30], capable of competing with the labeled compound for incorporation into DNA. On the other hand Fernbach *et al.* advanced the hypothesis of the contemporary presence of two factors, i.e. thymidine itself and a true inhibitor of DNA synthesis, although they suggested also that excess of thymidine could produce DNA-synthesis inhibition [25].

If the properties of UIF are taken into account, it seems difficult to assess possible identity or non-identity of UIF with any of the factors described in the literature. In fact few data are available concerning similar factors produced either by normal lymphoid and cancer cells *in vitro*. Of particular interest for its analogy with UIF seems to be the dializable factor capable of inhibiting bone marrow colony formation described by Metcalf [19]. The material was not species specific, was heat-resistant and was produced by cultured normal bone marrow, thymic spleen or lymph node cells as well as by leukemic cells. On the other hand UIF production was depressed by FUdR (Table 5), an inhibitor of the biosynthesis of endogenous thymidine [14]. This observation seems to confirm the hypothesis advanced by Opitz *et al.* [30], that UIF activity would be, at least in part, due to thymidine released by lymphoid or tumor cells in tissue culture. Nevertheless UIF was partially heat-labile and reduced in its activity by proteolytic enzymes In particular a plateau was found when graded doses of pronase were used (Table 6), being equally active at 50 μg/ml and at 500 μg/ml in reducing UIF titers. This opens the possibility that UIF might be a complex of soluble factors, including a heat stable factor not destroyed by proteolytic enzymes, which could well be thymidine, and other heat-labile enzyme-sensitive factor(s) of possible protein nature, capable of interfering with proliferation of normal or tumor cells.

The biological importance of UIF is difficult to establish. No relationship was found between UIF production and strain reactivity against *Hh* alloantigens. In fact spleen cells of anti-*Hh* high responder [B10.129(5M) [3, 4] and BALB-Nu [6, 8, 32]] or low responder [SJL [4]] strains produced comparable amounts of UIF (Table 2). However, no studies were conducted with the heat-labile or heat stable fraction of UIF, in order to test whether such relationship could be found with one of these two fractions.

In addition impairment of T-dependent or T-independent immune responses by *in vivo* or *in vitro* lethal irradiation [8], i.v. administration of silica particles [13], or pretreatment of donor mice with IDF [10, 12] did not prevent UIF production by splenocytes.

Nevertheless we cannot exclude that UIF could play a role in cell proliferation inhibition in antitumor immune responses [5, 8, 33, 34] and give account, at least in part, for the decline of tumor cell proliferation in

lymphoma-bearing mice close to leukemic death [9]. In any case when *in vitro* tests involving cell proliferation monitored by the uptake of DNA-labeled precursors are carried out, the possible production of UIF should always be taken into consideration. The presence of UIF in the assay medium could result in significant interference with uptake of precursors, leading to misinterpretation of the results.

Acknowledgements—We thank Dr. J. G. Mayo and Mr. C. Reeder of the Mammalian Genetics and Animal Production Section, National Cancer Institute, Bethesda, Maryland, for providing us with inbred, "nude" and hybrid mice. We thank also Mr. Mario Andrielli of the Institute of Pharmacology of the University of Perugia and Mr. Claudio Cerbini of the Institute of Hygiene of the University of Perugia for the excellent technical assistance.

The Effect of Neonatal Thymectomy on the Growth Kinetics of a Virus-induced Renal Sarcoma of the Rat*

W. LANG,† H. ZOBL and A. GEORGII

Department of Pathology, Medical School, Hannover, West Germany

Abstract—*Growth kinetics of Polyoma virus induced renal sarcomas in normal and neonatally thymectomized Wistar rats are compared. Both groups of animals show an exponential tumour growth from the* 20th *to the* 50th *day of life. Thymectomized rats have a significant reduction of tumour doubling time* (76 hr) *compared to non-thymectomized rats* (110 hr). *The main parameters of tumour growth, cell cycle time, proliferative fraction and cell loss rate are determined at the* 30th *and* 50th *day after virus infection of the animals. The reduction of doubling time in tumours of thymectomized rats is due to an increase of the proliferative fraction despite increased cell loss rates. The extent of cell loss in the resting and cycling cell compartment is specified for both groups of rats.*

INTRODUCTION

THE INFLUENCE of early thymectomy upon the incidence of virus induced tumours, especially by Polyoma virus has been known a long time [1–9]. Furthermore it was shown that after infection of Wistar rats with Polyoma virus the number of distinct tumour foci at the beginning of cellular proliferation and also the tumour mass as a whole in one kidney was significantly increased in thymectomized animals [10]. The growth kinetics of these fibrosarcomas in normal immune-competent rats had been studied previously [11]. Therefore it was interesting to compare their kinetics to the growth of sarcomas in immune-deficient thymectomized rats by a complete analysis of all important kinetic parameters. This comparison should bring some more understanding for the striking difference in growth kinetics of Polyoma virus induced tumours between thymectomized and normal rats.

MATERIAL AND METHODS

1. *SE-Polyoma virus*

Cultivation and preparation of the virus has been described previously [11, 12]. The $TCID_{50}$ of the virus suspension used was 10^6 or 10^7 per 0.3 ml. HA-titre: 768.

2. *Animals*

Non-inbred male and female Wistar rats from the conventional colony strain of the Breeding Institut for Experimental Animals, Hannover, West Germany.

One group of animals was inoculated with 0.3 ml virus suspension s.c. within 24 hr. after birth. A second group was thymectomized before virus inoculation using the same dose and virus preparation. Thymectomy was performed within the first 24 hr. post partum by the method of Martinez [13]. If any thymus gland was found macroscopically or histologically after sacrifice the animal was excluded from further evaluations.

3. *Histomorphometrical determination of tumour weights*

One hundred and forty-nine non-thymectomized animals were sacrificed between the 25th and 62nd day of life, 1–6 animals (3 on average) per day. The blood volume was reduced by cardiac puncture before nephrectomy.

The fresh kidneys were cleaned from adhering tissue and weighed on an analytic scale. Further procedure see Zobl *et al.* [11].

The total tumour weight was determined by

Accepted 25 August 1977.

† To whom correspondence should be sent.

the equation:

$$W_t = W_k \times A_t / A_k; \quad \text{(I)}$$

W_t: weight of tumour;
W_k: weight of kidney;
A_t: area of tumour;*
A_k: area of kidney.*

The specific weight of the kidneys with or without tumour is between 1.0 and 1.1.

Seventy-seven thymectomized animals inoculated with the same virus preparation as the non-thymectomized ones were sacrificed between the 25th and 60th day of life, 1–4 animals (2 on average) per day. The tumour weights were determined analoguously.

4. *Historadioautography with* 3H-*thymidine*

The autoradiographic technique has been described previously as well as the evaluation of the autoradiograms [11]. The following kinetic parameters were determined by this technique in 30- and 50-day old animals:

(a) Labelling index 1 hr after a pulse of 3H-thymidine (LI1h). Dosage: 1 μCi/g body weight; specific activity: 5 Ci/mmole.

(b) Cell cycle times and phase durations including time distributions by the %-labelled mitoses method [14]. The evaluation of the PLM-data was made by computer analysis [Dr. G. G. Steel-15].

(c) Proliferative fraction (PF) from PLM-data following method of Lala and Patt [16].

(d) Cell production rate (CPR), cell loss rate (CLR) and mode of cell loss specifying loss from proliferative (PCL) and non-proliferative compartment (QCL) determined by continuous labelling with 3H-thymidine. Details of infusion technique see Eve and Robinson [17]. Dosage: 1 μCi/g body weight per 24 hr; Specific activity: 5 Ci/mmole. Continuous infusion was done in 190 non-thymectomized and 90 thymectomized rats. The labelling index was determined every 2 hr between 46 and 76 hr after the start of labelling. On average 2 tumours were evaluated at each point of time as far as sufficient labelling was found in the autoradiograms. Three to four thousand cells were counted per tumour within a representative area independently by 2 observers.

RESULTS

Twenty days after virus inoculation in new born rats sarcomatuous neoplasms are histologically recognizable in the kidneys with great consistancy in both thymectomized and non-thymectomized animals [8]. In this study tumour kinetics of 30 and 50-day old animals, i.e. 10- and 30-day old sarcomas are described. In the following, the age of tumour bearing animals will be given exclusively.

(1) *Tumour incidence*

From 149 non-thymectomized rats 41 unilateral and 65 bilateral renal sarcomas were obtained, a yield of 171 tumours in 298 kidneys equal to 57.5%. In 77 thymectomized rats 17 unilateral and 44 bilateral sarcomas were found, a yield of 105 tumours in 154 kidneys equal to 68.5%.

(2) *Growth curve*

In Fig. 1 the logarithms of tumour weights ($\log_{10}$, mean values) are plotted against the age of animals between the 25th and 60th day of life. Up to the 50th day there is an increase of tumour weights for both groups of animals. Thereafter a slow-down of growth or even an incipient regression is observed. Because of the wide spread of the tumour weights a simple exponen-

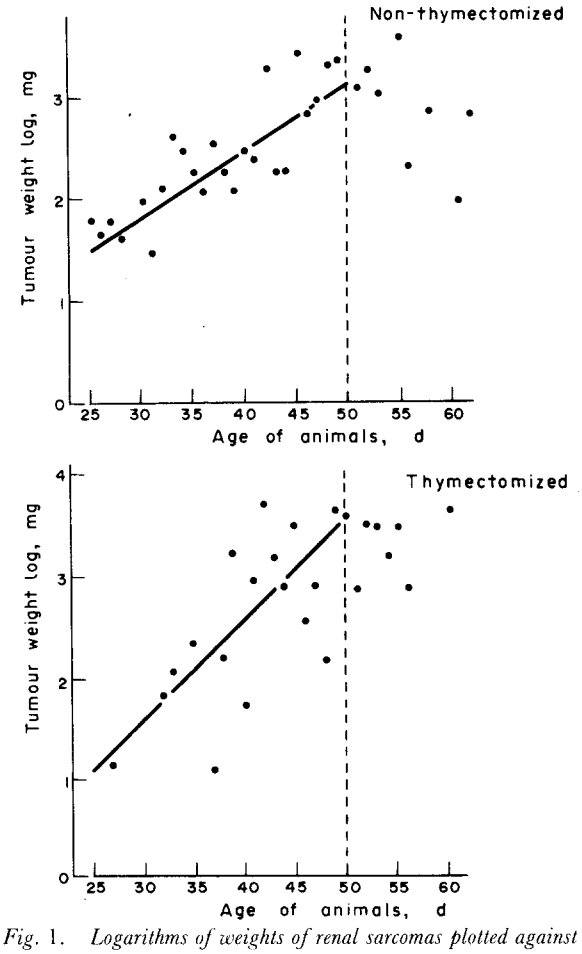

Fig. 1. Logarithms of weights of renal sarcomas plotted against the age of non-thymectomized and thymectomized tumour bearing rats. Points represent mean values of 2–6 tumours. Regression analysis performed between the 25th and 50th day. The regression lines are entered into the Fig. indicating a tumour doubling time of 110 hr *in non-thymectomized and* 76 hr *in thymectomized animals.*

* Determined at a level of greatest diameter of tumour in serial sections through the kidney.

Table 1. Labelling index 1 hr after a pulse of 3H-thymidine (LI1h) into rats with PV-induced renal sarcomas. Proliferative fraction (PF) calculated by method of Lala and Patt [16]. Potential tumour doubling time (T_{dpot}) calculated following Steel [18]. Actual tumour doubling time (T_d) estimated by a histomorphometrical experiment

Age of animals (days)	LI(1h) %	PF %	T_{dpot} (h)	T_D
30	13	42	105	110
30*	13	55	43	76
50	15	48	55	110
50*	18	58	38	76

* Tumours of thymectomized animals.

tial function was fitted to the experimental data from the 25th to the 50th day. The regression coefficient of the tumour weights of non-thymectomized animals is $W_1 = 0.0655$ (± 0.007) and of thymectomized animals $W_2 = 0.0951$ (± 0.002). The respective regression lines are entered into Fig. 1. Therefore tumour doubling time (T_d) is calculated amounting to 110 hr in the non-thymectomized group and 76 hr in the thymectomized group (see Table 1). A significant difference is calculated in the *t*-test ($P = 0.05$).

(3) *Cell cycle times and phase durations*

The results of the PLM-experiments are shown in Table 2 and Fig. 2. A computer analysis was performed (by Dr. G. G. Steel), distributions of cycle times being part of evaluation (Fig. 3). Because of the high standard deviations significances were not tested. The older tumours of both groups show a wider spread of their cycle times especially towards the long end of individual cycle times.

(4) *Proliferative fraction*

PF was calculated by the equation:

$$PF = LI_{experimental}/LI_{theoretical} \qquad (II)$$

following Lala and Patt [16]. The values of LI (1 hr), PF and potential tumour doubling time (T_{dpot}) derived by method of Steel [18] are given in Table 1.

(5) *Cell production rate and cell loss*

The cell production rate (CPR) was calculated by the known values of PF, $\bar{T}_C$ (mean cycle time) and data obtained by a continuous labelling experiment. Additionally, continuous labelling data and the known actual tumour doubling time (T_d) give the cell loss rate (CLR) and the mode of cell loss. The latter specifies to what extent proliferative and resting cells are affected by loss.

The evaluation of continuous labelling data was done by method of Lang *et al.* [19]. According to it, the theoretical increase of LI in a growing cell population under continuous labelling is given by the equation:

$$LI_t = 1 - (1 - a)\exp[\phi(-T/\bar{T}_C)]; \quad (III)$$

LI_t : expected labelling index at a time t;
a : proliferative fraction (PF);
T : duration of 3H-thymidine labelling;
$\bar{T}_C$: mean cell cycle time.
The value e^{ϕ} was determined by an optimal fit of the model function (III) to the experimental data. ϕ includes the following parameters (calculation see Lang *et al.* [19]):
β : cell production rate (CPR);
δ_P : loss rate of P-compartment (PCL):
δ_Q : loss rate of Q-compartment (QCL);
In Table 3 cell production and loss rates are

Table 2. Cycle times, phase durations estimated by the labelled mitoses technique in PV-induced renal sarcomas of 30- and 50-day old thymectomized and non-thymectomized rats (computer analysis by Dr. G. G. Steel)

Age of animals (days)	Phase durations and cycle times Mean values and standard deviation (h)			
	T_{G_1}	T_S	T_{G_2}	T_C
30	10.8 ± 12.5	7.8 ± 2.6	2.5 ± 1.1	21.1 ± 12.8
30*	14.8 ± 10.8	7.0 ± 1.7	2.9 ± 1.3	24.7 ± 10.5
50	16.3 ± 14.3	10.5 ± 5.1	3.0 ± 2.5	29.8 ± 15.4
50*	15.3 ± 12.4	10.5 ± 6.2	2.7 ± 1.2	28.5 ± 13.9

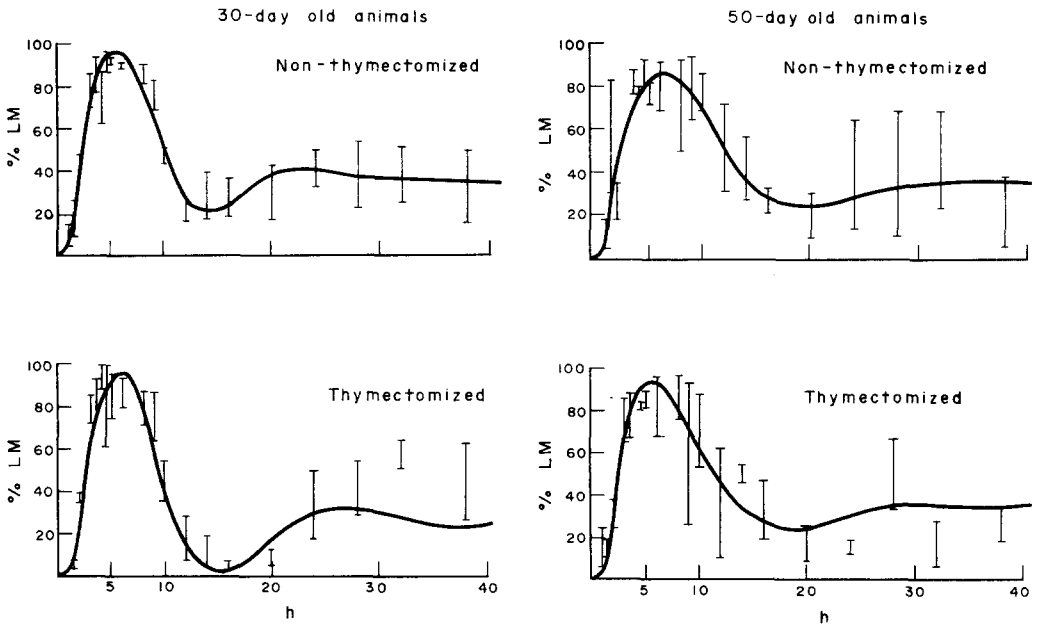

Fig 2. Percent-labelled-mitoses curves after pulse labelling with ^{3}H*-thymidine in tumours of* 30*-and* 50*-day old non-thymectomized and thymectomized rats. The curves are drawn following a computer analysis of the PLM-data (by Dr. G. G. Steel, London).*

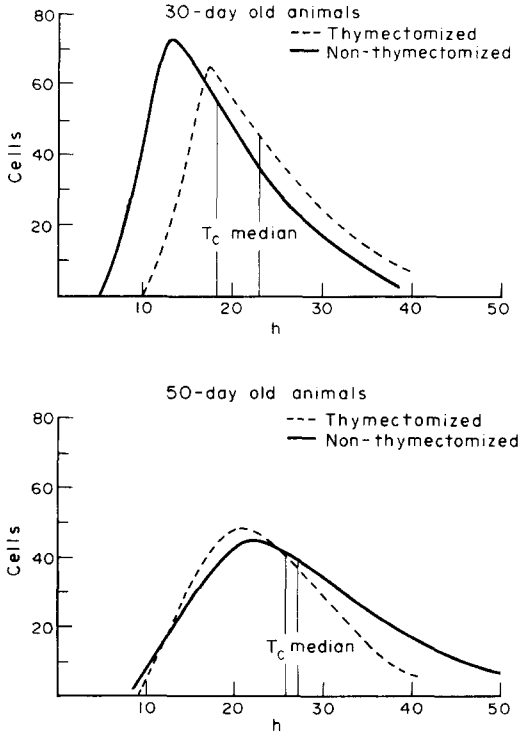

Fig. 3. Distribution of cell cycle times on the basis of computer analysed PLM-data in tumours of 30*- and* 50*-day old non-thymectomized and thymectomized rats. Vertical line: mean cycle time.*

given. Additionally, cell loss is given as a cell loss factor (CLF), i.e. the quotient of CLR and CPR in percentage. Finally, the P- and Q-cell loss per hour as a percentage of the respective compartment is differentiated and the relation between both rates added.

In younger animals the QCL is fairly higher than PCL especially in non-thymectomized animals. For older tumours no essential difference between QCL and PCL can be seen.

The PF and CPR are higher in sarcomas of thymectomized rats. An estimation of their standard deviations and a test of significance is not included. Since PF is determined by the use of PLM-data the phase durations with their wide standard deviations enter into the calculation and obscure a relatively low difference of PF values of about 10–15%. However, an increase of PF in thymectomized rats is to be accepted since only this parameter may explain the significant increase of the overall growth rate whereas cycle times are nearly identical and cell loss rates even higher in thymectomized animals.

For sarcomas of 50-day old thymectomized animals there is no satisfying fit of the model function (III) to the experimental data (see Fig. 4). That means PF obtained by the PLM-data is underestimated. A modification of loss parameters would not give a better fit. The remainder of the theoretical labelling curves shown in Fig. 4 give a satisfying accordance with the experimental values, i.e. reliable values of loss rates.

DISCUSSION

Thymectomy in new-born Wistar rats preced-

Table 3. Cell production rate and cell loss in PV-induced renal sarcomas of 30- and 50-day old thymectomized and non-thymectomized rats. The values are calculated by evaluation of continuous labelling data following method of Lang et al. [19], T_d *and PF. CPR: cell production rate per hour; CLR: cell loss rate per hour; CLF: cell loss fraction* $= CLR/CPR \times 100$; *PCL: P-cell loss as a percentage of total P-compartment lost per hour; QCL: Q-cell loss as a percentage of total Q-compartment lost per hour. QCL/PCL: quotient of absolute loss rates*

Age of animals (days)	CPR (1/h)	CLR (1/h)	CLF (%)	PCL (%/h)	QCL (%/h)	QCL/PCL
30	0.0066	0.0003	5	0.03	1.70	70
30*	0.0160	0.0069	43	0.63	1.02	1.7

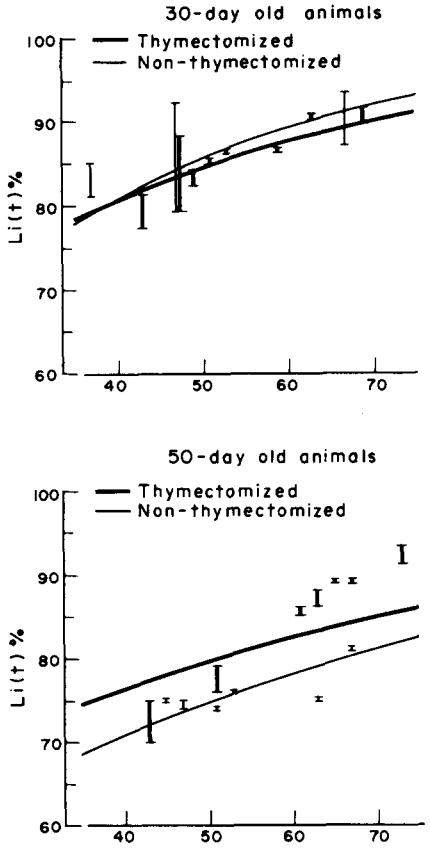

Fig. 4. Continuous labelling by intraveneous infusion of 3H-thymidine into 30- and 50-day old non-thymectomized and thymectomized rats. Experimental data with spread of values entered as vertical bars. The curves represent an optimal fit of a model function [19] *to the experimental data. The function renders the expected increase of the labelling index under continuous labelling.*

ing inoculation of Polyoma virus results in a significantly higher yield of renal sarcomas. This was already found in previous studies [8] and now confirmed within these experiments as an additional result. This is in accordance with the well known increase of tumour incidence in immune-deficient animals after viral or chemical tumour induction [1–9, 20–25].

The main conclusions from these studies may be characterized as follows: thymectomy increases the growth rate of sarcomas significantly whereas no remarkable influence on the timing of the cell cycle is seen. The accelerated growth rate is due to an increased PF. There is also no decrease of PF with increasing tumour age like in sarcomas of non-thymectomized hosts as previously shown [11].

The cell loss rate is essentially lower in tumours of non-thymectomized animals. This is remarkable because the retarded tumour growth of immune-competent rats may not be explained by an increased cell loss resulting from cytotoxicity of thymocytes as might be expected. It seems therefore that cell loss is caused merely by hypoxemia like in some further solid tumours [26–33]. The apparent lack of lymphocytes among the sarcoma cells in non-thymectomized rats may confirm this view.

There is another explanation for the different growth behaviour of tumours in thymectomized rats that could result from the depletion of T-lymphocytes. The immuno-deficiency might prolong the period of virus replication thereby extending the period of cell transformation. A sustained development of "new" tumour cells may provide a higher PF in contrast to immune-competent hosts. Still another factor affecting PF by immunological alterations is conceivable. The known influence of a stimulated immune system on G_2-cells [34] might be connected with a change of PF. Usually, this influence leads to a prolongation of the G_2-cycle phase or to preferential cell loss during this phase [35]. However, if a G_2-cell arrest would be suggested this could explain a reduction of PF too.

Changes of tumour cell kinetics under an altered immune situation of hosts are reported in

the pertinent literature [34, 36–39]. According to it, a retardation of the overall growth rate by immune pressure is known. These observations are comparable with our results indicating a decreased growth rate in immune-competent rats. Further parallels may be drawn with some solid tumours showing a decreased cell production rate after immunisation of the host [37] and a fairly good consistency of cell cycle times despite an immunological disturbance [34, 37]. Consequently, the change of cell production rate also results from a change of PF like in the renal sarcomas.

Interesting is a report on a solid tumour of rats treated with antithymocyte serum [38]. An increase of PF and decrease of T_d is observed in contrast to immune-competent hosts. So far it agrees well with the behaviour of the renal sarcomas. However, a substantially shorter cell cycle time in untreated rats is found leading to a reduced T_{dpot} and consequently to a higher cell loss factor.

Information about the mode of cell loss in tumours under immunological disturbance are sparse. Janik [35] reports a random loss from P- and Q-compartment under immune pressure. This finding is in accordance with our results except for small tumours of non-thymectomized rats with a predominant loss from the resting cell compartment.

Interaction of Androgens with Oestradiol-17β Receptor Proteins in DMBA-Induced Mammary Tumours—a Possible Oncolytic Mechanism

R. I. NICHOLSON, P. DAVIES and K. GRIFFITHS
Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath Park, Cardiff, CF4 4XX, Wales, U.K.

Abstract—*A series of androgens have been examined for their ability to* (1) *compete with* [^{3}H]*oestradiol-17β for the cytoplasmic oestradiol-17β receptor protein isolated from DMBA-induced mammary tumours and* (2) *facilitate the nuclear translocation of the oestrogen receptor. The most effective androgen examined was androst-5-ene-3β,17β-diol. Compounds that did not compete with* [^{3}H]*oestradiol-17β for cytoplasmic oestradiol-17β binding sites were unable to instigate the translocation of the oestrogen receptor. Androgen-transferred oestrogen receptors were found to have a relatively short nuclear retention time and readily bound* [^{3}H]*oestradiol-17β at* 4°C.

INTRODUCTION

A NUMBER of reports have demonstrated an oncolytic action for androgens in both human [1, 2] and rat [3–6] mammary tumours. The mechanism by which such compounds inhibit tumour growth has for the most part remained unknown. Since we have previously demonstrated that the growth of the DMBA-induced rat mammary tumour requires the presence of cytoplasmic oestradiol-17β receptor proteins [7–9] the tumour represents a good model system by which the hypothesis that the oncolytic effects of androgens are mediated via the oestrogen receptor system can be tested. The present study therefore examines the direct action of testosterone and other C_{19}-steroids on the binding of oestradiol-17β to its receptor protein in both cytoplasmic and nuclear compartments of DMBA-induced mammary tumours.

A preliminary report of this work has been presented [10].

MATERIAL AND METHODS

Animals

Mammary tumours were induced in virgin female Sprague–Dawley rats (50±2 days old) by intubation with a single dose of DMBA (20 mg in 1 ml sesame oil). Animals were housed in groups of 4 and fed diet and water *ad libitum*. Beginning 5 weeks after intubation with DMBA, rats were palpated for tumours at weekly intervals and tumour size recorded as the mean of two perpendicular diameters, one measured across the greatest width. Tumours which did not attain an approximate size of 20 mm mean diameter in the 23 week period following carcinogen administration were not used in this study.

Preparation of subcellular fractions

Soluble supernatant (cytosol) preparations were obtained as described by Nicholson, Golder, Davies and Griffiths [8] using a homogenisation procedure resulting in maximum breakdown of tumour cell membranes with minimum damage to cell organelles [11]. Nuclei were prepared by a method described by Davies and Griffiths [12].

Competitive binding studies on cytoplasmic fractions

Aliquots (200 μl) of tumour cytosol preparations (approximately 20 mg protein/ml) from ovariectomised animals (operation performed one day previously) were incubated for 2 hr at 4°C with equal vol of 50 mM-Tris–HCl buffer, pH 7.4, containing 5 mM EDTA and 1 mM dithiothreitol (Tris–HCl buffer) and also [^{3}H]oestradiol-17β (5 nM; [2, 4, 6, 7 $^3H_4$]-

Accepted 17 October 1977.

oestradiol-17β, specific activity 85 Ci/mmole, Radiochemical Centre, Amersham) in the presence and absence of various amounts of diethylstilboestrol or other potential ligands (5 nM–5 μM). After incubation, tubes were maintained at 4°C and an equal vol (400 μl) of charcoal suspension (0.5% (w/v) Norit-A, 0.05% (w/v) Dextran T-70, 0.1% (w/v) gelatin) in Tris–HCl buffer added. The resultant mixture was shaken for 60 min at 4°C and charcoal removed by centrifugation at 800 ***g*** for 10 min. Aliquots (200 μl) of the supernatant containing protein-bound [^{3}H]oestradiol-17β were added to 6 ml scintillation fluid (1 litre toluene, 500 ml Triton X-100, 10 g PPO) and radioactivity measured in a Nuclear Chicago (Mark II) liquid scintillation spectrophotometer using external standardisation.

Determination of nuclear sites by [^{3}H]*oestradiol-17β exchange—'total sites'*

The method for the determination of nuclear oestradiol-17β binding sites is a slight modification of that described in a previous communication [9]. Briefly, receptor protein present in the nuclear fraction (200 μl aliquots) was precipitated by protamine sulphate (1 mg/ml in 50 mM Tris–HCl buffer). [^{3}H]Oestradiol- 17β (20 nM) in Tris–HCl buffer (200 μl) containing 5 nM sodium bisulphite or [^{3}H] oestradiol-17β plus a 1000-fold higher concentration of cold diethylstilboestrol was added to the precipitated receptor and the mixtures incubated for either 4 hr at 15°C or 16 hr at 4°C. After incubation, the tubes were cooled at 4°C and washed repeatedly in Tris–HCl buffer. The final pellet was extracted with ethanol, centrifuged and the ethanolic supernatant counted as before.

Determination of oestrogen binding sites following the in vivo *administration of either oestradiol-17β or various C_{19}-steroids*

(a) Thirty ovariectomised animals bearing 50 mammary tumours were divided randomly into ten groups (5 tumours/group). Each group received either oestradiol-17β (0.5 or 5 μg), testosterone (1 mg), 5α-dihydrotestosterone (1 mg), epitestosterone (1 mg), androstenedione (1 mg), 5α-androstane-3β, 17β-diol (100 μg or 1 mg), or androst-5-ene-3β, 17β-diol (androstenediol) (100 μg or 1 mg) in 1 ml vehicle (steroid solutions were prepared by addition of the requisite compound to propylene glycol and diluting to volume with 0.15M NaCl) by i.v. injection.

Tumour biopsy samples (approx. 200 mg tissue) were removed aseptically from Nembutal®-anaesthetized animals at time 0 (prior to injection) and at 10, 25, 40 and 60 min after injection. Cytosol fractions were assayed for accessible oestradiol-17β binding sites while nuclear fractions were assayed for both total and accessible sites.

(b) Fifteen ovariectomized animals bearing 20 tumours were divided randomly into 4 groups (5 tumours/group). The experimental design was as described in (a) except that animals were treated with either oestradiol-17β (5 μg), 5α-dihydrotestosterone (1 mg), 5α-androstane-3β,17β-diol (1 mg) or androstenediol (1 mg) and tumour tissue was biopsied at time 0, and at 0.5, 1, 2, 4, 8, 16 and 24 hr after injection. Nuclear fractions were assayed for both total and accessible oestradiol-17β binding sites.

Chemical analyses

The DNA content of nuclear fractions and the protein content of cytosol fractions were estimated using the methods of Burton [13] and Lowry, Rosebrough, Farr and Randall [14], respectively.

RESULTS

Specificity of the accessible cytoplasmic oestradiol-17β binding assay

The data presented in Fig. 1 shows the competition by various non-radioactive steroids with [^{3}H]oestradiol-17β for accessible cytoplasmic binding sites. Addition of 25 nM unlabelled oestradiol-17β decreased the binding of [^{3}H]oestradiol-17β to approximately 40% of the control value. The binding continued to decrease with increasing oestradiol-17β concentrations. There appears also to be competition for receptor binding between [^{3}H]-oestradiol-17β and the dihydroxysteroids. Androstenediol and 5α-androstane-3β, 17β-diol in a 1000-fold excess decreased the binding of [^{3}H]oestradiol-17β to 25 and 42% of the control value respectively. Of the other C_{19}-steroids tested, testosterone and 5α-dihydrotestosterone were partially inhibitory but only at very high concentrations, while androstenedione, epitestosterone and dihydroepiandrosterone were without any substantial effect.

In vivo *effects of oestradiol-17β and C_{19}-steroids on* [^{3}H]*oestradiol-17β binding*

Within 40 min following the *in vivo* administration of 0.5 μg oestradiol-17β, an approximately 50% reduction in the binding of [^{3}H]oestradiol-17β to specific cytoplasmic binding proteins was observed (Fig. 2). This corresponds to a concomitant progressive increase in specific nuclear oestradiol-17β binding sites. Elevation of the level of oestradiol-17β adminis-

tered *in vivo* to 5 μg resulted in a more pronounced translocation of cytoplasmic binding sites to the nuclear fraction. Like oestradiol-17β, single injections of either androstenediol (Fig. 3) or 5α-androstane-3β, 17β-diol (Fig. 4) reduced accessible cytoplasmic oestradiol-17β binding sites in a dose-dependent manner. The nuclear binding sites, however, unlike the oestradiol-17β-translocated receptor, appear to be present in a form which is readily accessible to exogenous hormone at 4°C. *In vivo* administration of testosterone resulted in a slight decrease of cytoplasmic binding sites at the higher dose level and a corresponding low nuclear uptake of the receptor complex (Fig. 5). A considerable amount of nuclear binding occurred at 4°C. Administration of dihydrotestosterone was more effective than testosterone at reducing cytoplasmic oestradiol-17β binding sites *in vivo*, but less so than either oestradiol-17β, androstenediol or 5α-androstane-3β,17β-diol (Fig. 5). Again, considerable translocation of the

receptor complex to the nucleus occurred. The receptor bound [^{3}H]oestradiol-17β with equal efficiency at 15 or 4°C. Androstenedione and epitestosterone were without effect on receptor translocation (not illustrated).

Extension of the experimental time period to 24 hr after oestradiol-17β administration (Fig. 6) showed that nuclear binding sites, as determined by exchange assay at 15°C, peak at 2 hr and remain elevated over the 24 hr period. Accessible nuclear binding sites were low throughout the experimental period. The pattern of nuclear binding following androstenediol and 5α-androstane-3β, 17β-diol was substantially different from that produced by oestradiol-17β. Maximum nuclear binding occurred at 2 hr. However, unlike the oestradiol-17β-mediated response, the levels were not maintained over the 24 hr period and returned to values indistinguishable from control levels by 4 hr. 5α-Dihydrotestosterone behaved in a manner similar to androstenediol and 5α-androstane-3β,17β-diol.

DISCUSSION

The data presented in Fig. 1 show that androstenediol and 5α-androstane-3β,17β-diol were the most effective compounds examined in reducing the specific binding of [^{3}H]-oestradiol-17β to its cytoplasmic binding protein. Substantial inhibition of [^{3}H]-oestradiol-17β binding was observed at concentrations of these dihydroxysteroids as low as 25 nmole/l, that is at a concentration only 5-fold higher than that of the radioligand. The relative affinity of androstenediol for the oestradiol-17β receptor protein based on comparative binding

studies is approximately 10–20 fold lower than that observed for oestradiol-17β. These observations are consistent with our earlier findings [15] and also with the suggested physiological [15, 16] and pharmacological [10] role of these substances in the growth of mammary tumours.

It is now quite clear that at relatively high dose levels certain androgens can bind to the cytoplasmic oestrogen receptor and induce its translocation to the tumour cell nuclei in a dose-dependent manner. The process appears to be related to the relative affinities of the compounds for the oestradiol-17β receptor protein. Androgens that do not compete with oestradiol-17β for its specific binding protein are unable to affect the translocation process. Similar observations have been made with 5α-dihydrotestosterone in rat uteri by Ruh, Wassilak and Ruh [17] and Rochefort and Garcia [18]. These data are not consistent with specificity previously attributed to the translocation phenomenon [19].

The androgen-transferred receptor is different from the oestrogen receptor complex in both its short nuclear retention time and also in its ability to extensively bind [^{3}H]oestradiol-17β at 4°C. Such data may infer different conformational states for the respective receptors. An analogous finding has been observed with the receptor complex induced by the antioestrogen, tamoxifen, and that formed by oestradiol-17β [20]. Sucrose density gradient centrifugation analysis of rat mammary tumour cytosol fractions reveals that [^{3}H]oestradiol-17β binds specifically with the sedimentation coefficient of 8 S [20–22], while [^{3}H]tamoxifen gives a value of 4–5 S [20]. The exact role or significance of the 4–5 S moiety is unknown. Rochefort, Lignon and Capony [23] demonstrated that the uterine nuclear oestrogen receptor translocated by 5α-dihydrotestosterone bound [^{3}H]oestradiol-17β at 4°C and displayed the characteristic 5 S nuclear oestradiol-17β binding pattern. This latter characteristic does not in itself exclude differences between the respective complexes; rather it may emphasise the relative limitations of the techniques available.

The transitory nuclear retention observed for androgen-transferred oestrogen receptor is similar in character to that observed for oestriol. This steroid apparently acts as a weak oestrogen principally because of its short nuclear retention time [24, 25]. When oestriol is present continually, either by multiple injections [25] or by chemical modification of the compound [26], thus maintaining the nuclear concentration of the receptor complex, it acts as a potent oestrogen without antagonistic properties. In view of these data it may prove valuable to maintain the nuclear concentration of the androgen-transferred oestrogen receptor complex and determine whether it too acts as an oestrogen or has enhanced anti-tumour activity.

In summary, we have shown that certain androgens, most notably androstenediol, translocate the oestrogen receptor to tumour cell nuclei. We propose that this property may form the basis for the known anti-tumour activity of androgens.

Letter to the Editor

Preservation of Enzymatically Prepared Rabbit VX2 Tumour Cells *In Vitro*

SUDHIR A. SHAH and JOHN A. DICKSON

Cancer Research Unit, University Department of Clinical Biochemistry, Royal Victoria Infirmary, Newcastle upon Tyne, England

GALASKO and Haynes [1] have recently reported that suspensions of VX2 carcinoma cells in saline after storage in liquid nitrogen failed to produce tumours in rabbits. However, VX2 tumour cells which had been stored at −70°C in tissue culture medium (TC 199) containing 10% DMSO did give rise to tumours when transplanted into rabbit thigh muscle. The tumour-bearing animals survived longer than the rabbits used for routine passage of tumour. Galasko and Haynes [1] employed a mechanical method for obtaining single cells from the VX2 tumour.

In this communication, we report our experience in preserving the VX2 tumour cells *in vitro*. Initial work with a variety of mechanical techniques for disaggregating the VX2 tumour revealed a viability of only 5–10% in the liberated tumour cells, as determined by trypan blue dye exclusion [2]. Such a low viability suggested that many of the non-staining cells might be damaged to a varying degree. Separation of viable from non-viable VX2 tumour cells was performed by differential flotation on Ficoll–Hypaque density solutions as described by Mavligit *et al.* [3]. The yield of viable VX2 cells recovered from the floating fraction was too poor to render the procedure of practical value.

An enzymatic method as described previously by Muckle and Dickson [4] for disaggregating the VX2 tumour was therefore employed for the present work. In addition to trypsin and deoxyribonuclease, 0.1% collagenase (Type 1 containing protease and peptidase activity, Sigma Chemical Co., St. Louis, U.S.A.) was also added to the enzyme mixture. The viability of the VX2 tumour cells obtained by this method was always greater than 95%. Usually $1–3 \times 10^8$ VX2 cells were obtained from 10 g of tumour. The VX2 cells were washed 2× and resuspended in either Waymouth culture medium (Difco 5043-37-5 TC Medium MB 752/1 Dried) containing 1% bovine serum albumin (BSA: Sigma Chemical Co., Albumin, bovine, fraction V) or in Dulbecco's modified Eagle's medium (MEM: Flow Laboratories, IF-017A, Dried) containing 20% newborn calf serum (Flow Laboratories, 4-053 D). These two media contained penicillin (100 units/ml), streptomycin (100 μg/ml) and Mycostatin (100 units/ml).

The following three methods were employed for storing the VX2 cells.

1. *Storage at room temperature* (*RT*, 20°C)

The VX2 tumour cells were left at RT for 7 days in Waymouth medium containing 1% BSA. The viability of the tumour cells at the end of 7 days was 60–70%. One million viable tumour cells were implanted into the left hind leg muscle of New Zealand white rabbits as described previously [4, 5].

2. *Short-term VX2 cell cultures* (37°C)

The VX2 cell suspensions in MEM + 20% calf serum were seeded into 30 ml (75 cm^2) Falcon flasks (Falcon Plastics, Los Angeles, CA, U.S.A.) using 10 ml suspensions with 1×10^6 cells/ml for each flask. The flasks were incubated at 37°C in an atmosphere of 5% CO_2 in air using a CO_2 incubator. After 24 hr, the cells were put on 50% conditioned medium. The medium was renewed every 2 days using fresh medium after the second day. After 5–6 days, the primary cultures were treated with trypsin–versene (5 ml; 1 vol of 0.25% trypsin + 4 vol of 0.02% versene) and

Accepted 12 September 1977.

passaged—the cells of one flask being split into 2 new flasks as described by Souhami *et al.* [6]. The VX2 carcinoma cells were maintained in culture for up to 6 weeks. One million cells from the short-term cultures were transplanted into rabbits at weekly intervals after initiating the cultures.

3. *Freezing in liquid nitrogen* (−196°C)

The VX2 tumour cells were stored in Waymouth medium containing 1% BSA and 10% glycerol or 10% DMSO. The sealed glass ampules each containing 5×10^6 cells in 1 ml of the above medium were initially placed in a deep freeze at −70°C for 20 hr. Subsequently the ampules were transferred into a liquid nitrogen storage tank at −196°C. When required, the ampules were rapidly thawed in a waterbath at 37°C, and the cells were washed twice in BSA-containing medium followed by BSA-free Waymouth medium. The viability of the VX2 cells preserved in 10% glycerol-containing medium decreased from 95 to 40% after storage of cells in liquid nitrogen for 3 yr. On the other hand, the viability of VX2 cells stored for this period of time in 10% DMSO-containing medium was usually less than 5%. Cell lysis was often observed in the tumour cell suspensions recovered from DMSO-containing medium; this did not occur when glycerol was used as preservative.

Bioassay

The growth characteristics of the tumours obtained in rabbits after inoculation of fresh VX2 cells, or cells stored at RT, in liquid nitrogen and in short-term cultures were similar. From an i.m. inoculation of 1×10^6 viable cells the tumour became palpable by 4 weeks and all animals died with metastases in the lungs, regional and para-aortic lymph nodes at 70 ± 7 days after injection. The VX2 tumour cells grown in culture for over 3 weeks failed to produce tumours when inoculated into rabbits. We have reported the use of such short-term cultures of VX2 tumour cells in microcytotoxicity assays for testing lymphocytes and serum from VX2 tumour-bearing rabbits treated by hyperthermia [7].

The results reported here support the previous findings [1] that VX2 carcinoma cells can be stored *in vitro* and do not necessarily have to be passaged *in vivo*. Galasko and Haynes [1] observed a fibrin clot formation when the VX2 cells were stored at −70°C in TC 199 containing DMSO. Furthermore, successful transplantation of the tumour was ensured only when the fibrin clot was implanted into the thigh muscles of the rabbit. Cells stored for 13 months failed to produce tumours in rabbits [1]. In the present study with the enzymatically prepared VX2 cells, fibrin clot formation was never observed. The VX2 tumour cells stored in liquid nitrogen for up to 3 yr gave rise to tumours on inoculation into rabbits, and glycerol was clearly superior to DMSO as a low temperature preservative for long-term storage of these cancer cells. The greater viability of the initial cell population and the use of storage medium containing albumin as well as glycerol may account for the superior results obtained in the present work.

Announcement

EUROPEAN ORGANISATION FOR RESEARCH ON TREATMENT OF CANCER

A training fellowship supported by the EORTC Foundation is currently available to enable European clinicians or scientists to spend one year in an institution outside their own country but within Europe. Applicants should submit a curriculum vitae, outline of the research or training programme to be followed and letter of acceptance from the host institution.

Salary will be on the host country's clinical or academic scales, the point on the scale depending on the candidate's age and previous experience.

Apply to Professor E. H. Cooper,
Secretary EORTC Fellowship Committee,
Unit for Cancer Research,
University of Leeds,
Leeds LS2 9NL,
Yorkshire, England.

Europ. J. Cancer Vol. 14, pp. 450–451. Pergamon Press 1978. Printed in Great Britain

Perspectives in Cancer Research

Suppressor Cells of Immune Reactivity in Malignancy

H. KIRCHNER
Institute of Virology, German Cancer Research Center, Heidelberg, Federal Republic of Germany

A MAJOR advance in the field of immunology during the past few years has been the concept that immune reactions are controlled by negative feedback mechanisms through suppressor cells [1, 2]. In many immunologic model systems such suppressor cells of various types, particularly suppressor T cells, have been described [3, 4]. There have been a number of reports that suppressor cells may also play a role in the immunosuppression observed in tumor bearers which will be reviewed in the present article.

Immunosuppression plays an important role in many aspects of the cancer problem which may be summarized as follows:

1. According to the immunosurveillance concept a failure of the immune system has been implicated in the development of cancer [5].
2. Specific immune reactivity against tumor cells which has been well documented to exist in many instances [6] appears to be prevented from being operational *in vivo* by immunosuppressive mechanisms [7].
3. Most tumors after they reach a certain size cause a general suppression of the immune system [8]. This suppression is nonspecific in nature but it may well add to the suppression of specific anti-tumor immunity.

SUPPRESSOR CELLS AND IMMUNOSURVEILLANCE

Clinical observations have supported the existence of an immune surveillance mechanism against tumors [9]. A strong case for immune surveillance can be made in the case of virus-induced tumors [10]. However, convincing evidence has been presented that spontaneous tumors are nonantigenic [11]. A concept has been recently offered how to explain this obvious contrast between the nonantigenicity of spontaneous tumors and the role of immunosurveillance against virally induced tumors [10]. Suppressor cells have been described in virally induced tumor systems after the tumors had reached a considerable size [12]. There are no data available supporting the existence of suppressor cells during the early development of virus-induced tumors. Thus, there is at present no indication for a role of suppressor cells in the breakdown of cellular immunosurveillance against virally induced tumors. However, experiments in more suitable models such as in polyoma-virus-induced tumorigenesis have not been performed as yet.

SUPPRESSION OF SPECIFIC ANTI-TUMOR IMMUNITY BY SUPPRESSOR CELLS

There is now a large body of data available to indicate that tumor cells possess antigens which can be recognized by immune lymphocytes of the tumor bearing host *in vitro*. Effector mechanisms of many kinds have been defined but it remains unclear why these are not successfully operative *in vivo* (for review see references [6, 8, 13]). Conceivable, the observed immune reactivity only represents an epiphenomenon which *a priori* has no *in vivo* significance (as for example the immune response to a myocardial infarction [14]). Even if this were so, it would be of importance to study these mechanisms with the goal to alter them for therapeutic use either by modification of the antigenicity of the target cell or by enhancing the activity of the effector cells.

However, it is also possible that the anti-tumor immune response is quite potent, but that it is prevented from being active by blocking mechanisms. This is suggested by the so called "eclipse" phenomenon, observed in certain

experimental tumor systems [15]. In these, anti-tumor cellular immunity can be observed at an early stage of tumor growth, but no longer during progressive tumor growth, presumably due to a tumor-induced immunosuppression. The mechanisms of this immunosuppression are not known. Likewise, little is known about the mechanisms of the suppression of the specific anti-tumor immune response in situations where the eclipse phenomenon does not apply.

Quite extensive evidence has been presented for the involvement of blocking factors, i.e. soluble products capable of interfering with the immune reactivity against tumor cells [7]. Depending on the system studied, these have been suggested to represent antigen, antibody, or antigen–antibody complexes [16–18]. There is beginning evidence to indicate that there is an involvement of suppressor cells in the suppression of the specific anti-tumor immune response. Kirkwood and Gershon have demonstrated suppressor T cells that affect the immune response to an allografted methylcholanthrene-induced sarcoma [19]. Umiel and Trainin [20] and Small and Trainin [21] have shown that in mice bearing the syngeneic Lewis lung tumor suppressor T cells are generated which are able to enhance tumor growth upon transfer into new recipients. In this system, it was also found that adult thymectomy which is known to preferentially remove suppressor T cells, led to a reduction in tumor development. The most convincing evidence for a role of suppressor T cells ablating the host's immune response against a tumor, stems from the work of Fujimoto and his colleagues [22, 23]. These authors have studied mice bearing the syngeneic methylcholanthrene-induced sarcoma 1509a. Solid immunity against a second challenge with this tumor was induced after surgical removal of the primary tumor. Injection of T cells of tumor bearers was found to effectively and specifically interfere with the existing immunity, leading to an inhibition of tumor rejection. Takei and his colleagues have observed that specific killer cells against the syngeneic mastocytoma P815 in DBA mice could be found only at early stages of tumor growth. At later stages specific suppressor T cells were demonstrated which inhibited the cytotoxic activity of killer cells [24, 25].

Thus, in different experimental systems suppressor T cells have been found to interfere with the anti-tumor immune response. These data may be related to Prehn's earlier work which has shown that under certain circumstances immune lymphocytes from tumor bearers have the effect of enhancing tumor cell growth in Winn type assays [26].

SUPPRESSOR CELLS AS A CAUSE OF TUMOR-ASSOCIATED IMMUNOSUPPRESSION

Clinically, many human tumors lead to a depression of cellular immunity [8] and immunosuppression has been also observed in animals bearing experimental tumors [27]. However, in some tumor systems, when the lymphocyte functions measured where not expressed on a per cell basis but per lymphoid organ (such as the spleen which is often enlarged in tumor bearers) it was calculated that these functions were actually increased. It was concluded that the effect of a tumor on the immune system was a stimulatory one [28]. Subsequently, using similar *in vitro* assays, we have brought up a concept which may explain how *stimulation* of the immune system will nevertheless cause *immunosuppression* namely through the activation of suppressor cells [29]. In the meantime similar suppressor cells have been described in many different tumor systems by a number of laboratories [30–40]. These tumors have included a considerable variety of spontaneous and virally and carcinogen-induced tumors of mice and rats. The suppressor cells inhibited the *in vitro* lymphoproliferative reactions to a variety of stimuli. While the suppressor cells were non-specific in nature, tumor-specific immune functions such as the mixed leukocyte tumor cell interaction, or the generation of specific killer cells were also inhibited. The suppressor cells were non-T cells and most investigators now agree that they belong to the monocyte–macrophage series. However, the possibility that they may be B lymphocytes still remains to be ruled out more vigorously.

The occurrence of suppressor macrophages seems not to be restricted to the tumor situation. For example, they have also been found in spleens of mice undergoing a graft vs host reaction or mice injected with *Corynebacterium parvum* [41]. Also, macrophages from untreated rabbits, rats and mice may suppress lymphocyte proliferation [42–45]. Thus, macrophage-mediated suppression of lymphoproliferation may represent quite a general phenomenon which gains particular relevance in the tumor situation. In this context, it has been recently pointed out that the depression of mitogen reactivity by macrophages in spleen cell cultures from tumor bearing rats may be caused only by their increased numbers [40]. This possibility definitively exists, but it also represents a distinct alternative that suppressor macrophages are a particular subclass of macrophages or cells of a state of increased activation.

Yet another type of suppressor cell has been recently described in mice bearing subcutaneously growing plasmocytomas [46]. These also had the characteristics of macrophages and inhibited primary *in vitro* antibody responses to sheep erythrocytes. They had no suppressive effect on mitogen reactivity. Conversely, the suppressor macrophages found in mice bearing murine sarcoma virus-induced tumors which actively suppressed mitogen responses were without effect on the *in vitro* antibody responses to T cell dependent and T cell independent antigens (Kirchner and Chused, unpublished observation). It will be of interest to do parallel tests of both assays using lymphocyte populations from animals bearing the two different tumors.

A suppressor cell has been also described in spleens of mice infected with murine leukemia virus [47, 48]. However, these mice contain leukemia cells in their spleen, which when admixed with lymphocytes have been shown to have marked immunosuppressive effects [49, 50]. The exact nature of the suppressor cell in leukemic spleens remains to be determined.

Suppressor cells of mitogen reactivity have also been found in the blood of owl monkeys [51]. Owl monkeys injected with Herpes virus Saimiri develop a lymphoma which may represent a useful model for lymphoma in man. Suppression of mitogen reactivity of blood lymphocytes was observed even before signs of ouvert leukemia could be detected. The nature of the suppressor cells has not been identified.

The *in vivo* relevance of the suppressor cells of general immunity described above remains to be determined. Unfortunately, there are no approaches available to obtain animals free of macrophages such as neonatally thymectomized or nude mice which are free of T cells. Furthermore, the performance of adoptive transfer experiments is complicated by the fact that macrophages are also functioning as anti-tumor effector cells (e.g. see references [52, 53]. It will be of great importance to determine whether suppressor macrophages and anti-tumor macrophages represent different subpopulations or populations of a different degree of activation or not. Until now it has not been possible to physically separate the cells with the two functions. We are facing the problem that cells with anti-tumor activity are contained in the same fraction as the cells which suppress lymphocyte activity. Such two types cells are found not only in spleens of tumor bearers but also in spleen injected with the immunoadjuvant *C. parvum* widely used in immunotherapy of tumors [41, 54]. The potential significance of such findings for the development of immunotherapy protocols seems to be appealing.

SUPPRESSOR CELLS IN MALIGNANT DISEASE OF MAN

In man, suppressor cells have been found to account for the *in vitro* immunosuppression observed in two lymphoproliferative disorders, Hodgkin's disease and myeloma [55, 56]. More recent reports have demonstrated suppressor cells of lymphoproliferation in patients with a variety of lymphoid tumors [57–60]. In addition, suppressor cells have also been demonstrated in patients with non-neoplastic diseases, such as common variable immunodeficiency [61] and in fungal infections [62]. The latter two cells appeared to be T lymphocytes, while the suppressor cells in the patients with the above-mentioned malignancies, similar to the data in the animal systems, belonged to the monocyte series.

It has been well established that defective humoral immunity is associated with myeloma. Recently, Broder and his associates have found severely depressed responses of peripheral blood lymphocytes from myeloma patients in the *in vitro* assay of pokeweed mitogen-induced immunoglobulin synthesis [55]. They have also found that leukocytes from myeloma patients actively suppressed immunoglobulin synthesis by B lymphocytes from normal individuals. The cell mediating this suppression appeared to be a monocyte. Furthermore, this group has also presented data in a mouse plamocytoma model which supported their previous findings in myeloma patients [63].

In Hodgkin's disease immunosuppression, predominantly of cellular immunity has been a well known clinical feature. Hersh and Oppenheim have shown that the peripheral lymphocytes of patients with Hodgkin's disease were hyporeactive in assays of *in vitro* lymphoproliferation [64]. It was subsequently shown that leukocytes of these patients were also poor *stimulators* in the mixed leukocyte reaction [56]. Removal of adherent cells reconstituted the stimulatory capacity suggesting that the defective stimulation was caused by an adherent suppressor cell. More recently, it was directly shown by Schechter and Soehnlen that monocytes from patients with Hodgkin's disease were suppressing lymphoproliferative reactivity [65].

An initial report has been given as an abstract that in some patients with cancer, the depressed responses of peripheral lymphocytes to mitogens

were caused by suppressor cells [57]. More recently, Blomgren and his associates have shown that the responses of lymphocytes from patients with advanced cancer to PPD-tuberculin and to allogeneic cells were suppressed by suppressor cells [58, 59]. A well documented report of similar results has been presented by Zembala *et al.* [60]. In all the reports evidence for the monocyte/macrophage nature of the suppressor cells was presented. However, in two patients of Zembala's series suppressor T cells were found [60].

CONCLUSIONS

In conclusion, in animal tumor models basically two types of suppressor cells have been described, a suppressor T cell interfering with specific anti-tumor immunity and a non-T suppressor cell, believed by most investigators to be a macrophage, the activity of which may be measured in a number of *in vitro* tests of cellular and humoral immunity. These tests are non-specific in that they don't measure specific anti-tumor immunity. This does, however, not exclude that the nonspecific suppressor cells suppress specific anti-tumor immunity as well.

In the human situation the former suppressor cell will be difficult to detect at present because of the relatively late stage of tumor development at which the investigator has an opportunity to study lymphocyte reactivity and because of the lack of definitive knowledge on the specificities of the anti-tumoral immune response in the human situation [66]. The latter type of suppressor cell has been identified in patients with lymphoproliferative diseases and in patients bearing solid tumors. Probably, when systematic tests will be undertaken, this type of suppression will be found even more frequently. The *in vivo* significance of such suppressor cells remains to be determined. However, since the same is obviously true for the different mechanisms of blocking by soluble mechanisms which have been previously described, further studies of suppressor cells should be encouraged.

Irradiation of the Lungs as an Adjuvant Therapy in the Treatment of Osteosarcoma of the Limbs

An E.O.R.T.C. Randomized Study

K. BREUR,† P. COHEN,‡ O. SCHWEISGUTH|| and A. M. M. HART§

Department of †Radiotherapy, ‡Radiodiagnostics and §Statistics Antoni van Leeuwenhoek Hospital, Amsterdam, The Netherlands and Department of ||Pediatric Oncology, Institut Gustave-Roussy, Villejuif (Paris) France

Abstract—*In* 1970 *a controlled clinical trial was started by the E.O.R.T.C. Radiotherapy Cooperative Group. The aim was to evaluate the effect on the development of lung metastases of an adjuvant irradiation of the lungs after "radical" treatment of primary osteosarcoma of the limbs. Five treatment Centers in France and two in The Netherlands have been participating in this trial. Early* 1975 *the trial was stopped. At that time* 86 *patients had been randomized into a group of* 42 *patients without any adjuvant therapy and a group of* 44 *patients with adjuvant lung irradiation to a dose of* 2000 rad *in* 2 *weeks. The results show that this dose of radiation can significantly decrease the percentage of cases in which metastases develop. This effect is especially seen in the group of patients under* 17 yr *of age, also resulting in a better survival rate for that group. Surprisingly it was found that in one of the participating Centers no beneficial effect from lung irradiation could be demonstrated. No other explanation could be found for this phenomenon than that a selection of patients with unfavourable prognosis is being referred to that Center. The results obtained make it necessary to include, apart from chemotherapy, lung irradiation in future trials on adjuvant therapy in osteosarcoma patients.*

INTRODUCTION

PROGNOSIS for patients with osteosarcoma is very poor. The 5-yr survival rate does not exceed 20–25%. Irrespective of the method of treatment of the primary tumor, prognosis is almost entirely dependent on the appearance of hematogenous metastases. Although metastases may appear in different organs such as skeleton, secondaries in the lungs are the main cause of death. Improvement in prognosis therefore can only be expected through reducing the growth of metastases and particularly of those arising in the lungs. In 1969 it was decided by the clinical cooperative group on radiotherapy of the E.O.R.T.C. to start a controlled clinical trial (O_2) to evaluate the effect of X- or gamma irradiation of the lungs on the percentage of cases in which lung metastases later become demonstrable.

Accepted 29 August 1977.
Address correspondence to K. Breur, Antoni van Leeuwenhoek Ziekenhuis, Plesmanlaan 121, Amsterdam, The Netherlands.

From data in the literature and from a study by Abbatucci [1] the conclusion was made that a dose of 2000 rad in 2 weeks could be considered as a safe dose with regard to radiation damage of the lungs.

It was decided to apply a dose of 1750 rad in 10 sessions during 12 days, without correction for the lesser absorption in the air-containing lungs. The actual dose to the lung tissue will then be a little less than 2000 rad, when using telecobalt gamma rays or megavoltage X-rays.

Such a dose, assumed to be the maximum permissible one for a "prophylactic treatment" at first sight seems to be inadequate to increase the number of cures. Metastases, detectable on the X-ray of the chest, have a diameter of at least 6–10 mm and contain 10^8 or more tumor cells. Experience has shown that such metastases seldom if ever can be completely destroyed by X-rays even in much higher doses. Apart from the specific radiosensitivity of a certain type of tumor, a chance of cure by radiation is also dependent on the number of viable tumor cells

initially present in the tumor. On the base of radiobiological data it can be demonstrated that for a linear increasing number of equal fractions of X-radiation one can expect an exponential decrease of the number of cells that still can proliferate. When a dose of fractionated X-rays, able to reduce the number of clonogenic cells in the tumor to 10% (D_{10}), is followed by another dose equal to D_{10}, the number of viable cells will be reduced to about 1% and so forth. Though it is improbable that the actual cell survival curve for fractionated radiotherapy will follow such a strict exponential law, it nevertheless may indicate that for a good probability of cure one will need about 11 times D_{10} for a tumour of 10^{10} cells, while for a tumor of 10^4 cells a dose equal to 5 times D_{10} would be sufficient. Assuming a D_{10} of about 400 rad for osteosarcoma, 2000 rad should prevent growth of metastases if the number of tumour cells in the lungs does not exceed 10^4 or 10^5 cells. This might even be higher if local or general defence mechanisms in the body could cope with a small number of viable cells.

To estimate the chances for such a situation in a group of patients with osteosarcoma, Breur reexamined data from earlier measurements on the growth of pulmonary metastases [2, 21].

By extrapolating growth curves backwards in time till the first day of treatment of the primary tumor, it was shown that in the majority of his 13 cases the number of cells present at that time was in all probability already 10^7–10^9, i.e. just invisible on the chest X-rays. In 4 cases, however, the number of tumor cells present in the lungs would have been in the order of 10^5 or less. Thus in theory there seemed to be a possibility for a cure in about 1 out of 4 patients with subclinical metastases at the time of treatment of the primary. Abbatucci [1] also made calculations and came to the same conclusions. It was therefore considered justifiable to start a controlled clinical trial in order to investigate whether radiation of the lungs at the time of initial treatment of the primary tumor would modify the natural course of the disease.

A proposal to irradiate one lung in each patient, using the contralateral lung as a control, was rejected on ethical grounds. The trial was started in January 1970 and was terminated in January 1975.

The following Centres participated:

Institut Gustave Roussy, Villejuif-Paris, France (coordinator: Dr. O. Schweisguth).

Centre Léon-Bérard, Lyon, France (coordinator: Dr. J. P. Gérard).

Centre Françoise Baclesse, Caen, France (coordinator: Dr. J. S. Abbatucci).

Centre Claudius Régaud, Toulouse, France (coordinator: Dr. A. Pons).

Hospices Civils (Centre Hospitalier Régional), Strasbourg, France (coordinator: Dr. J. M. Grunewald).

Rotterdams Radiotherapeutisch Instituut, Rotterdam, The Netherlands (coordinator: Dr. J. G. van Andel).

Antoni van Leeuwenhoek Hospital, Amsterdam, The Netherlands (coordinator: Dr. K. Breur).

The secretarial tasks for the trial were done in Amsterdam, respectively by Mrs. H. A. van Peperzeel, K. Breur and P. Cohen.

MATERIAL AND METHODS

Selections of patients

Criteria for patients suitable to enter the trial were:

(a) under 60 yr of age;
(b) histologically verified diagnosis of osteosarcoma;
(c) tumour location in one of the extremities;
(d) absence of clinically detectable metastases.

The age limit was laid down to exclude cases of osteosarcoma in patients with Paget's disease of the bones, because of the almost uniformly fatal prognosis for this group.

The histological slides of the tumor tissue, obtained by an open biopsy, were reviewed by R. O. van der Heul, one of the pathologists of the Dutch Bone Tumour Registry. For the diagnosis of osteosarcoma strict criteria were maintained, the main one being the evidence of bone or osteoid formation directly by the tumor cells. Histologically specific types were distinguished like fibrosarcomatous, teleangiatatic types a.o. Also the mitotic activity was noted.

All roentgenograms of the primary tumor as well as the whole lung tomograms were reviewed by one roentgenologist (P. Cohen).

Methods of randomization

Just prior to the planned date for adjuvant lung irradiation, the patient was assigned to one of the two groups:

Group O_2A without adjuvant lung irradiation;
Group O_2B with adjuvant lung irradiation.

This randomization was performed per centre by means of the envelope method, either directly after primary ablative surgery or during the course of the radiation treatment of the primary tumor.

In view of experimental data [3, 4] suggesting an increase in the number of pulmonary metastases after lung irradiation if applied at a time when an actively growing primary tumor is

still present, it was advised to delay the start of the lung irradiation until a dose of at least 4000 rad had been delivered to the primary tumor.

Treatment of the primary tumor

Owing to the fact that in the participating Centers different methods of treatment were applied, no strict rules were given in this respect, as long as such a treatment aimed at a complete local cure. Three main methods of treatment are to be distinguished:

(a) Radiation of the primary tumor to a very high dose (8000–9000 rad) was practised in most French Centers. Ablative surgery was only performed if necessary, i.e. in cases of a local recurrence or complications in the treated area.

(b) Radiation of the primary tumor to a dose of about 6000 rad in 5–6 weeks, followed by an observation period of 4–6 months. After that period ablative surgery was only performed in those cases in which no metastases could clinically be detected. This scheme, which was introduced by S. Cade [5], was practised as a rule in all Dutch Centers.

(c) Immediate primary ablative surgery was performed in a minority of patients (5 in group A, 8 in group B). In two cases (1 in A, 1 in B) the indication was based on histological criteria, suggesting a slightly better prognosis [6, 7]. Furthermore primary surgery was performed in cases with a serious dysfunction of the limb or with a pathological fracture.

Examination of the patient had to include physical examination, roentgenograms of the tumor area, whole lung tomography and blood analysis (blood count, S.R.E., alcaline phosphatase levels). Chest X-rays in two directions and tomography of the lungs had to be repeated just prior to randomization. Isotope scanning of the skeleton and lung function tests were optional.

Lung irradiation

With telecobalt gamma rays or megavoltage X-rays the lungs were irradiated through an anterior and a posterior field with beams encompassing the total contents of the thoracic cavity. Without correction for lesser absorption in the air-containing lungs, a dose of 175 rad was given per session in the mid-plane of the thorax. With 5 fractions per week a total dose of 1750 rad was applied within 12 days. The actual dose delivered to the lung tissue thus has been little less than 2000 rad. This radiation was performed as soon as possible after ablative surgery, or in case of primary irradiation of the bone tumor, when a dose of approximately 4000 rad had been delivered.

Follow-up

Patients were examined from the time of initial treatment at 4- to 6-week intervals during the first year, at 2-month intervals during the second year and 3-month intervals during the third year and later with 4-month intervals. These follow-up investigations included chest X-rays and blood analysis. Other investigations, such as X-rays or isotope scans of the skeleton were only performed on clinical indication.

All data was sent to the secretariat.

Material

When the trial was closed in January 1975, 86 patients had been included, of which 44 patients received lung irradiation. Distribution over the participating centers is shown in Table 1.

Table 1. *Number of patients per center*

Center	O_2A	O_2B	Total
Toulouse	6	3	9
Villejuif	19	18	37
Lyon	5	7	12
Caen	2	0	2
Strasbourg	1	2	3
Rotterdam	5	5	10
Amsterdam	4	9	13
	42	44	86

Of the 120 patients initially registered, 34 had to be excluded before randomization for various reasons. In 4 patients metastases were found just before treatment of the primary tumor. In 15 patients pulmonary metastases could already be demonstrated during the course of radiotherapy of the primary tumor and before randomization. In 4 patients, follow-up data was incomplete, because of emigration. The remaining 11 patients were excluded for different reasons: no confirmation of the histological diagnosis (1 patient); the primary treatment not performed in one of the participating centres (8 patients); patients being over 60 yr of age (1 patient); intercurrent death during treatment of the primary (1 patient).

Sex ratio. The distribution is practically the same in both groups.

In group A: 28 males and 14 females.

In group B: 27 males and 17 females.

The age distribution is presented in Fig. 1, the site of the primary tumors in Table 2. There are no significant differences between the two groups in these respects.

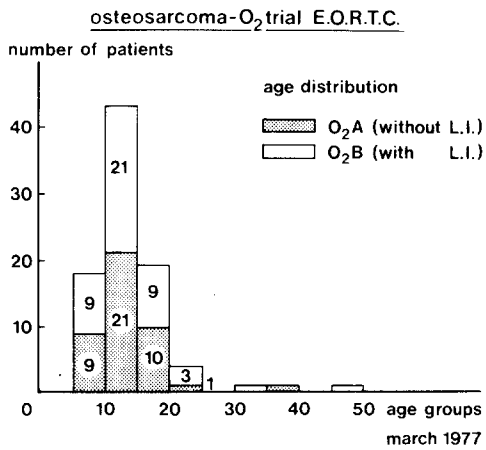

Fig. 1. Distribution of the patients in the O_2 trial over various age groups. The partition is indicated for the groups O_2A without adjuvant lung irradiation (L.I.) aand O_2B with lung irradiation.

Table 2. Site of the primary tumor

	Number of patients		
	O_2A	O_2B	Total
Humerus	3	4	7
Femur	25	29	54
Tibia	13	7	20
Fibula	1	2	3
Radius	—	2	2
	42	44	86

Roentgenology

All X-rays of the primary tumor and of the chest, as well as the tomograms were reviewed by P. Cohen. All tumors showed a more or less typical picture of a malignant bone tumor with characteristics compatible with osteosarcoma, except for one case (group O_2A) in which the X-rays showed a normal cortex and medulla, with periosteal spicules being the only abnormality.

Histology

The diagnosis of all cases included in the trial, was confirmed by the pathologists. It is remarkable that none of the cases had a typical fibrosarcomatous type of tumor. Grading with regard to mitotic frequency and other histologic characteristics did not show any difference between both groups.

Treatment of the primary tumor

As mentioned before three main modalities of treatment of the primary lesion can be distinguished: immediate operation, radiation therapy with delayed amputation (Cade's principle) and high-dose radiation therapy with no surgical procedure planned. The distribution of these treatments over both groups is shown in Table 3.

Table 3. Distribution of patients according to treatment modalities

	Number of patients	
Treatment modality	O_2A*	O_2B*
Direct ablative surgery	5	8
Radiotherapy + delayed surgery ("Cade")	7 (2)	9 (7)
High-dose radiotherapy	30 (13)	27 (10)

*O_2A = without adjuvant lung irradiation.
O_2B = with adjuvant lung irradiation.

Note: The number of patients on which later on amputation was performed is indicated between parentheses.

In 16 patients for whom surgery was planned after radiotherapy 9 patients had no demonstrable lung metastases after the 6 months observation period and underwent an amputation. Of these, 2 patients were in the O_2A group and 7 in the O_2B group. This difference may suggest a delay in appearance of lung metastases in the group with adjuvant lung irradiation. Of 57 French patients who were treated by means of high-dose radiotherapy, 23 had to undergo ablative surgery (13 in O_2A, 10 in O_2B) because of local complications and in a few cases because of renewed tumor activity.

RESULTS

The main criterion for the evaluation of the effect of adjuvant lung irradiation is the percentage of patients without any signs of metastases during the follow-up period.

The periods in which patients could be observed varied from 6 yr to 26 months. The number of patients entered during the successive years is shown in Table 4.

The statistical analysis of the data was done by A. A. M. Hart. The significance tests and the calculations of *P*-values were performed according to the method of Mantel [8]. To compare groups of patients with and without lung irradiation, a one-side test could be used, as it was only of importance to know whether lung irradiation could improve results. To calculate

metastases-free period and survival curves, the product-limit estimator according to Kaplan and Meier [9] was applied. The results presented here reflect the situation in March 1977.

Table 4. Number of cases yearly admitted to the trial

	Year of treatment	Number of patients O_2A	O_2B	Total
	1970	5	4	9
	1971	15	8	23
	1972	8	13	21
	1973	7	8	15
	1974	5	10	15
January	1975	2	1	3
	Total:	42	44	86

The lapse of time during which the two groups of patients are free of metastases is shown in Fig. 2. The difference between the curves is in favour of the group O_2B with adjuvant lung irradiation. The value $P_1 = 0.059$ indicates a significant difference at a 6% level.

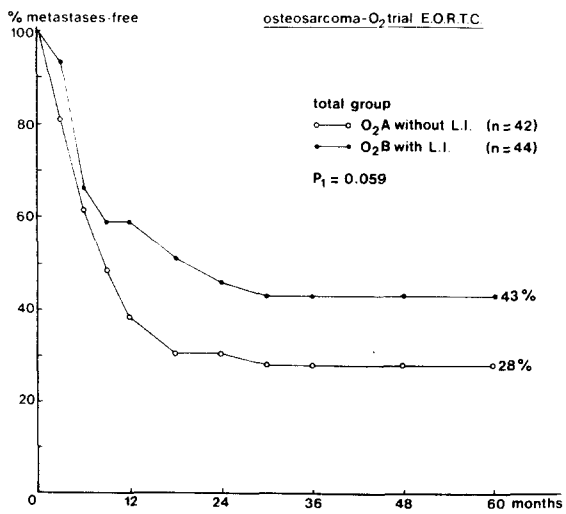

Fig. 2. Actuarial curves for the percentages metastases-free period, respectively for the group O_2A without adjuvant lung irradiation and the group O_2B with adjuvant lung treatment.

The few cases with extrapulmonary metastases are included in the results as all but one of them also developed lung metastases prior to the extrapulmonary metastases.

Both curves remain horizontal after an interval of about 2 yr, indicating an ultimate metastases-free percentage of 43 for the lung irradiated group as compared with 28 in the control group.

Influence of age

The results of adjuvant lung irradiation are relatively better in younger age groups. By breaking down the number of patients in each group into one group above and one under a certain age, it can be shown by the P_1 values (Fig. 3) that for patients under 17 yr of age, the

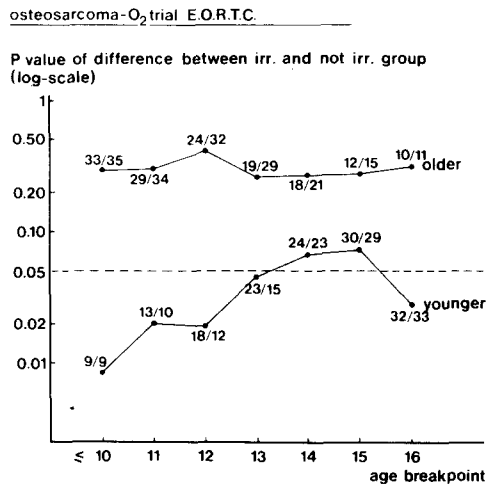

Fig. 3. P_1 values for the difference with regard metastases-free period between the groups of patients without or with adjuvant lung irradiation. At each age the total number in each group is divided into the number of patients of that age or younger (placed on the lower line) and the number of patients above that age (placed on the upper line).

Example: For the age breakpoint 16: there were 32 patients in the non-irradiated group and 33 in the lung irradiated group with an age of 16 or younger; respectively 10 and 11 with an age above 16 yr. For most of the breakdowns the younger age groups show a significant increase in metastases-free period by adjuvant lung irradiation.

difference in favor of adjuvant irradiation remains statistically significant in most of the breakdowns. On the other hand it can also illustrate that for the older age groups, the difference is insignificant.

Looking at the group under 17 yr of age (16 yr and younger), being the group seen in children's hospitals, the curves in Fig. 4 show a postpone-

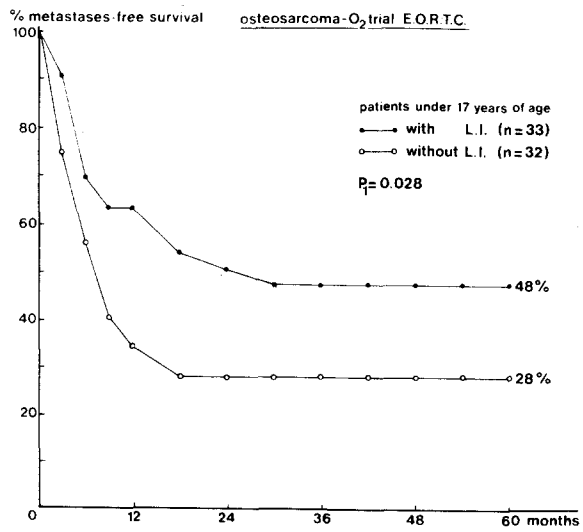

Fig. 4. Patients under 17 yr of age (16 yr and younger). Acturial curves for the percentages metastases-free period, respectively for the group O_2A without adjuvant lung irradiation (L.I.) and the group O_2B with adjuvant lung treatment.

ment of the appearance of pulmonary metastases in the lung irradiated group and a constant percentage of patients remaining free of metastases after 3 yr of 48% compared with 28% in the control group. This indicates that the applied dose of irradiation to the lungs can permanently prevent growth of subclinical metastases in about 28% of the cases. The difference between the curves is statistically significant. ($P_1 = 0.028$).

Influence of treatment modality for primary tumor

In Table 5 the actually observed number of patients who remain free of metastases during observation periods of more than 2 yr (up to 6 yr) are presented. A comparison of results between the groups O_2A and O_2B is not possible for the small groups of patients that underwent direct ablative surgery. Moreover, as mentioned earlier, this intervention almost always was carried out on a special indication, either for bulky tumors, fractures, or in a few cases for an histology suggesting a favorable prognosis. The results of primary radiotherapy with planned surgery (Cade principle) and those of primary high dose radiotherapy (with amputation only if necessary) do not differ significantly. There proves to be a striking resemblance between the chances for metastases-free survival indicated by the actuarial curves (Fig. 2) and the actually observed percentage for the total number of patients in both groups after more than two years observation.

Results according to treatment Centers

The great contribution of patients by the Institut Gustave-Roussy (Villejuif, Paris) made it possible to compare this group of 38 patients with the group of 48 patients treated by the other participating centers. This comparison revealed remarkable differences (Fig. 5). The metastases-free period was markedly shorter for the Paris Group than for the others. The ultimate metastases-free percentage for patients treated in Paris is 33% in the adjuvant treatment group, which is hardly different from the 27% found in the control group. For the patients in the other Centers the percentages are 50% in the treated group and 30% in the controls; this is a

Table 5. Actually observed number of patients remaining free of lung metastases during a follow-up of more than 2 yr

Total:	12/42 (28.5%)	19/44(43%)

*O_2A = without adjuvant lung irradiation.
O_2B = with adjuvant lung irradiation.

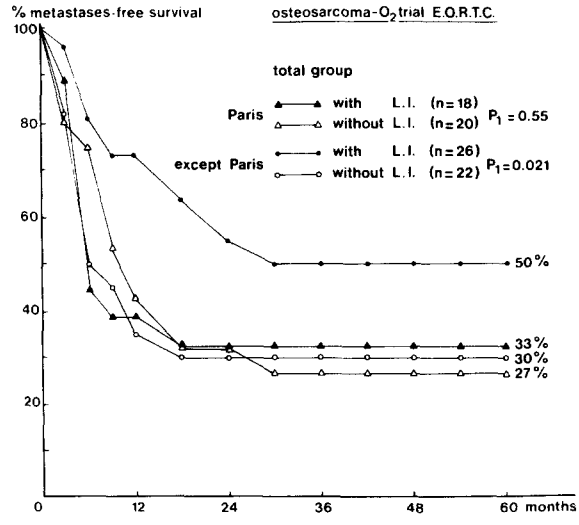

Fig. 5. Percentage metastases-free survival curves for patients treated in the Institut Gustave-Roussy ("Paris") and the combined group of patients treated in the other centers ("except Paris"), comparing the groups with or without lung irradiation (L.I.).

statistically significant difference ($P_1 = 0.021$).

The difference between Paris and the other Centers with respect to the effect of elective radiotherapy on the metastatic free interval still might be due to chance alone ($P = 0.12$). However, tests for these kind of differences—in this case an analogue of the test of Zelen [10] based on the results of the Mantel test on the effect of elective radiotherapy in the two groups (viz. Paris and other centres)—are rather insensitive, making a non-significant result not very conclusive.

The same shift in results could be observed for the patients under 17 yr of age (Fig. 6); practically no difference between the groups for the Paris patients and a highly significant one for patients in the other Centers, of which the lung irradiated group remains free of lung metastases in about 60% of the cases.

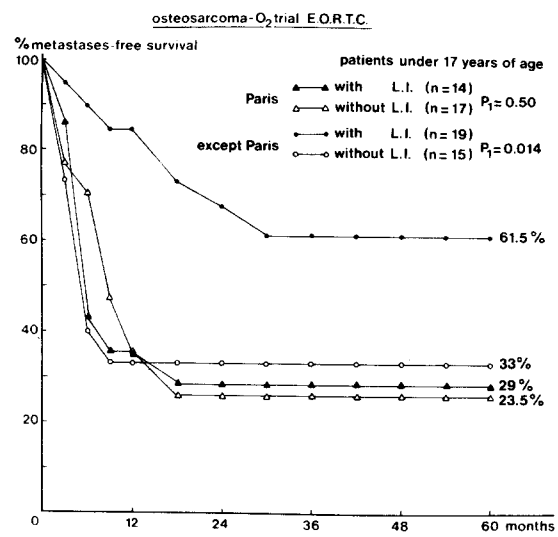

Fig. 6. Patients under 17 yr of age (16 yr or younger). Percentage metastases-free survival curves for patients treated in the Institut Gustave-Roussy ("Paris") and the combined group of patients treated in the other centers ("except Paris"), comparing the groups with or without lung irradiation (L.I.).

In order to find an explanation for the deviating results obtained in Paris, all available criteria have been examined. The criteria for admission and randomization procedure were reexamined and proved to have been followed conscientiously. No apparent differences could be found between the group of patients treated in Paris and those in the other centers with regard to the distribution in site, size, histology or radiographical characteristics of the primary tumor. The average time interval between the first symptom and the first treatment does not seem to have been longer in Paris than in the other Centers. The primary treatment in Paris, as in all other French Centers, has been a high-dose radiotherapy. Since in the Dutch centers the primary tumor was also irradiated primarily (Cade scheme) in most cases and only a minority of cases had direct ablative surgery, the differences in results cannot easily be explained by the method of primary treatment (see also Table 5).

One marked difference, however, was that in 12 out of 49 patients initially registered in Paris lung metastases became demonstrable already during the first weeks of treatment of the primary tumor, while in the other Centers this was only 3 out of 52 patients. Obviously the percentage of patients with metastases in just subvisual size at the time of the first treatment is larger in Paris than in the other Centers.

Extrapulmonary metastases

Skeletal metastases were observed in 12 patients (14%), of which 4 in group O_2A and 8 in group O_2B. In all but one case pulmonary metastases were also present, which makes the presented data also valuable for the criterion disease-free period.

Survival

After appearance of metastases the clinicians were free in their choice of further treatment. In many cases some form of chemotherapy has been applied. In a small number of cases surgical removal of lung metastases was performed: 5 in group O_2A and 3 in group O_2B. This proved to have been successful in 4 cases, respectively 2 in group O_2A and 2 in group O_2B. Because of these treatments the survival curves have to be interpreted with reserve. A longer observation time is needed and probably will show differences more clearly.

For the total groups (Fig. 7) the curves end up with a difference of 15% in favour of the

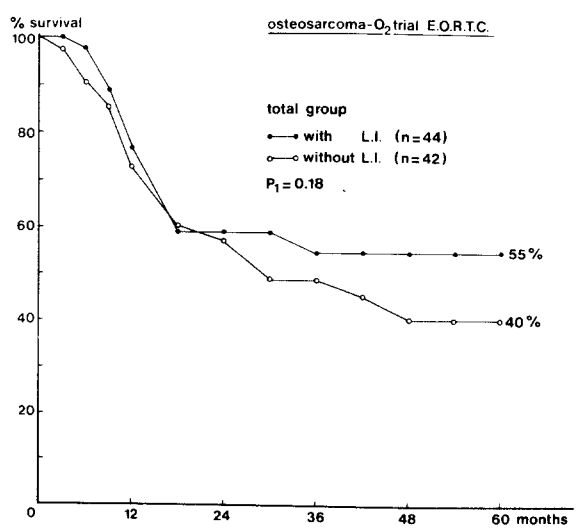

Fig. 7. Actuarial percentage survival curves for the groups of patients with or without lung irradiation (L.I.).

adjuvant treatment, but this difference is not statistically significant. For the patients under 17 yr of age (Fig. 8) the difference after 4 yr between the treated group (59%) and the controls (35%) is almost statistically significant ($P_1 = 0.052$). Comparison of the survival curves for the patients under 17 yr in Paris and in the other centres (Fig. 9), again indicates a different

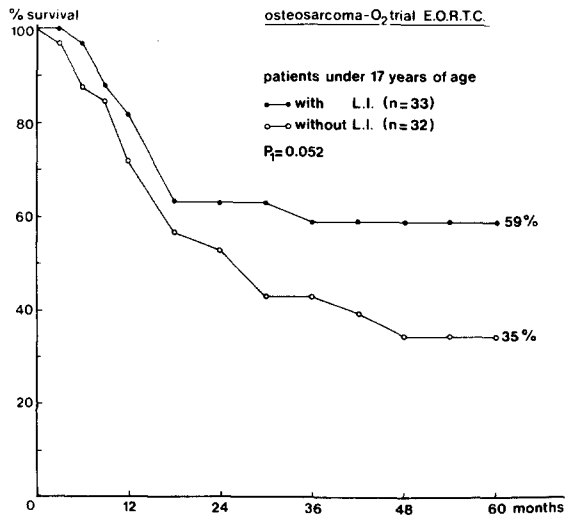

Fig. 8. Patients of 16 yr *of age or younger. Actuarial percentage survival curves for the groups of patients with or without lung irradiation (L.I.).*

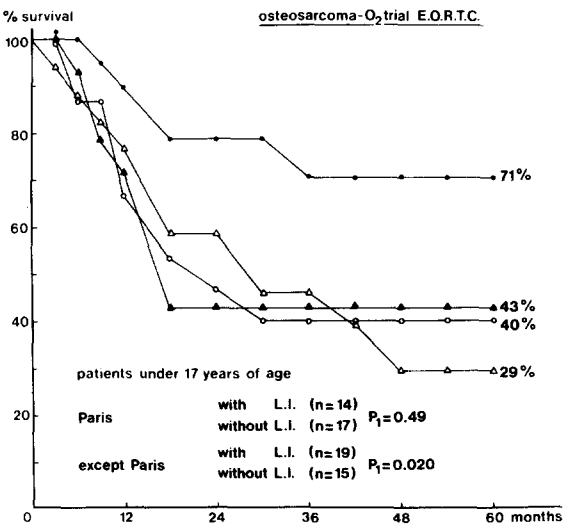

Fig. 9. Patients of 16 yr *of age or younger. Actuarial percentage survival curves for the groups of patients with or without lung irradiation (L.I.). Presented separately for patients treated in the Institut Gustave Roussy ("Paris") and those treated in the other centers ("except Paris").*

effect for the Paris patients. The percentage of surviving for more than 3 yr for patients in the Centers outside Paris reaches the high level of 71% suggesting a possibility of adjuvant lung irradiation to reduce the number of deaths in this age group by half.

The survival curves after the appearance of metastases (Fig. 10) are identical for the treated group and the controls which suggests the absence of a differential effect of the treatment for metastases between the groups.

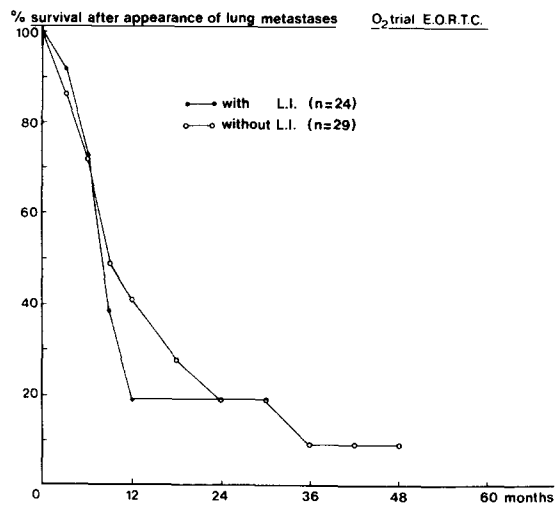

Fig. 10. Survival after the date on which lung metastases were clinically detected. There is no difference in the actuarial percentual survival curves for the groups of patients with or without adjuvant lung irradiation (L.I.).

Complications

The adjuvant lung irradiation of 2000 rad in 2 weeks has caused no symptoms of impairment of the lung function in any of the patients. As the performance of lung function tests was optional, a regular check of the lung function during follow-up has been done only in a small number of cases, in which up till now no decrease in function has been found. [11] No skeletal deformities or growth retardation have been reported.

DISCUSSION

At the start of the E.O.R.T.C. trial early in 1970 no data was available in literature on the effect of any form of adjuvant therapy following treatment of osteosarcoma.

In 1972 Newton [12] published his results of elective lung irradiation in patients with osteosarcoma. Compared to other published data the proportion of the patients in whom lung metastases could be demonstrated after 11 months seemed less (4 out of 11) in the lung irradiated group. Later the results proved to be less convincing. Recently Rab *et al.* [13] published their results of a study on 53 patients with osteosarcoma of whom 26 received whole lung irradiation to a total dose of 1500 rad combined with oxygen breathing and actinomycin D. Randomized by consecutive order of registration the other group of 26 cases did not receive any

adjuvant therapy. No significant difference in survival was found between the groups. In the adjuvant treated group no detrimental effects on the lungs were observed clinically.

During the past 5 yr several reports have been published on the initial results of various schemes of chemotherapy as adjuvant treatment in osteosarcomas [14–16]. Most of these showed a marked postponement of the appearance of metastases, suggesting the possibility of an increase in final cure rate. Unfortunately these trials were not performed as randomized studies, but data from historical series have been used for comparison. That such a method can hardly provide a conclusive evidence may be illustrated by the data presented by Taylor *et al.* [17] showing a marked increase in percentage survival during the latter years without any adjuvant therapy. Most of the published results on adjuvant chemotherapy were only initial in view of the rather short observation periods after the end of the treatment courses, being one to two years after treatment of the primary. For some of the series a few patients were even still under treatment at the time of evaluation of results. Since, it has become evident that in an appreciable number of cases metastases start to appear after stopping the administration of the chemotherapeutic agents. Still these rather premature reports unfortunately made the E.O.R.T.C. group decide to stop entering new patients in the trial early 1975, in order to enable the clinicians to explore the possibility of chemotherapy. Thus the number of patients in each arm of the trial remained rather low. In contrast to most of the authors on adjuvant chemotherapy, our clinical cooperative group decided not to publish results before a sufficiently long follow-up period for the majority of the patients had been reached. This in order not to evoke unjustifiable optimism.

The results of the E.O.R.T.C. trial as presented here, show that 2000 rad of supervoltage X-rays, administered in 2 weeks to the lungs, can permanently suppress the growth of subclinical metastases. This effect is the more striking in the group of patients under 17 yr of age. For this group also a significant increase in overall survival can be expected.

A disconcerting result of the analysis is the finding that the adjuvant irradiation did not improve results in a convincing way for the group of patients treated in the Paris Center. The available characteristics of the group of patients did not provide for an explanation. It has to be accepted that a different selection of patients is referred to this Center, resulting in less effect of the lung irradiation.

It may be assumed that metastases becoming clinically manifest only after a long interval, did contain fewer tumor cells at the time of treatment for the primary as those appearing shortly after the first treatment. Several of the metastases-free survival analysis show a diverging with time of the curves for the groups with and without lung irradiation. This means a larger growth delay period for the later appearing metastases and a greater radiosensitivity of the very small tumor deposits.

The hypothesis that by suppressing the growth of lung metastases extrapulmonary metastases could develop and become clinically detectable in a higher proportion of the cases, has not been confirmed. It was found that 14 from the total group of 86 patients have developed skeletal metastases. This proportion (14%) is within the usual range for other series.

The fact that 8 occurred in the lung irradiated group and 4 in the control group, does not have any real significance, as the cases in the irradiated group had lung metastases at the same time as well.

During the past 5 yr it could be shown that surgical removal of lung metastases of osteosarcoma can result in a definite cure of the patient. Especially in cases where the number of metastases is low and the appearance was more than half a year after the primary treatment or when the growth rate was lower than a volume doubling time of 40 days, the chances for success of metastatectomy are considerable [18–20].

At this moment it remains very difficult to describe an optimal treatment for patients with osteosarcoma. As adjuvant chemotherapy several combinations of drugs have been proposed in various schedules, spread over periods up to 2 yr. In contrast to the 10 sessions of lung irradiation in two weeks, that are tolerated without any difficulty to the patients, the burden of most of the chemotherapy courses to the patients is considerable and sometimes even unbearable. A few fatal casualties and some serious complications during chemotherapy have been reported [14]. Late effects of such intensive therapy are as yet not fully known. In view of all this and the fact that about 20–30% of the patients do not need this adjuvant therapy, it is the more distressing that a reliable estimate of the ultimate improvement in survival still cannot be given.

As some centers cannot confirm the extremely good results reported in the literature, the long-term value of adjuvant chemotherapy still has to be demonstrated in reliable controlled studies. The results obtained in the O_2 trial (E.O.R.T.C.) do make it inevitable to include a

comparison between adjuvant chemotherapy and adjuvant lung irradiation in new trials to be undertaken. Also the possibilities of a combination of lung irradiation and chemotherapy should be seriously investigated. The clinical cooperative group on radio- and chemotherapy of the E.O.R.T.C. is organizing a pilot study on the feasibility of such combination with regard to lung tolerance. A new trial on adjuvant therapy in osteosarcomas is also being prepared by the group. Cooperation of many centres will be needed to guarantee a sufficient accrual rate of patients in such a trial.

CONCLUSIONS

1. A dose of approximately 2000 rad megavoltage or telecobalt radiation to the lungs is able to reduce the probability of clinically detectable lung metastases in patients treated for osteosarcoma.
2. This effect is even more convincing in patients under the age of 17.
3. The results in one of the participating Centers (Paris) are different from those in the other Centers. In Paris the lung irradiation had no significant effect. It seems likely that at the time of adjuvant lung irradiation the occult metastases in Paris were larger on the average than those in the other Centers.
4. Such differences in results between centers can only be detected in cooperative trials in which many centers participate. Exceptionally good or bad results from one center therefore can be misleading as a guide for therapy.
5. In view of the results of the E.O.R.T.C. trial lung irradiation should be included in future clinical trials.

Effect of Tamoxifen Pre-Treatment on the Retention of Tritiated Oestradiol and 5α-Dihydrotestosterone and on Glucose Metabolism in Human Breast Carcinomas

N. DESHPANDE, IRENE MITCHELL and D. HUGHES*

Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, England,
** Department of Surgery, Luton and Dunstable Hospital, Luton, Bedfordshire, England*

Abstract—*The effect of pre-treatment with tamoxifen glucose metabolism and retention of injected oestradiol-17β and 5α-dihydrotestosterone by human breast carcinomas were studied in patients undergoing mastectomy. The following effects were observed:* 1. *The pretreatment reduced retention of oestradiol-17β whereas a small but statistically significant rise in 5α-dihydrotestosterone accumulation was observed.* 2. *There was an increase in both phosphofructokinase (PFK) and glucose-6-phosphate dehydrogenase (G6PDH) activities in tumours from treated patients whereas α-glycerolphosphate dehydrogenase (α-GPDH) activity was significantly reduced in the same tumours.* 3. *The significance of these findings is discussed and it is argued that these changes in carbohydrate metabolism may not be due to the blocking of hormone receptors.*

INTRODUCTION

TAMOXIFEN (ICI 46474) is classed as an anti-oestrogenic compound in some species [1] and this property of the drug is considered to be the main reason for its successful use in the treatment of patients with advanced breast cancer [2–4]. Earlier studies on mammary tumours indicate that the effect is probably due to competition with oestradiol for binding at target sites [5–7] but recent investigations on breast cancer patients and on oligospermic men suggest that the drug can induce major alterations in the endocrine environment [4, 8]. It is known that human breast tumours have the ability to retain *in vivo* or bind *in vitro* oestradiol-17β and 5α-dihydrotestosterone (5α-DHT) [9–12] and, therefore, if the action of the drug on the neoplasm is mediated via the depletion of cytoplasmic receptors, there should be alterations in retention of the hormones. On the other hand, if the drug affects the tumour indirectly by altering the endocrine environment, then this may be reflected in other biochemical processes. It is known that both oestrogens and androgens induce changes in the levels of enzymes associated with carbohydrate metabolism in hormone-dependent tissues [13, 14]. Therefore, it was decided to investigate the effect of tamoxifen treatment on the retention of oestradiol and 5α-DHT and on the changes in the activities of some of the enzymes associated with glucose metabolism. This paper reports our findings.

Accepted 6 October 1977.

MATERIAL AND METHODS

All the chemicals used in the study were purchased from British Drug Houses Ltd. and were of analytical grade. α-GPDH, TPI, G6PDH, aldolase, NADH, $NADP^+$, ATP, F-6-P, G-6-P, 6PG and pyruvate were purchased from Boehringer Mannheim. G-1-P was purchased from Koch-Light Ltd. DHAP was prepared from the dicyclohexylammonium salt of the dimethylketal according to the manufacturer's (Boehringer Mannheim)

instructions.* [6, 7-^{3}H]-oestradiol (Sp. act. 56 Ci/mmole), [4-^{14}C]-oestradiol (Sp. act 31.8 mCi/mmole), [1α, 2α(n)-^{3}H]-5α-dihydrotestosterone (Sp. act 55 Ci/mmole) and [4-^{14}C]-5α-dihydrotestosterone (Sp. act. 56.1 mCi/mmole) were purchased from the Radiochemical Centre, Amersham, England and were purified by paper chromatography before use. The maker's specific activities were not checked. The tritiated compounds were then dissolved in ethanol to a concentration of 50 μCi/ml. oestradiol and 20 μCi/ml. 5α-DHT. Tamoxifen was purchased from Imperial Chemical Industries.

The patients in these investigations were women with breast carcinoma, undergoing mastectomy, whose informed consent was obtained prior to treatment. All the patients were admitted to the hospital three days before the operation and those who underwent tamoxifen treatment prior to mastectomy were immediately put on the regime. The drug was administered orally (50 mg twice a day) for three days. Just before the operation the tritiated hormone was diluted with 20 ml of 0.9% NaCl and injected into an antecubital vein. The malignancy of the neoplasm was confirmed prior to the operation by drill biopsy. After the mastectomy the tumour was removed, cut into two pieces, frozen immediately on solid carbon dioxide and remained in that state until further processing.

One piece of tumour was thawed, cleared of the surrounding fat or connective tissue, weighed and cut into small pieces. The radioactive compounds from the tissue were extracted and isolated according to the procedures described previously [9, 12, 15–17]. The results are expressed as mean ±S.D. and the differences in retention of tritiated hormones were tested for significance by a Student's "*t*"-test.

Measurement of enzyme activities in breast tumours

The second piece of tumour was used for the measurement of PFK G6PDH, 6PGDH, PGM, LDH, α-GPDH and PHI activities according to the procedure of Shonk and Boxer [18] as modified by Deshpande, Mitchell and Millis [19]. Deoxyribonucleic acid (DNA) was measured according to the procedure of Burton [20]. The results were calculated on the basis of units (U) of enzyme activity per gram wet weight of tissue or milligram of DNA. A unit is defined as that amount of enzyme which will catalyse the transformation of 1 μmole of substrate per min. The results were analysed in two ways: as units of enzyme activity per gram wet weight of tissue or per mg of DNA. They are presented as mean ±S.D. and were tested for significance by a Student's "*t*"-test.

RESULTS

The activities of seven enzymes associated with glucose metabolism in tumours from 12 patients treated with tamoxifen and from 29 control patients are shown in Table 1.

The activities of PFK and G6PDH were significantly raised in neoplasms from treated patients. α-GPDH activities were not different when expressed in terms of gram wet weight but were significantly low in treated cases when expressed on the basis of DNA measurements.

The retention of 5α-DHT and oestradiol-17β after a single intravenous injection of 20 and 50 μCi of tritiated compounds, respectively, is shown in Table 2.

There was a statistically significant increase in the retention of 5α-DHT in the neoplasms of patients who underwent the tamoxifen treatment prior to mastectomy. The retention of oestradiol-17β was significantly lower in tumours from treated cases than in neoplasms from control cases.

DISCUSSION

Most research on the mechanism of action of antioestrogenic compounds is directed towards their ability to inhibit oestrogen induced growth in rat mammary tumours or uterus [21–23]. It has been reported that, like oestradiol, tamoxifen induces early effects such as: depletion of cytoplasmic receptor, concomitant increase in nuclear receptor, subsequent replenishment of cytoplasmic receptor and increases in RNA polymerases B and A activities. Unlike oestradiol, it fails to maintain these changes for a longer period [24]. Furthermore, long term administration of the drug to recurrent breast cancer patients also alters both pituitary and ovarian function [4]. Thus, in any clinical investigation the differences observed in treated cases and controls could be due to direct competitive

*The following abbreviations are used in this paper. *Enzymes:* α-GPDH, α-glycerolphosphate dehydrogenase; TPI, triosephosphate isomerase; G6PDH, glucose-6-phosphate dehydrogenase; PFK, phosphofructokinase; 6PGDH, 6-phosphogluconate dehydrogenase; PGM, phosphoglucomutase; LDH, lactate dehydrogenase; PHI, phosphohexose isomerase.
Co-enzymes: NADH, reduced nicotinamide adenine dinucleotide; $NADP^+$, nicotinamide adenine dinucleotide phosphate; ATP, adenosine triphosphate.
Substrates: F-6-P, fructose-6-phosphate; G-6-P, glucose-6-phosphate; 6PG, 6-phosphogluconate; G-1-P, glucose-1-phosphate; DHAP, dihydroxyacetone phosphate.

action of the drug on the tumour, indirect effect through an altered endocrine environment or a combination of both these factors. Administration of the drug to DMBA-treated rats has resulted in the reduced retention of radioactive oestradiol *in vivo* or lower binding to cytoplasmic receptors in mammary tumours *in vitro* [22]. A similar phenomenon is reported for human breast tumour cells in continuous tissue culture [6]. Therefore, it is reasonable to assume that the reduction in the uptake of radioactive oestradiol reported here in tumours from tamoxifen treated patients is probably due to the occupation of available binding sites by the drug. The other possibility, that the reduction in uptake is due to changes in prolactin secretion, may be discounted since plasma prolactin levels in DMBA-treated rats [23] or in breast cancer patients [4] did not alter after the administration of the drug.

The role of androgens in human breast cancer is not clearly understood. About one fifth of the patients with metastatic disease respond to treatment with androgens [25] and similar responses are seen in rats bearing DMBA-induced mammary tumours [26, 27]. Specific receptors for 5α-DHT have been identified in human breast tumours [10, 11] and the ability of these neoplasms to retain the hormone has been recorded [12]. Our preliminary results on a small series of patients indicate that pre-treatment with tamoxifen slightly increases the uptake of radioactive 5α-DHT. However, further studies are needed to confirm these findings and to investigate the mechanism of action of the drug on androgen receptors.

If the growth of human breast tumours is dependent on oestrogenic stimuli, then the effect(s) may be mediated via alterations in energy generation in the cells. Since the cell's

energy requirements are largely satisfied by carbohydrate metabolism, the measurement of selected enzyme activities in neoplasms of patients treated with tamoxifen and in controls may give insight into the hormonal regulation of glycolysis. Therefore, we have measured the activities of certain key enzymes in breast tumours and observed that the activities of 6PGDH, PGM, LDH and PHI were similar in both treated and untreated patients which suggests that the drug does not affect either glycogen metabolism or lactate production. The tumours from treated patients showed significantly higher activities of PFK and G6PDH and lower activity of α-GPDH. Since PFK represents the first regulatory step unique to the glycolytic pathway, an increase in its activity together with unchanged lactate production indicates that either pyruvate or other intermediary substrates are channelled into other metabolic pathways. Increase in G6PDH activity could be a way of providing reduced NADP and/or precursors for nucleic and amino acid synthesis via the pentose–phosphate pathway. Further significant reduction in the activity of α-GPDH in tamoxifen treated tumours is an indication that lipids are channelled into the pathways of carbohydrate metabolism rather than fat deposition.

As these changes in enzyme activities were observed at a time when the uptake of oestradiol was significantly reduced and that of 5α-DHT increased, a simple interpretation would be that oestradiol regulates PFK and G6PDH activities through an inhibitory control mechanism whereas it has a stimulatory effect on the activity of α-GPDH. However, it is contrary to the findings reported for DMBA-induced rat mammary tumours where oophorectomy reduced G6PDH activity [13] or for human breast tumours in primary cultures [27] in which addition of oestradiol-17β increased the enzyme activity in oestrogen dependent tumours. Further evidence that the changes in PFK, G6PDH and α-GPDH activities may not be mediated via the blocking of oestrogen receptors was obtained in another study of breast tumours from untreated Japanese patients, in which the activities of all the enzymes were similar to those observed for British patients treated with tamoxifen (Deshpande unpublished observation) and since the receptor levels are similar in Japanese and western women [28], it appears that the differences observed in treated and untreated tumours in British women may not be due to inhibition of oestrogenic stimuli. Therefore, it is possible that the drug acts directly on tumour cells or indirectly by altering the endocrine environment. Attempts are now being made to investigate these hypotheses.

Surface Characteristics of Lymphoma Cells in Relation to Treatment, Response and Survival

G. STATHOPOULOS, H. E. M. KAY, IRIS M. E. HAMLIN and A. M. McKAY
The Royal Marsden Hospital and Institute of Cancer Research, Fulham Road, London, SW3 6JJ, United Kingdom

Abstract—*Tumour cell suspensions from 34 patients with non-Hodgkin's lymphoma were typed by E-rosetting and surface immunoglobulin techniques and the proportions of T and B cells so revealed were compared with the histological classification. Eighteen patients had a preponderance of B-cells and seven had a preponderance of T-cells; in three cases most cells had no marker and in six cases there were approximately equal mixtures of T- and B-cells The patients were treated and followed for periods of one to three years since analysis. The response to treatment and survival times have been correlated with the T and B properties. Patients with B-cell neoplasms appear to have a more favourable prognosis than those with T-cell neoplasms.*

INTRODUCTION

RECENT work on the properties of the lymphocyte cell membrane and the application of techniques to characterise and analyse the cells found in malignant lymphoproliferative disorders have provided a possible basis for a classification of those disorders as T, B or no-marker (null) cells [1–8].

It is not known yet whether this kind of classification has any practical value; in particular whether there is any difference between "T" and "B" cell tumours regarding the response to the treatment and survival; but recently [9] it has been shown that there is a poor prognosis in acute lymphoblastic leukaemia (ALL) with cells having T characteristics as opposed to the commoner form of ALL with null characteristics.

We have investigated 34 patients with lymphoid neoplasms using T- and B-cell markers and have looked at the response to treatment and the survival time of each group of patients as classified according to the T- and B-cell markers.

MATERIAL AND METHODS

Material

Thirty-four malignant lymphomas were studied between 1972 and 1975. They were classified in general according to Rappaport's classification [10]; eleven were nodular, one nodular and diffuse, the remainder were diffuse; seventeen were lymphocytic, eleven histiocytic, two mixed histiocytic/lymphocytic, two undifferentiated and one "immunoblastic sarcoma" (originally histiocytic diffuse [10]) and one immunoblastic lymphadenopathy progressing to mixed lymphocytic–histiocytic diffuse lymphoma.

Accepted 11 October 1977.

Methods

Fresh biopsy material from lymph nodes was used in all cases except for one where malignant cells from a pleural effusion were studied.

The lymph nodes were pressed through a steel mesh and the cells were made into suspensions in medium 199.

The cells were then washed three times in 199, counted and made up to a concentration of 4 $\times 10^6$/ml in medium 199 before the following techniques were performed.

Techniques

(a) Spontaneous E-rosette formation with sheep red blood cells (SRFC) was used as a T-cell marker.

(b) Fluorescent polyvalent antiserum to human immunoglobulin was used as a B-cell marker.

Both techniques were performed as previously described [11].

It should be mentioned that in reading the tests no distinction could be made between presumed neoplastic and normal cells in well-differentiated lymphoma but in poorly-differentiated lymphomas it was often possible to see that the rosetted or fluorescent cells had the morphology of the neoplastic cells.

Treatment

Cells from 17 patients were tested at initial diagnosis and before any form of treatment; 17 were tested at the time of a relapse. Four patients had only radiotherapy and 17 had only chemotherapy. Eleven had both chemotherapy and radiotherapy, while two patients with lymphoma of good prognosis were not treated during the period of this study.

Radiotherapy (mainly Cobalt) was given either locally to an upper mantle field or as total nodal irradiation. Chemotherapy consisted mainly of combinations of cytotoxic drugs. The majority of the patients had COPP (cyclophosphamide–vincristine–procarbazine–prednisolone) or COP (without procarbazine) or MOPP (mustine in place of cyclophosphamide) or MVPP (vinblastine in place of vincristine). Several patients had the same chemotherapy schedule on relapse or different ones including drugs such as methotrexate, bleomycin or adriamycin. Chlorambucil was also given either in combination with other drugs or as a single agent.

It will be appreciated that although rather diverse treatments were given, this is not an unusual circumstance and in no instance was the treatment influenced by the results of these studies.

RESULTS

The patients have been placed in 4 different groups according to the results of the T and B markers.

These groups were the following:

(a) Eighteen lymphomas in which the majority of the cells have detectable surface immunoglobulin. The proportion is between 60 and 88%, most of the remainder being accounted for as T-cells (see Table 1).

(b) Seven lymphomas in which 60–79% of the cells formed E-rosettes with a minority of surface-immunoglobulin positive B-cells (Table 2).

(c) In this group there were three patients in which the majority of the cells were negative to both tests (Table 3).

(d) Fourthly there were 6 patients with no majority of either T- *or* B-cells (Table 4).

In Table 5 the response to the treatment is presented with the number of patients from each group who achieved a complete remission, partial remission or showed no response; and in Figs. 1 and 2 the survival times are presented to

dominant Hodgkin's disease where the great majority of the cells present are normal non-malignant reactive lymphocytes. The same may be true in some non-Hodgkin lymphomas especially perhaps those of mixed cellular type. On the other hand apparent heterogeneity of cell morphology may be associated with a single clone with otherwise uniform properties. Classification by morphology has also been misleading where tumours designated on account of cell size, abundance of cytoplasm etc. as "histiocytic" [10] have been shown by modern immunological techniques to have some properties of a lymphocyte.

Provided the data are not over-interpreted as indicating either that the cells in the majority are necessarily the neoplastic cells or that a distinctive B or T property necessarily indicates the cell of origin of the neoplasm, it is worth while examining lymphomas to see if relatively

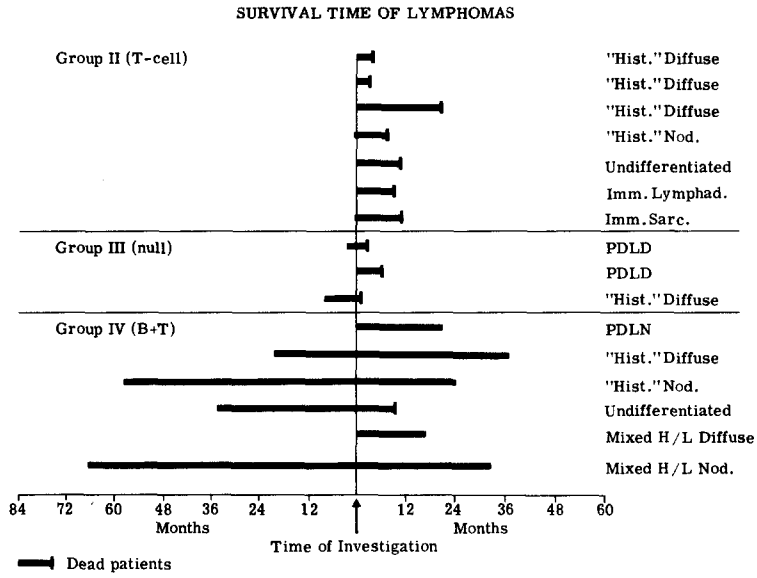

Fig. 2. Survival of patients before and after the time of investigation, where the lymphoma cells had T-cell characters, were "null", or where there was a mixture of cells.

illustrate the relations between histological type, surface properties and survival both from first diagnosis and from the time of testing.

DISCUSSION

The classification of lymphoid neoplasms is notoriously difficult and dependent on subjective criteria. The lymphomas comprise a wide spectrum of neoplasms of different degrees of malignancy and with diversities related to site, structure, cell-type and the age of the patient. Furthermore in any one neoplasm it may be difficult or impossible to distinguish the neoplastic cells from the interspersed non-malignant cells. An extreme example is lymphocyte pre-

simple tests of the cell-membrane can give useful information. In this study it was possible to analyse the patients into four main groups according to the type of cells in the tissue sampled which seemed to be in a majority. It is worth noting that in groups I, II and IV the proportion of cells with one of the two markers comprises 65–100 of the total and thus there was no evidence of the presence of double reacting cells. Nor is there any evidence to suggest that with the passage of time the proportion of cells with surface markers declines [6].

The main conclusion from our data is that patients with lymphomas having B-characteristics (which for convenience may be called B-cell lymphomas) have fared better than

those with T-cell lymphomas (Tables 1 and 2, Figs. 1 and 2); for example, all with T-cell lymphomas are dead, mostly within 1 yr, whereas the median survival for the B-cell cases will be in excess of two years. This difference is largely accounted for by the predominance in the B-cell group of tumours of "lymphocytic" type the majority being described as poorly differentiated. By contrast all the T-cell cases but one were of "histiocytic" or "immunoblastic" type. However even within the "histiocytic" category the prognosis for the B-cell patients appears to be rather better than for the T-cell patients. All 3 patients with cells of non-reactive "null" type did poorly, but it should be noted that this is not universally the case since the cells of typical childhood acute lymphoblastic leukaemia are also "null" and, with modern treatment, have a good prognosis. We have not included such cases in this report and the three "null" cases were in non-leukaemic adults.

The 6 patients with roughly equal mixtures of T and B cells have on the whole done well. They include the only two who were histologically classified as mixed histiocytic-lymphocytic (one nodular, one diffuse) and it is tempting to think that these are B-cell neoplasms with an infiltrate of non-neoplastic T-cells.

No therapeutic implications can be drawn from these findings since treatments were diverse and no comparisons are possible. However the fact that T-cell properties indicate a relatively poor prognosis suggests that all future therapeutic claims must be based on series of lymphomas analysed for T and B properties.

Acknowledgements—We are indebted to the various clinicians under whose care these patients were studied and to the surgeons who refrained from plunging their excellent biopsy samples into fixative.

Abstract—*Mice bearing transplanted syngeneic tumors of different etiology are sensitized to at least 3 different types of antigen. One of them is related to the mouse encephalitogenic protein, the other ones are present in fractions which have been separated by Sephadex G-200 filtration following* 3 M KCl *technique. Sephadex G-200 filtration separated a common tumor antigen from individually distinct antigens. With regard to their* in vitro *specificity the latter ones behave like the distinct TATAs of chemically or physically induced tumors. The possible relationship between a fetal antigen and the cross-reacting tumor-antigen is discussed. Antigenicity was measured by the EM technique using lymph node cells from tumor-bearing animals.*

INTRODUCTION

IN A RECENT paper cross-reactions were shown among mouse tumors of different etiology by means of macrophage electrophoretic mobility (MEM) test [1]. The conclusion was drawn that mice bearing transplanted syngeneic tumors are sensitized to a common antigen which is detectable by the MEM-test and which is apparently different from the individually distinct tumor-associated transplantation antigens (TATA) of physically or chemically induced tumors.

Since the lymphocytes of tumor-bearing mice reacted with an encephalitogenic protein one of the cross-reacting antigens is presumably related to this protein. This resembles the situation in human tumor patients where the lymphocytes are sensitized to the human encephalitogenic protein [3]. Furthermore fetal antigens may be involved in the sensitization to tumors [2].

Accepted 14 September 1977.

In order to study the antigenic components which lead to sensitization in tumor-bearing animals different soluble preparations from normal and malignant tissues were tested by the EM technique.

MATERIAL AND METHODS

1. *Antigens*

Soluble tumor-associated antigens (TAA) were prepared according to Meltzer *et al.* [4] with some modifications [5]. In brief, tumor tissue from solid tumors was homogenized in 3 M KCl/PBS (tissue : buffer = 1 : 10 w/v) at pH 7.3. After 16 hr/4°C of extraction the suspension was centrifuged for 1 hr/100,000 ***g***. The clean supernatant was dialyzed against PBS (24 hr) followed by concentration using Visking tubes and polyethyleneglycol (type 20,000, Serva, GFR). This material was termed extract A. After centrifugation at 1 hr/200,000 ***g*** part of extract A was precipitated with an equal volume of saturated ammonium sulphate solution and

stored at 4°C/12 hr. The precipitate was collected by centrifugation 0.5 hr/30,000 *g*, dissolved in PBS, dialyzed against PBS (24 hr) and centrifuged if not clean. This part represents extract B. Part of the dissolved precipitate B was fractionated on Sephadex G-200 and 3 fractions C1, C2, C3 were collected (see Fig. 1). The protein solutions were concentrated by diafiltration to a content of 1–1.5% protein and stored at −25°C before using.

Mouse encephalitogenic protein (MEP) was prepared from mouse brain using the same technique previously described for rabbit encephalitogenic protein (REP) [1].

Fetal antigen was prepared from mouse embryos at an age between 12 and 18 days of gestation according to soluble tumor extract B.

2. *Donors of lymph node cells*

Donors of lymph node cells were inbred mice of the CBA/Bln and XVII/Bln strains. Tumor-bearing mice had i.m. transplanted tumors of different etiology. The size of the tumors varied between 10–20 mm dia. Tumors in XVII/Bln mice were ultraviolet-induced sarcomas UV-Bln/14306, UV-Bln/15264 and a GRAFFI-virus-induced leukemia LEU-Bln/Gr 101. Tumors in CBA/Bln mice were chemically induced by benzpyrene (sarcoma BP-Ros/01), methylcholanthrene (sarcoma MC-Bln/7149), nitrosomethyl-urea (leukemia NMU-Bln/131 and sarcoma NMU-Ros/01) and by implantation of polyvinyl chloride platelets (sarcoma PVC-Bln/11677). Furthermore a transplantable Mamma Ca in CBA mice (Ma-Bln/21224) was tested. The tumors are maintained by serial in transplantation in syngeneic recipients.

3. *Electrophoretic-mobility-(EM) test*

Lymphocyte sensitization was measured by EM-technique as previously described [6, 7], using guinea pig macrophages or tanned sheep red blood cells as indicator cells. Briefly, 1.3 $\times 10^6$ lymph node cells taken from tumor-bearing mice or controls were incubated with 200 μg antigen in 2 ml Eagle MEM for 1.5 hr/37°C. Supernatants from these mixtures were incubated with 1 ml of indicator cell suspension (10×10^6 tanned red blood cells or 7×10^6 macrophages) for 1.5 hr/23°C. Thereafter, the electrophoretic mobilities were measured in the cytopherometer (Fa. Opton, GFR). Results were expressed as slowing in percentage as compared with the electrophoretic mobility of the controls. As controls we used (1) indicator cells solely in the presence of antigen and (2) indicator cells after addition of supernatants from lymphocytes which had been incubated without antigen. A slowing $\geqq 5\%$ was arbitrarily considered positive. Data given in the tables are representing the mean values of repeated identical experiments.

RESULTS

Mice bearing transplanted syngeneic tumors are sensitized to an encephalitogenic protein which was isolated from mouse brain (Table 1). The reactions were also positive when extracts B from fetal mice were used as antigen. Normal mice did not react as well as were tumor bearers negative against B extracts from normal tissues.

When using A extracts from tumors, extensive cross-reactions were observed.

B extracts of tumors reacted preferably with lymphocytes from mice bearing the homologous tumor, i.e. extracts isolated from UV-Bln/14306 were positive in EM-test with lymphocytes from UV-Bln/14306 sarcoma-bearing mice and extracts from UV-Bln/15264 were positive with lymphocytes from UV-Bln/15264 tumor bearers. However, cross-reactions were frequently observed among both tumors (Table 2).

In comparative studies with extracts A, B and C2 from 3 tumors each a separation of antigenic activities could be observed (Table 3). According to the results in Table 2 the B extracts from tumors showed extensive cross-reactions. Thus, cross-reactions were observed among the sarcomas induced by benzpyrene, methylcholanthrene and nitrosomethyl-urea. However, individually distinct antigenicity appeared in fraction C2. Extract A reacted in a non-specific way even with lymphocytes from normal donors. In Fig. 1 the Sephadex G-200 elution profile of sarcoma MC-Bln/7149 (extract B) is correlated with the pattern of antigenic distribution in the fractions. Lymphocyte donors were mice bearing the homologous tumor MC-Bln/7149 and mice bearing tumor BP-Ros/01. Three peaks C1, C2, C3 according to mol. wt of >180,000, 120,000–180,000, 50,000–80,000, were obtained after Sephadex G-200 filtration of tumor extract B. Whereas C1 was antigenically inactive, C2 revealed individually distinct antigenicity in that it only reacted with lymphocytes from mice bearing the homologous tumors. C3 appeared to be the cross-reacting antigen. It showed positive reaction for instance also with lymphocytes from BP-Ros/01 tumor bearers.

In order to rule out non-specific activity of the A, B and C extracts they were tested against lymphocytes of normal animals (not shown in the table). Except extract A the slowing of

indicator cells was less than 3% which is in the range of the controls.

C2 and C3 fractions isolated from several other tumors were tested against lymphocytes of different tumor bearers (Table 4). The data show in conformity with those in Fig. 1 that C2 contains the individually distinct antigen of the tumors while C3 has a cross-reacting common tumor antigen.

DISCUSSION

Mice bearing transplanted tumors are obviously sensitized to a number of different antigens which are associated with the neoplasm. Sensitization to different kinds of antigen is preferentially demonstrable by *in vitro* techniques such as the EM-test. Our data show that at least 3 types of antigen are involved [1] an

antigen which is identical with or related to the encephalitogenic protein, [2] the cross-reacting antigenic component C3 of tumors and [3] fraction C2 which shows individually distinct antigenicity. Whether C3 corresponds with the cross-reacting fetal antigen is not yet known. The similar pattern of reactivity obtained with C3 and the fetal antigen is striking. Data published in a previous paper [1] indicated the sensitization of tumor-bearing mice to rabbit encephalitogenic protein but not to human encephalitogenic protein. Here is also shown the sensitization to mouse encephalitogenic protein. Furthermore, human tumor patients are sensitized to human encephalitogenic protein but not to rabbit encephalitogenic protein (unpublished results). Thus, encephalitogenic proteins of related species seem to have common antigenic components.

When using B extracts as antigen no clear-cut results were obtained with regard to the pattern of reaction. Specificity of reactions dominated, i.e. the reactivity of antigen in the homologous tumor-host system was generally higher in comparison with the reactivity against another tumor. This was particularly evident in the case of the UV tumors 14306 and 15264.

In an attempt to separate the presumed antigenic components the B extracts were filtered through a Sephadex G-200 column. Identical elution patterns were obtained with several B tumor extracts an example of which is shown in Fig. 1. In this way, cross-reacting and individual distinct antigenic extracts could be separated. It remains an open question whether the fraction containing the individually distinct antigenic component C2 is related to the individually distinct antigens of chemically or physically induced tumors. Because of the characteristic pattern of reaction C2 is now also being studied in cross-resistance tests *in vivo*. In our hands, B extracts from tumors are immunogenic in syngeneic recipients and produce tumor-specific transplantation resistance [8].

The antigenic activity of the fractions C2 and C3 corresponds well with the profile of 2 protein peaks. It should be mentioned, however, that the active fractions can be best selected according to the EM test results. There are a number of reports now on the fractionation of tumor extracts [9–12]. Hypertonic salt extraction and/or ammonium sulphate precipitation were the most frequently used techniques. However, the results obtained are not directly comparable since the antigenic activities have been tested by different immunological methods.

Our experiments show that the EM technique is suitable to the measurement of cellular sensitization as well as to the analysis of antigenic components in tissue extracts.

Cross-Reactivities of Ethylnitrosourea-Induced Neurogenic Rat Tumors Studied by *in vitro* Assays For Cell-Mediated Immunity

YOSHIFUMI ODA,* HAJIME HANDA† and JØRGEN KIELER‡

The Fibiger Laboratory§ and the Department of Neurosurgery, Kyoto University Medical School, Japan

Abstract—*Neurogenic tumors were induced in inbred Wistar rats by the transplacental administration of ethylnitrosourea (ENU). The tumors were transplantable in syngeneic rats and they could easily be grown* in vitro.

Migration inhibition tests (MIT) were carried out with KCl extracts of several neurogenic tumors, a spontaneous mammary carcinoma and of various normal adult and fetal tissues. Thymocytes and lymph node cells for these tests were obtained from primary tumor hosts, recipients of transplanted tumors and from rats hyperimmunized with Mitomycin C treated tumor cells.

An indirect ^{51}Cr-release test as well as an indirect DNA inhibition test were carried out with culture supernatants derived from mixed cultures of neurogenic tumor cells and sensitized or non-sensitized lymphoid cells.

All three assays revealed tumor associated antigens with cross-reactions between various neurogenic tumors. Cross-reactions were also demonstrated by MIT between neurogenic tumors and fetal tissues. A peripheral neurinoma showed cross-reaction with adult brain and a trigeminal nerve neurinoma cross-reacted with the spontaneous mammary carcinoma. None of the neurogenic tumors cross-reacted with adult liver. Thus, ENU induced neurogenic tumors share one or several common antigens which, however, are not tumor specific.

The reactivity of lymphoid cells derived from tumor bearing rats was considerably smaller than that of lymphoid cells from hyperimmunized rats. It was also found that the reactivity of lymphoid cells from thymus and lymph nodes was considerably stronger than that of splenocytes.

INTRODUCTION

THE INDUCTION of nervous system tumors by methylnitrosourea in rats was first reported by Druckrey *et al.* [1] in 1964. Since then the oncogenic effect of many different nitroso derivatives has been described by a number of authors [2]. The oncogenic effect of ethylnitrosourea (ENU) administered by the transplacental route is of particular interest. Almost all rats exposed to certain amounts of ENU in the late phase of embryonic life develop tumors in the nervous system later in adult life.

The importance of the biochemical and immunological characterization of these tumors has been stressed [3]. Generally speaking, individual specificities are typical of tumor associated antigens in chemically induced tumors. However, conflicting views on this point are held in the case of ENU induced neurogenic tumors.

In the present study, the cross-reactivities of ENU induced neurogenic rat tumors were studied by various *in vitro* tests for cell mediated immunity.

MATERIAL AND METHODS

Inbred rats of the Wistar strain (Wistar/AfHanMolFib) were used throughout these experiments. The animals were bred and maintained under "minimal disease" conditions at the Fibiger Laboratory.

Accepted 11 October 1977.

*On leave of absence from the Department of Neurosurgery, Kyoto University Medical School with the support by grants from the Danish Cancer Society and the Japanese Ministry of Health and Welfare.

§Sponsored by the Danish Cancer Society.

Ethylnitrosourea (ENU) was obtained from Nakarai Chemicals, (Kyoto, Japan).

Induction and transplantation of tumors

Sixty milligrams per kilogram of ENU were injected intraperitoneally into pregnant rats in the third week of gestation. ENU was first dissolved in the ethanol and then diluted with 10 vol of phosphate buffered salt solution (PBS). The off-spring were observed until spontaneous death or until the preterminal stage.

In 99 rats a total of 110 tumors were demonstrated. In most cases the histological diagnosis was either malignant neurinoma (41%) or malignant oligodendroglioma (25%), but mixed gliomas. astrocytomas, ependymomas and meningiomas were also seen.

The transplantability of 9 neurogenic tumors and the mammary carcinoma was tested in newborn as well as adult recipients. They all produced tumors and permanent tumor lines were established in 2–3 months old Wistar rats of both sexes.

Explantation and cultivation of tumors

Small (1–2mm) pieces of tumor tissue were placed at the bottom of T-25 or T-75 plastic flasks and preincubated for 1–2 hr at 37°C and 5% CO_2. When the fluid medium after this preincubation was added carefully to the cultures, most of the explants would remain fixed to the bottom. The medium (Fib 41B) was a modification of Eagle's medium (MEM) with a two-fold concentration of the aminoacids, a four-fold concentration of vitamins and glutamine and with a 35% increase of the glucose concentration. This medium was fortified with 15% fetal calf serum (FCS). The cultures were incubated in a humid 5% CO_2 incubator for varying periods of time. For subcultivation, the cells were brought into suspension with the aid of trypsin. The medium was renewed 2–3 times weekly.

Tissue extracts

Tissue extracts were prepared with 3 M KCl [4, 5] from the following tissues: One malignant neurinoma from a peripheral nerve (T1) and two from the trigeminal nerve (T2 and T3), a mixed glioma (T4) and a spontaneous Wistar rat mammary carcinoma (T9). In addition extracts were prepared from adult brain and liver, 2 weeks fetal brain, 2 weeks fetal mixed tissues without brain and spinal cord, 1 week whole fetuses. The extracts were stored at −80°C and thawed immediately before use. No sample was subjected to more than one cycle of freezing and thawing.

Immunization procedures

Tumor cell suspensions were prepared by mild homogenization of small pieces of tumor tissue in a Daunce glass homogenizer followed by filtration through a monolayer of Nylon mesh (pore size 80 μm) and pretreated with 250 μg mitomycin C (MMC) per 2 ml PBS containing 10^7 cells. After incubation for 3 hr at 37°C the cells were resuspended in PBS and injected subcutaneously into 2–3 months old Wistar rats. Each rat received 10^7 MMC treated cells 5 times at weekly intervals. Seven to ten days after the last injection the rats were sacrificed and thymus and lymph nodes (axillar, brachial, inguinal, parathymic and submandibular) were removed. A suspension of lymphoid cells was prepared following the same procedure used for the tumor material.

Migration inhibition test (MIT)

Mixed thymus and lymph node cells (T + LN) were washed 5 times in PBS and once in Parker's medium 199 with 15% heat inactivated horse serum, 100 i.u./ml of penicillin and 100 μg/ml of streptomycin. This medium also served as migration medium. After the last centrifugation, the packed lymphoid cells were resuspended in 6 vol of the migration medium and sucked into 20 μl Drummond capillary tubes with a vacuum pump. The capillary tubes were presealed at the upper end by heating. When filled with lymphoid cell suspension, the capillary tubes were turned round and centrifuged at $750 \times g$ for 3 min. Finally they were cut at the cell-fluid interphase and fixed to the bottom of the migration wells of Sterilin No. 308 migration plates (Richmond, U.K.) with silicon grease.

Each well received 0.4 ml of migration medium. Antigen (ag) was added at a concentration of 100 μg protein/ml, which in pilot studies was found to be optimal. Protein determinations were made with Lowry's method. After sealing of the wells with coverslips, the migration plates were incubated for 22–24 hr at 37°C in a CO_2 incubator. After incubation the migration plates were placed in a Liesegang projector and the circumference of the projected migration zones were drawn on paper and cut out. The migration areas (MA) were quantitated by weighing, and the average results in each experimental group were calculated.

In each group, 6 migration cultures were studied. The migration inhibition index (MII) for each migration culture was calculated as:

$$\text{MII} = \frac{\text{MA with ag}}{\text{Av. MA without ag}}$$

A significant difference between the average MII with lymphoid cells from sensitized and non-sensitized rats was established by P values $\leqq 0.05$ by the Student's two tailed t-test.

Indirect ^{51}Cr release test

The immune response to ENU induced tumor cells was also studied by an indirect cytotoxicity test, using ^{51}Cr labeled C3H mouse ascites tumor cells—C3H-L1/a [6]—as test cells.

In the first step of this test 4×10^5 neurogenic tumor cells were seeded in 5 ml Fib 41B without FCS in T-75 tissue culture flasks and incubated overnight at 37°C in a CO_2 incubator. Sensitized and non-sensitized lymphoid cells were subsequently added at a lymphocyte/tumor cell ratio of 200/1. After 48 hr of additional incubation, the supernatant culture medium was harvested and concentrated 100 times in dialysis bags with Aquacide-III. The nutritional conditions were finally restored by redilution of the concentrate (to the desired concentration) with fresh Fib 41B with 5% FCS.

During the second step C3H-L1a test cells were suspended in Fib 41B with 5% FCS at a concentration of 5×10^6 cells per ml. The test cells were labeled with 175 μCi of ^{51}Cr (Amersham) for 2 hr at 37°C. After labeling, the test cells were washed 5 times with Fib 41B with 5% FCS. The first washing was carried out with ice cold medium.

Finally the test cells were resuspended in fresh medium at a concentration of 2×10^6 cells/ml. From each suspension a sample of 10 μl was withdrawn and placed directly in vials for counting in a Selektronik gamma counter (Hørsholm, Denmark) in order to determine total radioactivity.

Other 100 μl samples were mixed with 500 μl tissue culture supernatants prepared as described in sterile test tubes. Fresh medium was used for the demonstration of spontaneous ^{51}Cr-release. The mixtures were incubated for 48 hr at 37°C. After centrifugation at $750 \times g$ for 10 min, 500 μl samples of the supernatant fluid were withdrawn and placed in the gamma counter. The relative ^{51}Cr-release from cells treated with the test supernatants was calculated as percentage of the total activity (T.A.) after correction for spontaneous release (S.R.):

$$\frac{\bar{x} \text{ counts/min [test]} - \bar{x} \text{ counts/min [S.R.]} \times 6}{\bar{x} \text{ counts/min [TA]} - \bar{x} \text{ counts/min [S.R.]} \times 5} \times 100$$

Indirect DNA inhibition test

This test will be described in greater detail elsewhere. It is carried out in two steps. In the first step lymphoid cells react with cultured neurogenic tumor cells using the same method as in the indirect ^{51}Cr-release test except that the incubation time is reduced to 16–18 hr.

In the second step microcultures of hamster PM_1 cells [7] are prepared in Linbro Disposo Trays (FB-48 clear type) obtained from Dansk Mikrobiologisk A/S, Århus, Denmark. Each well is seeded with 2×10^4 tumor cells in 0.2 ml Fib 41B with 10% FCS. The cultures are preincubated at 37°C in a humidified atmosphere of 5% CO_2 and 95% air until a uniform monolayer of cells covers the bottoms of the wells. This usually takes 12–24 hr. After washing 3 times with Fib 41B each well receives 0.2 ml of the supernatant media prepared as described during the first step of the test.

The microcultures are replaced in the CO_2 incubator and after an additional period of incubation of 17 hr the cultures are labeled for 3 hr with (6-^{3}H) thymidine (TRA 61—Radiochemical Centre, Amersham. England) which is added to yield a final concentration of 0.2 μM and a specific activity of 40 μCi/ml.

At the end of the labeling period, 25 μl of a 22 mM cold thymidine solution in Fib 41B are added. After a final period of 30 min incubation, the medium is removed and the cultures washed twice with PBS before fixation of the cells for 5 min in ethanol/glacial acetic acid (4:1). After fixation the microcultures are treated with TCA (5%) for 5 min and washed with fixative before air-drying at room temperature for 20–30 min.

Finally the bottoms of the wells with all the test cells are cut off and placed in vials containing 10 ml of toluene with PPO (4 g/l) for counting in a Beckman LS-100 scintillation counter. Each vial is counted twice for 10 min.

RESULTS

Migration inhibition test (MIT)

MIT was carried out as described with KCl extracts of the following tumor material: T1, T2, T3, T4, a mixture of T1 with a few other neurinomas and a spinal ependynoma (Tmix), and a spontaneous rat mammary carcinoma. Furthermore, extracts were prepared from various normal adult and fetal tissues as previously mentioned. Lymphoid cells were obtained from (1) primary tumor hosts, (2) recipients of transplanted tumors and (3) from rats

hyperimmunized with MMC treated tumor cells.

Lymphoid cells derived from 39 primary hosts carrying various types of neurogenic tumors were tested against 3 M KCl extracts of transplanted neurogenic tumors (T1, T2, T3, Tmix) and of normal adult brain. In 19 cases a significant inhibition (MA with ag < MA without ag) was obtained with at least one of the extracts. All extracts including extracts of normal brain were active. The percentage of positive tests varied from 36 (T3) to 60% (brain) as shown in Table 1.

*Table 1. Migration inhibition test with lymphoid cells from the original tumor bearing rats**

Source of antigen	T-mix	T1	T2	T3	Brain
No. of pos. cases/total	4/7	8/20	4/7	5/14	3/5
Percentage	57	40	57	36	60

*19/39 rats showed positive migration inhibition against at least one of the tumors.

The results of these pilot studies might be explained by the presence of a common antigen shared by a number of ENU induced tumors and normal brain. However, they do not allow any conclusions concerning the specificity of the reactions.

Table 2 shows the results of some experiments in which the sensitized lymphoid cells were derived from rats transplanted s.c. with T1 (1.—2. pass), T2 (1.—6. pass) and T3 (1.—3. pass). Most of the donors were moribund, carrying huge tumors. The specificity of the reactions was tested by comparison to T + LN lymphoid cells from normal, non-sensitized adult rats. 3 M KCl extracts of transplanted T1, T2 and T3 tumors served as antigen.

As a whole, migration inhibition was modest. MII values which represent a significant difference between MI ± ag are underlined in the Table.

In a number of cases a significant difference was established between lymphoid cells from tumor-bearing and normal rats, indicating a specific reaction.

A significant inhibition of MA by tumor antigen combined with a significant difference between MII values obtained with sensitized and nonsensitized lymphoid cells was seen in the following combinations. Anti-T1 lymphocytes challenged with T1 and T3 extracts. Anti-T2 lymphocytes challenged with T1 extracts. Anti-T3 lymphocytes challenged with T1, T2 and T3 extracts.

These results indicate a cross reaction between T1 and T3.

For the further elucidation of these antigenicities, lymphoid cells were prepared from rats immunized 5 times with MMC treated tumor cells. KCl extracts of malignant and nonmalignant tissues served as antigen. The results are presented in Tables 3–5. Most of the values are based on 6 migration cultures.

A majority of extracts which served as antigen in these experiments caused a significant inhibition of the migration of anti-T1, anti-T2 as well as anti-T3 lymphoid cells (MA + ag < MA − ag).

The specificity of the reactions is demonstrated by a significant difference between the MII values obtained with sensitized and nonsensitized lymphoid cells as shown in the Tables. However, it also appears from the tables that the sensitized lymphoid cells reacted not only with malignant extracts, but in some cases also with fetal extract and in a single case with extract from adult brain.

The cross reactions observed in these experiments are summarized in Table 6 from which it is seen that T1 and T3 seem to share at least one common antigen which also is present in T4 and mixed fetal tissues of 1 week of gestation. Extracts of a spontaneous mammary carcinoma (T9) and fetal brain (2 weeks of gestation) caused a specific inhibition of anti-T3 lymphoid

T3	+	−	+	+	+	+	+	+	−	−

*Without brain and spinal cord.

cells while the difference between non-sensitized and anti-T1 lymphoid cells was only on the borderline of statistical significance.

Extracts of T1 and fetal brain tissue cross-reacted with anti-T2 lymphoid cells, while T2 extract only reacted with anti-T1 lymphoid cells. The antigenic strength of this tumor seems rather weak.

Indirect ^{51}Cr-release test

The cytotoxicity of the supernatant medium from mixed cultures of T1 or T3 tumor cells propagated *in vitro* and sensitized or non-sensitized lymphoid cells was tested by the indirect ^{51}Cr-release test as described. From Table 7 it appears that T1 tumor cells stimulated T2 and T3 sensitized T + LN lymphoid cells but not T1 sensitized lymphocytes to produce a cytotoxic supernatant, while sensitized spleen cells were without any effect.

T3 tumor cells stimulated T + LN lymphoid cells sensitized to T1 and T3 in a similar way. Sensitized spleen cells were less efficient.

Even though no reaction between T1 and anti-T1 could be demonstrated in this experiment, the cross-reactions demonstrated by MIT were confirmed.

Indirect DNA inhibition test

The production of DNA inhibiting factors by T1, T2 and T3 sensitized lymphoid cells mixed with T1 or T3 tumor cells propagated *in vitro* was tested as described. The specific DNA inhibition (SDI) was calculated as per cent inhibition in comparison to control supernatants derived from mixed cultures of tumor and non-sensitized lymphoid cells.

As shown in Table 8, media from mixed cultures of all 3 types of sensitized lymphoid

*Specific DNA inhibiting effect calculated as per cent inhibition in comparison to control.

cells and T1 tumor cells had a significant DNA inhibiting effect with SDI values varying from 19 to 27%.

Similar results were obtained with T3 tumor cells and anti-T1 or anti-T3 lymphoid cells (SDI: 15 and 32%, respectively), but not with anti-T2 lymphocytes.

DISCUSSION

The immunogenicity of ENU induced neurogenic tumors has been tested in transplantation experiments which have shown that young recipients are more susceptible than older ones [8, 9]. Furthermore, intracerebral transplantations have been reported to yield a higher rate of takes than subcutaneous inoculations [8]. These observations indicate the presence of transplantation antigens on the ENU induced tumor cells.

In the present investigation the antigenicity of ENU induced neurogenic rat tumors was confirmed by direct migration inhibition tests as well as by indirect ^{51}Cr-release and DNA inhibition tests. Cross-reactions were observed between peripheral nerve neurinoma (T1), trigeminal nerve neurinoma (T2, T3) and mixed glioma (T4).

The immunogenic effect of T2 was quite low, but lymphocytes sensitized to this tumor did respond to extracts of the T1 tumor in the migration inhibition test and to T1 cells in the indirect ^{51}Cr-release and DNA inhibition tests. Cross-reaction with T3 tumor cells was seen in the ^{51}Cr-release test. The cross-reactions between T1 and T3 were confirmed by all 3 types of assays. In MIT these tumors also cross-reacted with T4.

These results indicate that the ENU neurogenic tumors share at least one common antigen of varying strength. Similar results have been published by Cornain *et al.* [10], who used a microcytotoxicity assay. However, by selective elimination of spleen cells carrying surface Ig and C3 receptor, a T-cell enriched lymphocyte population was obtained which in the microcytotoxicity assay revealed distinct antigenic specificities, confirming the results of *in vivo* rejection tests.

In our investigation thymocytes and lymphonode cells were used. For unknown reasons spleen cells were found to be less responsive. Whether a purification of the mixed T+LN population will disclose tumor distinct specificities remains to be shown. The direct MIT will probably be suitable for such a study. However, in a few preliminary studies, we have been unable to demonstrate such specificities *in vivo* by active protection and tumor neutralization tests.

Toh [11] failed to show cross-reactions between Schwannomas and gliomas by a direct mixed culture method, which was taken as a sign of the immunogenic weakness of the Schwannoma tumor cells. It is possible that the method employed was not sensitive enough to detect the antigens of the Schwannoma cells, but the negative results might also be due to the fact that the lymphoid cells were derived from tumor bearing rats in which circulating antigens or immune complexes could have caused antigenic inhibition of the effector cell.

In the present investigation, MIT with lymphoid cells derived from tumor bearing animals (Table 2) only showed a modest response as compared to the results obtained with lymphoid cells from healthy animals immunized with MMC treated tumor cells (Tables 3–5).

Our material includes a single spontaneous mammary tumor. Extracts of this tumor (T9) cross-reacted with anti-T3 lymphocytes in the migration inhibition test. Similar cross-reactions with unrelated tumors were reported by Cornain *et al.* [10] who found that this cross-reaction

could be eliminated by purification of the spleen cell population.

Fields *et al.* [12] raised 2 antisera in C3H mice against ENU induced neurogenic rat tumors. These antisera defined two cell surface antigens, i.e. a common antigen shared by rat brain, embryonic tissues and neurogenic tumors and a restricted antigen present in 6 tumors but not in normal adult or embryonic tissues.

Antigens cross-reacting with fetal antigens has previously been reported in human neurogenic tumors by Oda [13] and by Trouillas [14]. However, this was not confirmed by Dittmann *et al.* [15] who failed to demonstrate five fetal antigens present in human fetal brain, in human glioblastomas and meningiomas. Alpha-feto protein was also absent from these tumors. On the other hand, using rabbit antisera raised against human neurogenic tumors several antigens not present in fetal or adult brain were found. However, these antigens cross-reacted with antigens present in normal liver and were therefore not tumor specific.

In the present investigation the migration inhibition test revealed cross-reactions between extracts of fetal tissues and lymphoid cells sensitized to T1, T2 and T3 tumor cells. The most consistent results were obtained with anti-T3 lymphoid cells. In addition anti-T1, but not anti-T2 and T3, cross-reacted with extracts of normal adult brains.

These observations indicate that ENU induced neurogenic tumors share a common antigen which may be a fetal antigen. But it cannot be excluded that they share more than one common antigen, some of which may be tumor specific.

The expression of fetal antigenicity seems to reach its maximum during the second week of gestation [16]. Therefore, it is a little astonishing that anti-T1 lymphoid cells cross-reacted with fetal tissue at 1 week of gestation but not at 2 weeks. However, the difference between MII of sensitized and non-sensitized lymphoid cells exposed to 2-week-fetal brain was on the border-line of statistical significance and may possibly be substantiated on reinvestigation.

The T1 tumor also seems to share an antigen with adult brain. In contrast to the above mentioned observations by Fields *et al.* [12], our findings indicate that the cross-reaction with fetal tissues and adult brain depend upon at least two separate antigens.

No cross-reaction was found with adult liver. The cross-reaction with adult brain might therefore depend on the presence of nerve specific proteins in ENU induced neurogenic tumors. Even if S-100 was found to be present only in minimal amounts in human glioblastoma [15] it has been demonstrated in ENU induced neurogenic tumors [17–19] which also contain the 14–3–2 protein [20].

Moreover, human glioblastoma has been found to be rich in glial specific protein [15] and Bignami [21] has demonstrated GFA in organ cultures of human and ENU induced rat tumors.

Common antigens also could be of viral origin even in chemically induced tumors. Diwan *et al.* [22] found that ENU induced mouse leukemia and pulmonary lung adenomas were positive for both type-C RNA tumor virus and its group specific antigen. Denlinger *et al.* [23] reported the presence of viral articles in ENU induced neurogenic mouse tumors, and Lantos [24] discussed the origin and the significance of two intracytoplasmic virus like structures which he found in ENU induced rat gliomas.

Thus a number of observations indicate that chemically induced neurogenic tumors share one or several common antigens which generally seem to be rather weak and not tumor specific. The origin of these antigens is still unclear, but it does not seem unlikely that both fetal proteins and nerve specific proteins play a role. The individual specificities reported by some authors remain to be confirmed.

Vincristine (NSC 67574) in Non-Small Cell Bronchogenic Carcinoma. Results of a Phase II Clinical Study

A. BRUGAROLAS,*† A. J. LACAVE,* A. RIBAS‡ and M. T. GARCIA MIRALLES‡
*Departments of *Oncology and ‡Pathology, Hospital General de Asturias, Oviedo, Spain*

Abstract—*A Phase* II *study of vincristine* (*NSC* 67574) *in pathologic categories* 1, 3 *and* 4 (*WHO*) *bronchogenic carcinoma was performed. Partial objective responses were observed in* 5 *of* 15 *patients with adenocarcinoma. Responses were observed in pulmonary masses* (5/15), *metastasic cervical nodes* (2/5) *and hepatic metastases* (1/2). *Median survival for patients presenting a response to VCR was* 339 *days, compared to* 73 *days for non-responders.*

Only 1 *of* 10 *patients with epidermoid carcinoma and none of* 10 *patients with anaplastic-large cell carcinomas responded to VCR therapy.*

It was concluded VCR is active in adenocarcinoma of lung and it might deserve further evaluation in Phase III *trials.*

INTRODUCTION

A REVIEW of current literature indicated that vincristine (NSC 67574) has not been adequately evaluated in bronchogenic carcinoma [1]. In a recent report, Hansen confirmed the early suggestions of activity of vincristine (VCR) in small cell bronchogenic carcinoma [2, 3]. In this study, partial objective responses were obtained in approximately one-third of patients resistant to a previous combination chemotherapy [4]. Since this report, VCR has been widely used in the intensive combination therapy of small cell carcinoma of the lung [5].

However, there appeared to be no available information on the effect of VCR in the therapy of the other pathologic types of lung cancer. This information can be considered important because VCR is a suitable drug for combination chemotherapy. Consequently, a Phase II study, to determine the activity of VCR, in epidermoid carcinoma, adenocarcinoma and anaplastic large cell carcinoma was designed. The objective of this report is to present the results obtained in this study.

MATERIAL AND METHODS

Patients were selected according to the following criteria: (1) Pathology proven bronchogenic carcinoma of the categories 1, 3 and 4, or epidermoid, adeno and anaplastic-large cell carcinomas, of the WHO [6]. (2) Advanced, non-resectable disease. (3) Measurable, previously untreated disease in the chest that could be easily followed in the chest X-ray. (4) Performance status above the 40% on the Karnofsky scale. (5) No previous chemotherapy. (6) Ability to continue out-patient follow-up. (7) Patients with marked senility or life expectancy of less than 3 weeks were excluded as well.

Eligible patients, stratified according to the tumor cell type received vincristine, 1.5 mg fixed dose in 200 cc 5% dextrose solution infusion over 4–6 hr. Vincristine was administered weekly for 10 weeks unless progression was documented earlier. After 10 weeks an evaluation was made and patients with stable disease or objective response were continued on the weekly dose until toxicity was noted at which time the drug was given every other week.

Neurologic toxicity was considered mild if there were tolerable paresthesias and loss of tendon reflexes. Moderate toxicity were painful paresthesias, disabling weakness, sensory loss and abdominal cramps. When a moderate neurotoxicity was noticed, VCR was discontinued for 2 weeks or one month and if improved during the interval it was again resumed at the same dose every other week.

The results were classified as objective response and progression. Objective responses were complete and partial. Complete response was defined when all evidences of measurable

Accepted 12 October 1977.
†To whom requests for reprints should be addressed.

and non measurable disease disappeared and the patient remained free of disease for more than 1 month. Partial response was a decrease of more than 50% of the tumor size measured by the product of the two longest perpendicular diameters in all measurable disease with improvement in the non-measurable disease maintained for more than one month.

Progression was a decrease of less than 50% the tumor size, prolonged stable disease and progressive growth of the tumor.

All patients cases presenting a diffuse interstitial or alveolar pattern in the chest X-ray received a pretherapy course of antibiotics and/or digitalis before the proper baseline control films were taken.

RESULTS

VCR was given according to the study design to 35 previously untreated patients. There were 28 males and 7 females. Ages ranged from 44 to 76 yr, with a median age of 61 yr. Regarding to the performance status, 7 patients rated 40–50 in the Karnofsky scale, 17 patients rated 60–70 in the Karnofsky scale and 11 patients rated 80–100 in the Karnofsky scale. Eighteen patients had stage IV disease and 17 patients had stage III disease. Seven patients had received previous surgery or radiation therapy.

Response

Category 3 (*adenocarcinoma*). Five partial responses were observed among 15 patients with adenocarcinoma (Figs. 1–4). Objective responses were determined after 3–8 weeks of therapy. The median time to response was 6 weeks. The duration of responses ranged from 103 to 415 days. The objective response rate for this group was 33%. Some patients not qualifying for objective response showed some antitumor effect due to VCR, 2 patients presented less than 50% decrease in tumor size and 3 other patients presented decrease of pleural effusion or very prolonged stabilization of disease which progressed rapidly upon discontinuation of the drug after a certain period of time. These patients however were considered ineligible for objective partial response.

None of the patients presenting initial progression to VCR responded subsequently to a second drug therapy. One patient responding initially to VCR presented a second partial response to methotrexate for a period of 10 months.

Category 1 (*epidermoide carcinoma*). One partial objective response was observed among 10 patients with epidermoid carcinoma. This response was observed at the 4th week and lasted 175 days. Upon progression this patient received alkylating agent and presented a second objective partial response.

Only 1 of 9 patients in this category not responding to the initial treatment with VCR responded to a subsequent drug therapy.

Category 4 (*anaplastic-large cell carcinoma*). None of 10 patients in this category responded to the treatment with VCR. There were no subsequent responses to other drug therapies among this group of patients.

The influence of response upon survival can be seen in Table 1. Table 2 demonstrates the response rate for each tumor type according to the site of metastasis.

Toxicity

Moderate neurologic toxicity was usually evaluable in patients receiving VCR for 10 weeks. Seven of 11 patients treated with VCR for 10 weeks or more presented moderate toxicity; 3

Table 1. *Median survival time in days*

	Partial response	Progression
	(Number of patients)	
Epidermoid carcinoma	992 (1*)	72 (9)
Adenocarcinoma	339 (5)	73 (10)
Anaplastic carcinoma	—	80 (10)

*This patient presented a second objective partial response upon progression to VCR.

Table 2. *Responses according to site of metastases*

	(Responses/number of patients)				
	Lung	Lymph nodes	Skin	Liver	Bone
Epidermoid carcinoma	1/10	1/7	0/1	—	0/1
Adenocarcinoma	5/15	2/5	0/1	1/2	0/1
Large-cell carcinoma	0/10	0/4	0/3	0/3	0/1

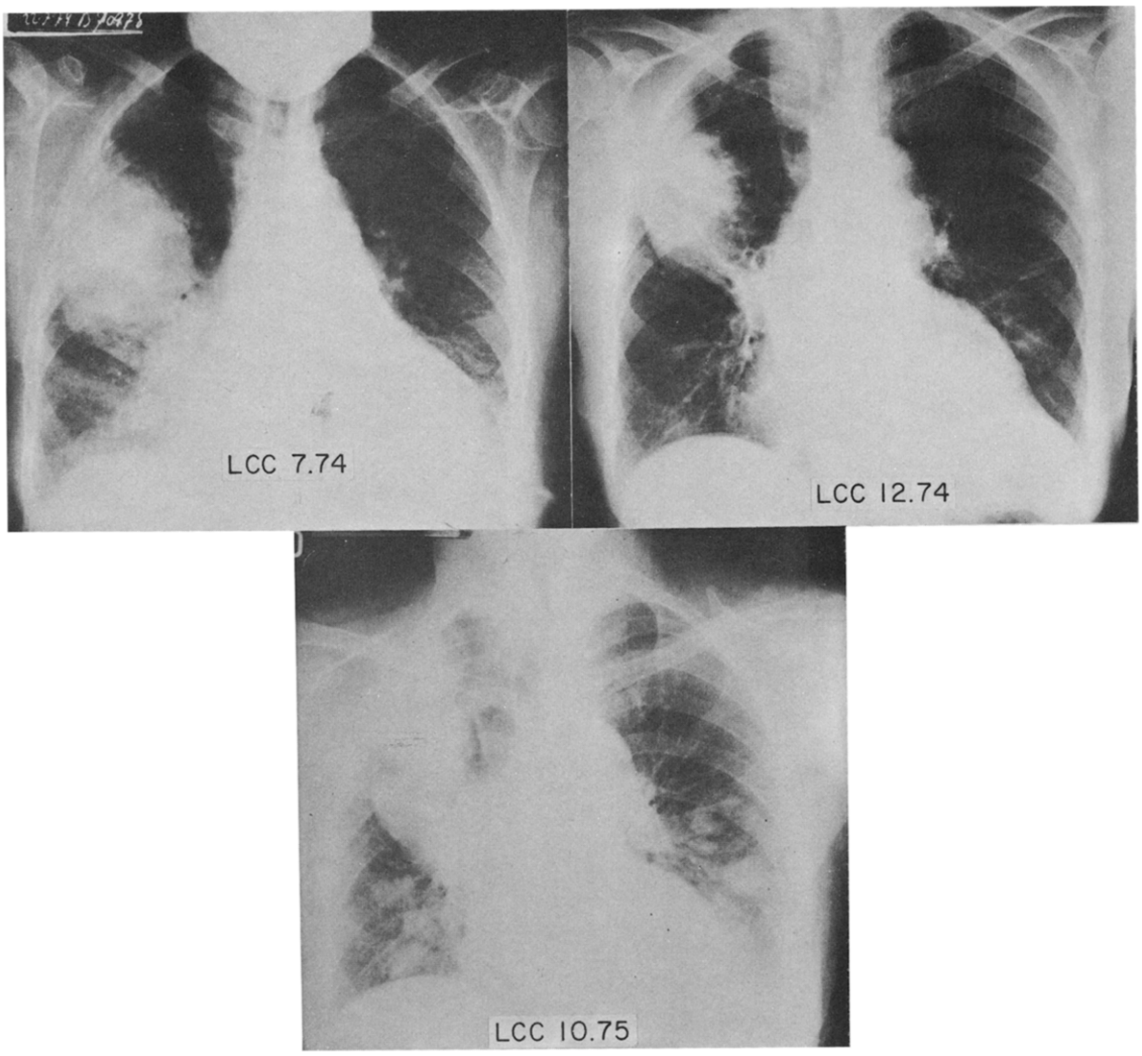

Fig. 1. Adenocarcinoma.

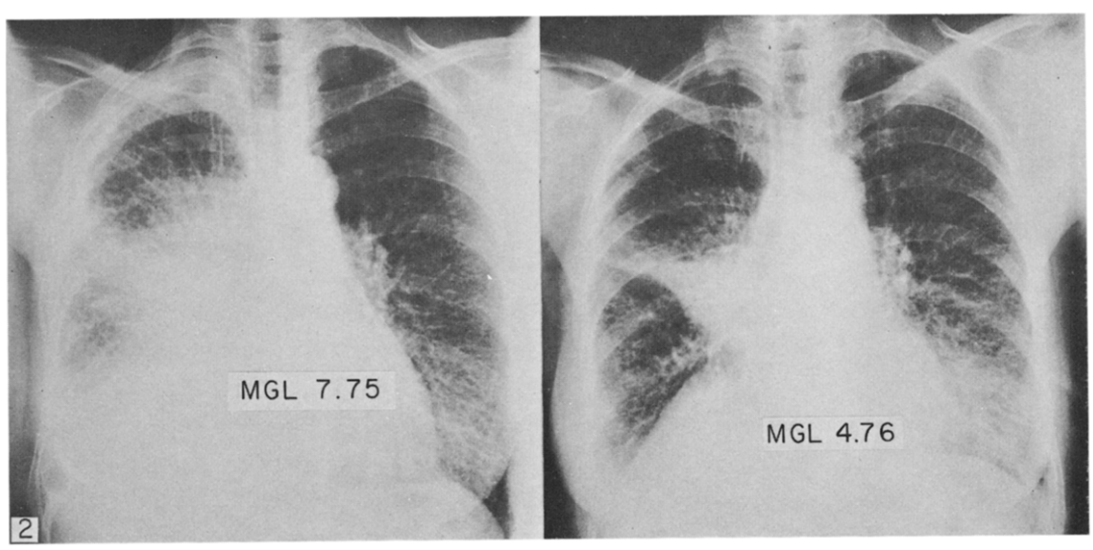

Fig. 2. Moderately differentiated adenocarcinoma.

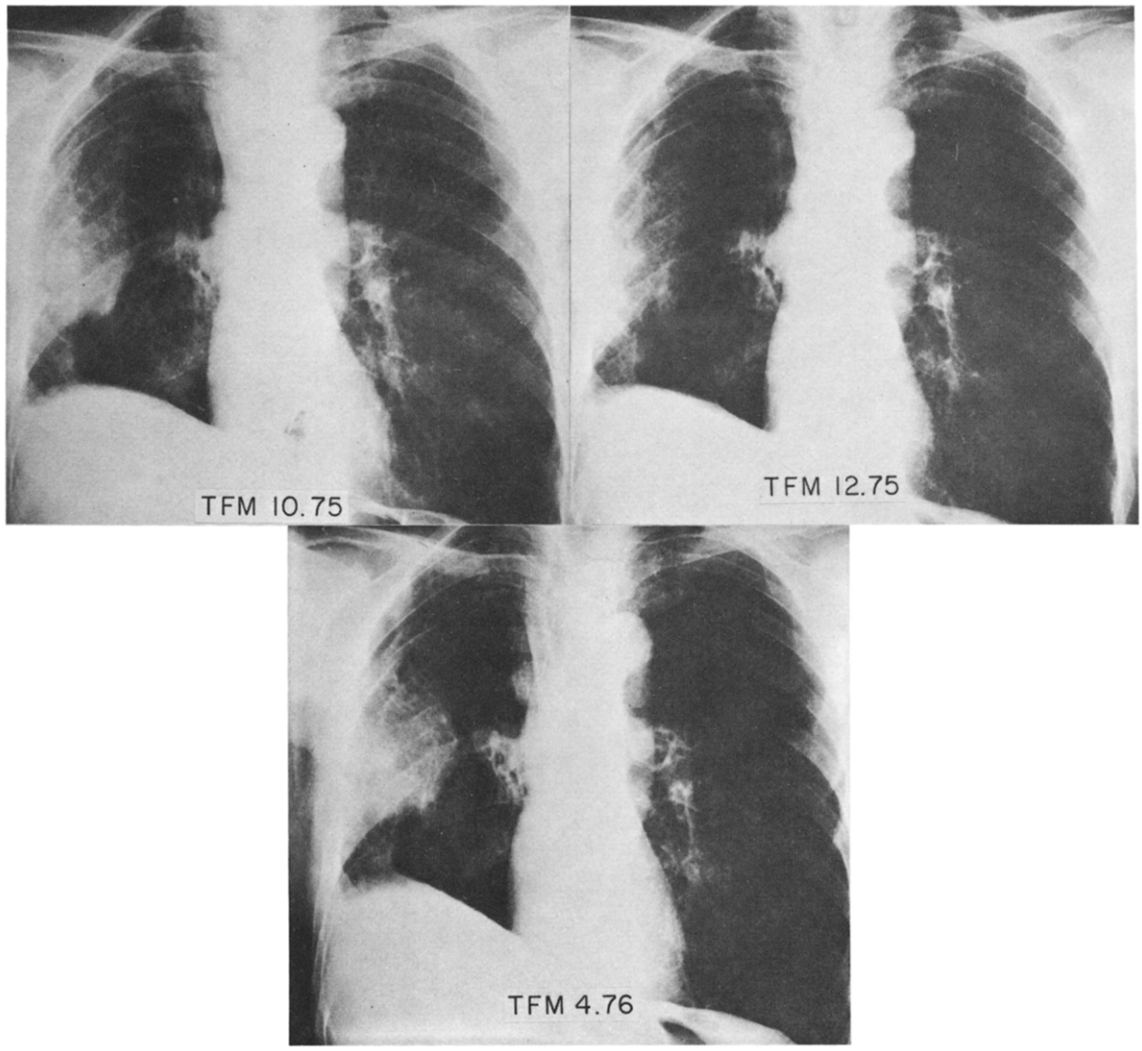

Fig. 3. Adenocarcinoma, well differentiated.

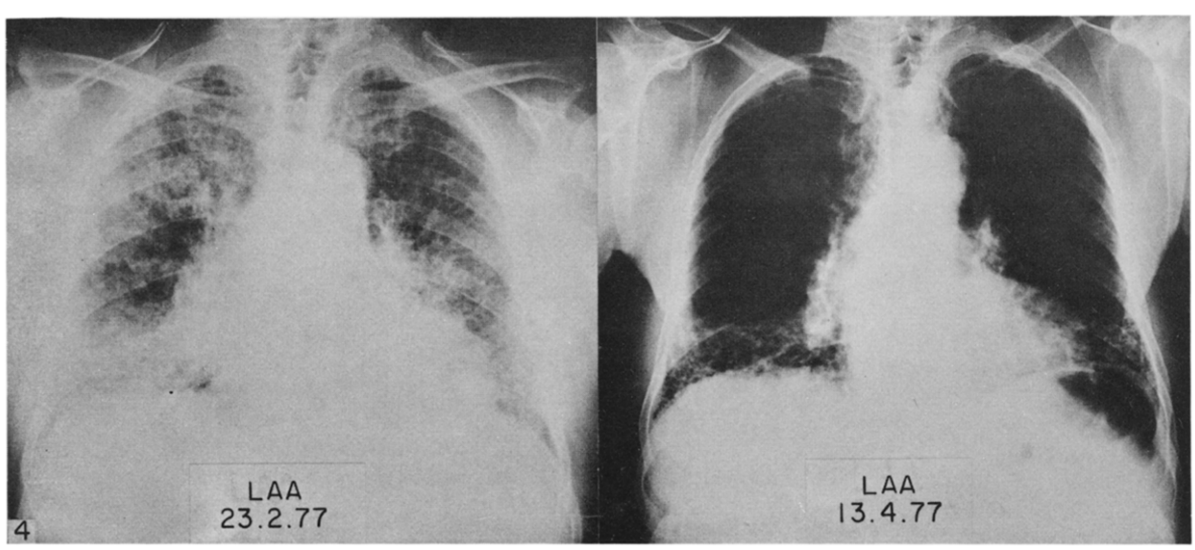

Fig. 4. Well differentiated adenocarcinoma, papillary type, bilateral.

with abdominal cramps or severe constipation and 4 with disabling weakness as the leading symptom. Four of these 7 patients continued VCR every other week after a period of rest of 2 weeks and appeared to tolerate it well. Two patients needed one month rest period and then continued receiving VCR every other week with good tolerance. One patient had VCR definitely stopped at his own request.

Mild neurologic toxicity was readily observed after 4 weeks of therapy. After discontinuation of the drug the symptoms regressed in 1–2 months.

No other clinically significative toxic manifestations could be attributed to VCR therapy in this study.

DISCUSSION

VCR appears to be active in adenocarcinoma of the lung, tumor relatively resistant to chemotherapy [1]. This activity has not been uncovered earlier because the systematic Phase II study design of the modern chemotherapy was not in use during the early sixties, when VCR was entering clinical trials. Otherwise, the activity of VCR in this cell type it is not completely unexpected since some activity is found in other adenocarcinomas such as breast cancer [7]. Further experiences using VCR in single or combination chemotherapy for bronchogenic adenocarcinoma remains a task for the large groups since this tumor type is relatively uncommon, and large number of patients are needed to establish firm conclusions.

In this study VCR appeared to have poor activity in epidermoid and anaplastic-large cell carcinoma.

The dosage of VCR used in this study is somewhat unorthodox. The reasons for using a low dose of Vincristine in this study were: (1) Dose-related neurotoxicity probably reflects the cumulative dose given. In this respect, it was postulated that a low dose schedule would delay the appearance of significant neurotoxicity allowing for a prolonged initial course in the majority of the patients. (2) One might hypothesize from a kinetic approach that in adult slow growing solid tumors it might be more important to schedule the drug administration: that is, frequency and length of the infusion, than the total amount of drug given per single dose. Consequently, emphasis was put on the weekly administration of a slow infusion.

Moreover, when one considers the total amount of drug administered in a given period of time, the long term optimal schedule of VCR used as a single agent it is probably unknown and it has been seldom utilized [8]. (3) And finally, it was thought that if the most important single prognostic factor of survival in lung cancer is the performance status of the patient, neurotoxicity should be avoided or delayed because it could have a direct bearing in the performance status quality of the patients. In this regard it was postulated that a weekly standard dose of VCR could produce unacceptable toxicity and a low dose could be more suitable.

In restrospective analysis, the dose schedule used proved to be adequate in the induction and maintenance of the responses obtained. This might have had a particular interest since some patients could be carried on the VCR infusions for over 1 yr with a near normal active life.

It was concluded that VCR is active in bronchogenic adenocarcinoma and further trials, possibly of combination chemotherapy with other active agents, should be conducted.

Pharmaco-Kinetics of Melphalan Following Oral or Intravenous Administration in Patients with Malignant Disease*

M. H. N. TATTERSALL,†‡ M. JARMAN,§ E. S. NEWLANDS† L. HOLYHEAD,† R. A. V. MILSTEAD§ and A. WEINBERG¶

†*Department of Medical Oncology, Charing Cross Hospital and* §*Mass Spectrometry Laboratory, Division of Chemistry, Institute of Cancer Research, England and* ¶*Department of Immunology, Burroughs Wellcome*

Abstract—*The distribution and excretion of* C^{14}*-labelled melphalan has been determined in seven patients with disseminated malignant disease. Following intravenous administration, melphalan was distributed in the total body water and disappeared with half-lives of approximately* 67 min *and* 160 hr. *Up to* 65% *of label was recovered in the urine over a period of seven days following intravenous administration. Following oral melphalan, peak blood levels were seen at* 2 hr; 30% *of the administered label was recovered in the urine over* 9 *days and* 20–50% *of administered label in faeces over* 6 *days. These results show that absorption following oral melphalan treatment is incomplete and that the drug has a prolonged terminal plasma half-life. Drug metabolism is not extensive and the majority of label recovered from plasma and urine taken within* 5 *and* 40 *min of i.v. drug administration cochromatographed with melphalan.*

INTRODUCTION

MELPHALAN was introduced into clinical use in the late 1950's and has since established itself as an agent with a wide spectrum of antitumour activity. It is used extensively in the treatment of ovarian cancer and myeloma and as adjuvant therapy in breast cancer [1–3]. Tables are the most commonly used preparation but, in some situations, i.v. melphalan is preferred.

Although melphalan has been used clinically for nearly 20 yr, there is little information on its clinical pharmacology. [4] We now report pharmaco-kinetic studies of labelled melphalan in 7 patients with disseminated malignant disease. In 4 patients, melphalan was given as an i.v. injection. In the others, the drug was given orally—in 2 patients on the first day of a 5-day course of melphalan treatment and, in the third patient, on the 3rd day of a 5-day course of treatment.

Accepted 3 October 1977.

‡Present address: Ludwig Institute for Cancer Research, Sydney University, N.S.W. 2006, Australia.

MATERIAL AND METHODS

Universally C^{14}-labelled melphalan (3.6 mCi/nmole) was supplied by the Radiochemical Centre, Amersham, England and C^{14}-labelled melphalan in tablet form (20 mCi/1.9 mg) was prepared from this material. Prior to i.v. administration, the identity and purity of the C^{14}-labelled melphalan were confirmed by chromatographic analysis. The i.v. solution was sterilized by millipore filtration and then mixed with unlabelled melphalan to give the required total dose. Unlabelled melphalan tablets were given with the labelled tablet to make up the appropriate dose.

Clinical details

Details of the 7 patients studied are shown in Table 1. Patients received either a single intravenous injection of melphalan (20–23 mg/m^2, 14 mCi) or 20 mCi of labelled melphalan was given orally during a 5-day course of oral melphalan treatment (4.4–6.4 mg/m^2/day). In 2 patients (JM and BS), labelled drug was given with the first oral dose of melphalan, while JT received 2 days of unlabelled melphalan and then the labelled compound.

Table 1. *Patient details*

Patient	Sex	Tumour	Age	Melphalan dose (mg)	Route	Surface area

†J.T.	F	Myeloma	70	10 (× 5d.)	0	2.3
B.S.	M	Adenoca. colon	76	10 (× 5d.)	0	1.5

*Labelled melphalan given on first day of course.
†Labelled melphalan given on third day of course.

Renal function was normal in all patients but hepatic function in one was severely deranged. In this patient (AL), bilirubin levels were falling rapidly, following a cholecystojejunostomy for treatment of carcinoma of the head of the pancreas.

At regular intervals, following the administration of labelled melphalan, blood was drawn and plasma separated. All urine and stool specimens were collected for periods up to 9 days following labelled melphalan treatment and aliquots were taken for counting. Specimens were stored at −30°C until analysis.

Extracting and counting procedures

One half millilitre aliquots of plasma were suspended in 10 ml of monophase 40 and counted in a liquid scintillation counter. One to two millilitre aliquots of plasma were ultrafiltered at 1000 ***g*** through amicon membrane cones (type CS50A), which exclude greater than 97% of plasma proteins and 0.5 ml aliquots of the ultrafiltrate were counted in monophase 40. Lymphocyte and red cells were completely combusted to carbon dioxide and water in a Packard tricarb sample oxidizer. The carbon dioxide was collected in 10 ml of carbosorb and permafluor V and counted for 10 min. Aliquots of stool samples were combusted in a similar manner and counted. Aliquots of the 24-hr urine specimens were centrifuged to remove solids and 0.5 ml of the supernatant counted for 10 min in 10 ml of monophase 40. On patient JS the concentration of unmetabolised melphalan in the first two urine samples was measured directly, using mass spectrometry. C^{14}-labelled carbon dioxide in expired air was measured daily following labelled drug administration and, after collection of one mole of carbon dioxide in a carbon dioxide absorbant with a phenolphthalein indicator, the absorbant was counted.

Quantification of Melphalan in plasma and urine (Patient JS)

Plasma and urine samples were collected from one patient and metabolites of melphalan were sought.

Plasma samples. Fifty microlitres of melphalan solution (5 mg per 5 ml in 0.1 N HCl) was added to 1 ml plasma. This was added to 10 ml of a 1 : 2 mixture of acetone: ethanol and shaken for 15 sec before brief centrifugation. The supernatant was decanted and evaporated to dryness. The concentrate was dissolved in 100 µl of water and 100 µl of this solution was spotted on a silgur plate and run overnight in butanol : water 86 : 14.

Urine samples. One hundred microlitres of urine were added to 50 µl of melphalan solution (5 mg per 5 ml) and 100 µl of the resultant solution spotted on a silgur plate and run overnight in butanol : water 86 : 14.

All plates were scraped in 1 cm bands into counting vials, stood overnight with 0.5 ml HCl (N/10) and counted after dilution with 10 ml scintillation fluid (naphthalene, POP and POPOP in ethanol, dioxan and toluene) on a Packard Tricarb 3320 scintillation counter. In addition, the concentration of melphalan in the first two urine samples (0–40 min and 40–110 min) was measured directly as follows: 1 ml sample was taken and 20 µl melphalan-d_2 (1 mg/ml in 0.1 N HCl) as internal standard was added. The sample was adsorbed on to an XAD 2-column (8 × 1 cm)® and washed with 25 ml distilled water, which was discarded. The melphalan was eluted with 10 ml CH_3OH and the eluate concentrated to dryness. The concentrate was taken up in 0.5 ml CH_3OH and allowed to stand with 0.5 ml ethereal diazomethane for 10 min at room temperature, then concentrated to dryness, taken up in methanol and spotted on to a fluorescent silica thin-layer chromatographic plate which was developed in

chloroform : methanol 19 : 1 alongside a plate spotted with melphalan which had been similarly methylated. The melphalan methyl ester (R_F 0.55) was eluted with methanol and the ratio of melphalan to deuterated melphalan in the sample determined by the ratio of peaks at m/e 230–232 $(M\text{-}CH(NH_2)CO_2Me)^+$ for d_0-d_2-ester) on mass spectrometry.

Mass spectrometry

Mass spectra were determined using an AEI-MS12 spectrometer after concentration of methanol solutions onto the direct insertion probe. The ionizing voltage was 70 eV, trap current 100μA and ion-source temperature *ca.* 120°C. For determination of the ratio of melphalan : melphalan-d_2 in samples, spectra were scanned repetitively at 10 sec/decade. The intensities of peaks in the region containing the ions of interest (m/e 230, 232) were recorded using an Instem Maxi data system. The average of about 10 scans was taken. For reduction of observed peak intensities to give the molar ratio of melphalan : melphalan-d_2, correction factors were applied for:

(a) The contribution to m/e 232 (base peak for d_2-analogue) of the $^{37}Cl^{35}Cl$-containing ion corresponding to m/e 230 which is present in the mass spectrum of the d_0-analogue;

(b) The contribution to m/e 230 due to the small percentage (1.25%) of non-deuterated melphalan present in the d_2-standard.

A linear relationship, after applying these correction factors, was demonstrated between the composition of mixtures of synthetic d_0 and d_2-forms and the corrected peak intensities.

Synthesis of melphalan-d_2 standard

A solution of melphalan (0.2 g) in deuterium chloride in D_2O (20% w/v, 1 ml) was heated under reflux for 20 min. The cooled solution was diluted with methanol and applied to a column (22 × 2 cm) of amberlite IR45 ion-exchange resin which had previously been washed with methanol. The product was eluted with 200 ml methanol and was recrystallised from this solvent (2 ml) to yield melphalan-d_2 (20 mg) as a white solid.

The mass spectrum showed a molecular ion $(M^{+\cdot})$ at m/e 306 (3% rel. int.) and a base peak at m/e 232 $(M\text{-}CH(NH_2)CO_2H)^+$. From the ratio m/e 232 : m/e 231 : m/e 230 the product contained the d_2, d_1 and d_0 forms in the ratio 100 : 5.0 : 1.25.

By analogy with the corresponding conversion of aniline mustard® into a d_3-analogue, melphalan is probably deuterated at the positions *ortho* to the N-mustard substituent.

Thin layer chromatography

For assay by radioactivity, silgur-25UV$_{254}$ plates (Camlab Ltd., Cambridge), 20 × 20 cm were used. Samples were applied as 3 cm-wide strips to the Kieselguhr zone of these plates. U.V.

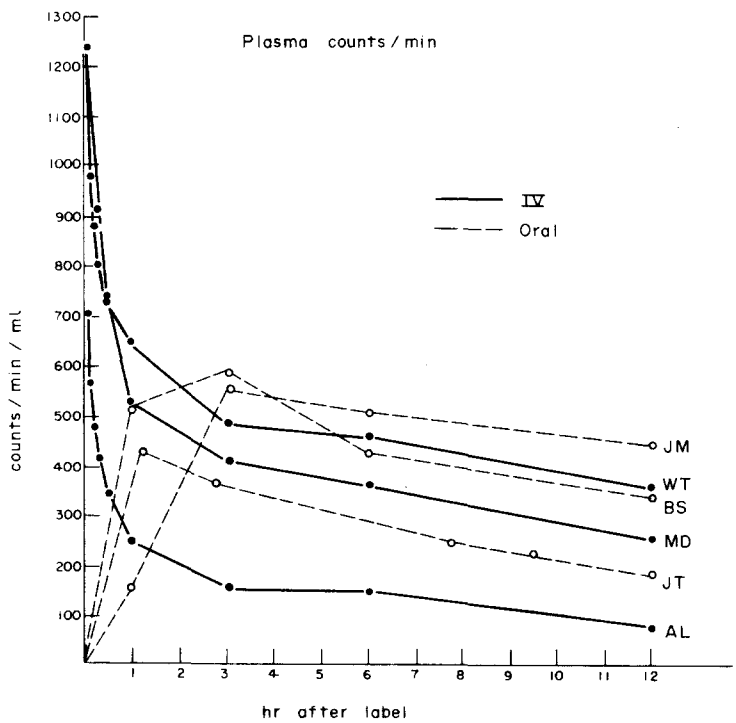

Fig. 1. Plasma pharmacokinetics of labelled melphalan administered to six patients with malignant disease.

absorbing bands were located using a Hanovia chromatolite. For thin-layer chromatography of melphalan methyl ester prior to mass spectrometry, glass plates (20 × 5 cm) coated with Merck Kieselgel GF $_{254}$ were used.

RESULTS

Figure 1 shows the plasma levels of melphalan with time following the administration of melphalan to six patients. Plasma concentrations of melphalan in JS are presented in Table 2 and Fig. 2. Extrapolation of the initial linear portion of the curve to $t=0$ gives a theoretical volume of distribution of 44.3 litres and a plasma $t\frac{1}{2}$ for the drug of 67 min. It is clear that there is a prolonged terminal phase in the disappearance of label from the plasma as demonstrated in Figs. 1 and 3 and the half-time approximates 160 hr. Following oral administration, peak label occurred in plasma at 2 hr and then declined with a similar half-life to the i.v.-treated patients (Figs. 1 and 3).

Table 3 shows the percentage of plasma counts retained on plasma protein after filtration. In all patients studied except AL, over 50% of the counts were retained. The percentage of counts retained increased with time following treatment and over 90% of the plasma counts were unfilterable after 12 hr..

AL was markedly icteric at the time of melphalan treatment and studies were undertaken with plasma from other jaundiced patients. Preliminary studies indicate that jaundice serum binds melphalan less well than normal serum (data not presented).

Figure 4 shows the cumulative excretion of labelled melphalan in the urine and stool of 4

patients on whom data are available. The results indicate that only small amounts of label are recoverable in the stool following i.v. melphalan treatment and, in the 1 patient with complete data, approximately 60% was recovered in the urine 24-hr after administration—with only a small amount of further label being recovered over the next 5 days. Throughout this period, faecal recovery was minimal. In 3 patients receiving labelled melphalan orally, between 20 and 50% of the label was recovered in the faeces over 6 days.

Figure 5 shows cumulative urinary excretion of label with time in 6 patients. The patients who received labelled melphalan orally excreted substantially less label in their urine than those patients receiving the drug i.v. Approximately 30% of the administered label was recovered in the urine in the oral group over a period of 6 days while, in the i.v. group, urine recoveries varied betwen 35 and 65%. In each case, the pattern of label recovered was very similar, with the majority being recovered in the first 24 hr following treatment. There was no suggestion that prior loading with melphalan (patient JL) altered the pattern of recovery.

Table 4 shows the level of melphalan recovered in the urine of patient JS following intravenous administration. The results indicate that the levels of melphalan measured by mass spectrometry or by calculation from radioactivity are very similar.

No labelled carbon dioxide was measured in expired air.

Metabolite studies

Figures 6 and 7 are histograms of the chromatography plates for a 5-min plasma sample and 40-min urine sample from patient JS. The principal radioactive peak in both cases was exactly coincident with the u.v. detectable melphalan band. These results indicate that major metabolism of the labelled melphalan had not taken place at this time.

DISCUSSION

This is the first study of the clinical pharmacology of melphalan given both orally and intravenously. The results indicate that there is incomplete absorption of melphalan given by mouth. This finding raises the possibility that a standard oral dosage regimen, such as is used widely as adjuvant treatment of operable breast cancer, may be absorbed erratically and, in some patients, adequate blood levels of Melphalan may not be reached. These results do not identify

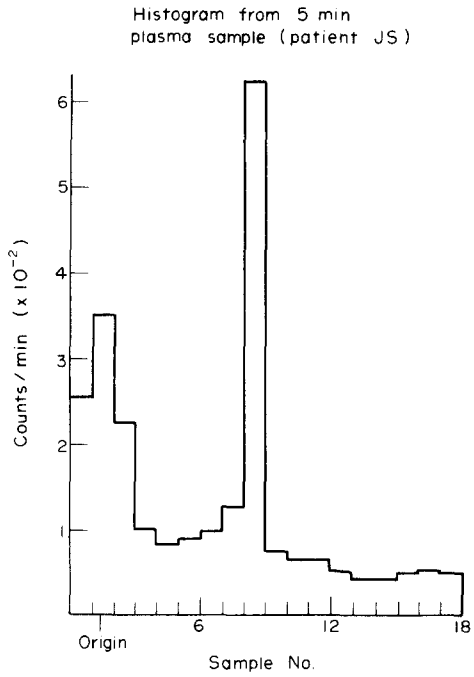

Fig. 6. Chromatogram of labelled melphalan extracted from plasma 5 min after drug administration (patient J.S.).

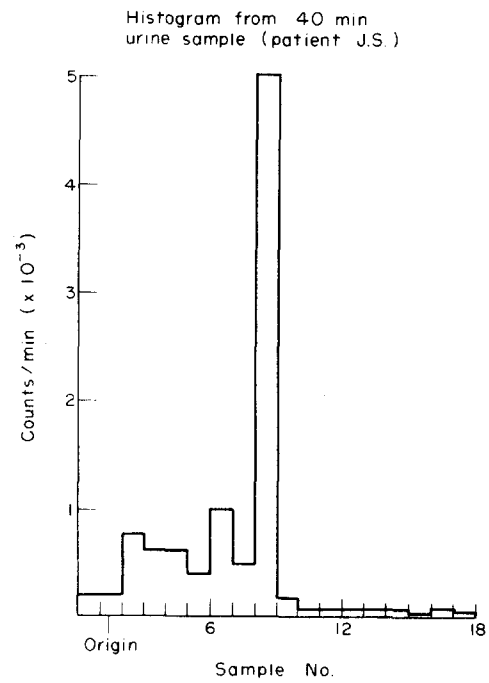

Fig. 7. Chromatogram of labelled melphalan extracted from urine passed 40 min after drug administration (patient J.S.).

factors influencing melphalan absorption and more detailed study may lead to improved understanding of these variables. At present, it would seem unwise to use a standard dosage of oral melphalan but rather to increase the dose with each course until myelosuppression is seen.

Melphalan given i.v. is distributed rapidly in the total body water and then disappears from the blood with a biphasic pattern. Following i.v. injection, 50% of the administered melphalan is recoverable in the urine within 24 hr. The plasma protein binding studies suggest that immediately after i.v. administration melphalan is only partially bound to plasma proteins but, with increasing time (and lower absolute melphalan concentrations), the proportion of drug associated with plasma proteins increases. The observation that hyperbilirubinaemic plasma bound less melphalan than normal plasma requires further study, but it indicates that competition may occur between melphalan and other drugs for plasma proteinbinding sites.

Following i.v. administration, melphalan is not excreted in the stool, while up to 50% of orally-administered drug may be recovered in the stool. The latter patients excreted less melphalan in the urine but the total recovery was higher than in the patient given melphalan intravenously.

Our studies of blood and urine collected within 5 and 40 min respectively of drug administration do not suggest that melphalan is metabolised significantly. The finding contrasts with the studies of melphalan pharmacology in dogs [5]. The general pattern of melphalan distribution in man and dogs appears to be similar but, in dogs, there is evidence of 6 chromatographically different products in extracts of different tissues. It is not known if such metabolites are present in human tissues. It is known that melphalan is not stable in aqueous solutions and it may be difficult to distinguish metabolic degradation of melphalan from physical instability. Nevertheless, our results on specimens taken soon after i.v. administration do not indicate significant metabolism.

The Effect of Syngeneic Lymphoid Tumors Upon Mouse B-Lymphocyte and Granulocyte–Macrophage Colony Forming Cells*

M. H. CLAËSSON and G. R. JOHNSON
The Cancer Research Unit, The Walter and Eliza Hall Institute of Medical Research, The Royal Melbourne Hospital, Victoria, Australia

Abstract—*Granulocyte–macrophage (GM-CFC) and B-lymphocyte colony forming cell (BL-CFC) numbers have been determined in the lymph nodes, spleen and bone marrows of mice bearing either subcutaneous B or T lymphomas, or a mammary carcinoma. During the exponential period of tumor growth, all animals had increased levels of BL-CFC in the regional lymph nodes and spleen irrespective of the type of tumor. Mesenteric lymph nodes were unaffected by subcutaneous tumor growth.*

Tumors of B lymphocyte origin did not specifically influence levels of host BL-CFC. In the late plateau phase of tumor growth only the regional lymph nodes of the mammary carcinoma-bearing mice showed increased levels of BL-CFC whereas the incidence of BL-CFC was normal or subnormal in regional lymph nodes and spleen of the lymphoma transplanted mice.

The incidence of GM-CFC increased 5–200 times in spleen and bone marrow of mice transplanted with B lymphoma, plasmacytoma or carcinoma cells, whereas the growth of T lymphoma cells did not influence the levels of GM-CFC. Serum obtained from B lymphoma or plasmacytoma-bearing mice in the late period of tumor growth demonstrated a lack of inhibitory activity when compared with normal mouse serum or serum harvested in the early period of tumor growth.

The proliferation of B lymphocyte and granulocyte–macrophage precursors in mice transplanted with syngeneic tumors during the exponential period of tumor growth may represent a host protective response against tumor cells.

INTRODUCTION

HAEMOPOIETIC changes have been shown to occur in animals bearing transplantable tumors [1, 2, 3]. The dynamics of haemopoietic and lymphoid precursor cells of tumor bearing animals may be of importance to the understanding of the host-tumor balance, therefore we have examined these precursor cells in mice inoculated with syngeneic B or T lymphoma cells, or with carcinoma cells.

Abbreviations used: BL-CFC = B-lymphocyte colony-forming cells. GM-CFC = Granulocyte–macrophage colony-forming cells. GM-colonies = Granulocyte-macrophage colonies. EBSS = Eisen's balanced salt solution. BM = Bone marrow. DME = Dulbecco's modified Eagles medium. 2-ME = 2-mercaptoethanol. SRBC = Sheep red blood cells. GM-CSF = Granulocyte-macrophage colony stimulating factor.

Fluctuations in B-lymphocyte colony-forming cells (BL-CFC) and granulocyte–macrophage colony forming cells (GM-CFC) have been examined in lymphoid and haemopoietic organs of tumor-bearing mice, using a semi-solid agar cloning system developed in this laboratory [4, 5]. The extent of tumor-infiltration of host lymphoid organs has been determined from numbers of tumor-colonies growing in the agar-cultures. Finally, the effect of serum from tumor-bearing mice on the cloning efficiency in agar-medium of the four tumor-lines employed has been studied.

MATERIAL AND METHODS

Animals

Inbred female BALB/c mice, 2–3 months of age were obtained from the Institute stock.

Tumor lines

All tumor lines studied were derived from BALB/c mice. They were maintained and

generously provided by Drs. A. Harris and N. Warner. The tumor cells used were obtained from continuous cell lines cultured as described by Harris *et al.* [6]. The following four tumor lines were used in the present work: ABLS-8, an Abelson virus induced early B-lymphocyte tumor [7]; P3K, a mineral oil-induced plasma cell tumor; WEHI-7, a T lymphoma induced as a thymic tumor by fractionated irradiation [6]; and EMT-6, a spontaneous breast carcinoma [8].

Tumor cells were washed twice and inoculated subcutaneously in the right flank as 10^7 cells in 0.2 ml saline.

Preparation of cell suspensions

At various periods of time after inoculation of tumor cells (or 0.2 ml saline i.e. controls) groups of three mice were bled for serum preparations and killed. The right axillary lymph nodes, the spleen, the mesenteric lymph nodes and the subcutaneously growing tumor were removed from each mouse and in some cases weighed. Single cell suspensions were made of pools of similar organs by teasing the organs with fine needles in 1–2 ml Eisen's balanced salt solution (EBSS). Bone marrow (BM) cells were flushed from the femoral cavity using 5 ml EBSS to 6 femora. A viable cell count was determined for all cell suspensions using eosin dye exclusion and the suspensions diluted in EBSS to the required cell number.

Culture technique

The general techniques for colony formation by B lymphocyte and granulocyte–macrophage precursors have been described in detail elsewhere [4, 5, 9]. Briefly, cells in vol of 0.2 ml were added to an equal vol mixture of double strength Dulbecco's modified Eagle's medium (DME) and 0.6% Difco Bacto agar. B lymphocyte cultures contained 5×10^{-5}M 2-mercaptoethanol (2-ME) and 0.05 ml 60% washed SRBC per 1 ml of agar-medium. Granulocyte and macrophage colony formation was stimulated by 0.1 ml of mouse lung conditioned medium (GM-CSF) [10] per 1 ml culture. The influence of serum on tumor colony formation was tested at various dilutions in 0.1 ml added to the empty culture dish prior to the addition of the agar-medium containing the tumor cells. All cultures were incubated in 33 mm plastic dishes at 37°C in fully humidified atmospheric air containing 10% CO_2 for a period of 6–7 days. Colonies (50 cells) were scored with an Olympus dissection microscope. Granulocyte–macrophage colonies were removed with a fine Pasteur pipette, placed on a microscope slide, allowed to air dry. After staining with aceto-orcein, colony morphology was determined according to previously published criteria [11]. The agar-medium for cloning of tumor cells was identical to that used for BL-CFC.

Identification of tumor cells in lymphatic organs and BM

All cultures for BL-CFC were set up in quadruplicate with and without 2-ME in the agar-medium. Since the WEHI-7, the P3K and the EMT-6 tumor cells grew independently of the addition of 2-ME, as few as 1 tumor colony forming cell per 25,000 lymph node or spleen cells could be detected by comparing the cultures with and without 2-ME. ABLS-8 tumor cells were dependent on addition of 2-ME but these tumor-colonies had a typical morphology, enabling them to be easily distinguished from B lymphocyte colonies [12].

Mixing experiments

To examine the influence on B-lymphocyte and GM-colony-formation of tumor colony proliferation constant numbers of normal spleen or BM cells (10,000 and 50,000/ml respectively) were mixed with varying numbers of tumor cells prior to agar seeding. The number of developing B-lymphocyte and GM-colonies was determined as outlined above.

Correction of mean colony counts

Individual data were normalized as follows: the average colony count of the same organ from 15 individual control groups was calculated (A). Normalized mean colony counts for the same organs in an individual group of tumor bearing mice were calculated as $A \times B/C$ where B represented the mean colony count of the experimental organ-pool and C represented the mean colony count in the corresponding control organ pool. All BL-CFC and GM-CFC-counts were corrected in this manner.

RESULTS

Tumor growth

Subcutaneous injection of 10^7 ABLS-8, P3K, WEHI-7, or EMT-6 tumor cells killed the recipient mice within a period of 3–4 weeks. Figure 1 shows the growth curves for the four tumor types. At the time of death, individual tumors weighed from 4 to 8 g.

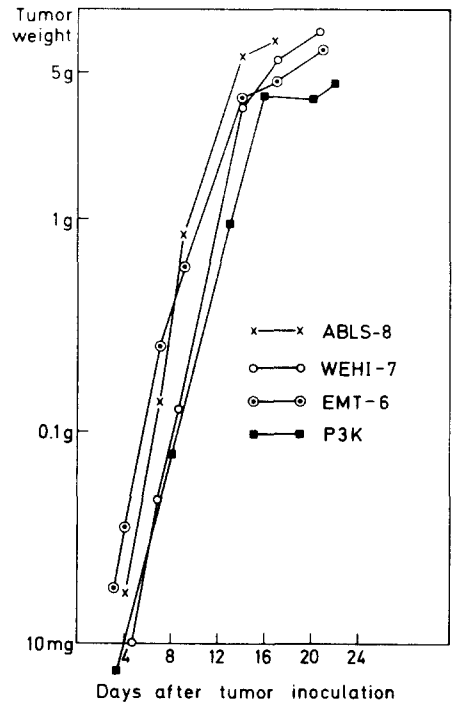

Fig. 1. In vivo *growth curves for the four tumor lines studied.* 10^7 *tumor cells were inoculated at* day 0. *Groups of* 3 *mice were killed at intervals as indicated. Data represent the mean tumor weight per animal.*

Lymph node and spleen weights

The regional axillary lymph node and spleen weights for groups of mice inoculated with 10^7 tumor cells are shown in Fig. 2. These data do not include those organs with extensive tumor cell infiltration (see below). In mice injected with ABLS-8 and P3K tumor cells, the spleen and lymph node weights increased only by a factor of 1.2–2.0, whereas T lymphoma cells did not influence spleen weight and only caused a slight weight increase in the axillary lymph nodes (Fig. 2). However, mice injected with carcinoma cells (EMT-6) showed weight increases in axillary lymph nodes and spleen by a factor of 4–6 regardless of the fact that very few tumor cells could be detected in the respective lymphoid organs (see below). Mesenteric lymph node weights were not influenced by tumor proliferation with any of the tumors tested.

BL-CFC in regional lymph nodes and spleen

The corrected mean values for BL-CFC in the regional axillary lymph nodes and the spleens of mice at different days after injection of tumor cells are shown in Figs. 3–4. Also shown are the numbers of tumor-colonies present in these organs. It is seen that only very few tumor cells were present in the cultured lymphoid organ suspensions, even during the latter part of the experimental period. Figures 3–4 do not include data from 3 groups of WEHI-7 tumor bearing mice (day 17, 21 and 22) and one group injected with ABLS-8 tumor cells (day 17). These 4 groups showed enormous enlargement of the axillary lymph nodes and spleen, the cultures being crowded with tumor colonies (i.e. 1000–

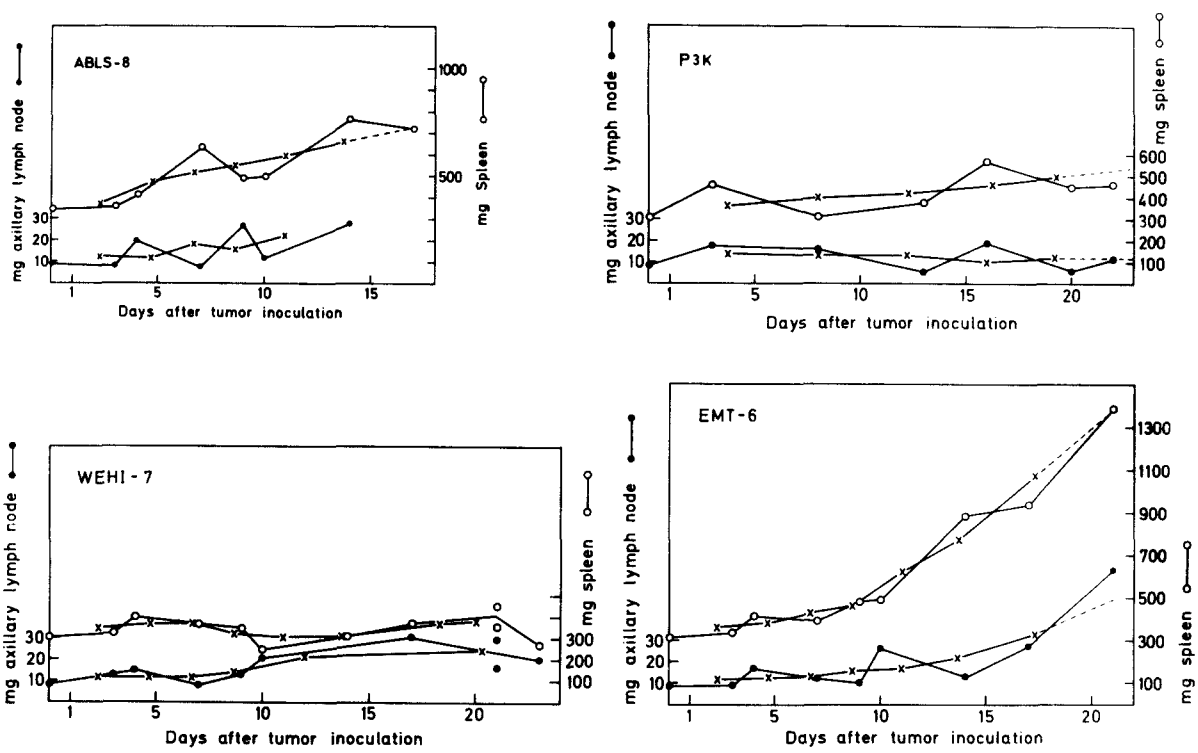

Fig. 2. *Weight curves of the axillary regional lymph nodes and the spleen of tumor bearing mice. Data represent weights of organs from groups of three animals. Data were fitted according to the least squares method* (× ——— ×).

5000 tumor colonies per 25,000 cells plated), making it impossible to determine the actual number of B lymphocyte colonies. With all types of tumor hosts there was an initial increase in the frequency and the total number of BL-CFC by a factor of 2–5. This increase was followed by a decline in frequency of BL-CFC, either below control values (the P3K tumor host) or to levels close to control values (WEHI-7 and ABLS-8 tumor hosts). For the EMT-6 bearing mice the frequency of BL-CFC decreased with time in the spleen whereas it increased in the regional lymph nodes. Except for the P3K hosts, there was an increase in the total number of lymph node and spleen BL-CFC in the latter phase of the tumor growth period partly due to the increased size of the organs.

The low frequency of tumor colonies detected in the regional lymph nodes and spleen, taken together with the very high cloning efficiency of these tumor cells (cf. Table 2), indicates that the lymphoid cell suspensions in the late period of tumor growth contained at most 2–5% tumor cells.

Bone marrow cellularity

Table 1 shows the total numbers of bone marrow cells in mice bearing each of the four tumor types studied. An influence on cell numbers (depression) was only observed in mice

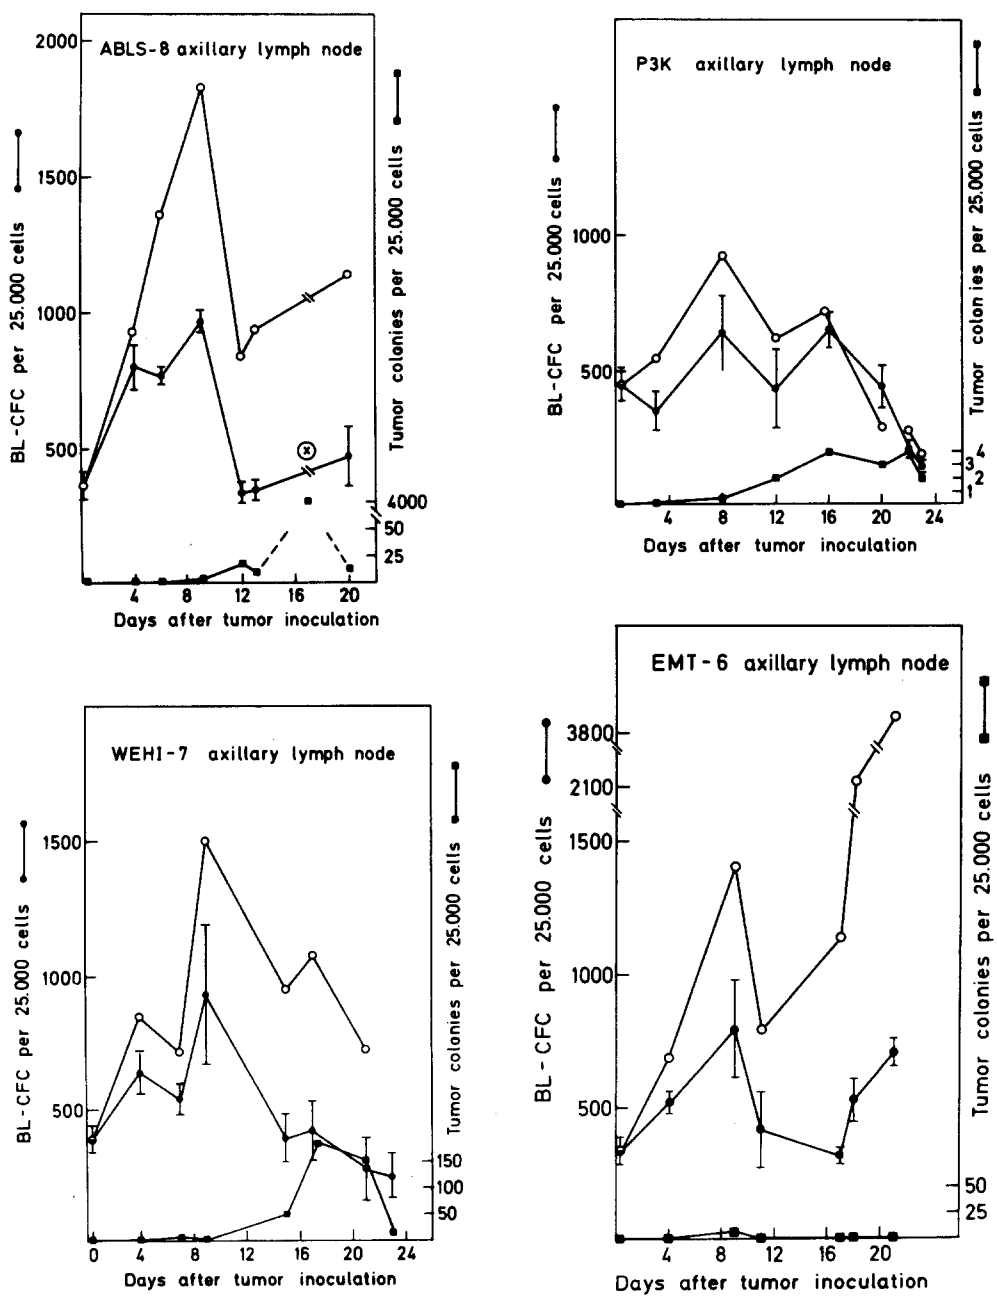

Fig. 3.

bearing ABLS-8 and WEHI-7 tumors during the last stages of tumor growth.

GM-CFC in spleen and BM

Figure 5 shows the incidence of GM-colonies in the spleens and BM of tumor bearing mice. Growth of the WEHI-7 tumor did not alter GM-CFC frequency, whereas the bone marrow of ABLS-8 and EMT-6 tumor bearing animals and the spleens of ABLS-8, P3K and EMT-6 tumor bearing mice showed a 5–200 fold increase in GM-colony frequency. At all times after tumor innoculation, no changes were observed in the proportions of neutrophil, mixed neutrophil–macrophage or macrophage colonies, when compared with normal control mice. No tumor colonies were detected in the bone marrows of ABLS-8, P3K or EMT-6 tumor bearing mice. Low numbers of tumor cells were detected however, in the bone marrows of WEHI-7 tumor bearing animals.

Loss of serum inhibition of tumor colony growth

Normal mouse serum was found to exert a strong inhibitory effect on the growth of tumor colonies at concentrations from 2½ to 5% (Table 2). Serum obtained from tumor bearing mice during the first two weeks after inocculation did not differ from normal serum with respect to this inhibitory effect. In contrast, data in Table 2 show that serum obtained from some of the groups of mice during the late period of tumor growth (the end of the third week) had partially lost the inhibitory property when tested against the four tumor types. Only serum obtained from WEHI-7 bearing mice showed inhibition in the tumor colony assay comparable to that of control serum. It is evident from Table 2 that this loss of serum inhibition was completely unspecific.

Mixing experiments

From 100 to 2500 tumor cells (ABLS-8, P3K and WEHI-7) were mixed with 10.000 normal spleen cells prior to assaying for B lymphocyte colony formation. No stimulatory or inhibitory effect on B lymphocyte growth was observed by this co-cultivation of tumor cells and normal lymphoid cells. Similarly mixing experiments with WEHI-7 tumor cells (1000–4000) and normal bone marrow cells did not inhibit or potentiate the formation of GM-colonies.

DISCUSSION

The present data show that increased levels of BL-CFC occur in the regional lymph nodes and spleens and that GM-CFC levels increase in the bone marrow and spleens of mice bearing

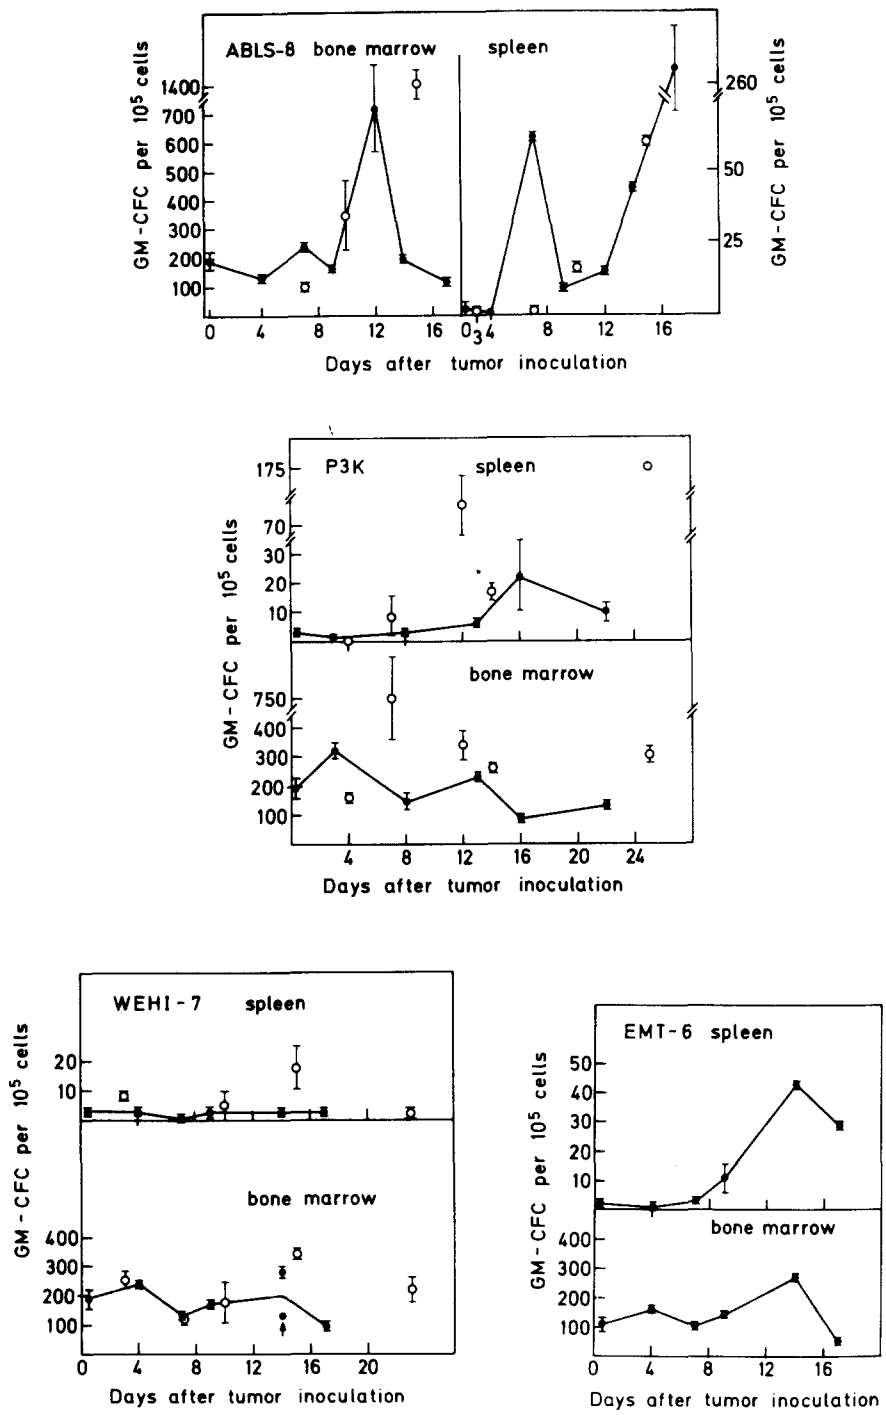

Fig. 5. Frequency of GM-CFC in spleen and bone marrow of tumor bearing mice. Data are mean values of pools of 3 animals cultured in four replicate culture dishes. ↑: Tumor colonies present in the bone marrow culture.

subcutaneously transplanted B lymphoma, plasmacell tumor, or a mammary carcinoma. Mice with transplanted T lymphoma showed only elevated numbers of BL-CFC whereas the GM-CFC levels were not influenced by tumor growth. Lymphoid organ weights and numbers of bone marrow cells were only slightly affected by tumor growth in mice transplanted with B and T lymphomas whereas the mammary carcinoma-bearing mice showed an enormous enlargement of both the regional lymph nodes and spleen. The observed increase in lymphoid organ weights or bone marrow cell counts in tumor bearing mice was not due to infiltration of the organs with tumor cells since no or very few tumor cells could be detected in the respective organs.

BL-CFC represent a subpopulation of B

lymphocytes with a potential for cell proliferation *in vitro* i.e. colony formation [4]. *In vivo* this subpopulation represents 5–10% of all B lymphocytes, from immature, early B lymphocytes to the postantigen, memory type B lymphocyte. The function of the colony-forming cells and factors which regulate the numbers of BL-CFC *in vivo*, are poorly understood [13, 14].

During the early period of tumor growth, both the incidence and the total numbers of BL-CFC were elevated in the regional lymph nodes and the spleen irrespective of the tumor type employed. The mesenteric lymph nodes seemed to be unaffected by tumor growth. The data may suggest that excessive proliferation of neoplastic B lymphocytes (i.e. ABLS-8 and P3K tumors) does not specifically influence normal B lymphocyte colony forming cell levels in tumor-bearing mice. The increased levels of BL-CFC may simply reflect a host response to the presence of antigens introduced by tumor proliferation (e.g. dead tumor cells or secondary infections). Also specific antigens, present on the tumor cell types studied might trigger B lymphocytes *in vivo* and lead to increased levels of BL-CFC. Since methods are not available to test B lymphocyte colony cells for antibody production against such tumor associated antigens, the mechanisms underlying the observed response can not be fully explored. The negative results of the tumor-spleen cell mixing experiments, indicate however that the tumor cells themselves do not produce factors which influence B lymphocyte colony formation.

During the latter part of the tumor-bearing period the BL-CFC response became more complex. The lymphoma and plasmacytoma-bearing mice all showed normal or decreased incidences of BL-CFC, whereas the mice transplanted with mammary carcinoma cells showed increased levels of colony forming cells in the regional lymph nodes. Due to the increase in lymphoid organ weight in the late part of the experimental period, the total number of BL-CFC in ABLS-8 and WEHI-7 bearing animals increased, whereas plasmacytoma-bearing mice showed reduced frequency and numbers of BL-CFC in the regional lymph nodes and the spleen. A possible explanation for the tendency towards decreased BL-CFC levels may be that these stressed animals exhibit increased amounts of circulating corticosteroids; hormones which *in vivo* selectively depress BL-CFC relative to non-colony-forming lymphocytes [9, 13].

It has been shown that bone marrow and spleen GM-colony levels are elevated in mice transplanted with syngeneic plasmacell or breast tumors [15]. Similarly, granulocytopoiesis and the number of spleen colony-forming cells are increased in some tumor-bearing mice [1, 2]. Thus, the present observations showing a 5–200 fold increase in GM-colony forming cells in the spleen of B lymphoma, plasmacytoma and mammary tumor bearing mice, confirm and extend these earlier observations. The observed increase might reflect an unspecific protective response against the growing tumor cells which may be mediated by increased levels of circulating GM-CSF known to occur in tumor-bearing mice [15]. Surprisingly, no effect on GM-colony forming cell levels was observed in T lymphoma-bearing mice, where in fact the frequency of bone marrow derived GM-CFC tended to decline during the late tumor-bearing period. This obvious lack of a "protective response" in WEHI-7 bearing mice might bear some relationship to the more frequently observed infiltration of the host lymphoid organs, spleen and bone marrow by this tumor type. Differences in levels of GM-colonies in tumor-bearing mice might moreover reflect different capabilities of individual tumors to produce *in vivo* the factors which stimulate colony formation *in vitro* [15–16].

Normal unfractionated mouse serum exhibits a high, non-specific, colony-inhibitory activity when added to cultures of B lymphocytes, GM-precursors, lymphoid leucaemic, plasmacytoma and mastocytome cells [17]. These findings were confirmed in the present study where non-specific inhibitory activity was present in serum from early lymphoma and plasmacytoma bearing mice. In contrast, serum obtained from late B lymphoma- and plasmacytoma-bearing mice did not inhibit colony formation *in vitro* by any of the four cell types used. However, serum from late T lymphoma-bearing animals showed normal inhibition of colony formation. It is known that serum inhibitory activity against GM-CFC is lowered by starvation of the serum donor [18] and starvation due to the weak condition of tumor-bearing animals might be held responsible for the observed lack of inhibitory activity in serum of these mice. Factors occurring in serum of late tumor-bearing mice might, on the other hand, neutralize its inherent inhibitory activity or perhaps directly stimulate growth of tumor cells leading to the observed phenomenon.

Prospective Study of the α and β Subunits of Human Chorionic Gonadotrophin in the Blood of Patients with Various Benign and Malignant Conditions*

M. DOSOGNE-GUÉRIN, A. STOLARCZYK and A. BORKOWSKI†
Service de Médicine Interne et Laboratoire d'Investigation Clinique, Institut Jules Bordet, 1 rue Hèger-Bordet, 1000 Bruxelles, Belgium

Abstract—*A prospective study of HCG-β (the human chorionic gonadotrophin and its free β subunit) and of H-α (the free α subunit) was carried out in the plasma of 414 patients with malignant tumours and 99 patients with benign diseases (chiefly benign tumours and benign conditions associated with tissue hyperplasia).*

HCG-β and excessive free α subunit concentrations were found with a similar frequency (in 16–21% of the patients); both were found as frequently in the benign and in the malignant conditions; furthermore there was no clearcut predisposition according to the pathology except for choriocarcinomas.

However the benign and the malignant conditions differed from each other in that the concentrations of HCG-β were significantly higher in the latter whereas the very high plasma concentrations (>50 ng/ml) of HCG-β or of H-α were specific for malignant conditions.

The patients with HCG-β were not the same as those with excessive H-α concentrations: 75% of the latter had no detectable HCG-β, indicating that the production of the α subunit can be regulated independently from that of HCG-β.

Unlike in the patients with excessive H-α, in the patients with HCG-β there was a very significant correlation between the HCG-β and the corresponding free α subunit concentrations: this indicates that the production of HCG-β was linked to that of the free α subunit whereas the reverse was not necessarily true.

The concentrations of HCG-β in plasma were qualified according to the elution profiles on Sephadex chromatography and the relative affinity of our antibody to HCG and the free β subunit. The presence of the free β subunit and of abnormal chorionic gonadotrophin was demonstrated.

INTRODUCTION

HUMAN chorionic gonadotrophin (HCG) and its free α subunit (HCG-α) are normally secreted by the placenta [1].

The α subunit of HCG is practically identical to that of the follicle-stimulating hormone (FSH), the luteinizing hormone (LH) or the thyroid-stimulating hormone (TSH) and cannot be distinguished by radioimmunoassay. Therefore, this common free α subunit (H-α) is found in the blood of normal, non-pregnant individuals. Its concentration in blood increases when the secretions of FSH, LH or TSH are stimulated, as in postmenopausal women or in patients with primary hypothyroidism [2]. However, once the normal limits of the free H-α concentrations have been determined, men or non-pregnant women with normal pituitary function but excessive free H-α concentrations should be suspected of ectopic secretion.

HCG, on the other hand, is immunologically unique because of its characteristic β subunit (HCG-β). It was hoped therefore that HCG-β would be a specific tumour marker in non-pregnant individuals [3, 4]. However, as HCG was found recently in normal testes [5], in normal pituitaries [6] and in the blood of

patients with gastro-intestinal inflammatory disorders [1], this view must be reconsidered.

The present work constitutes a prospective study of H-α (as the common free α subunit) and of HCG-β (as the free β subunit and as part of the molecule of HCG) in the blood of more than 500 patients admitted consecutively in our hospital. The concentrations of these proteins in blood were correlated with the benignity or the malignancy of the disease and with the pathological diagnosis; they were also correlated with each other to help in the understanding of their genetic regulation.

MATERIAL AND METHODS

1. *Design of the study*

HCG-β (as the free β subunit and as part of the molecule of HCG) and H-α (as the free α subunit, common to the various glycoproteic hormones including HCG) were measured in a prospective fashion, prior to therapy, in all the patients hospitalized in our Institute. The plasma concentrations of these proteins were correlated with the pathology; they were also correlated with each other. The normal controls were members of the medical staff and healthy people consulting for a preventive medical examination.

2. *Patients* (*see also Tables* 1 *and* 2)

(a) *Malignant tumours:* 414 *patients.* There were 116 mammary carcinomas, 50 bronchial carcinomas (including 24 epidermoid carcinomas, 14 oat-cell carcinomas, 4 undifferentiated large cell carcinomas), 37 gastrointestinal tumours (including 14 gastric, 6 colic, 11 rectal and 2 pancreatic carcinomas), 45 gynaecologic carcinomas (29 of the cervix, 10 of the endometrium and 6 of the ovaries), 12 thyroid carcinomas (8 follicular, 3 medullary and 1 undifferentiated carcinoma), 20 melanomas, 5 testicular tumours (including 3 choriocarcinomas), 29 lymphomas or leukaemias (14 lymphosarcomas, 4 Hodgkin's diseases, 8 chronic lymphoid leukemias and 3 myelomas), 51 carcinomas of the oropharynx or larynx (including 13 of the larynx, 10 of the tongue and 6 of the gums), 38 miscellaneous (including 13 basal cell carcinomas of the skin, 9 sarcomas, 2 bladder carcinomas, 6 cerebral tumours and 2 hypernephromas).

Table 1. *Patients with significant HCG-β concentrations*

Diagnosis	Numbers	Percentages	Ranges of concentrations (ng/ml)	Median concentrations (ng/ml)
Malignant tumours (68/414 = 16%)				
Mammary carcinomas	24/116	21%	1.6–7.6	2.4
Bronchial carcinomas (5 squamous cell, 1 oat cell carcinomas)	6/50	12%	2.1–3.5	2.5
Gastro-intestinal carcinomas (1 parotid, 1 gastric, 1 gallbladder, 1 pancreatic, 3 rectocolic carcinomas)	7/37	19%	1.6–17	1.7
Gynaecologic carcinomas (4 cervical, 2 endometrial, 1 ovarian carcinomas)	7/45	16%	2.4–>50	2.9
Thyroid carcinomas (2/8 follicular, 1/3 medullary carcinomas)	3/12	25%	1.6–2.8	1.8
Melanomas	3/20	15%	1.7–>50	1.8
Choriocarcinomas	3/3	100%	>50 in all	>50
Lymphomas and leukemias	3/29	10%	1.6–2.3	1.7
Basal cell carcinomas of skin	2/13	15%	1.6–2.8	—
Carcinomas of the oropharynx and larynx	3/51	6%	1.6–4.4	2.3
Miscellaneous (including 1 mesothelioma, 2 hypernephromas, 1 bladder and 1 bladder + oat cell carcinomas)	7/38	18%	1.7—>50	2.4
Benign diseases (16/99 = 16%)				
5 multinodular goiters, 1 parathyroid adenoma, 1 uterine fibroma, 1 benign ovarian cysts, 2 chronic adenitis, 1 severe osteoporosis, 1 liver + bone tuberculosis, 1 liver cirrhosis, 2 perforated colic diverticulitis, 1 severe int. hemorroids			1.6–2.6	1.75

Table 2. Patients with excessive free α subunit concentrations

Diagnosis	Numbers	Percentages	Ranges of concentrations (ng/ml)	Median concentrations (ng/ml)
Malignant tumours (87/414 = 21%)				
Mammary carcinomas	35/116	30%	2.5–>50	7
Bronchial carcinomas (4 squamous cell, 1 oat cell carcinomas)	5/50	10%	2.5–12	3.3
Gastro-intestinal carcinomas (3 gastric, 3 rectal, 2 pancreatic carcinomas)	8/37	22%	3.4–13	8.2
Gynaecologic carcinomas (12 cervical, 1 endometrial, 3 ovarian carcinomas)	16/45	36%	2.6–>50	3.7
Thyroid carcinomas (3/9 follicular carcinomas)	3/12	25%	4.5–5	5
Melanomas	6/20	30%	2.7–30	5
Choriocarcinomas	2/3	67%	7.8–>50	—
Lymphomas and leukemias (Hodgkin's disease)	1/29	3%	>50	—
Basal cell carcinoma of skin	1/13	8%	3	—
Carcinomas of the oropharynx and larynx	6/51	12%	2.5–7.6	3.4
Misellaneous (2 sarcomas, 1 mesothelioma, 1 prostatic carcinoma)	4/38	11%	3.2–12	8.5
Benign diseases (16/96 = 17%)				
9 multinodular goiters, 1 uterine fibroma + ovarian cysts, 1 endometrial hyperplasia, 1 fibrocystic hyperplasia of breasts, 1 liver + bone tuberculosis, 2 perforated colic diverticulitis, 1 essential hypertension			2.5–8.2	3.9

(b) *Benign diseases: 99 patients.* There were 34 euthyroid nodular goiters, 4 parathyroid adenomas, 4 diseases of the breast (3 fibrocystic hyperplasias, 1 intraductal papilloma), 16 gynaecologic diseases (including 3 ovarian cysts, 7 uterine fibromas, 2 endometrial hyperplasias, 1 polyp of the cervix), 10 diseases of the liver and the gastrointestinal tract (including 1 liver cirrhosis, 1 liver steatosis, 1 chronic cholecystitis, 1 liver tuberculosis, 2 perforated colic diverticulitis, 1 duodenal ulcer), 31 miscellaneous (including 3 benign chronic adenitis, 2 prostatic adenomas and 1 retroperitoneal fibrosis).

3. *Radioimmunoassays*

All assays were carried out in duplicate by the double-antibody technique. Highly purified HCG-β subunit (SB-6) and the corresponding rabbit antibody were generously provided by the National Institute of Arthritis, Metabolic and Digestive Diseases (N.I.H., Bethesda, Md). Highly purified LH-α subunit (~100 i.u. IRP-HMG per mg) and the corresponding rabbit antibody were obtained from commercial sources (Calbiochem, U.S.A.). HCG-β was iodinated by the method of Vaitukaitis *et al.* [7]; H-α was iodinated by the chloramine T method [8]. The first incubation was carried out at 4°C during 3–5 days; the 0.4 ml incubates were composed as follows: 0.1 ml of plasma, 0.1 ml of phosphate buffer containing 2.5% rabbit serum, 0.1 ml of phosphate buffer with 0.5% bovine serum albumin containing ~10,000 counts/min of labeled hormone, 0.1 ml of the same buffer containing the antibody (final dilution of the antibody to HCG-β: 1/120,000 and of the antibody to H-α: 1/4,000). At the end of the first incubation an appropriate amount of sheep anti-rabbit gamma globulin was added and the second incubation was carried out at 4°C during 6 hr. The samples were then centrifuged, the supernatants decanted and the precipitates counted. In the absence of unlabeled ligand, 30–40% of the labeled ligand was precipitated by the second antibody (B_0).

Remarks about the HCG-β radioimmunoassay: the HCG-β standards were dissolved in normal human serum; however some material reacting like HCG-β was still found in the plasma of many normal controls; the highest plasma concentration of this material in the normal controls was 1.5 ng/ml (see Results) and B/B_0 was then 60%. The specificity of the HCG-

β assay was investigated: there was a cross-reaction of the order of 12% with HCG but no cross-reaction with LH-β, LH, FSH and TSH; the assay measured therefore the free HCG-β subunit and, with much less sensitivity, HCG itself (see Discussion).

Remarks about the H-α radioimmunoassay: the sensitivity of the assay was 0.2 ng/ml; it was specific for the free α subunit since the cross-reaction with HCG or LH repurified by column chromatography was less than 5%.

In view of the structural similarities of HCG with LH, plasma LH was measured in the normal controls to find out if the material cross-reacting with HCG-β in our radioimmunoassay correlated with plasma LH. The luteinizing hormone (1 mg = 66 mg ± 6 LER 907) and the antibody used in this assay were obtained from the Radiochemical Centre of Belgium (I.R.E.); the assay was similar to that of H-α.

4. *Column chromatography*

The serum of some patients with very high HCG-β concentrations was fractionated on Sephadex G-100 in order to determine the relative importance of HCG and of its free β-subunit [9]. The void volume (V_o) of the column, measured by the elution of dextran blue, was 55 ml; its total volume (V_T) was 150 ml. The column was calibrated by determining the elution peaks (V_e) of labeled HCG, β and α subunits. In separate experiments, standards of unlabeled HCG, β and α subunits were similarly eluted: their respective V_e/V_o: 1.31, 1.38 and 1.75 were identical to those of the labeled proteins; the corresponding kav were: 0.20, 0.25 and 0.48. The concentrations of the β and α subunits were measured as described above in 0.1 ml of each elution fraction. The concentrations of HCG were measured apart with an antibody to HCG which could not be used in unfractionated plasma because of its cross-reaction (18%) with LH; HCG used in this assay was obtained from the National Institute of Health (U.S.A.) and the antibody was obtained from the I.R.E. (Belgium); the assay was similar to that of H-α.

5. *Statistical analysis*

The data were evaluated by a non-parametric analysis of variance [10].

RESULTS

1. *Plasma concentrations in the normal controls*

(a) "*HCG-β*". A material cross-reacting with HCG-β was found in the normal controls. The mean concentrations and the standard deviations (s.d.) were as follows: 0.34 ng/ml (s.d. 0.52) in 26 men, 0.47 ng/ml (s.d. 0.51) in 10 premenopausal women and 0.58 ng/ml (s.d. 0.44) in 16 postmenopausal women. There was no significant difference between the three populations ($P=0.31$); therefore all the data were grouped and the highest "normal concentration", i.e. 1.5 ng/ml, was taken as the "normal upper limit".

(b) "H-α". The mean H-α concentrations were as follows: 0.53 ng/ml (s.d. 0.43) in the 26 men, 0.36 ng/ml (s.d. 0.47) in the 10 premenopausal women and 1.39 ng/ml (s.d. 0.51) in the 16 postmenopausal women. The concentrations in the postmenopausal women were significantly higher ($P<0.0001$) than in the two other groups; therefore, the highest concentration found in the postmenopausal women, i.e. 2.4 ng/ml was taken as the normal upper limit.

(c) *Correlation analysis between "HCG-β" and H-α concentrations.* There was no significant correlation between the plasma concentrations of H-α and those of the material cross-reacting with HCG-β.

(d) *LH.* With regard to LH, the following mean concentrations were found: 2.6 ng/ml (s.d. 1.3) in the men, 4.7 ng/ml (s.d. 5.5) in the premenopausal women and 11.8 ng/ml (s.d. 3.4) in the postmenopausal women; there was no significant correlation between the concentrations of LH and those of the material cross-reacting with HCG-β ($P=0.13$) but the concentrations of LH correlated very significantly with those of H-α ($P<0.0001$).

2. *HCG-β in the patients: plasma concentrations above* 1.5 ng/ml (*Table* 1)

(a) *Frequency of these HCG-β concentrations according to the disease.* Malignant tumours vs benign diseases: 68 of the 414 patients with malignant tumours (16%) and 16 of the 99 patients with benign diseases had high plasma concentrations of HCG-β, thus the same percentage in each population.

According to the pathology of the malignant tumours, except for the choriocarcinomas which obviously formed a distinct entity, the frequency of high HCG-β concentrations was of the same order of magnitude in all types of malignant tumours although the frequency might have been somewhat lower in the tumours of the oropharynx and larynx.

According to the pathology of the benign diseases, it is of interest that 5 of the 34 benign nodular goiters (15%) had high HCG-β concentrations in plasma.

(b) *Range of these plasma concentrations according to the disease.* HCG-β measured by our radioimmunoassay was actually the free β subunit, the whole molecule of HCG or a combination of both. With these reservations in mind (see Discussion), it is interesting to see that the plasma concentrations of HCG-β were significantly higher in the patients with malignant tumours. Indeed, of the 68 patients with a malignant tumour described in Table 1, 7 had concentrations above 50 ng/ml (3 had a choriocarcinoma, 1 an oat-cell carcinoma plus a carcinoma of the bladder, 1 a mesothelioma, 1 a melanoma and 1 a carcinoma of the endometrium) whereas the highest concentration in the benign diseases was 2.6 ng/ml; furthermore, in the remaining 61 patients with a malignant tumour, the plasma concentrations of HCG-β (mean = 2.8, median: 2.3, range: 1.6–17 ng/ml) were still significantly higher ($P = 0.004$) than in the patients with benign diseases (mean = 1.9, median: 1.8, range: 1.6–2.6 ng/ml).

However, among the patients with malignant tumours there was no significant difference of concentration according to the pathology of the tumour except for the choriocarcinomas where the plasma concentrations were always > 50 ng/ml.

(c) *Correlation analysis between these HCG-β and the H-α concentrations.* The correlation between these HCG-β concentrations (Table 1) and the corresponding H-α concentrations was statistically very significant ($P \sim 0.001$).

3. *The free α subunit in the patients: plasma concentrations above* 2.4 ng/ml (*Table* 2)

(a) *Frequency of these high H-α concentrations according to the disease.* Malignant tumours vs benign diseases: 87 of the 414 patients with malignant tumours (21%) and 16 of the 95 euthyroid patients with benign diseases (17%) had excessive H-α concentrations; thus, again, the percentage was similar in the benign and in the malignant conditions.

According to the pathology of the malignant tumours: the frequency was perhaps somewhat higher in the patients with mammary carcinomas, gynaecologic carcinomas or melanomas and to a lesser extent with thyroid or gastrointestinal carcinomas; it is of interest that only one of the three patients with a choriocarcinoma had very high (> 50 ng/ml) H-α concentrations in plasma.

According to the pathology of benign diseases: it is remarkable that 9 of the 34 euthyroid nodular goiters (26%) had high H-α concentrations in plasma.

(b) *Range of these plasma concentrations according to the disease.* As shown in Table 2, the highest plasma concentration of H-α in the 16 patients with benign diseases was 8.2 ng/ml whereas 27 of the 87 patients with a malignant tumour had concentrations above 8.2 ng/ml; 5 patients with a malignant tumour had actually plasma concentrations above 50 ng/ml (1 choriocarcinoma, 2 generalized mammary carcinomas, 1 ovarian carcinoma, 1 Hodgkin's disease); although the medians were similar (respectively 3.9 and 4.5 ng/ml) and the difference was not statistically significant between the benign and the malignant conditions it is obvious that the patients with plasma concentrations above 50 ng/ml belonged to a distinct population: they all had a malignant tumour.

Again, as for HCG-β, there was no difference of H-α concentration according to the pathology of the malignant tumour.

(c) *Correlation analysis between these H-α and the HCG-β concentrations.* No significant correlation was found between these H-α and the corresponding HCG-β concentrations; actually, among the 103 patients described in Table 2, 77 had no detectable HCG-β in their plasma; furthermore, among the 5 patients with plasma H-α concentrations in excess of 50 ng/ml, 3 had no detectable HCG-β.

4. *Chromatographic characterization of HCG and its subunits*

The elution profiles were variable. Four examples are presented in Figs. 1–4. Figure 1: patient De Pot (oat cell carcinoma and carcinoma of the bladder): HCG, the free β and the free α subunits were all found at high concentrations in the serum of this patient; however, the elution profiles of these proteins were normal (respective kav: 0.18, 0.25 and 0.44). Figure 2: patient Hou (melanoma): the serum contained essentially HCG and its free β subunit (normal kav again: respectively 0.19 and 0.25). Figure 3: patient Ar (very malignant choriocarcinoma): only HCG was found in the serum (normal kav again: 0.18). Figure 4: patient Del (carcinoma of the endometrium): although fresh serum was passed on column chromatography, only a very abnormal HCG was found (very low kav: 0.09 and thus presumably increased molecular weight).

DISCUSSION

With regard to HCG-β, our antibody was specific but was more sensitive to the free β subunit than to the chorionic gonadotrophic hormone itself. Therefore our measurements in

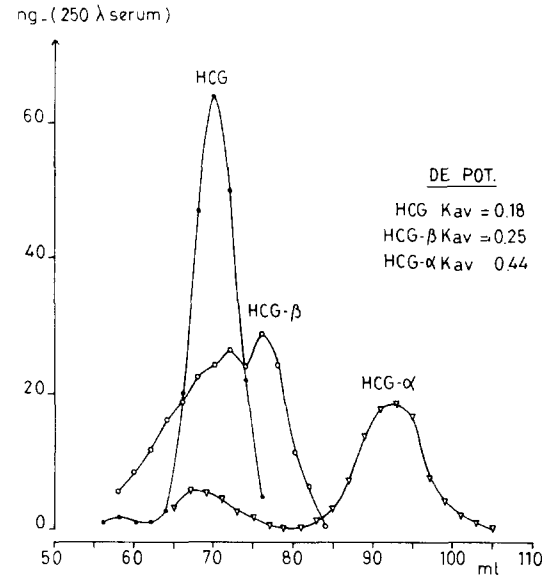

Fig. 1. Elution profiles of the ectopic proteins on Sephadex G-100. Patient De Pot.: oat cell carcinoma and carcinoma of the bladder.

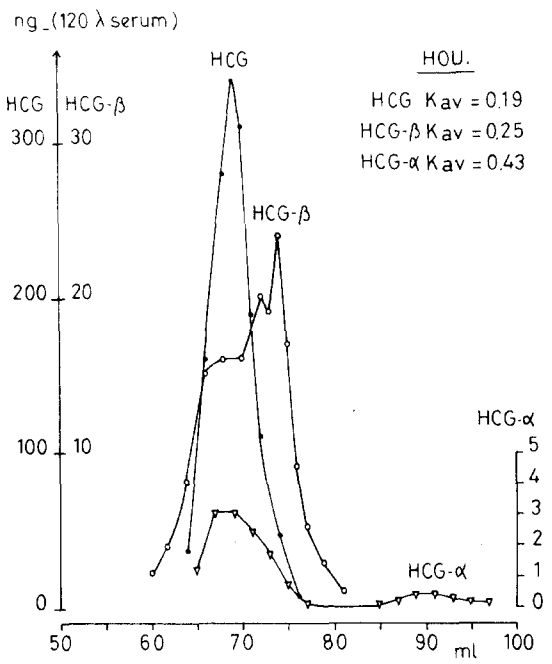

Fig. 2. Elution profiles of the ectopic proteins on Sephadex G-100. Patient HOU: melanoma.

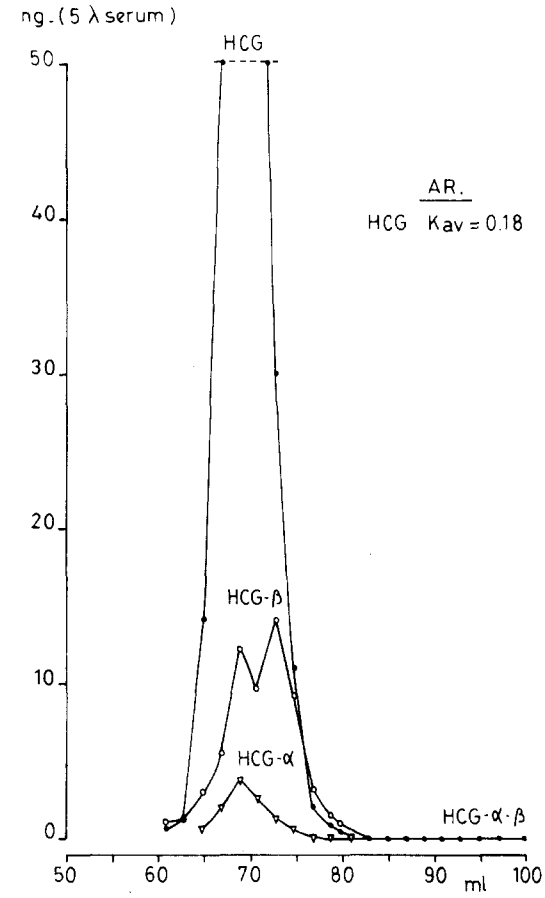

Fig. 3. Elution profiles of the ectopic proteins on Sephadex G-100. Patient Ar.: very malignant choriocarcinoma.

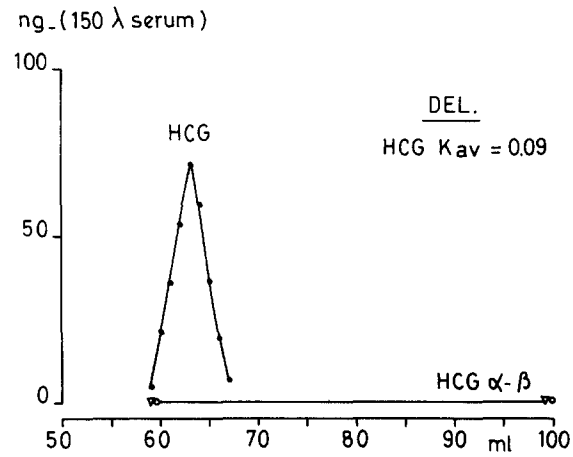

Fig. 4. Elution profiles of the ectopic proteins on Sephadex G-100. Patient Del.: carcinoma of endometrium.

the patients were not really quantitative: the plasma concentrations of HCG-β corresponded to relatively small concentrations of the free β subunit, to relatively high concentrations of HCG, or to a combination of both. This was illustrated by our chromatographic analyses. The latter showed in addition that plasma HCG (or its free β subunit) had sometimes an abnormal structure with increased molecular weight, as found in pre-hormones: such abnormalities could decrease the affinity of the antibody to the β subunit and further interfere with the quantitative evaluation. Finally, part of what was measured in plasma was presumably a non-specific material, cross-reacting with the antibody to HCG-β, since present in many normal individuals. The lower affinity of our antibody to normal or to abnormal HCG and

the presence in the plasma of a non-specific background could mask differences of HCG concentrations between the various populations of patients and mask also quantitative correlations with the α subunit. When such differences and correlations were found they were thus all the more significant but had to be qualified, particularly in terms of preferential free β subunit production, as will be discussed below.

Our data confirmed at first the work of Vaitukaitis *et al.* [1] who showed that HCG-β in the blood of non-pregnant individuals was not specific for malignant tumours. However, our finding that significant plasma concentrations of HCG-β were as frequent in the patients with benign diseases as in the patients with malignant tumours was unexpected. It is of interest, therefore, that the patients admitted at our Institute with benign diseases were certainly selected: most of them had benign tumours such as nodular goiters, parathyroid adenomas, uterine fibromas, papillomas of the breast or had benign conditions associated with tissue hyperplasia such as hyperplasia of the endometrium, fibrocystic hyperplasia of the breast, ovarian cysts, inflammations of the gastrointestinal tract, chronic adenitis. Another unexpected finding was the absence of any predisposition according to the pathology, both in the benign and in the malignant conditions, except for the choriocarcinomas; Braunstein *et al.* [3], in the first extensive study of HCG-β in patients with malignant tumours found a higher incidence of HCG-β in the patients with gastrointestinal carcinomas, although their study was not prospective. This lack of specificity suggests, as proposed by Vaitukaitis *et al.* [1], that a common anomaly, perhaps enhanced cellular proliferation, was the source in all instances of plasma HCG-β. This lack of specificity indicates also that the measurement of HCG-β in plasma has not much interest as a screening procedure, except probably when very high plasma concentrations (above 50 ng/ml) are found. Indeed, the benign and the malignant conditions differed in that the plasma concentrations of HCG-β were significantly higher in the patients with a malignant tumour. Since our antibody to HCG-β was much more sensitive to the free β subunit than to HCG itself, this difference of concentrations could result to some extent from a relatively higher production of the free β subunit in the malignant conditions; this difference could then be both qualitative and quantitative; in this regard, it may be relevant that Vaitukaitis *et al.* [2] showed that the free β subunit was an index of more severe malignancy in the patients with trophoblastic tumours [1].

With regard to the free α subunit, the percentage of patients with abnormal plasma concentrations was similar to that found for HCG-β. This percentage, again, was practically the same in the benign and in the malignant conditions, and there was no clearcut predisposition according to the pathology except probably for the choriocarcinomas, although it is remarkable that unlike for HCG-β not all the patients with choriocarcinomas had elevated plasma concentrations of HCG-α. Furthermore, as for HCG-β, the very high plasma concentrations of the α subunit (above 50 ng/ml) were found exclusively in the malignant conditions. Consequently, the measurement of the free α subunit in plasma is of no more interest than that of HCG-β as a screening procedure and a common cellular anomaly might be responsible for both excessive H-α and HCG-β productions. It should be noted however that the patients with excessive free α subunit in plasma were not the same as those who had HCG-β: indeed, there was no correlation between their free α subunit concentrations and their corresponding HCG-β concentrations; furthermore, most of these patients, even with the highest H-α concentrations, had no detectable HCG-β. This indicates that the production of H-α can be regulated independently from that of HCG-β, H-α being secreted as an isolated subunit or in association with the other glycoproteic hormones.

Although the patients with high free α subunit concentrations were not the same as those with HCG-β, it is interesting that in the latter we found a very significant correlation between the HCG-β and the corresponding free α subunit concentrations. This is comparable to what is found during pregnancy, since the normal placenta secretes the free α subunit together with HCG [4]; to some extent, this is also comparable to what is found in the normal postmenopausal women and in primary hypothyroidism where the free α subunit secretion increases in parallel with that respectively of FSH and TSH [2]; finally, this is similar to our own observations in the normal controls where there was a very significant correlation between the plasma concentrations of LH and those of the free α subunit. Such quantitative correlations between HCG-β and the free α subunit in our patients, between LH and the free α subunit in our normal controls, are compatible with the concept of a common genetic regulation linking the α and the β subunits in the synthesis of the glycoproteic hormones, the production of the β subunit being the rate-limiting step.

Our observations deserve a last word of

comment: HCG-β and the excessive H-α concentrations presumably reflect an ectopic secretion; according to the "endocrine cell" hypothesis the ectopic hormones are secreted by cells which have some endocrine properties under normal conditions (cells of the APUD series) [11, 12]; the absence of predisposition according to the pathology in our patients does not support this hypothesis as far as HCG and its subunits are concerned.

Acknowledgements—We thank very much Mr. Sylvester from the Data Center of the EORTC in Brussels, for the statistical analysis. We are grateful to the Hormone Distribution Officer, NIH, Bethesda, MD, for the gift of HCG, of HCG-β, and of the antiserum to HCG-β. We are grateful to Mr. Ectors (Ecole Vétérinaire, Bruxelles) for the gift of the second antibody.

Therapeutic Effects of Cysteine Adducts of α,β-Unsaturated Aldehydes on Ehrlich Ascites Tumor of Mice. II*

H. M. TILLIAN, E. SCHAUENSTEIN and H. ESTERBAUER

Institute of Biochemistry, University of Graz, Halbärthgasse 5, 8010 *Graz, Austria*

Abstract—*The antitumor activity of a cysteine-crotonal and a cysteine-hydroxypentenal adduct was studied against Ehrlich ascites tumor of mice. When female animals were treated with daily doses* (3rd–7th day *following tumor transplantation*) *of* 2.5, 5.0, 10.0 *and* 20.0 mg/10 g *body weight of the crotonal adduct* 30, 30, 36 *and* 33% *survived the* 90th *test day completely free of ascites and solid tumor. The remaining animals responded with an increase of survival time of* 18, 107, 98 *and* 123%. *Male animals receiving daily doses of* 2.5, 5.0 *and* 10 mg/10 g *body weight of the crotonal adduct showed increase of survival time of* 78, 171 *and* 108% *but in none of the animals tumor growth was completely prevented.*

A similar dependence of the therapeutic action on the sex of the treated mice was observed with the hydroxypentenal adduct. In 40% *of female mice injected with daily doses of* 3.5 mg/10 g *body weight of this adduct tumor growth was completely inhibited and the remaining animals showed a significantly prolonged survival time of* 137%. *Male mice treated under equal conditions with the hydroxypentenal adduct responded with an increase of survival time of only* 20%. *The lowest therapeutic active dose of the hydroxypentenal adduct is between* 0.9 *and* 1.75 mg/10 g *body weight.*

Compared on a molar basis crotonal bound to cysteine is 6–11 *and hydropentenal at least* 22 *times less toxic than in the free form. The results indicate that adducts prepared by condensing of* L-*cysteine with α,β-unsaturated aldehydes inhibit growth of Ehrlich ascites cells in mice. Tumor cells growing in female animals, however, are much more susceptible to the compounds than cells growing in male animals.*

INTRODUCTION

IT HAS been reported that the reversible binding of α,β-unsaturated aldehydes with antitumor activity to cysteine offers a promising means of a prolongated action of these aldehydes *in vivo*. Thus it was shown that an adduct prepared by binding of hydroxypentenal (HPE) to cysteine possesses a pronounced therapeutic effect on the growth of EATC in mice [1, 2]. In preliminary experiments it was also found that the adduct prepared by binding of one mole crotonal to two moles cysteine has anticancer activity [1]. In the present paper we report on a more extended study of the latter compound and on some additional experiments conducted with the HPE-cysteine adduct.

Accepted 18 October 1977.

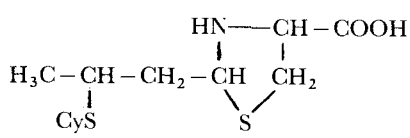
MATERIAL AND METHODS

Experimental animal. NMRI mice of own stock; both sexes; body weight at the beginning of experiment: 20–25 g.

Tumor. Ehrlich ascites tumor, strain Lettré-Heidelberg; harvested 8 days after implantation.

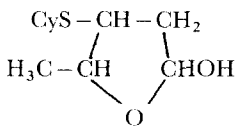
Reagents. The reaction of cysteine with α,β-unsaturated aldehydes and the properties of the so-formed adducts were described in an earlier paper [2]. For the experiments described in this paper, the following adducts were used:

1. Cysteine–crotonal-2:1 adduct (2, 3-trans-butenal) mol. wt: 294; white, hygroscopic powder; m.p.: 168–171° (dec.).



Cysteine–hydroxy–pentenal-1:1-adduct

mol. wt: 221; white, very hygroscopic powder; m.p.: 145° (dec.).



Both the compounds were prepared as zwitter ions. For injection the desired amount was dissolved in 0.9% saline.

Method

For standard implantation approximately 2×10^7 cells (diluted 1:1 in 0.2 ml isotonic NaCl solution) per animal were administered intraperitoneally. Experimental and control animals received $4–5 \times 10^5$ EATC per 10 g of body weight delivered intraperitoneally in 0.25 ml isotonic NaCl. The number of implanted cells was determined before each experiment by means of hematocrit and it was made sure that each animal received the same quantity of cells in relation to its body weight.

For statistical evaluations the bilateral Student's *t*-test was used.

RESULTS

Toxicity

The high toxicity of α,β-unsaturated aldehydes is diminished to a great extent by binding of the aldehydes to L-cysteine [1]. In mice the LD_{50} of a single intraperitoneally dose of hydroxypentenal or crotonal is 0.8 and 1.6 mg respectively per 10 g of body weight [3], cysteine adducts exhibit a LD_{50} which is higher than 45 mg per 10 g body weight (Table 1) [4]. Comparing the toxicity on a molar basis it results that in the cysteine bound form crotonal is 6–11 and hydroxypentenal at least 22 times less toxic than in the free form.

Therapy with the cysteine–hydroxypentenal 1:1 *adduct*

Separate groups of female and male mice bearing the Ehrlich ascites tumor were treated on days 3–7 following transplantation with various doses of the adduct and observed for 90 days (Table 2). Growth of ascites and solid tumor was completely prevented in 40% of the female mice by a dose of 3.5 mg per 10 g of body weight. The remainder of the animals showed a highly significant increase of the survival time of 137% [1]. The same dose administered to male mice could not prevent tumor growth and produced only a 20% extension of the survival time. Doses of 0.9 mg per 10 g of body weight were ineffective in both male and female animals. According to previous results [1] female animals treated with 1.75 mg/10 g of body weight responded with highly significant inhibition of tumor growth. This indicates that for the female animals the lowest therapeutic active dose is in the range of 0.9–1.75 mg per 10 g of body weight.

Therapy with the cysteine–crotonal 2:1 *adduct*

Table 2 compares the therapeutic effectiveness of increasing doses of the adduct against Ehrlich ascites tumor cells growing in female and male mice. In the female group 30, 30, 36 and 33% respectively of the animals were tumor-free on the 90th day when treated with doses of 2.5, 5.0, 10.0 and 20.0 mg/10g of body weight on days 3–7 after transplantation. In the remainder of the animals tumor growth was clearly delayed and the survival time was increased by 18, 107, 98 and 123% respectively. In male mice the adduct proved to be considerably less effective in respect to complete prevention of tumor growth. Thus daily doses of 2.5 and 5.0 mg per 10g of body weight indeed extended the survival

Table 1. Toxic effects of cysteine-HPE 1:1 *adduct and cysteine–crotonal* 2:1 *adduct on NMRI mice (male, 20–25 g of body weight*

Substance	Single dose	Aldehyde bound	Animals Treated	Animals Survivors

(3) Ascites tumor-free, however, with solid tumor.
($\pm s_x$) = standard deviation.
m = male; f = female; * = significant; † = highly significant.
(A) = One animal died at 78th day, free from ascites and solid tumors; cause of dead unexplainable.
(B) = Three animals were certainly free from ascites tumors, but died, between the 48th and 63rd day after implantation from exceedingly developed solid tumors.

time by 78 and 171% but none of the animals was completely free of tumor on the 90th day. A daily dose of 10 mg/10 g of body weight did completely prevent growth of the ascites tumor in 33% of the treated animals. These animals, however, died approximately two months after transplantation from fast developing solid tumors growing at the side where the peritoneum was punctured.

DISCUSSION

The results described give further support for the concept that the reversible binding with cysteine is a promising way of increasing the therapeutic effectiveness of tumor inhibitory α,β-unsaturated aldehydes.

The use of cysteine adducts for tumor therapy has the advantage that the adducts are several times less toxic than the free aldehydes. It is assumed that the cysteine adducts are storage forms which slowly and gradually release the bound aldehyde in the tumor cells and thus provide a prolonged action. The liberated aldehyde in turn reacts with SH-groups of functional importance for DNA synthesis and thereby prevents growth of tumor cells. It has been shown by histochemical methods that incubation of EATC with a cysteine adduct leads to a release and concomitant binding of the aldehyde to proteins in nuclear area [5]. The therapeutic effectiveness depends upon the stability of the adducts. Thus the very stable cysteine–acrolein 2:1 adduct and the cysteine–HPE 2:1 adduct are therapeutically ineffective [1] while the less stable cysteine–HPE 1:1 adduct and the cysteine–crotonal 2:1 adduct are therapeutically effective. Both adducts completely prevent or significantly inhibit growth of EATC in female mice. Treated with the HPE adduct (1.75–14.0 mg/10 g of body weight) 22–40% of the animals remained macroscopically free from ascites and solid tumor while in the remainder of the animals the survival time was extended up to 289%. Similar results were found for the crotonal adduct (2.5–20.0 mg/10 g of body weight) which completely prevented tumor growth in 22–35% of the animals and delayed it in the remainder of the animals up to 123%. In male animals the adducts proved to be much less therapeutically effective.

Depending on the dose male mice responded with an increase of survival time between 78 and 171% when injected with the crotonal adduct. With the HPE adduct the extension of survival time was 20%. The considerable lower therapeutic effectiveness of the adducts in male animals may be due to an increased rate of detoxification and excretion, to a lower activity of an enzyme catalyzing the liberation of the aldehyde in the tumor cells or to a hormonally controlled interaction between the host and the tumor cells. Up to now, however, no certain decision can be made which factors actually are responsible for the sex difference.

The results confirm the previous findings [1] that cysteine adducts of α,β-unsaturated aldehydes possess antitumor activity. The therapeutic effectiveness against Ehrlich ascites tumor of mice strongly depends on the sex of the animals.

Abstract—*A synergistic degree of cell killing was obtained with cyclophosphamide and CCNU in the L1210 leukaemia, the Lewis lung carcinoma and the mouse C22LR osteosarcoma. Drug synergism was also demonstrated in both resting and rapidly proliferating haemopoietic stem cells. By scheduling the 2 drugs we attempted to obtain selective cell kill of tumour cells over vital normal cells. The optimum antitumour schedule was found to be that when the drugs were given simultaneously. This tumour based schedule however, proved to be the most toxic for bone marrow stem cells as well. Therefore, the clinical relevance of this synergistic drug combination is expected to be limited.*

INTRODUCTION

THERE is ample evidence at both the preclinical and clinical level that combination chemotherapy is more effective than single drug treatment. The experimentalist should try not only to discover new therapies but to investigate also how to use existing drugs more effectively: what are the optimal conditions for their usage and what are the underlying mechanisms leading to improved therapy. While there are many perspectives on chosing combinations of agents, there is but one goal: that being to maximize the killing of malignant cells while minimizing the killing of normal cells.

Drug schedule design can be devised on the basis of toxicological, cell kinetic, biochemical and pharmacological considerations. Our selection of agents, however, has been empirical. The two-drug combination of cyclophosphamide (Cyclo) plus a nitrosourea was found to be therapeutically potentiating against various spontaneous or transplanted murine tumour lines [1]. However, if a combination of two chemotherapeutic agents produces an increased cytotoxic effect on tumour tissue with a concomitant intensified toxicity to host tissues, then the therapeutic gain of a so-called synergistic drug combination will be negligible.

Therefore, we have investigated whether Cyclo in combination with CCNU was synergistically active in a range of animal tumours as well as in the most critical normal tissue, bone marrow stem cells.

Stimulated by our 5-fluorouracil–CCNU findings [2], our approach was to investigate whether we could improve the therapeutic ratio by drug scheduling: CCNU was given simultaneously with or at a time interval of 24 hr before or after Cyclo.

If several experimental tumour lines show a similar response to a particular drug schedule, it is warranted to extrapolate the results to clinical treatment. Moreover, the reactions of the bone marrow cells to cytostatic drug treatment in mice and in man are not essentially different. Therefore, the conclusions of our preclinical animal work will allow us to extrapolate them to cancer patients with some degree of confidence.

The purpose of this study was to investigate the effect of Cyclo–CCNU combination chemotherapy in widely different tumour cell lines as well as in bone marrow and secondly to determine whether, by suitable drug scheduling,

a difference between malignant and normal tissues could be therapeutically exploited.

MATERIAL AND METHODS

Material

The Lewis lung carcinoma was maintained by s.c. serial transplantation in the C57Bl/Ka mouse and transplanted into (C57Bl/Rij × CBA/Rij)F1 mice (hereafter called BCBA F1) for chemotherapy experiments. The C22LR osteosarcoma studies were performed in BCBA F1 mice with tumour of passages 83 and 84 from frozen samples of passage 77. The volume doubling time of both solid tumours when measured at between 200–800 mm^3 is 2.5 days [2]. The L1210 leukaemia was obtained from Dr. C. von Essen, Yale University, New Haven, CT, in 1969. The leukaemia was initially maintained in our laboratory by weekly transfer in (C57Bl/Rij × DBA/2)F1 hybrid mice. Since 1975 (BALB/c × DBA2)F1 (hereafter called CD2 F1) hybrids have been used. In 1973 the leukaemic cells were adapted to growth *in vitro* and maintained by alternating *in vivo* and *in vitro* transfer. The doubling time of our exponentially growing L1210 *in vitro* is 10 hr. CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea NSC-79037, was kindly supplied by Laboratoire Roger Bellon S.A., Neuilly sur Seine, France. The drug was suspended in 2% carboxymethyl-cellulose. Cyclophosphamide, NSC-26271, was a gift from Asta-Werke, Brackwede, Germany. Both agents were injected i.p. and the maximum dosages used were less than 0.5 of the LD_{10} dosages, except for the experiments shown in Tables 1 and 2.

Table 1. The effect of treatment of Lewis lung carcinoma with different drug doses expressed as growth delay

	CCNU mg/kg		
		10	20
Cyclo mg/kg	0 ± 0.5	2.7 ± 0.8	4.1 ± 0.8
100	6.8 ± 1.7	8.1 ± 1.8	14.8 ± 2.0
200	16.4 ± 1.6	2/5 NED	4/5 NED

BCBA F1 mice were inoculated s.c. with 10^6 Lewis lung tumour cells on day 0. Treatment was given on day 10. NED indicates no evidence of disease on day 62.

Methods

Cells from a tumour suspension were inoculated s.c. or i.m. in mice [2]. Treatment with Cyclo and CCNU was either simultaneously or sequentially: CCNU 24 hr before (CCNU → Cyclo) or 24 hr after Cyclo injection (Cyclo → CCNU). Tumours were measured twice weekly with calipers. The endpoint of treatment of both solid tumour lines was growth delay in days: the displacement in time between the growth curve of the control group and the growth curve of the tumours recurring after treatment. The Student's *t*-test applied to individual tumour growth delay data was used for the evaluation of the results of treatment with the different combinations.

From an exponentially growing L1210 in *in vitro* culture, 10^5 cells were injected i.p. in CD2 F1 mice. The percentage increase in lifespan (% ILS) was used as an index of antitumour activity and was based on the median day of death of the group. The effect of treatment on L1210 leukaemia was also investigated by a combined *in vivo* and *in vitro* technique [3]. In treated leukaemic mice, the number of surviving L1210 cells was determined by cloning *in vitro*. The surviving fraction was calculated as the ratio of the number of donor leukaemic colony forming units (CFU) per femur of a treated group to that of a control group.

To assess the activity of drugs against normal cells, we determined the survival of resting haemopoietic stem cells by the spleen colony technique of Till and McCulloch [4]. After treatment with a cytostatic drug, the normally resting stem cells will be recruited into cycle and this may result in increased drug sensitivity. Therefore, we also investigated the effect of treatment on recruited, rapidly proliferating normal bone marrow stem cells [5]. The survival of resting and proliferating CFU was calculated as the ratio of the mean number of CFU per donor femur and per spleen, respectively, of treated to that of simultaneously assayed control mice.

Table 2. The effect of high dose treatment with cyclophosphamide and CCNU in osteosarcoma: the change in tumour volume doubling time (TVD) of the recurrent tumours

Treatment	Growth delay (days)	T.V.D. (days)
Control	Mean ± S.E.: 0 ± 0.4	2.5
Cyclo and CCNU	Individual: 17, 46, 55, NED, NED	2.5, 8, 12

One million osteosarcoma cells were injected s.c. into BCBA F1 male mice on day 0. Treatment with Cyclo 100 mg/kg i.p. and CCNU 20 mg/kg i.p. was given on day 7. NED indicates no evidence of disease on day 121.

RESULTS

Three different endpoints were used in our experiments: growth delay, lifespan and cell survival. Tumour growth delay is, under specific conditions to be discussed, correlated with tumour cell kill; therefore, if the joint action of agents is greater than the algebraic sum of their individual effects, we interpret this as drug synergism. The same definition is used for the results of treatment of the leukaemic mice. If the percentage increase in lifespan (%ILS) is greater than the algebraic addition of the response achieved with either drug alone, the drug combination acts synergistically. For the cell survival experiments, synergism is found when the observed surviving fraction is smaller than the product of the individual survival fractions.

The effect of single drug treatment and the results of combination chemotherapy on mice with s.c. inoculated Lewis lung tumour cells are shown in Table 1. The expected growth delay of the drug combination CCNU 20 mg/kg and Cyclo 100 mg/kg is 4.1 plus 6.8 or approximately 11 days. However, the observed growth delay is 14.8 days. Therefore the therapeutic synergistic effect with these drug dosages is about 4 days. For the highest dose combination used, the difference between expected (20.5 days) and observed growth delay is more than 40 days, since 4 out of 5 mice showed no evidence of disease at day 62.

Data on the Cyclo + CCNU combination for the C22LR osteosarcoma are presented in Table 3 and for the L1210 leukaemia in Tables 4 and 5. Note that when more effective drug dosages are used the standard error of the mean tumour growth delay will increase (Table 3). Table 2 shows an extreme example: the growth delay varies between 17 and 55 days. This variation in growth delay is caused by a dramatic change in volume doubling time of the tumours in the treated animals; only one out of 3 recurrent tumours has the original doubling time of 2.5 days.

The influence of drug scheduling (Cyclo → CCNU and CCNU → Cyclo) on the L1210 leukaemia, the Lewis lung carcinoma and the C22LR osteosarcoma is shown in Tables 4, 5, 6 and 7. All experiments (except experiment No. C 128 in Table 4) show the same pattern: the optimal drug sequence for tumour treatment is when both drugs are given simultaneously (Cyclo + CCNU).

In order to evaluate therapeutic gain, we also investigated the effects of both drugs on resting and proliferating bone marrow stem cells (Table 8). The agents were given either simultaneously or in different sequences. The simultaneous, Cyclo + CCNU, treatments are synergistically active and, in comparison with the sequential treatments the most effective ones. Therefore the most toxic drug schedule is when both drugs are given at the same time (Cyclo + CCNU) in both states of bone marrow proliferation.

DISCUSSION

The observed effect of treatment with Cyclo + CCNU on the Lewis lung carcinoma, the C22LR osteosarcoma and the L1210 leukaemia is more than expected from the effects of treatment with single drugs. This synergism of Cyclo with one of the nitrosoureas has been demonstrated in the AKR lymphoma [6], the KHT fibrosarcoma [7] and the Lewis lung carcinoma [8], as well as three different experimental colon tumour lines [9]. Therefore, it is frustrating to discover that the integration of these preclinical findings into clinical cancer treatment have not resulted in therapeutic improvement. Two negative treatment reports [10, 11], together with our own experience with 12 patients with advanced renal cell carcinoma (unpublished observations) do not support the clinical application of the preclinical findings of Cyclo-nitrosourea synergism.

The disappointing therapeutic results may be the result of the concomitant increased toxicity of the drug combination. Although a group of investigators in St. Louis showed in preliminary data an enhanced cell kill of L1210 cells over normal haemopoietic stem cells with 1,3-bis(2-chloroethyl)-1-nitrosourea and Cyclo [12], our data seem less promising. The synergistic effect on our two solid tumour lines (Tables 1, 3, 6 and 7) and on the L1210 leukaemia (Tables 4 and 5) was accompanied by an increased cell killing effect on bone marrow stem cells (Table 8). Therefore it will be difficult to increase the therapeutic ratio: the enhanced effect of treat-

Table 3. The synergistic effect of treatment with cyclophosphamide and CCNU in osteosarcoma

Treatment	Mean growth delay and standard errors (days)
Control	0 ±0.4
Cyclo 100 mg/kg i.p.	8.6 ±0.9
CCNU 10 mg/kg i.p.	4.1 ±0.8
Cyclo + CCNU	27.1 ±4.0

One million osteosarcoma cells were injected s.c. into groups of 5 BCBA F1 male mice on day 0. Treatment was given on day 7.

Table 4. The influence of drug scheduling with cyclophosphamide and CCNU on the lifespan of leukaemic mice

	% ILS				
Exp. No.	C127	C128	C129	C131a	C131b
Cyclo	12.5	—	—	0	10
CCNU	37.5	—	—	20	20
Cyclo→CCNU	37.5	55	55	20	40
Cyclo+CCNU	87.5	55	111	60	110
CCNU→Cyclo	50	44	44	20	50

L1210 cells were injected i.p. into groups of at least 5 CD2 F1 mice. Treatment was given within 6 days after cell inoculation. A dose of 10 mg/kg CCNU was given i.p. in combination with a dose of Cyclo which varied in the different experiments between 50 and 100 mg/kg i.p. Drug induced deaths in nontumour bearing animals were not observed. Data are expressed in terms of the percentage increase in survival as determined by the equation:

$$\frac{\text{median survival of treated animals (days)}}{\text{median survival of control animals (days)}} \times 100 = \%\,\text{ILS}.$$

Synergism is evident when the observed % ILS is greater than the algebraic sum of the individual % ILS. The effect of single drug treatment was not investigated in experiments C128 and C129.

Table 5. Surviving fraction of L1210 cells treated with cyclophosphamide and CCNU

	Surviving fraction	
Treatment	Experiment I	Experiment II
Cyclo 30 mg/kg i.p.	0.23	0.16
CCNU 10 mg/kg i.p.	0.11	0.18
Cyclo→CCNU	0.03	0.05
Cyclo+CCNU	0.002	0.01
CCNU→Cyclo	0.02	0.02
Calculated effect of combination	0.02	0.03

Synergism is evident when the observed surviving fraction is smaller than the expected surviving fraction calculated by multiplying the individual surviving fractions.

Table 6. The effect of sequential treatment with cyclophosphamide and CCNU in Lewis lung carcinoma

Treatment schedule	Mean growth delay and standard errors (days)	
Control	0 ±0.3	
Cyclo 100 mg/kg i.p.	3.5±0.5	
CCNU 10 mg/kg i.p.	0.5±0.5	
Cyclo→CCNU	12.0±0.6	$P<0.001$
CCNU+Cyclo	19.0±1.6	
CCNU→Cyclo	9.0±0.7	$P<0.001$

Groups of 10 BCBA F1 male mice were inoculated i.m. with 10^6 Lewis lung tumour cells on day 0. Cyclo was given either simultaneously, 24 hr before or 24 hr after CCNU treatment on day 5.

Table 7. The effect of sequential treatment with cyclophosphamide and CCNU in osteosarcoma

Treatment schedule	Mean growth delay and standard errors (days)	
Control	0 ±0.3	
Cyclo 50 mg/kg i.p.	5.0±0.4	
CCNU 10 mg/kg i.p.	4.2±0.7	
Cyclo→CCNU	14.3±0.9	$P<0.005$
CCNU+Cyclo	18.0±0.5	
CCNU→Cyclo	13.6±0.8	$P<0.001$

One million osteosarcoma cells were injected s.c. into groups of 10 BCBA F1 male mice on day 0. Cyclo was given either simultaneously, 24 hr before or 24 hr after CCNU treatment on day 5.

ment on tumours will always be accompanied by more host toxicity.

In all experimental systems in which less than approximately half the LD_{10} dosages were used, drug synergism was evident. When higher dosages were applied in the solid tumour experiments, we observed an increase in tumour volume doubling time (Table 2). After treatment with nitrosourea, the regrowing tumours may consist of a selection of cells which are more slowly dividing than were the cells of the original tumour [13]. In this situation, it is inappropriate to use the growth delay as an indirect parameter of tumour cell kill. Conclusions on synergism based on tumour regrowth times should only be made when the growth curves of the recurrent tumours are parallel to the control curve and as long as there is a linear dose–response relationship. To avoid deviation from these conditions, we have used low dosages of Cyclo and CCNU. A second artificially induced drug synergism may be produced by an enhanced tumour cell kill through an immunological phenomenon. After intensive treatment a small tumour mass may be further reduced by an immunological attack. If this occurs, the observed synergistic effect of drug treatment should not be interpreted as a result of drug interaction only. In our mouse tumour systems, the Lewis lung carcinoma is immunogenic; the C22LR osteosarcoma, however, is not. Moreover, the Cyclo–CCNU combination shows the more than additive effect on such a variety of cell lines that the explanation for synergism must probably be sought in a biochemical interaction of both drugs. This finding is of theoretical importance, since, in clinical management, the cancer chemotherapist tries to avoid drugs with the same mechanism of action in a drug combination. This policy should not be confused with the principle of alternating drugs or drug combinations in order to circumvent cross resistance. Nevertheless, we have here a very effective drug combination of two agents both of which have alkylating moieties [14].

The combination Cyclo–CCNU acts synergistically on neoplastic as well as normal tissues and there is no simple way to design a treatment schedule in which drugs are given sequentially which may lead to better therapeutic results. Therefore, the clinical application of our findings with this drug combination in whatever schedule given are expected to be disappointing, particularly if a large fraction of sensitive normal cells are in cell cycle. From a theoretical point of view, the combination is extremely interesting, although, for the above reasons, its relevance to clinical practice is limited.

Abstract—*Fluid from five cystic secondary melanomas was examined for its effect on the migration of peripheral blood leukocytes from melanoma patients and control donors. Two samples selectively inhibited the migration of melanoma leukocytes. Fractionation showed the mol. wt of the active component(s) to be between* 41,000 *and* 95,000. *Fluid of this type, though not ideal, may be used as a source of antigen in the leukocyte migration technique and presumably in other techniques.*

INTRODUCTION

METHODS for extracting antigens from tumour cells remain imperfect and may distort membrane characteristics peculiar to the tumour, yielding products unrepresentative of the relative proportions or configurations of antigens *in vivo*. Ideally, antigens should be clinically accessible, and not require complex or damaging preparation prior to use.

Partial necrosis of tumours is common, and such areas may undergo cystic degeneration. Fluid from such cystic tumours might be a convenient source of tumour antigens. Previous studies of fluid from a cystic melanoma showed that it reacted in an apparently specific manner with melanoma patients' leukocytes, causing blast transformation of lymphocytes [1] and inhibiting leukocyte migration [2]. The active fraction had a mol. wt. of less than 100,000. The present study was to ascertain how frequently melanoma cyst fluids showed selective activity, and to characterize the active component by using previously proven methods, involving chromatography and electrophoresis e.g. [3, 4,] and [5]. We have therefore applied these techniques to melanoma cyst fluids and tested the fractions for activity in leukocyte migration inhibition assays.

MATERIAL AND METHODS

Leukocyte donors

Peripheral blood was obtained from 32 patients with histologically proven and clinically staged malignant melanomas. Controls [34] were patients with non-malignant diseases and healthy individuals.

Source of antigen

Fluid (0.3–1.0 ml) was obtained by needle aspiration of the melanomatous lymph nodes of four patients and from a cystic local tumour recurrence of one of these patients. Fluids were stored at −20°C until tested.

Preliminary titrations indicated a suitable concentration for the detection of cell-mediated reactivity to be 500 μg protein per ml of leukocyte suspension, and all tests with unfractionated cyst fluid were performed at this concentration. Details of the preparation of leukocytes and the leukocyte migration inhibition assay have been published [6].

Statistical analysis

Groups of four replicate migration areas with and without antigens for each individual were compared using the Mann–Whitney–Wilcoxon U test of ranking. Positive reactivity was where the difference between quadruplicate observations in the presence and absence of antigen was significant at the 5% level. The frequency of positive reactions in each group of leukocyte donors was compared using the chi-squared test.

Fractionation procedures

A flow chart of the procedures employed is shown in Fig. 1.

Gel filtration

Aliquots (0.5 ml) of melanoma cyst fluids

Accepted 20 October 1977.
*This study was supported by the Cancer Research Campaign and the Medical Research Council.

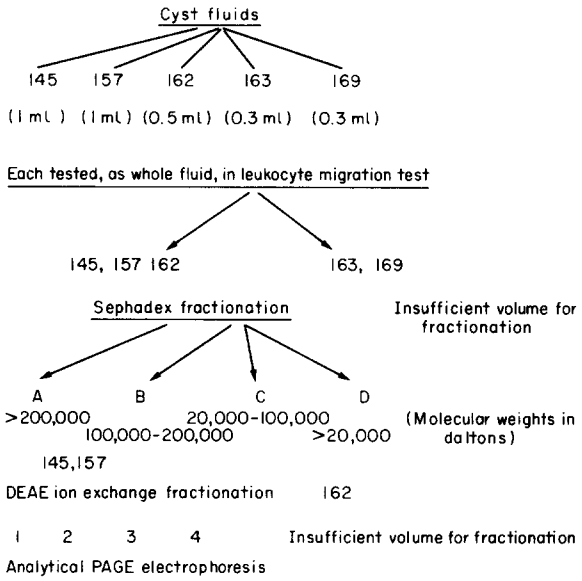

Fig. 1. Separation protocol of melanoma cyst fluids.

(where sufficient was available) were applied to a Sephadex G150 column (2.6 × 40 cm) equilibrated with phosphate buffered saline (PBS). The flow rate was maintained at 30 ml/hr and all operations were performed at 4°C. Fractions (5 ml) were collected into pools A–D, as shown in Fig. 2 and concentrated by dialysis against

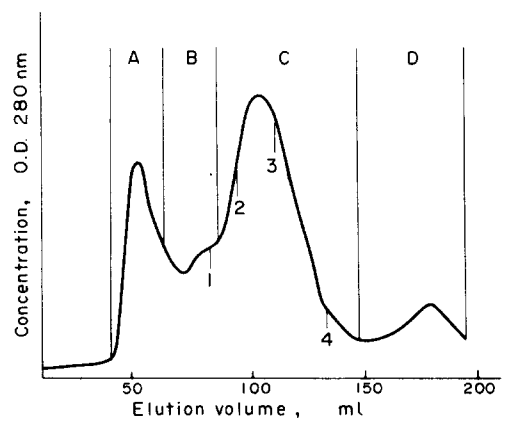

Fig. 2. Elution profile of melanoma cyst fluid No. 162 from Sephadex G150. Molecular weight markers. 1. Human γ-globulin (180,000). 2. Transferrin (80,000). 3. Haemoglobin (65,000). 4. Trypsin (25,000).

Aquacide II (Calbiochem, London) to the original sample volume. They were then extensively re-dialysed against PBS and stored at −20°C. The column was calibrated by elution of proteins of known mol. wt (human γ-globulin, 180,000; transferrin, 80,000; haemoglobin, 65,000; and trypsin, 25,000).

Ion exchange chromatography

Pooled fractions B and C from Sephadex G150 chromatography were dialysed against 0.005 M Tris–HCl (pH 8.0) and 0.3 ml aliquots applied to a DEAE-52 cellulose column (1.5 × 25 cm) equilibrated in the same buffer. Fractions (5 ml) were eluted with a linear gradient of increasing salt concentration from 0.005 M Tris–HCl to 0.75 M NaCL in 0.005 M Tris–HCl (pH 8.0). Flow rate was maintained at 15 ml/hr and fractions pooled (1–4) as shown in Fig. 3, dialysed against PBS and concentrated to the original sample volume by dialysis against Aquacide II. Samples were extensively re-dialysed against PBS. All procedures were performed at 4°C. The amount of fluid in the fractions was too small to allow determination of protein concentration; aliquots of 10 μl were added to each well in the leukocyte migration tests.

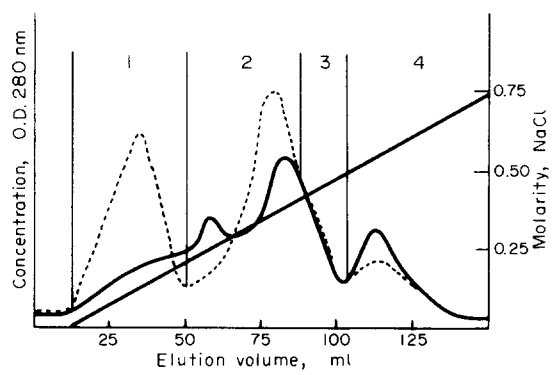

Fig. 3. Elution profile of melanoma cyst fluids 145 (broken line) and 157 (full line) from DEAE 52.

Analytical polyacrylamide gel electrophoresis

This was performed as described previously [7]. Electrophoresis was continued at 3 mA per tube, until bromophenol blue, added as a tracker dye, had passed to the bottom of the gel. Each gel was stained for protein with 0.5% Coomassie Blue. Molecular weight was estimated by comparison of the migration of proteins of known molecular weight relative to bromophenol blue.

Protein concentration

Approximate protein concentrations of the whole cyst fluids and Sephadex fractions were determined by absorption at 280 nm.

RESULTS

Whole cyst fluids

The luekocytes of 16 out of 29 melanoma patients (55%) and 6 out of 26 control individuals (23%) were selectively inhibited by the cyst fluids (melanoma leukocytes, 29/56 tests positive, 52%; control leukocytes, 12/50 tests positive, 24%) ($P = <0.01$), as seen in Table 1.

Analysis of the results on the basis of the reactions induced by indivudual fluids showed

Table 1. *Effects of whole cyst fluids on migration of leukocytes from melanoma patients and control donors*

Cyst fluid	Leukocyte donor	Inhibition alone Individuals positive/ total tested	(%)	Significance

that all antigens inhibited melanoma leukocytes. While two, 157 and 169, showed significant selective inhibition, the other three showed non-selective reactivity, inhibiting control leukocytes, such that differences between tests and controls were not significant. Enhancement was encountered only rarely in these studies and did not alter the patterns of reactivity observed.

Leukocytes from Stage I melanoma patients were more often inhibited than those from Stage II patients (Table 2).

Table 2. *Effects of cyst fluids on migration of leukocytes from melanoma patients and control donors; comparison by stage for selectively active fluids* 157 *and* 169 *and non-selective fluids* 145, 162 *and* 163

Fractionated cyst fluid

Sufficient cyst fluid was available from two "non-selective" samples (145 and 162) and one selectively active sample (157) to allow fractionation on Sephadex G150. All gave similar elution profiles (O.D. 280 nm. trace), a representative sample of which is presented in Fig. 2. In migration studies, fractions from the three samples showed similar patterns of activity, and are therefore presented together in Table 3. Pigmented material was observed in two regions, corresponding to mol. wt of approximately 200,000 and 20,000.

A total of 24 melanoma patients' and 18 control leukocytes were studied. Material from region A (mol. wt >200,000) of fluids 145 and 157 was available for assessment. Both induced a similarly low frequency of migration inhibition in control and melanoma patients' leukocytes was noted in fraction C (mol. wt 20,000–100,000) (Table 3). Fraction B also inhibited more melanoma patients' leukocytes than con-

Table 3. Effects of Sephadex fractions on migration of leukocytes from melanoma patients and control donors

trol leukocytes, but the difference in reaction frequency was not significant ($0.10>P>0.05$). Preferential activity was thus induced in the previously non-selective samples by Sephadex G150 chromatography. Fraction D (mol. wt <20,000) caused a low frequency of migration inhibition in both leukocyte donor groups. Activity was not associated with the fractions containing pigmented material. At the concentration of antigen used in the tests no fraction showed gross toxic effects, i.e. frequently inhibiting leukocytes of both melanoma patients and controls.

Because of the apparent preferential activity of fraction pools B and C the residue of that material from fluid 157 was pooled and further separated on DEAE 52 ion exchange columns. As a control, the comparable regions from the non-selective fluid 145 were similarly separated. Elution profiles of the samples were similar, though not identical (Fig. 3). Analysis of the four DEAE 52 fractions from each sample by polyacrylamide gel electrophoresis revealed a heterogeneous mixture of between two and six bands in each fraction, with mobilities between 0.43 and 0.81 relative to bromophenol blue. These correspond to mol. wt of 26,000–110,000 although individual fractions generally contained proteins of more restricted molecular weight range. Migration studies were performed using these fractions as antigens. None of the fractions inhibited the migration of control leukocytes (8 individuals, 36 tests), but inhibitions were detected in 10/41 tests with melanoma patients' leukocytes (4 out of 9 patients). Inhibitory activity was not confined to any one fraction and was observed in both samples.

DISCUSSION

The studies of these cyst fluids indicated preferential inhibition of the migration of melanoma patients' leukocytes relative to control donors' leukocytes. Analysis of the individual preparations, however, showed only two samples to have significant selective activity. These active samples were from tumorous lymph nodes (157 and 169), as were two of the three non-selective samples (145 and 163); the third being from a locally recurrent nodule from one of these (145). The relatively high number of control donors having leukocytes which were inhibited by contact with these three non-selective fluids present problems of interpretation. The unseparated fluids were characterized by their capacity frequently to inhibit leukocytes from both melanoma patients and control donors, perhaps indicating the presence of toxic materials which were not, however, demonstrated in any of the fractions.

The observation that cyst fluid contains materials with some degree of tumour specificity is in accordance with previous reports [1, 2], although care must be taken in the selection and assessment of each sample prior to extensive

investigation. Attempts to purify the active materials in these fluids were hindered by the small amounts available. Active fractions could be separated by gel filtration on Sephadex G150. Maximum activity was present in a fraction containing materials of mol. wt 20,000–100,000, and further separation suggested a mol. wt between 41,000 and 98,000. Selective activity persisted after DEAE 52 fractionation, but reactions were less frequent, perhaps reflecting the importance of using an optimum dose of this material. It is, however, likely that the active materials within these cyst fluids are a heterogeneous group of molecules of variable characteristics, since cyst formation results from a degenerative process which may lead to the breakdown of antigenic entities *in vivo*. Such autodigestive phenomena in association with necrosis are well recognized.

The range of molecular weights determined for the active fractions in this study is in agreement with those isolated from melanomas by various procedures. Thus, a fraction active in inducing delayed hypersensitivity from sonicated melanoma membrane preparations, isolated by gel filtration and polyacrylamide gel electrophoresis, had a mol. wt of 38,000 [8]. Similarly, 3M KCL extracts of melanoma, following gel filtration [5], resulted in similar molecular weight fractions to those described here.

When fractions were separated by chromatography, selective activity was revealed in previously non-selective samples. Such induction of reactivity by purification has been described previously [5, 8] and suggests the presence of blocking factors or inhibitors in the cyst fluids. Unfortunately, insufficient material was available to permit recombination of fractions in order to investigate this phenomenon further.

Cyst fluid is thus a practical though not ideal material for the study of sensitisation to tumour antigens. It has the advantage of clinical accessibility and requires no complex or damaging preparative manoevres prior to use. A direct comparison of active materials derived from such fluids with materials released from tumour membranes by KCL, sonication, detergents, or enzymic digestion, would be of particular interest.

Dehydroepiandrosterone and Androstenediol in Human Primary Breast Tumours*

P. V. MAYNARD, MARGARET BIRD, P. K. BASU,† R. SHIELDS† and K. GRIFFITHS

Tenovus Institute for Cancer Research, Heath, Cardiff, Wales and †Department of Surgery, University of Liverpool, Liverpool, U.K.

Abstract—*Dehydroepiandrosterone (DHA) and 5-androstene-3β,-17β-diol have been measured in a series of primary human breast tumours. All the tissues contained significant quantities of DHA and there was a negative correlation of these values with the age of the patient. Only just over one half of the tumours contained detectable levels of androstenediol but there was an over-all correlation of this steroid with the DHA, although concentrations of DHA were generally much greater. No relationship between the steroid content of the tumour and the oestrogen receptor levels was established although receptor was not measurable in the relatively small number of tumours which contained high levels of either steroid. Quantities of endogenous C_{19}-steroids would seem to be high enough to exert some influence on the activity of the oestrogen receptor* in vivo.

INTRODUCTION

THE RELATIONSHIP of C_{19}-steroids to breast cancer is not clearly understood although the evidence from studies of urinary steroid excretion [1–4], plasma steroid assays [5–6] and data on the paraendocrine behaviour of some tumours [7–9] would indicate that involvement of dehydroepiandrosterone (DHA) or its sulphate is of major importance.

More recently [10–11] it has been shown that androgens can directly displace oestradiol from the oestrogen receptor protein present in a number of breast tumours and may exert an influence on the activity of the tumour cells. In order to determine whether C_{19}-steroids are present in sufficient concentration within the tissue itself to affect tumour growth or activity DHA and 5-androstene-3β, 17β-diol (androstenediol) levels in a series of human primary breast tumours have been determined using a gas chromatographic–mass spectrometric technique previously described [12] and are compared to the level of cytoplasmic oestrogen receptor in the tissues.

Accepted 21 October 1977.

MATERIAL AND METHODS

Tissues

Primary breast tumours were collected by the Department of Surgery, University of Liverpool, stored dry at −20°C and transported to the Tenovus Institute, Cardiff in dry ice. A 15% (w/v) homogenate of the tumours was made in 10 mM Tris–HCl buffer for assay of oestrogen receptor and portions of the total homogenate were stored at −20°C until assayed for steroid content.

Assay of DHA and androstenediol

The details of the method of analysis have been published in full [12]. Briefly the procedure consisted of equilibration of homogenate with internal standards to monitor recovery of steroid followed by extraction of lipid materials with acetone/ethanol. Much of the non-steroidal lipid was removed by solution of steroid in hot aqueous $CaCl_2$ [13], and the partially purified, dried residue derivatised by the addition of bis-trimethylsilyl acetamide (BSA). After standing at room temperature overnight, aliquots (1.5 μl) of the BSA were injected into a g.l.c. column containing 3% OV-17 and the eluate passed into a Varian MAT 731 mass spectrometer set up for high resolution single ion monitoring. Standards were run with every set of extractions and results

expressed as ng of steroid per g wet weight of tissue.

Oestrogen receptor assay

The oestrogen receptor content of the tissues was measured by methods routinely used in the Institute. The procedure involved the incubation of portions of a high speed supernatant with varying amounts of [^{3}H]oestradiol with separation of free and bound steroid by dextran coated charcoal. Binding site concentration was determined using equations derived from the Law of Mass Action and processed by computer using a Newton–Raphson iterative curve fitting technique [14]. The results were expressed as fmole of high affinity oestradiol binding per mg cytosol protein.

RESULTS

The assay procedures have been shown to measure specifically non-conjugated DHA and androstenediol [12] and in this series a large number of primary breast tumours have been analysed for both steroids. All the tissues examined were found to contain measurable quantities of DHA in levels ranging from 2.5 to 466.0 ng/gm tissue. There was a highly significant ($P<0.001$) correlation between the DHA content of the tumour and the age of the patient, younger women generally bearing tumours with considerably higher amounts of DHA than older women (Fig. 1). The negative correlation was greater when the values of DHA were expressed as logarithms ($R=-0.44$).

In contrast androstenediol was measurable in just over one half of the tumours, 42% of the tissues contained less than 1 ng steroid/gm. The range of values in those tumours where androstenediol was present was much lower than those of DHA, up to 40 ng/gm (Fig. 2). No significant correlation was found between androstenediol levels in the tumour and the age of the patient although the highest amounts were found in tissues taken from younger patients (Fig. 2). Despite this there was a very significant ($P<0.001$) positive correlation ($R=0.47$) between DHA and androstenediol levels in tumours where both these steroids were measured in one extract (Fig. 3).

Since the correlation of DHA with age of patient could be due to the menopausal status of the women it is of interest that amounts of DHA, but not of androstenediol, were significantly ($P<0.05$, Mann–Whitney U test) higher in tumours from women who were pre-menopausal. The range of values were 5.4–300.0 ng/g in this group compared to 3.2–81.8 ng/g in tissues from women known to be at least two years past the menopause.

No significant correlations were seen between the levels of DHA or of androstenediol in the whole tumour and the amount of available oestradiol receptor sites in the cytoplasm. As can be seen from Figs. 1 and 2, tumours classified as receptor negative or positive (greater than

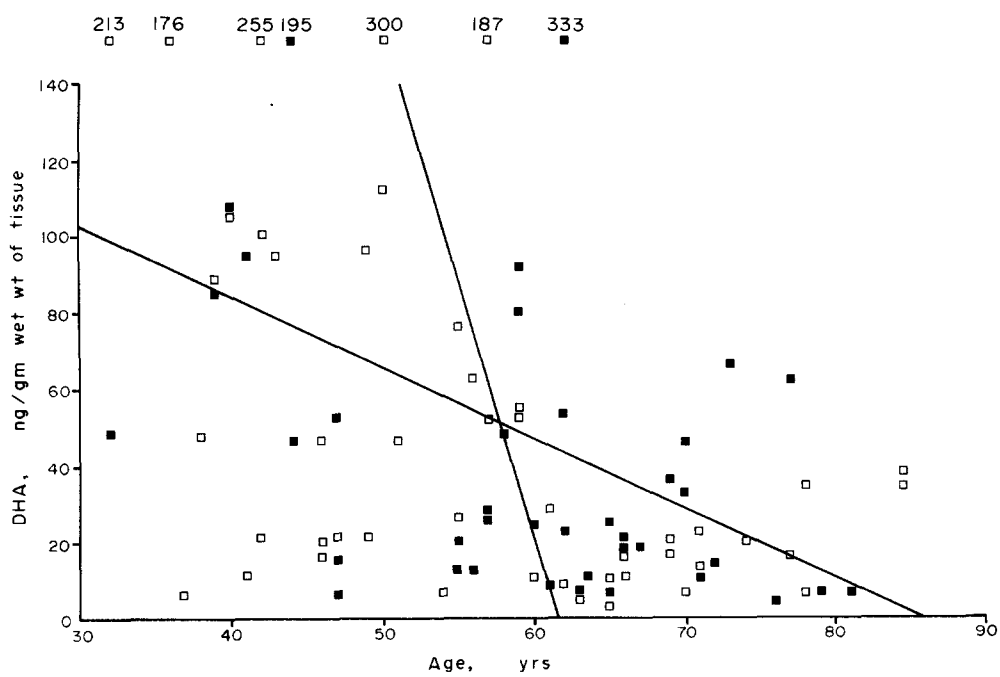

Fig. 1. DHA levels in human primary breast tumours. The lines are the regression lines, and the correlation between steroid levels and age ($R=0.38$) is significant ($P<0.001$). □ = oestradiol receptor negative and ■ = oestradiol receptor positive tumours.

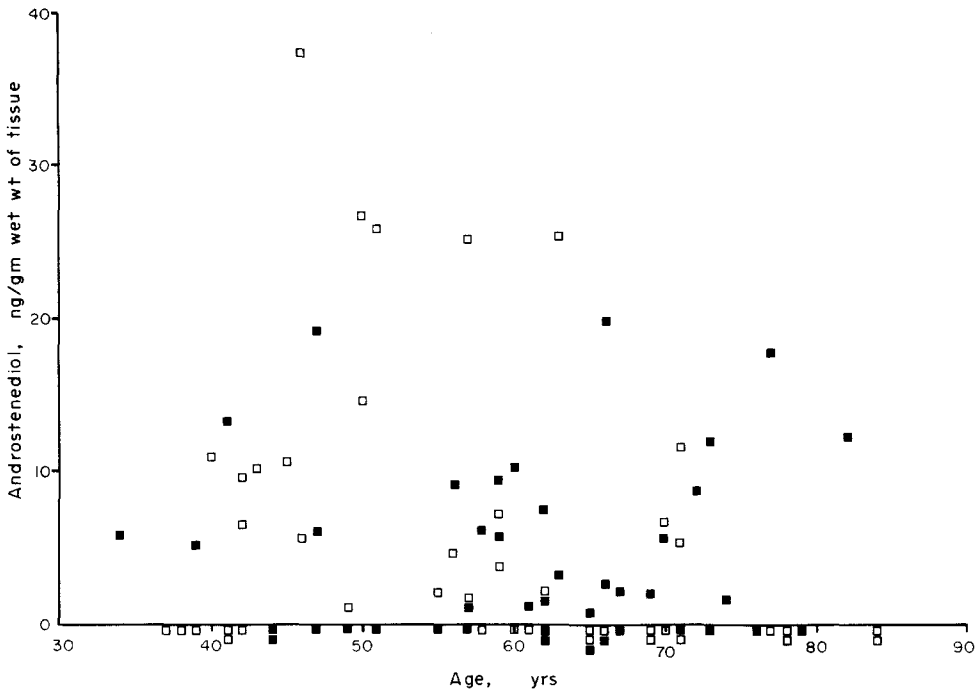

Fig. 2. Androstenediol levels in human primary breast tumours. □ = oestradiol receptor negative and ■ = oestradiol receptor positive tumours.

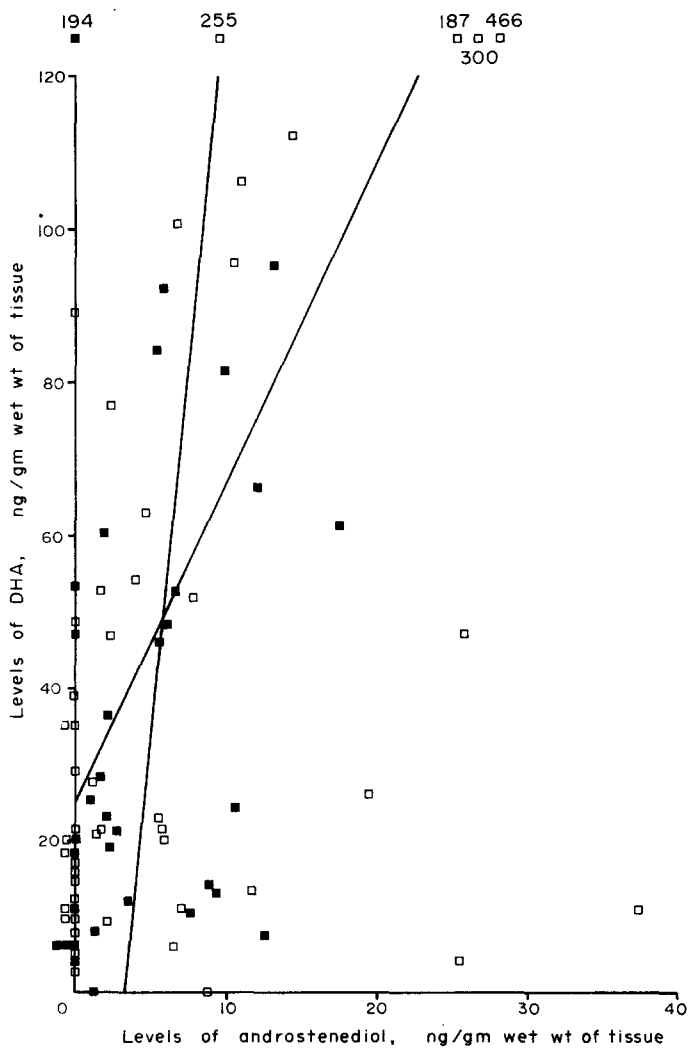

Fig. 3. Correlation between DHA and androstenediol content of primary breast tumours, both steroids measured in one extract. The two lines are the regression lines and the correlation between DHA and androstenediol levels ($R = 0.47$) is significant ($P < 0.001$). □ = oestradiol receptor negative and ■ = oestradiol receptor positive tumours.

5 fmole/mg cytosol protein) were found to contain high or low amounts of either steroid. Furthermore, tumours containing non-measurable amounts of androstenediol had the same distribution of receptor as those containing greater than the limit of the assay. However, tumours containing a high level of DHA (greater than 100 ng/g) were found to be mainly oestradiol receptor negative (7 out of 10 tissues), and similarly tumours with high levels of androstenediol (greater than 20 ng/g) also lacked measurable cytoplasmic receptor (5 out of 6 tissues). In the three tumours containing high levels of both steroids (Fig. 3) no specific cytoplasmic oestradiol binding could be detected.

DISCUSSION

All the tumours investigated contained measurable amounts of non-conjugated DHA at levels considerably greater than would be expected from contamination by plasma. Plasma DHA levels have been quoted [15] as being around 4.5 ng/ml in pre-menopausal women which drop to approximately 1.5 ng/ml after the menopause, whereas levels in these primary breast tumours were from 2.5 ng/gm to over 450.0 ng/gm. The correlation found between the level of this weak androgen in the tumour and the age of the patient might suggest that one possible source of the steroid may be the DHA sulphate found in high concentration in the plasma (over 2 μg/ml in pre-menopausal women and about 450 ng/ml post-menopause [15]). This would indicate that virtually all the breast tissues examined contained an active steroid sulphatase enzyme system, a concept which would agree with earlier work from these laboratories both *in vitro* [7] and *in vivo*, by perfusion [8], one of the principal metabolites of [^{3}H]DHA sulphate was shown to be the free steroid.

Dao and Libby [16] have suggested, however, that the level of steroid sulphotransferase activity correlates with response to endocrine therapy and more recently Godefroi *et al.* [17] have tentatively shown that there is a correlation between sulphotransferase activity and oestrogen receptor levels. The amounts of DHA found in these tumours may thus reflect a balance between the activities of sulphatase and sulphotransferase enzyme systems.

In the present series no correlation has been found between DHA levels in the tumour and the quantity of oestrogen receptor in the cytoplasm, with the exception that when amounts of endogenous steroid are high, tumours seem more likely to contain less available receptor sites. It is possible that if all the DHA is in the cytosol fraction there may be a direct effect on the oestrogen receptor assay although it has recently been shown [11] that DHA itself does not displace oestradiol from its receptor markedly even at very high concentrations.

If a relationship does exist between DHA in the tumour and physiological activity of the oestrogen receptor it would appear to be more likely that a metabolite of the C_{19}-steroid is responsible, possibly oestradiol itself or probably a C_{19}-steroid containing an hydroxyl group at the 3 and 17 positions. Many such steroids do displace oestradiol from its receptor [11], the most effective being androstenediol. Since this steroid is formed from DHA in both human [8] and rat [18] breast tumours, its concentration in the tissue may be very important, both in relation to the assay for the receptor, but more significantly, in its ability to modify the activity of the cell.

The correlation between DHA and androstenediol (Fig. 3) suggests that in many of the tumours there is an active 17β-hydroxysteroid dehydrogenase enzyme system. Although it has been reported that a similar conversion of oestrone to oestradiol and of androstenedione to testosterone occurs more frequently in neoplastic breast tissue than in normal tissue [19], it was of interest to find that in many tumours there were non-detectable levels of androstenediol. In these tumours it may be that this enzyme system is absent or that any androstenediol formed is rapidly metabolised to other compounds and does not accumulate within the tissue. In those tumours where androstenediol was found, however, the concentrations were again considerably greater than could be explained by reported plasma levels of this steroid [15].

Although it remains to be seen whether the DHA and androstenediol being measured are present in the cytoplasm of the cell or bound to particulate material or indeed merely stored in the fat particles in the tissue, the levels are, in many tumours, very high and may well be capable of affecting the oestrogen receptor and thus the activity of the cell. In some cases, these C_{19}-steroids in the primary tumour may act as a store of steroid precursor material from which oestrogens could be synthesised. It will be of particular interest to see whether the steroid content bears any relationship to the course of the disease or to the response to therapy of subsequent metastatic deposits.

Acknowledgements—We would like to thank Mrs. Patricia Clark, Mr. K. Jones and Mr. A. W. Pike for skilled technical assistance, and in particular the surgeons and staff of the many hospitals in the Liverpool district from which tissue was obtained.

Biologic Characterization and Chemotherapeutic Response of MS-2 Tumor: a Non-Regressing Mouse Sarcoma Derived from MSV-M-Induced Sarcoma

F. GIULIANI, O. BELLINI,* A. M. CASAZZA,* F. FORMELLI,* G. SAVI and A. DI MARCO

Division of Experimental Oncology B, Istituto Nazionale per lo Studio e la Cura dei Tumori, Via G. Venezian 1-20133 *Milano, Italy*

Abstract—*MS-2 tumor produced in BALB/c mice by transplant of* in vitro *cultivated cells derived from a primary MSV-M tumor in mice did not show spontaneous regression but grew progressively and killed the host. The MS-2 tumor was histologically classified as a malignant sarcoma. In syngeneic BALB/c mice, the i.m. transplanted MS-2 tumor had a mean doubling time of* 2.5 days *when the tumor mass was* 500 mg *and* 14 days *when the tumor reached* 4.0 g. *MS-2 tumor cells showed a high ability to metastatize (tested by bioassay). The organ mainly involved was the lung. In a small percentage of mice, metastases were also detected in spleen, liver, kidney, brain and blood. The activity of: cyclophosphamide, daunorubicin, adriamycin and 4′-epi-adriamycin on the MS-2 tumor was evaluated. The effects on both tumor growth and pulmonary metastases were detected. In parallel, the drugs were tested on the highly immunogenic T-MSV tumor, obtained by serial* in vivo *passages of the primary MSV-induced tumor. Daunorubicin did not have any therapeutic effect on the growth of MS-2 tumor; adriamycin produced a marked delay of the tumor growth and a significant increase of the life span; cyclophosphamide produced a longer delay in tumor growth than adriamycin did, but the life span was only slightly increased. On the T-MSV tumor, daunorubicin and adriamycin reduced tumor growth and did not affect spontaneous tumor regression; cyclophosphamide reduced tumor growth but completely abolished the spontaneous regression. Adriamycin and its new derivative 4′-epi-adriamycin, given to mice in which the MS-2 tumor had been surgically removed, inhibited the presence of tumor cells at the lung level.*

The MS-2 tumor studied in parallel with the T-MSV tumor allows the comparison of drug activity on a highly or weakly immunogenic tumor. Moreover, the MS-2 tumor is a viable model for studying the activity of chemotherapeutic drugs on lung metastases and their adjuvant effect on surgery.

INTRODUCTION

IN A RECENT report we have described a cell line, referred to as MS-2, established *in vitro* in our laboratory [1, 2] and derived from Murine Sarcoma Virus-Moloney (MSV-M)-induced tumors in BALB/c mice. Contrary to MSV-M-induced tumors, the tumor produced by injection of MS-2 cells into syngeneic hosts, called MS-2 tumor, did not show spontaneous regression, but grew progressively and killed the host [3]. The lack of spontaneous regression could be attributed to the low antigenicity of MS-2 cells due to the low sarcoma virus release: in mice with growing MS-2 tumor no concomitant immunity was detectable [3]. The MS-2 tumor can be used as a new experimental model for investigations on the activity of antineoplastic drugs. Parallel experiments on the MS-2 tumor and on the spontaneously regressing MSV-M tumor can supply information on the ratio between antitumor and immunodepressive activity of antineoplastic drugs.

In the present report, the metastatic dissemination and other biological properties of MS-2 tumor are described, as well as the chemotherapeutic activity of cyclophosphamide, daunorubicin, adriamycin and 4′-epi-adriamycin, a recently synthesized analog of adriamycin [4, 5].

Accepted 24 October 1977.

MATERIAL AND METHODS

Animals

The animals used throughout these experiments were 6–8 weeks-old syngeneic BALB/c, DBA/2, C3H, C57BL/6 mice and hybrid BDF_1 (C57Bl × DBA/2) mice, obtained from Charles River Breeding laboratories, Calco, Italy.

Tumors

MS-2 tumor was maintained by serial intramuscular (i.m.) passages of a tumor cell homogenate into the right hind leg. The experiments were performed on mice with tumors at the 36–46th generations. In the studies on the growth characteristics of the MS-2 tumor, cell dispersion was accomplished by Reinhold's method which was slightly modified [6]. A Moloney transplanted sarcoma (T-MSV-M) was originally induced in BALB/c mice by i.m. infection with MSV-M. This tumor has been maintained by serial i.m. passages in syngeneic hosts for more than 2 yr [3]. Tumor growth was followed by caliper measurement of two perpendicular diameters and tumor weight was estimated according to Geran *et al.* [7].

Oncogenic dose 50 (OD_{50})

Serial dilutions of viable cells were inoculated i.m. into syngeneic mice. The OD_{50} was derived graphically from a plot relating the size of the inoculum to the number of mice developing tumors within 120 days from the day of tumor inoculation.

Assays for metastasis detection

Lung, spleen, liver, kidney and brain from mice bearing MS-2 tumor were tested for the presence of tumor cells by bioassay. Blood metastases were detected by i.m. or i.v. injection of 0.2 ml/mouse of heparinized blood from tumor-bearing mice. The tumor-bearing mice were killed by cervical dislocation at intervals of 5–10 days after i.m. transplant of 10^6 tumor cells. The organs were removed aseptically, minced, inserted into a syringe with a small amount of 199 medium, and injected s.c. into the right inguinal region of normal BALB/c mice.

The organs from each animal were bioassayed individually, except for liver. The whole liver from each mouse was carefully minced and divided into two equal fractions. Each fraction was then implanted s.c. into the right inguinal region of a recipient mouse. The tumors grown after s.c. implant of organs tested for the presence of metastatic cells were always examined histologically. Mice were observed for 100–120 days after tissue implantation.

In some experiments, pulmonary metastases were also evaluated by lung perfusion with a suspension of India ink (15% v/v in water) followed by fixation in Fekete's solution [8].

Surgical tumor removal

One million MS-2 sarcoma cells were injected into a footpad; surgical amputation of tumor-bearing legs was performed on animals anesthetized with Farmotal (Farmaceutici Italia). A skin incision was made all around the upper thigh as far as possible above the area of tumor growth. The muscle and femur were cut with steril scissors. the wound was closed by clamping with metal wound clips. Surgical removal resulted in less than 10% surgical mortality.

Chemotherapeutic assays

BALB/c mice were inoculated with MS-2 or T-MSV-M tumor cells and treated i.v. or i.p. (Cyclophosphamide was received from the Division of Cancer Treatment, National Cancer Institute, Bethesda, MD. Daunorubicin, adriamycin hydrochloride, and 4′-epi-adriamycin were supplied by Farmitalia, Milan, Italy. The drugs were dissolved in Ringer solution immediately before use and injected at equitoxic doses in a vol of 10 ml/kg of body weight.

Histological examination

The tumor, lung and liver samples for microscopic examination were fixed in 10% formaldehyde or Bouin's solution, embedded in paraffin, and stained with hematoxylin and eosin. One portion of tumor was fixed in Karnowsky's solution and embedded in epoxy–Epon resin (0.75 nm thick). Semithin sections were stained with methylene blue and Azur II. Gomori's silver impregnation method was used for reticulum fibers.

RESULTS

Growth characteristics of MS-2 tumor

Table 1 shows the results obtained in mice injected with graded numbers of MS-2 tumor cells. The OD_{50} was 4.4×10^2 cells/mouse.

Table 2 presents data from nine experiments carried out in mice injected with 10^4 MS-2 cells/mouse. On 217 injected mice we observed 100% tumor takes: the average of tumor insurgence was 14.2 days and no spontaneous regressions and no survivors were observed. The median day of death from 9 experiments was day 42.8, with a range of medians in single experiments of 38–53 days and a range of deaths in individual mice of 19–76 days.

In Fig. 1 the growth curve for MS-2 tumor is

Table 1. Oncogenicity of MS-2 tumor cells implanted i.m. in adult BALB/c mice

No. cells/mouse	No. of tumor takes/total*	%
10^4	30/30	100
10^3	24/30	80
5×10^2	18/30	60
10^2	6/30	20
5×10	2/30	6.6

*Mice observed for 100 days.

Table 2. Life span of BALB/c mice implanted i.m. with 10^4 MS-2 cells/mouse

Exp. No.	Average time of tumor insurgence (days)	Median life span (days)	Range of deaths (days)	No. of survivors/ total
MC-31	17.3	38.5	27–54	0/10
MC-34	17.0	40.0	35–62	0/10
MC-35	13.8	47.0	33–56	0/10
MC-36	16.7	40.5	29–55	0/10

MS-98	12.0	41.0	27–69	0/57
MS-102	12.0	46.0	19–54	0/91
MS-108	12.1	39.0	32–50	0/9
MS-112	14.3	53.5	47–76	0/10
Average of all experiments	14.2	42.8	19–76	0/217

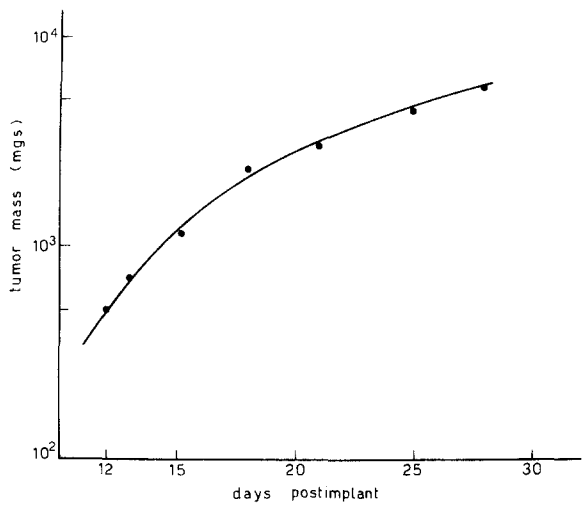

Fig. 1. Gompertz fitted growth curve for MS-2 tumor implanted i.m. into adult BALB/c mice (10^6 cells/mouse). Mean of 224 animals.

shown. The growth of i.m. injected MS-2 tumor is well described by a Gompertz function, and the doubling time increases from 2.5 days for a 0.5 g tumor (500 mg) to 3 days for a 1.0 g tumor, and reaches 14 days when the tumor is 4.0 g.

The i.m. transplant of MS-2 tumors in syngeneic, allogeneic and hybrid mice was tested. Results summarized in Table 3 show that progressive tumor growth was obtained only in syngeneic BALB/c mice, in DBA/2 mice bearing the same H-2 locus allele, or in BDF_1 (BALB/c × DBA/2) mice. In allogeneic C3H and C57 BL/6 mice, the MS-2 tumor did not grow.

Table 3. Effect of i.m. transplant of MS-2 tumor cells in syngeneic and allogeneic mice

Mouse strain	Allele of H-2 locus	Growth of MS-2 tumor
BALB/c	d	progressive
DBA/2	d	progressive
BDF_1 (C57Bl × DBA/2)	d	progressive
C3H	k	absent
C57BL/6	b	small tumors which regress

Histological characteristics

The general histological features of the MS-2 tumor 16 days after MS-2 cell injection have been previously described [2]. Microscopic examination of the tumor revealed that there

was little or no evidence of the establishment of a capsule that would form any sort of barrier to extension of tumor growth. The s.c. connective tissue in the region of the spreading tumor showed edema, sparse inflammatory cell infiltration and hyperemic blood vessels (Fig. 2). At the periphery of the tumor, where the cells were loosely arranged, they appeared rounded or slightly elongated (Fig. 3). The cytoplasm was basophilic and homogeneous and the nuclei were round or oval and hypercromatic. The nucleous membrane enclosed delicate or dense chromatin granules and one or more large nucleoli (Fig. 4). Many mitotic features were observed. The tumor had numerous reticular fibers (Fig. 5) intimately associated with the cells. On the basis of these features, the tumor was classified as a malignant sarcoma.

Metastases

The ability of i.m. transplanted MS-2 tumor to metastatize was tested by bioassay of lung, liver, spleen, kidney, brain and blood of MS-2 tumor-bearing mice at different times after tumor transplant. The results are summarized in Table 4. Five days after tumor transplant no tumor cell was present in the tested samples except in liver. At 10 days, the incidence of lung metastases was already 100% in mice bearing a palpable tumor. Spleen and kidney metastases were detected the 20th day after tumor implant in a small percentage of mice. Brain metastases were present only at a very late stage of the disease. In liver, tumor cells were detected only occasionally. In blood, tumor cells were detectable only 30 or 40 days after the tumor transplant in one or five mice tested; i.v. injection of blood from tumor-bearing mice produced similar results.

The histological features of lung and liver metastases are shown in Figs. 6 and 7. The metastatic cells appeared rounded with hyperchromatic nuclei. In lungs, gross metastatic nodules were observed, with tumor cells invading the large vessels (Fig. 6). In liver, grapes of 2–3 tumor cells were observed in the capillary lumen (Fig. 7). All tumors were classified as malignant sarcomas.

Lung metastases were also evaluated by gross examination of lungs after perfusion with a suspension of India ink. Marked differences existed between the two evaluations. As expected, the Wexler's method was definitely less sensitive than the bioassay.

The histological features of tumor derived from s.c. implant of lung and liver are similar to those of MS-2 tumor.

The lung of BALB/c mice bearing footpad tumors were bioassayed 8, 10, 13, 16 and 20 days after tumor implant. The results reported in Table 5 show that when surgical removal was performed 8 or 10 days after tumor implant, 53 or 66%, respectively, of mice had developed lung metastases. When surgical removal of the tumor was performed 13 days after tumor implant, 100% of the mice had developed metastases.

Response to drug treatment: activity on primary tumor and on lung metastases

The effects of daunorubicin, adriamycin and cyclophosphamide on the growth of MS-2 and T-MSV-M tumors, tested in parallel in BALB/c mice, are shown in Figs. 8 and 9 and Table 6. The drugs were administered i.v. or i.p. 6, 10, 14 and 18 days after the i.m. tumor implant. In MS-2 tumor-bearing mice (Fig. 8 and Table 6)

*Detected by bioassay of donors lungs.

treated according to this schedule, daunorubicin did not show any therapeutic effect. Adriamycin, administered i.v. at the dose of 3.5 mg/kg/day, produced a delay of tumor growth (Fig. 8) and a significant increase of the life span ($P<0.01$; $T/C\% = 145$) (Table 6). Cyclophosphamide produced a higher delay in tumor growth but a slightly lower life span increase at the highest doses tested (50 mg/kg/day i.v. and 60 mg/kg/day i.p.; $P<0.05$).

On T-MSV-M tumor, treatment with adriamycin or daunorubicin (Fig. 9) resulted in a slight inhibition of tumor growth followed by tumor regression which was more rapid than in controls. The treatment with cyclophosphamide resulted in inhibition of tumor regression: most mice died with progressively growing tumors.

The effect of adriamycin and 4'-epi-adriamycin on lung metastases is shown in Table 7. The experiment was carried out on MS-2 tumor-bearing mice in which the tumor was removed 10 days after implant. The mice were treated i.v. with the two drugs 2, 9, 16 and 23 days after tumor removal. The lung bioassay was carried out 3 days after the last treatment. At the lowest and highest doses tested (8 and 12mg/kg/day), adriamycin, administered according to this schedule of treatment did not inhibit the appearance of lung metastases. At the intermediate dose tested (10 mg/kg/day), the appearance of lung metastases was slightly inhibited 4'-epi-adriamycin was more active than adriamycin in reducing the percentage of lung metastases. In mice treated with 4'-epi-adriamycin, at the intermediate dose (10mg/kg/day), no tumor cells were detected by the bioassay at the lung level.

DISCUSSION

Model systems involving transplantable tumors have been used extensively in the screening and evaluation of antitumor agents and the value of such systems in the selection of compounds with activity in clinical neoplasia has been documented [9]. The MS-2 tumor used in this study possesses several biological characteristics desirable in a chemotherapeutic model for human cancer, the majority of which are slow growing tumors. The MS-2 tumor has the

histologic features of malignant sarcoma, i.e. high oncogenicity, a slow growth rate, low antigenicity [3] and rapid metastatization and these characteristics were maintained after thawing. The MS-2 tumor, similarly to the Ki-MSV non producer tumor described by Ikawa *et al.* [10], is derived from cells infected with MSV-M; but it differs from the MSV-M-induced tumor in several characteristics, mainly in its lack of spontaneous regression. The MS-2 tumor differs from the Ki-MSV non-producer tumor in that it has been obtained from cells infected *in vivo* with MSV-M and because it has been histologically classified as a sarcoma, whereas the Ki-MSV non-producer tumor was classified as an epithelial tumor [10].

In a previous paper [3] we have reported that the MS-2 tumor was not sensitive to treatment with daunorubicin and adriamycin. The experiments reported here show that, with the schedule of treatments applied, adriamycin and cyclophosphamide, but not daunorubicin, were able

to inhibit the MS-2 tumor growth. Cyclophosphamide was more effective than adriamycin in delaying the tumor growth, but adriamycin was slightly more active than cyclophosphamide in increasing the life-time of the tumor-bearing mice.

An explanation for these findings was afforded by the data obtained on the highly immunogenic, spontaneously regressing T-MSV-M tumor. It was observed that adriamycin did not hamper tumor regression, but cyclophosphamide strongly inhibited this process. Therefore, it can be supposed that, although cyclophosphamide produced an inhibitory effect on the primary MS-2 tumor, it was probably ineffective in curing pulmonary metastases. In fact, the development of metastases is influenced by the immunologic competence of the host [11, 12] and the immunologic impairment has been shown to have a more striking effect on metastatic growth and development than on primary tumor growth [13]. Moreover, in a recent report Carmel and Brown [14] found a significant enhancement of lung colony formation by pretreatment of mice with cyclophosphamide.

The data reported here show that adriamycin and its new derivative 4′-epi-adriamycin given to mice in which the MS-2 tumor has been surgically removed inhibit the presence of tumor cells at the pulmonary level. The optimal dose was, for both compounds, 10 mg/kg/day; at higher doses both compounds were less active, probably because of the immunodepressive effect [15, 16].

In the experiments carried out by surgical removal of i.m. implanted tumors, an undesired complication is often present due to local recurrence of the primary tumor, which can hamper the validity of the final results [17]. We have overcome this by implanting the MS-2 tumor cells into the foot-pad: surgical removal of the primary tumor is facilitated and local recurrence of primary tumor is minimized.

The availability of a new model system which allows the detection of antitumor activity, effect on metastases, immunodepressive activity (even if indirectly by comparison with data obtained in other models), can be of usefulness for chemotherapeutic studies. In addition, the MS-2 tumor offers the possibility to study the *in vitro* activity of antitumor agents [1]. These data confirm that results of chemotherapeutic activity on MS-2 and T-MSV-M tumors can be of great help for a better understanding of the properties of antitumor drugs.

The MS-2 tumor, besides allowing the comparison of drug activity on highly or weakly immunogenic tumors, is a viable model for studying the activity of chemotherapeutic drugs on lung metastases and their adjuvant effect on surgery.

The Effects of Prednisolone on Normal Pigs*

SERENA E. BROWNLIE,† J. G. CAMPBELL,† K. W. HEAD,† P. IMLAH,† H. S. McTAGGART† and J. G. McVIE‡

†*Royal (Dick) School of Veterinary Studies, University of Edinburgh, Great Britain and* ‡*Department of Clinical Oncology, University of Glasgow, Great Britain*

Abstract—*Prednisolone at doses of* 0, 2, 4 *and* 6 mg/kg *was given daily* 5 *days/week for* $5\frac{1}{2}$ *weeks to* 4 *pairs of normal Large White sibling pigs. One of each pair was then killed. Treatment caused a dose-related reduction in the size of the thymus with "overshoot" on recovery. A similar but less spectacular reduction, without "overshoot", on recovery, occurred in the lymph nodes and blood lymphocyte counts. There was also a reduction in serum total globulin levels and a complementary increase in serum albumin during treatment. Treated pigs showed a reduced contact sensitivity to DNFB during the last week of treatment. No changes attributable to treatment were observed in blood neutrophil and platelet counts nor in the red cell pictures.*

It is concluded that the pig falls in the "corticosteroid-resistant" group of species which includes man.

INTRODUCTION

THE EXISTENCE of a hereditary form of lymphoma in Large White Pigs was first reported by McTaggart *et al.* [1]. The clinical, haematological and pathological features of 53 cases were described by Head *et al.* [2]. The condition has been shown to be transmitted in association with an autosomal recessive gene. Diagnosis may be made as early as 4 weeks of age but more commonly at 2–3 months. Clinical features include marked stunting of growth, lymphadenopathy, muscle wasting and the development of a pot belly. No affected pig has yet reached functional sexual maturity (normally reached at about 6 months) despite the fact they may live to the age of 15 months. As the disease is now known to be predictable in its course, it seemed appropriate to use the herd for evaluation of new cytotoxic drugs. The tumour has marked similarities to poorly differentiated lymphocytic lymphoma in man and may prove a more predictable system than established small laboratory animal lymphomas. The suitability of the pig as a model was examined by testing with a selection of drugs already in common use.

Accepted 27 October 1977.

Prednisolone was chosen as the first drug for assessment as it is known in several experimental models to be a useful cytolytic agent for lymphocytes [3]. It induces a limited temporary remission in acute lymphatic leukaemia in children, although it has a much enhanced effect when combined with vincristine. It also has beneficial effects in B lymphocyte tumours such as some of the non-Hodgkin lymphomas, myeloma and macroglobulinaemia [4].

This paper will describe the methods used in toxicity testing with particular reference to the monitoring of the effects of different levels of prednisolone on non-lymphomatous Large White pigs. The effects of prednisolone on pig lymphoma cases and of other steroids and cytotoxic drugs will be reported later.

MATERIAL AND METHODS

Animals

A litter of 8 normal Large White pigs (5 females, 3 castrated males) was used. These animals were of the lymphoma strain but were of non-carrier parentage. They were weaned at 8 weeks and housed in the same pen. Monitoring was commenced 2 weeks later. Animals were fed on "Breeder's Cubes" (SAI Ltd.) with water *ad libitum*. At weekly intervals from 3 weeks before treatment commenced the animals were weighed and blood samples were taken from the anterior vena cava [5]. An EDTA sample was taken for

routine haematology and a clotted sample for calcium, magnesium, inorganic phosphate, sodium, potassium, chloride, total protein and protein fraction estimations. Animals were also sensitised with dinitro-fluorobenzene (DNFB) so that recall to this antigen could be tested at later periods throughout treatment. Four groups of 2 pigs selected by lot were treated with 2, 4 or 6 mg/kg of prednisolone sodium phosphate solution (Codelsol, MSD, 16 mg/ml) or with normal saline corresponding to the volume of the 4 mg/kg injection. The dose was given i/m daily for 5 days each week. Clinical observations were undertaken each day. After $5\frac{1}{2}$ weeks of treatment a bone marrow core biopsy was taken from the crest of the ileum, using an 11 gauge Jamshidi needle (Kormed Inc.). One pig from each pair was then killed by intravenous pentobarbitone overdose and an immediate autopsy carried out. Treatment of the remaining animals continued during the week, being reduced to half, quarter and one-eighth during the last 3 days before being finally discontinued. Five weeks later, when it was considered that the visible effects of the drug had disappeared, a bone marrow core biopsy was taken and the animals were slaughtered.

Haematology

Red and white cells were counted using an electronic counter (Coulter Electronics Ltd., Model ZF). Platelets were counted using a white cell pipette, an Improved Neubauer haemocytometer and Baar's diluting fluid without brilliant cresyl blue. White cell differential counts were based on 200 cells counted in Leishman-stained smears. Haemoglobin was estimated by the cyanmethaemoglobin method using a Coulter haemoglobinometer, and packed cell volume (PCV) using a Gelman Hawksley microhaematocrit centrifuge. Mean cell volume (MCV), mean cell haemoglobin concentration (MCHC) and mean cell haemoglobin (MCH) were obtained by calculation.

Biochemistry

Serum sodium and potassium were measured by flame emission and calcium and magnesium by atomic absorption spectrophotometry (Shandon Southern, Model A3400). Serum chloride was measured in an EEL chloride meter (Evans Electroselenium Ltd.) and inorganic phosphate by the method of Fiske and Subbarow [6]. Total protein was estimated by the biuret method of Henry *et al.* [7] and albumin by the bromcresol green dye-binding method described by Dumas *et al.* [8]. On selected occasions a more detailed analysis of protein fractions was carried out by electrophoresis on Millipore cellulose acetate strip (Phoroslide) at 100 V for 20 min. Proteins were stained with Ponceau S, decolourized with 5% acetic acid, dehydrated in ethyl alcohol for 5 min, cleared in acetic acid-ethyl acetate for 1 min and dried in a warm oven. Protein fraction readings and a permanent trace were obtained for each sample using a Millipore Phoroscope densitometer.

Cell-mediated response

Delayed hypersensitivity reactions were measured by contact sensitivity to DNFB in equal volumes of acetone and dimethylsulphoxide (DMSO) [9]. An area of skin between the shoulder blades or the iliac crests was prepared by removing the hair with scissors and cleaning with spirit. On each occasion 5 μl DNFB solution was applied with an automatic micropipette and spread within an area of 14 mm in diameter with the flattened end of a glass rod. Pigs were sensitized with 10% DNFB. A preliminary test 20 days later with 1% DNFB indicated that this concentration was too weak (Table 1). Subsequent tests were carried out during and after the course of prednisolone treatment, using 5 or 10% DNFB, readings being made at 24 hr and, sometimes, at 48 hr. An interval of at least 7 days was allowed to elapse between tests.

Pathology

The autopsy examination was started immediately after an animal had been killed so that the tissues selected for fixation were placed in buffered neutral formol saline within a few minutes and never more than 20 min after death. These tissues were processed to paraffin wax, sectioned at 6 μm and stained with haematoxylin and eosin. Certain sections were also stained with Gordon and Sweet's stain for reticulin fibres, Martius scarlet blue, periodic acid-Schiff reaction, Perls' prussian blue method for haemosiderin and Leishman's stain.

In the course of the autopsy the lymph nodes throughout the body, thymus, spleen, kidney, liver and adrenal glands were dissected out and weighed. In the case of bilateral organs, mean values were obtained for kidneys and adrenals but only one of a pair of lymph nodes, always from the same side, was weighed. The absolute weights were then expressed as relative weights in centigrams per kilogram of body weight. The relative

0, negative; 1, slight erythema; 2, erythema and swelling; 3, small ulcerations; 4, large ulcerations. Treatment with prednisolone commenced on the 11th day and ceased or was tailed off from the 44th day after sensitization.

weights of the "bronchial", "head" and "iliac" groups of nodes represent the totals for the various nodes in each of these regions.

The biopsy core samples of bone marrow were initially fixed in buffered neutral formol saline and then post-fixed in Bouin's fluid for 48 hr and decalcified in EDTA. In addition, the bone marrow of the body of the first lumbar vertebra and the wing of the ileum including the crest were taken as 5 mm slices cut with a saw and decalcified in formic formol before processing to paraffin wax. These latter samples were used to assess the value of the biopsy method.

To facilitate comparison between samples during the histological examination groups of sections were ranked in degree of change using a split-field comparator microscope. Where a structure could be drawn in outline (e.g. liver lobule, hepatic cell, white pulp pattern of spleen or thymic lobule), a microscope fitted with a Wild drawing tube was employed to demonstrate the degree of change present.

RESULTS

Clinical observations

Throughout the experiment, all pigs were bright and active. Prednisolone did not appear to depress interest in food but as individual intakes could not be measured the effect on appetite could not be assessed. Rectal temperatures fluctuated from day to day within the normal range for pigs of this age. All pigs on prednisolone, irrespective of dose, were noted to have marked polydipsia and polyuria. At the higher dose levels, they became pot-bellied. After 3 weeks of treatment, the 2 pigs receiving 4 mg/kg doses showed rectal eversion but this corrected itself spontaneously. The mean weight gain during the 5 weeks of treatment (Table 2) was lower in the 6 mg dose group (5.5 kg) than in any other group (controls, 8.5 kg; 2 mg dose, 7.5 kg; 4 mg dose, 9.0 kg). Similarly, during the post-treatment period, weight gain was lowest in the 6 mg dosed pig (14.5 kg as against 18.5, 18.0 and 19.0 kg respectively), despite the fact that its commencing weight was average for the litter.

Haematology

There was a steady decline in mean absolute lymphocyte counts in all groups during the treatment period. This decline was dose-related, being least in the controls and greatest in the 6 mg dosed group (Table 3, $r=0.75$, df=6, $P<0.05$, >0.02; $y=1835+564\ x$). The percentage drops in lymphocyte counts in the 4 groups were 5.8, 23.8, 31.5 and 42.6 respectively. During the posttreatment period the absolute lymphocyte counts remained more or less static.

Eosinophil counts showed a mean decrease in the control group during the treatment period whereas the treated groups all showed increases (Table 3).

Neutrophil counts showed a mean decrease in all groups during the treatment period (Table 3) but, as in the case of platelet counts and red cell pictures, there were no differences between groups which could be attributed to the treatments.

Biochemistry

Observations based on electrophoresis indicated that serum albumin levels increased in all groups during the treatment period (Table 4). This increase was exaggerated in

the control group because one pig had a pretreatment value of only 10.7 g/l compared with a mean of 24.1±S.D. 2.2 g/l for the other 7 pigs. If this latter figure is taken as a more acceptable pre-treatment value for the control group, then it is found that, whereas the control and 2 mg dosed groups showed mean increases in albumin of only 1.7 g/l (+7.05%) and 1.2 g/l (+4.8%) respectively, the 4 mg and 6 mg dosed groups showed mean increases of 9.0 g/l (+36.9%) and 7.8 g/l (+36.1%) respectively.

Table 4 also indicates that whereas the control group showed increases in mean total

globulin values and in all globulin fractions during the treatment period, the treated groups showed much smaller increases or even decreases in the corresponding values.

Since alpha-1 and alpha-2 globulins were not always distinguishable on the Phoroscope trace, it is not possible to give separate figures for these sub-fractions.

Total serum globulin values obtained by differences from chemical analysis of total proteins and albumin (but unconfirmed by the electrophoretic method because of inadequate samples) suggest that in the 4 mg and 6 mg treated groups the total globulins reached a nadir of about 20 g/l during the 4th week of treatment. A similar effect was noted in the 2 mg treated group but the nadir was not so low (*ca.* 24 g/l) and did not appear until a week later.

None of the serum inorganic elements showed any differences between groups which could be attributed to the treatments. In particular, there was no evidence of sodium retention nor of potassium or calcium depletion in the treated groups.

Cell-mediated response

It appears from Table 1 that during the last week of prednisolone treatment (42–43 days after sensitization) there is an anergy in the prednisolone-treated pigs as compared with the controls. There is a tendency for this anergy to be reversed in the 3 treated pigs after withdrawal of the drug, i.e. 81–82 days after sensitization.

Post mortem and histological findings

The most spectacular finding was in the thymus. At the end of the treatment period there was a dose-related reduction in relative weight of the thymuses of the treated pigs (Table 2, $r=-0.99$, df=2, $P=0.01$; $y=90-11.3x$). When compared with the control, the reduction amounted to 24, 58 and 72% in the 2, 4 and 6 mg dosed pigs respectively. As the thymus of this control was more involuted than would be expected in a normal pig of this age, these percentage reductions are probably underestimated. Histologically, the thymus lobule size of the treated pigs was reduced, the cortex being more involuted than the medulla, but the density of the cell population of both cortex and medulla was normal. The lymphoid involution was paralleled by a relative widening of the fat and connective tissue interlobular septa (Fig. 1).

In those pigs killed 5 weeks after treatment was discontinued, the relative thymus weights represented 156, 142 and 165% respectively of the corresponding control value. Despite this "overshoot", all were histologically normal (Fig. 2).

A less spectacular reduction in relative weights was found in the lymph nodes of

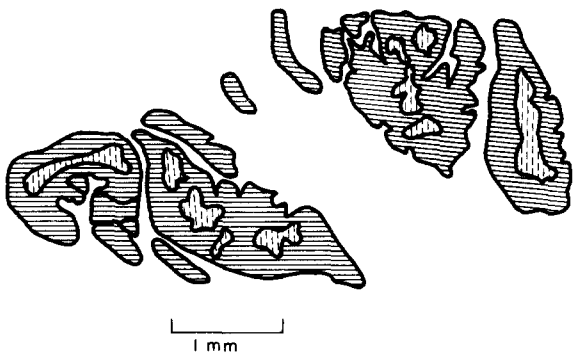

Fig. 1. Drawing of transverse section of whole thymus gland of pig receiving 6 mg/kg *prednisolone and killed at end of* 5 *weeks' treatment.*

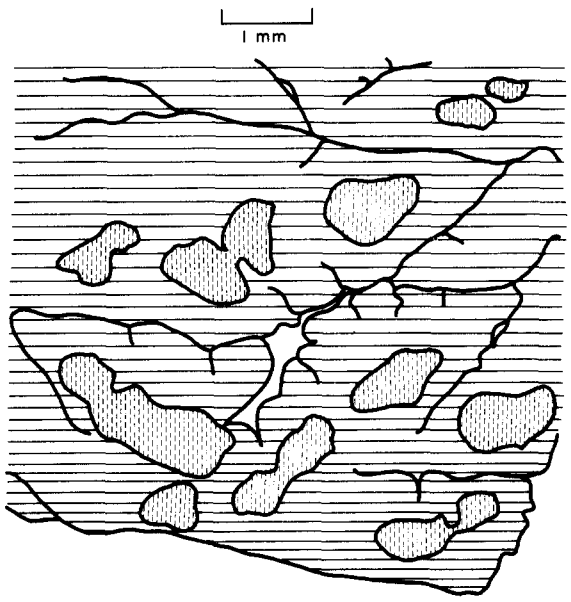

Fig. 2. Drawing of approximately half of cross section of thymus of control pig killed at end of experiment.

the treated pigs slaughtered at the end of treatment (Table 2). This was not dose-related but averaged 23% in the splanchnic nodes and 13% in the superficial nodes.

Histologically, the lymph nodes of the 6 mg dosed pig killed at the end of treatment, were distinctive in several respects. In contrast to the control and other treated pigs killed at the same time, (1) the submandibular node showed many "blast" cells with numerous mitotic figures both in the reaction centres and in some of the paracortical regions where there was a reduction in small lymphocytes (Figs. 3 and 4); (2) the prescapular node had virtually no lymphocytes in the cortex (Figs. 5 and 6); (3) the medulla of the mesenteric lymph node was reduced in size and the paracortical zone was more extensive than usual (Figs. 7 and 8); (4) the external iliac node showed more foci of megakaryocytes and normoblasts in the medulla; (5) the Peyer's patches were the smallest in the series and the cells in the open centre were inactive (Figs. 9 and 10). This animal had similar amounts of adipose tissue to the others, its poor weight gain being attributable to poor bone and muscle development.

There was no evidence of "overshoot" in the relative lymph node weights of the pigs killed 6 weeks later; indeed, although the superficial nodes were now comparable in relative weight to the control nodes, the splanchnic nodes averaged only 72% of the relative weight of the control nodes. Histologically, the external iliac lymph nodes of all pigs killed at this time showed more extramedullary haemopoiesis than in any of those killed earlier. In addition, the ratio of cortex to medulla was reversed from 1:3 to 3:1, this being attributable to an increase in size of both the reaction centres and the paracortical zone.

There was some variation in the relative weights and in the histological appearances of the white pulp of all 8 spleens, but these were not correlated with dose of prednisolone nor timing of death; nor were the variations in the white pulp related to the weight of the organ.

Lung, liver, kidney, adrenal and stomach were normal and similar in all cases. No pig showed any evidence of ascites or osteoporosis.

The bone marrow samples showed only differences that were attributable to age and growth rate. The core biopsies were comparable to the post mortem specimens.

The only evidence of intercurrent disease was in the second control pig which had a mild inflammation of the caecum associated with spirochaetes.

DISCUSSION

The extent and rate of development of the lytic effects of prednisolone on the lymphoreticular system of the pigs, in particular the thymus, the lymph nodes and the blood lymphocytes, clearly place them in the corticosteroid-resistant group of species which includes man, ferret and guinea pig, as opposed to the corticosteroid-sensitive mouse, rat, hamster and rabbit, in which the lytic effects are much more severe and rapid at comparable dosage [3].

The reduction in size of the thymus during treatment and its recovery with "overshoot" after withdrawal of treatment is a phenomenon

which has been described in non-lymphomatous children treated with prednisone or triamcinolone [10]. The growth retardation observed in the 6 mg dosed pigs has also been encountered in corticosteroid-treated children [11]. The latter usually show a rapid increase in growth after treatment is discontinued but this effect was not observed in any treated pigs during the 5 weeks post-treatment period. The growth retardation observed suggested that a dose of 4 mg/kg/day might be more suitable than 6 mg/kg/day for the therapeutic study which followed.

In the absence of any evidence of ascites, the pot belly observed at the two higher levels was presumed to be attributable to muscle relaxation. This was supported by the fact that the apparent distension disappeared when an affected animal was laid on its back.

The observed depression of serum globulin and increase in serum albumin levels associated with treatment have also been observed in man but mostly in relation to corticosteroid therapy of chronic diseases. It is popularly believed that corticosteroids affect especially the γ-globulin fraction but Bernfeld *et al.* [12] demonstrated that in ACTH-treated patients the beta fraction was mainly affected.

In our own experiments, the effects of prednisolone treatment on serum proteins were more obvious in lymphoma cases than in normal pigs. For this reason these effects will be discussed more fully in a later paper.

With respect to corticosteroid suppression of cell-mediated immunity, the pigs again fell within the steroid-resistant group of species since it has been shown that, although corticosteroids can suppress skin sensitivity reactions in that group, large doses or prolonged treatment are required. In man, for example, prednisone given orally in 40 mg/day doses had to be administered on average for 13.6 days to negate the effects of the PPD tuberculin test [13].

The immediate neutrophilia and eosinopenia which are to be expected in man receiving over 10 mg prednisone per day and which persist while treatment lasts [11] were not observed even transiently in any of the treated pigs. We have, however, observed neutrophilia in pigs treated with corticosteroids in another connection.

It is thus evident that the reactions of normal pigs to prednisolone show promising similarities to those occurring in man. Further, no laboratory animal in common use is also comparable to man both in size and in being omnivorous. Young pigs are relatively easily handled and yet are large enough to permit sizeable samples of blood and biopsy materials being taken repeatedly without ill effect. As will be emphasised in a later paper, the survival time of lymphomatous pigs is much closer to that of children than is that of small rodents. All these features point to the practicability and advantages of using the pig as a model for the testing of cytotoxic drugs.

Reversible Morphological Changes in Human Breast Fibroblasts Exposed to Stilboestrol*

P. A. RILEY, A. LATTER and P. M. SUTTON

Division of Pathology, University College Hospital Medical School, University Street, London, W.C.1., United Kingdom

Abstract—*Fibroblast cultures derived from human breast material treated with pharmacological doses of stilboestrol* (115 μm) *undergo a morphological transformation to an epithelial appearance. The effect is rapid and reversible. It is independent of RNA and protein synthesis and is not inhibited by an oestrogen antagonist* (*tamoxifen*).

INTRODUCTION

IN THE course of long-term studies on the *in vitro* behaviour of human breast tumour cultures we have examined the effects of steroids and steroid analogues on fibroblast strains derived from explants of tissue into fibrin clots to try to establish whether the response of these connective tissue cells is distinct from that of the predominantly epithelial primary cultures previously reported by us [1]. We report here observations on fibroblast strains from breast cancer, fibroadenoma and chronic cystic disease of the breast treated *in vitro* with the synthetic oestrogen analogue, stilboestrol, which may shed some light on the report published by Bishun and colleagues [2] drawing attention to a change in morphology of cells in fibroblast-dominated cultures derived from breast tumours.

MATERIAL AND METHODS

(*a*) *Culture medium*

In all the experiments referred to the cells were grown in a medium composed of Eagle's minimum essential medium (MEM) buffered with bicarbonate and Hepes, containing penicillin and streptomycin 100 units per ml., L-Glutamine 2mM and supplemented with foetal bovine serum (1, 10 or 20% as stated), all obtained from Flow Laboratories, Irvine, Scotland.

(*b*) *Chemicals*

A sterile aqueous solution of α,α′-diethyl-4,4′-stilbenol disphosphoric acid ester was obtained from Ward Blenkinsop and Co. Ltd. under the name of Honvan (250 mg per 5 ml ampoule). This was used in a dose of 10 μl per 10 ml of medium giving a final concentration of 115 μm and administered once with each medium change except when stated otherwise. Tamoxifen was kindly supplied by Dr. A. H. Todd of I.C.I. Pharmaceuticals Division. Sterile solutions in ethyl alcohol were used in a dose of 10 μl per 10 ml of medium giving final concentrations of 10^{-4} 10^{-5} and 10^{-6} M. Oestradiol and testosterone were used as described in [1]. Actinomycin D (Merck, Sharp and Dohme International) in aqueous solution containing 10 mg/ml mannitol, and cycloheximide (Sigma) in phosphate-buffered saline, were added to the culture medium to give final concentrations of 5 μg/ml and 50 μg/ml respectively. Colchicine (B.D.H.) dissolved in distilled water and filter sterilised was added to give a final concentration of 0.12 mg/ml of medium.

(*c*) *Cells*

The cells used in this investigation were derived from explants of human breast tissue removed at operation. The material was placed in serum free MEM containing penicillin and streptomycin and kept at 4°C. Within 24 hr of removal the tissue was chopped into small fragments and mechanically disrupted

Accepted 24 October 1977.

for 3 sec in a Colworth "Stomacher 80" and released cells filtered through fine gauze. The residual tissue was cut into pieces measuring about 1 mm^3, placed into polystyrene tissue culture flasks (Corning) and secured by a fibrin clot formed by mixing 3 vol of citrated human plasma with one volume of a solution of calcium chloride (2% aqueous) and placing a drop on the explanted fragment. In early experiments the entire surface of the flask was coated with fibrin but this was found to be unnecessary and wasteful. When the clot had formed 10 ml culture medium supplemented with 20% serum was added. Cells migrating into and growing in the fibrin meshwork had the typical bipolar morphology of fibroblasts and most explanted fragments gave rise to these fibroblastic outgrowths, in particular those portions which included adipose tissue. Fragments of tissue from carcinomas, fibroadenomas, chronic cystic disease of the breast and two cases of gynaecomastia were cultured. All these gave rise to fibroblasts although the details of their behaviour differed in some respects, as will be described elsewhere (Riley, Latter and Sutton, manuscript in preparation). Flasks showing dense fibroblastic outgrowths were trypsinised (trypsin 10% in a buffered Ringers solution) and the cells resuspended and inoculated into further flasks to which fresh medium was added. Stocks of cells were built up by subsequent passages and representative cells frozen in liquid nitrogen at about the fifth passage. The experiments reported here were made on cells between the passage numbers 3–16 and the tabulated values, given in the Results, obtained from the 3rd–7th passage after liberation from the fibrin clot. For comparison of the effects of stilboestrol some other cultures were also tested, including human fibroblastic cells from a biopsy of an axillary lymph node, the human foetal lung fibroblast line MRC5 (obtained from Dr. J. P. Jacobs) and the murine fibroblastic line 3T3 (obtained from Dr. R. Weiss). These cells were cultured in Hepes-buffered MEM with 10% foetal bovine serum supplementation. Subculturing in all cases was by trypsinisation, the cells being washed and resuspended in 1 ml of medium. Cell counts were made on 20 μl aliquots suspended in 10 ml 0.9% saline using a Coulter counter (Model A) calibrated to register particles with a spherical diameter greater than 3 μm. On the basis of the counts the stock cells were diluted with medium to give calculated seeding densities and inoculated into culture flasks. Doubling times were calculated for cells cultured in the presence of 1, 10 and 20% serum and when stilboestrol was added to the culture medium. Morphological changes were recorded by photographing representative areas using a Nikon inverted photomicroscope with phase-contrast optics. Changes in one culture (FDF/Ed) were filmed using a Vinten time-lapse Camera (MK. II) mounted on an inverted microscope. The result of adding stilboestrol and the effect of subsequent washing and change to normal medium was recorded on Ilford FP4 film using intermittent green-light illumination with a lapse interval of one minute per frame.

RESULTS

(1) *Morphological alteration*

In all instances a profound and persistent change in the morphology of the cells was observed within 24 hr after the addition of stilboestrol to the culture medium (Fig. 1). The degree of alteration varied between cultures, being most marked in the fibroblasts derived from chronic cystic disease (CCD) and carcinomas of the breast. To some extent this might be related to the initial appearance of the cells which we have found to be more characteristically fibroblast-like (i.e. elongated, bipolar cells with small oval nuclei) in fibroblastic cultures from chronic cystic disease and cancers than those derived from fibroadenomas of the breast. The latter resemble 3T3 cells more than MRC5's in being more spread out on the substratum. The major morphological features of the stilboestrol-treated cells are that they are more cuboid and resemble epithelial cells: such an alteration is more visually dramatic from an initial bipolar appearance than if the cells are already relatively spread out, and in this sense it might be said that the fibroadenoma fibroblasts have the normal appearance of being partially affected by stilboestrol and this is also true for their growth behaviour (see below). Although the strain of fibroblasts from the axillary tissue was less responsive to stilboestrol than those derived from breast tissue the fact that both MRC5 and 3T3 cells were sensitive to the agent (Table 1) excludes the possibility that in general mammary fibroblasts are differentially sensitive.

Reversibility of morphological change

The reversibility of the effect of stilboestrol addition was shown for cells which were subcultured by trypsinisation and reinoculated into normal culture medium (Fig. 1c). That

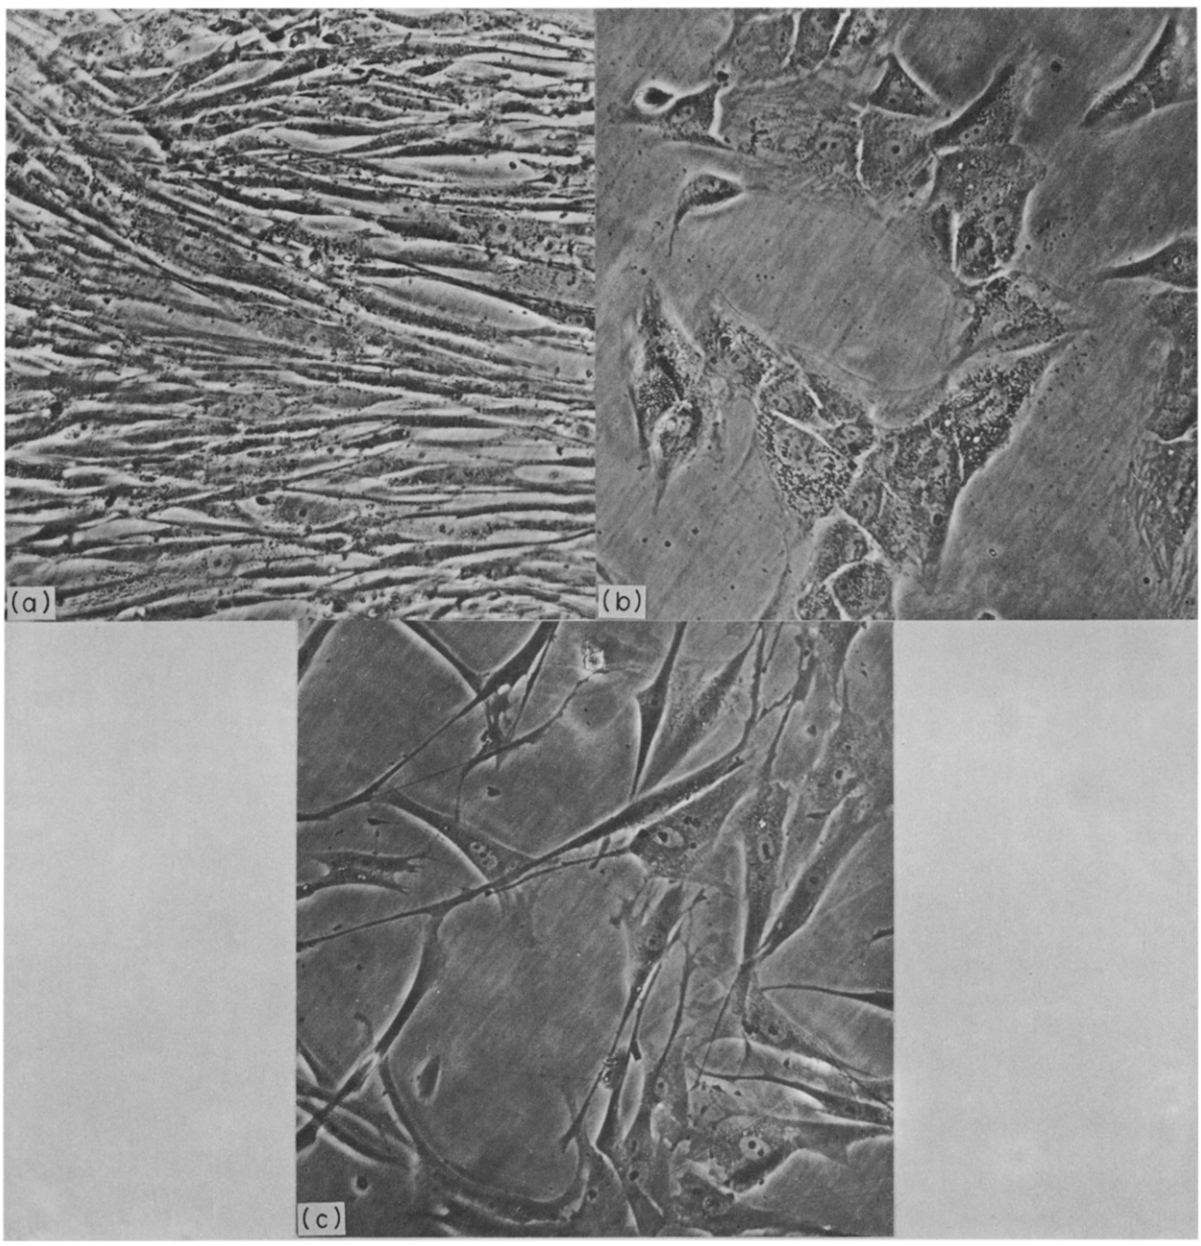

Fig. 1. *Fibroblast culture before* (*a*) *and five days after* (*b*) *stilboestrol addition to the medium. In addition to this obvious change to an epithelial morphology there is increased cytoplasmic vacuolation.* (*c*) *Reversion of cells to fibroblastic shape after trypsinisation and re-inoculation into control medium* 18 hr *after reinoculation.*

Table 1. *Mean shape indices of control and stilboestrol-treated cultures*

Cell strain	Mean shape index (Treatment time in days)		
	Control	+stilboestrol	Post stilboestrol
NDF (9)	11.8	2.7 (1)	4.3 (2)
		1.3 (5)	
		1.4 (8)	
CDF (8)	12.1	2.2 (1)	
		2.0 (8)	3.4 (1)
FDF (6)	8.6	1.9 (1)	
		2.0 (6)	5.5 (1)

The shape index was estimated as described in the text and illustrated in Fig. 2. The numbers in parentheses indicate the numbers of cultures on which observations were made.
NDF = normal breast tissue-derived fibroblast cultures;
CDF = cancer-derived fibroblasts;
FDF = fibroadenoma-derived fibroblasts.

this reversibility was not contingent upon the action of trypsin was shown for cultures which were washed twice with medium after removal of the stilboestrol-containing medium and before the introduction of control medium. This proceedure was also employed in the case of the culture observed by time-lapse cinemicroscopy which showed a rapid return to the usual bipolar fibroblastic morphology.

Rapidity of effect

Changes were observed within 18 hr of addition of stilboestrol and were very marked in all the treated cultures by 48 hr. Examination of the time-lapse film indicated that some reduction in the localisation of the leading lamella occurs in some cells within a few minutes of the addition of stilboestrol. The cells rather gradually assume their final epithelial appearance, although some cells, which seem to be more sensitive, round up and show circumferential blebbing. In growing cultures the cells continued to undergo mitosis normally except that the division products reattached and spread on the culture surface less rapidly than control cultures. To what extent this is the result of competition for space on the culture surface is not clear. Experiments with actinomycin D or cycloheximide present in the medium in concentrations sufficient to inhibit RNA or protein synthesis by more than 95% during stilboestrol treatment showed that the effect of stilboestrol is independent of new synthesis.

Reversibility

The alteration in morphology was found to revert rapidly on withdrawal of stilboestrol. The time-lapse film showed almost total reversal in 30–60 min after washing out the agent.

To try to quantify the major morphological change (i.e. that of the shape of the general outline of the cell) measurements of cell diameters were made and expressed as a ratio of the longest diameter to the orthogonal diameter at its midpoint. This crude shape parameter, illustrated in Fig. 2, gives a measure of the shape change. Mean values for representative cultures are given in Table 1. Some indication of the rates of shape change was obtained by plotting against time the ratio of these measurements made from the projected image of single cells at various intervals (see Fig. 3). Reversal of the morphology was not dependent on RNA or protein synthesis, as shown by the failure of actinomycin D and cycloheximide to inhibit the reassumption of bipolar shape when stillboestrol was removed.

Effect on the doubling time

The overall growth rates of the cultures, assessed by the calculated doubling times were found to be extremely variable for different

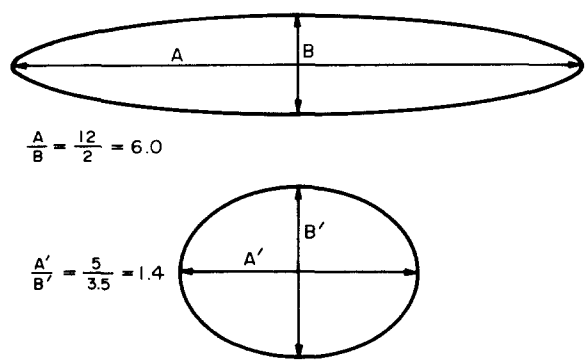

Fig. 2. *Estimation of simple morphological parameter. The ratio of the longest cell diameter* (*A*) *to the diameter orthogonal to it at the midpoint* (*B*) *gives values of* 6.0 *and* 1.4 *for the upper and lower shapes respectively.*

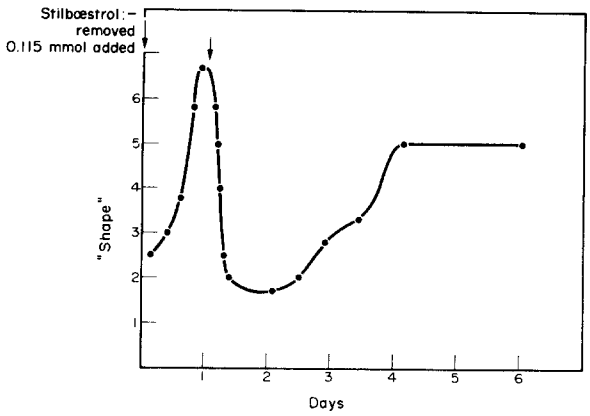

Fig. 3. Shape change of cells exposed to and removed from effects of stilboestrol. Data from time lapse films.

cultures. In general the doubling times for fibroblasts derived from non-tumour material (NDF cultures) were shorter than cancer-derived fibroblast (CDF) cultures. The fibro-adenoma-derived fibroblasts (FDF) included in these experiments grew very slowly. The growth indices (reciprocal doubling times) are tabulated in Table 2 and show that stilboestrol addition to the medium is inhibitory to the growth of the cells. The mitotic rate was lower in treated cultures but part of this effect must be ascribed to loss of cells by displacement from the culture surface giving rise to negative values. Recovery after stilboestrol treatment in the case of cells trypsinised and re-inoculated into fresh medium was found to be less rapid than indicated by the rate of shape recovery in the filmed culture but this may have been due to the fact that the seeding density in these cultures was often of necessity lower than the optimum with resulting lag in the initiation of growth. Reattachment of the cells appeared to occur normally and this was also found in two instances where treated cells were trypsinised and reinoculated in medium containing stilboestrol.

DISCUSSION

Our results show that stilboestrol present in culture medium in a dose of 115 μm produces morphological changes in fibroblasts from several sources. The changes are reversible. The alteration in shape makes the cells resemble epithelial sheets. Since the effect was found to be independent of RNA and protein synthesis we conclude that it is not exerted through an inter-action with specific oestrogen receptors. This view is consistent with the responsiveness of all the tested cells, irrespective of their origin, and also with the failure of the oestrogen antagonist Tamoxifen to inhibit the response. Although it is possible that more than one class of oestrogenic receptor exists, particularly in view of recent reports of uptake of radio-actively labelled oestrogens by the nuclei of myocardial cells [3], specific oestrogen receptors are saturated in the nano- to pico-molar range of oestrogen concentrations [4] whereas the effects which we have observed are detected at much higher doses. Similar findings with oestrogens have been reported by Lippman *et al.* [5] in relation to thymidine incorporation by MCF-7 human breast cancer cells *in vitro*. They found that at concentrations of oestradiol greater than 0.1 μm, thymidine incorporation is inhibited even by the 17-α analogue which does not bind to the oestrogenic receptors. The change in cell shape is associated with a reduction in growth rate and an increase in cytoplasmic vesiculation. It is probable

Table 2. Effect of stilboestrol addition on the generation times of fibroblast strains

Cell strain	Mean growth index		
	Control	+stilboestrol	Post stilboestrol

The growth indices represent the reciprocal of the mean doubling time of the cultures in days. In addition to the cells tabulated in Table 1. there are: 2°CDF = fibroblasts from secondary carcinoma in an axillary lymph node; MBDF = male breast-derived fibroblasts; 3T3 is the Swiss mouse line of fibroblastic cells and MRC5 is a diploid human fibroblastic line.

that these stilboestrol effects are unrelated to oestrogen receptor binding but due to inter-action of the compound with one or several other components of the cell. The hydrophobic properties of steroid hormones and their analogues make it likely that the cell membrane will adsorb significant amounts. Uptake measurements at heptane/water interfaces give a distribution coefficient of 2.3 for diethylstilboestrol indicating a high preference of the compound for a hydrophobic environment and saturation of the interface occurs when the concentration in the aqueous phase reaches about 5×10^4 molar after which there is a linear decline in the interfacial tension [6]. It is possible that in the concentration range we have used it is this detergent effect of stilboestrol which is demonstrated, acting either on the plasma membrane or some protein component of the cells which determines their morphology in monolayer culture. Evidence favouring some membrane effect was obtained by the observation that the addition of hydrocortisone after stilboestrol treatment induced a marked vesiculation of the cells.

Alternatively, the non-specific action of stilboestrol could be exerted through an effect on cytoskeletal elements, particularly in view of its action in inhibiting mitosis. Lettré [7] was the first author to describe the inhibition of mitosis produced by oestrogenic agents on cultures of chick heart fibroblasts exposed to diethylstilboestrol and disodium oestradiol phosphate in concentrations exceeding 40 μg/ml in the culture medium. Since this effect required ten times the dose of α-phenyl-β-(p-methoxy phenyl) ethylamine Lettré suggested that an aminated derivative of oestrogens might be more effective and attempted to show a general structural relationship between adrenalin, colchicine and sterols. The morphological alterations induced by exposing the fibroblasts used in our experiments to colchicine were qualitatively similar to those induced by stilboestrol. We examined transmission electron micrographs of our material which failed to show the usual microtubular structures, but while this is consistent with the view that the reported action of stilboestrol is by a non-specific interference in microtubule assembly it does not constitute proof of the mechanism involved. Since stilboestrol takes several hours to manifest its full effect (i.e. it has a much slower action than colchicine) and the time-lapse film shows cells completing mitosis for up to 12 hr after the beginning of exposure we suggest that stilboestrol may undergo metabolic conversion to a form which affects cell division.

It is highly probable that the effect on the cell membrane or the cytoskeleton which we suggest is an action ascribable to natural steroid hormones as well as synthetic compounds such as Tamoxifen if they are used in pharmacological concentrations. For example, Bishun *et al.* [2] have described what appear to be similar morphological changes in human breast carcinoma-derived fibroblasts grown in a medium containing 18.3 μm 17-β oestradiol.

In our system androgens did not differ from oestrogens in their effect whereas Hsie and Puck [8] have shown a fibroblastic transformation in Chinese hamster ovary cells in the presence of androgens and relate this to effects on cyclic nucleotide concentrations. It is probable that different cell types respond in differing ways to exposure to high concentrations of steroid hormones.

Acknowledgement—We thank Dr. R. J. B. King and Dr. J. Lagnado for helpful discussions. We are grateful to a number of colleagues for their cooperation, in particular Mr. N. O'Higgins of the University College Hospital Breast Unit, and Mr. D. A. Bailey for biopsy material.

Non-Hodgkin Malignant Lymphomas. Clinico-Pathologic Correlations with the Kiel Classification

Retrospective Analysis of a Series of 274 Cases

C. MEUGÉ, B. HOERNI, A. DE MASCAREL, M. DURAND, P. RICHAUD, G. HOERNI-SIMON, J. CHAUVERGNE and C. LAGARDE

Abstract—*Three hundred and sixty case histories of patients followed for non-Hodgkin lymphoma between 1965 and 1976 were reviewed from the histologic point of view for classification according to Kiel's nomenclature. The diagnosis was rectified for 86 patients and confirmed for the 274 remaining ones; these latter cases were classified and their clinico-pathologic and evolutive correlations studied. The most striking fact is a very distinct difference between the so-called low grade forms, which have a non-corrected median survival of four and a half years, whereas in the high grade forms it is 7 months. Except for a few minor differences, the observations noted in this series cross-check those previously published.*

INTRODUCTION

The HISTOLOGIC classification of non-Hodgkin malignant lymphoma (NHML) has been, for a long time, submitted to numerous variations. During the last few years the most frequently used classification has been the one of Rappaport [1]. As for as we are concerned, we have applied this classification for several years without obtaining a distinct clinico-pathologic correlation [2]. We therefore decided to try Kiel's new classification, first proposed by Lennert [3], then by several European pathologists [4] in order to test its validity. This classification was applied, in a retrospective manner, to all cases observed during the last 12 yr; clinico-pathologic and evolutive correlations were particularly investigated. The results of this study are presented in this paper.

MATERIAL AND METHODS

This study included 434 case histories (with histologic documents that could be reviewed) of patients treated and followed up at the Fondation Bergonié for NHML between January 1965 and December 1976.

Seventy-four cases were eliminated due to insufficient material for review (incomplete specimens, tissue sections improperly fixed or too thick, only one slide). Consequently only 360 case histories could be considered.

Throughout the period studied the patients were submitted to the same simple routine investigations according to the recommendations of Rye's symposium for Hodgkin's disease [5] with a complete clinical examination, a thoracic X-ray and tomography of the mediastinum, an abdominal lymphography and the usual biologic investigations. There were no exploratory laparotomies. Bone marrow biopsy was done only when clinical and/or biological data were considered suspicious for bone marrow involvement.

On the other hand, the treatments varied considerably during the period studied, with particular improvement in chemotherapy and more frequent indication of radio-chemotherapeutic associations; but these treatments were never conditioned by the histologic type.

All histologic specimens were examined after routine staining by Hematoxylin-eosin, Gomori, PAS and Giemsa. In all cases the specimen reviewed was the one on which the initial diagnosis was based. The pathologist who reviewed the slides knew the age of each patient and the site of the biopsy.

For 86 patients the initial diagnosis of NHML was modified as indicated in Table 1. For the 274

Accepted 24 October 1977.

cases in which the diagnosis of NHML was confirmed, Kiel's classification was applied (Table 2).

Fifty of these patients had been priorly treated and were taken in charge by the Fondation Bergonié at the time of a relapse; the other 224 were seen as soon as the diagnosis was established, prior to any treatment.

RESULTS

The distribution of the 274 NHML, confirmed by the histologic revision, according to Kiel's classification, is indicated in Table 3. The most important groups of centroblasto-centrocytic (CB-CC) lymphomas could be divided into three subgroups: nodular CB-CC (59 patients); nodular CB-CC with sclerosis (18 patients); diffuse CB-CC (24 patients).

The distribution according to age and sex is shown in Fig. 1. Low grade lymphomas are rarely observed before 30 yr and never before 20 yr; the sex ratio is 1.2.

The distribution by clinical stage prior to any treatment is indicated in Table 4. On one hand the patients are equally divided between stages I and II and stages III and IV. There is no difference according to the histologic type, except for lymphocytic forms where stages III and IV predominate and lymphoplasmocytoid forms where stages I and II predominate.

Table 4 gives the main initial tumoral sites. The frequency of visceral localizations and Waldeyer's ring in lymphoplasmocytoid forms and of mediastinal lesions in lymphoblastic forms, may be pointed out. On the whole, lymph nodes opacified by lymphography, are more often involved in low grade forms than in high grade ones.

During evolution, 19 secondary leukemias were observed; 9 in the LC, 3 in the CB-CC, 7 in the LB and 1 in the unclassifiable.

The distribution of 23 cases with positive Coombs' test and 4 cases with monoclonal dysglobulinemia shows no significant difference.

Table 6. Survival of patients as of April 1st 1977

	Low grade			High grade				
	LC	LP	CB-CC	CB	LB	IB	Unclassifiable	Total
Alive in complete remission	6	11	44	0	7	4	2	72
Alive with evolutive disease	6	5	10	1	2	3	1	28
Dead of lymphoma	4	12	40	1	27	38	8	130
Dead of intercurrent disease	3	2	4	0	0	2	3	14
Dead of undetermined cause	4	1	3	0	3	3	4	18
Total	23	31	101	2	39	50	18	274

The evolution is indicated by uncorrected actuarial survival curves. The state of the patients as of April 1st 1977 is indicated in Table 6. There is a high death rate due to intercurrent causes or to undetermined cause in relation to the old age of many patients. The Figs. 2–5 show a very clear difference between the low grade forms which have a median survival of 4.5 yr whereas that of the high grade ones is of 7 months, closely related to the unclassifiable forms. There is no definite difference between the main subgroups for the high grade (Fig. 3) nor for the low grade (Fig. 4). On the contrary, the subdivision of the CB-CC forms shows a less favorable evolution for the diffuse forms ($0.025 < P < 0.05$) situating them as intermediary between the high grade and the low grade, with a median survival of 2 yr.

Lastly, Fig. 6 shows the evolution of survivals for the 224 patients who received their first treatment at the Fondation Bergonié, in function

of the period of treatment; it demonstrates a moderate but regular improvement, in the results between the beginning and the end of the decade in consideration, comparable in the two main histologic groups.

DISCUSSION

The histologic revision of 360 case histories of patients who had initially been diagnosed as having NHML first led to the exclusion of 84 cases; the diagnosis of these cases has been

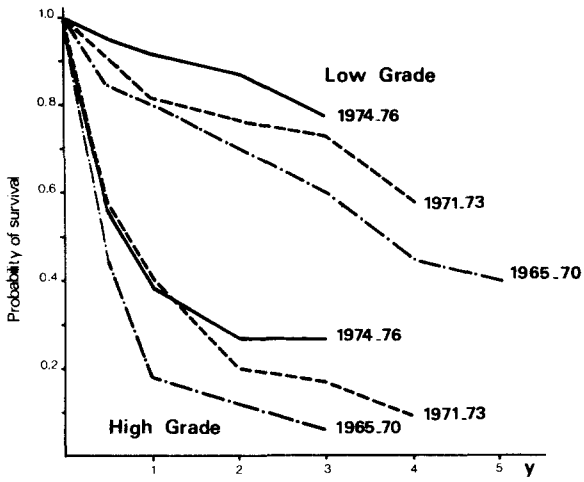

Fig. 6. Crude actuarial survival curves according to the year of diagnosis and first treatment.

modified (Table 1). For forty of them it was really lymph node metastases of undifferenciated carcinoma (anaplastic carcinoma, oat cell carcinoma of the lung, nasopharyngeal carcinoma) or even thymona, melanoma, seminoma, embryonal sarcoma or neuroblastoma. These diagnostic readjustments were largely facilitated during the second reading by the routine use of special stains and, in particular, slow staining Giemsa; this stain only weakly colors metastatic cells, while the cytoplasm of the lymphoid elements are generally bluish or dark blue.

The good technical quality of the sections and the stains is the first condition necessary in order to reduce classification difficulties. Kiel's classification is sufficiently explicit to avoid problems in the large majority of the cases. There may be some hesitations between LC, LP or diffuse CB-CC types, or between LB and IB types; however, there is rarely a hesitation between low grade and high grade forms. Each of these two main groups is characterized by definite cytologic criteria which are based on the size of the cellular elements and their nucleus, the staining characteristics of the cytoplasm, the outline of their nucleus (round, clived, convoluted) the character of their chromatin and the presence or absence of nucleolus, their size and number [3].

The main criticism which can be attributed to our work lies in the fact that the slides were read by only one pathologist. It would have been preferable, of course, to have the slides read by two or three different pathologists.

Our results may be confronted with those previously published concerning the same histologic classification [6–9].

We have thus observed a relatively higher proportion of high grade forms in comparison with most of the other series. The distribution according to sex and age for each histologic subgroup is, on the contrary, comparable in all series. All forms are more frequent in elderly patients. Low grade forms were not observed in children. For the high grade forms, the distribution of the LB is bimodal with two peaks, one around 20 yr and another around 70 yr, while the frequency of the IB increases with age.

It is more difficult to compare the distribution by stages; in other series, there was a pathologic staging according to Ann Arbor Symposium [10], whereas we have used a clinical staging according to Rye Symposium [5]. This fact explains why we have almost as many I and II stages as III and IV stages, whereas in other series stages III and IV clearly predominate.

In all series, the correlation between evolution and histology demonstrates a very significant difference between the low grade and the high grade forms. This difference is more striking in our series than in preceding ones. In all series the CC have a prognosis slightly less favorable than the other low grade forms. The difference, which is especially distinct, between the nodular CB-CC and the diffuse CB-CC is significant in our series. This difference had not previously been observed by the German investigators, but appears here particularly important. In contrast with other data [11], there is no difference in our series between survival of patients with nodular CB-CC, with or without sclerosis. Like Brittinger *et al.* [8], we did not observe a difference between LB and IB, while Musshoff *et al.* [7] observe a more favorable evolution for the LB than for the IB. At last, in all series the survival regularly decreases for the low grade forms, while it has a tendency to stabilize after an initial rapid deterioration for the high grade ones. This tendency which begins to appear in our series is particularly evident in the one of Dühmke and Quäck [9] in which the two curves meet at 10 yr.

As far as we are concerned, this classification gave us a histoprognostic correlation which was much more interesting than the one obtained with Rappaport's classification [2]. It is close to the one independently proposed by Lukes [12] and indicate two very distinct categories of NHML for which a different therapeutic attitude must be proposed. The evolution, very different between these two types of NHML effectively calls for a treatment adapted to the gravity of the disease [13]. Only the subgroup of diffuse CB-CC lymphomas has an intermediary prognosis but it represents less than 10% of the patients (24/274). The group of histologically unclassifiable cases shares the poor prognosis of the high grade forms.

Consequently, our results confirm that Kiel's

classification is useful in indicating the prognosis and guiding the treatment of NHML. The question as to whether these results are reproducible remains unanswered. The convergence of the main series of different teams published until now seems to indicate that this reproducibility is good; however, only studies presently underway involving comparisons between several pathologists will shed more light on this subject.

Abstract—*Forty-one benign and malignant ovarian tumors and* 12 *normal ovaries were studied immunologically, with extracts of gastric mucosa as reference, in the presence of antimucosa antisera, adult gastric antipepsinogens (anti Pg* I-II, *anti Pg* III *and anti Pg* IV) *and fetal gastric antipepsinogens (anti Pg* IV).

Pepsinogens were identified in 7 *out of* 24 *benign tumors, all of the mucinous type and in* 1 *out of* 17 *malign tumors. Pepsinogen secretion did not occur in normal ovaries.*

The potentiality of pepsinogen synthesis by tumoral ovaries was the same as that of other antigens of the gastric or intestinal type as recently found in the same tumors. This potentiality did not seem to be linked to the malignancy of the tumors studied.

INTRODUCTION

ANTIGENS of the gastric or intestinal type are known to exist in benign and malignant tumors. Tachibana in 1929 and Cariker-Dockerty in 1954 identified "intestinal enzymes" in ovarian tumors. Antigens common to the intestine were also found in ovarian tumors by McNeil *et al.* [1], Nairn *et al.* [2], and Marchand *et al.* [3]. More recently, Bara *et al.* [4] reported common antigenicities between gastric mucoproteins and mucinous ovarian cysts.

According to Evans [5], the histogenesis of ovarian tumors involves a unilateral endodermic development at the expense of multipotential cells capable of giving rise subsequently to the intestinal tract. This known histogenic multipotentiality prompted us to look for gastric pepsinogens in normal and tumor-bearing ovaries. The immunochemical materials and the immunoelectrophoretic and catalytical nomenclature used in our study of pepsinogens has been described previously [6–8].

MATERIAL AND METHODS

Forty-one ovarian tumors of the adenocystic type or solid were studied from material obtained surgically; they included 24 benign tumors and 17 malignant tumors (See Tables 1 and 2).

Accepted 25 October 1977.

Twelve histologically normal ovaries, taken from women 35–75 yr of age were studied concomitantly as controls. (Eight ovaries were from women 35–48 yr of age and 4 ovaries from women 48–75 yr of age.)

(A) *Preparation of the ovarian extracts*

(a) *Tumoral extracts and normal control extracts.* Soluble extracts were prepared by homogenization of the tissues with demineralized water in an Ultraturrax, ultracentrifugation for 20 min at 25,000 rev/min at +4°C and lyophilization of the supernatants.

(b) *Adenocystic secretions.* Intracystic fluids were centrifuged at 25,000 rev/min at +4°C for 20 min and the supernatants were lyophilized. The protein concentrations of the lyophilized extracts, as determined by the biuret reaction, varied between 20 and 40 mg/ml according to their solubility. We used both the secretion fluids and whole-tumor extracts of the 31 tumors of the secreting type. The histological nature of the tumors was studied systematically.

(B) *Reference Material (Gastric pepsinogens)*

*Extracts of gastric mucosa (M*1). These were obtained from the normal looking areas of material removed surgically, according to a procedure described earlier [7]. They contained the 3 pepsinogens which we have defined according to their decreasing electrophoretic mobilities, their antigenicity in the presence of anti-gastric mucosa (normal) antisera, and their optimal proteolytic activities at pH 2.0:

Fig. 4. *The immunochemical relationship of the Pg* III *pepsinogen in the gastric mucosa* (M_1) *the seminal plasma (S) and in a mucinous ovarian tumor extract (Ov.). Antiserum. antiseminal plasma anti Pg* III.

Antisera. For the anti-human pepsinogen antisera, we used: 1-anti-M1 (adult) antiserum (AM1) obtained against the 3 gastric pepsinogens, 2-anti-fetal gastric mucosa antiserum (AMF) obtained against pepsinogen Pg IV (or fetal Pg) [8], 3-anti-human seminal fluid (ALS) which reacted strongly only against gastric pepsinogen Pg III.

Methods

Standard microimmunoelectrophoresis on gelose (DIFCO) and two-dimensional immunoelectrophoresis were used systematically. The bidimensional migrations were made in 1% agarose (Indubiose IBF, Gennevilliers, France) and in a 0.02 M veronal buffer at pH 8.2. For the first dimension, migration occurred for 2 hr under a continuous current of 30 mA and 6V/cm at +4°C. Migration during the second run was for 18 hr in a gel containing 2 and 3 ml of antiserum (according to the experiment) and under 2.5 mA and 2V/cm at +4°C.

The plaques were examined for proteolytic activity of the pepsin type after they were washed (24 H) in buffered physiological saline at pH 7.4 and dried. The films of gel were incubated in a substrate of 1.0% bovine albumin serum (ICN Biochemicals, Cleveland, U.S.A.) in 0.2 M HCl-glycine buffer at pH 2.0. After 30 min at room temperature, the samples were incubated at 37°C for 30 min and fixed in 5% acetic alcohol for 30 min. The proteolytic activities were observed after coloration with Amidoschwarz (hydrolysis bands were clear), Figs. 1–3.

RESULTS

The results are summarized in Tables 1 and 2 and in the Figs. The proteolytic activities of pepsin and the immunochemical identification of the pepsinogens were noted in 8 of the 41 ovarian tumor extracts studied. Seven of these cases were non-degenerated tumors of the mucinous type. The 8th case was a primary papillary germinative epithelioma.

Identification of the pepsinogens in the secreting tumors was more frequent in the secretions than in extracts prepared from the solid tumoral part: of the 7 cases with positive cysts, pepsinogens were identified only twice in extracts from the solid material.

In the 12 ovarian extracts of the normal controls, as well as in the secreting tumors of the serous type, no precipitin bands of pepsinogen or pepsin activity were detected.

Studies by double immunodiffusion (Ouchterlony) allowed us to observe the antigenic similarities first between the gastric pepsinogens and seminal fluid and then between the ovarian constituents. (Fig. 4).

Nature of the pepsinogens identified

The 3 pepsinogens of the normal gastric mucosa were present simultaneously only in 2 cases of non-degenerated tumors: 1 enteroid cyst and 1 dermoid cyst that were partially mucoid. Two other cysts contained 2 pepsinogens at the same time. In the 4 other cases, only a single pepsinogen was evident. Pepsinogen Pg III was found most often (7 out of 8 times). Pg I–II was found 4 times and Pg IV 3 times. The degenerated tumor contained only Pg I–II (see above).

DISCUSSION

From the above results it appears that ovarian tumors are at times capable of synthesizing pepsinogens. These pepsinogens are identical with those of the gastric mucosa, as observed from their electrophoretic and catalytic immunological characteristics [6, 7]. Three facts should be emphasized:

1. The identification of the pepsinogens was most frequent in non-degenerated ovarian tumors: in 7 out of 24 non-degenerated tumors and only 1 out of the 17 ovarian cancers studied. It is also possible that only the benign part of the cancer produced the pepsinogens. (Fig. 3). All the non-degenerated tumors containing the pepsinogens were of the mucinous cystic type.

2. Identification of pepsinogen Pg III was particularly frequent (7 out of 8 times). Pepsinogen Pg IV, which we identified earlier as the principal fetal pepsinogen [8], was identified only 3 times. In the gastric cancers and in the gastric metaplasia of the intestinal type studied earlier, the same fetal pepsinogen was constantly present while pepsinogens Pg I–II and Pg III were decreased or absent.

3. A seminal pepsinogen was reported earlier by Lundquist and Seedorf in seminal fluid [9]. We found it to be identical with Pg III of the gastric mucosa [10]. In this work, we were able to determine the immunochemical identity of the Pg III pepsinogens of the gastric mucosa, seminal fluid and ovary. It should be noted that Pg III did not exist in the normal ovaries studied. As for the seminal fluid, it has not been possible to explain the role and the mecanism of appearance of a precursor of pepsin (active at very acid pH) in the alkaline media which represent the cystic secretions of ovarian origin. Our

studies on the synthesis by the tumoral ovary of constituents having a gastric antigenicity may be compared to the work of J. Bara *et al.* [4] who identified high molecular weight glycoproteins that were common to the normal gastric mucosa in mucinous cysts of the ovary.

Similarities between the antigenic groups of the gastro-intestinal tract and the tumoral ovary was shown by McNeil *et al.* [1] and Stone *et al.* [11] who detected carcinoembryonic antigens (CEA) in cancers of the ovary. Nairn *et al.* [2] identified antigens of the intestinal type in sections of cystic adenomas using immunofluorescence. This work was confirmed by Marchand *et al.* who identified CEA in the ovarian adenocarcinomas of the mucinous but nor serous type [3].

More recently, Bara *et al.* [4] identified a sulfoglycopeptide normally associated with the caliciform cells of the colic mucosa, in 5 mucinous tumors of the ovary.

In our patients, the appearance of pepsinogens in the tumoral ovary seemed less frequent than the findings of CEA by others in tumors of the ovary. Moreover, the presence of pepsinogens does not appear to be linked to the idea of malignancy, since their frequency was much greater in non-degenerated tumors.

Glucose Metabolism in British and Japanese Breast Carcinomas

N. DESHPANDE, IRENE MITCHELL, ROSEMARY MILLIS* and S. KUMAOKA†

*Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX, England, *Hedley Atkins Unit, New Cross Hospital, London, SE15 5ER and †National Cancer Centre, Tokyo, Japan*

THE INCIDENCE of breast cancer in Japan is significantly lower than in Western countries [1, 2] and, furthermore, the survival rate in Japanese patients is better than in their Western counterparts [3, 4]. Attempts have been made to explain these differences on the basis of endocrine status as measured by concentrations of hormones and their metabolites in body fluids [5, 6]. However, no major differences were observed between the two populations. As far as Japanese cancer patients are concerned, the urinary titres of androgen metabolites, the amounts of oestrogen receptor in the neoplasm and responsiveness to endocrine treatment is similar to that in British or American patients [7, 8].

Despite similarities in endocrine status, there are certain histopathological differences between Japanese and Western tumours in that the incidence of medullary carcinomas with lymphoid stroma is significantly higher in Japanese patients [9] and there is more intense infiltration of other carcinomas by plasma or lymphoid cells [4, 10, 11]. This, and the higher frequency of sinus histiocytosis noted in the axillary lymph nodes of Japanese patients [10, 11] has led to the postulate that both transformation of the normal cell to incipient carcinoma and of incipient to invasive carcinoma may be related to host resistance which results in the differences observed in prognosis. Whether these pathological differences are reflected in alterations in biochemical processes such as glycolysis, is not known and a comparative study between carcinomas from Japanese and Western patients might give further insight into the findings. Therefore, an attempt was made to estimate the activities of certain enzymes in Japanese carcinomas and to compare them with tumours from British patients.

The details of enzymes, co-enzymes and substrates used in the study are described in detail elsewhere [12]. Primary breast carcinomas were obtained from 22 Japanese and 49 British women undergoing mastectomy. The Japanese tumours were kept on cardice during transport to Britain and remained frozen until further processing. The malignancy of tumours was confirmed by histological examination. The tissues were cleared of any surrounding fat, weighed and cut into small pieces. The semi-frozen tissues were then homogenised in a Silverson homogeniser according to the procedure of Shonk and Boxer [13]. The homogenates were centrifuged (800 ***g*** for 15 min) at 4°C, the cytosol fraction was decanted off and used as a source of enzymes. A 5% solution of tumours was used in these estimations. The activities of α-glycerol-phosphate dehydrogenase (α-GPDH), glucose-6-phosphate dehydrogenase (G6PDH), phosphofructokinase (PFK), 6-phosphogluconate dehydrogenase (6PGDH), phosphoglucomutase (PGM), lactate dehydrogenase (LDH) and phosphohexose isomerase (PHI) were measured. Enzyme assays were performed in a Beckman recording spectrophotometer according to the procedure of Shonk and Boxer [13], with the exception that one minute readings were recorded automatically for 5 min and a mean of the last four was taken as an average change in optical density. Deoxyribonucleic acid (DNA) was estimated according to the procedure of Burton [14]. The results were calculated on the basis of units (U) of enzyme activity per milligram of DNA. A unit is defined as that amount of enzyme which will catalyse the transformation of 1 μmole

Accepted 10 October 1977.

of substrate per minute. The results are presented as mean ± S.D. (Table 1). The means were tested for significance by a Student's *t*-test.

Table 1. *Enzyme activities* (μmole *of pyridine nucleotide reduced or oxidised*/min/mg *of DNA*) *in British and Japanese tumours*

Enzyme	U/mg DNA British	Japanese
PFK	0.033 ± 0.019*	0.101 ± 0.073
G6PDH	0.077 ± 0.042*	0.281 ± 0.213
6PGDH	0.084 ± 0.048†	0.046 ± 0.021
PGM	0.892 ± 0.542	0.871 ± 0.543
LDH	3.820 ± 1.930	4.017 ± 2.261
α-GPDH	0.168 ± 0.116*	0.079 ± 0.062
PHI	4.955 ± 2.481	5.380 ± 2.986

They are expressed as mean ± S.D.
*Significant differences between the two groups $P < 0.001$.
†Significant differences between the two groups $P < 0.01$.

Our results from this pilot study show that there are certain similarities between enzyme activities in breast carcinomas from Japanese and British patients. The activities of PGM, LDH and PHI were similar in the two groups. Assuming that results expressed in terms of DNA measurements cancel out any cellularity differences between two groups of tumours, it appears that the rates of glycogen breakdown and lactate production are similar in both groups. In contrast, significantly higher PFK and G6PDH and lower 6PGDH and α-GPDH activities were observed in the Japanese tumours. The higher activities of PFK in these tumours could indicate increased activity of the whole glycolytic sequence. Whereas lower α-GPDH activities suggest decreased exchange of substrates between lipid and carbohydrate metabolism at this point. Whether these differences in enzyme activities correlate with either prognosis or the histopathological differences mentioned in the introduction remains to be explored.

Letters to the Editor

Improvement of Therapeutic Effects of Cytosine-Arabinoside on Walker-Carcinosarcoma after Different Synchronization with Hydroxyurea

JÜRGEN MATTERN, KLAUS WAYSS and MANFRED VOLM

German Cancer Research Center, Department of Experimental Pathology, Im Neuenheimer Feld 280, 6900 *Heidelberg, Federal Republic of Germany*

VARIOUS studies have reported that the therapeutic results of various cytostatic agents are improved after partial synchronization of animal and human tumours [1, 2]. Some authors have questioned, however, whether these improved therapeutic results are really due to a partial synchronization of the tumour cells or whether the results might not be explained by the combination therapy with a particularly favourable timing for the application of the substances [3, 4]. In earlier experiments we demonstrated that drugs with activity for specific phases of the cell cycle gave better therapeutic results if they were given at a certain phase of the cell cycle. Thus cytosine arabinoside (Ara-C), hydroxyurea (HU) and vincristine (VCR) produced better therapeutic effects on the Walker-carcinosarcoma after partial synchronization (with HU) if these drugs were given at the G_1/S border or S-phase [5].

To test if these improved therapeutic results are really due to a partial synchronization of tumour cells, we chose for synchronization two different experimental models:

1. Application of 6 × 50 mg/kg HU (Fig. 1 left, top) [5]. The blockage at the G_1/S border lasted 8.5 hr and ended 1.5 hr after the last application of HU.
2. Application of 1 × 300 mg/kg HU (Fig. 1 right, top). The blockage lasted 4 hr.

At specific times after the last HU-application the synchronized and non-synchronized animals with solid Walker-carcinosarcoma (transplanted s.c. in the skin of the back 4 days before synchronization) were treated with 1 × 400 mg/kg Ara-C i.p.

The tumour size was measured between the 1st and 3rd day after treatment using a movable gauge and its daily growth was determined (Fig. 1 bottom). As is evident, the effects of therapy with Ara-C can be related to the single phases of the cell cycle. With the two different procedures of synchronization the clearest effect of therapy is obtained at the G_1/S border. As compared with the non-synchronized animals, no better effects of therapy on the synchronized animals can be demonstrated in the G_2-phase and M-phase. These results agree with those of Persohn *et al.* [6] who could demonstrate with a synchronized human lymphoma cell line that the uptake of radioactive Ara-C is greatest during the early S-phase and declines steadily.

The results of these experiments indicate that the improved therapeutic effects of Ara-C are in fact due to the synchronization of the tumour cells.

Accepted 12 October 1977.

EDITORIAL

Pergamon Press—Statement on the New U.S. Copyright Law for Editors, Authors and Contributors

IN 1978 a new Copyright Law became effective in the U.S. and one of the results is that journals published by Pergamon Press will be asking authors for copyright on each article. How this has come about and why it is important to all of us, requires an explanation.

Traditionally, a transfer of copyright from authors to the publisher or society owning a journal was assumed to be implicit in the process of submitting a manuscript and getting it refereed and accepted for publication. In each journal issue, a copyright notice was printed and was taken to apply to the journal issue as a whole and to each article in it separately. Armed with this understanding, the publisher could not only publish the journal but could distribute reprints of separate articles, authorize others to reprint selectively or cover-to-cover, negotiate translation rights, authorize indexing and abstracting services to use material from the journals, authorize free fair-use copying by individuals and libraries, produce and market microform editions of the journals, etc. All of this has been done successfully by Pergamon in the spirit of actively advancing and diffusing the knowledge contained in its journals.

The new 1978 U.S. Copyright Law changes the situation in at least three important respects. First, it vests statutory copyright in each individual article with the authors of that article, or with their employers in the case of a "work made for hire". This copyright can now be transferred only in a formal written manner. The submission of a manuscript for publication without a formal transfer gives the publisher only the right to publish it as part of the entire issue of the journal in printed and other formats.

The second major change in the U.S. law: The copyright of a journal issue which the publisher registers formally with the Register of Copyrights and which he prints on the inside of the front cover of the journal, under the new law, applies only to the issue as a whole and not to the articles separately. In order for an article to be covered separately, a copyright notice will have to appear on the first page of the article and this requires a transfer of copyright to Pergamon from the author. Otherwise, for each future republication use, each of the original authors would have to give written permission. This would be extremely cumbersome and would clearly inhibit the whole current information distribution system.

The third major change in the U.S. law affecting journals is a much more rigorous definition of the conditions under which libraries may make photographic copies. Individuals or non-profit libraries acting for them will still be free to make copies of articles for their use in research and teaching. However, for commercial libraries and microfilm services the limits of copying are severe; without clear authorization from the copyright holder, distribution through these channels simply cannot legally take place. This obstructs the information distribution system.

Therefore, journals require a transfer of copyright in order to allow for a continuation of the methods that have been used in the past for the dissemination of scientific information. Thus, a transfer of copyright agreement for each article will be required of each author and you are requested to sign the accompanying form and return it to your editor. The author will continue to hold all other traditional rights. For example, there are proprietary rights other than copyright such as patent rights; by definition, these are not transferred. We mention this explicitly since many people confuse patent rights with copyright. It will continue to be an explicit part of our permissions policy that anyone who wishes to *reprint* charts, graphs, etc. from an article will need only the author's permission. For reprinting complete articles, permission of the publisher *only* is required.

Finally, the author retains the right to use the article in his or her future works—for example to include it in a reprint volume. Naturally, authors as individuals will also have fair-use privileges for research and teaching. These points will be covered in the new copyright notice published in the cover of the journal.

Although your journal is not published and edited in the U.S., nevertheless a substantial proportion of the authors and subscribers operates under U.S. law. Since, by convention, copyrighting in the U.S. is automatically applicable in most other countries, the safest plan is to copyright under the U.S. provisions, which are now amongst the most stringent.

We hope you will understand the necessity of our taking action to protect copyright of the material published in our journals, and thereby achieve maximum dissemination of your work.

Robert Maxwell, Publisher
PERGAMON PRESS

Notice on inside front cover of journal

"The appearance of the code on the first page of an article in this journal (serial) indicates the copyright owner's consent that copies of the article may be made for personal or internal use, or for the personnal or internal use of specific clients. This consent is given on the condition, however, that for copying beyond that permitted by Sections 107 or 108 of the U.S. Copyright Law, the copier pays the per-copy fee included in the code. The appropriate remittance should be forwarded with a copy of the first page of the article to the Copyright Clearance Centre Inc., PO Box 765, Schenectady, NY 12301. This consent does not extend to other kinds of copying such as copying for general distribution for advertising or promotional purposes for creating new collective works or for resale. Copies of articles published prior to 1978 may be made under similar conditions."

Tumor Associated Lymphocyte Cytotoxicity Correlated with Stage of Disease in Patients with Colon Adenocarcinoma

*A Preliminary Report**

PATRICK J. GANNON, E. DOUGLAS HOLYOKE and MARTIN H. GOLDROSEN†

Tumor Immunology Group, Department of Surgical Oncology, Roswell Park Memorial Institute, 666 Elm Street, Buffalo, New York 14263, U.S.A.

Abstract—*Whole lymphocyte populations and T and non-T subpopulations from 22 colorectal carcinoma patients (8 preoperative; 6 postoperative disease free; 8 postoperative residual disease) and 6 control Stage III melanoma patients were tested in parallel on a colon cell line (P-4788) and a melanoma cell line (M-7292). All three effector populations from the four patient groups were cytotoxic on both cell lines. Within the different donor groups, the unfractionated lymphocytes from preoperative colon patients displayed significantly greater cytotoxicity than the Stage III melanoma patients on the colon cell line. Conversely, the Stage III melanoma patients displayed significantly greater cytotoxicity than the postoperative disease free colon patients on the melanoma cell line. Furthermore, the unfractionated lymphocytes and non-T subfraction from preoperative and postoperative disease free colon carcinoma patients showed significantly stronger cytotoxic effects on the colon cell line than on the melanoma cell line. These two lines of evidence suggest that both tumor associated cytotoxicity and spontaneous or non-selective cytotoxicity are present; and the presence of tumor associated cytotoxicity is dependent on the stage of the disease. Furthermore, thr level of cytotoxicity associated with both postoperative colon carcinoma groups was lower than the preoperative colon carcinoma groups. However, this depression was not evident in subfractions of lymphocytes that demonstrated apparent tumor associated cytotoxicity and thus may reflect a decline in general immune competence.*

INTRODUCTION

CELL-MEDIATED immunity to human tumors is estimated by the *in vitro* lymphocytotoxicity assay [1–3]. In recent years, however, extensive testing has revealed cytotoxic reactivity by normal individuals [4] and lack of histological type specific reactivity in cancer patients (spontaneous or non-selective cytotoxicity) [5]. Furthermore, selective enrichment of T and non-T subpopulations of lymphocytes by rosetting techniques have indicated that T-cell peripheral blood lymphocyte enriched fractions are more cytotoxic than T-cell depleted fractions from patients with melanoma [6] and colon carcinoma [7]. However, in another recent melanoma study, cytotoxic reactivity was found to be associated with the non-T cell fraction [8].

These contradictory findings imply that still another factor with regard to differential cytotoxicity may be involved. These studies have not adequately looked at the effect of disease status as an added factor of variability on associated cytotoxicity. Different tumor bearing states or the stage of disease may dictate the relative contribution of different effector cell mechanisms. This has been demonstrated with Maloney sarcoma virus induced tumors [9, 10]. Consequently, a study was undertaken to see if differences in cytotoxicity could be related to disease status, particularly with regard to selectively enriched lymphocyte subpopulations in patients with colon adenocarcinoma.

MATERIAL AND METHODS

Colon patients

Twenty-two colorectal carcinoma patients were tested. The ages ranged from 40 to 81 yr with

Accepted 16 September 1977.

† To whom reprint requests should be sent.

an average of 65 yr. Eight Dukes D patients were tested preoperatively. Two postoperative groups included 6 patients with no evidence of disease (Dukes B and C) and 8 patients with residual metastatic disease (Dukes D). All postoperative patients in this study were evaluated at least two weeks post-surgery.

Melanoma patients

Six Stage III melanoma patients were used as controls for histological specificity. These patients were receiving chemotherapy for metastatic disease but were tested prior to treatment.

Target cells

RPMI-4788, an established colon carcinoma cell line, was used as the principle target cell: HCT-8, an established colon carcinoma cell line and RPMI-7292 (M-4), an established amelanotic cell line, were used as indicators of histological specificity. All cells were propagated as monolayer cultures in RPMI-1640 with 15% fetal calf serum (FCS) with penicillin and streptomycin. Cells were harvested for testing with 0.25% trypsin and 0.25% EDTA.

Lymphocyte preparation

Lymphocytes were separated from EDTA-anticoagulated whole blood on a double discontinuous Ficoll–Hypaque gradient with modifications to selectively remove platelets and monocytes [11]. All cell populations used had greater than 95% viability as assessed by trypan blue and consisted of greater than 94% lymphocytes as assessed by Wright's stained differential of cytocentrifuge cell preparations.

T and non-T cell preparation

T-cell rosettes were formed as follows: 1 ml of 1% sheep red blood cells (SRBC) washed (×5) in normal saline was added to 1×10^7 lymphocytes and these suspensions were centrifuged at 200 ***g*** for 3 min. The resulting pellets were refrigerated at 4°C, usually overnight, to allow (T) rosettes to form. Pellets were disrupted by gentle Pasteur pipetting and the number of (E) rosettes was quantitated by microscopic counting. Counts averaged between 40 and 60% (E) rosettes. The resulting T and non-T cells were separated by layering an aliquot of the rosette cell suspension on 3 ml of Ficoll–Hypaque (s. g. 1077) and spinning at 400 ***g*** for 20 min. Non-rosetted cells stay at the interface and rosetted cells pellet. All three subsequent cell populations, whole, T and non-T were treated with Boyle's solution for 5 min to lyse SRBC's and then were pelleted and washed twice in RPMI-1640. Homogeneity of effector cell populations was monitored by immunofluorescence and T-cell rosetting. By these two criterion, the rosetted fractions (T-enriched) contained approximately 80% T-cells while non-T fractions (T-depleted) contained 50–60% B cells with less than 10% contaminating T cells.

Microcytotoxicity test

The microcytotoxicity test was performed as described by Takasugi and Klein [12]. The lymphocytes were tested in ratios of 100, 75 and 50 per target cell and each was tested in six replicates. Residual target cells attached to the bottom of the test wells were enumerated by a semi-automated technique devised by this group [13]. In this assay, mean percent cytotoxicity is 1 minus the ratio of the mean number of target cells in the presence of lymphocytes to the mean number of target cells in the absence of lymphocytes (medium control). To simplify the presentation of data, the results of Table 1 are presented as a mean target cell reduction calculated according to the method of Takasugi *et al.* [5] utilizing the following formula:

$$\text{Mean } \% \text{ reduction} = \frac{A+B+C}{3}$$

Where

A = Mean % cytotoxicity at E : T ratio 100 : 1
B = Mean % cytotoxicity at E : T ratio 75 : 1
C = Mean % cytotoxicity at E : T ratio 50 : 1

The Mann–Whitney U-Test was used to compare experimental groups. A P value of less than 0.05 was considered significant.

RESULTS

Lymphocytes (whole, T and non-T) from colorectal patients and melanoma patients showed cytotoxic effects of all three effector to target cell ratios and on both target cell lines. The cytotoxicity observed with both T- and non-T effector cells was similar to the cytotoxicity observed with the whole lymphocyte population. No significant observations were obtained when the cytotoxic effects of whole, T- and non-T lymphocytes from colorectal and melanoma patients were compared. However, when the colorectal patients were divided into subgroups on the basis of disease status, significant observations could be made between different subgroup effector populations on the same cell line, as well as between the same subgroup effector population on different cell lines.

In a comparison of different subgroup effector populations on the same cell line (Table 1),

Table 1. Mean percentage of cytotoxic effects of lymphocytes from colon carcinoma and malignant melanoma patients on established colon and melanoma cell lines

Whole effector cells	Colon	P*	Melanoma
Colon carcinoma patients			
Preoperative	90.2	0.05	67.6
Postop. disease free	65.4	0.05	51.1
Postop. residual disease	64.1	NS	57.6
Melanoma patients stage III	66.6	NS	66.3
Non-T effector cells			
Colon carcinoma patients			
Preoperative	72.2	0.05	59.3
Postop. disease free	65.2	0.05	47.6
Postop. residual disease	49.2	NS	55.0
Melanoma patients Stage III	68.8	NS	60.0
T effector cells			
Colon carcinoma patients			
Preoperative	80.6	NS	81.8
Postop. disease free	49.4	NS	45.1
Postop. residual disease	48.5	NS	55.8
Melanoma patients Stage III	58.0	NS	42.5

* Statistical comparison of cytolytic ability of the same effector cells on histologically distinct target cells. Comparison between effector cells on the same target cell is presented in the text.

preoperative colon carcinoma patients were significantly more reactive than Stage III melanoma patients on the colon cell line ($P < 0.05$). In contrast, these two groups of patients displayed the same degree of cytolysis on the melanoma cell line. Furthermore, the Stage III melanoma patients were significantly more reactive than the postoperative disease free group on the melanoma cell line ($P < 0.05$). In contrast, these two groups gave the same degree of cytolysis on the colon cell line.

In a comparison of the same subgroup effector population on different cell lines, the whole effector cells from both the preoperative and postoperative no evidence of disease group were more cytotoxic on the colon cell line than the melanoma cell line ($P < 0.05$). In contrast, the same degree of cytotoxicity was observed on both cell lines with the postoperative residual disease group and the Stage III melanoma group. Furthermore, this pattern of cytolytic activity was mirrored by the non-T cell subpopulation And not by the T-cell subpopulation.

In addition, it was observed that the whole effector cells from the preoperative group were more cytotoxic than either of the postoperative groups (Table 2). This difference was most pronounced in the T-cell subpopulation, but was also observed with the non-T effector cells from the postoperative residual disease group.

Table 2. Degree of reduction in percentage of cytotoxicity preoperative vs postoperative†*

Clinical status	Effector cells		
	Whole	T	Non-T
Postoperative residual disease	28.9%	39.8%	31.8%

† On colon carcinoma target cells.

DISCUSSION

The purpose of this study was to evaluate disease status as a factor influencing tumor associated cytotoxicity. Initially, the cytotlytic ability of effector cells from normals, colon patients and melanoma patients was evaluated on two established colon adenocarcinoma cell lines (P-4788, HCT-8) and one control melanoma cell line. The cytolytic ability of normal effector cells from various age groups varied considerably [14] and, thus, precluded their use as a control group. As a similar pattern of cytotoxicity was observed on both HCT-8 and P-4788 cell lines, the HCT-8 cell line was dropped in favor of testing a larger group of patients.

No significant results were observed when the cytotoxic effects of lymphocytes from colorectal and melanoma patients were compared. However, by comparing the cytolytic ability of the different patient subgroups (preoperative, postoperative disease free and postoperative residual disease) on the same cell line and the same patient subgroup on the two histologically distinct cell lines, it appeared that both tumor associated cytotoxicity, as well as spontaneous or non-selective cytotoxicity could be detected. Thus, in trying to assess the presence of tumor associated cytotoxicity, it is important not only to take into account the type of disease the patient has, but also the stage of the disease.

A similar pattern of differentially stronger cytotoxicity was observed with lymphocytes from Stages I and II melanoma patients on a melanoma cell line, in comparison to a bladder carcinoma cell line [15]. Thus, both studies are in accordance with the concept of tumor associated cytotoxicity superimposed on spontaneous cytotoxicity. Furthermore, it is evident from this study that both T- and non-T effector cells demonstrated spontaneous cytotoxicity. However, tumor associated cytotoxicity appeared to be associated with the non-T effector subpopulation. Contradictory findings about subpopulation lymphoid activity have been reported in the literature. O'Toole *et al.* [16] and de Vries *et al.* [8] reported that tumor associated cytotoxic activity could be recovered in the non-T effector population with bladder carcinoma and malignant melanoma patients, respectively. In contrast, Wybran *et al.* [6] and Nind *et al.* [7] reported that the tumor associated cytotoxic activity could be recovered in the effector subpopulation. It may be noted that in the former group, rosetted cells were treated with Boyle's solution to lyse the sheep red blood cells, whereas in the latter group, the rosetted fraction was not treated with Boyle's solution, but sheep red blood cells were added to the non-rosetted fraction to obtain the same cell density. Any effects of ammonium chloride treatment on cell-mediated immune reactivity are not well characterized at present.

Whole, T- and non-T effector cells from postoperative colon carcinoma patients with residual disease and Stage III melanoma patients displayed the same degree of cytolysis on the two cell lines. The cell-mediated antitumor immune response of Stage III melanoma patients has been previously characterized. De Vries *et al.* [15] reported that lymphocytes from Stage III melanoma patients displayed the same degree of cytotoxicity on the melanoma cell line and on a control bladder carcinoma cell line. Furthermore, Marti and Thomson [17] demonstrated a markedly decreased response by Stage III melanoma patients in a leukocyte adherence inhibition test in comparison to Stage I melanoma patients. Thus, our observations are in accordance with the above studies.

Colon adenocarcinoma patients were monitored before and after surgery. After surgery, there was a reduction in the level of cytolysis, both with the lymphocytes from patients with residual disease, as well as from patients who were clinically free of disease.

Several studies [18–20] have reported on a depression of the cell-mediated immune response following surgery. However, their studies were conducted one to two weeks after surgery. The patients included in this study were evaluated a minimum of two weeks after surgery. Thus, surgery may have a long-term immunosuppressive effect. However, it is also important to note that the greatest immunosuppressive effect was associated with the subpopulation of effector cells that did not appear to demonstrate tumor associated cytotoxicity. Consequently, surgery may depress the patients' general immune competence, but not the patients' ability to generate a tumor specific immune response. While this data is suggestive of tumor associated cytotoxic reactivity being present during some but not all stages of colon carcinoma, it is imperative that a larger study be carried out with additional patients and a larger number of cell lines so that definitive statements with regards to tumor specific reactions can be made. Furthermore, this study should evaluate the cytolytic effects of normal healthy volunteers so that spontaneous or non-selective cytotoxicity will be defined both as the lack of histological type specific reactivity in cancer patients, as well as the cytotoxic effects of normal donors. This information is necessary to interpret the observed decline in the cell-mediated immune response following surgery.

Effect of Antiestrogen Therapy on Human Mammary Carcinomas with Different Estrogen Receptor Contents*

HELENA WESTERBERG,† BO NORDENSKJÖLD,† ÖRJAN WRANGE,‡ JAN-AKE GUSTAFSSON,‡ SOLVEIG HUMLA,† NILS OLOF THEVE,§ CLAES SILFVERSWÄRD and PER-OLA GRANBERG¶

†*Department of Oncology, Radiumhemmet, Karolinska Hospital, S-104 01 Stockholm 60,* ‡*Department of Chemistry, Karolinska Institutet, S-104 01 Stockholm 60,* §*Department of Surgery, Sabbatsbergs Hospital, S-113 82 Stockholm,* ‖*Department of Tumour Pathology, Karolinska Hospital, S-104 01 Stockholm 60 and* ¶*Department of Surgery, Karolinska Hospital, S-104 01 Stockholm 60 Sweden*

Abstract—*Sucrose gradient centrifugation analysis was used to measure estradiol receptor levels in 35 patients with inoperable or recurrent mammary carcinomas that were subsequently treated with the antiestrogen tamoxifen (Nolvadex ICI). Carcinomas from eighteen patients demonstrated specific estradiol binding. Twelve of these patients responded to therapy. Seventeen patients had tumors without measurable estradiol binding. One of these responded to therapy. Tumors binding less than approximately* 0.1 fmole *of estradiol per* μg *DNA demonstrated a low response rate to tamoxifen* (1/26).

Electrofocusing of the estradiol receptor at pH 6.6 *in polyacrylamide gel was found to be a quantitative and very sensitive method for the measurement of the estradiol receptor content in mammary carcinoma. Sixteen patients had their tumors analyzed with electrofocusing and all demonstrated some specific estradiol binding. The amount of estradiol binding in tumors from responders to tamoxifen or ovariectomy was approximately* 20 *times greater than the amount bound in tumors from non-responders.*

We conclude that there exists a positive correlation between the amount of specific estradiol binding in human mammary carcinomas and their response to subsequent antiestrogen therapy.

INTRODUCTION

SEVERAL lines of evidence have shown that many human mammary carcinomas are estrogen dependent. (1) Many breast cancers contain specific estrogen receptors [1]. (2) About one third of the human mammary carcinomas respond to alteration in estrogen concentration induced by oophorectomy, adrenalectomy or additive estrogen therapy [1]. (3) A strong correlation has been established between estrogen receptor content and the response to these types of therapy [1]. (4) Human breast cancer cells replicating *in vitro* may be stimulated by estrogen or inhibited by antiestrogen [2].

A positive correlation has been demonstrated between the amount of estradiol binding in mammary carcinomas and their probability of response to various types of endocrine therapy [3].

This report purports to explore the correlation between the quantity of estrogen receptors and the response to antiestrogen therapy. Moreover, we will give some further information on the correlation between the response to ovariectomy and the quantity of estrogen receptors.

MATERIAL AND METHODS

Patients and tumours

Fifty-one tumor samples from 43 women with advanced mammary carcinoma were analyzed prior to therapy. The samples were obtained from eleven inoperable breast cancers, 27 subcutaneous metastases and five lymph node metastases.

Accepted 25 October 1977.

*This work was supported by the Swedish Cancer Society, by Cancerföreningen i Stockholm and by Lotten Bohmans fond.

Therapy and evaluation

Thirty-five postmenopausal women received 20 mg orally twice daily of the antiestrogen tamoxifen (ICI-46 474; NSC-180 973). Eight premenopausal women were treated by oophorectomy.

Only patients with measurable soft tissue disease were included in the study. The criteria for evaluation were previously described [4] and these specify that remission had occurred when the sum of the products of the two largest tumor diameters had decreased by 50 %.

Measurement of estrogen receptor

Surgical biopsies were provided by two of us (POG) and (NOT) and immediately transferred to the laboratory in icecold saline. They were trimmed of fat and normal tissue and analyzed immediately or frozen at −70°C. The incubation of fresh or quickly thawed carcinomas with ^{3}H-estradiol and the receptor quantification using sucrose gradient centrifugation were previously described [6].

Recently we have improved the electrofocusing procedure for measurement of estradiol binding in human mammary carcinomas [5]. The method is based on the focusing of the partially trypsinized estradiol receptor in polyacrylamide gel at pH 6.6. It is more specific and more sensitive as compared to sucrose gradient analysis and it is not dependent on parallel incubations with excess ligand [5]. Comparison of twenty-five mammary carcinomas that were receptor positive with both sucrose gradient analysis and electrofocusing assay (not illustrated) yielded an average of 2.1 times higher specific estradiol binding values as compared to sucrose gradient analysis. These higher values are probably explained by the facts that the electrofocusing is much more rapid and minimises ligand dissociation and that all receptor material is quantitatively recovered in a sharp peak of radioactivity [5].

RESULTS

Sucrose gradient analysis and results of endocrine therapy

Figure 1 compares specific estrogen binding as measured by sucrose gradient analysis and results of therapy. The binding varied between 0.03 and 3.3 fmole/μg DNA.

Twenty-two patients did not respond to tamoxifen. Six of them had tumors with detectable estradiol binding and one non-responder demonstrated a high binding capacity of 0.7 fmole/μg DNA. Thirteen patients responded to therapy (6 complete and 7 incomplete responders). Twelve of these 13 patients had "receptor-positive" tumors while, in 1 tumor, we were unable to measure the binding. The amount of estradiol binding in the "positive" tumors from responders to tamoxifen varied within wide limits (0.16–3.3 fmole/μg DNA) and there was no obvious difference in binding between complete responders and incomplete responders respectively.

Previous results with patients treated with ovariectomy have demonstrated that receptor-negative patients infrequently respond to endocrine therapy. Our data in Fig. 1 are in accordance with that interpretation.

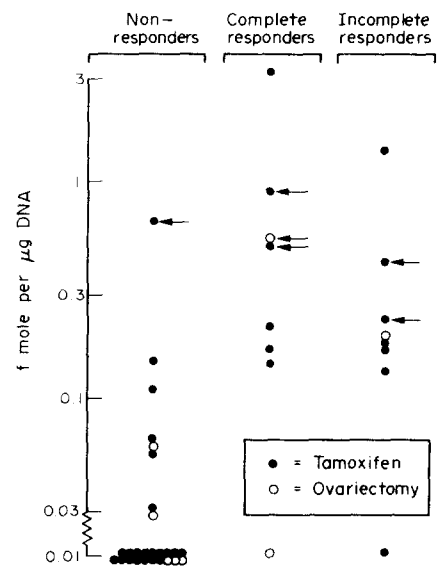

Fig. 1. Estradiol binding as determined by sucrose gradient analysis and response of therapy. Biopsies were removed from mammary carcinomas subsequently treated with tamoxifen (●) or ovariectomy (○). Estradiol binding for each patient in three different response categories is indicated. Arrows indicate tumors with estrogen receptor sedimenting as an 8S complex.

Electrofocusing analysis and results of endocrine therapy

Figure 2 compares specific estradiol binding, as measured by electrofocusing and results of treatment with tamoxifen or ovariectomy in 16 patients.

Tumors from all 16 patients demonstrated some binding. The non-responders bound 0.01–0.23 fmole/μg DNA while tumors from seven responders bound 0.07–1.0 fmole/μg DNA.

DISCUSSION

The antiestrogens bind to the cytoplasmic estrogen receptor in targent cells and are probably transported into the nucleus [7]. The

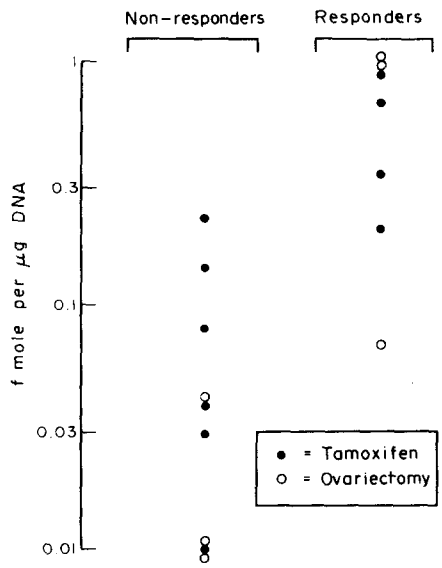

Fig. 2. Estradiol binding as determined by electrofocusing and response to tamoxifen or ovariectomy.

exact intranuclear mechanism of action remains unclear but it is obvious that binding to the estrogen receptor is necessary for biologic action of antiestrogen.

Recent reports indicate that response to antiestrogen therapy only occurs in tumors with estrogen receptors [8].

With several types of endocrine therapy most investigators observed an increased response rate among receptor positive carcinomas [1]. Some investigators using sensitive technique that classified approximately 80% of the mammary carcinomas as "receptor-positive" did, however, report a poor response rate among positive tumors [9–10]. It was therefore suggested that the quantity of receptor per unit tissue should be taken into account and that the labelling of all tumors with specific estradiol binding as "receptor-positive" is not meaningful [9–10].

When this work was initiated we considered sucrose gradient analysis to be most adequate for quantitative analysis. Using this technique we found that 12 out of 13 tumors from responders to tamoxifen bound 0.16–3.3 fmole estradiol per μg DNA while two out of 22 non-responders demonstrated specific binding within this range. This difference is highly significant ($P<0.1\%$). We therefore interpret the data in Fig. 1 to mean a strong correlation between estradiol binding in mammary carcinomas and their response to tamoxifen therapy. Estradiol binding below 0.1 fmole/μg DNA as measured by sucrose gradient analysis does not appear to be associated with an increased response rate to tamoxifen. Two patients were marked exceptions to this pattern. One incomplete responder had a negative tumor and one non-responder had a tumor with significant binding. There are several possible explanations to these exceptions including receptor inactivation in the non-binding tumour or inadequate selfmedication by the non-responder with a strongly binding tumor.

The electrofocusing method used in recent analysis is more sensitive than sucrose gradient analysis and detected some specific binding in all sixteen patients illustrated in Fig. 2. Most tumors from non-responders demonstrated only small amounts of receptor focusing in the pH 6.6 region and the median binding with the non-responders was 0.04 fmole/μg DNA as compared to a median of 0.8 fmole for responders.

Electrofocusing yields average specific estradiol binding values about twice as high as sucrose gradient analysis. We therefore interpret our data in Figs. 1 and 2 to mean that estradiol binding less than 0.2 fmole/μg DNA as measured by electrofocusing is not associated with a clinically significant response rate to tamoxifen. It should, however, be realized that estradiol binding data should be interpreted with caution. Several factors influence the data including deterioration of the receptor during tumor handling [11], differences in receptor level in different parts of the same tumor [11], differences in tumor cellularity and *in vivo* blockade of the receptor by circulating estradiol [12].

It has been suggested by Wittliff *et al.* [13] that part of these difficulties in quantification may be overcome if only the estradiol receptor sedimenting as an 8S complex in sucrose gradients is considered significant. Our data in Fig. 1 do in fact demonstrate that the 8S complex indicated with arrows was exclusively demonstrated in tumors with high specific binding capacity. However, several patients with gratifying remissions demonstrated only 4S receptor in their tumor. The presence of 8S receptor complex is an indirect measure of high specific binding capacity. This information may also be obtained with other methods such as electrofocusing and since we think that electrofocusing offers better quantification we have selected this method for receptor quantification in a prospective study in which the value of prophylactic tamoxifen therapy is explored in operable mammary carcinomas with defined receptor levels.

Association of Carcinoembryonic Antigen (CEA) and Influenza Antigen

CHRISTIAN SAUTER,* MORAG ELLISON† and JEAN LINDENMANN‡

* *Division of Oncology, Department of Medicine, University of Zürich,* 8091 *Zürich, Switzerland,* †*Unit of Human Cancer Biology, Ludwig Institute for Cancer Research (London Branch) in conjunction with the Royal Marsden Hospital, Sutton, Surrey, SM2 5PX, England and* ‡*Division of Experimental Microbiology, Institute for Medical Microbiology, University of Zürich,* 8028 *Zürich, Switzerland*

Abstract—*An avian influenza A virus (FPV) was adapted to human bronchial carcinoma cells containing carcinoembryonic antigen (CEA) at their surface. Influenza hemagglutinin and CEA were physically associated at the level of the cell membrane. In the envelope of the mature FPV particle no substantial amount of CEA could be found. The important fraction of viral oncolysates for immunotherapeutic purposes—where an association of tumor associated and viral antigens is required—thus appears to be the cell membrane fraction. These experiments show furthermore that a cell surface constituent can be attached to erythrocytes by influenza virus hemagglutinin. This attachment by hemagglutinin might be an interesting tool for experimentation with other cell surface constituents.*

INTRODUCTION

AUGMENTATION of the immunogenicity of tumor cells by infection with viruses has been shown in several systems [1–4]. Enveloped viruses were used for this purpose, since the association of viral and tumor-associated antigens (TAA) at membrane sites is apparently important for such augmentation [5]. The experiments described in this report were undertaken to see whether this association occurs mainly at the cell membrane or in the viral envelope. An answer to this question is important in the preparation of viral oncolysates for immunotherapeutic trials such as the one being carried out by the Swiss group for clinical cancer research in acute myelogenous leukemia [6].

In this paper we demonstrate that a physical association of carcinoembryonic antigen (CEA) and influenza hemagglutinin (HA) takes place. This association is found mainly at the level of the cell membrane.

A human bronchial carcinoma cell line which produces CEA [7] was infected with avian influenza A virus. This system was chosen for several reasons:

1. Cells: these cells contain CEA at their surface (Ellison and Robertson, unpublished observation), the location where influenza viruses are budding. In addition, CEA is the most intensely studied human tumor-associated antigen and it can easily be measured [8, 9].
2. Virus: the hemagglutinating antigen of influenza A virus is a surface antigen and can readily be determined.
3. An avian influenza A virus (FPV) was chosen since its replicative ability in human tumor cells was known [10–14].

MATERIAL AND METHODS

Cells, CEA determination, virus

The bronchial carcinoma cells (BEN) and the methods of CEA determination have been described previously [7,8]. The fowl plague virus (FPV; A/Turkey/England/63, Hav 1, Nav 3, Langham strain) which we used in these experiments had the following passage history: obtained from H. G. Pereira, World Influenza Centre, Mill Hill, London, England, after four allantoic passages; the virus was adapted to grow in human epithelial tumor cells, the last passage being in a primary culture of a human bronchial carcinoma [10].

FPV replication in BEN cell monolayer cultures

The replication of FPV in BEN cell monolayer cultures (as shown in Fig. 1) was carried out in the following way: A 25 cm^2 Falcon plastic flask (Falcon Plastics, Oxnard, Calif.) containing a monolayer of BEN cells was washed twice with 5 ml of Eagle's minimum essential medium (MEM). One third of a milliliter of a FPV suspension (for starting titer, see Fig. 1) was then added. The infected culture was incubated for 20 min at 36°C

with agitation every 5 min for virus adsorption. MEM, 4.67 ml, with 2% fetal calf serum was then added and incubation continued. The supernatant was removed (and replaced by 5 ml of fresh medium) at 4, 24, 48, 72 and 96 hr of incubation. The removed samples were put into sterile glass ampoules and stored at −80°C until infectivity titration could be performed.

Virus infectivity assays. Hemagglutinin determinations

Virus infectivity assays were carried out in Falcon 3040 microplates containing chicken embryo fibroblast monolayer cultures. The monolayers were infected with 0.1 ml of serial 10-fold dilutions of virus in MEM without serum. Six holes per dilution were used. After 5 days of incubation at 37°C the monolayers were checked for cytopathogenic effect. Holes with incomplete destruction of the monolayers were tested for hemagglutinin. The 50% tissue infectious dose ($TCID_{50}$) was calculated according to Reed and Muench [15]. The hemagglutinin titrations were effected using WHO standard procedures. Values are given in hemagglutinating units (HAU).

RESULTS

After two passages in BEN cells the infectivity titers of FPV in BEN cells reached almost 10^8 infectious particles per ml after 96 hr of incubation (Fig. 1) whereas the hemagglutinin titer reached 160 HAU/ML. FPV replication was as good as in chicken embryo fibroblast monolayer cultures [10]. The FPV therefore appeared to be optimally adapted to grow in BEN cells.

In a first experiment FPV infectivity, FPV HA, and CEA were determined in the 1000 g culture supernatant at different points in time. As seen in Table 1, CEA content did not differ in supernatants of FPV infected cultures from that in uninfected control cultures.

Since in this first experiment there was no obvious association of mature FPV (i.e. FPV which had left the cell) and CEA, centrifugation and hemadsorption experiments were undertaken to see whether there was an association at earlier stages of FPV development. By 2000 g centrifugation the bulk of cell bound viral antigen was separated from mature viruses. Table 2 shows that substantial amounts of FPV-HA (77%) and of CEA (58% in FPV infected cultures, 40% in control cultures) were sedimented at 2000 g. By further centrifugation of the 2000 g supernatant at 50,000 g (see Table 3) the infectivity and the hemagglutinin could again be concentrated (40 × and 100 × respectively). The CEA concentration on the other

Table 2. FPV infected and control BEN cell cultures (after incubation for 75 hr). FPV infectivity, FPV hemagglutinin, and CEA before and after low speed centrifugation (2000 g)

control culture	—	—	21 ×

Four 75 cm^2 Falcon plastic flasks containing monolayers of BEN cells were infected with $10^{2.5}$ $TCID_{50}$ of FPV, whereas the monolayers of the other two flasks served as controls. Each flask contained 15 ml of MEM with 2% fetal calf serum. After 75 hr of incubation at 36°C the flasks were put at −20°C until the content was frozen. After thawing there were no cells attached to the plastic bottle any more. The content of the two virus infected flasks as well as the one of the two control flasks was pooled and centrifuged at 2000 *g* for 30 min at 4°C. Infectivity, hemagglutinin, and CEA were determined in the supernatants and the sediments. The numbers given in the Table are total amounts of $TCID_{50}$ (log_{10}), HAU and CEA (μg) per two 75 cm^2 Falcon flasks.

Table 3. FPV infected and control BEN cell cultures (75 hr of incubation). FPV infectivity, FPV hemagglutinin and CEA before and after high speed centrifugation (50,000 g)

	$TCID_{50}$	HAU	CEA
Before 50,000 *g* centrifugation (after 2000 *g*)

Times concentrated by 50,000 *g*			
FPV infected culture	40 ×	100 ×	4 ×
control culture	—	—	1.04 ×

The 2000 *g* supernatants obtained as described in the legend to Table 2 were centrifuged at 50,000 *g* for 60 min at 4°C. Infectivity, hemagglutinin and CEA were determined in the supernatants and the sediments. The numbers given in the Table represent the total amounts of $TCID_{50}$ (log_{10}), HAU and CEA (μg) per two 75 cm^2 Falcon plastic flasks.

Table 4. FPV infected and control BEN cell cultures. Adsorption to and release from human erythrocytes of FPV hemagglutinin and CEA of the 2000 g sediment

		HAU	CEA
FPV infected			
2000 *g* pellet:	before adsorption to erythrocytes	20,480	39
	after adsorption to erythrocytes	1600	27
	adsorbed to erythrocytes	18,800	12
	released from erythrocytes (after 37°C)	12,640	4
Control			
2000 *g* pellet:	before adsorption to erythrocytes	—	39
	after adsorption to erythrocytes	—	41
	adsorbed to erythrocytes	—	0
	released from erythrocytes (after 37°C)	—	0

2000 *g* sediments were obtained as described in legend to Table 2. One milliliter of virus infected or control sediments were mixed with 9.0 ml MEM with 2% fetal calf serum containing 3.2×10^9 washed human 0 Rh negative erythrocytes. This mixture was kept at 0°C for 60 min with gentle agitation every 10 min. Thereafter the erythrocytes were spun down at 100 *g* for 15 min at 4°C. Nine milliliters of the supernatant were then carefully removed for HA and CEA assays. To the remaining 1.0 ml which contained the 3.2×10^9 erythrocytes 9.0 ml MEM with 2% fetal calf serum were added. These 10 ml were then incubated at 37°C for 60 min with gentle agitation in a water batch. Afterwards the erythrocytes were centrifuged again at 100 *g* for 15 min at 4°C. Released HA and CEA were determined in the supernatant.

The numbers given in the Table represent total amounts of HAU and CEA (μg).

hand did not increase very much in the 50,000 *g* sediment (4× for the FPV infected cultures, 1.4× for the control cultures).

These centrifugation experiments suggest a physical association of FPV–HA and CEA in the 2000 *g* sediment. If this were the case then CEA of this fraction of the FPV infected cultures and not of the control cultures should—by the action of the viral hemagglutinin—adsorb to erythrocytes and—through the viral neuraminidase—be released again from erythrocytes. Two thousand *g* sediments and 2000 *g* supernatants of FPV infected and control cultures were therefore mixed with human erythrocytes. The results of such an adsorption and release experiment with 2000 *g* sediments are shown in Table 4. From the pellet of FPV infected material 31% of the CEA was adsorbed to erythrocytes whereas from the control pellet none was adsorbed. After incubation of the erythrocytes at 37°C one third of the CEA was released again from the red cells which had been in contact with the FPV infected material. No CEA was released from erythrocytes which had been mixed with uninfected control material. In the 2000 *g* supernatants, no CEA adsorption to erythrocytes could be detected either with the FPV infected or with the control material.

DISCUSSION

Previous work from this laboratory showed adaptation of an avian myxovirus (FPV) to different human tumor cells [10–14]. In the present report we have demonstrated that this virus can also be adapted to grow in a human bronchial carcinoma cell line (BEN). Since these cells contain CEA at their surface we were in a position to examine if there was a physical association of CEA and viral antigen during the budding process of the virus. Low speed centrifugation of viral oncolysates (i.e. virus-destroyed tumor cells) where most of the cell membrane fragments sediment indicated an association of viral HA and CEA at the cell membrane (Table 2). This association was confirmed by hemadsorption (Table 4). Concentration of free FPV but almost no concentration of CEA by ultracentrifugation (Table 3) suggested a lack of CEA and HA association in the envelope of mature FPV. The slight concentration of CEA achieved by 50,000 *g* with the virus infected material (Table 3) might have been due to residual membrane fragments not sedimented at 2000 *g*. Our results accord with the results of immunization experiments where it was shown that membranes [16] but not purified viruses [17] from virus infected tumor cells protected animals against challenge with viable tumor cells.

In conclusion: fowl plague virus hemagglutinin and carcinoembryonic antigen (CEA) are physically associated at the level of the cell membrane. In the envelope of the mature FPV particle no substantial amounts of CEA were associated with viral HA. Immunoelectron

microscopic experiments which we are undertaking at present will show whether there is any CEA at all in the envelope of FPV grown in BEN cells.

These experiments may have the following consequences:

1. The important fraction of the viral oncolysate for immunotherapeutic purposes where an association of tumor-associated and viral antigens is required, appears to be the 2000 ***g*** sediment, which contains most of the cell membranes. Preparation of viral oncolysates on a large scale for clinical studies [6] could therefore be simplified by avoiding ultracentrifugation for collecting mature virions if other tumor-associated antigens behave similarly to CEA.
2. The association of CEA with influenza virus hemagglutinin allows the attachment of CEA to the surface of erythrocytes. Attachment of cell surface constituents to erythrocytes might be useful for the study of such constituents including the detection of immunological reactions against them.

Sequential Studies of Melanoma Leukocyte-Dependent Antibody Activity in Melanoma Patients*

P. HERSEY, A. E. EDWARDS, E. MURRAY, W. H. McCARTHY and G. W. MILTON

Kanematsu Memorial Institute and Melanoma Unit, Department of Surgery, University of Sydney, Sydney Hospital, Sydney, Australia

Abstract—*Sequential assays of leukocyte dependent antibody (LDA) activity against melanoma cells were carried out on melanoma patients with localized tumour growth before and after surgical removal of their tumour. In approximately a third of the patients, LDA activity appeared in their sera after surgical removal of their tumour and this showed a gradual decline over several months. The absence of melanoma LDA in their sera prior to surgery appeared to result from the presence of serum blocking factors against LDA in their sera prior to surgical removal of the melanoma. Melanoma LDA in the pre-surgery sera, could be shown by removal of blocking factors by gel chromatography procedures and the "unblocked" LDA appeared specific for melanoma cells. In a second group of patients, no LDA activity was seen and a third group showed high levels which were present before surgery and showed no significant decline after surgical removal of their melanoma. The second group of patients were mainly males who also had a high incidence of regional lymph node involvement whereas the third group were all multiparous women. The present data do not allow evaluation of the prognostic significance of these respective patterns of LDA activity.*

The results indicate the melanoma LDA can be detected in a high proportion of patients at an early stage of tumour growth. They confirm our previous findings of blocking factors against melanoma LDA in patients with disseminated melanoma and establish that the LDA blocking activity has biological significance in relation to tumour growth in melanoma patients.

INTRODUCTION

ANTIBODY dependent cell mediated cytotoxicity (ADCC) induced by leukocyte dependent antibody (LDA) has now been described against a number of tumours in experimental animals [1–6] and against several tumours in human subjects, such as bladder carcinoma [7], leukaemia cells [8] and melanoma cells [9–11]. We have recently shown that LDA against melanoma cells can be shown in the sera of melanoma patients and that several different antigens can be defined on melanoma cells by these assays which show limited cross-reactivity between melanoma cells from different individuals [11]. It was also found that in patients with disseminated melanoma, LDA activity was often completely blocked by factors in their sera and that the frequency of LDA in melanoma patients may therefore be much higher than that revealed by assay of their unfractionated sera [12, 13].

In the present study, the incidence of melanoma LDA in patients with early melanoma was examined and sequential studies were carried out before and after surgical removal of melanoma to detect any changes in this antibody activity related to the change in disease activity induced by surgery. Our results showed that several patterns of LDA activity were observed in melanoma patients. One pattern appeared related to the disappearance of blocking activity against LDA in the sera of melanoma patients after surgery and changes in LDA activity induced by these factors appeared to correlate with clinically determined melanoma growth in these patients.

MATERIAL AND METHODS

1. *Patients*

The study included 13 female patients and 20 male patients who presented to the Melanoma Unit for surgical removal of primary melanoma (Stage 1) or melanoma localised to regional lymph nodes (Stage 2). Pertinent clinical data on these subjects is shown in Table 1. Control sera were obtained from four normal laboratory workers and serial samples were taken from eight patients with malignancies other than melanoma who were admitted for surgical removal of their tumour.

2. ^{51}Cr-*release assays*

The assay procedures used have been described in detail in previous reports [11, 13] and are described briefly below.

(i) *Target cells* (*TCs*). Melanoma cells from the continuous human line MM 200 were used as the main target cell in these studies. This cell line, as well as other melanoma lines used in the study, were kindly supplied initially by Dr. J. Pope of the Queensland Institute of Medical Research. These cell lines, including the melanoma antigens expressed on their surface, have been described previously [11]. Autologous studies were carried out on melanoma cultures established from fresh surgical specimens, as described previously. The non-melanoma tumour cultures were also established from fresh surgical specimens and

T = trunk; H = head and neck; L = leg; A = arm; stage 1 = primary melanoma; stage 2 = primary melanoma + regional lymph node involvement; stage 3 = disseminated melanoma; D = dead.
*Figures in parentheses indicate duration to first recurrence when surgery was for second recurrence.

were treated as described for the melanoma cultures. All cultures were grown in RPMI 1640 (Gibco) supplemented with 20% foetal bovine serum (FBS) (Australian laboratory services batch 42) and were harvested by incubation with 0.25% Trypsin for 15 min immediately prior to use.

(ii) *Effector cells.* Mononuclear cells were obtained from defibrinated blood samples by centrifugation on Hypaque–Ficoll mixtures of specific gravity 1.078 after methods described by Boyum [14]. All sera were tested with effector cells from both the patient and normal laboratory personnel. The cells were re-suspended in RPMI 1640 + 10% FBS at a concentration of 10^6/ml for use in the assays.

(iii) ^{51}Cr *labelling.* TCs were labelled with ^{51}Cr by incubation with 100 μCi of Na_2CrO_4 (Amersham, Bucks, UK) for 2 hr. The cells were washed twice in 25 ml of Eagles minimal essential medium (MEM) (CSL Melb.) and resuspended in RPMI + 10% at a concentration of 10^4/ml for use in the assays.

(iv) *LDA assays.* Sera were assayed for LDA by addition of 100 μl at the dilutions indicated to cultures containing 5×10^3 TCs in 500 μl. This was followed by the addition of 5×10^5 effector cells in 500 μl. The cultures were in duplicate 12 × 75 mm round bottomed plastic tubes (Sterilin, Filtrona, Melbourne), which were capped and incubated overnight for 16 hr at 37°C in 7% CO_2 in air. Assays were terminated by centrifugation for 7 min at 400 ***g*** and 500 μl of the supernatant were removed for estimation of ^{51}Cr release. Samples were counted in an automatic Wallac 1280 gamma counter.

The percentage of the ^{51}Cr release was estimated by the formula

$$\frac{a \times 2.2}{a+b} \times 100$$

where $a = {}^{51}$Cr counts in the supernatant background counts and b = counts in tube with remaining supernatant and cells-background counts. Results are expressed as percent ^{51}Cr release above or below the baseline ^{51}Cr release from the TCs in the presence of the effector cells alone. (This level of cell mediated cytotoxicity (CMC) varied from subject to subject and has been discussed previously [15].

3. *Gel exclusion chromatography*

Whole sera were separated into several fractions on the basis of molecular size using Sepharose CL-6B (Pharmacia) in a column 2.6 × 70 cm, (type k26/70), (Pharmacia). Two milliliters of whole serum was applied to the column and eluted with 0.5 ml saline in Sorensen's glycine buffer at pH 2.8 containing 0.02% Sodium Azide by upward flow at a rate of 0.5 ml/min at 4°C. Fifty fractions of 6 ml each were collected.

Ultraviolet (u.v.) absorbance of the fractions was measured at 280 nm on a Unicam SP1800 u.v. Spectrophotometer and the fractions were pooled into 4 groups according to molecular size, on the basis of chromatogram results. The large molecular weight (mol. wt) fractions were concentrated back to 2 ml in an Amicon Diaflo cell, using a PM10 membrane and the small mol. wt fraction using a UM-2 membrane. They were then dialysed twice against 500 ml 0.9% NaCl. Immunoglobulins in each were identified by immunodiffusion on Tri-Partigen Plates (Hoechst).

Statistical analysis

Student's *t*-test was used to compare the percent of ^{51}Cr release of cultures with and without LDA activity and findings were considered significant when $P < 0.05$.

RESULTS

1. *Patterns of melanoma LDA activity in sera from melanoma patients*

In Fig. 1 the effect of adding serum from subject DT taken before and 10 days after surgery, to cultures of the MM 200 TC and effector cells from DT is shown. Before surgery serum at a 1/10 dilution had slight blocking activity of the direct CMC. After

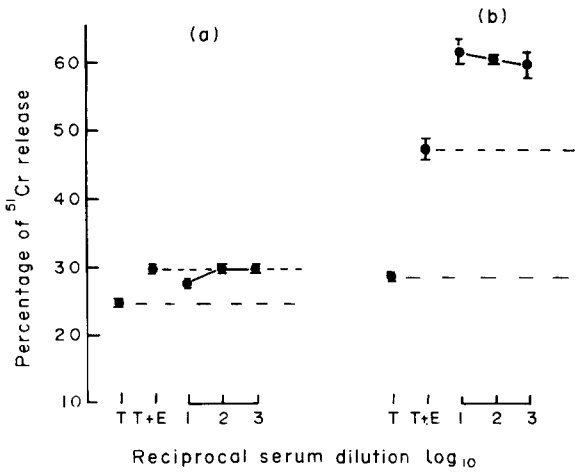

Fig. 1. Serum LDA activity and serum blocking of spontaneous CMC of subject DT (a) before and (b) 10 days after surgery. T = spontaneous release from MM 200 TCs alone. T+E = ^{51}Cr release from TC due to spontaneous release and direct CMC of effector cells. Values above this line indicate LDA activity in the serum and values below this line indicate blocking of the spontaneous CMC. Values are means ± 1 standard error (S.E.).

surgery the serum had LDA activity to a titre exceeding $1/10^3$. The direct CMC of DT was also increased after surgery. The appearance of melanoma LDA activity after surgery was seen in 12 of the 33 patients in the study and the results at a single dilution of serum at various time periods after surgery, is shown for 10 of these patients in Fig. 2. (Each serum was tested at three dilutions, as in Fig. 1, but for clarity only the activity at the 1/10 serum dilution is shown in Fig. 2 and 3). Sera from these patients taken prior to surgery had no LDA activity and sometimes had blocking of the spontaneous CMC of the effector cells. By 2–4 weeks after surgery, LDA activity was detectable in their sera and this activity showed a gradual reduction over the next few months. Clinical data on the 12 patients in this group is shown in Table 1. One female patient in this group died approximately 5 months after the initial operation and three other subjects have had evidence of regional lymph node recurrence (a, b, c and d correspond to patients MC, DT, SD and EM in Table 1, respectively).

The LDA activity in sera taken before and after surgery from the other patients is shown in Fig. 3. Sixteen patients had no LDA activity in their sera or had blocking of the spontaneous CMC to melanoma cells prior to surgery. After surgery, reduction in blocking activity against spontaneous CMC occurred in several patients but no LDA activity was seen. Clinical data on the 16 patients in this group in Table 1 indicates that there was a predominance of males in this group and most patients had regional lymph node involvement. Two of the patients died during the period of study and there were three other patients with regional lymph node recurrences (a′, b′, c′ and d′ correspond to patients GM, HP, GA and LH in Table 1, respectively).

Also shown in Fig. 3 are the results of studies on 5 patients in which melanoma LDA activity was present before surgery and and persisted essentially unchanged during the period of study. In Table 1 it is seen that all 5 subjects were women and all were multiparous. One of the 5 has had local recurrence of melanoma. (Constant levels of LDA activity against the MM 200 target cell were also seen in 13 other women who have attended the Clinic over a 2-yr period and who did not have pre-surgery serum samples available for LDA assays. All but one of these women were multiparous. Two of these patients have since died from disseminated melanoma. One patient has had liver metastases for approximately 15 months and remains in reasonable health on no therapy. Another patient had apparent complete remission from disseminated melanoma concurrent with the administration of methyl-CCNU.)

2. *LDA activity in the 7s IgG containing fractions of melanoma sera*

To further understand the reason for absence of melanoma LDA activity in the pre-surgery sera, the IgG fraction of the sera were tested in parallel with the unfractionated sera against

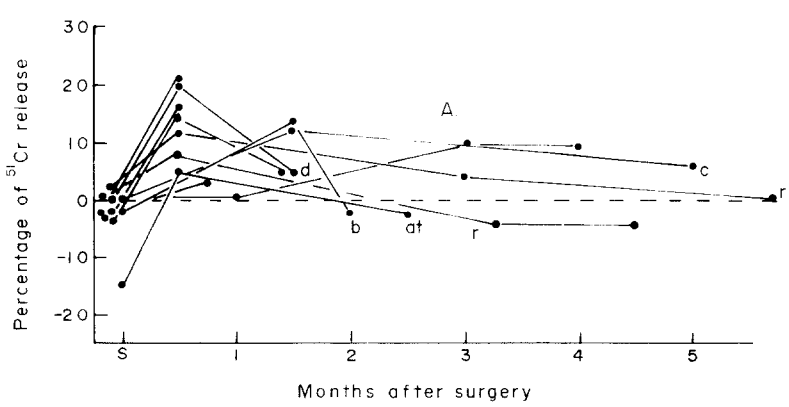

Fig. 2. Serum LDA and blocking of spontaneous CMC against the MM 200 target cell before and after surgery. The spontaneous CMC in the absence of serum is taken as the baseline and values above this line indicate LDA activity and values below the line, blocking of CMC. The spontaneous ^{51}Cr release from the TC in the presence of the effector cells ranged from 30 to 55%. The effects of the sera on CMC in the Fig. are those recorded at a dilution of 1 in 10. †=patient who subsequently died of recurrent melanoma. r=patient with recurrence of melanoma. (S.E. of the points $< \pm 2\%$, $P < 0.05$ for points showing ^{51}Cr release of 5% above or below base line in absence of serum).

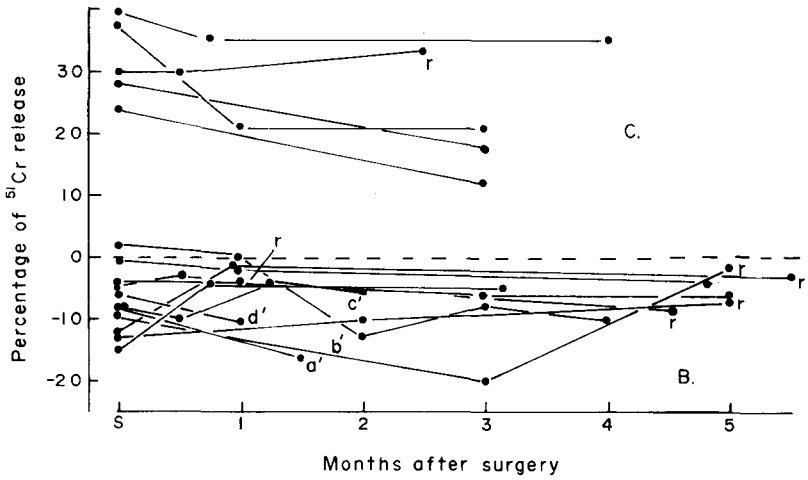

Fig. 3. Serum LDA and serum blocking activity against spontaneous CMC of melanoma patients before and after surgery. (See also legend to Fig. 1). In pattern B no serum LDA was seen and varying levels of blocking of CMC are indicated by depression of CMC below the level in the absence of serum. In pattern C relatively constant levels of LDA are seen before and after surgery. r=Patients who had recurrence of melanoma. (S.E. of points $< \pm 2\%$. $P<0.05$ *for points showing* ^{51}Cr *release of* 5% *above or below base line in absence of serum).*

the MM 200 target cell. One such study is shown in Fig. 4 where it can be seen that the IgG fraction at the time of surgery had strong LDA activity even though the unfractionated sera had no LDA activity. At 3 weeks after surgery, the LDA activity of the IgG fraction was less and weak activity was also seen in the unfractionated sera. By 2 months, no LDA activity was seen in either the IgG fraction or the whole sera.

In Table 2, the results of similar melanoma LDA assays on fractionated and unfractionated sera before and after surgery for 4 patients from group A and 4 from group B are shown. (The patients selected for study are indicated a, b, c and d in Fig. 2 and a', b', c' and d' in Fig. 3. The assays were carried out at 3 dilutions of the IgG fractions but only the 1/10 dilution is shown for clarity and because these results accurately reflected the general trend of the results at the other dilutions.) All patients showing LDA activity after surgery in group A had LDA activity in the IgG fraction prior to surgery and this showed a gradual reduction after surgery. Patients in group B however, did not have LDA activity detected in the IgG fraction of sera taken prior to or after surgery.

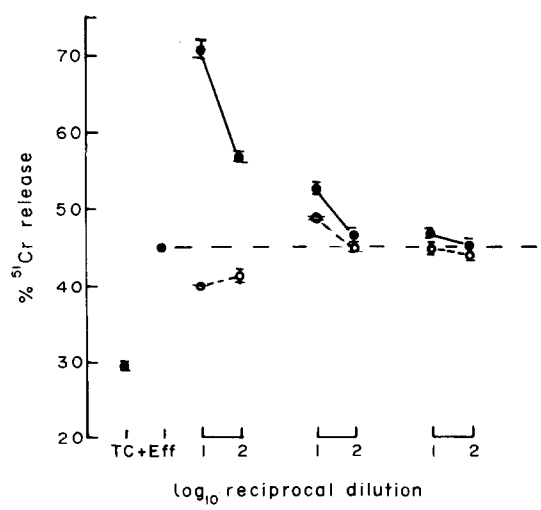

Fig. 4. LDA activity of unfractionated sera (indicated by dashed lines) compared to the IgG fraction separated from sera at the time of surgery, 3 weeks and 7 weeks after surgery.

Table 2. Melanoma LDA activity of the IgG fraction of melanoma sera before and after surgery

Melanoma patients	Days after surgery				
	0	14	28	42	60–90
Group A

(d') LH	2±2	—	2±1	—	0±2

Values indicated are the percent ^{51}Cr release above or below the CMC values alone at a dilution of 1 in 10±1 S.E.

3. *LDA activity in sera from control subjects*

Sera were taken from two groups of control patients at the same time intervals before and after surgery as the melanoma patients discussed above. One group were melanoma patients who had previously had their melanoma removed 6–8 weeks before admission for a second operation for wider excision and skin graft of the site of the original primary. As shown in Table 3, no LDA activity appeared in the sera of these subjects after surgery, and no LDA activity was seen in the 7s fraction from 2 of these subjects.

The second group of controls were patients with malignancies of various types, as indicated in Table 2. The patients with Hodgkin's disease and acute myeloid leukaemia underwent surgery for splenectomy. The other subjects had curative removal of primary tumours. The whole sera of many of these subjects had blocking activity of spontaneous CMC to the MM 200 target cell but no detectable LDA activity. The 7s fractions of pre-surgery and post-surgery sera from the patients with carcinoma of the breast and larynx also did not show LDA activity against melanoma cells, indicating that the absence of LDA activity was not due to blocking factors in their sera.

4. *LDA activity of melanoma sera against non-melanoma cells*

The specificity of LDA revealed in the melanoma sera after surgical removal of the melanoma was examined by assay of 7 of the most reactive sera from group A and a 7s fraction from 1 patient in group B (GA) against several different types of carcinoma cells and cells from the Chang liver cell line. All sera were tested at 3 dilutions from 1/10 to 1/1000. The results at the 1/10 serum dilution are shown in Table 4 and indicate very little LDA activity against these non-melanoma cells. Two positive reactions were seen with serum GD against an ovarian and a lung carcinoma and one positive reaction by GA against the squamous cell carcinoma (SCC) cells. Insufficient amounts of the sera from other patients in group A were available for extensive specificity assays but all were negative against the Chang cell and 1 breast carcinoma cell. The sera from patients in group C did not react with the Chang cell, 1 breast carcinoma or 1 ovarian carcinoma.

5. *LDA activity of unfractionated and the 7s fraction of melanoma sera against different melanoma cells*

To examine the possibility that the absence of LDA activity in patients in group B may be due to the absence of cross-reactivity with the MM 200 TCs, the 7s fraction and the unfractionated sera of 8 subjects from group B were tested in LDA assays against other melanoma cell lines and when possible, against

Figures in the Table indicate LDA or blocking of spontaneous CMC at a serum dilution of one tenth. The figures in parentheses indicate the ^{51}Cr release from the TCs. The numbers in parentheses below these indicate the CMC values above the spontaneous release from the TCs. SCC = squamous cell carcinoma.

the autologous target cell. The results showed that this possibility was unlikely in that a low level of LDA activity (<5% above base line) was seen only against two autologous TCs.

6. *LDA activity in patients with recurrent melanoma*

During the period of study, several patients followed since surgery had recurrence of their melanoma. The LDA activity in their sera, prior to detection and after surgical treatment of the recurrent melanoma, is shown in Fig. 5. Three patients (JM, SD and JR) who had previously shown melanoma LDA after surgery, had a gradual reduction in LDA activity to baseline levels or below the baseline levels at the time of detection of the recurrent melanoma. After surgical removal of the recurrence, LDA activity appeared again in the sera of JM and JR but not SD.

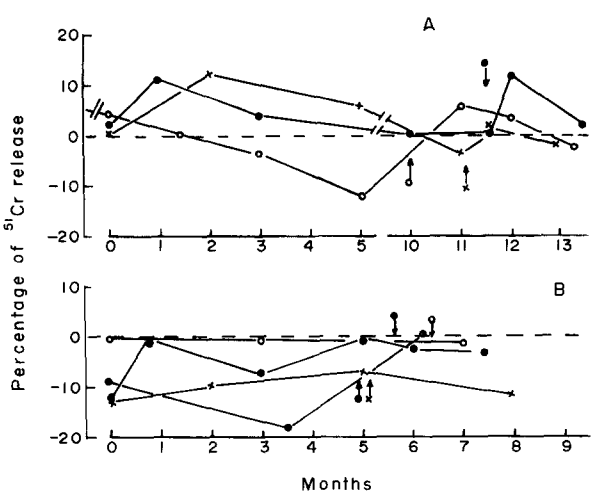

Fig. 5. Serum LDA activity against the MM 200 melanoma cell after surgery for recurrent melanoma. The arrows indicate time of surgery for second recurrence. Serum dilutions 1 in 10. (S.E. of points < ±2%. P<0.05 for points showing ^{51}Cr release of 5% above or below base line in absence of serum).

Patients who had previously had pattern B (HP, CC, CS and KJ, Table 1) had no consistent change in the LDA activity prior to detection of the recurrent melanoma. After surgical removal of their tumours, the pattern of LDA activity continued to show either blocking of spontaneous CMC or had no effect on the level of CMC. No LDA activity to the MM 200 line was seen after surgery in either the 7s fraction of the unfractionated sera of these patients.

DISCUSSION

It is apparent from the above study that LDA activity can be detected after surgical removal of melanoma in approximately a third of melanoma patients and that failure to detect this activity at the time of surgery in these patients was due to the presence of blocking factors against LDA in their sera. On theoretical grounds, absence of LDA prior to surgery could result from other factors, such as sequestration of antibody by the growing tumour mass or result from failure of antibody production before surgical removal of the tumour. However, the demonstration that melanoma LDA activity can be shown in the IgG fraction of the sera before surgery is against these possibilities and suggests that failure to detect melanoma LDA at this time is due to the presence of factors in the unfractionated sera which block the LDA activity as described in our previous reports [12, 13]. Similar blocking of ADCC in an experimental animal tumour model has also recently been described [16]. The nature of these factors is currently under investigation but our pre-

liminary results have shown that they are glycoproteins of 15,000 mol. wt and these factors can also be found in the supernatants of melanoma cell cultures. This evidence therefore, suggests that they are surface antigens released from the melanoma cell.

Transfusions were given at the time of surgery in several of the patients but this could not account for the rise in LDA in most of the patients. There was also no significant difference in the number of people receiving transfusions in either of the three groups of patients. Variation in the activity of antibody dependent (AD) effector cells also did not account for the increased LDA activity. Most patients in the study had no significant increase in AD effector cell activity after surgery when tested in parallel studies against sensitized Chang cells and there were no significant differences in AD effector cell activity between the three groups of subjects (Manuscript in preparation).

The LDA activity revealed in the 7s fraction of sera taken prior to surgery, or in the sera of melanoma patients following surgery appeared relatively specific for melanoma. Sera from patients with tumours unrelated to melanoma did not show LDA activity to melanoma cells, before or after surgery and did not have LDA activity in the 7s fraction of their sera. Conversely, when the sera or the 7s fraction of melanoma sera were tested against non-melanoma tumour cells and the Chang cells there was no, or very little, LDA activity against these cells. Many of the sera with melanoma LDA activity were also from young or middle aged men so that prior sensitization to HLA or foetal antigens during pregnancy was not possible and in most cases there was no previous history of blood transfusions. The decrease in the antibody titres after surgical removal of the melanoma also suggested that the continued presence of antigens on the melanoma cells were required for antibody production.

Despite the detection of these disease-related changes in LDA assays of sera from some melanoma patients, it is apparent that this activity was not reflected in the LDA assays of sera of many of the patients in the study. In some patients this appeared to be largely due to an absence of detectable LDA against the melanoma target cell. Early recurrence of melanoma was noted in 5 of the 16 patients in this group, which suggests that in some the absence of detectable LDA may have been due to continued presence of occult melanoma. If so, the antibody may have been sequestered by the tumour or the method of "unblocking" LDA used in this study may not have been adequate to remove the blocking activity from the LDA in these patients. It was also noted that there was a high incidence of regional lymph node involvement in this particular group of subjects and perhaps this may have resulted in suppressor activity against antibody production.

In previous studies it was noted that melanoma antigens appeared to vary between different melanoma cells and that not all melanoma sera reacted with the melanoma TC used in this study. Many of the unreactive sera were therefore tested against other melanoma cells but no significant increase in LDA activity was seen against the other melanoma cells. These results therefore suggest that melanoma LDA was absent in the sera from these patients and that failure to detect LDA was not merely due to selection of target cells without cross reacting melanoma antigens.

The patients showing a high level of melanoma LDA in group C were also of interest in that they were all multiparous women. It was shown previously that sera taken from women during pregnancy had antibodies to melanoma cells which could be absorbed on foetal tissue and that some of the reactivity of sera from women with melanoma could also be absorbed on foetal tissue. Extensive absorption studies of this nature have not been repeated on all the sera in the present study but 2 of the 5 sera had reduced LDA reactivity after absorption on foetal tissue. These results suggest that the high, relatively constant, LDA activity in these women may have resulted from prior sensitization to foetal antigens during pregnancy. We have previously reported that prior sensitization during pregnancy to foetal antigens may account for the better survival of women who have had previous pregnancies compared to those who have not [17]. The high levels of LDA however, did not confer absolute protection against recurrence from melanoma in the present patients in that one of the five women in this study and 3 of 13 women from among the general clinic patients with similar high levels of LDA, developed recurrent melanoma despite high LDA levels.

The present data do not allow any significant comparison to be made of the relative survival rate between the patients in this study, although there is a suggestion that patients with the high constant levels of melanoma LDA may have a better survival than patients with no detectable LDA activity. Further studies of these patients are continuing in order to answer this question.

Although the biological significance of melanoma LDA in protection against melanoma is not clear at this stage, the present study has

shown that the assays can be used to monitor the presence of blocking activity in the sera of melanoma patients. This activity (which appears to be melanoma antigen) has shown good correlation with disease activity in the present study and in studies in progress in which blocking activity has been tested against melanoma sera known to be reactive in LDA assays. The use of these assays may therefore provide a much needed monitor of disease activity in these patients which can be used to detect early recurrence of melanoma and assist in the planning of more effective therapeutic regimes against the tumour.

Acknowledgements—We would like to thank Sisters Combet, Frew and Becher for assistance in collection of clinical samples and the excellent secretarial services of Miss D. Stone in this study. We would also like to thank Professor F. O. Stephens, Department of Surgery, University of Sydney, for supply of clinical samples from patients with various types of malignancy used in this study.

Abstract—*In a randomized study on 59 patients with inoperable bronchogenic carcinoma, the chemotherapeutic efficacy and toxicity of ADM–DNA was compared with that of free ADM and that of the association cyclophosphamide–vinblastine.*

No significant differences in initial chemotherapeutic response could be observed between the groups of patients treated respectively with cyclophosphamide–vinblastine, free adriamycin or adriamycin–DNA. The cardiotoxicity of ADM seems however reduced by its combination with DNA, since no signs of cardiotoxicity were observed, even in the 15 patients who received a total dosage of adriamycin–DNA exceeding 500 mg/m².

INTRODUCTION

THE PRINCIPLE of lysosomotropic chemotherapy of cancer has been described and tested experimentally by one of us with daunorubicin–DNA [1] and adriamycin–DNA [2].

These drugs are presently undergoing clinical trials in the treatment of leukemia, non-Hodgkin lymphomas [3] and breast cancer [4]. The present study attempts to assess the value of this lysosomotropic chemotherapy in the treatment of inoperable bronchogenic carcinoma for which efficacy and toxicity of adriamycin (ADM) and adriamycin–DNA (ADM–DNA) are compared with those of a classical drug association cyclophosphamide–vinblastine (CPM–VBL).

MATERIAL AND METHODS

A total of 78 cases of inoperable bronchogenic carcinoma have been introduced in the study.

In every patient, the diagnosis was proved by histological and/or cytological methods and any possibility of surgical treatment had been excluded.

We also excluded the cases previously treated by surgery radio or chemotherapy.

All patients hospitalized in the pneumologic unit of the University of Louvain in Godinne between 10/1/1974 and 6/1/1976 and responding to these criteria have been included in the study.

From the 78 initial patients, only 59 have been retained for the appraisal of results since they had been clinically and radiologically checked after the 2nd drug perfusion.

The 19 patients lost correspond with 3 deaths and 16 refusals of treatment before the 2nd perfusion.

The patients were randomized in two groups: Group I (29 cases): every 3 weeks, i.v. perfusion, lasting 1 hr, of cyclophosphamide (CPM) (900 mg/m²) with an i.v. bolus of vinblastine (VBL) (9 mg/m²). Group II (30 cases): every 3 weeks, i.v. perfusion of ADM (free or combined with DNA) (75 mg/m²). Group II patients were randomized again in two subgroups: II_A (16 patients) ADM–DNA, prepared as described earlier [1] from the beginning of the treatment; II_B (14 patients) free ADM for the 3 first perfusions (at a 3 weeks interval) and from the 4th perfusion on ADM–DNA.

These two subgroups II were constituted in order

(1) to compare the chemotherapeutic efficacy of free and complexed ADM after three perfusions;

Accepted 19 October 1977.
†To whom requests for reprints should be addressed.

(2) to evaluate the cardiotoxicity of ADM–DNA;
(3) to compare the efficacy of ADM–DNA alone or preceded by free ADM with that of a standard CPM–VBL combination.

In another trial, still in progress, the preliminary results of which will be reported here, cases of undifferentiated carcinoma were randomized in 2 therapeutic groups, analogous to the two subgroups II described above, including ADM–DNA in the first subgroup and free ADM followed by ADM–DNA in the order.

During the evolution of the disease and according to the toxicity phenomena the interval between the perfusions was progressively increased from 3 to 4, 6 and 8 weeks. The total number of perfusions varied between 2 and 14, with a median value of 6.5.

The therapeutic response was evaluated according to the criteria of Kenis [5]. In this evaluation, the regression of the tumor was only taken into consideration, with exclusion of the atelectasic retractions or the resorption of infectious processes. The tumor size was monitored by X-rays and each X-ray plate was examined separately by 2 chest physicians.

In case of discordant interpretation, the opinion of a third observer was considered as determinant.

The following types of therapeutic response were considered:

(1) Complete remission (CR): complete disappearance of the tumor, for at least 1 month.
(2) Partial remission (PR): decrease of the tumor greater than 50% of the product of the two diameters, without progression of any other lesion and without appearance of any new lesion during a period of at least one month.

A partial remission is evenly stated when a marked or unequivocal decrease (3/4 or more) is observed in non-measurable lesions.

(3) Non total failure (NTF): decrease of the tumor, as in partial remission, but lasting less than 1 month or definite decrease in some lesions, occurring together with progression of other.
(4) Total failure (TF): either decrease of the tumor inferior to 50%, or status quo or progression of the disease.

Groups 1 and 2 are considered together as remissions, while groups 3 and 4 are classified as "failures".

The toxicity of therapeutic regimens was assessed with great care in the 4 following areas:

(1) Alopecia
(2) Gastrointestinal disturbances: these were considered as minor when they involved anorexia, nausea or infrequent vomiting; and qualified as major if nausea and vomiting occurred for one week or more.
(3) Bone marrow depression: drug perfusion was postponed or the doses were decreased when the number of neutrophilic polymorphonuclear leucocytes was inferior to 1800 per μl and/or when the platelets count was lower than 100,000 per μl.
(4) Cardiotoxicity: electrocardiograms and dosage of creatine phosphokinase (CPK) were performed systematically, before every perfusion of ADM or ADM–DNA.

As summarized in Table 1, the groups

Table 1. Characteristics of patients

	Group I	Group II		
	Total group I CPM–VBL	Total group II	Subgroup A ADM + ADM–DNA	Subgroup B ADM–DNA
Number	29	30	14	16
Age—limits	41–77	44–77	48–77	44–73
—mean	60	64	64	64
—median	61	65	64	67

anaplastic (small cell)	4	11	5	6
undifferentiated (large cell)	1	3	1	2
glandular		1	—	1
Tumor localization				
central	21	19	9	10
peripheral	8	11	5	6

and subgroups were very similar with regard to number of patients, age, tumor localization (central or peripheral).

The number of undifferentiated small cell epithelioma is however higher in group II than in group I.

Data on duration of survival were evaluated by life table analysis [6]. Chi-squared analyses were performed for comparison between the results of both groups.

RESULTS

1. *Tumoral response to chemotherapy*

Table 2 summaries the objective responses observed. The percentage of remissions (23.3%) due to ADM and/or ADM–DNA is not significantly superior to that obtained with the CPM–VBL association (17.2%) ($P=0.20$). The remission rate observed in subgroup II_B (free ADM followed by ADM–DNA) seems higher than that of subgroup II_A (ADN–DNA alone); this difference is however not significant ($P=0.71$).

Various results are obtained in relation to the histological types of the tumor (Table 3).

Well differentiated tumors (squamous cells carcinoma and adenocarcinoma) respond better to CPM–VBL association (21%) than to ADM/ADM–DNA (6%). On the contrary, undifferentiated (anaplastic small and large cell

Table 2. Objective response to treatment

carcinomas) are more sensitive to ADM/ADM–DNA (43%) than to CPM–VBL. As shown in Fig. 1, the actuarial survival curve of patients is similar in groups I and II ($P=0.279$). There is however a significant difference ($P<0.01$) between the survival curves of patients with response to treatment and those without response (Fig. 2).

2. *Toxicity*

As summarized in Table 4, alopecia is almost always present and complete in patients treated with ADM/ADM–DNA. With CPM–VBL, alopecia is less frequent (62%) and less complete. Gastrointestinal troubles are equally frequent in both groups as well as bone marrow depression, which is remarkably mild.

No cases of cardiotoxicity are observed, neither in patients treated with ADM–DNA nor in those receiving first ADM alone. The total dose of drug varies between 150 and 1.050 mg/m^2 (median 480); 15 patients receive a total amount equal or superior to 500 mg/m^2.

Table 4. *Toxicity*

	Group I	Group II
Alopecia	18 (62%)	27 (90%)
Gastrointestinal complaints		
Minor	13	17
Major	5	3
Total	18 (62%)	20 (66%)
Bone marrow depression	5 (17%)	8 (26%)

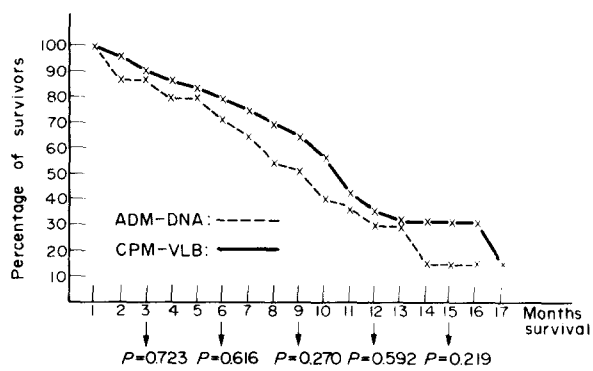

Fig. 1. *Survival curves of patients treated with ADM–DNA and with CPM–VLB. No statistically significant difference.*

DISCUSSION

Our results show that in inoperable bronchogenic carcinoma ADM–DNA (preceded or not by ADM) induces a therapeutic response comparable to that of a combination of CPM–VBL.

Results from the literature [7–10], summarized in Table 5, show that the rate of remission obtained by us with ADM–DNA preceded or not by free ADM (23%) falls in the range of remissions obtained by other authors with free ADM.

From data of Table 2, it seems that some difference exists between the response rate in patients treated with free ADM followed by ADM–DNA and that recorded in patients receiving only ADM–DNA.

These differences are however not significant. Preliminary results from another study still in progress on a greater number of patients with undifferentiated carcinoma (Table 6) show however that after three perfusions remission rates with ADM–DNA look more similar to those obtained with free ADM ($P=0.57$).

This very important aspect of the ADM–DNA combination is presently submitted to further studies since one of the possible drawbacks of the macromolecular-linked-drug could diffuse more slowly in badly irrigated solid tumors and could have more difficulties in crossing capillary barriers than the free drugs.

Moreover, our knowledge of the endocytic properties of lung tumor cells is still partial.

No. of remissions	7	10
No. of failures	5	3
Remission rate	58%	77%

$\chi^2=0.32$; $P=0.57$.

Table 5. *Remission rate (complete and partial) obtained with adriamycin in inoperable bronchogenic carcinoma*

		No. of remissions / No. of patients	% of remissions
Bonadonna	1971	4/14	28.6%
Blum and Carter	1974	44/229	19%
Cortes *et al.*	1975	9/31	29%
Kenis	1975	16/50	32%
Selawry	1975	68/377	18%

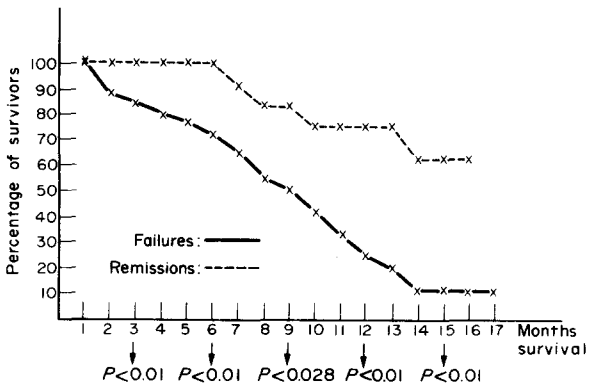

Fig. 2. Survival curves comparing patients in whom remission was induced and those in whom it was not. Survival in the latter group was significantly shorter.

The first results of the study in progress indicate that the trend in favor of free ADM is less marked than in the present study: linking ADM to DNA seems not to reduce markedly the chemotherapeutic efficacy of ADM in bronchogenic carcinoma.

In the present study, the results obtained with ADM are much better in undifferentiated epitheliomas (43% remissions) than in squamous cell carcinomas (6% remissions). This difference is just statistically significant ($P=0.05$). Our observations contrast with those obtained on a greater number of patients by Blum and Carter [7] indicating a greater sensitivity of the squamous cell carcinomas to ADM and with those of Selawry [10] suggesting an equal sensitivity of both histologic types to ADM.

The use of ADM linked to DNA does not reduce the frequency and extent of alopecia. Stomatitis, a frequent complication of adriamycin treatment [7], was not observed in our material, nor were more infrequent complications like cutaneous rashes [11] and fibrinolysis [12].

Although systematical E.C.G. controls and CPK assays were performed, patients of group II did not show any cardiotoxicity: these results gain still more significance if one considers that, as shown in Table 7, 15 patients received more than 500 mg of ADM/m^2: the cardiotoxicity of free ADM increases indeed very much when the administered amount exceeds 500 mg/m^2, as shown from the data of Gilladoga *et al.* [13] summarized in Table 7 and from the data of Lefrak *et al.* [14] indicating that when the total dosage of ADM exceeds 500 mg/m^2 cardiotoxicity appears in about 20% of the cases and even in 30% when the total amount exceeds 550 mg/m^2.

In our results, one can find a first indication that linking ADM to DNA leads to a decrease of cardiotoxicity of ADM in human patients.

Acknowledgements—We thank Dr. Lulling for his help in the statistical studies, Dr. Steyaert, Dr. Moia, Professor Renoirte and Dr. Modave for their help in the study of their patients.

Bladder Carcinogenesis Using Bilharzia-Infested Swiss Albino Mice

ABDELBASET ANWER EL-AASER,* SAMIRA MOHAMED HASSANEIN,† MOHAMED NABIL EL-BOLKAINY,† SHERIF OMAR,‡ ISMAIL EL-SEBAI,‡ and MAHMOUD MOHAMED EL-MERZABANI*

Departments of Cancer Biology, Pathology† and Surgery,‡ Cancer Institute, Cairo University, Cairo, Egypt*

Abstract—*Experimental studies were carried out on female Swiss albino mice to evaluate the possible role of: liver injury, urine inborn carcinogens and local irritation of bladder mucosa in the development of bilharzial bladder cancer. In mice, the liver and intestine are only involved by parasite, but the urinary bladder is spared. Mice with induced liver injury due to either: bilharzial infestation alone, hepatocarcinogens alone (2-naphthylamine (2-NA) or 2-acetylaminofluorene (2-AAF)), or both together, did not develop bladder tumors. Also, mice receiving 1% indole (a tryptophan precursor) either alone, or after bilharzial infestation, did not show any change in bladder mucosa. Conversely, the insertion of glass beads in the bladder induced carcinomas in 26.6% of mice after 70 weeks. The induction of bladder tumors by glass beads was enhanced by 2-AAF treatment (40%), but not by bilharzia infestation (25%), 2-NA (27%) or indole (27%). The urinary bladders with glass beads were invariably the seat of bacterial infection (E-coli and gram + ve cocci) and showed epithelial hyperplasia and metaplasia.*

INTRODUCTION

THE ETIOLOGIC relationship between chronic bilharzial cystitis and bladder cancer has been established. Since the original report of Ferguson [1], many valuable contributions have been added [2–5], but the exact mechanism of carcinogenesis is still unknown.

Different theories have been postulated including the mechanical effect of ova [1], miracidial toxins [2], associated chronic inflammation [3] and the presence of certain urinary carcinogenic agents such as tryptophan metabolites [4–7].

The aim of the present work is to evaluate the role of liver injury and mechanical irritation of bladder mucosa in the production of bladder cancer in an experimental animal model. Liver injury was induced either by bilharzial infestation and/or chemical carcinogens.

MATERIALS AND METHODS

Animal model and experimental groups

Mice were selected for this study, as in such animals, we get hepatic bilharzial infestation without bladder involvement, since the blood vessels of the mouse bladder are too small to allow the parasite to reach the bladder. The possible role of mechanical irritation of the bladder by the passage of ova was imitated by surgical insertion of glass beads in the bladder cavity.

Female Swiss albino mice, 6–8 weeks old, about 20 g bred at Cairo Cancer Institute were used. The mice were randomly divided among the different groups (Table 1). Animals were maintained on a standard diet containing 20% protein and were given water *ad libitum*. In groups given oral chemical carcinogens, 1% 2-naphthylamine (2-NA) and 0.06% 2-acetylaminofluorene (2-AAF) were mixed with the diet separately. Indole, a tryptophan precursor, was mixed with the diet in a concentration of 1%.

The majority of mice were sacrificed after 70 weeks. However, in the groups receiving chemical carcinogens (2-NA and 2-AAF), the experiments were terminated after 30 weeks due to the development of severe toxicity. The experiment was started by 480 mice. A total of 130 animals were either sacrificed or found dead during the experiment, thus leaving 350 mice at the termination of study.

Bilharzial infestation

The mice were immersed for 1 hr in water containing cercaria of *S. mansoni*, 20–30 per ml. Six weeks later, the stools of mice were

Accepted 7 October 1977.

Table 1. *Frequency of bladder carcinomas in Swiss albino mice*

Group	Period treatment (WK)	Number of mice	Tumors Number	Tumors Percent
i. Normal control	70	45	0	0
ii. Liver injury:				
(a) Bilharzia	70	46	0	0
(b) 2-Naphthylamine (2-NA)	30	20	0	0
(c) 2-Acetylaminofluorene (2-AAF)	30	20	0	0
(d) Bilharzia + 2-NA	30	17	0	0
(e) Bilharzia + 2-AAF	30	22	0	0
III. Local bladder irritation: (glass beads)	70	30	8	26.6
IV. Bladder beads + liver injury:				
(a) Beads + bilharzia	70	20	5	25.0
(b) Beads + 2-NA	30	18	5	27.0
(c) Beads + 2-AAF	30	25	10	40.0
V. Tryptophan precursor:				
(a) Indole	70	25	0	0
(b) Indole + bilharzia	70	20	0	0
(c) Indole + beads	70	22	6	27.7
(d) Indole + beads + bilharzia	70	20	5	25.0

examined for the presence of ova to confirm the infestation. Only mice with positive ova in the stool were selected for the experiments.

Insertion of glass bead in the bladder

Under intraperitoneal nembutal anaesthesia [8], a spherical glass bead with rough surface, about 7–9 mg, was inserted into the lumen of the bladder following the technique of Allen *et al.* [9].

Pathologic techniques

At autopsy, the left lobe of liver and urinary bladder were excised, then fixed overnight in 10% neutral formalin in saline. The fixed bladder was transected horizontally at 3 different planes. Tissues were processed by routine paraffin embedding and hematoxylin and eosin staining.

RESULTS

Pathology of liver

All the mice infested with *Schistosoma* showed bilharzial granulomata in the portal areas, but the normal liver cytology and lobular pattern were preserved. Around the bilharzia ova, histiocytes, fibroblasts lymphocytes and eosinophils were arranged in a concentric pattern. A black granular bilharzial pigment was also observed in the granulomatous areas and bilharzia worms were at times seen in portal veins. Bile ducts showed moderate to marked hyperplasia. The liver of mice treated with 2-naphthylamine (2-NA) or 2-acetylaminofluorene (2-AAF) showed mild fatty degeneration and cellular pleomorphism with hyperchromatic nuclei. However, no hepatomas were observed.

Pathology of urinary bladder

In the normal bladder, the transitional epithelium was 2–4 layers in thickness, with a surface layer of large cells. No epithelial changes were observed in mice infested with bilharzia or fed 2-NA or indole. A mild patchy epithelial hyperplasia was encountered in mice fed 2-AAF. Conversely, the bladders with glass beads showed marked transitional cell hyperplasia, both of surface epithelium and cell nests of Brunn. In addition, squamous metaplasia and columnar metaplasia were commonly observed. An inflammatory reaction was always present in the subepithelial stroma (lamina propria). Bacteriologic studies on urine revealed evidence of *E-coli* and gram positive *cocci*.

Malignant tumors of the urinary bladder only developed in the groups with glass beads (Table 1). Enhancement of tumor development occurred in mice fed 2-AAF, but not with other treatments (2-NA, indole or bilharzial infestation). All the tumors were deeply infiltrative. Of the 39 induced tumors, 21 were transitional carcinomas, 8 were transitional in type with focal squamous differentiation, and 10 were anaplastic with areas of spindle cells or sarcomatoid pattern. In spite of the advanced stage, and high grade of the majority of tumors, no distant metastases were observed.

DISCUSSION

Impairment of liver function in bilharzial patients, with subsequent disturbance of tryptophan metabolism, was considered a possible factor in bladder carcinogenesis [4]. However, hepatic bilharziasis affects mainly mesenchyme and spares liver cells, hence, very little change in liver function is observed except in very advanced cases [10–12]. In the present study, liver injury due to either: bilharzial infestation, hepatocarcinogens, or both together, failed to induce bladder tumors or atypical urothelial changes. Feeding indole (tryptophan precursor), also failed to produce changes in bladder mucosa.

In the present report, bladder tumors only developed in the groups of mice with intravesical glass beads. The induction of carcinomas was enhanced by treatment with 2-acetylaminofluorene, but not enhanced by bilharzial infestation, 2-naphthylamine or indole. These findings suggest that local factors are more important than systemic factors for bladder carcinogenesis in the present model.

The various hyperplastic, metaplastic and neoplastic changes observed in the bladders with glass beads are similar to those previously reported by Roe [13]. A comparable spectrum of lesions was also reported in the urinary bladder of bilharzial patients [14]. However, in human, squamous metaplasia and squamous carcinoma that follow bilharzial cystitis tended to show more abundant keratinization than those observed in mice.

Two factors are possibly operable in bladder carcinogenesis following glass bead implantation, namely: (a) chronic mechnical irritation and/or (b) the associated bacterial infection. The bacterial types identified (*E. coli* and *cocci*) were known to be capable of synthesizing nitrosamines from nitrate and secondary amines [15, 16]. These nitrosamines proved to be potent carcinogens in different laboratory animals [17].

Nitrate is a normal dietary component, being present in large amount especially in agricultural areas in Egypt, where nitrate is commonly used as a fertilizer. Secondary amines are also produced by intestinal flora and excreted in urine. Therefore, the environmental conditions of the Egyptian farmers, who are heavily infested with bilharziasis, associated with bacterial cystitis and drinking water with high nitrate content, should raise a great possibility of *in situ* formation of different carcinogenic nitrosamines in the bladder.

At present, further studies are carried out at the Cairo Cancer Institute to evaluate the possible factors involved in the induction of bladder cancer in bilharzial patients.

Repair of Potentially Lethal Radiation Damage in Mouse Embryo

N. OHNUMA,* M. URANO,† S. KOIKE and T. TERASIMA

Division of Clinical Research, Division of Physiology and Pathology, National Institute of Radiobiological Sciences, 4-9-1 Anagawa, Chiba 280, Japan

Abstract—*The ability of mouse embryo cells to repair potentially lethal damage was studied. Female mice of the* 15th *gestation day were irradiated with X-rays or neutrons* (30 MeV *deuteron→berylium*) *and embryos were removed at various times thereafter. Surviving fractions of embryo cells determined by colony formation method* in vitro. *Survivals increased rapidly if embryos were left* in utero *for more than* 2 hr *after X-irradiation and reached a plateau at* 4 hr, *indicating that embryo cells can repair potentially lethal damage. The magnitude of this kind of repair was found dose-dependent.*

INTRODUCTION

REPAIR of potentially lethal radiation damage was first demonstrated by Phillips and Tolmach in exponentially growing cultured cells [1]. This kind of repair has been observed in stationary phase cells and in animal tumors [2–4]. Potentially lethal damage refers to the radiation-induced damage which is originally lethal but can be repaired in a certain post-irradiation condition or by some kinds of post-irradiation treatments. Several factors which may affect the repair of potentially lethal damage have been extensively studied [5–7]. Post-irradiation conditions which are suboptimal for cell growth are reported to favor this kind of repair. Conditions which are formed by hypoxic foci in tumor tissue may facilitate this kind of repair. Accordingly, it was predicted that only hypoxic tumor cells can repair potentially lethal damage. As already reported, we tested it in an animal tumor system and found that not only hypoxic tumor cells but also aerobic tumor cells might be capable of repairing potentially lethal damage [8]. Our study also suggested that this kind of repair is, at least partly, attributed to the "cell-to-cell contact" *in vivo*. Therefore, further studies were made on the capability of normal tissue to repair the potentially lethal damage.

MATERIAL AND METHODS

Mouse embryos were used throughout. Parent animals were 8–10-week-old C3Hf/He mice which were derived from our specific pathogen free (SPF) colonies. They were kept in an animal facility where SPF condition was maintained as well as constant temperature and humidity. Animals were provided sterilized purina pellets and chlorinated water *ad libitum*. Two days were allowed for mating and pregnant female mice were used for studies at the 15th gestation day.

An X-ray machine was operated at 200 kVp and 20 mA with a filter of 0.5 mm Cu and 1 mm Al. Target skin distance was 50 cm. Half value layer was 1.2 mm Cu. The dose rate measured by Victoreen thimble ionization chamber, was approximately 100 rad/min at the center of the animal. Neutrons were produced by bombarding 30 MeV deuterons to a thick berylium target. Animals were irradiated at TSD of 150 cm and the dose rate was $\simeq$ 50 rad/min. During irradiations, animals were kept in a lucite phantom which can hold 12 animals separately and whole bodies were irradiated without anesthesia.

Animals were sacrificed by cervical dislocation and embryos were removed. Single cell suspensions were prepared as follows: to begin with, head, extremities and internal organs were excised from each embryo and the rest of the body was minced by scissors.

The mince was trypsinized at 37°C for 45 min in a culture bottle which had 0.25% trypsin (Difco 1:300) in Ca and Mg-free Dulbecco's solution. The supernatant was removed and centrifuged at 1500 rev/min for 5 min. The sediment was resuspended with sufficient amount of complete F10 medium supplemented with 10% calf serum and antibiotics. Number of cells was counted on a hemocytometer and single cells were seeded in plastic petri dishes (Falcon 60 × 15 mm) after appropriate dilution of the cell suspension. Lethally irradiated embryo cells were used as a feeder layer: $5–8 \times 10^4$ embryo cells/dish were grown overnight and irradiated with 4000 rad immediately before plating of the test cells. They were incubated for 12–14 days in a CO_2 chamber at 37°C to which humidified 5% CO_2-air was constantly supplied. Colonies containing more than 50 healthy cells were counted as survivors after methylene-blue staining. The plating efficiency was usually ≃5%.

RESULTS

Female mice of the 15th gestation day received a whole body irradiation of 1000 rad. Embryos were excised at various times thereafter and cell survival was determined *in vitro*. As presented in Fig. 1, surviving fraction was progressively increased if embryos were allowed to remain *in utero* and reached a plateau at 4–6 hr, the value at 24 hr not indicating any significant change. It was noteworthy that survival of the embryo left *in utero* for 4 hr and that of embryo left

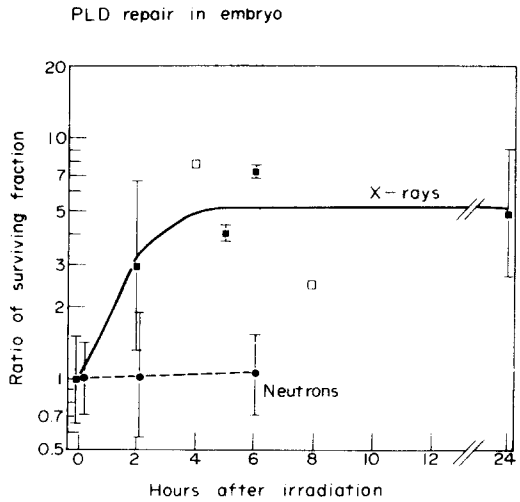

Fig. 1. The increase of survival of embryo cells as a function of time left in utero *after irradiation. Squares and circles indicate survivals after X-rays and neutrons respectively. Solid symbols are sums of more than 2 experiments while open squares indicate single experiment results. Vertical bars represent standard deviations.*

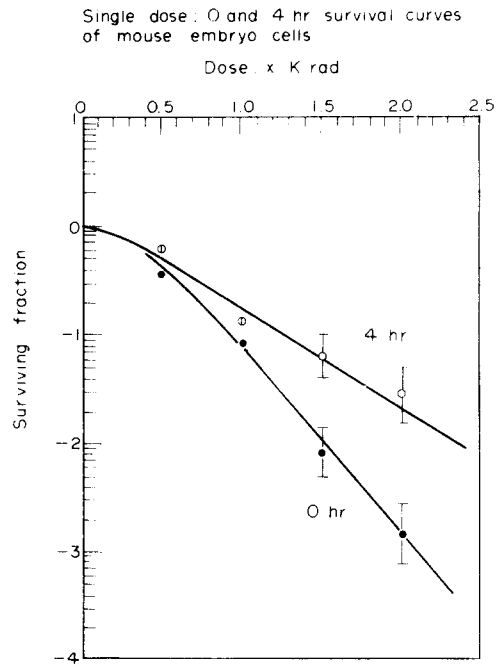

Fig. 2. Dose response curves of embryo cells irradiated with 200 kV p *X-rays and excised immediately (solid circles) or at* 4 hr *thereafter (open circles).*

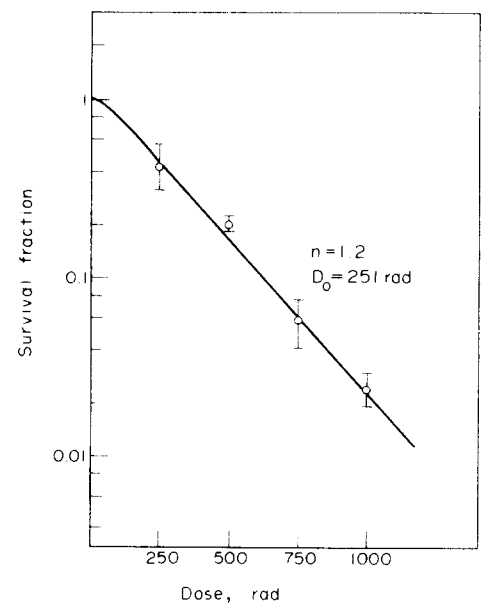

Fig. 3. X-ray dose-cell survival relation of embryo cells which were derived from primary culture of 15*-day-old embryos. Vertical bars indicate standard deviation.*

for 24 hr were consistent within an experimental error.

Dotted line in the same figure represents the survivals of embryo cells irradiated with neutrons of 500 rad and excised at various times thereafter. No increase of cell survival was observed, while a single neutron dose of 500 rad reduced survivals more effectively than an X-ray dose of 1000 rad.

Dose–response relations were assayed after single X-ray doses. Embryos were excised immediately or 4 hr after irradiation. Dose–cell survival curve of embryos left *in utero* for 4 hr after X-rays was found less steep than that of embryos excised immediately after X-rays. The D_0 value of the latter was 260 rad, while that of the former was 465 rad.

Our embryo cells appeared to be more radioresistant than other mammalian cells. Thus, the dose–cell survival relation of embryo cells which were derived from the primary culture of 15 day-old embryos and had been harvested *in vitro*, was examined. Single cells were plated and irradiated with X-rays 24 hr later. Number of colonies was counted at 14 days thereafter. As presented in Fig. 3, D_0 was 250 rad and was roughly comparable to that of embryos excised immediately after X-rays (Fig. 2).

DISCUSSION

Factors which facilitate the repair of potentially lethal radiation damage have been extensively studied *in vitro* and *in vivo* [5–7]. Among them, those applicable to normal tissue cells are: (a) the presence of non-proliferating or slowly proliferating cells and (b) the cell-to-cell contact, as suggested in our previous results.

Demonstration of this kind of repair *in vivo* requires comparison of surviving fractions of cells removed immediately after irradiation with that of cells left *in situ* for a certain time. Accordingly, only such cells which produce colonies *in vitro* can be tested for the repair capability and none of the normal tissue cells are susceptible to this test except for embryo cells. A disadvantage to use embryo cells for this kind of experiment was very low plating efficiency. However, this might be inevitable because many organs are already formed at the 15th gestation day and many cells are well differentiated and losing proliferative capability.

Our results clearly indicated that embryo cells can repair potentially lethal radiation damage over 4–5 hr after X-rays and the capability of repair was dose-dependent. It was also noteworthy that embryo cells were unable to repair the potentially lethal damage after neutron irradiation. All the results were consistent qualitatively with those obtained with animal tumors [3, 4, 7, 8] indicating that repair of potentially lethal damage is not a phenomenon which distinguishes normal tissues and malignant tissues.

Dynamics of Immunity in Syngeneic Lymphoma-Bearing Mice

M. JURIN and B. PLAVŠIĆ
Ruđer Bošković Institute, Zagreb, Yugoslavia

Abstract—*Following a short interval of increased reactivity against third party antigens (allogeneic skin graft and sheep red blood cells) C3Hf/Bu mice bearing syngeneic lymphoma develop progressive immunodepression. In order to overcome this depression, the animals were injected with* 10^8 *lymph node or spleen cells from normal syngeneic donors. Lymph node cells restored skin allograft rejection time, as well as the number of plaque forming cells (PFC) in the spleen of tumorous host, but spleen cells failed to do so. In order to investigate the role of the tumor environment on the reactivity to third party antigens,* 10^7 *spleen cells from mice, at different stages of tumor disease, were injected into syngeneic, lethally irradiated recipients. The PFC values were higher in mice injected with spleen cells from tumor-bearing mice than in those injected with spleen cells from normal syngeneic donors, regardless of the stage of tumor growth. The results were discussed as to suggest that central defect in the depression of humoral and cell-mediated immunity in tumor-bearing host is due to altered T-cell population.*

INTRODUCTION

GENERALIZED depression of cellular and humoral immunity is associated with growth of syngeneic tumor and becomes stronger in advanced stage of tumor disease [1, 2]. Since the immunodeprived host is not able to reject allogeneic tumor, the probability of rejecting syngeneic tumor, which is much less antigenic, would be rather unlikely [3]. Furthermore, infection of mice with murine leukemia virus results in a marked impairment of immune responsiveness to various antigens–sheep red blood cells (SRBC), allografts, bacterial extracts [4, 5]. Besides tumor viruses, which could be considered to cause immunosuppression directly, various virus-associated factors, such as soluble extracts of tissues of virus-infected mice, or ascitic fluid, also resulted in immunosuppression [5, 6].

Current questions are: A. whether this immunodepression is caused by the tumor itself, B. if so, whether it is first localized in the microenvironment of the tumor, where interactions with host's immunocytes first occur and C. whether or not the immunodepression caused by the tumor itself provides it with a mechanism of evading the host immune surveillance [3].

To this end, changes of immunity against third-party antigens (allogeneic skin graft and SRBC) were investigated in C3Hf/Bu mice transplanted with syngeneic lymphoma cells, during tumor disease. The intention was to establish: (a) the degree of the immunodepression at different times of tumor disease, (b) the ability of different types of lymphoid cells to restore the host's immune reaction against the antigens and (c) the influence of the environment dominated by the tumor on the ability of immunocytes to react.

Accepted 8 November 1977.

MATERIALS AND METHODS

Experimental animals

Male mice of C3Hf/Bu and C57BL strains, bred in our colony were used. They were about 12–16 weeks old at the beginning of the experimental procedures.

Tumor

The tumor used in these experiments was a lymphoma which arose spontaneously in the thymus of a male C3Hf/Bu mouse [7]. The fourteenth isotransplant generation of a tumor transplant was kept in liquid nitrogen at −193°C. In the present experiment, "source" mice had been injected with frozen cells thawed immediately before implantation; cell suspensions were made from growing tumors of source animals and injected into the experimental mice. Following the injection of 10^6 viable tumor cells, the standard dose used,

the tumor became palpable 10–12 days later. Progressive growth continued and the host died about 40 days after the tumor became palpable. Morphological and immunological aspects of this lymphoma were previously described [8, 9]. Briefly, in comparison to the controls, the patterns of moderate immunological activity, comprising an increasing number of germinal centers as well as of lymphoblasts in the paracortical area, occurred in regional lymph node 2–3 days following lymphoma transplantation. This was followed by a decrease resulting in lymphoid tissue atrophy of the outer cortex in the third week of the disease. Simultaneously, the metastases of tumor cells occurred in the medulla and in the paracortical area and lymphoma cells destroyed the normal structure of lymph node about 10 days later. This chain of events occurred in other lymph nodes too, but it was postponed for about a week. Three days after tumor cell transplantation the number of lymphoblasts increased around the central arterioles in the white pulp of the spleen and increased number of germinal centers and plasma cells could be seen in hyperplastic white pulp 3–4 days later. This pattern of strong immunological activity persisted until the end of the third week following tumor transplantation, when the number of lymphoid cells started to decrease mainly around the central arteriole. Towards the end of the first month after tumor transplantation, the first tumor cells could be seen around the central arteriole and the tumor started to invade the organ, but more slowly than the lymph nodes.

Tumor cell suspension

Grossly intact pieces of the tumor isotransplant, removed from source mice, were minced, the mash was poured into a beaker containing cold Hanks' solution and mixed with a 10 ml syringe. The beaker was placed on ice so as to allow large particles to settle down. Five minutes later the supernatant was removed using a syringe with 22-gauge needle and passed through a Swinney filter into test tubes. The specimen was spun down on 150 ***g*** during 10 min, the supernatant was discarded and the pellet resuspended. All visible clumps were removed using a Pasteur pipette so that the cells were dispersed as a single cell suspension. The viability was tested by Trypan blue exclusion; more than 90% of tumor cells were scored as viable. A one tenth of a milliliter inoculum, containing 10^6 viable tumor cells, was injected subcutaneously into the right thigh of recipient mice.

Preparation of spleen and lymph node cell suspensions

Donor mice were killed by cervical dislocation and spleen, as well as lymph nodes (axillary, inguinal brachial and cervical) were harvested. The organs were minced in cold Hanks' solution using scissors. The mash was passed through the nylon patch into a beaker and placed on ice. Five minutes later the supernatant was discarded with a syringe, the pellet was passed in the test tube and washed 3 times on 150 ***g*** for 10 min each in Hanks' solution. The number of viable cells was determined and finally adjusted to 10^7 or 10^8 Trypan blue negative cells/ml.

Plaque forming cells assay

SRBC (Institute of Immunology, Zagreb) had been washed 3 times on 180 ***g*** for 5 min each and 10% suspension was made using Hanks' solution. A half milliliter of the suspension had been injected intraperitoneally to recipient mice. The immunologic response to SRBC was determined by counting the cells forming haemolitic antibodies (plaque forming cells—PFC) in the spleen according to the method of Jerne *et al.* [10] modified for use on microscopic slides [6]. SRBC had always been injected 4 days before the animals were sacrificed to determine PFC numbers. Lymphoma cells by themselves do not form plaques with SRBC (unpublished).

Skin graft technique

A piece of skin approximately 1 × 1 cm was applied to a suitably prepared graft bed and secured with a bandage [11]. The bandages were removed 7 days later and graft inspected daily. Graft was scored as rejected when there was no visible remaining epithelium.

Statistics

Mean values and standard errors were calculated for each group of experimental and control animals. The significance between two mean values was calculated by using the *t*-test.

RESULTS

1. *Dynamics of immunosuppression in lymphoma-bearing mice*

1.1. *Skin allograft rejection time.* C3Hf/Bu mice were grafted with skin from C57BL mice at various terms after tumor cell transplantation. On each particular day 10–12 tumorous mice and 4–5 normal mice were grafted. Results in all normal mice were pooled. The allograft rejection times are presented in Table 1. Mice grafted at the same time when tumor

cells were injected, or 2 days later, rejected the grafts like control mice and mice grafted 5 days after tumor transplantation rejected the graft even 1 day earlier than the controls without the tumor. However, from 9th day following the tumor transplantation, skin allograft survived up to 9 days longer on lymphoma-bearing mice. The bigger the tumor, the longer was the allograft survival.

1.2. *The number of PFC in the spleen.* One, 3, 9, 12, 15, 23, 30 and 40 days following lymphoma cell injection 4–6 mice from experimental group and 4–5 normal mice were sacrificed and PFC assay performed. All the mice have been injected with SRBC 4 days before. The PFC counts in experimental mice were then correlated with counts in the controls (at each particular day) and presented as a percentage of control values in Fig. 1. As presented, the spleens of C3Hf/Bu mice, injected 3 or 9 days before PFC assay with lymphoma cells, contained higher numbers of PFC to SRBC than control mice. However, towards the end of the second week following tumor cell injection, when the tumor became palpable, a pronounced decrease of the PFC

Table 1. *Survival of C57BL skin graft on lymphoma-bearing mice and normal C3Hf/Bu mice*

Days after injection of 10^6 tumor cells	Days of allograft survival (Mean ± S.E.)	Number of mice	Significance to controls (*t*-test)
Non-injected mice	11.4 ± 0.1	30	
0	11.9 ± 0.7	10	N.S.*
2	11.0 ± 0.5	11	N.S.
5	10.2 ± 0.4	11	$P<0.02$
9	12.9 ± 0.5	12	$P<0.01$
14	14.4 ± 0.4	10	$P<0.01$
21	15.4 ± 0.4	11	$P<0.01$
28	20.3 ± 0.6	11	$P<0.01$

*Not significant.

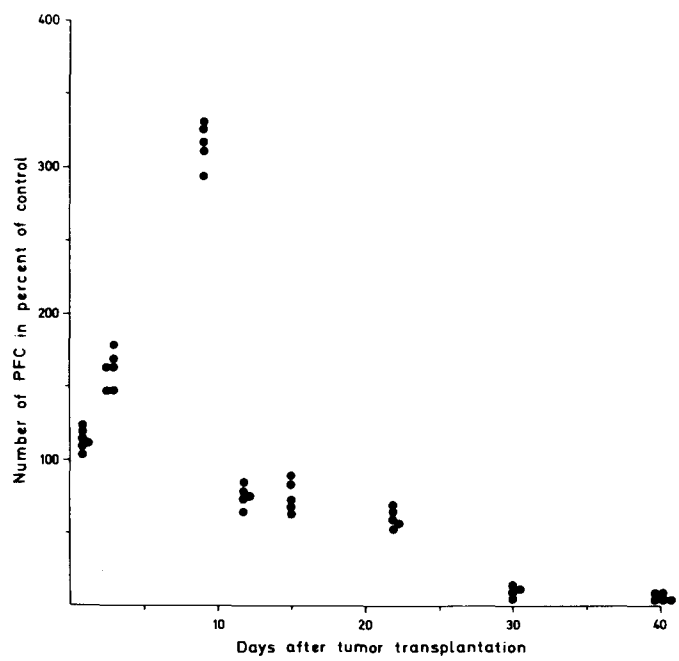

Fig. 1. *Number of PFC, expressed in percent of control, in C3Hf/Bu mice at particular days following lymphoma cell transplantation. Except on the* day 1, *the values are significantly different from the controls with* $P<0.05$, *on the* days 3, 12, 15 *and* 23, *as well as with* $P<0.01$ *on the* days 9, 30 *and* 40 *respectively.*

number in the spleens was noticed. About a month following tumor cell injection, the values reached very low levels, under 10% of the number in the spleen of normal animals.

Thus, initial stimulation of the reaction to third party antigens (skin allograft and SRBC) in lymphoma injected mice changed into progressive immunosuppression. To check the ability of various lymphoid cell populations to abolish this immunosuppression and restore normal reactivity, the following experiments were performed.

2. *Restoration of immunoreactivity in lymphoma-bearing mice*

2.1. *Skin allograft rejection.* Mice with lymphoma received intraperitoneal injection of 10^8 viable cells from lymph nodes of normal syngeneic mice 14 or 25 days after lymphoma transplantation and allogeneic skin graft was applied on the same day. The rejection time of allogeneic skin graft was shortened back to control value seen in normal mice, or became even shorter (Table 2). The same injection did not change the ability of normal mice to reject the allograft.

Injection of 10^8 spleen cells failed to restore immunoreactivity in lymphoma bearing mice (Table 2).

2.2 *Plaque-forming cell response.* Intraperitoneal injection of 10^8 cells from syngeneic lymph nodes, given 3 days before SRBC injection, significantly increased the number of PFC in the spleen of mice with lymphoma (Table 3). In mice having had the tumor for 14 days the PFC response was restored back to the values seen in normal mice, but in the mice having had the tumor for 25 days the PFC response was restored only partly and still remained below that in normal mice.

Similarly to the failure in restoring the skin graft rejection the injection of spleen cells from normal syngeneic donors did not reverse the decrease of the PFC values in tumor-bearing mice (Table 3).

Hence, lymph node cells, but not spleen cells from normal syngeneic donors, rescue the mice with tumor from the state of immunodepression. In order to determine the influence of environment altered by the tumor on the ability of the available immunocytes to react, the following experiment was performed.

3. *Transfer of spleen cells from tumor-bearing mice to syngeneic lethally irradiated recipients*

An injection, comprising 10^7 spleen cells from a lymphoma-bearing mouse or from a normal mouse, was given i.v. into lethally irradiated syngeneic recipients. Namely, 10^7 cells from the spleen of each donor were injected to a separate recipient. SRBC were injected 4 days before PFC assay, i.e. 3 days after transfer of spleen cells. The results are given in Table 4. Spleen cells from mice that have had lymphoma for 15 or 30 days produced significantly ($P<0.01$) higher number of PFC in the spleens of the recipients than the spleen cells from normal syngeneic donors without tumor. The difference was present even when the results were calculated in terms of the total number of splenocytes from each type of donor (lymphoma-bearing or normal) as shown in Table 4.

DISCUSSION

Recent studies have mainly focused the attention on impaired immune response to the tumor itself, both in man and in selected animal tumor models [5–9] rather than on generalized immunosuppression accompanying tumor growth.

As presented, the growth of syngeneic lymphoma in C3Hf/Bu mice was accompanied by generalized impairment of the immunological response to antigens such as SRBC (a T-cell dependent antigen) or skin allograft (which induces T-cell dependent response). In these mice a progressive depletion of lymph nodes and spleen has been expressed and the appearance of tumor cells in these lymphoid organs occurred in the late stage of the disease [9]. Our results prove that the prolongation of allograft survival time and the decrease of plaque-forming ability in lymphoma-bearing mice could be corrected by injecting lymph node cells from normal syngeneic donors. This might indicate a reduced number of lymphoid cells in tumorous host as a simple cause of the depression. But, the results of transplantation of the spleen cells from tumorous donor to lethally irradiated recipients clearly show that these donors possessed a confident number of reactive lymphoid cells.

The increased number of suppressor cells and a high level of immunosuppressive humoral factors, as blocking factor, fetal tissue antigens, normal immunoregulating proteins, are considered to be responsible for generalized immunosuppression of tumorous host [12]. These factors could compete for T lymphocytes and thus interfere with efferent limb of the immune response to tumor [5, 6]. Furthermore, the response of spleen cells to mitogenic or antigenic stimulation was suppressed if the cells had interacted with syngeneic tumor

Table 2. Survival of C57BL skin allograft on C3Hf/Bu mice bearing lymphoma for 14 and 25 days respectively and injected with lymphoid cells from normal syngeneic donor at the time of grafting

Interval after injection of tumor cells	Source of 10^8 syngeneic lymphoid cells	Number of mice	Days of allograft survival (Mean ± S.E.)	Significance (*t*-test)

P_1 significance to tumor bearing mice injected with lymphoid cells.
P_2 significance to normal mice (neither tumor cells, nor lymphoid cells injection).
N.S. not significant.

Table 4. Number of PFC in the spleen of lethally irradiated C3Hf/Bu mouse, determined 7 days after injection of 10^7 spleen cells either from normal syngeneic mouse or from the mouse bearing syngeneic lymphoma for 15 or 30 days respectively

Donors of spleen cells	Number of PFC per spleen of lethally irradiated recipient (Mean ± S.E.)	Significance (*t*-test)	Number of PFC calculated per spleen of donor (Mean ± S.E.)	Significance (*t*-test)
15 days after tumor cell transplantation (10 mice)	505 ± 36	$P < 0.01$	28,126 ± 4042	$P < 0.01$
Normal mice (6 animals)	360 ± 8		8338 ± 2050	
30 days after tumor cell transplantation (12 mice)	481 ± 11	$P < 0.01$	23,880 ± 1500	$P < 0.01$
Normal mice (6 animals)	282 ± 24		9462 ± 1020	

cells *in vitro* [13]. Thus, progressive immunosuppression in tumorous host could result from direct "subversive" action of the tumor, which may be mediated through prostaglandin pathway [3, 13]. These factors do not induce antigenic competition and do not influence the serum components necessary for various functions of macrophages and other lymphoid cells; instead they affect T lymphocytes [14].

T-cells, but not B-cells, were shown to be suppressed by the syngeneic tumor and the central defect in the depression of humoral and cellular immunity in tumor-bearing host seems to be in T-cell population [3, 6]. With this in mind, normal syngeneic lymph node cells were given to tumorous host, supposing that injected cells—mostly T (T_2 cells) population—would overcome immunosuppressive factor(s) in tumorous host, and destroy allogeneic skin grafts and enhance the response of B-cells against SRBC in PFC assay. Our results fully confirmed the supposition. However, the possibility that tumor cells could be attacked following lymph node cells injection was not investigated in our system. On the other hand, the injection of spleen cells from a normal donor was not able to restore the reactivity of the tumorous host: this is probably due to the small number of T-cells (mostly T_1-cells) among the macrophages, K-cells and B-cells in the spleen.

It was further shown that the response of spleen cells to SRBC could be enhanced by the addition of T-cells educated to a second non-cross-reacting antigen, but only if the educating antigen is present [15]. This could explain initial high level of PFC to SRBC in spleen of present and other [16, 17] models of tumorous host, when the cells are educated to tumor's antigens. Later, due to the suppressive action of the tumor, these educated cells, as well as those influenced by them, were not able to react. In our system, lymphoma cells were presented in the spleen of mice bearing tumor for 25 days, but not in those bearing tumor for 15 days only [9]. As presented here, the decrease of the PFC number in the spleens of these two groups was significant to controls, being more pronounced in the 25-day group. One can speculate that progressive depletion of lymphoid cells from the spleen, combined with the immunosuppressive factor(s) existing in tumorous host, (probably potentiated by the presence of tumor cells in the spleen) is responsible for the depletion of PFC. Restoration of PFC number succeeded completely if the lymph node cells from normal donor had been injected in the mice bearing tumor for 15 days and partly in these bearing lymphoma for 25 days. However, our results proved that transfer of spleen cells from tumor-bearing host to lethally-irradiated syngeneic recipient resulted in a significantly higher PFC response to SRBC than when normal donor spleen cells have been injected. A higher number of PFC in lethally irradiated host injected with spleen cells from that donor bearing various, non-lymphoid, tumors in comparison to those injected with normal spleen cells was also observed in our laboratory (to be published). Spleen of tumorous host contained thus a satisfactory number of T and B cells to mount any immune reaction.

The action of immunosuppressive factors, existing in tumorous host, could be overcome by an additional injection of syngeneic T-cells, or diminished by removing the immunocytes from the tumor influenced environment. However, whether immunologic dysfunction in malignancies is a necessary component of neoplastic process or only (merely) an inconsequential sequele remain still a very challenging question.

Effect of Medium Conditioned by Acute Myeloid Leukaemia Cells on Normal Marrow Colony-Forming Ability and Sensitivity to Cytosine Arabinoside*

M. Y. GORDON, I. D. C. DOUGLAS† and N. M. BLACKETT

Department of Biophysics, Institute of Cancer Research, Sutton, Surrey, United Kingdom

Abstract—*Medium conditioned by acute myeloid leukaemia cells (LCM) inhibits colony formation by normal human bone marrow cells. The degree of inhibition was related to the growth characteristics, in agar, of the leukaemic cells used to prepare the conditioned medium. Treatment with LCM also altered the sensitivity of the normal colony-forming cells to cytosine arabinoside (ara-C) in a manner proportional to the level of inhibition caused by exposure to LCM.*

INTRODUCTION

In acute myeloid leukaemia (AML) not only does the marrow contain a large population of leukaemic cells but normal haemopoietic elements are reduced. This implies a relative growth advantage to the leukaemic cells which could be due, at least in part, to a suppressive effect of these cells on the normal precursor population in the marrow. Although it is uncertain whether such an effect is operative *in vivo*, data are available which show that cells from AML patients, or medium conditioned by AML cells, inhibit the proliferation of normal bone marrow cells in agar culture *in vitro* [1–3].

The action of several drugs used in the treatment of AML, notably cytosine arabinoside (ara-C), depends on the proliferative characteristics of the target cells. Consequently, an inhibitory effect of leukaemic cells which altered the proliferation of the residual normal cells could also reduce the toxicity of the drug to normal haemopoietic tissue.

It is well known [4, 5] that cases of AML at diagnosis show different growth patterns in agar *in vitro*. Some produce colonies and/or clusters of cells while others do not grow at all. It may be speculated that leukaemic cells showing different growth patterns in culture may also exert different inhibitory effects on normal marrow cells *in vitro*. The purpose of this study was to investigate the relationship between the growth of leukaemic marrow cells in culture and their inhibitory effects on normal precursor cells both in terms of colony formation and their altered sensitivity to the drug cytosine arabinoside (ara-C).

†Present address: Department of Haematology, St. Lukes Hospital, Guildford, Surrey, United Kingdom.

MATERIAL AND METHODS

Two-5 ml of marrow was aspirated from the iliac crests of AML patients at presentation or from patients with solid tumours. In the case of the solid tumour patients there was no evidence of marrow involvement by tumour and these patients were considered to be haematologically normal. A total of 21 untreated leukaemic samples and 18 normal marrow samples were used for this study.

The colony-forming ability of all marrow samples was assayed using an Agar Diffusion Chamber technique which has been described in detail elsewhere [6]. For this, 2×10^5 nucleated marrow cells, suspended in agar-medium, were introduced into diffusion chambers which were then inserted into the peritoneal cavities of irradiated (900 rad) C57Bl mice. Seven to eight days later the granulocytic colonies in the agar were counted.

Conditioned medium was prepared from both normal and leukaemic marrow cells according to the method of Chiyoda *et al.* [3]. Washed bone marrow cells were diluted to 3×10^6/ml in McCoys medium containing 15% Special Bobby Calf Serum (Gibco Bio-cult, Scotland). This suspension was incubated at

37 C for 3 days when the supernatant was obtained by centrifugation and frozen at −20°C until use (within 1 month).

Normal bone marrow cells were exposed to these conditioned media in suspension cultures: 1 ml cultures containing $2\text{–}3 \times 10^6$ normal marrow cells and varying amounts of conditioned medium were set up in McCoys Medium containing 15% serum, gassed with 10% CO_2 in air and incubated at 37°C for 3 hr. These suspension cultures were then diluted 10-fold and colony formation was assayed in Agar Diffusion Chambers. The mean control yield, following incubation without added conditioned medium, was 35.9 ± 5.2 colonies per chamber. Four chambers were scored for each experimental group so that each control group contained in excess of 100 colonies.

The sensitivity of normal bone marrow cells to cytosine arabinoside (ara-C) was measured using the method described by Gordon and Douglas [7]. After 3 hr incubation in suspension culture with conditioned media, the cells were seeded in diffusion chambers and the chambers implanted into mice. The cells within the chambers were exposed to ara-C by intravenous injection of 200 mg kg^{-1} of the drug into the host mouse. Two hours later the chambers were transferred into secondary recipients and colony formation was scored after a further 7–8 days.

RESULTS

The leukaemic cells used to condition medium for these experiments were grouped into 3 categories which were based on the maximum aggregate size achieved in agar culture in diffusion chambers. These groups were defined by (1) no growth; (2) the formation of small clusters of fewer than 30 cells; (3) the formation of large clusters (30–50 cells) and/or colonies of more than 50 cells.

Figure 1 shows the dose-dependent inhibition of normal colony formation by medium conditioned with non-growing leukaemic cells (LCM). The LCM was added to suspensions of normal marrow cells at concentrations of up to 25% and incubated for 3 hr when colony formation was assayed. Where more than one point was shown for a given concentration, different normal marrows were used for each measurement. All further experiments used a concentration of 10% LCM.

The preincubation period of 3 hr was used because the yield of colony forming cells from normal marrows incubated without the addition of CM for this length of time averaged 90% of their initial value. Longer periods of incubation resulted in a rapid reduction of colony-forming ability. Furthermore, when the marrow was seeded in diffusion chambers immediately after the addition of LCM no colony inhibition was seen, while the level of inhibition increased with the length of the preincubation period (data not given).

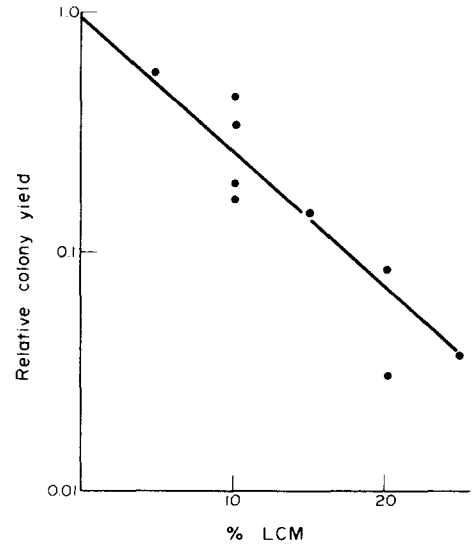

Fig. 1. Level of normal marrow inhibition as a function of the concentration of leukaemic cell conditioned medium (LCM).

Leukaemic CM derived from non-growing, small cluster forming or large cluster and colony forming leukaemias gave different levels of inhibition of normal colony formation. Medium conditioned by normal bone marrow cells had little, if any, inhibitory effect (Fig. 2). LCM from non-growing leukaemic cells gave the greatest and most consistent inhibition while inhibition by small cluster forming LCM was more variable. Medium conditioned by large cluster and colony forming leukaemic marrow was least inhibitory. The effect of large cluster and colony forming LCM was not significantly different from that of normal cells CM (Student's *t*-test). The inhibition of colony formation by non-growing LCM and small cluster forming LCM was significantly different from the controls ($P<0.001$; $P<0.01$ respectively) and from the effects of large cluster and colony forming LCM ($P<0.001$; $P<0.01$ respectively). There was, however, no significant difference between the inhibitory effects of non-growing and smaller cluster forming LCM.

Figure 2 also shows the results of repeated measurements made using individual batches of LCM against different normal marrow cells. It is evident that there was little variation

in the effect of each LCM or different target cells and no significant loss of inhibitory activity during the time between the measurements. The data in Fig. 2 was obtained within

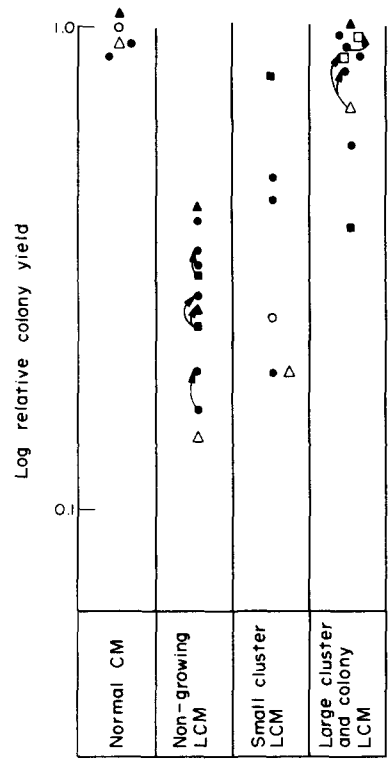

Fig. 2. The different effects of leukaemic cell conditioned medium (LCM) derived from non-growing, small cluster forming and large cluster or colony forming leukaemias, compared with the effect of medium conditioned by normal bone marrow cells. Arrows indicate where one LCM preparation was tested against different normal marrows. (●) shows where one CM preparation was assayed against an individual normal marrow. The other matched symbols show where different CM preparations were assayed against the same normal marrow.

a month of LCM preparation. Some loss of activity was detected when LCM was tested more than 2 months after it was prepared and these data are not included in the figures.

The effect of cytosine arabinoside (ara-C) on the normal cells forming colonies following incubation with LCM is shown in Fig. 3. Treatment of cells with ara-C, following incubation in suspension culture without the addition of CM, gave a survival of 35–45% of the control value. Addition of normal cell CM during the preincubation period did not alter the sensitivity of the colony forming cells to the drug. In contrast, LCM from non-growing and small cluster forming leukaemias tended to reduce the sensitivity of normal cells to ara-C while medium conditioned by large cluster and colony forming leukaemic cells tended to increase their sensitivity to the drug, although these effects could not be shown to differ significantly from the controls. However, cell sensitivity to ara-C, following incubation with large cluster and colony forming LCM was significantly different

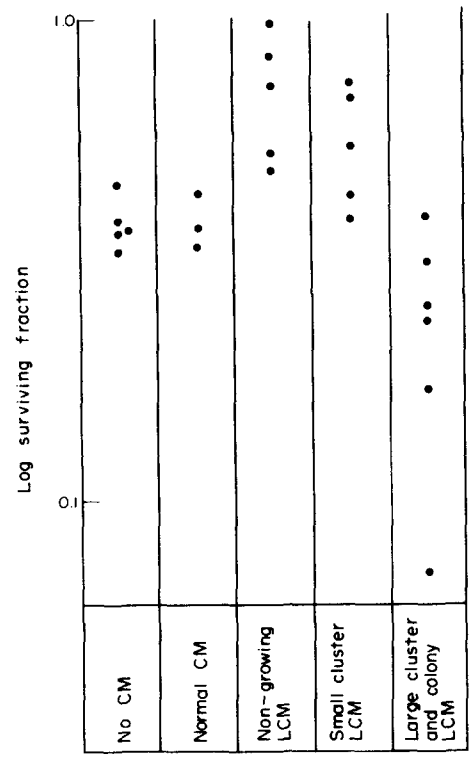

Fig. 3. Survival of cells treated with 200 mg kg^{-1} *ara-C following exposure to leukaemic or normal CM, compared with the survival of cells not exposed to CM.*

from that observed after incubation with non-growing or small cluster forming LCM ($P<0.01$; $P<0.01$ respectively).

It is apparent, from the results in Figs. 2 and 3, that the conditioned media which inhibit normal colony formation also tend to lower the sensitivity of the remaining colony forming cells to ara-C. Cells treated with less inhibitory CM show a trend towards increased drug sensitivity. These data are combined in Fig. 4, showing more clearly the relationship between the two parameters. ($r=0.79$; $P<0.001$).

DISCUSSION

The aim of cancer chemotherapy is to achieve differential cell kill between normal and tumour cells thus increasing the chances of tumour eradication without intolerable damage to normal tissue. Experimental studies have measured drug toxicities against normal and malignant cells *in vitro* with a view to selecting compounds meeting this requirement. Such studies are often made using

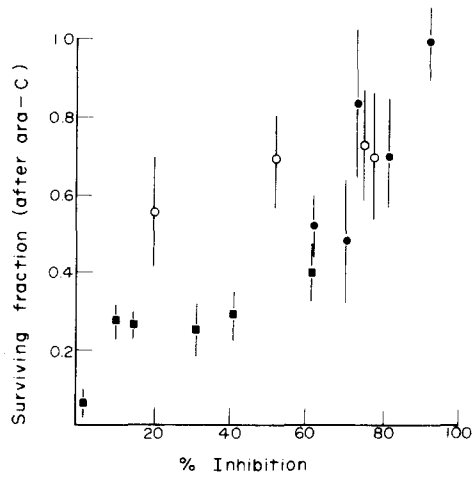

Fig. 4. Relationship between the level of normal marrow inhibition by leukaemic cell conditioned medium (LCM) and sensitivity to ara-C following exposure to LCM derived from ● non-growing, ○ small cluster forming or ■ large cluster and colony forming leukaemias.

normal animal or human cells whose sensitivity may then be compared with that of tumour cells. However, data obtained in this way can be valid only with the *caveat* that the presence of tumour does not in any way modify the drug sensitivity of normal cells.

Chiyoda *et al.* [2] and Morris, McNeill and Bridges [1] found inhibition of normal colony formation then normal marrow was cultured in the presence of leukaemic cells *in vitro*. In addition, Chiyoda *et al.* [3] measured normal colony inhibition by a homogenate of leukaemic cells, its fractionated extracts and medium conditioned by leukaemic cells. The use of conditioned medium was chosen for this study since it can be stored frozen for a limited period [3] and we were not therefore always dependent upon the availability of normal and untreated AML marrow samples at the same time.

Culture of untreated AML samples in Agar Diffusion Chambers gives similar patterns of growth to those seen in agar *in vitro* [4, 5]. The inhibitory effects on normal marrow of CM from leukaemic cells belonging to the three culture groups (no growth; small cluster forming; large cluster and colony forming) were different. Thus, although the finding that leukaemic cells inhibit normal colony formation is not new, we are not aware of any published data relating the level of inhibition to the initial growth pattern in culture.

There have been several reports of the prognostic value, in AML, of leukaemic cell culture [4, 5, 8]. Moore *et al.* [4] used the abnormal proliferation of AML cells *in vitro* to define groups of patients with good and bad prognosis. More recently, Spitzer *et al.* [5] have provided a simpler classification of *in vitro* growth and prognosis but identified different culture groups from Moore *et al.* [4]. On the other hand, Curtis *et al.* [8] found no correlation between culture findings and the rate of remission induction. Our data (unpublished), using Agar Diffusion Chambers to investigate 100 untreated AML, patients indicate that colony forming leukaemias have a lower remission rate than non-growing or cluster forming leukaemias. This is in agreement with Spitzer *et al.* [5] although Moore *et al.* [4] found a higher remission rate in colony forming leukaemias than in non-growing or cluster forming groups.

The present study has shown that normal cell inhibition by LCM depends on the ability of the leukaemic cells themselves to grow in culture. There was also a wide range of inhibitory activity within each culture group (Fig. 2). Should these ranges correlate with prognosis, such data would be useful in increasing the accuracy of prediction based on leukaemic cell culture alone. At the present time, the number of patients investigated for both growth in culture and inhibitory activity is too small to show whether the relationship between the two parameters will aid prognosis.

Of further interest is the relationship between the level of normal cell inhibition and their sensitivity to ara-C. The inhibition of normal bone marrow colony formation by factors derived from leukaemic cells suggests that the proliferative characteristics of these colony forming cells may be changed. It is, therefore, reasonable to suggest a resultant change in normal cell sensitivity to drugs, particularly those whose action depends on the proliferation rate of the cells. A correlation between inhibition, modified drug sensitivity and the clinical outcome of patients would then indicate protection of normal colony forming cells in certain leukaemic individuals during induction chemotherapy and allow more aggressive chemotherapy to be considered during the cytoreductive phase of their treatment. Although the normal cells may not regain their chemosensitivity until the leukaemic cell population had been considerably reduced, this approach would be limited in practice by the numbers of leukaemic cells required to produce the inhibitor.

Changes in Cytotoxicity and Viability of Immune Lymphocytes after X-Irradiation*

CHANG W. SONG and SEYMOUR H. LEVITT

Radiobiology Laboratories, Department of Therapeutic Radiology, University of Minnesota Medical School, Box 494 University Hospitals, 420 Delaware Street S.E., Minneapolis, Minnesota 55455, U.S.A.

Abstract—*The effect of X-irradiation on cytolytic immune lymphocytes was studied* in vitro. *The splenic lymphocytes of C57BL mice immunized against mastocytoma P815-X2 cells of DBA/2J mice were irradiated and the sequential change in cytotoxicity against the tumor cells was measured by the* ^{51}Cr *release method* in vitro. *From the extent of* ^{51}Cr *release, the relative numbers of cytolytic lymphocytes (lytic unit) were then calculated. The change in viability was also measured by the trypan blue exclusion method at various time intervals after irradiation.*

A slight but statistically significant decrease in the number of lytic units was observed immediately after irradiation with doses higher than 125 rad. *The number of lytic units declined exponentially at a dose-dependent rate so that almost no cytotoxicity could be detected later than* 10 hr *post-irradiation with* 500 rad. *The shape of the dose–effect curve suggested that the cytotoxic immune lymphocytes from the spleen are heterogeneous with respect to radiosensitivity.*

The viability of lymphocytes did not change for 2 hr *after irradiation with* 75–500 rad, *but declined during* 2–7 hr *after irradiation and then slowly thereafter. A small portion of the lymphocytes was still viable* 10 hr *after irradiation with* 500 rad, *suggesting the presence of relatively radioresistant lymphocytes in the spleen.*

The variance in the rate of changes in the cytolytic function and viability of immune lymphocytes suggested that the decrease in the cytolytic ability of lymphocytes following irradiation is due to qualitative as well as quantitative changes in the immune lymphocyte population.
