CELLULAR immune reactions are mediated by thymus-derived lymphocytes (T cells), while humoral immune reactions are mediated by bone marrow-derived lymphocytes (B cells) [1–4]. In view of the frequent use of radiation to suppress host-rejection of allografts, and the extensive use of radiation for treatment of malignant tumors, a better understanding of the effect of radiation on the immune responses mediated by T and B cells is highly desirable. Although lymphocytes are generally regarded as radiosensitive [5–6], immune cytotoxic T cells have been reported to be rather radioresistant [7–10]. Ritter *et al.* [11] reported that immune C57BL anti-DBA/2 spleen cells were cytotoxic after irradiation with 50–100 rad. These investigators, however, found that the lymphocytes were no longer cytotoxic 18 hr after irradiation, even though the potential for antibody formation was still present.

In these studies the change in the total cytotoxicity of the lymphocyte population was measured. On the other hand, we investigated the sequential change in the concentration of cytotoxic immune lymphocytes at various times after various doses of irradiation *in vitro* in the present study. We also studied the change in viability of lymphocytes to determine the correlation between the change in the relative number of cytotoxic lymphocytes and the viability of splenic lymphocytes.

MATERIAL AND METHODS

The splenic lymphocytes of C57BL mice immunized against mastocytoma P815-X2 cells of DBA mice were used as immune lymphocytes. The extent of damage to the target cells by the immune lymphocytes was measured by the ^{51}Cr release method *in vitro*. This system has been used by a number of investigators and is believed to be the simplest and the most defined for the study of

T cell-mediated cytolysis of immunogenic grafts or tumors [9, 12 20].

Immunization and lymphocyte preparation

DBA/2J mice (Jackson Laboratories, Maine) were transplanted with syngeneic P815-X2 mastocytoma cells and the ascitic tumor cells were harvested several days later. The cells were washed 3 times with RPMI 1640 medium (Associated Biomedic Systems, Buffalo, NY) and the number of viable cells was counted using the trypan blue exclusion method. About 3×10^7 cells in 0.3 ml of RPMI 1640 medium were injected i.p. into 8–10 week-old C57BL male mice (inbred in our laboratory). Control mice received the same volume of medium alone. Spleens were removed from the control and immunized mice 10 or 11 days later, minced with scissors and pressed through a stainless steel screen. The cells were left in a petri dish for 40 min at room temperature and the non-adherent cells from 3 spleens were pooled for each experiment. The lymphocytes were further purified by centrifugation on a Ficoll–Hypaque gradient [20]. After several washings, the lymphocytes were re-suspended in RPMI 1640 medium supplemented with 100 units/ml of penicillin, 100 μg/ml of streptomycin and 10% heat-inactivated fetal calf serum (hereafter this will be referred to as complete medium) and the number of viable cells was counted. The viability at this time was about 95% and less than 5% of the viable cells were nonlymphocytes.

Irradiation

Immune and non-immune lymphocyte suspensions at 7×10^5 cells/ml were transferred to plastic culture flasks (Falcon 3013) and irradiated with 220 kV X-rays at 15 mA, using a 1 mm Al filter and a dose rate of 290 rad/min. A portion of lymphocytes was treated the same but sham-irradiated and used as non-irradiated controls.

Target tumor cells

The P815-X2 mastocytoma cells were harvested from DBA/2J mice and cultured as a suspension culture for 2–3 days in complete medium. About 2×10^6 exponentially growing tumor cells obtained from the culture were incubated with 100 μCi of $Na_2{}^{51}CrO_4$ in 1 ml of complete medium for 40 min at 37°C with gentle rocking. The cells were then washed 3 times and resuspended in complete medium. To remove the loosely-bound ^{51}Cr from target tumor cells, the cell suspension was incubated for 20 min at 37°C and washed twice.

Cytotoxicity and viability of lymphocytes

One ml of lymphocyte suspension containing 7×10^5 cells was transferred into plastic culture tubes (Falcon 3033) immediately after irradiation, and kept stationary in a 37°C incubator gassed with humidified air containing 5% CO_2. At various times after the irradiation the viability of the lymphocytes was determined by the trypan blue exclusion test and also the cytotoxicity measured. For the determination of cytotoxicity, 1×10^5 ^{51}Cr-labeled tumor cells in 1 ml of complete medium were added to the lymphocyte suspensions and incubated for 6 hr at 37°C with gentle rocking (6 cycles/min). After 6 hr, the total radioactivity in the tubes was counted using a γ-scintillation counter. The tubes were then centrifuged at 2000 rev/min for 5 min. One ml of the supernatant was carefully transferred to another tube, mixed with 1 ml of water to equalize the counting geometry and the radioactivity counted. The percent ^{51}Cr release was calculated using the following formula:

$$\%\ ^{51}\text{Cr release} = \frac{^{51}\text{Cr activity in 1 ml supernatant} \times 2}{\text{Total } ^{51}\text{Cr activity}} \times 100$$

A number of investigators have used the ^{51}Cr activity which could be released from the target cells by freeze-thawing as the total ^{51}Cr activity for the calculation of percent ^{51}Cr release. However, we used the total ^{51}Cr activity incorporated into the target tumor cell for the calculation because we, as well as other investigators, found that the activity of ^{51}Cr recoverable following freeze-thawing lysis of target cells is sometimes variable [14, 21]. Non-immune lymphocytes were used as control in all of the experiments.

RESULTS

We first investigated the relationship between the per cent ^{51}Cr release and the ratio of the number of immune lymphocytes to the number of target cells. As shown in Fig. 1, the percent ^{51}Cr release from 1×10^5 labeled target cells increased linearly as a function of the logarithm of the number of immune lymphocytes up to 10 $\times 10^5$ lymphocytes. This relationship is in agreement with that found by other investigators [17, 21–24]. In the following experiments, 7 $\times 10^5$ immune or non-immune lymphocytes were used with 1×10^5 tumor cells in 2 ml incubation mixtures. Using immune lymphocytes under the above conditions, 64.2 $\pm$ 1.5% of the total ^{51}Cr was released from the labeled target cells in 6 hr. When corrected for the ^{51}Cr release induced by 7×10^5 non-immune

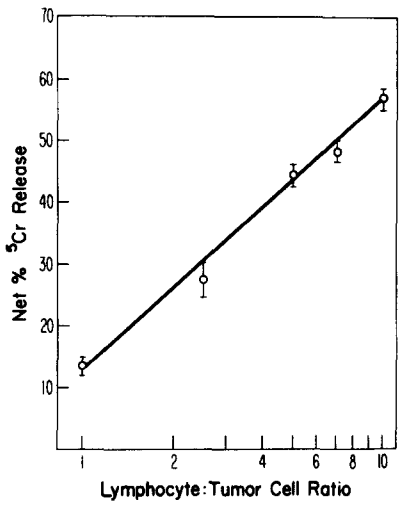

Fig. 1. Net % release of ^{51}Cr from labeled target cells as a function of immune lymphocyte to target cell ratio. Incubation mixtures containing 1×10^5 target cells and immune lymphocytes ranging from 1×10^5 to 1×10^6 cells were incubated for 6 hr, and the ^{51}Cr release was measured. The ^{51}Cr released by non-immune lymphocytes was subtracted from that released by immune lymphocytes to obtain the net ^{51}Cr release. Averages of 7 experiments with duplicate measurements and S.E. are shown.

lymphocytes, which was $15.7 \pm 0.8\%$, the net ^{51}Cr release induced by the immune lymphocytes was 48.5%. This number of immune lymphocytes was arbitrarily considered to possess 1 lytic unit [2]. Based on the net percent ^{51}Cr release from labeled target cells, the number of cytotoxic lymphocytes in each experimental lymphocyte population was graphically estimated from Fig. 1. The number of lymphocytes thus obtained was then divided by 7×10^5 to obtain the number of lytic units present.

Figure 2 shows the changes in the number of lytic units in non-irradiated and irradiated immune lymphocyte populations as a function of time. The 0-rad curve shows that the number of

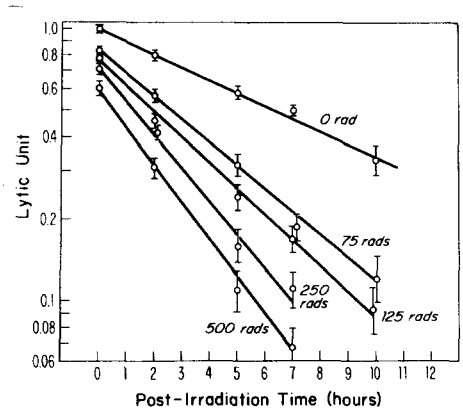

Fig. 2. The number of lytic units at various times after irradiation. Immune lymphocytes were irradiated with various doses of X-rays and the number of lytic units determined from the ^{51}Cr release. The cytotoxicity of non-irradiated immune lymphocytes (0 rad) at 0 hr is designed as one lytic unit. Averages of 10 experiments with duplicate measurements and S.E. are shown.

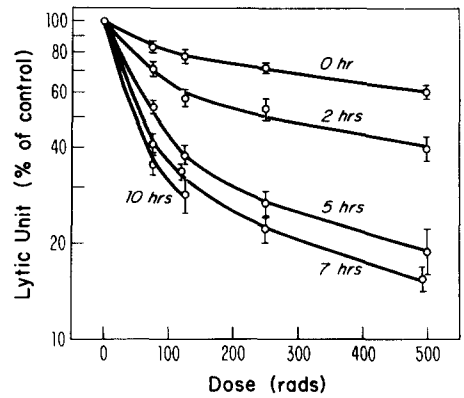

Fig. 3. Changes in lytic units as a function of irradiation dose. The numbers of lytic units at various times after irradiation were expressed as a per cent of the number of lytic units of non-irradiated lymphocytes (0-rad) at the corresponding time of measurements. Averages of 10 experiments with duplicate measurement and S.E. are shown.

lytic units of non-irradiated lymphocytes decreases exponentially as a function of time, reaching a value of 0.35 in 10 hr. The number of lytic units of lymphocytes decreased immediately after irradiation. Although the decrease was rather small, it was statistically significant after doses higher than 125 rad ($P < 0.05$). The number of lytic units of irradiated immune lymphocytes falls exponentially up to 10 hr, the extent of our observation. It appears that the higher the dose of radiation, the faster the decrease in number of lytic units. Using the same data, shown in Fig. 2, the change in number of lytic units was plotted as a function of radiation dose at various times after irradiation of lymphocytes in Fig. 3.

The number of lytic units of non-irradiated immune lymphocytes incubated for various lengths of time (0-rad curve of Fig. 2) was taken as the control value for the time and the number of lytic units of irradiated immune lymphocytes at various times was expressed as a percentage of the corresponding control. For example, in Fig. 3, the number of lytic units decreased to 60 and 15% of the unirradiated control immediately after and 7 hr after X-irradiation with 500 rad, respectively. Regardless of the time of measurement, the dose–effect curves were initially steep, up to a radiation dose of 125 rad and became less steep as the radiation dose increased, suggesting that the cytotoxicity of the immune splenic lymphocytes used here are heterogeneous with regard to sensitivity to irradiation.

Immediately after preparation, about $95.3 \pm 1.2\%$ of the non-irradiated lymphocytes were found to be viable as tested by the trypan blue exclusion test. The change in viability of immune lymphocytes as a function of time after irradiation is shown in Fig. 4. At all doses of

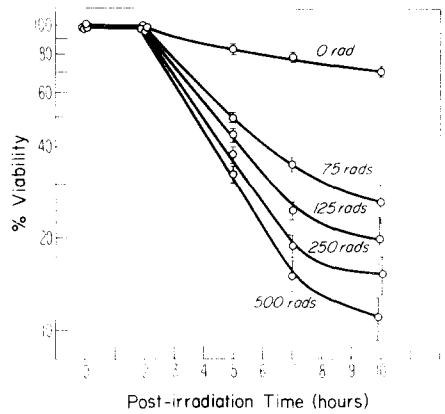

Fig. 4. Changes in viability of immune lymphocytes at various times after irradiation. The lymphocytes were irradiated with various doses of X-rays and cultured in vitro *for various time periods and the viability measured by the trypan blue exclusion method. The viability of non-irradiated* (0-rad) *lymphocytes at* 0 hr *was taken as* 100% *viable. Averages of* 10 *experiments with duplicate measurements and S.E. are shown.*

irradiation tested, there was no change in variability during the first 2 hr *in vitro*, even with a dose as high as 500 rad. The viability of non-irradiated immune lymphocytes began to decrease gradually thereafter, reaching 70% of the original value at 10 hr. The viability of irradiated lymphocytes also started to decrease after a 2-hr lag period. The rate of decrease in the viability was exponential during the 2–7 hr post-irradiation period, after which the rate of decrease became considerably slower. The rate of decrease in viability was radiation dose-dependent; the higher the radiation dose, the faster the rate of decrease. The viability of irradiated immune lymphocytes is replotted as a function of radiation dose in Fig. 5. The shape of the curves again suggests that the immune splenic lymphocytes used here are heterogeneous

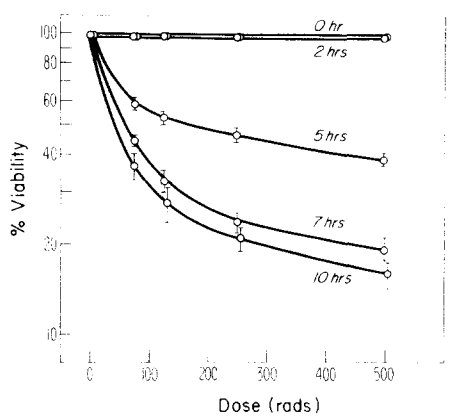

Fig. 5. Changes in viability as a function of irradiation dose. The viabilities at various times after irradiation were expressed as percent of the viabilities of non-irradiated lymphocytes (0-rad) *at the corresponding time of measurement. with regard to radiosensitivity. While the majority of the cells are radiosensitive and are killed by a dose of less than 125 rad as determined in 7–10 hr after irradiation, a small proportion of the population are still viable and are thus radioresistant.

The viability of non-immune lymphocytes after irradiation was essentially the same as that of immune lymphocytes after irradiation (data not shown).

DISCUSSION

This study shows that the number of lytic units or the relative frequency of cytotoxic cells in the immune lymphocyte population decreases slightly, immediately after irradiation with doses as small as 75 rad. This decrease continues exponentially with increase in time after irradiation. This study also shows that the cytotoxic lymphocytes from spleens of mice are heterogeneous with respect to radiosensitivity.

The effect of radiation on the cytolytic activity of immune lymphocytes observed in this study may appear to be large when compared with our previous results [25] and with those of Ritter *et al.* [11]. This is due to the fact that while the changes in release of isotopes from labeled target cells was directly used to express the radiation damage on the lymphocytes in our previous report and in the study by Ritter, the ^{51}Cr release was converted to the number of lytic units in the present study because the extent of isotope-release is linearly proportional to the logarithm of the number of cytotoxic immune lymphocytes as shown in Fig. 1. For example, the net percent ^{51}Cr release by the unirradiated control immune lymphocytes was 48.5%, as described before. Immediately after irradiation of the lymphocytes with 500 rad, the net percentage of ^{51}Cr release decreased to 40.4%. This is a decrease of 16.7% [(8.1/48.5) × 100]. An analysis using Fig. 1 indicates that the decrease in net percent ^{51}Cr release from 48.5 to 40.4% is equal to a decrease in the number of lytic units from 1 to 0.6, or a decrease of 40%.

At 2 hr after irradiation (Fig. 2), the number of lytic units of irradiated lymphocytes decreased considerably while the viability of the lymphocytes remained almost intact (Fig. 4). This suggests that the initial decrease in lytic units of the lymphocyte populations after irradiation may have resulted from functional changes in the lymphocytes rather than from the death of the lymphocytes, as judged by the trypan blue exclusion test. That is, lymphocyte functions necessary for cytolytic activity such as the metabolic activity of the lymphocytes [2, 12, 13,

18, 26] or the ability to move and form aggregates with target cells [1, 12, 14, 17–19, 27–30], may be significantly damaged within 2 hr. Christensen and Jackson [31] also reported that metabolic disturbances to rat thymocytes could be observed much earlier than their decrease in viability following exposure to 1000 rad of X-rays.

A number of investigators reported that immune responses which do not require proliferation of lymphocytes are radioresistant; for example, production of migration inhibition factors (MIF) by mature T cells [32] and synthesis and secretion of antibodies by fully differentiated B cells [33]. On the other hand, immune reactions which do require proliferation of lymphocytes are radiosensitive. Katz and his colleagues [34, 35] and others [36–38] demonstrated that while the helper function of T cells can be effectively abolished when radiation is administered before T cells are differentiated, the helper function is retained when radiation is given after T cells have fully matured. The killing of target cells by immune lymphocytes does not require further proliferation of lymphocytes. Thus, it is not surprising that, in the present study, the immune lymphocytes which in time eventually die of radiation damage were still highly cytotoxic immediately after irradiation.

It has been repeatedly demonstrated that the immune lymphocytes which cause the release of ^{51}Cr from the labeled allogeneic target cells are T cells [13, 14, 16, 18, 39, 40]. Therefore, the change in the number of lytic units of splenic lymphocytes after irradiation as observed in the present study, can be attributed to the loss of functions and death of cytotoxic T cells, which constitute probably not more than 4% of the total lymphocytes of the spleen [28]. On the other hand, the decrease in viability demonstrated by the trypan blue exclusion test reflects the death of not only the cytotoxic T cells, but also of other splenic lymphocytes and macrophages, which could not be removed completely by the procedure we used. While the number of lytic units was found to decrease exponentially until 10 hr after irradiation (Fig. 2), the decrease in viability was significantly slowed down from 7 hr after irradiation (Fig. 4). This suggests that the cytotoxic T cells are more radiosensitive than other spleen cells. The shape of the dose–effect curve in Fig. 3 suggests that the cytotoxic T cells themselves are heterogeneous in radiosensitivity. Perhaps this could be attributed to the differential radiosensitivity of the cytotoxic T cells in various stages of maturation or differentiation [7, 8].

Radiotherapists are becoming more interested in the effect of radiotherapy on immunocompetence, particularly the cell-mediated immune response [41]. We feel our observation in the present study of the radiation effect on effector cells is important for the understanding of the change in host immune response against tumors in patients undergoing radiotherapy.

Growth of a Thymoma in Diabetic Mice Treated with Insulin

KREŠIMIR PAVELIĆ and MILIVOJE SLIJEPČEVIĆ
"Rudjer Bošković" Institute, Department of Experimental Biology and Medicine, 41001 Zagreb, P.O. Box 1016, Zagreb, Yugoslavia

Abstract—*A transplantable thymoma of C_3H/f mice produced severe hypoglycemia in recipient mice and corrected hyperglycemia in mice with experimentally induced diabetes. Moreover, the level of the insulin content in the cell-free extract of tumour was higher than the level of insulin in sera and was very low in the muscle cell-free extract of tumour-bearing mice. The tumour grew more slowly in diabetic animals than in non-diabetic ones. However, its growth in diabetic mice treated with insulin was accelerated and resembled that in control (non-diabetic) animals. According to these data, it would seem advisable to monitor needs for insulin or other anti-diabetic medications in diabetic patients with a tumour, since this treatment may accelerate the tumour growth.*

INTRODUCTION

HYPOGLYCEMIA is observed in many animals with primary and metastatic tumours and is particularly severe in terminal stages of tumour growth [1–5]. The degree of hypoglycemia depends on the size and viability of the tumour: the larger the tumour the greater the decrease in blood glucose. Necrotic tumours are less effective in this respect [6].

A transplantable thymoma used in our laboratory [7] involves no necrosis or a minimal necrosis of the tumour tissue. It could be used, therefore, to test the working hypothesis that hypoglycemia reflects the number of live tumour cells and, for this reason, progresses with enlargement of the tumour mass. We have also investigated the influence of insulin on the rate of tumour growth and on the level of glucose in peripheral blood of mice with this transplantable tumour.

MATERIAL AND METHODS

Animals

Male C_3H/f mice, 20 weeks old, weighing about 23 g, were used in these experiments. They were obtained from the breeding colony of this Institute. Pelleted food and tap water were given *ad libitum*.

Accepted 16 November 1977.
The abbreviations used are D = diabetic, TB = thymoma-bearing, TB-D = thymoma-bearing diabetic, TB-DI = thymoma-bearing diabetic treated with insulin.

Tumour

The thymoma developed spontaneously in a C_3H/f mouse in 1970 at the M. D. Anderson Institute, Texas, U.S.A. and has been maintained in that strain by serial intramuscular transplantation of 3.5×10^6 cells into the flank. We obtained this tumour in 1972. Suspensions of tumour cells were prepared and counted by a standard technique [8]. The largest tumour diameter was recorded by caliper (Cambridge Scientific Industries, Cambridge).

Diabetes

Diabetes was induced by intravenous injection of alloxan (Merck, Darmstadt)—100 mg/kg. Hyperglycemia and glucosuria was checked 2, 8, 18 and 26 days after injection. The level of glucose in peripheral blood were determined using Hyvarinen and Nikkila's method [9]. The concentration of glucose in urine was assessed by Glukotest strips (Boehringer, Mannheim). Mice with induced diabetes and transplanted thymoma were treated daily with insulin (Pliva, Zagreb) administered intramuscularly, 8 units per mouse.

Biochemical analysis

Immunologically active insulin in sera and in cell-free-tissue extracts was determined by the two antibody method of Morgan and Lazarow [10], using porcine ^{125}I-insulin and crystalline rat insulin standards (CEA-IRE-SORIN).

Table 1. Survival of non-diabetic and diabetic mice after transplantation of thymoma and after insulin therapy

Experiment No.	Treatment	Abbreviation	No. of mice	Mean survival time (days ± S.D.)
1	Thymoma	TB	9	27.3 ± 4.2
	Alloxan and thymoma	TB-D	15	43.6 ± 2.8*
	Alloxan, thymoma and insulin	TB-DI	17	28.2 ± 6.3
2	Thymoma	TB	6	30.2 ± 4.2
	Alloxan and thymoma	TB-D	8	48.3 ± 3.9*
	Alloxan, thymoma and insulin	TB-DI	8	29.3 ± 5.9

Tumour cells were transplanted to the recipients 1 day after alloxan injection. Insulin was given daily starting 1 day after tumour implantation.
*$P < 0.05$ as compared with the control group receiving tumour cells only.

Tumour cells were transplanted to the recipients 1 day after alloxan injection. Insulin was given daily starting 1 day after tumour implantation.
*The level of glucose in control mice was determined 7 days after injection of Hanks' solution.
†$P < 0.05$ as compared with the group receiving Hanks' solution.
‡4–5 mice per point.

Statistics

The results are presented as mean ± standard deviation (S.D.). Significance of differences was assessed by Student's *t*-test, the level being set at 5% ($P < 0.05$) [11].

RESULTS

Survival time of thymoma-bearing (TB) mice and thymoma-bearing diabetic mice treated with insulin (TB-DI) was approximately the same (28 days). However, the survival time of tumour-bearing diabetic mice without insulin (TB-D) was significantly longer, that is 44 days (Table 1).

The body weight varied during the tumour growth and was higher in TB and TB-DI mice than in TB-D mice and in diabetic mice without tumour (D) (Fig. 1). TB-D mice lost some weight at the onset of the experiment, but later regained part of the loss. Their weight remained somewhat lower than of TB and the TB-DI mice. The body weight of diabetic mice (D) fell continuously throughout the experimental period, to about two-thirds of the initial value after 28 days.

Tumours grew more slowly in TB-D mice than in TB and TB-DI (Fig. 2). There were no differences in the rate of tumour growth between TB mice and TB-DI mice. In other words, insulin treatment of diabetic mice "restored" the tumour growth rate back to the level seen in non-diabetic controls.

Glucose in peripheral blood was measured 2, 8, 18 and 25 days after injection of tumour cells. At the onset, the level of glucose in peripheral blood of TB mice resembled that in control mice treated with Hanks' solution, but later declined to as low as 32 mg% (Table 2). Diabetic mice with tumour (TB-D) had an initially high level of glucose in blood (480–518 mg%), similar to that maintained in diabetic mice without tumour (D) (470–580 mg%), but 18 days after tumour transplantation the level decreased to half of the initial value. Only the diabetic mice without tumour maintained a high level of glucose throughout the experiment (470–580 mg%). The treatment with insulin decreased the glucose level in diabetic mice with tumour, but these mice (TB-DI) still had higher concentrations of glucose in peripheral blood than TB mice (76–214 mg% vs 32–120 mg%).

Sixteen days after transplantation of the tumour, the level of insulin was higher in the sera of tumour-bearing mice than in control mice without tumour (Fig. 3). However, in the terminal phase of the disease the level of insulin became rather low, about 60% of the values in

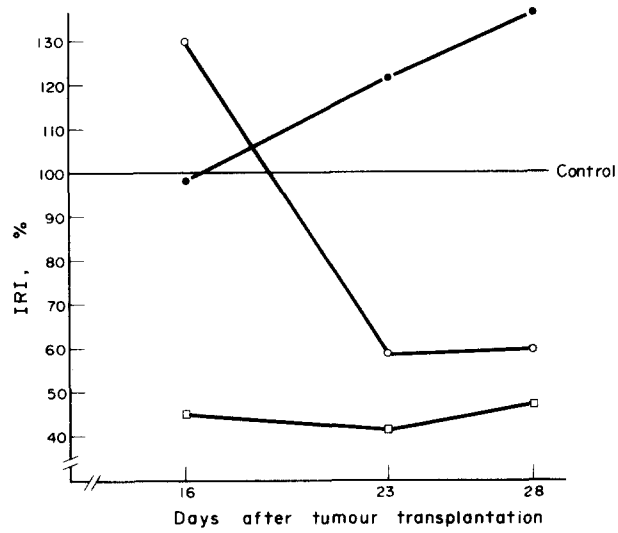

Fig. 3. Mean Insulin concentration in the sera of mice without tumour (control, n = 8), in the sera of thymoma-bearing mice (○, n = 10), in the cell-free extract of thymoma (●, n = 5) and in the cell-free extract of the muscle (□, n = 5) of thymoma-bearing mice. Concentrations of insulin have been expressed as percents of the concentration in sera of control mice.

mice without tumour. We also found that the concentration of IRI in the cell-free extract of tumour tissue was significantly higher than in cell-free extract of the muscle of the same mice.

DISCUSSION

Present studies indicate that transplantable thymoma grew faster in non-diabetic mice (TB) and in diabetic mice treated with insulin (TB-DI), than in diabetic mice deprived of insulin (TB-D). In consequence, TB-D mice survived longer than mice from the former two groups.

Diabetic animals without tumour (D) lost weight, while the other groups bearing the tumour, whether diabetic or not, gained weight. Thus, the weight gain can be attributed to the tumour. The concentration of glucose in the peripheral blood of TB-D mice decreased during the experimental period and reached half of the initial level at the end of the experiment. Hypoglycemia was particularly conspicuous in terminal stages of tumour growth. This is in agreement with other experimental studies which have demonstrated hypoglycemia in animals with tumours [1–5]. Perhaps the membranes of tumour cells are more permeable to glucose than membranes of normal cells, so that the tumour "consumes" much glucose and thus causes hypoglycemia. Indeed, many tumours contain high levels of lactic acid [6, 12] which might indicate extensive glycolisis in tumour cells. In some experimental tumours caused by viruses, transport of glucose [13] and hexose [14] into transformed cells was found to be faster and this was attributed to changes of the tumour cell membrane [13].

An alternative explanation for hypoglycemia during the tumour growth would be that the tumour secreted insulin or insulin-like substances which promoted the transport of glucose into the tumour cells [15, 16]. Another source of insulin required for that purpose could be the host. Since diabetic tumour-bearing mice do not have sufficient amounts of insulin, their tumours cannot grow as fast as in normal healthy mice. Exogenous supply of insulin would then, obviously, promote tumour growth.

We found that thymoma-bearing mice were hypoinsulinemic. This could be due to the very fast growth of tumour cells and to the fact that in the tumour cell-free extract we found significantly higher values than in muscle-cell-free extract of tumour-bearing mice. These data did not exclude the possibility that thymoma-cells produced insulin or insulin-like substances.

Hypoglycemia observed in TB-DI mice in first stages of tumour growth progressed during further growth of the tumour. This may indicate that here, also, tumour cells consumed glucose and, therefore, diminished the glucose level in the peripheral blood. Since the tumour growth was faster and survival time shorter in the TB-DI mice than in TB-D, it seems that tumours require adequate supply of insulin for their growth.

Glucagon deficiency should also be taken into account. Indeed, an acquired form of glucagon

deficiency has been found in certain human cancers [16]. In our future experiments, we shall check this parameter as well.

According to these data, a note of caution might be considered in regard to the therapy of patients with both diabetes mellitus and tumour. Diabetic patients with tumour might need monitoring as to their needs for insulin or other anti-diabetic medication, since such treatment may accelerate tumour growth, perhaps by promoting uptake of glucose into tumour cells.

Parameter Analysis of Gompertzian Function Growth Model in Clinical Tumors

ATSUO AKANUMA

Department of Radiology, Faculty of Medicine, University of Tokyo, Hongo, Tokyo 113, *Japan*

Abstract—*In analysis of clinical tumors a conventional exponential growth model is often insufficient in clinical practice. Gompertzian function growth model is one of the practical alternatives. The way to obtain the parameters of the function is discussed with application to tumors in clinical practice. The function can be extrapolated forward and backward, which is one of the major points of interest in the practice of malignant therapy. Tumor characteristics differences are also discussed in relation to the growth parameters.*

INTRODUCTION

LAIRD [1], based on her empirical observations and an analysis of literature, proposed a Gompertzian function to tumor growth model. The idea of this model is that a tumor grows exponentially but the growth rate declines exponentially, which results in an asymptote of the tumor volume.

Clinically the mathematical function for a tumor growth model needs to be practical and simple, both are fulfilled by a Gompertzian function model, although there are some criticisms [2]. Whether this function is appreciable to human tumors is uncertain. Continuous slowing of human tumor growth rate has been reported [3] and possible existence of a maximum tumor volume has been observed, at least, in breast carcinoma skin metastases [4]. As a Gompertzian growth model comprises the exponential growth, this method of analysis can also be applied to an exponential growth. The function has been applied in this study to clinical tumors in order to obtain the values of the growth parameters.

Gompertzian function is explained by Laird [5] as "exponential growth process limited by exponential retardation", which means that growth is essentially exponential but the growth rate is exponentially reduced. This can be expressed mathematically as follows.

$$dV/dT = A^*V \quad (1)$$

$$dA/dT = -R^*A \quad (2)$$

where V stands for tumor volume, A for growth rate, R for retardation factor. These two equations lead to

$$V = Vi^* \exp[Ai/R^*(1-\exp[R^*T])] \quad (3)$$

where Vi and Ai are tumor volume and growth rate at the beginning of the observation, respectively. Equation (3) implies the following three factors.

1. *Retardation of growth rate*

In equation (3) Ai is the initial growth rate which decreases according to the following equation.

$$A = Ai^* \exp(-R^*T) \quad (4)$$

And this growth rate (A) is easily obtained by measuring the tumor at least twice within a short interval. Since

$$A = dV/dT/V \doteqdot (\log V_1 - \log V_2)/(T_1 - T_2) \quad (5)$$

log = natural logarithm.

This growth rate is only the initial value which would regress soon, as has been observed in skin metastases from breast carcinoma.

2. *Maximum volume*

Tumor does not grow beyond a certain volume which is the asymptote of the equation. (Maximum volume (asymptote volume) is symbolized by Vm). As discussed below, various reasons have been reported which account for the limitation of tumor growth. The continuous retarding effect produces the limitation of tumor

size and the maximum volume is:

$$Vm = Vi^* \exp(Ai/R) \tag{6}$$

In tumor treatment it would be convenient to know the maximum size of each tumor type. The maximum size is not only dependent on the pathological type of the tumor. Equation (6) indicates that the maximum volume also varies according to the value of R which would be influenced by the tumor environment, for example, by the blood supply.

3. *Growth rate and volume*

Equation (3) describes the uninterrupted tumor growth. When the tumor growth is disturbed, for example, when half of the tumor is excised, how does the maximum size change? Equation (3) itself does not answer this question. Todaro *et al.* [6] reported that partial removal of cells from a contact inhibited culture of normal cells induces abundant mitosis. Breur [7] described a case of mammary carcinoma with a doubling time of about 700 days which was treated by a course of chemotherapy and the mass regressed remarkably but considerably increased its growth rate. Volume dependency of growth rate is a widely accepted fact and has been discussed [8]. From equations (3) and (4).

$$A - Ai = -R^* \log(V/Vi)$$

Replacing Vi with Vm, then $Ai = 0$

$$A = -R^* \log(V/Vm) \tag{7}$$

The term $\log(V/Vm)$ must be the indicator of cell population pressure in tumor. Hence mathematically this growth model function is expressed in the following two equations.

$$A = -R^* \log(V/Vm)$$
$$dV/dT = A^* V$$

MATERIAL AND METHODS

A. *Method*

Growth parameters. For quantification of tumor therapy, it is required to obtain the values of parameters in Gompertzian function. (The computations are shown in Appendix employing at least three sets of data.)

for R

$$\frac{\log V_1 - \log V_2}{\log V_3 - \log V_2} = \frac{\exp(-R^*(T_1 - T_2)) - 1}{\exp(-R^*(T_3 - T_2)) - 1} \tag{8}$$

for Vm

$$\frac{\log V_1 - \log Vm}{\log V_2 - \log Vm} = \frac{T_1 - T_2}{T_3 - T_2} * \log\left(\frac{\log V_3 - \log Vm}{\log V_2 - \log Vm}\right) \tag{9}$$

These formulae are too complicated and a computer is required to obtain the values.

The practical approximate values can be obtained using a semi-logarithmic scale. Equations (5) and (7) are employed. The measurements usually involve considerable errors, therefore, three sets of measurements are preferable to obtain a differential value of equation (5) as is shown on the curve in Fig. 1A.

In order to avoid the extreme variation, three adjacent plots are used to obtain the gradient. The middle points of two adjacent plots are connected successively. The gradient is read using the doubling time of this line segment. The middle point of the line segment is supposed to be the corresponding tumor volume. The interrelationship between the growth rate and the doubling time is as follows:

$$A = \log 2/Td \tag{10}$$

where A is growth rate and Td for the doubling time. For example (see the curve in Fig. 1A), upper part has a doubling time of 47 days which is supposed to be the doubling time of the volume 305 mm^3. From equation (10) the growth rate is calculated and is 0.0148/day. Lower part has a doubling time of 15 days which is supposed to be that of 135 mm^3 and the growth rate is 0.0463/day.

The derived growth rates are plotted on a semi-logarithmic scale as shown in Figs. 2 and 3. The slope of this straight line is the value of retardation factor (R). However, as decimal semi-logarithmic scale is used, equation (7) has to be changed into decimal–logarithmic,

$$A = -2.3^* R^* \log_{10}(V/Vm) \tag{11}$$

The point where this straight line crosses the abscissa is the maximum volume of the tumor (Vm). For example in Fig. 2,

$$R = 0.0149/\text{day and}$$
$$Vm = 1480\ mm^3$$

Extrapolation. The use of the initial growth rate when a tumor consists of a single malignant cell raises the following hypothetical questions.

1. Whether or not it is justified to extrapolate this model to so far backward [9]?
2. Whether or not a single malignant cell is able to originate the process of a malignant tumor [10]?

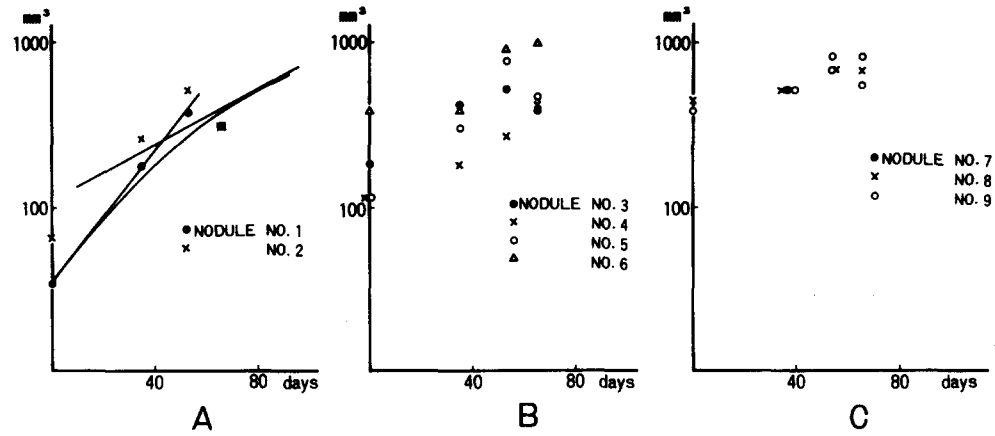

Fig. 1. Measured volumes of breast carcinoma skin metastases. The nodules are grouped according to their general sizes. A. Smaller nodules; B. Intermittent nodules; C. Larger nodules. Smaller nodules show greater growth rate. The lines in Portion A illustrate the method to obtain the doubling time of each nodule from adjacent three measurements.

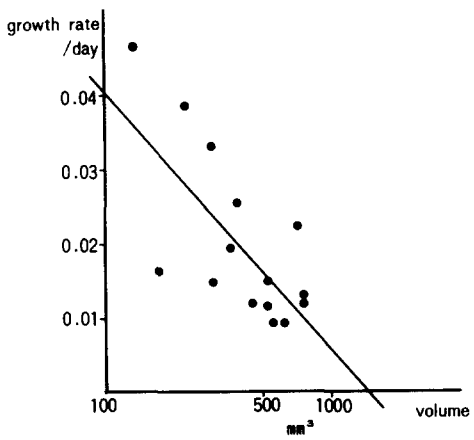

Fig. 2. Growth rate vs logarithm of volume in breast carcinoma skin metastases. Regression line $A = -0.0148^* \log(V/1480)$. *(Significant with* $P = 0.05$ *in analysis of variance.)*

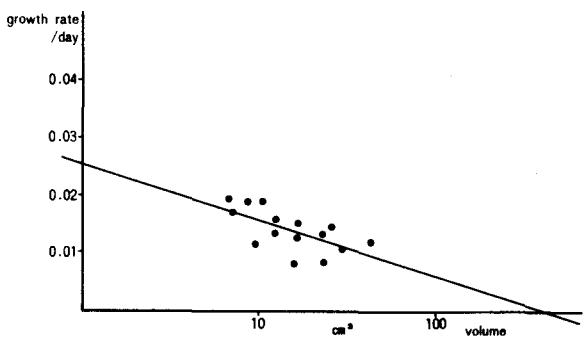

Fig. 3. Growth rate vs logarithm of volume in lung metastases from uterine leiomyosarcoma. (Abscissa in logarithmic scale.) Regression line $A = 0.00423^* \log(V/402)$. *(Significant with* $P = 0.05$ *in analysis of variance.)*

Hence it is practical to employ the possible smallest tumor size that is clinically detectable. Tumors smaller than one cubic millimeter are usually subclinical, therefore, growth rate is preferably standardized at the volume of one cubic millimeter (symbolized *As*).

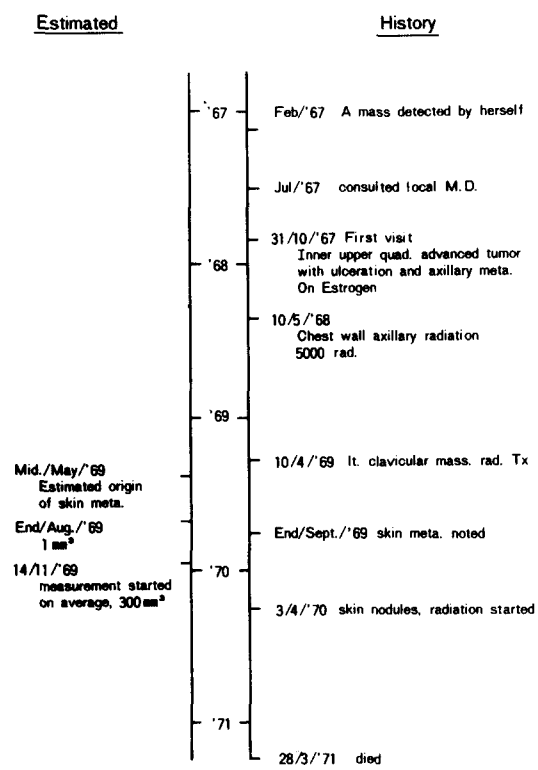

Fig. 4. Illustration of the clinical history in case 1. 72 yr *old female left breast intraductal carcinoma, T3N3M1. The estimated origin of skin metastases is in the middle of May* 1969 *and the nodules grew up to* 1 mm^3 *in a short period.*

B. *Illustrative patients*

Cautions have been taken during the measurements to avoid inaccuracy. Yet as the data have come from clinical measurements they will still contain errors.

Case 1. Figure 1 shows the measured growth curves of skin metastases from a breast carcinoma. The clinical course is illustrated in Fig. 4. The volumes of each metastatic nodule are

calculated as a rotating ellipsoid around the longer diameter measuring right angle longer and shorter diameters of a nodule. The computed volumes of this case are shown in Table 1 and are plotted on semi-logarithmic scale in Fig. 1 divided into three groups A, B and C simply according to their general sizes. The tumors are observed for 65 days and then treated. (The curves are drawn so that they go through the middle point of the two adjacent points or parallel to the line which the two points form.)

All nodules except Nos. 4 and 6 show the slowing of growth rate which the Gompertzian function predicts. In particular the three nodules in the largest group have strong tendency to flatten as if they are close to the maximum volume of these tumors. Table 2 shows the graphically measured doubling times of lower and upper portion of each curve. The mean doubling time of each volume ranges:

100–300 mm^3 is 24 days

300–500 mm^3, 47 days and

> 500 mm^3, 55 days.

(Two very large and one negative doubling times are excluded.) These observations above indicate that growth rate is volume dependent and the small nodules can be considered growing with the growth rate of the portion A of Fig. 5. (Gompertzian curve calculated with $R=0.0149$ and $A=0.1092$ at one mm^3.) The large nodules grow with a growth rate of the portion C (the straight lines A, B, C in Fig. 5 indicate the inclinations of doubling times 24, 47 and 55 days).

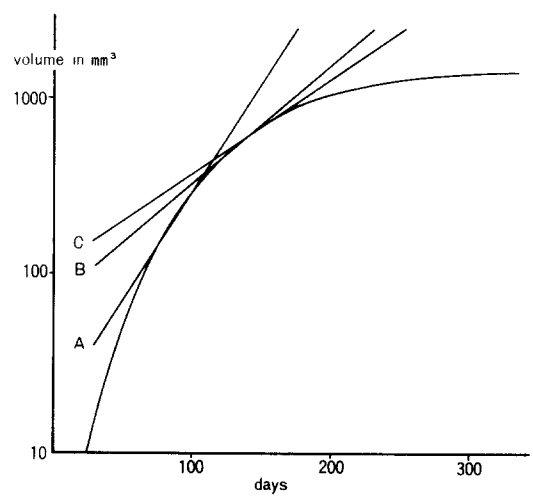

Fig. 5. *Gompertzian growth curve with parameters obtained from the data in Fig.* 1. *Lines A, B and C are the growth lines of nodules in Fig.* 1*A*, 1*B and* 1*C respectively.*

Case 2. The case has multiple lung metastases from a leiomyosarcoma of uterus. The clinical course is illustrated in Fig. 6. Two years prior to her initial visit to the clinic the patient underwent total hysterectomy and subsequently multiple courses of radiation and chemotherapy. During the observations the patient received radiation to abdomen. Sequential chest X-rays were taken and the sizes of the lung metastases measured. At the end of observation the patient was given another course of chemotherapy.

The computed tumor volumes are shown in Table 3 and graphically in Fig. 7 dividing into

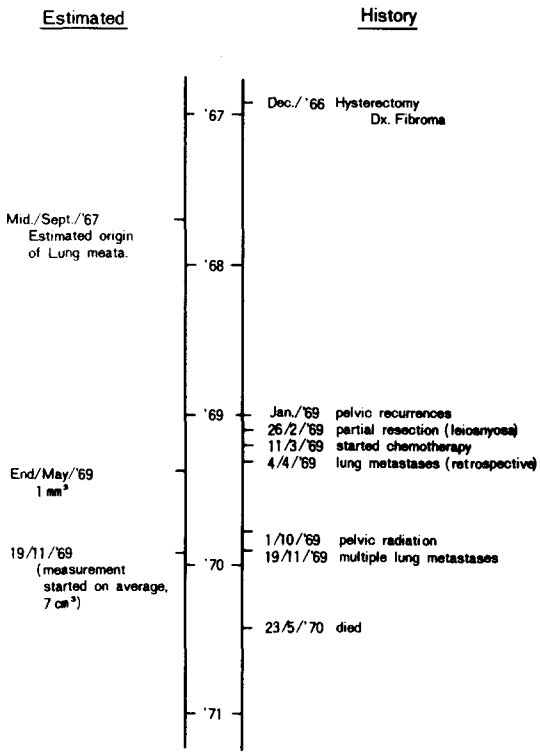

Fig. 6. Illustration of the clinical history in case 2. 42 yr old female leiomyosarcoma of uterus. The estimated origin of lung metastases is in the middle of September 1967 and they grew slowly.

three groups according to general sizes of lung lesions. Despite of the long observation period, the curves of Fig. 7 show little flattening, suggesting that the effect from retardation factor is little. Convexity downward of curves in Fig. 7(A) may be due to measurement errors or to the progression of smaller tumors [11]. Tumors in the lungs are accompanied with surrounding inflammation which are difficult to identify in the X-ray films and give us inaccurate measurements when the tumors are small. The data below an approximate volume of 6 cm^3 had to be excluded to obtain significant values, therefore, only the data of Fig. 7(C) were used in the computation.

Table 4 shows the graphically measured doubling times. (The first and last row show the doubling times obtained from the first and last two sets of measurements in Fig. 7(C), otherwise the doubling times are obtained as explained in Material and Methods.) Table 4 indicates that the mean doubling times of tumors—

$< 10\,cm^3$ is 45 days

10–20 cm^3, 50 days and

$> 20\,cm^3$, 56 days.

This change in doubling time suggests that Gompertzian function is still applicable to this case.

As a rule every metastatic nodule grows independently and each can be expected to follow the same growth curve. So if multiple lesions are available only two sets of measurements enable us to obtain the values of retardation factor and maximum volume. The values of Tables 2 and 4 are plotted on Figs. 2 and 3.

RESULTS

Applying least square law the regression lines of Figs. 2 and 3 are obtained which are the lines of equation (7). And results of the calculations are:

Case 1

$R = 0.0149$/day

$Vm = 1480\,mm^3$

$As = 0.1088$/day

$Tdo = 53$ hr

Case 2

$R = 0.00423$/day

$Vm = 4.02 \times 10^5\,mm^3$

$As = 0.0351$/day

$Tdo = 6.71$ days

One cubic millimeter of tumor contains 10^6 cells, therefore, the original doubling times at one cell (Tdo) are in Case 1, 53 hr and in Case 2, 6.71 days which are not far from the range of reported doubling times in cell cultures [12]. Figure 5 is the computed Gompertzian function curve of Case 1 with $R = 0.0149$/day and $Vm = 1480\,mm^3$. The figure shows exact curving of

calculated doubling times from Table 2. The reported cell cycle times in cell cultures range from 10 to 40 hr. Our computed original doubling time is close to this range.

It is also interesting to extrapolate the growth curves, that is to know how long ago the tumors originated and how soon they will come to the steady phase. Using equations (4) and (7) in Case 1 the time was calculated in which a 200 mm^3 tumor reaches 90% of its asymptote volume. The result is 198 days. In Case 2 a 7 cm^3 tumor took 863 days more to reach the steady phase which is postulated here above 90% of asymptote volume. The time which these tumors required to grow from one cell to the size of 1 mm^3 is also calculated using equations (4)

Case 1 = 71 days and

Case 2 = 255 days.

Figure 5 which is the Gompertzian function curve with the parameters of Case 1 shows that a nodule of average size (300 mm^3) was the size of 1 mm^3 14.5 weeks prior to the initial observation. Ten weeks prior to this size the nodule started to proliferate. A single 3 mm skin nodule had been noticed 7 weeks before the initial measurement, which is predicted approximately from this curve. In Case 2, the computation states it takes 528 days for the leiomyosarcoma to grow from one cell to 7 cm^3 a retrospective survey of chest X-rays showed the first metastasis 150 days prior to the initial measurement. The calculation using equations (4) and (7) reveals that this tumor of 0.2 cm^3 requires 149 days to attain 7 cm^3 which is about the average size at the time of first measurement. This result suggests that these metastatic tumors were in average of 0.2 cm^3 when the first two lung lesions

were detected on her chest X-ray, which were approximately 5 mm in diameter. But it is presumed the initial doubling time of this tumor 6.7 days, which is a little longer than the reported cell cycle time, is due to the chemotherapy and is not the real initial doubling time.

DISCUSSION

There is a possibility that human tumor growth does not follow a Gompertzian function, but grows exponential. This method of parameter analysis of Gompertzian function can be applied to human tumors if they follow an exponential function growth, because exponential function is a special form of this function where the factor of R is zero. Therefore, the growth rate is constant and the regression line in the Fig. 2 has to be parallel to abscissa. Figure 7 appears that the growth rates are not retarded. But the analysis in detail in Fig. 3 did not show the parallel regression line to abscissa.

So long as the tumor growth model of Gompertzian function was inferred according to empirical observations [1] it lacked biological theoretical background, particularly in the assumption that growth rate declines exponentially. Slowing of growth rate has been explained by decreasing growth fraction and by increasing cell death [13]. In cases of skin squamous cell carcinomas, cell death rate goes up to 90% [14]. Although there is still criticism of this model e.g. it ignores tumor progression [11], it is shown here this function fits practically to tumor growth curves over a wide time scale and the extrapolation of this function gives us reasonable values.

Extrapolation forward predicts how large the tumor will grow and what is its probable mean maximum volume. For example in Fig. 5, these adenocarcinoma metastases in the skin have the mean maximum volume of 1480 mm^3 and it takes six more months that these metastases become a nearly steady state. In Case 2, a 402 g tumor in a lung frequently causes serious symptoms. Even slow growing tumors require to be treated when the significantly large maximum volume is expected. Clinically, measurement of retardation constant is important.

To solve problems in tumor treatments, such as whether the metastases originated before or after surgery, this function has to be extrapolated backward. The calculation with these cases yielded reasonable values for the backward extrapolation and suggested good clinical applicability.

Laird [1] mentioned that stimulation of natural growth retardation factors might be of practical importance in reducing the incidence of clinical malignancy. What causes the retardation is still not clear. Laird [15] states it is due to genetically programmed cell death. Besides, it can be considered that factors which make constant cell loss or differentiation of proliferating cells affect also retardation factor (R), e.g. hormone therapy, chemotherapy or irradiation. So the effect of treatments can be evaluated measuring retardation factor (R). Cell contact can be one of the factors in tumor growth retardation. It is known, cell contact is an efficient method of cell communication [16]. Immunological relation of host and tumor is also a factor of retardation. Retardation factor can be considered variable according to tumor host relationship. So constant observation is required even in the cases which have "steady" tumors, particularly in the cases that "steady" tumors are kept with treatmenrs.

Slight stimulation can cause the decrease of R too. Hell and Cruickshank [17] reported that a slight wound on skin causes remarkable increase of tritiated thymidine uptake among the cells surrounding the wound and the severe wound causes an even greater uptake.

CONCLUSION

Gompertzian function growth model appears complicated but the parameters can be obtained without difficulty in the cases of multiple lesions. Extrapolation of this model forwards and backwards is possible with these parameters with clinical accuracy. The sample cases indicate that skin metastatic adenocarcinoma from breast has a strong tendency of growth retardation and has restricted tumor maximum size. Whereas leiomyosarcoma has hardly any growth retardation and has enormous tumor maximum size.

Purification of an Inhibitor of DNA Synthesis in Mammary Cells*

RAMONA GONZALEZ† and WALTER G. VERLY†
Department of Biochemistry, University of Montreal, Montreal, Canada

Abstract—*A small molecular weight inhibitor of DNA synthesis, specific for normal and malignant mammary cells but devoid of species-specificity, has been isolated from bovine mammary glands; this factor has little effect on the overall RNA metabolism.*

INTRODUCTION

CELLULAR multiplication appears to be controlled by stimulatory and inhibitory factors. However, so far, in the case of the mammary epithelium, attention has been focused only on hormones acting as stimulatory factors. Some studies have been done *in vitro*, and insulin, the epidermal growth factor, estrogens [1] and a serum factor [2] were shown to stimulate DNA synthesis in mammary cells.

We have previously reported the isolation from bovine mammary glands of a small molecular weight inhibitor of DNA synthesis in normal and malignant mammary cells; this factor had no gross effect on RNA metabolism [3]. In this paper, we describe the method of purification of this inhibitor.

MATERIALS AND METHODS

A. *Solutions*

Hanks' solution. To 100 ml of 10-fold diluted Gibco 406 S, sterilized by 15 min heating at 130°C, are added 2.5 ml of sterile 5% $NaHCO_3$; the pH is 7.4 in a 95% air–5% CO_2 atmosphere.

PBS (*xM* NaCl). The solution contains 0.01 M phosphate buffer, pH 7.2 (KH_2PO_4, Na_2HPO_4), with the specified NaCl concentration.

Dulbecco's PBS solution. It contains 10-fold diluted Gibco 408 and is sterilized by 15 min heating at 130°C; the pH is adjusted at 7.2 with sterile 5 N NaOH.

Saline–EDTA solution. The solution contains, per liter, 0.2 g EDTA, 8 g NaCl, 0.2 g KCl, 0.2 g KH_2PO_4 and 1.15 g Na_2HPO_4; it is sterilized by 15 min heating at 130°C.

MEM solution. After dissolution in water of 10.7 g of minimum essential medium (Eagle) powder (with spinner salts and L-glutamine; Gibco F-14) and 2.2 g $NaHCO_3$, 4.0 ml of phenol red solution are added (0.05 g/l; Gibco 510); the solution is then brought to 1 liter with water and sterilized by passing through a 0.45-μm millipore filter.

MEM antibiotic solution. To 1 liter of MEM solution are added 5 ml of antibiotic solution (penicillin-streptomycin; Gibco 514). Sterilization is carried out by passing the solution through a 0.45-μm millipore filter.

Thymidine-saline solution. It contains 0.1 g of thymidine (Sigma) and 9g NaCl per liter of water.

B. *Cell lines*

Ehrlich cells. The cell line was received from Dr. V. Fredette, Armand Frappier Institute, Montreal. Male Swiss white mice are injected intraperitoneally with 10^7 cells in 0.2 ml of Dulbecco's PBS. The ascites fluid, collected 7–8 days later, is centrifuged 2 min at 500 × *g*. The cells are then washed twice with 10 ml of Dulbecco's PBS and finally resuspended in MEM solution (approximately 2.9×10^6 cells/ml).

HeLa cells. The cell line came from Dr. T. P.

Accepted 9 November 1977.

†Present addresses: R. Gonzalez: Biochemistry Department, McGill University, Montreal, P.Q. H3G 1Y6, Canada and W. G. Verly: Biochimie, Faculté des Sciences, Université de Liège au Sart Tilman (par Liège 1), 4000 Liège, Belgique.

Abbreviations: TCA = trichloroacetic acid; EDTA = ethylenediaminetetraacetic acid; PPO = 2,5-diphenyloxazole; dimethyl-POPOP = 1,4-bis-2-(4-methyl-5-oxazolyl)-benzene; dTMP, dTDP and dTTP = thymidine monophosphate, thymidine diphosphate and thymidine triphosphate, respectively.

Brent, then at the McGill Cancer Research Unit, Montreal. The cells are grown as monolayers in MEM-antibiotic solution supplemented with 5% calf serum (Tissue Culture Service, Ltd.). After 1 week, they are detached with saline–EDTA solution, washed twice with 10 ml of Dulbecco's PBS, and resuspended in MEM solution (approximately 2.9×10^6 cells/ml).

C. *Inhibitor assays*

The inhibitor preparation (0.2 ml sample), or an equal volume of solvent (control), is mixed with 0.7 ml of MEM solution containing 2×10^6 cells (hemacytometer count).

In the direct assay [methyl-^{3}H]thymidine (4 μCi; 6 Ci/mmole; New England Nuclear) in 0.1 ml of Hanks' solution is immediately added bringing the total volume to 1 ml and the incubation carried out for 15 min at 37°C, with gentle shaking, in a 95% air–5% CO_2 atmosphere.

In the preincubation assay, the cells are kept for 2 hr at 37°C with the inhibitor preparation (or an equal volume of solvent) before addition of the labeled thymidine. The test is then pursued as described for the direct assay.

In both cases, the incubation is stopped by cooling the tubes in ice and adding 10 ml of cold thymidine–saline solution. After shaking on a Vortex mixer, the cell suspension is filtered on a fiber glass filter (Whatman GF/C); the filter is washed twice with thymidine saline solution, then with 10 ml of cold 10% trichloroacetic acid (TCA) and 10 ml of ethanol. The filter is transferred in a vial and dried before the addition of 10 ml of scintillating solution (4 g of PPO, 0.1 g of dimethyl-POPOP/liter of toluene). The radioactivity, counted in a Packard Tri-Carb spectrometer, after correction for the background, is given in counts/min. With Ehrlich cells and no inhibitor, the standard deviations on the radioactivity measurements are 6 and 22% in the conditions of the direct assay and preincubation assay, respectively.

The biological activity of the inhibitor preparation is estimated from the fractional decrease (I.F. = inhibited fraction) of labeled thymidine incorporation into the TCA-insoluble cell fraction:

$$\text{I.F.} = \frac{\text{"control"} - \text{"sample"}}{\text{"control"}}$$

where "sample" and "control" are the radioactivities of the TCA-insoluble fractions from the cells incubated with and without inhibitor respectively. A negative value of I.F. indicates a stimulation of the incorporation of labeled thymidine.

D. *Protein determination*

The protein is determined by the micromethod of Lowry *et al.* [4] with Sigma bovine serum albumin as standard.

EXPERIMENTS AND RESULTS

A. *Preparation and biological activity of supernatant from bovine mammary glands*

The mammary glands of a cow, taken immediately after the animal has been killed, are cut in large fragments which are cooled on ice. From then on, unless otherwise stated, all manipulations are carried out at 4°C. The mammary tissue is minced into small pieces with scissors, homogenized in water (2 ml/g of tissue) with a Waring Blendor for 90 sec and lyophilized; the powder is kept at −20°C. When needed, this powder is dispersed in PBS (0.15 M NaCl) (100 mg of powder/ml) with a Potter–Elvehjem homogenizer (25 strokes). The suspension is centrifuged at 10,000 rev/min for 10 min in the rotor SS-34 of a RC-2B Sorvall centrifuge. The recovered supernatant is then spun for 120 min at 30,000 rev/min in the rotor 30 of a Beckman L2-65 centrifuge; the clear zone, between the upper and lower turbid layers, is carefully taken with a Pasteur pipette (105,000 × *g* supernatant).

Ehrlich and HeLa cells are preincubated for various times, from 0 to 120 min, in the presence

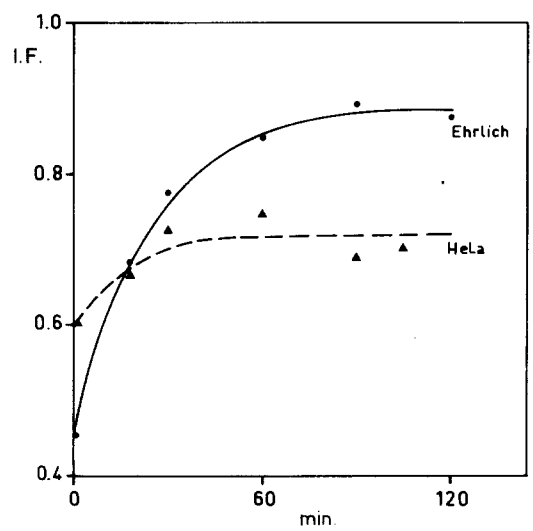

Fig. 1. Action of preincubation on the inhibition of labeled thymidine incorporation into DNA by the supernatant of bovine mammary glands. The cells are preincubated with the supernatant for the time indicated (min) *before addition of labeled thymidine; the DNA radioactivity is measured* 15 min *later. The decrease of radioactivity relative to a control without supernatant (I.F.) is calculated.* (●) *Ehrlich cells;* (▲) *HeLa cells.*

or absence of mammary 105,000 × *g* supernatant (3.2 mg of protein in 0.2 ml) before addition of the labeled thymidine and incubation in the conditions of the direct assay (see "Materials and Methods"). Figure 1 shows that, when there is no preincubation, the supernatant is more active on HeLa cells than on Ehrlich cells; but the inhibition of labeled thymidine incorporation into the DNA of Ehrlich cells increases with the preincubation time, and, when this preincubation time reaches 2 hr, the supernatant is more active on Ehrlich cells than on HeLa cells. We decided to purify the inhibitor which is more active on Ehrlich cells after a 2-hr preincubation.

7.5 ml are collected and the absorbance at 230 nm is read on each fraction.

To measure the inhibitory activity, the chromatography is run in dilute PBS; the fractions are pooled as indicated in Fig. 2. Aliquots (5 ml) are lyophilized and the residue redissolved in 0.5 ml of water; after centrifugation, 0.2-ml portions of the clear supernatant are used for the assays. Suitable controls are prepared with the chromatography solvent in order to calculate I.F. Two main peaks of inhibitory activity are separated (Fig. 2).

Because PBS (0.15 M NaCl) is used in the next purification step, the Sephadex G-50 chromatography is repeated in this solvent.

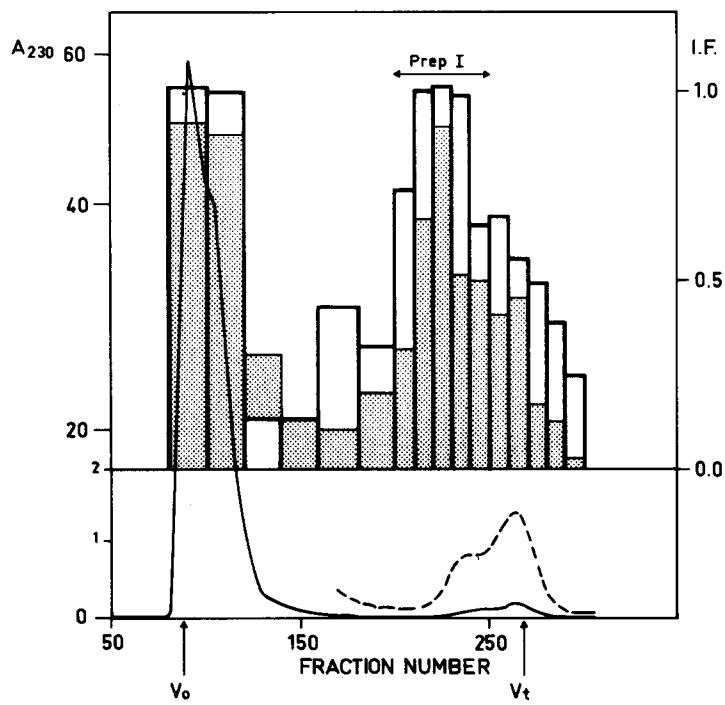

Fig. 2. Sephadex G-50 chromatography. The Sephadex G-50 chromatography is run in 10-fold diluted PBS (0.15 M NaCl). The absorbance at 230 nm (A_{230}) is read on each fraction; the continuous line corresponds to the 0–60 scale, whereas the dashed line corresponds to the 0–2 scale. The fractions are then pooled as indicated and aliquots used to determine the biological activity (see text); I.F. values are calculated relative to controls prepared with the chromatography solvent. Light frames surrounding stippled areas give the results of the direct assay, whereas the heavy frames give the results of the preincubation assay.

B. *Purification of the inhibitor*

Sephadex G-50. A column (5 × 100 cm; Pharmacia) is filled with Sephadex G-50 fine and equilibrated with PBS (0.15 M NaCl) or 10-fold diluted PBS (0.15 M NaCl) in the cold room. The clear 105,000 × *g* supernatant (100 ml; 1.6 g of protein) is applied to the column and the elution performed with PBS or dilute PBS at a flow rate of 100 ml/hr; fractions of

Determination of the biological activity is not possible because of the high salt concentration, but the absorbance curve at 230 nm is identical with that obtained with dilute PBS so that we can locate the two main peaks of inhibitor. Peak I is constituted of high molecular weight compounds; because some of them might be enzymes destroying the labeled thymidine or an amino-acid in the incubation medium, the lower molecular weight inhibitor (Peak II; K_{av}

$=0.91$)* is selected for further purification. Fractions 200 to 250 are pooled to give Prep I.

CM-Sephadex. A column (2.6 × 70 cm; Pharmacia) is filled with CM-Sephadex C-25 and equilibrated with PBS (0.15 M NaCl) in the cold room. Prep I from four Sephadex G-50 chromatographies run simultaneously in PBS (0.15 M NaCl) are pooled (1600 ml; 96 mg of protein) and applied to the CM-Sephadex column at a flow rate of 80 ml/hr; the elution is performed with PBS (0.70 M NaCl) at the same flow rate. Fractions of 7.5 ml are collected and the inhibitory activity is measured by the direct and preincubation assays.

Figure 3 shows that the rapid transition from 0.15 to 0.70 M NaCl concentration in PBS is associated with an increase of inhibitory activity in the fractions which is relatively more important for the direct assay. In spite of the fact that, from fraction 270 onward, most of the inhibition, measured against a control containing PBS (0.15 M NaCl), is likely due to the high osmolality, two peaks of inhibitors are detected by the preincubation assay: peak II, which is more important and associated with less protein, is chosen for further purification. Fractions 350 to 366 are pooled to form Prep II.

Concentration step. Prep II (112 ml) is diluted with phosphate buffer without NaCl (411 ml) to have a final 0.15 M NaCl concentration. This solution is applied, in the cold room, at a flow rate of 25 ml/hr, to a column (0.9 × 15 cm;

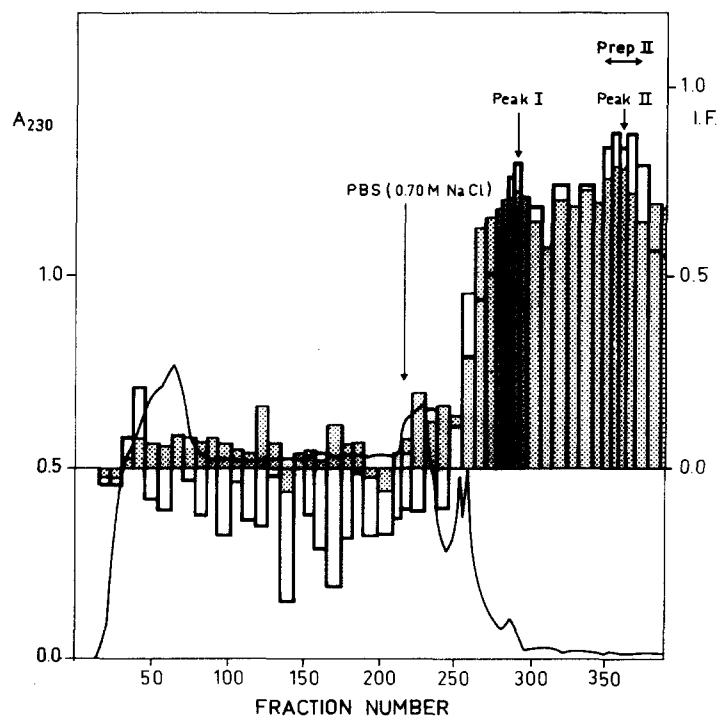

Fig. 3. CM-Sephadex chromatography. Prep I (*Fig.* 2) *in PBS* (0.15 M NaCl) *is applied to the CM-Sephadex column; elution with PBS* (0.70 M NaCl) *starts where indicated. The absorbance at* 230 nm (A_{230}) *is read on each fraction* (*continuous line*). *The fractions are then pooled as indicated and the biological activity is measured on* 0.2-ml *aliquots from each pool;* 0.2 ml *of PBS* (0.15 M NaCl) *is used for the control and I.F. calculated. Light frames surrounding stippled areas are used for the direct assay, whereas heavy frames are used for the preincubation assay.*

Pharmacia) filled with CM-Sephadex C-25 and previously equilibrated with PBS (0.15 M NaCl). The elution is performed with PBS (1.15 M NaCl) and 1-ml fractions are collected. Figure 4 shows that the inhibitor is concentrated in 5 ml of eluent (Prep III).

Sephadex G-25. Prep III (5 ml; 0.53 mg of protein) is applied, in the cold room, at a flow rate of 20 ml/hr, to a column (1.6 × 100 cm; Pharmacia) filled with Sephadex G-25 fine and

*Elution constant

$$K_{av}=\frac{V_e-V_o}{V_t-V_o}.$$

The void volume V_o is measured with blue dextran (Pharmacia) whereas the total volume V_t is calculated from the dimensions of the gel. V_e is the elution volume corresponding to the peak maximum.

previously equilibrated with PBS (0.15 M NaCl). The elution is carried out with the same buffer; fractions of 2.6 ml are collected. Figure 5 shows one main peak of inhibitory activity centered on a small absorption peak at 230 nm; the elution constant $K_{av}=0.53$ corresponds to that of a 2000–3000 mol. wt peptide. Fractions 50–56 are pooled to form Prep IV.

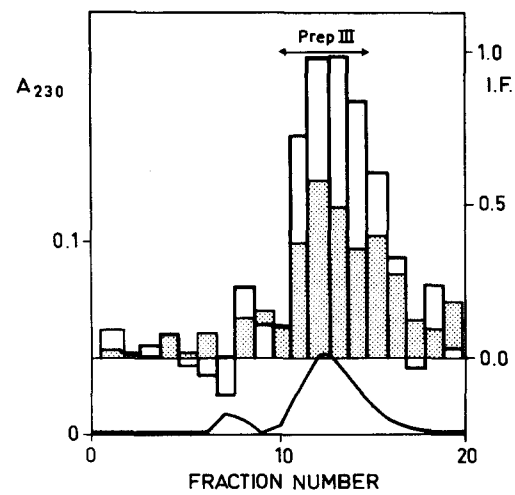

Fig. 4. Concentration on CM-Sephadex. Prep II (*Fig.* 3), *diluted in such a way that the solvent becomes PBS* (0.15 M NaCl), *is applied onto a short CM-Sephadex column; elution with PBS* (1.15 M NaCl) *and collection of the fractions start together. The absorbance is read at* 230 nm (A_{230}; *continuous line*). *Aliquots of* 20 µl *from each fraction are used for the biological assays; suitable controls enable us to calculate I.F. Light frames surrounding stippled areas are used for the direct assay, whereas heavy frames correspond to the preincubation assay.*

C. *The inhibitor unit; calculation of yield and purification factor*

Increasing amounts of Prep IV in PBS (0.15 M NaCl) are tested in the conditions of the direct and preincubation assays (Fig. 6). The unit is defined as the amount of the inhibitor needed to have an I.F. of 0.50 in the conditions of the preincubation assay. The aliquot introduced in the assay medium is diluted so that I.F. is between 0.50 and 0.70 and the number of inhibitor units is calculated from the curves of Fig. 6 corresponding to the preincubation assay.

Table 1 gives the number of units and the specific activity (units per mg of protein) at each step of purification. An overall yield of 12.5% and a final purification factor of 2300 are calculated; these are minimum values as shall be discussed later.

D. *Polyacrylamide gel electrophoresis*

The electrophoreses are carried out in a cooled bath, using β-alanine–acetic acid, pH 4.5 buffer, at 3 mA per tube, for 120 min with the native

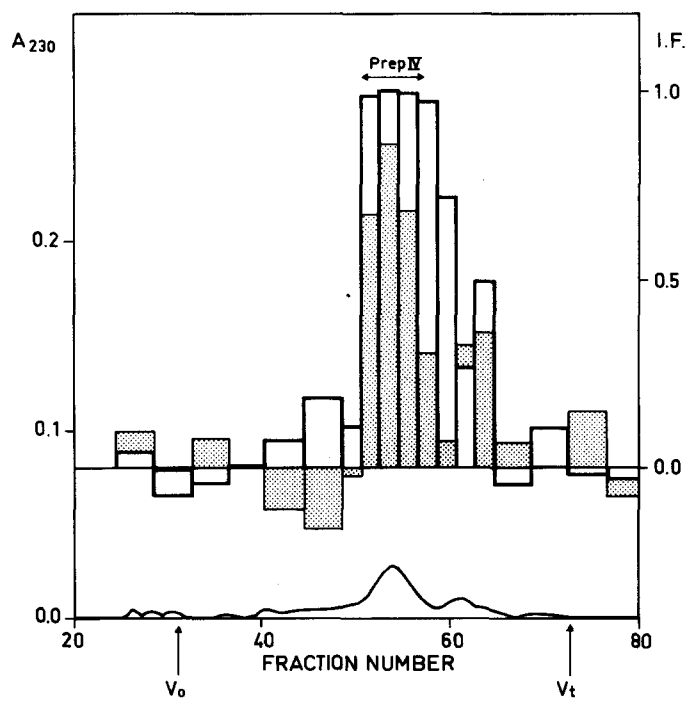

Fig. 5. Sephadex G-25 chromatography. Prep III (*Fig.* 4) *is applied to a Sephadex G-25 column which is eluted with PBS* (0.15 M NaCl). *The absorbance at* 230 nm (A_{230}) *is read on each fraction* (*continuous line*). *The fractions are then pooled as indicated and* 0.2-ml *aliquots are taken for the biological assays; suitable controls are prepared to calculate I.F. Light frames surrounding stippled areas give the results of the direct assay, whereas heavy frames are used for the preincubation assay.*

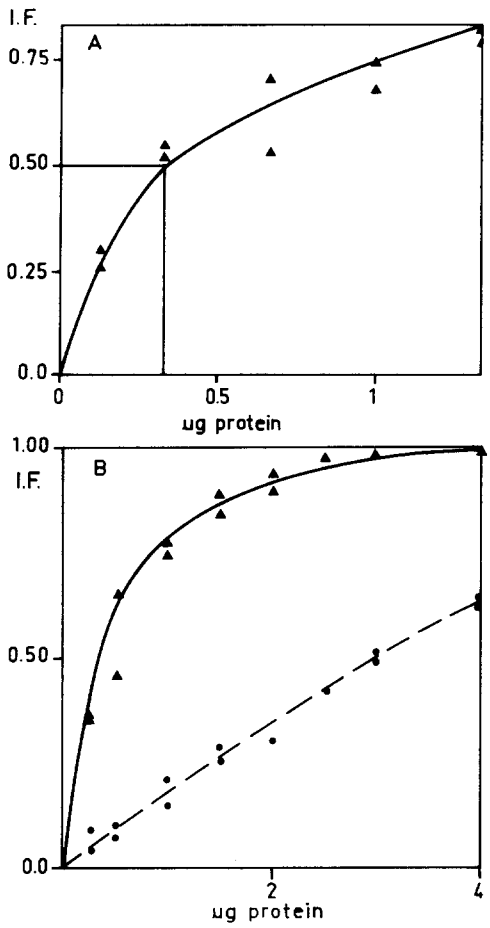

Fig. 6. Dose–effect relationship with the purified inhibitor (Prep IV). The fractional decrease (I.F.) of labeled thymidine incorporation into Ehrlich cell DNA is given as a function of the amount (μg protein) of Prep IV (Fig. 5). (●) direct assay (part B; dashed line); (▲) preincubation assay (parts A and B; continuous line).

inhibitor and 150 min with the inhibitor in 8 M urea. The gels stained with Coomassie blue are scanned at 550 nm.

Prep IV is desalted by passing through a Sephadex G-25 column run in water or in 0.05 mM EDTA.

Gel electrophoresis of native inhibitor. A slightly modified standard method is used [5]. The gel, which contains 6% acrylamide and 0.32% bisacrylamide (w/v), is submitted to a preelectrophoresis for 4 hr in potassium acetate, pH 4.3 buffer. The solution of the inhibitor in 0.05 mM EDTA is lyophilized, the residue is dissolved in 10% sucrose and 15-μl aliquots (20 μg of protein) are applied immediately on two identical gels. After electrophoresis, one gel is stained with Coomassie blue; the densitometric record presented in Fig. 7 shows a single absorption band. The other gel is cut into 4-mm slices and each slice is crushed with a glass rod in 0.6 ml of

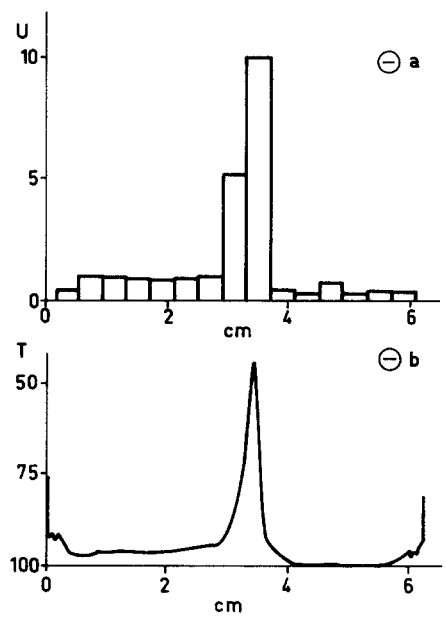

Fig. 7. Gel electrophoresis of the native inhibitor. Aliquots of desalted Prep IV are applied on two identical gels and the electrophoresis is carried out in the conditions described in the text. One gel is stained with Coomassie blue, scanned at 550 nm and the percent transmittance (T) is recorded as a function of the migrated distance (cm) toward the cathode (part b); the other gel is cut in 4-mm slices for the determination of the biological activity (U = number of inhibitor units) (part a).

Table 1. Purification of the inhibitor

Purification step	Units	Yield %	Protein mg	Specific activity units/mg	Purification factor
Supernatant	4900	100	6150	0.8	1
Prep I	800	16	97	8.3	10
Prep II					
Prep III	725	14	0.53	1360	1700
Prep IV	611	13	0.33	1850	2300

After determination of I.F. in the preincubation assay, the number of inhibitor units is calculated; the specific activity is the number of units per mg of protein. Yields and purification factors are calculated relative to the values found in the supernatant. Prep I is obtained from Sephadex G-50 (Fig. 2), Prep II from CM-Sephadex (Fig. 3), Prep III from the concentration step (Fig. 4) and Prep IV from Sephadex G-25 (Fig. 5). The high salt concentration in the fractions from the CM-Sephadex (Prep II) did not allow a reliable estimation of the biological activity.

0.1 M sodium phosphate, 0.15 M NaCl, pH 7.2 buffer; after centrifugation, the biological activity is measured on 100-μl aliquots from the supernatant and the number of inhibitor units is calculated. Figure 7 shows that the biological activity migrates as a single peak which has the same position in the gel as the band colored with Coomassie blue.

Gel electrophoresis in 8 M *urea.* The solution of the inhibitor in water is lyophilized, the residue is dissolved in 40% sucrose, 8 M urea and 15-μl aliquots (20 μg of protein) is applied to the gel. The method of Traub *et al.* [6] is followed. The stacking gel contains 2.5% acrylamide and 0.625% bisacrylamide, whereas the separating gel contains 10% acrylamide and 0.2% bisacrylamide (w/v). The densitometric record of the gel stained with Coomassie blue shows a single absorption band (Fig. 8).

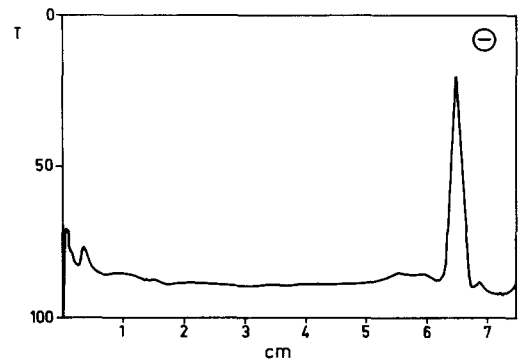

Fig. 8. Gel electrophoresis of the purified inhibitor in 8 M *urea. An aliquot of desalted Prep* IV *is submitted to gel electrophoresis in* 8 M *urea as described in the text. The gel is colored with Coomassie blue and scanned at* 550 nm. *The figure gives the percent transmittance* (*T*) *as a function of the migrated distance* (cm) *toward the cathode.*

E. *Some properties of the purified inhibitor*

Action of preincubation time on the inhibition of [^{3}H] *thymidine incorporation into Ehrlich cell DNA by Prep* IV. Ehrlich cells are preincubated for 0–120 min in absence [control with PBS (0.15 M NaCl)] and in presence of the purified inhibitor [Prep IV (2 and 12 units) in the same buffer], the [^{3}H] thymidine is added and the incubation is pursued under the conditions of the direct assay. The results are given in Fig. 9. For the smaller dose (2 units), there is, during the first 30 min, a fast increase of I.F. which remains then unchanged for longer times. For the higher dose (12 units), I.F. increases rapidly during the first 15 min, then at a slower and steady rate.

Effect of incubation at 37°C *on the inhibitor biological activity.* The inhibitor [Prep IV in PBS (0.15 M NaCl); 20 μg of protein/ml] and a control (buffer alone) are incubated at 37°C for 0–300 min before measuring the biological activity on Ehrlich cells under the conditions of the direct and preincubation assays. Figure 10 shows that the inhibitory activity tested in the direct assay increases during the first 30 min, then decreases; after an incubation of 4 hr, the biological activity has practically disappeared from the preparation. When tested in the preincubation assay (the preparation is first incubated for the indicated time, the cells are then added and the suspension is preincubated for a further 2 hr), there is no initial activation and, after a plateau of 60 min, the inhibitory activity decreases to be negligible after 4 hr.

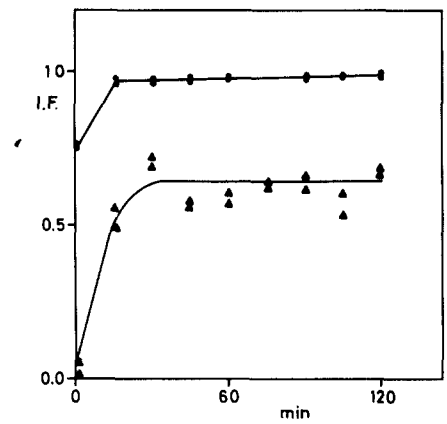

Fig. 9. Action of preincubation on the inhibition of labeled thymidine incorporation into DNA by Prep IV. *The cells are preincubated with Prep* IV *for the time indicated* (min) *before addition of labeled thymidine; the DNA radioactivity is measured* 15 min *later. The decrease of radioactivity relative, to a control without Prep* IV (*I.F.*) *is calculated.* (●) 12 *units;* (▲) 2 *units.*

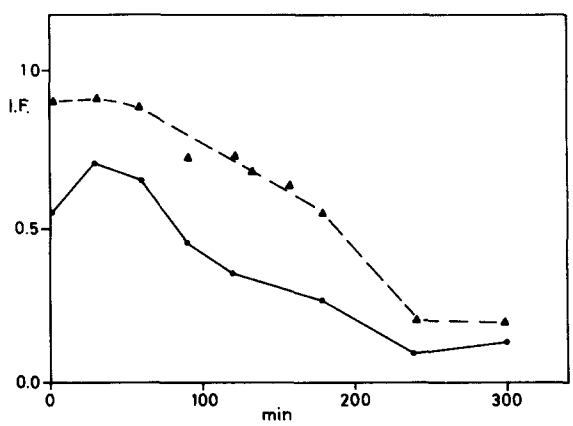

Fig. 10. Action of incubation at 37°C *on the biological activity of Prep* IV. *Prep* IV *is incubated at* 37°C *for the time indicated* (min) *before addition of cells; the biological activity is then measured by the direct assay* (●) *or the preincubation assay* (▲).

DISCUSSION

If the action is tested immediately, the supernatant of bovine mammary glands inhibits the exogenous thymidine incorporation into DNA more in HeLa cells (maligant cells derived

from the cervix epithelium of human uterus) than in Ehrlich cells (malignant cells from mouse mammary gland). On the contrary, the action is greater on Ehrlich cells than on HeLa cells when the cells are preincubated for 2 hr with the supernatant before addition of the thymidine. The supernatant thus seems to contain an inhibitor rather specific for Ehrlich cells the action of which on thymidine incorporation into DNA increases during the first 2 hr of contact with the cells. This inhibitor has been purified in three chromatographic steps: Sephadex G-50, CM-Sephadex, and Sephadex G-25 (the second CM-Sephadex before the Sephadex G-25 is only a concentration step). The elution constant from the Sephadex G-25 ($K_{av}=0.53$) indicates a rather small molecular weight. Gel electrophoresis at pH 4.3 gives a single band stained by Coomassie blue corresponding exactly to the inhibitory activity; the purity of the final product is confirmed by gel electrophoresis in the presence of 8 M urea which also gives a single band after staining with Coomassie blue.

We have defined an inhibitor unit and studied, with the purified inhibitor, the relationship between dose and effect on labeled thymidine incorporation into Ehrlich cell DNA. This enables us to calculate the total number of units and the specific activity (number of units per mg of protein) at each step of purification (Table 1). A 13% overall yield and a purification factor of 2300 are calculated for the purified inhibitor; the true values must be higher because reference is made to the 105,000 × *g* supernatant which contains many other inhibitors.

Inhibition of exogenous [^{3}H]thymidine incorporation into DNA does not mean necessarily a decrease in DNA synthesis: the same results can be obtained by dilution of the labeled precursor with nonradioactive thymidine [7, 8], by addition of enzymes destroying thymidine [9], by inhibition of thymidine kinase, or by a greater contribution of the endogenous synthesis of the DNA precursors. We have reported elsewhere [3] that the purified mammary inhibitor truly inhibits DNA synthesis: in Ehrlich cells incubated with [^{3}H]thymidine, Prep IV increased the radioactivity in the three phosphorylated derivatives of thymidine (dTMP, dTDP and dTTP) while producing a strong decrease of the DNA radioactivity; the metabolic block is thus between dTTP and DNA. The incubation medium also contained [^{14}C]orotate; ^{14}C incorporation into DNA was inhibited to approximately the same extent as the ^{3}H incorporation showing that the endogenous synthetic pathway and the salvage pathway are both affected; ^{14}C incorporation into RNA was the same as in the control which suggests that the inhibitor does not disturb the overall RNA metabolism. We also showed [3] that the purified mammary inhibitor is far more active on the three kinds of mammary cells that were tested (Ehrlich, Walker and isolated mammary cells from mice at mid-gestation) than on cells deriving from other tissues (chick embryo, Novikoff and HeLa cells).

The 2-hr preincubation, before addition of [^{3}H]thymidine, used in the assay to follow the inhibitor specific for mammary cells was chosen after an experiment with the crude mammary supernatant which contains many nonspecific factors (Fig. 1). The influence of preincubation had thus to be reinvestigated with the purified inhibitor (Fig. 9); for the smaller dose used (2 units), which is about the amount used to quantitate the inhibitor, I.F. reaches after 30 min a plateau which still lasts at 120 min. It thus appears that adequate conditions were chosen to measure the number of units at each step of purification.

The purified factor is quite labile at 37°C (Fig. 10), being practically inactivated after 2 hr. Drastic conditions, like lyophilization, destroy the activity. Therefore the purification is carried out in a continuous way without lyophilizing or freezing the intermediate preparations. After the final step, the purified inhibitor (Prep IV) can be kept frozen at −20°C in PBS (0.15 M NaCl) with little loss of activity.

Tissue growth appears to be controlled by two kinds of factors: stimulatory and inhibitory. The inhibitory factors might be produced by the tissues themselves so that their growth would be regulated by a negative feedback mechanism. Inhibitors of this kind were named "chalones" by Bullough [10]; chalones are not species-specific, but they are tissue-specific: the action of a chalone is limited to the tissue which releases it. We have purified from cow mammary glands a DNA synthesis inhibitor of small molecular weight which appears specific for mammary cells, but which is devoid of species-specificity; the bovine inhibitor is active on murine mammary cells. It might be a mammary chalone. The isolated compound is interesting from a fundamental point of view as a tool to probe the control mechanism of the cellular division cycle; because of its activity on malignant cells derived from breast tumors, it might also be interesting from a clinical point of view considering the high incidence of mammary carcinoma.

Immunosuppression in Mice Bearing Primary Tumors*

RICHARD B. WHITNEY, BARBARA S. KELLY and JULIA G. LEVY

Department of Microbiology, University of British Columbia, Vancouver, British Columbia, V6T 1W5, Canada

Abstract—*Spleen cells from C57Bl/6, BALB/c and CBA/J mice bearing primary methylcholanthrene induced sarcomas and C3H/HeJ mice bearing primary spontaneous mammary tumors gave suppressed responses to mitogens. Those spleens also contained a population of suppressor cells which inhibited the mitogen responses of normal spleen cells. Immunoglobulin rich fractions of sera from all these mice except the BALB/c tumor bearers, contained a suppressive factor which inhibited the mitogen response of normal syngeneic spleen cells.*

INTRODUCTION

MOST studies in tumor immunology have been performed using transplanted tumors in animal systems. There is little doubt that a considerable amount of valuable information has been obtained from such studies concerning the relationship of tumor growth to the immune system. However, it seems necessary to demonstrate that the observed effects in transplanted tumor systems correspond to the effects of primary tumors on the immune system, for such studies would more closely correspond to the human situation.

In previous work from this laboratory, using a variety of transplanted tumors, suppression of general immunity [1] and development of suppressive serum factors [2, 3] and suppressor cells [4] in mice with progressively growing tumors has been reported. Others have reported similar observations in both animals [5–8] and humans [9–12]. Thus, much evidence now supports the contention that progressive tumor growth results in progressive immunosuppression and this immunosuppression may be due to the development of suppressor cells and/or suppressive serum factors.

The purpose of the present experiments was to test immune competence and suppression in mice of different strains bearing chemically-induced primary sarcomas or spontaneous mammary tumors. The similarity of the results from these mice with previous results from mice bearing transplantable tumors serves to strengthen the concepts and to show a closer correlation with the human situation. Although these studies are somewhat limited in their scope, in that only a limited number of assays could be done on each animal bearing a primary tumor, all the observations indicate a close similarity between primary and transplantable tumors, in their effect on general immune competence.

MATERIALS AND METHODS

Mice

BALB/c, CBA/J and C57Bl/6J females aged 6–8 weeks were obtained from Jackson Laboratory and were used when 2–4 months old. Retired C3H/HeJ breeders were also obtained and used as a source of spontaneous mammary tumors. Age matched controls were maintained and used throughout.

Tumors

Primary sarcomas were induced in BALB/c, CBA/J and C57/Bl mice by intramuscular injection in the right hind leg of 0.5 mg of 3-methylcholanthrene (MCA) suspended in 0.1 ml trioctanoin. Spontaneous mammary tumors developed in a high proportion of the C3H/HeJ females at an age of about 12 months.

Collection and preparation of serum

Blood was collected from the retro-orbital sinus or by exsanguination from the heart of normal or tumor-bearing mice (tumors > 3.0 g). The blood was allowed to clot overnight at 4°C after which the sera were separated, inactivated at 56°C for 30 min and stored at −20°C.

Fractionation and assay of mouse serum

Whole serum was fractionated on Sephadex G-150 in order to obtain the immunoglobulin containing fraction. The Ig peak was precipitated with 40% saturated $(NH_4)_2SO_4$ and reconstituted to its original volume in physiological saline as previously described [13]. The immunosuppressive activity of the Ig fraction was assessed by titration at various concentrations in culture with ConA and normal spleen cells from the strain syngeneic to the tumor bearer.

Culture system for mitogen stimulation

These methods have been described in detail previously [1–4]. Spleen cells were cultured in 0.2 ml of RPMI-1640 medium containing 50 μg/ml gentamycin in microtiter plates with 5% fetal calf serum (FCS) in tests for competence and suppression by tumor bearer spleen cells and 2% FCS in tests with serum preparations. Mitogens were added in 0.05 ml vol at final concentrations of 4 μg/ml for concanavalin A (ConA) or 25 μg/ml for lipopolysaccharide (LPS). One μCi of ^{3}H-thymidine was added to each culture after 48 hr and the cultures were harvested 18 hr later.

Enrichment of suppressor cells by centrifugation on Hypaque–Ficoll

This method was completely described elsewhere [4].

Data presentation

Mitogen stimulation results were expressed as mean CPM of 3 replicate cultures. Standard deviations were always less than 10%. Differences greater than 15% are statistically significant by Student's *t*-test at the level of $P = < 0.05$.

RESULTS

Mice developing primary tumors were sacrificed and heart bled at various times after tumor development. General lymphocyte competence in these primary tumor-bearers was assessed by their spleen cell responses to ConA, a T cell mitogen [14] and LPS, a B cell mitogen [15]. Significantly depressed mitogen responses were observed in all animals with tumors >3.0 g and in some animals with tumors between 2.0 and 3.0 g. This was the case in all the species tested regardless of whether the tumor was a primary MCA-induced sarcoma or a spontaneous mammary tumor. Results of these studies are shown in Tables 1–3. It can be seen that with the smaller tumors (<3.0 g) responsiveness to ConA was either normal or close to the normal range. However, as tumors progressed there appeared to be a loss of competence which correlated roughly with tumor size. The LPS response in the various mouse strains appeared, in general, to be less affected by the presence of tumor, although suppression of the response was noted in mice with large tumors. The exception to this rule was the C3H/He mice with mammary tumors. Normal mice of this strain had very low responses to LPS, and they did not appear to be markedly altered during tumor growth.

were tested for their ability to suppress the mitogen responses of normal spleen cells [4]. Spleen cells to be tested were taken from mice with large tumors (>3.0 g) for this experiment. The results are shown in Table 4. Spleen cells from every animal bearing a primary tumor significantly suppressed the ConA response of normal spleen cells with the exception of CBA/J (T_3). Centrifugation of tumor bearer spleen cells on Hypaque–Ficoll produced an enriched population of suppressor cells in the light fraction [4] from all mice but two C3H tumor bearers (T_1, T_2). It appears that suppressor activity may be enriched for by cell separation, for spleen cells from CBA/J (T_3) were not suppressed as a whole population. However, when they were separated on Hypaque–Ficoll, they did show a degree of suppression. The LPS responses were also suppressed to some extent by the spleen cells of the primary tumor bearers, but to a lesser extent than the ConA response. Cell separation did not appear to increase this suppressive effect. It has been shown previously in this laboratory, that separation of spleen cells from normal animals do not enhance for the suppressive effect with either mitogen.

In order to determine that the suppressor cell activity noted with tumor bearer spleen cells was not a unique aspect of the mitogen dose or the timing of the cultures, dose and timing studies were done with suppressor cells

for the ConA response. Representative results are shown in Table 5. It can be seen that suppression was observable at all times and over a wide range of ConA doses. However, most consistent results were observable at 72 hr over the range of 1–8 μg/ml of ConA. This merely reflects the optimal timing and dose range in the unsuppressed cells.

The Ig rich fractions (Sephadex G-150) of serum from all C57/Bl, CBA/J and C3H/HeJ primary tumor bearers were highly immunosuppressive when compared to equivalent normal serum fractions (Table 6). In contrast, the BALB/c tumor bearers had no suppressive activity in their Ig fractions. The suppression caused by the serum of the tumor bearing animals was found to be independent of mitogen dose. A titration of a representative serum sample is shown in Table 7.

DISCUSSION

Previous studies from our and other laboratories have demonstrated that spleen cells from mice with progressively growing tumors usually exhibit depressed mitogen responses [1, 5, 6] indicating a general suppression of the ability of their lymphocytes to be stimulated. Further, these animals develop a population of cells in their spleens and a factor in their serum both of which can suppress mitogen responses of normal lymphoid cells [2–4, 8]. The nature and mechanism of action of the suppressor cells and factors are currently under extensive investigation by us and others with the aim of understanding the mechanism(s) of general immunosuppression in tumor-bearers. These studies seem to be of real importance considering that general immunosuppression is often observed in human cancer patients [9–12].

In view of the potential importance of this subject, it is essential to establish valid animal systems which will correlate with the human situation. All previous work with animals has involved the uses of transplanted tumors. Such tumors are very useful and have many advantages in that extensive studies can be done on large groups of tumor bearing animals. However, it seems necessary to show that these transplanted tumors behave similarly

to primary tumors which are more analogous to the human situation.

The data presented in this paper show that in general, mice of various strains with primary tumors have depressed mitogen responses indicating a probable suppression of general immune competence. While this assessment of immune status is indirect, it should be emphasized that in all previous work using transplantable tumor models, the correlation between lowered mitogen responsiveness and loss of specific immune functions was invariant and proportional [1]. We have also shown that animals bearing primary tumors have cells in their spleens which are capable of suppressing the mitogen responses of normal syngeneic spleen cells. These cells are enriched in the light fraction of Hypaque–Ficoll separated cells. These observations correlate directly with a study done in this laboratory on non-specific suppressor cells in mice bearing a transplantable methylcholanthrene induced tumor [4].

The Ig-rich fraction of the serum from mice bearing primary tumors was found to be immunosuppressive, as assessed by its ability to suppress mitogen responsiveness in normal syngeneic splenocytes. This also correlates directly with previous work carried out in this laboratory. This factor, found in the serum of mice bearing transplantable tumors, has been shown to inhibit not only mitogen responsiveness but also most specific *in vitro* immunologic functions [2, 3, 13]. Studies with immunoabsorbent columns have shown that the suppressive material may be some kind of immunoglobulin, since it can be removed by anti-mouse k and anti-mouse λ antisera [16]. We have no direct or conclusive evidence that the suppressive serum factor demonstrated in mice bearing primary tumors is identical to the factor characterized in mice with transplantable tumors. The paucity of serum obtainable from a single mouse with a primary tumor precludes such a study. However, insofar as was possible to test, it appeared that these serum factors were comparable.

An interesting observation was made that all BALB/c mice tested here had suppressed mitogen responses and splenic suppressor cells but no demonstrable suppressive serum activity. This was observed by us earlier with another primary spontaneous BALB/c tumor of unknown origin and also with a long established transplantable BALB/c melanoma [2]. The lack of suppressive activity is obviously not due to the tumor type as was originally thought but is instead a peculiarity of the BALB/c strain. Further work would determine whether this factor is indeed absent or is masked in some way which our separation procedures are not sufficient to unmask. In any event, it is not an unreasonable observation since there are numerous human cancer patients who do not exhibit serum inhibitors, despite their being immunosuppressed, even though other patients with identical tumor types do have suppressive factors. The present data provide further support for evidence of immunosuppression in individuals bearing progressively growing tumors.

Potentiating Action of Cobra Venom Cytotoxin on the Antitumour Effects of an Alkylating Agent (Melphalan)

B. M. BRAGANCA and A. V. HOSPATTANKAR
Biochemistry Division, Cancer Research Institute, Parel, Bombay, India

Abstract—*Cytotoxin P_6 isolated from cobra venom which can inhibit the growth of several tissue culture cell lines and also the growth of Yoshida sarcoma in rats has been shown to considerably enhance, the growth inhibition produced by melphalan on HeLa and KB cells. It can also potentiate the effects of melphalan, on the growth of Yoshida sarcoma cells in rats. The effective dose of mephalan required to produce* 100% *inhibition of cell growth in rats bearing Yoshida sarcoma tumour could be decreased from* 0.65 μmole/kg *body weight to* 0.07 μmole/kg *body weight in animals which had been injected with cytotoxin P_6 four hours before receiving melphalan injection. In view of the earlier evidence showing that cytotoxin P_6 attacks the plasma membrane of susceptible cells, the potentiating effects described are presumably brought about by promoting preferential penetration of the nitrogen mustard into the tumour cells.*

INTRODUCTION

PREVIOUS studies [1] have demonstrated that a basic polypeptide (cytotoxin P_6) isolated from cobra venom shows preferential cytotoxicity to certain cells. The Yoshida sarcoma cells in particular have been found to be highly susceptible to destruction by the cytotoxin which is also able to prevent the growth of this tumour in rats. Other investigations have demonstrated that it binds with components on the cell surface of susceptible cells [2]. This paper describes experiments designed to examine the action of cytotoxin P_6 on the antitumour effects of the alkylating agent such as melphalan. It is consistent with the data obtained using tumour cell lines and rats bearing Yoshida sarcoma that the cytotoxin potentiates the antitumour effects of melphalan possibly by facilitating preferential penetration of the nitrogen mustard into tumour cells.

MATERIALS AND METHODS

Melphalan was kindly supplied by Dr. T. A. Connors, Chester Beatty Research Institute, London. Eagle's medium as modified by Dulbecco was obtained from BIOS, Bombay, India. Cytotoxin P_6 was prepared according to the procedure described earlier [1].

Accepted 18 November 1977.

Yoshida sarcoma cells

The tumour was regularly maintained in Wistar rats by biweekly transplantation of 0.8 ml fluid derived from the intraperitoneal cavity. The ascitic fluid containing Yoshida sarcoma cells was withdrawn from the animals four days after transplantation of this tumour.

Tissue culture cells

The tissue culture cell lines KB (Human oral carcinoma), HeLa (Human cervix carcinoma) were obtained from Virus Research Centre, Poona. These were maintained as monolayers adherent to glass in Eagle's medium modified by Dulbecco. The medium supplemented with 15% human AB serum was replaced twice a week. For use in experiments the bottles were generally seeded with 2.5×10^6 cells and allowed to grow at 37°C for 48 hr. The cells were removed from the glass surface by 0.3% trypsin treatment for 2 min at 37°C.

Protein determination

Protein was assayed by absorbance method described by Kalckar [3].

Preparation of melphalan solution

Melphalan was dissolved in ethanolic HCl–propylene glycol buffer pH 7.2. This was prepared immediately before use.

Assay of cytotoxicity in tissue culture cells

Per cent inhibition of growth of tissue culture

cells by cytotoxin P_6 or melphalan was determined as described [4] except that the cells were grown as monolayers in Leighton tubes. For this purpose 80,000 cells (KB or HeLa) 1 ml of growth medium were seeded in each Leighton tube. Sixteen tubes were used for each group, containing varying amounts of the inhibitor and a control group without the inhibitor. The cells were grown for 48 hr. At the end of this period half the number of tubes in each group were trypsinised and cells counted in a haemocytometer. The medium and the inhibitor in the remaining tubes were replaced and cells were allowed to grow for another 48 hr. The cultures were then trypsinised and counted as before.

The combined effect of cytotoxin P_6 and melphalan on each type of tissue culture cells was studied as follows: four groups each containing 16 Leighton tubes were seeded with 80,000 cells in 0.5 ml growth medium. Groups 1 and 2 were treated with cytotoxin P_6 and incubated for 30 min at 37°C. At the end of incubation period groups 2 and 3 were treated with melphalan. Group 4 was the control to which 10 μl of propylene glycol buffer pH 7.2 used in the preparation of melphalan was added. The final volume of each tube was made to 1 ml with growth medium. The cells were allowed to grow for 48 hr. At the end of this period half the number of tubes of each group was used for counting the cells as before. In the remaining tubes the inhibitors and medium were replaced as described and grown for another 48 hr and the percent inhibition was calculated as above.

Determination of tumour inhibition in rats

Yoshida sarcoma ascitic tumour cells obtained from the intraperitoneal cavity of rats in which the tumour was routinely maintained were inoculated into several groups of male Wistar rats. 1×10^8 cells of tumour inoculum given intraperitoneally to each rat (140–150 g body weight) was found to kill the animal within 8–10 days.

Each experimental group containing four animals was injected i.p. with graded doses of cytotoxin P_6 or melphalan. Each dose was divided into four equal parts and injected at 24 hr intervals. The first injection (i.p.) was given 24 hr after the tumour inoculation. The material was injected in 0.25 ml solution. The control group was injected with 0.25 ml propylene glycol buffer pH 7.2 used to dissolve melphalan.

On the sixth day after inoculation of tumour, the animals were anaesthetised and the ascitic fluid from intraperitoneal cavity was withdrawn and collected in 0.9% saline solution. To collect most of the cells, the intraperitoneal cavity was washed with saline. The total volume was recorded and the percent inhibition of growth of cells in the treated animals was calculated from counts of cells in the control and the experimental groups.

To determine the combined action of cytotoxin P_6 and melphalan on the growth of Yoshida sarcoma cells in rats, the following procedure was adopted. Each dose of cytotoxin P_6 and melphalan was divided into four equal parts and injected at 24 hr intervals as follows: The animals were injected with a dose of cytotoxin P_6 in 0.25 ml distilled water, followed by an injection of a dose of melphalan in 0.25 ml propylene glycol buffer given 4 hr after. The control group was injected with the same volume of propylene glycol buffer. On the 6th day after inoculation of tumour the growth of Yoshida sarcoma cells was determined as described above.

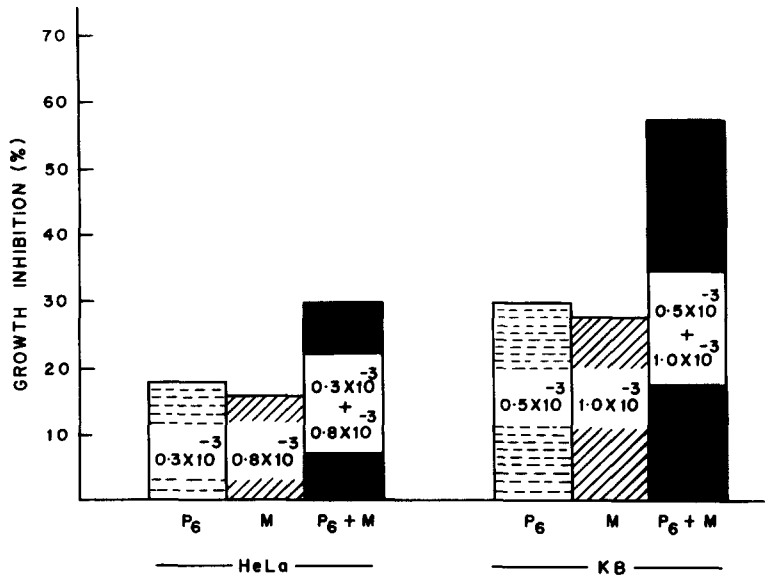

Fig. 2. Effect of simultaneous addition of P_6 and melphalan (M) on HeLa and KB cells. Amounts of inhibitors indicated are μmole/ml *in the system (average of four experiments).*

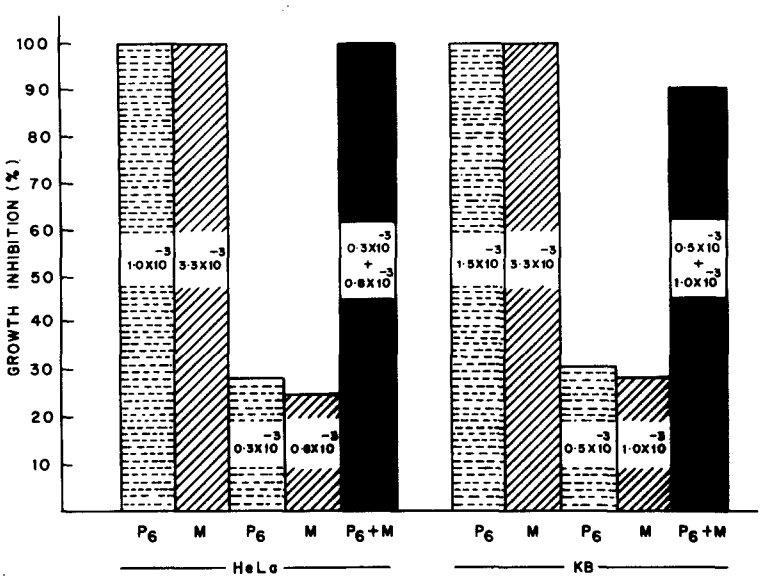

Fig. 3. Potentiating effect of P_6 on melphalan (M) inhibition of growth of HeLa and KB cells. Inhibitor amounts indicated are μmole/ml *in the system (average of four experiments).*

RESULTS

Before examining the composite effects of cytotoxin P_6 and melphalan on HeLa and KB cell lines, the growth of these cells was studied in the presence of varying amounts of each of the inhibitors. Results given in Fig. 1 describe growth inhibition of HeLa and KB cells produced by varying amounts of cytotoxin P_6 and melphalan when added separately. It is seen that 1×10^{-3} μmole/ml of cytotoxin P_6 inhibited the growth of HeLa cells by 100% and 1.5×10^{-3} μmole/ml were required for complete inhibition of KB cells. Melphalan in concentration of 3.3×10^{-3} μmole/ml inhibited by 100% the HeLa cell system and same amount of melphalan produced 95% inhibition of growth of KB cells.

Experiments in which the combined effects of melphalan and cytotoxin P_6 were tested on HeLa and KB cells showed that if the cytotoxin and melphalan were added as a mixture the resultant inactivation was generally additive. It is seen in Fig. 2 that doses of melphalan and cytotoxin P_6 which inhibited the HeLa cells by 16 and 18% respectively, inactivated this cell

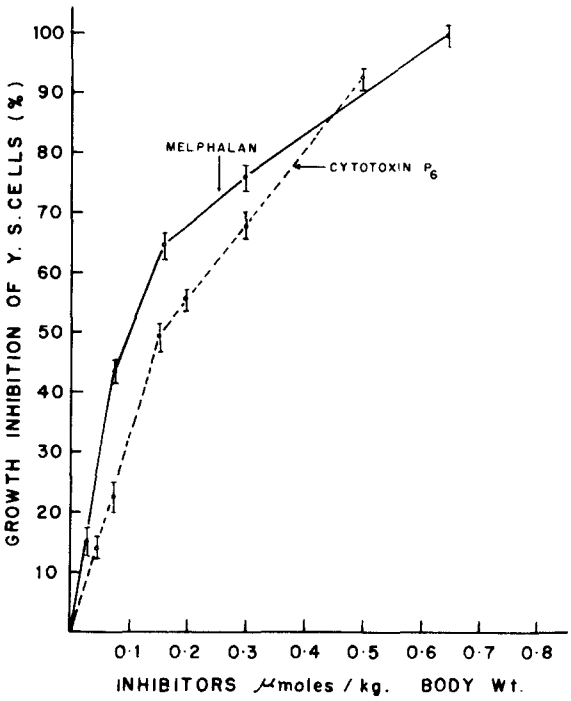

Fig. 4. Percent inhibition of growth of Yoshida sarcoma cells in rats obtained with varying amounts of P_6 and melphalan (M).

system by 30% when added as a mixture. In KB cells a dose of melphalan which by itself inhibited the cells by 28% when mixed with cytotoxin P_6 (a dose which produced 30% inhibition) produced 57% inactivation.

In the next series of experiments attempts were made to facilitate the penetration of melphalan into the cells by their prior exposure to the cytotoxin P_6 which is known to change the membrane permeability [5]. The cells were treated with cytotoxin P_6 and incubated at 37°C for 30 min at the end of which melphalan was added to the experimental tubes. Control tubes containing cells without the inhibitors were treated under identical conditions (see Materials and Methods). Results given in Fig. 3 demonstrate that 0.8×10^{-3} μmole/ml of melphalan when added to HeLa cells primed with 0.3×10^{-3} μmole/ml cytotoxin brought about 100% inactivation of growth. Whereas these quantities of melphalan and cytotoxin when added individually inhibited the cells by 25 and 28% respectively. Similar experiments using KB cells have shown that doses of cytotoxin P_6 (0.5×10^{-3} μmole/ml) which produced 30% inhibition and melphalan (1×10^{-3} μmole/ml) which inhibited these cells by 28% produced 90% inactivation when added sequentially.

Following the observations using tissue culture cells, attempts were made to study the potentiating action of cytotoxin P_6 on melphalan inhibition of cell growth in rats bearing Yoshida sarcoma. Initially the decrease in Yoshida sarcoma cells was determined in the presence of varying quantities of melphalan or cytotoxin P_6. The results obtained with graded doses of melphalan or cytotoxin P_6 ranging from 0.1 to 0.65 μmole/kg body weight are shown in Fig. 4. It was seen that in the control group inoculation of 1×10^8 cells increased to 1×10^9 cells on the 6th day. In the group receiving melphalan, 100% inhibition of cell growth was obtained with 0.65 μmole/kg body weight. Inhibition of 50% was produced with 0.11 μmole/kg body weight. The cytotoxin P_6 produced 94% inhibition with 0.5 μmole/kg body weight and 50% inhibition with 0.15 μmole/kg body weight. To aid the selective penetration of melphalan into the tumour cells, the cytotoxin P_6 was injected 4 hr prior to the injection of melphalan, as described in Materials and Methods. The combined effect was tested with 0.05 μmole/kg body weight of cytotoxin P_6 and 0.04 μmole/kg body weight of melphalan. In these amounts cytotoxin P_6 and melphalan if added separately produced negligible effects on cell growth as compared to the control group (Fig. 4). When the same dose of cytotoxin P_6 was injected i.p. 4 hr prior to melphalan (i.p.), however, the combined inhibition obtained was 65% (Fig. 5). By increasing the dose of melphalan from 0.04 to 0.07 μmole/kg body weight, the inhibition rose to 92%. This concentration of melphalan by itself inhibited the cell growth by 20%.

Animals treated with cytotoxin P_6 and melphalan in doses of 0.05 and 0.07 μmole/kg body weight respectively (Table 1) did not survive for more than 21 days whereas the lifespan of control was 8–10 days. Sequential injection of cytotoxin P_6 and melphalan under same conditions used as above increased the survival time for more than four months. The animals appeared completely normal at the end of this period.

DISCUSSION

Alkylating agents are widely used in human cancer therapy. Like all anticancer agents, they are highly toxic and produce side-effects. A great deal of evidence indicates that the site of action of alkylating agents such as melphalan is in the nucleus brought about by binding to the DNA [6, 7]. As cytotoxin P_6 isolated from cobra venom has been shown to be preferentially destructive to certain tumour cells through binding to plasma membrane constituents [5], the present study was an attempt to determine whether cytotoxin P_6 in minimal doses could enhance the selective penetration of melphalan into the tumour cells and so help to reduce the

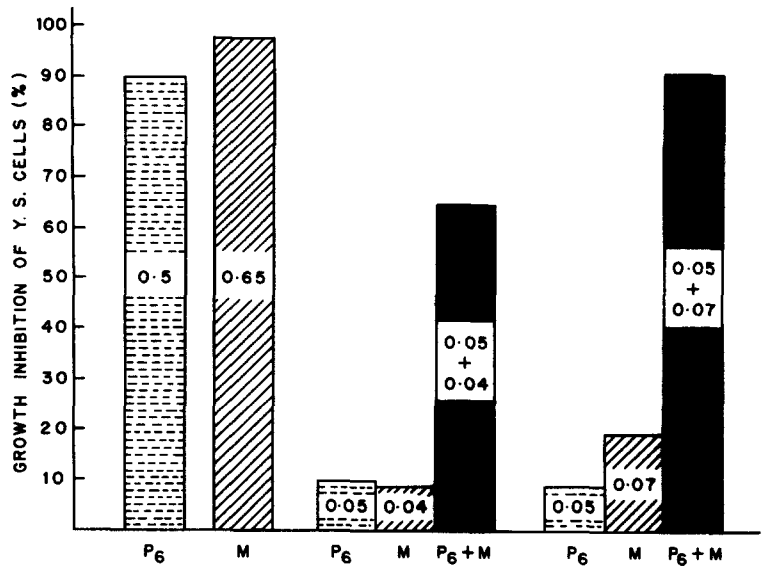

Fig. 5. Potentiating effect of P_6 on the antitumour action of melphalan (M) on the growth of Yoshida sarcoma in rats. Amounts of inhibitors indicated are μmole/kg *body weight. (Average of four experiments).*

Table 1. Lifespan of Yoshida sarcoma rats—control and treated

Sr. No.	group (rats)	Dose of inhibitor (μmole/kg body wt)	Survival (No. of days)
1.	Yoshida sarcoma cells (1×10^8)	—	8–10
2.	Yoshida sarcoma cells (1×10^8) + Cytotoxin P_6	0.05	9–14
3.	Yoshida sarcoma cells (1×10^8) + Melphalan	0.07	8–21
4.	Yoshida sarcoma cells (1×10^8) + Cytotoxin P_6 + Melphalan	0.05 + 0.07	>120

effective dose of this drug. In the *in vitro* experiments with HeLa and KB cells it is seen that when mixtures of melphalan and cytotoxin P_6 were added to the cell system the resultant growth inhibition was additive. This could presumably be due to the slower penetration of the cytotoxic protein into the active sites of cells, as other studies have shown that the cytotoxic action of P_6 on cells is time dependent [8]. However, in experiments in which the HeLa and KB cells were first incubated with cytotoxin P_6 to make them more permeable and then melphalan was added synergistic effects were observed. By the prior priming of the cells with cytotoxin P_6 the effective dose of melphalan required to produce 100% growth inhibition of HeLa and KB cells could be decreased by 75 and 66% respectively. The *in vivo* experiments using Yoshida sarcoma bearing rats demonstrate that when melphalan was injected 4 hr after treatment with cytotoxin P_6, the effective dose of melphalan to produce 100% inhibition of cell growth could be decreased from 0.65 to 0.07 μmole/kg body weight. Experiments in which survival was studied have also indicated that doses of melphalan (0.07 μmole/kg body weight) and cytotoxin P_6 (0.05 μmole/kg body weight) which when tested individually were not able to significantly increase the lifespan of the animal against the tumour prolong the survival to more than four months if injected sequentially as described above. It is interesting to note that on molar basis the cytotoxin P_6 (mol. wt 10,500) appears to be more effective as a growth

inhibitor on HeLa and KB cells than melphalan. Both are approximately of same potency in preventing growth of Yoshida sarcoma in rats. It is also seen that the cytotoxin P_6 displays quantitative differences in its cytotoxicity to HeLa and KB cells. This may be a reflection of differences in the biomembrane structure of these two cell types. Melphalan inhibition was more uniform. The overall data suggests that the cytotoxin P_6, in minute concentration can significantly enhance the antitumour effects of melphalan conceivably by producing preferential changes in membrane permeability of tumour cells.

In Vivo Studies with Hexamethylmelamine*

C. J. RUTTY,† T. A. CONNORS,† NGUYEN-HOANG-NAM,‡ DO-CAO-THANG‡ and H. HOELLINGER‡

†*Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London SW3 6JB, England and*
‡*INSERM—Unité de Recherche de Toxicologie Expérimentale, Hôpital Fernand Widal 200 Rue du Faubourg Saint Denis, 75475 Paris Cédex 10, France*

Abstract—*Uptake and distribution studies using* C^{14}*-Hexamethylmelamine in normal and non-tumour bearing mice have shown no selective uptake by the tumour, but a marked concentration of label in the small intestine. Binding of both ring and methyl-*C^{14}*-HMM to liver and to a lesser extent to tumour has been shown to occur. In mice 4 major urinary metabolites were detected. namely* N^2, N^4, N^6*-trimethylmelamine,* N^2, N^4*-dimethylmelamine, monomethylmelamine and melamine. No quantitative difference between HMM and its inactive trimethyl derivative was found in their ability to undergo demethylation* in vivo.

INTRODUCTION

HEXAMETHYLMELAMINE (HMM) has demonstrated consistent activity against a wide range of solid tumours [1]. Of particular interest are the remissions obtained against carcinoma of the lung, which range from 11% for epidermoid carcinomas to 36% for small cell carcinomas [2–5]. Although the efficacy is not particularly striking in any tumour type, clinical interest in HMM continues.

HMM is structurally related to triethylenemelamine (TEM), a known alkylating agent [6], but its metabolism and mechanism of action appear to be completely different [7]. Worzalla *et al.* have shown in both rats and man that the major pathway for metabolism of HMM *in vivo* is *N*-demethylation to lower methylmelamines [8, 9]. HMM is also an effective chemosterilant for house flies [10] and its metabolism in flies has been studied by Chang *et al.* [11], who report that the principal metabolic transformation of HMM again involves *N*-demethylation.

Several suggestions have been made as to how HMM exerts its antitumour activity [12, 13], but the exact mechanism of action remains uncertain. In an earlier paper [14] it was shown that HMM requires metabolic activation in order to exert its antitumour effects *in vitro* and that *N*-methylols may well represent the active form of the drug. Two such derivatives have shown activity against PC6 plasma cell tumour *in vivo* and very marked activity against a human lung tumour (P246 epidermoid carcinoma of the bronchus) growing in immune deprived mice [15], in common with the parent compound.

In the present paper a study of the uptake and tissue distributions of C^{14}-HMM in normal mice and in mice bearing tumours sensitive to HMM is reported. The binding of both ring and methyl labelled HMM *in vivo* has also been looked at in an attempt to ascertain if the activity of these methylols is inherent, or whether they act as formaldehyde releasers, which is itself the tumour-active agent.

A method for measuring blood levels of formaldehyde produced as a result of the demethylation of HMM and its analogues is also described. Finally the urine metabolites from mice treated with a tumour-curative dose of HMM have been examined.

MATERIAL AND METHODS

Chemicals

2,4,6-C^{14}-Ring HMM, specific activity 32 mCi/mmole, was prepared at Services des

Accepted 30 August 1977.

*This work was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council (Grant No. G973/787/K) and the Cancer Research Campaign; in part by Research Grant C.R.L. International No. 77.5.046.2 to Unité de Recherche de Toxicologie Expérimentale, Hôpital Fernand Widal from the Institut National de la Santé et de la Recherche Médicale, France. One of us (C.J.R.) wishes to acknowledge a S.R.C. Case Fellowship held in conjunction with Beecham Research Laboratories.

Molecules Marquees C.E.N., Saclay, France, from ^{14}C-urea by a 2-step synthesis. ^{14}C-urea was cyclized in *o*-dichlorobenzene to (2,4,6-^{14}C) cyanuric acid, purified by chromatography on an ion exchange resin column Sephadex SPC-25. Direct amination of acid in presence of HMPT and dimethylamine gave 2,4,6-C^{14}-Ring HMM, purified by silicagel adsorption column chromatography; radioactive overall yield: 18% based on ^{14}C-urea [16].

2,4,6-N($^{14}CH_3$)$_2$-HMM, specific activity 8.4 mCi/mmole, was generously provided by the Stanford Research Institute, Menlo Park, California.

Unlabelled HMM was provided by the National Cancer Institute, Bethesda.

Animals and tumours

Female CBA/LAC mice were used for normal studies. The P246 human bronchial carcinoma was implanted as tumour pieces s.c. into the flank of immune-deprived male CBA/LAC mice according to the method of Mitchley *et al.* [17]. The tumours were used 8–9 weeks after implant when they had grown to a weight of approx. 3 g.

The ADJ/PC6 plasma cell tumour was obtained by s.c. transplantation of tumour fragments in the flank of female BALB/c mice and used 24 days after transplantation, i.e. when antitumour testing is normally started.

Measurement of blood levels of formaldehyde

Groups of 5 normal CBA mice were treated with a tumour-curative dose (90 mg/kg) of the drug under study, injected intraperitoneally as a suspension in arachis oil. At various time intervals from 0 to 4 hr after injection the animals were killed using solid carbon dioxide and the blood collected after snipping the heart. Blood samples taken were added to a solution containing semicarbazide (1.11 mg/ml) kept on ice and deproteinised immediately by the addition of 1 vol sodium tungstate followed by 1 vol 0.67 ml H_2SO_4. The deproteinised samples were kept on ice for approx. 15 min and the protein precipitate then removed by centrifugation. The resulting supernatant was neutralized by adding 0.0167 vol of 0.67N NaOH and formaldehyde estimated according to the method of Nash [18].

Uptake and distribution of C^{14}-HMM

C^{14}-Labelled HMM was administered to mice (2.4 mg/kg i.p. in ETOH/oil) and at various time intervals after injection the major organs and tumour were removed. The larger organs, namely liver, tumour, small intestine and large intestine, were homogenized in distilled water (1 g wet weight tissue to 4 ml water) and a 1 ml aliquot of homogenate digested by heating with 1 ml 25% tetraethylammonium hydroxide (TEH) at 50°C overnight. One tenth of a millilitre of the digest was then added to 10 ml scintillation fluid and counted in a scintillation counter (Packard Tricarb Model 3380).

The smaller organs were solubilized using Soluene 350 (100 mg/ml) 0.1–0.25 ml aliquots of each digest were then taken for scintillation counting as above.

Binding of C^{14}-HMM

The binding of ring and methyl-labelled HMM to the TCA-insoluble fraction of liver, tumour and small intestine was measured using aqueous tissue homogenates prepared from organs of mice treated with C^{14}-HMM as described above.

A 1.0 ml aliquot of homogenate was taken and an equal volume of 10% trichloroacetic acid (TCA) was added to precipitate protein and nucleic acids. The centrifuged material was redissolved in 2 ml TEH by heating overnight at 50°C to give a measure of the amount of bound label. The supernatant was used to measure free label. Samples were assayed for radioactivity by taking an aliquot (100 µl) in 10 ml scintillation fluid and counting as before.

Urine metabolites

A group of 10 non-tumour bearing CBA/LAC mice were treated with 90 mg/kg HMM, consisting of 1 mg ring-C^{14}-HMM: 9 mg unlabelled drug and urine samples collected every 24 hr for 3 days. The urine samples were purified by column chromatography according to the method of Worzalla *et al.* [8], and subjected to t.l.c. analysis on MN Cel 300–10 cellulose plates using dimethylamine/methanol/H_2O (4:9:2) as developing solvent.

RESULTS

Formaldehyde blood levels

It has been possible to detect a Nash positive metabolite in the blood of mice treated with HMM and its analogues. It is uncertain as to whether formaldehyde is actually being measured directly in this system or indirectly from methylol extracted with the blood, which would then break down spontaneously under the assay conditions employed since this involves heating to 60°C for 30 min. In either case, this technique

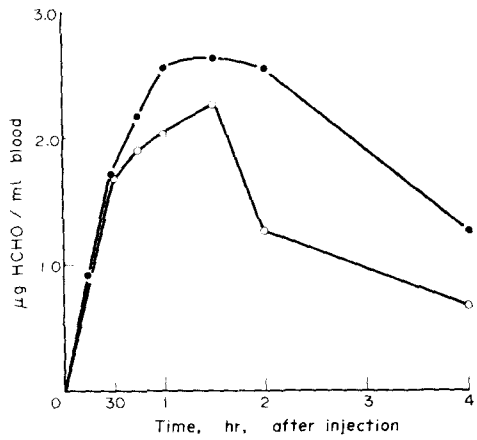

Fig. 1. Formaldehyde levels in blood following treatment with hexamethylmelamine (90 mg/kg) *and trimethylmelamine* (90 mg/kg). [*Figs. 1 and 2, each point represents mean value for 5 mice*].

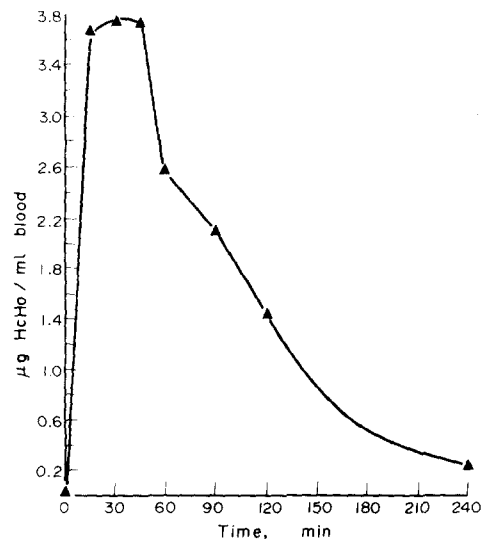

Fig. 2. Formaldehyde levels in blood following treatment with pentamethylmonomethylolmelamine (90 mg/kg).

may be usefully employed as an index of metabolism *in vivo*.

From Fig. 1 it can be seen that following administration of HMM the level of formaldehyde in the blood rises sharply reaching a maximum of 2.6 µg HMM/ml blood at 90 min and then falls again less steeply. A second experiment using trimethylmelamine, which has been shown to be inactive as an antitumour agent, shows a similar curve again reaching a peak after 90 min, except that the level of formaldehyde is slightly lower, i.e. 2.3 µg/ml blood and there is a sharp initial decrease in blood formaldehyde.

Figure 2 shows a similar type of experiment using the monomethylol derivative of HMM (CB10-369), which is the postulated intermediate in the primary demethylation of HMM. In this case, the blood level of formaldehyde is seen to rise even more sharply than for either HMM or TMM, reaching a maximum after about 30 min or possibly earlier when the level of formaldehyde is equal to 3.7 µg/ml blood, i.e. somewhat higher than for the two methylmelamines. The blood level of formaldehyde also falls away very sharply for PMM-methylol so that after 4 hr very little formaldehyde is detectable.

Uptake and distribution of C^{14}*-HMM*

Using ring-C^{14}-HMM in normal mice it is clear that the excretory organs, liver and kidney, showed high concentrations of label (Fig. 3), while only relatively low levels of label were found in organs such as muscle and brain. However, one very interesting feature is the marked concentration of label in the small intestine of these mice which is 2–3 times higher than in either liver or the corresponding large intestine.

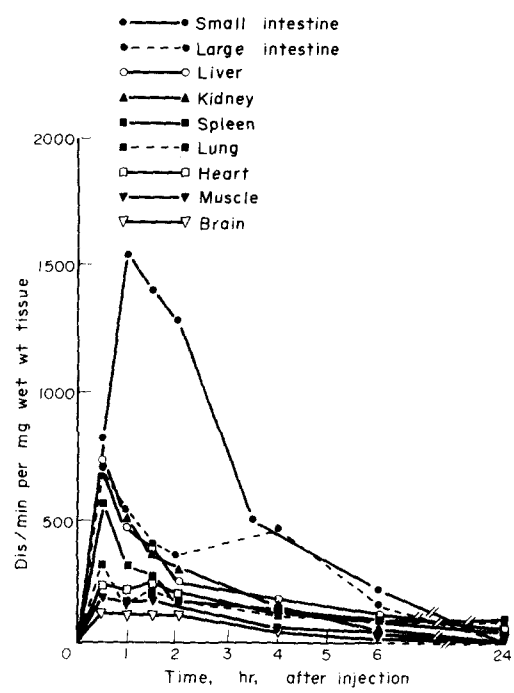

Fig. 3. Distribution of ring-C^{14}-Hexamethylmelamine in normal mice.

Using ring-C^{14}-HMM in PC6 tumour bearing mice (Fig. 4) it can be seen that there is no selective uptake of the drug by this particular tumour (tumour: liver ratio 0.48) despite its sensitivity, but again there is an especially high localization of radioactivity in the small intestine which is three times greater than the large intestine concentration.

The same observations apply to mice bearing the P246 human tumour xenograft (Fig. 5) although here uptake of drug by the tumour is

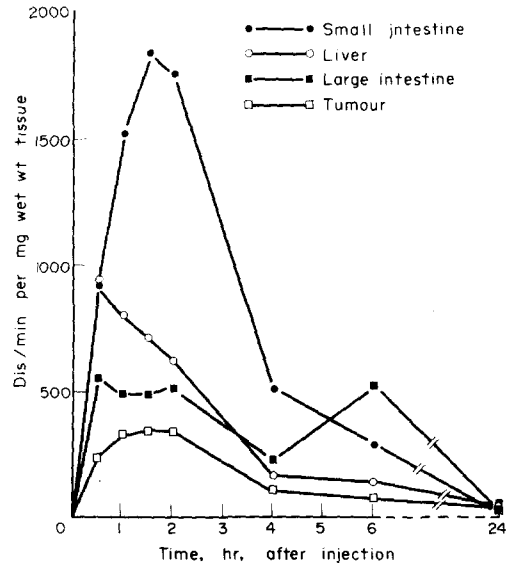

Fig. 4. Distribution of ring-C^{14}-HMM in PC6 tumour-bearing mice.

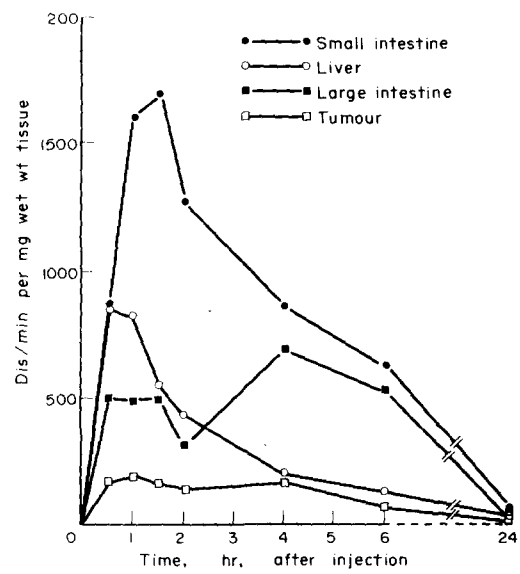

Fig. 5. Distribution of ring-C^{14}-HMM in P246 human tumour-bearing mice.

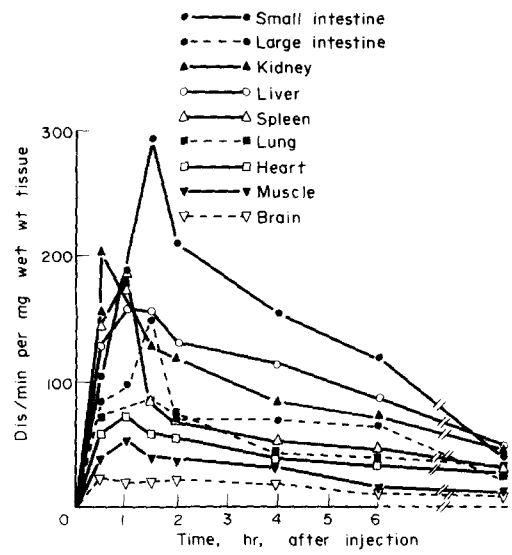

Fig. 6. Distribution of methyl-C^{14}-HMM in normal mice

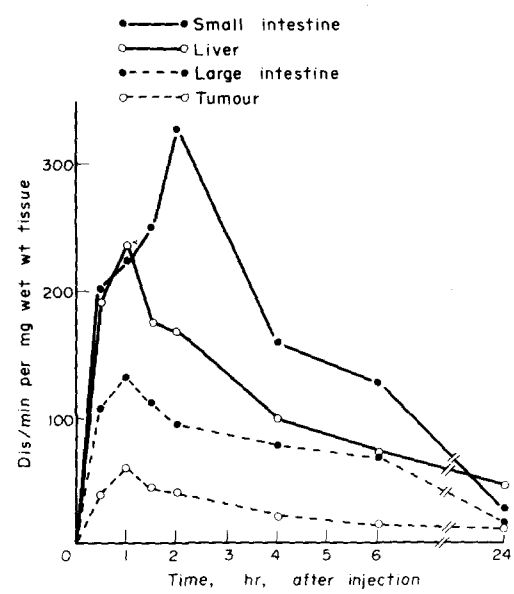

Fig. 7. Distribution of methyl-C^{14}-HMM in PC6 tun bearing mice.

even lower (tumour: liver ratio = 0.23), although this low level of drug appears to be maintained over a longer period of time compared with other organs, as is also seen to a lesser extent with the PC6 tumour. Generally uptake of ring-C^{14}-HMM is rapid in all organs, reaching a maximum at about 30 min and declining almost equally rapidly.

Using methyl-C^{14}-HMM (Fig. 6) uptake of label is slightly slower in most organs with maximum levels reached after about 60 min and there is a corresponding slower fall in radioactivity. The overall tissue distribution for the methyl labelled material is much the same as for ring-C^{14}-HMM with again this large concentration of label in the small intestine. This is found consistently in both PC6 (Fig. 7) and P human tumour bearing mice (Fig. 8), with every case a three fold difference between sı and large intestine concentrations. The ratio for methyl C^{14}-HMM in both tun types is again of the order of 0.24–0.26, cle demonstrating non-selective uptake.

Binding studies

Figure 9 shows that binding of both ring-methyl-C^{14} HMM to liver occurs in no mice. Initially there is little difference ir degree of binding between the two types of l but after 24 hr binding of the ring-C^{14} pound is significantly higher than the m

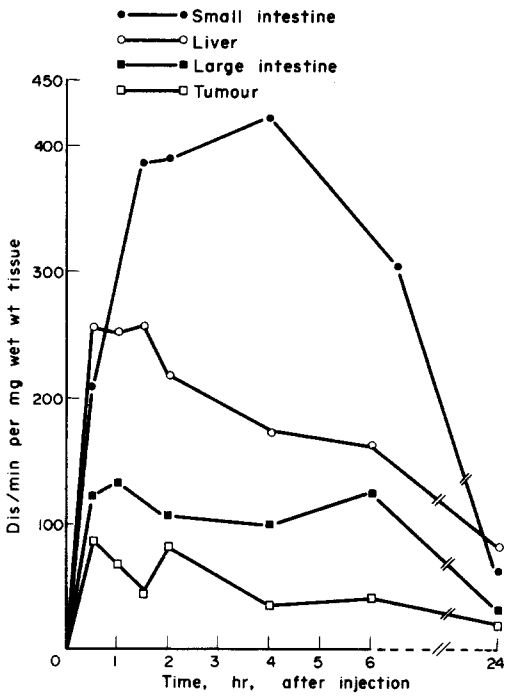

Fig. 8. Distribution of methyl-C^{14}-HMM in P246 human tumour-bearing mice.

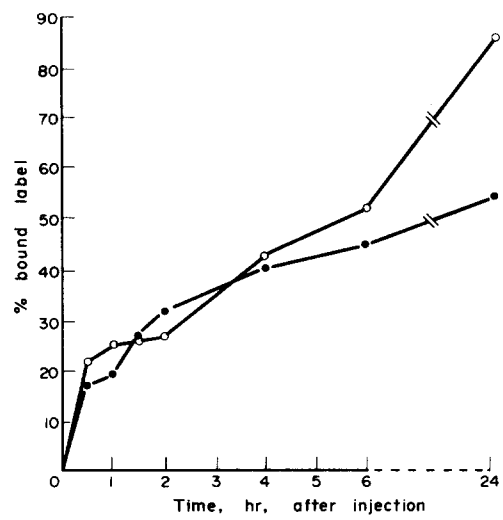

Fig. 9. Binding of ring- and methyl-C^{14}-HMM to TCA-insoluble fraction of liver in normal mice.

labelled drug, i.e. 88 as opposed to 50% bound label. Although the percentage of drug in the TCA-insoluble fraction increased with time the actual amount of bound material remained more or less constant.

In PC6 tumour bearing mice (Fig. 10) binding of both types of label was found to be higher in liver than in tumour, but binding of methyl-C^{14}-HMM is greater than for ring-C^{14}-HMM in both organs in these animals.

In mice bearing the human bronchial tumour the same situation occurs, i.e. that tumour binds

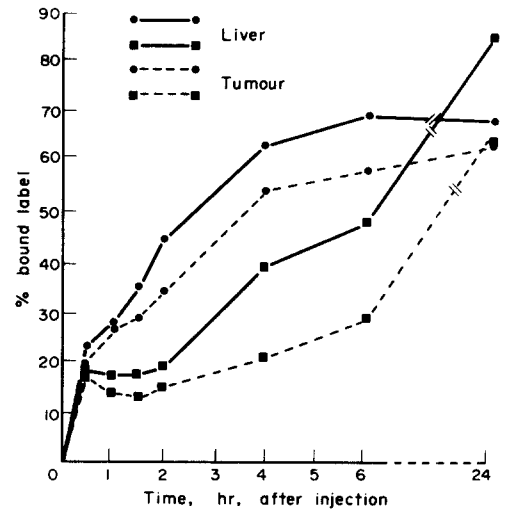

Fig. 10. Binding of ring- and methyl-C^{14}-HMM to TCA-insoluble fractions of liver and tumour in PC6 tumour-bearing mice.

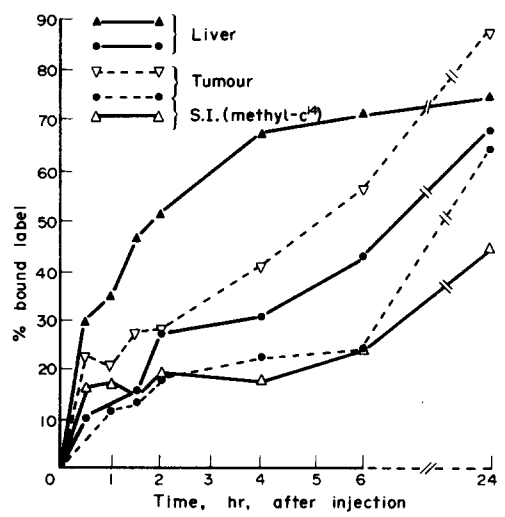

Fig. 11. Binding of ring- and methyl-C^{14}-HMM to TCA-insoluble fraction of liver, tumour and small intestine in P246 human tumour-bearing mice. [Figs. 3–11, each point represents mean value for at least 2 mice].

both types of labelled drug to a lesser extent than liver and the situation for normal mice is again reversed in that methyl-C^{14} binding is greater than ring-C^{14} binding for both liver and tumour tissue (Fig. 11). Figure 11 also shows that despite the high concentration of methyl-C^{14} label in

Monomethylmelamine	0.49	4.5%
Melamine	0.36	0.61%
X	0	0.18%

the small intestine, the amount of bound material is relatively small compared with liver and tumour.

Table 1 shows that when mice were treated with ring-C^{14}-HMM at a tumour curative dose almost 90% of the injected radioactivity could be found in the urine and that the vast majority of this radioactivity was found in the first 24 hr sample.

Thin-layer chromatographic analysis of the purified urine sample revealed the presence of 4 major metabolites of HMM (Fig. 12). These have been identified as N^2, N^4, N^6 trimethylmelamine, N^2, N^4-dimethylmelamine, monomethylmelamine and melamine (Table 2). Thus dimethylmelamine is the major methylmelamine metabolite. A small unidentified peak of radioactivity was also found at the origin.

When the acidified urines (0.1N) were added to the Dowex (Cl^-) column and eluted with 0.1N HCl, 98% of the radioactivity was recovered. Total radioactivity recovered following 2.4N and 6N HCl wash of Dowex 50W (H^+) column in the second stage of purification was only 89%.

DISCUSSION

It has been suggested that HMM may exert its antitumour activity through formaldehyde release [12]. Assuming this theory to be correct from the formaldehyde blood level studies reported here it is difficult to explain the difference in antitumour activity between HMM and trimethylmelamine. Both compounds have been shown to produce similar levels of formaldehyde over more or less the same time course and yet HMM has shown good activity against both the PC6 mouse tumour and human bronchial tumour, whereas the trimethyl derivative is quite inactive in both test systems [14, 15]. It may be argued that, if formaldehyde is the active metabolite, the rate of release of this agent is the determining factor, since the level of formaldehyde produced by HMM is seen to fall more slowly than for trimethylmelamine, or less likely that the final level of formaldehyde obtained is critical in determining whether or not a compound has antitumour activity.

However, both these explanations are unlikely and a better explanation of these findings can be made assuming that *N*-methylols represent the active metabolite. In this case a structural difference between the methylols formed by HMM and tri-MM may explain their differences in activity, or perhaps a difference in stability between the respective methylol intermediates.

When the monomethylol of HMM is looked at in this system the sharp rise and fall in blood level formaldehyde produced by this compound is consistent with its being an intermediate in the metabolism of HMM in which the rate determining step is in the initial hydroxylation, followed by a more rapid breakdown to formaldehyde. These findings provide a reasonable explanation for the *in vivo* antitumour tests using the PC6 tumour [14] in which the two methylols were found to have a lower therapeutic index than the parent compound. When HMM is the starting compound, levels of the active metabolite may be maintained over a period of time, whereas methylols are unstable and will break down fairly rapidly *in vivo*.

Support for the theory that an *N*-methylol rather than formaldehyde represents the active metabolite comes from binding experiments with ring- and methyl-C^{14}-HMM. It is of interest that in tumour tissue ring-labelled

HMM is found to bind to a high degree to cellular macromolecules, indicating that the complete molecule is binding and not only metabolized methyl groups, as would be the case if only methyl-C^{14}-HMM was found to bind.

Binding studies with C^{14}-HMM have also shown an apparent difference between normal and tumour-bearing mice in their ability to bind the ring- and methyl-labelled drug. In both types of tumour bearing mice the fact that binding of methyl-C^{14}-HMM is greater in liver and tumour than for the ring-C^{14} compound suggests either increased metabolism of the drug by tumour-bearing mice, a different type of metabolism, or alternatively a different site of binding.

The relatively poor uptake of labelled HMM by tumour compared with other organs is not surprising in view of the fact that many effective antitumour agents, with the exception of some sulphonamidetriazenes, are not selectively concentrated by tumour cells [19]. That high drug uptake is not necessarily important for antitumour effect is shown by the relatively poorer uptake by the xenografted tumour compared with the mouse plasma cell tumour, the latter being much less sensitive.

The very marked concentration of radioactivity found in the small intestine and correspondingly low level in the large intestine has led to the suggestion that HMM is excreted in the bile, with the possibility of entero-hepatic circulation. Other experiments have indicated that this does appear to be the case, and further that conjugation of the drug to form a glucuronide [20] may be occurring, e.g. an *o*-glucuronide of the methylol. Of interest in this respect is the finding that those tumours sensitive to HMM possess high levels of the lysosomal enzyme β-glucuronidase. An explanation of the selectivity of this drug may therefore be found in the selective breakdown of a glucuronide derivative of HMM by such tumour cells.

Using isolated liver microsomes it was found that demethylation of trimethylmelamine *in vitro* does not occur to any significant extent [14]. From the *in vivo* experiments in which blood formaldehyde is measured, however, HMM and tri MM appear to be equally well demethylated. Furthermore, if HMM is demethylated *in vitro* using a 10,000 *g* supernatant metabolizing system an increase in metabolism of the order of 30% is observed, and lower methylmelamine metabolites can be isolated, suggesting perhaps that soluble factors are also involved in the oxidative demethylation of this compound.

These findings are supported by an examination of the urine metabolites of ring-C^{14}-HMM, since only lower methylmelamines were found, predominantly dimethylmelamine, although some melamine was also detected. There was no evidence of higher methylmelamines being present so that in mice HMM must be rapidly and completely demethylated. The unidentified minor urine metabolite X may represent a glucuronide conjugate of an HMM metabolite.

Acknowledgements—The authors (C. J. R. and T. A. C.) wish to thank George Abel for his assistance with the demethylation studies. The authors (N. H. N., D. C., H. H.) would like to thank Dr L. Pichat, Head of the Department of Labelled Molecules at the Centre d'Etudes Nucleaires—Saclay, for his interest of the Labelling experiment.

Letter to the Editor

Antitumour Effect of Cyclofenil (F6066) on DMBA-Induced Rat Mammary Tumors*

N. DEVLEESCHOUWER,† G. LECLERCQ,† A. DANGUY‡ and J. C. HEUSON†

†*Service de Médecine et Laboratoire d'Investigation Clinique H. J. Tagnon,§ Institut J. Bordet,* 1000 *Brussels, Belgium*
‡*Laboratoire d'Histologie, Faculté de Médecine, Université Libre de Bruxelles,* 1000 *Bruxelles, Belgium*

AMONG synthetic non steroid weak estrogens, cyclofenil [1] (F6066, Fig. 1) is a substance having also a weak antiestrogenic activity (about 1/400 of clomiphene) [2]. Although its mode of action is unknown, some of the physiological effects of the drug might be mediated through estrogen receptors since it was reported to bind with a rather high binding affinity to the cytoplasmic uterine receptors [3, 4] as all other antiestrogenic–estrogenic substances. A tridimentional conformation analysis suggested that the affinity of the drug might be due to geometrical similarities with estradiol or diethylstilbestrol [4]. Since strong antiestrogens (U11, 100A; CI 628; ICI 47,464 . . .) were shown to be active in the treatment of mammary carcinomas, it was of interest to evaluate whether a weak antiestrogen such as cyclofenil with a somewhat higher binding affinity for the receptors than strong antiestrogens [3] might also be effective.

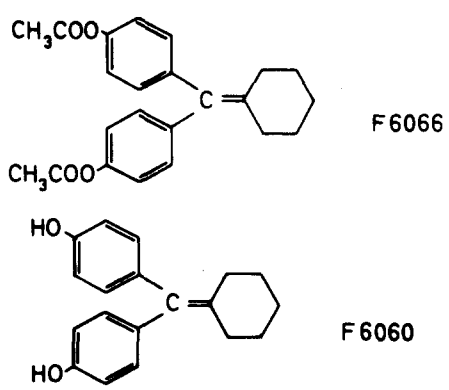

Fig. 1. Formula of cyclofenil (F6066) and its deacetylated form (F6060).

Accepted 29 November 1977.

*This work was supported by a grant from the Fonds Cancérologique de la Caisse Générale d'Epargne et de Retraite de Belgique and by NCI contract No. N01-CM-53840. It was also performed under contract to the Ministère de la Politique Scientifique (Actions concertées) within the framework of the Association Euratom/University of Brussels/University of Pisa.

§This service is a member of the European Organisation for Research on Treatment of Cancer (E.O.R.T.C.).

The dimethylbenz(a)anthracene (DMBA)-induced rat mammary tumor system is a well known model to evaluate the potential antitumor efficiency of antiestrogenic–estrogenic substances. Evidence was reported indicating that tumors responding to these substances contain significant amounts of estrogen receptors. The biological characteristics of cyclofenil led us to evaluate its antitumor activity on this model. The binding affinities of the drug and of its deacetylated form (F6060; Fig. 1) for the tumor estrogen receptors were also analysed.

Mammary tumors were induced in female rats, aged 50 days, by a single i.v. injection of a lipid emulsion containing 5 mg DMBA. Tumor cytosol was prepared in 10 mM Tris–HCl buffer pH 7.5 containing 3 mM EDTA and 6 mM β-mercaptoethanol as previously described [5]. The ability of F6066 and F6060 to bind to the tumor cytosol estrogen receptors was tested by inhibition of the binding of ^{3}H-estradiol. This ability was compared with that of unlabeled estradiol. Cytosol fractions were incubated with a saturating concentration of ^{3}H-estradiol (6×10^{-9} M) (115 Ci/mmole; The Radiochemical Centre, Amersham, U.K.) in the absence or presence of increasing amounts of a drug or unlabeled estradiol (Sigma Co, St Louis, Mo). An inhibition curve was observed in the presence of each competitor (Fig. 2). Fifty per cent inhibition was achieved at the following concentrations: unlabeled estradiol, 7×10^{-9} M; F6060, 10^{-7} M and F6066, 5×10^{-7} M. These values suggest binding affinities roughly 14 and 70 times lower than estradiol for F6060 and F6066 respectively. It is of interest that the affinity of the deacetylated form of the drug (F6060) was slightly higher, which suggests that (a) phenolic group(s) of the molecule participate(s) in its binding to the receptors as in the case of estradiol. Exchange assays [6] showed that bound drugs were displaced from the receptors by ^{3}H-estradiol indicating a reversible binding.

Table 1. Effect of F6066 on growth of established tumors

B	250	407	(+157)	495 (+245)	529	(+279)
C	228	292	(+64)	268 (+40)	265	(+37)

*Increase of tumor surface.
†Statistical significance: A vs control: ns, B vs control: ns, C vs control: $P<0.02$ (Wilcoxon test on the paired differences).

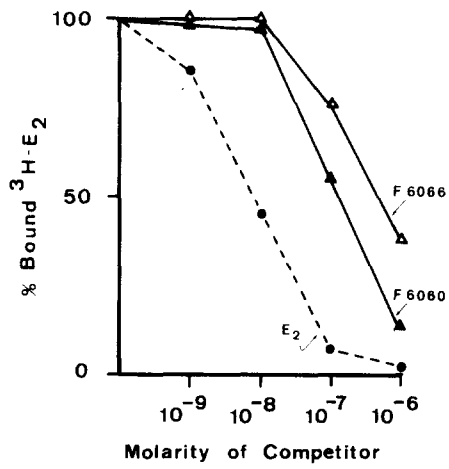

Fig. 2. Inhibition of the binding of ^{3}H-estradiol (^{3}H-E_2) to DMBA-induced rat mammary tumor cytosol by unlabeled competitors: estradiol (E_2), F6066 or F6060. Aliquots of 100 µl of cytosol were incubated overnight at 4°C with an equal volume of buffer containing ^{3}H-E_2 at the final concentration of 6×10^{-9} M in presence or absence of increasing amounts of an unlabeled competitor. Bound ^{3}H-E_2 was then measured after extraction of unspecifically bound components by the dextran-coated charcoal method [7].

The effect of F6066 on the growth of established tumors was analyzed. Tumor-bearing rats were matched into "blocks" according to the number and sizes of the tumors, the latter being expressed as "surface", that is the product of two perpendicular diameters as measured by means of a caliper. The animals of each block were randomized into 4 groups of 12 rats each and were subjected to daily subcutaneous injection for 6 days per week during 6 weeks. Groups A, B and C received respectively 0.1, 1 and 10 mg/kg F6066 suspended in 0.1 ml sesame oil; the control group received sesame oil only. The rats were weighed weekly and their tumor surface was measured every two weeks. Treatment effects were estimated by the differences of total tumor surface (sum of individual tumor surface) between matched rats. Results are reported in Table 1. After 2, 4 and 6 weeks of administration at each dose, F6066 induced a reduction of tumor growth as compared to the controls. At the end of experiment the reduction observed at 10 mg/kg was significant ($P<0.02$; Wilcoxon test on the paired differences) whereas the lower doses were not. A small decrease in gain of body weight was recorded (per cent weight gain in, controls: +6, group A: +4, group B: +2, group C: −3). This difference was non-significant ($P>0.1$, Mann–Whitney U test) thus suggesting that the reduction of tumor growth was not due to a systemic toxic effect of the drug and resultant weight loss.

Vaginal smears, taken daily, showed irregular estrus cycles in controls and treated rats. At the end of the experiment the animals were sacrificed. A reduction of the weight of the ovaries was recorded (percentage of weight loss as compared to the controls; group A: −15, group B: −20, group C: −40). There was a similar reduction in uterine weight (percentage loss as compared to the controls, group A: −9, group B: −14, group C: −21). Histological examination of the ovaries from the rats receiving 10 mg/kg revealed the presence of numerous atretic follicles; no corpora lutea were found. In contrast, controls showed a normal ovarian histology. All these data are consistent with the reported weak antiestrogenic activity of F6066 [1, 2].

The present data demonstrate that cyclofenil is an effective antagonist of the growth of the DMBA-induced mammary tumors of the rat. In contrast to all presently tested antiestrogens, the drug produces its antitumor effect without detectable modification of the estrus cycle; all other antiestrogens were reported to induce a permanent diestrus. These results indicate that a strong antiestrogenic activity is not required to interfere with tumor growth and suggest, thereby that weak antiestrogens might be useful for the treatment of human breast cancer. It may be speculated however that a strong enough binding affinity for estrogen receptors might be a prerequisite for antitumor activity.

Acknowledgements—We wish to thank the Ferrosan Co. (Malmö, Sweden) for the gift of F6066 and F6060 as well as for a financial support. We also thank Dr. P. E. Schurr (the Upjohn Co, Kalamazoo, Mich.) for the preparation of DMBA Emulsion. Finally, the technical assistance of Mrs. G. Wijnands was highly appreciated.

Announcement

N.C.I.–E.O.R.T.C. SYMPOSIUM ON NEW DRUGS IN CANCER THERAPY

To be held on 7–8 September, 1978 at the Institut Jules Bordet, Brussels.

Chairmen: F. MUGGIA and H. J. TAGNON

September 7: E.O.R.T.C. and N.C.I. Investigational Drugs
September 8: Adriamycin and Anthracycline Derivatives

A small number of free communcations will be integrated in the program. Abstracts must be sent to Dr. M. Rozencweig, Division of Cancer Treatment, National Cancer Institute, Bldg 37, Rm 6A17, Bethesda, Maryland 20014. U.S.A. *before* 15 *July*, 1978.

Among the participants:

P. ALBERTO (Geneva), N. BACHUR (Baltimore), L. BAKER (Detroit), R. BENJAMIN (Houston), G. BONADONNA (Milan), S. K. CARTER (Palo Alto), M. CASAZZA (Milan), H. CORTES-FUNES (Madrid), J. DANIELS (Stanford), H. DAVIS (Madison), S. GARATTINI (Milan), M. GHIONE (Milan), A GOLDIN (Bethesda), H. HANSEN (Copenhagen), D HENRY (Research Triangle Park), Y. KENIS (Brussels), G. MATHÉ (Paris), F. MUGGIA (Bethesda), C. MYERS (Bethesda), C. PRAGA (Milan), M. ROZENCWEIG (Bethesda), M. STAQUET (Brussels), H. TAGNON (Brussels), A. TROUET (Brussels), D. VON HOFF (Bethesda).

Number of participants will be limited to 200.

For details and registration, write to Dr. M. Staquet, E.O.R.T.C. Data Center, Institut Jules Bordet, rue Héger-Bordet 1, 1000 Bruxelles, Belgium. (Phone: 538.57.90—Telex: 22773).

The symposium will be held 2, rue Evers (1st floor), 1000 Bruxelles. Registration fee: 3000 Belgian francs.

THE NETHERLANDS CANCER INSTITUTE (ANTONI VAN LEEUWENHOEK-HUIS) INTERNATIONAL CONFERENCE ON "ENVIRONMENTAL CARCINOGENESIS: OCCURRENCE. RISK EVALUATION AND MECHANISMS OF ACTION OF CHEMICAL CARCINOGENS"

On the occasion of the opening of the new Research Laboratory of the Netherlands Cancer Institute an international congress will be held 7–11 May, 1979, at the RAI-Congress Centre in Amsterdam.

Some 20 invited speakers will discuss the epidemiology of cancer, occurrence of carcinogens and mechanisms of their action, transplacental carcinogenesis; Host factors as carcinogen metabolism and DNA-repair; Modifying factors: dietary components, enzyme inducers, promoters, anticarcinogens; Evaluation of animal experiments and risk assessment of low doses of carcinogen in large populations; Evaluation of short-term assays for identifying chemical carcinogens.

At the end of each daily session a period of one hour is reserved for open discussion.

For further information, write: Dr. E. Kriek, secretary Organizing Committee, The Netherlands Cancer Institute (Antoni Van Leeuwenhoek-Huis) Plesmanlaan 121, Amsterdam-Slotervaart, The Netherlands.

Abstract—*The biosynthesis of pyruvate kinase isozymes has been studied in rat liver during the administration of carcinogen 2-acetylaminofluorene. Transition from a predominance of isozyme L to K was observed during hepatocarcinogenesis. Changes in isozymic pattern and specific activity of pyruvate kinase were observed before histological alterations typical for cancer formation in rat liver could be detected. The dedifferentiation during hepatocarcinogenesis results in switching on the gene for isozyme K and switching off the gene for isozyme L. Within a single liver cell, however, both genes are not functioning simultaneously. Metabolic consequences of the observed changes are discussed.*

INTRODUCTION

THREE distinct isozymes of pyruvate kinase (PK) named L, K and M have been detected in mammalian tissues. Each of these isozymes consists of four identical or almost identical polypeptide chains [1, 2]. It has been demonstrated in several laboratories that isozymes of pyruvate kinase differ in electrophoretic mobility [3–7], isoelectric point [1, 8, 9], kinetics [10–14] and immunological properties [15, 16]. The presence of both divalent and monovalent cations is necessary for pyruvate kinase activity [17, 18].

L type isozyme of PK has been found in hepatocytes, intestine, kidney [19–21] and it probably also occurs in erythrocytes [6, 22]. This isozyme plays an important role in regulation of glycolysis and gluconeogenesis [5, 23, 24]. L type PK displays cooperative kinetics with respect to phosphoenolpyruvate [10, 14, 25] and its activity is inhibited by various metabolites: ATP, L-alanine, L-proline, L-valine and L-phenylalanine [13, 15, 26, 27]. Fructose-1, 6-bisphosphate changes its kinetics from sigmoidal to hyperbolic [22, 28, 29]. It has been suggested that isozyme L is present in two interconvertible forms which differ in their kinetic characteristics [22, 30]. Recently, L type of PK has been separated into three activity fractions by means of isoelectrofocusing [8]. activity of the L-type isozyme is known to change under dietary and hormonal conditions [3, 13, 31–38].

Isozyme K PK is widely distributed in most adult tissues and is found in all fetal tissues [3, 19, 28, 39]. Like the L isozyme, K type PK exhibits cooperative kinetics with respect to phosphoenolpyruvate [40, 41] and is affected by many allosteric modifiers. Fructose-1, 6-bisphosphate causes the kinetics to shift from sigmoidal to hyperbolic [41]. L-Phenylalanine, L-isoleucine, L-alanine, L-proline and L-tryptophan are also inhibitors of K type PK [27]. The inhibition by L-phenylalanine, L-isoleucine and L-tryptophan is much stronger in the case of K isozyme than with L-type PK [15, 27]. This isozyme appears to exist in two inconvertible forms which are kinetically distinguishable [41].

Isozyme M is found in skeletal muscles, mammalian heart and brain [6, 17, 42–44]. It displays Michaelis–Menten kinetics with respect to phosphoenolpyruvate and is unaffected by fructose-1, 6-bisphosphate [13].

The abbreviations used in this paper are: PK—pyruvate kinase (ATP: pyruvate phophotransferase, EC 2.7.1.40): AAF—2 acetylaminofluorene (identical with *N*-2-fluorenyl-acetamide).

It has been shown that K and L isozymes are products of two different genes [45]. The molecular differences between M type and the other isozymes suggest strongly that the M isozyme is also the product of a third independent gene. In fetal liver in early stages of development only K isozyme is present [46–47]. In later stages of ontogeny isozyme M appears [21]. These conclusions are, however, controversial and the problem has been poorly investigated. On the day of birth, isozymes K, L and probably M are observed [21, 46]. In hepatocytes of regenerating liver the biosynthesis of isozyme K is highly increased [20]. However, normal isozyme electrophoretic pattern appears after completion of the regenerating process [20].

Neoplastic transformation changes the isozymic pattern of pyruvate kinase. In well differentiated, slowly-growing hepatomas, isozymes K and L have been observed [46, 48, 49]. The activity of isozyme K in this system was remarkably increased in comparison with the levels in normal liver. In several cases electrophoretic resolution revealed three bands of pyruvate kinase [46, 50]. Although changes in the isozymic pattern of PK were the subject of several reports relatively little is known about the behavior of pyruvate kinase isozymes during the process of hepatocarcinogenesis.

The aim of the present investigation was to examine the isozymic pattern of pyruvate kinase during the process of hepatocarcinogenesis induced by 2-acetylaminofluorene (AAF) and to compare these findings with the histological alteration of liver. Because isozymes have been shown to be excellent gene markers it seems possible to elucidate the functioning of pyruvate kinase genes.

As the carcinogen we used 2-acetylaminofluorene because the effects of this compound constitute a useful model for the study of biochemical changes during neoplastic transformation of liver in rats. The lesions develop slowly over a period of months and can be followed from hyperplastic areas to hyperplastic nodules and later to hepatomas.

MATERIALS AND METHODS

Chemicals

Phosphoenolpyruvate (tricyclohexylammonium salt) and NADH were purchased from Sigma (St. Louis, MO, USA), fructose-1, 6-bisphosphate was obtained from Koch-Light Labs. (Colnbrook, Bucks, England). ADP was supplied by the School of Medicine in Łódź (Poland), lactic dehydrogenase was purchased from Boehringer (Ingelheim, W.-Germany) and L-phenylalanine was from Fluka (Switzerland). 2-Acetylaminofluorene was synthetized by Dr. R. Tyka and kindly supplied by the Technical University of Wrocław.

Animals

One hundred and thirty male albino rats (Wistar strain) weighing 150–200 g, of 12 weeks of age, were divided in two groups and fed as described previously [51]. The first group (30 animals) was fed on bread crumbs and water *ad libitum* with carrots one day per week. The animals of the second group (100 rats) were maintained on the same diet supplemented with 11.25 mg AAF per rat daily. The rats of both groups were killed 2, 3, 4, 5, 6, 7, 8, 9 and $9\frac{1}{2}$ months after the diet began. The animals were decapitated between 8 and 9 a.m. After exsanguination, livers were quickly removed, washed with cold 0.01 M Tris–Cl–1mM EDTA buffer, pH 7.5. Each liver was sectioned into small pieces and these were randomly selected for histological examination and biochemical analysis. At the end of experiment nine animals with liver tumors were left. Homogenization of liver tissues was carried out with a motor-driven homogenizer with teflon pestle in 1:0.5 w/v of 0.01 M Tris–Cl-1 mM EDTA buffer, pH 7.5. The homogenates were centrifuged at 75,000 × *g* for 1 hr at 3°C. The clear supernatants were used for assay of PK-activity and electrophoresis.

Cellulose acetate electrophoresis

Zone electrophoresis on cellulose polyacetate strips (Sepraphore III, Gelman Instr., Co., Ann Arbor, Michigan, USA) was performed following the method described by Susor and Rutter [4]. Pyruvate kinase isozymes were revealed by the procedure described by the above authors [4].

Enzyme assay

Activity of pyruvate kinase was determined spectrophotometrically following the decrease of absorbance of NADH at 340 nm by the method of Bücher and Pfleiderer [42], as modified recently by Osterman and Fritz [3]. The reaction was started by the addition of 1 µl of liver extract to a 3-ml cuvette containing the following chemicals (final concentration): 50 mM Tris–Cl, pH 7.5, 1 mM EDTA, 75 mM KCl, 8 mM $MgSO_4$, 2 mM phosphoenolpyruvate, 2 mM ADP, 0.15 mM NADH and 1 U/ml of lactic dehydrogenase. The activity measurements of PK in the presence of L-phenylalanine were carried out in the same way but in the presence of 0.3 or 2 mM phosphoenolpyruvate and 0.6 or 2 mM of L-phenylalanine,

respectively. All assays were performed at 25°C using either an Acta M VI (Beckman Instr., Fullerton, USA) or Specord UV-VIS (Zeiss-Jena, E. Germany) spectrophotometers.

RESULTS

Zone electrophoresis of pyruvate kinase in liver extracts is shown in Fig. 1. Corresponding photomicrographs of rat liver sections obtained during hepatocarcinogenesis are presented in Fig. 2. The PK isozyme pattern of rats from the control group remained unchanged. The activity which corresponds to the isozyme L is very strong and only a trace of activity of isozyme K could be detected (Fig. 1A). The specific activity of PK was in the range 0.84–1.60 U/mg protein (Table 1).

In early stages of hepatocarcinogenesis, after 2–4 months of AAF administration when only slight pleomorphism of hepatocytes was found (Fig. 2B) the specific activity of PK was slightly decreased (Table 1). However, electrophoretic examination revealed an increase of activity of isozyme K (Fig. 1B).

After 5–7 months of administration of AAF, when microscopic examination revealed cirrhosis of the liver, focal dilatation and proliferation of bile ducts (Fig. 2C), marked decrease of specific PK activity was observed (Table 1). In the electrophoretic profile the activity of isozyme L was diminished in comparison to the control group (Fig. 1C).

After feeding AAF for 8–9 months the rats livers contained two types of tumors: hepatoma and cholangiocarcinoma (Fig. 2D and E). Biochemical examinations were performed in six hepatomas and three cholangiocarcinomas. The specific activities of PK in extracts of the three cholangiocarcinomas lie in the range 0.50–0.78 U/mg protein (Table 1). Electrophoresis demonstrated three activity bands of PK (Fig. 1D). Two of them corresponded to isozymes L and K, the third very faint band had the same mobility as isozyme M. This was proved by performing electrophoresis with muscle extract.

The activity of PK in hepatomas are summarized in Table 1. In two tumors the activities were within the range of control values. In two cases the specific activities were approximately 40% of the control values; in two hepatomas the PK activities per mg of protein were very low. The electrophoretic profile of three hepatomas displayed the presence of two strong activity bands of both isozymes K and L (Fig. 1E). In two liver tumors electrophoresis demonstrated three activity bands L, K and probably M (Fig. 1G). In one hepatoma only isozyme K was present (Fig. 1F).

To support the assumption that the activity band with cathodic mobility observed in hepatomas is derived from isozyme K, measurements of PK activity were performed in the presence of L-phenylalanine, a strong inhibitor of K isozyme. The results are given in Table 2. The PK activity in normal liver was only slightly diminished in contrast to the hepatoma (Fig. 1F), where more than 90% of activity was inhibited.

DISCUSSION

The above data give the evidence for an increase of biosynthesis of isozyme K during hepatocarcinogenesis caused by AAF administration. It is interesting that after 2–4 months of drug administration when only pleomorphism of hepatocytes was observed, the increased biosynthesis of K isozyme takes place.

In the precancerous state, i.e. proliferation of hepatocytes and bile ducts with concomitant cirrhosis, further increase of activity of isozyme K is observed. Simultaneously the specific activity of pyruvate kinase decreased to 60% of the control values. These results are similar to the data reported by Walker and Potter [46], who induced hepatomas by 3'-methyl-4-diaminoazobenzene. The above authors observed elevated activity of isozyme K and decreased total PK activity. As in our experiment these investigators took pieces of cancerous liver for biochemical and histological examinations. However, Yanagi *et al.* [52], who also used AAF as a carcinogenic agent and isolated hyperplastic nodules, observed a twofold increase of K-type PK but without change in total PK activity. In non-nodular areas neither changes in isozymic pattern nor in total activity were found [52]. Perhaps these different results were caused also by different ways of administration of carcinogens.

AAF besides its carcinogenic properties is also toxic [53]. Cirrhosis, observed in the precancerous state is caused by its toxic properties. The question is raised whether cirrhosis itself caused changes in isozymic pattern of PK. However, we have not observed any alteration in the isozyme pattern of PK after prolonged administration of carbon tetrachloride when rat liver cirrhosis is evident [54]. Thus changes in the isozymic pattern seem to be characteristic for neoplastic transformation.

For three cholangiocarcinomas specific PK activity was about 40% lower than control values. For the same tumour Yanagi *et al.* [52], obtained very high total PK activity, similar to the poorly differentiated hepatomas. Our results

L-Phenylalanine Phosphoenolpyruvate	=0.6 mM =0.63 mM	82.6%	10.0%

*Concentrations of all remaining reagent used for pyruvate kinase assay are given in "Materials and Methods" section.

†Pyruvate kinase activity remaining under the conditions of analysis expressed as percentage of the activity of identical sample but assayed without L-phenylalanine.

of PK activity measurements and electrophoretic pattern for six well-differentiated and slowly growing hepatomas are in agreement with the data reported for well differentiated Morris hepatomas [48, 52, 55].

The electrophoretic profile of five tumors revealed the presence of three activity bands. Two of them corresponded to isozyme K and L while the third activity band can be ascribed to either isozyme M or to a particular hybrid of isozymes L and K, since one of the L–K hybrid set should have a mobility similar to isozyme M. The presence of this molecular form of PK in hepatomas was also observed by Walker and Potter [46] as well as Tanaka *et al.* [50]. *In vitro* the L–K hybrid set was obtained by Dyson and Cardenas [56]. Susor and Rutter [57] and Susor *et al.* [58], electrophoretically resolved 5-membered set of PK-activity bands in extracts of 18-day fetal liver and in the livers of newborn rats. They ascribed the observed electrophoretic pattern to the 5-membered L–K hybrid set. However, Criss [9] using electrofocusing technique found in well differentiated hepatomas four molecular forms of PK one of which has an isoelectric point identical to isozyme M. During hybridization *in vitro* no preferential formations of only one hybrid was observed [56, 57]. Thus, the hypothesis that the third molecular form of PK is the isozyme M seems to be rationalized. We want to stress that the electrophoretic technique on polyacetate strips is sufficiently sensitive to resolve PK hybrids, because in control experiments we revealed a 5-membered hybrid set in rat jejunum extracts, according to Osterman and Fritz [3].

The above results may lead to the following conclusions concerning the expression of PK genes in hepatocytes during hepatocarcinogenesis. In adult precancerous liver as well as in liver tumors only L and K isozymes were detected. The absence of L–K hybrids suggests that in a typical hepatocyte two PK genes are not functioning at the same time. Thus the synthesis of L isozyme stops when the synthesis of K isozyme begins in the same hepatocyte. Garnett *et al.* [20] reported that the L and K genes behave in a similar manner in regenerating rat liver. The expression of pyruvate kinase genes is, therefore "alternate" and similar to such enzymes as: phosphofructokinase [50, 59], esterase [60], hexokinase (Weinhouse *et al.*, 1972), glycogen phosphorylase [61], adenylate kinase [55] and branched chain amino acid transaminase [62]. However, the functioning of PK genes during neoplastic transformation is quite different in comparison with aldolase for which simultaneous expression of A and B genes in the same hepatocyte was observed [63].

During the hepatocarcinogenesis the switching on of the gene for K isozyme of PK is associated with switching off the gene for L isozyme. In some hepatomas presumably the third PK gene is switched on. Therefore, the isozymic pattern is similar to that of fetal liver. This is consistent with the hypothesis of dedifferentiation during neoplastic transformation [64–66].

The biochemical changes in gene expression of PK are characteristic for carcinogenesis and even in early stages of oncogeny can be distinguished from cirrhosis. The changes are of great importance to liver metabolism. The PK is a rate-limiting glycolytic enzyme. In gluconeogenic tissues (e.g. liver) the predominant form of PK is L isozyme, which is especially sensitive to changes in concentration of various metabolites. The compounds which are utilized for glucose synthesis (e.g. L-alanine, free fatty

acids, acetyl-CoA) inhibit the activity of isozyme L [23, 67, 68]. The activity of isozyme K is not so precisely controlled [32, 33, 69]. Therefore, the elevated biosynthesis of isozyme K in rat liver promote glycolysis which reflects the growing demand in this tissue for energy and carbon sources for the new tumor-cell formation.

Cell Cycle Stage-Dependent Induction of G_2 Phase Arrest by Different Antitumor Agents*

BARTHEL BARLOGIE† and BENJAMIN DREWINKO‡

Departments of Developmental Therapeutics† and Laboratory of Medicine‡ at the University of Texas System Cancer Center, M. D. Anderson Hospital and Tumor Institute, 6723 Bertner, Houston, Texas 77030, U.S.A.

Abstract—*A variety of chemically unrelated antitumour compounds has been shown to block cell cycle progression in G_2 phase. Using thymidine synchronized human lymphoid cells, we have investigated the cycle stage dependency of this kinetic response. For anthracycline antibiotics (adriamycin, adriamycin–DNA complex and rubidazone) and the epipodophyllotoxin derivative VP16, cells in S phase were most susceptible to the induction of G_2 block in the immediate life span. Alkylating agents (melphalan, peptichemio and Yoshi 864) displayed a peculiar sensitivity pattern: G_1 cells were effectively delayed in the subsequent G_2 phase, whereas this kinetic event was transmitted to the daughter cell population when treatment was commenced in G_2 phase. The time of manifestation of G_2 block after incubation in S phase varied among the three alkylating agents and was a function of the position in S phase. In general, there was no correlation between phase sensitivity for induction of G_2 block and lethal cell damage.*

INTRODUCTION

A VARIETY of physical and chemical agents have been reported to interfere with cycle progression in the G_2 phase of mammalian cells [1–11]. In fact, Tobey recently showed that some of these agents can arrest cells at distinct stages of G_2 phase [12]. In previous publications, we demonstrated that the extent and duration of antitumor drug-induced G_2 block are a function of the concentration and time exposure to the agent [13–17]. In this report, we provide evidence that the position of cells in the cell cycle at the time of drug treatment is another determinant for onset, degree and duration of the G_2 arrest.

MATERIALS AND METHODS

Our experiments were carried out on a human lymphoma cell line (T_1 cells), which was derived from a patient with lymphocytic lymphoma [18]. T_1 cells are grown as monolayer cultures in Ham's F10 medium supplemented with 20% fetal calf serum, glutamine, vitamins and antibiotics, in a 5% CO_2 humidified atmosphere at 37°C. Employing the pulse labeled mitoses technique, the recently determined cell cycle time was 31 hr with $T_{G_1} = 15$ hr, $T_S = 10$ hr, $T_{G_2} = 6$ hr [16]. The influence of cell age at the time of drug application on magnitude and duration of subsequent G_2 block was analyzed on synchronized cultures. Previous studies had demonstrated that excess thymidine treatment yields a high degree of cell synchrony maintained over the period of at least 1 cell cycle [19, 20]. At selected intervals after release of the thymidine block, T_1 cells were treated for 1 hr with the antitumor agent under investigation at a concentration that had proven effective in inducing G_2 phase arrest after exposure of asynchronous cells. Cycle progression was monitored by serial measurements of cellular DNA content after fluorochromation with mithramycin [21] in a Phywe ICP 11 pulse cytophotometer [20, 22]. DNA histograms were obtained at 6–12 hr intervals for a total period of at least 6 days (i.e. 4–5 times the generation time of exponentially growing cultures). Thus, the time of onset, degree and duration of delay in the transit through G_2 phase could be determined as a function of cycle stage where the treatment was conducted.

Three anthracyclines, 3 alkylating agents, and

Accepted 18 November 1977.

Table 1.

Drug	Drug abbreviation	Concentration μg/ml
Anthracycline antibiotics		
Adriamycin; hydroxydaunorubicin	ADR	0.5
Adriamycin–DNA complex (herring sperm-DNA:ADR; 20:1)	ADR–DNA	0.5 (ADR)
Rubidazone; benzoylhydrazone daunorubicin	RUB	1.0
Alkylating agents		
L-Phenylalanine mustard	L-PAM	2.5
Peptichemio; multipeptide complex of *m*-(di-(2-chloroethyl)-amino) L-Phenylalanine	PEP	5.0
Yoshi 864; 3,3′-iminodi-1-propanol, dimethanesulfonate (ester), hydrochloride	Yoshi	100
VP-16-213: 4′demethylepipodophyllotoxin 9-(4,6-0-ethylidene-β-D-glucopyranoside)	VP-16	5.0 10.0

the epipodophyllotoxin derivate VP16, were investigated at the concentrations indicated in Table 1. For the concentrations and incubation times used in this analysis, there was no significant interference with the transverse through stages of the cycle other than G_2 phase [11, 13–17].

All drug solutions were prepared with growth medium immediately prior to each experiment. ADR (in vials of 10 mg) was obtained from Farmitalia, Milan, Italy. ADR–DNA complex was prepared as follows: herring sperm DNA (highly polymerized, type VII; Sigma Chemical Company, St. Louis, MO), at a concentration of 2.34 mg/ml in 0.9% NaCl solution, was kindly provided by Dr. A. Trouet, Laboratoire de Chimie Physiologique, Université de Louvain, Louvain, Belgium. The DNA solution was autoclaved for 15 min at 120°C and cooled slowly. One-tenth of a milliliter of a 10 mg/ml aqueous solution of ADR was dissolved in 5 ml of DNA solution. Further dilution was performed with 0.9% NaCl solution and medium, respectively, for the appropriate concentration of ADR, i.e. 0.5 μg/ml. Thus, a 20:1 molar ratio of DNA mononucleotide to ADR was achieved [23]. RUB was supplied by the Societé des Usines Chimiques Rhône-Poulenc. VP16-213, manufactured by Sandoz Laboratories, Basel, Switzerland, was received in an organic solvent and further dilutions were made in growth medium. Yoshi 864 was supplied in 100 mg vials by Ben Venue Laboratories, Bedford, Ohio and reconstituted in 5 ml of distilled water. L-Phenylalanine mustard was obtained as Alkeran through Burroughs Wellcome Company, Research Triangle Park, N.C. One hundred milligrams of L-PAM was dissolved in 1 mg of Wellcome acid alcohol, and 9 ml of Wellcome diluent was added. Further dilutions were made with growth medium. PEP, a multipeptide complex of *m* - (di - (2 - chloroethyl) - amino) - L - phenylalanine was kindly provided by Professor A. De Barbieri, Istituto Sieroterapico Milanese S. Belfanti, Milan, Italy.

RESULTS

ADR irreversibly accumulated more than 70% of the cell population in G_2 phase, independent of cycle stage of administration (Fig. 1A). However, while drug exposure in S and G_2 phase elicited an immediate accumulation, treatment in G_1 phase yielded a progressive G_2 increment over a period of 4 days. This effect suggests that some cells treated before the onset of DNA synthesis can escape the blocking effect of ADR during their life span. However, their progeny will be blocked in the subsequent G_2 phase, thus contributing to the total accumulation in that stage. When ADR was administered complexed to DNA, a phase dependent sensitivity in G_2 arrest induction was observed (Fig. 1B); treatment of cells throughout S and in early G_2 phase elicited a largely irreversible G_2 block of 80–90%; in contrast, treatment in late G_2 and in G_1 phase caused a transient increment of cells in G_2 (20 and 40%, respectively). The degree and extent of the G_2 block following incubation with RUB was also a function of cell age; treatment of T_1 cells in early and mid S phase was most effective in interfering with the traverse through the subsequent G_2 phase (Fig. 1C).

Exposure of T_1 cells to three alkylating agents showed a novel feature of the kinetic response pattern; the time of manifestation of the delay in G_2, whether evident during the life span of the treated cells or within that of their immediate progeny, varied with cell age at the time of drug exposure (Fig. 2). Treatment of T_1 cells with L-PAM in G_1 phase effected a largely irreversible G_2 increment of 75% within the same life cycle (Fig. 2A). Drug incubation in S and G_2 phase did not interfere with cycle traverse to mitosis

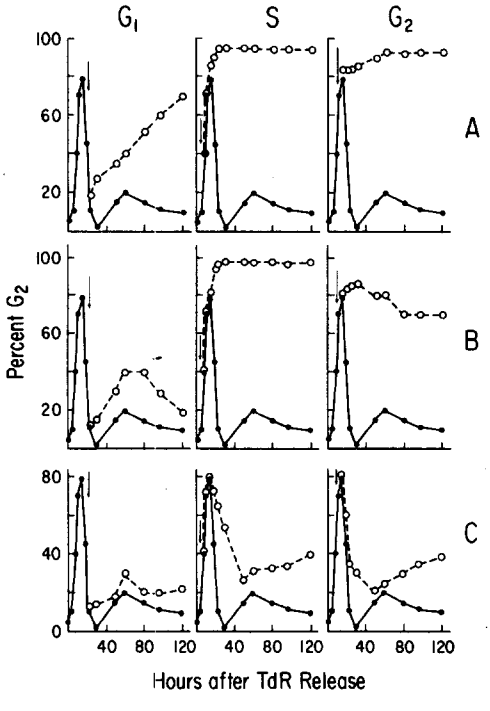

Fig. 1. Effect of anthracycline antibiotics on G_2 traverse of T_1 cells as a function of the stage of treatment (G_1, mid S and early G_2 phase). The solid lines (●—●) represent the proportion of control cells in G_2 phase, the dashed lines (○ - - - ○) connect values after 1 hr treatment in the 3 different phases. The time of treatment is indicated by the arrows. A: ADR 0.5 μg/ml, 1 hr. Induction of a high degree of irreversible G_2 accumulation of 70–95%, independent of the cycle stage of drug exposure. The time of G_2 maximum is delayed for cells treated in G_1 phase. B: ADR–DNA 0.5 μg/ml, 1 hr. Compared to ADR, initiation of treatment in G_1 phase causes only a transient G_2 accumulation of 40%. C: RUB 1.0 μg/ml, 1 hr. S phase cells are most effectively delayed during their traverse through G_2 phase, while exposure of cells in G_1 phase effects a minor increase of the G_2 compartment.

and the subsequent progression through G_1 and S phase of the progeny cells; yet, a significant block was noted in the consecutive G_2 phase. Thus, in all circumstances, DNA synthesis in drug free medium preceded the induction of G_2 block by L-PAM. PEP mimicked very closely the kinetic effects of L-PAM in asynchronous cultures; for a given drug concentration, similar degrees of G_2 accumulations were observed. Yet, notable differences were noted on synchronized cells. Cells treated with PEP in both G_1 and early and mid S phase were effectively delayed upon their arrival in the immediate G_2 phase (Fig. 2B). Drug exposure of cells in late S and G_2 phase transmitted this perturbation effect to the daughter cells. For Yoshi 864 (Fig. 2C), similar, yet more transient cycle stage dependent manifestations of G_2 delay were noted.

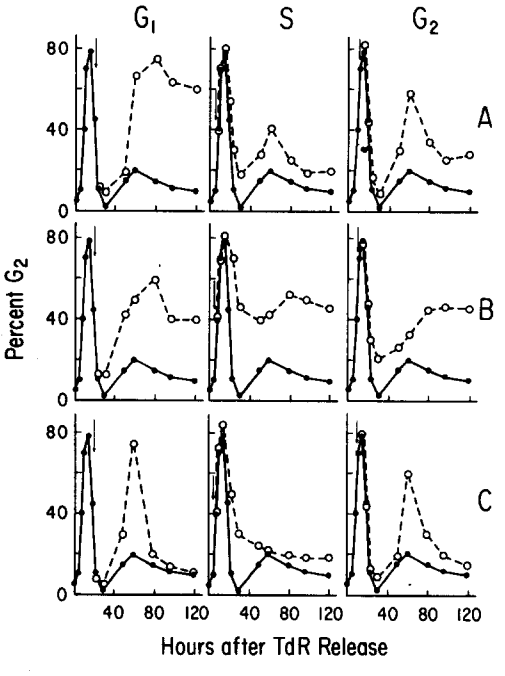

Fig. 2. Effect of alkylating agents on G_2 traverse of T_1 cells as a function of the stage of treatment (G_1, mid S and early G_2 phase). Symbols as in Fig. 1. The time of treatment is indicated by the arrows. A: L-PAM 2.5 μg/ml, 1 hr. Induction of marked accumulation in the immediate G_2 phase following treatment of cells in G_1. Exposure of cells in S and G_2 phase does not impair the traverse through the immediate G_2 phase nor the progression through G_1 and S of the progeny cells. G_2 transit of the daughter cells is prolonged, visualized by the G_2 increase at 60 hr. B: PEP 5.0 μg/ml, 1 hr. Treatment of cells in G_1 phase elicits a high degree of G_2 accumulation in the target cells. Following exposure of cells in early and mid S phase, a delay of G_2 transit is noted and 40–50% of the total population is irreversibly arrested in G_2 phase. Cells treated in late S and G_2 phase are blocked in the G_2 phase of the next life cycle. C: Yoshi 864 100 μg/ml, 1 hr. Manifestation of G_2 accumulation as a function of cycle stage is similar to that observed after treatment with PEP. However, peal values of G_2 increase are higher, and the effect is largely reversible.

Induction of G_2 accumulation by VP16 was also age dependent (Fig. 3); for the lower concentration of 5 μg/ml (Fig. 3A), sensitivity to the induction of a G_2 block decreased in the following order: early and mid S phase > later S phase > early G_2 > late G_2 > G_1 phase. Dose escalation to 10 μg/ml (Fig. 3B) partially abrogated the pronounced phase sensitivity: treatment in both early and late G_2 phase was equally effective as drug exposure in S phase to produce maximal G_2 accumulation.

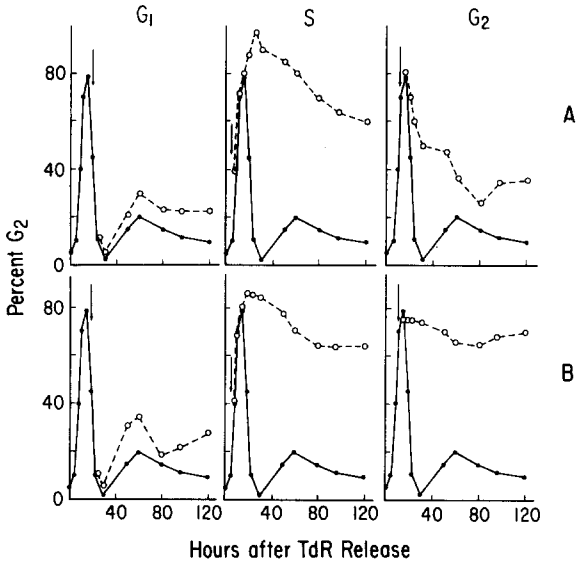

Fig. 3. Effect of VP16 (Symbols as in Fig. 1) on G_2 traverse of T_1 cells as a function of the stage of treatment (G_1, mid S and early G_2 phase). The time of treatment is indicated by the arrows. The cell age dependent induction of G_2 accumulation is modulated by drug concentration. A: 5 μg/ml, 1 hr. Treatment in mid S phase produces the highest degree and longest duration of G_2 accumulation. Following exposure of cells in early G_2 phase, about 30% of the total population experienced only a minor delay in G_2 phase; the residual population resumes cycle progression with a delay of 35 hr. Treatment of G_1 cells causes a small G_2 increment of 10%. B: 10 μg/ml, 1 hr. Dose escalation renders G_2 cells equally susceptible to the induction of G_2 block as S phase cells.

DISCUSSION

Our results indicate that a variety of chemically related and unrelated antitumor compounds delay cycle progression in G_2 phase. However, the phases of greatest sensitivity for induction of this shared kinetic response differ. For alkylating agents, the significance of cell age as a determinant for this kinetic perturbation was particularly striking, since it conditioned the time of manifestation of a G_2 block in the life span of the treated cells or in their immediate progeny.

Previous investigations using this cell line have shown that there is no correlation between the degree of reduction in survival and the extent or duration of G_2 block [15, 16, 17, 24, 25]. Likewise, there is a discrepancy between phase sensitivities for lethal damage and degree or duration of G_2 accumulation [26]. Only for L-PAM and Yoshi 864, maximal cell kill resulted from treatment in those phases where a G_2 block was induced in the same life cycle. Thus, kinetic and lethal effects may not be related and caused by injuries to different target sites.

Our studies demonstrate that various antitumor agents elicit perturbation of normal traverse of mammalian cells through the cell cycle. Although this effect has a common endpoint, G_2 phase arrest, different drugs yield this result via different modes or pathways. This is attested by the variation in cell cycle stage where maximum effect can be elicited after brief treatment. The shared effect of G_2 phase arrest may be the end result of damage or inhibition of certain postulated division-specific enzymes [27], while cell cycle dependency of the various drugs may be the result of damage or inhibition of precursors of these specific enzymes. For VP16, we have demonstrated that the cell age dependency of G_2 phase arrest can be modulated by drug concentration. Thus, treatment with such drugs may provide a valuable probe for investigating the nature of the macromolecular mechanisms related to cell division.

Density-Dependent Mitosis in the Walker 256 Carcinoma and the Influence of Host Age on Growth

D. BELLAMY and S. M. HINSULL

Department of Zoology, University College, Cardiff CF1 1XL, U.K.

Abstract—*The Walker 256 carcinoma was tested for the density dependence of cell division that has been found in normal tissue. It was found that autoregulation did occur to some extent in the tumours growing in young hosts, but that, in old hosts, the mitotic pattern resembled that observed in normal tissues. The rates of tumour growth and overall cellular proliferation were also significantly lower in old compared with young hosts.*

INTRODUCTION

DESPITE early theories [1–3] that neoplasia is a result of uncontrolled mitotic regulation there is increasing evidence that a growth regulatory system persists in certain tumours. This work has been mainly concerned with the interaction between primary tumours and secondary tumour cell population, that arise elsewhere in the body, and has, therefore, centred around hypothetical systemic factors [4–7].

Where interest has concentrated on growth control within solid tumours, the aim has been to investigate the retardation of growth as the tumours increase in size. This growth retardation has been attributed to a relative inadequacy of local blood supply [8], competition for nutrition [8, 9], inhibitory tumour by-products [10] and immunological factors [11]. Relatively little attention has been paid to the possibility that the phenomenon is an expression of an autoregulatory system similar to that governing the size of mitotic cell populations in normal organs. It was the aim of the present work to test Walker carcinoma for the density dependence of cell division that has been found in normal thymus [12], and secondly to examine the role of the host in growth regulation.

MATERIALS AND METHODS

Animals

Twenty or 120 week old male rats of an inbred WAB substrain, were used throughout the following experiments. Tumour tissue was obtained from 20 week old donor rats bearing a solid, subcutaneous Walker 256 carcinoma. A 6 mg fragment of tumour tissue was inserted subcutaneously into the middorsal region. The animals were killed, by cervical dislocation, 3, 4, 6, 7, 8, 9 or 10 days later and the tumour tissue removed.

Colchicine administration

Mitosis was hindered at metaphase by intraperitoneal administration of 0.2 mg colchicine per 100 g body weight, 4 hr prior to death.

Histology

Tumour tissue was fixed in Bouin's fluid for 36 hr, dehydrated through graded alcohols and embedded in paraffin wax. Sections were cut at 5μm and stained with Mayer's haematoxylin.

Cell counts

The total cell fragment numbers in 200 microscope areas (180 μm dia) were counted and the number of mitotic figures scored. Necrotic areas were avoided and only obvious tumour cells counted. The actual whole cell numbers were obtained by application of the Floderus correction formula [13].

RESULTS

Figure 1 shows the growth of the tumours in 20 week- as compared with 120 week-old animals. It can be seen that during the initial stages, when the tumour is adapting to its new environment, little growth occurred and no difference in the tumour size was observed between the two age groups until

Accepted 25 November 1977.

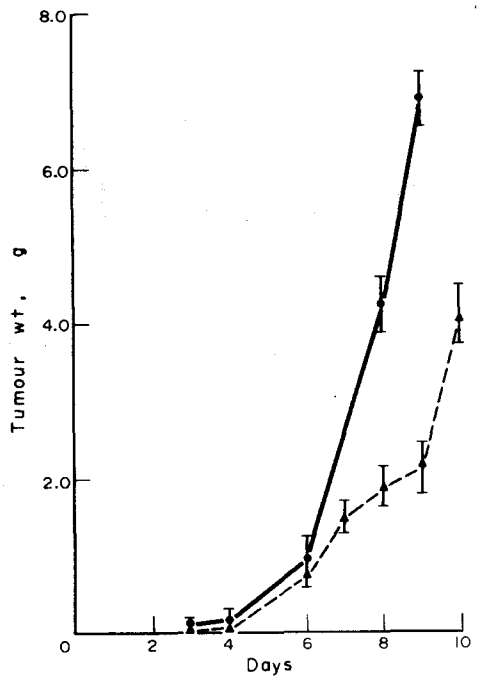

Fig. 1. The growth rate of subcutaneous Walker 256 carcinoma in young ● and old ▲ hosts, from 0 to 10 days after implantation. (Results expressed as mean ± S.E. tumour weight g n = 10.)

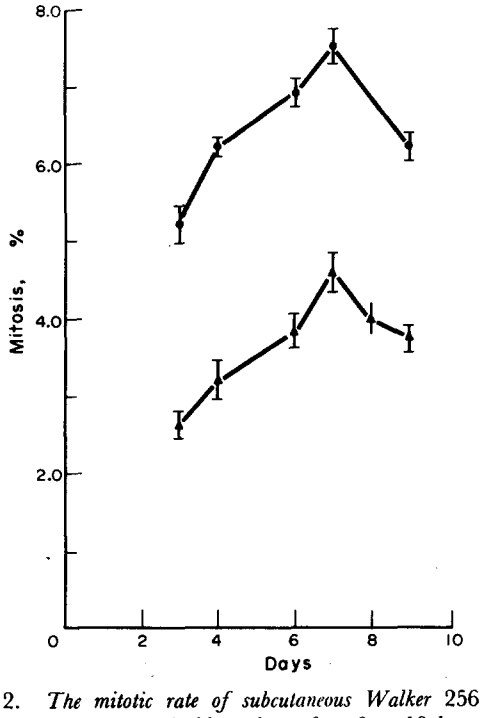

Fig. 2. The mitotic rate of subcutaneous Walker 256 carcinoma in young ● and old ▲ hosts from 0 to 10 days after implantation. (Results expressed as mean ± S.E.% mitosis.)

six days after transplantation. Thereafter, the growth rate of the tumours in the older group was significantly lower than that observed in 20 week-old animals.

The tumour growth curve in the younger hosts conformed to the Gompertzian model of Walker 256 tumour elaborated by Laird [14], but the tumour growth retardation in the older animals resulted in an almost complete deviation from this pattern.

In accordance with the growth pattern, overall cellular proliferation in the tumours in 120 week-old animals was significantly lower than that observed in 20 week-old hosts (Fig. 2), at each stage of the tumour growth. The magnitude of this difference in tumour cellular proliferation, between the two age groups, increased from 100% 3 days after transplantation to 300% 6 days post-operatively. It can be seen, therefore, that a significant difference in tumour cell proliferation between the two groups occurs before any difference in the tumour weight becomes apparent.

The pattern of overall tumour cell proliferation for the two groups was identical even though the absolute values were different. In both age groups, cellular proliferation increased up to a peak at 7 days after transplantation and thereafter declined. The rapid rate of cellular proliferation observed between 3 and 7 days after transplantation corresponded to the period of high growth rate when the newly formed cells outnumber those lost due to degeneration. Tumour growth continued despite the decline in mitotic rate after 7 days. However, at this time, the tumours in both groups of animals underwent extensive necrosis and liquefaction, and the hosts became moribund.

In order to investigate the distribution of the mitotic figures in the tumours the microscope areas counted were categorized according to the cell density. Category 1 consisted of between 1 and 10 cells per area, through to category 8 with between 71 and 80 cells per area. The distribution pattern of cell density categories during the phase of high proliferation, at 4 days and at the time when mitotic rate was declining at 9 days, is shown in Fig. 3. It can be seen that in both age groups, and at both stages after tranplantation, the cell density distribution patterns were essentially similar. The majority of areas counted fell into categories 5–7, with a slightly wider spread of cell density distribution at 4 days as compared with 9 days. When the rates of mitoses were related to the cell density categories, a definite pattern of mitotic cell distribution emerged (Figs. 4 and 5). During the establishment of the tumour and initiation of a high rate of cellular proliferation at 3 days, mitotic rate was distributed throughout the cell density categories. Following this stage few mitotic figures were observed below

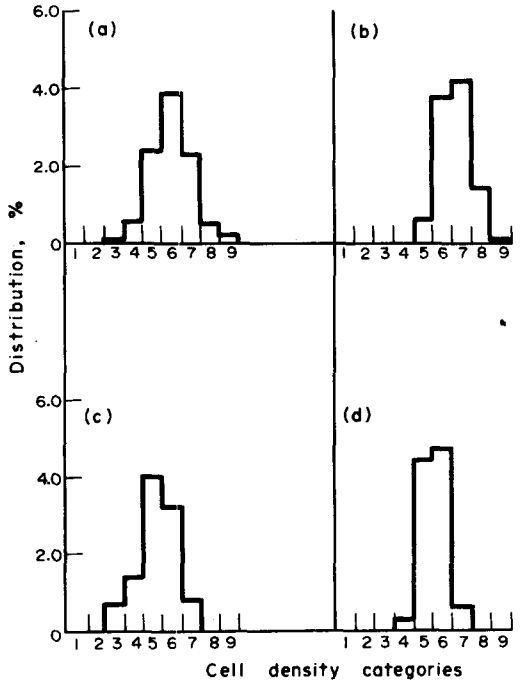

Fig. 3. The distribution of standard microscope areas counted in relation to cell density categories in: the old host A—4 days *and B*—9 days *after implantation and in the young host C*—4 days *and D*—9 days *after implantation (Category 1 consisted of 1–11 cells/area—category 9, 81–90 cells. Results expressed as % distribution of areas).*

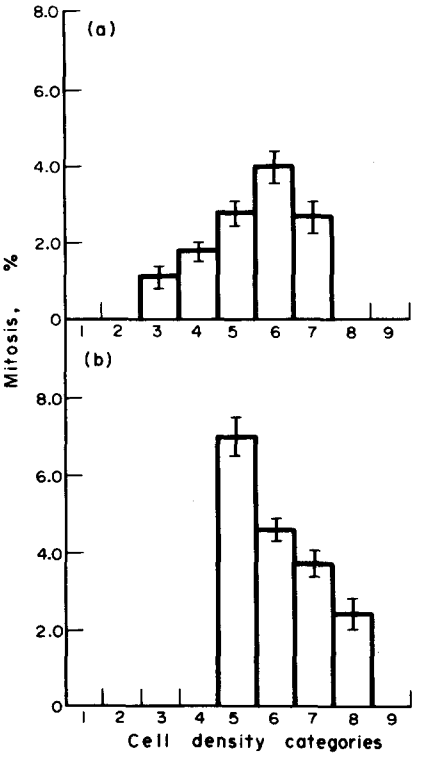

Fig. 5. The mitotic rate of tumour cells, in relation to cell density, in old hosts. A—3 days *and B*—7 days *after implantation. (Results expressed as mean ± S.E.% mitosis for each category.)*

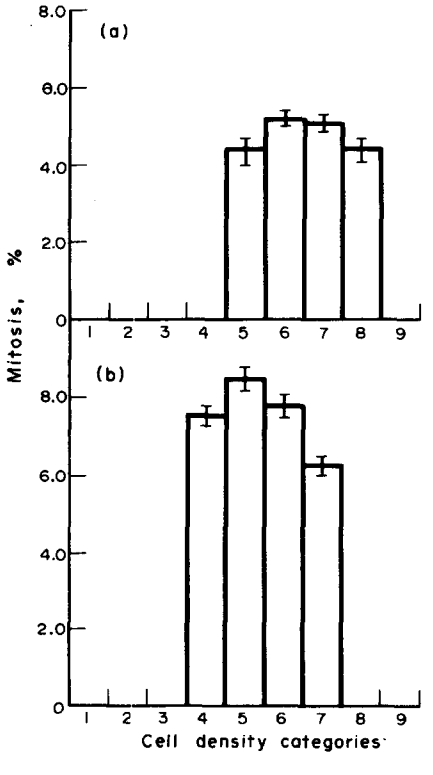

Fig. 4. The mitotic rate of tumour cells, in relation to cell density, in young hosts. A—3 days *and B*—7 days *after implantation. (Results expressed as mean ± S.E.% mitosis for each category.)*

category 5; beyond this category, mitotic rate declined with increasing cell density.

This concept of decreasing mitotic rate with increasing cell density was borne out in tumours established in old hosts and did not fluctuate appreciably with tumour development in either age group.

DISCUSSION

The finding that Walker 256 carcinoma grew to a greater size and had a higher rate of cellular proliferation, in young compared with old hosts is in agreement with the early work of Bischoff and Lang [14]. It has been suggested that two of the factors which may result in this difference are, partial failure of tumour blood supply and nutrition, or an alteration in the non-tumour specific antibody response in the older host [15, 16].

A number of investigators have suggested that neoplasms arise though failure of normal mitotic autoregulation. Wheldon [3] postulated that tumour cells are unable to produce inhibitors, supporting the earlier theory of Osgood [1] that early cell death in tumours results in the lack of differentiation of inhibitor secreting cells. However, subsequently it has been shown that tumour cells do produce

a factor which inhibits mitosis in the equivalent normal tissue type [17] although only low concentrations of this factor are found in malignant compared with normal tissue [18]. This may be a result of inactivation of the inhibitor in the malignant tissue [19]. It has been suggested that failure of malignant cells to respond to this factor is due to a change either in the cell-specific carrier or receptor, resulting in non-recognition of the cell by its tissue specific inhibitor [20].

A previous work has shown that, in the thymus, the mitotic rate increased with increasing cell density to a peak at the mean cell density, but thereafter declined [21]. Similarly, the present findings show that the highest rate of mitosis occurs at the mean cell density, but that at higher densities cellular proliferation is inhibited. This suggests that as cell density increases and extracellular space declines, an inhibitory influence is brought into play.

A model has been proposed to account for this pattern of mitosis assuming that there is a balance between internally produced inhibitors and stimulators of mitosis, related to cell density, which maintains a constant cell mass of proliferative tissue [12]. In particular, high cell densities are thought to be associated with high inhibitor concentrations. This idea fits the present data with regard to the decline in mitosis as the tumour mass ages; the mean mitotic index is reduced at the same time as the mean cell density is increased. The crucial factor in this model is the ratio of extracellular space to cells, in that the larger this ratio, the lower the inhibitor concentration. It may be that, in tumours, the excessive rate of death prevents the major part of the cell population attaining this limiting density, where the extracellular space is reduced sufficiently to increase the concentration of inhibitor to its optimal level. This results in the failure of mitotic autoregulation to stabilize at a fixed cell density. However, this failure of the autoregulatory system does not result in an indefinite growth of the tumour. Rather the tumour stabilizes at a limiting size in the later stages of its growth course, this limitation in tumour size possibly resulting from a failure in the blood supply and nutrients.

With regard to the age of the host it appears that mitosis is more dependent upon cell density in tumours of old hosts. Indeed, generally the mitotic pattern of tumours of old hosts is closer to that observed in normal tissues, implying a better regulation. The differences between the tumours must originate in the age difference between young and old hosts and this will be the basis for future work.

Weekly Administration of *Cis*-Diamminedichloroplatinum (II) without Hydration or Osmotic Diuresis*

VICTOR L. RANDOLPH and ROBERT E. WITTES

Solid Tumor Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York City, NY 10021, U.S.A.

Abstract—*In order to develop a regimen of* cis-*diamminedichloroplatinum* (II) (*DDP*) *suitable for outpatient use, we treated* 15 *patients with a once weekly dosage schedule of* 40 mg/m^2/week *without prehydration or the induction of an osmotic diuresis. Dose-limiting nephrotoxicity was seen in about* 50% *of the treated patients; myelosuppression was also achieved in a significant number and nausea and vomiting were severe enough to be considered dose limiting in* 4. *Objective antitumor responses were seen in* 6/13 *patients with known or suspected head and neck cancer. We conclude that the present regimen probably produces more renal damage than a comparable dose and schedule given with an osmotic diuresis* (2) *and significantly more subjective distress than intermittent high-dose DDP.*

INTRODUCTION

STUDIES [1] have shown that the nephrotoxicity of *cis*-diamminedichloroplatinum (II) (DDP) can be substantially blunted by a forced diuresis induced by saline and mannitol. This technique has permitted the relatively safe administration of high doses of DDP; unfortunately the procedure used at Memorial Hospital is also a costly one, requiring hospitalization and close supervision of the patient by the professional staff. Recently, Corder *et al.* [2] have developed a modification of this procedure which allows the weekly administration of lower doses of DDP to outpatients. These investigators have also shown a virtually complete absence of clinically significant nephrotoxicity, with myelosuppression the chief dose-limiting side effect.

The present study was undertaken to establish a regimen by which DDP could be used safely in our outpatient department and which might be amenable to combination therapy, once its safety had been established. Since no evidence at present indicated that a forced osmotic diuresis was necessary for protection of the kidneys when relatively modest weekly doses of DDP were used, we decided to begin without such a diuresis.

MATERIAL AND METHODS

Fifteen patients with far advanced, non-resectable carcinoma were selected for therapy. Criteria for selection included:

1. Histologically confirmed carcinoma
2. Measurable disease
3. Serum creatinine less than 1.2

Prior to therapy, all patients had a complete history and physical examination, complete blood count, twelve-channel screening profile, serum creatinine and chest X-ray. Additional tests were performed only if clinically indicated. Baseline creatinine clearance was measured in most patients.

The treatment program consisted of administration of DDP at a dose of 40 mg/m^2 once a week. On the day of, or the day prior to treatment, the serum creatinine, WBC, hemoglobin and platelet count were determined; treatment was given unless the serum creatinine was greater than 1.4 mg/dl, the WBC <4000, or the platelet count $<150{,}000$. In the event of any of the latter, the treatment was withheld until restitution of normal values. No special effort was made to hydrate the patient prior to drug administration or to encourage diuresis except for an occasional patient whose excessive nausea and vomiting from a previous DDP dose led to apparent dehydration (elevation of BUN with no elevation of creatinine). In that situation patients were given 500 cc D_5 1/2 NS just prior to receiving DDP. In all cases the DDP was given by intravenous infusion over

20–30 min. Response categories are as defined previously [3].

RESULTS

1. *Patient characteristics*

Table 1 shows the distribution of patients with respect to sex, age, primary site and prior therapy. All except for 1 patient had received previous radiotherapy and/or surgical ablative procedure. Only 4 patients had received prior chemotherapy, one with pyrazofurin and the remainder with at least 2 of the following drugs; cyclophosphamide, adriamycin, methotrexate and bleomycin.

Table 1. *Weekly* DDP: *patient characteristics*

Sex:	Male	10	
	Female	5	
Age:	Median	57	
	Mean	59	
	Range	47–76	
Primary Site:	Oro-or hypopharynx	11	
	Unknown primary	2	
	Lung	1	
	Skin appendage	1	
Histology:	Epidermoid	14	
	Adenocarcinoma	1	
Prior therapy:	None		1
	Major surgical ablation		10
	Radiotherapy		11
	Chemotherapy		
	None		11
	CAMB		1
	Polydrug other than CAMB		2
	Pyrazofurin		1

2. *Toxicity*

Of the 15 patients started on therapy with weekly DDP, 4 had therapy stopped after two doses because of rapid tumor progression. These 4 showed minor serum creatinine elevations to less than 1.4 mg/dl as well as minor nausea and vomiting, but no true dose-limiting side effects at the time the drug was stopped. Thus, in the course of therpay, 11 patients achieved some sort of dose-limiting toxicity, which we describe in more detail below.

a. *Nephrotoxicity.* Of the 15 patients who were entered on the study, the incidence of nephrotoxicity is shown in Table 2. In order for a patient to be evaluable for nephrotoxicity, he had to have received the specified number of weekly doses *and* returned one week after the last specified dose for a repeat serum creatinine. Thus, only 13 patients are listed as having received one dose because 2 of the 15 entered did not return on schedule one week after the first dose for a serum creatinine and a repeat dose of the drug. Of the 13 who are evaluable for the effects of a single dose, one developed dose-limiting nephrotoxicity the week immediately following administration of the dose. A second patient had treatment withheld following a cumulative dose of 80 mg/m^2. Two more patients became toxic after three consecutive doses, while another withstood four weekly doses before developing dose-limiting creatinine elevation. Thus, of 11 patients who received weekly DDP to some kind of dose-limiting side effect, 5 had their treatment limited by nephrotoxicity.

When the entire patient group is considered, including those whose weekly treatments were interrupted for dose-limiting side effects other than impaired renal function 10 patients received at least 3 doses of DDP at 40 mg/m^2/dose by day 22 of therapy. Of these, 5 developed at least one episode of dose-limiting nephrotoxicity by day 29. Of 6 patients who received 4 doses of DDP, all within a 29-day span, three patients developed dose-limiting nephrotoxicity. No patient received more than 160 mg/m^2 in consecutive weekly doses because of either nephrotoxicity, myelosuppression, nausea, or disease progression. Two patients did receive a total cumulative dose of 200 mg/m^2 in 6 and 8 weeks respectively and 1 of these developed nephrotoxicity as well. No patient developed a creatinine elevation >2 mg/dl.

b. *Myelosuppression.* Suppression of bone marrow function was also a frequent dose-

Table 2. *Nephrotoxicity from weekly doses*

Number of doses 40 mg/m^2/dose	Number of patients receiving specified number of weekly doses	Number of patients showing nephrotoxicity one week after the last weekly dose	Cumulative number showing nephrotoxicity
1	13	1	1
2	10	1	2
3	7	2	4
4	4	1	5

limiting side effect. As seen in Table 3, 7 of 14 evaluable patients had WBC nadirs below 4000. Five of these 7 patients also had platelet nadirs below 150,000. Only those patients receiving a cumulative dose of DDP of 120 mg/m^2 or greater showed count suppression. Myelosuppression was delayed, with the WBC nadir occurring at a mean of 37 days and platelet nadir at 31 days. In addition, count suppression was generally quite prolonged (mean duration for WBC, 13 days; for platelets, 14 days). No episodes of drug-related sepsis or bleeding occurred in this series. A fall in hemoglobin concentration of >2 g/dl was noted in 7 patients; none manifested clinically apparent bleeding. Drug-induced suppression

Table 3. *Myelosuppression*

WBC nadir	No. of patients	Platelet nadir	No. of patients
>4.0	7	>150	9
3.0–3.9	4	100–149	3
2.0–2.9	2	50–99	2
1.0–1.9	1	<50	0
<1.0	0		

of erythropoiesis appears to be the likely explanation. This manifestation of bone marrow toxicity has been noted in a previous report [3].

c. *Other.* Anorexia, nausea and vomiting were universal reactions to treatment. In most patients the nausea and vomiting lasted only for a few hours on the day of treatment, but in four patients this reaction was severe enough to be considered a true-dose-limiting side effect after 1, 2, 3 and 4 doses of DDP respectively. No patient developed tinnitus, clinically apparent hearing loss, alopecia, or hypersensitivity reactions.

Responses

Objective responses were seen in 6/13 patients with known or presumed head and neck cancer. Of these 6 responses, 1 was a complete response lasting 2 months and 3 were PR lasting 1+, 2 and 3+ months respectively. Two patients showed minor responses of less than 50%. The patient with epidermoid lung carcinoma showed no antitumor response and the patient with a skin appendage primary never received an adequate trial of therapy because of poor compliance. Responding sites included locally and regionally recurrent disease in previously irradiated and/or resected areas as well as more distant metastatic sites.

DISCUSSION

We undertook the present study in an effort to establish a convenient and effective schedule of DDP administration, suitable for outpatient use and amenable for combination with other agents. To do this, we explored a dose of DDP which:

(1) is below the dose-limiting nephrotoxic level for the large majority of patients when given every three weeks [4];

(2) has been shown by Corder *et al.* [2] to be non-nephrotoxic when accompanied by a forced diuresis program which, although time-consuming, can be given to outpatients;

(3) adds to approximately the same cumulative dose, if given weekly, as we have explored previously in head and neck cancer patients using an intermittent high-dose schedule with forced diuresis [3]. This dose has also been explored previously by others [5], who found a similar spectrum of toxicities in a small series of 4 patients.

We have found that more than 50% of patients show some evidence of nephrotoxicity when treated according to the present schedule. It may be argued that we should not have regarded creatinine elevations to only 1.4 mg/dl as dose-limiting. Since, however, all but one of the patients had pre-treatment values of $\leqq$1.1 mg/dl, we did not wish to risk further impairment if the serum creatinine had increased by (and, presumably, the glomerular filtration rate had decreased by) nearly 30% of the starting value, until we had verified by subsequent determination that renal function was improving.

We deliberately employed no measures for pre-hydration or diuresis, in order to keep the program as simple as possible. Perhaps even a minimal effort at diuresis or pre-hydration might eliminate some of the nephrotoxicity noted here and yet preserve the convenience of outpatient administration. On the other hand our facilities for outpatient chemotherapy administration are currently strained

to the limit and we felt that, for example, a randomized trial of hydration vs no hydration prior to DDP administration would pose difficult logistical problems. Corder *et al.* [2] have administered DDP in the same dose and schedule as we report here but also employ a vigorous program of forced diuresis with mannitol and intravenous hydration requiring a minimum of 5 hr per patient treatment. These authors report essentially no dose-limiting nephrotoxicity; the mean maximum increase in serum creatinine reported by Corder *et al.* was 0.14 mg/dl (patients received 2–11 treatments, mean 4.6, median 4), while our mean maximal increase in the 11 evaluable patients was 0.53 mg/dl (patients received 2–5 treatments, mean 3.9, median 4). It seems highly likely, therefore, that the Corder regimen conserves renal function more than a similar program withour provisions for hydration and diuresis. Nevertheless, to establish this impression definitely, a prospective randomized comparison of the two methods would be required, with careful matching to insure comparability of the patient groups

In addition to the nephrotoxicity, the nausea and vomiting were a significant feature of this regimen to the patients. When a drug which causes significant emesis is repeated frequently, as here, several hours of emesis has far more significance than it does when the drug is repeated every three to four weeks. At least 4 of our patients regarded the intensity and duration of the vomiting unacceptable and were prepared to discontinue therapy on this account. Our previous experience with high-dose intermittent DDP given once every three to four weeks included *no* withdrawals for this reason.

The antitumor responses to the treatment are noteworthy. Although the numbers are small, the response rate in patients with epidermoid carcinoma of the head and neck (30%) appears comparable to that achieved with the higher dosage schedule of DDP [3] in previously treated patients; the numbers are too small, however, to allow firm conclusions.

In conclusion, our results suggest that weekly DDP does have significant anti-tumor activity at least in epidermoid carcinoma of the head and neck. We feel, however, that the relatively high incidence of nephrotoxicity in this dose and schedule, when the drug is given without a protective diuresis, makes it an impractical agent for combination of methotrexate, whose excretion is almost entirely through the urine and whose toxicity is markedly enhanced in the presence of renal failure. Further efforts to establish a simple, safe and effective outpatients regimen continue.

The Modification of the Growth Characteristics of the Landschütz Ascites Tumour by Neuraminidase

JOHN BRAZIL and HUGH McLAUGHLIN
Department of Pathology, University College, Dublin 2, Ireland

Abstract—*The effect of* Vibrio cholerae *neuraminidase (VCN) on the* in vivo *growth characteristics of the Landschütz ascites tumour has been studied. A considerable reduction in tumour cell numbers following the transplantation of VCN-treated cells as compared to untreated cells has been shown which is readily reversible by* in vitro *incubation of the treated cells for a short period prior to transplantation. The possible significance of this is discussed.*

INTRODUCTION

INJECTION of viable tumour cells pretreated *in vitro* with *Vibrio cholerae* neuraminidase (VCN) has been shown to produce immunospecific regression of some chemically induced solid tumours [1–5] and to reduce the transplantability of a number of ascites tumours including the Landschütz tumour [6–10]. We present here a study of the effects of VCN on Landschütz ascites tumour cell proliferation in Schofield albino mice.

MATERIALS AND METHODS

Mice

Eight to twelve week old animals were obtained from a closed colony of random-bred Schofield albino mice maintained at this laboratory.

Tumour

A sub-line of the Landschütz ascites tumour was maintained by weekly intra-peritoneal passage of 0.2 ml of undiluted tumour bearing ascites fluid into healthy female recipients. Tumour cells required for experiment were obtained by collecting ascites fluid into approximately four times its volume of sterile phosphate-buffered saline (P.B.S.) pH 7.2. This prevented clotting without necessitating the use of an anticoagulant. The cells were then sedimented by centrifugation at 150 ***g*** for 5 min and washed three times in fresh P.B.S.

The tumour cell concentration in the washed suspension was determined by visual identification in a haemocytometer. Cell viability was assessed using trypan blue dye exclusion and only suspensions of 90% or greater viability were used. The concentration of viable cells was adjusted to the desired value by the addition of P.B.S.

Neuraminidase treatment

Tumour cells at a concentration of 2×10^7 cells ml^{-1} in Tris buffered saline (T.B.S.) pH 7.2 containing 1 mM $CaCl_2$ were incubated with 5 units of *Vibrio cholerae* neuraminidase (Grade B, 500 Uml^{-1}, Calbiochem) per 10^7 cells at 37°C for 60 min after which the cells were sedimented by centrifugation (150 ***g*** for 5 min) and washed three times in fresh T.B.S. The cells were finally resuspended in phosphate-buffered saline (P.B.S.) pH 7.2 and the cell viability determined by trypan blue dye exclusion. The concentration of viable tumour cells was then adjusted to the desired value.

Tumour cells treated with V.C.N. were suspended in MEM with Earles salts and 25 mM HEPES (Gibco) at a concentration of 10^7 cells ml^{-1} and incubated at 37°C for 3 hr. The cells were then sedimented (150 ***g*** for 5 min) and resuspended in P.B.S., the viability was checked and the concentration of viable cells adjusted to suit.

Assessment of total tumour load

Sheep red blood cells in Alsever's solution (Gibco) were sedimented by centrifugation at 500 ***g*** for 15 min and resuspended in 25 ml P.B.S. plus 0.2 ml of sodium (Cr^{51}) chromate (1 mCi/ml, Radiochemicals). After being gently shaken for 1 hr at room temperature the cells were re-sedimented and washed four times in

Accepted 28 November 1977.

fresh P.B.S. to remove any unbound radioisotope. Tumour bearing animals were injected with 1 ml of this suspension and 10 min later after the red cells were fully dispersed, the animals were sacrificed under ether anaesthesia. The abdominal skin was opened leaving the peritoneum intact and 1 ml of ascites fluid was recovered using a syringe and needle and added to 1 ml of 3.8% trisodium citrate solution. One millilitre of uninjected red cells was treated similarly to act as a standard. Radioactivity counting was performed in a Philips gamma counter.

The tumour cell concentration was determined visually using a haemocytometer and after allowing for various dilution factors, the total tumour load was calculated from the equation

$$\frac{\text{Radioactivity injected (counts/min/ml)}}{\text{Radioactivity recovered (counts/min/ml)}} \times \text{tumour cell count/ml} = \text{total number of tumour cells}$$

This method allowed accurate quantitation of cell numbers down to 5×10^5.

Growth curves

Three groups of 32 male mice were injected intra-peritoneally with 10^7 viable tumour cells per animal. The control group received unmodified cells, the second group received cells freshly treated with V.C.N. and the third group were injected with enzyme-treated cells allowed to stand in tissue culture medium for 3 hr. Growth curves were constructed by determining the total number of tumour cells present in groups of 4 animals at intervals after transplantation.

Statistical analysis

The results obtained with VCN treated cells, either freshly treated or allowed to stand, were compared to the normal values using Student's *t*-test.

RESULTS

The mean (±S.E.) number of tumour cells in each group is shown in Table 1 and Fig. 1.

Growth of untreated cells

Cell proliferation commenced immediately after transplantation and near-exponential di-

7	8.73±0.10	8.04±0.06	8.73±0.06
9	9.13±0.07	8.47±0.03	8.95±0.07
11	9.24±0.05	8.95±0.06	9.12±0.06
15	9.22±0.06	9.17±0.02	9.25±0.05
		$P<0.001$	N.S.

vision (doubling time approximately 20 hr) resulted in the maximum number of tumour cells (2×10^9) being attained eleven days later.

Growth of cells freshly treated with VCN

Although the rate of cell multiplication and maximum cell numbers were comparable with those of untreated cells, a fall in the number of cells to less than 10% of those transplanted resulted in maximum cell number not being attained until fifteen days later. This fall occurred within 24 hr of transplantation and was statistically highly significant ($P<0.001$).

Growth of cells allowed to recover from VCN treatment

No statistically significant difference between these cells and untreated cells was observed (Student's *t*-test).

DISCUSSION

The results presented here show that pretreatment of Landschütz ascites tumour cells by VCN produced a marked retarding effect on the early part of the growth curve when these cells were transplanted into normal mice. This effect was of short duration and the growth curve, after 4 days, paralleled that obtained when normal cells were transplanted indicating that the VCN treated tumour cells retained their ability to proliferate within the host at a rate comparable to untreated cells.

VCN treated tumour cells which were washed and incubated *in vitro* for a relatively short period of time before transplantation showed no difference in growth curve characteristics from untreated cells.

The low recovery of VCN treated tumour cells 24 hr after injection may be due to a number of factors. Tumour cell adherence to the peritoneum may have occurred. It is known that both normal and malignant cells are more adherent after VCN treatment [11]. However, there was no evidence of this in the present experiment and the incidence of solid tumours was similar in mice receiving normal and VCN treated tumour cells. It is possible that VCN treatment impaired viability of tumour cells resulting in transfer of a smaller number of viable cells. Viability was not affected as judged by trypan blue exclusion and it has been shown that much larger concentrations of VCN did not affect cell viability assessed by radioisotope incorporation [12]. Another possibility is that VCN treatment resulted in the exposure of new antigenic sites on the tumour cell membrane with which cytotoxic factors, possibly "natural" antibodies, could react resulting in *in vivo* destruction of the majority of tumour cells [13, 14]. This latter hypothesis is supported by the observation that *in vitro* culture of VCN treated tumour cells for a short period of time reversed the observed effect possibly by allowing regeneration of removed membrane components with recovery of normal antigenicity. Finally it is known that VCN remains bound to treated cells despite repeated washings and this cell bound VCN may have as yet undefined *in vivo* effects which may explain the observed difference in growth curve characteristics [15].

The ability of VCN treated Landschütz ascites cells to proliferate *in vivo* in an immunologically competent host is at variance with a previous report [9]. Differences in enzyme concentration and incubation conditions are unlikely to be responsible for this discrepancy since it has been observed that near maximal removal of sialic acid residues is obtained under conditions employed in the present study [16].

VCN treatment enhances the immunogenicity of many tumours [1–10]. Proposed mechanisms for the enhancement of immunogenicity include alteration of membrane deformability facilitating phagocytosis [11] and exposure to neoantigens and/or the modification of existing antigens resulting in the induction of a strong and cross reactive immune response against unaltered antigens [7]. The rapid reduction in tumour cell numbers which follows transfer of VCN treated tumour cells raises the possibility that one mechanism of action of VCN may be to predispose these cells to attack by preexisting defences resulting in a dramatic reduction in tumour load below numbers required for a successful take.

Influence of Vasoactive Drugs and Ischaemia on Intra-Tumour Blood Flow Distribution

J. MATTSON, L. APPELGREN, L. KARLSSON and H.-I. PETERSON

Laboratory of Rheology, Department of Surgery I, Sahlgrenska University Hospital, Göteborg, Sweden

Abstract—*The intra-tumour blood flow distribution in two transplantable rat tumours was studied by isotope technique. Intravenous infusion of noradrenaline reduced significantly the blood flow distribution in both intramuscularly transplanted tumours and in normal muscle. This effect was counteracted by pre-treatment of animals with an alpha-receptor blocking agent, phenoxybenzamine. Tumour and muscle blood flows were moderately increased after ischaemia.*

INTRODUCTION

NO ADRENERGIC innervation of tumour vessels was found in two intramuscularly transplanted rat tumours, in spite of topographically good vascular connections with normal vessels of the transplantation area in at least one of the tumours, a sarcoma [1]. This observation, which is in accordance with a previous study [2] does, however, not exclude alpha-adrenergic receptors in tumour vessels and the possibility to influence the tumour blood flow by vasoactive drugs acting on these receptors.

In previous studies the tumour blood flow was found to be increased after local X-ray irradiation of the same rat tumours. Furthermore, a post-ischaemic increase of the total relative tumour blood flow was found by plethysmography [3]. Other recent experimental studies have also suggested that the tumour blood flow might be influenced by vasoactive drugs [4, 5].

The aim of the present study was to investigate the influence on the intra-tumour blood flow distribution in the two earlier studied rat tumours by ischaemia, by noradrenaline and by an alpha-receptor blocking agent, phenoxybenzamine.

MATERIALS AND METHODS

Animals

Inbred rats from a Lister strain of animals and with a mean body weight of 150 g were studied.

Accepted 29 November 1977.

Tumours

A 20-methylcholanthrene induced sarcoma (MCH-H) in its 125th to 129th transfer generations and a hepatoma (Hep-H) in its 212th to 213th transfer generations were studied. These tumours have been described in detail previously [3]. Tumours were transplanted intramuscularly into one hindleg of the animals by a trochar technique and the experiments were performed two weeks after tumour transplantation with a mean tumour diameter of 15 mm.

Noradrenaline

Inj-Noradrenaline 1 mg/ml (Apoteksbolaget, Sweden). One millilitre of a saline solution with 0.01 mg noradrenaline/ml was slowly injected into the lower caval vein during 5 min. This injection was immediately followed by isotope injection.

Phenoxybenzamine

Dibenyline® (Smith, Kline & French Lab. Ltd, England). Five tenth mg/100 g body weight in 0.5 ml saline was injected intravenously into a tail vein 60 min before the experiment [6].

Isotope

^{86}Rubidium (^{86}Rb), dissolved in distilled water to an isotonic solution, was injected intravenously in a dose of 500 μCi and a volume of 0.1 ml. It was obtained from Kabi Diagnostica, Studsvik, Sweden.

Ischaemia

The aorta and lower caval vein were clamped through a lower transverse abdominal incision under ether anaesthesia for 10 min. Blood flow distribution was studied within 3 min after removal of clamping.

Recording of the intra-tumour and intra-muscle blood flow distribution

The intra-tissue blood flow distribution was studied by an isotope technique according to Sapirstein and recently described in detail [3]. Five hundred μCi ^{86}Rb in a volume of 0.1 ml was injected intravenously into the lower caval vein through a transverse abdominal incision under ether anaesthesia. A larger isotope dose than in the previous study was used due to the radiation properties of ^{86}Rb [3].

In previous studies [3] a stable isotope concentration plateau was reached in tumour about 20 sec after isotope injection and this stable plateau was maintained for several min. During this period the uptake and release of isotope balance each other despite recirculation and the fractional uptake of isotope within the tissue will reflect the intra-tissue distribution of blood flow as a fraction of cardiac output according to Sapirstein (see [3]).

The aorta and lower caval vein were clamped 60 sec after isotope injection. Tumours and normal muscle tissue from the contralateral hindleg were rapidly dissected and frozen in expanding carbon dioxide. Multiple 10–50 mg frozen specimens from each tumour and from normal muscle in each animal were taken for radioactivity recording. The isotope dose injected into animals was dissolved in 150 ml saline and three 1 ml specimens were taken as standards.

Tumour and muscle samples and standards were examined in a well-type scintillation counter with a pulse analyzer. Due corrections were made for background. The recorded activities in most tissue samples were 10^3–10^4 counts/min.

All results were calculated and are presented as % of injected dose/g tissue. This figure indicates the percentage of cardiac output/g tissue and should make possible a comparison between tumour and muscle blood flow if Sapirstein's conditions are fulfilled.

Blood pressure registration

The influence of ischaemia, noradrenaline and phenoxybenzamine on the mean arterial blood pressure was studied in three separate animals. Blood pressure was recorded continuously under ether anaesthesia by a polyethylene catheter (PE 50) in the left carotid artery, connected with a Grass polygraph recorder with a Statham pressure transducer.

RESULTS

Intravenous infusion of noradrenaline induced an insignificant increase of the mean arterial blood pressure, while phenoxybenzamine decreased the arterial blood pressure slightly (5–10 mm Hg). A normal blood pressure (125 ± 5 mm Hg) in phenoxybenzamine injected animals was restored by noradrenaline infusion.

The flow data presented for each experimental group are collected data from five animals in which about 20 tumour specimens and 15 muscle specimens were taken from each animal. A wide distribution of ^{86}Rb was found in tumours and in normal muscle. The isotope uptake was strongly reduced in both tumours and in normal muscle after infusion of noradrenaline. This reduction was counteracted by pre-treatment of animals with phenoxybenzamine. A moderate increase of isotope uptake was found in muscle and in tumours after ischaemia (Fig. 1a and b).

DISCUSSION

In the present study the intra-tumour blood flow distribution was recorded by an isotope technique. Two transplantable rat tumours with topographical differences in vascular supply were studied. Infusion of noradrenaline reduced the intra-tumour blood flow distribution in both tumours significantly as in normal muscle. This reduction was counteracted by pre-treatment of animals with an alpha-receptor blocking agent, phenoxybenzamine. Tumour and muscle blood flows were moderately increased by ischaemia.

The observations made in this study might suggest that tumour blood vessels could be influenced by vasoactive drugs acting on alpha-receptors. However, the similar response in tumour and normal muscle to infusion of noradrenaline might also indicate that changes of blood flow distribution in tumours are secondary to induced changes in normal tissue blood flow distribution in the transplantation area.

The possibility to influence tumour blood flow is of large clinical interest. Vasoactive drugs have been used in pharmacoangiography to enhance the contrast filling of tumour vessels. Thus, e.g. vasoconstriction by angiotensin or by epinephrine of normal vessels was suggested to

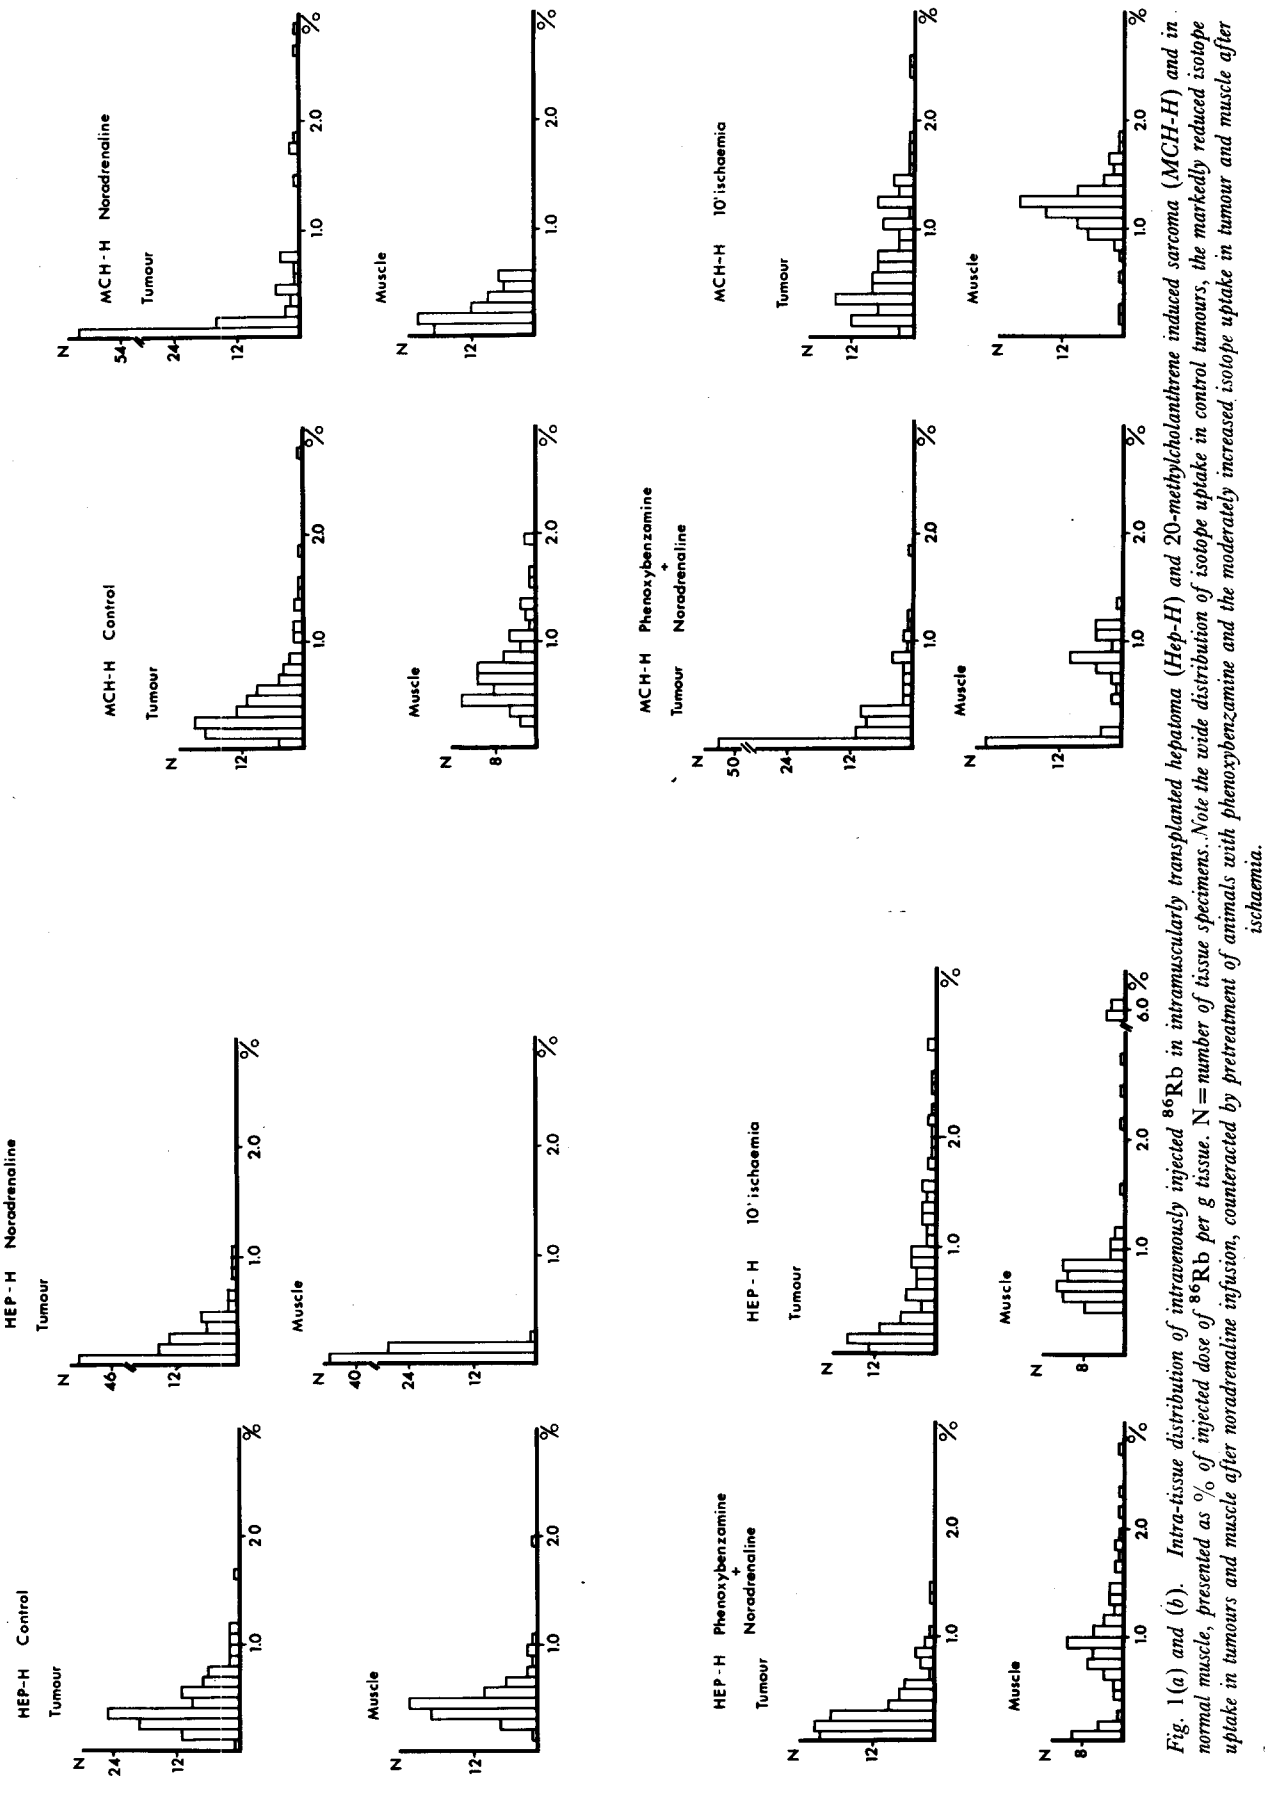

Fig. 1(*a*) *and* (*b*). *Intra-tissue distribution of intravenously injected* ^{86}Rb *in intramuscularly transplanted hepatoma* (*Hep-H*) *and 20-methylcholanthrene induced sarcoma* (*MCH-H*) *and in normal muscle, presented as % of injected dose of* ^{86}Rb *per g tissue.* N = *number of tissue specimens. Note the wide distribution of isotope uptake in control tumours, the markedly reduced isotope uptake in tumours and muscle after noradrenaline infusion, counteracted by pretreatment of animals with phenoxybenzamine and the moderately increased isotope uptake in tumour and muscle after ischaemia.*

stand out in contrast to non-reactive tumour vessels and to enhance the contrast filling of tumour vessels [7, 8].

The observations made in the present experimental studies indicate that tumour blood flow might be markedly influenced by vasoactive drugs. However, this effect on tumour blood flow might be a direct effect on alpha-receptors in tumour vessels, but might also be secondary to an influence on normal blood vessels in the transplantation area. This will be further studied. Topographical differences in vascular morphology between the tumours did not influence changes in tumour blood flow. The increased intra-tumour isotope distribution after ischaemia is in accordance with earlier observed increased total relative tumour blood flow by plethysmography after ischaemia [3].

Consequences of Inhibition of Purine Biosynthesis *de novo* by 6-Methylmercaptopurine Ribonucleoside in Cultured Lymphoma L5178Y Cells*

ROBIN A. WOODS,†‡¶ RUTH M. HENDERSON§ and J. FRANK HENDERSON†¶§
¶*Cancer Research Unit (McEachern Laboratory) and Departments of*† *Biochemistry and*§ *Pharmacology, University of Alberta, Edmonton, Alberta, Canada T6G 2H7*

Abstract—*6-Methylmercaptopurine ribonucleoside is an inhibitor of amidophosphoribosyltransferase and produces growth inhibition and loss of viability in cultured murine lymphoma L5178Y cells. Treatment with low concentrations of this drug leads to lowered concentrations of purine ribonucleotide concentrations, whereas those of pyrimidine ribonucleotides are elevated. At higher drug concentrations the concentration of the latter are also decreased. Concentrations of both purine and pyrimidine deoxyribonucleoside triphosphates are lowered by drug treatment. Treated cells lose protein, RNA and DNA into the medium.*

INTRODUCTION

6-METHYLMERCAPTOPURINE ribonucleoside (MeMPR||), in the form of its 5′-monophosphate, is an inhibitor of the first enzyme of the pathway of purine biosynthesis *de novo*, amidophosphoribosyltransferase (EC 2.4.2.14); there is good evidence that this is the primary, if not sole, site of enzymatic action of MeMPR in animal tumor cells (review: [1]. Previous studies [2–5] have shown that treatment with MeMPR results in alterations in the intracellular concentrations of purine and pyrimidine ribonucleotide concentrations; in particular, the concentrations of ATP and GTP decrease appreciably whereas those of UTP and CTP increase. In the present work, we have made further attempts to learn how inhibition of purine biosynthesis *de novo* by MeMPR leads to inhibition of cell growth and to loss of cell viability. In particular, we have studied further the effects of MeMPR treatment on purine and pyrimidine ribonucleotide concentrations, and have also measured its effects on purine and pyrimidine deoxyribonucleotide concentrations. In addition, the loss of proteins and nucleic acids from MeMPR treated cells has been detected.

Accepted 2 December 1977.

||Abbreviation used: MeMPR, 6-methylmercaptopurine ribonucleoside.

MATERIALS AND METHODS

MeMPR and purine and pyrimidine bases, nucleosides and nucleotides were supplied by Sigma Chemical Co., St. Louis, MO. Sucrose (density gradient grade) was supplied by Schwarz/Mann, Orangeburg, NY. [Methyl-^{3}H]thymidine (3 Ci/mmole), [8-^{3}H]hypoxanthine (10 Ci/nmole), and L-[2-^{14}C] leucine (46 mCi/mmole) were obtained from Schwarz/Mann, Orangeburg, NY and [1,2-^{14}C]glycine (101. mCi/mmole), from New England Nuclear Corp., Boston, MA.

The murine lymphoma L5178Y cells used in this study were grown in stationary suspension culture in Fisher's medium supplemented with 10% horse serum (Grand Island Biological Co., Grand Island, NY). Stock cultures were maintained in logarithmic phase by dilution at least every 48 hr to a density of *ca.* 0.2×10^5 cells per ml. In the experiments reported here, the average generation time was 11 hr. Cell densities were measured using a Model Z_f Coulter Counter.

The incorporation of radioactive precursors into perchloric acid-insoluble material was measured as described previously [6]. After 3 washes with cold perchloric acid, the acid-insoluble material was dissolved in 0.1 N NaOH and radioactivity was measured in a liquid scintillation counter using Bray's scintillation fluid [7].

Purine biosynthesis *de novo* was measured by determining the extent of incorporation of [1,2-^{14}C]glycine into total cellular adenine and guanine, as described previously [6].

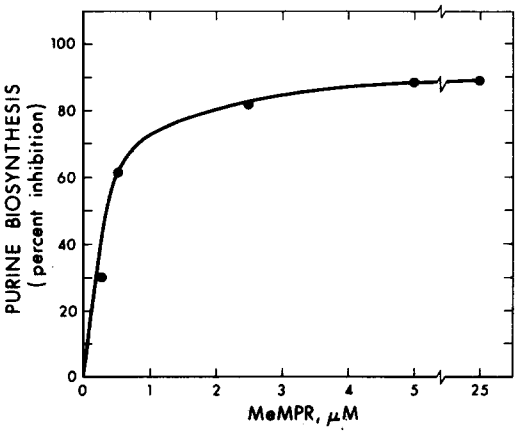

Fig. 1. Effect of MeMPR on Purine biosynthesis de novo. *Lymphoma* L5178Y *cells,* 0.94×10^5 *cells per* ml, *were incubated with various concentrations of MeMPR and* 100 μM [^{14}C]*glycine for* 30 min, *after which the incorporation of radioactivity into total cellular adenine and guanine was measured. These data are representative of results obtained in four experiments.*

Concentrations of acid-soluble purine and pyrimidine ribonucleotides were determined spectrophotometrically after their separation by high-pressure liquid chromatography using a Reeve Angel Partisil-10SAX column (25 cm × 4.6 mm; Mandel Scientific, Montreal, Que.) and a linear gradient of potassium phosphate and potassium chloride, pH 4.5, as described in detail elsewhere [8].

Concentrations of deoxyribonucleoside triphosphates were measured enzymatically, using a modification of the procedure originally developed by Solter and Handschumacher [9] as modified by Lowe and Grindley [10]. The assay was linear within the range of 2 to 50 pmole of each deoxyribonucleioside triphosphate.

Changes in DNA structure were detected by determining the molecular weight of DNA single strands by alkaline sucrose density gradient centrifugation by the method of Walters and Hildebrand [11].

To prepare cells for electron microscopy, they were collected by brief centrifugation, the medium was removed, 1 ml of the cells were suspended in 5% phosphate buffered glutaraldehyde fixative and then centrifuged. The pellet was dehydrated in a series of ethanols, embedded in Epon, sectioned,

double stained with uranyl acetate and lead citrate and examined using a JEM-7A electron microscope.

RESULTS

Initial studies were carried out to establish the relationship between MeMPR concentration and its primary biochemical effect, inhibition of purine biosynthesis *de novo* and between MeMPR concentration and growth inhibition. Figure 1 shows that inhibition of purine biosynthesis increased from *ca.* 30 to 90% as MeMPR concentrations were increased from 0.25 to 5.0 μM; further increases produced no further inhibition. Other studies showed that inhibition of purine biosynthesis by MeMPR declined slowly with time. For example, 0.5 μM MeMPR produced 62% inhibition immediately after addition of drug to the culture, but only 46% inhibition 8 hr later. Because of this variation with time it is difficult to establish the exact relationship between inhibition of purine biosynthesis *de novo* and inhibition of growth. However, an approximation is obtained by measuring cell growth 24 hr after addition of the same MeMPR concentrations as those used in Fig. 1. Control cells grew from a starting density of 5×10^4 cells/ml to a density of 17×10^4/ml after 24 hr. Cultures treated with 0.25, 0.5 and 2.5 μM MeMPR grew from the same starting density to 13.5, 9.8 and 5.2×10^4/ml, respectively. Cell numbers decreased to 4.0 and 3.0 $\times 10^4$/ml, respectively, in cultures treated 24 hr with 5.0 and 2.5 μM MeMPR. (Detailed growth curves were obtained, but are not reported here).

In order to study the immediate biochemical consequences of MeMPR treatment, we next studied the changes in intracellular concentrations of purine and pyrimidine ribonucleotides that resulted from treatment with this drug. Figure 2 reports concentrations of ribonucleoside triphosphates* both as a function of time of incubation with drug and as a function of MeMPR concentration. Concentrations of ATP and of GTP decreased within 4 hr at all concentrations of MeMPR used. In general ATP and GTP concentrations decreased to approximately the same relative extent in most cases, although there were some small differences. The magnitude of the initial decrease in purine ribonucleoside triphosphate concentrations increased with increasing MeMPR concentrations, from *ca* 40% of control at 0.25 μM MeMPR to *ca.* 10% of control at 25 μM MeMPR.

Concentrations of UTP and CTP increased following treatment with lower concentrations (0.25, 0.5, 2.5 μM) of MeMPR, although this increase lagged behind the decrease in ATP and GTP concentrations; the increase was greatest in cells treated with the lowest concentrations of MeMPR. MeMPR concentrations of 5 and 25 μM lead to decreases in pyrimidine ribonucleoside concentrations, with CTP concentrations declining more than those of UPT.

In order to obtain further information regarding the effects of MeMPR on nucleotide metabolism, intracellular concentrations of purine and pyrimidine deoxyribonucleoside triphosphates were measured. Figure 3 shows that concentrations of both dATP and dGTP decreased substantially within 2 hr of initiation of treatment with 25 μM MeMPR, and that

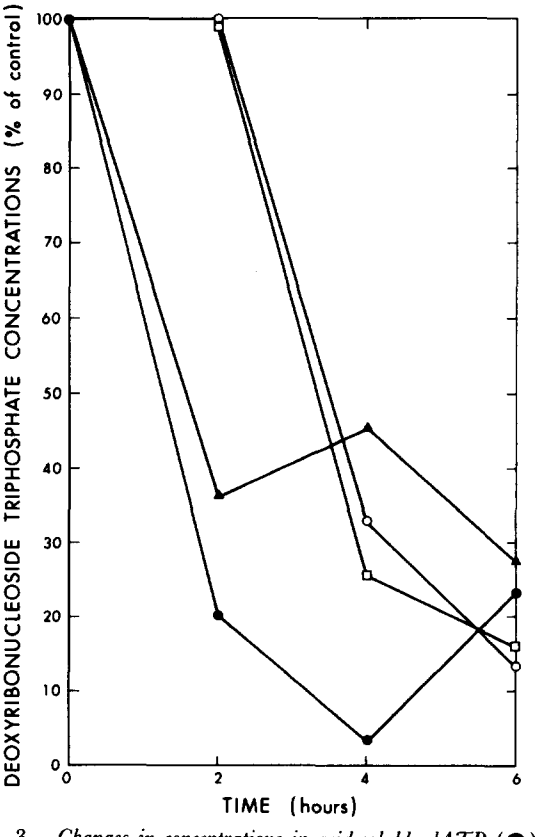

Fig. 3. Changes in concentrations in acid-soluble dATP (●), dGTP (▲), dCTP (□) and TTP (○) in L5178Y *cells treated with* 25 μM *MeMPR. Values for control (untreated cells) were dATP,* 15 nmole/10^9 *cells; dGTP,* 8 nmole/10^9 *cells; dCTP,* 98 nmole/10^9 *cells; TTP,* 28 nmole/10^9 *cells. These data are representative of those obtained in two experiments.*

*Concentrations of the purine and pyrimidine ribonucleoside mono- and diphosphates were less than 10% those of the corresponding triphosphates at all times. For convenience and brevity, and because the triphosphates quantitatively are the most important nucleotides, only the concentrations of the latter are reported here.

by 4 hr, concentrations of dCTP and TTP had also dropped appreciably.

The studies described so far provided a reasonable basis for understanding the growth inhibitory effects of MeMPR. However, these data by themselves did not appear to be sufficient to explain the loss of cell viability (3, 4 and unpublished observations) that is produced by treatment with this drug. The possibility that macromolecules were breaking down in cells treated with MeMPR was therefore considered. In these experiments, lymphoma L5178Y cells were first grown with a radioactive precursor, transferred to fresh medium without precursor for sufficient time to reduce acid-soluble radioactivity to low levels and then treated with MeMPR. At various times the cells were collected by centrifugation, and the amount of radioactive material that had passed from the cells into medium was measured. A portion of medium was treated with cold 0.4 M perchloric acid and the percentage of the total radioactivity in the medium that was acid-insoluble was calculated. [^{14}C]Leucine was used as a precursor of proteins, [^{3}H]hypoxanthine as a precursor of combined RNA plus DNA and [^{3}H]thymidine as a precursor of DNA.

Figure 4 shows that treatment with relatively high concentrations of MeMPR led to greatly accelerated loss of cellular protein, even as early as 4 hr after initiation of treatment. By 8 hr, *ca.* 3-times as much radioactivity was lost from treated cells as from untreated cells. More than 40% of the cellular radioactivity lost into the medium was acid-precipitable even at 2 hr and in the MeMPR treated cells this increased to *ca.* 80% by 8 hr.

Figure 5 shows the effects of a wide range of MeMPR concentrations in the total loss of radioactivity in cellular nucleic acids (RNA plus DNA) over the course of 24 hr treatment. In control cells, less than 10% of total cellular nucleic acid radioactivity was lost in 24 hr. Treatment with MeMPR, however, led to an accelerated loss that was time and concentration dependent. After treatment with relatively high concentrations of MeMPR for 24 hr, between 58 and 67% of the initial cellular nucleic acid radioactivity was lost into the medium. Further studies showed that a substantial proportion of the radioactivity lost of cells treated with MeMPR was derived from DNA.

Because substantial loss of RNA, DNA and protein was lost from MeMPR-treated cells, they were examined by electron microscopy in attempts to detect morphological consequences of such losses. However, no consistent differences between control and drug treated cultures were noted.

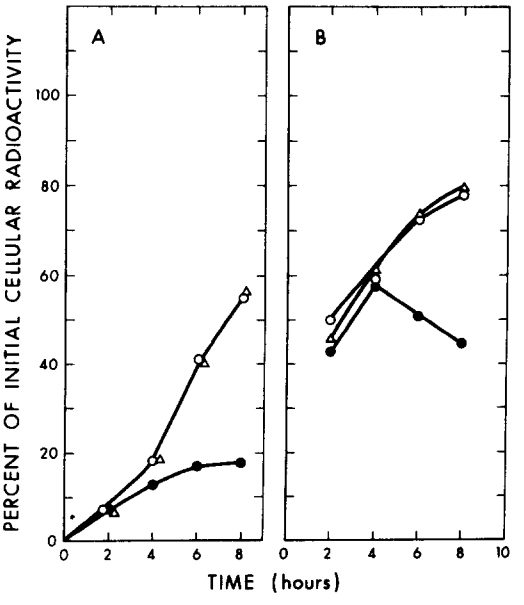

Fig. 4. Loss of radioactivity from cellular protein in lymphoma L5178Y *cells treated with MeMPR. Lymphoma* L5178Y *cells were grown for* 18 hr *with* 0.1 μCi/ml [^{14}C]*leucine. Cells were then transferred to fresh medium without precursor and grown for an additional* 4 hr. *The cell density was then adjusted to* ca. 10^5 *cells per* ml *and growth was continued for* 8 hr *with no addition* (●), 25 μM *MeMPR* (○), *or* 37.5 μM *MeMPR* (△). *At various times, samples were taken and radioactivity in the medium was determined. A, total radioactivity in the medium as a percentage of the total radioactivity originally present in the cells. B, acid-insoluble radioactivity in the medium as a percentage of the total radioactivity in the medium. These data are representative of those obtained in three experiments.*

DISCUSSION

In this study we have attempted to gain further information regarding the biochemical and biological consequences of inhibition of amidophosphoribosyltransferase in cultured lymphoma L5178Y cells. Although the line of L5178Y cells used in these studies appeared to be less sensitive to growth inhibition by MeMPR than that previously used by Warnick and Paterson [4], these authors added fresh drug daily, whereas we did not; the two types of experiments therefore cannot be directly compared.

As a consequence of inhibition of purine biosynthesis *de novo* by MeMPR, intracellular concentrations of purine ribonucleotides decreased. This result has of course been reported by other investigators [3, 4, 5], but this study has measured ribonucleotide concentrations at a wider range of MeMPR concentrations and times of drug treatment than

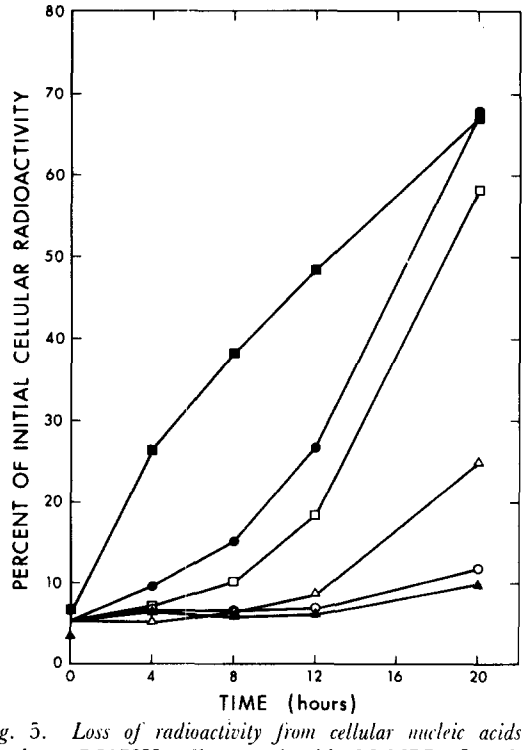

Fig. 5. Loss of radioactivity from cellular nucleic acids in lymphoma L5178Y *cells treated with MeMPR. Lymphoma* L5178Y *cells were grown with* 0.1 μCi/ml [^{3}H]*hypoxanthine as described in Chart 7 and finally grown with* 0 *MeMPR* (▲), 0.375 μM *MeMPR* (○), 0.75 μM *MeMPR* (△), 3.75 μM *MeMPR* (□). 7.5 μM *MeMPR* (●), *or* 37.5 μM *MeMPR* (■). *Results are calculated as total radioactivity in the medium as a percentage of the total radioactivity originally present in the cells. These data are representative of those obtained in two experiments.*

reported previously. The relative concentrations of purine ribonucleoside triphosphates were reduced to as low as 10% of control values as a result of treatment with 25 μM MeMPR. MeMPR treatment has previously been shown to produce elevated concentrations of pyrimidine ribonucleotide concentrations [3–5], particularly at low drug concentrations. However, it has not previously been observed to cause these concentrations to decrease at high levels of drug.

Decreased concentrations of purine ribonucleotides appeared to lead directly to decreased synthesis of purine deoxyribonucleotides, whose concentrations decreased rapidly following treatment with MeMPR. Concentrations of pyrimidine deoxyribonucleoside triphosphates decreased to almost the same extent; effects of MeMPR on deoxyribonucleoside triphosphate concentrations have not previously been reported.

The consequences of inhibition of amidophosphoribosyltransferase so far described would appear to be sufficient to explain the growth inhibitory effects of MeMPR. However, growth inhibition appears to be followed by loss of cell viability and this is more difficult to explain in biochemical terms. We have shown here that treatment of lymphoma L5178Y cells led to appreciable losses of protein, RNA and DNA from the cells, and that much of the material lost still was acid precipitable; i.e. was not broken down to free amino acids and nucleotides, nucleosides and bases. Although it may be supposed that these changes in MeMPR treated cultures are related to the observed decrease in apparent cell survival, it is not yet established whether they are causes or consequences of cell death. This point and the relationship of intracellular nucleotide concentrations to the processes of protein and nucleic acid breakdown, obviously require further study. It is of considerable interest, however, that reductions in GTP and dGTP concentrations in cells treated with mycophenolic acid, do not lead to such drastic catabolism of macromolecules [12]. Such catabolic processes, therefore, are not automatic concomitants of cytotoxicity.

Adaptation of Murine MOPC-315 Myeloma Cells to Growth *In Vitro* and Further Characterization of their C-Type Viruses

A. YANIV,* A. GAZIT, M. DVIR, D. GUTHMANN and E. EYLAN

Department of Human Microbiology, Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel

Abstract—*MOPC-315 murine myeloma cells were successfully adapted to growth in culture and the established cell line propagated in suspension and retained the capacity to induce plasma cell tumors in mice. The cultured myeloma cells constantly release RNA viral particles which by nucleic acids hybridization are indistinguishable from the C-type particles secreted into the ascitic fluid of mice bearing MOPC-315 myeloma tumors. Availability of an* in vitro *source of MOPC-315 murine myeloma viral particles facilitated additional biochemical characterization of these viruses. The myeloma particles were found to be infectious and capable of inducing syncytia in XC cells. The particles released in culture, unlike those secreted* in vivo, *showed high instability during the purification steps, but this was partially overcome by the addition of dithiothreitol.*

INTRODUCTION

IN A PREVIOUS paper [1] we reported that MOPC-315 murine myeloma cells secreted *in vivo* C-type particles which, unlike other myeloma viruses [2, 3], possess biochemical properties similar to those of known RNA tumor viruses. Although a high yield of viral particles can be obtained from the ascitic fluids of tumor-bearing mice, this *in vivo* source is inconvenient and rather costly. The tumor cells, for instance, have to be transplanted weekly and this necessitates a regular supply of animals. During such *in vivo* sequential transplantation, the myeloma cells are prone to contamination by other viruses of the host or, accidentally, by viruses from other animals kept in the same animal house. Viral preparations of *in vivo* sources also contain a high proportion of "old" virions with degraded molecular components as well as large amounts of contaminating cellular substances, rendering them unsuitable for determination of viral molecular constituents [4]. In addition to the mentioned drawbacks, there is also the difficulty in studying various aspects of the reproductive cycle of myeloma C-type particles.

Accepted 2 December 1977.

*Mailing address: Dr. A. Yaniv, Department of Human Microbiology, Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, Israel.

In view of all the above, we deemed it profitable to render MOPC-315 tumor cells amenable to growth in tissue culture. As will be shown in the present paper, we found that the viral particles released by the tumor cells during their replication *in vitro* were identical to those released by them *in vivo*. The availability of an *in vitro* source of MOPC-315 viral particles enabled further biochemical and biological characterization of these particles.

MATERIALS AND METHODS

Preparation of MOPC-315 cell line

A subcutaneous tumor induced in BALB/c mouse by MOPC-315 cells [5], was excised under sterile conditions and washed several times in phosphate-buffered saline (PBS), pH 7.2. The tumor specimen was minced with sharp scissors, then suspended in Eagle's modified medium and forced through a fine stainless-steel mesh inserted in a 30 ml syringe in order to obtain single cells. Following removal of tissue fragments by filtration through gauze, the cells were washed, resuspended in Eagle's modified medium supplemented with 10% calf serum (CS) and seeded in 75 cm^2 plastic (Nunc) flasks at a concentration of 0.5×10^6/ml. The cultures were incubated at 37°C in humidified air with 5% CO_2. Cells were subcultured at 3-day in-

tervals in a vol of 15 ml per flask at a concentration of 2×10^5 cells/ml.

DNA polymerase assay

Reaction mixtures (0.1 ml) for homopolymer-templated reactions contained the following: Tris–HCl (pH 8.2), 50 mM; potassium chloride, 48 mM; magnesium chloride, 8 mM; dithiothreitol (DTT), 0.4 mM; dATP, TTP(P.L. Biochemicals), 0.2 and 0.1 mM respectively; ^{3}H-TTP (40 to 50 Ci/mmole, New England Nuclear Corp.) to yield 300 counts/min/pmole and synthetic oligo$(dT)_{12-18}$ poly (rA) (P. L. Biochemicals), 0.4 μg. For assaying the endogenous enzymatic activity the reaction mixtures (125 μl) contained 100 μg/ml actinomycin D; 50 mM Tris-HCl (pH 8.2); 10 mM NaCl; 4 mM $MnCl_2$; 1.2 mM each of dGTP, dCTP, dATP and 600 μCi/ml of ^{3}H-TTP. Virus particles in 0.01 M Tris-HCl (pH 8.2) were disrupted in the presence of 0.05% Nonidet P-40 (NP-40) at 0°C for 10 min and then the appropriate reaction mixture was added. Reactions were incubated at 37°C and terminated as described in the text. Acid-precipitable radioactivity was tested after precipitation with cold trichloroacetic acid (TCA) at a final concentration of 10% and collection on nitrocellulose filters. Following exhaustive washings with cold 5% TCA, filters were dried and the radioactivity counted in 0.4% 2,5-bis-2(5-tert-butylbenzoaxozolyl) thiophene (BBOT) in toluene.

Isopycnic purification of particles

Medium was harvested 48 hr after seeding MOPC-315 cells at a concentration of 2×10^5 cells/ml. Medium was clarified from cells by centrifugation at 2000 ***g*** for 10 min and further centrifuged at 10,000 ***g*** for 10 min. The supernatant fluids were then centrifuged through 20% (v/v) glycerol in TNE (0.01 M Tris–HCl (pH 7.4), 0.1 M NaCl, 0.001 M EDTA) for 1 hr at 95,000 ***g*** in a Beckman SW-27 rotor. The pellet was resuspended in TNE, layered on a gradient of 20–55% (w/w) sucrose in TNE or on a glycerol gradient (1.12–1.24 g/ml) and centrifuged at 95,000 ***g*** for 16 hr at 4°C. The gradient was fractionated and densities were determined by refractive index measurement. Fractions were tested for DNA polymerase activity or for ^{3}H-radioactivity and those corresponding to the viral peak were pooled, diluted with TNE and sedimented at 95,000 ***g*** for 1 hr.

Preparation of cores

MOPC-315 cells were grown in the presence of ^{3}H-uridine (5 μCi/ml, 20 Ci/mmole) for 48 hr. Purified viral particles, concentrated from the 1.15 to 1.18 g/ml density region of a sucrose gradient, were resuspended in TNE and treated with NP-40 at a final concentration of 0.5%, in the presence of 0.1 M DTT, for 5 min at 0°C. The resulting solution was layered on a 20–65 (w/w) sucrose-TNE gradient and centrifuged at 100,000 ***g*** for 18 hr at 4°C. Fractions were collected from below and assayed for acid-precipitable radioactivity.

Isolation of viral RNA

Purified viral particles concentrated from isopycnic gradients were resuspended in TNE and treated with 1% SDS for 5 min at room temperature. The suspension was then deproteinized twice with an equal volume of phenol-cresol-8-hydroxyquinoline and the RNA was purified by centrifugation on a 10 to 30% (v/v) glycerol gradient, at 234,000 ***g*** for 90 min. The RNA-containing fractions were pooled and the nucleic acid was precipitated by the addition of two volumes of cold alcohol in the presence of 0.3 M LiCl.

Synthesis and purification of [^{3}H] *cDNA*

[^{3}H] thymidine-labelled cDNA was synthesized in an endogenous reverse transcriptase reaction with detergent-disrupted viruses in the presence of actinomycin D. The reaction was carried out at 37°C until the kinetics of ^{3}H-TMP incorporation reached a plateau level. The [^{3}H]DNA product was deproteinized and further purified by chromatography on G-50 Sephadex column equilibrated with 1 mM EDTA containing 0.2 M sodium bicarbonate. The peak radioactive fractions in the excluded volume were pooled, lyophilized and the RNA template was alkali-digested.

Hybridization conditions and analysis

Annealing reactions between [^{3}H]cDNA (1000 counts/min) and various amounts of viral 70 S RNA were performed in 10 μl reaction volume containing 0.06 M NaCl, 0.04 M Tris–HCl pH 7.2, 0.002 M EDTA and 0.1% SDS. The reaction mixtures were sealed in siliconized capillaries, kept at 100°C for 2 min, chilled on ice and then incubated at 68°C for varying periods of time to reach the desired Crt values. Hybrids were analyzed by re-

sistance to S1 nuclease [6] in the following manner. After incubation, samples were withdrawn, adjusted to 0.03 M sodium acetate (pH 4.5), 0.3 M NaCl, and 3 mM $ZnSO_4$ containing 10 μg/ml of denatured *M. luteus* DNA. This was equally divided into two tubes, to only one of which was added a titrated quantity of S1 nuclease (Miles Laboratories). Following incubation at 37°C for 1 hr, the nucleic acids were precipitated, collected on filters and the radioactivity measured in a liquid scintillation spectrometer. Data were plotted as percentage hybridization vs Crt to determine the $Crt_{1/2}$ values and the final extent of hybridization. Background counts corresponding to 5% or less of the input counts/min were subtracted from each time point.

Infectivity assay

BC wild mouse embryo clone SC-1 cells [7], in Eagle's modified medium containing 10% FCS, were seeded into plastic tissue-culture cluster plate (Costar) at a concentration of 5×10^5 cells/well (16 mm dia). After 24-hr incubation, cells were treated with DEAE-dextran (25 μg/ml, Pharmacia) for 1 hr, washed with culture medium and then infected with 0.05 ml MOPC-315 virus stock obtained from culture media filtered through 0.45 μm Millipore filters. Following 2 hr adsorption at 37°C, the viral inoculum was removed, the cells were washed and 1 ml of fresh medium was added. Cultures were incubated for 3 days at 37°C, then 2×10^5 DEAE-dextran-treated XC cells were added to each well. After 3 more days of incubation, the cells were fixed with methanol, stained with Giemsa and scanned for syncytia with an inverted light microscope.

RESULTS

Adaptation of MOPC-315 cells to growth in culture

As mentioned earlier (Materials and Methods) the MOPC-315 cell line was established from a subcutaneous tumor of BALB/c mouse. The tumor cells easily adapted to the *in vitro* environment and demonstrated a high growth rate in Eagle's modified medium supplemented with 10% calf serum. The cultured MOPC-315 cells are growing in suspension and at the time of writing are at the 210th generation having completed two years of cultivation *in vitro*. The growth curve of the myeloma cell line reveals a generation time of 19 hr and a saturation density of 10^6 cells/ml which is reached after 72 hr of growth. The tumorogenic potential of various generations of the MOPC-315 cell line was tested in BALB/c mice and it was found that upon intraperitoneal or subcutaneous injection of 10^6 cells, all animals developed plasma cell neoplasms within 10 days.

Optimal conditions for virus production

The viral yields from MOPC-315 cell line were estimated by the level of templated DNA polymerase activity in extracellular particles. The optimal cell concentration for maximal virus production was determined from the quantity of particles in tissue culture fluids of MOPC-315 cells seeded at various concentrations and grown for 72 hr. For this purpose, the particles were concentrated from 10 ml amounts of cell free tissue culture fluids, by sedimentation through 20% glycerol and assayed for DNA polymerase activity. Data obtained (Table 1) showed that the highest yield of particles was produced by MOPC-315 cells seeded at a concentration of 2×10^5 cells/ml.

Table 1. *DNA polymerase activity in culture fluids of MOPC-315 cells seeded at various concentrations*

Initial cell density/ml	pmole TMP incorporated*
1×10^5	67.4
2×10^5	158.9
3×10^5	121.3
4×10^5	23.4

*Assay performed as described in "Materials and Methods" on 100,000 *g* pellet from 10 ml clarified cell culture medium. The pmole values represent activity after 30 min reaction in the presence of oligo dT. poly rA template.

The next aim was to determine the optimal period of incubation necessary for maximal yield of particles. Towards this end MOPC-315 cells were seeded in 75 cm^2 plastic tissue culture flasks at a concentration of 2×10^5 cells/ml, then incubated at 37°C and the yield of particles possessing DNA polymerase activity measured after various periods of incubation. It was found (Table 2) that 48 hr of incubation was optimal for virus harvest.

Stability of MOPC-315 viruses in sucrose and glycerol gradients

The buoyant density of MOPC-315 viral particles was determined in sucrose–TNE and

glycerol–TNE equilibrium gradients. High-speed pellets obtained from cell-free culture fluids were subjected to isopycnic density centrifugation, the gradients then fractionated and aliquots tested for templated DNA polymerase activity. In sucrose and glycerol gradients, the particles banded at densities of 1.16 and 1.19 g/ml respectively (Fig. 1). It was further revealed that unlike the particles released into the ascitic fluids of mice bearing myeloma tumors [1], the MOPC-315 particles were extremely unstable in these gradients. However, when 3 mM DTT was incorporated into the gradient solutions, the viral particles acquired considerable stability, particularly in glycerol gradients (Fig. 1b).

Cores of MOPC-315 viral particles

To determine the density characteristics of the viral core component of myeloma particles, a "density-shift" experiment was performed. ^{3}H-uridine labelled particles were concentrated from the 1.15 to 1.18 g/ml density region of a sucrose gradient, treated with nonionic detergent and centrifuged to equilibrium in a 20–65% sucrose–TNE gradient, containing 3 mM DTT. The outcome of this experiment (Fig. 2) demonstrated that the detergent treatment released from MOPC-315 particles the internal nucleoid having a buoyant density of 1.26 g/ml. Recovery of the viral cores was law and most of the labelled material was found in the upper part of the density gradient. Evidently the core components of myeloma viruses are highly sensitive when freed from their outer membranes.

Sedimentation coefficient of virion RNA

To determine the sedimentation coefficients of the RNA species characteristic for MOPC-315 viral particles, the nucleic acid was ex-

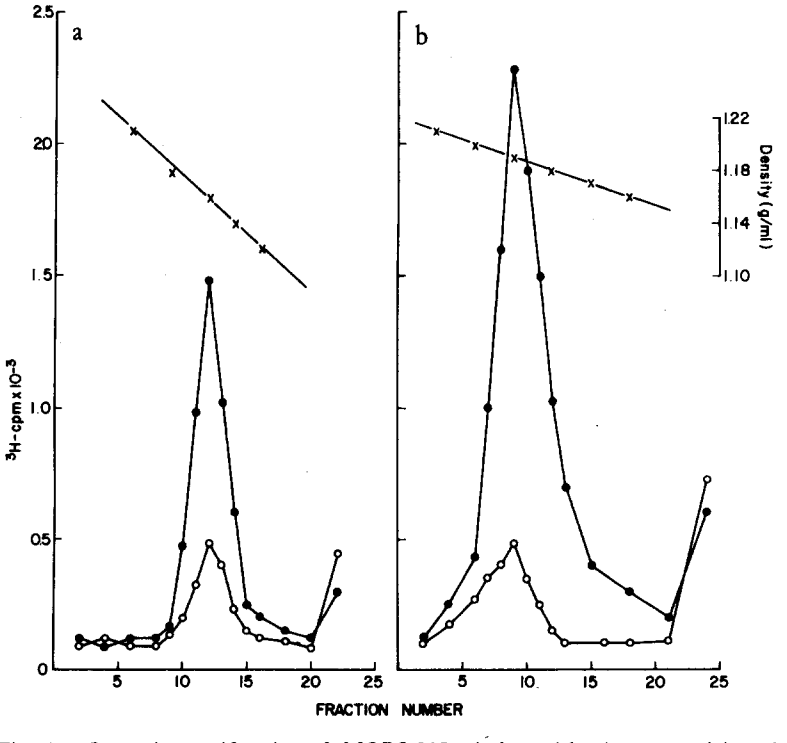

Fig. 1. Isopycnic centrifugation of MOPC-315 viral particles in sucrose (a) and glycerol (b) gradients with [●---●] or without [○---○] DTT. High speed pellets of clarified culture fluids were centrifuged to equilibrium and 20 µl aliquots of gradient fractions were tested for templated DNA polymerase activity. Reaction mixtures were incubated for 30 min at 37°C and assayed for acid-precipitable radioactivity as described in "Materials and Methods".

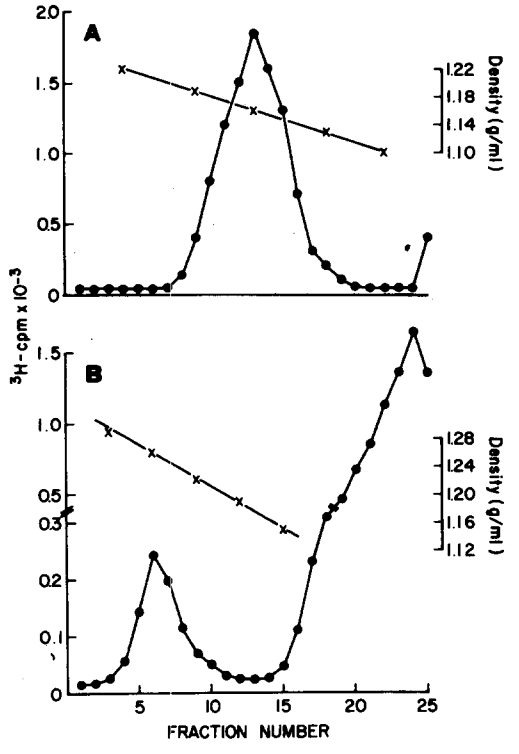

Fig. 2. Conversion of MOPC-315 viral particles to viral cores. ^{3}H-uridine labelled particles were centrifuged to equilibrium in 20–55% sucrose gradient. 20 µl aliquots of the gradient fractions were assayed for acid-precipitable radioactivity (A). Particles concentrated from the 1.15 to 1.18 g/ml density region were treated with NP-40 and subjected to isopycnic sucrose density centrifugation as described in the text. 30 µl aliquots of the gradient fractions were then tested for acid-precipitable radioactivity (B).

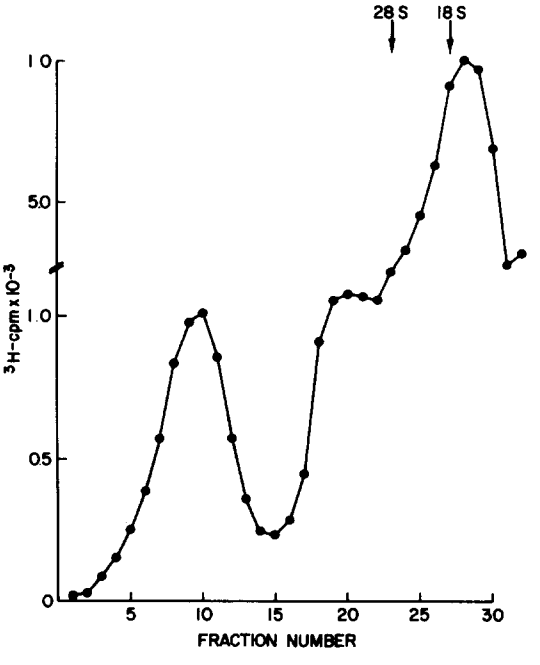

Fig. 3. Rate zonal centrifugation profile of MOPC-315 viral RNA. The nucleic acid was extracted from purified ^{3}H-uridine labelled particles and centrifuged in 10–30% glycerol gradient at 234,000 g for 90 min. Fractions were collected and assayed for acid-precipitable radioactivity. The external markers were 18 and 28 S ribosomal RNA.

tracted from purified ^{3}H-uridine labelled particles and analyzed in a 10–30% glycerol gradient. Two major species of RNA molecules were detected (Fig. 3): a heavy 70 S RNA and a lighter 15 S RNA. Occasionally 35 S RNA molecules, possibly degraded fragments of the high molecular weight RNA, were also detected.

Homology of MOPC-315 particles produced in vitro *to the one obtained from ascitic fluids*

Hybridization kinetic analyses were performed to establish the relatedness of the viral particles secreted by cultured MOPC-315 cells to the particles released *in vivo* by the parental cells. [^{3}H]cDNA prepared in an endogenous reaction of the viral particles isolated from tissue culture fluids of MOPC-315 cells was annealed at identical Crt values to 70 S RNAs extracted from viral particles of both sources (Fig. 4). The fact that both RNA species followed the same hybridization kinetic curve, the nearly identical and low $Crt_{1/2}$ values ($\sim 2.5 \times 10^{-1}$ mol/sec/liter), as well as the final

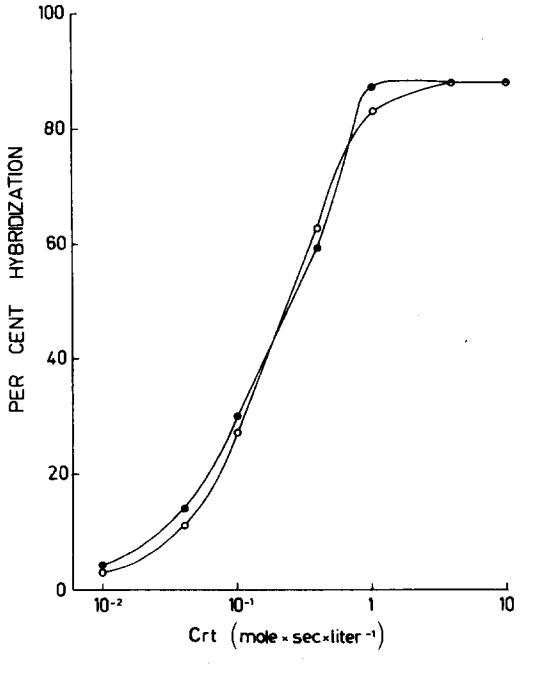

Fig. 4. Hybridization kinetic analysis of RNAs from viral particles produced by MOPC-315 cells grown in vitro (●) *or* in vivo (○). [^{3}H]*cDNA was synthesized in an endogenous reaction of viral particles obtained from cultured MOPC-315 cells. At the indicated Crt values the hybridization reaction was terminated and assayed for the acquisition of S1 nuclease resistance as described in "Materials and Methods".*

extent of hybridization (88%), all suggest that the nucleotide sequences of the examined viruses are indistinguishable.

Infectivity of MOPC-315 viral particles

The infectious potential of the viral particles produced by MOPC-315 cell line was assessed on SC-1 cells known for their high sensitivity to infection by ecotropic viruses of mouse origin [8]. The productive infection was determined by syncytia-inducing effect on XC cells. Syncytia with as many as 10–60 nuclei/cell were observed (Fig. 5). They contained vacuoles and usually were surrounded by a clear area of faintly stained cytoplasm. No syncytia were observed in control cultures.

When [^{3}H]cDNA of viruses produced by cultured MOPC-315 cells was annealed to 70 S RNA obtained from viral particles released by MOPC-315 cells or SC-1 infected cells, very similar $Crt_{1/2}$ values of about 2.2 $\times 10^{-1}$ mole/s/liter were detected. This indicates that the viral particles secreted by the infected SC-1 cells are generally related to the murine myeloma MOPC-315 viruses.

DISCUSSION

C-type particles have been isolated from several cultured murine myelomas [2, 3, 9] and although in all these instances, the viruses were derived from plasma cell tumors of BALB/c mice, they were found to differ in respect to buoyant density, RNA species and presence or absence of RNA-instructed DNA polymerase. In fact, in some of their biochemical features they differ also from the known murine oncornaviruses.

We have previously shown [1] that unlike other murine myeloma type C particles, the viral particles released *in vivo* by MOPC-315 tumor cells possess the ordinary characteristics of murine C-type viruses, i.e. a buoyant density of 1.16 g/ml in sucrose gradients, 60 to 70 S RNA and an RNA-instructed DNA polymerase that transcribes efficiently the viral RNA. The adaptation of MOPC-315 tumor cells to growth *in vitro* has enabled further bio-chemical and biological characterization of the viral particles produced by these myeloma cells. The *in vitro* secreted viruses, like those produced by FLOPC-1 cells [2], are unstable in sucrose and glycerol-TNE gradients. Such instability was not observed in the viral particles secreted *in vivo* by MOPC-315 cells, although the viral genome in both instances was indistinguishable as shown by our hybridization studies. Possibly the higher protein content or other substances in the ascitic fluids of tumor-bearing mice, exert a stabilizing effect on the myeloma C-type particles. A similar difference has been reported also in the case of Rous sarcoma virus where the particles contained in tumor extracts were found to be much more resistant than ones in the tissue culture supernates [10]. Volkman and Krueger [2] were able to partially stabilize the viral particles released from cultured FLOPC-1 cells by using gradients of glycerol in EBSS. Such gradients, however, did not exert any stabilizing effect on MOPC-315 particles. On the other hand, the addition of a reducing agent (DTT) conferred a substantial protective effect on MOPC-315 viral particles, probably by preventing the oxidation effect known to be largely responsible for inactivation of viral particles during their purification [11].

None of the C-type particles isolated thus far from murine myeloma cells has demonstrated any oncogenic potential. Possibly this inability to induce malignancy stems from the biochemical defects that had been detected in them. MOPC-315 viral particles, in contrast, are fully infectious as well as biochemically nondefective. Within the murine myeloma C-type viruses they are therefore a suitable candidate for testing whether this group of viruses is also potentially malignant. This possibility is now being investigated.

Functional Evaluation of Pulmonary Bilateral Irradiation Effects

J. S. ABBATUCCI,* A. BOULIER,† J. FABRE† and J. C. LOZIER*

*Centre François Baclesse, Cedex 14021, Caen, France, †Centre Hospitalier Universitaire, Cedex 14033, Caen, France

Abstract—*Early systematic bilateral pulmonary irradiation is to be considered with interest in patients with tumours which have a high metastatic risk for the lungs. Theoretical considerations show that this irradiation can sterilize from 15 to 30% of infra-radiological pulmonary metastases.*

This whole-lung irradiation is feasible provided that the dose does not exceed 2000 rad in 10 sessions of 200 rad over 2 weeks or 1500 rad in 4 sessions of 375 rad over 7 days (both regimens being equivalent to NSD = 870 rets).

The functional pulmonary deficit is negligible for such a dose but it will be advisable to exclude contraindications such as a chronic respiratory insufficiency or the association of some chemotherapies known as noxious to the lungs.

INTRODUCTION

BILATERAL pulmonary irradiation can be used to prevent the evolution of microscopic metastases potentially present in lungs after curative treatment of tumours giving a high percentage of pulmonary metastases [1–7].

From this standpoint the Radio-Chemotherapy Group of EORTC has studied through a controlled clinical trial the "prophylactic" value of a whole-lung irradiation of 2000 rad in patients treated for osteosarcoma. Breur *et al.* will report the results of this trial [8].

The aim of the present study is to analyze the effects of such a dose on the respiratory functions of 21 cases treated in the Centre François Baclesse [9]. These cases have been submitted to functional pulmonary exploration tests before and after irradiation, at regular intervals, over a period ranging from three months minimum to two years for a few patients.

MATERIALS AND METHODS

Selected patients

Patients entering this study were affected with various types of cancer having a high tendency for metastasizing to the lungs (Table 1).

Primary tumours received preliminary radical treatment (radiotherapy and/or surgery).

Table 1

Localization	Number of cases	Combination chemotherapy
Soft tissue Sarcomas	12	Actinomycin (500 μg X 5) 2 cases
Renal tumour	8	No
All others	3	Cytoxan 1 case

Only three patients had received moderate chemotherapy.

Radiological examination of the lungs, as well as functional exploration and blood-gas were normal before irradiation.

Throughout the follow-up and, in most cases, afterwards, no metastasis occurred radiologically.

Irradiation method

Irradiation was given with Cobalt 60, at a SAD of 80 cm.

The two lungs were irradiated entirely from the top to costodiaphragmatic sinuses without mediastinal protection. Two anterior and posterior opposed fields were used, the two fields being irradiated at each session.

Four doses of 375 rad were delivered over seven days, giving a total dose of 1500 rad calculated at mid-plane in the middle of each lung (Fig. 1).

Accepted 2 December 1977.

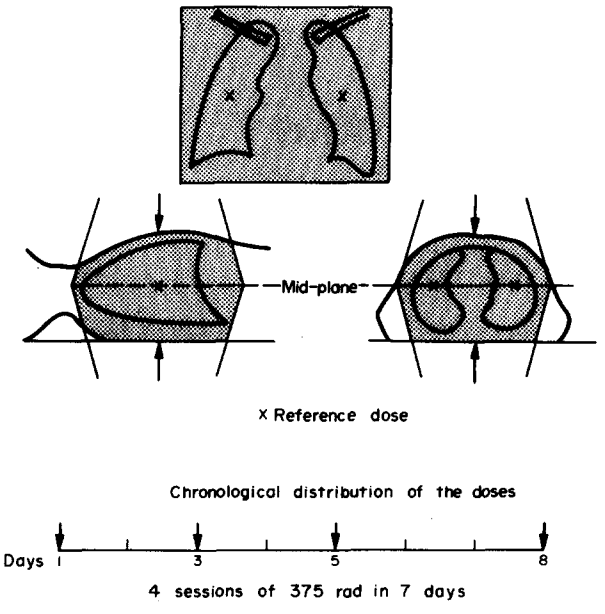

Fig. 1. Target volume and chronological distribution of the doses.

An air correction has been made for the lungs. According to Ellis formula, this treatment corresponds to 870 rets, that is, a dose equivalent to 2000 rad in 10 sessions over 14 days [10].

Functional tests consisted of: classical spirography (vital capacity, residual volume) and a study of carbon oxide transfer by steady state technique with calculation of total and partial ductances recommended by Lacoste [11]. This functional study was completed by an analysis of arterial blood-gas.

Theoretical values used were those of CECA for the spirometry, those of Dechoux and Pivoteau [12] for the carbon oxide transfer.

Chronology of examinations

The protocol included a complete functional study with measurement of blood-gas and radiological control the day before the irradiation. Successive tests took place on the 21st, 90th, 180th, 240th and 300th days. For a few patients, the tests could be continued after two years (three years for two patients).

The number of patients studied appears in Table 2.

RESULTS

General clinical and radiological tolerance was revealed to be good, confirming our previous results [1, 9] and those of many authors.

A slight dyspnea on exertion could however be noted in three patients on the 21st, 90th and 180th days, but never beyond the 6th month.

One patient who did not present clinical signs rasied a radiological alarm when pulmonary micronodules appeared on the 6th month after irradiation. This patient tested 2 yr later, presents neither any late noticeable functional effects, nor any radiological sequellae.

Functional tolerance has been revealed to be satisfactory as is shown by the evolution of the parameters in Table 2 and in the Figs. 2–4.

The pulmonary volumes are not modified and the observed variations (not significant) never exceeded −15%.

Table 2

	Days after radiotherapy	21	90	182	240	300	364	728	990	1200

values)	*P*	0.12	0.14	0.02	0.03	0.13	—	—	—	—

n = number of study patients.
M = average.
s = standard deviation.
P = significance probability of observed deviation.

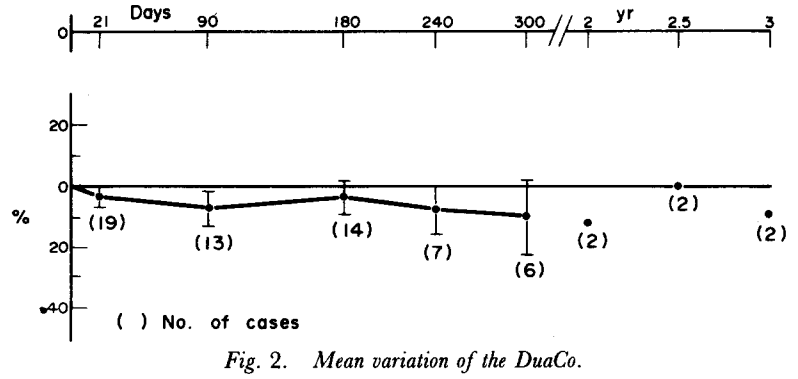

Fig. 2. Mean variation of the DuaCo.

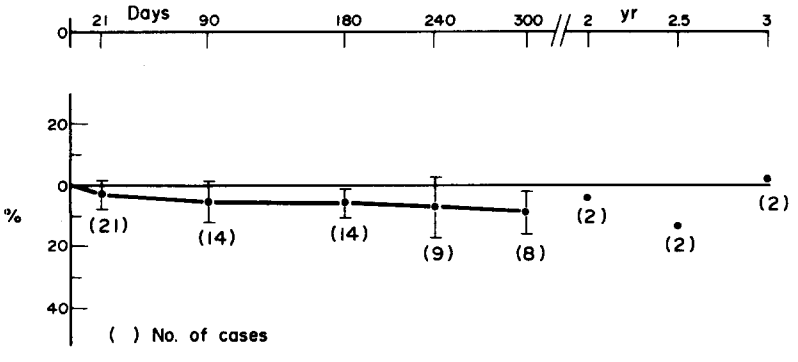

Fig. 3. Mean variation of the PaO2.

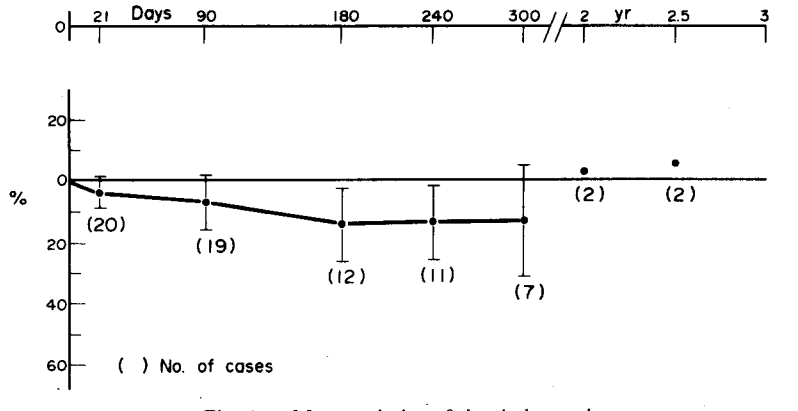

Fig. 4. Mean variation of the vital capacity.

The same is true for the PaO2, which decreased to 6 mmHg on the 180th day ($P = 0.01$).

The functional parameter whose modification is the most significant is without any doubt the alveoloarterial ductance (DuaCo), which explores the flow from the alveolar gas to the blood of the pulmonary capillary. This ductance decreased significantly ($P = 0.02$) from the 21st day, reaching $-8\% \pm 8\%$ on the 90th day ($P = 0.02$) and stabilized thereafter around -10% (standard deviation = 5 – 11%) (Table 2).

These functional modifications, although significant, can be considered to be negligible and do not seem to increase beyond one year's follow-up (Figs. 1–3). However, our material is too limited to allow a definitive conclusion beyond this period.

DISCUSSION

Functional tests can be said to have disclosed an effect of radiotherapy at the selected dose on the lung tissue. This dose can be considered as tolerable as long as pulmonary function is normal before radiotherapy.

The functional picture is very similar to that described by Emirgil [13] and Boushy [14] in man and those of Sweany [15] and

Teates [16] in animals: these authors observed a very pronounced restriction of pulmonary volumes and an important perturbation of gaseous exchanges for irradiation doses around 4000–5000 rad. Sweany investigated the effects of a whole-lung irradiation in animals with a dose of 4000 rad over 8 weeks (260 kV), and found a 54% drop in carbon oxide transfer capacity within 137 days. The observed deficiencies as well as the given doses are without any relationship with those that were stated in the present study.

Other authors performed more or less extensive irradiations with doses ranging from 1380 to 1838 rets. They observed carbon oxide transfer modifications ranging from 17 to 50% [17, 18].

Most of the studies in man concern patients with pulmonary metastases, making functional exploration interpretation difficult.

From the results presented here, it seems inadvisable to deliver doses above NSD 870, which probably can be regarded as the maxima.

Association with chemotherapy requires the radiation-dose to be decreased if the drugs which are used are known to have an action on pulmonary parenchyma [19].

In patients with respiratory deficiency, pulmonary irradiation is contra-indicated if ventilatory deficit exceeds 20% or if there are gaseous exchange disorders. However, in practice, it is necessary to weight the risk of lung metastases and that of inducing respiratory deficiency.

From a carcinological point of view, concerning the effects of such an irradiation, calculations show that 10 sessions of 200 rad over 14 days can destroy up to 30% of the infraradiological pulmonary metastases [2, 4]. It is even possible that the selected fractionation (4 sessions of 375 rad), also equivalent to 870 rets, has an increased effect on tumour cells [20]. The results obtained in the centre François Baclesse are encouraging, especially in soft tissue sarcoma [21].

Hemodialysis and Enzymatic Cleavage of Methotrexate in Man*

STEPHEN B. HOWELL,†‡ HENRY E. BLAIR,§ JACK UREN† and EMIL FREI, III†
†*Sidney Farber Cancer Institute, Boston, Massachusetts* 02115 *and* §*New England Enzyme Center, Boston, Massachusetts* 02111, *U.S.A.*

Abstract—*Renal insufficiency prolongs the serum half-life of methotrexate (MTX) and results in toxicity unless MTX can be removed, detoxified or its biochemical effects reversed. We studied the ability of hemodialysis and* in vivo *enzymatic cleavage with carboxypeptidase G_1 ($CPDG_1$) to reduce the serum MTX concentration in a patient with leukemia and renal failure. On three trials, a* 5 hr *hemodialysis failed to increase the serum MTX clearance or remove significant amounts of drug. On two trials, intravenous injection of $CPDG_1$ caused an immediate* 1.0–1.3 log *unit fall in the MTX concentration measured by a kinetic enzyme assay, but only a minor change in MTX measured by radioimmunoassay. This difference is accounted for by cross-reaction of the product of the enzymatic cleavage of MTX with the antibody used in the radioimmunoassay. This study demonstrates the inability to remove MTX from serum by hemodialysis in patients with high serum levels of MTX and poor renal function and defines some of the difficulties associated with enzymatic detoxification.*

INTRODUCTION

THE COMBINATION of high dose methotrexate (MTX) and leucovorin rescue is an important chemotherapeutic regimen with significant activity in osteogenic sarcoma [1], lymphoma [2] and carcinoma of the head and neck [3]. Significant response rates have also been reported for other human neoplasms [4–6]. The major toxicities of the MTX/leucovorin program are myelosuppression, mucositis and acute renal failure. Since MTX is excreted primarily by the kidneys [7], in the presence of preexisting renal disease or acute renal damage due to the drug itself, the serum half-life is prolonged and this may result in inadequate rescue by standard doses of leucovorin [8]. In such situations, life-threatening marrow and gastrointestinal toxicity is imminent unless serum MTX concentrations can be rapidly lowered, or the biochemical effect of MTX can be reversed.

We report here the results of trials, in a patient with severely imparied MTX excretion, of hemodialysis and enzymatic detoxification of MTX using carboxypeptidase G_1 ($CPDG_1$), a bacterial enzyme that rapidly cleaves the terminal glutamate from MTX.

MATERIALS AND METHODS

Patients

The patient was a 50-yr-old male with chronic myelogenous leukaemia in blast crisis resistant to all standard chemotherapeutic drugs. He had developed acute renal failure three months earlier in association with an episode of septic shock for which he was treated with cephalothin and gentamycin. At the time of these studies, he had a creatinine clearance of less than 1% of normal and required tri-weekly hemodialysis with a Cordis/Dow 1.3 m^2 hollow fiber kidney model 4 to maintain a serum creatinine of 5 to 12 mg/dl. Dialysis was performed at the Peter Bent Brigham Hospital Dialysis Center using regional heparinization.

Because of a rising blast cell count the patient was given three courses of MTX therapy at biweekly intervals at doses of 130, 130 and 400 mg/m^2 administered as a rapid intravenous pulse. On all three courses, thymidine rescue consisting of a continuous infusion of 8 g/m^2/day was started 24 hr

after the injection of MTX and continued until MTX levels measured by radioimmunoassay were less than 5×10^{-8} M. Dialysis studies were performed on the first course of therapy, and during the first 24 hr after MTX injection on the second course. Trials of $CPDG_1$ were carried out on the second and third courses. Written informed consent for these studies was obtained.

MTX and thymidine levels were measured by radioimmunoassay [9, 10]. In the studies involving $CPDG_1$, MTX levels were determined by both radioimmunoassay and kinetic enzyme assay [11]. EDTA 1 mM was added to freshly drawn blood samples to a final concentration of 0.1 mM. We found that this concentration of EDTA completely inhibited $CPDG_1$ and prevented cleavage of MTX during sample transfer and preparation (Uren, J., unpublished observations). The kinetic enzyme assay was performed using *L. Casei* dihydrofolate reductase.* Conditions of the assay were Tris Cl, 50 mM; NADPH, 80 μM; bovine serum 10%; dihydrofolate reductase 2.5×10^{-3} units/ml; dihydrofolate 50 μM; pH 7.4; 37°C. The enzyme was preincubated for 5 min at 37°C with the inhibitor and reaction mixture minus the dihydrofolate, and the reaction was initiated by the addition of dihydrofolate. Percent inhibition was calculated from the ΔOD_{340}/min determined over the initial 10 min of the reaction. In reaction mixtures containing human serum samples, the bovine serum level was adjusted such that the total serum concentration of the mixture was 10%.

$CPDG_1$ was purified from an unidentified gram negative soil bacterium at the New England Enzyme Center. The purified enzyme (specific activity 717 units/mg of protein) was sterilized by passage through a 0.45 μm filter and stored at −20°C at a concentration of 535 units/ml. This material was pyrogen-free on animal testing at 125 and 250 units/kg. For treatment, 4000 units (50 units/kg) were injected intravenously over 10 min. Serum $CPDG_1$ activity was measured as previously described [12]. 4-amino 4-deoxy-N^{10}-methyl pteroic acid (AMP) was a gift of Dr. Andre Rosowsky.

RESULTS

Hemodialysis was performed three times on two courses of MTX therapy. The serum MTX concentrations measured before, during and after dialysis are shown in Fig. 1. On none of the three courses did hemodialysis cause a significant drop in the MTX level over and above the expected change due to continuing excretion through poorly functioning kidneys.

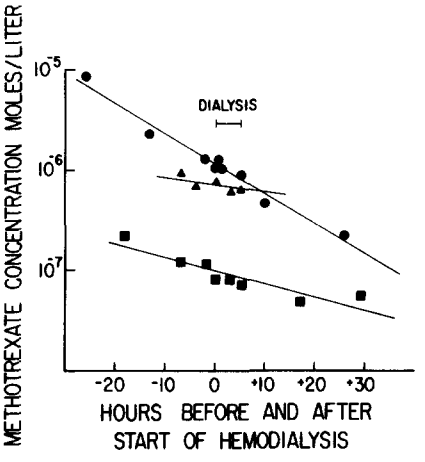

Fig. 1. Change in serum MTX levels during three 5 hr periods of hemodialysis in the same patient. Hemodialysis was performed from hr 50 to 55 (●--●) and 95 to 100 (○--○) after administration of the first course of MTX and from 19 to 24 hr (▲--▲) after injection of MTX on the second course.

Measurements of the MTX clearance across the dialysis coil were made at various flow rates during the first course of dialysis. The data in Table 1 show that the clearance was low at all flow rates tested. Calculations based on the observed clearances indicate that less than 2% of the injected dose was removed by a 5 hr dialysis with a blood flow of 300 ml/min.

$CPDG_1$ cleaves the terminal glutamate from MTX [13], producing AMP which is less cytotoxic than MTX [14]. $CPDG_1$ 50 units/kg was injected intravenously 24 hr after MTX on two courses of therapy. Injection of the enzyme over 10 min caused no change in vital signs and no manifestations of hypersensitivity. The serum MTX levels before and after $CPDG_1$ therapy measured by two different techniques, radioimmunoassay and inhibition of the MTX target enzyme dihydrofolate reductase (DHFR), are shown for both courses in Fig. 2. Within 5 min after completion of the $CPDG_1$ injection, the DHFR kinetic assay detected a 1.0–1.3 log unit decrease in the MTX concentration. Thereafter, serum levels fell with a half-life of 13 and 18 hr on courses one and two respectively. MTX serum concentrations measured by radioimmunoassay showed a different pattern. There was no immediate decrease in MTX

levels or changes in the serum half-life on course one and only a minor fall on course two, and following $CPDG_1$ therapy, measurement became erratic. Although no toxicity developed neither course was evaluable for the effect of $CPDG_1$ by itself on preventing clinical MTX toxicity since thymidine rescue was used concomitantly.

Whereas $CPDG_1$ activity was measurable in serum for many hours, the major effect of the enzyme on MTX concentration measured by the DHFR kinetic assay occurred within the first 5 min after enzyme injection. This discrepancy, plus the differences in serum MTX levels detected by the two assays, suggested that the product of the action of $CPDG_1$ on MTX, AMP, may interfere with the ability of both assays to measure MTX. Studies of the relative binding to the antibody currently used in the MTX radioimmunoassay showed equal affinity for MTX and AMP at concentrations between 10^{-5} and 10^{-8} M. Thus any AMP in the serum would be measured by the radioimmunoassay as MTX, which is consistent with the clinical observations.

Figure 3 shows the relative abilities of MTX and AMP to inhibit the DHFR kinetic assay. AMP is 0.29% to 4.6% as effective as MTX across the significant range of the ki-

netic assay. Thus, if all of the MTX present at the time of $CPDG_1$ injection were converted to AMP, the DHFR kinetic assay would be expected to measure an MTX level of only 1.6 log units lower due to the presence of AMP. This is close to what was actually observed.

Figure 4 shows the measurable enzyme activity as a function of time after injection of $CPDG_1$ on the first course of enzyme administration. The serum half-life of measurable enzyme activity was 6.5 and 4.4 hr on the first and second course of $CPDG_1$ treatment respectively. There was a log-linear fall in serum activity and measurable levels were still present up to 24 hr after injection. The volume of distribution was approximately 6.6 liters, indicating distribution primarily in plasma volume.

DISCUSSION

MTX is a small molecule with a mol. wt of 454. Henderson *et al.* reported that it is 50% bound to serum proteins over the concentration range attained by the high dose MTX/leucovorin program [15]. Based on these properties, MTX ought to be readily removed from blood by hemodialysis. This supposition is supported by the fact that MTX is filtered well across the glomerular basement membrane and that total blood folate levels are reduced by chronic hemodialysis [16, 17]. Several textbooks and reviews have stated that MTX is dialyzable but have not presented any data [18–20]. One brief report indicated that MTX was not readily dialyzable at low serum concentrations [21].

On all three trials in this study, hemodialysis failed to remove significant amounts of MTX. The differences in serum MTX levels before and after the 5 hr dialysis could be accounted for entirely by slow loss of MTX from the blood by other routes. The clearance of MTX by the artificial kidney was found to be low at flow rates of up to 300 ml/min. Extrapolation of the observed clearances indicates that a 5 hr dialysis at optimal flow rates could not have removed more than 6% of the injected MTX dose. In a 70 kg man with a serum MTX level of 1 μM, reduction of the MTX level to a nontoxic range would require removal of more than 95% of the drug. We conclude that hemodialysis is not likely to be useful in the management of patients with toxic levels of MTX and poor renal function. However, more detailed studies are required.

Chabner *et al.* [22] demonstrated that in

mice $CPDG_1$ rapidly reduced MTX levels by more than 10-fold and was as effective a rescue agent as leucovorin. Bertino used $CPDG_1$ (50 units/kg) as a rescue agent five times in three patients, and achieved prompt reduction of serum MTX levels to nontoxic concentrations [23]. The only adverse reaction to $CPDG_1$ observed in man was moderate anaphylaxis associated with the third course of treatment in one of these patients. In the study reported here, two courses of $CPDG_1$ given 13 days apart to the same patient caused no acute or delayed toxicity, and resulted in immediate fall in the MTX concentration of 1.0–1.3 log units measurable by the DHFR kinetic assay.

Several problems were encountered in assessing the results of $CPDG_1$ therapy. $CPDG_1$ activity was detectable up to 24 hr after injection, yet only minor changes occurred in serum MTX levels measured by radioimmunoassay, and what change took place in the MTX levels determined by the DHFR kinetic assay occurred immediately and then appeared to stop. These results can be explained by the following observations. The antibody used in the radioimmunoassay could not distinguish well between MTX and AMP, the product of the action of $CPDG_1$ on MTX. Thus, the radioimmunoassay could not detect conversion of MTX to AMP as shown by the experimental data in Fig. 2. On the other hand, AMP was found to inhibit the DHFR kinetic assay 10-fold less effectively than MTX, which is in agreement with previous reports [14]. Complete conversion of MTX to AMP would thus be expected to cause a 1–2 log unit drop in the MTX level measured by this assay. In fact, on two trials, 1.0 and 1.3 log unit decreases were measured by the DHFR kinetic assay, suggesting that $CPDG_1$ may have converted all the MTX present to AMP.

Enthusiasm for the use of $CPDG_1$ to detoxify MTX must be qualified by two important considerations. First, $CPDG_1$ is immunogenic. Repeated treatment has caused anaphylaxis in one patient [23], and has the potential of further compromising poor renal function by precipitating serum sickness or other pathologic processes associated with circulating antigen-antibody complexes. Secondly, very little is known about the toxicity of AMP. No toxicity was recognized in the 4 patients treated with $CPDG_1$ and limited screening has shown no antitumor effect against murine leukemia [14]. However, AMP is less soluble than MTX and could cause significant crystal-induced nephrotoxicity itself.

Abstract—*Our previous studies demonstrated a lack of correlation between sequential lymphocyte reactivity and clinical tumor progression in patients with surgically incurable malignant melanoma. The purpose of the present investigation was to determine whether sequential lymphocyte reactivity correlated with recurrence of disease in melanoma patients with little if any tumor burden. Sixteen stage* I and II *patients with a high risk of recurrence following potentially curative surgery were given adjuvant chemotherapy with dimethyl triazeno imidazole carboxamide (DTIC). Nine patients subsequently relapsed and 7 remained disease free for at least* 44 *months. Each patient was tested for sequential lymphocyte reactivity using cryopreserved lymphocytes and a standard allogeneic melanoma cell line in a microcytotoxicity assay designed to minimize technical variation. No statistically significant difference was found in sequential reactivity between patients who relapsed and those who did not, although lymphocytes from disease free individuals did exhibit a slightly greater increase in reactivity when compared to lymphocytes from patients who recurred. We conclude that the microcytotoxicity assay performed in this way is of little prognostic value in patients with relatively low tumor burdens.*

INTRODUCTION

RECENT publications [1–4] have described a lack of correlation between *in vitro* lymphocyte cytotoxicity assays and clinical tumor progression. However, in only two studies [3, 4] were serial assays performed and in only one [4] was an attempt made to standardize the day-to-day variations in test results. In the present investigation, we tested stage I and II melanoma patients who had definitive surgery (but were at high risk for recurrence) and whose lymphocytes had been cryopreserved throughout the post-operative course. In a retrospective study of sequential lymphocyte reactivity (microcytotoxicity) we attempted to detect a difference in patterns of reactivity between those patients who relapsed and those who remained clinically tumor-free. Thus, we evaluated lymphocyte reactivity serially, in patients with little (if any) residual tumor under circumstances designed to minimize technical variables.

MATERIALS AND METHODS

Lymphocyte donors

The melanoma patients studied for lymphocyte reactivity (microcytotoxicity) all had local (stage I) or regional (stage II) disease and were all subjected to potentially curative surgery. Entry to the present study was based on a high risk of recurrence: histologically positive regional lymph nodes and/or a primary lesion invasive to Clark's levels III, IV or V [5]. The clinical profile of the study

patients is presented in Table 1. Of interest, 11 of 16 patients had histologically positive regional lymph nodes. The general immunologic profile of the melanoma patients is presented in Table 2. As assessed by these parameters, the study patients were immunologically competent.

Between 4 and 8 weeks following definitive surgery, all patients were started on adjuvant chemotherapy with dimethyl triazeno imidazole carboxamide (DTIC): 2 mg/kg/d × 10 days (IV), every three months × 5. Blood samples for lymphocytes and serum were collected immediately prior to the initiation of each cycle of chemotherapy and every three months following completion of chemotherapy until relapse or for 20–22 months in patients who remained disease free. Non-relapsers were defined as those patients who remained disease free for at least 44 months after surgery and relapsers were those patients found to recur no sooner than 6 months after surgery.

Microcytotoxicity assay

Lymphocytes were separated from heparinized blood on a Ficoll–Hypaque gradient and stored in liquid nitrogen as described previously [6]. Blood from melanoma patients was allowed to clot at room temperature. The sera were separated by centrifugation, and stored at −20°C. Immediately prior to use, the sera were heat inactivated at 56°C for 30 min. A single melanoma cell line (M14), pooled and stored in liquid nitrogen as previously described [6], was used as the target cell throughout this study.

Our modification of the Takasugi and Klein [7] microcytotoxicity technique has been described in detail elsewhere [6]. Each experimental and control group consisted of 8 replicate wells. Prior to addition of lymphocytes, either heat inactivated fetal calf serum (FCS) diluted 1/6 with Prehn's modification of Eagle's medium (PEM; Associated Biomedic Systems, Inc., Buffalo, New York), or serum autologous to the lymphocytes being tested (also diluted 1/6 with PEM), was added to the target cells in 0.01 ml amounts. Patient's lymphocytes in PEM containing 20% FCS were then added to the target cells (300 lymphocytes/target cell) and the mixture incubated for 48 hr. The remaining melanoma cells were stained and counted as previously described [6]. To minimize test variation, pretreatment and post-treatment lymphocyte samples from a single patient were on the same plate. In addition, on each plate there were 8 wells containing target cells plus FCS diluted 1/6 with PEM.

Criteria for analysis

Changes in lymphocyte reactivity after surgery were determined by linear regression analyses. Student's *t*-tests were calculated to compare the slopes obtained for each patient in the presence of FCS and in the presence of patient's serum. Several comparisons of these slopes were made by the standard analysis of variance. Relapsers were compared with non-relapsers for reactivity both in the presence of fetal calf serum and in the presence of patient's serum.

RESULTS

To determine the change in reactivity, lymphocyte samples from each of the 16 melanoma patients studied were retrieved from liquid nitrogen and tested simultaneoulsy against allogeneic melanoma cells (M14) as described in Materials and Methods. All the lymphocyte samples collected during the 20–22 month period following surgery were tested for the non-relapsers (Fig. 1), while those of relapsers (Fig. 2) were tested up to the date of clinical recurrence.

Student's *t*-tests indicated that for each patient there was no significant difference between the slope of lymphocyte reactivity in the presence of FCS and in the presence of

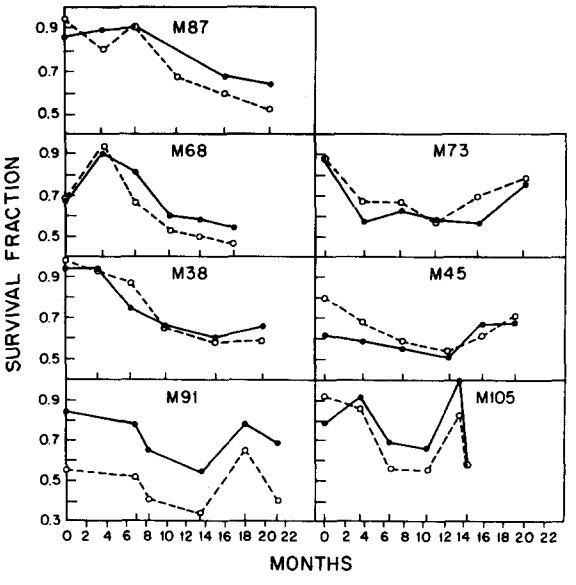

Fig. 1. Sequential reactivity against M14 melanoma cells of lymphocytes plus patient's serum (——) and lymphocytes plus fetal calf serum (– – –) from 7 stage I or II melanoma patients who were disease free ≧44 months following definitive surgical therapy. Survival fraction was calculated by dividing the number of tumor cells in wells containing lymphocytes plus serum by the number of tumor cells in the wells containing medium alone.

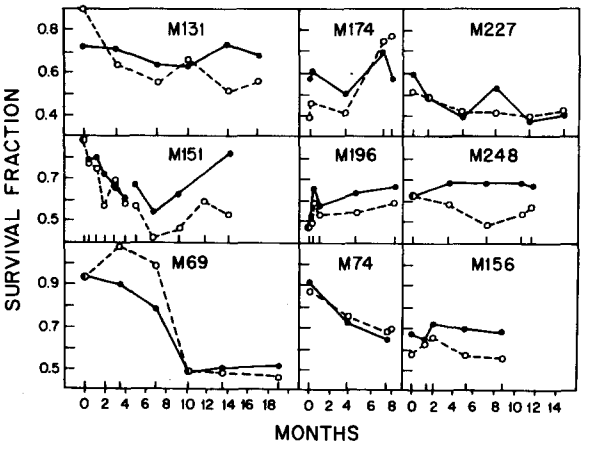

Fig. 2. Sequential reactivity against M14 melanoma cells of lymphocytes plus patient's serum (——) and lymphocytes plus fetal calf serum (– – –) from 9 stage I or II melanoma patients who relapsed between 7 and 20 months following definitive surgical therapy. Survival fraction was calculated by dividing the number of tumor cells in wells containing lymphocytes plus serum by the number of tumor cells in wells containing medium alone.

patient's serum, although the slope in the presence of FCS was often steeper.

Comparisons between relapsers and non-relapsers by the standard analysis of variance indicated no significant difference in slopes, although both in the presence of FCS and in the presence of patient's serum the average of the slopes was steeper for non-relapsers than for relapsers.

Linear regression analyses were also run after pooling data for each group and ignoring differences among patients. Again the slopes were not significantly different from each other, although again the slopes for the non-relapsers tended to be a bit steeper than those of the relapsers.

DISCUSSION

Several investigators have attempted to correlate the results of a single lymphocyte microcytotoxicity (LMC) assay with prognosis. Veronesi *et al.* [1] studied 18 stage I and II melanoma patients who had been subjected to potentially curative surgery. Seven of 12 LMC-positive patients relapsed (mean 8.4 months) as did 5/6 LMC-negative patients (mean 8.0 months) (P=N.S.). Nairn *et al.* [2] were also unable to correlate results of LMC testing with prognosis; 3/5 LMC-positive patients recurred. (The relapse rate for LMC-negative patients was not reported.) A firm conclusion regarding the prognostic value of a single LMC assay cannot be drawn from these preliminary data. Only a modest number of patients have had LMC measured serially. Hellström *et al.* [3] performed sequential studies of LMC in 10 melanoma patients. LMC was present in patients who were tumor-free or who had small tumor burdens as well as in patients with larger tumor burden. The data suggested that patients with more modest tumor burdens had more intense LMC than did patients with larger tumor burdens. In individual patients, LMC varied widely with time and was not useful prognostically. Pavie-Fisher *et al.* [4] used frozen lymphocytes and two long-term target cell lines in their serial studies of 25 patients (8 tumor bearing) for up to 10 months. In only 12/25 patients was LMC noted at least once. Despite this attempt at standardization of test conditions, wide variation in results was noted and there was no correlation with prognosis. The authors suggested that the variable cytotoxic capacities of control lymphocytes may have been a contributory factor. Heppner *et al.* [8] performed multiple LMC assays on a number of patients but these generally spanned a short time interval and no effort was made to correlate the LMC assay data with prognosis.

These studies may have failed to demonstrate a positive correlation between the results of the LMC assay and prognosis for a variety of clinical and technical reasons. Few patients have been studied serially through a protracted disease free interval to recurrence. Even when serial studies are performed, day to day variations in assay conditions make comparisons of data points on the same patient difficult. The important technical variables have been previously discussed in detail [9] and include: the target cell, effector cell to target cell ratio, inconsistent cytotoxicity of control lymphocytes, and duration of incubation. In the present study, an attempt was made to minimize these technical variables. One subculture of a single allogeneic melanoma cell target was used throughout. The effector cell to target cell ratio was constant. Medium and not "normal" lymphocytes was used as a control. Lymphocytes were cryopreserved and all samples on a single patient were tested on the same day and on the same plate. Further serial sampling over time allowed each patient to serve as his own control. In order to insure a homogeneous study population, with, at most, micrometastatic disease, patients who relapsed in less than six months following surgery were excluded. Despite these precautions, the present study failed to demonstrate a correlation between LMC data and prognosis.

The inability to distinguish between patients who relapsed and those who remained disease free could have been a result of several other factors. First there was a suggestion, although not significant, that the non-relapsers increased in lymphocyte reactivity to a greater degree than relapsers. A greater difference might have been masked by the chemotherapy. Since postsurgical patients receiving no treatment were not available for study, the effect of the DTIC treatment could not be determined. However, we were unable to demonstrate a significant difference in pre- and post-DTIC treatment LMC assays in patients bearing clinically evident melanoma [10]. Secondly, some of the non-relapsers may recur at a later date and thus were wrongly classified. To minimize this possibility, only patients who were disease free for a prolonged period (>44 months) were used as controls. The median disease free interval for relapsers was 12 months compared with 46 months for non-relapsers. Finally, despite indications of a

common melanoma antigen [9], allogeneic systems may not be appropriate for measuring tumor immunity. The use of autologous tumors in this study would have been completely impractical because of the numbers of patients involved.

Serum blocking activity may correlate more closely with prognosis than the LMC assay [3, 9]. Autologous serum effects were assessed serially in the present study and failed to distinguish those patients who relapsed from those who remained disease free. However, the conventional calculation of serum blocking effect (i.e. target cell survival in the presence of patient's lymphocytes and patient's serum minus target cell survival in the presence of patient's lymphocytes and control serum) was not attempted because the tests with patient's serum were not performed on the same plates as the tests with control serum.

In summary, it appears that the lymphocyte microcytotoxicity assay, as performed here, does not correlate with melanoma progression.

Ewing's Sarcoma, Adjuvant Chemotherapy and Pathologic Fracture

J. G. ROSENSTOCK,* PATRICIA MORRIS JONES, DOROTHY PEARSON† and M. K. PALMER
Christie Hospital and Holt Radium Institute, Manchester M20 9BX, England

Abstract—*Between* 1970 *and* 1975, 19 *patients under age* 15 *with Ewing's sarcoma have been treated with adjuvant chemotherapy in addition to radiotherapy to the primary tumour. The chemotherapy regimen of vincristine and cyclophosphamide was not rigorously structured and evolved over the six years. The two most recent patients have also had adriamycin. The median survival of* 45 *months is statistically better than the* 18 *months experienced by the* 31 *children treated without adjuvant chemotherapy from* 1956 *to* 1969. *Eight pathologic fractures have occurred in* 6 *of the* 19 *patients on adjuvant chemotherapy. Only one of the fractures was at diagnosis. The other* 7 *fractures occurred from* 3 *to* 72 *months following diagnosis with a median of* 6 *months. There were only* 3 *pathologic fractures in the* 31 *patients treated without adjuvant chemotherapy—two were at diagnosis and one was at a metastatic site. The increased risk of pathologic fractures appears to be related to the adjuvant chemotherapy.*

INTRODUCTION

THE EFFECTIVENESS of chemotherapy for microscopic metastases in Ewing's sarcoma [1, 2] has been supported by the recent experience (1970–1975) at the Christie Hospital and Holt Radium Institute and the Royal Manchester Children's Hospital. Analysis of the results of the patients treated with adjuvant chemotherapy suggest an increased risk of pathologic fractures unrelated to simple increased length of survival. In this era of chemotherapy which has generally increased the rate of cure in most childhood sarcomas and embryonal tumours the risk of therapy and quality of survival need to be observed closely. Children who are cured may well carry the side effects of therapy for many decades. As therapy regimens are refined, hopefully cure rates can be increased while reducing both short- and long-term morbidity.

MATERIALS AND METHODS

By 1970 the Christie Hospital and the Royal Manchester Children's Hospital had become the established centre in a large area of Northwest England for the care of children under 15 with malignancies. The Manchester Children's Tumour Registry's case finding method as well as pathology review system has been previously described [3, 4]. The registry shows that all patients in the geographical area from 1970 had been referred to the Christie Hospital following diagnosis and it also served as the source for the control group of children treated before 1970. The diagnosis of Ewing's sarcoma was accepted as such if a child was so listed in the Children's Tumour Registry.

The chemotherapy plan for the period 1970–1975 was not rigorously structured and evolved over the 6 yr of the study. However, the basic concept of frequent doses at moderate levels of vincristine and cyclophosphamide for at least one year remained consistent throughout the study. A total of 19 patients, 14 of whom had no metastases at diagnosis, were treated during the 6 yr period (1970–1975). Therapy evolved through three phases. The first 11 patients received vincristine 1.5 mg/M^2 alternating with cyclophosphamide 300–400 mg/M^2 weekly for 6 months, then the two drugs were given together every two weeks for 6–12 months more. The chemotherapy plan for the next 6 patients was changed so that the two drugs were given initially, in approximately the same doses as before, every two weeks together for 6 months, and then every month for one further year. Finally, because of very favourable phase two data [5] adriamycin has been

Accepted 28 November 1977.

*J. G. Rosenstock, present address: Children's Hospital of Philadelphia, 1, Children's Center, 34th and Civic Center Boulevard, Philadelphia, Pensylvania 19104, U.S.A.
†Reprints: Patricia Morris Jones, Christie Hospital and Holt Radium Institute.

added to the regimen of the most recent 2 patients. The chemotherapy programme remains as for the previous six patients, except that a single dose of adriamycin 40 mg/M^2 is given in addition every 6 weeks for 1 yr.

The radiation therapy has remained consistent for all patients since 1956. The radiation has been delivered to the whole affected bone, to a dose of 4000–4500 in three weeks at 4 MeV. It has not been possible to achieve this dose and fractionation for all of the flat bone lesions.

The control group consists of 31 patients treated from 1956 through 1969. Three of these 31 had amputations of the involved bone as primary therapy while none of the 19 patients since 1970 had an amputation as primary therapy. The age, sex and primary tumour sites of the two groups is delineated in Table 1. Evaluation of the patients treated before 1970 following their irradiation was not regimented though they usually had both chest and local lesion diagnostic X-rays every 1–3 months for the first year, and slightly less frequently during the second year. Since 1970 the patients have had diagnostic X-rays of the chest and local lesion routinely at least every one to two months for the first year and then every three months for the next 2 yrs. Other diagnostic tests were done as clinically indicated.

Table 1. *Ewing's sarcoma, Manchester* 1956–1974. *Age, sex and site of primary tumour*

	Control	Chemotherapy
No. of patients	31	19
Age range	2–14	<1–14
Median	8	11
Sex: male	17	12
female	14	7
Primary site		
Upper extremity	7	6
Lower extremity	15	5
Pelvis	5	4
Other	4	4

Statistical note

Curves for survival, local recurrence, metastases and pathological fracture were calculated by the product-limit method [6], and statistical significance of differences between groups of patients was analysed by the log-rank method [7].

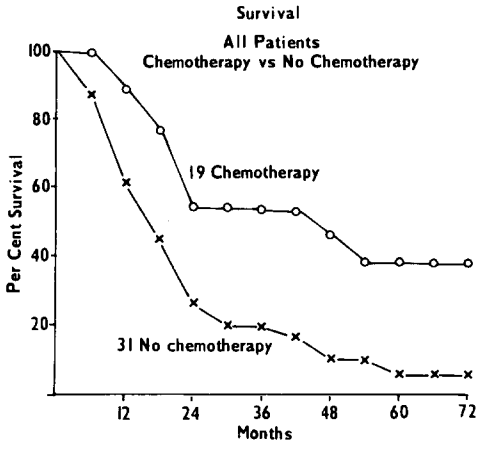

Fig. 1.

RESULTS

Survival

Of the 31 patients treated before 1970 only 2 survive while 11 of the 19 treated since 1970 are alive (Fig. 1). Of these 11 survivors, 3 are alive with disease. The median survival for the patients treated without chemotherapy was 18 months while it was 45 months for all patients treated with chemotherapy. For the 14 patients who had no evidence of metastases at time of diagnosis and treated with chemotherapy, seven are alive and disease-free for 10, 17, 22, 22, 63, 68 and 69 months (Fig. 2). One patient with a primary tumour in the distal femur, a positive groin node by biopsy and an abnormal lymphangiogram at diagnosis, is alive over 6 yr and has been off all therapy almost 5 yr. The difference in survival for the total group treated before chemotherapy compared to the group of 19 treated with chemotherapy is significant at the $P<0.01$.

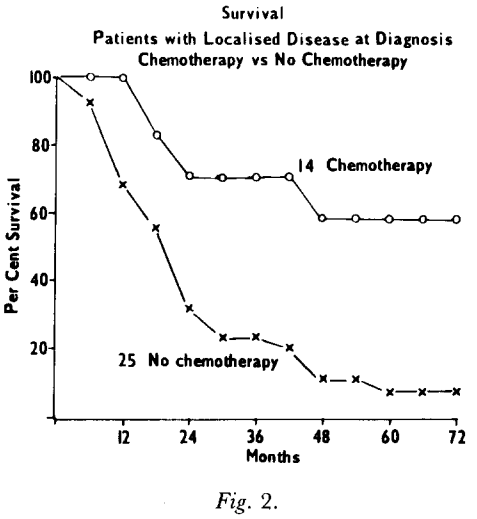

Fig. 2.

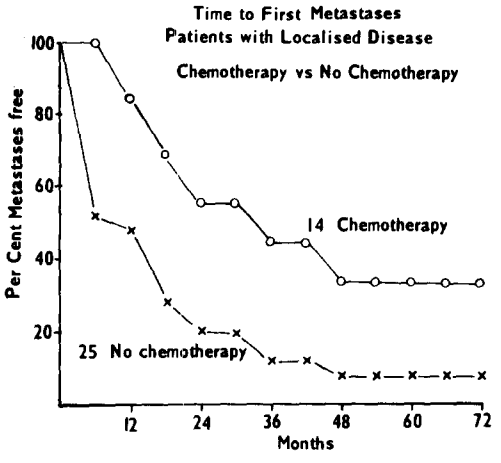

Fig. 3.

Metastases

As can be seen in Fig. 3, the rate of metastasis is greatly reduced in those patients who were disease-free at diagnosis and treated with adjuvant chemotherapy. The difference is significant at the 1% level. In the chemotherapy group, metastases did develop as late as 46 months from diagnosis though late metastases also occurred in the non-chemotherapy group.

Local recurrence

The 19 patients who were treated with chemotherapy had 3 local recurrences compared to 9 local recurrences in the 31 patients treated before 1970. Another patient on chemotherapy had radiographic changes consistent with a local recurrence five months following radiotherapy. An amputation was done, but no viable tumour was found and he remains well 5 yr later. The 3 local recurrences in patients treated with chemotherapy were at 13, 14 and 34 months. In the pre-chemotherapy group the local recurrences were diagnosed from 3 to 31 months from initial diagnosis and in 2 of these 9 the local recurrences were noted after there was evidence of distant spread. Analysis suggests that the frequency of local recurrence has been reduced by the chemotherapy though the P value (0.056) is not quite small enough for statistical significance.

Complications

Two patients in the pre-chemotherapy group developed significant complications. In one child diagnosed with a tibial Ewing's sarcoma at age 3, deformity secondary to the radiotherapy led to an amputation at age 7. She remains well 18 yr from diagnosis. In a second child who was 13 at diagnosis of her tibial Ewing's sarcoma, a local recurrence 17 months later was treated with local excision. However, she required an amputation due to poor local healing following this second procedure.

The chemotherapy was very well tolerated. There were no episodes of severe bone marrow depression and no episodes of sepsis or local infection. Reduction of the dose of cyclophosphamide or lengthening of the interval between doses was rarely indicated. There were two episodes of haemorrhagic cystitis. One occurred after 4 months of therapy and another after 12 months. Cyclophosphamide was discontinued in both, and both patients developed pulmonary metastases within 4 months and died.

Six of the nineteen patients treated with chemotherapy have developed 8 pathologic fractures at the primary tumour site. (Table 2). Only one of these fractures was at diagnosis and this patient has had a second pathologic fracture at 68 months from diagnosis. The other patient to develop two pathologic

Table 2. *Pathologic fractures in patients treated with adjuvant chemotherapy*

Patient	Primary site	Months from diagnosis of pathologic fracture	Results
WD	Distal femur	0	Union
		68	Immobilized
ND	Proximal tibia	8	Union
		72	Immobilized
GP	Proximal femur	3	Non-union
AF	Proximal humerus	4	Union
PF	Proximal humerus	6	Union—24 months later X-ray evidence of recurrence. Amputation. No tumour microscopically
JB	Pubis	6	Union—local recurrence 8 months later

fractures had his first fracture at 8 months and his second at 72 months following diagnosis. The median time to pathologic fracture was 6 months. Of the 8 fractures, 5 have healed following immobilization, two remain immobilized and one is a non-union. In only 1 of the 6 has a local recurrence been diagnosed and that occurrrd 8 months following fracture. Two patients have had fractures in upper extremities and 3 patients have had 5 fractures in lower extremities. It is also of interest that a 14-yr-old girl who was initially diagnosed as having a Ewing's sarcoma of the right eighth rib and treated accordingly with radiation and vincristine and cyclophosphamide, had her diagnosis eventually changed to undifferentiated sarcoma and is not included in this analysis. However, she developed a pathologic fracture 4 yr after diagnosis and it has failed to unite.

In contrast only 3 of the 31 patients treated before 1970 have developed pathologic fractures—two were at the primary site at the time of diagnosis and one was at a metastatic site. This increase does not appear to be due to greater length of survival in the chemotherapy group, but apparently to other factors since most pathologic fractures in the chemotherapy group were before the median survival time of the control group.

DISCUSSION

These results are consistent with other reports that adjuvant chemotherapy in Ewing's sarcoma markedly increases the length of disease-free survival and that it apparently improves the cure rate [8]. This series like all others to date is too small, considering all the prognostic variables, to determine which therapy regimen is most effective [9]. Programmes using similar therapy have produced comparable results and have been reviewed [8]. The report from Memorial Hospital, where a much more aggressive regimen for both radiotherapy and chemotherapy was used, appears to have better initial survival rates [10].

Two aspects of this study show very important changes produced by chemotherapy. Reviews of radiotherapy doses to sterilize the primary site have shown a plateau effect somewhere around 4500–5000 rad [11, 12]. Local recurrence rates have tended to be about 25% even in lesions irradiated above 6000 rad. However, in this series the rate of local recurrence tends to be lower in those patients who have received chemotherapy. This suggests that the chemotherapy is able to affect the local tumour, as suggested by Fernandez [12]. Why increasing doses of irradiation are unable to sterilize tumours that responded initially, is problematic. However, the prolonged courses of cytotoxic therapy may well be able to penetrate revascularized bone or affect cells when they come out of a resting phase. Increasingly higher doses of irradiation may only serve to increase local morbidity of both the bone and soft tissues, especially in growing children [13].

The high incidence of pathologic fractures appears to be a new problem. The occurrence of these fractures seems to be unrelated to length of survival, weight bearing or significant local trauma. None of the 8 fractures occurred after significant trauma and they occurred in both upper and lower extremities. This increase must be related to the addition of chemotherapy since the radiotherapy regimen at this institution has not changed during the time of the study. Hustu, Pinkel and Pratt [14] mention that 2 of their 15 patients also sustained pathologic fractures. Pathologic fractures of the pelvis and neck of the femur and of the humerus following radiation for uterine and breast tumours respectively, have been well documented [15, 16]. The radiographic bone changes produced following different energy irradiation has recently been well described [17].

The incidence of fractures in our patients is extremely high though all were treated with 4 MeV irradiation which is apparently less damaging to bone than lower energy irradiation. The radiation dose used is significantly lower than that of many other centres. Howland *et al.* [17] described a latent period for fractures whose mean is 3 yr. The short latent period in our group suggests added insults from the primary lesions as well as from the chemotherapy. The chemotherapy may act as a radiomimetic agent and it may also affect bone healing. Little is known about the effects on bone of cyclophosphamide and vincristine though cyclophosphamide can affect the development of ossification centres in foetal rats [18]. Another chemotherapeutic agent, methotrexate, is known to affect bone metabolism [19] but the mechanism of action of this agent is quite different from those of vincristine and cyclophosphamide. Pathologic fractures may become a major form of long-term morbidity in these patients.

The therapy of pathologic fractures under these circumstances remains to be evaluated. One of Hustu's *et al.* [14] two fractures became a non-union. Two of our fractures are too recent to speculate on the outcome. Boyes (1974) [20] reported a woman who, 6 months after diagnosis of a reticulum cell sarcoma of the femur, developed a pathologic fracture. Several types of internal fixation, besides bone grafts, were used to gain stabilization. The non-union persisted for 12 yr, but the internal fixation had stabilized the bone.

The use of operative therapy for these fractures should probably remain a last resort to be explored. How well damaged bone and skin will tolerate internal appliances as well as heal, needs to be evaluated.

Announcements

CANCER OF THE GENITOURINARY TRACT

"Cancer of the Genitourinary Tract" will be the topic of the 23rd annual Clinical Conference to be held in Houston at the Shamrock Hilton Hotel, 2–3 November, 1978. The conference will focus on alternatives in therapy for urological malignancies. Co-chairmen: Dr. Douglas E. Johnson and Dr. Melvin L. Samuels.

For additional information: Stephen C. Stuyck, Information Coordinator, M. D. Anderson Hospital and Tumor Institute, Houston, Texas 77030.

INTERNATIONAL SYMPOSIUM ON THE DIAGNOSIS OF LIVER METASTASES

The E.O.R.T.C. (European Organization for Research on Treatment of Cancer) is organizing an International Symposium on The Diagnosis of Liver Metastases which will take place in Brussels on 30 November–2 December, 1978 at the Institute of Sociology of the University of Brussels (U.L.B.).

The Symposium will analyse the various diagnostic methods currently used and their optimal combination for the detection of liver metastases. The technics concerned are: Ultrasonography, Radionuclide imaging (Scintigraphy), Computed Tomography (CT-Scan) and Peritoneoscopy.

The Organizing Committee: H. Bleiberg, J. Frühling and M. Osteaux, Jules Bordet Institute, 1, rue Héger Bordet, 1000 Brussels, Belgium

FOURTH CONGRESS OF THE MEDICAL ONCOLOGY SOCIETY, NICE, FRANCE

2, 3 and 4 December, 1978

Direct inquiries to: Pr. M. Schneider, Centre Antoine-Lacassagne, 36, Voie Romaine, 06054 Nice, Cedex, France.

SECOND INTERNATIONAL CONFERENCE ON THE ADJUVANT THERAPY OF CANCER

The Second International Conference on the Adjuvant Therapy of Cancer will be held in Tucson, Arizona, 28–31 March, 1979, under the sponsorship of the Cancer Center Division of the University of Arizona. Drs. Sydney E. Salmon and Stephen E. Jones will serve as Conference Co-Chairmen. The deadline for submission of abstracts (prepared in the format of AACR/ASCO) is 1 December, 1978. For further information, write to:
Ellen Gerrity,
Conference Coordinator,
Cancer Center Division,
University of Arizona,
Tucson, Arizona 85724.

Abstract—*Extensive early polykaryocytosis was consistently observed in mixed cultures of bovine leukemia virus (BLV) infected ovine cells and mouse sarcoma virus infected cat cells. It is shown that syncytia are induced by the BLV infected cells. There is a quantitative, but non linear relationship, between the amount of BLV infected cells and the syncytia response. Polykaryocytosis is at least partially mediated by complete leukemia virus or by some of the envelope and internal antigens. The reaction is specifically inhibited by bovine sera known to contain antibodies directed against BLV, but not by normal sera.*

Quantitative studies permitted to develop a simple, rapid and reliable in vitro *assay aimed at the detection of BLV related antibodies (EPI). The methodology to be applied for the analysis of the results and for the comparison of the potencies of different sera is described.*

A preliminary application of the assay to the survey of BLV infection in cattle gave results in accordance with those obtained in a parallel survey performed with the hematological and the complement fixation techniques. However, a higher sensitivity was found in the former. In addition, the sera of calves with lymphosarcoma and one case of cutaneous lymphosarcoma were found to react positively in the EPI assay suggesting that BLV genes are also involved in the sporadic forms of the disease.

INTRODUCTION

SYNCYTIAL formation was described by Cornefert-Jensen and her collaborators [1] in cocultures of certain cell lines with leukemic bovine lymphoid cells. They later found that sera from cattle with lymphosarcoma inhibited the formation of syncytia [2]. Although they referred to the causative agent as bovine syncytial virus, it was morphologically like a C-type virus and unlike the foamy-like bovine syncytial virus (BSV) described by Malmquist *et al.* [3]. A bovine C-type (leukemia) virus (BLV) released by cultured lymphocytes was described [4] and further shown to be involved in cattle leukemogenesis. Large scale surveys aimed at the detection of BLV infection in cattle using immunofluorescence [5, 6], immunodiffusion [7] and complement fixation [8] techniques gave results comparable to those previously obtained by Cornerfert-Jensen *et al.* [2].

Accepted 5 December 1977.

*This work was supported by the Institut National de la Santé et de la Recherche Médicale (Contrat Coopératif sur Programme 025), the European Communities (Research Contract n° CEE 00000 100) and the French Ministry of Agriculture (Convention de Recherche, Direction des Services Vétérinaires, Leucose Bovine).

The syncytia inducing ability of bovine leukemic cells was further investigated by Diglio and Ferrer [9] who found that this property could be attributed to BLV itself. They thus proposed a procedure for the titration of virus-neutralizing antibodies [10]. The syncytia that they described appear after a relatively long incubation period and the results of assays were evaluated after 4–8 days.

In addition to this cytopathogenic effect, Irgens *et al.* [11] found that syncytia were repeatedly obtained when the BLV infected fetal lamb kidney cell line (FLK-BLV) established by van der Maaten and Miller [12] was cocultivated with the murine sarcoma virus infected cat cell line (CC 81) prepared by Fischinger and his associates [13]. These syncytia were very abundant, with a maximum amount observed as soon as 24 hr after initiation of the cocultures. In addition, their size was most often considerably larger than previously reported. These observations prompted us to further investigate this phenomenon.

In this report we demonstrate the following: syncytia are induced by the BLV infected cells; there is a quantitative, but non linear relationship, between the number of BLV infected cells and the syncytia response; polykaryocytosis is at least partially mediated by complete bovine leukemia virus or by some of the envelope and internal antigens; the finding that the reaction is specifically inhibited by bovine sera, known to contain antibodies directed against BLV, but not by normal sera permitted us to develop a simple *in vitro* early polykaryocytosis inhibition (EPI) test, the results of which are obtained in 24 hr.

The EPI assay and the methodology to be applied for the analysis of the results and for the comparison of the potencies of different sera is described in this study. A preliminary application to the survey of BLV infection in cattle is also reported.

MATERIALS AND METHODS

Animals and sera

The hematological status of all animals studied was determined according to the leukosis evaluation guide of Bendixen [14].

Cow 333, a case of persistent lymphocytosis (LP), is maintained in our laboratory facilities. Its hematological status and virus production in cultures of buffy coat cells were previously described [15]. Serum 1121 of this cow has complement fixing antibodies to BLV antigens [16, 17]. Several samples of the serum were extensively used as reference in the studies on syncytia inhibition. Cow LB 44 was a referral case of adult lymphosarcoma (LSA); buffy coat cells of this animal release abundant C-type virus particles upon cultivation and the serum contains complement fixing antibodies. The control normal cow (H) kept in our facilities for several years has a normal blood picture and all the above tests were negative.

Serum 647 is from a cow with LP and was used directly or after centrifugation (50,000 ***g***, 1 hr) a procedure which increases the potency of the sera in EPI assays. Sera 1 to 11, kindly referred to us by Dr. C. Olson, were described elsewhere [18]. Serum 461 is from a cow with no hematological and immunological signs of leukemia or lymphocytosis and which belongs to a leukemia-free herd.

The other sera of cows with adult lymphosarcomas (LSA), juvenile lymphosarcomas (LSJ) or cutaneous lymphosarcoma (LSC) were from referral cases. Those from clinically and hematologically normal contact animals (NC) and from cows with LP were found in an epidemiological survey. The sera from normal cattle (N) were randomly selected in leukemia-free herds. All sera were heat inactivated (56°C, 10 min) prior to use in early polykaryocytosis inhibition assays.

Anti foamy-like bovine syncytial virus (BSV) serum 449 was generously supplied by Dr. J. F. Ferrer (School of Veterinary Medicine, University of Pennsylvania, New Bolton Center, Kennett Square, Pennsylvania). This serum was obtained from a cow in the BLV-free study herd BH [10] and is negative for BLV antibodies.

Cell cultures

Fetal lamb kidney cells chronically infected with the bovine leukemia virus (FLK-BLV) were kindly supplied by Dr. M. J. van der Maaten and Dr. J. M. Miller [12] (National Animal Disease Laboratory, U.S. Department of Agriculture, Ames, Iowa). Electron microscopic observation of these cells revealed abundant C-type virus production and no apparent cell degeneration associated with virus release. There was no evidence of mycoplasma or of other viruses common in cattle. The virus found in FLK-BLV cell cultures was indistinguishable by immunological and biochemical means from the virus obtained from cultures of bovine leukemic or lymphocytotic lymphocytes [12, 19].

The murine sarcoma virus infected cat cell line, CC 81 [13] was a gift of Dr. Péries (Institut de Recherche sur les Leucémies et les Maladies du Sang, Laboratoire d'Hématologie Expérimentale, Hôpital Saint-Louis, Paris, France).

The above cell lines were maintained as monolayers in RPMI 1629 culture medium supplemented with 10% heat inactivated (56°C, 30 min) foetal calf serum, 100 units/ml penicillin, 100 μg/ml streptomycin and 100 μg/ml fungizone.

Large amounts of lymphoid cells were obtained either by continuous flow centrifugation of whole blood as described elsewhere [17], or by the improved ammonium chloride solution method of Odajima and Sonoda [20]. Stationary cultures were prepared in RPMI 1640 spinner modified culture medium containing the same additives as for monolayer cell cultures.

BLV concentration and purification

The culture fluid used for the growth of FLK-BLV cells was the *in vitro* source of BLV. After differential centrifugation, the pellet was resuspended in buffer (Na_2HPO_4-citrate 0.02 M pH 7, NaCl 0.1 m, EDTA 0.001 M) and subjected to isopycnic centrifugation in preformed gradient of 20–50% sucrose in the same buffer (95,000 ***g***, 16 hr).

BLV antigens

All preparations of BLV antigens were made from virus purified by gradient centrifugation. For BLV internal antigens, 20 vol of peroxide-free ether were mixed with the BLV suspension and continuously agitated for one hour. Ether was then eliminated by evaporation in nitrogen. The aqueous phase was collected and the soluble internal antigens were clarified by centrifugation (100,000 ***g***, 1 hr).

In order to expose virion surface antigens more specifically, a method previously described (17) was employed. In brief, suspended purified BLV was fixed with 1.2% glutaraldehyde for 3 hr at 4°C. After dilution of the treated BLV preparation in phosphate buffered saline (PBS) and centrifugation (50,000 ***g***, 2 hr) the sedimented material was resuspended in a small volume of the same buffer and used as antigen. A control preparation was made in the same manner after concentration and purification of an equivalent amount of mouse radiation leukemia virus complex, Duplan isolate (RadLV-D) produced by the 13-3-C cell line [21].

Absorption experiments

To absorb with viral preparations, 0.125 ml reference serum 1121 was preincubated with an equal volume of virus internal antigen or glutaraldehyde-treated virus preparations. In some cases, the same volume of serum 1121 was mixed with 0.0625 ml virus internal antigen and the same volume of glutaraldehyde-treated virus preparations. After 1 hr incubation (37°C), the residual titer of the reference serum was estimated by the syncytia inhibition assay. The culture fluid of bovine cell cultures was also used as antigen. For this, 0.25 ml serum 1121 was mixed with 5 ml culture fluid. After incubation (1 hr, 37°C) the volume was brought back to 0.25 ml by Minicon B 15 concentration and the titer of the serum estimated as above.

To absorb with cells, FLK-BLV cells in culture and bovine leukocytes either cultured for 48 hr or non cultured were suspended in 0.25 ml PBS and incubated with an equal volume of serum 1121 for 1 hr at 37°C. After centrifugation (4000 ***g***, 10 min) the titer of the serum was determined.

Complement fixation technique

The technique described by Miller and van der Maaten [8] was used after modification as previously reported [16].

Syncytia assay

FLK-BLV and CC 81 cells, in culture medium supplemented with five times the usual amount of penicillin and streptomycin, were seeded at the desired combinations of concentrations into the wells of Falcon Microtest II tissue culture plates. These were then tightly closed with a sealing tape and placed in an ordinary incubator (37°C) for 14–24 hr. After washing three times with PBS, the monolayers were fixed with methanol (70%) and stained with Giemsa. The presence and number of syncytia per well were monitored with an inverted microscope (magnification 60) by examining the whole surface or only 8 mm^2, depending on syncytia concentration. Counts were performed at least in duplicate wells.

Early polykaryocytosis inhibition (EPI) assay

Two procedures were used for serum titrations; they are detailed in Table 1 and the

rational of the different steps explained in section "Results". The complete procedure requires careful counting of syncytia in FLK-BLV and CC 81 cell cocultures performed in Falcon Microtest II tissue culture plates, whereas the simplified EPI assay needs only an approximate overall eye estimation. In both cases, results may be obtained 24 hr after planting FLK-BLV cells. The titers of the sera are expressed as the reciprocal of the dilution which gives a 50% reduction of the number of syncytia as compared to the non treated controls cultures (50% syncytia inhibitory dose or SID_{50}). Mathematical and statistical treatments of the serum dose–syncytia inhibition response curves were performed after probit transformation of the response as described by Finney [22, 23]; details on the graphical method using logarithm-probability paper were given by Litchfield and Wilcoxon [24].

RESULTS

Respective roles of CC 81 and FLK-BLV cells in syncytia formation

In preliminary trials, mixtures of FLK-BLV and CC 81 cells were cocultivated so as to

obtain a confluent or nearly confluent monolayer after 24 hr incubation, a condition in which syncytial cells are easily visualized.

Concentrations between 0.5×10^4 and 2.0×10^4 CC 81 cells permitted an optimal visualization and numeration of syncytia. The trials were repeated varying the concentration of FLK-BLV cells. As shown in Table 2, the number of syncytia per well (s) increases with the concentration of both CC 81 and FLK-BLV cells. The average size of the syncytia was not constant. Indeed we noticed that they were small or very small when scarce, the number of nuclei increasing with the number of syncytia. The data also indicate that the ratio $100s$: number of FLK-BLV cells per well increases, but not proportionally with CC 81 cell concentration and decreases with FLK-BLV cell concentration. This kind of relationship suggests that if a syncytium originates from "contact" between the two kinds of cells, several CC 81 cells are required for its formation, whereas several FLK-BLV cells could participate in the induction of the same syncytium. This could also explain why the number and size of the syncytia increase simultaneously. The role of FLK-BLV cells as actual inducers of syncytia is also supported by experiments in which less than 100 ovine cells were seeded with numerous CC 81 cells or the proportions reversed. Indeed, whatever the amount of FLK-BLV cells, syncytia were observed only when the cat cells were in a sufficient number.

In the following experiments the concentration of 2.0×10^4 CC 81 cells per well was used because the number and size of syncytial cells obtained in cocultures even with a wide range of FLK-BLV cells concentration, was the most appropriate for an accurate numeration.

Correlation between FLK-BLV cell concentration and syncytia formation

As FLK-BLV cells appeared to be the actual syncytia inducers, it was important, for an ultimate use in different types of assays, to investigate the relationship between the number of syncytia appearing in cocultures of CC 81 and FLK-BLV cells and the concentration of the latter. Cocultures were seeded with 2.0×10^4 CC 81 cells per microtest well and a range of 15 FLK-BLV cell concentrations extending from 2.5×10^2 to 2.1×10^4 cells per well. Between 4 and 6 wells were prepared per concentration of FLK-BLV. The result was not a direct relationship between the number of syncytia per well (s) and the concentration of FLK-BLV cell (c), but the logarithm of s was found to be proportional to the logarithm of c (Fig. 1). The equation of

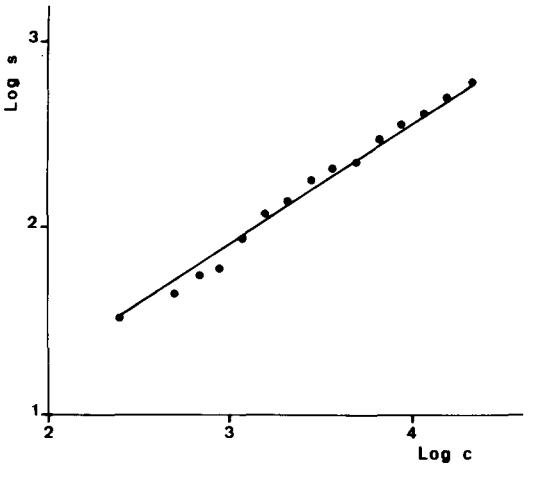

Fig. 1. Effect of the concentration of FLK-BLV cells on early polykaryocytosis in mixed cultures with CC 81 cells.

§Number of syncytia per well.
‖Ratio $\frac{\text{number of syncytia per well}}{\text{number of FLK-BLV cells per well}} \times 100$.

the representative curve can be theoretically expressed as:

$$\log s = k \log c + b. \quad (1)$$

For two reasons b can be estimated to be nil or close to nil. First, the ratio $\log s : \log c$ was found approximately constant for the 15 concentrations and comprised between 0.604 and 0.653 and on the other hand, syncytia were not encountered in control CC 81 cultures. Therefore equation (1) becomes

$$\log s = k \log c \quad \text{or} \quad (2)$$

$$s = c^k. \quad (3)$$

Experimental data permit to estimate $k = 0.6346 \pm 0.0146$.

This relationship indicates that one FLK-BLV cell is sufficient to induce one syncytium and that all FLK-BLV cells are equivalent in their syncytia inducing activity. With increasing concentrations, more FLK-BLV cells seem to cooperate to the formation of each syncytium, a phenomenon which is associated with an increase of the nuclei content per syncytial cell. An important application of equation (3) is the theoretical evaluation of the concentration of FLK-BLV cells required to obtain a desired number of syncytia per well:

$$c = s^{k^{-1}} \quad (4)$$

In most of our experiments we used the combination 5.0×10^3 FLK-BLV cells with 2.0×10^4 CC 81 cells per well. In these conditions, syncytia are of a sufficient size (generally comprised between 10 and 100 nuclei per cell) and number and adequately dispersed in the monolayer for an accurate numeration.

Even when standardized conditions were used in assaying FLK-BLV cells, limited fluctuations of the amount of syncytia induced were often observed from one experiment to another. These fluctuations could be ascribed to differences in the state of FLK-BLV cells at the time of removal from the maintenance cultures; therefore the influence of cell age after subculturing was investigated. Parallel FLK-BLV cell cultures were initiated at different densities in such a way that any part of the cell growth curve could be obtained. At daily intervals and for each concentration, a culture was removed, the cells counted and kept frozen until assayed in the same experiment for their ability to induce syncytia on CC 81 cells. As shown in Table 3, apart from degenerating aged cultured (96 hr) in which cells may have a reduced syncytia inducing potency, the variation factor of the amount of syncytia per FLK-BLV cell does not exceed 1.5. This result further indicates that in their usual conditions of maintenance FLK-BLV cells retain a constant syncytia inducing ability.

Inhibition of syncytia formation with bovine sera

Sera from cattle with persistent lymphocytosis (LP) or with the adult form of lymphosarcoma (LSA) were assayed for their eventual ability to inhibit syncytia formation in cocultivated FLK-BLV and CC 81 cells. The results obtained with sera 461 (normal), 1121 (LP) and 11 (LSA) are representative. Whereas, the sera from clinically and hematologically normal cows from leukemia-free herds do not interfere with syncytia formation at any dilution, the sera from animals with LP or LSA inhibit syncytia formation with different potencies, and their effect is dependent on the concentration of the serum added. When the percentage of syncytia in-

hibition is plotted against the logarithm of the serum concentration (Fig. 2) one can observe that the slopes of the linear part of the representative curves are comparable. This suggests that syncytia inhibition represents the same type of reaction for different sera. In the same type of assay, anti-BSV serum 449 does not interfere with syncytia formation.

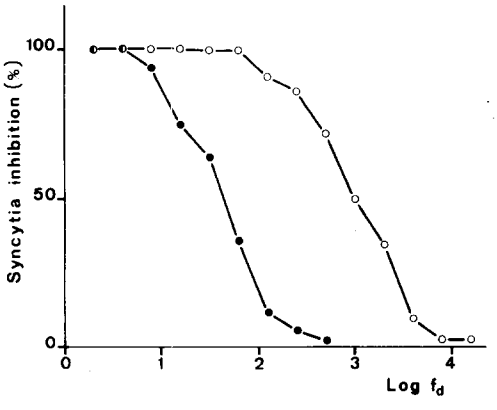

Fig. 2. Typical dilution assays of bovine sera using early polykaryocytosis inhibition. Plot of the percentage of syncytia inhibited versus the logarithm of the dilution factor (f_d). Serum 1121 *is from a cow with persistent lymphocytosis* (●) *and serum* 11 *from a case of bovine adult lymphosarcoma* (○).

These results support the hypothesis that FLK-BLV cells express on their surface or that they release substances responsible for syncytia induction recognized by antibodies contained in the sera of BLV infected animals. As syncytia are also induced by BLV infected bovine lymphocytes but not by normal lymphocytes cocultivated with CC 81 cells (unpublished results) it is logical to assume that syncytia inhibiting substances in the sera of diseased animals might be antibodies associated with BLV.

Absorption of bovine serum with BLV antigens

Bovine serum 1121 was preincubated with BLV antigens prior to assaying its syncytia inhibiting activity. Table 4 shows that preincubation of the positive serum with ether-treated BLV soluble antigens i.e. most likely internal antigens, resulted in a significant reduction of the titer; a similar result was obtained by use of a glutaraldehyde-treated BLV preparation, in which only viral envelope antigens are exposed to the serum action. The titer of the same serum was not modified when the preincubation was performed with a mouse leukemia virus (RadLV-D).

These data suggest that the inhibitory effect of a positive serum on syncytia formation is at least partially due to antibodies directed against some internal antigen(s) and BLV surface antigen(s), and conversely, that syncytia induction by FLK-BLV cells is mediated, at least in part, by these antigens.

Absorption of bovine serum with BLV infected cells or their growth medium

In an attempt to localize the BLV antigens responsible for syncytia formation, absorption of a bovine positive serum (1121) with BLV infected cells or their culture fluids was carried out prior to testing its inhibitory activity on syncytia induction. FLK-BLV cells, lymphocytes from cows with LP (333) or LSA (LB 44), both BLV infected as well as non BLV producing lymphocytes from cow (H) were used in these experiments. The lymphocytes were either not cultured, so no complete viral particles were released, or cultured for 48 hr, a condition for virus release by BLV infected lymphocytes.

‖A vol of 100 ml 13-3-C culture fluid was used.
¶Absorption performed with half the volume used in (1) and half the volume of (2).

The titers of the serum after the different absorption experiments are shown in Table 5. Uncultured lymphocytes have no significant effect on the serum titer whereas cultured LP or LSA lymphocytes or FLK-BLV cells reduce significantly the inhibitory activity of the serum on syncytia formation. Cultured lymphocytes which do not produce BLV have no effect. The culture fluid of BLV infected lymphocytes significantly reduces the titer of the absorbed serum. In contrast, the culture fluid of normal lymphocytes has no effect.

‖Lymphocytes LB44 are from an adult cow with lymphosarcoma.

¶Lymphocytes 333 are from a cow with persistent lymphocytosis.

**Figures between parentheses indicate the number of cells used in these experiments.

Our results suggest that the syncytia inducing activity of BLV infected cells is mediated in part by BLV antigens displayed at, or closely associated with, the cell membrane and in part by BLV or BLV antigens released by these cells. Quantitative data also support the possibility that in cocultures of BLV infected cells and CC 81 cells, BLV or BLV released antigens play a more pronounced role in syncytia induction than the cells themselves.

Probit transformation of the percentage of syncytia inhibition by bovine sera

More than 100 sera were assayed for their syncytia inhibiting activity. FLK-BLV cells at a concentration of 5.0×10^3 per well were preincubated with serial dilutions of log 2 intervals of the sera and cocultivated with 2.0×10^4 CC 81 cells per well.

No linear relationship was found between the number or the percentage of syncytia inhibited and the dilution. After logarithmic transformation of the dilution factor, the representative curve was partialy linear, and could permit an approximate estimation of the SID_{50} (Fig. 2). However, in these conditions only part of the information contained in the dilution assay could be taken into account. The examination of such a dose–effect relationship indicates that the rate of increase in response per logarithm of unit of dose (or of the dilution factor) is very low in the regions of 0 and 100% response and much higher in the intermediate regions. These characteristics are well exemplified in the representative serum assay curves which are of the sigmoid type.

Although the dosage–response in our serum assays is not strictly quantal, a probit transformation of the response can be applied for a better evaluation of the median effective dose according to Finney [22, 23]. Indeed, the use of probits instead of the real percentages, and of weighting coefficients for each observation result in the transformation of the normal sigmoid curve into an almost straight line and allows a more accurate determination of the SID_{50}. In these conditions a regression curve fitting all dose–response data for any serum can be drawn and the SID_{50} can be determined either graphically or by computer calculation.

The estimate of the logarithm mean effective dose or mean effective dilution factor (log SID_{50}) is the value of the intercept of the regression curve with $y = 5.0$ and the SID_{50} its antilogarithm.

The accuracy of the SID_{50} can be estimated using the variance (V) of log SID_{50} and the determination of a value of χ^2 to test for homogeneity of the data. The fiducial limits of log SID_{50} with 95% confidence are

$$\log SID_{50} \pm 1.96V. \quad (5)$$

Figure 3 shows such a probit transformation of the effect of bovine serum 647 on syncytia inhibition as a function of the logarithm of the

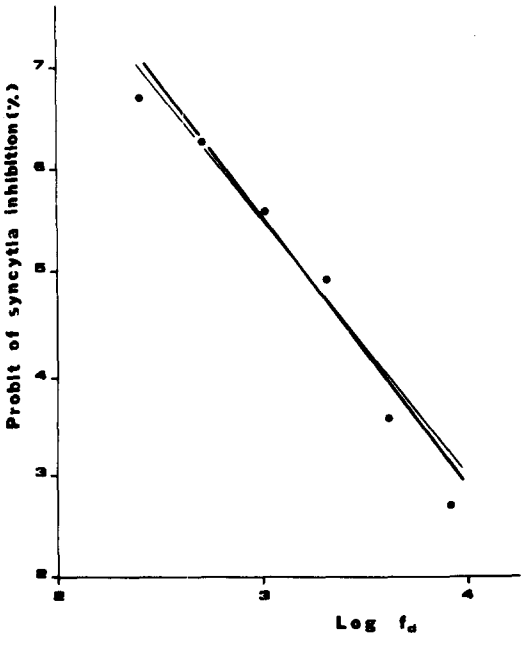

Fig. 3. Probit transformation of the percentages of syncytia inhibited by the serum of a cow with persistent lymphocytosis (647) after log 2 serial dilutions (f_d refers to the dilution factor; experimental data (●), empirical probit regression line (—), probit regression line (——).

serum dilution factor used. The regression was calculated and found linear according to equation

$$y = -2.615x + 13.346$$

and for $y=5.0$, x or log $SID_{50}=3.1916$, and $SID_{50}=1554$; the calculated linear regression is compatible with the experimental data ($P=0.02$) and the dilution factor corresponding to 50% inhibition is comprised between 822 and 2940 ($P=0.05$).

The fiducial limits found in this example are in the order of magnitude generally observed and the limits of the SID_{50} are roughly $\pm 50\%$ of its value (with 95% confidence). Therefore, we found convenient in most of the assays to replace the above methodology by a graphical method using "log-probit" graph paper on which the percentage of the probits is plotted against logarithm. In this way, the SID_{50} of serum 647 was evaluated as 1650 which is close to the calculated estimation and well inside of the fiducial limits. Figure 4 shows the graphical representation obtained with some sera from cattle with LSA (11,545), LSJ (5), LP (1121 and 647) and of a contact animal (640); it also shows that the slopes of the different representative assay curves are almost identical. The consistency of this observation favors that the syncytia inhibition reaction is of the same type and that the sera differ only by their relative syncytia inhibiting potencies.

Normalization of the expression of serum titers

Moderate fluctuations of the number of syncytia obtained with a fixed amount of FLK-BLV cells were frequently observed and probably due to inherent experimental errors even when standardized conditions of the assay were used. These variations were found to influence noticeably the results obtained in serum assays in such a way that the titer was diminished with increasing amounts of syn-

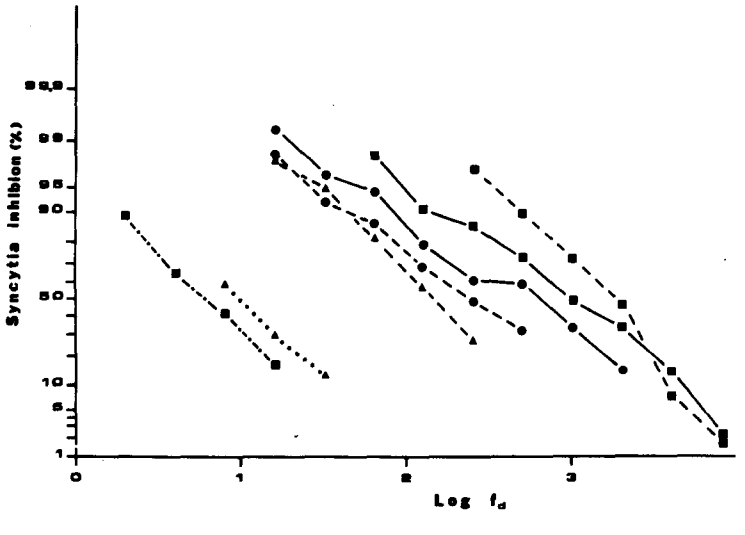

Fig. 4. Representation of the percentage of syncytia inhibition versus the logarithm of the serum dilution factor (f_d) as obtained by use of log-probit graph paper. Serum 640 is from a normal contact animal (-·-■-·-), 5 from a case of juvenile lymphosarcoma (···▲···), 647 (--●-- before centrifugation; --■-- after centrifugation) and 1121 (--▲--) are from animals with persistent lymphocytosis (—▲—), 545 (—●—) and 11 (—■—) are from cases of adult lymphosarcoma.

cytia in parallel non treated-control cultures and conversely. Thus, in order to compare the syncytia inhibiting activities of different sera, i.e. their potency, it was necessary to further investigate the influence of the number of syncytia on the estimation of the serum titer.

Serum 1121 was assayed in coculture combinations containing 2.0×10^4 CC 81 cells and 14 serial (log 1.33) FLK-BLV cell densities extending from 0.50×10^3 and 21.07×10^3 cells per well. After graphical measurement of the SID_{50} of serum 1121 in the different types of mixed cultures, a direct relationship between the logarithms of the titer (SID_{50}) and the amount of syncytia (s) could be ascribed in the limits of the FLK-BLV cell concentrations used (Fig. 5) according to equation:

$$\log SID_{50} = K \log s + b. \quad (6)$$

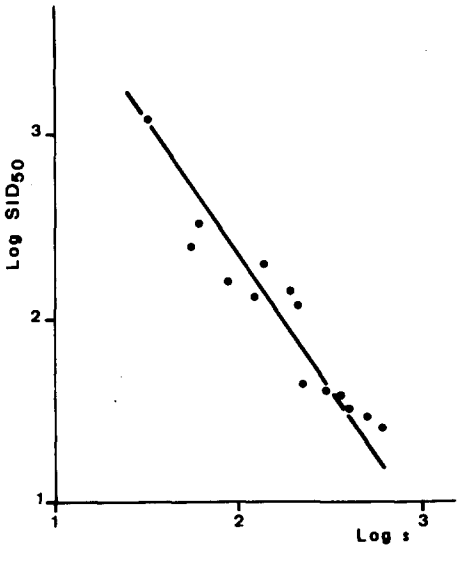

Fig. 5. Plot of the titer (SID_{50}) of serum 1121 (a case of persistent lymphocytosis) versus the logarithm of the number of syncytia in non serum-treated control cultures.

The calculus with experimental data indicates that a curve with equation:

$$\log SID_{50} = -1.2161 \log s + 4.7147$$

can be adjusted with 99% confidence; K must be comprised between -1.1052 and -1.2548 if 95% confidence limits are chosen.

In equation (6), b is dependent upon the inherent syncytia inhibiting potency of the particular serum tested and is not related to the number of syncytia obtained in the assay. Since the slopes (k) of the titration curves (equation 2) obtained with different sera were found almost constant, suggesting the same type of reaction, they also imply that the only differences between sera are their relative concentration in "syncytia inhibiting factor(s)" and therefore that the slope (K) of the representative curves corresponding to equation (6) remains constant whatever the serum assayed. In these conditions, the relation between the titer of a serum and the number of syncytia allows a normalization of the expression of the titer; with $SID_{50}N$ for the normalized titer of the serum, and S for the reference amount of syncytia, the equation (6) becomes:

$$\log SID_{50}N = K \log S + b \quad (7)$$

and from equations 6 and 7

$$SID_{50}N = SID_{50} \times (S/s)K. \quad (8)$$

This relation was applied to normalize the serum titers in different assays using $S = 300$, as such a quantity of syncytia is easily counted and allows a good estimation of the titers of sera with a low inhibiting activity.

Table 6 shows the consistency of $SID_{50}N$ calculated for several values of s with the serum (144$\hat{1}$) of a cow with persistent lymphocytosis.

Simplified early polykaryocytosis inhibition test

When a great accuracy of the serum titer was not required, like it is most often the case in routine serum titrations, the complete assay procedure was found quite unnecessary. Indeed, 100% and no inhibition can be easily seen without any count and the SID_{50} can be visualized fairly correctly even by a non trained experimentator.

As shown in Table 6, the SID_{50} determined by direct observation agreed well with those obtained by probit analysis and fell well inside of the 95% confidence limits. As the numbers of syncytia are not determined in this simplified assay, the titer of a serum must be estimated by comparison to a known reference serum previously titrated using the complete assay method. In a single experiment, if (R) and (A) denote the reference and the serum assayed, the following relation can be used:

$$SID_{50}N(A) = SID_{50}(A) \times \frac{SID_{50}N(R)}{SID_{50}(R)}. \quad (9)$$

Table 6 also shows that the use of the simplified EPI test gives $SID_{50}N$ estimates which are close to those obtained with the complete procedure.

Application of the EPI test to a preliminary survey of BLV infection in cattle

In a cooperative work, 11 reference bovine sera, kindly supplied to us by Dr. C. Olson, were blind assayed using both the EPI and the complement fixation technique. Table 7 illustrates the confrontation of our results with those obtained in 13 other laboratories with techniques routinely used in serological surveys aimed at the detection of BLV infected cattle (immunodiffusion, immunofluorescence and complement fixation) and totalizing 23 separate assays. Whereas we detected complement fixing antibodies only in the sera recorded as positive by other laboratories, early polykaryocytosis inhibition was observed with all. Indeed 2 sera were found completely negative in all other tests and one had only a slight complement fixing activity as detected by 3 laboratories including ours. It is noticeable that these sera which had low but significant $SID_{50}N$ originated from one calf with lymphosarcoma and two contact control animals previously non suspected of BLV infection. This observation supports the hypothesis whereby the EPI test detects antibodies that may not be revealed by the aforementioned methods.

The EPI and CF techniques were used in parallel in a preliminary survey including 105 bovine sera (Table 8). These sera were obtained from hematologically and clinically normal animals from leukemia-free herds (N), normal contact animals (NC), animals with persistent lymphocytosis (LP), with the adult from of lymphosarcoma (LSA), juvenile lymphosarcoma (LSJ) and cutaneous lymphosarcoma (LSC).

The results obtained with the EPI test are the following: among the animals which could be considered as suspect of BLV infection, the 6 with LSA were found positive with generally high titers (average 977); all those with LP were also positive with somewhat lower titers (average 104); the 4 LSJ, the LSC and all but one NC were positive with low titers (respective averages 16, 16 and 28); none of the N had a significant titer.

A similar pattern was obtained with the complement fixation technique, but the percentages of positive sera were smaller in all animal categories. Better agreement was found for clinically leukemic adult and hematologically suspect animals. The percentage was much smaller in animals with a normal hematologic picture but which could have been infected with BLV (NC). None of the LSJ or LSC were detected.

As it could be expected, a highly significant correlation was found between titers obtained in EPI and CF tests. Although it is possible that the two assays do not reveal quanti-

tatively and/or qualitatively the same antibodies, both detect BLV infection, and the main difference for use in a survey lies in their threshold of sensitivity. Indeed, in most cases, when the $SID_{50}N$ of a serum is nil, the titer is also nil by CF and, on the average, complement fixing antibodies are only detected when a titer higher than 60 is obtained with the EPI test.

DISCUSSION

Formation, morphology and frequency of syncytia appearing in cocultures of the BLV infected ovine cell line, FLK-BLV, and the murine sarcoma virus infected cat cell line, CC 81, are noticeably different from those described by several authors [1, 2, 9, 25, 26]. Indeed, in contrast to the previous observations of small or medium size syncytia, detectable only after a relatively long incubation period and in most studies in an unpredictable amount, our previously reported results [11] show that giant cells appear as soon as one hour after cocultivation of FLK-BLV and CC 81 cells. The maximum amount of syncytia is consistently observed after 24 hr incubation, thus allowing routine and reliable numerations. The size and the nuclei content of these giant cells are also larger, since cells containing more than 100 and up to 500 nuclei may be abundant in cocultures depending on the cell densities. The rapidity of appearance of the syncytial cells and the marked similarity between their nuclei and those of single CC 81 cells suggest that polykaryocytosis occurs by fusion of CC 81 cells rather than by repeated endomitosis. These aspects of "early" and extensive polykaryocytosis contrast with other observations where the phenomenon would be rather of the "late" type.

Among other hypotheses, the syncytia inducing factor(s) could be either BLV itself, BLV antigens, or (and) tumor specific cell surface antigens. Our data indicate that BLV itself can be responsible for syncytia induction. Indeed, the inhibitory effect on polykaryocytosis of spontaneous sera absorption with glutaraldehyde fixed highly purified BLV, prepared according to a technique known to preserve the integrity of the virus and to maintain the antigenicity of the viral envelope [17]. In addition, the implication of some internal component(s) of the virions is likely in view of the positive results obtained in similar absorption tests carried out with ether-resistant BLV antigens.

FLK-BLV cells, as well as BLV producing lymphocytes, absorb the syncytia inhibitory activity of anti-BLV sera. Thus, such cells probably display either on their surface or, in close association, antigens recognized by antibodies contained in the sera. The finding that the culture medium used for the growth of BLV producing cells has a higher absorbing potency than the cells themselves supports the possibility that BLV or BLV released antigens play the most important role in syncytia induction. In these conditions, BLV producing cells would act as "inducing centers" and the syncytia effect would be largely mediated through synthesis and release of BLV antigens.

The role of BLV in syncytia induction is also supported by the following: careful electron microscopic examinations of FLK-BLV cell cultures and of all lymphocyte cultures used in our study did not reveal the presence of viral particles of another type; there is a complete accordance between the presence of BLV-antibodies in the sera of cattle and the syncytia inhibiting activity; a specific anti-bovine syncytial virus antiserum [10] does not interfere with syncytia formation; and, as shown previously [3, 9, 25, 27] antigens of the bovine foamy-like or the bovine medi-like syncytial viruses do not react with BLV-antibodies and conversely. The quantitative data discussed below also rule out the possibility of a virus released by CC 81 cells to be inducer.

Onuma *et al.* [28] showed that sera with precipitin or complement fixing antibodies to BLV also contain a factor responsible for virus release inhibition. Although this factor is not yet identified, its implication in syncytia inhibition by spontaneous anti-BLV sera requires further studies.

The quantitative investigation of the interactions between FLK-BLV and CC 81 cells leading to syncytia formation shows that the frequency and size of syncytial cells are dependent upon the relative concentrations of the two kinds of cells, and that several CC 81 cells are required for the formation of each syncytium. When a fixed amount of CC 81 cells is used, the relationship between the number of syncytia and that of cocultivated FLK-BLV cells (formulae 3) indicates that: all FLK-BLV cells are equivalent in their syncytia inducing ability and only one is sufficient; with rising FLK-BLV cell concentrations, and in agreement with the observation of an increase of the nuclei content per syncytial cell, more and more FLK-BLV cells participate to the induction of each syn-

cytium. An important application of formulae (4) for the performance of different assays is the theoretical evaluation of the number of FLK-BLV cells required in order to obtain a determined number of syncytia.

As early polykaryocytosis is specifically associated with BLV expression or replication and is inhibited in a quantitative manner by sera from cattle known to contain antibodies to BLV, it seemed useful to develop a rapid and simple assay for the detection of BLV infection.

In preliminary serological tests based on early polykaryocytosis inhibition (EPI), FLK-BLV cells were preincubated with serial dilutions of the sera to be assayed and, to these mixtures, CC 81 cells were added; after 24 hr the percentage of syncytia inhibition was determined for each serum dilution. The unit chosen for the expression of the activity of bovine sera was the reciprocal of the dilution inhibiting 50% syncytia as compared to control cultures (SID_{50}). The reason for this is that the median effective dose can be estimated with more accuracy than other doses and in particular the 100% effective dose. A difficulty was immediately encountered due to the large fluctuations in the titers of the same sera when assayed in different experiments. The most probable causes for such a lack of reproducibility were: (1) variations in the amount of syncytia induced and (2) insufficient accuracy in the determination of SID_{50}.

A first improvement was obtained in the performance of the assay by the use of standardized conditions concerning the time of serum preincubation, the concentrations of FLK-BLV and CC 81 cells and the total length of the incubation period. The amount of syncytia recorded in this way per serum dilution and in control cultures became nearly constant.

The criterion of accuracy was difficult to approach in the absence of a linear or of a simple relationship between the number or the percentage of syncytia inhibited and the dilution of the serum. Indeed, in these conditions, only few dilutions would be taken into account for the calculation of the titer. The use of the logarithm of the dilution factor in place of real dilutions resulted in a sigmoidal response curve as often encountered in immunological assays. Such a curve can readily be approximated after probit transformation of the percentages by a weighted regression straight line. A statistical treatment of the sigmoid response curve, as described by Finney [22, 23], permitted the determination, with a good accuracy, of the median effective dose (or dilution) and fiducial limits on the basis of all the responses to the dilutions assayed. However, some fluctuations were still recorded from one experiment to another experiment. Indeed, even relatively small variations of the amount of syncytia induced in separate EPI tests were associated with noticeable inverse deviations of the titers of the same serum.

Therefore, the influence of the number of syncytia (s) on the titer (SID_{50}) was further studied. A direct relationship between the logarithms of the two parameters was found; this allowed the normalization of the expression of serum titers ($SID_{50}N$) by reference to a determined number of syncytia (S).

Depending on the accuracy required, a simplified procedure was found advantageous in most routine assays. The basic principles are similar to that described above, but the SID_{50} is directly eye estimated. The potency of the serum is appreciated by comparison with the SID_{50} of a reference serum concomitently assayed. The basic steps followed in the performance of the complete and of the simplified assay procedures are outlined in Table 1.

The incidence and potency of natural early polykaryocytosis inhibiting sera was investigated in a preliminary seroepidemiological survey of BLV infection carried out with 105 sera by use of the complete EPI test procedure. Although limited, our data indicated that BLV infection was encountered in all animal categories in which it was logical to expect it on hematological, pathological and/or epidemiological basis, i.e. leukemic (100 %), lymphocytotic (100 %) and normal contact animals (97 %). On the contrary, all sera from normal animals randomly selected in leukemiafree herds were negative. Among the categories of reactors, significant differences of the normalized titers were observed; those corresponding to the adult form of lymphosarcoma were on the average higher than those of lymphocytotic animals (977 and 104 respectively); the lowest titers were comparable in normal contact animals and in the few cases of juvenile or cutaneous lymphosarcoma tested (28, 16 and 16).

These seroepidemiological data were compared with those obtained in parallel experiments by complement fixation, a technique largely used in surveys. A highly significant correlation was found between the titers obtained by the two procedures; the main differ-

ence was the lower threshold of sensitivity of the EPI test. Apart from juvenile and cutaneous lymphosarcoma, reactors were found with both techniques in the same categories of animals; however, more positive sera were detected with the EPI test than with the complement fixation test, especially in normal contact animals. Statistically, the complement fixation technique would detect only those animals with a $SID_{50}N$ equal or higher than 60.

The high sensitivity of the EPI method for the detection of BLV associated antibodies was further indicated in a comparative study performed on 11 sera independently tested by 14 laboratories by use of complement fixation [8], immunodiffusion [7] and immunofluorescence [5, 6], techniques.

The results of our survey agree well with those reported by Cornefert-Jensen *et al.* [2] using the inhibition of late syncytia formation. All cattle with the adult form of lymphosarcoma were also detected, but not those with the calf type. The incidence of reactors among contact animals was much smaller than reported here; however, such a discrepancy could be ascribed to differences in the animals sampled.

The seroepidemiological data gathered with the EPI test are in accordance with those of tests for antibodies involving precipitins, complement fixation and immunofluorescence as well as those based on hematological criteria, They also fit with field epidemiological observations. However, it remains to be elucidated whether reactor animals have or have had infection with the virus. Our observations of positive reactions with the sera of calves with lymphosarcoma and of one case of cutaneous lymphosarcoma (two sporadic forms of the disease) supports the hypothesis that spread of bovine leukemia not only occurs on an horizontal mode but the etiological agent of the disease could also be vertically transmitted on a latent form and its expression activated in rare and still unknown circumstances. This view is further supported by the transmission experiments performed by Miller *et al.* [29] who succeeded in infecting experimental calves with BLV after inoculation with tumor material removed from calves with lymphosarcoma.

Effect of Immunomodulators on Thymocyte Suppressive Activity in Mice*

A. ANACLERIO, G. CONTI, M. L. MORAS, A. MACONI and F. SPREAFICO

Laboratory of Immunology and Cancer Chemotherapy, Istituto di Recherche Farmacologiche "Mario Negri", Via Eritrea 62, 20157 *Milan, Italy*

Abstract—Corynebacterium parvum (C. parvum), *Bacillus Calmette-Guerin (BCG) and Pyran copolymer (Pyran) are capable of significantly reducing thymocyte suppressive activity as assessed by the capacity of C3H thymus cells to inhibit the local graft vs host reaction (GVHR) mounted by C3H spleen cells in immunosuppressed H-2 histoincompatible hosts. This effect, which is dose related, is already evident* 2 days *after the injection of* C. parvum *or BCG and* 4 days *after administration of Pyran; it lasts* 1–3 weeks, *depending on the immunomodulator and is accompanied by a significant reduction of thymus cellularity. Evaluation of GVHR kinetics shows that thymus suppressive activity is inhibited by these agents at all phases of the reaction. No reduction of thymocyte suppressive activity is observed in adrenalectomized mice treated with* C. parvum *or Pyran.*

INTRODUCTION

THE ANTINEOPLASTIC efficacy of treatments with non specific immunomodulators has been repeatedly demonstrated in various experimental systems and in at least a number of clinical malignancies [1–5]. The mechanism(s) of action of these agents is complex and has not yet been entirely elucidated. Specifically, the effects of immunomodulators on suppressor cells have so far received only limited attention [6–8] although the activation or inhibition of lymphoid cells with suppressive activity has been reported to play an important role in neoplastic progression and in other pathological conditions [9–15]. The identification, therefore, of agents capable of modulating the activity of these cells could be of potential therapeutic interest.

On this basis and in an effort to acquire more information on the mode of action of this type of agents we investigated the effect of *C. parvum*, BCG and Pyran on murine thymocyte suppressive activity. Evidence will be presented that treatment with these agents can markedly reduce thymus suppressive activity, employing the inhibition of a local GVHR as suppressor cell assay.

Accepted 30 December 1977.

MATERIALS AND METHODS

Animals

C3H ($H\text{-}2^k$) and $(C57Bl/6 \times DBA/2)F_1$ (hereafter referred to as $B6D2F_1$ ($H\text{-}2^{bd}$)) female mice, 18–20 g of weight, 5–7 weeks old, obtained from Charles River, Calco, Italy, were used throughout.

Drugs

C. parvum (Lot CA 582 B) was obtained from Wellcome Research Laboratories, Beckenham, England. Fresh BCG was supplied by Pasteur Institute, Paris, France. Pyran (NSC 46015) was a gift of Dr. R. Geran, NCI, Bethesda, Md. Unless otherwise specified, the dose of *C. parvum* used was 1.4 mg/mouse given i.p. for two consecutive days, the dose of BCG was 1 mg/mouse i.v. and that of Pyran was 50 mg/kg i.p. These agents were resuspended or dissolved in sterile non pyrogenic saline. Control mice received equivalent amounts of sterile saline. Cyclophosphamide (Cy), kindly provided by Dr. H. J. Wood (NCI, Bethsda, Md.) was dissolved freshly in sterile saline before i.p. injection.

Assay of suppressor thymocytes

The concomitant injection of normal thymus cells has been shown to reduce

splenocyte-induced GVHR, an effect ascribed to the presence of a subset of suppressor cells in the thymus [16]. The popliteal lymphnode weight gain assay as described by Hardt and Claësson [17] was used as a measure of local GVHR. B6D2F$_1$ mice immunodepressed with 100 mg/kg i.p. of Cy 24 hr before, were injected into the right hind footpad with 5 $\times 10^6$ spleen cells from C3H mice in 50 μl Hanks' balanced salt solution (BSS), the controlateral footpad being injected with an equal number of splenocytes inactivated by exposure to 4% formol (30 min at room temperature). This number of splenocytes had previously been shown consistently to induce the highest GVHR in these conditions, higher inocula not being significantly more effective. Seven days later recipient mice were killed, both popliteal nodes were excised, carefully trimmed of accompanying tissue and immediately weighed to an accuracy of 0.01 mg. Severity of GVHR was expressed by the lymphnode index (L.I.), i.e. the ratio between the right and left node weights. In preliminary experiments it had been found that the L.I. of B6D2F$_1$ mice injected with 5×10^6 normal or inactivated syngeneic splenocytes was consistently in the 0.8–1.1 range.

When thymus suppressor cell activity was tested the organ was removed carefully excluding parathymic nodes adhering to the capsule, and 1.25×10^6 washed thymocytes from control or treated C3H mice were mixed with 5×10^6 syngeneic spleen cells and injected into the B6D2F$_1$ recipients in a total volume of 50 μl BSS. This number of normal thymus cells had previously been found to give optimal inhibition in these conditions.

Adrenalectomy

C3H mice were surgically adrenalectomized under nembutal anesthesia, kept in the dark and given sterile 0.9% NaCl solution *ad libitum* until used.

C. parvum or Pyran treatment was given 8 days after surgery and thymus cells were collected 2 or 4 days later respectively. The completeness of surgery was checked by gross inspection and animals with adrenal gland residues were discarded. Ectopic adrenal tissue has been reported to be rare in this strain of mice [18]. Shame-adrenalectomized controls were also prepared and kept under the same conditions.

Statistical analysis

Data are reported as the mean ±S.E. of at least 5 animals per group and statistical significance of the differences between L.I. values was assessed by the Duncan New Multiple Range Test [19].

RESULTS

As shown in Fig. 1 the administration of *C. parvum*, BCG or Pyran is followed by a reduction in thymocyte suppressive activity. In fact, when thymocytes from C3H mice treated with one of these agents were mixed with spleen cells, L.I. values similar to those of GVHR positive controls were obtained. This effect was first seen two days after the administration of *C. parvum* or BCG and four days after the administration of Pyran. The reduction of suppressive activity lasted up to day 14 after treatment with *C. parvum* and up to day 7 after treatment with BCG or Pyran. Similar results were obtained when *C. parvum* was given i.v. instead of i.p. and when increasing doses of treated thymocytes were

mixed with spleen cells. In fact as shown in Fig. 2 by one representative experiment with

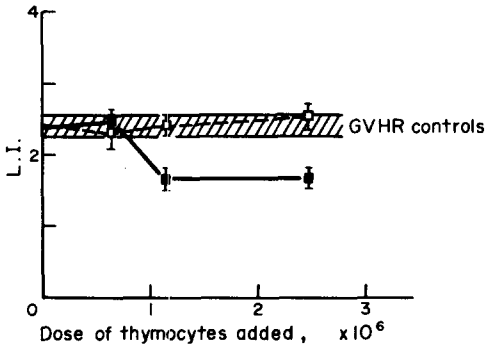

Fig. 2. Effect of different amounts of C. parvum *treated thymocytes on GVHR.* 5×10^6 *splenocytes were injected alone (GVHR controls, shaded area) or mixed with* 0.65, 1.25, 2.5 $\times 10^6$ *normal* (■———■) *or* C. parvum *treated* (□–––□) *thymocytes.*

C. Parvum, significant reduction of thymocyte suppressive activity was still seen when double amounts of *C. parvum* thymocytes were employed. Evaluation of thymus cellularity (Fig. 3) showed a significant decrease of thymus cell numbers in treated animals which roughly paralleled the reduction of thymocyte suppressive activity.

Localization of radiolabelled *C. parvum* in the thymus after parenteral administration in rodents has been described [20] and lymphoid tissue enlargement in animals given immunostimulants has been reported [21, 22]. Therefore in order to ascertain that the higher L.I. values observed employing thymocytes from *C. parvum* or BCG treated animals were not attributable to transfer with the cell suspensions of microorganisms or bacterial products not removed during the cell washings, the following experiments were performed. C3H thymocytes (1.25×10^6) obtained 2–7 days after *C. parvum* or BCG injection were mixed with C3H normal spleen cells and injected into Cy-pretreated C3H mice, the controlateral footpad being injected with mixtures of equal numbers of cells from normal mice. As controls a group of C3H mice was injected with normal thymocyte-spleen cells mixtures in both footpads. In these experimental conditions, involving no histocompatibility differences, no significant increases of L.I. were recorded 7 days after cell transfer comparing controls and mice injected with *C. parvum* or BCG thymocytes (Table 1). This was taken as an indication that thymus cell preparations did not contain *C parvum* or BCG microorganisms or their products in amounts

capable of directly inducing significant lymph-nodal enlargement. Similar results were also obtained employing thymocytes from Pyran treated mice.

On the basis of these previous observations, in the next series of experiments thymocytes from treated animals were obtained 2 days after the administration of *C. parvum* or BCG and 4 days after Pyran treatment.

Within the dose range examined the effect of these immunostimulants on thymus suppressive capacity on a GVHR appeared to be dose related (Fig. 4). In fact the lowest dose of these agents resulting in a reduction of GVHR-suppressive capacity was 0.7 mg/mouse of *C. parvum* or 12.5–25 mg/kg of Pyran, although L.I. values superimposable on those of GVHR-positive controls were observed when doses of 1.4 mg/mouse of *C. parvum*, given for one or two days and 1 mg/mouse or 50 mg/kg of BCG or Pyran respectively were administered.

Considering that in the experiments described the L.I. were evaluated only at the peak of the GVHR, i.e. 7 days after cell transfer, in subsequent tests the entire GVHR kinetics was followed in mice injected either

with spleen cells alone or with mixtures of splenocytes and thymocytes obtained from normal or treated animals. Figure 5 shows that when 1.25×10^6 normal thymocytes were transferred with 5×10^6 syngeneic splenocytes into the $B6D2F_1$ recipients a true depression of the GVHR ensued and not merely a delay in its peak. Conversely, when an equal num-

ber of thymus cells from drug-treated mice was injected, the GVHR kinetics observed was similar to that displayed by the GVHR positive controls except for a somewhat longer plateau observed when mixtures of splenocytes and *C. parvum* thymocytes were transferred. In fact, peak L.I. values were observed from day 7 up to day 12 and the first decrease in L.I. was detected only on day 14, i.e. 2–3 days later than in GVHR positive controls.

In view of the fact that thymus derived suppressor cells have been described as being steroid sensitive [23–25] it was of interest to obtain preliminary information on whether adrenal glands could be involved in the reported effect of these immunomodulators. Accordingly, the GVHR suppressive activity of thymocytes obtained 2 days after the injection of *C. parvum* (1.4 mg/mouse) or 4 days after the injection of Pyran (25 mg/kg) in adrenalectomized C3H mice was assessed measuring the L.I. 7 days after cell transfer. BCG-thymocytes were not employed because a relatively high mortality occurs in adrenalectomized mice treated with this agent. As shown in Table 2, no decrease in thymocyte suppressive activity could be observed in adrenalectomized mice treated with *C. parvum* or Pyran as compared to sham-adrenalectomized controls.

compatible hosts. This disappearance of suppressive capacity is dose-related and compounded by the marked reduction in thymus cellularity which follows treatments with these immunomodulators. Any discussion of the mechanism(s) through which these immunomodulators exert this effect on suppressor thymocytes would at the present time be mainly speculative. Since only a functional assay for suppressor cells was employed, it is impossible to state whether the reduction in thymus suppressive capacity in these experiments was due to inhibition or to destruction of these lymphoid elements and/or to their migration from the organ. The finding that suppressive activity is not reduced in adrenalectomized mice treated with *C. parvum* or Pyran suggests that adrenal glands may be involved. The lytic capacity of steroids for murine cortical thymocytes is well established and evidence has been provided that thymus derived suppressor cells or their precursors are steroid sensitive [23–25]. However, migration of suppressor thymocytes to the periphery cannot be excluded, as suggested by the work of Khalil *et al.* [21] whose findings favour thymocyte migration to T-dependent areas of the spleen in BCG treated mice. Also, the increased T suppressor cell activity found in the spleen of BCG treated mice [7] could be

Table 2. Effect of C. parvum *and Pyran on thymus suppressive activity in adrenalectomized mice*

5×10^6 splenocytes were mixed with 1.25×10^6 thymocytes from controls or mice treated with *C. parvum* (1.4 mg/mouse i.p.) or Pyran (25 mg/kg i.p.). Thymocytes were obtained 2 days after *C. parvum* and 4 days after Pyran.

*Thymocytes obtained from sham-adrenalectomized mice.

†$P<0.05$ vs controls.

DISCUSSION

Data presented show essentially that treatments with *C. parvum*, BCG or Pyran can induce a prompt, marked reduction in thymocyte suppressive activity, as deduced from the inability of thymocytes from treated animals to inhibit a local GVHR mounted by syngeneic spleen cells transplanted in H–2 in-

in support of this hypothesis, although a direct comparison of this study with our results cannot probably be made because higher doses of BCG were used.

Further studies are clearly needed in order to establish whether significant differences exist between these immunomodulators' effects on this specific lymphocyte subset in different lymphoid districts and more work is required

to assess fully the relevance of these changes in the antitumoral activity of these compounds. The observation that pretreatment with antilymphocyte serum abrogates the *C. parvum* antimetastatic effect in mice with Lewis lung carcinoma [26], a system in which tumor growth is conditioned by suppressor T cells [9, 27], is at this time only suggestive, it seems clear, however, that the mechanisms of action of these immunomodulators are more complex than expected.

Reduced Tumorigenicity by Addition *In Vitro* of Sendai Virus

YUTAKA MATSUYA, TOSHIHISA KUSANO, SUMIKO ENDO, NORIKO TAKAHASHI and ISAO YAMANE

Division of Microbiology, Research Institute for Tuberculosis and Cancer, Tohoku University, Sendai 980, *Japan*

Abstract—*Treatment of Ehrlich ascites tumor (EAT) with Sendai virus produced polyploid variants that could grow on selective media, whereas no cell growth occurred in untreated control cultures. All of these variants isolated had more chromosomes and showed less transplantability than EAT.*

The banding patterns of each chromosome were analyzed. The karyotypes of the variants appeared to be more heterogenous than EAT. Other biological properties of cultured control and its variants, agglutinability by concanavalin A and the anchorage dependency of cell growth proved to be unrelated to tumorigenicity. Similar variants were isolated by treating EAT with another cell-fusion inducers, lysolecithin or polyethylene glycol. Like the variants induced by Sendai virus treatment, they had more chromosomes and were less tumorigenic than EAT. However, the frequency of occurrence of these variants ($<10^{-7}$) was far less than that (10^{-5}) of the variants induced by Sendai virus.

It is probable that variants pre-existing in EAT begin to propagate in vitro *after the treatment with fusion-inducing agents.*

INTRODUCTION

IT HAS been shown that morphologically reverted cells are usually derived from cells transformed by exposure to oncogenic viruses or chemical carcinogens. The reverted cells have proved to be revertants or variants lacking some of properties of transformed cells, such as sensitivity to agglutination by plant lectins [1, 2], anchorage dependency of cell growth [3, 4] and tumor-specific transplantation antigens [5, 6]. Most revertants show an increase in chromosome number [7, 8] and a reduced transplantability [5, 9, 10].

We have found by chance that a variant cell appeared in the culture after the treatment of Ehrlich ascites tumor (EAT) with Sendai virus.

This paper reports a study of these cells and the experiments made to try to identify the mechanism of how they were produced.

MATERIALS AND METHODS

Cells

Ehrlich ascites tumor cells were maintained by weekly intraperitoneal transplantation into dd strain of mice.

Accepted 30 December 1977.

Isolation of variants induced by Sendai virus treatment

EAT cells were withdrawn from the peritoneal cavity of tumor-bearing mice who had been inoculated 8–10 days earlier. The tumor cells were suspended in Hanks' balanced salt solution (HBSS) and centrifuged. A suspension containing 5×10^6 to 1×10^7 EAT cells in 1 ml of HBSS was mixed with 1 ml of ultraviolet (u.v.)-inactivated Sendai virus (HVJ, Z strain) at the concentration of 500–1000 hemagglutination units (HAU). This virus was kindly supplied by Dr. M. Homma. The virus-cell mixture was incubated in a water bath at 37°C for 20 min. The treated cells were washed 2 times by centrifugation to remove the unadsorbed viruses. They were then suspended in enriched F12 medium (Nissui Seiyaku), fortified with the amino acids and vitamins of Eagle's MEM, containing 10% calf serum (Flow Lab.) and a reduced amount of sodium bicarbonate (0.05%), were plated in 5×10^5 cell aliquots in 60-mm Falcon plastic dishes. The cultures were incubated in a CO_2-incubator and the medium renewed twice a week. The cultures were terminated within 2 months and the variants were not used for longer than a

month of culture after thawing from the frozen stock for the transplantability testing.

Isolation of variants induced by lysolecithin treatment

Lysolecithin (LL, Sigma Chem.) solution was prepared by the method of Croce *et al.* [11]. EAT cells were centrifuged and resuspended in HBSS.

Then, 5×10^6 cells per 0.5 ml of HBSS were treated with 0.1 ml of the LL solution at final concentration of 4–10 μg/ml. After 1 min of exposure to LL, the LL in the suspension was neutralized by the addition of 0.4 ml of calf serum to each tube, and the treated cells were collected by centrifugation. The cells were resuspended in enriched F12 containing 10% calf serum and 0.05% $NaHCO_3$ and finally 5×10^5 cells were plated into each dish.

Isolation of variants induced by polyethylene glycol treatment

Polyethylene glycol (PEG, 6000, BDH Chem.) solution was prepared as described by Pontecorvo [12].

EAT cells were centrifuged and the supernatant was discarded. Then, 0.3 ml of 50% (w/w) PEG solution was added to the cell pellets. After exposure to PEG for 5 min, the suspension was rapidly diluted by the addition of 5 ml of MEM without serum (serum-free medium) and centrifuged. The treated cells were resuspended in 2 ml of serum-free medium and again centrifuged. The washed cell pellets were resuspended in enriched F12 containing 10% calf serum and 0.05% $NaHCO_3$ and 5×10^5 cells were seeded per dish.

Cell cloning

We cloned the cultured cells using Microtest II plate (Falcon plastic). A cell suspension (0.2 ml) containing 1 cell was placed in each microtiter well. Two weeks after plating, individual colonies were isolated.

Chromosome preparation

Chromosome preparation was made by the air-drying method after colchicine and hypertonic KCl treatment. The slides were stained with Giemsa for routine karyotyping. For the banding pattern analysis, the Giemsa-staining method with trypsin [13] was used.

Transplantability test

The transplantability of various tumor cells isolated was tested by intraperitoneal inoculation into 3–4 weeks old dd strain mice.

The cultured cells were trypsinized and resuspended in 0.2 ml of HBSS containing the cell suspension adjusted to the required cell number. In this case, trypsin did not influence the take rate of these cells, because in some experiments the tumorigenicity of the cells harvested without the treatment of proteolytic enzymes was very similar to those of the cells harvested with the treatment of trypsin. The animals inoculated were observed for 4 weeks and the take incidence was assessed from the number of mice killed by ascitic tumors.

Agglutination by concanavalin A

Agglutination assay for concanavalin A (con A, Sigma Chem.) was carried out by the method described by Burger [14]. The cultures were dispersed with 0.02% EDTA solution and washed 2 times with Ca- and Mg-free phosphate buffered saline. The agglutination reaction was performed in 35-mm Petri dishes with 0.5 ml of cell densities of 10^6 cells/ml and 0.5 ml of a solution with increasing concentrations of con A. After shaking gently for 30 min, the extent of agglutination was measured as the percentage of agglutinated cells. The concentration of con A(μg/ml) required to produce half maximal agglutination was determined.

Growth in medium containing methyl cellulose

The ability of cells to grow in medium containing methyl cellulose was tested according to the procedure of Risser and Pollack [15]. Each of cells was plated in 4 ml of a mixture of 10% calf serum, 1.2% methyl cellulose (Methocel, 4000 counts/sec, Dow Chem.), 90% MEM at the densities of 10^4, 10^3 and 10^2 cells. This mixture was layered onto a plate containing 6 ml of 0.9% agar (Bacto, Difco), 90% MEM and 10% calf serum (Methocel medium). The cultures were fed weekly with 4 ml of the medium.

The colonies were scored after 3 weeks of culture. Only colonies visible to the naked eye were scored.

RESULTS

Culture of EAT cells

EAT cells grew rapidly in MEM or F12 medium supplemented with 10% calf serum.

But almost all EAT cells failed in which the amount of sodium bicarbonate in enriched F12 plus 10% calf serum was reduced from its normal concentration of 1176–500 μg/ml or less. This phenomenon was not observed when MEM plus 10% calf serum was used under the same conditions. Further, EAT cells began to grow *in vitro* when MEM plus 10% calf serum was used without any added bicarbonate in an atmosphere of 5% CO_2 in air.

Detection of Sendai virus (HVJ)-induced variants

We happened to observe a following event: an Ehrlich ascites tumor variant appeared in the culture when EAT cells and human cells were hybridized in the presence of inactivated Sendai virus. These variant cells were then detected in the culture of EAT cells pretreated with Sendai virus on selective medium: a few colonies were found to appear on the plate in which the virus-treated EAT cells were seeded for 1–2 weeks, whereas no such colonies appeared in untreated cultures. This process was repeated about 20 times during 2 yr. In each experiment, these colonies appeared in the virus-treated cultures plated at the densities of 5×10^5 EAT cells/dish. Also, the growing cells were tested for their transplantability. The results showed that the cells were true variants (see Fig. 4).

The frequency of colony formation of these variants was about one per 10^5 EAT cells. Effect of the concentration of Sendai virus on the rate of formation of these variants was investigated: aliquots of 3×10^5 EAT cells were treated with inactivated Sendai virus at titers varying from 10–1000 HAU per tube, and then the treated cells were cultured in the selective medium for 2 weeks. The cultures were harvested, and the numbers of cells were counted. It was difficult to determine the exact rate of colony formation, because the numbers of cells in suspension increased with time. Approximately 3.5×10^5 cells/plate at concentration of 1000 HAU, 0.9×10^5 cells at the 300 HAU and 0.08×10^5 cells at the 100 HAU were counted, respectively. No growing cells were detected at the 30 and 10 HAU. The rates of appearance of true abnormal cells seemed to be dependent on the concentration of the virus. Hence, this virus proved to be a very important factor for the development of these variants.

Chromosome constitution of control cells and HVJ-induced variants

The histogram of chromosome numbers in EAT cells, cultured control cells and HVJ-induced variants is shown in Fig. 1. The histogram in EAT cells showed a major sub-tetraploid peak ranged from 66 to 76 chromosomes per cell with a minor sub-octaploid component ranged from 122 to 151 chromosomes per cell. The distribution pattern of chromosome number in the cultured control was very similar to that of EAT cells. HVJ-induced variants showed a bimodal distribution pattern of chromosome number. But the sub-tetraploid cells had a modal number of 85 chromosome per cell with a considerable scatter and the sub-octaploid cells were distributed in a range from 140 to 170 chromosomes per cell. The representative karyotypes of EAT cell and HVJ-induced variant are shown in Fig. 2.

Comparison of chromosome banding patterns of EAT cells and HVJ-induced variants

The analysis of chromosome banding pattern was carried out on 7 metaphase preparations of EAT cells and on 5 metaphase preparations of their variants. About 63% of the chromosomes in EAT cells and the variants were of normal origin. However, the origin of 19 telocentrics and 7 biarmed chromosomes in EAT cells could not be determined from the banding patterns, whereas 35 different telocentrics and 7 biarmed chromosomes of unknown origin were present in the variants. The results obtained on each metaphase of both cells are summarized in Table 1. Figure 3 shows the marker chromosomes of unknown origin in EAT cells and HVJ-induced variants. There was a striking variation from cell to cell in the range of chromosome types: the number of marker chromosomes which were not seen in any of HVJ-induced variants was 7 in EAT cells, whereas 23 marker chromosomes were present in HVJ-induced variants alone (Table 1).

Transplantability of control cells and HVJ-induced variants.

EAT cells and their variants were inoculated intraperitoneally into weanling mice at various cell densities,. The results of transplantability test showed that 100 EAT cells or 100 cultured control cells killed almost all the animals within 3–4 weeks. Table 2 also indicates that the TFD_{50} values of 5 independently isolated sub-tetraploid clones (clones 1–4) of which the number of chromosomes

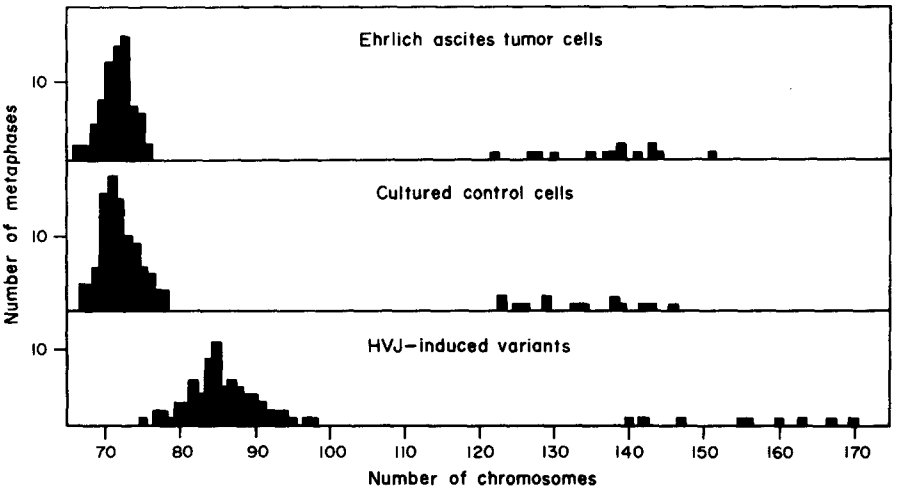

Fig. 1. Distribution of chromosomal number in Ehrlich ascites tumor cells, cultured control cells and HVJ-induced variants. The chromosomal analysis of the mitotic cells in cultured control and variants was performed after three weeks of culture.

ranged from 62 to 74 per cell were similar to those of EAT cells, but the values of 2 sub-octaploid clones (clones 5, 6) were lower than those of the sub-tetraploid lines. The inoculation of 5×10^5 HVJ-induced variants produced a 100% tumor take rate, though the TFD_{50} values were as high as about 10^5 cells as shown in Table 3. This indicates that these variants were approximately 10,000 times less malignant than EAT. Live Sendai virus as well as the inactivated virus had the ability to induce these variants, though with only one tenth the frequency of that induced by the inactivated virus. This suggested that these variants might be converted antigenically as a result of the viral treatment. No viral antigens were detectable by immunofluorescence assay of the variants, even the variants induced by treatment with live virus (K. Sugamura, personal communication). Thus, there was no sign of the synthesis of the viral antigens by the variant cells. To test whether the infectivity of Sendai virus affected the transplantability of the virus-treated cells, each of the variants induced by the live or inactivated virus was inoculated into mice. Table 3 shows that the transplantability of the variants was not influenced by the infectivity of the virus used. Effect of the ploidy of the variants on the transplantability was also compared, 3 sub-tetraploid clones (clones 3–5) to 2 sub-octaploid clones (clones 6, 7), there was no significant difference between them (Table 3). Total percentage of the lethal take in 17 experiments of EAT cells and in 28 experiments of the variants is summarized in Fig. 4.

Effect of cyclic adenosine-3′, 5′-monophosphate on cell growth

Effect of cyclic adenosine −3′, 5′-monophosphate (cAMP) on the growth of cultured control cells and their variants is shown in Fig. 5. The growth of the control was strongly inhibited by the addition of 0.3 mM cAMP (Sigma Chem.) to the medium. At the concentration of 0.05 mM cAMP, some inhibitory effect (about 10% inhibition) was found on the growth of the same cells. When dibutyryl cAMP at the concentration of 0.3 mM was added, it caused less inhibition of growth of the control than cAMP (Fig. 5). However, 0.3 mM cAMP had only slight effect on the growth of HVJ-induced variants.

Agglutination by con A

Cultured control cells were highly agglutinable by con A (less than 25 μg/ml was required for the half-maximal stage to be reached). The cell agglutination of HVJ-induced variants was very similar to that of the control.

Growth in methocel medium

The control cells and HVJ-induced variants after a month of culture were tested for their ability to form colonies in Methocel medium. The results are shown in Table 4. HVJ-induced variants gave 15–22 colonies per 100

cells, whereas the control produced far fewer colonies (0.02–0.08%).

Stability of these biological properties

The stability of the biological properties described above was re-tested in the control and the variants over a year period. The control and the variants obtained by cloning were maintained by the serial passage: these cells at the densities of about 10^5 cells were transferred without trypsinization once a week. The tumorigenicity in both cells was unaltered during the continuous culture *in vitro*. Observation on HVJ-induced variants reveals that the insensitivity of cells to exogenous cAMP and an ability to form colonies in Methocel medium was stable. On the other hand, the instability of these properties in the control cells was demonstrated during 3 months of culture.

When tested at 3 months after plating, the control cells behaved in a different fashion compared to when they were first cultured: the growth of the cells was unaffected by the addition of cAMP and the plating efficiencies in Methocel medium as well as in liquid medium were equal to those of the variants. Thereafter, the control cells were stable over a year period. The results indicated that the stable properties expressed by the control cells were acquired by a sub-set of cells in the original population during 3 months of continuous propagation. There was no correlation between the tumorigenicity and these biological properties. During the serial culture of the variants, we could not find any cells reverted to the control type even through *in vivo* passages.

Attempt to isolate the variants by influenza virus treatment

It is well known that Sendai virus, a parainfluenza virus Type I, possesses many

biological activities on the envelope of the virion. Our experiment on EAT cells suggest that one of these activities may be related to the occurrence of their HVJ-induced variants. Neuraminidase and hemagglutinating activities are present on the surface of influenza virus [16] as well as Sendai virus [17]. It is, therefore, supposed that variant cells might appear in the culture of EAT cells treated with influenza virus, if any of neuraminidase or hemagglutinating activity was associated with the induction of the variants.

An experiment was made using u.v.-inactivated human influenza virus, PR-8 strain (supplied by Dr. M. Homma). No colonies appeared in the culture, though $>5 \times 10^7$ EAT cells were treated with the virus and cultured.

Attempt to isolate the variants by LL treatment

Sendai virus is known to have high cell-fusing activity on the viral envelope [18]. It is shown from the result of structural analysis of Sendai virus that this virus contains LL in the envelope [19]. LL has an ability to induce cell fusion [20], like Sendai virus. LL is, therefore, expected to have an activity for inducing Ehrlich variants, if the fusion factor was concerned in the induction of the variants. In the repeated experiments, the variants were only detected in the culture of cells treated with 4 or 8 μg/ml of LL. These variants (LL-induced variants) occurred at very low frequency ($<1:10^7$ EAT cells). The frequency was far less than that of HVJ-induced variants.

LL-induced variants, like HVJ-induced variants, had an increased number of chromosomes per cell and a decreased transplantability, as compared with the control (Table 5).

Attempt to isolate the variants by PEG treatment

Recently, it has been reported that PEG can be used to induce cell fusion [12]. We tried to detect the variants from the culture of EAT cells after exposure to PEG. Only 2 colonies arose throughout these experiments. The frequency of colony formation was <1 per 10^7 EAT cells. Table 5 shows that the variants (PEG-induced variants) had more chromosomes and were less tumorigenic than the control. The histogram of chromosome numbers and the TFD_{50} values in LL- or PEG-induced variants showed to be very similar to those of HVJ-induced variants.

DISCUSSION

Ehrlich ascites tumors are highly malignant and have been passaged continuously in any strain of mice for more than seventy years. Therefore, it is probable that the polyploid variants showing less transplantability will be produced spontaneously and accumulated in the EAT population during the continuous passages *in vivo*.

In fact, we isolated many polyploid variant cells with less tumorigenicity from the culture of EAT by treating them with proteolytic enzymes or by modifying the culture conditions, such as low serum-containing medium or high serum albumin-containing medium, though the experiment is still in progress. In the present experiment, HVJ-induced variants appeared in the virus-treated culture of EAT cells at a frequency of one per 10^5 cells. The mechanism by which the variants pre-existing in the population began to propagate *in vitro* after Sendai virus treatment is unknown. Sendai virus possesses several biological activities on the envelope. It includes neuraminidase, hemagglutination [17], hemolyzing and cell-fusing activities [18]. But no such known factors seem to be important for the induction of these variants. Yamada and Hatano [21] have reported that cultured tumor cells persistently infected with Sendai virus have a decreased transplantability compared with the untreated control cells. This phenomenon suggests to be due to antigenic conversion of the tumor cells by the viral infection. However, antigenic conversion of EAT by the virus seem to be ruled out, since there was no evidence of any marker specific for the Sendai virus.

In general, the revertants obtained with the treatment of fluoro-deoxyuridine [8], bromo-deoxyuridine [22], colchicine [23], con A [7], and by plating on glutaraldehyde-fixed monolayers [10] have a higher chromosomes count than the transformed parent cells. The chromosome banding patterns of hyperdiploid EAT have been analyzed by Sasaki *et al.* [24]. They have reported that the cell population is highly heterogenous, and only 30% of the chromosomes are of normal origin, whereas the remaining chromosomes are altered structurally. All of the less tumorigenic Ehrlich variants in our system were characterized by an increase in chromosome number. The analysis of the chromosome banding patterns re-

Table 5. Chromosomal constitution and tumorigenicity of LL- or PEG-induced variants

veals that HVJ-induced variants had a much greater degree of chromosome heterogeneity than EAT. The marker chromosomes of unknown origin were common to both cells. Despite their similarity, the two cell lines were clearly different in the range of chromosome types. For example, 26 different marker chromosomes were present in the control, whereas 42 marker chromosomes were seen in HVJ-induced variants. In addition, each cell in the sample of HVJ-induced variants showed specific variation in the contents of marker chromosomes. Sachs *et al.* [25, 26] have proposed that the genetic control of malignancy in hamster tumor cells and their revertants is controlled by the balance between genes for expression and suppression of malignancy. They have assigned these genes to particular chromosomes. Similarly, specific chromosomes associated with either expression or suppression of malignancy in rodent tumor cells are identified in relation to the balance of these chromosomes [27, 28]. In our system, the suppression of malignancy was associated with an increase of the chromosome number. The analysis of chromosome banding patterns suggests that a group of the marker chromosomes present in HVJ-induced variants alone may be related to the suppression of malignancy. However, it is impossible to assign any specific chromosomes associated with the suppression of malignancy. HVJ-induced variants have more chromosomes ranged from 10 to 20 than the control. Therefore, there is a possibility that the variants might be an artifact resulting from the fusion in culture of EAT cells by the Sendai virus because EAT cells show a high fusion rate when treated with the virus. But the studies of chromosome banding patterns on HVJ-induced variants show that they were true variants pre-existing in their ascites population, since about half of the marker chromosomes in HVJ-induced variants was not seen in any of EAT cells. Yoshida and Funaki [29] have found that hyperdiploid EAT readily grows *in vitro* only after the treatment with Sendai virus, although no cell growth occurs in untreated control. The results obtained by the banding analysis of the chromosomes indicate that 2S cells originated from the hybrids formed between 2 different 1S cells and the cells shifted very rapidly from the 2S to the hyper-1S region. The chromosome constitution of our HVJ-induced variants was stable, and rapid and extensive loss in the chromosome number was not observed during the continuous propagation *in vitro*. In addition, each of LL- or PEG-induced va-

riants derived from EAT was polyploid and had 10–20 more chromosomes than the original EAT, as seen in HVJ-induced variants. The possibility that HVJ-induced variants arose as a result of cell fusion of EAT is unlikely.

Effect of CCNU on Survival Rate of Objective Remission and Duration of Free Interval in Patients with Malignant Brain Glioma—Final Evaluation*

E.O.R.T.C. BRAIN TUMOR GROUP†‡

Abstract—*The effect of CCNU on three clinical parameters was measured in patients with malignant brain gliomas, operated and treated by radiation therapy* (5500–6000 rad).

From 111 *selected patients included in the first trial* (*No.* 26741) 81 *were avialable for the final evaluation.*

Four questions were answered by this study:

(*a*) *Free interval can be measured in a selected group of patients with malignant brain glioma.*

(*b*) *CCNU* (*mean dosage actually given was over* 100 mg/m^2 *once every* 6 weeks) *does not prolong the free interval.*

(*c*) *Objective remission was observed in* 8 *out of* 27 *patients where this parameter was evaluable. The duration of the remission ranged from* 3 *to over* 14 *months.*

(*d*) *The median survival of patients who received CCNU only after relapse was* 22.5 weeks *from the recurrence and* 62 weeks *from the operation; the figures for patients treated earlier with CCNU were* 11 *and* 43 weeks. *These differences are significant at respectively* 2 *and* 7% *levels.*

Only survival time was measured in the second trial (*No.* 26742), *it was* 31 weeks *in patients treated with CCNU and* 21.5 *in the control group. Although only* 19 *patients were evaluated, the difference is significant at* 1% *level.*

Combined results of both trials suggest so far that: CCNU prolongs the total survival time, produces objective remission in about 30% *of cases and that it should be administered only after relapse, at least in patients with free interval.*

Accepted 6 January 1978.

INTRODUCTION

THIS study, in which we investigate the effects of CCNU on three clinical parameters: total survival time, objective remission and free interval between operation and relapse in patients with malignant brain gliomas, started in January 1973. The last patient was randomized in November 1975. The first evaluation of this investigation has been previously reported [1]. The purpose of this report is the final evaluation.

MATERIALS, METHODS AND STUDY DESIGN

Criteria for patient selection, evaluation of therapy, the design of the two trials and the administration of drugs and radiotherapy have been previously detailed [1, 2]. One hundred and eleven patients were entered into the first trial (26741). All patients had an

optimal resection of a histologically proven malignant glioma, three weeks prior to randomization for chemotherapy. Patients selected for this trial had minimal postoperative neurological deficit and did not require the administration of steroids. All patients were treated with 5500–6000 rad. After randomization, group I (early CCNU) received CCNU 130 mg/m^2 every 6 weeks whereas group II (late CCNU) remained without chemotherapy until the recurrence. After recurrence (end of the free interval) all patients received CCNU. The main clinical characteristics of the patients from groups I and II are compared in Table 1.

Trial 26741

The effect of CCNU on the free interval was evaluated in 81 patients. As shown in Fig. 1 the curves of the free interval duration for patients receiving CCNU and for the controls are very similar. The mean duration of the free interval being 34.5 weeks in patients treated with CCNU and 31.0 in the controls. The mean dosage of CCNU actually given was at least 100 mg/m^2 of the scheduled dose. When the free interval was considered in the whole group of 81 patients regardless of chemotherapy, it appeared longer in patients under 50 yr (median duration 60.2 weeks) than in the older group (28.6 weeks) Fig. 2. This interval tended to be shorter in patients with glioma multiforme (29 weeks) as compared with other pathological types (38 weeks), but the difference is not statistically significant. No differences in the length of the free interval were found by comparing: (a) males to females, (b) apparently total tumor resections to other neurosurgical procedures, (c) patients with neoplastic involvement of one lobe to those with lesions extending to more than one lobe.

Objective remission, defined as a clear cut clinical improvement lasting at least 6 weeks after a complete discontinuation of steroids was evaluable in 27 patients who received at least three courses of CCNU after the relapse. Such an objective improvement was observed in 8 cases (29%), its duration ranged from 3 to 14(+) months (median 7(+) months).

Table 1. *Distribution according to possible prognosis factors*

		Group I (early CCNU)	Group II (late CCNU)
Age	under 50 yr	22	24
	over 50 yr	33	28
		(4)	
Sex	male	41	30
	female	18	22
Pathology	glioblastoma multiforme	24	20
	astrocytoma grades III and IV	15	19
	other	20	13
Type of resection	biopsy	3	2
	partial	20	22
	total	22	17
	Other	14	11
Lobes involved	one	27	34
	more than one	32	18

Only 23 patients were entered in the second trial (26742). All of them required the administration of steroids after surgical removal of malignant glioma and their neurological examination was difficult to evaluate quantitatively. All patients were treated with 5500 to 6000 rad. After randomization 10 patients received CCNU 130 mg/m^2 every 6 weeks, 13 remained without chemotherapy. In this trial, the effect of CCNU was evaluated only with respect to the duration of the postoperative survival time.

RESULTS

The results of the two concomitant studies 26741 and 26742 will be considered separately.

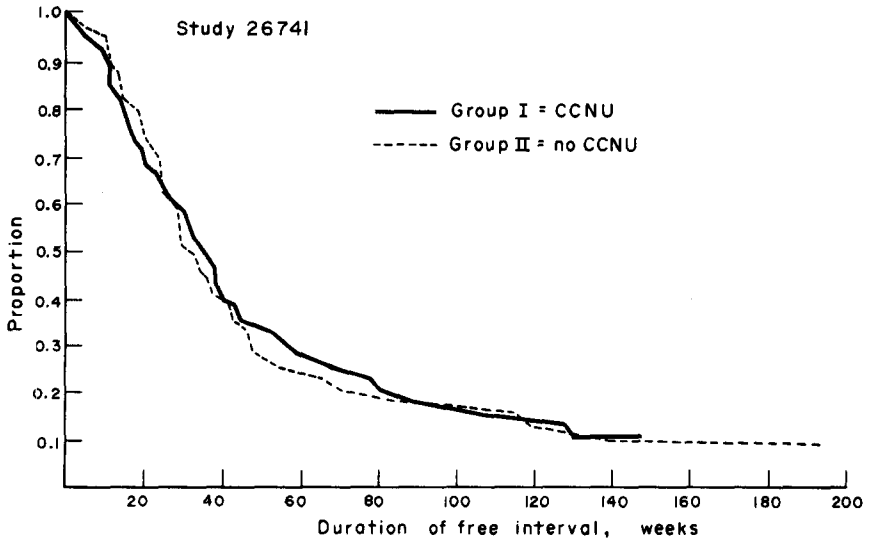

Fig. 1. Study 26741. Free interval length curves in 42 patients receiving CCNU (———) and 39 controls (– – –).

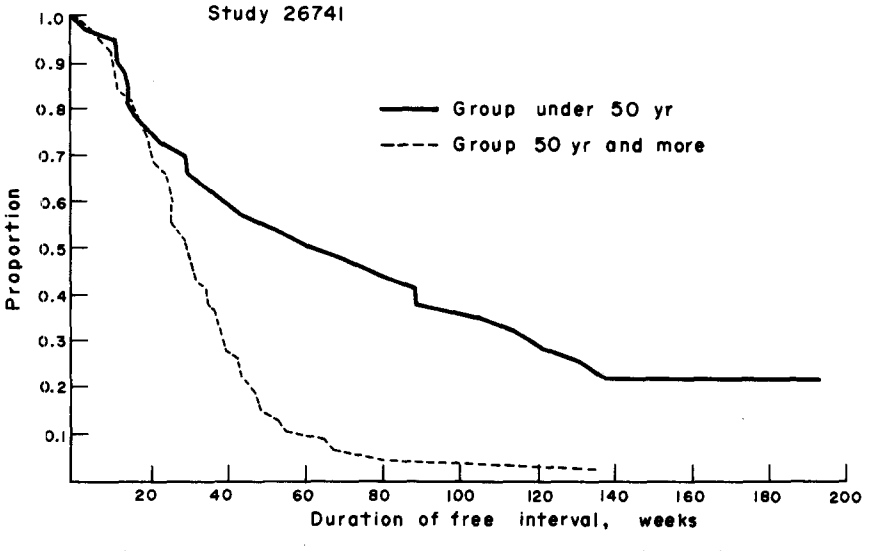

Fig. 2. Study 26741. Free interval length curves in 33 patients under 50 (———) and 48 patients aged 50 yr or more (– – –).

The median survival of patients who received CCNU only after relapse (group II) was 22.5 weeks from the recurrence and 62 weeks from the operation, the figures for patients treated with early CCNU (3 weeks after neurosurgery) were 11 and 43 weeks, the differences being significant at respectively 2 and 7% levels (Fig. 3). Total survival times tended to be longer in patients under 50 yr (63 weeks) as compared to the group of older patients (43 weeks) and in patients with astrocytome grades III and IV (56 weeks) as compared to glioma multiforme (43 weeks) but the differences were not statistically significant. The length of the postoperative survival was not related to sex, type of neurosurgical procedure or number of lobes involved by the tumor.

Severe hematological toxicity characterized by platelets under 60,000 per mm^3, leucocytes under 2500 per mm^3 and hemoglobin level under 10 g/100 ml were observed in respectively 13, 12 and 5 patients from group I and 8 and 4 and 4 patients from group II. Alteration of the liver test was observed in 2 cases. No death was attributed to chemotherapy.

Trial 26742

The median survival was significantly longer in patients who were treated with CCNU (31 weeks) when compared to controls not treated by chemotherapy (21.5 weeks), the difference is significant at the 1% level.

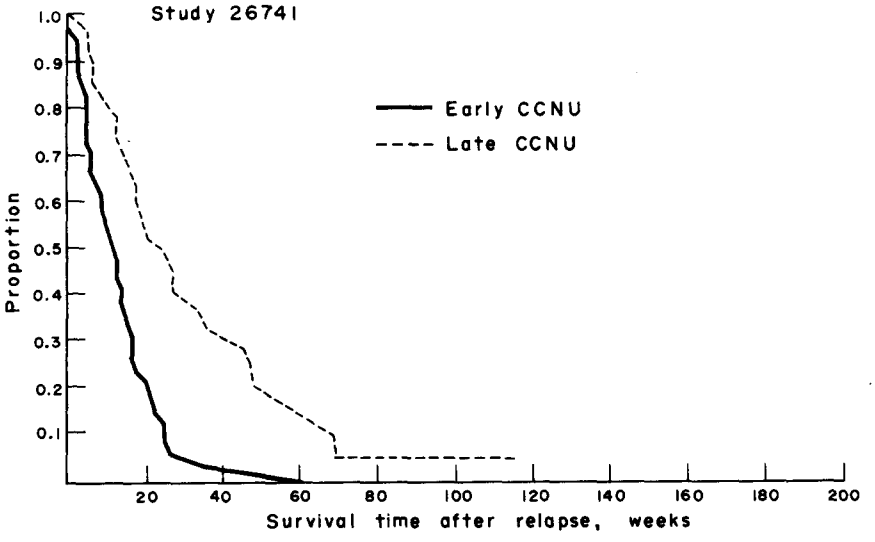

Fig. 3. Study 26741. Survival time curves after relapse in 24 patients treated with CCNU 3 weeks after neurosurgery (———) and in 34 patients treated with CCNU only after relapse (----).

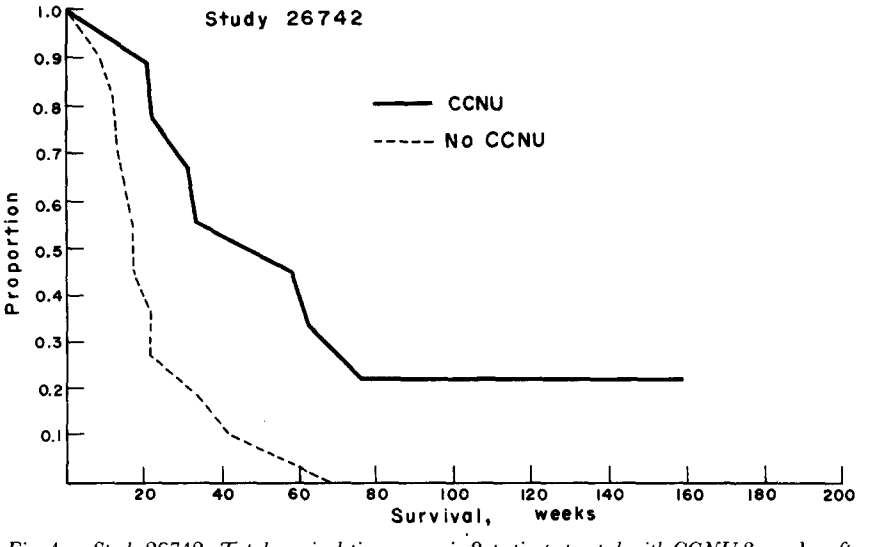

Fig. 4. Study 26742. Total survival time curves in 8 patients treated with CCNU 3 weeks after neurosurgery until death (———) as compared to 11 controls who received no chemotherapy (----).

DISCUSSION

This final evaluation of the two trials confirms the conclusions of the first report of our results concerning the use of CCNU in malignant brain gliomas [1]:

(a) In patients with clinically evaluable free interval the relapse of neurological signs is not delayed by CCNU (trial 26741).

(b) Objective remissions may be expected in about 30% of patients with recurring neurological signs due to malignant brain gliomas after treatment with CCNU (trial 26741).

(c) In a selected group of patients receiving CCNU after neurosurgery, CCNU prolongs the survival time (trial 26742).

How do these results compare with the data from the literature?

To the best of our knowledge, the effects of CCNU on the free interval (median time to progression) were reported in only one study where the free interval was found to be prolonged in patients who received CCNU [3]. The discrepancy between those results and our data are difficult to explain. Scheduled doses of CCNU were the same in both studies. In our trial no patients received dexamethazone before recurrence and the

number of cases studied was larger than in the report of Band *et al.* [3].

The mean dose of CCNU actually given in the present study was over 100 mg/m^2 once every six weeks, which represents 80% of the scheduled dosage. Blood-toxicity was the major limiting factor in patients who received less than the scheduled dosage. It is thus unlikely that, with the schedule used in this study, substantially higher doses of CCNU could have been given during mean periods of about 30 weeks.

Objective remissions after administration of the 3 nitrosourea derivatives currently used: BCNU, CCNU and methyl CCNU have been observed by various authors [4–7], BCNU being possibly slightly superior to the two others. The percentage of objective remissions observed in this study was lower than the figures reported for CCNU by Rosenberg *et al.* [5] and Wilson *et al.* [7], but comparable to the results of Reagan *et al.* [8]. These variations are due at least partially to differences in the definition of objective remission which includes in some studies a stabilization of the neurological status whereas in other trials, including ours, objective improvements were required. The length of objective remission due to CCNU found in this study is in agreement with the results of Wilson *et al.* [7]. Objective remissions were observed in the group of patients who received CCNU only after recurrence. This group of patients had a longer survival from the operation and from the relapse of neurological signs as compared with the group of patients treated with CCNU early after neurosurgery. Therefore, we should recommend that CCNU, when used alone, should be given only after the relapse of neurological signs. The failure of CCNU to prolong the free interval is not inconsistent with its ability to produce objective remissions. The two parameters may not measure the same phenomenon. One may speculate that patients with free interval are predominantly those with a slow postoperative tumor growth rate, possibly due to radiation therapy. Thus, early administration of CCNU will have little antitumor effect, but may select cells resistant to the drug. For the same reason, tumors of patients treated with CCNU only after recurrence may be more sensitive to the drug. In addition, because of the cumulative toxicity of the nitrosoureas, these patients can be treated more vigorously than those who received CCNU immediately after operation.

From various possible prognostic factors, evaluated in the present study which may affect the length of the free interval and the survival time, patients age and tumor pathology appeared as the most important. Younger patients survived longer and glioma multiforme had a worse prognosis than other malignant gliomas. Surprisingly the number of lobes involved by the tumor and the type and extent of the tumor resection were not correlated with the duration of the free interval or the postoperative survival.

The finding that in trial 26742 the survival was significantly longer in patients treated with CCNU as compared to the controls who did not receive chemotherapy at all needs future confirmation. Indeed the number of patients included into the trial is small and its results conflict with the findings of Reagan *et al.* [8] who failed to show in a randomized study a significant increase of the survival when CCNU was added to neurosurgery and radiation therapy.

A Comparison of the Effect of Metal–Bleomycin Complexes on the DNA Damage and Survival of Cultured Mammalian Cells

A. D. NUNN* and JOHN LUNEC†

Medical Research Council, Cyclotron Unit, Hammersmith Hospital, Ducane Road, London W12 0HS, United Kingdom

Abstract—*Parallel studies of DNA strand breakage and colony forming ability were carried out on cultured Chinese hamster V79 cells treated with both metal free bleomycin and the copper and cobalt complexes of this antineoplastic agent.*

It has been shown that Cobalt (III) *bleomycin is non-toxic towards cultured mammalian cells and, with the system used, does not cause any detectable DNA damage even though its binding to DNA is enhanced compared to other bleomycins. The effects of Copper*(II) *bleomycin on intact cells is similar to metal free bleomycin with regard to both cytotoxicity and DNA damage. The difference between these two metal complexes is explained by their different stabilities in the cells.*

INTRODUCTION

THE ABILITY of the bleomycin group of antineoplastic agents to bind metals and localise in tumours has been exploited in the field of nuclear medicine. The incorporation of appropriate radioactive metals into the bleomycin molecule has produced a variety of compounds useful for the imaging of tumours [1]. The importance of this metal binding capacity in chemotherapy with bleomycin is as yet unclear.

A likely mechanism for the efficacy of bleomycin in the treatment of cancer is its reported attack on DNA [2], but the role of metal ions in this attack is complex. In initial *in vitro* experiments with DNA, attack was only observed after the addition of sulphydryl compounds to the reaction mixture [3]. It was subsequently demonstrated that DNA attack could be observed *in vitro* in the absence of such sulphydryl compounds if more sensitive assay procedures were employed [4], indicating that such compounds merely enhanced DNA attack. It has been shown that under aerobic conditions Fe^{2+} enhances bleomycin attack on DNA in the absence of sulphydryl compounds [5] and a mechanism has been proposed [6]. Enhancement of attack has also been demonstrated for hydrogen peroxide [7] and the superoxide ion [8] but the addition of EDTA had no effect [9] or inhibited attack even in the presence of sulphydryl compounds [10]. The enhancement of bleomycin attack on DNA produced by sulphydryl compounds has been found to be inhibited by Cu^{2+}, Co^{2+} and Zn^{2+} [5].

It has been suggested that the role of the sulphydryl compounds is to compete with the bleomycin for metals that would normally interact with it and inhibit its attack on DNA [5, 11].

In the clinical situation it was thought that copper would be the metal most likely to inhibit the efficacy of bleomycin due to its abundance in the blood. Preliminary results with patients of a protocol designed to lower serum copper levels during bleomycin therapy are encouraging but assessment of the results is still in progress [12].

In order to understand and improve treatment with bleomycin it is necessary to determine the effect of metals on their action *in vivo*. We report here the effect of preformed metal–bleomycin complexes on the colony forming ability of cultured mammalian cells and the DNA damage produced in these cells.

MATERIALS AND METHODS

Bleomycin sulphate for injection (Lot 259) was obtained as a freeze-dried preparation

Accepted 11 January 1978.

*Current Address: Department of Nuclear Medicine, Suny Upstate Medical Center, 750 East Adams Street, Syracuse, N.Y. 13210.

†To whom reprint requests should be addressed.

in 15 mg ampoules (containing 15 units of activity) from Lundbeck Ltd., Luton. Beds. Due to differences in potency between the various bleomycins and slight changes in their ratios in the clinical preparation the ampoules contained only ~8.3 mg (wt) of bleomycin.

The cobalt III and copper II complexes were made by adding an equimolar amount of cobalt II or copper II dissolved in water (calculated assuming an average bleomycin mol. wt of 1425) to a weighed amount of bleomycin also in water. The pH was then adjusted to ~pH 7.5 with 0.1M $NaHCO_3$. This procedure allowed complete oxidation of the cobalt II to cobalt III when bound to the bleomycin. Details of the characterisation of metal–bleomycin complexes have appeared elsewhere [13–16].

Cell culture and treatment

Chinese hamster V79 cells were chosen for this study. They have a doubling time of 12 hr and from single cells produce colonies suitable for counting by naked eye within 6–7 days. The growth medium used consisted of Eagle's Minimum Essential Medium with Earle's Salts, plus 15% foetal calf serum. The pH of the medium during subculture and colony growth was controlled by adding 2.2 g $litre^{-1}$ of sodium bicarbonate and maintaining a 5% CO_2 atmosphere in the 37°C incubator. Throughout the course of these experiments the cells were grown as surface-attached monolayer cultures and subcultured whilst still in exponential growth.

Cells to be treated with the bleomycins were plated two days before exposure to the drug. Routinely, 20, 5 cm plastic Petri dishes were seeded from the same stock culture bottle with approximately 5×10^4 cells per dish, yielding $\sim 5 \times 10^5$ cells per dish at the end of the two day growth period. After one day, half of the cell samples were radioactively labelled with 0.02 μCi ml^{-1} of ^{3}H-thymidine (The Radiochemical Centre, Amersham. TRK418, 40–60 Ci $mmole^{-1}$). The level of activity was chosen to minimise the damage to DNA produced by the radioactive label itself (see results section for data). Exposure to the ^{3}H-thymidine was maintained for 15–16 hr at the end of which period the labelled medium was aspirated out of the culture dishes. Each cell sample was washed twice with 5 ml of label-free medium, after which the cells were grown for one hour in medium free of ^{3}H-thymidine before treatment with bleomycin. The same washing procedure was also carried out with the unlabelled cell samples so that as far as possible both sets of cell samples were exposed to the same conditions.

The cell samples were exposed to bleomycin for one hour whilst still attached to the Petri-dish. Small volumes of the bleomycin solution were injected directly into the full growth medium above the cells and mixed by gentle rocking of the dishes. During treatment the cell samples were kept in a 37°C incubator, which was humidified and gassed with a 5% CO_2 in air, gas mixture. At the end of the treatment period the bleomycin containing medium was aspirated out of the culture dishes and each cell sample was washed once with 3 ml of fresh medium and once with 2.5 ml of 0.1% trypsin made up in 0.9% NaCl. The cells were then incubated for 10–20 min at 37°C with 0.3 ml of the trypsin solution in each dish in order to detach the cells from the surface. At the end of trypsinisation each sample was suspended in 5 ml of culture medium which was then repeatedly drawn up into a narrow tipped pasteur pipette to produce a single cell suspension.

The labelled cells were used to assay for DNA damage and the unlabelled cells were diluted and re-plated to assess their clonogenic forming ability, which for the basis of these studies was the criterion used to define cell survival. A cell count was made with a haemocytometer for each cell sample treated so that the survival rate could be expressed in terms of the number of cells plated and then corrected for plating efficiency from the survival rate of untreated control cells. The colonies were stained with methylene blue after 6 or 7 days of incubation.

DNA damage assay

The method of treating the cells to unwind the DNA was similar to that described in detail by Rydberg [17] and was as follows.

Three one millilitre aliquots of each cell suspension were placed in ice-cold polystyrene centrifuge tubes and spun at 1000 rev/min for 5 min using an angle head. (Cat. No. 6885) in an MSE 6L centrifuge maintained at 4°C. The serum was separated from the sedimented cells by inverting each tube and lightly blotting the open end with absorbent paper. The tubes were then placed in an ice bath and 0.5 ml of the lysing

solution (0.03M NaOH, 1.0M NaCl, 0.5% Sarkosyl) was added to each, taking care not to disturb the tubes once the lysing solution had been added. This is the most sensitive step in the procedure [17]. After 15 min, during which they were protected from light, the solutions were neutralized by rapidly adding 1.1 ml 0.02M $NaHPO_4$ using a syringe and needle. Each sample was then sonicated for ten seconds using an MSE sonicator fitted with a 3 mm tip and set at 15 μm amplitude. After sonication 0.2 ml of a 2% SDS solution was added to each solution whereupon they were stored at 4°C for one to three days until chromatography was performed.

The hydroxyapatite was prepared in this laboratory using a' method described by Myazawa and Thomas [18]. The columns were made from the barrels of 2 ml polystyrene syringes, with glass fibre discs to retain the hydroxyapatite (millipore Cat. No. AP2001000) and 3.8 cm, 19 gauge needles to stabilize the flow. Each column contained 0.6 ml of settled hydroxyapatite, was maintained at 60°C in a heated aluminium block during use, and was stored in water at room temperature. Each column could be used for up to five separate determinations.

The chromatography of the DNA was performed in basically the same manner as described by Rydberg [17]. Before use each column was washed with 3 ml 0.5 M and 0.0125 M potassium phosphate buffer, pH 6.8. The ~1.5 ml samples were then loaded, eluted and followed by 3 ml 0.0125 M phosphate buffer. This 4.5 ml sample constituted the run through and the counts it contained gave a sensitive indication of the separation efficiency (see Results). The columns were then washed with 3 ml 0.125 M phosphate buffer, to elute the single-stranded DNA, followed by 3 ml 0.5 M phosphate buffer to elute the double-stranded DNA.

After use the columns were washed with 3 ml 0.5 M and 0.0125 M phosphate buffer prior to storage or reuse. The radioactivity in the fractions was measured in a Beckmann Scintillation Counter using 5 ml of scintillant consisting of 1.1 litres of triton X-100 mixed with 0.9 litres of xylene containing 0.3% PPO and 0.01% POPOP.

RESULTS

The technique of hydroxyapatite chromatography developed by Ahnstrom and Erixon [19] and studied in detail by Rydberg [17], was used to determine the amount of DNA damage in the cells by the bleomycin as it is better suited to the analysis of large numbers of samples than gradient sedimentation. Strand scission is measured by the percentage counts in the single and double stranded fraction of the DNA after unwinding. Initial experiments were performed on untreated cells to determine the optimum amount of ^{3}H-thymidine required to label the DNA, and the time of lysis. In agreement with Rydberg [17] the rate of unwinding was found to be linear with time. With 30 min lysis the highest background double stranded values (Fig. 1) were

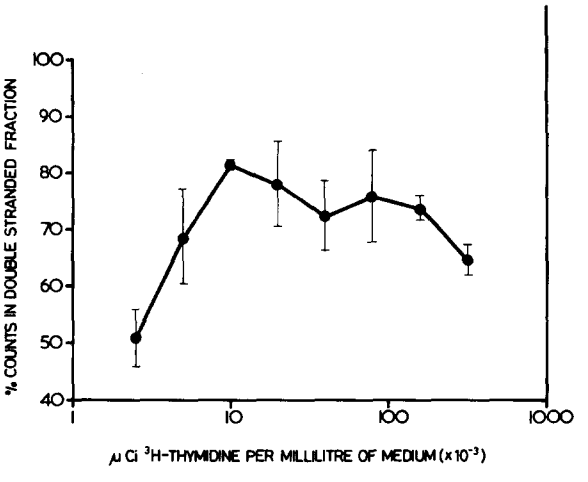

Fig. 1. The effect of the amount of ^{3}H-thymidine used to label the cells on their background DNA damage.

obtained when using a concentration of $\sim 2 \times 10^{-2}$ μCi ^{3}H-thymidine per millilitre of the medium ($\sim 10^5$ cells) and this concentration of label was used throughout the course of the experiments.

During the experiments an empirical rule was developed such that the results of an individual DNA-damage determination were rejected if the counts in the "run-through" fraction of that determination exceeded 0.5% of the total. This rule was developed because the results of determinations having high run-through counts invariably fell well outside the standard deviation of the remaining pair in each triplet and because this figure was high in experiments which had known defects in technique.

The cell survival and DNA damage studies were performed in parallel. Each study was performed on three or more occasions for each bleomycin formulation. The results are plotted as the means and standard deviations

of all the runs; as surviving fraction vs dose of bleomycin (in units of potency) in Fig. 2 and percentage counts in the double-stranded DNA fractions vs dose of bleomycin in Fig. 3. Points without error bars occur where studies for that dose were only made on one occasion. The percentage of counts in the double stranded fraction of the untreated cells was 93.6 ± 2.04 (10 studies) but for clarity the results in Fig. 3 are normalised to 95% background levels.

With the experimental conditions employed significant deviation from "background DNA damage" in untreated cells was not detectable until concentrations of ~ 0.1 unit bleomycin ml^{-1} were employed at which point cell survival was between 1 and 10%. This may be due to repair of DNA damage and/or lack of sensitivity of the system. (The latter could be increased by altering the lysing conditions see Rydberg [17].

Higher concentration of cobalt bleomycin showed increased double stranded counts over the untreated cells which may be an artefact caused by the binding of cobalt bleomycin to DNA interfering with the unwinding process in the alkaline lysing solution.

The cell survival data are expressed as per cent survival of untreated controls. There was no correlation between response to bleomycin treatment and the plating efficiency for untreated cells, which varied between 50–75% during the course of these experiments. The sensitivity of the V79 cells to metal free bleomycin is similar to that reported previously, with a relatively rapid initial response for drug concentrations up to 0.05 units ml^{-1} followed by a reduced rate of response with increasing concentration.

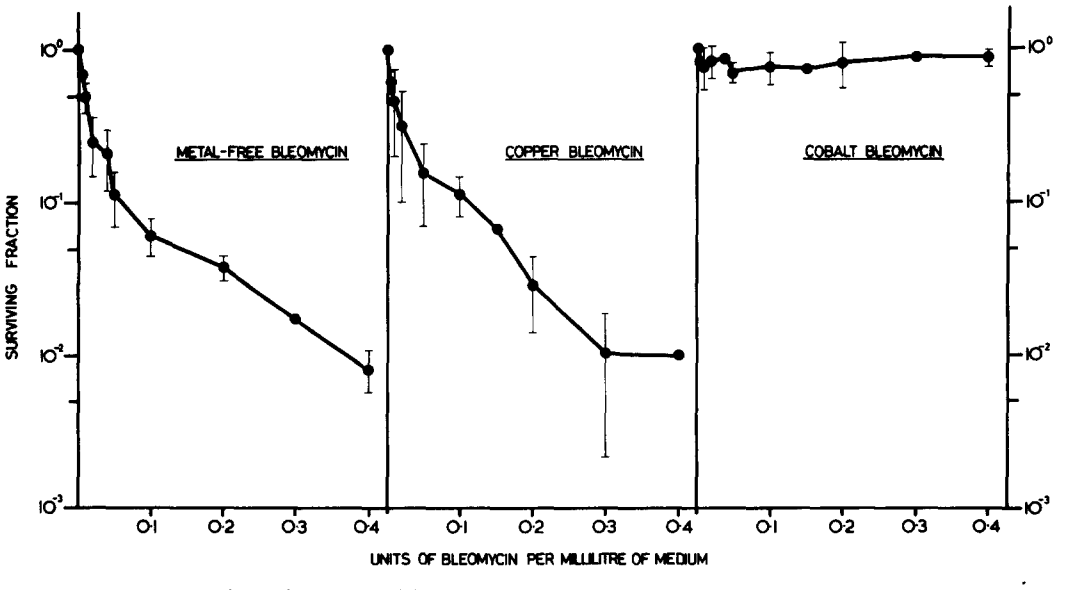

Fig. 2. The effect of the dose of bleomycin on the surviving fraction of cells exposed for one hour.

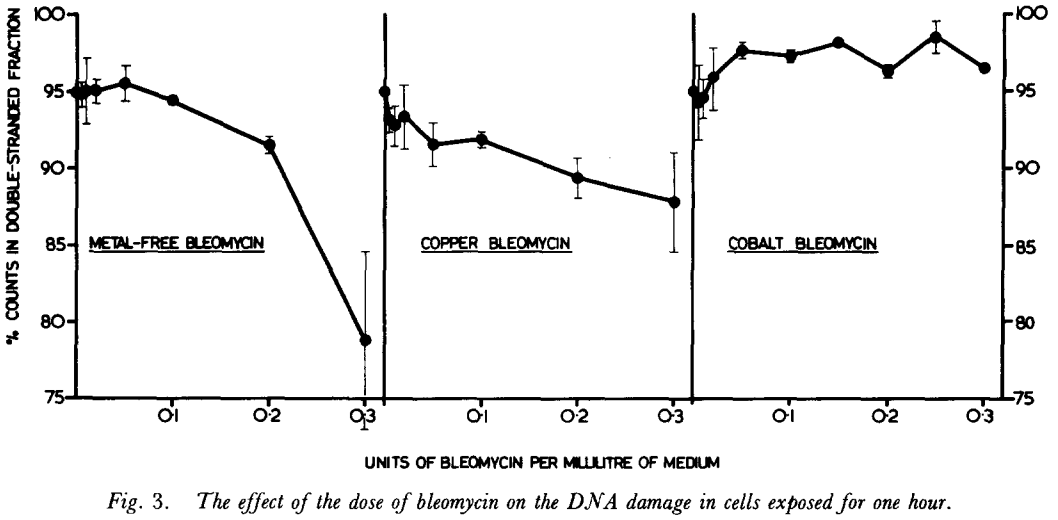

Fig. 3. The effect of the dose of bleomycin on the DNA damage in cells exposed for one hour.

The copper bleomycin survival curve was not significantly different from the curve obtained for metal free bleomycin. In sharp contrast to these two results the cobalt bleomycin was found to be relatively non-toxic for concentrations up to 0.4 units ml^{-1}, which was the highest level investigated.

DISCUSSION

It has frequently been demonstrated that *in vitro* DNA is attacked by bleomycin in the absence of 2-mercapto ethanol or other sulphydryl compounds [4, 6, 7]. It is also known that sulphydryl compounds, on their own, can attack DNA and cause single strand scission [7, 20, 21]. It is not clear whether *in vitro* bleomycin enhances DNA attack by sulphydryl compounds or vice versa.

Understanding of the situation is complicated by the fact that the mechanism involved in the attack of DNA by both bleomycin and sulphydryl compounds is probably the same. Lown *et al.* [7] have recently proposed a mechanism for bleomycin whereby free radials are produced by interaction between bleomycin, FeII and O_2. Wilson [22] describes an identical reaction between sulphydryl compounds, FeII and O_2 which is presumably responsible for the DNA attack attributed to sulphydryl compounds by various authors [7, 20, 21].

Cobalt II and Copper II react rapidly with bleomycin under approximately physiological conditions of pH and ionic strength to produce stable chelates [15]. Numerous other metals have been shown to bind relatively strongly to bleomycin and the complexes of some have been partly characterised [13, 14, 15]. Difficulty has been encountered in producing stable FeII and FeIII bleomycins [15, 22, 23] and Sausville *et al.* [6] have shown that FeII forms a complex that is moderately stable only in the presence of oxygen. Metals such as calcium and magnesium form relatively weak, non chelate complexes with bleomycin.

Binding of bleomycin to DNA *in vitro* occurs with or without the presence of sulphydryl compounds but it is inhibited in the presence of CuII, ZnII or EDTA [24]. Conversely, cobalt bleomycin has been found to concentrate in tumours to a greater extent than other bleomycins and enters the cells of the tumour to become localised in the nucleus, where it is firmly bound to DNA [1, 25]. Using gel filtration we have found that cobalt bleomycin has a greater affinity for calf thymus DNA than has metal-free bleomycin, in contrast to the inhibitory effect, on DNA binding of the metals noted above.

If the cytotoxic action of bleomycin is directly related to attack on DNA demonstrated *in vitro* one would expect that there would be no loss of viability in cells exposed to cobalt or copper bleomycin. Whereas this is true for cobalt bleomycin it is clearly not the case for copper bleomycin. Our results show that copper bleomycin and metal-free bleomycin produce survival curves which are almost identical and which are the normal downward concave type previously reported for mammalian cells [26].

The inhibitory role of cobalt in the attack of DNA by bleomycin *in vitro* is confirmed by the results reported here of the assay for DNA damage in intact cells when treated with cobalt bleomycin. Copper bleomycin and metal-free bleomycin produce similar DNA damage curves which are dose dependent. Thus cobalt bleomycin is not cytotoxic and, with the system used, does not produce any measurable DNA damage. On the other hand the effect of copper bleomycin on intact cells is similar to metal-free bleomycin with regard to both cytotoxicity and DNA damage.

The difference between cobalt bleomycin and copper bleomycin when acting on whole cells compared with their similarity of action on isolated DNA must be related to the greater complexity of the chemical environment in the cells.

Cobalt bleomycin is inert because the electron configuation of the Cobalt III is d^6 [27] and so the active site of the bleomycin is blocked both *in vitro* and in the cells. However, we have found using ^{61}Cu that the copper in copper bleomycin is labile under approximately physiological conditions of pH and ionic strength and without added reducing agents. the labile nature of the copper in copper bleomycin together with the presence of other possibly stronger copper binding ligands in the cell means that competition can occur for the copper, leaving the bleomycin free to attack the DNA if the competition is effective.

Recently Takahashi *et al.* [28] have also reported that copper bleomycin causes scission of DNA *in vivo* even though previous *in vitro* studies had shown that copper inhibits DNA attack by bleomycin. These authors

demonstrated that homogenates of rat ascites hepatoma AH66 cells contained small molecular weight substances that reduced the cupric ion of the bleomycin copper complex. This resulted in transfer of copper from the complex to cellular proteins, leaving metal-free bleomycin to attack the DNA of the cell. Our results are consistent with these findings.

The results reported here suggest that the original idea behind the penicillamine protocol to lower serum copper levels [12] may be invalid as copper does not affect the toxicity of bleomycin towards cells. Although assessment of the results is not yet complete the protocol does appear to have some benefit for patients treated with bleomycin. This may arise because the formation of the copper chelate in the blood affects the subsequent distribution and excretion of the bleomycin [25]. Alternatively the protocol may be affecting the tissue concentrations of other more critical metals; certainly serum zinc levels are known to change as a result of bleomycin administration [29].

Acknowledgement—We would like to thank Dr. I. P. Hesslewood for making the hydroxyapatite used in this study and Mr. R. Parker for technical assistance with some of the tissue culture.

In Vitro Effects of Oestrogen on Testosterone Metabolism by Human Breast Cancers

W. R. MILLER and A. P. M. FORREST

Department of Clinical Surgery, Royal Infirmary, Edinburgh, EH3 9YW, United Kingdom

Abstract—*The effect of* in vitro *addition of oestradiol on the metabolism of* $7\alpha^3H$ *testosterone by 15 human breast cancers has been investigated. Oestradiol significantly inhibited metabolism and conversion to 5α dihydrotestosterone, 5α androstanediol and Δ4 androstenedione.*

INTRODUCTION

HUMAN breast cancers can metabolise steroid precursors to active hormones such as 5α dihydrotestosterone [1, 2] and oestradiol-17β [3, 4]. Whilst the metabolism of testosterone by rat mammary tumours has been shown to be influenced by oestrogen both *in vitro* [5] and *in vivo* [6], little is known about the effects of hormones on steroidogenesis in human tumours. The aim of the present study was to determine *in vitro* the effect of oestradiol-17β on testosterone metabolism by human breast cancer.

MATERIALS AND METHODS

Tumours from 15 patients with proven cancer of the breast were studied: 10 subjects were at least 5 yr postmenopausal, 4 were premenopausal and had regular menstrual periods at the time of investigation. One patient had undergone bilateral oophorectomy 15 months previously.

Following excision the tumours, 10 of which were primary carcinomas and 5 recurrence on the chest wall, were processed at 0°C. They were finely sliced and split into duplicate portions each weighing 0.5 g to which Krebs Ringer phosphate buffer pH 7.4 (5 ml), an NADPH generating system and 20 μCi $7\alpha^3H$ testosterone (5.7 Ci/mmole from Radiochemical Centre, Amersham) were added.

Incubation was then carried out either in the presence of oestradiol (1.5 μg/ml) or its vehicle (propyleneglycol:ethanol 1:1) by shaking at 37°C in an atmosphere of oxygen for two hours. In two tumours oestradiol-3-methyl ether (1.5 μg/ml) was added to a further incubate as an additional control. The reaction was stopped by the addition of methanol (40 ml) and the incubate stored at −10°C.

Before extracting the metabolites, 500 μg each of non-radioactive testosterone, 5α dihydrotestosterone (5α DHT), 5α androstanediol, Δ4 androstenedione and oestradiol-17β were added to each incubate to monitor recovery losses. Details of the methodology for steroid purification by thin layer chromatography and characterisation by chemical derivative formation have been described previously [7].

Metabolism of testosterone was determined by measuring the incorporation of radioactive label into the appropriate metabolites after correction for recovery losses. Statistical comparisons between the results of incubates with and without added oestradiol were performed by paired *t*-tests after logarithmic transformation of the data.

RESULTS

The results are presented in Table 1. All 15 cancers converted testosterone to 5α DHT, 5α androstanediol and Δ4 androstenedione but synthesis of oestradiol was detected in only 8 tumours. In certain tumours, these products represented only a small proportion of the total metabolites; uncharacterized highly-polar compounds being responsible for most of the unidentified material.

The addition of oestradiol-17β to the incubates caused significant inhibition of the metabolism of testosterone ($P<0.01$) and its

conversion to 5α DHT ($P<0.01$), 5α androstanediol ($P<0.05$) and Δ4 androstenedione ($P<0.01$) as compared with control incubates. No effect was observed on the synthesis of oestradiol but the small conversions observed make comparisons difficult.

Oestradiol-3-methyl ether had no effect on the metabolism of testosterone in the two tumours (patients 1 and 8) in which its effect was investigated.

DISCUSSION

These results indicate that oestradiol-17β in general, inhibits the metabolism of testosterone by human breast cancer. However, there is considerable variation not only in its effect between tumours but also on the conversion of testosterone to individual metabolites in the same tumour. It is possible that differences in endogenous steroids within tumours may contribute to this variation. The concentration of oestradiol-17β added to the incubates was, in physiological terms, high. However, this was similar to that which has been used by others to study oestrogen sensitivity in human breast cancer [8] and pharmocological doses are used when treating patients with advanced breast cancer by oestrogen therapy.

That the effect of oestradiol-17β is not a non-specific effect of any steroid is shown by the fact that the same concentration of oestradiol-3-methyl ether was without effect in the two tumours to which it was added. Similar effects of oestrogen have, however, been described on 5α reduction of C19 steroids in the human adrenal cortex and prostate [9–10].

Although one of us reported that oestradiol-17β inhibited 5α reduction of testosterone in hormone dependent rat mammary tumours but not in two hormone independent tumours [5], there is no evidence for such a relationship in human tumours. If oestradiol's effect on steroid metabolism in human tumours were limited to those which are hormonally sensitive, one would not expect to observe

the general inhibitory effects described in this study. Further, in two patients with recurrent disease, endocrine treatment failed to induce remission despite demonstrable *in vitro* inhibition of 5α reduction by oestradiol-17β (patients 2 and 14).

Nevertheless, this study does indicate that metabolism of testosterone by human breast cancers is not an autonomous process but as in normal endocrine tissues, can be influenced by the addition of other hormones.

Failure of Neuraminidase Treatment to Influence Tumorigenicity or Immunogenicity of Syngeneically Transplanted Rat Tumour Cells*

M. V. PIMM, A. J. COOK and R. W. BALDWIN

Cancer Research Campaign Laboratories, The University, Nottingham NG7 2RD, England

Abstract—Vibrio cholerae *neuraminidase (VCN) and* Clostridium perfringens *neuraminidase (CPN) have been examined for their ability to reduce tumorigenicity of a range of seven different transplanted rat tumours. The enzymes released* 0.2 *to* 1.2 *μ mole sialic acid/*10^9 *cells, comparable to levels reported by other workers. However, in no case did treatment of tumour cells with either enzyme consistently reduce* in vivo *tumorigenicity over and above that caused only by the enzymes' buffer solution. Moreover, with a strongly immunogenic MCA-induced sarcoma, VCN treatment of cells did not improve their efficiency for active specific immunotherapy, and enzyme treatment of cells of a carcinogen induced mammary carcinoma, non-immunogenic by conventional criteria, did not render them immunogenic. Essentially, these studies fail to confirm the reduced tumorigenicity of neuraminidase treated cells, or their increased immunogenicity.*

INTRODUCTION

FOLLOWING the observations of Lindenmann and Klein [1] and Sanford [2] that tumour cells treated *in vitro* with neuraminidase showed reduced *in vivo* tumorigenicity, several other workers have demonstrated similar phenomena with a number of experimental tumours [3]. This has been interpreted as being due to modification of cell surface membranes following removal of sialic acid and/or permanent binding of enzyme molecules, facilitating host recognition and immune destruction. Moreover, the increased immunogenicity of enzyme treated cells has been reported to render them highly effective for active specific immunotherapy, particularly against transplanted 3-methylcholanthrene-induced sarcomas in the mouse [4], and this has led to their incorporation into vaccines for clinical immunotherapy [5, 6]. However, other groups have been unable to confirm the reduced tumorigenicity of neuraminidase treated cells [7, 8] and it has been ascribed, at least partly, only to direct cytotoxicity of the enzyme [9]. In addition, with some experimental tumours, neuraminidase treatment fails to augment their efficacy for immunotherapy [10, 11] and in some cases leads to positive facilitation of tumour growth [12].

In view of these conflicting reports the present studies were carried out to determine the influence of neuraminidase pretreatment on the tumorigenicity of cells of a range of transplanted rat tumours. In addition, the amount of sialic acid released has been quantitated, and the value of enzyme treated cells for active specific immunotherapy has been assessed.

Accepted 12 January 1978.

MATERIALS AND METHODS

Tumours

Tumours arose spontaneously or were induced with chemical carcinogens in rats of a Wistar derived, Nottingham Inbred strain (W/Not). Tumours were carried by routine subcutaneous transplantation in syngeneic rats of the same sex as the primary host. Sarcomas Mc7 and Mc40A were induced by subcutaneous implantation of 3-methylcholanthrene (MCA) [13]. Both are highly immunogenic, producing resistance to challenge in conventionally immunized animals against 5×10^6 tumour cells or whole grafts of tissue, although growing from inocula of 5×10^5 cells in untreated rats.

Hepatoma D23 was induced by feeding 4-dimethylaminoazobenzene. This tumour is moderately immunogenic, growing from an inoculum of 5×10^3 cells in untreated rats but producing resistance to challenge with up to 5×10^5 cells in immune animals [14, 15]. The ascitic variant of this tumour, D23As [16], used in some tests was similarly immunogenic, intraperitoneal injections of irradiated cells conferring protection against intraperitoneal challenge with up to 5×10^5 D23As cells.

Mammary carcinoma AAF57 was induced by repeated intraperitoneal administration of *N*-hydroxy-2-acetylaminofluorene. This tumour lacks detectable immunogenicity, pretreated rats failing to reject challenge with 1×10^3 cells, the minimum for growth in untreated control rats [17].

Epithelioma Sp1 arose spontaneously, and is only weakly immunogenic, immunized rats rejecting up to 5×10^4 cells compared with its minimum growth inoculum of 1×10^3 cells [18].

Fibrosarcomas Sp7 and Sp24 arose spontaneously and are weakly immunogenic, producing protection up to 1×10^5 and 1×10^3 cells respectively, the minimum inocula for growth [17].

Single cell suspensions of solid tumours were prepared by digestion of finely minced tissue in 0.25% (w/v) trypsin in Hanks' balanced salt solution (Baldwin and Barker, [14]) followed by washing and resuspension in medium 199. D23As cells were harvested by peritoneal aspiration with Hanks' solution, containing 5 units/ml heparin, washed and resuspended in medium 199.

The ability of tumour cells to exclude trypan blue was assessed by diluting suspensions in an equal volume of freshly prepared trypan blue dye (1 vol 4.15% w/v NaCl to 4 vol 0.2% w/v aqueous dye) followed by immediate microscopic examination.

Neuraminidase

Vibrio cholerae neuraminidase (protease free) was obtained from Behringwerke A.G. Marburg/Lahn, West Germany, as a sterile solution at 500 units/ml in pH 5.5 sodium acetate buffer.

Purified *Clostridium perfringens* neuraminidase (Type V) was obtained from Sigma Chemical Company, London as a freeze dried powder. It was dissolved in pH 5.5 sodium acetate buffer (0.05M sodium acetate/0.154M sodium chloride/5mM Ca^{2+}, pH adjusted with 1% v/v acetic acid) to 1000 units/ml, sterilized by passage through a 0.22 μM millipore filter and stored at $-20°C$.

The unit of enzyme used throughout is that defined by Mohr and Schramm [19] as the amount of enzyme to release 1 μg of *N*-acetyl-neuramininic acid from human α_1-acid glycoprotein, at pH 5.5 in 5mM Ca^{2+}, in 15 min at 37°C.

Release of sialic acid from viable tumour cells by neuraminidase

Single cell suspensions of tumour cells were sedimented by centrifugation at 30 g for 5 min, the supernatant removed and cells resuspended in 1–2 ml neuraminidase solution/1×10^8 to 2×10^8 cells. Control cells were incubated with pH 5.5 acetate buffer. Following incubation at 37°C for 30 min, the supernatant was removed, cells washed × 2 in 1 ml 0.15M NaCl and enzyme eluates and washings combined. The pooled eluates and washings were made 10% with respect to trichloroacetic acid (TCA) and the protein precipitate removed after 30 min by centrifugation at $1500 \times \boldsymbol{g}$. The clarified supernatants were stored at $-20°C$ for sialic acid assay. Cells were examined microscopically before and after treatment and their trypan blue exclusion compared with cells which had been retained in medium 199 at 37°C.

Assay of sialic acid

Sialic acid was assayed by a modification of the method of Warren [20]. The following reagents were used:—

(a) 0.2M sodium periodate in 9M orthophosphoric acid;

(b) 10% sodium arsenite in 0.5M sodium sulphate/0.1N sulphuric acid;

(c) 0.6% thiobarbituric acid in 0.5M sodium sulphate.

To 0.2–0.4 ml aliquots of test solution, in triplicate, was added 0.1 ml periodate solution, and samples incubated at room temperature for 20 min. One millilitre of arsenite solution was added, tubes incubated for a further 5 min and 3 ml thiobarbituric acid solution added. Samples were then heated in a boiling water bath for 15 min, and cooled in cold water for 5 min. The developed chromophore was extracted into an equal volume of cyclohexanone and optical density readings made at 549 nm with a light path of 1 or 2 cm against a blank of cyclohexanone extract of treated 10% TCA/0.15M sodium chloride.

The concentration of sialic acid was determined by reference to standard solutions of *N*-acetylneuraminic acid (at 0.025 to 0.4 μmole/ml) (crystalline synthetic *N*-acetylneuraminic acid, Type IV, Sigma Chemical Company, London). Standard solutions were prepared in 10% in 0.15M sodium chloride to be comparable with test samples of tumour cell eluates. The molecular extinction coefficient was found to be 59,000, comparable to that reported by Warren [20]. The amount of sialic acid released from tumour cells is expressed throughout as μmole/10^9 cells.

Total sialic acid content of tumour cells was measured by heating cells for 1 hr at 80°C in 0.1 N sulphuric acid. The cell debris was removed by centrifugation at $1500 \times g$ for 30 min and the assay carried out on the supernatant compared against standard *N*-acetylneuraminic acid solutions in 0.1 N sulphuric acid.

Assessment of tumorigenicity of neuraminidase treated cells

Tumour cells were suspended in neuraminidase (50–500 units/ml) in pH 5.5 acetate buffer at a concentration of 10^7–10^8 cells/ml, to give ratios of 5.25 units/10^6cells/ml. Control cells were suspended in pH 5.5 buffer alone, and a sample of stock cells retained in medium 199. Suspensions were incubated at 37°C for 30 min, washed ×2 in 10 ml medium 199, aliquots taken for trypan blue exclusion testing, and samples of stock, enzyme, and acetate treated cells diluted in medium 199 to a suitable concentration for injection. Cells of solid tumours were injected subcutaneously in the right flank. Rats were examined weekly for tumour growth, and mean tumour diameters calculated from caliper measurements in two planes. D23As cells were injected intraperitoneally and animals killed when moribund with ascitic growths.

Active specific immunotherapy of sarcoma Mc7

The efficiency of neuraminidase treated cells for active immunotherapy was assessed using the Mc7 active specific immunotherapy model previously described [21, 22]. Animals received a subcutaneous challenge inoculum of 5×10^5 to 2×10^6 Mc7 cells in one flank and a simultaneous treatment injection subcutaneously in the contralateral flank of 2×10^6 Mc7 cells (untreated, or previously exposed to 5 units/10^6 of neuraminidase) in admixture with 500 μg moist weight of BCG organisms (Glaxo Vaccine, B.P. (percutaneous) Glaxo Laboratories, Greenford, England). No progressive growth occurred from the mixed vaccine of Mc7 cells and BCG, and this led to concomitant control of challenge inocula in the majority of rats [21].

RESULTS

Vibrio cholerae *neuraminidase*

Quantitation of sialic acid release. Table 1 shows results of analyses of enzyme eluates from cells of six different transplanted rat tumours exposed to 5 units neuraminidase/10^6 tumour cells. With all tumours, detectable levels of sialic acid were present in enzyme eluates, at 0.21 to 1.00 μmole/10^9 treated cells. Sialic acid assays on acid digests of sarcoma Mc7 cells showed a total cell content of 3.6 μmole/10^9 cells. With only two tumours, sarcoma Mc7 and epithelioma Sp1, was sialic acid detectable in eluates of

cells exposed to only pH 5.5 acetate buffer. With most tumour cells examined, enzyme treatment reduced the proportion of cells capable of excluding trypan blue. This was most noticeable with hepatoma D23, mammary carcinoma AAF57 and the epithelioma Sp1, where only 58–77% of treated cells excluded the dye, whereas at least 90% of untreated cells were unstained. This toxicity could not be ascribed only to exposure to enzyme, however, since cells treated with only pH 5.5 buffer showed a similar, albeit smaller, increase in the proportion of cells taking up the dye.

Tumorigenicity of treated cells. Table 2 summarizes the results of tests to assess the *in vivo* tumorigenicity of neuraminidase treated tumour cells. Cells exposed to enzyme, at the ratio of 5–25 units/10^6 cells were, after washing in medium 199, injected subcutaneously into syngeneic recipients. Groups of control rats received cells treated with only pH 5.5 acetate buffer, and untreated stock cells. In each test care was taken

to inject the defined number of trypan blue excluding cells, since in some cases enzyme treatment greatly increased the proportion of cells taking up the dye.

With none of the 6 tumours examined was there any consistent reduction in *in vivo* growth potential over and above that caused by only pH 5.5. acetate buffer (Table 2, Fig. 1). For example, with hepatoma D23, in the first test, 1×10^4 neuraminidase treated cells failed to grow in all of five rats, compared with growth in 5/5 animals in groups receiving acetate buffer treated or stock cells. This was not reproducable in two further tests, however, and is probably attributable only to direct toxicity of the enzyme for the cells as evidenced by reduction in the trypan blue excluding populations from 91 to 67%. The rats which had injected 1×10^4 enzyme treated D23 cells were challenged 30 days later with 5×10^3 untreated D23 cells subcutaneously in the opposite flank. Tumours developed in 4/4 animals, comparable to growth in new controls rats (4/4). With none of the other tumours was there a single test in which neuraminidase treatment prevented growth, and in some cases tumour incidence were higher following enzyme exposure than from untreated cells. Thus with epithelioma Sp1 an inoculum of 5×10^3 neuraminidase-treated cells grew out in 4/6 rats, compared with only 1/6 animals receiving cells exposed only to pH 5.5 buffer and 3/6 rats receiving cells from the untreated stock suspension.

A further series of tests was carried out with the ascitic variant of the hepatoma D23, D23As (Table 3). Cells were harvested from the peritoneal cavity, washed and treated with neuraminidase without the need for trypsin digestion. Again, however, enzyme treatment at up to 25 units/10^6 cells was totally without influence on the ability of the cells to form rapidly fatal ascitic growths, from inocula as low as 5×10^3 cells.

Active specific immunotherapy with enzyme treated cells. To examine neuraminidase treated cells for increased immunotherapeutic efficiency a series of tests was carried out with the sarcoma Mc7 (Table 4). Animals received challenge inocula of 5×10^5–2×10^6 cells and were treated at a contralateral subcutaneous site with a vaccine of 2×10^6 viable Mc7 cells mixed with 500 μg BCG. Cells in this vaccine were treated with neuraminidase, or acetate buffer, and their therapeutic effectiveness compared with untreated cells admixed with BCG. It has previously been established that mixed inocula of Mc7 cells and BCG fail to produce progressively growing tumours and that there is concomitant generation of systemic tumour-specific immunity capable of suppressing growth of the contralateral challenge inocula in a high proportion of rats [21, 22]. In the first series of the present tests, with challenge inocula of 5×10^5 Mc7 cells (Expts. 1–4, Table 4), there was no evidence that neuraminidase treated cells gave a better therapeutic response than control cells. For example, in experiment 2, cells + BCG controlled tumour growth in only 2/5 rats, compared with suppression in all animals receiving enzyme treated cells and BCG, but in the third test these responses were reversed. The overall tumour incidences in the first four experiments were comparable in animals receiving enzyme treated cells and untreated cells (38% incidence compared with 34%), while the best response was given by cells exposed to only pH 5.5 acetate buffer (24% tumour incidence).

In the fifth and sixth tests the challenge inocula were increased to 1×10^6 and 2×10^6 cells respectively, at and above the limit normally controllable by a standard treatment inoculum of 2×10^6 Mc7 cells + BCG [21]. In neither test, however, were enzyme treated cells better than acetate treated cells or untreated cells, tumour incidence being comparable in all groups.

Immunisation against mammary carcinoma AAF57 with neuraminidase treated cells. Mammary carcinoma AAF57 lacks demonstrable immunogenicity, so that surgical removal of growing subcutaneous grafts or repeated implantation of irradiated cells fails to protect against a viable challenge inoculum of $1 \times 10^3 - 2 \times 10^3$ cells, the minimum for consistent growth in control rats [17]. In the experiment shown in Table 5 the immunizing capacity of AAF57 cells treated with neuraminidase was examined. Rats received three subcutaneous injections of 1×10^7 neuraminidase treated, irradiated AAF57 cells and were subsequently challenged with 2×10^3 untreated AAF57 cells. Tumours developed in 5/6 rats, compared with 7/7 takes in animals receiving irradiated acetate buffer exposed or untreated cells, and control rats.

Clostridium perfringens *neuraminidase*

In view of the failure of *Vibrio cholerae* neuraminidase to reduce tumorigenicity of the transplanted rat tumours examined, a further series of tests was carried out with an alternative preparation of the enzyme, that from *Clostridium perfringens*. The results were, however, comparable to those with the *Vibrio* preparation. Thus incubation in the enzyme at 5 units/10^6 cells released

0.48–1.28 μmole sialic acid/10^9 cells from the sarcoma Mc40A, mammary carcinoma AAF57 and sarcoma Sp24 (Table 6). Enzyme treated cells showed, however, no reduced *in vivo* growth potential, tumour incidence from low cell inocula being at least as high as that from cells treated with only pH 5.5 acetate buffer (Table 7).

DISCUSSION

Treatment of tumour cells with neuraminidase has been reported to reduce their

tumorigenicity with several different cell types including adenocarcinomas [2], leukaemias [23–25], carcinogen-induced fibrosarcomas [26–29] and ascitic tumours [30, 31]. *Vibrio cholerae* neuraminidase has been reported to be more effective than the enzyme from *Clostridium perfringens* [30]. In addition to reduced growth potential, enzyme treated cells show increased immunizing potential, and active therapy with them is highly effective against MCA-induced sarcomas in the mouse, including postsurgical residual disease [4, 32]. Based on these observations with experimental tumours Sedlacek *et al.* [33] have reported beneficial effects in immunotherapy of spontaneous mammary tumours in the dog with neuraminidase treated cells and clinically neuraminidase treated cells have been used for treatment of patients with melanoma [34], leukemia [5], and carcinoma of the breast, gastro-intestinal tract and ovary [6].

Decreased tumorigenicity, and enhanced immunogenicity of experimental tumours following neuraminidase treatment is thought to reflect enzyme-induced changes at the cell surface. Thus *Vibrio cholerae* neuraminidase (VCN) splits 2–3, 2–6 and 2–8 glycosidic linkages between terminal *N*-acylated neuraminic acids and cell surface sugar residues, while *Clostridium perfringens* neuraminidase (CPN) cleaves predominantly the 2–3 linkages [3, 9]. In addition neuraminidase may bind to cell surfaces, remaining attached and enzymatically active even after excessive washing [35, 36]. These modifications of the cell surface may reduce electro-negative charge, increase cell deformability and facilitate host recognition [3, 9].

In contrast to the reports of benificial effects of neuraminidase treatment, the present studies, using a range of seven different tumours, showed no consistent reduction in the tumorigenicity of VCN or CPN treated cells, over and above that ascribable to non-specific damage, although levels of sialic acid removed from the cells were comparable to those reported by other workers (e.g. 0.25 μmole/10^9 MCA-induced sarcoma cells in the mouse [28], 0.72 μmole/10^9 L1210 leukaemia cells in the mouse [23]. The tumours employed covered a range of immunogenicities, and were selected to optimise the possibility of detecting reduced tumorigenicity as a result of increased immunogenicity. The immunological nature of reduced tumorigenicity of neuraminidase treated cells in other systems is demonstrated by its abrogation in immuno-suppressed hosts [26, 27, 29]. In the present study animals which had rejected enzyme treated cells of the immunogenic hepatoma D23 were not immune to a further challenge with D23 cells, implying that in this case the rejection of the initial inoculum was not immunologically mediated.

Currie and Bagshawe [30] found that exposure of neuraminidase treated cells to trypsin reversed the beneficial effect of VCN, even after a subsequent, second, VCN incubation. In the present studies therefore tests carried out with the ascitic variant of the hepatoma D23, where trypsin exposure was not needed to prepare single cell suspensions for neuraminidase treatment. Again, however, neuraminidase treatment had no influence on their *in vivo* growth potential.

In addition to demonstrating no influence on tumorigenicity, the present studies also fail to demonstrate increased effectiveness of VCN treated cells of sarcoma Mc7 for active specific immunotherapy, sharply contrasting with the reports of Rios and Simmons [4] with MCA-induced sarcomas in the mouse, where established tumours may undergo specific immunological regression following active therapy with VCN treated cells. With the carcinogen induced mammary carcinomas AAF57, non-immunogenic by conventional criteria, neuraminidase treated cells, prevented from growth by irradiation, afforded no protection to viable tumour cell challenge, comparable to untreated irradiated cells.

In keeping with the present finding, however, other workers too have failed to demonstrate consistent beneficial effects following neuraminidase treatment of transplanted tumour cells. Thus Hauschka *et al.* [8] were unable to confirm the findings of Sandford [2] of reduced tumorigenicity of TA3 mouse mammary carcinoma cells, other than that attributable only to direct cytotoxicity of the enzyme. Similarly Yuhas *et al.* [7] working with a transplanted lung carcinoma in the mouse found no reduced tumorigenicity of VCN-treated cells, and demonstrated toxicity of the enzyme by *in vitro* studies, including ^{3}H-thymidine incoporation. With the B16 mouse melanoma Froese *et al.* [12] found no reduced tumorigenicity following VCN treatment, and enhanced tumour growth following pre-immunization with VNC-treated, irradiated cells. In a more recent series of studies with the Landeschütz ascites tumour trans-

planted into three strains of mice Smyth *et al.* [31] observed no reduced tumorigenicity of VCN treated cells in A2G mice, contrary to the earlier finding of Currie and Bagshawe [30] with the same tumour line and mouse strain. In other mouse strains (Schofield and BDF/1) reduced growth potential was only detectable with inocula below the LD_{100} in control animals. Similarly there was no improved beneficial effect of VCN treated cells for immunotherapy of an intracranially transplanted mouse glioma [10], while VCN treated irradiated cells were less efficient for immunotherapy of a mouse leukaemia than simply irradiated cells [11].

Essentially these studies indicate that, while neuraminidase may be efficient in many other experimental systems, it fails to influence the growth or immunotherapeutic effectiveness of transplanted rat tumour cells. This observation, together with other similar reports, including enhancement of growth, emphasises the need for caution in assuming the enzyme to be generally effective, especially in the clinical situation.

Intravenous BCG Therapy of Mammary Carcinoma in Bitches After Surgical Excision of the Primary Tumour

D. E. BOSTOCK* and N. T. GORMAN†

Department of Clinical Veterinary Medicine, University of Cambridge, Madingley Road, Cambridge, England

Abstract—*Thirty four bitches with defined histological forms of mammary carcinoma were studied post-mastectomy for over* 100 weeks. *They were randomized into* 3 *groups: (a) no further treatment* (11), *(b) placebo treatment* (10), *(c) intravenous BCG therapy* (13). *The mean survival time of the control groups was* 24 weeks *whereas for the treated group* 100 weeks. *This was significantly different* ($P<0.05$) *as calculated by the Chi² test* (χ^2).

INTRODUCTION

As IN women [1, 2] the mammary glands of bitches are the commonest single site for the development of neoplasms. Over 50% of all tumours in the female dog arise in the mammary tissues [3], half of the total number being histologically benign [4]. The overwhelming majority of the remainder can be classified morphologically as carcinomas. Canine mammary carcinomas normally exhibit clinical signs of malignancy by metastasizing to the regional lymph nodes and lungs, but unlike similar neoplasms in women very rarely spread to the bones, CNS or adrenal glands [4]. Inoperable local recurrence frequently complicates the clinical syndrome but is unusual in the absence of metastatic spread.

Retrospective follow-up studies on bitches treated surgically for mammary neoplasia [5] have shown that 60–70% of animals with an invasive mammary carcinoma die as a result of the initial tumour within a year of surgery, in spite of having no evidence of metastases when surgery was undertaken. The existence of this easily identified group of bitches, which can readily be predicted to develop metastases, closely resembles the situation in women with evidence of lymph nodal spread at mastectomy [6]. Any method of delaying the onset of metastatic disease is therefore of great comparative interest.

Owen and Bostock [7] demonstrated that pulmonary irradiation could increase the number of pulmonary metastases in certain cases. One possible mechanism involved in the observed increase may have been the destruction of some local immune mechanism. These workers subsequently reported that a course of intravenous BCG following complete excision of primary osteosarcoma delayed the development of pulmonary metastases [7, 8]. However, because of the extremely poor, and well documented, prognosis following amputation of a limb in canine osteosarcoma [9], it was difficult to justify the inception of a randomised controlled trial. These limitations do not apply to mammary carcinoma, where surgical excision of the primary is the treatment of choice and the effect of subsequent intravenous BCG on survival time can be justifiably compared to a control group receiving surgery alone.

MATERIALS AND METHODS

Spontaneously arising mammary neoplasms were surgically excised and submitted to the Department of Clinical Veterinary Medicine, Cambridge University for histological diagnosis. Tumours were classified

according to the criteria which have been previously described [5] into fibroadenomas, carcinomas and sarcomas. The carcinomas were further subdivided into either well defined or invasive on the basis of the boundary between the tumour and surrounding connective tissues. All dogs with an invasive carcinoma, either of solid or tubular morphology, were then subjected to a thorough clinical examination three weeks after surgery. Bitches with no palpable local or lymph node metastases and no radiological evidence of pulmonary metastases were randomised into three groups: (1) surgery alone, (2) surgery alone plus placebo, (3) surgery plus intravenous BCG.

The treated group received the contents of one vial of lyophilized BCG (Glaxo percutaneous strength) suspended in 5 ml of normal saline at a dose of 0.1 mg BCG/kg body weight. Prior to each injection each animal was injected intramuscularly with chlorphenirmine maleate BP[1] to avoid anaphylactic-like reactions following injection. This procedure was repeated at intervals of 1, 2 and 4 weeks and then every 8 weeks until 1 yr after surgery, when all treatment was ended. One control group received placebo treatment of intramuscular Piriton* and 5 ml of intravenous saline and the other had no further treatment. The study was continued for at least 100 weeks after surgery or until death, the cause being determined by post-mortem examination.

The survival time of dogs in the treated and control groups were compared using the Wilcoxon rank sum test and death rates with the Chi[2] test. In the former test, animals still alive were treated as equivalent at the highest rank.

*"Piriton", Allen and Hanburys Limited, London England.

RESULTS

Intravenous BCG was well tolerated in most cases, with only a transient pyrexia, malaise, and inappetence for 48–96 hours after each injection. Some dogs appeared to show a more prolonged depression after the fourth and fifth injection. However, only one dog had to have treatment withdrawn due to continued anaphylactic attacks despite premedication with Piriton (this case not included in results).

A total of 34 cases of histologically confirmed invasive mammary carcinoma were seen at this department three weeks post mastectomy. The bitches were assessed as tumour-free by the criteria described in Materials and Methods and randomised into three groups. The median survival time for each group is shown in Table 1. As can be seen this was very similar in the two control groups. However, the BCG treated group was significantly different from these controls ($P<0.02$). The median survival time could only be estimated (at 100 weeks) compared to 24 weeks for the controls, since the median bitches were still alive at the time of writing. The death rate in the first post-surgical year was significantly greater in the control groups (50 and 56%) than in the treated groups (15%) where only two dogs died as a direct result of the tumour. Where death is referred to in the text or tables this usually represents euthanasia in the terminal stages of illness, although four dogs in this study died of natural causes.

In Table 2 the findings in all those animals destroyed because of the tumour at the end of the follow-up period are

Table 1. *The effect of intravenous BCG on the median survival time and death rate of bitches following excision of an invasive mammary carcinoma*

Group	Number of dogs	Mean age at surgery (yr)	Median survival time (weeks)	%Dead after 1 yr	
				All causes	Tumour
Control surgery only	11	8.5	24	64	56
Control surgery + placebo	10	9.5	24	70	50
Treated surgery + BCG	13	10.0	100 (estimated)	23	15

Table 2. The cause of death in dogs following surgical excision of an invasive mammary carcinoma

Group	% Dead at time of writing	Number of bitches with: Local recurrence	Lung metastasis	Recurrence and metastasis	Other causes
Controls	81	1*	8	4	4
Treated	54		1	2	4

*No post-mortem was allowed on this animal.

summarised. As can be seen, 17 of the 21 control bitches were dead, 13 as a result of the original tumour and 4 of other causes. In one of the control animals still alive local recurrence and pulmonary metastases have been radiographically confirmed. In contrast 3 of the 13 BCG treated dogs died from the mammary carcinoma, whilst 4 had succumbed to unrelated diseases. Local recurrence was present in 24% of the controls and 15% of treated dogs whilst 57% of controls compared to 23% of treated dogs developed pulmonary metastases.

Survival curves for the combined control groups, and treated group, are compared in Fig. 1. The difference in overall survival rates is significant up to about 1 yr. After this, the rates become almost identical as deaths from other causes begin to exert their influence.

DISCUSSION

The survival curve for control bitches with invasive carcinoma in this study was very similar to that previously reported [5]. It illustrated the high mortality associated with recurrent or metastatic tumour during the first post-surgical year, followed by a lower rate due to other diseases. In the treated animals this initial high mortality was almost completely abolished and the death rate was linear over the whole follow-up period. There was no evidence that the incidence of local recurrence was reduced by intravenous BCG therapy and the results indicated that the main effect was a delay in the onset of pulmonary metastases. This was similar to the findings with canine osteosarcoma [7, 8].

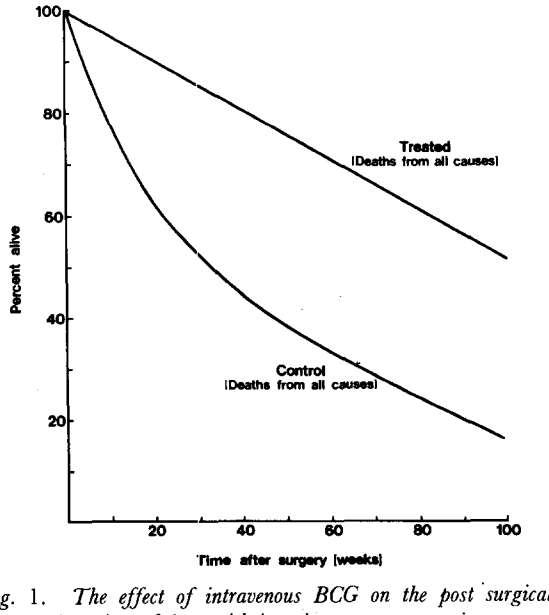

Fig. 1. The effect of intravenous BCG on the post surgical survival time of dogs with invasive mammary carcinoma.

Intravenous BCG in dogs was shown to induce a diffuse macrophage infiltration into the lung with focal granuloma formation [7, 10] and characteristic epithelioid granulomas were also identified in the liver. This resembled the reports of granuloma formation in man following intravenous and intralesional BCG administration [11–15].

The mechanism of the delay in onset of pulmonary metastases has been investigated in this unit. Lymphocytotoxicity studies have failed to provide conclusive evidence that non-specifically activated non-adherent cells were present following intravenous BCG [16]. However experiments have shown that mononuclear phagocytes associated with the pulmonary granulomas exhibit a marked non-specific tumour cell lysis *in vitro* [10]. This was not found with mononuclear phagocytes isolated from normal canine lungs.

The evidence suggested that the delay in onset of metastases *in vivo* was mediated by a non-specific mononuclear phagocyte response. This concept would support the experimental work of Baldwin and Pimm [17–19] who have demonstrated that intravenous BCG controlled pulmonary metastases without affecting the primary tumour. This was suggested to be comparable to the

restriction of tumour growth when BCG is administered locally [20–23].

The observation that intravenous BCG will significantly prolong the post-surgical survival time of dogs with mammary carcinoma is of great comparative interest. However, reports of the efficacy of intravenous BCG in man are conflicting and may obviate a direct extension from this useful canine model of spontaneous neoplastic disease. Further work in the dog should be aimed at identifying fractions of the organism which are responsible for the observed clinical improvement and improving the therapy regime [10]. This will require the study of a large number of animals and can only be done with the co-operation of a number of workers in different centres.

Acknowledgements—We would like to thank all those colleagues in practice who submitted clinical material. Without their help and active co-operation this work would have been impossible. We would also like to thank Miss M. Dye and Mr. K. Hunt for their invaluable technical assistance and Miss J. A. Newham for typing the manuscript.

This work was supported by grants from the World Health Organization, Cancer Research Campaign, Medical Research Council and the Jowett Fund. One of us (NTG) was in receipt of a Horserace Betting Levy Board Veterinary Research Scholarship.

Multivariate Biochemical Indicators of Breast Cancer: An Evaluation of Their Potential in Routine Practice*

DIANA M. COWEN,† FRANCES SEARLE,‡ A. MILFORD WARD,§ E. A. BENSON,¶ F. G. SMIDDY,¶ G. EAVES† and E. H. COOPER†

†*Department of Experimental Pathology and Cancer Research, University of Leeds, United Kingdom;* ‡*Department of Medical Oncology, Charing Cross Hospital, London, United Kingdom;* §*Protein Reference Laboratory, Hallamshire Hospital, Sheffield, United Kingdom; and* ¶*The Combined Breast Clinic, General Infirmary at Leeds, United Kingdom*

Abstract—*A vertical study has been made of the frequency of abnormalities of the levels of* 3 *tumour related antigens (CEA, βHCG and casein),* 2 *serum enzymes (gamma glutamyltranspeptidase and alkaline phosphatase),* 4 *acute phase reactant proteins (haptoglobin, acid glycoprotein, ceruloplasmin and antitrypsin) and a random study of C-Reactive protein in* 429 *women attending a breast clinic.*

Whilst the frequency of abnormality increases with tumour load, these parameters seem unable to discriminate high risk groups Stages II *and* III *from benign breast disease. The women are heterogenous with respect to their individual marker profiles. Elements within this panel of potential markers could be used to design a profile for longitudinal monitoring of recurrence in certain high risk groups, but as yet they do not appear to warrant their introduction into routine medical practice until they have been proven to aid clinical decision making.*

INTRODUCTION

THERE is still much controversy as to the optimum plan of therapy of breast cancer in women, be they pre- or post-menopausal. All will agree that the eventual outcome depends on whether the tumour has produced micro-metastases or overt metastases at the time of first presentation and whether local treatments can effectively prevent any residual local focus continuing as a source of metastases. The natural history of the disease is such that the evaluation of the combination of various modalities of treatment usually takes between 5 and 8 yr to provide an answer and even then it says nothing about the really late recurrences. Undoubtedly a reliable system of tumour markers to provide evidence of micro-metastases or an early warning of growth in previous dormant micro-metastases would be of help in planning the treatment for the individual patient; in particular the necessity for, and the timing of adjuvant chemotherapeutic or hormonic therapy.

Accepted 19 February 1978.

This study has been partially supported by the Yorkshire Cancer Research Campaign.

Several tumour related antigens (TRA) have been studied in breast cancer, carcinoembryonic antigen [1–3], β sub-unit of human chorionic gonadotrophin [4, 5] and kappa casein [6, 7]. In the main, these have been looked at as single tests. The overall impression is that these products can only be found in a proportion of women with breast cancer and this proportion increases slightly with the progression of the disease. Franchimont and his colleagues [8] have advocated that coincidental measurement of 4 tumour related antigens will result in the finding of at least one positive value in 69% of patients with T1–3, N0, N1, M0 cancers and 88% in the presence of metastases. This multivariate approach has been extended by Coombes *et al.* [9] to the point where they have attempted to apply most known cancer tests, 19 in all, to a group of 51 patients, 42 having active breast cancer and 9 with benign breast disease. But such a large number of variates inevitably will result in a higher background of random positivity of one or more above the 95 percentile of whatever set of values are chosen as being representative of the non-cancer patients. In this study we have

investigated whether the multivariate approach could be the basis of a monitoring system and to test it by a limited battery of tumour related antigens, serum enzymes changes associated with metastatic cancer and a profile for acute phase reactant proteins (APRPs). These tests have been applied, in the main, to a population of women attending the breast clinic of a large general hospital.

MATERIALS AND METHODS

Patients

Four hundred and twenty nine of the patients attending the Combined Breast Clinic of the General Infirmary at Leeds, between October 1975 and February 1977, were the main subject of this study. They were divided into the following principal groups: 42 controls being women in whom no abnormality was detected (mean age 37.5 yr, range 19–68); 100 with benign breast disease (mean age 44.1 yr, range 18–74); 48 with primary cancers (mean age 56.5 yr, range 29–82); and 238 patients attending the clinic after diagnosis and treatment of primary breast cancer. The latter group was divided into: 156 post-mastectomy clinically tumour free (mean age 59.0 yr, range 26–82); 52 with metastases (mean age 58.0 yr, range 36–76) 20 of whom were receiving medical treatment; and 30 women (mean age 70.0 yr, range 49–91) receiving medical and X-ray treatment for primary tumours, 11 of them having evidence of distant metastases. In addition, 133 sera from women (age not known) with primary breast cancer were received, 84 being from the Ludwig Institute, Lausanne and 49 from the Royal Marsden Hospital, London, for protein profile determinations only. The statistical study of the incidence of positive markers was based on a single blood sample. In the primary tumour group the blood was drawn prior to any form of therapy. In the remaining groups, samples were taken at least 6 weeks after surgery or X-ray therapy. In the patients with benign disease the samples were usually taken prior to biopsy. In all cases the diagnosis was based on appropriate histological examination. A limited number of sequential samples taken over a period of one year have been examined in some patients to investigate the stability of the markers within a given individual. During the course of the investigation 6 patients in the Leeds series were reported to have died of metastatic cancer; samples of all these women were taken at a time when they were still fit enough to attend the clinic. None of the patients in this series was sufficiently incapacitated by their disease to be considered in a terminal phase at the time of examination.

Methods

Carcinoembryonic antigen (CEA). CEA was assayed in serum (100 μl) by double antibody radioimmunoassay [10] using goat anti-CEA (Ace 36) kindly donated by Professor C. W. Todd, and horse antigoat antiserum (BW 402) from Burroughs Wellcome, the assay being adapted for automation [11].

β sub-unit of human chorionic gonadotrophin (βHCG). βHCG was measured according to the method of Kardana and Bagshawe [12].

K-Casein. K-Casein was assayed by an automated double antibody assay [11] performed in serum (100 μl) as described by Woods *et al.* [7].

The detection limit is 10 μl/l K-Casein; the within assay coefficient of variation was 3%, inter-assay coefficient of variation 18%.

Acute phase reactant proteins. α_1 Acid glycoprotein (AGP), α_1 antitrypsin (AT), ceruloplasmin (Cp), C-Reactive protein (CRP) and haptoglobin (Hp) were determined by single radial immunodiffusion [13], using antisera, standards and standard control plasma supplied by Behringwerke AG, Marburg, Lahn, Germany. The standards and standard control plasma were applied to each plate. The values for haptoglobin were corrected for differences in the molecular size of the various phenotypes. The correction factors were Hp1:1 $\times$ 0.6, Hp2:1 $\times$ 1.3, Hp2:2 $\times$ 1.5. The phenotypes were identified by electrophoresis in gradient polyacrylamide gels according to Baxter and Rees [14]. The choice of the proteins to be included in the profile was based on experience of other solid tumours [15, 16] and previous reports on Cp in breast cancer [17]. The day to day coefficient of variation (S.D./Mean $\times$ 100) of repeated assays over the whole range of values was AGP 6.7%, AT 9.4% and Hp 11.3%, the inaccuracies being greatest at the upper and lower limits of the assays.

Serum enzymes. Gamma glutamyltranspeptidase (GGT) (EC 2.3.2.1) was measured by the method of Jacobs [18] with the assays run

at 37°C. Alkaline phosphatase (ALKP) (EC 3.1.3.1) was determined by the *p*-nitrophenylphosphate method of Bessey, Lowry and Brock [19]. The enzyme assays were standardized using pooled serum from normal donors.

Statistical analysis. The 95th percentile of the values of the various proteins and enzymes in the controls and women with benign breast disease were determined by probit analysis with logarithmic transformation. Levels above these values were used as discriminants for reporting "positivity" in certain of the tables. Analysis of variance and Student's *t*-test were all made on log transformed data to compensate for the skewness in some of the distributions.

All the statistical analyses were run on the University of Leeds ICL 1906A computer using programs from the Statistical Package for Social Sciences.

RESULTS

Tumour related antigens

The frequency of elevation of CEA, βHCG and casein in the various groups of patients is shown in Table 1. It can be seen that whilst there is a higher incidence of raised levels of tumour related products in the blood of patients with metastatic cancer, both prior to treatment and whilst receiving treatment, these markers were low in incidence in Stages I–III cancer and could not be used as the basis of differential diagnosis from benign diseases of the breast. Likewise on the basis of a single reading in patients following mastectomy and thought to be clinically free of tumour, there is sufficient overlap with the benign disease to preclude using them as the basis of firm diagnosis of metastatic cancer, although a rising titre is extremely suspicious. In the patients who were being followed up routinely following surgery or medical treatment for a primary tumour, only 5/22 of the patients with an elevated CEA and 1/24 with elevated casein, showed consistent elevations of these markers on consecutive measurements and none of the 21 patients with an elevated βHCG showed persistent elevation of this marker.

Acute phase reactant proteins and enzymes

Table 2 shows the means and standard deviations of the 2 enzymes investigated and of the 4 APRPs. Patients receiving medical treatment, which is mainly hormonal manipulation, have been excluded as the pharmacological effects of this treatment have a direct effect on the synthesis of several of the markers [20]. An analysis of variances showed that significant differences occurred between and within the groups for Hp, AGP and Cp but the variation of AT in the different patient populations was not highly significant.

Further analysis showed that the levels of Hp in the primary tumours of stages I–III were significantly different ($P = < 0.001$) from that of stage IV and the clinically free patients on follow-up were significantly different at the same level from those with proven untreated metastatic cancer. The noticeable feature of the behaviour of the serum enzymes is the very large variances encountered in metastatic cancer; this is a reflection of particularly high values in some of the patients with clear-cut evidence for hepatic metastases as indicated by raised GGT and alkaline phosphatase or those with a high alkaline phosphatase and normal GGT as observed when there is an established metastasis in bone.

Table 3 shows the frequency of values

Table 1. *Incidence of Leeds patients with raised levels of tumour related antigens*

falling above the calculated 95th percentile (as determined for the benign group) for Hp, AGP, Cp and alkaline phosphatase. These figures have then been added to those for the tumour related antigens to show the relative frequency of various combinations.

By application of the binomial theorem it can be shown that by chance alone with a linear combination of 4 markers using the discriminant value of the 95th percentile of the benign breast disease group, the intrinsic probability of finding 1, 2, 3 or 4 markers positive is: 0.17, 0.014, 0.004 and 0.000006 respectively, that is assuming some of the women with cancer may also have coincidental benign disease. For this reason, we have used two of the non-specific markers at levels above the discriminant level as an indication that there is suspicion of recurrence. It will be observed that the cut off values for Hp and Cp are considerably higher than the published 95th percentile in a "normal" population which are quoted as 2.2 and 0.45 g/l respectively [21]. On the other hand, AGP is at the 95th percentile of a normal population.

C-Reactive protein

After completion of the main results presented in this paper, a survey was made of the levels of C-Reactive protein. A level of >10 mg/l was used as a discriminant to identify patients outside the normal range (0–10 mg/l). The following results were obtained: primary tumours stages I–III 11/81 (13.5%): stage IV 11/26 (42%); overt metastases after mastectomy without treatment 7/24 (29%); follow-up mastectomy clinically tumour free 3/102 (2.9%); benign breast disease 0/55 (0%) and Controls 0/26 (0%). Eighteen out of the 32 positive results (56%) had evidence of at least one other acute phase reactant protein elevated above the discriminant level.

DISCUSSION

It is convenient to consider the tumour related antigens (CEA, βHCG and casein) separately from the acute phase reactant proteins and enzymes.

Tumour related antigens

There have been several studies of the levels of serum or plasma CEA encountered in breast cancer. Steward [2] found elevated CEA in 6/22 patients with primary breast cancer, without clinical evidence of distant metastases. The levels recorded were below 10 μg/l (Thomson [22] assay, cut off 2.5 μg/l/1) except in one instance of 15 μg/l associated with local spread. The incidence of positivity increased to 37/47 (78%) with metastatic disease, levels being scattered between 2.5 μg/l to >30 μg/l. Serial CEA measurements in metastatic breast cancer lead the authors to conclude that initial CEA levels before therapy had little bearing on the prognosis but that in general sustained normal CEA levels after therapy correlated with a good response.

Chu and Nemoto [1] using the Hansen assay [23] considered that CEA might not be an adequate monitor of chemotherapy because clinical inprovement in their series sometimes preceded fall in CEA levels. Borthwick *et al.* [3] detected elevated CEA levels in 55% of women with primary breast cancer; 38/74 fell in the range of 0.1–0.4 U/ml, but they also found that 27/200 randomly selected women had a detectable CEA level in this range; 3/74 of the primary breast cancer patients had circulating levels of >0.4 U/ml. In patients with advanced breast disease 40% had levels >0.4 U/ml whereas in benign disease 10% had detectable CEA values. When clinical response to antioestrogen therapy was assessed, 6/19 responders showed a distinct fall in CEA values while only 1/22 non-responders showed a fall over a 3 month period. Unfortunately 6/19 responders increased their CEA level which would have complicated the interpretation if encountered prospectively. Our results seem to support the general finding that a low level of incidence of apparent positivity on CEA assay is found in the sera from patients with primary breast cancer. The exact immunological relation between the material in the serum on breast-tumour derived extracts and colonic cancer-derived CEA awaits corroborative study.

The ectopic production of human chorionic gonadotrophin by non-trophoblastic tumours has been investigated by Braunstein *et al.* [4] and Gailani *et al.* [5] using radioimmunoassays specific for the β subunit of the glycoprotein. In breast cancer, elevated plasma levels in 4/33 and 6/20 patients were found by these workers respectively. In addition Braunstein *et al.* [4] established parallelism between the material in the plasma of a patient with adenocarcinoma of the breast and standard human chorionic gonadotrophin. The elution pattern on chromatography through Sephadex G-100 was also very

similar. Our assay for human chorionic gonadotrophin, specifically directed to the β subunit, has established transient slight elevations of human chorionic gonadotrophin in the serum of some patients with breast cancer but these are not sustained sufficiently to be of use in monitoring the disease.

The frequency of a raised K-casein in the serum of our series of patients is lower than that reported by Franchimont and his colleagues [6]. In particular there was a low frequency of elevation of this marker in the women presenting with stage IV tumour or at first discovery of metastatic cancer (4/34); this suggests it will not have wide application for the follow-up of the management of metastatic cancer. However, in a previous series from our laboratories we have shown that if the tumour is a K-casein producer its level in the blood can reflect responses to therapy [7].

Acute phase reactant proteins and enzymes

The non-specific response of APRPs in metastatic cancer is a well recognised phenomenon in tumours of a variety of different tissues of origin [15, 16]. Longitudinal studies have shown that the changes in the protein profile in an individual can provide useful information about the evolution of cancer, especially in those tumours where specific tumour markers are absent or occur in a limited portion of the disease bearing patients [15, 24]. However it is evident the variance of some of these proteins coupled with the phenotypic variation seen in Hp and AT may obscure their value as potential markers when studied in a vertical series as presented in this paper. Our data shows that the APRPs cannot help in the discrimination of benign breast disease from primary breast cancer (stages I–III). On the other hand patients presenting with stage IV disease frequently but not invariably have a disturbed plasma protein profile. The behaviour of alkaline phosphatase and gamma glutamyltranspeptidase indicates they are both helpful in monitoring metastatic cancer though inevitably their rise signals advanced metastases involving bone or liver or both sites. The normal distribution of the levels of these enzymes in women without evidence of metastatic cancer indicates they both have potential in the profile test for longitudinal studies as they appear to have fairly stable patterns in health. Such longitudinal studies made for several years after resection of bowel cancer indicate that the patient's own values of these enzymes tends to remain within a narrow range [25].

The battery of markers used in this study is clearly too insensitive to separate unequivocally non-malignant and malignant breast disease except in its advanced stages. Whatever marker or combination of markers are chosen the variance within the disease groups is such that from a single reading, with the exception of a proportion of women with metastatic cancer, little can be said about the clinical significance of the pattern. However, these studies do indicate there are significant trends in the proportion of the markers that become abnormal in the progression from localised to metastatic breast cancer.

In practical terms it is the long term post-operative surveillance of high risk groups, for example pre-menopausal women with stages II and III cancer, where monitoring may be used with the aim of identifying early recurrence or the assessment of the effect of adjuvant chemotherapy. If this is to be done, then the problem still lies in choosing the best combination of markers for the individual patient. This can be influenced partly by the spectrum of TRAs produced by the primary and aided by serial monitoring of APRPs especially using those without phenotypic variation such as AGP and Cp and preferably unaffected by oestrogens; antichymotrypsin has recently been shown to have these properties [26]. Clearly then it is the clinician who must make the decision as to whether he feels the lead time given by any monitoring system could seriously influence his choice of therapy. It still needs to be proven that monitoring could avoid subjecting women who are "cured" of breast cancer to aggressive adjuvant chemotherapy on the basis of statistical probability of recurrence. The tests, at 2–3 monthly intervals, would be a trivial burden to that of chemotherapy though to be of any real use they would have to provide a considerable lead time in the warning of recurrence compared to standard clinical investigations. The challenge to the scientists would then be to make sure the system is both effective and cost effective.

Effects of Cytostatics on Proliferating and Stationary Cultures of Mammalian Cells

EDIT OLAH,* I. PALYI and J. SUGAR

Research Institute of Oncopathology, Budapest H-1122, Hungary

Abstract—*The cytotoxic effects of dibromodulcitol (DBD), dianhydrodulcitol (DAD), vincristine (VCR), N-formyl-leurosine (F-LEU) and bleomycin (BLM) were studied on logarithmically growing and plateau-phase cultures of Chinese hamster cells. One hour treatment with DBD yielded sigmoid type survival curves. Synchronized cells were sensitive to the drug throughout the cell cycle, especially at late G_1. DBD killed rapidly growing cells at a higher rate than plateau-phase cells. DAD proved to be equally toxic to both types of cells. At DAD concentrations above* 15 μg/ml *plateau-phase cells were more sensitive than logarithmically growing cultures. The dose-dependent survival curves for DAD were of the same type as the DBD curves. VCR and F-LEU produced survival curves characteristic of phase-specific drugs, killing specifically S-phase cells in synchronous cultures. Plateau cells were more sensitive to VCR than log cells, while F-LEU especially killed log cells. BLM produced biphasic survival curves, damaging plateau-phase cells almost* 18 *times more effectively than log cells.*

INTRODUCTION

BETTER knowledge of the effects anticancer drugs have on cells should enhance the effective design of chemotherapeutic schedules. The tissue culture system is widely used for the experimental study of mechanisms of drug toxicity. While exponentially growing cell cultures provide information about the effects drugs have on proliferation kinetics, the action of drugs on non-cycling cells may best be studied on plateau phase cells.

Plateau cultures, in which a very slow cellular turnover occurs, may be better models for *in vivo* tumours [1, 2], hence the recent attention paid to this type of culture in evaluating anti-cancer drugs [3–7]. In this work we have studied the cytotoxic effects of antitumour drugs on logarithmically growing and synchronized cell populations and on plateau phase cultures of Chinese hamster cells.

MATERIALS AND METHODS

Cell culture

Clone 451 of a Chinese hamster cell line [8] has been carried in our Laboratory for over 10 yr in medium 199 (Flow Laboratories) supplemented with 10% fetal calf serum and incubated in a 5% CO_2 95% air atmosphere. The cells were subcultured three times a week to keep them continually in logarithmic growth. Under these conditions the cells had a cell cycle time of 16.5 hr, as determined by the labelled mitosis method [9]. The average length of the G_1 phase was 5.5 hr, S-phase 7.5 hr and the G_2 phase 3.5 hr. The population doubling time was 18 hr.

Cell synchrony

Synchronized cell populations were used to study the cell cycle phase specificity of the drugs. Synchrony was achieved by mitotic selection [10]. At least 93% of the selected cells were in the M-phase.

Induction of plateau cultures

Replicate Petri plates, 60 mm in diameter, were seeded with 2×10^6 cells each and incubated without changing the medium. The cell number, mitotic index and ^{3}H-TdR labelling index were determined daily in replicate cultures. The cultures were considered to have reached the plateau phase when the cell number became constant, the mitotic index was about 0.1% and between 1 and 4% of the nuclei were labelled. This was achieved by the second day of the culture.

Drugs

The agents studied are widely used in clinical practice, with the exception of F-LEU. This new Vinca alkaloid derivative is very promising in the treatment of malignant diseases of the hemopoietic organs, and unlike VCR has no neurotoxic side effects [11, 12]. The drugs and their manufacturers are listed in Table 1. Stock solutions were prepared in physiological saline, and diluted for use with physiological saline or with medium.

Dose–response experiments

Exponentially growing cells were treated with different concentrations of the drugs as follows: cultures were exposed for 1 hr to DBD, DAD and BLM, and for 3 hr to VCR and F-LEU. The drug was removed and the plates rinsed with Hanks' solution. The cells were then trypsinized and seeded into culture flasks at 500 cells per 25 cm^2 flask. The pH was adjusted with 5% CO_2 in air. After 8 days of incubation the medium was removed and the cells stained with a saturated solution of crystal violet 0.85% NaCl. Colonies containing more than 50 cells were counted under a dissecting microscope, and the surviving fraction (SF) was caluaculated as follows:

$$SF = \frac{\text{plating efficiency of treated culture}}{\text{plating efficiency of untreated culture.}}$$

The same procedure was applied to plateau cells. Late plateau cells on the fifth day after subcultivation were treated by adding the drugs to the exhausted medium. This was done to avoid growth stimulation by fresh medium.

The plating efficiency of untreated control cultures of logarithmically growing cells, late plateau phase cells and mitotically selected cells were 86, 76 and 66%, respectively.

RESULTS

Dose–response studies on plateau cultures and logarithmically growing cells

Survival curves of cells treated with DBD and DAD are shown in Figs, 1 and 2, respectively. Both drugs yielded sigmoid survival curves. As can be seen from Fig. 1, DBD was more toxic to logarithmically growing cells. DAD was equally toxic to plateau and proliferating cells at concentration up to 15 μg/ml. At higher drug concentrations, plateau cells were more sensitive (Fig. 2).

The survival curve of exponentially growing cells treated with VCR was biphasic. Survival dropped sharply at VCR concentrations up to 0.025 μg/ml. Plateau phase cells had a similar concentration-dependent survival curve, but showed a higher sensitivity to the drug than proliferating cells (Fig. 3). Figure 4 demonstrated the dose dependent sensitivity of asynchronous cells to the new Vinca alkaloid F-LEU. Survival decreased with increase in drug concentration, and reached a minimal constant level at F-LEU concentration of 150 μg/ml, thus indicating that the drug has specific toxicity to cells in a certain phase of the cell cycle. F-LEU was toxic to a lesser degree to plateau cultures.

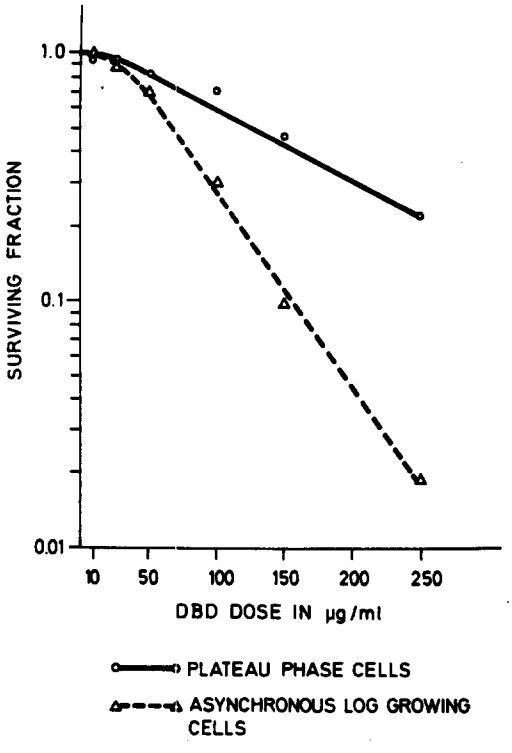

Fig. 1. Dose–response curve of Chinese hamster cells with DBD. Cells were exposed to different concentrations of the drug for 1 hr *after which the drug was removed and the cells washed with Hanks' solution. Cell survival was determined as described in "Materials and Methods."*

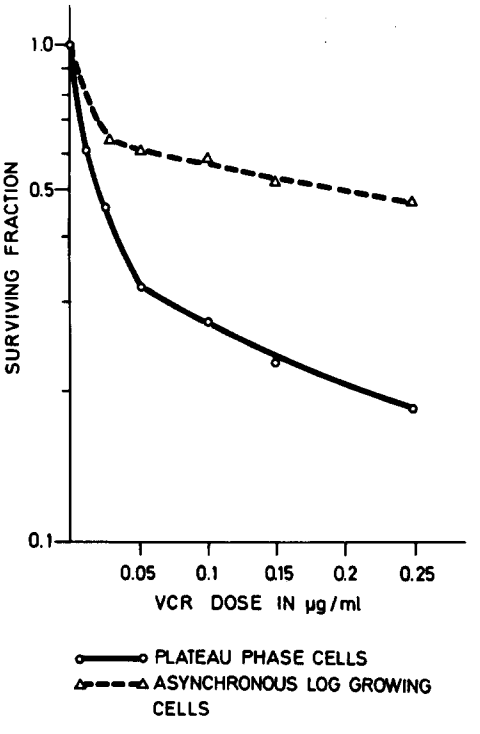

Fig. 3. Dose–response curve of Chinese hamster cells with VCR. Protocol was the same as in Fig. 1., except that the exposure to the drug was for 3 hr.

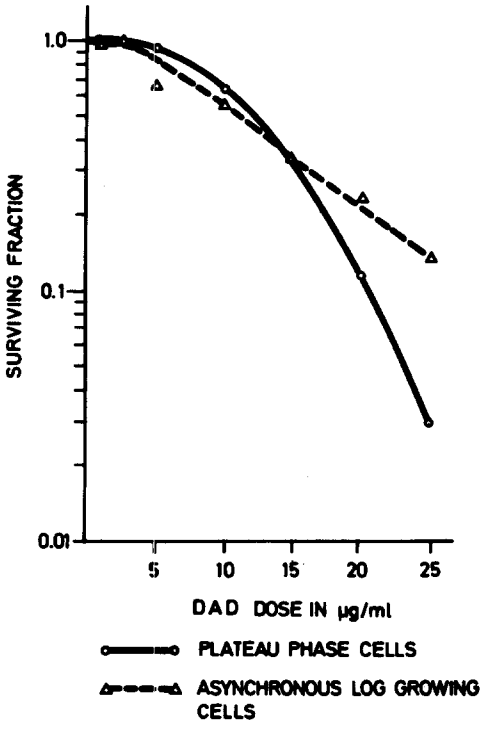

Fig. 2. Dose–response curve of Chinese hamster cells with DAD. Cells were exposed to different concentrations of drug for 1 hr. *Protocol was the same as in Fig. 1.*

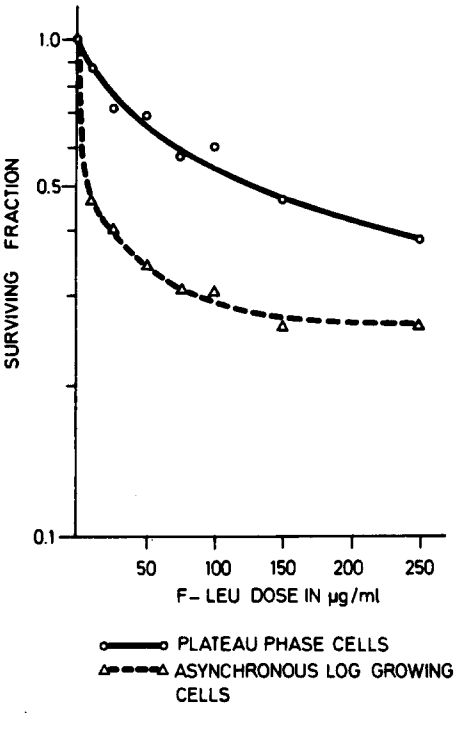

Fig. 4. Dose–response curve of Chinese hamster cells with F-LEU. Protocol was the same as in Fig. 3.

The sensitivity of plateau and logarithmically growing cells to BLM is shown in Fig. 5. Plateau phase cells were much more sensitive to the drug than proliferating cells. At a concentration of 100 μg/ml only 2% of the treated plateau cells survived compared to over 50% survival of the cycling cells.

Sensitivity of the synchronized cultures

The dose response of exponentially growing cells to F-LEU suggested that the drug has a phase specific toxicity as opposed to DBD, which judging by its survival curve should have no phase specific toxicity to cells.

Synchronized cultures were treated with DBD at 150 μg/ml for 1 hr. Similar treatment killed 90% of asynchronously growing cultures. As is shown in Fig. 6, DBD was toxic to cells throughout the cell cycle, but cells in late G_1 were more sensitive.

When synchronized cultures were treated for 30 min with F-LEU at 10 μg/ml a clear phase specific toxicity could be demonstrated. As is evident from Fig. 7, F-LEU was specifically toxic to cells in the S-phase, with little or no effect on cells in the other phases of the cell cycle.

DISCUSSION

We have tested the toxic effects of the alkylating agents DBD and DAD, the alkaloids VCR and F-LEU, and the antibiotic BLM on Chinese hamster cells. DBD showed a dose-dependent toxicity to both logarithmically growing and plateau phase cells, but proliferating cells were much more sensitive to the drug than cells in the plateau cultures. DAD affected cells from both types of cultures in essentially the same way, though at high drug concentrations plateau cells had lower survival. These results are in agreement with the experimental results of Lapis [13] who reported that *in vivo* low concentrations of both DBD and DAD were effective only on young NK ascites lymphomas. Only DAD at a high concentration inhibited old tumors.

When tested on synchronized cell populations, DBD exerted varied toxicity on cells throughout the cell cycle. Cells in the late G_1 phase were especially sensitive to the treatment, and showed a very low survival compared to cells in other phases or to logarithmically growing cells. These results confirm our preliminary experiments [14] where alterations in the nuclear DNA content and in the cellular ultrastructure were used as indicators of drug effect.

Our experiments with DBD clearly indicate that the drug is non-phase specific. The survival curve of cells treated with DAD

The variation in survival between the replicate plates was* 15%.

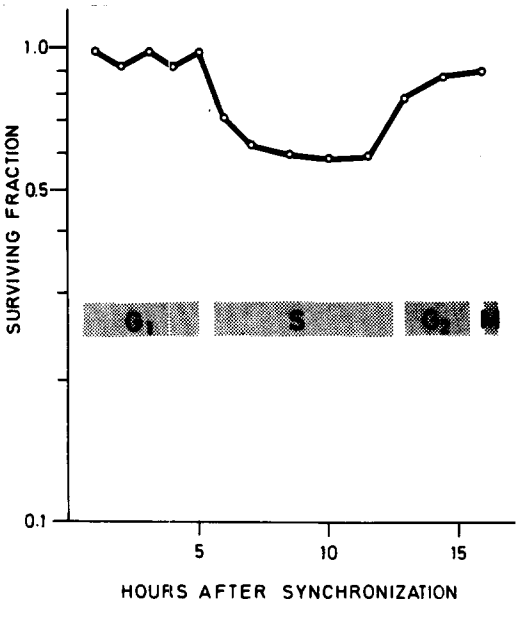

Fig. 7. Sensitivity of synchronous Chinese hamster cells to F-LEU. The cells were treated for 30 min *with* 10 μ/ml *and survival determined as described in Fig.* 6.

indicates that DAD too is non-phase specific. Palyi [15] and Barranco and Flournoy [16] arrived at the same conclusion when they reported that DAD was effective throughout the cell cycle with cells in S phase being the least sensitive. The different toxicity of DBD and DAD to logarithmically growing and to plateau phase cells cannot be attributed to altered binding to serum in fresh compared to "exhausted" medium, or to their stabilities for the duration of the treatment, but to the capacity of the cells to recover from the drug induced damage [16, 17]. Our results also strongly suggest that DBD and DAD differ in the mechanism of toxicity to cells, and that DAD is not the active metabolite of DBD [18].

Cells treated with the new Vinca alkaloid derivative, F-LEU, had a survival curve typical for phase specific drugs. When tested on synchronized cells F-LEU proved to be S-phase specific. Plateau cells were less sensitive to F-LEU. In contrast, non proliferating cells were much more sensitive to VCR, which is also an S-phase specific drug [19]. In all tested concentrations VCR had a much higher toxicity to plateau cells compared to proliferating cells. Rosner *et al.* [20] reported that, on long exposure to 20 μg/ml, VCR killed non-proliferating lymphoid cells at a higher rate than growing cells. In a previous report from this laboratory [21] we have found that clones of tumor cells of different biological characteristics exhibited different sensitivities to VCR and F-LEU.

The fact that these known mitotic spindle poisons are toxic also to non-proliferating cells may explain why metaphase-arresting ability is not necessarily associated with tumor inhibitory effect.

The antibiotic BLM was much more toxic to plateau cells than to proliferating cells. This difference in sensitivity cannot be attributed to binding of the drug in fresh medium [3, 5]. Barranco *et al.* [3] and Hahn *et al.* [6] have also reported that plateau phase cells are particularly sensitive to BLM. Twentyman and Bleehen [7] have treated fed plateau phase cells with BLM and found that the sensitivity of these sultures was largely dependent on the length of time the cells were maintained in the non-proliferating state. These experiments using fed plateau cells and our results from unfed plateau cells indicate that BLM is especially toxic to cells in the late plateau phase.

We observed great variability between the different drugs in regard to their toxicity to cells in proliferating and plateau cultures. Proper evaluation of cytotoxic effects of drugs thus requires testing on both exponential and plateau phase cell cultures.

Prognostic Factors in Malignant Germ Cell Tumors of the Ovary in Children Excluding Pure Dysgerminoma

FRANCOISE FLAMANT,* BERNARD CAILLOU,† MARIE-HÉLÈNE PEJOVIC,‡ RÉMI GERARD-MARCHANT,† MICHÈLE GOUT,* JEAN LEMERLE,* DANIÈLE SARRAZIN,§ JEAN-MICHEL ZÜCKER* and ODILE SCHWEISGUTH*

**Department of Pediatrics*, †*Department of Pathology*, ‡*Department of Medical Statistic and* §*Department of Radiotherapy, Institut Gustave-Roussy*, 94800 *Villejuif, France*

Abstract—*Forty cases of malignant germ cell tumors of the ovary in children are presented, excluding pure dysgerminoma. They are classified according to the WHO classification.*

The histological typing and the stage have prognostic value, so they should be defined as accurately as possible.

The choice of therapeutic should take these two prognostic factors into account.

INTRODUCTION

AMONG the malignant germ cell tumors of the ovary in children, the pure dysgerminomas have a high rate of curability [1]. As this group represents another simpler problem in therapeutic management, they will not be included in this presentation. For the other malignant tumors of germ cell origin, the results of therapy remain poor [2–4]; the purpose of this study is to identify some prognostic factors in order to adapt the treatment.

MATERIALS AND METHODS

Population description

Forty girls with malignant germ cell tumors of the ovary, excluding pure dysgerminomas, have been evaluated in the pediatric department of our hospital between 1954 and 1976. There was no treatment administered, other than surgery, prior to the admission in our hospital. The mean interval between diagnosis and time of referral is 23 days. The median age at diagnosis is 11 yr.

The initial work up consisted of initial surgical procedure, chest radiography, and lymphangiography for the 26 most recent cases. Determination of alpha 1 feto-protein was done in the 22 most recent cases, prior to surgery or within the first post operative week, as the half life of alpha 1 feto-protein is approximately 6 days. Skeletal radiography, hormonal investigations, cytology of ascites fluid, liver scan, bone marrow examination were made when indicated. All patients were staged after the complete work up using a staging system inspired from Wollner [5].

Stage I included patients with disease limited to one ovary. Stage II included patients with disease limited to one ovary, and ipsilateral para-aortic nodes, and patients with bilateral primary tumor without pelvic extension, with or without para-aortic nodes involvement. Stage III included patients with disease spread to pelvis or abdominal wall, peritoneum, diaphragm, liver or other organs in the peritoneal cavity or patients with hemorragic ascitis or with clear ascitis with malignant cells. Stage IV included patients with distant metastases (lung, bones, brain, distant nodes).

The evaluation of intra abdominal extension is operatively and macroscopic. In 3 cases a second laparotomy was needed to assess the extent of abdominal tumor.

Histopathology

All slides were reviewed for this study; the number of blocks of tissue per case ranged from 6 to 30, the average being 13. The

Accepted 18 January 1978.

routine stain was Hematein-phloxin-Safran. In some cases, special stains (Gordon-Sweet PAS) were performed. The WHO histopathology classification was used [6], Figs. 1, 2 and 3.

Patients presenting immature teratoma associated with yolk sac tumor or with embryonal carcinoma were classified as yolk sac tumor or embryonal carcinoma.

Treatment

The treatment did not depend on pathology, but changed over time. Before 1967 the treatment of the primary tumor was surgery alone. From 1967 to 1970, a chemotherapy schedule similar to the Li protocol [7] has been systematically added to the surgery. It consisted of courses of MAC (methotrexate 7 mg/m^2/day × 5, actinomycin D 300γ/m^2/day × 5, cyclophosphamide 130 mg/m^2/day × 5) repeated every 3 months for 5 courses.

Since 1970 the protocol has been changed for patients with stage III and stage IV disease. For patients with stage III disease the protocol "OT 70" consists of one course of MAC followed by a radiotherapy: 4000 rad (Co 60) in five weeks four times a week on the whole abdomen without protecting the remaining ovary. The liver is blocked at 3000 rad and one or both kidneys at 1300 rad. With radiotherapy a specific diet is systematically administered [8]. After radiotherapy, courses of MAC are repeated every two months for four courses.

Patients with stage IV disease are treated with chemotherapy alone consisting of MAC with higher doses, bleomycin and adriamycin.

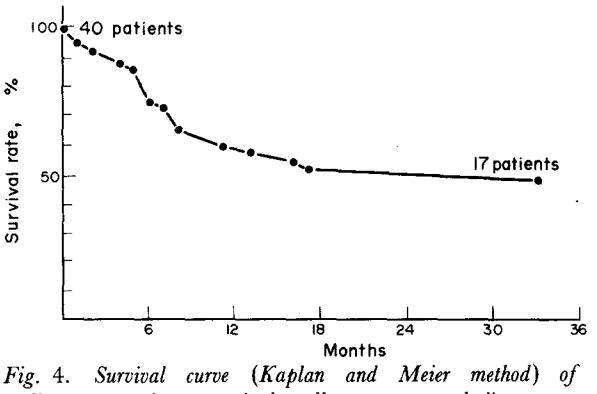

Fig. 4. Survival curve (Kaplan and Meier method) of malignant ovarian germinal cells tumors excluding pure dysgerminomas.

RESULTS

The origin of survival is the time of primary surgery. All the patients have at least a 24-month follow up and half of the patients have 7.5 yr follow up. Figure 4 shows the survival curve for the 40 patients.

The criteria chosen to test the prognostic value of stage and histology is the proportion of patients living with no evidence of disease two years after surgery, because the median of the time between diagnosis and local or distant relapse is 5 months, the latest relapse being observed 21 months after primary surgery. Table 1 gives the proportion of patients living with no evidence of disease for each stage and histology: it is different ($P<0.05$) between stage I and stage III and between yolk sac tumor, embryonal carcinoma and immature teratoma ($P<0.01$).

DISCUSSION

The survival of the population of children with malignant germ cell tumor of the ovary,

Table 1. Proportion of patients living with no evidence of disease after 24 months for each stage and histology (Living/Total)

	Stage (there was no stage II patients)			
Histology	I	III	Iv	Total
Yolk sac tumor*	1/2	1/11	0/2	2/15
Embryonal carcinoma†		5/10		5/10
Immature teratoma‡	7/8	3/4		10/12
Choriocarcinoma		0/3		0/3
Total	8/10	9/28	0/2	17/40

*1 patient with yolk sac tumor and immature teratoma. 1 patient with yolk sac tumor and dysgerminoma.
†2 patients with embryonal carcinoma and immature teratoma.
‡1 patient with immature teratoma and dysgerminoma.

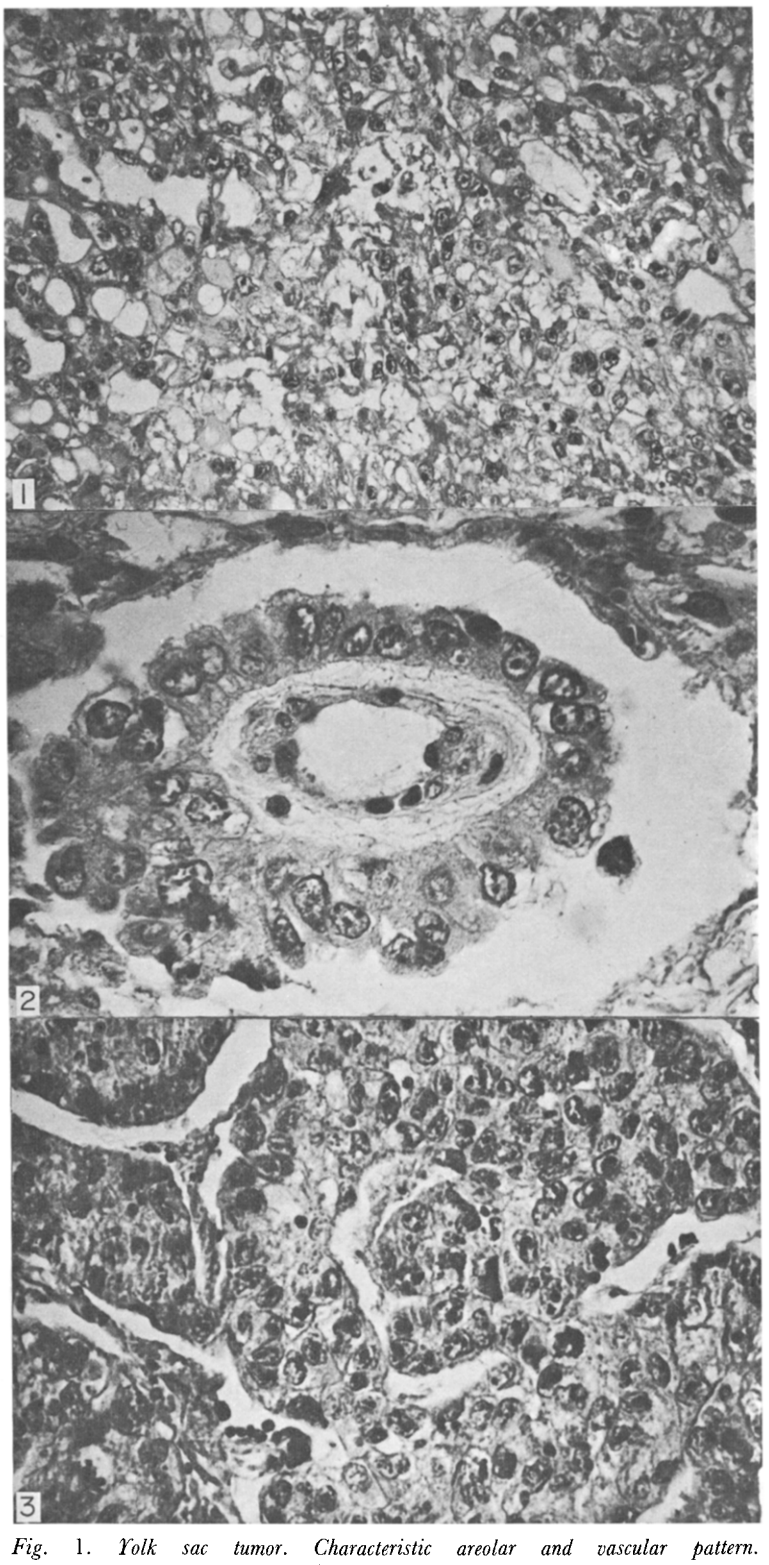

Fig. 1. *Yolk sac tumor. Characteristic areolar and vascular pattern.* (*H.P.S.* × 128).

Fig. 2. *Yolk sac tumor. Schiller Duval bodies. Note from the center to the outside: vessel stroma, epithelial structure with columnar cells, empty space and flattened cells.* (*H.P.S.* × 800).

Fig. 3. *Embryonal carcinoma: embryonal epithelial structures which are not considered as yolk sac tumor. Note the papillary and trabecular pattern; areolar and vascular structures are absent or difficult to find. There is no Schiller Duval bodies arrangements—the cytoplasm of the cells is dark or granular. In nuclei, nucleoli are prominent.* (*H.P.S.* × 128).

excluding pure dysgerminomas, studied here is similar to the survival reported by Wollner [5] on a comparable population. This study shows the prognostic value of stage and histology which should be defined as accurately as possible.

To determine the stage, the surgeon should examine the liver, peritoneal nodes, opposite ovary, uterus and remove all suspect elements for histologic examination. The child should be sent to a specialized service as soon as possible, this in order to avoid a second laparotomy.

In the determination of histology, immature teratoma and yolk sac tumor are well individualized entities but embryonal carcinoma is uneasy to define.

We classified immature teratoma according to the criteria defined by Thurlbeck and Scully [9]: there were 6 grades I, 4 grades II and 2 grades III tumors. We found a good prognosis of these tumors, as Norris [10], but their number is too small to assess the prognostic value of his grading.

Yolk sac tumor almost certainly originates from vitelline structures; however the term "endodermal sinus tumor" referring to a special vitelline structure of rodents [11, 12] is yet questionable; there are numerous intra and extra cellular hyalin globules containing alpha 1 feto-protein as demonstrated by immunofluorescence [13–15].

Embryonal carcinoma is a controversial entity; in the WHO classification there is no microphotograph and it is stated that it is an exceptional tumor in this organ; Kurman and Norris [16] have distinguished it from yolk sac tumor on histological and immunohistochemical characteristics and published 15 examples. Wollner *et al.* [5] defined embryonal carcinoma as "tumor growth showing densely packed undifferentiated neoplastic cells bearing amphophilic to basophilic cytoplasm". It is probably an heterogenic group, part of which could be undifferenciated yolk sac tumor, but further studies are needed.

Alpha 1 feto-protein dosage in blood by radio-immuno assay was done for the 22 most recent cases. For the 7 yolk sac tumors, alpha 1 feto-protein level was elevated. The other cases were negative, except one embryonal carcinoma and one immature teratoma; the patient with embryonal carcinoma had had chemotherapy prior to surgery and the tumor was necrotic at pathological examination. No yolk sac component was found on the slides available for the patient with immature teratoma. However, in our opinion, alpha 1 feto-protein secretion is a good indication of yolk sac tumor component.

For yolk sac tumor and embryonal carcinoma in adults and children, Kurman [17] observed different survival rates close to the rates reported here and noted the possible good prognosis of stage I disease.

The choice of therapeutic should take stage, pathology and alpha 1 feto-protein dosage into account. For immature teratoma and embryonal carcinoma a conservative surgery, that is to say unilateral oophorectomy, should be done on stage I patients, chemotherapy may even be unnecessary; for stage III patients radiotherapy associated to chemotherapy seems to have changed the prognosis: 6 patients out of 7 having received the OT 70 protocol are living with no evidence of disease two years at least after primary surgery.

For yolk sac tumor and choriocarcinoma, there are very few stage I patients, it is thus difficult to give a therapeutic indication; for stage III patients the disease progresses very quickly, short remissions were obtained with chemotherapy. Only more aggressive chemotherapy administered early might induce and prolong remission.

Acknowledgements—The authors thank Dr. Sarah Donaldson (Stanford University Medical Center, U.S.A.) for the translation of the manuscript into English. Dr. Buffe (CNRS, Villejuif, France) who performed the alphafetoprotein assays and the many surgeons who operated on the patients and referred them to us.

Announcement

FIRST ANNOUNCEMENT: QUANTITATION OF TUMOUR RESPONSE: A CRITICAL APPRAISAL

The 9th L. H. Gray Conference will be held in Cambridge, England, during the week of 10–14 September, 1979. The topics of the meeting are intended to stimulate a critical appraisal of the techniques that are currently in use both experimentally and clinically for assessing tumour response after therapy. The topics will include:

In situ measurements of tumour response, including improved methods of tumour detection in clinical studies.
Factors of prognostic significance.
In vitro assays of tumours excised after treatment *in vivo*.
The choice of suitable experimental models in rodents.
The role of human tumour xenografts.
Statistical evaluation of tumour response data.
The limitations and artefacts of each assay technique.
The relationship between cell survival and the *in situ* response.

Further information from Dr. J. Denekamp, Gray Laboratory, Mount Vernon Hospital, Northwood, Middlesex, England.

Chemotherapy of Advanced Breast Cancer

Results of a Controlled Trial Comparing two Three-Drug Regimens

Abstract—*Seventy patients with breast cancer in an advanced stage were treated, at random, according to one of the two regimens of cyclic administration, associating, on one hand, doxorubicin + vincristine + methotrexate and on the other hand, vincristine + cyclophosphamide + 5 fluorouracil. Only the immediate results are studied in this controlled trial in 61 evaluable patients. They are significantly better with the first association: 63% measurable objective responses vs 47.5% ($0.025 < P < 0.05$) and 30% of tumoral regressions superior to 50% vs 3.2% ($0.001 < P < 0.010$). The toxicity is hardly more marked (mainly cardiovascular and hematological) in the second regimen than in the first one, but remains altogether acceptable for an induction chemotherapy.*

INTRODUCTION

THE INTEREST of drug associations is generally recognized and has been particularly affirmed in the chemotherapy of breast carcinoma [1–3]. In the last few years a variety of therapeutic protocols of discontinuous application have been exposed and have been shown, regardless of the principle which guided their elaboration, very close in their effects as well as in their side effects.

Effectively, numerous publications give similar results, but they are difficult to compare and few randomized studies have been performed [4–8]. The announced percentages of objective global responses are usually superior to 50% with combinations of the drugs which are most often utilized: methotrexate, 5 fluorouracil, thiotepa, cyclophosphamide and vincristine.

The recent introduction of doxurubicin (adriamycin) in the therapeutic armamentarium along with the recognition of its efficacity in breast tumors [9, 10] has brought its insertion in new associations [11, 12]. This is what we have personally undertaken in a preliminary study which has rapidly given encouraging results. It thus becomes necessary to define the place of this combination chemotherapy by confronting its results with those obtained by the aid of the regimen that we have previously experienced (vincristine + cyclophosphamide + 5 fluorouracil) and which followed from the conclusions of comparative studies defining the most satisfying therapeutic index efficacy/tolerance [13].

The present controlled trial concerns only the determination, in a global manner, of the respective value of these two methods of treatment in order to assure further choice of a chemotherapy regimen to apply in priority for metastatic breast cancers. This analysis, limited in time, is available only for immediate effects and does not take into consideration the duration of the remissions or the influence on the survival of the patients

Accepted 28 November 1977.

(these long term effects should be ulteriorly studied). In any event, in the case of a favorable conclusion for the regimen including doxorubicin, a prolonged treatment is excluded because of the myocardic toxicity of the cumulative doses of this drug [14, 15] limiting it thus to an induction treatment.

This controlled trial was conducted from October 1st, 1975 to April 30th, 1976 in cooperation with 8 French Cancer Centers according to a commonly established study programme and identical means of data registration [16, 17].

MATERIALS AND METHODS

Treated patients

Seventy patients were included in this trial. The relative data are given in Table 1.

All included patients had either: a local relapse or an untreated breast cancer beyond surgery and radiotherapy; or a metastatic diffusion without any prior chemotherapy and without hormonotherapy of endocrine surgery since at least 3 months. All patients had at least one tumoral evaluable focus which allowed an objective evaluation of the efficacy. The precise histological diagnosis was established for all cases, with a predominance of differentiated adenocarcinomas (44 out of 70).

The main cause of exclusion (outside of the usual biological, psychological, familial or social conditions) was cardio-vascular history because of the known cardiotoxicity of doxorubicin. A balanced distribution was realized by randomization which lead to the

formation of 2 homogenous groups in function of the date given in Table 1.

Treatments

Each group of patients received a chemotherapy according to one of the regimens described in Table 2. The first one combines vincristine + cyclophosphamide + 5 fluorouracil (VCF), the second one doxorubicin + vincristine + methotrexate (DVM).

The follow up was identical for the two treatments and bore on the clinical state (especially neurologic and cardiovascular with an electrocardiogram before each cycle) and on the hematological state (the scheduled cycle was postponed for 8 days if the number of leukocytes was less than 3000 and/or the number of platelets less than 80,000).

The general modalities of application of each protocol are indicated in Table 3. The treatment was considered a failure after a delay of two months, unless there was an evident aggravation after one month. During this period, the CVF cycles were less numerous than DVM cycles, because the free intervals are larger in the first than in the second. The treatment was discontinued during the trial, especially for failure, 18 times with CVF regimen and 5 times with DVM regimen. Nearly half of the patients (34 out of

70) continued their chemotherapy until the date of analysis of the study.

Tolerance

The tolerance was studied for all patients of the two groups. The *clinical manifestations* of toxicity evaluated according to usual procedures [4, 7] were on the whole frequent; only 3 patients in each group did not present any side effects during the treatment. These manifestations were minor as indicated in Table 4: general reactions (asthenia), digestive (nausea and vomiting), cutaneomucous (alopenia, 21 times with CVF and 23 times with DVM; the latter in addition was responsible for 5 stomatitis). They generally responded correctly to symptomatic medications, but necessitated the discontinuation of the treatment in one patient submitted to CVF regimen and 3 patients submitted to DVM. Among these three last cases there was one cardiac ischemic attack (precordialgia and electrocardiographic signs); other cardiovascular disturbances particular to the DVM protocol because of doxorubicin were more mild: prolonged hypertension in one case; rhythmic disorder (tachycardia, extrasystoles) in two cases; electric abnormalities (repolarization disorders) in two cases. All in all the frequency and the intensity of the intolerance reactions were relatively more frequent with DVM than with CVF, but in any event, they were responsible for no death during chemotherapy.

The *hematological consequences* show little difference between the two regimens. The impairment was moderate, particularly for the erythrocytes, more important for the platelets and especially for the leucocytes. In one case a leukothrombopenia induced by the treatment (DVM) had been rapid and severe and caused infectious complications and lethal hemorrhages (the patient was in very poor condition when the treatment was started). No significant relationship was found between the toxicity and the number of cycles; with the prolongation of the treatment the tolerance was usually stationary and sometimes paradoxically better from the clinical as well as from the hematological point of view.

Table 4. Manifestations of intolerance and toxicity

	Regimens							
	VCF				DVM			
	IT1*	IT2	IT3	IT4	IT1	IT2	IT3	IT4

thrombocytopenia	4	1	0	0	3	4	1	1

*IT1: minor intolerance, without incidence on the treatment.
IT2: intolerance implying a modification of the treatment.
IT3: major side effects necessitating the discontinuation of the treatment.
IT4: toxicity leading to death.

RESULTS

The efficacy was judged subjectively and objectively.

1. *Subjective effects*

Forty-six evaluable cases of patients presenting at the beginning of the treatment either functional and/or subjective manifestations linked to tumoral evolution are divided into half for each group. The results are practically identical for the two types of treatment. The

numerical advantage is poor for DVM regimen (18 positive responses vs 15) but the antalgic effects of that association are particularly precocious, sometimes after the 1st cycle, bringing about a general subjective improvement which can compensate, in a very appreciable way, the manifestations of intolerance.

2. *Objective effects*

For 61 out of 70 patients of 2 groups having received a sufficient chemotherapy (minimum of 2 cycles) which permitted the analysis of the results, 46 or 75% (Table 5) manifested an objective response to the treatment evaluated by an estimation of the global tumoral mass (primitive tumor + lymph nodes + totality of the metastases) before and after treatment and codified by criteria already cited [4, 7]. The global difference observed between non responding and responding patients ($E \geqq 1$) is in favor of the DVM combination (response in 93% of the cases) and is statistically very significant ($P < 0.001$). A measurable regression of the lesions was registered in 29 cases (47.5%). It was obtained 10 times with CVF (32%) and 19 times with DVM (63%). The difference is again significant ($0.025 < P < 0.05$). Finally there is a distinctly higher proportion of regressions superior to 50% of the initial tumoral volume: 9 cases (30%) with DVM vs 1 (3.2%) with CVF ($0.0001 < P < 0.010$).

In global evaluation of responses, no complete regression was obtained, but the examination of the objective effects by tumoral sites (Table 6) shows 2 disparitions of pulmonary metastases, one in each group, and a total

Table 5. *Appreciation of therapeutic response*

obliteration of cutaneous nodules in one case of DVM. Outside of the localizations generally responsive to chemotherapy (the same for primitive lesions and lymph nodes) there is an action particularly distinct in patients having hepatic metastases: 4 objective regressions with 3 of which superior to 50%, for 6 patients with an important hepatomegaly, along with concomitant retrocession of the jaundice which existed for 2 of them and the scintigraphic normalization in one case.

The first objective effects observed with DVM were frequently rapid (after the first and the second cycle) and were progressively reinforced to reach a maximum until the 5th or the 6th cycle.

The results in each group were significantly influenced neither by the age of the patient nor by the histologic type. The same was true for the hormonal status (genital activity or menopause). The delay of tumoral evolution (from the initial diagnosis to the beginning of the chemotherapy) does not substantially modify the quality of the responses obtained in the 2 series of patients.

DISCUSSION

The analysis of this controlled trial bearing on 2 groups of patients with advanced breast cancer, divided after randomization into similar groups and submitted to two different protocols of chemotherapy, showed a very significant advantage in favor of the association DVM: doxorubicin + vincristine + methotrexate, in discontinuous administration of 5 days cycles every 3 weeks. Even though the global immediate results are sensibly inferior to those of most other published studies (probably because of the differences in patient recruitment and the criteria adopted to evaluate the obtained effects), the homogenity of the conditons of the test allowed to bring about a useful comparison of the respective value of two applied therapies.

The side effects were discretely more frequent and more marked with the most efficacious association. They appeared nevertheless acceptable under reserve of indications correctly born and an attentive surveillance, especially cardiovascular and hematological. The total cumulative doses of doxorubicin should not however exceed 500mg/m^2, since beyond that limit the risk of myocardic toxicity augments substantially and does not authorize the continuation of the treatment. Consequently, the briefness of the cure should allow that chemotherapy only as a first sequence of treatment. This implies necessarily a continuation with one or several other protocols designed to maintain or to reinforce the obtained remissions.

It is a long term study of this type which has been now undertaken to determine the interest and the exact place of that association in more complex therapies, in order to improve the results of the palliative chemotherapy of advanced breast cancers.

Abstract—*A randomized cooperative clinical trial has been conducted in inoperable carcinoma of the lung. One hundred and eighty-seven patients under age* 72 *of both sexes of all cell types were admitted provided they had had no previous surgery, chemotherapy or radiotherapy with the exception that patients having received less than* 2 g *of cyclophosphamide or less than* 2 weeks *of chemotherapy of any kind could be included. Treatment was assigned by randomization, stratified by institution and cell type, to one of the following treatments:* (1) *continuous radiotherapy* (6000 rad *at the rate of* 1000 rad *per week*), (2) *split-course radiotherapy* (3 *series of* 2000 rad *each administered in three* 2-week *periods separated by* 8-week *intervals*), (3) *continuous radiotherapy plus cyclophosphamide*, (4) *split-course radiotherapy plus cyclophosphamide. Cyclophosphamide was given at the dose of* 20 mg/kg *i.v. or i.m. every* 15 *days starting* 15 days *after the completion of continuous radiotherapy or* 15 days *after the first course of radiotherapy for those receiving the split-dose schedule.*

No statistically significant differences in survival were seen between treatment groups.

INTRODUCTION

THIS report describes the results of a randomized clinical trial conducted by the E.O.R.T.C. designed to answer two principal questions: (1) Does long-term chemotherapy improve survival rates for primary inoperable bronchogenic carcinoma treated by radiotherapy? (2) Is split-course radiotherapy better than continuous radiotherapy? At the time this trial was begun there was some evidence from radiobiologic experiments suggesting that split-course radiotherapy might produce longer remissions. Interest in this concept still exists [1–3], for although radiation has been used in the treatment of inoperable bronchogenic carcinoma for several decades, the optimal method of using this therapy has not been determined and reports in the literature are often difficult to evaluate because of very dissimilar prognostic categories and failure to make randomized comparisons. At the time this trial was designed the role of single agent chemotherapy in inoperable lung cancer was unclear. A previous controlled randomized trial of the E.O.R.T.C. Lung Cancer Cooperative Group [4] did not show any increase in survival in patients with limited inoperable disease treated with radiotherapy and concomitant short-term chemotherapy with cyclophosphamide compared to radiation therapy alone. The

Group decided thereafter to implement another trial with long-term chemotherapy after radiotherapy. Although much more information is available on these subjects today, it is felt that all trials, whatever their results, should be published in order to provide a firm foundation for designing new trials. This is particularly true with respect to evaluating the role of prognostic factors and considerable attention will be devoted to that subject in this report.

MATERIALS AND METHODS

Between November 1968 and August 1971 patients from 12 hospitals in Holland, Belgium, France and Italy were admitted to this study.

In order to be eligible for the trial patients had to have primary bronchogenic carcinoma either histologically confirmed or with sufficient presumptive evidence (cytology and clinical presentation) that the patient was treated as having that condition.

Patients under age 72 of both sexes and of all cell types were admitted provided they had had no previous surgery, chemotherapy or radiotherapy with the exception that patients having received less than 2 g of cyclophosphamide or less than 2 weeks of chemotherapy of any kind could be included. Patients having received chlormethine (nitrogen mustard) were excluded no matter what the dose had been. In addition, the clinical stage was required to be such that radiotherapy was indicated, that is, limited inoperable lung cancer. Other criteria for exclusion included cavitary forms, massive tumors which could not be contained in the field of irradiation, that is, exceeding 225 cm^2 (15 × 15), those cases with significant pleural effusion which was cytologically positive, patients with metastases with the exception of mediastinal metastases which could be included in the field of irradiation and patients having other primary cancers with the exception of cutaneous epitheliomas previously cured or curable. All histological forms of lung cancer were considered eligible for the trial. Patients were required to have clinical and hematological status which would permit aggressive treatment with radiotherapy and chemotherapy. Finally, the patients' sociopsychological condition was required to be such that the physician treating them could expect that the treatment would be followed regularly and completely.

Treatment was assigned by randomization stratified by hospital and cell type (epidermoid carcinoma, anaplastic carcinomas—including small cell and undifferentiated carcinomas—and other) to 1 of 4 groups: a single series of continuous radiotherapy (R10), continuous radiotherapy plus cyclophosphamide (R1C), split-course radiotherapy in 3 series (R30), or split-course radiotherapy plus cyclophosphamide (R3C). The schema is given in Fig. 1. Continuous radiotherapy consisted of 6000 rad tumor dose given at a rate

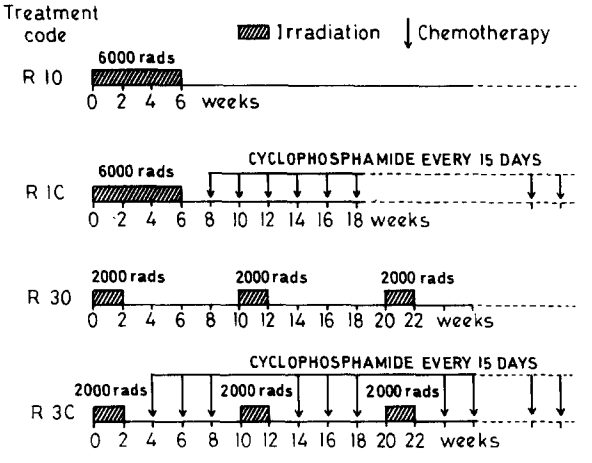

Fig. 1. Schema of the study.

of 800–1000 rad per week for a total duration of about 6 weeks. The irradiated area was not allowed to surpass 225 cm^2 (15 × 15). The radiotherapy was given by a high energy source, either cobalt or betatron. The split-course radiotherapy was given in 3 series of 2000 rad each administered over 3 two-week periods separated by 8-week intervals giving a total treatment duration of about 22 weeks. Remarks concerning the area of irradiation and the type of radiotherapy are the same as for the continuous radiotherapy.

Chemotherapy consisted of cyclophosphamide administered in a dose of 20 mg/kg or 700 mg/m^2 of body surface area not to exceed 1200 mg given i.v., or intramuscularly if intravenous injection was not possible. This therapy was repeated as a single injection every 15 days. Treatment began 15 days after the completion of radiotherapy for the group receiving continuous radiotherapy and 15 days after the completion of the first course for those receiving split-course radiotherapy. As shown in Fig. 1, the patients receiving split dose radiotherapy received 3 injections of cyclophosphamide between courses, but did not receive chemotherapy during courses of radiotherapy. If the white cell count was less than 4000 or the platelet count less than

100,000 the interval between doses was increased by 1 week without diminishing the dose of cyclophosphamide. If the leukocyte count and platelet count did not exceed these values at the end of one week, further 1 week waiting periods were added as necessary without diminishing the doses of cyclophosphamide. If the white cell count fell below 2000, radiotherapy was interrupted for a period not to exceed 2 weeks. If this period was insufficient for recovery of the white cell count to a value of greater than 2000 the treatment was terminated. If the tumor became worse in the group receiving split-course radiotherapy without chemotherapy in the interval between 2 series, radiotherapy was reinitiated or other therapy could be given provided the reasons were stated. Other treatments before radiotherapy were not permitted with the exception of atropine and antibiotics. Corticoids were specifically prohibited except in cases of absolute necessity.

Patients receiving continuous radiotherapy were examined every week for the first 6 weeks. For those receiving split-course radiotherapy, the examinations at the third and fifth week could be omitted. Between 6 and 12 weeks patients were examined every 2 weeks and from 12 to 20 weeks every 4 weeks. After 20 weeks patients were examined every 6 weeks for the rest of the study. The principal criteria of evaluation were time until recurrence or metastasis and survival. Performance was evaluated according to the criteria of Karnofsky [5]. Additional treatment could be introduced as indicated at the time of recurrence or metastasis.

The analysis presented here describes the results for 187 patients for whom initial data, details of treatment and adequate follow-up were available. Before analyzing the data detailed computer editing was performed to detect coding errors and to check the consistency of the data. Errors were resolved by checking the original data forms. Survival curves were constructed using the actuarial method [6] and tested for significance using the Mantel–Haenszel technique [7]. The effect of prognostic variables on response rates were examined using logistic regression techniques (see Appendix) and the effect of prognostic factors on survival were examined using a mathematical model incorporating covariate information based on the Weibull distribution (see Appendix).

RESULTS

Treatment received

Patients assigned to continuous radiotherapy were more likely to receive a full dose of radiotherapy compared to those assigned to split-course therapy (Table 1). For the 2 groups receiving continuous radiotherapy combined, 84% received between 5500 and 6500 rad compared to 55% for the 2 groups on split-course radiotherapy combined. Patients assigned to split-course radiotherapy were, of course, at greater risk of recurrence, metastasis, or death before completing their course of radiotherapy and, in some instances, they may have failed to return to the clinic to complete their therapy. Despite the striking difference between the number of patients receiving a full course of radiotherapy, all survival curves are based on the initial assignment to treatment groups. It would be incorrect to delete the patients in the split-course groups who did not receive the full course of therapy since this would bias the comparisons in favor of the split-course radiotherapy by eliminating the patients who experienced early recurrence, metastasis or death.

Table 1. *Dosage of irradiation received by treatment group*

The 2 groups of patients receiving chemotherapy were reasonably comparable with respect to the average number of injections received, the average total dose, the minimum values of platelets observed during treatment and the minimum white blood cell counts (Table 2). Other than the effects on the hematological system, the chemotherapy produced no unusual toxicity and weakness, nausea and diarrhea were only rarely reported.

Prognostic factors

A large number of variables concerning the patient's status at the time of entry to the trial were recorded. These included previous therapy, various symptoms, performance status (Karnofsky score), cell type, size of the tumor and other variables related to the radiological appearance of the tumor (such as the presence or absence of atelectasis, the location of the tumor and the nature of the tumor image). In order to determine which of these variables most affected survival, death rates (defined as the number of deaths per 100 patient months of follow-up) were computed for each variable at its different levels. Those variables showing definite prognostic significance are shown in Table 3. Since these variables are likely to be interrelated, they will not all be needed to assess prognostic significance, and in a later section a summary analysis will be presented. However, the treatment groups may be compared with respect to these variables known to influence prognosis. Such an analysis is presented in Table 4 along with χ^2 statistics testing whether the distributions of these variables differ according to treatment group. In all cases the test statistic is non-significant indicating that the randomization procedure was effective in producing comparable treatment groups.

In addition to the variables listed in Table 3 other variables were recorded which concerned the radiological appearance of the tumor. These included the presence or absence of atelectasis, a characterization of the tumor image as complex or non-complex, information on the portion of the total pulmonary field occupied by the tumor and the location of the tumor. Some of these variables showed a definite relationship to prognosis. We mention this fact to encourage investigators to record information on atelectasis, size and location of tumors in future studies.

Age was not a significant prognostic factor in this study. The age range was 39 to 77 (2 patients over age 72 were admitted to the trial, 1 aged 73 and 1 aged 77). The median age was 61 and the age distribution was somewhat skewed toward the younger age group with mean 60.1 and standard deviation 7.3. There were 180 male patients and 7 female patients, so the data were inadequate to assess sex as a prognostic factor.

We were particularly interested in the results of the tuberculin test as a prognostic factor since in previous reports [8] it had been suggested that a negative tuberculin test was associated with diminished survival and that a negative reaction may become positive after the removal of the primary tumor. Patients in which this has happened have experienced particularly long survival. In our study tuberculin tests were performed in 62 cases of which 16 were negative and 46 were positive.

The death rate among the negative cases was 14.61 per hundred patient months vs 8.89 for the positive cases. An F-test comparing these two death rates gave a *P*-value of 0.079. Although this result is not convincingly significant, possibly because of the small number of cases, it is in the direction reported in other studies suggesting a more favorable response for patients who had positive tuberculin tests. However, we have examined the relationship of the tuberculin test result to three other prognostic variables, the presence of dyspnea, the presence of an anaplastic tumor, and the presence of weakness. Patients with a negative tuberculin test were 2.75 times more likely to have dyspnea, 2.74 times more likely to have an anaplastic tumor and 7 times more likely to have weakness. We are therefore hesitant to draw conclusions about the meaning of tuberculin test results. It may be that the prognosis is worse simply because as the tumor becomes more advanced the test becomes negative. The alternative explanation would be that the tumor becomes more advanced because the tuberculin test is negative, demonstrating that the patient has diminished immunologic capacity. Further studies will be required to resolve this issue.

Using covariates to predict survival

In order to study the relationship between the various prognostic factors shown in Table 3 a parametric survival model incorporating covariate information was used (see Appendix). The model chosen is based on a Weibull distribution in which the death rate is a function of the initial characteristics of the patients; this model permits the death rate to increase or decrease as a function of time. If the death rate is constant over time, then survival is governed by an exponential distribution which is a special case of the Weibull distribution. Details of the fitting procedure are given in the Appendix. In this study all of the variables listed in Table 3 were entered into the model. All variables were coded 0, 1 (except Karnofsky's score which was coded 0, 1, 2) in order of death rates and then systematically removed until the fit of the model

to the observed data was significantly affected. This procedure allows us to study the interrelationships of the prognostic variables since each can be examined separately while adjusting for the effects of the other variables. We found that survival could be adequately predicted using only three of these variables, the Karnofsky score, the presence or absence of anorexia and the presence or absence of dysphonia. The Karnofsky score may be thought of as an overall measure of patient's status while anorexia is probably most closely correlated with cachexia from progressive disease and dysphonia probably indicates patients in whom the tumor has spread to the mediastinum. Using these three variables we defined four risk groups based on increasing values of the predicted death rate for individual patients. The characteristics of these risk groups are shown in Table 5. The patients in the first risk group had normal levels for all three variables. Those in risk group 2 were characterized by Karnofsky scores of 70–80 in the absence of unfavorable values for the other two variables. Patients in risk group 3 tended to have abnormal values for anorexia or dysphonia or a Karnofsky score less than 70. Patients in risk group 4 always had abnormal values for at least two of the three variables. Also shown in Table 5 are observed and predicted survival figures at 1 yr for the four risk groups and the values of regression coefficients for the model. There appears to be reasonable agreement between the model and observed data. The plot of observed and predicted survival for the four risk groups is shown as Fig. 2. This plot is on the logarithmic scale. The fact that all the lines bend downward indicates that the death rate is increasing with time and justifies fitting the Weibull model. The value of the shape parameter was 1.351. If the death rate had been constant in time the value of the shape parameter would have been near 1.00.

Tumor response

Although survival is of paramount interest in a study of advanced lung cancer, the response of the tumor may give clues that might lead to improved therapy. Variables which are important in predicting survival may differ from those useful in predicting response to treatment and must be examined separately. In this study tumor response was designated as slight, moderate or marked. For this analysis we have grouped all responses together. The first question of interest was to examine response by cell type. Results of this analysis are given in Table 6. Despite some variability in the table, there are no significant differences between the response rate for the four therapies within any given cell type. The overall response rate was about 66% and patients who responded to therapy survived significantly longer than those who did not ($P < 0.02$). In order to predict response to therapy we examined many possible prognostic

+	+	+	3	66.7	17.0	2	1
All patients			187	65.8		123	122

*The fitted prediction equation was $ln(p/(1-p)) = 1.523 - 1.059\ \chi_1 - 0.852\ \chi_2 - 1.197\ \chi_3$ where χ_j, $j = 1, 2, 3$ takes the value 1 if the unfavorable factor is present and 0 otherwise. χ_1 = involvement of recurrent laryngeal nerve, χ_2 = tumor size >5 cm or unknown and χ_3 = poorly differentiated epidermoid lesion. The T-values (regression coefficients divided by their standard errors) for the three variables were −2.32, −2.51 and −2.78 respectively.
†Rounded to nearest whole number.

factors. After eliminating variables not needed, we found that response to therapy could be adequately predicted with three variables: involvement of the recurrent laryngeal nerve, tumor size greater than 5 cm or tumor size non measurable and poorly differentiated epidermoid lesions. These variables were used in a logistic regression equation to predict survival (see Appendix). The results of our predictions compared to the observed responses (Table 7) indicate that the model fits the observed data quite well. However, it should be noted that we have examined a large number of variables in obtaining these three and thus we are not able to assess the true significance level for these variables since we are fitting the model to the same data used in estimating the coefficients. However, it is reasonable to identify these variables as being importantly related to response to treatment. Response to treatment was less likely if there was involvement of recurrent laryngeal nerve, if the tumor was greater than 5 cm or was not measurable, or if the lesion was of the poorly differentiated epidermoid type on histological examination. It is probable that the tumor was not measurable because of its infiltrative character or the presence of atelectasis which makes it impossible to measure the tumor accurately. For this reason tumors of unknown size behave like large tumors.

Treatment comparisons

Survival curves for the four treatment groups are shown in Fig. 3(a) and the median survival times are given in Table 8. It is apparent from examining this Figure that there were no significant differences in survival between the four treatment groups and this impression is confirmed by formal significance tests. In Fig. 3(b) survival of patients receiving continuous radiotherapy is compared with the group receiving split-course radiotherapy. Again the difference is not significant. In Fig. 3(c) patients receiving chemotherapy are compared with those who did not receive chemotherapy. Again there are no significant differences. In Fig. 3(d) survival curves are shown according to cell type. As has been reported in many other studies, patients with epidermoid or other kinds of bronchial carcinoma survive longer than patients with anaplastic tumors. There was no significant difference between epidermoid carcinomas and other histologic types with the exception of anaplastic tumors. In these treatment comparisons all patients have been included whether or not they received a complete course of their assigned therapy. This policy is necessary in order to avoid introducing serious biases in analyzing the data. Nevertheless parallel analyses were done using only patients who received a full course of radiotherapy or who received 80% or more of their intended dose of chemotherapy. These analyses did not reveal any significant differences between the four treatments.

Although data were often incomplete on Karnofsky scores as treatment progressed, the available data were studied to see if the quality of life might be better for some treatments compared to others. However, no significant differences were noted. In addition, the data were examined to see if there were differences in survival by treatment group

within the three major cell types. The numbers available for these analyses were small and no significant differences were detected.

DISCUSSION

In this analysis we have demonstrated the importance of several prognostic factors, both for response to treatment and for survival, in patients with advanced bronchogenic carcinoma. The fact that these variables have such an important effect on either response rates or survival rates indicates the desirability of conducting randomized clinical trials if meaningful treatment comparisons are to be made in patients with advanced lung cancer.

The multivariate methods used in this study both for prediction of survival (the Weibull model) and for the prediction of response to therapy (the logistic regression model) will be useful in analyzing other studies characterized by marked heterogeneity of patients. These techniques allow adjusted treatment comparisons in non-randomized studies and may be employed to refine treatment comparisons in randomized ones. In addition they may teach us valuable lessons about the natural history of the disease.

No treatment comparisons in this study were significant. The median survival time (9 months) for patients with epidermoid carcinoma are close to the ones observed in other studies utilizing radiotherapy with or without chemotherapy [1, 2, 9]. The absence of improvement with cyclophosphamide confirms the results of several other randomized trials [10–12] including the previous trial of our own group with short-term chemotherapy [4]. Only one randomized trial has shown an increase in survival over radiotherapy alone in patients treated with cyclophosphamide and radiation therapy [13]. In this latter study chemotherapy was also given intermittently but at higher doses. Bleomycin plus radiotherapy was found superior to radiotherapy alone, in terms of survival, in a controlled

Table 8. Median survival time

Anaplastic	43	5.306	(21.22)
Other	45	8.742	(34.97)

*Estimated from actuarial curves.

trial performed on a small number of patients with squamous cell carcinoma [14]. For the same cell types, the median survival was longer than one year in two non-randomized trials using combination chemotherapy and radiotherapy [15, 16].

For other cell types, the comparison of our results with more recent studies is difficult because the group of anaplastic carcinomas included not only small cell but also undifferentiated carcinomas without other specification, and the group "other" is too heterogenous. Recent data seem to indicate a definite advantage of combining different treatment modalities in small cell carcinoma. The median survival with combination chemotherapy plus radiotherapy is longer than 1 yr in a number of recent series, including patients with extensive disease [17–19]. The lack of improvement in survival in the present series with the adjunction of chemotherapy may be due either to the low efficacy of single agent chemotherapy compared to combination chemotherapy in small carcinoma, or to the fact that a possible positive effect in small cell anaplastic carcinoma would have been negated by an adverse effect in other cell types.

The importance of prognostic factors pointed out by others was confirmed in our studies: the prominent value of the performance status as a factor of prognostic significance was stressed by Zelen [20]. Lanzotti *et al.* [21] have found that weight loss was of major importance and is indeed related to anorexia. The same authors mentioned age (>70) as a prognostic factor. This parameter cannot be evaluated in our series because the number of patients older than 70 is quite small, the age limit being 72 in our protocol. The volume of the tumor, its infiltrative character as manifested by laryngeal nerve paralysis and the presence of atelectasis also seem to be important factors.

In conclusion, this trial has not shown a favorable action of long-term chemotherapy with cyclophosphamide in patients with inoperable limited lung cancer treated with radiotherapy but the total dosage of chemotherapy was relatively small. Split-course radiotherapy is as effective as the classical six-week continuous course. Prognostic factors play a very important role in the response of patients to treatment and must be taken into account when preparing protocols of treatment in lung cancer.

STATISTICAL APPENDICES

I. *The Weibull model for survival incorporating covariates*

We assume that the probability of death at time t for the i'th patient is given by

$$f(t)=\lambda_i k t^{k-1}\exp(-\lambda_i t^k) \qquad (1)$$

where $\lambda_i=\underline{\beta}'\underline{\chi}_i$. If there are m covariates then $\underline{\chi}_i$ is an $m+1$ column vector where χ_{i0} is taken as 1 to represent an intercept and the χ_{ij}, $j=1,2,\ldots,m$, represent the values of the m covariates. The $m+1$ column vector $\underline{\beta}$ represents the regression coefficients associated with the covariates and k is a parameter governing the shape of the survival curve. The hazard (instantaneous death rate) for patient i at time i is given by $h(t)=\lambda_i k t^{k-1}$. If $k>1$ the hazard increases with time and the converse is true for $k<1$. For $k=1$ the Weibull model reduces to the simple exponential distribution with a constant hazard. The cumulative survival curve at time t for hazard λ is given by

$$S(t)=1-F(t)=\exp(-\lambda t^k). \qquad (2)$$

The log likelihood for a right-censored sample of size n, $i=1,2,\ldots,n$, is given by

$$\ln L=\sum_{i=1}^{n}[z_i ln(\underline{\beta}'\underline{\chi}_i)+z_i\ln k + z_i(k-1)\ln t_i-(\underline{\beta}'\underline{\chi})t_i^k] \qquad (3)$$

where

$$z_i=\begin{cases}1 & \text{if patient } i \text{ died at time } t_i\\ 0 & \text{if patient } i \text{ was alive at time } t_i\end{cases}$$

The parameters k and $\underline{\beta}$ were estimated by the method of maximum likelihood using an iterative procedure based on a vector analog of the Newton–Raphson procedure.

II. *The logistic regression model for* 0, 1 *response variables*

The logistic model we have used assumes that the relationship between p_i, the probability of response for patient i, $i=1,2,\ldots,n$, and the covariate vector $\underset{\sim}{\chi}_i$ is given by

$$\ln[p_i(1-p_i)]=\underset{\sim}{\beta}'\underset{\sim}{\chi}_i, \tag{4}$$

where for m covariates $\underset{\sim}{\chi}_i$ is an $m+1$ column vector with χ_{i0} taken as 1 to represent an intercept and the χ_{ij}, $j=1,2,\ldots,m$, represent the values of the m covariates. The likelihood for a sample of n observations is given by

$$L=\prod_{i=1}^{n} p_i^{y_i}(1-p_i)^{1-y_i} \tag{5}$$

where $y_i=1$ if observation i was a response and 0 if it was a non-response.

Inverting eq. 4 we obtain

$$p_i=[\exp(\underset{\sim}{\beta}'\underset{\sim}{\chi}_i)]/[1+\exp(\underset{\sim}{\beta}'\underset{\sim}{\chi}_i)]$$

and

$$(1-p_i)=1/[1+\exp(\underset{\sim}{\beta}'\underset{\sim}{\chi}_i)]$$

Using these relationships, taking logarithms and simplifying, we obtain the log-likelihood as

$$L=\sum_{i=1}^{n}[y_i(\underset{\sim}{\beta}'\underset{\sim}{\chi}_i)-\ln(1+\exp(\underset{\sim}{\beta}'\underset{\sim}{\chi}_i)] \tag{6}$$

The vector of regression coefficients $\underset{\sim}{\beta}$ may be estimated by maximum likelihood using an iterative procedure based on a vector analog of the Newton–Raphson procedure.

An Assessment of the Effects of Steroid Hormones and Antiestrogens on Short-Term Organ Culture of Human Endometrial Carcinoma

S. JACOBELLI,* G. SICA,* F. RANELLETTI* and G. BARILE†

**Laboratorio di Endocrinologia Molecolare, Istituto di Clinica Ostetrica e Ginecologica, Università Cattolica S. Cuore, Largo Gemelli, 00168 Roma, Italia and †Laboratorio Tecnologie Biomediche, Consiglio Nazionale delle Ricerche, Via G.B. Morgagni, 00100 Roma, Italia*

Abstract—*Fifteen human endometrial carcinomas were maintained in organ culture in the presence of various steroid hormones and antiestrogens. The effects of the compounds have been assessed by measuring the incorporation of tritium-labelled thymidine into DNA. No significant effects on tumour cell incorporation rate due to hormones have been observed.*

INTRODUCTION

THE MOST common form of therapy in the treatment of advanced endometrial carcinoma is based upon administration of progesterone or progestational compounds and objective remission of tumours has been observed in approximately one of three patients with pulmonary metastases [1, 2]. The mechanism by which progesterone produces regression of endometrial carcinoma is still uncertain; nor is it known why certain carcinomas respond while others do not. Since hormonal dependence or responsiveness has no specific histological correlation, it would be important if an *in vitro* test to identify hormone-responsive tumours could be devised which might aid in selecting patients for therapy.

Organ cultures have been successfully used by several investigators to study the effects of hormones on both normal and neoplastic tissue growth [3–6]. The advantage of these techniques is that the hormonal effects can be studied directly on individual tissue components without the interference of systemic factors and endocrine feedback mechanisms present *in vivo*. The effect of progesterone on endometrial carcinoma *in vitro* has been studied by Heckmann [7], Hackl [8], and Nordqvist [9, 10]. The latter showed that progesterone acts directly on the cancer cells and that different carcinomas may respond to different concentrations of the hormone. We have conducted a further study of the effects of various steroid hormones and antiestrogens on short term organ culture of human endometrial carcinoma using tritium-labelled thymidine incorporation into DNA to assess therapeutic responses.

Accepted 30 December 1977.

MATERIALS AND METHODS

Culture methods and hormones

A total of 740 explants from 15 endometrial carcinomas have been studied. Specimens were obtained at hysterectomy from patients, aged 46–73, previously untreated for their neoplastic disease. Tissues were placed into sterile containers and transported to the laboratory within 15–30 min. Representative fragments were fixed in 10% formaldehyde and processed for histology. The remainder of the tissue was thoroughly washed with phosphate-buffered-saline (PBS) containing gentamycin (200 μg/ml) and cut under aseptic conditions into small fragments approximately 1 mm thick by 2–3 mm dia. Explants from each tumour were equally divided among different groups (3–9 explants/group, depending upon

the amount of available tissue) and 3 explants were mounted onto a strip of lens paper resting on a stainless grid in a well of a Multi-dish plastic box (Sterilin Ltd, England). The basic culture medium contained Parker TC 199 (Gibco Labs) supplemented with 30% foetal calf serum (Flow Labs), crystalline insulin (5 U/ml), Hepes 20 mM and gentamycin (50 μg/ml). The well was filled with medium in such a way that the surface of the solution was just touching the paper and keeps it moistened. The culture dishes were then incubated at 37°C in a humidified atmosphere of 5% CO_2 in air. The medium was changed after the first 24 hr of culture and at that time the hormones were added. Hormones were dissolved in ethanol and diluted to a final concentration of 0.1% ethanol in the medium; the same concentration of ethanol was present in control cultures. The hormones used were: progesterone,* 17α-hydroxy-progesterone, Calusterone, Gestonorone capronate, 17β-oestradiol, Nafoxidine, and CI-628.

Assay of tritium-labelled thymidine (^{3}H-TdR) incorporation into DNA

After 3 days in culture from the addition of hormones, tissue explants were transferred to the well of a Multi-dish box containing fresh medium and ^{3}H-TdR (21 Ci/mM, The Radiochemical Center, Amersham) at the final concentration of 0.5 μCi/ml and incubated at 37°C for 60 min. Residues of small uncubation, the explants were thoroughly washed in cold PBS containing 0.1% unlabelled thymidine and lysed in 1 ml of 0.5 M NaOH at 37*C for 60 min. Residues of small undissolved tissue were removed by centrifugation at 3000 rev/min for 10 min. The absorbance at 260 μm of the supernatant was measured. 0.4-ml of 100% trichloroacetic acid (TCA) were added and the tubes were kept in an ice-bath for 30 min. The tubes were centrifuged at 3000 rev/min for 30 min at 2°C and the precipitate was washed three times with 10% TCA. The final precipitate was dissolved in 1 ml of Soluene 350 (Packard Instr.) during 2 hr at 45°C and counted in 10 ml of scintillation fluid (5 g PPO/l. toluene) in a Nuclear Chicago (mod. Marck II) liquid scintillation spectrometer with a counting efficiency of 33%. The results are expressed as counts/min incorporated into TCA-precipitable material ("DNA") per unit absorbance at 260 μm.

*The following common names and abbreviations are used: Calusterone, 17β-hydroxy-7β, 17-dimethyl androst-4-en-3 one (Upjohn); Gestonorone capronate, 17α-hydroxy-19-norpregn-4-en-3,20 dione (Schering); Nafoxidine(U-11, 100A), 1-(-[p-(3,4-dihydro-6-methoxy-2-phenyl-1-naphthyl)]-phenoxy ethyl)pyrrolidine hydrochloride (Upjohn); CI-628, α-(pyrroli-dinoethoxy)-phenyl-4-methoxy-α-nitrostilbene (Parke-Davis).

RESULTS

The tissue showed good preservation of their morphology after 4 days in culture (Fig. 1). To enable meaningful assessment of the effects of hormones, control experiments were carried out to determine the range of ^{3}H-TdR incorporation which could be observed in replicate samples. Seven experiments using separate tumours were conducted using between 6 and 15 replicates in each case. Each replicate sample consisted of 3 explants cultured together in a well of a Multi-dish box as described above. The results are shown in Table 1, which records absolute values and the standard deviations from the mean. The results show a wide scatter and reveal the extent of variation required to be present before definitive hormonal effects can be assessed by the present methods. These wide variations appear to be a reflection of the differing neoplastic cellular components of different areas of the same endometrial carcinoma.

and CI-628, whilst Table 3 shows the incorporation in the same tumours cultured with varying hormone concentrations. The overall range of ^{3}H-TdR incorporation in these tissues cultured with steroid hormones and antiestrogens is more clearly demonstrated in Fig. 2, which shows the range of incorporation in 740 explants derived from 15 endometrial carcinomas. The tritium incorporation for each sample is expressed as a multiple of the corresponding estimation in a cultured control from the same tumour. Most tissues showed approximately the same level of ^{3}H-TdR incorporation as their cultured control from the same tumours and the majority of the remainder fell within the range which might be expected among replicate samples. One tumour showed a 4-fold decrease in incorporation over its cultured controls in the presence of calusterone; another tumour showed a 6-fold decrease in incorporation in the presence of gestonorone capronate. Finally, 2

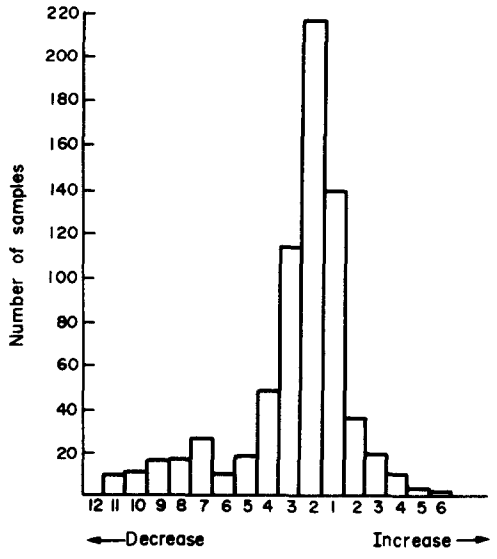

Fig. 2. Tritiated thymidine incorporation in a series of human endometrial carcinomas. The incorporation in each case is expressed as a multiple of that in its cultured control.

tumours showed a 3-fold decrease in incorporation, one in response to nafoxidine and the other to CI-628. 17β-Oestradiol alone or in combination with progesterone did not affect ^{3}H-TdR incorporation.

Applying Friedman's analysis of variance in ranks, we found no group of tumours showing significantly different thymidine incorporation in response to hormones than would be expected in a control group. Similarly, no dose–response effects were observed.

DISCUSSION

Progestagens are the primary choice for therapy of advanced endometrial carcinoma no longer within the reach of surgery or radiotherapy. In a recent study, Reifenstein [11] reported that in 314 women with progressing advanced endometrial cancer and no longer responding to established anticancer measures, therapy with hydroxyprogesterone capronate induced in 37% an objective response consisting of regression in 30.2% and arrest of the disease in 6.8%. Selection of patients likely to respond to hormonal therapy is still largely empirical. Despite extensive research into the endocrine status of individual patients [12], hormone receptor sites concentration [13], and direct effects of hormones on cultured tissue, no predictive tests of clinical value has yet emerged.

The assessment of the effects of hormones on tumours cultured *in vitro* has been most frequently evaluated by organ culture. In general, for solid human tumours, this culture technique can be considered to be close to the *in vivo* situation. One obstacle to the routine use of this technique for an assay system is the great difficulty of assessing the effects of the hormones. Measurement of cell number and viability are often very difficult and most assessments of viability of the tissue after culture have been made on the basis of histological examination of sections of the organ culture, which is extremely difficult to quantitate. The technique of measuring the uptake of a specific DNA label, such as radioactive thymidine, has been successfully used for quantitative measurement of viability of cell in culture [14]. In the case of cultured explants, direct measurement of radioactivity in the tissue seems to be preferable to autoradiographic analysis since radioactive uptake is seen only in the periphery of the specimens, labelling depth does not usually exceed 100–200 μm [15]. Moreover, the distribution of labelled cells often varies considerably in the same tissue, particularly in tumours making determination of labelling index hazardous or even impossible [16].

Using ^{3}H-TdR incorporation into DNA, we failed to demonstrate any significant effect on incorporation due to hormones compared with the controls. These results are in disagreement with those of Hustin [17], who found a significant decrease in incorporation of radioactive thymidine after incubation of endometrial carcinoma with progesterone, even though the method of analysis was by labelling index and not by direct measurement of radioactivity in the tissue and only limited statistical analysis was carried out. His culture conditions are quite similar to those used in our study, the only differences arise from our use of higher concentrations of serum and insulin in the medium. The presence of the last hormone at 5 U/ml resulted in an increase of ^{3}H-TdR incorporation of approximately 30% as compared to culture conditions using insulin at 0.1 U/ml. Moreover, in this study we did not observe the marked fall in incorporation after 3 days of culture which Hustin noted in the absence of hormones and it is possible that optimum *in vitro* growth conditions are not the best for detecting hormonal effects.

The variation in tritium counts between replicate samples indicates that the techniques used here may not be sensitive enough to detect small hormonal variations which might occur in short term organ culture of this particular type of cancer. Recent work by

Gullino *et al.* [18] on hormone dependent tumours in the rat suggests that interpretation of the results from incorporation of tritiated thymidine in terms of tumour growth or regression may not be possible in short term cultures. The variation in experimental results due to the heterogeneity of the tissue poses considerable problems in detecting direct hormonal effects using organ cultures. It is possible that cell monolayer cultures as used by Sekiya *et al.* [19] assessed by incorporation of thymidine into DNA or by survival of cell colonies may eventually yield more satisfactory results for development of *in vitro* tests to predict the therapeutic effects of hormones on endometrial cancer.

Studies on Informational RNAs and Ribonucleoproteins of Normal Rat Liver, Zajdela Hepatoma and Liver of Hepatoma-bearing Rats

A. V. LICHTENSTEIN, R. P. ALECHINA and V. S. SHAPOT

Laboratory of Biochemistry, Oncological Scientific Center, Academy of Medical Sciences, Moscow, U.S.S.R.

Abstract—*DNA-like RNA (D-RNA) species, both as constituents of RNP particles and protein-free molecules, isolated from normal rat liver, Zajdela ascites hepatoma and liver of tumor-bearing animals were compared with respect to their sedimentation and chromatographic behaviour. A selective labelling of D-RNA was carried out under actinomycin D-induced block of rRNA synthesis. No detectable differences in nuclear D-RNAs of the tissues compared could be observed whereas cytoplasmic D-RNAs of hepatoma and liver of tumor-bearing rats appear to be much more heterogeneous as compared to those of normal liver. The kinetics of the labelled D-RNAs appearing in the cytoplasm in case of malignant cells also differs from that characteristic of normal liver cells. The comparative analysis of cytoplasmic RNP complexes in the sucrose density and CsCl isopycnic band centrifugation revealed a shift in the ratio of polyribosome-bound and free complexes in favour of the latter in the tumor and liver of tumor-bearing rat as compared with normal liver. The data presented are interpreted to indicate a certain impairment in the selective nucleus-to-cytoplasm transport of RNA in tumor cells, the cells of tumor-bearing animal occupying in this respect an intermediate position between normal and tumor tissues.*

INTRODUCTION

No pronounced differences between nuclear D-RNA species of normal and tumor cells have been revealed so far [1]. Qualitative diversions in the nuclear RNA spectra in neoplasms as compared with homologous normal tissues are relatively small being not constant in their direction in different model systems and presumably can be regarded just as manifestation of tumor progression [2–13], rather than a feature of malignancy itself.

The absence of the above distinctions is surprising since normal *resting* cells have been usually compared with *growing* tumor cells, i.e. the cells in various functional states are used. Indeed, to reproduce itself the tumor cell must synthesize in a short time a great number of different structural and enzymatic proteins including those the normal non-dividing cell does not produce. So, a shift from resting to dividing cells is not necessarily coupled with significant alterations at the transcriptional level as was shown in a number of reports [14–17]. Hence, the important part, which post-transcriptional levels play in the control of protein synthesis in the animal cell, both normal and malignant, may be easily deduced [18–26].

So, it becomes clear that the studies of not only nuclear but also cytoplasmic D-RNAs and RNP complexes are of great importance in comparison of normal and tumor cells.

The paper presented summarizes the data of investigation of sedimentation and chromatographic characteristics of nuclear and cytoplasmic D-RNAs and cytoplasmic RNP complexes containing D-RNAs of normal rat liver cells, Zajdela ascites hepatoma cells as well as of liver of tumor-bearing rats. The latter was meant to reveal possible distant effects of the tumor on the tissues of the host.

MATERIALS AND METHODS

Wistar rats (150–200 g) fasted for 24 hr

Accepted 30 December 1977.

before experimentation were used. One half of a milliliter of a nondiluted suspension of ascites Zajdela cells was transplanted under sterile conditions. The animals were sacrificed 5 days after tumor transplantation. D-RNAs from tissues studied were single (^{14}C) or double (^{3}H and ^{14}C) labelled with 40–100 μCi/rat of radioactive precursors (orotic acid and uridine for liver and hepatoma cells, respectively).

D-RNAs were selectively labelled due to actinomycin D-induced block of rRNA synthesis: 1 hr before sacrifice the animals were injected with 80 μg actinomycin D. In order to obtain a complete block of DNA-dependent RNA synthesis in chase-experiment 1 mg/rat actinomycin D was administered.

In some experiments RNAs of hepatoma cells were labelled *in vitro* by incubation in the Eagle medium, containing 10% bovine serum and 1 μCi/ml ^{3}H-uridine (to inhibit rRNA synthesis the cells were preincubated with 0.05 μg/ml actinomycin D for 30 min).

Nuclear D-RNAs were isolated by means of phenol-temperature fractionation procedure within 50–70°C interval [27]. Cytoplasmic RNA were obtained from the post-mitochondrial supernatant treated with the phenol–chloroform (1:1) mixture in the presence of 0.5% sodium dodecylsulphate.

Cytoplasmic RNP particles were obtained from the post-mitochondrial supernatant by magnesium precipitation according to the method by Leytin and Lerman [28].

RNA fractionation by sucrose density centrifugation and ion-exchange chromatography on the column of methylated albumin-kieselguhr in salt and temperature gradients was conducted as described previously [29, 30].

For a further study of cytoplasmic RNP complexes a novel technique (nucleoprotein-Celite chromatography) elaborated by us recently [31, 32] was used. This method permits fractionation of RNA species according to the tightness of their bonds with proteins within native RNP particles. Cytoplasmic RNAs are separated by this method onto 18S and 28S rRNA, mRNA of polyribosomes and messenger-like RNA of free cytosol particles [32].

Cytoplasmic RNP particles were fractionated by centrifugation in a linear (15–35%) sucrose gradient in a Spinco L2 centrifuge, SW 25.2 rotor at 23000 rev/min and 4°C for 3.5 hr.

CsCl-band centrifugation of RNP particles was performed as described by Spirin *et al.* [33]. RNPs were fixed with formaldehyde for 24 hr (final concn. 4%) before centrifugation on a pre-formed CsCl gradient in a Spinco L2 centrifuge, rotor SW 50, at 44000 rev/min and 4°C for 18–24 hr.

Cytoplasmic poly(A)-containing RNAs were selectively adsorbed on poly(U)-Sepharose [34].

For the determination of radioactivity an RNA carrier (100 μg/ml) and trichloroacetic acid to a final concentration of 5% were added to the samples. In the experiments when a single label was used (only ^{14}C-labelled precursors) the precipitates were collected on Millipore® filters and after drying were measured in scintillation cocktail (4 g of PPO and 0.2 g of POPOP/l. of toluene) in a liquid-scintillation counter Nuclear-Chicago Mark 2 with a counting efficiency of about 70–80% as determined by the channels-ratio method. The samples of RNA double labelled with ^{3}H- and ^{14}C-precursors were collected on Millipore filters as described above followed by the hydrolysis with hot acid (0.5 ml of 1 N HCl per filter at 80°C for 15 min) and counting of the hydrolysate in homogeneous system by mixing the sample with 9 vol of Triton X-100-toluene (1:2) mixture. Discrimination of ^{3}H- and ^{14}C-radioactivity was carried out with the use of external standardization and computation of the results obtained on the "Olivetti Programma 101" system.

RESULTS

Nuclear and cytoplasmic RNAs

Figure 1 represents the methylated albumin-kieselguhr (MAK) chromatography of nuclear RNAs of normal rat liver, liver of tumor-bearing rats, and ascites hepatoma double labelled with ^{3}H and ^{14}C radioactive precursors (2hr and 24 hr, respectively). The MAK-chromatography is known to fractionate RNA molecules according to both their size and nucleotide composition, thus providing the opportunity to study separately ribosomal and informational RNAs [30, 35–37]. Nuclear RNAs are separated by the MAK-chromatography onto two main fractions: the "salt" RNA eluted by NaCl linear (0.6–1.5 M) gradient at 37°C and containing predominantly rRNAs and their precursors and the "temperature" RNA tightly bound to the column and eluted by 1.5 M NaCl and temperature (37°–98°C) gradient (on Fig. 1 both fractions are separated by the arrow). The "temperature"

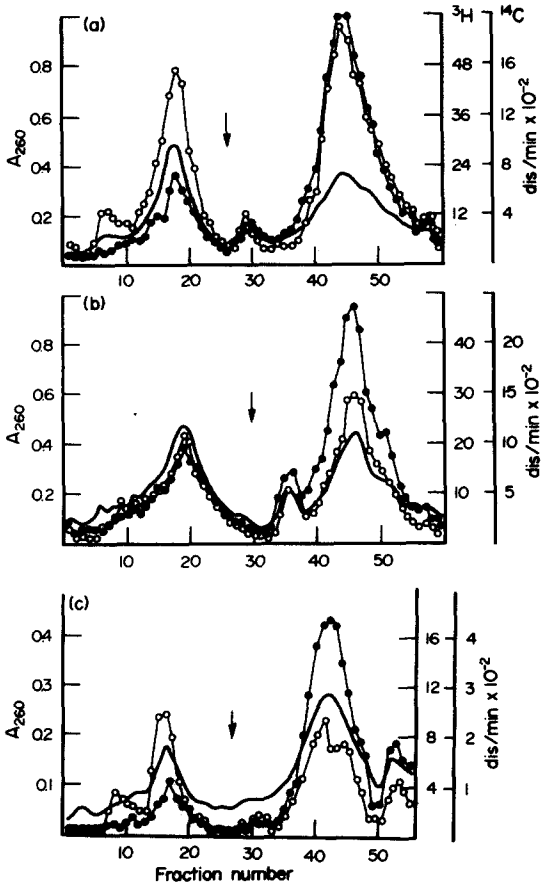

Fig. 1. MAK-chromatography of nuclear RNAs doubled labelled with ^{3}H-orotic acid (100 μCi/rat, 2 hr) and ^{14}C-orotic acid (40 μCi/rat, 24 hr). A—normal liver, B—liver of tumor-bearing rat, C—Zajdela ascites hepatoma (in this case ^{3}H-uridine and ^{14}C-uridine were used). ———, A_{260}; ●——●, ^{3}H-radioactivity; ○——○, ^{14}C-radioactivity. The arrow indicates the start of the temperature gradient.

fraction comprises the bulk of rapidly labelled nuclear heterogeneous RNA [30, 37]. These data taken together with the fact, that "temperature" fraction contains over 70% of nuclear poly(A)-containing RNAs (our unpublished results), suggest that the tenaciously bound fraction represents the nuclear precursors of cytoplasmic mRNAs. However, a certain part of the latter may be localized in the "salt" fraction [36].

The use of a double label showed that the chromatographic distribution of pulse and long-term labelled RNA molecules of the cell nucleus is very similar, though their $^3H/^{14}C$ ratio was found to be different and constantly higher (1.5–3-fold) in the "temperature" fraction as compared with the "salt" one. This fact indicated a more rapid turnover of tenaciously bound RNAs and/or a higher relative content of short-lived molecules among them.

It should be noted here that the chromatographic profiles of the total nuclear RNAs as well as their pulse and long-term labelled subpopulations (the curves of optical density, ^{3}H- and ^{14}C-radioactivity, respectively) were very similar in all three tissues studied.

The MAK-chromatograms of cytoplasmic RNAs labelled under the conditions of actinomycin D-induced block of rRNA synthesis are seen on Fig. 2. In this case the radioactive label is selectively incorporated in 14–16S RNA (presumably mRNA) whereas 18S and 28S rRNAs remain practically unlabelled (not shown here).

The comparison of Figs. 1(a) and 2(a) (the MAK-chromatograms of nuclear and cytoplasmic RNAs from normal rat liver, respectively) shows that in the latter case practically no tenaciously bound "temperature" fraction exists and cytoplasmic mRNAs (radioactivity curve) is localized in the "salt" fraction on the right shoulder of the rRNA peak. Such drastic differences in chromatographic distribution of nuclear pre-mRNAs and their cytoplasmic products reflect apparently the intranuclear processing and selective nucleus-to-cytoplasm transport of RNA molecules.

Unlike nuclear RNAs of all tissues studied whose chromatographic profiles seem to be very close to each other, those of cytoplasmic RNAs are rather different (see Fig. 2). Indeed, proceeding from MAK-chromatograms presented one can state that the

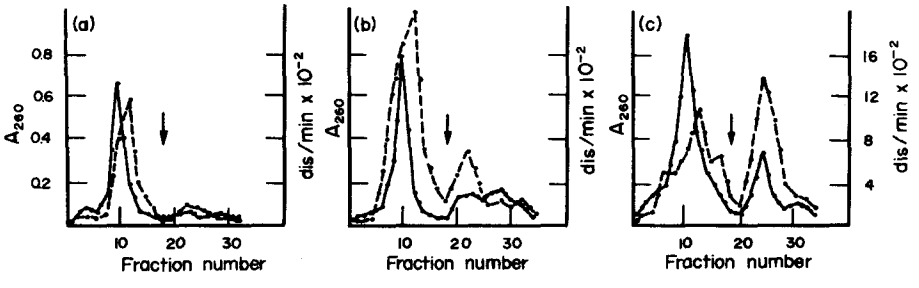

Fig. 2. MAK-chromatography of cytoplasmic RNAs labelled under the condition of actinomycin D-induced block of rRNA synthesis (100 μCi/rat, 60 min). A—normal liver, B—liver of tumor-bearing rat, C—Zajdela ascites hepatoma ———, A_{260}; — —, ^{14}C-radioactivity. The arrow indicates the start of the temperature gradient.

sets of cytoplasmic RNAs from liver of tumor-bearing rat and especially from Zajdela hepatoma cells are more heterogeneous than that from normal liver. In the first two tissues a significant proportion of the rapidly labelled cytoplasmic D-RNA is revealed in the "temperature" fraction which is practically absent from the cytoplasmic RNAs of normal liver cells.

Cytoplasmic poly(A)$^+$-RNAs

A significant proportion of cytoplasmic mRNA is known to be polyadenylated. Figure 3 shows the sedimentation distribution of cytoplasmic poly(A)$^+$-RNA of normal liver cells

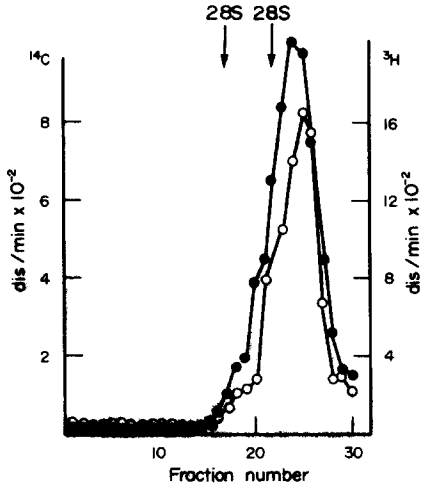

Fig. 3. Sucrose-density-centrifugation of cytoplasmic poly(A)-RNA from rat liver labelled as described in the legend to Fig. 1. ●——●, ^{3}H-radioactivity; ○——○, ^{14}C-radioactivity. The arrows indicate the location of 18S and 28S rRNA markers.

isolated by poly(U)-Sepharose adsorption technique. The RNAs were previously double labelled with ^{3}H- and ^{14}C-orotic acid for 2 hr and 24 hr, respectively. It is seen that the cytoplasmic poly(A)$^+$-RNA sediments as a narrow band with the maximum at 14–16S. It is worth mentioning here that the pulse-labelled poly(A)$^+$-RNAs are somewhat larger in size than the long-term labelled ones as was shown earlier by others [38, 39].

The relative amounts (in %) of poly(A)$^+$-RNA in total cytoplasmic RNA of normal liver, liver of tumor-bearing rat and Zajdela hepatoma before and after complete actinomycin D block of RNA synthesis are presented in Table 1. Two points attract attention. First, the content of poly(A)$^+$-RNA is a little lower in normal liver as compared with that in the two other tissues. Secondly, a complete actinomycin D-induced block of

Table 1. Content of poly(A)-containing RNAs (in % to the total cytoplasmic RNA) in normal liver, liver of tumor-bearing rat and ascites hepatoma Zajdela at different time intervals after actinomycin D-induced block of RNA synthesis (mean values of two independent determinations)

Tissue	Duration of chase (hr)	Content of poly(A)-RNA (%)
1. Normal liver	0	0.92
	2	0.72
	4	0.55
2. Liver of tumor-bearing rat	0	1.03
	2	1.05
	4	1.08
3. Zajdela ascites hepatoma	0	
	2	—
	4	1.17

RNA synthesis entails a rapid reduction of the content of polyadenylated RNAs in normal liver cells but neither in the cells of liver of tumor-bearing animal, nor in the Zajdela hepatoma cells this phenomenon takes place. This fact may indicate a greater stability of polyadenylated RNAs from liver of tumor-bearing animal and hepatoma than those from normal liver. Alternatively, the phenomenon above mentioned may be resulted from a large pool of nuclear pre-mRNAs in the liver of tumor-bearing rat and hepatoma, which is able to maintain a constant nucleus-to-cytoplasm transport of RNA during some time in spite of the arrest of RNA synthesis. From this point of view the normal liver cells contain a relatively small pool of nuclear pre-mRNAs, which is rapidly exhausted after RNA synthesis is blocked.

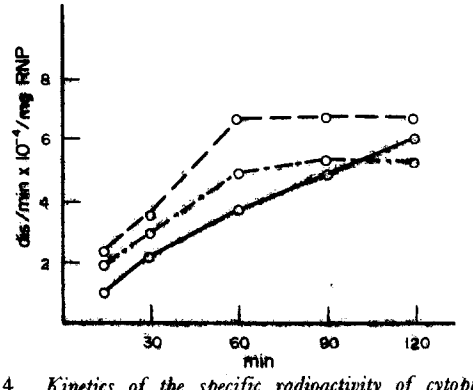

Fig. 4. Kinetics of the specific radioactivity of cytoplasmic RNP particles labelled with 100 μCi/rat of ^{14}C-radioactive precursors during time intervals indicated under the condition of actinomycin D-induced block of rRNA synthesis. ○——○, normal liver, ○—·—○, liver of tumor-bearing rat, ○———○, Zajdela ascites hepatoma.

An indirect evidence favouring the latter possibility was obtained from studying the kinetics of the labelled D-RNA appearing in the cytoplasm of tissues studied (Fig. 4). It could be seen that the cytoplasmic D-RNAs of hepatoma and liver of tumor-bearing rat become labelled very rapidly and reach the plateau earlier than the cytoplasmic D-RNAs of normal liver cells and consequently they turn over rapidly.

Cytoplasmic RNP Particles, containing D-RNA

Centrifugation of RNP particles of tissues studied in sucrose density gradient revealed certain differences in their fractional composition (Fig. 5).

It is seen that in hepatoma cells a relative content of monoribosomes is drastically increased at the expense of polyribosomes—the fact, which is in line with the observations on a number of other tumors [40]. Besides this, in hepatoma cells the content of polyribosomal mRNA (the radioactivity curve) is found to be markedly reduced as compared with rapidly labelled messenger-like RNA of post-ribosomal zone.

As to the sedimentation profile of the RNP particles of liver of tumor-bearing animal,

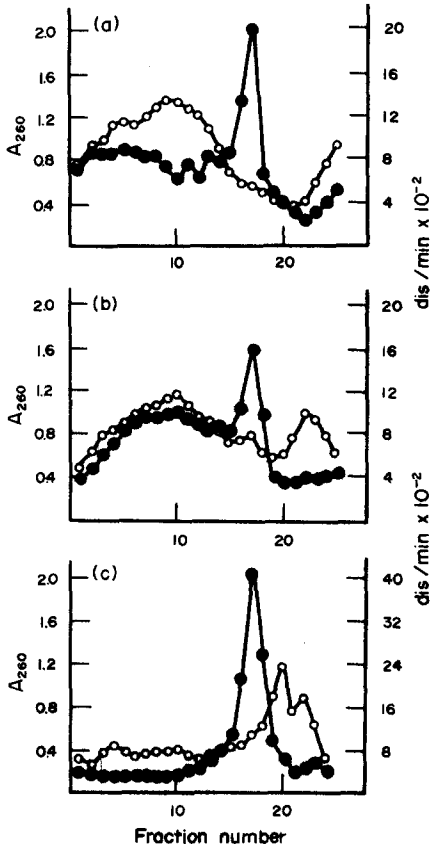

Fig. 5. Sucrose-density-centrifugation of cytoplasmic RNP particles labelled as described in the legend to Fig. 2. A—normal liver, B—liver of tumor-bearing rat, C—Zajdela ascites hepatoma. ●——●, A_{260}; ○——○, ^{14}C-*radioactivity.*

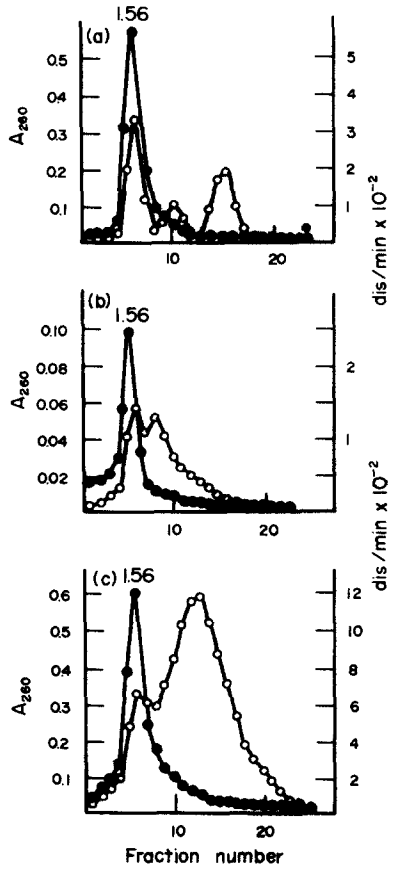

Fig. 6. CsCl-band centrifugation of cytoplasmic RNP particles labelled as described in the legend to Fig. 2 (RNP particles were previously fixed with formaldehyde, see Material and Methods). A—normal liver, B—liver of tumor-bearing rat, C—Zajdela ascites hepatoma. ●——●, A_{260}; ○——○, ^{14}C-*radioactivity. The arrows indicate the location of ribosomes (buoyant density* 1.56 g/cm^3).

it is similar to that of normal tissue, but unlike the latter, the relative content of post-ribosomal messenger-like RNA is somewhat increased.

The above observation of a higher proportion of informosomes in hepatoma and liver of tumor-bearing animals was verified by the results of isopycnic band centrifugation of cytoplasmic RNP particles in CsCl (Fig. 6). This technique permits separation of ribosome-associated mRNP particles (buoyant density 1.56 g/cm^3) from post-ribosomal informosomes (buoyant density 1.38–1.45 g/cm^3). It could be seen from Fig. 6 that in the hepatoma and liver of tumor-bearing rat the proportion of the radioactive material beyond the ribosomes (the main peak of the optical density curve) is significantly higher than that observed in the normal liver.

Recently, a novel fractionation technique (gradient elution of nucleic acids from nucleoprotein-Celite column, NPC-chromatography) was elaborated in our laboratory, which enables a separation of nucleic acids in corres-

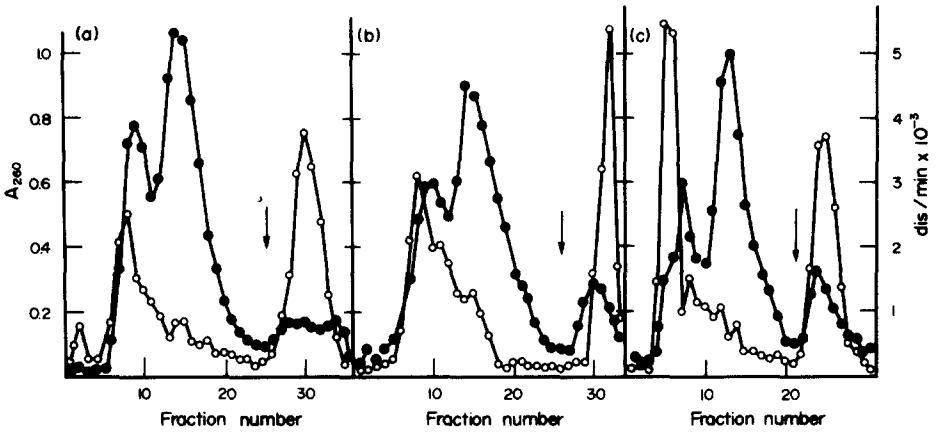

Fig. 7. Nucleoprotein–Celite chromatography of cytoplasmic RNP particles labelled as described in the legend to Fig. 2. A– normal liver, B—liver of tumor-bearing rat, C—Zajdela ascites hepatoma. ●——●, A_{260}; ○——○, ^{14}C-*radioactivity. The arrow indicates the start of the temperature gradient.*

pondence to the tightness of their bonds with proteins within native complexes [31, 32]. This method applied to cytoplasmic RNP particles separates rRNA onto 18S and 28S components (two main components on the optical density curve) and nonribosomal RNAs—onto messenger-like RNA of informosomes and mRNA of polyribosomes (fractions 3–13 and 23–35 on the radioactivity curve of Fig. 7, respectively). The identification of chromatographic components obtained by the nucleoprotein-Celite chromatography was presented earlier [31, 32]. One can see that significant changes in the quantitative proportions of mRNA and messenger-like RNA occur in tissues studied analogous to those obtained by independent methods (see Figs. 5, 6): in liver of the tumor-bearing animal and especially in the hepatoma a proportion of rapidly labelled and non-associated with ribosomes RNAs is greatly increased.

DISCUSSION

The main conclusion which can be drawn from our experiments is that the nuclear DNA-like RNAs of tissues studied are very similar when analysed by the methods used whereas the cytoplasmic nonribosomal RNAs were found to be different in some respects.

The question arises whether differences in cytoplasmic RNAs are due to various extent of nuclear contaminations of preparations studied. Though this possibility can not be completely ruled out at present, it seems very unlikely. First, the kinetics of labelling and actinomycin D-induced decay of nuclear and cytoplasmic DNA-like RNAs were different in all tissues studied (not shown here). Secondly, the cytoplasmic RNP particles of all three tissues appeared to be extremely sensitive to the treatment with EDTA thus demonstrating the characteristic of namely cytoplasmic but not of nuclear RNP complexes.

Finally, a number of current data indicate that the bulk, if not all, of nuclear RNAs are tightly associated with the chromatin fibrils not only at the time of their synthesis but also during all their life-span in the nucleus [41–43]. The appearance of free RNP particles in the nuclear sap and their contamination of cytoplasmic structures thereafter seem to be artifacts caused by the action of endogenous nucleases [21]. In this connection a very low nuclease activity in Zajdela hepatoma cells [44] may be considered as a factor diminishing a nuclear leakage of RNP particles.

On the other hand, the question arises as to the validity of the results obtained with the use of actinomycin D which was shown to exert some side effects including those operating at the level of nucleus-to-cytoplasm RNA transport [45, 46]. However, the doses of the drug which we employed throughout all our work to selectively prevent rRNA synthesis were approximately from one to two order of magnitude lower than those used in "chase" experiments and which appear to interfere with RNA transport. The rates of labelling and the sedimentation velocities of cytoplasmic mRNAs either selectively labelled with the use of actinomycin D or isolated by poly(U)-Sepharose chromatography without treatment with this drug were essentially the same (our unpublished results). Analogous results evidencing against low-dose-actinomycin D-induced damages of mRNA

metabolism were also obtained in our preliminary short-term (less than 30 min) labelling experiments in which rapidly labelled cytoplasmic mRNAs incorporated radioactive precursors selectively since they appeared in the cytoplasm earlier than rRNAs. No notable differences were observed between these mRNAs and those labelled under the conditions of low actinomycin D block with respect to the sedimentation velocities and rate of appearing in the cytoplasm.

As to the "chase" experiments with high doses of actinomycin D which were also carried out in our study (see Table 1) they are more open to criticism. We can not at present rule out the possibility that it was some side toxic effect of actinomycin D that caused observed differences in the rates of a disappearance of cytoplasmic poly(A)-containing RNAs (Table 1), though it seems to us unlikely, especially concerning normal liver and liver of tumor-bearing animals.

With all these reservations in mind and proceeding from the kinetics of labelling and chromatographic profiles of D-RNAs from tissues studied one can suggest the less selectivity of nucleus-to-cytoplasm transport of RNA molecules in hepatoma and liver of tumor-bearing rat as compared with normal liver. A number of observations attest to an important role of the nuclear-cytoplasmic transport in regulation of gene expression in both normal and malignant cells [6, 9, 12, 13, 18–26].

Differences in the tissues studied are manifested also by various distribution of rapidly labelled RNA molecules between polyribosomes and post-ribosomal informosomes, the latter prevailing in liver of tumor-bearing animal and hepatoma unlike the situation in normal liver. The reason for the above phenomenon remains unclear and only speculations on this subject may be put forward. It is possible that there are certain peculiarities in the process of translation in hepatoma cells, e.g. an elevated rate of elongation and termination of polypeptide chains whereas the rate of initiation remains unchanged can result in a decrease in size of polyribosomes and an increase in the pool of monoribosomes and post-ribosomal particles.

According to our observations the liver of tumor-bearing animal occupies an intermediate position between hepatoma and normal liver cells with respect to several properties studied. It seems likely that these alterations are due to distant effects of the tumor on the host's tissues. Recent data of Schumm and Webb are consistent with this proposition [47].

Circadian Dependence of Host and Tumor Responses to Cyclophosphamide in Mice*

S. S. CARDOSO,† T. AVERY,‡ J. M. VENDITTI§ and A. GOLDIN§

†*Department of Pharmacology, University of Tennessee Center for the Health Sciences, Memphis, Tennessee, U.S.A.,*
‡*Department of Biochemical and Clinical Pharmacology, St. Jude Children's Research Hospital, Memphis, Tennessee, U.S.A.,* §*National Cancer Institute, Bethesda, Maryland, U.S.A. and Scientific Editor, J. Gilbert, St. Jude Children's Research Hospital, Memphis. Tennessee, U.S.A.*

Abstract—*In a series of five experiments,* 505 *female* BDF_1 *mice were standardized for periodicity studies by exposure to alternating periods of* 12 hr *of light and* 12 hr *of darkness. The mice were inoculated intraperitoneally with* 1 million L1210 *murine leukemia cells and beginning approximately* 24 hr *later, were injected by the same route with a single dose of cyclophosphamide at* 1500, 1800, 2100, 0600 *or* 0900 hr. *At each time point, different groups of mice were treated with* 300 *or* 360 mg *of cyclophosphamide per* kg *of body weight. Cured mice* (60-day *survivors*) *as well as mice dying from drug-induced toxicity or tumor were noted for each interval of treatment.*

The magnitude of the effects produced by cyclophosphamide varied widely from experiment to experiment, suggesting that factors presently unidentified also influenced host responses to the drug. Nevertheless, the composite data indicated that both the therapeutic and the toxic effects of cyclophosphamide were quantitatively related to the circadian phase of drug administration. The frequency of cures was highest (34%) *when the drug was administered at* 1800 hr *and lowest* (7%) *when given at* 0900 hr. *In addition, drug-induced toxicity exhibited a reverse pattern of cyclic activity in which the minimum value* (20%) *resulted from administration at* 1800 hr *while the maximum number of deaths* (52%) *occurred after treatment at* 0900 hr. *Due, in part, to this reciprocal relationship between cure rate and drug-induced death rate, the selective timing of cyclophosphamide administration resulted in greatly divergent modification of the risk versus benefit ratio. As the result of treatment at* 0900 hr, *approximately* 7 *mice were killed for each mouse that was cured while, after treatment at* 1800 hr, 1.7 *mice were cured on the average for each mouse that was killed. Thus by taking advantage of temporal fluctuations in host resistance to cyclophosphamide, enhanced therapeutic responses without equivalent increases in toxicity may be produced.*

INTRODUCTION

THE EFFECTIVENESS of antitumor drugs depends, for the most part, on narrow but exploitable quantitative differences between tumor cell susceptibility and host resistance to chemotherapy [1]. To achieve optimum therapeutic results, therefore, it may be necessary to use dosages that approach the lethal level for the host [2–5]. Thus, any measures that would decrease the toxic component of drug action should improve the prospects for more effective cancer chemotherapy. Studies over the past few years have indicated that toxic as well as beneficial responses to drugs depend significantly on the time of day (or circadian phase) of their administration [6]. Chronotherapy, or the administration of drugs on schedules adjusted to circadian systems, should, therefore, permit the use of higher drug dosages, possibly at more frequent intervals. Evidence supporting this concept and extending it to cancer chemotherapy has been presented [7–16].

Early studies by Badran *et al.* [17] identified the circadian phases during which cyclophosphamide produced maximum and minimum effects on the mitotic activity of a transplantable mammary carcinoma. Subsequently, mitotic rhythms, as well as biochemical and cytokinetic endpoints, served as guides in the design of chronotherapeutic schedules for the administration of cytosine arabinoside, 5-fluorouracil, and actinomycin-D to rats, with emphasis on minimizing host toxicity [7]. These

studies, which were later confirmed in tumor-free and tumor-bearing mice [8, 13–16], indicated that host toxicity could indeed be reduced through the judicious application of chronotherapy.

Haus *et al.* [15] have shown that the susceptibility of several strains of non-tumor-bearing mice to cyclophosphamide follows a definite circadian pattern. Preliminary results from later studies [10, 12] suggested that, in mice with L1210 leukemia, both tumor and host responses to cyclophosphamide were affected by the time of day that the drug was administered. When different groups of mice were treated at either 1200, 1500, 1800, 2100, 2400, 0300, 0600 and 0900 hr, with varying dosages of cyclophosphamide (180–400 mg/kg), the number of drug-induced, or toxic, deaths was highest among animals treated at 0600 or 0900 hr [10]. The difference in the frequency of toxic deaths between animals at or shortly after the onset of darkness (1800–2100 hr of the day) and those treated at or shortly after the onset of light (0600–0900 hr of the day) was statistically significant. These results allowed us to identify the most appropriate circadian phases (0600–2100 hr) for conducting subsequent studies with cyclophosphamide.

Reported here are results from follow-up experiments that confirm the circadian dependence of cyclophosphamide-induced cures and toxic deaths. The results also support a two-step approach to chronotherapeutic studies: (1) a preliminary identification of circadian phases that include maximum and minimum host sensitivity to the given agent and (2) follow-up studies using this range of time points for final determinations of circadian-dependent responses to the given agent.

MATERIALS AND METHODS

Mice

A total of 505 BDF_1 female mice, obtained either from Simonsen Laboratories, Inc. (Calif.) or Southern Animal Farms (Ala.) through the Division of Cancer Treatment, National Cancer Institute, were used in a series of five experiments conducted over a period of 18 months. When received, the mice ranged in weight from 16 to 21 g. Prior to treatment, they were grouped so that the intercage variation in weight did not exceed 1 g and were exposed to alternating periods of light (0600–1800 hr) and darkness (1800–0600 hr) for at least one week. Temperature in the animal facility was maintained at $23 \pm 2°C$ and the mice were given free access to food (Purina Lab Chow) and water. Between 0900 and 1200 hr of day zero, one day prior to the initiation of treatment, each mouse was inoculated intraperitoneally with one million L1210 murine leukemia cells. In each of the five studies, inoculations were performed only once; therefore, it was possible to inoculate every mouse in a single study with ascites tumor drawn from the same population of tumor cells. In each study, one group of tumor-inoculated mice were injected with 0.9% sodium chloride solution in lieu of cyclophosphamide. The mean post-inoculation life span of these mice served to confirm that the inoculum actually delivered was, indeed, of the intended magnitude. It also afforded one basis for evaluating responses to treatment; nevertheless, toxic deaths and cures were expected to provide more definitive indications of the relative effectiveness of treatment at different times. Thus, the effects produced on these end points by varying the time of drug administration were the chief variables to be assessed. In this respect, the responses manifested by any treatment group served as a partial control for every other group.

Drug treatment

At 1500, 1800 and 2100 hr of the day after tumor transplantation and at 0600 and 0900 hr of the subsequent day, different groups of mice were injected once, intraperitoneally, with cyclophosphamide. At each time, one group of mice was treated with 300 mg/kg while another received 360 mg/kg. Two levels of dosage were used with the expectation that the possibilities for obtaining an equitable distribution of toxic deaths, tumor deaths, and cures would be increased. No significant differences (statistically) were found between these dosages; consequently, in each experiment, the results obtained with 300 and with 360 mg of cyclophosphamide per kg were pooled. All animals were reweighed immediately before drug administration and cyclophosphamide (NSC 26271), supplied by Mead Johnson, was dissolved in 0.9% sodium chloride solution and administered at the rate of 0.01 ml/g of mouse weight.

Collection and evaluation of data

Cures, deaths resulting from drug toxicity or tumor, and the mean survival time of mice dying with tumor were the endpoints by which responses to treatment were gauged. Mice that died before the 10th day after tumor transplantation, without macroscopic evidence of tumor, were considered to have succumbed to

toxic effects produced by cyclophosphamide. Treated animals that survived 60 days after transplantation and, at that time, lacked gross evidence of tumor, were considered cured. From the collected data, estimates of central value and dispersion were calculated for the various treatment groups. The statistical inference of inter-group responses to cyclophosphamide was evaluated by Chi-square analysis and by analysis of variance (ANOVA).

RESULTS

Collectively, in five replications of the same experiment, cyclophosphamide was administered once to each of 480 tumor-bearing mice. The results, in terms of cured mice and those mice that were killed by the tumor or by the drug, itself, are presented in Table 1.

Tumor deaths

Altogether, 202 mice, 42% of those treated, died from effects produced by the tumor. Statistical ANOVA indicated that both the frequency of tumor-induced deaths and the post-inoculation life span of mice killed by the tumor were independent of the photo-periodic timing of drug administration. The incidence with which treated mice were killed by tumor varied significantly among the different replicates of the study ($P>0.01$) but the post-inoculation life span of such mice did not differ significantly as a function of replication. Those 202 treated mice lived 23.9 ± 7.8 days on the average;

†Mean survival time ± 1 S.D. post inoculation for mice that died with tumor. Tumor bearing mice not treated with cyclophosphamide served as controls in each experiment. The mean day of death for controls (pooled data) was 7.1 ± 1.1 days after tumor inoculation.

‡The difference between cures at 0900 and 1800 hr was highly significant by Chi-square analysis ($P<0.01$), as was the difference between toxic deaths at these time points ($P<0.005$). See text for comparisons between other groups. The percentages of mice cured or dying from drug toxicity, as function of time of treatment are shown in Fig. 1.

thereby, they exceeded the life span of 23 untreated, tumor-inoculated mice (7.1 ± 1.1 days) by 16.8 days (237%).

Cured mice

Twenty-two per cent (105) of the mice that were injected with cyclophosphamide were cured. According to ANOVA, the frequency with which cures were produced varied significantly with replication ($P<0.1$) and also with the timing of drug administration ($P<0.01$). The maximum cure rate, 34%, was produced when cyclophosphamide was given at 1800 hr. By Chi-square evaluation, it exceeded significantly that obtained when the drug was given either at 0600 hr or at the nadir of response, 0900 hr ($P<0.01$ at least). Furthermore, the cure rates produced by treatment at 1500 hr and at 2100 hr also exceeded, significantly, the 7% rate of cure produced by treatment at 0900 hr.

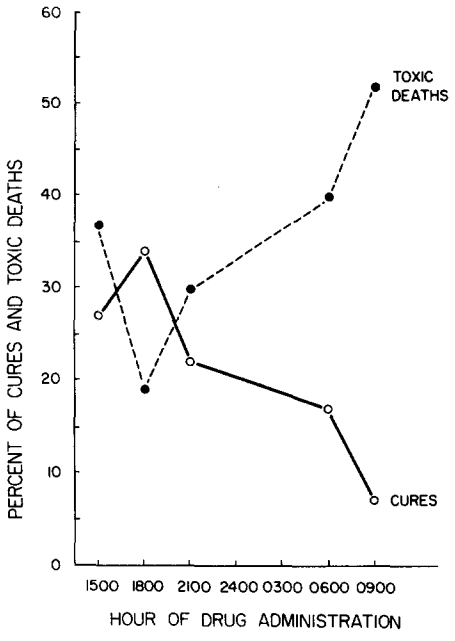

Fig. 1.

Drug-induced lethality

Of the 480 mice that were treated with cyclophosphamide, 173 (36%) died from toxic effects that were produced by the drug. By ANOVA, the frequency with which mice were killed by cyclophosphamide varied significantly with replication ($P<0.01$) but was indicated to be independent of the timing of drug administration. Substantial differences in toxicity were noted, however, that, nevertheless, appeared to be correlated with the timing of treatment. In terms of drug-induced lethality, maximum toxicity was produced by treatment at 0900 hr: 52% (50 of 96) of the mice treated at that time were killed by the drug. Conversely, only 20% (19 of 96 mice) were killed by treatment at 1800 hr. By Chi-square analysis, the frequency of toxic deaths after treatment at 0900 hr was significantly greater than that produced by treatment either at 1800 hr or at 2100 hr ($P<0.005$). In addition, toxic deaths also occurred in significantly greater numbers when cyclophosphamide was given at 0600 hr than after treatment at 1800 hr.

DISCUSSION

The composite data from the five experiments that have been described indicate that the therapeutic as well as the toxic effects produced by cyclophosphamide were clearly related quantitatively to circadian systems of the host. Significantly more mice were cured when cyclophosphamide was administered at 1800 hr than when given at 0600 or 0900 hr. Even when the drug was given at 1500 or 2100 hr, times that were, respectively, 3 hr earlier and 3 hr later than the optimal time of 1800 hr, the cure rates that were produced significantly exceeded the 7% nadir that resulted from treatment at 0900 hr. On the other hand, for reasons which are unclear at the present time, neither the frequency of tumor-induced deaths nor the post-inoculation life span of the mice that died with tumor were altered significantly by varying the time of treatment.

As depicted in Fig. 1, the order of drug-induced deaths was essentially the reverse of the pattern with which cures were produced. Maximum toxicity was produced by treatment at 0900 hr, the nadir for cure rate. Conversely, the nadir for toxic deaths was produced by treatment at 1800 hr, the time that resulted in the maximum rate of cure.Because of this reciprocal relationship between cure rate and drug-induced death rate, the overall therapeutic advantage derived from the selective timing of drug administration appears to have been compounded. Not only were fewer mice killed, an improvement in itself, but, in addition, some of the extra mice that survived the effects of the drug were also cured. The risk versus benefit relationship is presented in Table 2 in which the ratio of cured mice to mice killed by drug is recorded. At 0900 hr, the time at which treatment proved most toxic and produced the fewest cures, approximately 7 mice were killed by treatment for each mouse cured. On the other hand, when cyclophosphamide was administered at 1800 hr, 1.74 mice were cured on the average for each mouse that was killed by the drug.

Table 2. Risk versus benefit ratios observed with the administration of cyclophosphamide at different times of the day

Time of treatment*	No. cures	No. toxic deaths	Risk vs benefit ratios: Cures/toxic deaths	Risk vs benefit ratios: Toxic deaths/cures
1500	26	36	0.72	1.39
1800	33	19	1.74	0.58
2100	22	29	0.76	1.32
0600	17	39	0.44	2.29
0900	7	50	0.14	7.14

*A total of 96 BDF_1 mice bearing L1210 leukemia were treated at each treatment time (hr of the day).

The susceptibility of tumor-free mice to treatment with cyclophosphamide has been also reported to be circadian dependent [15]. In addition, these workers noted pronounced variation in such rhythmicity among 5 studies in which differences in mouse strain and sex constituted uncontrolled experimental variable of unknown importance.

In the studies described in the present report, L1210-inoculated, BDF_1, females were used exclusively. Nevertheless, only the post-inoculation life span of treated mice killed by the tumor was independent of the variability produced by replication. Statistically significant inter-replicate variation was identified with respect to the frequency of drug-induced deaths, the cure rate, and the incidence with which deaths were produced by the tumor. Such inter-experimental variability suggests that factors presently unidentified can also influence host responses to cyclophosphamide.

Thus, while unidentified variables continue to limit its full potential, the value of chronotherapy in the management of neoplasia has been established and, certainly, additional studies should be conducted to identify the circadian phases of susceptibility for those other agents that are currently used alone and in combination in experimental and clinical chemotherapy.

List of compounds

Cyclophosphamide: NCS-26271; CAS Reg. No. 6055-19-2; 2H-1,3,2-oxaza-phosphorize, 2 (bis(2-chloroethyl)amino) tetrahydrozoxide, monohydrate.

Serological Reactivities of Human and Baboon Sera Against EBNA and *Herpesvirus papio*-determined Nuclear Antigen (HUPNA)*

SHINSUKE OHNO,† JANOS LUKA,† LAWRENCE A. FALK‡ and GEORGE KLEIN†

†*Department of Tumor Biology, Karolinska Institutet, S-10401, Stockholm, Sweden and* ‡*Department of Microbiology, Rush-Presbyterian-St. Luke's Medical Center, 1753 West Congress Parkway, Chicago, Illinois* 60612, *U.S.A.*

Abstract—*Using our recently developed acid-fixed nuclear binding technique, an EBNA-like antigen was detected in both virus-producer and non-producer baboon lymphoid cell lines that carried* Herpesvirus papio (*HVP*). *We designated the antigen as HUPNA. Serological comparison of EBNA and HUPNA showed that:* (i) *all EBNA-positive sera reacted with both EBNA and HUPNA;* (ii) *none of the anti-HVP(VCA)-positive baboon sera reacted with EBNA; and* (iii) *approximately half of the anti-HPV(VCA)-positive baboon sera tested reacted with HUPNA. HUPNA could not be visualized by anticomplement immunofluorescence* in situ.

INTRODUCTION

Herpesvirus papio (HVP) is an Epstein–Barr virus (EBV)-related lymphotropic herpesvirus of baboons [1, 2]. HVP-producer lines express early antigen (EA) and viral capsid antigen (VCA), readily detected with human sera containing antibodies to EBV [1]. However, neither HVP-producer nor non-producer lines have been found to express a nuclear antigen by anticomplement immunofluorescence (ACIF) staining *in situ*. In a previous paper [3], we reported the presence of an EBNA-like nuclear antigen in HVP-transformed lymphoid lines, using our recently developed acid-fixed nuclear binding (AFNB) technique [4]. AFNB provides an amplification system for antigen detection, compared to ACIF staining *in situ*. We have found that HUPNA could be detected with EBNA-positive human sera [3]. It was previously shown, however, that anti-HVP(VCA)-positive baboon sera do not react with EBNA. It was therefore of interest to explore whether any of the baboon sera contain antibody against HUPNA, as detected by the AFNB technique. In this paper, we show that this is indeed the case and some but not all baboon sera contain anti-HUPNA antibodies that do not react with human EBNA. We are thus dealing with a certain "asymmetrical" cross reactivity. A somewhat similar situation was found previously by Gerber *et al.* [5, 6] in relation to the EBV-related chimpanzee virus (*Herpesvirus pan*), detectable by ACIF staining *in situ*.

MATERIALS AND METHODS

The baboon (*P. hamadryas*) HVP-DNA-carrying non-producer line 26CB-1 [1] and the EBV-carrying human non-producer lymphoma line Raji [7, 8] were used to prepare complement-fixing (CF) soluble antigens. An EBV-negative human lymphoma line Ramos [9], a marmoset fibroblast line HF-2 [10], and chicken red blood cells (CRBC) were prepared as targets for the AFNB technique. All lines were grown in RPMI-1640 medium containing 10% heat-inactivated fetal calf serum, 100 i.u. penicillin and 100 μg streptomycin per ml. Preparations of EBNA and HUPNA, acid-fixed nuclear binding to

Accepted 5 January 1978.

methanol–acetic acid-fixed targets and ACIF staining were performed as previously [3, 4, 11]. *In situ* ACIF tests were carried out on methanol-acetone (1:2)-fixed cells [12].

RESULTS AND DISCUSSION

The sera used in this study were: Human—anti-EBV(VCA)+/anti-EA- (healthy donors, anti-EBNA 1:80), anti-EBV(VCA)+/anti-EA+ (African Burkitt lymphoma patients, anti-EBNA 1:80—1:640), or no antibodies to EBV (controls, anti-EBNA<1:2); Baboon—anti-HVP(VCA)+/anti-EA−; Squirrel monkey—anti-HVP(VCA)-/anti-EA− (Table 1).

In the ACIF test for EBNA, EBNA-positive human sera stained both Raji and AW-Ramos cells [9] but failed to detect any EBNA-like antigens in baboon cells (8CB-1, 13CB-1 and 26CB-1) [1]. Anti-VCA-positive baboon sera did not stain EBNA in Raji or in AW-Ramos cells and detected no EBNA-type antigens in HVP-carrying baboon cells. The AFNB technique detected the HVP-associated nuclear antigen (HUPNA) in a HVP-DNA-carrying non-producer baboon line (26CB-1) and also in producer lines [3]. As shown in Table 1, all EBNA-positive human sera reacted with both EBNA and HUPNA, bound to three different target cells (CRBC, Ramos and HF-2). No positive ACIF-reactions were obtained with anti-EBNA-negative human sera. Using HF-2 cells as targets, approximately half of HVP(VCA)-positive baboon sera tested stained HUPNA (7/16), although they did not react with EBNA. Neither EBNA nor HUPNA was stained by HVP-negative squirrel monkey

sera. When CRBC were used as targets for CF-antigen binding, all sera from baboon and squirrel monkey were absorbed with acid-fixed CRBC prior to the AFNB test because of nonspecific anti-CRBC reactions with the sera.

The staining reaction obtained by the AFNB procedure is illustrated by Figs. 1–16. The positive ACIF-reactions were shown in Fig. 1 (CRBC/EBNA/human serum), Fig. 5 (CRBC/HUPNA/human serum), Fig. 7 (CRBC/HUPNA/baboon serum), Fig. 9 (HF-2/EBNA/human serum), Fig. 13 (HF-2/HUPNA/human serum) and Fig. 15 (HF-2/HUPNA/baboon serum). Figs. 2, 3, 4, 6, 8, 10, 11, 12, 14 and 16 show negative controls. In HF-2 cells (Figs. 9, 13 and 15), ACIF-reactions were positive not only with interphase nuclei but also with metaphase chromosomes.

These experiments revealed that: (i) EBNA-positive human sera reacted with both EBNA and HUPNA, (ii) none of baboon sera reacted with EBNA and (iii) approximately half of baboon sera (7/16) gave a positive staining with HUPNA. These results indicate that EBV-positive human sera contain antibodies that react with both EBNA and HUPNA while HVP(VCA)-positive baboon sera either contain no detectable antibodies to EBNA or HUPNA, or react with HUPNA but not EBNA.

The presence of an EBNA-like nuclear antigen was recently demonstrated in chimpanzee lymphoid lines [5, 6]. Chimpanzee virus-carrying lymphoid lines contain DNA sequences homologous to approximately 34–45% of human EBV–DNA [5]. The antigen (Ch-NA) was stained by some human, chimpanzee or orangutan sera in ordinary ACIF.

Different explanations may be considered for the asymmetrical cross reactivity between EBNA and HUPNA. By and large, human anti-EBNA-positive sera have higher titers against a variety of EBV-related antigens, compared to the corresponding reactivity of the baboon sera against baboon HVP-related antigens. HUPNA is present in lower concentration than EBNA, because it can not be detected by ACIF staining *in situ*. Therefore, anti-EBNA-positive human sera are more comparable to hyperimmune sera than anti-HUPNA baboon sera that may reflect a less intense or less prolonged immunization. It is known that hyperimmunization tends to induce more cross reactive antibodies than immunization at a less intense or less prolonged level. Alternatively, the asymmetrical cross reactivity may reflect a true antigenic difference, rather than the different consequences of hyper vs low degree immunization. If so, it would follow that human EBNA has additional specificities, over and beyond the specificities that cross react in HUPNA and EBNA. These specificities would only be detected by the human anti-EBNA-positive, but not the baboon anti-HUPNA-positive sera. Absorption experiments should clarify this question.

Polycyclic Hydrocarbon-Induced Rat Sarcomas Correlated to Disturbances in the Deoxyadenylate Regions of the Tumor DNAs*

RONALD W. PERO,† TOMAS BRYNGELSSON,† CHRISTINA RUDDUCK† and GÖRAN LEVAN‡

†*Nucleic Acid Biochemistry and* ‡*Institute of Genetics, Lund University, Wallenberg Laboratory, Fack* 7031, 220 07 *Lund, Sweden*

Abstract—*Ten separate groups containing a total of* 51 *rat sarcomas induced by the polycyclic hydrocarbons were examined for inducing agent-related abnormalities in their DNAs. The levels of deoxyadenylate (dA) regions in normal and tumor rat DNAs were estimated from annealing* [^{3}H]*-polyuridylic acid to DNA and treatment of the resultant hybrids with ribonuclease A. All the tumor material had significant reductions in the (dA) regions of their DNAs when the levels were compared to normal rat DNA. Although the (dA) reductions were rather heterogeneous from one tumor group to the other no matter the inducing agent, the greatest decreases tended to be found with tumors induced by* 20*-methylcholanthrene (MC) and* 7,12*-dimethylbenz(a)anthracene (DMBA). No relationship was found between (dA) alterations and the types of chromosomal aberrations in the tumor cell populations. However, normal and tumor DNAs, fractionated into A+T rich and G+C rich DNA by thermal elution from hydroxylapatite columns, showed specific neoplastic-associated (dA) disturbances in the A+T rich DNA of tumors induced by* 3,4*-benzopyrene (BP), MC and DMBA. The base compositions of the tumor material were also analyzed and compared to normal rat DNA. Tumors induced by DMBA showed highly significant decreases in* % *A+T whereas BP and MC induced tumors tended to show only small increases in* % *A+T. Some tumors induced by BP, MC and DMBA were unaltered in base composition. Together our results are consistent with the hypothesis that DMBA is the strongest carcinogen in the series because it interacts preferentially with A+T rich DNA, which is the type of DNA most important for polycyclic hydrocarbon-induced neoplasm in the rat.*

INTRODUCTION

THE PRESENCE of (dA) rich stretches and polypyrimidine runs in eukaryotic DNA has now been validated by several laboratories [1–11]. The (dA) or (dT) rich sequences and other polypyrimidine stretches were approximately 25–200 nucleotides in length [2–4, 6, 10] and were concentrated into repeated sequences in the DNA [4, 7, 11]. The fact that these oligohomopolymeric rich regions could not have arisen from a random selection model [1], together with their specificity for location into repeated DNA, have strongly suggested a biological function for these regions.

These observations are further supported from similar work on nRNA. It has been shown that oligo(U) and oligo(A) regions of approximately 25–35 nucleotides are a normal component of nRNA [12–14] indicating that their template for transcription must have been the (dA) or (dT) regions in the DNA [13]. The oligo (U) regions in nRNA have also been shown to be located primarily in the

Accepted 12 January 1978.

The abbreviations used are: (dA), deoxyadenylate; (dT), deoxythymidylate; (U), ribouridylate; (A), riboadenylate; BP, 3,4-benzopyrene; MC, 20-methylcholanthrene, DMBA, 7,12-dimethylbenz(a)anthracene; SSC, 0.15 M NaCl + 0.015 M sodium citrate, pH = 7.2; T_M, temperature at which 50% native DNA becomes single stranded nRNA, nuclear RNA.

5'-end of nRNA which is mainly transcribed from repeated DNA template [14, 15] and confirms the location of (dA) clusters there. Since the 3'-end of nRNA contains unique DNA transcript or the mRNA, then the implications are that (dA) transcripts or the oligo(U) regions might play a role in the proposed processing of nRNA into mRNA [16]. At any rate, the exact function of (dA) transcripts is still unknown although some biological function most certainly can be implied.

Our laboratory has assumed an important function for the (dA) regions in either the transcription or processing of genetic information, and has attempted to assign a role to them in neoplasm. Our results have shown that (dA) alterations could be demonstrated in the DNA from human breast tumors [17], human CLL lymphocytes [18] and rat tumors induced by Rous sarcoma virus or DMBA [19]. Generally, the more malignant cell types were associated with reduced levels of (dA) regions in their DNAs. Although (dA) disturbances were found in both A+T rich and G+C rich DNA [17], some specificity of change was observed for both main band and low repeated DNAs (18). However, our ability to demonstrate specific (dA) alterations common to neoplasm has been complicated by looking at neoplasms where the oncogenic agent is not known. Presumably, the (dA) alterations caused from viral carcinogenesis where the viral genome is involved could be quite different from those arising from chemical carcinogens. Therefore, in this study we have examined rat tumors induced by a class of closely related carcinogens, the polycyclic hydrocarbons, and where the carcinogenic potency varies in a predicted way [20, 21]. With this well defined tumor induction model, we have tried to show that tumors induced by structurally-related chemicals have (dA) alterations in specific areas of their DNA.

MATERIALS AND METHODS

Tumor induction and normal tissue

Inbred Wistar–Furth rats 8–35 days of age were inoculated subcutaneously in the right thigh with 1–4 mg doses of BP, MC or DMBA dissolved in 0.1 ml tricaprylin. Tumors developed to 100% and were harvested 6–8 weeks after they were palpable (<7 months). Some individual tumors were analyzed for karyotypic abnormalities by direct fixation according to Levan *et al.* [22]. Other tumors induced by the same carcinogen were pooled and not karyotyped. The groups of tumors designated DMBA-17 and DMBA-19 were transplanted for a single passage in newborn Wistar–Furth rats as described elsewhere [23]. All tumors were frozen and stored at −70°C until used for DNA extraction.

The livers, spleens, inner skin covering the abdominal cavity and full term embryos were dissected from adult Wistar–Furth rats and either processed directly or stored at −70°C. These tissues were taken from apparently healthy animals and served as the control sources of normal rat DNA.

Extraction of DNA

The rat tissues were minced in ice cold 0.1 M EDTA–0.1 M NaCl, pH 7.5 and homogenized at 4°C by 2 × 15-sec pulses at 1 min intervals with an Ultra-Turrax. The DNA was extracted from the homogenates by the Marmur method [24] except for the final alcohol precipitation. Instead of the precipitation step, 100 μg/ml ribonuclease A (Sigma) and 100 μg/ml alpha amylase (Sigma) were added to the DNA solutions and the mixture dialyzed overnight against 5 l 0.1 × SSC at room temperature. Finally, the enzyme-treated DNA solutions were made 5% sodium dodecyl sulfate and precipitated with alcoholic sodium perchlorate solution as described by Wilcockson [25]. In our hands, DNA prepared in this way was essentially free from glycogen (anthrone method), RNA (orcinol method) and protein of which contamination was always less than 5% (μg protein/μg DNA, Lowry method). We have noticed in our liver preparations from unstarved animals that high concentrations of glycogen (100 μg/ml DNA solution) can occur in our final DNA preparations, if alpha amylase treatment was omitted. We have also observed that such high levels of glycogen contamination of DNA interferes with the poly(U) hybridization on filters (data not shown).

Poly(U) annealing method

We have described elsewhere [7] the essential details of our poly(U) hybridization method and the factors which limit its reproducibility. However, we have now introduced modifications which have reduced much of the variability encountered in our earlier experiments. Approximately 15 μg samples of DNA dissolved in 2 × SSC were denatured by heating at 100°C for 10 min followed by another 10 min with an equal volume of 4 M NaCl. Treating denatured DNA with hot 2 M NaCl insured retention of (dA) rich sequences

and improved on selective removal of any residual contaminating protein [7]. The solutions were cooled immediately in an ice bath, loaded onto nitrocellulose filters (Millipore®) with suction and baked in an oven for 2–4 hr at 80°C. In order to improve on our yield of DNA from smaller tumors, the alcohol precipitated DNA was often collected by centrifugation. These DNA preparations tended to contain lower molecular weight DNA fragments that are normally left behind when the DNA is spooled and thus these DNA solutions retained less on the filters. Previously severely sheared DNA affected the annealing of poly(U) [7]. However, we have compared only DNAs which retained between 75–100% on the filters, and with this level of retention the estimation of (dA) regions was unaffected by the amount of DNA immobilized (data not shown). Commercial [^{3}H]poly(U) (Miles Laboratory, 75 μCi/μM monophosphate) was dissolved in 2 × SSC and adjusted to a final concentration of 6.0 μg/ml with unlabelled poly(U) (Sigma). The DNA containing filters were placed in the [^{3}H]poly(U) solution and annealed for 17 hr at 25°C with continuous mixing from the aid of a magnetic stirrer. Unannealed poly(U) was removed from the filters by ribonuclease A treatment in 2 × SSC at 5 μg/ml for 6 hr at 25°C. It was important, especially in cases where many filters were treated batchwise, to have efficient stirring for both the annealing and RNAase steps if unnecessary variability was to be avoided. The details involving radioactive counting on filters, quantitative determination of DNA and estimation of (dA) "pure" sequences from the % poly(U) annealing to DNA after 6 hr RNAase treatment were unchanged from our earlier studies [7]. Routine poly(U) analyses were replicated 10–30 times. The amount of DNA hybridizing to poly(U) was always determined on the nitrocellulose filters after RNAase treatment and scintillation counting.

T_M fractionation of DNA on hydroxylapatite

The T_M fractionation was carried out as we have described earlier for human DNA [17] except for a few minor details. Native DNA was loaded onto hydroxylapatite in 0.01 M phosphate buffer at 60°C and the A+T rich DNA fraction eluted between 60 and 91°C in 0.12 M phosphate buffer.

Base composition analysis

The method used for base analysis was the same as reported by Wang [26]. Briefly, it is based on the fact that all the bases except adenine react with *N*-bromoacetamide to cause reduction in UV absorption. Standard solutions of dAMP, dCMP, dGMP and dTMP were prepared in 0.5 M H_2SO_4. Since at this acid concentration dAMP and dGMP were depurinated, then the molar absorbancy coefficients used to adjust the final standard concentrations to 0.05 mM were as given: adenine ($E_{270} = 11.56 \times 10^{-3}$), dCMP ($E_{270} = 11.44 \times 10^{-3}$), guanine ($E_{270} = 7.4 \times 10^{-3}$) and dTMP ($E_{270} = 9.58 \times 10^{-3}$). Mixtures of the 4 standard solutions were used to prepare a standard curve ranging from 100% A+T to 100% G+C. It was necessary in our experiments to heat the DNA solutions in 0.5 M H_2SO_4 for 3 hr at 50°C to insure complete depurination and allow accurate estimation of base composition. Other important details such as the preparation and addition of the brominating agent and the calculation of % A+T from the u.v. absorption changes were carried out as described by Wang [26].

RESULTS

A total of 51 rat sarcomas induced by the polycyclic hydrocarbons were pooled into 10 different groups and compared to normal tissues for alterations in the (dA) regions of their DNAs. A quantitative estimation of the (dA) regions in the DNA from normal rat tissue was always the same whether the sources used were embryo, skin or liver + spleen (Table 1). A constant level of (dA) regions in normal somatic cell DNA of the rat has thus provided the analytical basis for its comparison to the (dA) levels in neoplastic DNA. All groups of tumors reported in Table 1 regardless of inducing agent had statistically significant reductions in the (dA) regions of their DNAs. The level of (dA) reductions in the tumor DNAs varied considerably from one tumor group (MC-69) to another (DMBA-17), but there was a tendency for MC- and DMBA-induced tumors to have the greatest (dA) reductions (Table 1). Such heterogeneity in the (dA) alterations of DNA from tumors induced with so structurally similar carcinogens, or even when induced by the same carcinogen (i.e., MC-12 and MC-69), suggests that additional DNA template changes involving in part the (dA) regions, have accompanied those DNA changes responsible for the neoplastic event itself.

One possible way to judge the degree of additional DNA changes which might occur along with those DNA changes necessary for

The DNAs from groups of pooled tumors and from normal tissues of the rat were extracted, immobilized onto nitrocellulose filters and annealed to [^{3}H]poly(U) in 2 × SSC at 25°C for 18 hr. Non-specific binding of [^{3}H]-poly(U) was removed by treatment of the filters with 5 μg/ml ribonuclease A dissolved in 2 × SSC for 6 hr (for further details see Ref. 7 and the text).

*BP = 3,4-benzopyrene; MC = 20-methylcholanthrene; DMBA = 7,12-dimethylbenz(a)anthracene.

†For estimation of (dA) regions divide % poly(U) value by 2.

‡%/tumor/agent represents the average % poly(U) annealing to the DNA from all the tumors induced by the same polycyclic hydrocarbon. Hence, the average (dA) alterations expected for a tumor induced by particular polycyclic hydrocarbon in question.

polycyclic hydrocarbon-induced neoplastic transformation, might be to compare those tumors which contain high frequencies of either similar or different chromosomal aberrations. It has been shown [27, 28] that specific chromosomal abnormalities are associated with tumors induced by the polycyclic hydrocarbons, and some of these abnormalities such as the trisomy A2 can be found in tumors induced by all 3 of the carcinogens BP, MC and DMBA [22, 27]. In Table 2 we have selected BP- and MC-induced tumors which had high incidences of a particular type of chromosomal aberration in the tumor cell populations. This protocol has allowed us to try and standardize the initial amount of DNA damage inflected by the carcinogen at the time of transformation, as evidenced by the similar chromosomal aberrations in the subsequent tumor cell population, and to test whether these chromosomal similarities were specific enough to reflect similar (dA) alterations. Table 2 clearly demonstrates that a high incidence of a distinct chromosomal deviation such as trisomy or the presence of a marker chromosome in the tumor cell population, or even the absence of abnormalities altogether, does not predict the neoplastic-associated (dA) alterations in the DNA. Apparently the presence of other random chromosomal aberrations in the tumor cells must mask any specificity shown by the non-random, distinct chromosomal deviations, at least, as far as any correlation to (dA) alterations are concerned. In fact, support for this interpretation can be drawn from the fact, as we already observed in Table 1, that again there was a rather good correlation to inducing agent; namely, MC-induced tumors all had greater reductions in the (dA) regions of their DNAs than did BP-induced tumors (Table 2). Such a correlation to inducing agent would take into account the total altered genome and not just the chromosomal aberrations which were either specific, non-specific or absent.

We have further pursued our efforts to distinguish the more specific neoplastic-associated (dA) changes from those non-essential DNA changes which might accompany polycyclic hydrocarbon induction of rat sarcomas, by measuring the (dA) levels in A

Table 2. Lack of correlation between the chromosomal aberrations in polycyclic hydrocarbon-induced rat tumors and the (dA) alterations of their DNAs.

+T rich and G+C rich subfractions of the native tumor DNAs. Table 3 indicates that when the tumor DNAs were eluted from hydroxylapatite in 0.12 M phosphate buffer at 91°C, which was close to the T_M for normal rat DNA (56.5% of the DNA melted), varied amounts of the native tumor DNAs were melted (44.6–73.0%). Although small changes in temperature (<1°C) around the T_M can seriously alter the amount of DNA melting, the results nonetheless suggest base compositional changes in the tumor DNAs. At any rate, the A+T rich fractions of BP, MC and DMBA tumor DNAs all showed significant reductions in their (dA) levels except for MC-12 ($P<0.10$) (Table 3). However, the opposite was true for the G+C rich fractions where only 2 of the 8 tumor groups had

The DNAs from groups of pooled tumors and from normal rat liver and embryo were loaded onto hydroxylapatite columns in 0.12 M sodium phosphate buffer at 60°C and the A+T rich DNA fractions collected at 91°C (see text). The A+T and G+C fractions were immobilized onto nitrocellulose filters and annealed to [^{3}H]-poly(U) for estimation of the (dA) regions (for further details see Ref. 7, 18 and text).

*BP=3,4-benzopyrene; MC=20-methylcholanthrene; DMBA=7,12-dimethylbenz(a)anthracene.

†P values for comparison to normal rat tissue; Means ±S.D. are shown; NS=not significant.

significant (dA) alterations (Table 3). These results were interpreted to mean that the majority of (dA) alterations specifically associated to neoplastic transformation induced by the polycyclic hydrocarbons must have occurred primarily in the A+T rich DNA.

The possibility of base compositional changes in the polycyclic hydrocarbon induced tumor DNAs, which was previously suggested from our data in Table 3, was determined for 2, 2 and 4 groups of BP-, MC- and DMBA-induced tumors, respectively. The results in Table 4 indicate rather heterogeneous but statistically significant effects on the base composition of the tumors induced by the polycyclic hydrocarbons, where increases, decreases and no changes at all were observed if comparison was made to normal rat DNA. However, all the groups of tumors examined in Table 4 regardless of whether their base compositions were increased, decreased or unchanged, still had significant reductions in their (dA) levels. As a result, a particular kind of overall base compositional change in native tumor DNA was not a necessary prerequisite for demonstrating the (dA) disturbances associated with polycyclic hydrocarbon-induced carcinogenesis. Another striking parallel to our base analysis data is the fact that the DMBA-induced tumors tended to cause reductions in the % A+T in their native DNAs, whereas BP- and MC-induced tumors tended to cause increases or no changes at all in the % A+T (Table 4).

This study of (dA) alterations in neoplasm was carried out on the rat, but we have previously shown that similar neoplastic-associated (dA) disturbances can be found in the human [17, 18]. Therefore, we have compared the normal human and normal rat genomes to study if their (dA) regions are distributed within their respective genomic DNAs in a similar way. Table 5 demonstrates that (dA) regions can be found in essentially all classes of DNA from the rat and the human. However, the human differs in its (dA) distribution pattern from the rat by having a (dA) enrichment in main band human DNA when compared to the G+C rich and A+T rich human DNA fractions. The rat genome differed by having the same (dA) level in both G+C and main band rat DNA fractions.

DISCUSSION

We have tried to show that rat tumors have small but detectable DNA template changes when compared to normal somatic cell rat DNA. Detection of these base changes have been carried out by a conventional base analysis method [26] and by utilization of a poly(U) probe to measure (dA) rich regions in polypurine rich DNA. In the latter case it

The DNAs from groups of pooled tumors and from normal rat liver and embryo were subjected to base composition analysis by measuring the reduction in u.v. absorption following bromination with *N*-bromoacetamide (for further details see Ref. 26 and the text). The same DNAs were also analyzed for (dA) alterations as reported in Table 1.

Approximately 500–850 μg of DNA from normal rat and human tissues were mixed with a CsCl solution to an initial density of 1,710 g/cm^3 and centrifuged for 72 hr at 44,000 rev/min in a Ti60 rotor. Twelve drop fractions were collected and then pooled into G+C rich (rat=26.1%, human=31.7%), main band (rat=33.3%, human=29.9%) and A+T rich (rat=40.6%, human=38.4%) fractions of the native DNAs. Each DNA fraction was then annealed to [^{3}H]poly(U) for estimation of the (dA) regions as already described (see Ref. 7 and the text).

*Means ±S.D. are shown.

can be argued that homopolymeric hybridizations to DNA have inherent methodological disadvantages, especially with formation of poly(U)-DNA hybrids which have low melting temperatures and are thermally more unstable. These disadvantages stem from the fact that the (dA) sequences are quite small in DNA and are close to the minimum stable length for molecular hybrid formation. As a result, we have shown that poly(U)-DNA hybrids are unusually sensitive to protein contamination, glycogen contamination, salt concentration, molecular weight, temperature and ribonuclease digestion [7, unpublished results]. However, we have been aware of these methodological difficulties and have taken them into consideration in our experiments. Nonetheless our results could have been influenced to some degree by such uncontrollable factors as specific tumor-associated nuclease effects on DNA preparation or acidic proteins bound very tightly and specifically to (dA) regions. Indeed these possibilities seem extremely remote explanations. Even if such explanations were proved to be responsible for our experimental observations, then our results would still indicate important biological variations of DNA that are associated to neoplasm.

Our results on the (dA) disturbances in DNAs from polycyclic hydrocarbon-induced rat tumors have indicated that all were significantly altered from normal DNA (dA) levels. There was also quite a heterogeneous distribution in the degree of (dA) changes among the different chemically induced tumor groups and even within the tumor groups induced by the same carcinogen. Nevertheless, there was a trend for the stronger carcinogens (DMBA and MC) to cause greater (dA) changes (Tables 1 and 2). This overall heterogeneity in distribution of (dA) changes among the various tumor groups can probably best be understood when considering the nature of chemically induced neoplasia. In such cases, there is an abnormally high exposure of carcinogen to target cells, and it is quite reasonable to suspect that high levels of DNA damage are inflected. Cells that do transform might carry not only base compositional changes associated with neoplasm but additional base changes not associated with neoplasm, and yet their presence in the genome does not alter cellular metabolism enough to cause a reduced cell survival. These non-neoplastic associated base changes would naturally vary from one tumor to another as a result of varying carcinogen reactivity in the original transforming cells. This type of base compositional change could involve (dA) regions, and if so would explain the observed heterogeneity in neoplastic associated (dA) changes.

Other previous work [20, 21] has established that DMBA is the strongest carcinogen as it induces the highest frequency of tumors or cell transformations at the lowest doses. It has also been shown that DMBA binds more to DNA in cultured cells [29] and in epithelial homogenates [30] than does BP or MC. This is supportive evidence for the increased carcinogenic potential of DMBA when viewed from the mutational theory of cancer. Our data have also been able to distinguish the DNAs from DMBA-induced tumors from those of either BP- or MC-induced tumors. Although BP, MC and

DMBA tumor DNAs all had significant reductions in the (dA) regions of their A+T rich DNA fractions when compared to similar normal DNA fractions (Table 3), only DMBA tumor DNAs were altered in base composition toward a more G+C rich DNA (an indication of preferential DMBA attack in A+T rich DNA, Table 4). Whether any correlation exists between the preference of (dA) alterations to appear in the A+T rich DNA fractions of tumors induced by the polycyclic hydrocarbons (Table 3) and the overall increased carcinogenicity of DMBA, still remains only speculative. However, if such a correlation were proved to be true it would be of importance to the mutational theory of cancer.

We would like to point out that extreme caution should be exercised when extrapolating our results to neoplasms in animal systems other than the rat. Guttman *et al.* [31] have shown that the DNAs from 15 different mammals, analyzed by CsCl-netropsin density gradient centrifugation, contain quite different profiles with respect to their distribution patterns of (dA.dT) clusters. Indeed this has been our experience so far with normal and neoplastic DNAs from the rat and human. If we compared our T_M-DNA fractionation experiments with human neoplastic DNAs [17] to our similar experiments with rat tumor DNAs, then the (dA) regions in the A+T rich fractions of human neoplastic DNAs were increased over those in normal A+T rich human DNA, whereas in the rat tumor A+T rich DNAs the opposite was true (Table 3). Of course there are several reasonable explanations for this discrepancy such as the probable differences in oncogen between the human breast tumors and the rat tumors, or the fact that in the human experiments the T_M fractionation at 88°C yielded a 46% fraction of A+T rich DNA and in the rat experiments the T_M fractionation was carried out at 91°C and yielded a 56.5% fraction of A+T rich DNA. However, still the most likely explanation for the varying neoplastic-associated disturbances observed between the rat and human, is probably correlated to differences in genomic distribution of (dA) regions. The data in Table 5 supports this argument. The (dA) regions in normal rat DNA are distributed equally into the G+C rich and main band DNAs but in the normal human genome they are not.

Effect of Antileukaemic Chemotherapy on Helper and Suppressor Activity of T Cells on Immunoglobulin Production by B Cells

P. H. ATHANASSIADES,*† T. A. E. PLATTS-MILLS,* G. L. ASHERSON* and R. T. D. OLIVER‡§

*Division of Immunological Medicine, Clinical Research Centre, Harrow, Middlesex HA1 3UJ, England, and ‡ICRF Department of Medical Oncology, St Bartholomew's Hospital, London E.C.1, England

Abstract—*Fifteen patients with AML in complete remission, receiving immunotherapy, have been studied for T cell function before and after intermittent maintenance chemotherapy. The regulatory influence of patients' T cells on normal B cells* in vitro *was estimated by IgG production. Immediately after chemotherapy there was a slight reduction of helper activity of patients' T cells detectable when equal numbers of B and T cells were cultured together. This rapidly recovered producing a rebound above that prior to chemotherapy. The suppressive influence of high ratios of purified T cells was not immediately affected by chemotherapy. However, at* 14 *and* 21 days *the suppressive effect of excess T cells appeared to be increased. Until antigen markers of helper and suppressor T cells become available in man it will not be possible to say whether this phenomenon is due to a delayed effect of chemotherapy on suppressor cells or an indirect effect of the changes in helper activity.*

INTRODUCTION

THE REGULATORY influence of T cells on B cell function both as stimulators of antibody production [1] and as depressors of already functioning B cells [2] is well established in mice. There is considerable interest in the occurrence of helper and suppressor T cells in malignancy as these may be important in influencing antibody responses. Antibody responses to tumors might be directly helpful or alternatively harmful because of the production of immune complexes [3].

Ideally it would be desirable to measure helper and suppressor cells which influence specific antibody production to tumor antigens. However, at present in man it is only possible to investigate the ability of human T cells to help and suppress antibody production by normal B cells [4]. The present paper studies the ability of T cells from patients with acute myeloid leukaemia (AML) in remission to influence immunoglobulin production by normal B cells in the presence of pokeweed mitogen. It shows that T cells from these patients have the same ability to help and suppress immunoglubulin production as normal T cells. Intermittent maintenance chemotherapy slightly reduces T cell ability to help but this activity rapidly recovers and a rebound increase above pre-treatment levels occurs.

MATERIALS AND METHODS

Patients

Fifteen patients with AML, aged 47–70 yr, were studied. They had received standard induction chemotherapy with daunorubicin and cytosine arabinoside [5] at least 5 months previously and most of them were on maintenance chemotherapy consisting of 5 day courses of daunorubicin and cytosine arabinoside alternating with thioguanine and cytosine arabinoside at approximately monthly intervals [6]. Five patients in early relapse with normal peripheral blood received a new combination therapy consisting of vincristine, adriamycin, cytocine arabinoside and prednisolone [7]. None of the patients had abnormal cells present in their peripheral blood at the time of study. Three of these 5 patients had

not received chemotherapy for several months. All the patients except one were on weekly immunotherapy (BCG or BCG plus allogeneic cells) [8], which had been started at least 6 months previously. Heparinized blood samples were obtained immediately before a course of maintenance treatment and between 21 and 28 days after the course. Blood samples were taken sequentially from 4 patients at 7, 14, 21 and 28 days after treatment. Ten normal donors aged 35–50 yr served as controls.

Assay system

Peripheral blood lymphocytes were separated on a Ficoll–Triosil gradient. For rosetting T lymphocytes, sheep red blood cells (2%) were treated with neuraminidase (Behringewerke) 15 μm/ml at 37°C for 25 min and were mixed with lymphocytes (10×10^6) and absorbed foetal calf serum in a ratio 2:1:1 volumes and were centrifuged at 150 ***g*** for 8 min. After 15 min the pelletted cells were gently resuspended, centrifuged again and subsequently incubated for 60 min at room temperature. The E-rosetted lymphocytes were then separated on a second Ficoll-Triosil gradient after centrifugation at 400 ***g*** for 35 min. After centrifugation the Ficoll-Triosil was discarded and the pellet containing E-rosette forming cells (T-cells) and sheep red blood cells was treated with 0.91% ammonium chloride at 37°C for 10 min. The T lymphocytes remaining after lysis of the sheep red blood cells were then washed three times in medium (L15). The composition of T lymphocytes was not checked in all experiments; in 8 cases T cells contained from 89–96% E rosetting cells and less than 1% cells staining with anti-macrophage serum, see Janossy *et al.* [4] and Lee and Oliver [9]. No consistent difference in purity was observed in T cells separated from pre- or post-treatment samples. B lymphocytes were obtained from tonsils of unselected tonsillectomies and were prepared as described by Janossy *et al.* [10]. Purified tonsil B lymphocytes were suspended in RPMI 1640 medium (Flow Laboratories, Irvine, Scotland) with 10% foetal calf serum, glutamine, and antibiotics and were set up in cultures in flat-bottomed microplates (Microtest II, tissue culture grade, Flow Laboratories). Varying proportions of the T cells under study were added to B cells maintaining the total number of cells (1×10^6/ml) and the volume (0.25 ml) constant. All cultures were stimulated with 2 μl Pokeweed mitogen (Gibco, lot no. 657412) and incubated at 37°C in the presence of 5% CO_2 for 7 days. IgG was measured in the supernatant by double antibody inhibition radioimmunoassay [11]. The results were expressed in μg of IgG/1×10^6 B cells present at the beginning of culture.

Statistical analysis

Statistical analysis was performed by Student's *t*-test.

RESULTS

When normal purified blood T cells are cultured with normal tonsil B cells at a wide range of ratios, in a standard volume, IgG production by B cells is optimal at a ratio of B:T cells $\simeq$50:50. If the ratio of B:T cells is decreased, a reduction of IgG production per B cell present occurs. Thus typical results were: 90B:10T – 2.6μg/1×10^6 B cells; 80B:20T – 4.4 μg/1×10^6 B cells; 50B:50T – 18.2 μg/1×10^6 B cells; 20B:80T – 4.4 μg/1×10^6 B cells; 10B:90T – 0.4 μg/1×10^6 B cells. On the basis of these results, which are similar to those described by De la Concha *et al.* [12], two types of cultures were used to study T cells from patients and normal controls. Cultures with optimal B:T ratio (50:50) and cultures with excess T cells (B:T ratio 20:80). For ease of presentation the results in normal subjects and the leukaemic patients will be considered separately, although the cultures and assays were carried out in parallel. Table 1 shows that cultures with normal T cells (controls) produced an average 14.0 μg IgG/1×10^6 B cells at the optimal ratio of 50:50. When a ratio of 20B:80T was used IgG production fell to 6.1 μg/1×10^6 B cells which represents a reduction of 58%.

T cells were obtained from patients before and between 21–28 days after the commencement of intermittent maintenance therapy. The results in Table 2 show that T cells before therapy behaved very similarly to normal T cells, at a ratio of 50B:50T. However, at a ratio of 20B:80T there was slightly greater immunoglobulin production in the presence of T cells from patients than from normals. The reduction in IgG production due to excess T cells from patients was only 38%. Three to four weeks after the beginning of therapy the immunoglobulin production at the optimal ratio increased by about 60% and was significantly greater than in normal subjects and the patients before treatment ($P < 0.01$ and < 0.05 respectively). In cultures with excess T cells (20B:80T) IgG production was only slightly increased and the reduction

$$\text{Reduction*: } 100 \times \frac{\text{IgG production in cultures with 50\% T cells} - \text{IgG production in cultures with 80\%T cells}}{\text{IgG production in cultures with 50\%T cells}}$$

IgG production when purified B and T cells were cultured alone was 1.9 $\mu g/l \times 10^6$ cultured B cells and 0.4 μg respectively (mean values).

due to the presence of excess T cells was 54%, similar to that seen with an excess of normal T cells (58%).

Four patients were studied in more detail to determine the time course of these changes. Figure 1 shows that there was a slight depression of the ability of the T cells to help immunoglobulin production 2 days after completing the course of therapy (day 7) but by day 14 a rebound had begun which peaked by day 21. Using excess T cells (20B:80T) the initial effect of chemotherapy was to enhance the relative and absolute degree of suppression. This peaked on day 14 when there was a 71% reduction in IgG production at a time when helper function was already apparently higher than pretreatment. By contrast on day 28 the reduction due to excess T cells was only 21%.

IgM production was also measured in 6 experiments. The results showed changes that were very similar to the results for IgG production (data not shown).

DISCUSSION

It is well established that continuous chemotherapy has a more pronounced effect on immune responses than intermittent chemotherapy [13, 14]. However, with intermittent chemotherapy there is evidence for transient loss of T cell function and a more pronounced suppression of B cell function [13]. The previous studies of T cell function have mainly used lymphocyte mitogenic assays and delayed hypersensitivity skin testing. It was the purpose of this study to see whether the intermittent chemotherapy used in the treatment of these patients, which causes about a 30% reduction in total lymphocyte count, effects T cell interaction with B cells using the assay described by Janossy *et al.* [4].

Patients' T cells were cultured with normal

tonsil B cells and the effect on IgG production was measured. Using two ratios of B and T cells it is possible to detect two types of activity. The first one at ratios of 50B:50T is a helper effect of T cells on IgG producing B cells. The second activity seen at ratios of 20B:80T is thought possibly to be a measure of suppressor activity of T cells on IgG producing B cells [12]. It seems unlikely that the suppressive effect of excess T cells is due to macrophages because the number of contaminating macrophages is generally less than 1% [4]. Furthermore in separate experiments an excess of T cells which had been depleted of macrophages by nylon wool filtration or with silica have shown very similar suppression of B cell Ig production (T. A. E. Platts-Mills and M. J. Snajdr, unpublished observations). This regulatory influence of T cells on B cells both as stimulators and as depressors of already functioning B cells is well established in mice [2] and it has been suggested that there are different differentiation antigens on the surface of the T cells involved in the two roles, i.e. LY 1 positive T cells are helpers, LY 2,3 positive T cells are suppressors [15].

The results presented in this paper show that although chemotherapy does cause some suppression of helper activity during the first seven days, there is a rapid recovery with rebound above control levels by 14 days. This is the same as has been seen in studies of other T cell functions in patients on intermittent chemotherapy [13, 14]. In contrast IgG production in the presence of excess T cells (20B:80T) does not increase until 21 days after starting chemotherapy. So that the suppressor activity of T cells appears to be slightly increased following chemotherapy and only begins to decrease on day 21. These data could be interpreted as showing differential susceptibility of two distinct cell types to the effect of chemotherapy. On the other hand when helper activity is maximum at days 14–21 the reduction due to excess T cells is also at a maximum. A clear distinction between these two possibilities will only be established when markers for human T cell subsets become available.

Although these studies were undertaken in acute leukaemia, the findings may apply more generally to other patients receiving intermittent chemotherapy. It seems unlikely that the results are due to immunotherapy as this was started 6 months to 1 yr before the present observations were made and one patient who had received no immunotherapy showed the same rebound phenomenon. It is possible that immunotherapy might have altered the rapidity and the height of the rebound but insufficient cases who had not received immunotherapy have been studied to establish this point. It is clear that intermittent maintenance chemotherapy can cause changes in the balance between helper and suppressor effects of T cells *in vitro*. However, it is also clear that cytotoxic agents in the doses used here have no dramatic effect on the ability of T cells to help *in vitro* IgG production.

Absence of Cross-Resistance to Alkylating Agents in Cyclophosphamide-Resistant L1210 Leukemia*†

GALEN L. WAMPLER,‡ WILLIAM REGELSON and THOMAS J. BARDOS

Department of Medicine, School of Medicine, Medical College of Virginia, Richmond, Virginia 23298 (*G.L.W., W.R.*) *and Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, New York* 14214 (*T.J.B.*), *U.S.A.*

Abstract—*A cyclophosphamide resistant strain of* L1210 *leukemia was sensitive to treatment with any of eight other alkylating agents containing either β chloroethylamine or aziridine functional moieties including mechlorethamine (nitrogen mustard); Tris(aziridinyl)phosphine sulfide (ThioTEPA); alanine,* 3-[p-[*bis*(2-*chloroethyl*) *amino*] *phenyl*]-*monohydrochloride* (*melphalan*); *four Tris*(*aziridinyl*)*phosphine oxide* (*TEPA*) *analogs and* 1,3,4,5-*Tetra* o-*acetyl*-2-(*di*-2-*chloroethyl*)*amino*-2-*deoxy*-D-*glucopyranose. Cross resistance was virtually absent excepr in the case of o-*[*bis*(1-*aziridinyl*)*phosphinyl*]-*N-hydroxyurethane and melphalan where partial cross resistance was documented.*

INTRODUCTION

THE MOTIVATION leading to this investigation related to our interest in contrasting the properties of 1,3,4,6-tetra-*o*-acetyl-2-(di-2-chloroethyl)amino-2-deoxy-D-glucopyranose (TGM) with other alkylating agents. TGM, like streptozotocin, contains a glucosamine moiety and we previously showed that the schedule dependency of optimal treatment for TGM resembled that of streptozotocin in that the drug is best given on a daily or multiple daily treatment schedule [1]. Human tumors resistant to other nitrosoureas apparently are sensitive to treatment with streptozotocin [2] and this raised the question whether neoplasms resistant to standard alkylating agents could be successfully treated with TGM. In the present investigation we studied cross resistance in a cyclophosphamide (CTX) resistant strain of L1210 leukemia to a number of alkylating agents. Formulae of all the newer drugs used are shown in Fig. 1.

MATERIALS AND METHODS

TGM,*o*-[bis(1-aziridinyl)phosphinyl]-*N*-hydroxy-urethane (AB180), *N*-[bis(1-aziridinyl)phosphinyl]-*o*-acetyl-*N*-hydroxyurethane (AB181) and *o*-[bis(2,2)dimethyl-l-aziridinyl) phosphinyl]-*N*-hydroxyurethane (AB182) were synthesized by Hsiao and Bardos by previously published methods [1, 3]. The preparations of ethyl bis(2,2-dimethyl-l-aziridinyl)phosphinate (AB163) and alanine, 3-[*p*-[bis-(2-chloroethyl)amino]phenyl]-monohydrochloride (PAM) used were those in use for clinical investigation. AB163 was synthesized by Starks Associates, Buffalo, New York. A parenteral preparation of PAM (Burroughs Wellcome, Research Triangle, N.C.) was used. Standard commercial preparations of parenteral forms of all other drugs were used: Mechlorethamine (HN2) (Merck, Sharp & Dohme, West Point, Pa.); Tris(aziridinyl)phosphine sulfide (ThioTEPA) (Lederle Laboratories, Pearl River, N.Y.); CTX (Mead Johnson Laboratories, Evansville, Indiana).

The CTX resistant strain of L1210 leukemia was obtained through the Chemotherapy Department of Southern Research Institute, Birmingham, Alabama, which was

originally developed by William DeWys, University of Rochester, Rochester, New York. His method of inducing tumor resistance and some characteristics of this line have been published [4]. The standard L1210 leukemia utilized was originally obtained from Microbiological Associates, Rockville, Maryland.

Both tumors were maintained in our laboratory by weekly i.p. passage of 10^5 cells into DBA/2 mice. Approximately once each month, CTX was administered to animals bearing the CTX resistant tumor strain to maintain drug resistance. C57BL/6 × DBA/2 (hereafter called B6D2F$_1$) female mice, eight per group, were used for the test animals. Each test animal received 10^5 i.p. tumor cells that led to death of untreated animals in 7–11 days.* For all experiments, groups of mice were kept 8/cage in an air conditioned, light cycle controlled environment. Animals were observed daily for deaths; life span was recorded.

In all experiments, drugs (except TGM) were administered as a single i.p. dose 24 hr after tumor inoculation. TGM was given on a twice daily i.p. schedule for 8 days starting 24 hr after tumor inoculation. These schedules are the known or presumed (based on available evidence) optimum treatment schedules for all drugs utilized. In most cases, duplicate or triplicate trials of each drug in each of the tumor lines were conducted. For statistical analysis, all the data from optimum treatment groups were pooled combining the results from ten experiments which included 7 runs with standard L1210 leukemia and three runs using CTX resistant L1210 leukemia. In order to combine experiments for comparative analysis, only those experiments which utilized a comparable tumor burden were included, e.g. when 10^5 tumor cells injected i.p. were given and when the median life span of the controls fell between 8 and 10 days. Formulation of medication, time of administration and route of administration were identical in the treatment of mice bearing the two tumor lines. The log interval between doses was identical with few exceptions (listed in footnotes in Table 1). This implies that the probability of missing the optimum dose was no greater for one tumor line than for the other.

For statistical analysis, the Kruskal–Wallis one-way analysis of variance by ranks method was used to determine the difference between L1210 and CTX resistant L1210 treatment results. The median test was used to determine differences in results of treatment between pairs of drugs [5]. *P*-values of 0.05 or less were considered significant.

RESULTS

Table 1 lists the optimum results seen for each experiment. The optimum result is based on a calculation of the median life span. (In one instance, the optimal dose would have been different if the number of survivors had been the determining factor.) The raw data from the groups listed in Table 1 have been analyzed as indicated above and the *P*-values obtained in making the various comparisons are listed in Table 2.

Comparison of the standard and CTX resistant L1210 by the method of analysis used indicated that control life span was significantly greater for the CTX resistant tumor. However since animals were observed only daily for deaths the life span difference in these two groups was no greater than the resolution of the time measurement. Consequently, considerable caution should be applied to any conclusions drawn regarding the meaning of this difference.

There was no statistical difference in the

*Four per cent (2 animals) of the standard L1210 leukemia controls lived longer than 11 days.

†The optimal dose is based on the highest recorded median life span. When more survivors occurred with a different dose, this is noted. All drugs were given as a single i.p. dose 24 hr after i.p. tumor inoculation of 10^5 cells except TGM was given twice daily for eight days starting 24 hr after tumor inoculation. Injections of TGM were three hours apart. The total cumulative dose of TGM was 16 times the dose given in the Table.

‡Female $B6D2F_1$ tumor bearing mice.

§Percentage increased life span calculated as follows: [Median life span (treated) × 100/Median life span (controls)] −100.

‖Only one treatment group was used in this experiment.

¶The doses used were not at logarithmic intervals. Doses were 2.5, 3 and 3.5 mg/kg.

**Only two treatment groups were used.

††A higher dose (56 mg/kg) produced 2/8 survivors.

§Significant at $P<0.05$.

life span of animals bearing the two tumor strains when treated with TGM, HN2, AB181, AB182, AB163, or ThioTEPA. Only with treatment using AB180, PAM or CTX was the *P* value less than 0.05. In this tumor which is almost completely resistant to CTX, no cross resistance was detected to any of the other alkylating agents used except AB180 and PAM and in these instances the cross resistance was so incomplete or marginal that 33% of the AB180 treated animals and 42% of the PAM treated animals were cured by a single drug injection given 24 hr after inoculation of 10^5 CTX resistant tumor cells.

To analyze drug potency alterations in the CTX resistant leukemia, the median test [5] was used to evaluate the relative effectiveness of every possible pair of drugs used in treatment of both tumor lines.

Drugs could then be ranked in groups such that drugs in each group were not statistically different in their effect on prolonging the life of leukemic mice but were statistically better or worse than drugs in different groups (see Table 3). It can be seen that in comparing L1210 leukemia with the CTX resistant leukemia, CTX goes from one of the best to the least effective drug while AB180 and PAM are shifted from the most effective to the intermediate grouping. The type of shift seen with AB180 and PAM would be predicted from the knowledge that in this tumor line partial cross resistance to these drugs exists.

DISCUSSION

These results clearly show that in this CTX resistant L1210 tumor there is little cross resistance to the other alkylating agents studied. *P*-values of 0.05 or less for the comparisons in Table 2 denote partial cross resistance (AB180 and PAM), whereas non-significant *P*-values indicate that no cross resistance has been demonstrated.

Our results essentially confirm and extend those of Schabel who studied the activity of PAM but not the other seven alkylating agents in this very same CTX resistant leukemia. He reported it as sensitive to PAM as is L1210 leukemia [6]. He did not, however, utilize a rigid statistical comparison which is responsible for our demonstration of a marginal partial cross resistance.

At the time the studies were done, we were not aware of the published characteristics of this CTX resistant L1210 leukemia. DeWys had shown that these tumor cells repair sublethal damage to the same degree and at the same rate as standard L1210 tumor cells. He suggested either a difference in cellular drug uptake or a difference in intracellular handling of drug as possible

mechanisms of resistance [4]. Goldenberg *et al.* studied the mechanism of CTX transport by L5178Y lymphoblasts and identified a two component carrier mediated facilitated diffusion process which was not inhibited by other alkylating agents including HN2, PAM, chlorambucil, isophosphamide or even activated CTX but CTX itself did inhibit the uptake of CTX-^{14}C. They concluded that CTX was transported by an independent mechanism [7]. If loss or damage to such a transport mechanism were the cause of drug resistance one would not expect to see any cross resistance with other alkylating agents. The transport mechanism for HN2 has also been studied and appears to be specific, e.g. not inhibited by other alkylating agents [8] but inhibited by choline, the natural substrate for the carrier [9].

On the contrary, if drug resistant cell lines utilized a mechanism of resistance involving an increased ability to repair DNA damage cross resistance with other alkylating agents, radiation treatment or possibly other types of chemotherapy could result. In at least one instance, a CTX resistant tumor has been shown to be cross resistant to an anti-metabolite, 6-mercaptopurine ribonucleoside [10].

In HN2 resistant L5178Y lymphoblasts, Goldenberg [11] reported that there was a direct correlation between HN2 resistance and percent tetraploidy (and also between HN2 resistance and cellular thiol content).

With polyploidy, there may be increased genetic information to allow for possibly more efficient repair or function in heavily damaged cells.

Mechanisms of intracellular handling of drugs may or may not be specific to the drug. Drug activation mechanisms (as in the case of CTX) are specific to a given drug and its congeners. Drug inactivation mechanisms likely are directed to the functional group and if so cross resistance might be expected.

The stepwise development of resistance in CTX resistant L1210 leukemia suggests that multiple determinants are involved [4] and it seems likely that different resistant cells utilize a different mix of the many possible resistance mechanisms. It would appear that strains of L1210 leukemia can be developed that are cross resistant [12], partially or incompletely cross resistant [13] or virtually non-cross resistant to other alkylating agents.

What is the situation regarding the cross resistance of alkylating agents in man? This can only be answered in a general way. Animal studies have shown a heterogenous situation exists relative to the propensity to the development of resistance to alkylating agents and the evidence on balance at this time would indicate that in L1210 leukemia, which is generally conceded to be the best model for predicting activity in man, cross resistance is likely to be incomplete or almost entirely absent.

The superior activity of the new alkylating agents used in this study, when they are compared with the nearest clinical analog, along with the knowledge that alkylating agents are not alike after all, strongly supports the continued development of the newer drugs in clinical trials.

Prednisolone Treatment of Hereditary Pig Lymphoma

SERENA A. BROWNLIE,* J. G. CAMPBELL,* K. W. HEAD,* P. IMLAH,* H. S. McTAGGART* and J. G. McVIE†

*Royal (Dick) School of Veterinary Studies, University of Edinburgh, Great Britain and
†Department of Clinical Oncology, University of Glasgow, Great Britain

Abstract—*Two age-matched pairs of pigs with hereditary lymphoma were treated with prednisolone sodium phosphate in daily intramuscular doses of* 4 mg/kg *on* 5 days/week *for* 5.5 weeks. *One of each pair was then killed and autopsied, the other* 5 weeks *later.*

Treatment resulted in marked reductions in blood mononuclear cell count, serum globulin (chiefly gamma) levels and lymph node, thymus and adrenal size. Increases in PCV (haematocrit), platelet counts and in serum albumin and magnesium levels occurred. The red cell picture continued to improve until two weeks after treatment ceased. All these changes reversed rapidly during the post-treatment period. Neutrophilia occurred only during the fifth week of treatment.

Serum Na, K, Ca, *chloride and inorganic phosphate levels showed no treatment-related changes.*

The skin hypersensitivity reaction to DNFB, absent before treatment, became positive during and after prednisolone treatment but was never as marked as in sensitised normal pigs.

INTRODUCTION

FOLLOWING the establishment of 4 mg/kg as a suitable dose of prednisolone for pigs [1], an experiment was set up to determine the effects of the drug on cases of hereditary lymphoma of pigs [2] and to establish whether these effects were comparable to those occurring in lymphoid neoplasia of man.

MATERIALS AND METHODS

Two pairs of pigs numbered 30, 37 and 52, 56, which were 6 and 5 months old respectively at the start of the experiment, were used. The latter pair were littermates. All were female and affected with lymphoma which had been diagnosed between 8 and 10 weeks of age.

The same monitoring methods were used as in the corresponding experiment on normal pigs [1] except that all four pigs received the same dose of prednisolone sodium phosphate (Codelsol, M.S.D.), namely 4 mg/kg administered intramuscularly once daily 5 days/week for 5.5 weeks. In addition, a bone marrow core biopsy sample was taken from the wing of the ileum before treatment commenced as well as prior to slaughter. The expiratory girth at the level of the umbilicus and the length and breadth of the inguinal and precrural lymph nodes were measured once weekly. The lymph node measurements were taken with ball-pointed calipers without compressing the node and without lifting it into a fold of skin.

Since it is not always easy to differentiate the various types of mononuclear cells in routine smears from lymphoma cases, differential counts were based on "total mononuclear cells".

All pigs were given supportive therapy throughout the experiment with a vitamin-mineral feed supplement (Nutrequin, Berk). During prednisolone treatment, they also received framycetin sulphate (Feed Additive, C. Vet.) at prophylactic dose level.

Accepted 20 January 1978.

Correspondence to H. S. McTaggart, Department of Veterinary Medicine, Easter Bush, Roslin, Midlothian, Scotland.

At the end of 5.5 weeks treatment, one pig of each age pair was killed (Group I, pigs 30 and 56). Treatment of the survivors (Group II, pigs 37 and 52) was tailed off during the succeeding three days and they were killed 5 weeks later.

Pig 54, an unaffected littermate of the younger age pair, whose only abnormality was a congenital right deviation of the nasal bones and nasal septum, was killed as an untreated control two days after its Group I sibling.

Further autopsy controls were provided by the use of data from 17 untreated lymphoma cases which had died or had been killed at comparable ages to the treated pigs.

RESULTS

Clinical observations

Before the commencement of treatment, all four pigs ate fairly well, but they were less active and easier to handle than normal pigs of similar size. Weight gains were poor. Within a few days of starting treatment, there was a marked improvement in appetite and general fitness and the pigs became much more lively. Weight gains were not improved during treatment (Table 1). All pigs showed polydipsia and polyuria but had normal faeces. Rectal temperatures varied within the normal range (37.5–39.7°C) apart from a period of febrile response (up to 40.1°C) in two pigs associated with infected abrasions and bite wounds.

During prednisolone treatment, the lymph nodes decreased in size. The length of the left inguinal node was taken as representative since both lengths and breadths of the other nodes showed similar changes. Its mean length in the 4 pigs was 66 ± S.D. 5.7 mm before treatment. After 4 weeks of treatment, it was 45.5 ± 4.7 mm, a decrease of 31%. During the rest of the treatment period, the glands were too soft to be accurately measured. Five weeks after treatment was withdrawn, the mean measurement in the two remaining pigs was 64.5 ± 6.7 mm, an increase of 41.8%, these measurements being compara-

In the case of bilateral organs only one side was weighed, except kidney and adrenal which are mean values.

ble to those at the beginning of the experiment. The pot-bellied appearance associated with the disease increased during the treatment period, despite the fact that girth measurements made while the animals lay on their backs remained fairly steady in three pigs and actually decreased progressively from 880 to 800 mm in the fourth (pig 37). There was no clinical evidence of ascites; in particular, little or no fluid could be detected by paracentesis abdominis. During the post-treatment period, the two surviving pigs showed increases of 110 mm (pig 37) and 100 mm (pig 52) in girth measurement which were associated with increases in body weight (Table 1).

Haematology

The most spectacular haematological effect was on the mononuclear cells (Fig. 1) whose value dropped from an overall pretreatment mean of $20.5 \pm 5.6 \times 10^9/l$ to a nadir of $4.1 \pm 0.5 \times 10^9/l$ during the fifth week of treatment when no recognisable tumour cells were observed in the peripheral blood. By the end of treatment, the mononuclear cells had risen to $7.4 \pm 2.2 \times 10^9/l$. During the next five weeks, the mononuclear counts of the two surviving pigs rose progressively to approximately pretreatment levels.

During the pretreatment period, absolute neutrophil counts fluctuated widely in individual pigs, with an overall mean of $9.7 \pm 6.7 \times 10^9/l$ (Fig. 1). During the second week of treatment, this dropped to $6.2 \pm 2.7 \times 10^9/l$, rising to $15.6 \pm 2.5 \times 10^9/l$ during the fifth week and falling again to $9.5 \pm 1.4 \times 10^9/l$ at the end of treatment. This fall continued in the two Group II pigs during the post-treatment period, reaching $3.6 \pm 0.4 \times 10^9/l$ 5 weeks after treatment ceased.

Two weeks before treatment started, all four pigs had low thrombocyte counts (mean $99 \pm 20 \times 10^9/l$ (Fig. 1). By the fifth week of treatment, the mean had risen to $359 \pm 19 \times 10^9/l$. During the last week, it fell to $283 \pm 56 \times 10^9/l$. Four weeks later, the 2 surviving pigs had a mean count of $206 \pm 86 \times 10^9/l$.

Eosinophil counts remained at a low level throughout the experiment in all pigs except No. 37 (Group II) in which they fluctuated considerably.

The packed cell volume (Fig. 2) tended to fall during the pretreatment period but rose rapidly from a mean of 0.26 ± 0.01 at the commencement of treatment to 0.30 ± 0.02 three weeks later, remaining at about this level until the second week after treatment ceased. During the last three weeks of the experiment there was a rapid fall to 0.24 ± 0.03. RBC and haemoglobin showed similar changes.

The only discernible treatment-related effects on the derived red cell indices were in Group II where, during the post-treatment period, the mean cell volume rose from 51.0 ± 1.6 fl to 59.1 ± 5.1 fl and the mean cell haemoglobin concentration dropped from 35.2 ± 2.7 to 31.9 ± 1.4 g/dl.

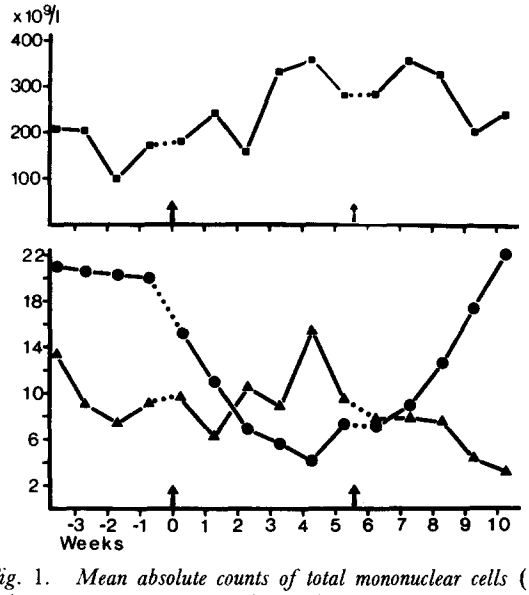

Fig. 1. Mean absolute counts of total mononuclear cells (●–●), neutrophil granulocytes (▲–▲) and platelets (■–■) of lymphomatous pigs before, during and after treatment with prednisolone. Arrows indicate beginning and end of treatment.

Serum biochemistry

The mean serum magnesium concentration, which had remained fairly steady at an overall mean of 0.84 ± 0.05 mmole/l during the pretreatment period, showed upward fluc-

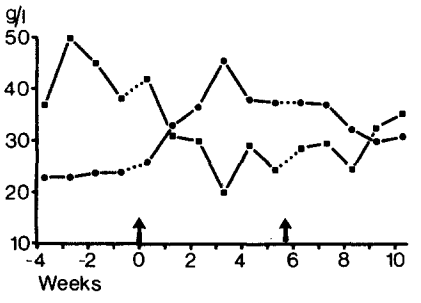

Fig. 4. Serum albumin (●–●) and serum globulin (■–■) of lymphomatous pigs before, during and after treatment with prednisolone. Arrows represent beginning and end of treatment.

tuations during treatment (Fig. 3) but remained within the normal range for the pig (0.8–1.25 mmole/l). After treatment ceased, it fell immediately in the two surviving pigs to 0.75 mmole/l and remained below that level during the rest of the experiment. No signs of hypomagnesaemic tetany were observed.

The mean serum potassium concentration remained unchanged throughout the experiment (Table 2). The mean serum sodium, calcium, chloride and inorganic phosphate concentrations all showed small progressive increases during the course of the experiment (Table 2).

The total serum globulin level (Fig. 4) fluctuated considerably before treatment having an overall mean of 43.1 ± 7.9 g/l. During treatment it fell sharply, reaching a nadir with a mean of 21.0 ± 5.2 g/l during the fourth week. From then on it tended to rise again but within the period of observation, never reached the pretreatment level.

The mean serum albumin level (Fig. 4) remained relatively steady before treatment with an overall value of 23.6 ± 4.0 g/l. During treatment it showed changes more or less complementary to those in globulin. At its peak during the fourth week it had a mean of 46.0 ± 3.9 g/l.

These effects were exaggerated when the albumin/globulin ratio was calculated. Before treatment this had an overall mean of 0.57 ± 0.17. The ratio increased rapidly during treatment reaching a peak during the fourth week with a mean of 2.28 ± 0.5. Thereafter it fell again but remained above unity until the last two weeks of the experiment.

Electrophoretic analysis showed that the drop in globulin during treatment was attributable essentially to a 50% reduction in the gamma fraction (Table 3).

Cell-mediated immunity

Before therapy began, the skin hypersensitivity reaction to 10% DNFB was minimal or absent in all four lymphomatous pigs. During and after therapy, a response of score 2 (erythema and swelling) was apparent (Table 4). The reaction of the untreated non-lymphomatous pig was much more severe (large ulcerations, score 4).

Post-mortem and histological findings

Group I pigs resembled normal animals except that the lymph nodes were slightly enlarged. As in untreated lymphoma, the cortex and medulla were not distinguishable on the cut surface but, unlike such cases, the nodes were firm not soft.

Group II pigs showed lesions typical of advanced, untreated cases of the disease as described by Head *et al.* [2], except for the thymus and alimentary tract (q.v. below).

The relative weights of organs are summarised in Table 1. In Group I, treatment had reduced the relative weights of the splanchnic lymph nodes to well below the minimum value of the 17 untreated cases, but they were still about three times greater than those of the untreated normal pig. In Group II, the withdrawal of treatment resulted in marked recrudescence so that the splanchnic nodes were nearly 6 times larger than in Group I and approximated to the mean value of the untreated cases. The increase in relative weight was greatest in the mesenteric and colonic nodes and least in the bronchial group.

Similar, but less spectacular effects were observed in the superficial nodes both individually and as a group.

On histological examination, treatment in Group I had caused a depletion of cells in the paracortical region of the lymph nodes and the few nodules found had reverted to primary small structures (Figs. 5, 6 and 7). The increase in size of the nodes was due to paracortical tissue in which a few probable tumour cells were seen, but none in mitosis. This area in the gastric and mesenteric nodes had much fibrin deposition. Regrowth of tumour in Group II nodes resulted in replacement of normal structure almost completely by tumour cells and some small lymphocytes, except for a few small nodules (Figs. 5 and 8).

The inguinal nodes of Group I were unique in that one pole showed lymphoid depletion described above but the other pole was replaced by tumour so that it resembled a Group II node.

The relative weight of the thymus was about twice as great in Group II as in Group I. All were above the average for the un-

treated cases but none was as high as the untreated normal pig. Histologically, the thymuses of Group I pigs were reduced to lobules of adipose tissue with occasional epithelial cells and groups of up to 50 lymphocytes. The recovery of normal cortical and medullary structure when treatment was stopped resembled that seen in prednisolone treated normal pigs [1], but the more rapidly regrowing tumour had caused some thymus suppression in pig 52.

The effects on the splenic relative weights were similar to those on the lymph nodes, so that histologically the Group I white pulp showed no nodules and the red pulp, though large, was depleted of cells (Fig. 9). Five weeks without treatment allowed tumour to regrow, nodules to reform and extramedullary haemopoiesis to develop in Group II so that the spleen resembled that of a typical late stage untreated lymphosarcoma (Fig. 10).

When bone marrow biopsies were taken immediately prior to slaughter, they were found to be representative of the picture in the decalcified bone sections. The pretreatment biopsies all showed tumour tissue but in the post-treatment samples no tumour cell masses were found, although there were more haemopoietic cells and less adipose tissue than normal. In the Group II post-mortem samples, there seemed to be an increase in normoblast foci, a reduction in megakaryocytes and large islands of tumour cells. Whereas the decalcified lumbar vertebral body and wing of the ilium are normal sites of haemopoiesis, the marrow of the femoral shaft is a fat store in this age of pig. It it noteworthy, therefore, that it was haemopoietic in Group I and both haemopoietic and neoplastic in Group II pigs.

In contrast to other lymphoid sites, the Group I pigs showed large reaction centres in the stomach, Peyer's patches and caecum, particularly in pig 56. Moreover, in the sites occupied by tumour in Group II pigs, there was a sparsely cellular zone with no obvious tumour cells in mitosis.

In some organs, e.g. the ovarian stroma and the adventitia of both the arcuate vessels of the kidney and the blood vessels of the fat of the vertebral canal, a tumour lymphocyte infiltrate was present in Group II but absent in Group I. In other organs of Group I some foci of small lymphocytes were present, whereas they were absent (e.g. periportal) or smaller (e.g. peribronchial) in normal pigs. These areas in Group II animals were occupied by large proliferating tumour masses.

DISCUSSION

There are three main areas of interest in these results: firstly the effect on the marrow in which tumour was reduced but haemopoeisis was stimulated; secondly the effect on serum biochemistry, in particular the changes in albumin/globulin ratio and in magnesium levels; thirdly the differential sensitivity of tumour cells in different organs.

The percentage reduction in circulating mononuclear cells was twice as great as that observed even at the highest dose level of 6 mg/kg in normal pigs [1]. This is in keeping with the observation of Schrek [3] that in man leukaemic lymphocytes were more sensitive to steroids than were normal lymphocytes.

The observed reduction in total serum globulin and increase in serum albumin during treatment was to be anticipated from the observation in man that control of symptoms by corticosteroid therapy is usually associated with such an effect [4]. The reduction in globulin may have resulted from steroid lympholysis primarily of tumour cells which were producing an excess of gamma globulin. However, we have not been able to demonstrate that the high level of gamma globulin found in lymphoma pigs is produced by the tumour cells. Indeed, these appear to be neither T nor B cells since the percentage of cells forming rosettes with sheep RBC and of cells showing fluorescence for immunoglobulin is very low compared with normal pigs (unpublished data). It may be that the gamma globulin came from normal B cells in response to the presence of the tumour. These cells were then involved in the steroid lympholysis or reduced their production of globulin as the tumour disappeared, or both.

The increase in serum albumin levels during treatment appears to result from an osmotic mechanism acting through the hepatic interstitial fluid so that the production of albumin by the liver is inversely related to the globulin concentration [5]. Increased albumin production would be helped by prednisolone-induced improvement in appetite, resulting in increased protein uptake and improved utilisation following reduced interference with organ function by the tumour or its products.

The suspicion that in normal pigs prednisolone produced a nadir in total serum globulin values before the end of treatment [1] was borne out in the lymphoma pigs in which it was accompanied by a peak in the serum albumin. These effects and the nadir in

Fig. 10. *Spleen from lymphoma pig* 52 *at the end of the post-treatment period. Note regenerating white pulp top left surrounded by tumour tissue; on the right small dark nuclei of normoblasts and some megakaryocytes can be seen. Compare with Fig.* 9. *H&E* × 500.

mononuclear cells and peaks in neutrophils and platelets during the fifth week of treatment suggest that thereafter the effects of the treatment began to decline. Shaw *et al.* [6] observed that the effects of prednisolone on chronic lymphocytic leukaemia of man were transient and Rosenthal *et al.* [7] reported that remissions obtained in lymphocytic leukaemias of children and other lymphoid neoplasia with ACTH or cortisone were of short duration. This waning of effect may be due to suppression of the hypothalamic–pituitary-adrenal axis [8]. Certainly, the mean relative weight of the adrenals of Group I pigs at the end of treatment was only two-thirds that of Group II 5 weeks after withdrawal and only one-third that of the 17 untreated lymphoma cases (Table 1).

The continued improvement in the red cell picture into the second week after treatment was discontinued might be due to a stimulating effect of prednisolone on early red cell precursors in the marrow so that the resulting increased population of maturing cells in the "pipeline" continued to appear in the peripheral blood for some time.

Increased levels of serum magnesium (up to 1.85 mmole/l which is within the cardiotoxic range) have been observed during treatment of human patients with leukaemia and have been attributed to the release of the element from damaged malignant cells [9]. The reduction to subnormal levels observed in our lymphoma pigs once treatment was withdrawn may be associated with increased uptake of the element from the blood stream by the rapidly regrowing tumour.

Such a mechanism would be expected to affect serum potassium levels similarly [10], but these remained unchanged throughout the experiment. Potassium and calcium loss only result from high dosage or prolonged treatment with corticosteroids [9].

Although the average skin hypersensitivity reaction score of 2 was not as high as that observed in the normal untreated pig, it was higher than that observed in untreated lymphoma pigs (unpublished data). These reactions show that prednisolone had a slightly beneficial effect on the cell-mediated response of the treated lymphoma pigs. This response is unlike that observed in normal pigs receiving prednisolone, where the effect was to suppress the hypersensitivity reaction [1].

The absence of increases in body weight during treatment and the increases observed in Group II after its withdrawal are in keeping with the known growth-depressive effects of prednisolone [11]. It is not clear, however, to what extent these effects are attributable in lymphomatous pigs to changes in tumour mass as reflected in the superficial lymph node measurements and post-mortem findings.

The problem of identifying isolated non-dividing tumour cells sparsely scattered through a population of other lymphoid cells remains unsolved. It is, therefore, difficult to state whether treatment destroyed all the tumour cells in an area or reduced their number and mitotic rate so that they were not detectable by conventional histology. It is clear from our results, however, that tumour growth was suppressed to different degrees in different sites in the body, e.g. completely in the kidney but not in the gastro-intestinal tract. Even in a single organ only localised suppression was sometimes achieved, e.g. the inguinal lymph node.

In the early drug-induced remission period, one might expect to see the supporting connective tissue stroma of the tumour now depleted of tumour cells. The gastric and splenic lymph nodes, which are the organs most enlarged in the untreated case, certainly showed a zone of fibres and blood vessels between the paracortical area and the medulla which would fit this concept. This, and comparable areas in other lymphoid organs, often showed fibrin deposition, suggesting some defect in the integrity of the blood vascular system. In these areas, large "blast" cells were seen which may have been unmasked reticuloendothelial cells or possibly tumour cells prevented from progressing through mitosis.

It is clear from the foregoing discussion that hereditary lymphoma of pigs is a good model for comparison with the human. In addition to changes associated with prednisolone treatment that were predicted from previous work (e.g. red and white cell parameters, albumin/globulin ratio and weight gain) new features have come to light such as magnesium fluctuations, differential tumour sensitivities and correction of anergy. These open up new avenues of research and may lead to changes in our fundamental thinking about lymphoid neoplasia.

Osteosarcoma of the Long Bones

Clinical Observations and Experiences in the Netherlands

P. COHEN

Department of Diagnostic Radiology, Antoni van Leeuwenhoek Ziekenhuis, Amsterdam, The Netherlands

Abstract—*The diagnostic and clinical aspects of* 176 *patients with osteosarcoma of the extremities, treated during the years* 1962–1969 *are retrospectively reviewed. A classification based on the radiographic appearance of the tumour was made. A specific method for measurement of the primary tumour is defined. In the majority of cases* (75%) *the planned management was by primary irradiation and selective delayed amputation. The* 3- *and* 5-*yr survival rates are* 30 *and* 22% *respectively. Prognosis was influenced by histology and radiographic characteristics. The local palliation obtained by radiotherapy was not adequate to justify delay in amputation. For that reason and in view of the results obtained so far by elective treatment (prophylactic irradiation of the lungs and chemotherapy), immediate ablative surgery is recommended as the treatment of choice.*

INTRODUCTION

In 1953 a study group for bone tumours was formed in the Netherlands, the members of which included radiologists, pathologists, orthopaedic and general surgeons. This committee which later came to be called the Netherlands Bone Tumour Registry (NBTR) initially collected sections of bone tumours and data concerning the patients from the archives of departments of pathology. Files were established as soon as complete case histories were available. After some time requests for advice concerning diagnosis and treatment gradually increased. To day the NBTR has acted for more than 20 yr as a reference centre for bone tumours. Pathologists and clinicians present their cases to the Registry, which re-examines the histologic slides and radiographs. From which it makes a final diagnosis and gives advice on treatment.

In 1971 the NBTR made, at our request, its files available for a retrospective study on the clinical aspects of osteosarcomas of the extremities. For the purpose of uniformity of the series some tumours were excluded:

1. parosteal or juxtacortical osteosarcomas, which have lowgrade malignancy and a good prognosis;
2. sarcomas arising in previously abnormal bone. In this respect Paget's sarcomas have almost uniformly a fatal prognosis but are fortunately extremely rare in the Netherlands as compared with the United States and England;
3. secondary sarcomas arising in previously irradiated bones.

Our series includes 176 patients which were consecutively treated between 1962 and 1968. The follow-up period was at least 3 yr; 147 cases were followed for 5 yr or more. In 1974 our study was published as a thesis [1].

Accepted 20 January 1978.

MATERIALS AND METHODS

The incidence of osteosarcomas, irrespective of its location is similar in the Netherlands to that of England, i.e. 1:400,000 annually [2].

Age and sex distribution are shown in Fig. 1. As in other large series the incidence shows a peak during the 2nd and 3rd decades. More than 68% of our patients were treated in the 2nd decade of age.

As is generally reported tumour incidence is greater in males than in females. In the youngest age group (up to 13 yr) however, the incidence in our series is relatively greater in girls (Fig. 2). The cumulative frequency of the disease in the male patients increases after the age of 15 yr, 3 yr later than in girls. In

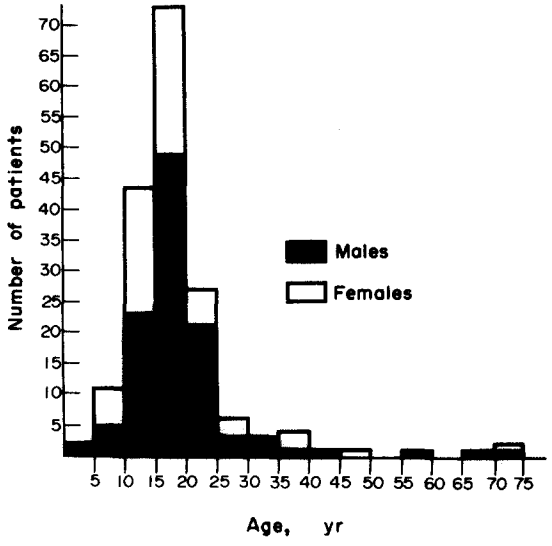

Fig. 1. Age and sex distribution of 176 patients.

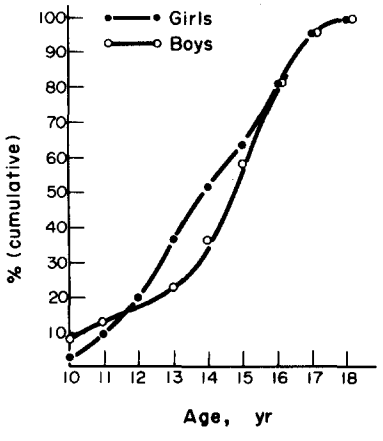

Fig. 2. Cumulative frequency of osteosarcoma in 41 girls and 62 boys between 9 and 18 yr of age.

analogy the curves representing the average increase in bodylength of boys and girls separately, and even the rate of growth of their individual long bones, show the same characteristics as the curves which represent tumour incidence according to age [1]. These differences are possibly correlated with the onset of the growth spurt during puberty. Also the many large tumour volumina in our series during and shortly after puberty may point to a correlation with a relatively large rate of growth in this period of life.

Fraumeni's conclusion [3] that children with osteosarcomas under the age of 18 yr are significantly taller as compared to those in a control group with non-skeletal tumours also points to a connection with the rate of growth during puberty.

Location

The location of the 176 tumours in our series is represented in Fig. 3. In agreement with other publications most tumours are

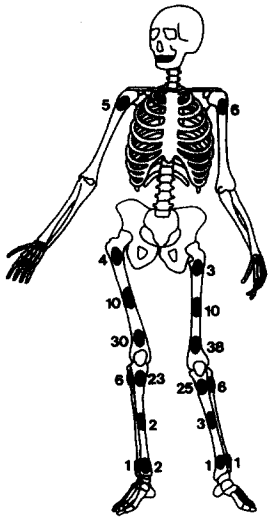

Fig. 3. Location of 176 osteosarcomas.

found in the region of the knee (65%). The primary site within the long bones is predominantly the metaphysis, sometimes extending into the shaft and in a minority of cases into the epiphysis. The numbers for right- and left-sided tumours were not significantly different.

In the distal femur the neoplasm was often found in the lateral part, whereas in the proximal metaphysis of the tibia the process was usually located in the medial part. These differences proved to be statistically significant.

Invasion into the epiphysis was extremely rare in cases with open epiphyseal plates (2 out of 57 cases in contrast to 42 out of 52 cases with closed epiphyseal plates).

Pathology

As a strict criterion for the histologic diagnosis of osteosarcoma was maintained a primary malignant tumour arising in bone which forms osteoid or bone tissue directly, i.e. without an intermediate cartilaginous stage.

The histologic slides of all cases have been critically reviewed by a small team of pathologists, all members of the NBTR. According to the dominant intercellular component a classification into osteoblastic, chondroblastic and fibroblastic types is possible, although we cannot be too emphatic in stating that with regard to the last two types such a classification is not identical clinically with chondro- and fibrosarcomas. Apart from the dominant

intercellular component we distinguish fibrosarcomatous, telangiectatic and cystic types of tumour. Fibrosarcomatous osteosarcomas were described by van der Heul [4] and are histologically characterized by a fasciculated arrangement of the tumour cells. The same author also found a more favourable prognosis for patients with such a tumour. Telangiectatic osteosarcomas are richly vascularized and contain blood filled cavities.

In accordance with the advice of the Bone Registry, in 168 cases a diagnosis was made by open biopsy, usually preceded by a short course of pre-operative irradiation within 24 hr before the biopsy (2×400 rad). In 8 patients the diagnosis was made only after a needle or drill biopsy. As to the location of the biopsy we stress the role of the clinical radiologist to guide the surgeon in the choice of the most appropriate area, i.e. the region where on the radiograph the malignant characteristics of the process are most distinctive. Only in this way can the pathologist be sure of examining a piece of tissue which represents the true nature of the tumour. This is especially important in osteosarcomas where the histologic diagnosis can be extremely difficult and even impossible when the biopsy contains only the periphery of the tumour. For that reason the biopsy should include the medulla, cortex and the surrounding soft tissue parts.

In our material 10 fibrosarcomatous and 6 telangiectatic types were found.

Radiography

As to the radiographic appearance a classification was made. We distinguish the following types:

1. a mixed osteolytic–sclerotic type (103 cases = 59%);
2. a predominantly focal sclerotic type (26 cases = 15%);
3. a predominantly osteolytic type (29 cases = 16%);
4. a cystic (7 cases) and
5. a periosteal type (10 cases).

The last two types are rare. The periosteal type was introduced by von Ronnen [5]. It is mainly characterized by spicules and with little or no changes at all in the underlying medulla. Type 1 represents the classical type and is seen in more than 50% of our cases.

In most tumours the cortical borders were completely or partially destroyed.

Periosteal changes (spicules, lamellar deposits of bone, local thickening and Codman's triangles) together with tumourous calcium deposits in the surrounding soft tissues were considered as one entity i.e. the extra-cortical reactions. These reactions lead to a great variety of radiographic characteristics, which may sometimes show very complex structures. Spicules were most often seen. Codman's triangles were apparently related to age: the older the patient the less frequently they appeared.

In our series a correct X-ray diagnosis by experienced radiologists could be made in about 2/3 of all cases. This is also mentioned in other series [6–8]. The following diagnoses were made by the radiologists of the NBTR:

X-ray diagnosis	No.	Percentage
"typical" osteosarcoma	124	70
malignant tumour, probably osteosarcoma	27	15
other malignant bone tumour	23	13
malignant bone tumour (unspecified)	2	2
Total	176	100

The differential diagnosis gave the greatest problems in cystic types of tumour, especially since the process in such cases was often initially considered as a benign one.

In our series arteriography was rarely performed. In these cases it did not provide further information concerning the malignant character of the process.

Tumour volume

In regard to the tumour size we calculated the volume roughly as follows. The process was assumed to have a cylindrical shape, the depth of which corresponded with the maximal length on the radiograph. The radius of the cross section was the average value of the maximal and minimal width as measured on both radiographs. It was not possible to make such a determination of tumour size in every case (cases with microfilms only, tumours with indistinct borders or with a pathological fracture with dislocation etc.). Tumour volume could be determined in 150 cases, being considered as small when the volume did not exceed 100 cm^3 (63 cases = 42%) and large where a volume of 200 cm^3 or more was found (41 cases = 27%). The number of medium sized tumours (100–200 cm^3) was 46 (31%). Large tumours were especially found in the

femur, the smallest in the capitulum fibulae. As we mentioned earlier the relatively great number of large tumour volumina during and shortly after puberty was striking (50%, in contrast to 25% for patients older than 20 yr).

Symptomatology and clinical examination

The average duration of the interval between onset of symptoms and treatment was $3\frac{1}{2}$ months. In 65% (111 patients) therapy was started within 3 months. Especially in the very young children symptoms were as a rule present for a few weeks only. In 23 patients first treatment was inadequate because the process was at first considered to be a benign condition such as osteomyelitis, arthritis or a cyst. No correlation between tumour size and duration of symptoms was found. Trauma was mentioned with 51 patients (28%).

The symptoms most often seen were pain and swelling. In only a few cases swelling preceded the pain. Pain was absent from 21 patients. Physical examination revealed the following findings:

1. swelling of the bone and/or soft tissues which usually was tender;
2. discoloration of the skin, sometimes with hypervascularization;
3. impairment of the normal function of the joint, sometimes with contracture;
4. muscular atrophy, especially of the thigh in cases of a location near the knee;
5. paresis of the peroneal nerve in tumours occurring in the proximal end of the fibula.

The blood sedimentation rate before biopsy was performed in 99 patients. In 29 cases only elevated values were found. In 95 patients the blood alkaline phosphatase was determined before treatment. In only 26 of these 95 cases was the determination repeated at regular intervals during and after treatment. It was found that in 52 patients (54%) the initial values were increased i.e. exceeding the values regarded in the particular hospital laboratory as normal for the age of the patient. In regard to tumour volume we found a positive correlation between increased alkaline phosphatase levels and tumour volume (Table 1), which indicates that in osteosarcoma quantitative factors may be of greater influence on the alkaline phosphatase activity than qualitative characteristics of the tumour. In all cases an increase of the alkaline phosphatase during follow-up was associated with a rapid clinical manifestation of pulmonary metastases, although there was in some cases local tumour activity after radiotherapy as well. In 10 patients a pathological fracture, most frequently in the humerus, was found before a final diagnosis was made. Telangiectatic tumours which clinically were characterized by hypervascularization with redness and elevated temperature of the overlying skin, lead in some cases to the erroneous diagnosis of an osteomyelitis.

Metastatic patterns

The main factor in the course of the disease is the occurrence of pulmonary metastases. In our series these metastases occurred in over 78% of patients. During a follow-up period of more than 3 yr only 38 of 176 patients (22%) remained free from pulmonary metastases. In 5 cases (3%) these metastases were already present at the time of diagnosis.

The median time for a clinical metastases-free interval was 8 months from the start of treatment. In our series 40% of all patients developed lung metastases within 6 months and 60% within one year (Fig. 4).

In 86 chest X-rays, which showed the metastases for the first time the location was found to be unilateral in more than 50%. In most cases the number of these metastases was initially limited. In 13 patients tumourspread to the lungs was multiple and diffuse from the beginning.

Most metastases were dense with rather sharp borders, the configuration being round or oval.

Table 1. Correlation tumour volume and alkaline phosphatase

Alkaline phosphatase	Tumour volume					
	< 100 cc		100–200 cc		> 200 cc	
	No.	%	No.	%	No.	%
Increased	15	42	12	54	17	71
Normal	21	58	10	46	7	29
Total	36	100	22	100	24	100

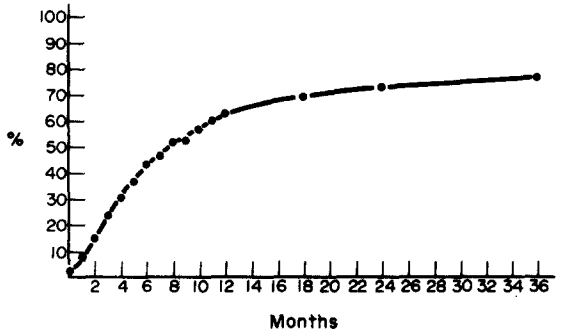

Fig. 4. The cumulative frequency of pulmonary metastases in 176 patients.

Calcification of metastases may occur, sometimes at an early stage, combined with a decrease in growth rate or even arrest of growth. Such a phenomenon was seen in 10 cases. Calcification of miliary metastases was observed in 5 out of 6 of these cases within 4 months. In general, calcification of solitary secondaries occurred at a later stage, although always within 10 months. Except in one of the 10 patients all cases presented a tumour which was radiologically of a sclerotic type. In the beginning pulmonary metastases produce few symptoms, but may be suspected where cough, fever and dyspnoe occur. Haemoptysis is rare. Cytology of the sputum is usually tumour negative. In exceptional cases a superior vena cava obstruction or intercostal neuralgia was found. We saw 3 cases with a hyperplastic osteoarthritis. Pleurisy usually is a terminal complication. A pneumothorax is not uncommon (12 cases). In one patient mediastinal emphysema developed a few days before death.

In 26 patients it was possible to measure the increase in diameter of 49 lung metastases after a known interval. Measurements were performed as described by Collins [9] and Breur [10]. Plotting the logarithm of the diameter as a function of time on a linear scale the growth curves obtained corresponded with a straight line. Based on this line we calculated the volume doubling time (T_d) of each metastasis separately.

Apparently these secondaries have a constant rate of growth during the stage of their clinical development. Variations between the growth rate are shown in Table 2. The mean doubling time was 38 days. Except for a few cases measurements in the same patient did not result in significant differences of the T_d. Survival time after the diagnosis of pulmonary metastases decreased with increasing growth rates (Table 3). In all cases extrapolation of the growth curves lead to the conclusion that these metastases existed already at the moment that treatment was started. Data on 8 pulmonary metastases in 5 patients during and after radiotherapy of these foci gave evidence of an exponential decreasing curve, the gradient of which was steeper than the original growth curve before treatment. In one case spontaneous disappearance of one metastasis also occurred after a period of exponential decrease. The frequency of osseous metastases was about 13% (24 out of 176 cases).

Three patients with skeletal metastases died without clinically detectable lung metastases. In 7 of 21 patients the detection of the skeletal and pulmonary metastases took place at the same time. In 2 patients the osseous metastases manifested themselves one to two months before the detection of the pulmonary secondaries. In 14 cases however, pulmonary metastases were already present. As a rule the period between the detection of the pulmonary and skeletal metastases was relatively

Table 2. Doubling times in days of 49 pulmonary metastases in 26 patients

	10–20	20–40	40–80	80–160	>160
Number of metastases	5	19	22	2	1

Table 3. Doubling time of pulmonary metastases and survival

Doubling time in days	No. patients	Mean survival in months	Median survival in months
0–20	2	8	—
20–40	12	14.6	12
40–80	10	18.9	16.5
>80	2	43	—

short (up to 2 months). The radiological aspect of the osseous metastases was identical to that of the primary tumour.

Clinical symptoms of cerebral metastases developed in 8 patients. Histologic confirmation was possible in 3 cases. All these patients succumbed within 2 months.

Other locations of tumour spread in our series were the subcutaneous tissue (3 cases), kidneys and peritoneal cavity (6 cases).

The literature as well as our own data give unsatisfactory information on the frequency of metastatic involvement of the regional lymph nodes. Most publications mention percentages based on post-mortems and on examination of surgical specimens. Systematic lymphography in osteosarcomas points to a relatively high incidence of lymphatic involvement as compared to other malignant bone tumours [11]. In our material metastatic lymph nodes were found on physical examination in 8 cases only.

Treatment

From 1954 until 1974 the NBTR has advised, as the treatment of choice, primary radiotherapy followed where indicated by ablative surgery at a later time, following the same line of reasoning as advocated by Cade [12]. In accordance with this policy the therapeutic measures taken were as follows.

1. After histologic confirmation of the diagnosis the tumour was irradiated to a tumour dose of 6000–7000 rad in 5–6 weeks (128 cases);
2. Ablative surgery was only performed when after an observation period of 4–6 months no clinical evidence of metastases was found (65 cases).

In the absence of metastases immediate radical surgery was done in:

1. cases where according to histologic or radiographic criteria a more favourable prognosis was to be expected (fibrosarcomatous types, tumours with a low mitotic index, periosteal and cystic forms) (15 cases);
2. cases with a pathological fracture or with serious impairment of normal function or when the skin was infiltrated by the tumour; (7 cases);
3. cases in which for some time inadequate treatment had been given because a non-malignant condition was assumed to be present (3 cases).

The advice of the NBTR was followed by most of the clinicians. A few surgeons however, preferred amputation for all their cases (17 patients).

Table 4 gives a survey of the methods of treatment used in our cases. In 5 cases treatment of the primary tumour was palliative from the beginning since pulmonary metastases were already present at the time of the first examination. In one case the available data were incomplete. In 128 patients (75%) treatment was started with radiotherapy. In this group 65 amputations were performed after an observation period, as no metastases had occurred. 63 other patients developed pulmonary metastases within the post-irradiation observation period. In 9 cases a palliative amputation had to be done in spite of metastases. Primary amputation was performed in 42 patients. In accordance with other publications [13–15] microscopy of the amputated irradiated limbs showed viable tumour tissue in about two-thirds of the specimens. The palliative effect of radiotherapy on the local symptoms was variable and unpredictable. In a group of 80 patients with a well documented history during the first months after radiotherapy we found clinical evidence of recurrent tumour growth in more than 50% (43 cases). Especially in those patients where pulmonary metastases manifested themselves at an early stage, complete tumour remission was the less frequent, meaning that in cases where no curative ablative surgery

Table 4. Therapy of 170 patients with osteosarcoma

Therapy	No.	%
Radiotherapy only	54	32
Radiotherapy + ablative surgery (curative)	65	38
Radiotherapy + palliative amputation	9	5
Primary amputation	42	25
Total	170	100

was indicated the local response after irradiation was the less favourable. We estimate that at the time of death the tumour in non-operated cases was active in about 75%. In agreement with the experience of Jenkin [16] we conclude that preoperative irradiation has failed in its role of providing adequate local palliation.

RESULTS

Survival in both sexes is identical. The gradient of the survival curve is steepest between 4 and 12 months after starting treatment (Fig. 5). Within a year mortality in our series was about 40%. The 3- and 5 yr survival rates are 53/176 (30%) and 33/148 (22%) respectively.

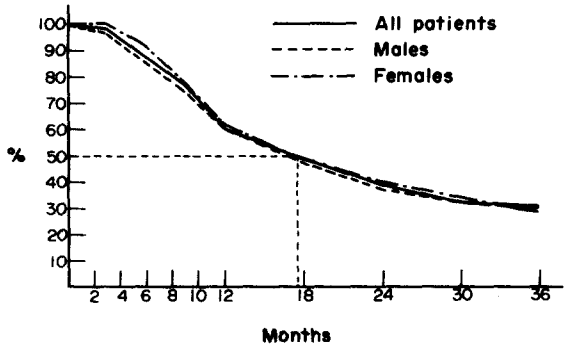

Fig. 5. Survival curves of 176 patients (111 males and 65 females).

Considerable differences in survival can only be shown for selected groups of patients. For instance, survival will greatly improve after primary radiotherapy when an amputation is performed after a metastases-free interval (Fig. 6). The results of a primary

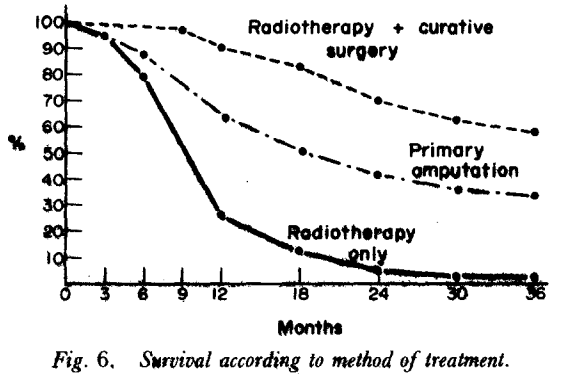

Fig. 6. Survival according to method of treatment.

amputation are influenced by selection of cases with favourable prognostic criteria.

In our series survival after primary radiotherapy in a group of 128 patients is as follows:

Primary radiotherapy		
	3-yr-survival	5-yr survival
Total series	39/128 = 30%	23/105 = 22%
Radiotherapy only	2/63 = 3%	1/49 = 2%
Radiotherapy + planned delayed amputation	37/65 = 57%	22/56 = 39%

From these results it becomes clear that radiotherapy followed by operation after an observation period results in a selection of patients for which prognosis is significantly more favourable. The survival rates after primary ablative surgery are:

Primary surgery		
	3-yr survival	5-yr survival
Total series	14/42 = 33%	10/38 = 26%
Patients with favourable prognostic criteria	8/15 = 53%	6/12 = 50%
Other cases	6/27 = 22%	4/26 = 15%

In these 42 patients differences in indication for treatment have also lead to differences in therapeutic results.

Prognosis

No differences in prognosis were found as to age, sex and tumour site. For patients with a histologic fibrosarcomatous type of tumour, as described by van der Heul [4], prognosis was more favourable. Six of 10 cases with such a tumour are alive, more than 5 yr after the beginning of treatment. A low number of mitoses, i.e. 1–2 mitoses as seen in more than one microscopic field, magnification 500–700 ×, also corresponded with a better prognosis. For these patients a 3-yr survival of 52% and a 5-yr rate of 33% were found. For that reason the advice of the NBTR to perform a direct amputation has retrospectively been justified. The volume of the tumour appeared to have no relation with prognosis.

In accordance with the opinion of von Ronnen [5] the radiological cystic and periosteal types have a more favourable prognosis. In 4 of 7 cystic types, however, the number of mitoses was also low. Furthermore 2 of these 4 tumours could be classified as

fibrosarcomatous as well. The 5-yr survival rates of the cystic and periosteal types are 6/7 and 4/10 respectively. Calculation of the survival rates for tumours classified according to various amounts of spicules and lamellar periosteal bone deposits showed surprisingly a positive correlation with prognosis. We started from the observation that a large number of patients with a survival of 5 yr and more had suffered from a primary tumour with relatively many periosteal spicules and/or lamellar bone deposits.

The percentage of these periosteal reactions was calculated as follows. On the a.p. and lateral radiograph of the tumour we measured along every border separately the total length (l_i) of the spicules and lamellar deposits as well as the total length (L_i) of all visible extra-cortical reactions. All l-values were added up, divided by the sum of all L-values and multiplied by 100. Figure 7 gives an imaginary example.

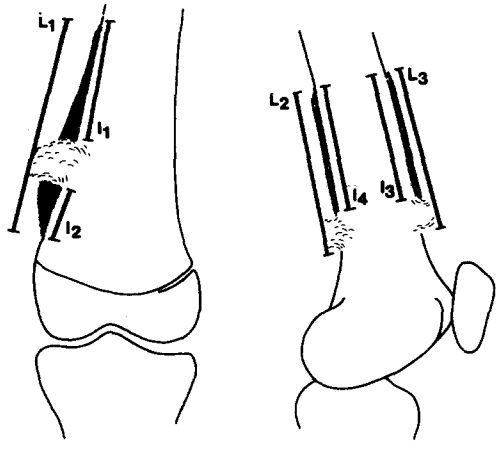

Fig. 7. Calculation of percentage spicules and lamellar bone deposits in relation to the tumour surface (see text). Percentage is:

$$\frac{l_1+l_2+l_3+l_4}{L_1+L_2+L_3} \times 100.$$

Based upon the percentage spicules and lamellar deposits a classification into 4 groups was made (Table 5). As can be seen prognosis improves in proportion to the increase of the amount of spicules and lamellar deposits.

Table 5. Survival related to the amount of spicules and/or lamellar periosteal bone deposits

Percentage	3-yr survival		5-yr survival	
	No.	%	No.	%
Till 25%	5/33	15	3/32	9
25–50%	7/19	37	3/17	18
50–100%	13/30	43	9/22	40
100%	10/15	66	8/13	61

Differences in survival rate proved to be statistically significant.

These findings may be explained by differences in the rate of growth as an exponent of the grade of malignancy of the process. Rapidly growing tumours prevent periosteal formations with a more or less regular structure. This hypothesis is supported by the observation that in some cases the rate of growth of the tumour is slowed down by radiotherapy in such a way that spicules occur in an area where those structures originally were absent. We propose to refer to tumours covered for more than 50% with spicules and/or lamellar bone as "structural tumours".

In our series this relates to 45 patients (25% of the total group). From what has been said in regard to prognosis it follows that primary treatment for these structural tumours should be primary ablative surgery.

Naturally survival is determined to a great extent by the interval between start of treatment and appearance of the first pulmonary metastases

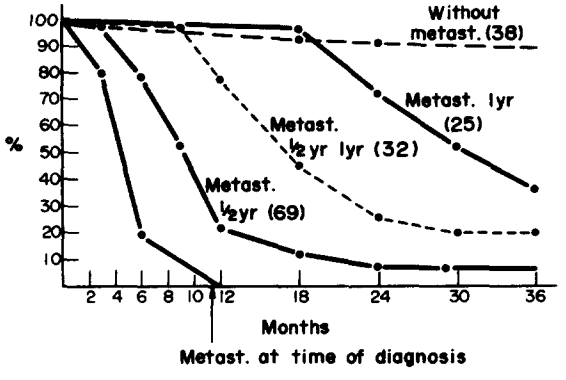

Fig. 8. Correlation 3-yr survival rate and time of detection of lung metastases. Note differences in steepness of curves.

(Fig. 8). We want to point out that the longer the metastases-free interval the less steep the survival curves. The course of the disease during the stage of lung metastases is prolonged in proportion to the later manifestation of these metastases.

DISCUSSION

From what has gone before it appeared (as was also shown by other authors) that some histologic and radiographic criteria often go together with a more favourable prognosis. We found that this also holds true for a new criterion, i.e. the structural tumours as was discussed earlier. In many cases however, there is a combination of different criteria, leading to a considerable overlapping of such prognostic features. Further analysis has lead

us to a classification into two groups. The first group is made up of tumours with one or more histologic and/or radiographic criteria correlated with better prognosis. This group composes in our series 69 patients.

The second group is formed by 106 patients suffering from osteosarcomas without such criteria. The 3-yr survival rate of group I is 52%, whilst that of group II is only 18%. Group I was subdivided into smaller units which show the 3-yr survival for the various prognostic features separately (Fig. 9). As was described

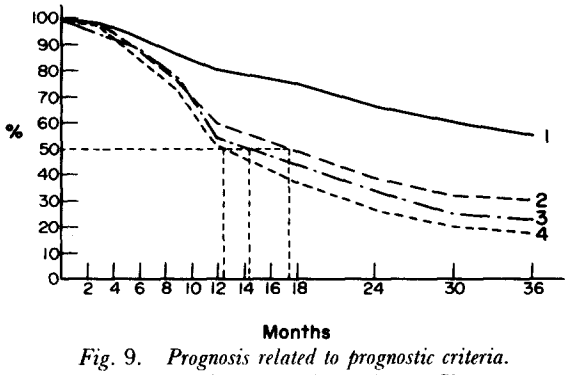

Fig. 9. Prognosis related to prognostic criteria.
1. 56 *patients with structural, cystic or fibrosarcomatous tumours;*
2. *all* 176 *patients;*
3. 52 *patients with tumours characterized by spicules and lamellar bone less than* 50% *of the total tumour surface;*
4. 129 *patients without prognostically favourable characteristics.*

previously, in the majority of cases treatment was started by radiotherapy. Taking into account the differences in indication for the various treatment schedules, the type of treatment, as long as aimed to be "radical", had no influence on prognosis.

Our own experiences and some new developments however, have caused doubts on the effectiveness of preoperative radiotherapy as the treatment of choice. First of all the "Cade" principle of radiotherapy and a post-irradiation observation period had been chosen to save the emotional stress of an amputation for about 75% of all patients in which ablative surgery does not add to the chance of a complete cure. All emotional and psychologic aspects of radiotherapy as a means of selection of patients where amputation is indictated at a later time are practically unknown until now. Furthermore the palliative local response of irradiation has proved itself insufficient in many cases. Jenkin [16] came to exactly the same conclusion, whereas Cade [12] pointed to the fact that amputation after radiotherapy was performed mainly for palliative reasons in 44 of 76 patients. The need for a delay of the amputation is far less for the group of patients with a prognostically more favourable tumour. In our series classification into structural tumours has enlarged the indication of a primary amputation to 32%.

Finally the results of elective irradiation of the lungs [17] and prophylactic chemotherapy [18–20] have also given a new dimension to a less fatal outcome of this tumour process. These elective treatments seem to be able to reduce the clinical manifestation of metastases considerably (about half of the total group). This will also diminish the urgency for a selection through an observation period.

As to the osseous metastases the curve representing the cumulative percentage in relation to the interval in months after treatment (Fig. 10) is practically identical to a

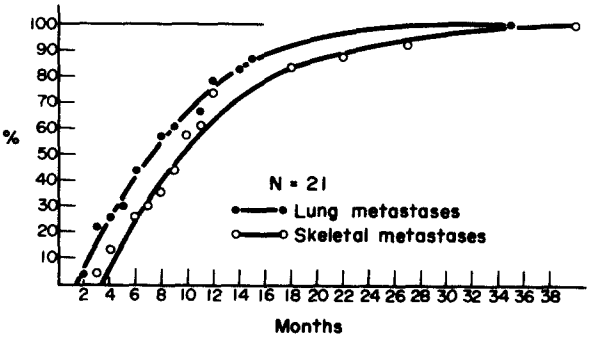

Fig. 10. The cumulative frequency of lung and skeletal metastases.

similar curve of the pulmonary metastases with a relative shift of about 2 months. This may suggest that most of the osseous metastases are true secondaries, similar to the lung metastases. The average short period between the clinical detection of the pulmonary and osseous metastases makes it very unlikely that a longer survival by prophylactic treatment will increase the number of patients in which osseous metastases will become manifest.

For cases where primary radiotherapy still remains indicated the possibilities of new radiation techniques should be examined such as fast heavy particles and combinations with hypoxic sensitizers.

In short we have come to the following therapeutic scheme for peripheral osteosarcomas which has been followed by the NBTR since 1975.

1. Ablative surgery for the primary tumour followed by elective treatment (irradiation of the lungs or chemotherapy) in all cases without detectable metastases. In particular radical surgery is strongly indicated for tumours fulfilling prognostic favourable criteria or in cases with a pathological fracture or

serious malfunction of the extremity. 2. Initial irradiation with a high dose of the primary tumour has to be considered in cases where amputation is refused. Elective treatment should also be considered. A proposition for amputation should be repeated afterwards. 3. For patients with metastases a combined treatment of radiotherapy and chemotherapy should be given.

All patients whose condition requires ablative surgery should be given expert guidance from the moment he comes in for treatment until he has mentally and physically adapted himself to his handicap. This is a subject which urgently requires further study. We are of the opinion that for an optimal care patients with osteosarcomas should be treated in oncological centres.

Effects of Antimitotic Agents Bound to a Macromolecular Carrier in Normal or Cancer Cells. Importance of the Mode of Binding of the Agent to the Carrier*

E. HEINEN,† R. BASSLEER†§ and CL. DESAIVE‡

†*Institut d'Histologie and* ‡*Institut de Pathologie, Université de Liège, 4020 Liège, Belgium*

Abstract—*Normal or cancer cells have been treated* in vitro *or in the animal with* cis-*dichloro-diammine platinum (II)* (cis-*Pt*), *a potent antimitotic agent. When the latter is covalently linked to a macromolecular carrier (DNA), or even to a mononucleoside (guanosine or adenosine) it loses its antimitotic activity. On the contrary, in the case of ethidium bromide (EB), another antimitotic agent, the cytotoxicity for tumour cells is maintained or even enhanced after binding (by intercalation) to DNA.*

INTRODUCTION

THE ANTITUMOUR efficiency of a chemical agent can be enhanced when it is bound to a macromolecular carrier. Trouet *et al.* [1, 2] have treated with success, murine or human leukemias with daunorubicin or adriamycin bound to high molecular weight DNA. We have demonstrated that ethidium bromide (EB) bound to DNA is more cytotoxic to Ehrlich ascites tumour cells than free EB [3, 4]. It is well known [1–4] that the complex antimitotic agent-macromolecular vector is absorbed by the cells; the agent is then released from the vector, which is digested by lysosomal enzymes, and diffuses in the cell. Cells with a high endocytic activity can absorb such complexes; various tumour cells do so. During this "lysosomal therapy", normal cells with low endocytic activity can be somewhat "protected" against the antimitotic agent. For example, EB–DNA added to the culture medium of chick fibroblasts provokes less cytological alterations than free EB does [5].

The mode of binding of the agent to the carrier is of great importance. The complex antimitotic agent-carrier must be stable in the extracellular medium but the agent must be liberated inside the cells. Up to now, daunomycin, adriamycin and ethidium bromide have been used after binding to DNA. These agents bind to DNA by intercalation between adjacent base pairs. This binding is stable in the extracellular medium but can be destroyed in the cells [1, 5]. We thought it was interesting to treat cells with a complex in which the cytotoxic agent is bound to DNA, not by intercalation, but covalently. We have chosen *cis*-dichlorodiammine platinum (II) (*cis*-Pt), discovered by Rosenberg and coll. [6]. This agent covalently binds to guanine bases [7]. *Cis*-Pt has a strong antimitotic activity in normal or cancer cells [8–11]. In the present study, we have treated normal or tumour cells with *cis*-Pt bound to DNA or to a nucleoside (guanosine or adenosine).

MATERIALS AND METHODS

Chick fibroblasts freshly prepared from embryos were cultivated in plastic Falcon dishes, in a liquid medium: 90% Eagle's minimum

medium, 10% foetal calf serum and 100 U penicillin per ml.

Mouse peritoneal macrophages were collected from the peritoneal cavity of C57 Bl. mice by washing with an isotonic Hanks' solution and then cultivated (in Falcon dishes) in a liquid medium: 45% NCTC 109 medium, 50% Hanks' solution, 5% foetal calf serum and 100 U penicillin per ml.

Ehrlich ascites tumour cells (tetraploid line) were collected from C57 Bl. mice bearing the tumour. The cells were then cultivated (in Falcon dishes) in a liquid medium: 45% NCTC 109 medium, 45% Hanks' solution, 10% foetal calf serum and 100 U penicillin per ml. The culture medium was renewed every 24 hr in order to maintain active cell proliferation.

Treatment by cis-*Pt*. *Cis*-Pt, free or bound to DNA, guanosine or adenosine was added to the culture medium at the final concentration of 5 μg/ml or injected into the peritoneal cavity of mice bearing Ehrlich tumour cells at the doses of 4.5 mg/kg fresh weight.

Preparation of the complexes. *Cis*-dichlorodiammine platinum (II) (Polysciences Inc.; NSC 119875; 200 μg/ml) was mixed with DNA (Sigma, PM $\pm 10^6$, calf thymus, 1 mg/ml in $NaClO_4$ 0.01 M) and NaCl (0.1 mM) at 37°C and in darkness. The reaction lasted 20 hr; only 2% *cis*-Pt or less remain free. Thereafter NaCl concentration was increased up to 0.1 M. The ratio of *cis*-Pt to DNA was of 0.20 to 0.25.

Cis-Pt-nucleoside complexes were prepared in a similar way: 200 μg *cis*-Pt per ml were mixed with guanosine (Schwartz Laboratories: 378 μg/ml) or adenosine (Schwartz Laboratories: 534 μg/ml).

The mitotic activity was estimated by calculating the mitotic index (number of mitotic cells for 1000 cells). In each case, 2000–3000 cells have been observed.

The number and the volume of the Ehrlich tumour cells was calculated with an electronic Coulter counter (Model B).

The DNA content was measured in individual cells by absorption cytophotometry after Feulgen reaction (hydrolysis by HCl 3.5 N, 20 min at 37°C) with a GN2 scanning microdensitometer from Barr and Stroud, at 540 nm.

The total protein content was measured in individual cells by cytophotometry after naphtol yellow S staining with a GN2 microdensitometer from Barr and Stroud at 435 nm.

The incorporation of tritiated guanosine, free or linked to *cis*-Pt (specific activity: 10 μCi/mM; final concentration: 10 μCi/ml) was analysed by histoautoradiography. After 30 or 60 min of contact, the cells were rinsed in an isotonic saline solution and fixed with absolute ethanol/acetone (1/1). The liquid emulsion method was applied (L4 Ilford emulsion, Microdol X as developer).

Electron microscope observations. Cells were fixed with 2.5% glutaraldehyde and postfixed with osmium tetroxide (1%). Inclusion was performed in Epon 812. Ultrathin sections were contrasted with uranyl acetate and lead citrate. The ultrastructural observations were realized with a Siemens Elmiskop 101 at 80 kV.

RESULTS

Effects of free cis-*Pt*

As we have shown previously, when chick fibroblasts cultivated *in vitro* or Ehrlich ascites tumour cells cultivated *in vitro* or propagated in the mouse are treated with *cis*-Pt, nucleolar and chromatin alterations are observed. The mitotic activity is inhibited (Figs. 1 and 4) and many cells are blocked either in the G1 or the G2 phase of the cycle (Fig. 2) according to the concentration that is used. Moreover, *cis*-Pt can provoke a considerable increase of the cell volume, because RNA and protein synthesis remain active (Table 1). Many abnormal mitotic figures appear in the treated cells (for more details, see [10, 11]).

Table 1. *Mean protein content measured by cytophotometry after naphtol yellow S staining in* cis-*Pt* (4.5 mg/kg) *or* cis-*Pt-DNA* (cis-*Pt:* 4.5 mg/kg) *treated Ehrlich tumour cells and in controls* (NaCl:0.1 M *solution*)

Controls	45.16 ± 0.92
Cis-Pt	81.92 ± 1.59
Cis-Pt-DNA	44.92 ± 1.45

The cells have been collected 6 days after the intraperitoneal injection of the solution. These mean values are expressed in arbitrary units and have been calculated from results obtained for 50 cells in each case. The standard error is indicated.

Cis-Pt (5 μg/ml) provokes nearly no alterations in mouse peritoneal macrophages cultivated *in vitro*: their cytological structure remains normal and their endocytic activity is not diminished (see also [12]).

Effects of cis-*Pt bound to DNA*

(a) When chick embryo fibroblasts or Ehrlich tumour cells are cultivated in the

presence of *cis*-Pt-DNA complex (*cis*-Pt: 5 μg/ml), no cellular alterations can be detected, even after 3 days. The fibroblasts (Fig. 1) and the tumour cells keep a normal mitotic activity. Moreover, measurements of the DNA content performed in these treated cells (fibroblasts or tumour cells) show no differences as compared to control cells.

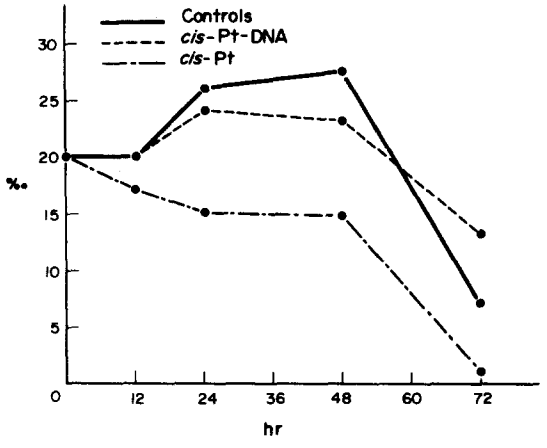

Fig. 1. Mitotic activity in cis-*Pt* (1 μg/ml) *or* cis-*Pt-DNA* (cis-*PT:* 1μg/ml) *treated fibroblasts cultivated* in vitro. *In abscissae: duration of the treatment; in ordinates: number of mitoses for* 1000 *cells.*

(b) Ehrlich ascites tumour cells were treated with *cis*-Pt-DNA (*cis*-Pt: 4.5 mg/kg) in the mouse peritoneal cavity. Their mitotic activity (index: 29–30‰) remains similar to that of the controls (24–35‰); their DNA content and their total protein content is not modified (Fig. 2 and Table 1). On the contrary, *cis*-Pt treated cells (4.5 mg/kg) are blocked in the G2 phase (Fig. 2) and their total protein content is strongly increased (Table 1). This is due to the fact that protein synthesis remains active whereas cell division no longer occurs.

(c) Mouse peritoneal macrophages treated *in vitro* with *cis*-Pt-DNA (*cis*-Pt: 5 μg/ml) have a normal morphology and are able to phagocyte latex particles at the same rate as the controls do, even after 72 hr of treatment.

After a treatment with *cis*-Pt-DNA, fibroblasts, macrophages and tumour cells contain cytoplasmic vacuoles filled with a dense material (electron microscope observations). These vacuoles are particularly numerous in macrophages treated *in vitro* with the complex (Fig. 3). We have shown with an electron microprobe that these vacuoles contain platinum. We think that these vacuoles (probably phagolysosomes) are filled with *cis*-Pt-DNA (see also [13]). *Cis*-Pt linked to DNA is thus absorbed by the cells but cannot exert any cytotoxic action.

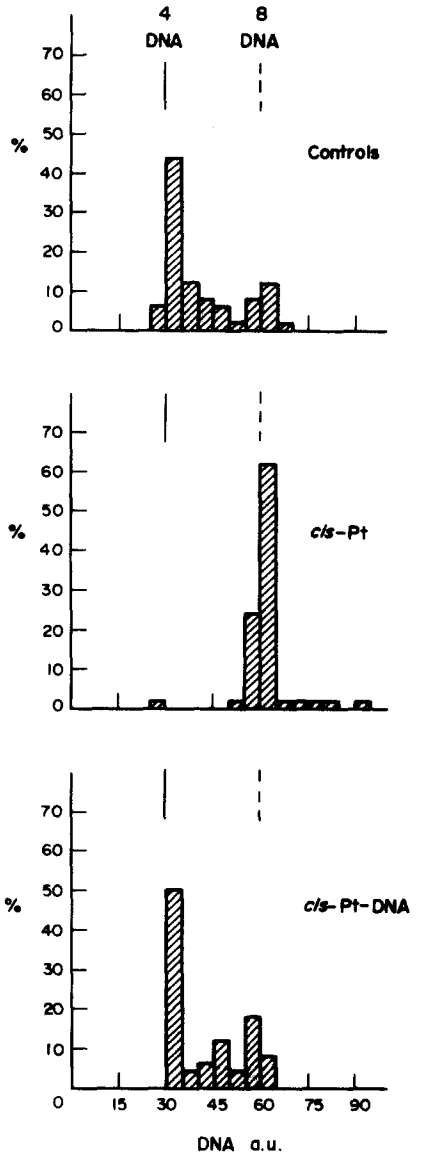

Fig. 2. DNA content measured by absorption cytophotometry in Ehrlich tumour cells treated with cis-*Pt* (4.5 mg/kg), *with* cis-*Pt-DNA* (cis-*Pt:* 4.5 mg/kg) *or with* 0.1 M NaCl (*controls*). *The tumour cells have been collected* 4 days *after the injection of the solution into the peritoneal cavity of mice bearing the tumour. In abscissae: DNA content in arbitrary units; in ordinates: percentages of cells in each class. Full lines at the top of the histograms indicate the mean DNA content measured in post-mitotic cells (tetraploid line); this value has been doubled (dotted lines).*

Effects of cis-*Pt bound to guanosine or to adenosine*

We have also treated cells (fibroblasts, macrophages or tumour cells) with *cis*-Pt bound to a mononucleoside (guanosine or adenosine). The aim of this experiment is to try to find out whether mononucleosides bound to *cis*-Pt which probably appear in the cell after depolymerisation of the complex *cis*-PT-DNA, are cytotoxic.

Tritiated guanosine bound to *cis*-Pt penetrates into cells (Ehrlich tumour cells and

macrophages): it can be detected by histoautoradiography in the cytoplasm and in the nucleus, mainly in the nucleoli.

When Ehrlich tumour cells are treated *in vitro* or *in vivo* with *cis*-Pt bound to guanosine (5 μg *cis*-Pt/ml in the culture medium or 4.5 mg *cis*-Pt per kg, by intraperitoneal injection), no morphological cellular injuries are detected and cell multiplication is unaffected: the mitotic index remains normal and results of DNA measurements show no differences as compared to the controls. When *cis*-Pt (4.5 mg/kg) bound to adenosine is injected into the peritoneal cavity of mice bearing an Ehrlich ascites tumour, the number of tumour cells is decreased a little, 2 and 4 days after the injection (Fig. 4), but after 6 days, it is at the same level as in control mice. Adenosine alone has no effect, but free *cis*-Pt strongly inhibits cell multiplication.

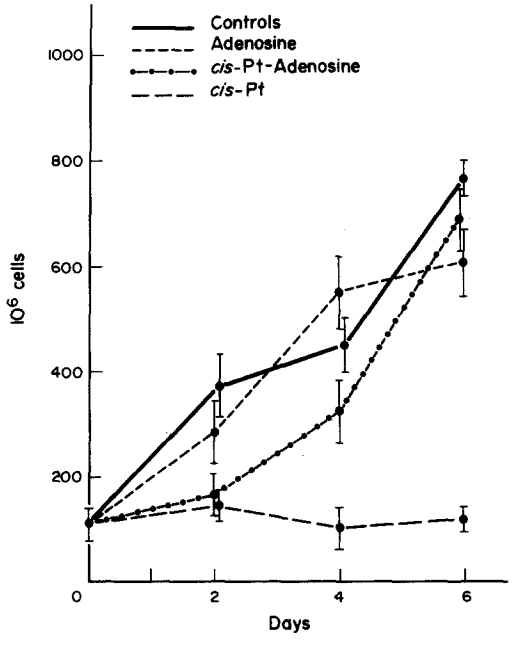

Fig. 4. Number of Ehrlich tumour cells, measured with an electronic Coulter counter, in mice treated with cis-*Pt* (4.5 mg/kg), cis-*Pt-adenosine* (cis-*Pt*: 4.5 mg/kg), *adenosine* (5.3 mg/kg) *or* 0.1 M NaCl (*controls*). *Each value is a mean calculated for* 8 *mice in each case. The standard error is indicated.*

DISCUSSION AND CONCLUSIONS

Cis-Pt is a cytotoxic agent, able to inhibit the mitotic activity and to kill cells [8–11]. In the present study, we show that, when cis-Pt is bound to DNA, it can penetrate into the cells (fibroblasts, macrophages, Ehrlich tumour cells) and accumulated inside cytoplasmic vacuoles, however this complex is nearly not cytotoxic. This loss of cytotoxicity seems to be related to the mode of linking of *cis*-Pt to DNA. In collaboration with C. Houssier and M. C. Gillet [14], we have demonstrated that lysosomal enzymes (extracted from rat liver), acid DNase and neutral DNase (deoxyribonuclease, Worthington) cannot liberate *cis*-Pt from DNA when the complex is incubated *in vitro* with these enzymes. The binding of *cis*-Pt to guanine base [7] is probably too strong. This interpretation is confirmed by our experiments concerning the effects of *cis*-Pt bound to nucleosides: when *cis*-Pt is bound to guanosine (this binding is very strong: the formation constant is about $10^9 M^{-1}$ [15]), no cytotoxic effects can be detected in the treated cells. However, this complex *cis*-Pt-guanosine penetrates into the cells, as we have shown by histoautoradiography. When *cis*-Pt is bound to adenosine (this binding is less strong than in the case of guanosine; the formation constant is about $10^5 M^{-1}$ [15]), some cytotoxic effects are observed; these could be due to some free *cis*-Pt present in the solution of the complex.

Other agents used after binding to DNA (adriamycin, daunorubicin, ethidium bromide, see Introduction) intercalate between base pairs in DNA; as soon as DNA is digested inside the cell, the drug is liberated. It seems that lysosomal hydrolases play an important role in this liberation [1]. We have demonstrated that ethidium bromide–DNA complex penetrates into the cells by endocytosis and accumulates in cytoplasmic vacuoles. EB is liberated and diffuses in the cell, reaching the nucleus and the mitochondria [5]. But the mode of binding of the agent to the vector is not the unique important factor. The cells must be able to endocyte actively the complex and to digest the carrier. In fact, in cells with a low endocytic activity, the free drug may act more intensively than the same drug bound to a carrier. We have observed this fact in chick fibroblasts cultivated in the presence of ethidium bromide [5]. In general, tumour cells have a relatively high endocytic activity; this can explain why daunomycin, adriamycin or ethidium bromide when bound to DNA are very cytotoxic for these cells [1, 2, 4]. But cells of the histiocytic system also have a very high endocytic activity and can thus absorb a great quantity of such complexes. Our observations related to ethidium bromide–DNA treated mouse peritoneal macrophages have in fact shown that these cells are very sensitive to this treatment [12].

The different clearance pattern between

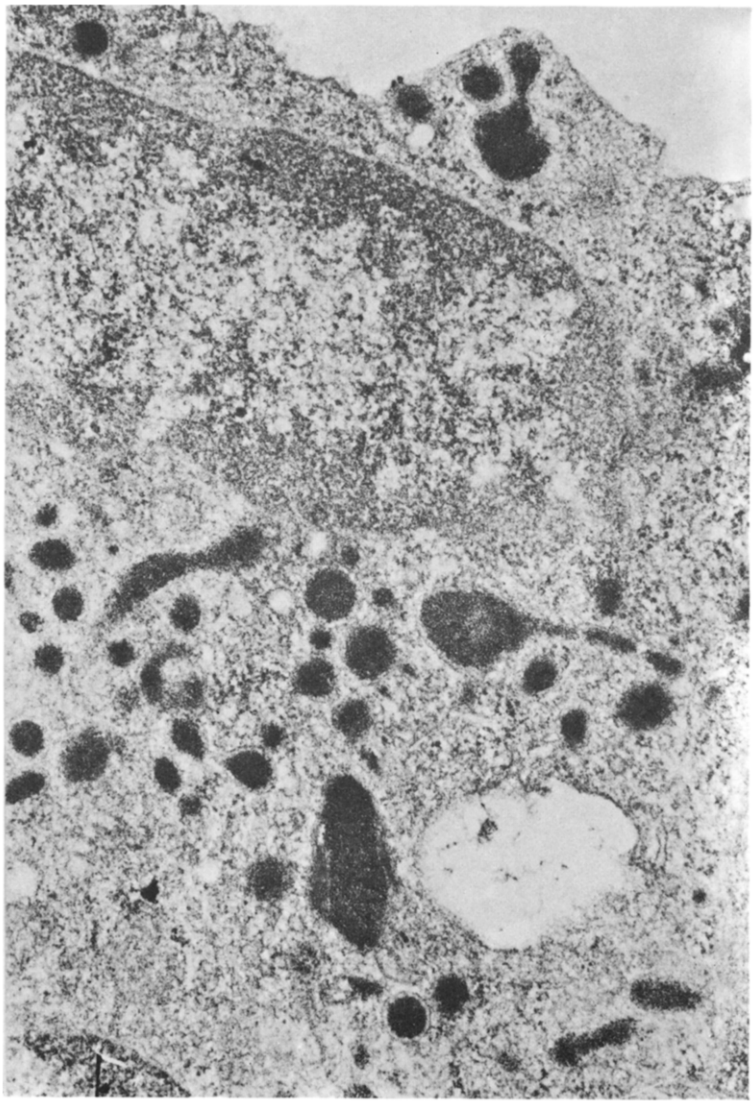

Fig. 3. Portion of a mouse peritoneal macrophage cultivated in vitro *for* 72 hr *in the presence of* cis-*Pt-DNA* (cis-*Pt:* 5 μg/ml). *In the cytoplasm, several vacuoles containing an electron dense material are visible* (*magn.* 33,000 ×).

free or bound drugs is another factor which has to be considered. In a previous study [4], we have demonstrated that EB bound to DNA persists after intraperitoneal infection for a longer time in the peritoneal cavity than free EB does. The ascites tumour cells are thus in contact for a longer period. This has been confirmed by fluorescence microscopy observations showing that EB–DNA treated tumour cells remain fluorescent during more hours than free EB treated tumour cells do [4]. Rozencweig *et al.* [16] drew similar conclusions concerning adriamycin and DNA–adriamycin complex injected to patients or mice, with regard to initial plasma levels and patterns of clearance from the plasma.

Abstract—*High dose methotrexate (MTX) therapy with leucovorin rescue is now frequently used in cancer chemotherapy especially in the adjuvant treatment of osteogenic sarcoma. Due to the large quantities of MTX required the cost of this therapy has limited its use in many European oncology centers. Since as much as* 90% *of the MTX dose is excreted largely unmetabolized in the urine during the first* 24 hr *following administration, the possibility of the recovery of the drug for re-use was investigated. From the urine of patients having received* 10–18 g *MTX, at least* 50% *of the initial dose was recovered for clinical re-utilization. MTX was purified from urine primarily by acid precipitation. Calcium phosphate treatment and ultrafiltration in the purification procedure were used for the removal of pyrogens. The urine-derived drug preparation was* 90–95% *MTX based on absorbance at* 260 nm *after fractionation on DEAE cellulose and contained impurities with spectral properties characteristic of pteridine compounds as found in the commercial drug. Most of the impurities detected in the recovered MTX were similar to those in the commercial drug with respect to chromatographic behavior and ultraviolet spectrum. Three new impurities detected in the recovered drug appeared to include the 7-hydroxy-metabolite of MTX. Uric acid was also present as a contaminant at a level of approximately* 1%. *Urine-derived MTX inhibited dihydrofolate reductase* in vitro *and was effective in tumor-bearing mice to a degree equivalent to commercial MTX. Two patients were treated with MTX isolated from urine resulting in favorable antitumor response and no adverse reaction.*

INTRODUCTION

MTX, 4-amino-4-deoxy-N^{10}-methylpteroyl-glutamate, is a folate antagonist that has been widely used in the chemotherapeutic treatment of a variety of neoplastic diseases [1]. More recently, high dose MTX followed by leucovorin rescue has been used successfully in combination with other antineoplastic agents in the treatment of osteogenic sarcoma [2–5]. Increasing interest in high dose MTX therapy will no doubt result in a markedly greater demand for this drug. High doses of 50–300 mg/kg could require as much as 25 g MTX per dose. The need for such large quantities of MTX presents an economic problem for many European countries hindering the use of high dose therapy. For this reason the present study was undertaken to determine the feasibility of the isolation of MTX from the urine of treated patients for re-use.

Pharmacokinetic studies of MTX administered in 6-hr infusions at high doses and followed by leucovorin rescue have been reported [3, 6, 7]. Following infusion MTX is rapidly cleared from the plasma with an initial half-life of 2–3 hr and is largely excreted in the urine. Although earlier studies on the metabolism of MTX in man at conventional low doses revealed only trace amounts of MTX metabolites [8, 9], a recent report by Jacobs *et al.* [10] has shown 7-hydroxy-MTX to be a significant urinary metabolite in patients receiving high doses. However, the level

Accepted 6 December 1977.

‡Reprint requests to: Dr. A. Layva, Oncology Unit, Department of Internal Medicine, University Hospital, Utrecht, The Netherlands.

of the 7-hydroxy-metabolite was still found to be 10% or less of the excreted MTX.

The present study describes a relatively easy and efficient procedure for the recovery of MTX from the urine of patients after receiving high doses. Evidence is presented that recovered MTX is chemically similar to and has the same therapeutic effectiveness as the initially administered commercial drug.

MATERIALS AND METHODS

Chemicals

The MTX reference standard (Lot no. 55192) and pharmaceutical MTX in 1 g vials were both products of Lederle Laboratories, Pearl River, New York and were supplied by the Drug Development Branch, Drug Research and Development, National Cancer Institute, Bethesda, Maryland. Leucovorin (5-formyltetrahydrofolate; calcium salt) was purchased and N^{10}-methylpteroylglutamic acid was obtained as a gift from Lederle Laboratories. All other chemicals were of the highest commercial grade available.

Source of recovered MTX

Five patients, 3 males and 2 females, ranging in age from 18 to 42 yr, were treated for osteogenic sarcoma with a chemotherapy regimen alternating vincristine-high dose MTX, cyclophosphamide and adriamycin [5]. The treatment schedule was as follows: day 1, vincristine, 1.5 mg/m^2 i.v.; day 2, MTX, 200 mg/kg in a 4-hr infusion (preceded by the administration of sodium bicarbonate to maintain urinary pH between 7 and 8.5) followed by leucovorin rescue, 9 mg every 6 hr for 3 days; day 15, cyclophosphamide, 40–60 mg/kg i.v.; day 28, adriamycin, 1.5 mg/kg i.v.; day 42, cyclophosphamide 40–60 mg/kg i.v.; day 56, cycle repeated. No other drugs were given during the vincristine-MTX administration.

Isolation of MTX from urine

MTX was purified from urine collected for 24 hr from patients after the commencement of a 4-hr infusion of 10–18 g MTX (200 mg/kg). The urine was collected in glass containers and frozen until time of processing. The following steps were carried out under subdued light and at 4°C. The urine was first filtered through a Whatman GF/c glass fiber filter to remove particulate material. This was followed by ultrafiltration through a PM10 Diaflo membrane (Amicon Corporation, Lexington, Massachusetts) to remove high molecule weight material. The alkaline filtrate initial pH 8.0–8.3, was acidified with 3N HCl to pH 4 to precipitate MTX. The precipitate was collected by centrifugation at 2000 × *g* for 10 min and washed 3 times with 600 ml 10^{-3} N HCl. The MTX precipitate was redissolved in distilled water by the addition of 1 N NaOH. The MTX concentration was at least 5 mM at pH 8.0. After filtration through a glass fiber filter to remove undissolved material, calcium phosphate (2 g/mmole MTX) was added while stirring and maintaining the pH at 8.0. After stirring for 2 hr the calcium phosphate was removed by glass fiber filtration and the filtrate was again passed through an ultrafiltration membrane as before. The calcium phosphate treatment and second ultrafiltration step were included for the removal of pyrogens (personal communication; Organon Nederland B.V., Oss, The Netherlands). MTX was again precipitated by the addition of HCl to pH4, washed with 10^{-4} N HCl followed by absolute ethanol and finally dried with nitrogen. The recovered MTX was further dried under vacuum in the presence of NaOH pellets and stored refrigerated with dessicant.

Chromatography

MTX preparations were analyzed for impurities by ion-exchange chromatography on a DEAE cellulose (DE-52, Whatman Ltd., Kent, England) column 0.9 × 28 cm [11]. The column was eluted with a linear gradient of 0.1–0.4 M ammonium bicarbonate, pH 8.3, at a flow rate of 2.0 ml/min. Gradient elution was preceded by a 30-min elution period with the low concentration buffer. The eluate was either monitored at 254 nm using an LKB Uvicord and recorder or collected in 3.1 ml fractions and the absorbance measured at 260 and 370 nm.

Spectrophotometry

Ultraviolet absorption spectra were performed on a Perkin–Elmer 124 recording spectrophotometer.

MTX assay

MTX levels were determined by either (a) ultraviolet absorbance at 370 nm in 0.1 N NaOH based on the molar absorptivity of 7.0×10^3 or (b) the enzyme-inhibition assay [12]. In the latter method the source of dihydrofolate reductase was *Lactobacillus casei* (New England Enzyme Center, Boston, Massachusetts) and the MTX standard was of Lot No. 55192 from Lederle Laboratories.

Test for pyrogens

MTX preparations were tested in rabbits for the presence of pyrogens according to the procedure and standards described by the *U.S. Pharmacopoeia* XIX [13]. Solutions of MTX, 30 mg/ml, in 4.3% sodium bicarbonate were first treated with activated asbestos (Seitz Werke GmbH, Bad Kreuznach, W. Germany), 5 g/l, and filter-sterilized using a 0.22 μm filter before injected in test animals at a dose of 200 mg/kg. Asbestos treatment immediately before sterilization was routinely used for the removal of traces of pyrogens in the preparation of solutions suitable for injection. Drug preparations were regarded as "pyrogen-free" according to U.S.P. standards if the maximum individual temperature increase was no greater than 0.6°C and the sum of the temperature increase per 3 rabbits was no greater than 1.4°C.

Evaluation of in vivo *antineoplastic activity*

The comparative antitumor effectiveness of commercial MTX and of drug preparations recovered from urine was evaluated against a series of murine leukemias. $CD2F_1$ mice of both sexes (20–22 g, obtained from Charles River Italy, Calco, Italy) were transplanted i.p. with 10^5 cells of the compatible L1210, P388 or L5178Y leukemias, whereas BALB/c hosts were used for the syngeneic Moloney virus-induced LSTRA lymphoma. Tumor cell viability was routinely checked microscopically by Trypan-blue dye exclusion and only preparations with 95% viability accepted. Graded doses of the compounds were administered i.p. in saline and their effectiveness expressed by the T/C% value, i.e. the ratio, expressed as per cent, of the median survival time (MST) of the treated over control group. Experimental groups consisted of at least 10 mice, each experiment was repeated 3 times and a gross autopsy was performed on each animal to confirm tumor presence at death. Statistical analysis was performed by Duncan's Test.

RESULTS

Isolation of MTX from urine

Urine collected from patients during 24 hr after the initiation of high dose MTX therapy contained 75–90% of the administered dose. Purification of MTX from urine by acid precipitation, calcium phosphate treatment and ultrafiltration yielded over 60% recovery of the drug present (Table 1). Following the initial filtration steps to remove particulate material and high molecular weight substances, a sample of urine was fractionated by DEAE cellulose chromatography and the eluate monitored at 254 nm. Figure 1 shows the elution profile of MTX before and after acid precipitation from urine. MTX eluted between 2.4 and 3 hr as the dominant peak. Several minor peaks were detected especially in the early part of the elution before MTX. After the urine was acidified and the MTX precipitate washed and redissolved, chromatographic analysis demonstrated that 4–5 peaks eluting during the first hour were largely removed (Fig. 1B). Subsequent steps in the purification procedure, calcium phosphate treatment and repeated ultrafiltration and acid precipitation, failed to remove the remaining ultraviolet-absorbing impurities since the chromatographic profile of the final MTX preparation was essentially unchanged. (Fig. 4).

Purity of recovered MTX

Ultraviolet spectral analysis indicated that recovered MTX was similar to commercially available MTX, both having identical absorption maxima at 258, 300 and 370 nm (Fig. 2). Absorption maxima for the Lederle product purified by DEAE cellulose chromatography were recorded at 258, 301 and 371 nm. Table 2 presents the molar absorptivities at the observed absorption maxima calculated on the basis of a molecular weight of 454. According to previously reported values for molar absorptivities of 23.0×10^3, 22.4×10^3 and 7.0×10^3 at the maxima 257, 302 and 360 nm, respectively [1], a degree of purity of

recovered MTX was estimated to be 89–101% compared to 86–97% for the commercial drug.

The biochemical activity of recovered MTX was quantitatively determined according to its inhibition of dihydrofolate reductase. A 5.0 mg/ml solution of recovered MTX was found to be 11.0 mM or 100% as active as the reference standard.

Commercially available MTX preparations for clinical use contain several impurities arising from the synthetic process or degradation, including N^{10}-methylpteroylglutamic acid and 4-amino-4-deoxy-N^{10}-methylpteroic acid [9, 11, 14–20]. Figure 3 illustrates the chromatographic fractionation of the Lederle drug used in the present study as the initially administered drug, demonstrating the presence of 7 peaks in addition to the MTX peak (peak 5). Absorption at 260 and 370 nm by 5 of the 7 non-MTX peaks (and by 6 of the peaks in 0.1 N NaOH, Table 3) indicated that most of these impurities had spectral properties characteristic of pteridine compounds. Based on relative peak area, peak 5, representing MTX, accounted for 94% of the absorbance at 260 nm. Peaks 3, 4 and 6 were the most significant impurities at 1.0, 1.9 and 2.4%, respectively. The sum of the areas of peaks 1, 2, 7 and 8 was approximately 0.5% of the total.

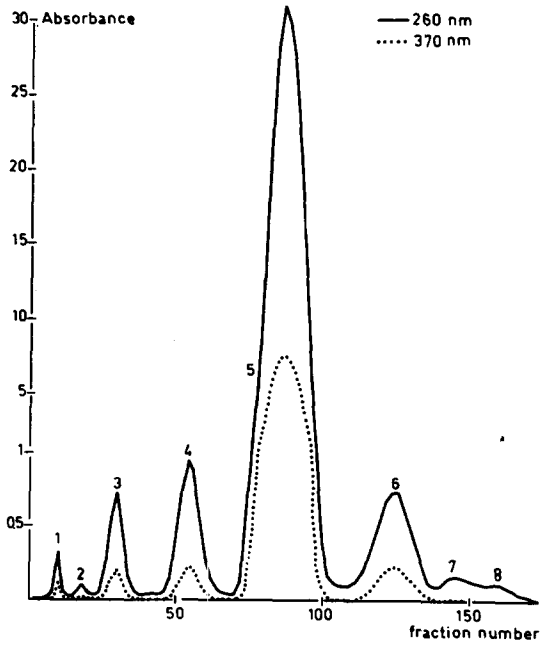

Fig. 3. DEAE cellulose chromatography of commercial MTX. 33 mg of Lederle MTX in 0.5 ml 0.1 M ammonium bicarbonate was chromatographed as noted in the text and 3.1 ml fractions were collected. Peaks were numbered according to order of elution.

Figure 4 illustrates the elution profile for a representative MTX sample purified from urine. The 7 impurities originally present in the commercial drug (Fig. 3) also appeared to be present in the recovered MTX preparation and were assigned the same numbers based on similarity in elution times. In addition, two new species were detected with different elution times and were assigned peak numbers 9 and 10. All impurity peaks demonstrated absorption at both 260 and 370 nm. Quantitation of peak areas at 260 nm indicated that the recovered drug was 93% MTX. Compared to the initial commercial product, peak 3 was increased (1.8%), peak 4 decreased (0.9%) and peak 6 decreased (1.6%). Peaks 1 and 2 were decreased but still detectable. Peaks 7 and 8 were increased, but could not be easily quantitated due to poor resolution. Regarding the new peaks observed,

				10	263	297	394

*Peak fractions were from the chromatographic separation in Figs. 3 and 4. Absorption spectra were determined after the addition of NaOH to a final concentration of 0.1 N.

peak 9 was just detectable, approximately 0.2%, and peak 10 was more notable at 1.4%. In other recovered MTX preparations from different patients, MTX as peak 5 represented 90–95% and peak 3 less than 4% of the total absorbance at 260 nm. Variation in the percentage of the other impurity peaks did not exceed ±0.5%, except for peak 10 which was in some samples less than 0.5%.

Peak fractions from the chromatographic fractionations of the initial commercial MTX and the recovered drug shown in Figs. 3 and 4 were characterized by ultraviolet spectrophotometry and their effect on dihydrofolate reductase activity. Table 3 lists the absorption maxima recorded between 230 and 450 nm. Chromatographic peaks 1, 4, 6 and 7 of recovered MTX corresponded to the respective peaks found in the commercial drug regarding both absorption maxima and the absorbance ratio at 260 and 300 nm (data not shown). Peak 2 of recovered MTX had similar absorption maxima but differed in the 260/300 ratio when compared to the corresponding peak of the commercial drug. The increased absorbance at 300 nm could have been due to overlapping by the larger peak 3. Peak 3 of recovered MTX differed largely from peak 3 of commercial MTX by a shift in absorption maxima from 302 to 295 nm and a decreased 260/300 ratio. Uric acid was found to co-elute with peak 3 providing an explanation for the spectral change due to the absorption maximum at 292 nm for uric acid. Furthermore, an assay of peak 3 for uric acid by the colorimetric phosphotungstic method indicated the presence of 0.2 mg uric acid per 25 mg of recovered MTX. A difference in spectral properties was found in peak 8 of recovered MTX compared to that of the initial commercial drug. There was an appearance of an absorption maximum at 302 nm which also resulted in a decreased 260/300 value. The absorption spectrum also demonstrated a shoulder at 340–350 nm and was similar to that of 7-hydroxy-MTX [20, 21]. Peaks 9 and 10, both unique for the recovered drug preparation, had spectral characteristics similar to MTX. However, peaks 9 and 10 differed from MTX having absorption maxima at 290 and 394, respectively.

Chromatographic peak fractions of both commercial and recovered MTX were examined for their effect on dihydrofolate reductase activity (Table 4). All fractions of either drug preparation demonstrated an inhibitory effect on enzyme activity which differed in degree. The assay system was routinely used to measure MTX levels in plasma at a maximum sensitivity of 10^{-9} M. Thus, the inhibitory effect on dihydrofolate reductase was expressed in MTX equivalents i.e. the equivalent concentration of MTX (reference standard used without further purification) required to produce the same degree of inhibition. Peak 5 exhibited 1600 and 1300 μM MTX equivalents for 33 mg of commercial drug and 25 mg of urine-derived drug, respectively. Peaks 3, 4 and 7 demonstrated 1.4–21 μM MTX equivalents or less than 2% relative to peak 5. Peak 3 was the most active in the inhibition of dihydrofolate reductase compared to the other impurities found in either drug preparation. Inhibition of enzyme activity by other impurity fractions was de-

tectable but estimated at less than 0.1% with respect to peak 5.

Removal of pyrogens

Table 5 shows the results of the effect of different purification procedures on the removal of pyrogens. The commercial MTX preparation produced a mean maximum temperature increase of 0.2°C, the highest recorded at 0.3°C. MTX recovered from urine by only acid precipitation produced a marked pyrogenic reaction with a mean increase in temperature at 2.1°C despite treatment with asbestos prior to testing. Calcium phosphate treatment was effective in reducing the pyrogenic reaction lowering the temperature increase to 1.2°C. The use of both calcium phosphate treatment and ultrafiltration did not result in the further removal of pyrogens

as indicated by the observed temperature increase of 1.2°C. The use of larger quantities of calcium phosphate to improve pyrogen removal was not examined due to a significant reduction in yield of MTX from urine. However, additional ultrafiltration steps, three in all including one immediately before preparation for injection, yielded a MTX solution which produced a mean temperature increase of 0.3°C with a range of 0.6°C meeting the U.S.P. standards for a pyrogen-free parenteral solution.

In vivo *antineoplastic activity of recovered MTX*

The effectiveness of recovered MTX was compared to the commercial drug in the treatment of mice inoculated with various leukemias. Three MTX preparations derived from urine differing in extent of purification were examined. No statistically significant differences in antileukemic activity could be observed in our testing conditions between commercial MTX and urinary MTX whether the latter was isolated by only acid precipitation, recovered as described in Table 1, or even further purified by column chromatography. As shown by representative data in Table 6, single injections on day 1 of these compounds were moderately effective on P388, L5178Y and LSTRA leukemias, significant and equivalent increases in survival being obtained with doses of MTX and all urine-derived MTX preparations above 10 mg/kg i.p. Similar results were obtained when a more prolonged (day 1–15) treatment schedule was employed in L1210-bearing mice (Table 7). It may be seen that whereas doses of 10 mg/kg of the 4 compounds were uniformly toxic in this condition, the degree of prolongation in survival recorded after doses of 0.75–3 mg/kg were not statistically different for the commercial and urinary drug preparations.

Clinical use of recovered MTX

In two patients treated with 1 and 7.5 g of recovered MTX, respectively, the effectiveness of the urine-derived drug was clearly demonstrated, while no adverse side-effects were observed. Before administration, recovered MTX was prepared for injection and tested for the presence of pyrogens as described in Materials and Methods. Only drug preparations which passed U.S.P. standards and thus pyrogen-free were used in clinical studies. Nonetheless, body temperature was monitored continuously during the 48-hr period during and after MTX administration.

The first patient was a 63-yr old female with a poorly differentiated squamous cell carcinoma of the epiglottis. Because of infiltration of the tumor in the surrounding of the larynx, the tumor had been only partially resected. Postoperative treatment consisted of the administration of 1 g MTX every week. MTX was given in a 24-hr infusion and was followed by leucovorin rescue. The remainder of the tumor, which could be seen at laryngoscopy postoperatively, was no longer visible after 4 courses of MTX which included 3 treatments with recovered MTX. This apparently complete remission had been achieved without any clinical complications due to the urine-derived drug.

The second patient was a 78-yr old female who had been referred to the oncology unit with an inoperable squamous cell carcinoma of the tongue and had been treated previously with radiotherapy. She received a 24-hr infusion of 1 g MTX every 3 weeks followed by leucovorin. The tumor showed no change during 4 treatment cycles. It was decided to proceed with MTX in a regimen as recently described by Pitman and Frei [22]. MTX was administered weekly in gradually increasing doses from 1 to 7.5 g. Following successive doses of 1 g recovered MTX and 2.5 and 5 g doses of commercial MTX, no increase in tumor size was observed. After the 7.5 g dose using urine-derived MTX, a significant reduction in tumor size was noted. Although exact measurement of the tumor was difficult there was no doubt that a good partial remission had been achieved with high dose MTX recovered from urine. Again, no adverse reactions due to the urine-derived drug were observed.

DISCUSSION

The present report is an initial investigation into the feasibility of recovering MTX given in high doses from the urine of treated patients for the purpose of re-use. MTX was isolated from urine in high yield allowing the recovery of more than half of the initial dose administered. Isolation of MTX from urine by acid precipitation proved to be an effective method for obtaining a drug preparation of a purity similar to that of commercial MTX. Both inhibition of dihydrofolate reductase *in*

†Purification of samples A, B and C are described in Table 6.

vitro and antitumor effectiveness in mice by urine-derived MTX was quantitatively equivalent to that observed with the commercial drug. Although recovered MTX and the commercial drug were essentially identical with respect to percent purity and biochemical activity, quantitative and qualitative differences were noted in the impurities detected by DEAE cellulose chromatography.

The estimation of the impurities in MTX preparations in this study was done by calculation of the relative peak areas of absorbance at 260 nm after chromatographic fractionation. Although such a determination of the level of impurities is limited to ultraviolet-absorbing substances and cannot yield absolute mass or molar quantities, it can be used to obtain relative values helpful in the comparison of different MTX samples. Chromatographic data indicated that commercial MTX represents 94% of the product based on absorbance at 260 nm in agreement with recently reported values [15, 17]. The urine-derived preparations were found to be 90–95% MTX. The major ultraviolet-absorbing impurity found in the commercial drug was identified as N^{10}-methylpteroyglutamic acid by its chromatographic and spectral properties when compared to a standard reference compound. The presence of this pteridine derivative was estimated to be 2.4%, consistent with the value 2.7% reported by Tong *et al.* [17]. These latter investigators also found in their analysis of commercial MTX by high pressure liquid chromatography one other notable impurity which was estimated to be 1.6% and identified as 4-amino-5-deoxy-N^{10}-methylpteroic acid. An impurity peak (peak 4, Fig. 3) was detected in the commercial drug in the present study which eluted before MTX and was found to represent 1.9% of the total absorbance at 260 nm. This impurity was not identified by comparison with the spectral and elution properties of a known standard compound, but was likely to be 4-amino-4-deoxy-N^{10}- methylpteroic acid based on previously reported chromatographic elution characteristics and the relative level detected.

These impurities mentioned above and several others having spectral properties characteristic of pteridines which were also present in the commercial drug were apparently present in recovered MTX at approximately equal or decreased levels. The unidentified impurity peak eluting before MTX was increased in the urine-derived drug. However, in the latter MTX preparation uric acid was detected in this chromatographic fraction. The amount of uric acid present was determined to be 0.2 mg per 25 mg of the MTX preparation. This was not surprising since uric acid is a major constituent of urine and is precipitated at acid pH. 7-HydroxyMTX was detected in the recovered drug and estimated to be less than 1% based on relative peak areas, indicating that the metabolic loss of MTX was low. No effect was observed by the presence of these low levels of 7-hydroxy-MTX and uric acid on the activity of recovered MTX *in vitro* or *in vivo*. Despite the known limited solubility of both of these compounds, no adverse effects were noted during the clinical use of recovered MTX at least in two patients. Any possible toxicity due to these impurities may have been circumvented by routine alkalinization (with sodium bicarbonate) prior to high dose MTX treatment. Regarding the two ultraviolet-absorbing contaminants (peaks 9 and 10, Fig. 4) found in urine-derived MTX but not detected in the commercial drug, they also exhibited spectral properties similar to MTX and produced inhibition of dihydrofolate reductase activity. It is conceivable that these impurities are metabolites of MTX or of the pre-existing impurities in the commercial drug preparation.

Patients undergoing MTX chemotherapy often receive simultaneously other drugs which could appear in the MTX preparations isolated from the urine. The patients whose urine was used in this study for the isolation of MTX received no antiemetics since little nausea due to high dose MTX treatment was experienced. Although vincristine was given 24 hr before high dose MTX in these patients, a recent study has shown that in man only about 9 and 12% of the vincristine dose is excreted in the urine during the first 24 and 72 hr, respectively, after administration, the drug being excreted primarily in the feces [23]. Since leucovorin (5-formyltetrahydrofolate) was given shortly after the start of high dose MTX, its presence in the form of its known metabolites [24], including 5-methyltetrahydrofolate in recovered MTX was possible. However, only 45 mg of leucovorin was given during the 24-hr period after the MTX infusion, about 1% or less of the amount of MTX which could be recovered. No leucovorin could be detected in the urine-derived drug and no decrease in pharmacologic (antitumor effectiveness) activity was observed with the recovered MTX compared with the commercial drug. It should be also noted that the removal of impurities from urine-derived

MTX by ion-exchange chromatography produced no significant difference in antitumor activity when tested in mice.

Removal of pyrogens from MTX preparations recovered from urine was necessary before testing in patients. This was accomplished with calcium phosphate treatment and ultrafiltration. MTX isolated from urine by only acid precipitation produced a severe pyrogenic reaction in rabbits despite treatment of the test solution with asbestos prior to testing. Asbestos, although now restricted in the United States, is still used in Europe for the removal of pyrogenic substances by absorption for the preparation of parenteral solutions. Asbestos treatment alone appeared to be ineffective in the removal of pyrogens. Attempts to eliminate pyrogens by calcium phosphate treatment, also based on adsorption, proved to be helpful but not completely satisfactory. The addition of ultrafiltration steps to the purification procedure did result in a drug preparation that was pyrogen-free according to U.S.P. standards [13]. Since pyrogens, which are primarily lipopolysaccharides released from bacterial cell membranes, are of a macromolecular nature [25], ultrafiltration would seem to be best suited for their removal from solutions of MTX. Ultrafiltration membranes used in this study were capable of retaining 10,000 mol. wt species, although not quantitatively. The use of other, more efficient molecular filtration membranes (e.g. Pellicon membranes, Millipore Corporation, Bedford, Massachusetts) especially suitable for pyrogen removal in pharmaceutical processing would undoubtedly be an improvement and possibly would eliminate the necessity for calcium phosphate treatment and multiple ultrafiltration steps.

The present study demonstrates the feasibility of the recovery of MTX from patients on high dose MTX therapy for re-use. The isolation procedure is relatively simple and the product is comparable to the commercial drug based on chromatographic analysis, *in vitro* inhibition of dihydrofolate reductase and antitumor effectiveness in mice. The urine-derived MTX preparation can be made pyrogen-free and suitable for use in patients. The trial of high dose treatment with recovered MTX in two patients has demonstrated desired antitumor activity without adverse effects. Further studies are needed, however, to fully identify all impurities present in both the commercial and recovered drug and to establish their possible toxicity or involvement in the antitumor action of high dose MTX therapy. Such information would provide a better understanding of the potential problems that could arise from the use of MTX recovered from urine. Improvements on the removal from the recovered drug of the residual impurities, especially those not present in the initial commercial drug would be just as desirable. The practical recovery of gram quantities of MTX with minimal levels of impurities from the urine of treated patients has been demonstrated; however it has not been determined at this time whether the recovery of urine-derived MTX is possible without significant accumulation of impurities. Indeed, the continuous re-utilization of MTX would increase its availability and would further reduce restrictions on high doses due to the cost.

The Effects of Cyclophosphamide Treatment on the Epithelium and Stroma of the Urinary Bladder

M. E. BEYER-BOON,* H. J. DE VOOGT† and A. SCHABERG*
*Departments of *Pathology and †Urology,*
University of Leiden, Leiden, The Netherlands

Abstract—*In a series of* 28 *patients treated with cyclophosphamide for non-urological diseases who developed haemorrhagic cystitis during treatment, seven showed "tumour-positive" cells in the urine sediment. The interval between the institution of cyclophosphamide treatment and the first urological symptom varied between* 4 days *and* 10 yr. *Cytoscopical examination revealed abnormalities of the bladder lining due to stromal changes, which explained the clinical picture. Two of the patients developed papillary tumours (histological grade* III).

In 4 *of the* 7 *patients the cytological abnormalities disappeared after the cessation of the therapy; in the other* 3 *they persisted fatally. In the one case in which autopsy was permitted, the results showed transitional cell carcinoma of the bladder with metastases in the lungs and bone marrow.*

INTRODUCTION

CYCLOPHOSPHAMIDE (Endoxan®) has been widely used since 1957 in the treatment of cancer and, more recently, as an immunosuppressive drug given before transplantations and in numerous non-neoplastic diseases such as rheumatoid arthritis and systemic lupus erythematosus. It is administered in an inactive form and is metabolized, mainly in the liver, into a potent cytotoxic agent [1, 2]. The drug and its metabolites are eliminated via the urine [3]. Since the bladder, unlike the renal pelvis and the ureters, is in prolonged close contact with urine, the urogenital toxic effects of the drug are seen predominantly in this organ [4–6].

Like the chemically related nitrogen mustard, cyclophosphamide is mutagenic [3, 7, 8] and carcinogenic [9]. Atypical cells are found in the urine of cyclophosphamide-treated patients [10, 11] and infiltrative bladder cancer has been reported in association with this drug [12–16].

In addition to the epithelial changes, cyclophosphamide may also induce alterations in the subepithelial vessels and stroma of the bladder leading to sterile haemorrhagic cystitis [16–18].

This retrospective study concerned a series of 28 patients treated with cyclophosphamide during the last 4 yr, all of whom had been free of urinary-tract diseases when this therapy was initiated, During treatment, 7 of these patients developed urological complaints and cytological abnormalities in the urinary sediments and the drug was withdrawn.

In two of these cases bladder cancer was diagnosed. Further cytological and histological investigations were undertaken to evaluate the character of these stromal and epithelial changes.

MATERIALS AND METHODS

Seven patients (Table 1) who developed urological symptoms with an abnormal cytological picture during cyclophosphamide treatment were analyzed.

The clinical histories of these 7 patients were reviewed with special attention to urological symptoms prior to cyclophosphamide treatment. Correlations were sought between the cystoscopical and histological findings (biopsy or autopsy) and the clinical data. Furthermore, the daily and total doses of cyclophosphamide and the interval between the beginning of the treatment and the onset of urological symptoms were determined. All of the patients had received the cyclophosphamide orally for a period of five days, every three or four weeks except one (No. 7), who had been given the drug intravenously. In cases 1, 2 and 6 the drug was administered in

Accepted 20 January 1978.

Table 1. Clinical, histological and cytological data of 7 patients treated with cyclophosphamide. Follow-up data after cessation of therapy

No.	Age in yr	Sex	Reason for CP treatment	Total dose	Daily dose	Time lapse	Urinary symptoms	Cystoscopy	Cytology	Histology	Time	Urological symptoms	Cytology	Histology
1	36	m	lymphocytic lymphoma	50 g	300–400 mg,	45 months	hematuria frequency	edematous red areas	positive		18 months	transient	negative	none
2	64	m	reticulum cell sarcoma	32 g	350 gr	13 months	burning hematuria frequency penile pain	edematous, red	positive	denuded edematous stroma, vascular changes	6 months	transient	positive	patient died (no autopsy) clinically of reticulum cell sarcoma
3	84	m	squamous cell carcinoma of lung	162 g	350 mg.	10 yr	hematuria	papillary tumors	positive	grade 3* carcinoma	12 months†	transient	negative	none
4	75	m	Kahler's disease	8.05 g	75 mg.	25 months	frequency hematuria voiding pain	papillary tumors	positive	grade 3* carcinoma	6 months	persistent	positive	patient died of widespread bladder carcinoma
5	52	f	Kahler's disease	27 g	200–300 mg.	4 yr	hematuria, burning	edematous, diffuse red	positive		24 months	transient	negative	none
6	46	f	mamma carcinoma	6 g	300 mg.	4 months	hematuria, scalding	red	positive		2 months	persistent	positive	patient died (no autopsy) clinically of mamma carcinoma
7	13	f	preparation for bone marrow transplant	11 g	2850 mg.	4 days	frequency, severe hematuria	edematous, red, teleangiectasia papillary folds	positive		3 months	transient	negative	none

*Graded according to the Bergkvist grading system [6].

†In this case the cytological report remained positive over a period of six months following the transurethral resection of the tumor, and the bladder mucosa was reported by the cystoscopist as papillomatous. After 12 months the cystoscopic findings and the cytology were negative, thus the epithelium returned to the normal state.

combination with vincristine and prednisone, in case 4 with prednisone only, and in cases 3, 4 and 7 without any other drug.

RESULTS

The patients had been free of urological disease before treatment and had no history of urological anomalies. The relevant data (age and sex, reason for cyclophosphamide treatment, daily and total doses given, interval between the beginning of therapy and onset of symptoms and the cytological and, if available, the histological findings) are given in Table 1. The daily dose varied between 75 and 2850 mg and the total dose between 6 and 162 g. In some cases the period before the onset of symptoms was short (4 days in No. 7); in others it was much longer (10 yr in No. 3).

In all cases the urological complaints had started with signs of bladder irritation (e.g. frequent urination, nocturia, burning and scalding) followed by haematuria. The urine was sterile in all cases. Treatment to control the bleeding was required in only one case (No. 7). During the follow-up period, which varied from 2 to 24 months, the urological symptoms proved to be transient in five cases and persistent in the other two (Table 1). The duration of the urological complaints did not always correspond with that of the cytological abnormalities.

Cystoscopically, the bladder lining showed a picture closely resembling that of carcinoma *in situ* [19], including edema, redness and teleangiectasia.

The cytological investigation performed at the onset symptoms revealed a large number of morphologically malignant cells in 4 cases (Fig. 1) and only a few "tumour-positive" cells in the other 3 cases (Nos. 1, 5 and 7). In the latter group the cytology returned to normal after termination of the therapy. Of the other four patients, two developed bladder cancer (Nos. 3 and 4) and 2 died of the primary malignancy (Nos. 2 and 6); an autopsy could not be performed in these two cases. In the cases with gross tumour growth, many papillary cancer cell groups were found. In one case the cell changes (Fig. 2) resembled those described by Forni *et al.* [11] as due to irradiation. The histological diagnosis of the urothelial tumours in patients 3 and 4 was grade 3 carcinoma (Bergkvist grading system [20]) (Fig. 3). Cytologically, there were no differences between the histologically confirmed and non-confirmed cases (Figs. 1 and 4). Stromal and vascular changes were seen in the biopsy specimens of the patients with urothelial neoplasms as well as in patient 2, in whom no macroscopical tumour growth was detected. The stromal changes included edema, fibroblastic proliferation, and degeneration (Fig. 5); the vascular changes consisted of proliferation and thickening of the intima of some vessels, fibrin deposits in the vessel wall, and dilatation of the vascular wall with ectasia (Figs. 5 and 6).

Except for the haematuria, the clinical picture in the patients with cyclophosphamide-induced haemorrhagic cystitis closely resembled that seen in our cases of primary carcinoma *in situ* [19].

DISCUSSION

Haemorrhagic cystitis induced by cyclophosphamide therapy is rare in patients in whom a high fluid intake is maintained and retention of urine in the bladder is relatively short [21]. The reported frequency of this side-effect ranges between 2 and 40% (8% in a recent article by Jayalakshmamma [22]), possibly as the result of differences in dosage. The combination of haemorrhagic cystitis and urothelial cell abnormalities may be even more rare [11].

The development of papillary tumours, as in two of our patients, very probably represents the end of a long process starting with epithelial regeneration (characterized by atypia and hyperplasia of the newly formed epithelium) and the formation of papillary folds [23–25]. These changes have even been found several months after cessation of the therapy [11]. "Tumour-positive" cells were found in the absence of clinical cancer in patients given cyclophosphamide for a relatively short time (Nos. 2 and 6), whereas the combination of true tumour cells and clinical cancer was seen in patients treated for a longer period (Nos. 3 and 4). It will take many years to determine the long-term significance of the atypical epithelium observed in those of our patients who have not yet developed cancer since cytological changes can precede clinical urothelial cancer by as much as 20 yr [26].

It is noteworthy that all of our patients showed an abnormal cystoscopical picture. The characteristic redness of the mucosa is a result of the increased vascularity and teleangiectasia. The dilated vessels bleed easily, as sometimes occurs even after withdrawal of the drug (patients 2 and 6).

In the acute phase, necrosis may be seen in the lamina propria of the bladder and in the blood vessels [5, 23]. Late effects of cyclophosphamide therapy include stromal fibrosis, as observed in children by Johnson and Meadows [27].

Although cytological changes caused by cyclophosphamide were first described many years ago [11], reports of fully developed bladder cancer have only been published in the last few years, the first by Worth in 1971 [16]. It seems likely that the carcinogenic potential of cyclophosphamide was less evident when this form of treatment was less successful than it is now. At present, however, the drug is widely used for non-neoplastic diseases, which means that a large number of patients are being exposed to the risk of developing this iatrogenic bladder cancer.

Since cytological changes are also found in patients without urinary bladder complaints [10, 11], it seems advisable to perform a cytological investigation of the urine of all patients treated with cyclophosphamide. Such investigations would make it possible to identify those patients who run the risk of developing bladder cancer and would also provide invaluable data on the incidence and nature of these cyclophosphamide-induced bladder changes.

The Effect of Cyclophosphamide upon Mitoses in the Cornea of Rats, a Circadian Dependent Effect

S. S. CARDOSO,*‡ K. M. PHILIPPENS† and H. VON MAYERSBACH

**Department of Pharmacology, University of Tennessee Center for the Health Sciences, Memphis, Tennessee 38163, U.S.A. and †Department fur Anatomie, Medizinische Hochschule, Hannover, Germany*

Abstract—*In these studies, the corneal epithelium was used to determine:* (1) *The magnitude and duration of mitotic inhibitory effect of cyclophosphamide upon a rapidly proliferating tissue of the host.* (2) *Whether isoproterenol-induced circadian phase-shifts, obtained through alterations of cell cycle kinetics, could in any way minimize the mitotic inhibitory effects (toxicity) of subsequently administered cyclophosphamide. The data presented suggest:* 1. *That marked differences in the duration of the mitotic inhibitory effect can result from the administration of cyclophosphamide at different "times of the day".* 2. *That pretreatment with isoproterenol enhances the circadian dependent responses of the rat's cornea to cyclophosphamide.* 3. *That with administration of cyclophosphamide at or shortly after the beginning of the animal's daily phase of full wakefulness, beneficial responses may be expected to reach maximum circadian levels.*

INTRODUCTION

STUDIES over the past few years have indicated that the magnitude of toxic as well as beneficial responses to drugs depend significantly on the time of day (or circadian phase) of their administration [1]. Chronotherapy, or the administration of drugs on schedules adjusted to circadian rhythms of the host should, therefore, permit the use of higher drug dosages, possibly at more frequent intervals. Evidence supporting this concept and extending it to cancer chemotherapy has been presented [2–11].

Badran *et al.* [9] observed a greater suppression of tumor growth in animals receiving cyclophosphamide at a time of the day in which circadian peak levels (as determined in non-treated control tumors) of cell division were present in the transplanted mammary tumor tissue. They suggested that the circadian dependent growth inhibitory effect of this anticancer agent was directly related to the cell division rates present in the tumor tissue at the time of drug administration [9]. More recently, with the use of BDF_1 mice bearing L1210 leukemia, Cardoso *et al.* [5] have shown that the toxic as well as the therapeutic responses to cyclophosphamide (180, 240, 300 and 360 mg/kg) are indeed circadian dependent. From those dose–response studies, the calculated LD_{35}'s (maximum death rates of 38% at 1800 hr) were found to be 360 mg/kg and 254 mg/kg, respectively for the best (1800–2100 hr) and worse (0600–0900 hr) circadian-phases treatment groups [10].

To verify the validity of Badran's proposition and to gain further knowledge of the mechanisms responsible for the circadian dependent responses to cyclophosphamide, additional studies were carried out to determine: (1) The magnitude and duration of mitotic inhibitory effect of cyclophosphamide upon a rapidly proliferating tissue of the host, (2) Whether isoproterenol-induced circadian phase-shifts [4, 6, 11] obtained through alterations of cell cycle kinetics [6, 12] could in any way minimize the mitotic inhibitory effects (toxicity) of subsequently administered cyclophosphamide.

MATERIALS AND METHODS

Male Sprague–Dawley rats with weight ranging from 100 to 120 g at arrival from Harlam Industries, Indiana were housed (six/cage) in a windowless room with temperature and humidity maintained, respectively, at 23°C and 50%. Artificial lights were kept on from 0600 to 1800 hr. The animals were kept in this environment for at least one week prior to their use in the experiments. Purina lab chow and water were available *ad lib*. Single doses of either cyclophosphamide (300 mg/kg) (Mead Johnson Research Center, courtesy of Dr. K. W. Wheeler) or isoproterenol HCl (25 mg/kg) (Sterling-Winthrop Research Institute, courtesy of Dr. F. C. Nahod) were administered to the appropriate groups of rats, by the intraperitoneal route at the times indicated under "Results". The rats were sacrificed by decapitation at the times indicated under "Results". The corneas were collected, fixed and stained as previously described [2]. Mitoses were counted with the use of a microscope (occular 10×, objective 100×) with a micrometer grid disc inserted in the occular piece. One hundred grid fields were counted in each cornea. All phases of mitoses were included with exception of those cells in early prophase and late telophase.

RESULTS

Magnitude and duration of cyclophosphamide's mitotic inhibitory effect

In Fig. 1 we are presenting the results obtained in two separate experiments. In the first (Panel A), a single dose of cyclophosphamide, 300 mg/kg, was administered at 0900 hr (arrow in the figure) by the i.p. route to the appropriate group of rats. Two hours after treatment, cyclophosphamide-treated- and non-treated control rats were sacrificed. Subsequent time-groups of control and treated rats were sacrificed at the times indicated in the figure. The results obtained with the administration of the agent at 1800 hr (2nd experiment) are presented in Panel B. All data obtained are expressed as mean number of mitoses/100 fields ± S.E. (5 rats/mean) of the mean values. Comparisons (*t*-test) between control and corresponding cyclophosphamide-treated groups of rats sacrificed between 1100 hr on day 1 and 0600 hr on day 3 (45-hr time span, Panel A), revealed the following *P* values: <0.005, <0.005, <0.025, <0.05, <0.02, <0.001, <0.001, <0.001, <0.05, <0.05 and >0.05. Similarly, for those rats treated at 1800 hr (24 hr time-span, Panel B) and sacrificed between 2200 hours on day 1 and 1800 hr on day 2, the *P* values were: <0.005, <0.001, <0.005, <0.02, <0.001, <0.05 and >0.05. Thus, a profound inhibition of mitoses without time alterations of the circadian rhythm, resulted from drug administration at either 0900 or at 1800 hr of the day. On the other hand, while this inhibition of cell division extended over 39 hr among the animals treated at 0900, it extended only over 21 hr among rats which received the drug at 1800 hr of the day.

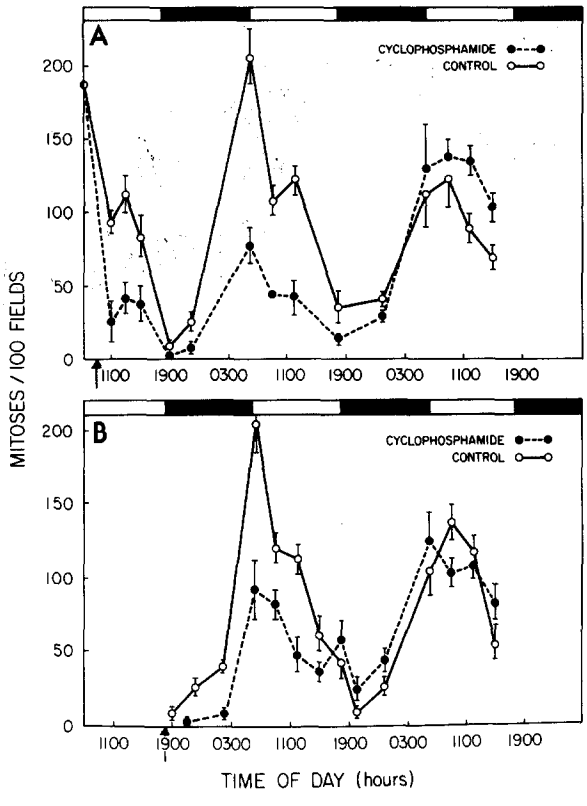

Fig. 1. The effect of cyclophosphamide upon mitoses in the cornea of rats. A single 300 mg/kg *dose of cyclophosphamide was administered (arrow) to rats at either* 0900 *(Panel A) or at* 1800 hr *of the day. Subsequently, treated* (5) *and non-treated control* (5) *rats were sacrificed at the times indicated in the figures. The mean and S.E. of the mean values (mitoses/100 fields) are presented. The full and open horizontal bars shown on the top of Panels A and B indicate the hours of darkness* 0600 hr) *and light* (0600–1800 hr) *to which the animals were exposed throughout the experiment.*

Isoproterenol-induced phase-shifts displacement in time of circadian peaks and troughs of mitotic activity

In Fig. 2, results obtained with the administration of a single (25 mg/kg) dose of isoproterenol at either 0600 or at 1500 hr of the day, are presented in Panels

A and B, respectively. Inspection of the curves reveal outstanding differences in the circadian mitotic rhythm in rats treated with the agent at 0600 hr, when compared with controls; as shown in Panel A, its effect extended over 3 successive circadian mitotic cycles. *First cycle:* displacement of the circadian mitotic peak from early morning (0600 hr) to mid-afternoon (1500 hr). *Second cycle:* pronounced suppression of the mitotic

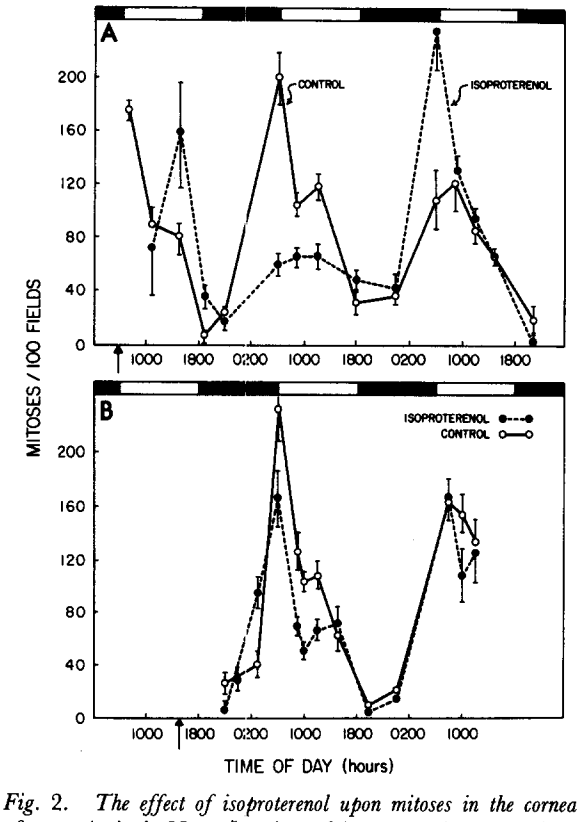

Fig. 2. The effect of isoproterenol upon mitoses in the cornea of rats. A single 25 mg/kg *dose of isoproterenol was administered (arrows) to rats at either* 0600 *(Panel A) or at* 1500 hr *(Panel B). Subsequently, control and treated rats were sacrificed at the times indicated in the figures. The mean* (5 *rats/time group) and S.E. of the mean values (mitoses/*100 *fields) are presented. The full and open horizontal bars represent hours of darkness and light, as in Fig.* 1.

cycle. The P values obtained from comparisons (t-test) between isoproterenol suppressed groups and corresponding controls were as follows: at 0600 hr $P<0.001$; at 0900 hr $P<0.005$ and at 1200 hr $P<0.001$. *Third cycle:* "Rebound" mitotic activity, with peak levels of cell division significantly above controls ($P<0.005$), occurring at the appropriate circadian phase, i.e. transition from dark to light, at 0600 hr of the day. Discrete suppression of mitoses without changes in the overall rhythm characterized the responses to isoproterenol administered at 1500 hr (Panel B)

The effects of cyclophosphamide upon mitoses in the corneas of rats pretreated with isoproterenol

In Fig. 3, the results obtained with the administration of cyclophosphamide (300 mg/kg) to rats previously treated with isoproterenol (25 mg/kg), are presented. In Panel A, the treatment times were 0600 and 0900 hr, respectively for isoproterenol and for cyclophosphamide. Both in Panels A and B, the results obtained with drug combination

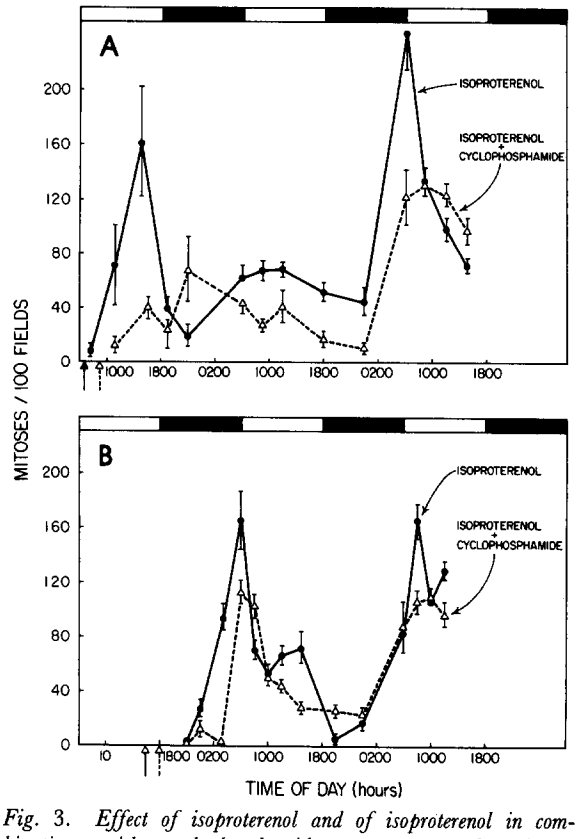

Fig. 3. Effect of isoproterenol and of isoproterenol in combination with cyclophosphamide, upon corneal mitoses. Isoproterenol and cyclophosphamide were administered (25 mg/kg *and* 300 mg/kg *respectively), singly or in combination, to rats at the times indicated by the arrows in the figures. The results obtained with the drug combination are compared with those obtained with the administration of isoproterenol alone. The mean* (5 *rats/time group) and standard error of mean values (mitoses/*100 *fields) are presented. The full and open horizontal bars represent hours of darkness and light as maintained in the animal quarters.*

are compared with the responses observed after the administration of isoproterenol alone. Figure 3 shows: (1) the profoundly different responses which follow drug administration (singly or in combination) at different circadian phases (Panel A vs Panel B); (2) that pre-treatment with isoproterenol enhances (compare with Fig. 1), the circadian dependent effects of cyclophosphamide: (3) that relatively low levels of cell division were present in the corneas of isoproterenol-treated

rats at the time of cyclophosphamide administration: (4) the absence of mitotic "rebounds" in the corneas of rats treated with the combination isoproterenol-cyclophosphamide.

DISCUSSION

The therapeutic index of many drugs depends, significantly, on the time of day (circadian dependent response) of their administration [1]. This knowledge has stimulated interest in chronotherapy as an approach to increase the efficacy of cancer chemotherapy. Improvements have been obtained [2–11]. Nevertheless, drug induced toxicity still remains as a major limitation to cancer chemotherapy.

More recently, efforts have been directed toward a reduction of the degree of anticancer drug toxicity, demonstrated to be circadian dependent. To this end and in preparations for chronotherapy, manipulation of the number of normal and neoplastic cells in a given phase to the cell cycle was attempted using a non-cytotoxic agent such as isoproterenol. To date such results, although non conclusive, have been encouraging [6].

The present work expands on the above work, with the following objectives: (A) To gain understanding of the cause and/or mechanism(s) of circadian dependent effect of cyclophosphamide. (B) Verifying whether isoproterenol, a non-cytotoxic agent with known effects upon circadian mitotic rhythms [6, 11] and kinetics of the cell cycle [12] could, in any way, modify and/or minimize the cytotoxic effects of cyclophosphamide.

A. *Cause and/or mechanism(s) of the circadian dependent effect of cyclophosphamide*

Circadian phases of maximum and minimum mitotic activity, respectively at 0900 and 1800 hr of the day, were selected for the administration of cyclophosphamide [5]. As presented in Fig. 1, a profound inhibition of corneal mitoses resulted from drug administration at either circadian phase. On the other hand, the duration of the drug's mitotic inhibitory effect was found to extend over a considerably longer period of time in those animals treated at 0900 hr (39 hr) than in animals treated at 1800 hr (21 hr).

The significance of the above finding, in terms of cause and/or mechanisms of host toxicity, can be appreciated only in light of: (1) the established synchrony of circadian mitotic rhythms in fast proliferating tissues of the host [11]; (2) the demonstrated value of the rats corneal epithelium as a predictive system for the cytotoxic effects of anticancer agents upon fast proliferating tissues of the host [2, 7, 11]. Thus viewed, our findings suggest that a relationship of cause and effect may exist between duration of mitotic inhibitory effect and circadian dependent responses to cyclophosphamide.

B. *Pretreatment with isoproterenol in attempts to minimize the cytotoxic effects of cyclophosphamide*

For this purpose, the circadian dependent effects of cyclophosphamide upon the corneal epithelium were further investigated with the use of (a) isoproterenol induced "circadian phase shifts" (time displacements of circadian peaks and troughs of mitotic activity); (b) cyclophosphamide administration to control and to phase shifted animals. Initially, isoproterenol was administered alone, at different circadian phases, in order to identify the most desirable time for the subsequent administration of cyclophosphamide. As shown in Fig. 2, markedly different responses resulted from isoproterenol administration at either 0600 or 1500 hr. On the other hand, an immediate and pronounced fall in the rates of cell division was a common response to treatment at either hour. For the purposes stated above (a, b), the initial phases of suppression of cell division by isoproterenol were chosen for use in the subsequent isoproterenol-cyclophosphamide combination studies. The data in Fig. 3 demonstrate that in response to treatment with the combination isoproterenol-cyclophosphamide, profound changes of rhythm and rates of cell division do occur: *1st Type* (Panel A) an intense suppression of mitoses along with a concomitantly abolished circadian mitotic rhythm; *2nd Type* (Panel B) less intense inhibition of mitoses along with a preserved circadian mitotic rhythm. Thus, the results indicate that isoproterenol can influence the target tissue's response to cyclophosphamide and that, therapeutically speaking, either beneficial (treatment at 1500–1800 hr) or adverse (treatment at 0600–0900 hr) responses may be obtained from the administration of cyclophosphamide in combination with isoproterenol. The results also indicate that the overall magnitude of cyclophosphamide's mitotic inhibitory effect is not directly related to cell division rates present in the target tissue at the time of its administration: as shown in Panels A and B, low rates of cell civision were present in the

target tissue at the time of cyclophosphamide administration to either group.

Experiments have been planned to investigate further the effects of the above drug combination, as well as that of isoproterenol with cell cycle phase specific agents, in tumor bearing animals. From the foregoing, isoproterenol (administered at the "proper time") may prove capable of exerting a favorable influence upon the therapeutic index of cyclophosphamide and. theoretically, even more so on that of agents such as cytosine arabinoside.

In conclusion, the data presented suggest:

1. That marked differences in the duration of the mitotic inhibitory effect can result from the administration of cyclophosphamide at different "times of the day".
2. That circadian levels of mitoses may not, *per se*, be responsible for the differences in toxicity which follow cyclophosphamide administration at different circadian phases. On the other hand, the ratio cycling/non-cycling cells may be related to and explain the circadian dependency of the agent's effects.
3. That the effect of isoproterenol on the corneal epithelium cells is reversible, while that of cyclophosphamide is (on many cells) irreversible.
4. That pretreatment with isoproterenol enhances the circadian dependent responses of the rat's cornea to cyclophosphamide.
5. That with administration of cyclophosphamide at or shortly after the beginning of the animal's daily phase of full wakefulness, beneficial responses may be expected to reach maximum circadian levels.

Quantitative Immunocytochemical Study of Plasma Cells in Skin Tumoral Stromal Reaction*

R. BUSTAMANTE, M. FAURE, F. BEJUI and J. THIVOLET

FRA INSERM No. 11, Recherche Dermatologique et Immunologie, Clinique Dermatologique, Hôpital Edouard Herriot, Lyon, France

Abstract—*Immunoglobulin producing cells in the perilesional infiltrate of various benign and malignant skin tumors were sought using peroxidase labelled anti-immunoglobulin antisera.*

The prominence of such cells in the infiltrate was in general proportionate to the malignancy of the lesion, malignant melanomata showing the fewest.

INTRODUCTION

THE INFLAMMATORY infiltrate around tumors probably develops as a host defense mechanism. This "stromal reaction" [1] is composed partly of immunologically competent cells. Little is known of the precise role of anti-tumoral immune reaction [2–12].

Immunocytochemical identification of immunoglobulin producing cells (IPC) in lymphoid formations of the digestive tract has been carried out using peroxidase conjugated anti-human immunoglobulin antisera [13, 14]. Similar techniques [15] were applied to the inflammatory infiltrates of various cutaneous hyperplastic and tumorous processes.

MATERIALS AND METHODS

Patients

One hundred and four cutaneous tumors from both sexes (age range 15–83 yr) were studied (see Table 1).

Table 1. Patients

Basal cell carcinomas	25
(2 cystic + 23 solid)	
Squamous cell carcinomas	16
Bowen's disease	4
Seborrhoeic warts	10
(basal cell epitheliomas)	
Keratoacanthomas	12
Benign intradermal naevocellular naevi	15
Malignant melanomas	22
7 superficial spreading melanomas	(SSM)
3 lentigo maligna melanomas	(LMM)
7 nodular melanomas	(NM)
5 recurrent SSM	

Preparation of tissues

Biopsies were embedded in paraffin after fixation in Bouin's solution for 24 hr. The maximum interval between embedding and labelling was 6 months.

Conjugates

Monospecific (anti IgA, anti IgG, anti IgM) peroxidase conjugated sheep anti-human immunoglobulin (Ig) sera were used (I. Pasteur, Paris). The sheep antisera were made specific for heavy chain determinants by solid-phase immuno-absorption. Specific antibodies were isolated on immunoglobulin-immunoabsorbents [16].

Immunoglobulins were conjugated to peroxidase according to the method of Avrameas and Ternynck [16]. Preparations contained 1.25 mg antibodies/ml. The optimal dilution determined by a previous titration was 1/20 for anti IgG and IgM sera and 1/30 for anti IgA sera.

Immunocytochemical technique

After dewaxing, 5 μm sections were washed in phosphate buffered saline (PBS) 0.01 M, pH 7.2 for 20 min at ambient temperature and subsequently incubated with the conjugates for 60 min at 37°C. The sections were then washed twice in PBS

Accepted 10 February 1978.

(5 and 25 min respectively) and in 0.2 M Tris–HCl, pH 7.6 for 10 min. The peroxidase activity was then revealed by Graham-Karnovsky media (5 mg 3.3′ diaminobenzidine (Sigma) in 10 ml 0.2 M Tris–HCl, pH 7.6 with 0.01 H202) for 8 min at ambient temperature, in darkness. The sections were again washed twice in PBS (5 and 25 min respectively) and counter stained with methyl green solution (0.25% Fast green FCF (Gurr) in distilled water + 1% acetic acid) for 10 min at ambient temperature. The preparation were rinsed for 10 min in distilled water, dehydrated and mounted in Canada Balsam.

Specificity

Specificity was determined using a sheep anti-rabbit Ig conjugate (I. Pasteur, Paris) on sections from the same tissue.

Table 2. Basal cell carcinomas (18 cases): Classes of IPC present in infiltrate and their staining intensity

	Number of tumors		
Presence of IPC	IgA PC	IgG PC	IgM PC
++(*)	8	10	4
+(†)	8	7	8
Total (out of 18)	16	17	12
Staining intensity			
Strong	12	7	5
Weak	4	10	7
Absence of IPC	2	1	6

(*) More than 1% of IPC for the relevant Ig class.
(†) Less than 1% of IPC for the relevant Ig class.
The percentages being calculated in relation to all cells present in the infiltrate.

Endogenous peroxidase activity was demonstrated by direct development with the Graham–Karnovsky media, without exposure to conjugate.

Histology

Sections were compared with haematoxylin–eosin–safranine stained specimens.

RESULTS

IPC were identified as large (12–15 μm) oval cells with eccentric nuclei with a clock-face chromatin pattern and abundant dark brown staining cytoplasm. IPC were found in cellular infiltrates, around or within the tumor (Figs. 1 and 2).

Cells with endogenous peroxidase activity (polymorphonuclear leukocytes, (PMN), histiocytes) could be identified by their morphology. Free melanin appeared as light brown clusters. Within melanophages, the mainly granular pigment stained lighter brown in colour than Ig. Connective tissue appeared deep green, with a slightly brownish tinge.

Basal cell carcinomas

None had either sebaceous, sweat gland or pilar differentiation [17]. Eighteen tumors showed IPC, in most of which all classes of Ig were observed (Table 2), although in 14 cases a predominance of IgG IPC was present (Table 3). In 7 cases, all with scanty infiltrate, no IPC was seen.

Squamous cell carcinomas

All three classes of Ig were represented among the IPC in nearly all 16 cases (Table 4) with a predominance of IgG (Table 3). All 16 lesions, 8 of which were ulcerated, were grade I (Broder's index) [18].

Table 3. Predominant immunoglobulin class in the IPC of the infiltrates of various types of tumors

		Number of tumors			
			Predominant Ig class

Bowen's disease (*Table* 5)

Two tumors were devoid of IPC. Where present, all Ig classes were seen.

Keratoacanthomas (*Table* 6)

IPC were seen in 6 out of 12 tumors, with a predominance for IgG IPC (Table 3).

Seborrhoeic warts (*basal cell papillomas*) (*Table* 7)

In 5 cases with little infiltrate, no IPC were seen. IgG IPC were predominant (Table 3) in the remainder.

Intradermal naevi

No IPC were seen.

Malignant melanomas (*Table* 7)

(a) Out of 7 SMM, 2 showed no IPC (scanty infiltrates). In 5 SSM with IPC, an intense peritumoral infiltrate (lymphocytes, plasma cells, melanophages, mononuclear cells, PMN) was observed. IPC were only found in upper dermis. Intensity of staining was weak. In one case, IPC comprised more than 1% of the infiltrate (Table 8). IgM IPC were seen only in one case. In 3 cases IgA IPC and in 2 cases IgG IPC were predominant (Table 3).

(b) In the 3 LMM, IPC were found in the upper dermis. IgA, with strong staining, predominated (Tables 3 and 8).

(c) IPC were seen in 2 NM only (Table 8), where they occurred lateral in the margins of the tumor in the superficial dermis only. The 5 NM with no IPC were devoid of infiltrate, or had few infiltrating cells.

(d) No recurrent melanomas had IPC.

DISCUSSION

IPC are generally considered to be mature plasma cells [13–15]; younger lymphoplasmocytic cells may also possess cytoplasmic Ig. This might explain observed differences in morphology and staining intensity of IPC. For IgA, greater intensity might result from a higher intracellular concentration. Ultrastructural study of the infiltrates [15] showed the peroxidase staining to be situated in the ergastoplasm of plasma cells, presumably during Ig synthesis. Plasma cells and IPC may be considered to be identical.

Plasma cells cannot be recognized by enzyme-histochemical studies alone [2]; immunofluorescence methods [19] require immediate interpretation and do not permit correlation of IPC with other cells of the infiltrate or tumor. Immunocytochemical techniques on fixed tissues avoid these difficulties.

IgM IPC were found least frequently (Table 3). Predominance of IgG over IgM IPC occurs during secondary humoral immune responses [20, 21]. An inflammatory reaction to tumor growth may correspond to such an immune response, in view of its long-term evolution (IgA IPC are the predominant type in LMM and SSM only).

Presence of IPC varies according to the type of tumor:

IPC are absent or scanty in naevocellular

naevi and Bowen's disease, where the infiltrate is poorly developed. In seborrhoeic warts and keratoacanthomas IPC were absent in half of cases and few when present. There was no correlation between the presence of IPC and general histological pattern of the lesions.

Basal and squamous cell carcinomas exhibit the greatest number of IPC. No relationship was found between number and kind of IPC and ulceration, or stage of dermal invasion. All squamous cell carcinomas were grade I. This would support the hypothesis that the presence of IPC is related to the degree of keratinisation and differentiation [6].

In malignant melanomas, in contrast to other studies [22], presence of IPC does not appear to depend on ulceration in our cases. However, IgM IPC were seen only in ulcerated tumors, which may indicate participation of new immuno-competent cells in an amplified anti-tumoral reaction.

No IPC were observed in recurrent melanomas, in this and other studies [2]. Observation of numerous plasma cells in metastases [7] has been made in the case of only two primary melanomas of undefined type. Proportionately lower number of DNA synthetizing lymphoid cells have been seen in metastases [10, 11].

In SSM, LMM and 2 NM, IPC were only seen in the upper dermis, as in previous studies [2]. No relationship could be established between presence of IPC and various other parameters [22, 23] (cell type, mitotic index, vascular emboli, angiogenesis ...). In the prognosis of malignant melanoma, the depth of invasion and histogenetic type of tumor are considered to be important [22, 23]. IPC appear to be always absent at deeper levels of the infiltrate. In NM, where the prognosis is very poor, IPC were found superficially in only 2 out of 7 cases. In SSM and LMM, IPC were found in 80% of cases. Presence of IPC may reflect the degree of malignancy.

Thus 3 kinds of tumors may be distinguished:

(A) benign dysplastic or degenerative lesions, with rare IPC, and a possible predominance of IgM IPC, when seen, in this group only. The rarity of IPC may however be related to the paucity of infiltrate.

(B) tumors with weak or mild degree of malignancy (basal and squamous cell carcinomas) with dense stromal reactions, many IPC (IgG). Identification of lymphoid cells in these infiltrates has shown a predominance of T. lymphocytes (high T/B ratio >4) [4, 24]. In such tumors, both kinds of lymphoid cells of immune response are present.

(C) highly malignant tumors (SSM, LMM and NM), with rare IPC (IgG and IgA). T lymphocytes are significantly less numerous [3, 24]. Both T and B lymphoid cells are rare in such infiltrates.

This study does not define whether or not these immunoglobulins have a specific antibody function [21]. Peritumoral immunoglobulin elution assays are at present being carried out. These studies, like those concerning activated macrophages [25, 26], antibody dependent lymphocytotoxicity [27] and direct killer effect of activated lymphocytes [28, 29], may eventually define the various antitumoral immunological mechanisms.

Cell Cycle Agents and Cyclophosphamide in the Treatment of Diffuse Histiocytic Lymphoma

GERMAN A. GOMEZ and LEON STUTZMAN

Department of Medicine, Roswell Park Memorial Institute, New York State Department of Health, Buffalo, New York 14263, *U.S.A.*

Abstract—*A regimen consisting of two three-day courses of large doses of methotrexate with leukovorin rescue, followed by cytosine arabinoside infusion, given during* days 1 *and* 7, *and on* day 15, *vincristine, cyclophosphamide and prednisone with a time interval of* 18–24 hr *between vincristine and cyclophosphamide was tested. A total of* 6 *such cycles were used in* 9 *patients with histiocytic lymphoma who had not received prior chemotherapy. All nine responded, with a complete remission in* 8. *Prolonged disease-free survival of* 48 *or more months were seen in* 3 *of the complete responders.*

The efficacy of the cell-cycle agents, methotrexate and cytosine arabinoside was demonstrated since they were used as the initial phase of therapy, during which time a 78% *response rate was observed.*

INTRODUCTION

In the past, the treatment of histiocytic lymphoma (HL), was associated with a high response rate but remissions were of short duration [1–3]. More recent reports indicate a marked improvement in duration of complete responses [4–6].

Levitt *et al.* [7] introduced the use of high doses of methotrexate (MTX) with leucovorin (LCV) rescue, followed by cytosine arabinoside (Ara-C) infusion, after initial induction with cyclophosphamide (CTX) and vincristine (VCR) in previously untreated patients with disseminated histiocytic lymphoma [7]. All patients had partial or complete remission (PR, CR) with a median survival of over 15 months. However, it was not clearly demonstrated that the favorable results were related to the addition of the MTX and Ara-C, since vincristine and high-dose cyclophosphamide were used for initial therapy. Previously, antimetabolites had been reported to have only limited antitumor effect in lymphomas [8, 9], and conflicting reports suggesting either synergism or antagonism [10, 11] with combination of Ara-C and MTX led to uncertainty regarding the effectiveness of these two agents.

As a preliminary phase, the present study explored the utilization of the antimetabolites alone in a group of patients with disseminated lymphoma resistant to a variety of routines of combination chemotherapy. Following demonstration of antitumor activity in half of these patients, the study was extended to a second phase utilizing MTX-Ara-C, followed by VCR, CTX and prednisone (PRD), in 9 patients with previously untreated histiocytic lymphoma.

MATERIALS AND METHODS

(A) In the preliminary phase of the study, MTX with LCV rescue followed by Ara-C were given to a group of 8 patients. No CTX, VCR or PRD was given. The drugs were given in the same dosage as in the second phase listed below, and the routine was repeated each week.

(B) The regimen of the second phase was as follows (Fig. 1): Day 1: MTX 30 mg/m^2 by mouth, every 6 hr times 4 was given, followed immediately by 150 mg/m^2 of Ara-C given intravenously in continuous infusion for 6 hr. Rescue was started with leucovorin 25 mg/m^2 every 6 hr times 4 intramuscularly 24 hr after the first

Accepted 21 February 1978.

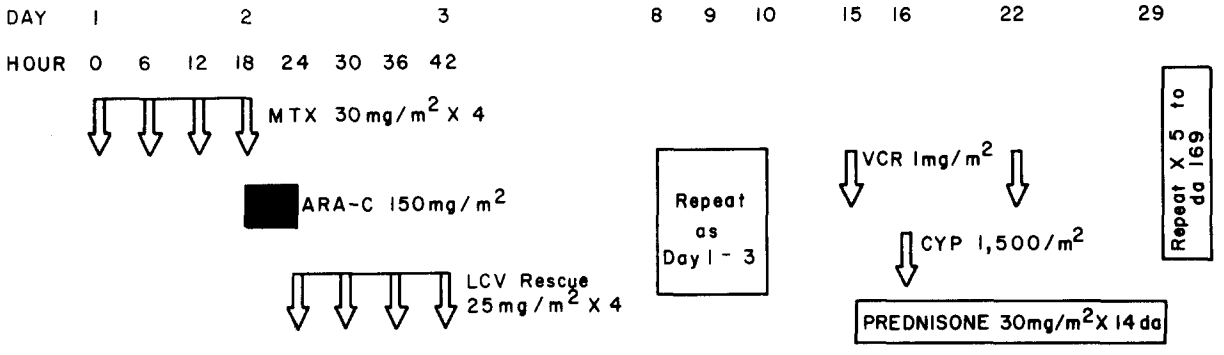

Fig. 1. Schema of therapy. Six such cycles were given over a 6-month period.

dose of MTX. Day 8: The treatment given on day 1 and 3 was repeated. Day 15: VCR, 1 mg/m^2 intravenously was given by push dosage and PRD 30 mg/m^2/days for 14 days, orally was started. Day 16: 18–24 hr after the VCR dose of day 15, a dose of CTX, 1500 mg/m^2 was given intravenously by push dosage. Day 22: VCR was repeated at the same dose as day 15. The first cycle was completed on day 28. Day 29: The second cycle was started.

Six such cycles constituted a course of therapy, following which no maintenance therapy was given.

All patients were admitted to the hospital for 24–36 hr for the Ara-C infusion and leucovorin rescue. The following dosage modification was utilized for bone marrow toxicity:

If granulocytes were more than 1000/mm^3 and platelets were more than 85,000/mm^3 on day of treatment, full doses of MTX and Ara-C were given. For counts below these levels, these drugs were omitted. CTX was modified to 75% when pretherapy platelet counts were from 65,000–85,000; and 50% for platelets of 45,000–64,000/mm^3. CTX was given at full dosage for pretherapy granulocyte counts of more than 1500, 50% for 1000–1500 and none for less than 1000/mm^3.

The VCR dose was reduced to 50% after appearance of significant weakness from neurotoxicity and omitted for over 50% reduction of expected muscle strength.

Therapy was discontinued if no response was seen after one full 28-day cycle of therapy, or if relapse occurred during therapy.

Patient selection

Preliminary phase. Eight patients with uncontrolled disseminated lymphoma who had failed to multiple combination chemotherapy programs, 6 with diffuse HL and 2 with mixed cellularity Hodgkin's Disease (HD) were treated in the preliminary phase. Most patients had WBC below 4000 and/or platelets below 100,000 from disease or former therapy.

Second phase. Nine patients with histologically confirmed disseminated diffuse histiocytic lymphoma, who had not had prior chemotherapy were admitted to this study. Three of them had received previous radiation therapy limited to 1–2 regions and 2 total nodal radiation, with complete response of tumor within radiation ports. All had normal WBC and platelet counts. Four had been recently diagnosed and had received no previous therapy. Five were male, 4 female. The range of age was 26–82 yr, with a median of 70 yr.

Complete remission was defined as complete disappearance of all measurable tumors.

Partial remission was defined as 50% or greater reduction in cross-sectional area of all measurable tumors.

No response was defined as progressive disease, no change, or minor improvement that did not qualify as a partial response.

Blood counts, biochemistry profiles, bone marrow aspirate and biopsy and radiographic studies of chest and abdomen were obtained in all patients before treatment. Blood counts were repeated before each dose of myelosuppressive drugs. Liver biopsy, lymphogram and radioisotope scans were obtained when indicated. Baseline studies included tumor measurements in two dimensions (except with bone marrow, spleen and liver involvement). Restaging including repeat bone marrow and liver biopsies when initially abnormal were repeated to confirm the existence of CR.

RESULTS

Preliminary phase

Four of the 8 patients treated during

Table 1. *Patient characteristics and response to therapy*

Patient	Age and sex	Predominant sites	Prior therapy	Response	Fate	Duration on study
1	60 F	Nodes, marrow	TNR*	CR	Died in remission, BM drug toxicity	3 months
2	68 M	Liver	RT,† mantle	CR	Died in remission, lung and liver fibrosis, drug toxicity	4 months
3	72 F	Nodes, marrow, soft tissue	None	CR	Died in remission with chronic lung disease and heart failure	5 months
4	82 M	Nodes, spleen	None	PR	Died in relapse	7 months
5	70 M	Nodes, spleen, SVC syndrome	None	CR	Died in relapse	9 months
6	58 M	Nodes, soft tissue	RT, mantle	CR	Died in remission with myocardial infarction	12½ months
7	26 F	Nodes, soft tissue	RT, shoulder	CR	Alive in CR	48+ months
8	73 F	Nodes, spleen	TNR	CR	Alive in CR	49+ months
9	77 M	Liver, nodes, soft tissue	None	CR	Alive in CR	53+ months

*TNR—Total nodal radiation.
†RT—Radiotherapy.

the preliminary phase showed partial response with the antimetabolites alone. None achieved CR. Responders included one with HD and 3 with HL. The duration of remission ranged from 6 to 92 days, with a median of 47 days. Two had fatal drug related hematologic toxicity (both were responders). Three others (two responders) had moderate hematologic toxicity, while three had little or no toxicity.

Second phase

I. *Response.* All 9 patients showed response, with CR in 8 (Table 1). Two patients of this group relapsed. One relapsed after CR and died at 9 months. The other relapsed from PR and died of disease at 7 months. Four died in remission, 2 with drug toxicity and two of unrelated disease. Three of those with CR had less than the programmed therapy (2 delinquent and 1 with severe prolonged infection), completing only 4, 10 and 14 weeks of therapy respectively and these three were still in remission at 48, 49 and 53 months after beginning therapy.

II. *Response rate to initial antimetabolite phase.* Seven of the 9 patients showed an antitumor effect sufficient to qualify for a PR in the first two weeks of the regimen during the MTX-Ara-C phase. None achieved CR during this initial period.

III. *Toxicity.* Six patients died during the study. Two deaths were directly related to drug toxicity; bone marrow aplasia and fulminant sepsis after the VRC–CTX–PRD phase in one and massive lung and liver fibrosis presumed to have been due to MTX toxicity after autopsy in the other (both were in CR). Two others died with lymphoma, in relapse from CR and PR. Two died of causes unrelated to the therapy or disease: one with severe congestive heart failure from underlying heart disease and chronic lung disease, and the other with acute myocardial infarction (both in CR).

It is important to emphasize that all but one were elderly patients with a median age of 70 yr and most had prior myocardial and vascular disease. Six of these 9 patients would not have qualified for the cooperative group protocols into which these patients might have been entered at this institution.

Aside from the one fatal reaction, hematologic toxicity was acceptable. During the first two weeks of each course of treatment, the MTX-Ara-C phase of therapy was followed by moderate thrombocytopenia but little if any leukopenia, while after the VCR–CTX–PRD phase, the reverse effect of leukopenia but much less thrombocytopenia was seen. Seven episodes of leukopenia of less than 2000/mm^3 occurred, requiring cessation of therapy for 2–3 weeks.

All these episodes occurred after the VCR–CTX–PRD phase of the study. Only two instances of thrombocytopenia of less than 100,000 occurred after the methotrexate-Ara-C phase.

All patients had severe alopecia. Nausea and vomiting occurred in all patients during Ara-C infusion and in some after CTX injection. No stomatitis was seen from the short periods of therapy with MTX. Only two patients manifested neurotoxicity of

sufficient severity to cause diminution of dosage of vincristine.

DISCUSSION

This study confirms the favorable results obtained by Levitt *et al.* [7] with introduction of antimetabolites for intensive treatment of histiocytic lymphoma. However, the therapeutic routine used in this study varied in three aspects from that of the Yale group.

First and most important was the introduction of MTX-Ara-C as the first modality of therapy. The efficacy of these two agents, with a 78% response rate, was clearly shown in the present study. However, this study does not demonstrate a preference in sequence of the agents, since none received VCR–CTX–PRD as first phase. The response rate reported here is approximately equivalent to that obtained by Levitt *et al.* utilizing CTX–VCR as first agents.

Second, the present regimen utilized careful sequential timing between the vincristine and cyclophosphamide. Experimental animal studies and clinical trials showed that the utilization of a time interval between antimitotic agents and either antimetabolites or alkylating agents produced significantly more antitumor effect than when both agents were given together [12–14]. Synchronization and recruitment mechanisms were suggested as the explanation for this potentiation of antitumor effect.

Third, the dose of VCR used in this program was lower than that used in Levitt's routine. This did not appear to interfere with the rate of response and resulted in a low incidence of neurotoxicity.

The 100% response rate of regimen in patients with HL, previously untreated with chemotherapy, with 88% CR was superior to that reported with standard CTX, VCR and PRD (COP) regimens with remission rates between 70 and 85%, and a CR rate from 35 to 50% [2, 4]. In experience previously reported from our department, the addition of other alkylating agents and of bleomycin to the COP routine did not result in better rates of either remission or survival [15]. However, recently a regimen consisting of bleomycin, adriamycin, cyclophosphamide, vincristine and prednisone (BACOP) was reported to produce 84% CR + PR (48% CR) with somewhat more strict criteria [6] for qualification of partial remission. These patients did not have prior radiation therapy and were much younger than our untreated group (median age 45 vs 70 yr). Prolonged disease-free survival of more than 3 yr with the possibility of "cure", has been reported in patients with HL with CR following completion of intensive combination chemotherapy [4, 5]. In our series, 4 patients have had prolonged remission. However, in three the chemotherapy program was not completed, indicating that prolonged remission, although dependent upon achieving a CR status, does not necessarily require prolonged courses of therapy.

Although there was good tolerance in most of the patients to these large doses of chemotherapy, the toxicity was unpredictable in some. One of the drug related deaths occurred after chemotherapy with VCR–CTX–PRD, indicating that potentiation of the antitumor effect by the time sequencing used in the study may be accompanied by potentiation of bone marrow toxicity. The extensive fibrosis of liver and lung observed in one of the responders is unique. Fibrosis as a toxic manifestation may occur after prolonged exposure to MTX [16], but there have been no reports of the simultaneous incidence of both liver and lung fibrosis with schedules utilizing large doses of MTX and LCV rescue.

The successful utilization of cell cycle dependent drugs would appear to open new aspects of therapy for histiocytic lymphoma. Intensive MTX followed by LCV has shown promise in lymphoma [17] and other tumors and is worth further investigation both alone and in combination with other drugs for therapy of this type of lymphoma. Other cell cyle dependent agents and further exploration of variations in sequencing may yield further improvements in the treatment of these diseases. The risk of increased toxicity from such intensive routines appears to be lower than expected.

This program of chemotherapy was also tested in 14 patients who previously failed during combination chemotherapy. Eleven had diffuse histiocytic and 7 had poorly differentiated diffuse lymphocytic lymphoma. Eleven patients responded with CR in 5. It was interesting that 5 of 9 of these patients who were failures to previous CTX–VCR–PRD routine given in standard doses responded to treatment with CR in 2. Among these 5 patients, three did not show response during the MTX-Ara-C phase but responded during the VCR–CTX–PRD phase, suggest-

ing that the time interval between VCR and CTX was an important factor in the restoration of the responsiveness. In addition, larger pulse doses of the CTX may have been a factor. This program offers an alternative to previously treated patients who fail to standard routines of chemotherapy [18].

Abstract—*The effect of Ara-C or cyclophosphamide (Cy) on the growth of Lewis lung carcinoma was monitored in C57Bl/6 mice by measuring the tumor uptake of ^{125}IUdR. Strong inhibition of isotope uptake occurred* 24 hr *after drug administration. However, rapid recovery of ^{125}IUdR uptake was found in Ara-C but not in Cy-treated neoplasms. Survival of tumor-bearing mice confirmed that Cy but not Ara-C was active in producing long-term inhibition of tumor growth. Similar studies conducted with murine (Lewis lung carcinoma) or human (HeLa) tumors in athymic "nude" mice suggested that Cy was more active than Ara-C in inhibiting tumor growth* in vivo. *In further experiments the ^{125}IUdR uptake of human colon carcinoma, liposarcoma, breast carcinoma, melanoma and Burkitt lymphoma was found to be depressed by treatment with drugs (i.e. 5-fluorouracil, Me-CCNU or adriamycin) or by exposure to X-rays. It is concluded that the ^{125}IUdR uptake test could be utilized for the rapid evaluation of the antitumor activity of antineoplastic agents against human tumors growing in nude mice.*

INTRODUCTION

IN RECENT years wide interest has been focused on athymic nude mice, largely incompetent of mounting T-dependent allograft [1] or xenograft responses [2]. One of the most attractive applications of the peculiar immunobiology of the nude mouse resides in the possibility of successful xenogeneic transplantation of human tumors [2–5] for biological [6–10] and chemotherapeutic studies [11–13].

A rapid and predictive test capable of evaluating the anti tumor activity of antineoplastic agents against human tumor cells, inoculated into nude mice, would be of great help in selecting the most active drugs for clinical application, tailored to the patient bearing the tumor used for xenotransplantation. The uptake of ^{125}IUdR has been used extensively for monitoring tumor growth [14], or tumor growth inhibition by antitumor agents [15] or immune responses [16].

Therefore studies were conducted in order to test whether the same technique would be applicable to the evaluation of growth or inhibition of human tumors inoculated into nude mice. The results reported in the present communication suggest that the ^{125}IUdR uptake method could be of value for measuring the extent of growth inhibition of neoplastic cells, induced by radiation or chemotherapeutic agents in tumor-bearing nude mice.

MATERIALS AND METHODS

Animals

Conventional inbred C57Bl/6Cr (*H*−2B),

or hybrid (C57Bl/6Cr x DBA/2Cr)F_1 (BD2F_1, $H-2^b/H-2^d$) female mice, 2–4 months old were used. BALB/c/A/BOMCr mice, ($H-2^d$ nu/nu, strain on BALB/c background, maintained in a closed but not strictly inbred colony, hereafter referred to as BALB-nu/nu), and randombred nude mice (hereafter referred to as Swiss-nu/nu) bred and maintained in a pathogen-free environment, 1–2 months old were used. Conventional mice were obtained from Dr. J. G. Mayo and Mr. C. Reeder of the Mammalian Genetics and Animal Production Section (National Cancer Institute, Bethesda, Maryland). BALB-nu/nu were bred at the Institute of Pharmacology, University of Perugia, Italy and Swiss-nu/nu were bred at the Stehlin Foundation for Cancer Research, Houston, Texas.

Tumors

Lewis lung carcinoma (LLC) of C57Bl/6 origin was passaged in C57Bl/6Cr mice by subcutaneous transplantation of tumor cells suspended in medium 199. The following human tumors were used: HBT-3 (breast carcinoma), FO No. 1 (melanoma), RA No. 1 (Burkitt Lymphoma), BA No. 1 (Liposarcoma), CR No. 1 (colon carcinoma), (CR No. 1, CR No. 8) or Swiss-nu/nu (FO (tumor line obtained after long-term passages in tissue culture in medium 199 containing 10% Fetal Bovine Serum, GIBCO). All these tumors except HeLa cells were used after several sc passages in BALB-nu/nu (CR No. 1, CR No. 8) or Swiss-nu/nu (FO No. 1, RA No. 1, BA No. 1) mice.

Drugs

Cyclophosphamide (Cy), adriamycin (ADM), cytosine arabinoside (Ara-C), 1-chloroethyl-3-4-methyl-cyclohexyl-1-nitrosurea (Me-CCNU), 5-fluorouracil (5-FU), 5-fluoro-2-deoxyuridine (FUdR) were supplied by Dr. J. B. Wood, Drug Synthesis and Chemistry Branch, Division of Cancer Treatment, National Cancer Institute, NIH, Bethesda, Maryland.

Irradiation

Mice bearing solid tumors were shielded with lead block 10 mm thick, leaving exposed to radiation the neoplastic area. Irradiation was carried out with a Westinghouse X-ray machine (Quadrocondex; 200 kW, 15 mA, 0.25 mm copper filter and 0.55 aluminum filter, 54 cm distance, irradiation rate 137 R/min).

^{125}IUdR uptake test

Normal control or tumor-bearing mice were injected i.p. with FUdR (25 μg/mouse) to inhibit the endogenous synthesis of thymidine [14], followed 1 hr later by 1–4 μCi/mouse of ^{125}IUdR i.p. (Radiochemical Centre, Amersham, England; specific activity 8–10 μCi/mg). One day later the tumor mass or comparable mass of normal subcutaneous or muscular tissue was removed and transferred into previously weighed plastic vials and weighed again. The radioactivity was measured in a well-type crystal scintillation counter (Packard, Model 5110).

RESULTS

Conventional C57Bl/6Cr mice were inoculated subcutaneously with 2×10^5 LLC cells. On day 4, 6, 10, 11, 14 and 17 after challenge the mice received FUdR and ^{125}IUdR for performing the uptake test. The percentage of ^{125}IUdR uptake by the neoplastic tissue in the course of tumor growth is illustrated in Fig. 1. Progressive

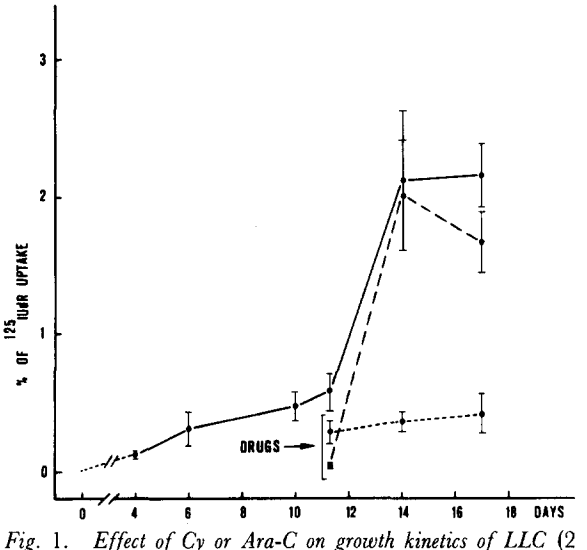

Fig. 1. Effect of Cy or Ara-C on growth kinetics of LLC (2 x 10^5 cells s.c.) in C57Bl/6 mice.

Each determination was performed with 7 mice/group. The first determination of ^{125}IUdR uptake after treatment with Cy (180 mg/kg) *or Ara-C* (1 g/kg) *was performed* 6 hr *after drug administration.*

The arithmetic mean ± standard error was calculated on the original count/minute.

but limited increase of isotope uptake was observed during the initial period of 11 days after LLC challenge. Marked increase occurred, from day 11 to 17 after challenge, when rapid and progressive growth of solid subcutaneous tumor was observed. Two

additional groups of mice were treated on day 11 with a single injection of Cy (180 mg/kg i.p.), a drug active in prolonging survival of LLC-bearing hosts [17], or with Ara-C (1 g/kg i.p.), extremely active in inhibiting DNA synthesis but scarcely effective in prolonging survival times of LLC-bearing mice [17]. The tumor uptake of ^{125}IUdR was initially inhibited in both Cy and Ara-C treated mice (Fig. 1). On day 14 and 17 after challenge (i.e. 3 and 6 days respectively after drug treatment), the values of tumor ^{125}IUdR uptake in Ara-C treated mice reached the levels of those of untreated controls, whereas they remained markedly low in Cy-treated hosts. The effect of Cy or Ara-C on tumor growth in terms of ^{125}IUdR uptake, tumor weight or mortality was studied in the same tumor system, as illustrated in Table 1. C57Bl/6 Cr or BD2F$_1$Cr mice were challenged sc with 2×10^5 cells of LLC and treated i.p. with Cy (200–180 mg/kg) or Ara-C (1 g/kg) on day 8. The ^{125}IUdR uptake test was carried out on day 13 or 14 after challenge (i.e. 5–6 days after drug treatment). The data confirmed the efficacy of Cy in inhibiting tumor growth as judged by significant decrease of ^{125}IUdR uptake or tumor weight, or by increase in survival time. On the contrary, marginal or no inhibitory effect on isotope uptake, tumor weight or survival time was found following Ara-C treatment.

The LLC model was used for studying tumor growth and drug-induced tumor inhibition in nude mice, as illustrated in Table 2. Successful allogeneic tumor growth occurred in $H-2^d$ nude mice as evidenced by tumor weight and tumor ^{125}IUdR uptake values on day 11. Moreover, significant inhibition of tumor growth occurred both in syngeneic conventional C57Bl/6 or allogeneic nude mice injected with Cy (180 mg/kg) on day 8 after LLC challenge. Again, marginal or no inhibition of tumor growth was found following treatment with Ara-C (1 g/kg).

Four human tumors, HeLa (2×10^6 cells), CR No. 1, CR No. 8 (tumor fragments) and BA No. 1 (10^7 cells), were inoculated subcutaneously into nude mice. When appreciable nodules appeared at the injection

site (24–30 days after challenge), the mice were assigned randomly to control or drug-treated groups. Mice bearing HeLa cells were treated on day 24 with a single i.p. injection of Cy (180 mg/kg) or Ara-C (1 g/kg), BALB nu/mu bearing CR No. 1 colon carcinoma were treated with a single i.p. injection of 50 mg/kg of 5-FU and nude mice bearing CR No. 8 colon carcinoma received a single i.p. injection of 5-FU (50 mg/kg) or Me-CCNU (20 mg/kg). Swiss nu/nu bearing BA No. 1 liposarcoma were treated with a single i.p. injection of 6 or 12 mg/kg of adriamycin (Table 3). The ^{125}IUdR test was performed two (BA No. 1) or three (HeLa, CR No. 1, CR No. 8) days after drug treatment. The results (Table 3) show that marked inhibition of HeLa growth was afforded by Cy but not by Ara-C. Adriamycin seems to provide growth inhibition of BA No. 1 liposarcoma. Moreover, 5-FU and Me-CCNU seem to be active in reducing the growth of CR No. 8, although the data were not statistically significant possibly as a result of the low number of observations.

In further preliminary studies, nude mice were inoculated s.c. with 10^7 cells of HBT-3, FO No. 1 or RA No. 1 tumors, on four sites located in the front or in the back of the animal.

Two of the four tumors of each animal were irradiated, and the ^{125}IUdR uptake test was performed 19 hr after irradiation.

The results of the experiment (Table 4) showed that substantial inhibition of tumor growth was found after exposure to 500–1200 R of HBT No. 3 and FO No. 1 melanoma tumors, or RA No. 1 Burkitt lymphoma.

DISCUSSION

The results reported in the present communication show the following: (a) the growth of a murine solid tumor can be monitored by the extent of ^{125}IUdR uptake by neoplastic tissue either in conventional or nude mice; (b) the growth of human tumors in nude mice can be monitored using the same technique; (c) drug or radiation-induced inhibition of murine or human tumor cells can be evaluated by measuring the reduction of ^{125}IUdR incorporation, in conventional and in nude mice as well. The labeled compound ^{125}IUdR is an analog of thymidine, and is incorporated into DNA in place of thymidine during the S phase of the cell cycle [14]. Therefore the evaluation of ^{125}IUdR uptake can be considered a rather accurate measure of cell proliferation [14]. The data obtained in conventional mice inoculated with LLC are in agreement

with previous studies in a similar experimental model [17]. The growth of LLC was comparable in C57Bl/6 and in allogeneic nude mice (Table 2), as judged by the ^{125}IUdR uptake values and tumor weights, which were even greater in allogeneic thymus-less than in syngeneic recipients. This is in agreement with previous findings showing lack of T-dependent allograft responses in nude mice [18]. Inhibition of ^{125}IUdR uptake by murine tumors seems to be a rather sensitive index of host-anti-graft

immune response either of T-dependent or T-independent origin [16, 19]. Therefore it can be suggested that LLC tumor cells (of $H-2^b$ origin) do not express tumor-associated antigens capable of eliciting non-T dependent transplantation resistance in nude mice, similar to that detectable against $H-2^b$ lymphomas [19]. This can be explained on the basis that tissues of hematopoietic origin possess Hh (Hematopoietic-histocompatibility) antigens capable of eliciting T-independent responses [20–22], whereas some tissues of non-hematopoietic origin do not express detectable amounts of such antigens (Cudkowicz, personal communication).

Successful growth of xenogeneic human tumors can be attained in nude mice, as previously reported [2–5]. The possibility of monitoring the extent of neoplastic growth by ^{125}IUdR uptake seems to be confirmed by data of Tables 3 and 4, showing that significant uptake of the isotope occurred in the human tumors inoculated into nude recipient mice.

The data concerning the effect of drug treatment on ^{125}IUdR uptake (Fig. 1) or tumor weight (Tables 1–2) or survival of tumor-bearing hosts (Table 1) lead to several hypotheses. Antineoplastic agents, either capable of marked inhibition of tumor growth such as cyclophosphamide, or strong inhibitors of DNA polimerase, such as Ara-C [23], but scarcely active on LLC in terms of host's survival [17], provoked almost complete block of ^{125}IUdR uptake within a few hours of drug administration (Fig. 1). Nevertheless a rapid recovery of ^{125}IUdR uptake occurred in LLC-bearing mice treated with the relatively inactive Ara-C, whereas long-lasting inhibition of DNA synthesis occurred in LLC of mice treated with an active drug, such as cyclophosphamide. Therefore the differential timing in the recovery of ^{125}IUdR uptake could be related to the sensitivity of neoplastic cells to the antitumor effects of chemotherapeutic agents.

The results obtained with HeLa tumor cells growing in nude mice (Table 3) would suggest that the tumor is sensitive to Cy rather than to Ara-C treatment, although no parallel studies on survival times have been made and no reduction of tumor weight was found in Cy-treated hosts, in which significant inhibition of ^{125}IUdR uptake occurred. However, further studies (Rivosecchi Merletti P., unpublished data) suggested that treatment with Cy but not with Ara-C was capable of producing limited inhibition of HeLa cells in nude mice, without affecting tumor size in a short-term range. The growth of liposarcoma BA No. 1 or colon carcinomas CR No. 1 and CR No. 8 seemed to be inhibited by ADM or 5-FU and Me-CCNU respectively. Nevertheless the experimental data did not reach the level required for statistical significance. This could be ascribed to the limited number of observations and to the high variability of the ^{125}IUdR uptake in control mice. Therefore higher number of animals will be required for further investigation.

Limited growth rate was found in human tumors in the experiments of localized irradiation (Table 4), as evidenced by the low ^{125}IUdR uptake detectable in non-irradiated neoplastic nodules. In irradiated tumors, reduction of tumor weight was generally found shortly after irradiation. However the decline of ^{125}IUdR uptake was much more pronounced than the decrease of tumor mass. In this case we cannot rule out that the extent of isotope uptake was a more sensitive and specific parameter than weight change for evaluating the cytotoxic and/or cytostatic effects of X-rays [24]. Nevertheless the results of this study are quite preliminary, since no kinetics of isotope uptake after irradiation have been made.

In conclusion the data obtained in the present investigation suggest that the evaluation of the uptake of ^{125}IUdR could be used as a sensitive method to monitor the growth and drug-induced growth inhibition of experimental or human tumors inoculated into nude mice. Further studies are required in order to assess the actual value of the method for predicting the efficacy of antineoplastic agents against selected human tumors.

Abstract—*DNA polymerase activities from the spleen of an individual rat with myelogenous leukemia induced by* N-*nitroso*-N-*butylurea were examined in view of their possible association with RNA tumor viruses.*

Viral-like DNA polymerase was not detected when DNA polymerase activities of the cells were analyzed as follows:

(1) *Phosphocellulose chromatography of the extract from leukemic spleen gave a single peak of poly(rA)·(dT)*$_{12-18}$ *directed activity which coincided with that of DNA polymerase γ obtained from normal rat spleen, whereas the chromatography of the extract from virus-producing cultured R*35 *rat mammary tumor cells or from those viruses themselves gave a unique peak of activity different from that of DNA polymerase γ. These viruses appeared to be one of the rat endogenous viruses similar to the R*35 *virus.*

(2) *The peak from the leukemic spleen showed several enzymatic properties similar to those of DNA polymerase γ obtained from normal rat spleen, but different from those of the R*35 *viral DNA polymerase.*

(3) *The peak from the leukemic spleen responded to poly(rCm)·(dG)*$_{12-18}$, *which is reported to be specific for viral reverse transcriptase. However, DNA polymerase γ fraction from normal rat spleen also responded to the template-primer to the same degree.*

(4) *Postmitochondrial fractions from the leukemic spleen gave poly(rA)·(dT)*$_{12-18}$*-directed activity sedimented at a density of* 1.17 g/cm^3 *on sucrose. However, addition of nonionic detergent was not required for the activity. In the case of our R*35*-like viruses banded at a density of* 1.16 g/cm^3, *the detergent was required for detection of the activity.*

INTRODUCTION

RNA VIRUSES of type C morphology are etiologically associated with leukemia, lymphoma, and solid tumors of a variety of mammalian species, including mouse, rat, hamster and cat.

On the other hand, a number of chemicals or radiation is known to induce tumors, including leukemia, in animal species [1]. The possibility that viruses are involved in such chemical or radiation carcinogenesis has been raised and discussed. Chemical reagents or ionizing radiation may trigger the activation of the hitherto latent viruses, which then could acquire a pathogenic potential, causing the development of tumors [1]. In fact, some chemicals, for example, bromodeoxyuridine, iododeoxyuridine, or cycloheximide are known to activate the endogenous RNA viruses in the mammalian cells *in vitro* [2, 3].

Oral administration of *N*-nitroso-*N*-butylurea (NBU) to the rat induces myelogenous leukemia in high frequency [4].

§To whom reprint requests should be addressed.

This myelogenous leukemia in rats appears to be more comparable to the human situation [4] than is the thymic lymphosarcoma of mice induced by NBU [5, 6]. No rat leukemia is known to be associated with virus, however [4]. With the leukemia rat, no successful attempt has thus far been made (1) to observe type C virus particles by electron microscope, (2) to prepare oncogenic cell-free filtrates, *or* (3) to detect group-specific cell surface antigen from the leukemia cells [4, 7]. Libertini and Adams, however, have suggested a possible involvement of virus in chemical carcinogen-induced rat mammary tumors through their analysis of RNA-directed DNA polymerase activities [8].

In the present study, we examined the activity of reverse transcriptase as a marker of virus association in the individual leukemic rat, using cell-free extracts of the enlarged spleen, in which leukemic cells were fully proliferated. We used poly(rA)·$(dT)_{12-18}$ as template-primer to detect the activity of reverse transcriptase in the cell extracts. However, since the cellular DNA polymerase γ also responds to poly(rA)·$(dT)_{12-18}$ very efficiently, the activities of the two enzymes must be discriminated from each other by some other means. Column chromatography, molecular weight determination, and comparison of several enzymatic properties were carried out for that purpose.

The results show that any unique DNA polymerase activity different from cellular DNA polymerase γ was not detectable from the spleen of a rat with leukemia, under the conditions where reverse transcriptase activity was detectable in the virus-producing control rat cells.

MATERIALS AND METHODS

Rats with myelogenous leukemia

To obtain rats with myelogenous leukemia, the methods of Odashima [4] were followed; female Sprague–Dawley rats at the age of 11 weeks (purchased from Clea Japan) were continuously given 0.04% (w/v) *N*-nitroso-*N*-butylurea (NBU) solution as their drinking water. The NBU solution was freshly prepared every day. After 20 weeks, the rats were then kept on the basic diet alone until they were sacrificed for autopsy. Spleen was removed from the rats and kept frozen at −80°C until used. The leukemic rats were characterized by hepatosplenomegalia and by, in most cases, a high level of white blood cell count in the peripheral blood. The spleen weighed 2.1 g on the average (0.5 g for normal rats) and normal spleen architecture was seldom seen due to the extensive metastatic infiltration of leukemic cells.

R35 rat mammary tumor cells

63-sp-6-Cl-8 [9], a subcloned culture of R35 rat mammary tumor cells which was established originally from transplantable spontaneous Haggins mammary fibroadenoma A [10] was grown at 37°C in GIBCO Nutrient mixture F-12 medium, supplemented with 10% fetal calf serum and 60 mg/l Kanamycin, in 250 ml plastic tissue culture flasks (Falcon Plastics). This culture line was established from original R35 tumors frozen in liquid nitrogen in 1963 and showed high reverse transcriptase titers [9]. These viruses were found to be one of the rat endogenous viruses [Y. Ikawa, unpublished observations]. They have been called R35 virus [11] and the capacity of this virus to transform cultured mammary epithelial cells was discussed [12]. Each flask was seeded with 5×10^4 viable cells per ml. The cell cultures were developed as confluent monolayers. The cells were collected by scraping them off from the bottom of flasks by using a rubber policeman. The cells were washed 2 times with the above medium but minus serum by centrifugation. The cell pellet was stored at −80°C until used.

R35 virus particles

R35 viruses were recovered from the above culture. The harvested culture medium was centrifuged first at $16{,}000 \times g$ for 15 min. The supernatant was then centrifuged at $106{,}000 \times g$ for 60 min. The pellet was washed once with a buffer containing 0.1 M NaCl–10 mM Tris–HCl (pH 7.5)–1 mM EDTA by centrifugation. The virus pellet was suspended in the above buffer and stored at 0°C until used.

Preparation of crude extracts for phosphocellulose column chromatography

Spleen extracts were prepared by a modification of the procedure described by Yang *et al.* [13]. All procedures were performed at 0°–4°C unless otherwise specified. Spleen from individual rats was separately thawed, minced, suspended in 4 vol of a buffer containing 0.4 M sucrose–50 mM Tris–HCl (pH 8.0)–50 Mm KCl–4 mM magnesium acetate–2 mM dithiothreitol (DTT), and

mechanically disrupted in a Potter Elvjheim homogenizer with 5 strokes. The homogenate was centrifuged at $1000 \times g$ for 10 min. Nonidet P40 (nonionic detergent) and KCl were added to the supernatant to give final concentrations of 0.5% (w/v) and 0.5 M, respectively. It was incubated at 37°C for 10 min. The pellet was suspended in a buffer containing 0.5% (w/v) Nonidet P40–50 mM Tris–HCl (pH 8.0)–0.5 M KCl–4 mM magnesium acetate–2 mM DTT-15% (v/v) glycerol, and incubated at 37°C for 10 min. The cytoplasm and nuclear fractions were separately centrifuged at $164,000 \times g$ for 90 min. The two supernatants were combined and dialyzed against buffer A containing 50 mM imidazol (pH 6.5)–0.1 M KCl–1 mM DTT–20% (v/v) glycerol [14] and then chromatographed directly on a column of phosphocellulose.

R35 mammary tumor cells were thawed, suspended in 4 vol of a buffer containing 0.5 M KCl–10 mM Tris–HCl (pH 7.5)–1 mM EDTA–2 mM DTT–4 mM magnesium acetate–0.5% (w/v) Nonidet P40–20% (v/v) glycerol, and sonicated by a Branson sonifier in iced-water until more than 98% of the cells were disrupted. The homogenate was frozen and thawed twice, centrifuged first at $100 \times g$ for 10 min., and then at $164,000 \times g$ for 90 min. The supernatant was dialyzed against buffer A (see above) and then chromatographed directly on a column of phosphocellulose.

R35 virus particles were suspended in a buffer containing 5% (w/v) Nonidet P40–0.7 M KCl% 10 mM Tris–HCl (pH 7.5)–1 mM EDTA–10% (v/v) glycerol–1 mM DTT, and kept overnight on iced-water in order to solubilize the enzyme from the virus particles [15]. The suspension was centrifuged at $106,000 \times g$ for 60 min and the supernatant dialyzed against buffer A and subjected to phosphocellulose chromatography.

Preparation of postmitochondrial fractions for sucrose density gradient analysis

Spleen was mechanically disrupted in a Potter–Elvjheim homogenizer in the same manner as described above and subjected to sequential sedimentation by differential centrifugation but in the absence of Nonidet P40, KCl, and magnesium acetate [16]. The postmitochondrial sediments obtained by a final centrifugation at $100,000 \times g$ for 60 min were suspended in phosphate-buffered saline (pH 7.2) and subjected to centrifugation analysis on a sucrose density gradient [16].

Phosphocellulose column chromatography

Phosphocellulose (Whatman P11) was washed with 0.5 M NaOH followed by 0.5 M HCl. The pH was brought to 6.5 by addition of solid Tris base [14]. A column was packed, using only gravity, and equilibrated with approx. 30 column vol of buffer A. The crude extracts from spleen, R35 mammary tumor cells, or R35 virus as described above were loaded onto the column and the elution was performed first with buffer A and then with a linear KCl gradient in buffer A.

Sucrose density gradient centrifugation

The postmitochondrial fractions from spleen or R35 virus fraction, which were obtained as described above, were layered onto an 11.6 ml 20–70% sucrose gradient in phosphate-buffered saline (pH 7.2) and centrifuged in a Spinco SW41 rotor for 16–18 hr at $150,000 \times g$ [16].

Fractions were collected and assayed for DNA polymerase activity. Densities of the fractions were calculated from refractive index measurements.

Glycerol gradient centrifugation

A portion of DNA polymerase fractions from phosphocellulose was dialyzed against a buffer containing 5% (v/v) glycerol–50 mM Tris–HCl (pH 7.5)–0.1 M KCl–1 mM EDTA, and layered over a 4.8 ml of 10–30% (v/v) linear glycerol gradient containing 50 mM Tris–HCl (pH 7.5)–0.25 M KCl–1 mM DTT–0.1 mM EDTA [17]. The gradient was centrifuged for 15 hr at 1°C at 60,000 rev/min in a Hitachi RPS65T rotor. Fractions of approx. 0.25 ml were collected from bottom of the gradient. Ten microlitre aliquots of each fraction were assayed for DNA polymerase activity in the presence of poly(rA)·$(dT)_{12-18}$ as template-primer. Sedimentation coefficient and molecular weight of the DNA polymerases were estimated by the method of Martin and Ames [18] using the protein standards: bovine liver catalase [11.3s, molecular weight (mol. wt) of 245,000], yeast alcohol dehydrogenase [7.6S, mol.wt of 150,000] and egg white lysozyme [2.1S, mol.wt of 17,200].

DNA polymerase assay

Two types of reaction mixture were used

as follows. They were essentially the same as those used by Yang *et al.* [13].

With synthetic template-primers. The reaction mixture (final volume of 50 μl) contained: 8.5 μg of bovine plasma albumin, 25 mM Tris–HCl (pH 8.0), 50 mM KCl, 0.5 mM $MnCl_2$, 2 mM DTT, 2 μCi of [^{3}H]dTTP -0.01 mM) or [^{3}H]dGTP (0.01 mM) and 2 μg of synthetic template-primer as specified.

With activated calf thymus DNA. The reaction mixture (final volume of 50 μl) contained; 8.5 μg of bovine plasma albumin, 25 mM Tris–HCl (pH 8.0), 40 mM KCl, 10 mM magnesium acetate, 2 mM DTT, 2 μCi of [^{3}H]dTTP (0.01 mM), other three deoxyribonucleoside triphosphates at 0.25 mM each and 10 μg of activated calf thymus DNA.

In both assay procedures, enzyme fraction was added to initiate the reaction, and the incubation was for 30 min at 37°C. Aliquots were withdrawn and the acid-insoluble fraction was precipitated on Whatman GF/C glass filters in cold 5% trichloroacetic acid–10 mM sodium pyrophosphate, washed 3 times with cold 5% trichloroacetic acid, once with ether-ethanol, and then once with ether. The filters were air-dried, and the radioactivity retained on them was measured in a Searle Analytic scintilation counter.

Preparation of synthetic template-primers

To prepare poly[rA)·$(dT)_{12-18}$, poly(rA) and oligo (dT) were mixed in 0.05 M Tris–HCl (pH 7.5) in a ratio of 4 to 1 to give a final concentration of 20 A_{260nm} units/ml. The mixture was heated for 10 min at 50°C followed by slow cooling and stored at −20°C until used. Poly(rCm)·$(dG)_{12-18}$ was prepared in the same manner as above except that heating was 80°C instead of 50°C.

Preparation of activated calf thymus DNA

Native calf thymus DNA (2.5 mg/ml) was digested with deoxyribonuclease from beef pancreas (DNase 1) to bring about 25% acid soluble ultraviolet absorbing materials. The procedures followed were Schlabach *et al.* [19].

Others

N-nitroso-*N*-butylurea was the product of Izumi Kagaku Yakuhin Co. Ltd. [^{3}H]dTTP (15–30 Ci/mmole) and [^{3}H]dGTP (10–20 Ci/mmole) were obtained from the Radiochemical Centre, Amersham. Poly(rA), poly(rCm), $(dT)_{12-18}$, $(dG)_{12-18}$, dATP, dTTP, dCTP and dGTP were obtained from P-L Biochemicals Inc. Calf thymus DNA, bovine liver catalase, yeast alcohol dehydrogenase, egg white lysozyme and *N*-ethylmaleimide were obtained from Sigma Chemical Co. Phosphocellulose (P11) was obtained from Whatman Biochemicals Ltd. DNase I and reverse transcriptase (AMV) were purchased from Worthington Biochemical Corp. and Boehringer Mannheim GmbH, respectively. DNA-cellulose and DNA polymerase γ from mouse myeloma cells were kind gifts of Dr. Matsukage of the Aichi Cancer Center Research Institute [17].

RESULTS

The aim of the present study was to examine whether RNA-directed DNA polymerase (reverse transcriptase) of RNA tumor virus is detectable in a rat with myelogenous leukemia which was induced by oral administration of *N*-nitroso-*N*-butylurea (NBU). No rat leukemia is so far known to be associated with virus [4]. Two kinds of approach were carried out for that purpose. One was to separate upon chromatography [14, 20] reverse transcriptase from cellular DNA polymerases. The other approach was to locate the DNA polymerase activity of the leukemic cell extract by centrifugation on a sucrose density gradient in which reverse transcriptase activity banded on the gradient at a density range characteristic of the virus particles [16].

Phosphocellulose column chromatography

Figure 1(a–d) exemplify the elution profiles of DNA polymerase activities on phosphocellulose column chromatography: crude extracts were obtained from a portion of the enlarged spleen of the individual rat with leukemia as described in Materials and Methods and directly chromatographed on the column. As control, extracts of spleen from a normal rat, the cultured R35 mammary tumor cells which continuously produced endogenous type C viruses [9] and the R35 virus particles were analyzed, respectively. To distinguish the activity of reverse transcriptase from that of cellular DNA polymerase γ, two kinds of template-primer were used for the assay, i.e. poly(rA)·$(dT)_{12-18}$ or poly(rCm)·$(dG)_{12-18}$; both enzymes respond to poly(rA)·$(dT)_{12-18}$, whereas only the viral enzyme is reported to respond to poly(rCm)·$(dG)_{12-18}$ [20, 21]. Activated DNA was also used as template-primer to locate the activity of DNA polymerase α and β [22].

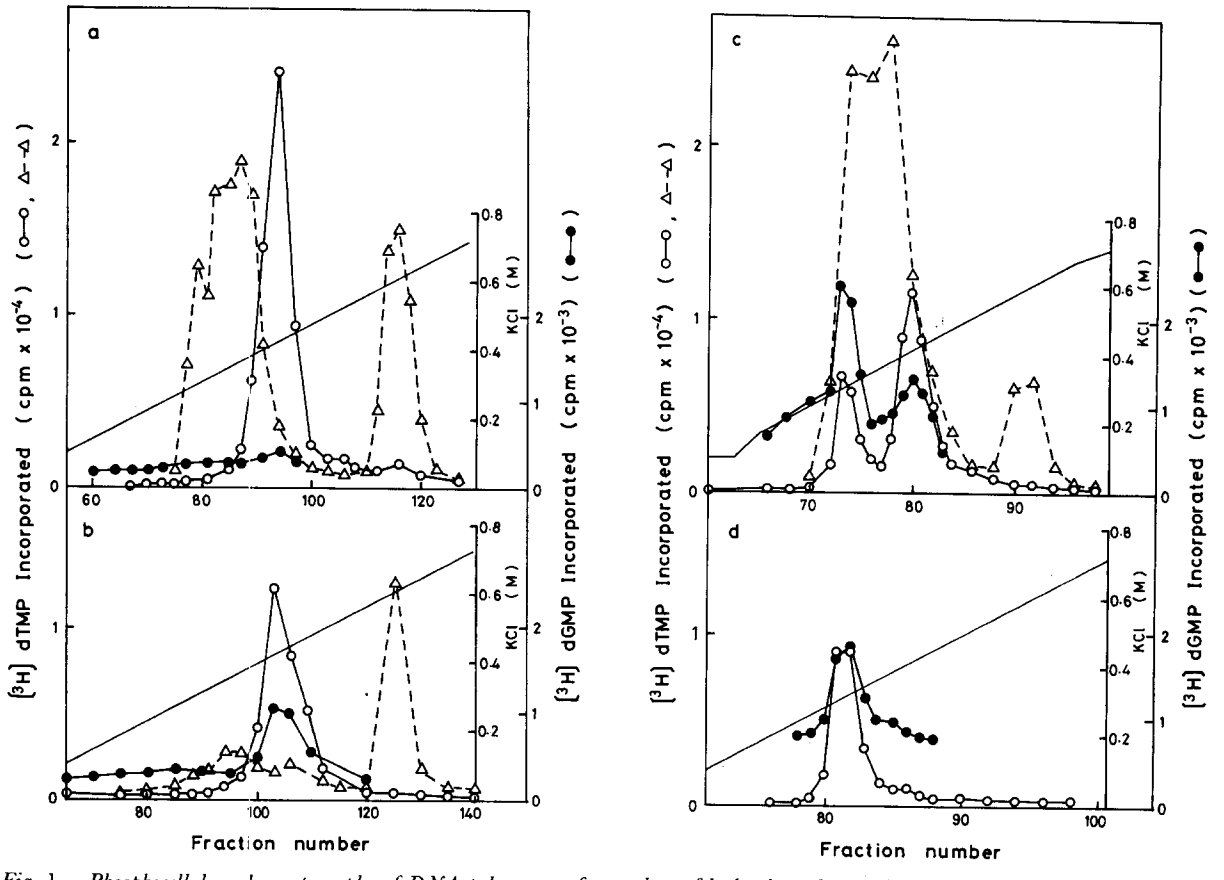

Fig. 1. Phosphocellulose chromatography of DNA polymerases from spleen of leukemia and normal rats and from R35 mammary tumor cells. Preparation of the crude extracts, column chromatography, and assay conditions for DNA polymerase activities were detailed under Materials and Methods. (a) Extracts from 1.9 g *parts of a rat spleen with NBU-induced leukemia were applied to a column* (1.5 × 23 cm) *of phosphocellulose. After a* 150 ml *wash with buffer A (see Materials and Methods), elution was carried out with* 300 ml *linear gradient of* KCl *from* 0.1 M *to* 0.8 M *at a flow rate of* 7 ml/hr. *Fractions of* 3 ml *were collected and* 5 μl *aliquots were assayed for DNA polymerase activities with poly(rA)·(dT)$_{12-18}$,* (○——○); *poly(rCm)·(dG)$_{12-18}$,* (●——●); *and activated DNA,* (△——△) *as template-primers, (b) Extracts from* 1.8 g *spleens of four normal rats together were chromatographed as in (a). (c) Extracts from* 0.5 g *of R35 rat mammary tumor cells were applied to a column* (0.8 × 20 cm) *of phosphocellulose. After a* 80 ml *wash with buffer A, elution was carried out with* 160 KCl *linear gradient from* 0.1 *to* 0.8 M *at a flow rate of* 3 ml/hr. *Fractions of* 1.5 ml *were collected and* 5 μl *aliquots were assayed for DNA polymerase activities. (d) Extract from R35 virus particles were applied to a column* (0.5 × 12 cm) *of phosphocellulose. After a* 20 ml *wash with buffer A, elution was carried out with* 20 ml KCl *linear gradient from* 0.1 M *to* 0.8 M *at a flow rate of* 1 ml/hr. *Fractions of* 0.5 ml *were collected and* 5 μl *aliquots were assayed for DNA polymerase activities.*

In the case of R35 mammary tumor cells (Fig. 1c), the activity with poly(rA)·(dT)$_{12-18}$ gave rise to two peaks; one at a KCl concentration of 0.31 M and the other one at 0.42 M. The former peak seems to represent the viral enzyme, since, (1) it coincided with the activity peak assayed with poly(rCm)·(dG)$_{12-18}$ and (2) the DNA polymerase activity from extracts of R35 virus particles eluted at the same KCl concentration (Fig. 1d). The latter peak may represent DNA polymerase γ, since it was present in all cases (Figs. 1a, b and c, respectively). It is also consistent with the data reported for other mammalian species [14, 20]. It is interesting that the latter peak also coincided with the activity directed by poly(rCm)·(dG)$_{12-18}$. Further chromatography on the DNA-cellulose column [17] of the latter peak fractions did not separate the activity directed by poly(rCm)·(dG)$_{12-18}$ from that directed by poly(rA)·(dT)$_{12-18}$ [data not shown]. It should be mentioned that these chromatographic tests were possible with 0.5 g parts of spleen or 0.3 g cultured cells and with a column of smaller size. With this smaller column, each test with five other rats with myelogenous leukemia and five normal rats gave results essentially identical to those shown, respectively, in Figs. 1(a) and (b). However, in Fig. 1(b) we used spleens from four normal rats together because of lower activities for normal rat spleen as compared to that of leukemic rat spleen. It is also noted that the extent of the enzyme activity directed by poly(rCm)·

$(dG)_{12-18}$ varied from time to time and from preparation to preparation for undetermined reasons (for examples, see the difference between the values in Figs. 1(a) and (b) and also in Experiments 1 and 2 in Table 1).

directed by each of the above two template-primers were sedimented at a density of around 1.17 g/cm^3 and also at the top of the gradient. The density of 1.16 g/cm^3 has been reported to be characteristic of RNA tumor viruses [23]. As controls, spleen from

*R35 virus refers to solubilized enzyme fraction after phosphocellulose chromatography (see Fig. 1d); MTC PC-I and MTC PC-II refer to pooled fractions from the 1st peak and the 2nd peak, corresponding to the viral enzyme and DNA polymerase γ, respectively, from phosphocellulose chromatography eluates of extracts from R35 mammary tumor cells (see Fig. 1c); L spleen PC and N spleen PC refer to pooled fractions from the peak corresponding to DNA polymerase γ obtained by phosphocellulose chromatography of the extracts from leukemic spleen and from normal spleen, respectively (see Figs. 1a and 1b); L spleen SDG and SDG-top refer to the fractions sedimented at a density of 1.17 g/cm^3 and at the top of the surcrose gradient, respectively, when extracts from leukemic spleen were centrifuged (see Fig. 2a); assay conditions for DNA polymerase see Materials and Methods.

Sucrose density gradient analysis

Postmitochondrial fractions were prepared from a portion of the enlarged spleen of each rat with leukemia. They were subjected to sedimentation on sucrose as described in Materials and Methods. After centrifugation the materials were fractionated and assayed for DNA polymerase activity using poly(rA)·$(dT)_{12-18}$ or activated calf thymus DNA as template-primer. Figure 2(a) shows the results obtained in the case of a rat with the leukemia. The enzyme activities a normal rats (Fig. 2b) and R35 virus particles (Fig. 2c) were analyzed in the same manner.

As for the DNA polymerase activities sedimented at a density of around 1.17 g/cm^3, the activity directed by poly(rA)·$(dT)_{12-18}$ was notable only in the case of rats with leukemia (5 out of 6 animals examined) but not in the case of normal rats. One may then assume that the activity detected at the density of 1.17 g/cm^3 is associated with the virus. From the following results,

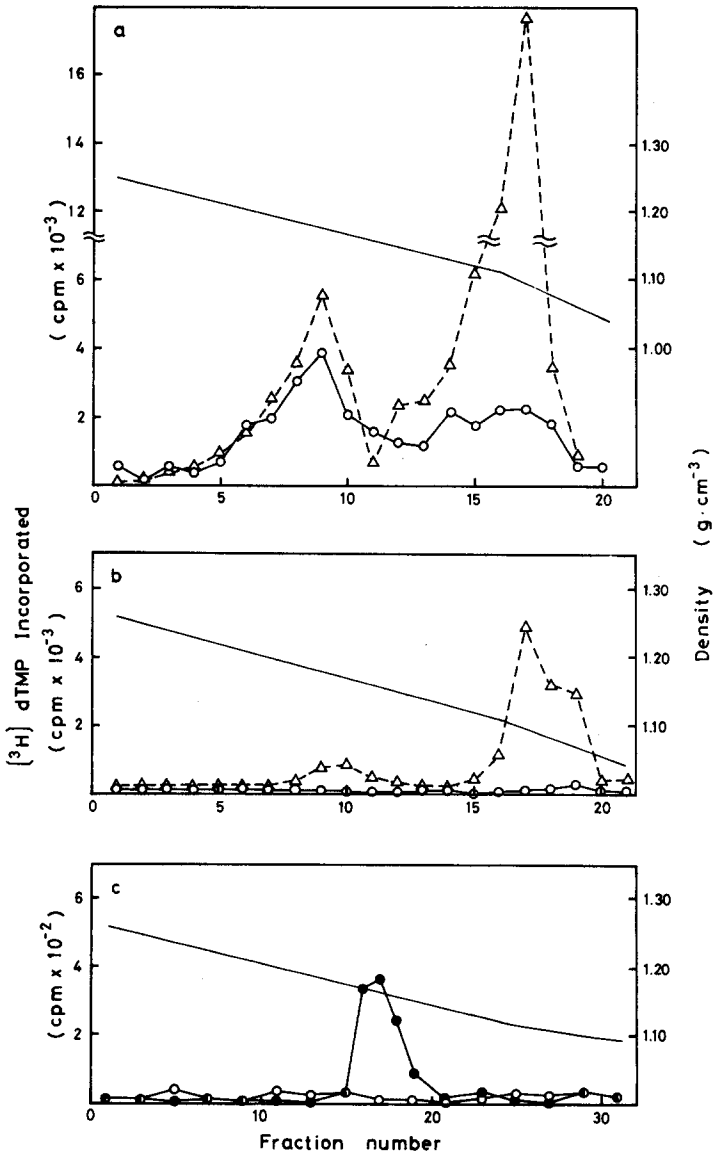

Fig. 2. Sedimentation analyses on sucrose of postmitochondrial fractions from spleen of a leukemia rat and of a normal rat and from R35 virus particles. (a) Postmitochondrial fraction from 0.4 g *of spleen of a leukemic rat was subjected to sedimentation on a sucrose density gradient. Preparation of postmitochondrial fractions and conditions for the centrifugation analysis were described under Materials and Methods. Fractions of* 10 *drops were collected and* 10 µl *aliquots were assayed for DNA polymerase activities with poly(rA)·(dT)$_{12-18}$,* (○——○); *and activated calf thymus DNA,* (△——△) *in the absence of Nonidet P40 as described in Materials and Methods. (b) Postmitochondrial fraction from* 0.4 g *of spleen of a normal rat was analysed as in (a). (c) R35 virus particles (for preparation see Materials and Methods) were subjected to sedimentation as in (a) but the assay was carried out in the presence* (●——●) *and in the absence* (○——○) *of* 0.7% w/v) *Nonidet P40, using* 20 µl *aliquots for the assay.*

however, we rather conclude that it is of cellular DNA polymerase γ: (1) The assay for the DNA polymerase activities described above was carried out in the absence of detergent, which is usually required for detection of the activities associated with virus particles [24, 25]. In fact, Nonidet P40 was required for the activity directed by Poly(rA)·(dT)$_{12-18}$ in the case of R35 virus (Fig. 2c). (2) The incorporation of dGMP directed by poly(rCm)·(dG)$_{12-18}$ was tested in the fractions of the sucrose density gradient

in the case of a rat with leukemia as shown in Table 1 (designated as Leukemic spleen SDG). The extent of the incorporation relative to that of dTMP directed by poly(rA)·$(dT)_{12-18}$ was not as prominent as that in the fractions from R35 virus particles. It should be mentioned that an attempt to visualize virus particles by an electron microscope with the negative staining method in the materials banded at a density of 1.17 g/cm^3 was without success in the case of the rat with leukemia (Fig. 2a).

Enzymatic properties

In order to further confirm that the poly(rA)·$(dT)_{12-18}$-directed DNA polymerase activity in the leukemic cells is identical with that of DNA polymerase γ, optimum assay conditions for the activity of the phosphocellulose peak from leukemic spleen was compared with that of DNA polymerase γ peak from normal rat spleen or for reverse transcriptase peak from R35 rat mammary tumor cells or from R35 virus particles; these peaks used were all obtained after phosphocellulose chromatography [Figs. 1(a–b) and legend to Table 1]. The results were as follows.

Effect of salt. Table 2 shows the optimum KCl concentrations for the activity of each peak fraction when poly(rA)·$(dT)_{12-18}$ or poly(rCm)·$(dG)_{12-18}$ was used as template-primer. Clearly, optimum KCl concentration for the activity of the peak fraction from leukemia spleen is the same as that for the DNA polymerase γ fractions obtained from spleen of normal rat, but different from that of the viral enzyme fractions either from R35 mammary tumor cells or from R35 virus particles.

Table 2. Optimal KCl *concentrations*

Enzymes	Optimum KCl concentration (mM)	
	Template-primer	
	poly(rCm)·$(dG)_{12-18}$	poly(rA)·$(dT)_{12-18}$
R35 virus	40	70
MTC PC-I	40	70
L spleen PC	5	130
N spleen PC	5	150

For identity of the enzymes see legend to Table 1.
The reaction conditions are specified in Materials and Methods.

Effect of divalent cations. Table 3 shows the optimum $MnCl_2$ concentrations for the activity of each peak fraction when poly(rA)·$(dT)_{12-18}$ or poly(rCm)·$(dG)_{12-18}$ was used as template-primer. The peak fraction from leukemic spleen was clearly distinguished from the viral enzyme fractions when poly(rCm)·$(dG)_{12-18}$ was used as template-primer. The optimum concentration for the peak from leukemic spleen was the same as that for DNA polymerase γ fraction from spleen of normal rat.

Table 3. Optimal manganese concentrations

Enzymes	Optimum $MnCl_1$ concentrations (mM)	
	Template-primer	
	poly(rCm)·$(dG)_{12-18}$	poly(rA)·$(dT)_{12-18}$
R35 virus	0.2	0.7
MTC PC-I	0.4	0.6
L spleen PC	2	0.7
N spleen PC	2	0.6

For identity of the enzymes see legend to Table 1.
The reaction conditions are specified in Materials and Methods.

Table 4 shows the optimum magnesium acetate concentration for the activity of each enzyme fraction when Mn^{2+} was replaced by Mg^{2+} in the reactions (see Table 3). The peak from leukemic spleen as well as from that of a normal rat required rather a broad range of Mg^{2+} concentrations of 6–15 mM when poly(rA)·$(dT)_{12-18}$ was used as template-primer. However, the viral enzyme fractions gave no detectable activity within any range of Mg^{2+} concentrations tested from zero to 16 mM. When poly(rCm)·$(dG)_{12-18}$ was used as template-primer, none of the four enzyme fractions showed detectable activity with Mg^{2+}.

Table 4. Optimal magnesium concentrations

Enzymes	Optimum magnesium acetate concentration (mM)	
	Template-primer	
	poly(rCm)·$(dG)_{12-18}$	poly(rA)·$(dT)_{12-18}$
R35 virus	n.d.	n.d.
MTC PC-I	n.d.	n.d.
L spleen PC	n.d.	6–15
N spleen PC	n.d.	8–15

n.d. means that the optimum condition could not be determined because essentially no activity was detected.
For identity of the enzymes see legend to Table 1.
The reaction conditions are specified in Materials and Methods.

pH optimum. Table 5 shows that with

Table 5. Optimal pH

Enzymes	Optimum pH	
	Template-primer	
	poly(rCm·$(dG)_{12-18}$	poly(rA·$(dT)_{12-18}$
R35 virus	>9	8.0–8.5
MTC PC-I	>9	8.0–8.5
L spleen PC	>9	7.7–8.0
N spleen PC	>9	7.5–7.8

Potassium phosphate buffer and Tris–HCl buffer were used for pH ranges from 7.0 to 7.5 and from 7.2 to 9.0, respectively.
Other conditions in the reaction are specified in Materials and Methods.
For identity of the enzyme see Table 1.

poly(rA)·$(dT)_{12-18}$ the peak fraction from leukemic spleen as well as from spleen of normal rat required pH values of 7.5–8.0 for optimum activity, while viral enzyme fractions required a little higher pH values of 8.0–8.5. With poly(rCm)·$(dG)_{12-18}$ as template-primer, incorporation of dGMP by the peak as well as by the other three enzyme fractions required pH values of more than 9.

Effect of inhibitor. Poly(rA)·$(dT)_{12-18}$-directed activity of the viral enzymes was inhibited to about 17% by 1 mM *N*-ethylmaleimide. Under the same condition the activity of the phosphocellulose peak fraction from the leukemic spleen or DNA polymerase γ fraction from normal spleen was not inhibited. When poly(rCm)·$(dG)_{12-18}$ replaced poly(rA)·$(dT)_{12-18}$ in the above test, only the viral enzymes were again inhibited. However, 1 mM of *p*-chloromercuriphenyl sulfonic acid inhibited the activity by 90% in all the above cases.

Molecular weight

Phosphocellulose peak fraction from spleen of the leukemic or normal rat was subjected to velocity sedimentation analysis on glycerol gradient. Both enzymes were sedimented at about 4S in solutions containing 0.25 M KCl. The value is equivalent to a mol. wt of 60,000 for a globular protein (data not shown). This value coincided with that reported for rat liver DNA polymerase γ in a high salt condition [26]. However, the relevance to this rather small value remains to be examined. Reverse transcriptase from R35 mammary tumor cells was sedimented also at about 4S. A mol. wt of 70,000 has been reported for R-MuLV [14] and M-MuSV (MuLV) reverse transcriptase [27].

DISCUSSION

The biochemical data obtained in this paper are consistent with the previous knowledge which does not support a viral etiology for tumorigenesis in rats [4, 7]. For example, in the NBU-induced leukemia rat, cell-free transmission was negative; electron microscopic studies and group-specific cell surface antigen were also negative [4].

By phosphocellulose chromatography we showed that the viral DNA polymerase was not noticeably present in the leukemic spleen (Fig. 1a); i.e. the extracts from the leukemic spleen gave only one peak of poly(rA)·$(dT)_{12-18}$-directed activity which coincided with that of DNA polymerase γ. On the other hand, the extracts from R35 virus-producing rat mammary tumor cells gave a unique peak of activity in addition to the peak of cellular DNA polymerase γ. The peak was characterized as the activity of viral enzyme, since it coincided with the activity peak obtained from extract of R35 virions (see Figs. 1c and 1d).

Further characterization on the enzymatic properties of these peaks made clear that the peak corresponding to DNA polymerase γ, either from leukemic spleen, normal spleen, or R35 mammary tumor cells, possessed the same properties, but they were different from those of the unique peak of R35 mammary tumor cells or R35 virions (Tables 2–5). Libertini and Adams [8] observed similar poly(rA)·$(dT)_{12-18}$-directed DNA polymerase activity in carcinogen-induced rat mammary tumor and also in normal lactating rat mammary tissues. They suggested a possibility that the activity is associated with endogenous viruses that may be produced in a normal rat as it is the case in mice. However, in our case, since the phosphocellulose chromatography and tests on enzymatic properties have clearly distinguished the rat viral enzyme from cellular enzyme as described above, we tend to conclude that no viral enzyme was detectable in the rat myelogenous leukemia cells.

It is noteworthy that, in the present study, cellular DNA polymerase γ fractions from rat responded to a synthetic template-primer, poly(rCm)·$(dG)_{12-18}$. This is in contrast to the previous reports claiming that poly(rCm)·$(dG)_{12-18}$ is specific for viral reverse transcriptase [20, 21]. A similar coincidence of the activity directed by poly(rC)·$(dG)_{12-18}$ (in which cytidine residues are not methylated), with that

directed by poly(rA)·$(dT)_{12-18}$, has been reported for DNA polymerase γ isolated from rat mammary tumor and normal mammary tissues [8], HeLa cells [28], or mouse L cells [29]. In our case, however, the activity directed by poly(rCm)·$(dG)_{12-18}$ was lost step by step during further purification of rat DNA polymerase γ by chromatography on a column of DEAE-cellulose of hydroxyapatite (Kozu and Seno, unpublished observations). In the case of mouse myeloma, poly(rCm)·$(dG)_{12-18}$-directed activity is also detectable in a crude DNA polymerase γ preparation but is not detectable in the further purified enzyme preparation (Ono and Matsukage, personal communications). One may therefore be cautious in using this template-primer as a specific means to discriminate viral reverse transcriptase from cellular DNA polymerase, especially when the enzyme preparation is crude. In this respect, further purification and characterization of DNA polymerase γ from rat spleen are under way.

The poly(rA)·$(dT)_{12-18}$-directed activity in the postmitochondrial fractions from the leukemic spleen but not those from normal spleen sedimented at a density of 1.17 g/cm^3 on sucrose (Fig. 2). It seems that the activity is associated with the virions. However, it is noted that the addition of the detergent was not required for the assay of activity, while it was required in the case of R35 virus particles (Fig. 2c). Hence, the activity is presumably of cellular DNA polymerase γ bound to cellular membranes [30] which coincidentally possessed a density value characteristic of RNA tumor viruses. In addition, virus-like particles were not observed in the active fractions by electron microscopy (data not shown). Therefore, the difference observed for postmitochondrial fractions between leukemia and normal spleen may possibly be due to the different growth rate of leukemic cells and normal cells.

Although we failed to detect reverse transcriptase activity in the leukemic cells which had proliferated metastatically in the spleen, this does not necessarily mean that oncogenic virus was not involved in the leukemia induced by NBU in the present study. Sarcomas induced in hamsters or rats with certain types of viruses usually do not reveal the presence of virus particles on electron microscopic examination [1]. In the process of *in vitro* transformation by infection of cells with oncogenic RNA viruses, it is reported that the reverse transcription from viral RNA to DNA occurs in the cells only in the early stages of infection, but it no longer occurs once the transformation is established [31]. By analogy, even if the virus was involved in the rat leukemia in our case, the viral gene may have been active only in a certain early stage of leukemogenesis that occurred in the bone marrow [32] and the viral gene expression could have been suppressed once the leukemic cells were established in the animal. Such possibility could not be ruled out in the present study.

Effect of Immunotherapy on the Kinetics of Proliferation of a Transplanted Rat Rhabdomyosarcoma

DO THE GIA* and F. LOISILLIER†‡

Institut de Cancérologie et Immunogénetique, Hôpital Paul-Brousse, 14, avenue Paul-Vaillant-Couturier, 94800 Villejuif, France and †Laboratoire d'Anatomie Pathologique des Services Communs du CNRS à Villejuif, 13 Rue Guy Mocquet 94800 Villejuif, France

Abstract—*Our experiment confirms the effect of BCG and of neuraminidase (VCN) associated with mitomycine C (MitoC) treated tumoral cells on a rhabdomyosarcoma serially transplanted in a rat, which have been shown to prevent or to delay the growth of many experimental tumors and also prolonged the survival time of the animals.*

We have determined the effect of active immunotherapy on some kinetic parameters on the tumor growth. The NS 104 tumor may provide a tool to determine, whether this action of immunotherapy on resting cells is also true for other types of tumors.

INTRODUCTION

NON SPECIFIC (i.e. BCG) and/or specific immunostimulations have been shown to prevent or to delay the growth of many experimental tumors.

This effect has been quantified according to various parameters such as: the minimal number of cells which are able to induce in 50% of inoculated animals, the delay of appearance of the tumor, the mean survival time. We report here a study on a rhabdomyosarcoma serially transplanted in rat. We have determined the effects of active immunotherapy of some kinetics parameter of the tumor growth.

MATERIALS AND METHODS

Animals

Six weeks old Fisher 344 rats were obtained from Microbiological Associates, Bethesda, Maryland, U.S.A. and 5 groups of 8 rats were randomly used.

Tumors

NS 104 tumor is a rhabdomyosarcoma induced by subcutaneous injection of 10 mg Nickel Sulphite in Fischer 344 rats and has been provided by The Mason Research Institute, Worcester, Massachusetts, USA.

Bacilli Calmette Guérin (BCG)

Fresh BCG, containing 75 mg of live bacilli has been provided by Pasteur Institute, Paris, France.

Vibrio cholerae neuraminidase (VCN)

Five hundred units/ml of VCN has been provided by General Biochemicals Inc., Chagrin Falls, Ohio, USA.

Mytomycine C (Ametycine)

This product has been provided by Choay Laboratories, Paris, France in dry power.

Experimental protocol

All rats were inoculated subcutaneously on the left flank with 5×10^6 live tumor cells and randomized into 5 experimental groups.

Group I. This group received only live tumor cells.

Group II. Animals of this group were treated with 1 mg of BCG suspended in 0.10 ml RPM 1640 inoculated at the same site as the live tumor cells. The first injection of BCG was done simultaneously with the cells, and a second injection was given 10 days later.

Group III. Animals of this group were inoculated with BCG as in group II, on day 0 and 10 but at a distance of 2 cm from the site of inoculation of live tumor cells.

Group IV. Animals received simultaneously

Accepted 15 July 1977.

live tumor cells and 5×10^7 live tumor cells previously incubated for 1 hr at 37°C with 25 units of neuraminidase (VCN) and 12.50 mg mitomycine C (MitoC). After incubation, cells were washed with fresh RPM 1640 and inoculated subcutaneously in 0.10 ml of medium in the right flank.

A second inoculation of VCN and MitoC treated cells was done on day 10 under the same conditions.

Group V. Animals of this group received 5×10^7 irradiated tumor cells on day 0 and day 10 on the right flank.

Groups I, II and V were repeated in a second experiment. In all groups, rats were palpated daily starting from day 10. Tumors were measured using a calliper. Delay of appearance of palpable tumor were recorded. Four diameters were measured and each one was measured 6 times.

The tumor was measured at least 6 times before death. For each point, the mean diameter was obtained and the volume of the tumor was calculated by assimilation of the tumor shape to a sphere and using the formula $V = \frac{4}{3}\pi(D^3/2)$, V is expressed in cubic centimeters. Results were plotted on a semi-logarithmic paper and the doubling time of the tumor during the exponential growth phase was determined.

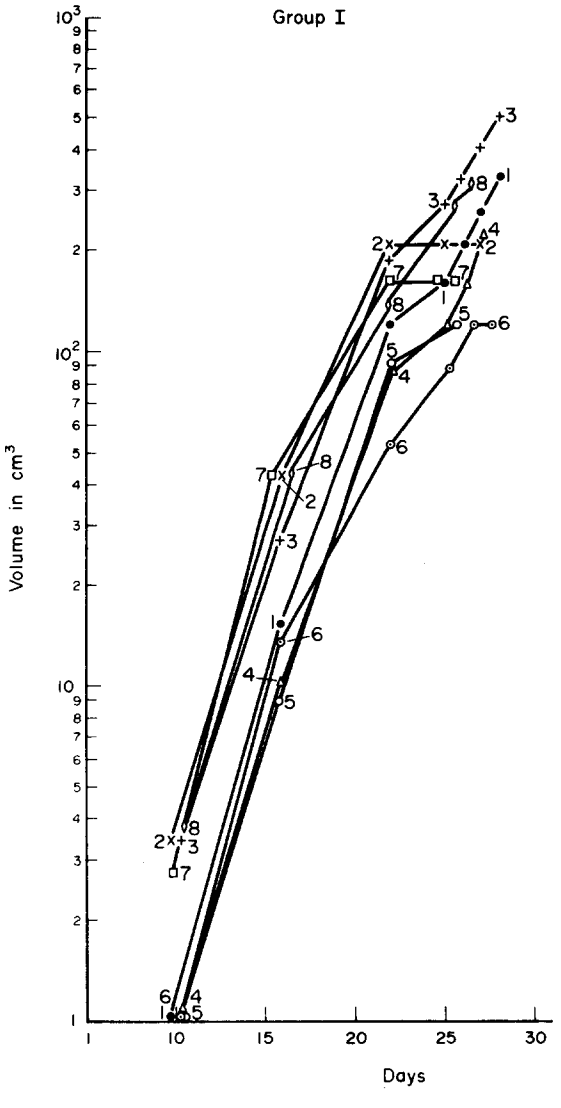

Fig. 1. Eight rats were randomly used in the first experiment of the control group (Group I) and the curves of the Fig. 1 represent the volume growth of the tumours in cm^3 *and the survival time in days for each rat.*

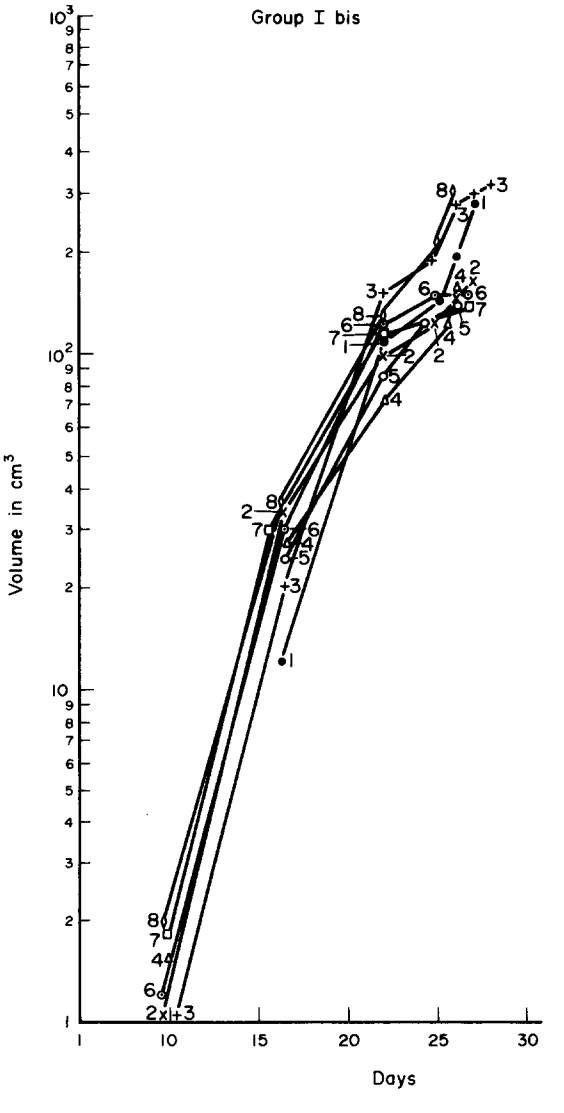

Fig. 2. Eight rats were randomly used in the second experiment of the control group (Group I bis) and the curves of the Fig. 2 represent the volume growth of the tumors in cm^3 *and the survival time in days for each rat.*

For each group, the mean and standard deviation of the doubling time, the survival time and the final volume of the tumor were calculated and compared using a student test.

Correlations between each value, in each group, were made using a computerized programme (compucorps).

Anatomopathological studies

In the first experiment, animals were sacrificed when they were dying.

In the second experiment, 6 animals were used for anatomopathological studies and sacrificed during the plateau phase of the tumor growth. Tumor, spleen, kidney and lymph nodes were systematically taken and fixed with buffered formol and included in paraffine.

Hematein, eosine, safranine, green methyl pyronine and PAS staining techniques were used.

times and tumoral volumes are summarized in Table 1.

The mean kinetic results can be summarized as follows:

Tumors from the control group were generally detected on day 10, when they measured 100–300 mm^3. The exponential growth phase of the tumor was clearly defined, mean doubling time of 2.27 ± 0.21 days was calculated. A plateau phase was

Eight rats were randomly used in this experiment and they were inoculated with BCG as in groups II *and* II *bis, on* day 0 *and* 10, *but at a distance of* 2 cm *from the site of inoculation of live tumor cells (Group* III*). The curves of Fig.* 5 *represent the volume growth of the tumor in* cm^3 *and the survival time in days for each rat.*

observed only in 2 animals out of 16. The mean final volume of tumor was $13.55 \pm 6.96\,cm^3$.

The inoculation of live BCG mixed with tumor cells on day 0 and 10 produced a clear cut effect on all parameters of tumor growth. In 5 out of 16 animals, tumors were detectable around the 15th day. In all animals, the doubling time of tumors was increased and a mean value of 3.39 ± 0.57 days was calculated. No real plateau phase was observed in this group and tumors reached a volume of $17.36 \pm 7.42\,cm^3$, a value was not statistically different from the control group. The survival time was increased to 38.60 ± 1.31 days.

In group III, the inoculation of BCG at 2 cm from the site of inoculation of tumor cells produced the same effects as the effects of BCG mixed with tumoral cells. The following values were calculated:

The mean value of survival time: $35.12 + 0.83$ days.

The mean value of doubling time: 2.79 ± 0.48 days.

The mean value of tumoral volume: $18.90 \pm 5.81\,cm^3$.

However, in contrast with group II, a clear plateau was observed in 6 out of 8 tumors. The plateau phase probably explains the significant prolongation of survival time which contrasts with a moderate increase of doubling time of tumors.

In group IV, injection of neuraminidase (VCN) associated with mytomycine (MitoC) treated with tumoral cells increased also

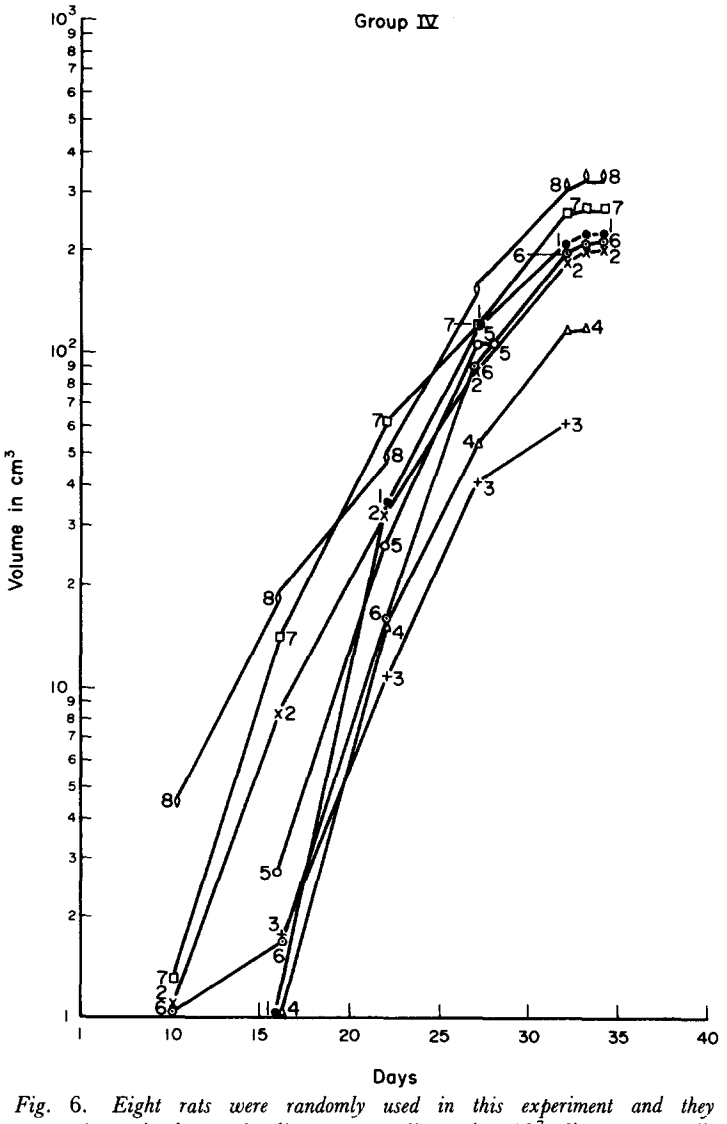

Fig. 6. *Eight rats were randomly used in this experiment and they were given simultaneously live tumor cells and* 5.10^7 *live tumor cells previously incubated for* 1 hr *at* 37°C *with* 25 *units of neuraminidase* (*VCN*) *and* 12.5 mg *of myitomycine C* (*MitoC*) *on* days 0 *and* 10 (*Group* IV). *The curves of Fig.* 6 *represent the volume growth of the tumors in* cm^3 *and the survival time in days for each rat.*

the mean value of survival time: 33.75 ± 0.75 days, the mean value of doubling time: 3.09 ± 0.50 days, the mean value of tumoral volume $11.26 \pm 5.60\,cm^3$. No real plateau phase was observed.

In group V, a great heterogeneity was observed as demonstrated on the curves and by the greater range of standard duration of this group.

comparison of the mean value of survival time and of doubling time of each group.

To determine which parameters were correlated, values from the two experiments were pooled and correlation coefficient were calculated. The results are summarized in Table 4. It appears that the most significant correlation ($r=0.7022$) is observed between the mean value of survival time and of doubling time. The correlation between the mean value of survival time and of tumoral volume is significant at the 1% level ($r=0.4233$). No correlation was found between the mean value of doubling time and tumoral volume ($r=0.1617$, $P<10\%$).

1.	Correlation of survival time and final volume of the tumor Coefficient of correlation: 0.4233 Significative correlation: $P<1\%$
2.	Correlation of doubling time in the exponential phase of tumor growth and the survival time of the animal Coefficient of correlation: 0.7022 very significant: $P<1\%$
3.	Correlation of doubling time and volume of the tumor Coefficient of correlation: 0.1617 No correlation: $P>10\%$

Anatomopathological studies

The NS 104 tumor has a typical histological aspect of rhabdomyosarcoma [1]. In all groups, large necrotic zones were seen. No peritumoral reaction was seen in the control group. Attempts to quantify this necrosis have been made by measuring its surface. The results are summarized in Table

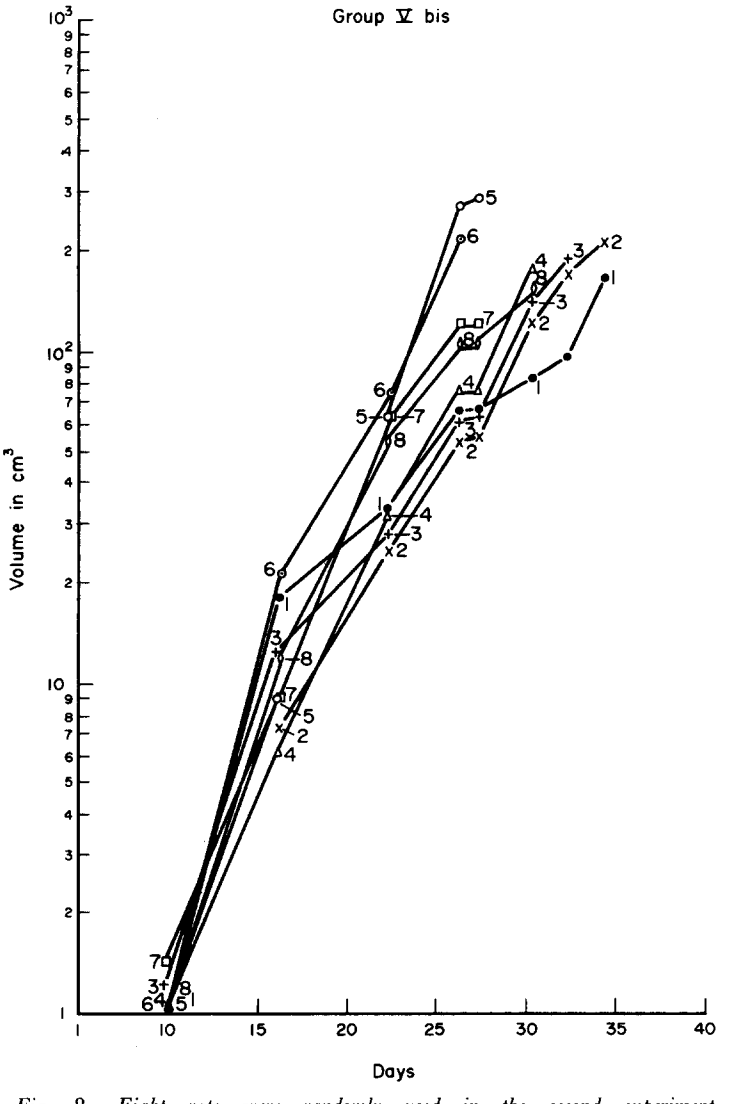

Fig. 8. *Eight rats were randomly used in the second experiment and they were given* 5.10^7 *irradiated tumor cells on* days 0 *and* 10 *in the right flank* (*Group* V *bis*). *The curves of Fig.* 8 *represent the volume growth of tumors in* cm^3 *and the survival time in days for each rat.*

5. The most striking difference was observed in group II, in which necrosis represented around 80% of tumor action. In some sections, the tumor was completely necrotic without living tumor tissues. No significative differences were observed between other groups. It has been noticed, that a liver steatosis was associated with tumor necrosis and the importance of the necrosis was correlated to the extent of tumor necrosis.

Table 5. *Comparative table of the necrosis of the tumor in percentage amongst the* 5 *groups after the histological studies*

No. of the animal	Group I	Group II	Group III	Group IV	Group V

Fig. 11. *In this rat treated with neuraminidase (VCN) associated with mitomycine C (MitoC), one observes that the tumor is necrotic but at the margin of the tumor there are only several vessels and some fat tissues without plasmocytic reaction.*

DISCUSSION

Our experiment confirms the effect of BCG and of neuraminidase (VCN) associated with mitomycine C (MitoC) treated tumoral cells on this transplanted rhabdomyosarcoma. The inoculation of BCG mixed with live tumor cells or at 2 cm from the site of inoculation of tumor cells completely prevented the growth of the tumoral cells inoculated in the right flank. BCG was also able to affect the growth of tumor cells inoculated in the opposite flank of the animals. However, all tumor cells multiplied and no animals survived in this experiment.

The different treatments modified significantly the tumoral volume, the doubling time of the tumor and the survival time of the animals.

Both BCG mixed with tumoral cells and to a lesser extent BCG injected near the site of inoculation of tumoral cells were the most effective in prolonging survival time [2, 3].

Treatment with neuraminidase (VCN) [4–6] associated with mitomycine C (MitoC) treated tumoral cells also prolonged the survival time of the animals [7–10]. Injection of irradiated tumoral cells produced a great heterogeneity of response. Some animals died early and were not affected by the treatment whereas other animals had a significant delay of death, indicating that probably the size of the tumor cell inoculum is at the upper limit of efficiency of immunotherapy [11–18].

Measurements of the doubling time indicate that inoculation of BCG mixed with tumor cells affects the most clearly the doubling time of tumor. Comparison of groups III (peritumoral BCG) and IV (Neuraminidase VCN) associated with mitomycine C (MitoC) treated cells shows a slight discrepancy between the survival time and the doubling time. This is explained by the existence of a plateau phase in animals at group III indicating perhaps is some ways a better tolerance to the tumor than in group IV.

Therefore, death might be at least partially related to a toxic effect which may not be directly proportional to the volume of the tumor.

Great variations of the tumor volumes shown by the ranges were observed in each group. This contrasts with the narrow ranges of survival time and doubling time in all but one group.

The absence of correlation between the doubling time and the tumoral volume, and the great correlation between the doubling time and the survival time underlines the importance of determining the doubling time of tumor to detect an anti-tumor effect of immunotherapy on established tumor.

Anatomopathological studies confirms that BCG is able to induce a local and general lymphocytic reaction with a marked peritumoral infiltration and a reaction in draining lymph nodes and in spleen [19–21]. The results of a details study will be reported later.

Our results stress the need for additional studies including the measure of labeled mitosis curves to determine more completely the effect of immunotherapy of kinetic parameters which have not been studied enough in the case of immunotherapy. It has been shown in L1210 leukemia [2, 3] that BCG is acting on cells in the G 1 phase and the availability of other models such as the NS 104 tumor may provide a tool to determine whether this action of immunotherapy on resting cells is also true for other types of tumors.

Temperature Effects During and After the Diethylnitrosamine Treatment on Liver Tumorigenesis in the Fish, *Oryzias latipes**

YORIKO KYONO

Zoological Institute, Faculty of Science, University of Tokyo, Tokyo 113, *Japan*

Abstract—*Four experimental groups of the medaka* (Oryzias latipes) *were treated with diethylnitrosamine (DENA) at the concentration of* 100 ppm *for* 8 *weeks. Two of them were kept at a high temperature* (22 ± 2°C) *and others at a low temperature* (5–6°C). *After the DENA treatment, one of the high temperature groups was kept again at a high temperature in normal tap water (H.H-group) and the other was transferred to a low temperature (H.L-group). In the similar way, L.H- and L.L-groups were made. Eight and twelve weeks after the beginning of the experiment, about* 10 *fish in each group were sacrificed for histological observation.*

Both in H.H- and H.L-groups, many tumor nodules were found in their livers. But the number and the size of tumor nodules were larger in H.H-group than in H.L-group. On the contrary, no tumor nodules were observed in L.H- and L.L-groups which were treated with DENA at a low temperature. From these results, an appropriate high temperature is considered to be necessary in the formation and the growth of tumor nodules.

INTRODUCTION

IN RECENT years, several works have been reported about tumorigenesis in aquarium fish by various carcinogens [1–5]. The small aquarium fish, such as zebra danio, guppy and medaka, are thought to be very useful in the research of environmental carcinogens [6], for they are rather susceptible to carcinogens and can be easily reared without special facilities. Besides, fish are available for the experiment to ascertain the temperature effects on tumor induction and tumor growth, because of their poikilothermicity. Recently, we reported that no tumor nodules but only one altered hyperbasophilic focus were induced by the administration of diethylnitrosamine at a low temperature, though almost all the fish treated with DENA at a high temperature had many well developed tumor nodules [7]. In previous experiment the fish had been kept at different temperatures during the DENA treatment. In this work, the process of liver tumorigenesis was divided into two periods, one was the period of DENA treatment and the other was the post-treatment period. Keeping each period at a high or low temperature, the difference in the incidence and the development of the liver tumors in each experimental group were examined and discussed.

MATERIALS AND METHODS

In the present experiment, about 160 fish of himedaka (an orange–red variety of medaka) were used. They were obtained in our laboratory, 9 months old and 23–27 mm in body length. They were kept outdoors before the experiment. In order to be acclimatized to the different temperatures, fish were divided into two lots and kept at 22–25°C or about 5°C for 3 weeks. Then 7 experimental groups were made.

The fish of the 1st and the 2nd groups were administered diethylnitrosamine (DENA, Tokyo Kasei Co., Ltd., Tokyo) in the water at the concentration of 100 ppm for 8 weeks at a high temperature (water temperature = 22 ± 2°C). Then the fish were transferred to normal tap water and kept at a high

Accepted 9 March 1978.

*This study was supported in part by a grant to Prof. N. Egami from the Ministry of Education, Science and Culture in Japan.

temperature (22±2°C, H.H-group) or at a low temperature (water temperature= 5–6°C, H.L-group) for 4 weeks. The fish of the 3rd group were kept in normal tap water at a high temperature throughout the experiment as a control of the high temperature group (H.C-group).

The 4th and 5th groups were kept at a low temperature (5–6°C) during the DENA treatment. DENA was given at the same concentration for 8 weeks. After the end of the treatment, each of them was transferred to normal tap water and kept for 4 weeks at a high temperature (L.H-group) or at a low temperature (L.L-group). The 6th group kept at a low temperature without DENA treatment served as cold control (L.C-group).

The water was changed once a week throughout the experiment. The fish of the experimental groups were reared in 8 liter glass tanks. They were illuminated with fluorescent light from 6.00 a.m. to 7.00 p.m. The fish were fed with Tetramin (Tetra Werke, West Germany) once a day during the course of the experiment.

When the DENA treatment was stopped and the experiment was finished (8 and 12 weeks after the beginning of the experiment), 8–11 fish in each group were killed and autopsy was carried out. Then the fish were fixed in Bouin's solution. After the samples were transferred into 70% alcohol, the body weight and the liver weight were measured in each individual. The liver-somato indices were calculated. Histological serial sections of whole liver were made by a routine procedure and stained with hematoxylin and eosin.

Besides, as the 7th group, some of the fish treated with DENA at a low temperature were administered DENA successively until 13 weeks under a low temperature condition. After that they were transferred to normal tap water at a high temperature for 4 weeks (L'.H-group). The livers of these fish were also observed histologically.

RESULTS

The results of the liver-somato index are summarized in Fig. 1. Comparing L.C- with H.C-group, it was indicated that the liver weight became heavier at a low temperature than at a high temperature. Electronmicroscopic observation suggested that the increase

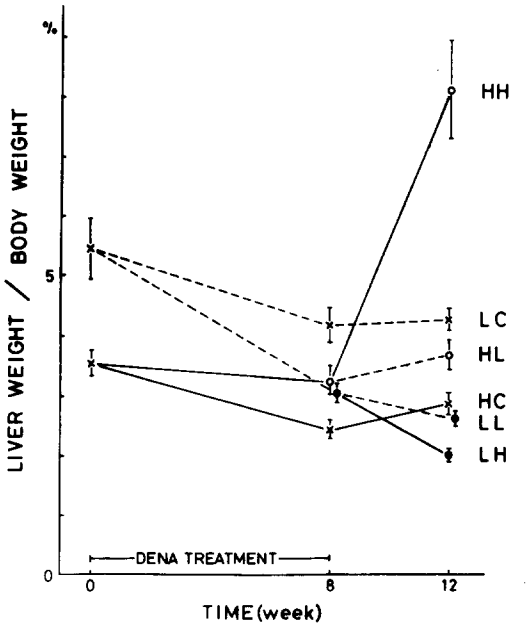

Fig. 1. The ratio of the liver weight to body weight in fish of each group. Experimental procedures were written in the text. The ratio of H.H-group was significantly higher ($P<0.001$) than those of other groups. Broken lines show low temperature period. Vertical bars indicate standard errors.

was mainly owing to the accumulation of glycogen granules in hepatocytes [8].

The fish of H.H-group had markedly enlarged livers. Twelve weeks after the beginning of the experiment, the value was about 8%. It was significantly higher than those of other groups ($P<0.001$). It was clear, by autopsy, that the high value was due to the development of large tumor nodules.

Results obtained from the histological observations of each group are as follows.

Control group (H.C-, L.C-groups)

The livers of the fish fixed at 12 weeks after the start of the experiment were histologically observed. At a high temperature, the fish had reddish livers (H.C-group), but the color became pink when they had been kept at a low temperature for a period of 12 weeks (L.C-group).

The normal liver consisted of polyhedral hepatocytes containing a round to oval nuclei with single centrally-localized nucleolus. The hepatocytes had little stained cytoplasm and showed sheetlike structures along the vascular sinusoides (Fig. 2). Small necrotic parts were occasionally observed in half of the fish kept at a high temperature. However, all fish reared in normal tap water did not show any indication of liver tumorigenesis.

Experimental groups

Eight weeks after the start of the DENA treatment. All the fish treated with DENA at a high temperature showed histologically abnormal livers. They had some small tumor nodules, 1–13 nodules per liver. The size of the tumor nodule was markedly smaller than that of the fish fixed 4 weeks later (H.H-group). Other parts of the liver consisted of enlarged hepatocytes stained eosinophilically and of many non-parenchymal cells.

In contrast to this, all the fish treated with DENA at a low temperature for 8 weeks did not show any histological changes. The livers were similar to those of the control fish kept at a low temperature.

Four weeks after the ending of the DENA treatment H.H-group. All the fish kept at a high temperature during and after the DENA treatment had enlarged whitish livers (11 fish out of 15 fish survived) and some small or large tumor nodules were observed. The tumor nodules seemed to be trabecular hepatoma or liver cell carcinoma. Hyperbasophilic and undifferentiated cells were observed rather frequently in the central part of the nodules. Many mitotic figures were observed especially in small tumor foci (Figs. 3 and 4). These fish had 2–16 tumor nodules per liver, maximum diameter being 100 μm. One fish had so many tumor nodules close together that the number was not able to be counted.

In addition to the hyperbasophilic nodules, hyperbasophilic nodules and the non-parenchymal cells were often observed in the residual parts of the livers. The latter were similar to the cells of connective tissue or lymphatic system.

H.L-group. In this group, the mortality rate was higher than those of other groups after they were tranferred to a low temperature. Eight out of 18 fish survived at the ending. Most of them had whitish livers and also had baso-hyperbasophilic tumor nodules mentioned above. But the nodules were rather smaller (maximum diameter = 28 μm) than those of H.H-group. The fish had 1–7 tumor foci per liver, this number was also smaller than that of H.H-group. It is worth to note that the mitotic figures were scarcely found in these tumor foci (Fig. 5).

In these fish, hyperbasophilic or normal stained altered foci were also observed more frequently than in the fish of H.H-group. Some fish showed the proliferation of bile duct epithelium. One fish did not have any baso-hyperbasophilic foci, but had many abnormal parts containing eosinophilically enlarged hepatocytes (Fig. 6).

L.H-group, L'.H-group. In L.H-group, all of 21 fish survived when they were transferred to high temperature after the DENA treatment. Most of the fish had normal looking reddish livers as those of the control fish. The hepatocytes had well stained cytoplasm compared with the control one. Some small vacant spaces which contained no cells or some cells of connective tissue were observed (Fig. 7). It is highly probable from the observation that some hepatocytes were killed by the DENA treatment.

Four fish out of 5 treated with DENA for 13 weeks at a low temperature (L'.H-group) showed abnormal livers in which mass of hepatocytes were found here and there. The regular structure of hepatocytes was completely broken down (Fig. 8). The liver consisted of many small vacant spaces and of infiltrating non-parenchymal cells.

L.L-group. Thirteen out of 17 fish survived until the end of the experiment. The livers were pink in color and somewhat small in size. No tumor nodules were observed in this group. Some small vacant spaces were also found as well as L.H-group, but the number was not so large in comparison with that of L.H-group. As the histological character, the hepatocyte had a round nucleus which contained the nucleolus frequently localized on the margin of the nucleus (Fig. 9).

DISCUSSION

The results of the present experiment made it sure that the tumor nodules did not appear in the fish treated with DENA at a low temperature. This result was in good agreement with the preliminary experiment. Even though the sufficient time for tumor growth was given at a high temperature after the end of the DENA treatment, no tumor nodules were observed in the fish treated at a low temperature. And only the histological changes were noticed in low temperature groups, which seemed to be induced by the toxicity of the drug as mentioned previously [7].

In the groups treated with DENA at a high temperature, the tumor nodules continued to grow when the fish were kept again at a high temperature after the DENA treatment (H.H-group).

Many mitotic figures were found in these nodules. However, in the fish kept at a low temperature after the DENA treatment, the nodules scarcely grew and the mitotic figures were hardly found (H.L-group). At a low temperature, cell division was inhibited and the tumor nodules were not able to grow. Considering the necessity of an appropriate high temperature in the induction of the tumor nodules, cell division is probably required in the step of the transformation. In fact, it is known that several cell generations are necessary for the fixation and expression of the transformed state in malignant transformation of cultured mouse cells [9].

In mammals, it is well established that nitrosamines become tumorigenic only after the metabolic activation by microsomal enzymes, and that the dealkylated products are related to the carcinogenesis [10–14]. Montesano *et al.* [15] reported that the liver slices of trout and goldfish could metabolize dimethylnitrosamine, but the degree of nucleic acid methylation was very low in comparison with the value of mammals [15]. Although the enzymatic activity and the metabolic pathway of the drug are unknown in medaka, the process of tumorigenesis by DENA is thought to be identical with that of mammals. Ermar could not succeed in tumor induction by the injection of DENA solution in stickleback [16], and the author also failed to observe any histological changes in medaka by a single injection of DENA solution. Since the metabolic activity of microsomal enzyme is very low in fish, chronic accumulation of the damages induced by DENA seemed to be required in the tumor formation. This is thought to be the reason why tumor nodules did not appear by the injection of DENA solution and why an appropriate high temperature was necessary in this experiment. At a high temperature, normal hepatocytes may be killed by the damages induced with DENA and the compensatory cell division during the DENA treatment is probably related to the tumor formation.

Cytokinetic Changes in Two Cases of Plasma Cell Leukemia Treated with a Multipeptide Derivative of *m*-[di(2-chloroethyl)amino]-L-Phenylalanine (Peptichemio)

ALBERTO RICCARDI.*† AGOSTINO MARTINOTTI* and SERGIO PERUGINI*

**Istitulo di Patologia Medica I and †Centro di Studio per l'Istochimica del C.N.R., Università di Pavia, Italia*

Abstract—*In two patients with plasma cell leukemia (PCL) the cytokinetics of blood and bone marrow plasmocytomatous cells was examined shortly after Peptichemio (PTC 40 mg/alternate days for 6–7 doses) therapy by combined DNA cytofluorometry and* in vitro *tritiated thymidine (^{3}H-TdR) cytoautoradiography. In both cases a rapid fall in circulating plasma cells was induced by the treatment and in one of them the percentage of bone marrow plasma cells was also diminished. After treatment the values of labeling index (LI) and growth fraction (GF) were increased both in blood and bone marrow plasma cells and proliferating bone marrow plasma cells were mostly in early S phase. Their mean grain count (MGC) did not change. Increased population of U-like cells. i.e. damaged cells, was found in the bone marrow. By examining the possible explanations of the findings, the authors relate them to a cellular recruitment following tumor mass reduction. DNA content only was also determined in the blood during the treatment and an increased percentage of* 2n–4n *plasma cells was found. The significance of this last finding is not known at the present.*

INTRODUCTION

THE MITOTIC activity, as expressed by the percentage of tumor cells incorporating tritiated thymidine into DNA (^{3}H-TdR labeling index, LI) is quite low in plasmocytomas at diagnosis [1–8]. In sensitive tumors, alkylating therapy both diminishes the neoplastic cell number and induces a significant increment of the LI among the residual plasmocytomatous cells [1, 6, 8, 9]. This last finding has been regarded by some authors [1, 6, 8, 9] as a proof of the recruitment into the proliferative cycle of previously quiescent cells and, therefore, of an increase of the tumor's growth fraction (GF). This view, however, is questionable, since the simple observation of a raised LI after treatment did not necessarily mean increased proliferative activity [10].

In 1974, we successfully treated 2 patients with plasma cell leukemia (PCL) with Peptichemio (PTC), a multipeptide derivative of *m*-[di(2-chloroethyl)amino]-L-phenylalanine with alkylating and antimetabolic properties [11], and we investigated by combined DNA cytofluorometry and ^{3}H-TdR cytoautoradiography the modifications induced by therapy on other cytokinetic parameters besides the LI. The observed results gave additional information about cytokinetic changes occurring in sensitive plasma cell dyscrasias following tumor mass reduction and are referred to in this paper.

MATERIALS AND METHODS

Two patients with PCL were studied. The first patient (CM) was a 65-yr-old man who was successfully treated for an IgG plasmocytoma, k type, from February

Accepted 22 February 1978.

to August 1972 with L-phenylalanine mustard (melphalan). Subsequently (October 1972), a short cycle of cyclophosphamide (CTX) was stopped due to pancytopenia. His condition progressively deteriorated up to April 1974 when he was hospitalized in our Institute with the clinical picture of terminal PCL.

The second patient (FL) was a 66-yr-old man who had been suffering from systemic, palpable, small, non-tender lymphnodes since December 1973. He came to our Institute on May 21, 1974. Serum immunoelectrophoresis showed monoclonal IgA paraproteinemia, k type. A lymphnode and bone marrow biopsy disclosed plasma cell infiltrates. The peripheral blood picture was typical of PCL.

The case histories of both patients were given in more detail elsewhere [12].

Both patients were given PTC (Istituto Sieroterapico Milanese, Milan, Italy) as 40 mg infusions during 1 hr, each infusion being repeated at the times shown in Fig. 1.

Peripheral blood (10 ml) and bone marrow (2 ml) samples were collected before, during and after treatment, at the times indicated in Fig. 1.

For each peripheral blood sample, the absolute number of plasma cells per μl was determined by counting 200 nucleated cells on May-Gruenwald-Giesma (MGrG) stained smears. On bone marrow samples, the percentage of plasma cells among nucleated cells (by counting 1000 cells) and their mitotic index (MI) (by counting 3000 plasma cells) were obtained.

On all peripheral blood and bone marrow samples, the nuclear DNA content of 100 randomly selected plasma cells was determined cytofluorometrically on Feulgen stained smears by using a Leitz MPV2 microscope-photometer. The technical characteristics of the instrumentation are detailed by Prenna *et al.* [13] and in our previous papers [14, 15]. The obtained data were evaluated as described elsewhere [14].

Both on blood and bone marrow obtained before and after therapy, the *in vitro* incorporation of ^{3}H-TdR (Radiochemical Amersham Center, S.A. 1.9 Ci/mM) was evaluated according to Foadi *et al.* [16]. The incubation time was 1 hr. The autoradiographs were prepared using Kodak NTB2 nuclear track emulsion and then exposed at 4°C for one week. The labeling index (LI) was determined by counting 4000 plasma cells and the mean grain count (MGG) by examining 50 labeled cells. The growth fraction (GF) was evaluated on the same autoradiographs according to the method of Gavosto *et al.* [17] recently confirmed by Matera and Masera [18].

On bone marrow autoradiographs only, the nuclear DNA content of ^{3}H-TdR labeled and unlabeled plasma cells was determined according to Ernst and Killmann [19].

RESULTS

Figure 1 shows: (1) the doses and the times of PTC administration, (2) the times of blood and bone marrow sampling and (3) the fall of the circulating plasma cell number during treatment in the two cases of PCL studied.

The cytologic, cytofluorometric and cytoautoradiographic findings are reported in Tables 1 and 2 and in Figs. 1–3.

Case 1 (CM)

In the first patient, during the period of study, an exponential decrease of circulating plasma cells was observed (Fig. 1), while the percentage of bone marrow plasma cells was not significantly reduced (Table 1).

Concomitantly with their numerical fall, the DNA content distribution of circulating plasma cells was modified. The percentage of diploid (2n) cells was reduced (from 94 to 81%), while the population of cells with 2n–4n DNA content (2n–4n plasma cells) was increased (from 5 to 19%). Twenty-four hours after the last PTC administration, the ^{3}H-TdR LI of the same cells was twice that observed before therapy (Table 1).

In bone marrow plasma cells, 24 hr after the last dose of PTC, both the MI and the percentage of diploid cells were distinctly lower than before therapy, while the cells with 2n–4n and 4n DNA content, as well as the ^{3}H-TdR LI and GF, were increased (Table 1).

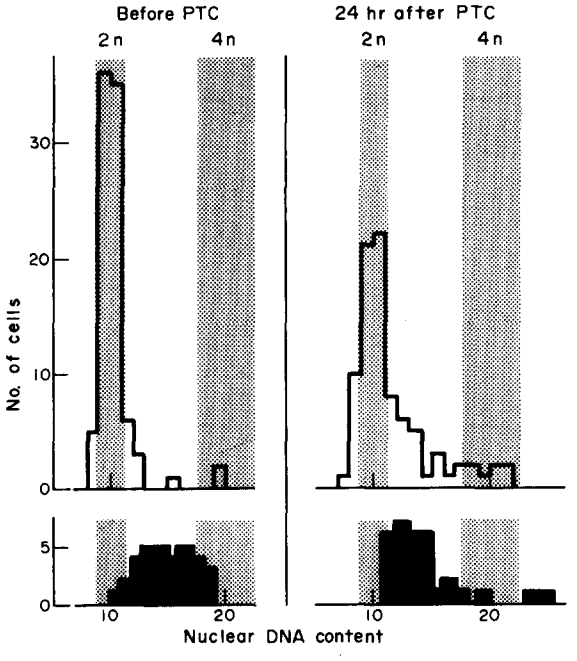

Fig. 2. Distribution of the nuclear DNA content of ^{3}H-*TdR unlabeled* (□) *and labeled* (■) *bone marrow plasma cells in the case* 1 (*CM*).

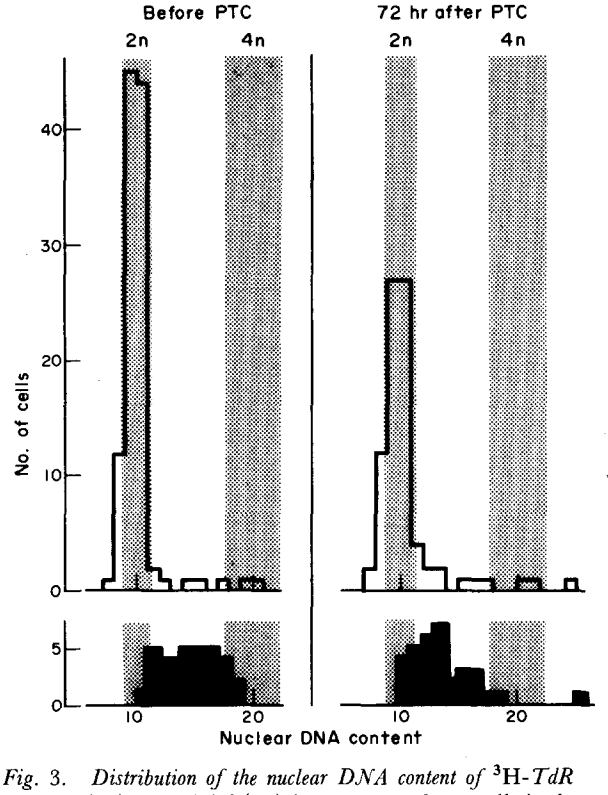

Fig. 3. Distribution of the nuclear DNA content of ^{3}H-*TdR unabeled* (□) *and labeled* (■) *bone marrow plasma cells in the case* 2 (*FL*).

The rate of ^{3}H-TdR incorporation, as expressed by the MGC, was not significantly different before and after therapy, both in the blood and bone marrow proliferating plasma cells (Table 1).

In bone marrow before therapy, the DNA values of ^{3}H-TdR labeled plasma cells were fairly evenly distributed between the 2n and 4n modes (Fig. 2), while 24 hr after therapy they were more frequent (78%) in the early S phase. On the contrary, before therapy the great majority of ^{3}H-TdR unlabeled plasma cells was diploid and some (10%) had 2n–4n DNA content (U-like cells). After therapy this last aliquot was much higher (27%).

Case 2 (*FL*)

In the second patient, the circulating plasma cell decrease during therapy was more conspicuous and rapid than in the first one (Fig. 1), and the percentage of bone marrow plasma cells was also diminished (Table 2).

The cytokinetic changes during and after PTC therapy were substantially similar to those observed in the first case.

Minor differences can be summarized as follows: (1) in the peripheral blood the percentage of plasma cells with 2n–4n DNA content increased during the first 32 hr of the treatment (Table 2) but, unlike in the first patient (Table 1), returned to the pretreatment value thereafter; (2) in the bone marrow, 72 hr after the last dose of PTC, the increase of the population of both 2n–4n plasma cells (Table 2) and of the U-like cells (Fig. 3) was less pronounced than in the first case (Table 1 and Fig. 2) 24 hr after PTC; (3) at the above times after therapy, the LI and GF of both blood and bone marrow plasma cells were less increased in the second (Table 2) than in the first patient (Table 1).

DISCUSSION

In our patients with PCL, successful PTC therapy has altered plasma cell kinetics in a similar way, both in bone marrow and in peripheral blood. We will consider separately the bone marrow and peripheral blood findings. Differences between the two cases in relation to quantitative variation of some cytokinetic parameters will be discussed later.

In bone marrow the main cytokinetic changes after PTC can be stated as follows: (a) increase of ^{3}H-TdR labeling index (LI) and of growth fraction (GF); (b) decrease of the population of 2n and increase of the percentage of 2n–4n plasma cells; (c)

build up of DNA-synthesizing plasma cells in early S phase and (d) increased frequency of U-like plasma cells.

An augmented ^{3}H-TdR LI in bone marrow plasma cells has been already reported [1, 8, 9] in plasmocytomas after alkylating-induced tumor mass regression. As formerly stated in acute leukemia [20, 21, 22], a recruitment into cell cycle of previously quiescent cells following tumor mass reduction has been postulated by Salmon [8] in such cases. This view, although accepted by Alberts and Golde [9] and by Drewinko *et al.* [1], has been recently questioned by Baccarani and Santucci [10], since the finding of a raised LI alone after treatment is not adequate proof of increased tumor GF. Cell recruitment has been strengthened however by Pileri *et al.* [6, 23] from cyto-autoradiographic evidence of activated macro-molecular metabolism, i.e. increased RNA and protein synthesis and actinomycin binding, accompanying LI and GF rise in plasmocytomatous cells a few days after CTX therapy.

In this context, change of the DNA distribution pattern concomitant with LI and GF increases in plasmocytomatous cells observed in our patients shortly (24–72 hr) after PTC treatment, further substantiate Salmon's hypothesis [8].

Indeed, although the increased frequency of 2n–4n cells (Table 1 and 2) cannot be ascribed to increased mitotic activity only, since U-like cells are also present (Figs. 2 and 3), the prevalent distribution of DNA synthesizing bone marrow plasma cells in early S phase strongly suggests that several diploid cells have entered into proliferation at the same time, i.e. are recruited.

Furthermore, cell recruitment is also supported by examining other alternative explanations of the LI increase.

The augmented frequency of U-like plasma cells after treatment (Figs. 2 and 3) is in accordance with the known greater effectiveness of PTC [11, 24], as are other alkylating agents [25–27], on proliferating rather than on quiescent cells. Therefore this finding opposes the possibility of preferential cell kill of diploid cells.

The occurrence of DNA repair in non-lethally damaged plasma cells, already excluded in plasmocytomas treated with melphalan [9], is not likely, since its demonstration requires a cytoautoradiographic exposure time longer than the seven days employed by us. Moreover, DNA repair is evidenced by a nuclear grain count much lower than that observed in our cytoautoradiographs [28, 29].

Finally, a delayed cell progression through S phase, as observed in acute leukemia blasts after 1-β-D-arabinofuranosylcytosine (ARA-C) [20, 21, 30] or amethopterin (MTX) [20, 31], can account for increased LI. A lowered grain count over labeled nuclei is reported, however, in such an event [30, 32], but is not observed after PTC in our cases (Tables 1 and 2).

In light of the above findings, cell recruitment is the most likely explanation of the cytokinetic changes that occurred after effective PTC treatment in PCL. The decrease of MI is not contrary to this interpretation, since it is probably dependent on a delay in G_2 progression [33], as evidenced by the augmented frequency of tetraploid plasma cells (Tables 1 and 2).

The LI increase of bone marrow plasma cells was quite modest in our patients, as compared to those reported in patients treated by other authors [1, 6, 8, 9].

Differences in planning the investigations can account for this finding. In fact we studied cytokinetic changes a short time (24–72 hr) after repetitive PTC schedule, whereas the above authors studied them 3 weeks after melphalan–prednisone therapy [1, 9] or a few days after high doses of CTX administered for 3 consecutive days [6]. This can imply that, in our patients, a more conspicous LI increase was hampered by the fact that the repeated PTC administrations killed the newly proliferating, i.e. recruited cells, as suggested by the augmented frequency of U-like cells after the end of therapy.

As far as the peripheral blood findings are concerned, the changes of LI, GF and DNA distribution of plasmocytomatous cells *after therapy* were similar, although less pronounced, to those observed in the bone marrow (Tables 1 and 2); their significance is probably the same as that of the bone marrow changes. On circulating plasma cells only, we further studied the DNA distribution *during therapy* and observed, in both cases, an increase of the population of 2n–4n cells (Table 1 and 2), as already reported by us [34] and by Lutz *et al.* [35] in peripheral blasts from acute leukemias during combination therapy. Since in ours and in Lutz's studies cytoautoradiography was not combined, it was not clear whether 2n–4n cells

were recruited or U-like or S-synchronized cells. In subsequent studies we were able to examine the peripheral blood of leukemic patients during ARA-C or vincristine (VCR) treatment by both DNA flow cytofluorometry and ^{3}H-TdR cytoautoradiography [36]: increased aliquots of 2n–4n cells were also found which were mostly U-like cells after VCR, whereas an increased percentage of labeled cells was also observed after ARA-C. The significance of 2n–4n circulating cells after PTC must be ascertained by similar methodological approach.

As already mentioned, we must now consider why the magnitude of some cytokinetic changes, i.e. of the increase of the aliquot of 2n–4n plasma cells and of their LI and GF, has been greater after therapy in the first (CM) than in the second (FL) patient (Tables 1 and 2).

Since the 2n–4n plasma cells were mostly U-like cells (Figs. 2 and 3), their more pronounced increase in the first patient can be accounted for by the fact that bone marrow and blood samples were obtained in this case sooner (24 hr after the last administration of PTC) than in the second (72 hr after the last administration of PTC), since the U-like cells are rapidly cleared by macrophages.

The greater LI increase in the first patient must be related to the fact that in this case PCL was the terminal event of a plasmocytoma, whereas in the second PCL was a primitive disease. As pointed out by Bergsagel and Pruzanski [37], the plasmocytoma doubling time is greatly shortened during the "acute terminal phase" and this can account for the more rapid and marked cell recruitment that occurred in case 1.

The origin of recruited cells is debated at present.

Pileri *et al.* [6, 38] have proposed that circulating B-lymphocytes, most of them carrying and synthesizing in culture membrane Ig idiotipically identical to the M component [39–42], or morphologically unrecognizable stem cell, as in mouse plasmocytoma [43], account for both tumor supply in steady state and recruitment after chemotherapy. According to these authors, such functions cannot be accomplished either from the proliferating plasma cell compartment, since it is not a stem compartment but only a transit one toward differentiation [5], or by the non-proliferating plasmocytomatous cells, owing their high differentiation in Ig synthesis and the stability of their macromolecular template [44, 45].

The problem however is still unsolved.

Salmon has recently grown clusters of neoplastic plasma cells in agar cultures [46].

Moreover, in immunized rats lymphnodes, DNA synthesis has been observed in plasma cells producing IG and/or specific antibodies [47, 48]. Such findings show that plasmocytic differentiation does not hamper proliferative activity. Whether or not steady tumor supply and recruitment after therapy originate from B-lymphocytes or from plasma cells, or from both, is yet to be demonstrated.

Leukocyte Migration Inhibitory Activity in the Serum of Patients Affected by Hodgkin's Disease and Other Immunoproliferative Diseases

F. AMBROGI, R. POLIDORI, A. AZZARA, M. PETRINI and B. GRASSI

Cattedra di Patologia Medica 2r, University of Pisa, Italy

Abstract—*Leukocyte migration inhibition was studied by employing the agarose plate method. The inhibitory effect of blood sera from healthy subjects, from patients affected by lymphomas or other immunoproliferative diseases and from patients with diseases not involving the immuno-system has been investigated.*

No inhibitory effect was detected in the sera of patients affected by various pathology including four solid neoplasia.

It was possible to demonstrate the presence of an inhibitory factor in the sera of patients affected by Hodgkin's disease as in sera of patients affected by other immunoproliferative diseases.

INTRODUCTION

THE LEUKOCYTE migration inhibition test (LMIT) [1] has been widely employed for the evaluation of cell-mediated immunity in human malignant neoplasia [2–7]. This method represents a useful means to elucidate the problem of the existence of serum "blocking" factors which interfere with the antitumoral activity of lymphocytes and macrophages [8–12]. In fact if the presence of such "blocking" factors can be definitely proved, then the progression of the tumor mass, in spite of an immunological anti-tumor reactivity, can be explained.

Recently these serum factors have been studied by the LMIT in a considerable number of patients with malignant neoplasia [13]. The results of these studies increased the interest for this research. However, employing the agarose plate method [14–18] which is more rapid than the capillary system and has a good reproducibility [19], we studied the effect of blood sera of healthy subjects, of patients with lymphomas or other immunoproliferative disease and with diseases not involving the immuno-system. The migrating leukocytes were obtained from healthy donors.

Accepted 10 March 1978.
Correspondence: Dr. F. Ambrogi, 1ª Clinica Medica Generale, Ospedale S. Chiara, 56100 Pisa, Italy

MATERIALS AND METHODS

Patients

The study was carried out on 18 healthy normal donors and on 40 patients. They were divided in three groups: Hodgkin's disease (HD), immunoproliferative disease as defined by Dameshek [20, 21] and miscellaneous disease. All the patients were untreated. The diagnosis was based on clinical and haematological findings and in HD on histological examination of lymph nodes and spleen.

Sera

Five millilitres of blood were collected from each patient and donor. The blood was centrifuged at $800 \times g$ for 10 min, then the sera to be tested were stored at 4°C for not less than one week.

Preparation of leukocytes

Blood from 25 healthy donors was especially employed to prepare the leukocytes used for migration. No more than three sera were tested against each leukocyte suspension.

Twenty millilitres of heparinized blood from fasting donor were diluted 3:1 v/v with Emagel (Behringwerke) and were allowed to sediment for about 45 min at 37°C in inverted plastic syringe. The supernatant was taken, centrifuged at $800 \times g$

for 10 min and the cellular sediment (leukocytes and erythrocytes) was washed three times at 800 × *g* for 10 min.

A final cell suspension of 25–30 × 10^6 leukocytes was prepared.

Hanks' solution without Ca^{2+} and Mg^{2+} (HS) (Eurobio) supplemented by 20 mM *N*-2-hydroxethylpiperazine-*N'*-2-ethanesulfonic acid buffer (HEPES) (Eurobio) was employed both for washing and final cell suspension.

Agarose gel preparation

A solution containing 73.3% of a pure agarose (Behringwerke) 0.94% solution in distilled water previously prepared at 100°C, 12.5% of fetal calf serum (Difco) and 14.2% of HS with HEPES, was prepared in a water-bath at 50°C.

Migration inhibition assay

Two millilitres of agarose gel, prepared as previously described, were poured into Petri dishes (35 mm ϕ, Falcon Plastic). After the gel had solidified, holes (ϕ 2.5 mm) were punched and 5 μl of leukocyte suspension were introduced into each one. The test sera were put into the holes at final concentration of 16 or 32%. In the reference holes the sera were replaced by HS with HEPES. All the assays were carried out in quadruplicate. The dishes were incubated for 21 hr at 37°C in humid atmosphere.

The diameters of migration areas were measured and the leukocyte migration index (LMI) calculated as:

$$\frac{\text{average diameter test}}{\text{average diameter reference}} \times 100.$$

Statistical methods

Mean and standard deviation of the mean were calculated by standard methods.

Differences between means were calculated according to the *t*-test for unpaired samples. A difference was considered significant when $P < 0.1$ or less.

The migration index was considered significant when it was smaller than 89 and 87% respectively for 16 and 32% concentrations of sera.

RESULTS

Normal sera did not produce a considerable migration inhibitory effect either at 16% or at 32% and in both cases the S.D. from the mean was low (Table 1).

The LMI of 14 sera from patients with miscellaneous diseases showed a mean value of 94.09 ± 4.70 at 16% and of 92.28 ± 4.99 at 32% without significant variation from the normal mean. In fact significantly lowered values found only in 3 patients (16%) at 16% and in 2 patients (14%) at 32%. (Table 2).

The mean LMI in 17 patients with HD was 83 ± 15.5 at 16% and 70.1 ± 19.2 at 32%. These values are significantly lower

than normal ($P<0.001$ both at 16 and 32%). It should be noted that the patients with significantly lowered LMI were 11 (65%) at 16% and 14 (82.5%) at 32%. (Table 3).

The sera of 9 patients with immunoproliferative diseases showed a mean LMI of 84.22 ± 16.08 at 16% and of 70.23 ± 25.46 at 32% which are values significantly lower than normal ($P<0.01$ at 16% and $P<0.001$ at 32%). It is important to point out that cases Nos. 53, 54 and 57 (two cases of Chronic Lymphatic Leukemia and one case of non Hodgkin's lymphoma) had a particularly low LMI, especially at 32%. Moreover we can observe that the patients with significantly lowered LMI were 5 (55%) at 16% and 6 (66%) at 32% (Table 4). All these results are summarized in Fig. 1.

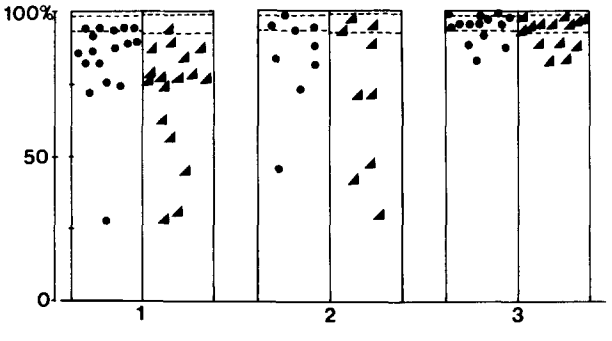

Fig. 1. Leukocyte migration index of the sera from patients affected by Hodgkin's disease (1) Immunoproliferative diseases (2) Miscelleeaneous diseases (3).

The area within the two dotted lines represents the normal mean value ± S.D. of 18 healthy donors.

● *Serum concentration* 16%.

▲ *Serum concentration* 32%.

DISCUSSION

The sera of healthy donors did not cause inhibition of leukocyte migration and the statistical analysis shows the good reproducibility of the method we used.

In the sera from patients with Hodgkin's disease we were able to demonstrate a factor capable of inhibiting leukocyte migration (LMIF) even at the lowest concentration used in our experimental protocol.

This factor was present even in the more heterogeneous group of immunoproliferative diseases, but it should be pointed out that the two cases of CLL and the single case of non-Hodgkin's lymphoma greatly contribute to lowering the mean value, especially at higher serum concentration.

No inhibition of leukocyte migration was detected in the sera of our patients which we refer to using the term of "miscellaneous diseases"; moreover it should be noted that four sera from solid neoplasia were included in this group.

Finally, comparing our results with other authors studies [13] it is important to point out that we did not observe the increase in leukocyte migration found in the sera of some patients with malignant neoplasia.

As yet we have insufficient information to decide whether to ascribe the factor to tumoral antigen–antibody complexes present in the sera in cases of solid neoplasia [22–26] or to the macroglobulinemic factor found in sera of patients affected by Burkitt's lymphoma [27] or whether it may be connected with the lymphocytotoxic factors found in sera from patients affected by Hodgkin's disease or by autoimmune disease [28–37].

We must remember that recently this factor was found also in infectious diseases [38] and by the same authors it was correlated to a good delayed hypersensitivity of the patient [39]. This last finding correlates well with the "MIF-like" nature of the serum factor detected in some patients with lymphoproliferative diseases [40].

Our work confirms the interest of the method of Clausen in evaluating this property of sera from patients with cancer and in observing that LMIF seems particularly related to the proliferative diseases of the immune system.

Our group is now involved in further studies on the nature of this factor.

Acknowledgements—The authors wish to express appreciation for the sera from healthy donors, kindly provided by Dr. P. V. Fosella (Servizio di Immunoematologia e Trasfusione del sangue degli Spedali Riuniti di S. Chiara, Pisa).

The technical assistance of Mr. B. Puccini and Mrs. R. Testi is gratefully acknowledged.

We also thank Miss N. Simonini for reviewing the manuscript.

The LMI Assay in Lung and Colorectal Cancer: The Use of Allogeneic Extracts Prepared by Different Methods

P. B. ILES,*†‡ M. B. McILLMURRAY,*§ R. W. BALDWIN† and M. J. S. LANGMAN*

**Department of Therapeutics, Nottingham City Hospital, Nottingham, Great Britain and †Cancer Research Campaign Laboratories, University of Nottingham, Nottingham, Great Britain*

Abstract—*We have examined the effects of simple tumour homogenates, and of* 3MKCl *and papain extracts upon the* in vitro *migration of leucocytes obtained from* 56 *patients with lung or colo-rectal cancer and from* 43 *control individuals.*

Although there was considerable overlap between the ranges of results, leucocyte migration was significantly slowed in response to the crude homogenates, in response to two of the three 3MKCl *colorectal tumour extracts and to the* 3MKCl *lung tumour extract, as compared with results obtained from patients without cancer, or in patients whose cancer was of the alternative type. No responses, tumour specific or otherwise, were obtained when a papain extract was used and when a third* 3MKCl *colorectal extract obtained by an identical method to the two other extracts was used.*

INTRODUCTION

THE LEUCOCYTE migration inhibition (LMI) test is an *in vitro* assay that correlates well with delayed hypersensitivity *in vivo* [1]. It has been used extensively to demonstrate specific tumour-directed immunological reactivity of lymphocytes from patients with cancer [2–9]. We have observed a greater degree of leucocyte migration inhibition with a crude colorectal tumour extract in patients with large bowel cancer than in matched non-cancer controls [2], but the marked overlap between the two groups made interpretation of individual results difficult. By using a more refined tumour extract, it might be possible to improve the discriminative value of the LMI test. Tumours can be solubilized by 3M potassium chloride and by papain digestion, and extracts prepared in this way have been shown, by lymphocytotoxicity assays [10], by lymphocyte transformation and by cutaneous delayed hypersensitivity reactions [11] to contain tumour specific antigens. We have therefore repeated the LMI test in further groups of patients with colorectal and with lung cancer using such extracts, in an attempt to separate the responses of the cancer patients from those of the non-cancer patients more clearly. A secondary virtue of the test lies in its relative simplicity, which allows the test to be used in demonstrating the ability of a tumour extract to elicit tumour-orientated responses and thus justifying the investigation of such active extracts in other *in vitro* techniques.

MATERIALS AND METHODS

Patients

Blood samples were obtained from 30 patients awaiting surgery for carcinoma of the colon or rectum, 26 pre-operative patients with primary lung carcinoma and 43 hospital in-patients, who were suffering from a variety of non-malignant conditions such as vascular disease, peptic ulcer and diverticular disease. All patients appeared to be in reasonably good health. None had received blood transfusions or immunosuppressive therapy. The mean ages of the colorectal cancer patients, the lung cancer patients and the non-cancer controls were 62.3, 62.0 and 64.3 yr respectively.

Leucocyte preparation

Leucocytes were harvested from heparinised

peripheral venous blood after separation by simple sedimentation for 1 hr at 37°C.

The cells were then washed thrice in Eagles Minimum Essential Medium (MEM) and then resuspended in the requisite volume of Eagles MEM supplemented with 10% foetal calf serum.

Preparation of extracts

(i) 3MKCl *extracts.* Individual tumour specimens were obtained within 30 min of excision and then stored at −20°C. Three 3MKCl colon tumour extracts (I, II and III) were prepared, each one from pools of 18-tumour specimens, as follows. The tumour specimens were thawed, dissected free from fat, normal and necrotic tissue and minced with scissors. Fifty grams of the pooled tumours were resuspended in 200 ml 3MKCl and homogenized using an Ultraturrax homogenizer operated at $\frac{1}{3}$ to $\frac{1}{2}$ maximum output. The homogenate was incubated for 18 hr at 4°C with stirring. The suspension was centrifuged at 78,000 × ***g*** for 60 min and the soluble supernatant dialysed against H_2O, concentrated by dialysis against aquacide, and dialysed against phosphate buffered saline, pH 7.3, overnight. Finally the preparation was centrifuged at 78,000 × for 60 min and the soluble fraction collected and stored at −20°C. A lung tumour extract was also prepared by an exactly similar method.

(ii) *Papain extract.* This was prepared from a single patient who died with metastatic colon carcinoma. The tumour tissue was taken from hepatic metastases 8 hours post mortem. After dissecting it free from normal liver and necrotic debris, the tissue was minced with scissors, and suspended in 0.25M sucrose, 1 mM $NaHCO_3$, 2 mM $CaCl_2$, 2 mM $MgCl_2$, pH 7.6 at a concentration of 4 ml/g wet weight prior to homogenization. The preparation of the soluble "antigen" fraction was performed by limited papain digestion of a crude membrane fraction of a tumour homogenate as described by Baldwin *et al.* [10]. Soluble proteins, obtained by elution of the papain digest from a DEAE-cellulose ion exchange column using 0.5 M Tris–PO_4, at pH 7.8, were precipitated by the slow addition of saturated ammonium sulphate to the extract to give a final concentration of 66.7%. The precipitated proteins were sedimented at 600 × ***g*** for 15 min and redissolved in phosphate buffered saline (pH 7.3) (PBS). The resulting solution was dialysed at 4°C for 24 hr against three changes of PBS. This fraction was taken as the final antigen preparation and has been shown specifically to inhibit lymphocytotoxicity of colorectal cancer patients' cells for cultured colorectal tumour cells [10].

(iii) *Tumour homogenates.* Minced tumour tissue was suspended in PBS at 4 ml per gm wet weight of tissue and then homogenized using an Ultraturrax at approximately $\frac{1}{3}$–$\frac{1}{2}$ maximum output until 80 to 90% cellular disruption had been achieved. Suspensions were centrifuged at 1500 × ***g*** for 30 min and the supernatants were collected and stored at −20°C.

All procedures in the preparation of extracts were performed at 0–5°C unless otherwise stated. Protein concentrations were determined using the method of Lowry *et al.* [12] with crystalline bovine serum albumin as the standard.

LMI assay

For this assay we used our previous technique [2], and also the modification described below. Briefly, a series of plastic tubes were prepared by the addition to each of 100 μl of tumour extract at the required concentration. One hundred microlitres of a final leucocyte suspension were then added to each of these tubes. The contents of the tubes were mixed by gentle agitation and then allowed to incubate for 1 hr at 37°C in a humidified 5% CO_2 in air atmosphere. Control cultures consisted of leucocytes with 100 μl PBS in place of tumour extract. After incubation the leucocytes were resuspended and then drawn up into triplicate 25 μl glass capillary tubes (Drummond Microcaps), one end of each then being sealed with 'Cristaseal', inert clay (Hawksley glass). The capillary tubes were then centrifuged for 150 × ***g*** for 5 min, collecting the cells at the sealed end. Each capillary was then cut at the cell-medium interface and the cell containing portions mounted in the wells of plastic migration plates (Sterilin Ltd.), embedding the sealed ends in a little siliconized stopcock grease. The wells were filled with medium and a circular glass coverslip carefully applied, avoiding air bubbles. The wells of the migration plates were then coded and the plates incubated for 16 hr at 37°C in a humidified 5% CO_2 in air atmosphere. After incubation the plates were removed, the fan of leucocytes in each migration well projected and traced onto paper, and the areas of migration measured by planimetry.

Several concentrations of each extract were examined in the assay. The concentrations used ranged between 0.5 and 4 mg/ml because it was found that the optimal concentrations varied for each of the active extracts. The number of tests performed on each patient's blood sample was determined by the leucocyte yield.

Calculations

The mean areas of migration for each set of triplicate capillaries were calculated, and then a Migration Index (MI) derived by the formula:

$$\text{Migration Index} = \frac{\text{Mean Area of leucocyte migration with extract}}{\text{Mean Area of leucocyte migration without extract}}$$

The results obtained with the leucocytes from patients from each diagnostic group were compared by the Wilcoxon rank sum test to assess the significance of differences of migration. All *P*-values are 2-tailed.

RESULTS

Table 1 gives the results obtained with the crude homogenate and papain extracts, whilst Table 2 gives the results obtained with extracts obtained by the 3MKCl method.

Crude homogenates of both lung and colorectal cancers significantly inhibited white cell responses of patients with the same tumour type, but not with the other tumour type ($P<0.01$ for the comparison of responses to colorectal cancer extract by colorectal and lung cancer patients' white cells and $P<0.01$ for the comparison of responses to lung cancer extract by lung cancer and colorectal cancer patients' white cells (Wilcoxon rank sum test).

No significant responses or trends could be obtained in response to the papain extract in the patients tested.

Again, no difference in migratory responses were noted between cells obtained from colorectal cancer patients or hospital non-cancer controls when 3MKCl extract I was used. However, changes were noted in response to extracts II and III and to the lung cancer extract. Responses to colorectal cancer extract II differed significantly in colorectal cancer patients' white cells and in those of lung cancer and non-cancer controls ($P<0.02$ and $P<0.01$ respectively, Wilcoxon test). Likewise there were significant differences between the responses of colorectal cancer patients' white

Lung cancer				
Patients				
Non-cancer control	1.08	8	0.04	$P<0.05$
Lung cancer	0.91	12	0.05	
Colorectal cancer	1.06	7	0.03	$P<0.05$

cells to extract III as compared with responses in lung cancer and non-cancer controls, ($P<0.01$, $P<0.02$ respectively, Wilcoxon test). Similarly, the 3MKCl lung cancer extract significantly inhibited the responses of lung cancer patients' white cells as compared with those of colorectal cancer or control patients ($P<0.05$, $P<0.05$ respectively, Wilcoxon test). Responses to colorectal cancer extract II manifested themselves as an apparent loss of a stimulatory response seen when a colorectal cancer patients' white cells were incubated with a colorectal cancer extract, whereas with extract III the responses showed as apparent inhibition of migration in response to a similar tumour extract.

There was considerable overlap between the responses of control and test groups, of patients' cells and this is illustrated in Figs. 1 and 2 which show the results from all the tests performed with the tumour homogenates and with the 3MKCl colorectal extract III and 3MKCl lung cancer extract respectively. These two figures indicate that half of the responses of patients with lung cancer or with colorectal cancer fell within the normal range as defined by mean ± 2 S.D.

DISCUSSION

Cell-mediated immune reactions to tumour extracts have been demonstrated in a variety of human cancers by both *in vitro* and *in vivo* methods. The extraction procedure used in preparing the antigen may be of critical importance to the success or failure of any particular assay system. Aqueous extracts have been used with some success to produce specific inhibition of both leucocyte migration and adherence amongst patients with, for example, colonic, breast and lung cancers, and malignant melanoma [3–5, 13–15]. Our results likewise show the specific activity of simple extracts. The value

of papain extracts (which contain tumour cell membrane proteins and glycoproteins) has not been fully assessed. Papain-solubilized material prepared from leukaemic blood has been shown, by serological methods, to contain a leukaemia specific antigen [16] and a colon tumour extract prepared in this way can specifically inhibit lymphocyte cytotoxicity for human colon cancer target cells maintained *in vitro* [10], but using this same extract we were unable to demonstrate tumour specific reactivity in the LMI test. Two possible reasons for this are failure to choose the correct extract concentration and failure to remove blocking material from the leucocyte preparations, but both these are unlikely. The extract concentrations we used covered a wide range extending to levels which include those used in showing migration inhibition in the presence of non-papain solubilized extracts. The importance of repeated washing of leucocytes has been emphasized [17] and we adopted a standard washing procedure which has proved effective in the past [2] and in using the other extracts in this study. Unfortunately, there was insufficient extract to test a larger number of patients in the LMI assay. In view of the relatively low yield of extract when using the papain digestion method [10], we then concentrated on the other extraction methods. Nevertheless, we feel that papain extraction is probably unsuitable for preparing antigen for use in the LMI test, though more extensive testing is clearly needed.

3MKCl extracts contain a broad spectrum of solubilized and soluble material derived from all constituents of the tumour cell. They can be effective in demonstrating cutaneous delayed hypersensitivity and in inducing lymphocyte blastogenesis [11, 18, 19] and have been used in demonstrating LMI in patients with lung cancer [6], breast cancer [20] and malignant melanoma [21]. In this study we were unable to detect activity of one 3MKCl colorectal cancer extract, but with the other two extracts prepared in a similar manner, tumour specific patterns of reactivity could be found. The reasons for these differences are unclear.

The reasons why 3MKCl extracts vary in their capacity to induce LMI are unclear, as are the reasons why slowing of migration in response to one colorectal extract appeared as inhibition compared with an unaltered control, whilst with the second extract control responses were somewhat greater than in the absence of extracts, but this variation has been observed previously [7, 22]. This variable property of the extracts, combined with the general lack of discrimination between the findings in test and control groups prevent the use of the test as a diagnostic procedure. It is also clear, from our results and those of others, that the 3MKCl extraction confers no gain in reliability or discrimination compared with simple aqueous extracts, unless a panel of such extracts is used in the manner described by Zoller *et al.* [8, 9].

White Cell Stimulation Responses to 3MKC1 Extracts of Allogeneic Tumours in Lung and Colorectal Cancer*

P. B. ILES,†‡ P. J. WEBB,‡ R. W. BALDWIN‡ and M. J. S. LANGMAN†

†*Department of Therapeutics, Nottingham City Hospital, Nottingham, Great Britain and* ‡*Cancer Research Campaign Laboratories, University of Nottingham, Nottingham, Great Britain*

Abstract—*We have studied the stimulation responses of white cells from 71 pre-operative patients with primary lung or colorectal cancer and from 34 non-cancerous control patients. The cells were incubated with allogeneic 3MKC1 extracts of lung and colorectal cancers which we had previously shown to induce tumour-specific responses in the LMI Assay and were cultured with PHA.*

The stimulation observed in response to tumour extracts was infrequent and was not tumour specific; thus, 7 of 71 patients tested with homologous extracts showed a significant cellular response, compared with 4 of 53 patients tested with heterologous extracts. When cells from non-cancer control patients of similar age were tested with these extracts 6 of 51 responses showed significant stimulation.

We also sought to determine if pre-incubation with levamisole could enhance the frequency or specificity of cellular responses, but found that levamisole, in a concentration which significantly enhanced cancer patients' cellular responses to PHA, did not augment responses to allogeneic tumour extracts. Possible reasons why allogeneic extracts are ineffective in the stimulation assay are discussed.

INTRODUCTION

INHIBITION of leucocyte adherence to glass, of lymphocyte cytotoxicity for neoplastic cells and of leucocyte migration in the presence of neoplastic cell extracts has been generally noted in assays of cell mediated immune reactivity [1–5]. In addition, stimulatory responses have been observed in lymphocytes obtained from colorectal or lung cancer patients when the cells have been cultured with tumour cells [6] or when cultured with 3MKC1 extracts of tumours [6–8], and with crude tumour homogenates [9].

Most of such investigations have concentrated upon the responses to extracts prepared from the patient's own tumour [6, 7, 9–11] and this limitation prevents any assessment of the value of such assays as diagnostic procedures. We have therefore compared the responses of white cells from cancer patients and non-cancer controls to 3MKC1 extracts prepared from pooled allogeneic tumour tissue, using lung and colorectal cancer extracts which had both been shown to elicit tumour-specific patterns of reactivity in the leucocyte migration inhibition assay [12].

As levamisole, when administered *in vivo* or applied *in vitro* has been shown to enhance the cellular responses ot immunodepressed patients or those with malignant disease [13–15], we also sought to determine if levamisole pre-treatment would augment any responses detected.

Accepted 10 March 1978.

MATERIALS AND METHODS

White cell preparation

Twenty to twenty five millilitres of venous blood were mixed with 500 i.u. preservative-free heparin (Weddel Pharmaceuticals) in sterile glass universal bottles. Lymphocytes were obtained by centrifugation of blood samples on a gradient if Ficoll (Pharmacia, Uppsala, Sweden) and Triosil (Nyeggard & Co., Oslo, Norway) essentially by the method of Böyum [16]. Blood was diluted 1:1 with phosphate-buffered saline (PBS) pH 7.3 and 12 ml aliquots were layered onto 8 ml of an

aqueous solution of Ficoll (6.35%) and Triosil (13.4%) in 25 ml Universal bottles. The gradients were centrifuged at $500 \times g$ for 15 min, during which the granulocytes and erythrocytes sedimented through the Ficoll/Triosil phase. Mononuclear cells formed a layer between the diluted plasma and the Ficoll/Triosil phase and were collected by aspiration. The cells were then washed thrice in Eagles' Minimum Essential Medium (MEM) and then finally resuspended in Eagles' MEM supplemented with 10% heat inactivated foetal calf serum, benzyl penicillin (200 i.u./ml) and streptomycin (100 μg/ml) (Eagles 10% FCS) at a final cell density of 1.0×10^6 cells/ml or 2.5×10^6 cells/ml., according to the culture technique used. Cell viability was determined by Trypan blue dye exclusion and was always greater than 99%.

Tumour extracts

Two tumour extracts were used, a 3MKCl extract of primary lung cancer and a 3MKCl extract of colorectal cancer. The preparation and *in vitro* reactivities of each are described in the previous paper [12], the colorectal cancer extract being extract III.

Patients

White cell responses were studied in 36 hospital in-patients with lung cancer, in 35 patients with colorectal cancer, in 27 patients with non-malignant medical conditions and in 7 healthy volunteers. All the cancer patients were tested before surgery, and, in all patients, histological confirmation of the tumours was obtained. The lung and colorectal cancer patients were each of similar age (mean 64 yr, range 54–71; mean 64 yr, range 49–75 respectively) to the hospital controls (mean 62 yr, range 47–74) who had a variety of non-malignant conditions, mainly strokes, myocardial infarctions and chronic bronchitis. The healthy volunteers were members of the hospital and laboratory staff (mean age 27 yr, range 21–32).

Lymphocyte culture

(a) *Glass test tube method.* This method was based on that of Ling [17] for the mitogen stimulation of lymphoid cells. One millilitre aliquots of leucocyte suspension (1×10^6 cells/ml in Eagles 10% FCS) were added to sterile glass (Pyrex) 7.5 × 77.5 mm test tubes (Jobling glass) and tumour extracts were then added where appropriate. More Eagles—10% FCS was added to each tube to bring the final culture volume to 1.2 ml. Tubes containing medium alone and cell suspension without extracts were set up as controls. A range of concentrations of tumour extract of 1–1000 μg/ml was used. All tests were carried out in triplicate; it was usually possible to test four or five combinations of extract type and concentration. The tubes were capped with sterile, loose-fitting aluminium lids, shaken gently to mix the contents and incubated in a humidified 5% CO_2 in air atmosphere at 37°C for 4 days. Thirty microlitres of I^{125} iodoxuridine (I^{125} UdR, specific activity 50 μCi/ml) were then added to each tube. After a further 16 hr culture the tubes were centrifuged at $600 \times g$ for 15 min, the supernatant discarded and the cell pellet resuspended in 0.85% saline. The washing procedure was repeated and then the tubes with their cell pellets were counted for 5 min in a gamma counter.

(b) *Microplate method.* Microplate cell cultures were set up in which the responses of lymphoid cells to tumour extracts alone were compared with responses to PHA alone. These responses were also compared with the same responses observed when lymphoid cells had been preincubated with levamisole in phosphate buffered saline (PBS) or with PBS alone.

The method of lymphocyte culture in microplates was based on that of Dean *et al.* [18]. Aliquots of 30 or 60 μl of the tumour extracts were firstly added to replicate wells in Falcon II microplates (Sterilin), leaving empty the peripheral wells; the volumes were then increased to 100 μl by the addition of Eagles 10% FCS and then 200 μl of leucocyte suspension were added to each well. A range of concentrations of tumour extracts of 25–500 μg/ml was used. In experiments which included levamisole pre-treatment, washed lymphocytes were resuspended in 10 ml of Eagles' MEM which was then divided into two aliquots. To one of these were added 100 μl of sterile levamisole solution (10 mg/ml in PBS) to give a final concentration of 200 μg/ml, a concentration which we had found to enhance the reactivity of cancer patients' lymphocytes to PHA. To the other aliquot were added 100 μl of PBS alone. Both aliquots were incubated side by side for 1 hr in a humidified 5% CO_2 in air atmosphere at 37°C. Both aliquots were then centrifuged at $200 \times g$ for 5 min, the supernatants discarded and the cell pellets each resuspended in Eagles 10% FCS at a cell density of 2.0×10^6 cells/ml.

The cultures of cells which had been preincubated with levamisole or PBS included

replicate wells containing PHA (Wellcome Reagent grade) at a final dilution within the well of 1/100 of the reconstituted solution. The lymphocyte culture control wells contained lymphocyte suspensions with added Eagles 10% FCS instead of PHA or tumour extracts and the medium control wells contained Eagles 10% FCS alone. The empty peripheral wells were filled with medium to avoid any "edge effect" [19] and the microplates were then incubated in a humidified 5% CO_2 in air atmosphere at 37°C. After 4 days incubation 10 μl I^{125} UdR (Specific activity 50 μCi/ml) were added to each well. Sixteen hours later 230 μl of the supernatants were removed by aspiration using a needle mounted through a plastic block so as to limit the depth of the needle tip. The cells were washed twice in PBS and then resuspended in 200 μl PBS. One hundred microlitres of this suspension were then harvested onto numberd filter discs (Whatman 3M grade; 1.9 mm dia). The discs were washed twice in 10% trichloracetic acid, rinsed in methanol and then in diethyl ether and allowed to dry. The discs were each counted for 5 min in a gamma counter.

Calculations

The counts obtained from each disc or test tube were converted to counts per minute (CPM) and stimulation indices were calculated using the formula:

Stimulation Index (SI)

$$= \frac{\text{CPM cells} + \text{extract (or PHA)} - \text{CPM medium alone}}{\text{CPM cells alone} - \text{CPM medium alone}}$$

Lymphocyte stimulation by tumour extracts was regarded as significant within groups when the paired counts of stimulated and control cultures differed significantly when tested by Students *t*-test ($P<0.05$). Individual differences were arbitrarily judged as significant when the stimulation index was greater than 2·0, this criterion being the same as that adopted by others [9, 11, 20].

The effects of levamisole on responses were assessed by comparing the increments or decrements produced by levamisole over PBS pre-treatment only. The effects of levamisole were analyzed statistically using the Wilcoxon matched pair signed ranks test, calculating all probability values with two tails.

RESULTS

Figures 1 and 2 show the individual results from the test tube assay of stimulation responses to colorectal and lung tumour

extracts in colorectal cancer and lung cancer patients and in control individuals using tumour extract concentrations of 1–1000 µg/ml. There were no significant differences in the mean values obtained with cancer patients' cells in response to homologous or heterologous tumour extracts or between the responses obtained when the cells were those of cancer bearing or non-cancerous individuals. The pattern and magnitude of the stimulation results obtained from the microplate cultures were very similar to those already illustrated.

Significant stimulation responses in individuals (defined as an index greater than 2·0) were observed on 17 occasions (Table 1) over the whole range of extract concentrations used; they occurred rather more frequently when using the microplate culture method. It is clear, however, that there was no consistent pattern in these unusual responses; thus though 7 were obtained in 71 patients in response to homologous tumour extracts, 4 were observed in 46 patients in response to heterologous extracts and 6 in 51 comparisons in hospital controls.

Effect of levamisole

Figure 3 shows the effects of levamisole pre-treatment on responses to PHA.

When lymphoid cells were incubated with levamisole prior to incubation with PHA, augmented responses to the PHA were noted in 12 of the 14 cancer patients (6 lung cancer and 6 colon cancer) studied with diminished responses in 2, as compared with enhanced responses in 8 control patients and diminished responses in 6. The difference in the cancer patients' results was statistically

(○ = healthy volunteers; ● = non-cancer hospital in-patients; △ = lung cancer patients; ▲ = colorectal cancer patients).
L^- = cultures of cells pre-incubated with PBS alone.
L^+ = cultures of cells pre-incubated with levamisole in PBS.

significant ($P<0.1$, Wilcoxon test), but not in the controls ($P>0.4$). However, when the same concentration of levamisole was used to try to augment the responses of cancer patients' cells to tumour extracts, no consistent effects were demonstrable, responses being enhanced in seven patients and diminished in seven. Table 2 summarizes these findings and shows that mean changes were virtually equivalent in the test and control groups.

DISCUSSION

We have found that when peripheral blood mononuclear cells from cancer patients and age matched non-cancer controls were incubated with allogeneic 3MKC1 extracts, stimulation responses were infrequent and did not suggest any tumour specific pattern of reactivity. These disappointing results could theoretically be due to poor culture methods or to the use of inactive tumour extracts. Our microplate culture methods were based on those of Dean *et al.* [18] for the stimulation of white cells by tumour extracts and we have used them to detect tumour specific responses in an animal model with 3MKC1 extracts of syngeneic antigenic tumours [21]. The test tube method [7] has been used in our laboratories for demonstrating responses in animal tumours [22] and is similar to those widely reported in human studies [6, 7, 20, 23].

Furthermore, we have already shown in our companion paper that the identical extracts could be used to detect specific reactivity in the LMI test [12]. Our methods could therefore have reasonably been expected to succeed if stimulation could be induced by allogeneic tumour extracts.

A third possibility is that lymphoid cells of cancer patients do not respond because of a generalized depression of reactivity as evidenced by depression of response to PHA. We think this explanation unlikely, because responses in the LMI test can be induced, but when levamisole was added to our culture media in concentrations sufficient to correct reduced responsiveness to PHA

Table 2. The effects of levamisole on leucocyte stimulation responses to tumour extracts

Stimulation responses (S.E. ± 1 S.E.M.) of patients' cells				
	Colorectal cancer extract		Lung cancer extract	
Culture	L^-†	L^+*	L^-	L^+
Colon cancer patients (7)	1.41 ± 0.19	1.13 ± 0.12	1.48 ± 0.02	1.08 ± 0.22
Lung cancer patients (7)	1.07 ± 0.32	0.95 ± 0.16	1.38 ± 0.54	1.30 ± 0.33
Hospital control patients (7)	0.85 ± 0.09	1.14 ± 0.21	0.97 ± 0.12	1.13 ± 0.18
Health volunteer (7)	0.84 ± 0.04	1.03 ± 0.08	0.87 ± 0.08	0.88 ± 0.10

$P>0.1$ in each case.
*L^+ = Cells pre-incubated with levamisole in PBS.
†L^- = Cells pre-incubated with PBS only.

there was no improvement in responses to tumour extracts. We were unable to explore the possible virtues of other concentrations of levamisole, because supplies of the active 3MKCl tumour extract were exhausted, but the absence of any possible useful trends in the levamisole responses must make a positive result at another concentration very unlikely.

Dean *et al.* [18, 24], investigating breast cancer patients, have reported similar findings to our own, namely that allogeneic 3MKCl tumour extracts which could elicit tumour specific responses in the LMI assay would only induce frequent and non-specific responses in the lymphocyte stimulation assay. These authors in discussing their results felt that histocompatibility antigens present within the extracts were the cause of the different patterns of response [24].

We have no direct evidence to bear on this conclusion, but it may be signifiacant that lymphocyte blastogenic responses to tumour cells or extracts usually require 5 or more days' culture [6, 7, 18, 20, 24], and it is this time course which is used in assays measuring the stimulation responses of unsensitized lymphocytes to histocompatibility antigens [25]. Furthermore, since it has been shown that HL-A antigens may be extracted by 3MKCl solubilisation [26], it would seem inevitable that such antigens will be present in tumour extracts and thus may mask the more subtle reactions to tumour-associated antigens.

Abstract—*A prospective study on both bone and liver scanning was undertaken in patients with Stage* I, II *and* III *breast cancer immediately following the operation. In both series of scans the diagnostic values were evaluated in patients with more advanced breast cancer. No cases of occult metastases of the liver were identified, and* 2.3% *of* 129 *patients showed equivocal scannings with Stages* I, II *and* III *breast cancers and there were no patients with postoperative liver metastases. Ten of* 114 (8.8%) *patients with breast cancer at Stages* I, II *and* III *showed positive bone scans. However,* 6 *of them were excluded because of degenerative diseases or influences of operation, noted as the cause of a positive scan. Therefore,* 4 *of* 114 (3.5%) *patients showed abnormal positive scans which were otherwise unaccounted for. Out of these patients, only* 1 *had developed bone metastases. It may be that the bone and liver scans are restricted to patients who have a high risk of recurrence at the time of the operation, and that they could be used for the detection of early metastases during the follow-up study.*

INTRODUCTION

IT HAS been a general agreement that some of the "early breast cancers" have already widely disseminated metastases at the time of the first diagnosis. Thus, making clinical staging procedures without considering the occult metastase may be unsatisfactory [1, 2]. Furthermore, it has been interesting to see whether the scanning with technecium labelled compounds could detect clinically or roentgenographically occult metastases at the time of operation. In relation to this, there is a problem of the selection of adequate adjuvant treatments for the breast cancer. There has been much controversy concerning the evaluation of the bone scans on the above mentioned problems in patients with early breast cancer [1–11]. There were a few reports on the value of the liver scanning in the early breast cancer patients. It is more helpful to detect a liver metastasis in its early stage, because the response to treatments has been particularly poor in the later stages [12].

In the present study, both liver and bone scans were performed on patients with breast cancer at Stages I, II and III, they were evaluated for their usefullness as screening procedures to locate occult metastases. Both scans which were taken in patients with more advanced breast cancer were then compared for evaluation of the diagnostic accuracy of the scans.

MATERIALS AND METHODS

Previously untreated patients with breast cancer between September 1972 and June 1977 at the National Kyushu Cancer Center Hospital were examined and "staged" according to the UICC, TNM (1973–1977) Stage Classification. Namely, the patients were divided into three stages as follows:
Stage I

($T_{1a}N_0M_0$, $T_{1a}N_{1a}M_0$, $T_{1b}N_0M_0$, $T_{1b}N_{1a}M_0$);

Accepted 13 March 1978.

Stage II

$$(T_0N_{1b}M_0,\ T_{1a}N_{1b}M_0,\ T_{1b}N_{1b}M_0,\ T_{2a}N_0M_0,\ T_{2a}N_{1a}M_0,\ T_{2b}N_0M_0,\ T_{2b}N_{1a}M_0,\ T_{2a}N_{1b}M_0,\ T_{2b}N_{1b}M_0)$$

or Stage III (any T_3 with any N, any T_4 with any N; any T with N_2, any T with N_3, with M_0). Bone roentgenograms were routinely obtained in the regions of the skull, the cervical, thoracic and lumbar spines, the pelvis including the upper two thirds of the femurs, the ribs and the sternum. When an equivocal bone metastasis was noted on the roentgenograms or scans, the tomographies of the regions were added.

Liver scanning was performed in 129 patients with breast cancer at Stages I, II and III and in 126 patients with metastatic or advanced (Stage IV) breast cancer. Of these advanced cancer patients, 84 were laparotomized for the major endocrine ablation therapy such as adrenalectomy and were examined macroscopically relative to the presence of liver metastases.

Bone scans were obtained in 114 patients with Stages I, II and III cancer and in 110 patients with advanced or metastatic breast cancer. The scans were performed 2–4 weeks after radical operation. In more advanced cases, the scans were obtained before the beginning of the treatment. All the patients were followed up on and recurrence of malignancy was reviewed.

Liver scans were initiated 15 min after the injection of 1.5–2.0 mCi of ^{99m}technetium-phytate or -sulfur colloid, using a Toshiba GCA-II gammacamera. Anterior, posterior and right lateral views were obtained for each patient.

Bone scans were obtained by using ^{99m}technetium polyphosphonate (pyrophosphonate, diphosphonate, or methylene diphosphonate) with the varied dose between 10 and 15 mCi. Bone scans were performed 4 hr after injection of the tracer, with a Shimazu SCC-15W scintiscanner or a Toshiba GCA-II gammacamera.

RESULTS

Positive liver scans were obtained in 6 out of 84 patients with advanced (M_1) or metastatic breast cancer on whom laparotomies were performed as part of major endocrine ablation therapy, as shown in Table 1. One positive and 10 eqivocal scans were noted in patients in whom no liver metastases were shown macroscopically upon laparotomy. Positive scans were obtained in 35.7% (5 of 14) in the patients who showed liver metastases on laparotomy and there were 14.3% which had equivocal readings. When the size of a liver metastasis was less than 3 cm in diameter, the liver scans showed positive readings in one of 8 cases or 12.5%. And there was the same incidence of equivocal scans. In cases of liver metastasis over 3 cm in diameter measured on laparotomy, positive scans were noted in 4 of 6 cases (66.7%) and there were 16.7% equivocal scans.

There were no positive liver scans with 3 (2.3%) equivocal findings in 129 patients with breast cancer at Stages I, II and III (Table 2). No liver metastasis has developed during the postoperative follow up periods of 2–36 months (with an average of 17 months) in this group of patients.

The results of bone scans in patients with advanced or metastatic breast cancer

Table 1. Correlation between results of liver scanning and findings of liver metastasis noted on laparotomy in patients with advanced or metastatic breast cancer

Liver metastasis on laparotomy*	No. of patients	Liver scan Positive (%)	Liver scan Equivocal (%)
Negative	70	1 (1.4%)	10 (14.3%)
Positive	14	5 (35.7%)	2 (14.3%)
less than 3 cm in diameter	8	1 (12.5%)	1 (12.5%)
more than 3 cm in diameter	6	4 (66.7%)	1 (16.7%)
Total	84	6 (7.1%)	12 (14.3%)

*Liver metastases were checked macroscopically on laparotomy, most of which were confirmed histologically.

Table 2. Results of liver scanning in patients with primary breast cancer (Stages I, II and III)

Stage	No. of patients	Liver scan Positive (%)	Liver scan Equivocal (%)
I	14	0	0
II	68	0	2 (2.9%)
III	47	0	1 (2.1%)
Total	129	0	3 (2.3%)

Table 2a. *Results of liver scanning in patients with primary breast cancer* (*Stages* I, II *and* III)

N 1b	0/4 (0/4)	— —	0/20 (0/20)	— —	0/7 (0/7)	— —	0/1 (0/1)	0/3 (0/3)	— —	0/35 (0/35)
N 2	— —	— —	0/8 (0/8)	— —	— —	0/1 (0/1)	— —	0/8 (0/8)	0/2 (0/2)	0/19 (0/19)
N 3	0/1 (1/1)	— —	— —	— —	— —	— —	— —	0/2 (0/2)	— —	0/3 (1/3)
Total	0/18 (0/18)	0/1 (0/1)	0/71 (2/71)	0/1 (0/1)	0/14 (0/14)	0/2 (0/2)	0/1 (0/1)	0/18 (0/18)	0/3 (0/3)	0/129 (3/129)

Numbers in parenthese show the equivocal readings.

Table 3. *Correlation between results of bone scanning and roentgenograms in patients with advanced or metastatic breast cancer*

Bone roentgenogram	No. of patients	Bone scan Positive (%)	Equivocal (%)	Negative (%)
Positive	75	62 (82.7%)	7 (9.3%)	6 (8.0%)
Negative	35	11 (31.4%)	5 (14.3%)	19 (54.3%)
Total	110	73 (66.4%)	12 (10.9%)	25 (22.7%)

were compared with those of bone roentgenograms (Table 3). Out of 110 patients with advanced cancer, 75 patients had distinct bone metastases revealed on roentogenograms. In these patients, 62 or 82.7%, had positive bone scans, 7 or 9.3% had equivocal scans and 6 or 8.0% of the patients had negative scans. Therefore, when the equivocal scans were included in the negative group, the true positive rate of bone scans were shown to be 82.7%, with 17.3% of false negative rate on the basis of bone roentgenograms. On the contrary, in 35 patients without bone metastases on roentgenograms, bone scans showed 11 (31.4%) positive, 5 (14.3%) had equivocal findings with 19 (54.3%) having negative scans, thus showing 31.4% false positive rate and 69.6% of true negative rate. Thus in the diagnosis of bone metastases by bone scans as compared with roentgenography, there were less false negative cases and higher incidence of false positive cases.

In this study on the bone scans in patients with early breast cancer, we firstly checked the abnormal accumulation of isotope on the scans without knowing the results of bone survey in the afore-mentioned regions. These tentative results were shown in Table 4.

Table 4. *Results of bone scanning in patients with breast cancer at Stages* I, II *and* III

Stage	No. of patients	Bone scan Positive (%)	Equivocal (%)
I	14	1 (7.1%)	2 (14.3%)
II	66	7 (10.6%)	8 (12.1%)
III	34	2 (5.9%)	6 (17.6%)
Total	114	10 (8.8%)	16 (14.0%)

Positive bone scans were obtained in 8.8% or 10 of 114 patients with breast cancer at Stages I, II and III. Fourteen per cent or 16 patients showed equivocal scans. The positive rates in the groups of Stages I, II and III were more or less similar.

Table 4a. *Results of bone scanning in patients with breast cancer at Stages* I, II *and* III

Numbers in parentheses show the equivocal readings.

The recurrence of malignancy was investigated in 114 patients with primary breast cancer according to the results of the bone scans occurring during periods lasting from 2 to 52 months (with an average of 13 months) after the radical operation (Table 5). In 10 patients with positive bone scans there was one patient with bone metastases. Two of 16 patients with equivocal scans had shown the recurrence; however, the sites were not osseous. Recurrences not related to the bone had occurred in 4 of 88 patients with negative scans during the post-operative course. This may suggest that there are some false positive cases in the bone scans in early breast cancer patients, although some small parts of the positive scans indicate a real bone metastasis of breast cancer. This may partly come from the unspecificity in the accumulation of the radioisotope on the sites of cancerous metastases. We observed, among 15 cases with benign diseases investigated in this hospital by bone scanning, that 4 cases or 26.7% were positive and 5 or 33.3% were equivocal.

Therefore, some factors that may influence the positive nature of the scans were studied. The distribution of the positive accumulation of the tracer isotopes including the equivocal one was compared in the following three groups: 1. patients with Stages I, II and III breast cancer (114 cases); 2. patients with recurrent or advanced breast cancer whose bone metastases could not be confirmed roentgenographically (35 cases); 3. patients with distinct bone metastases (75 cases) (Table 6). Higher incidences of abnormal isotope accumulation in the early breast cancer group or in the advanced cancer group not related to bone metastases were concentrated in the lumbar spines and pelvis, and to the operation sites such as the sternum, ribs and clavicle. Equivocal scans

Table 5. *Recurrence of breast cancer in patientst at Stages* I, II *and* III *according to the results of the bone scans*

Numbers in parentheses show the number of patients with equivocal scans.

were dominant also in these regions and including the skull. This suggests that false positive bone scans may have occurred in these regions.

We tried to find whether benign diseases or operable procedures had an effect on the positive nature of the scan in these regions studied. As shown in Table 7, the presence of osteoporosis and/or spondylosis deformans was examined on the lumbar spines with two direction roentgenograms and it was compared with the results of the bone scans in the examined region. When the roentgenograms exhibited positive signs of osteoporosis and/or spondylosis, we took positive bone scans in 3 out of 53 cases or 5.7%, with the same percentage of equivocal scans. On the contrary, in the negative signs of these benign changes, only equivocal scans were noted in 2 of 61 (3.3%). This difference indicates that some, if not all, of these benign diseases had an influence on the positive nature of the bone scans in the lumbar spines. If these positive scans probably due to the benign diseases, were excluded from the total positive number of cases, the positive scans would be reduced to 6.0% (7 of 114) with 11% (13 of 114) equivocal scans in the breast cancer patients.

The Halsted radical mastectomy and an extended operation which included parasternal lymph nodes dissection following the resection of the cartilages of 2nd, 3rd and 4th ribs were performed as a standard method for the Stages I, II and III breast cancer in our hospital. The relationship between the operation method (resection of cartilages) and the bone scans were studied, comparing the two methods (Table 8). Three (4.1%) positive and 5 (6.8%) equivocal scans were shown in 73 patients subjected to the extended radical mastectomy. Radical mastectomy alone did not influence the positive nature of the scans. If these positive scans, probably due to the resection of ribs were excluded, positive scans would be reduced to 3.5% (4 of 114) with 8.8% (10 of 114) of equivocal scans (Table 9).

This incidence may be maximal, because some cases in the positive scans may be excluded from the true positive due to some unknown benign changes. Only 1 patient had developed bone metastases postoperatively in this group, and the remaining 3 patients with positive scans had not yet

shown the signs of bone metastases clinically or roentgenographically.

DISCUSSION

The value of bone and liver scans at the time of the initial treatment was determined in patients with early breast cancer. The diagnostic value of both scans was evaluated in patients with more advanced breast cancer. Fifty per cent of the patients who showed liver metastases on laparotomy were positive on the liver scans including the equivocal ones, with a 15.7% false positive rate (Table 1). Especially in the early stages, the liver metastasis could be identified only in 12.5% of the patients. The liver scans with ^{99m}Tc-phytate of -sulfur colloid did not surpass the scans using ^{198}Au colloid in the detection of metastasis. Namely, in our investigation of liver metastases from postoperative liver metastasis in this group, the estimation of liver scans as a detector of metastasis is still uncertain. However, the investigation of liver metastasis by scans may be too expensive to be performed in all patients with early breast cancer, considering the low ability to detect an early metastasis of the liver from the breast cancer.

It has been widely accepted that the bone scanning is more sensitive than radiography for the detection of early skeletal metastases of the breast cancer [1]. In the present investigation within 110 patients with recurrent breast cancer, there were 17.3% false negative cases and 31.4% false positive cases, as compared to the roentgenograms, when the equivocal scans were considered as negative (Table 3). Bone scans, thus inherently, have a high incidence of recognized false positive abnormalities. This

relative non-specificity of the isotope accumulation is perhaps rather controversial concerning the incidence of positive scans and the predictability of the future bone metastases. Many investigators have noted a higher incidence of positive scans in about 10–40% of the patients with early breast cancer and most of them emphasized a higher incidence of development of bone metastases in the patients postoperatively [1–5]. Sklaroff and Sklaroff [6], however, showed that patients with positive scans had a slight but statistically significant increase in incidence of the metastatic disease, particularly in the bone, but that 40% of the patients with positive scans and negative roentgenograms survived 8 yr without evidence of any metastatic disease. In the present study, 10 out of 114 (8.8%) patients with Stages I, II and III breast cancer have showed positive scans (Table 4). However, 6 of these patients can be excluded, because of reasons other than metastases, such as degenerative diseases (Table 7) and the influences of operation (Table 8) [15] could be shown as the cause of the positive nature of the scan. Only 4 of 114 (3.5%) patients showed abnormal scans, otherwise unexplainable (Table 9). This percentage is equivalent to those reported recently, [7–9] and much lower than others reported elsewhere [1–5]. Among them only 1 patient had developed bone metastases in the part of the sites indicated by the scan at the time of the radical operation. Al-Domeiri and Shroff [10] and Baker *et al.* [11] showed that there were much higher percentages of the positive scans in Stage III breast cancer patients than those with Stages I and II breast cancer. Our results are not so demonstrative as theirs, but the higher frequency of equivocal scans in patients with breast cancer at Stage III may be considered as having a similar tendency (Table 9).

Our study is even now in progress and further follow up studies will be necessary to determine the value of the scans in the patients. Although there are certainly a few patients who already have metastases at the initial diagnosis of early breast cancer, it would be too expensive to examine all patients with bone scans.

It may be more likely that the bone and liver scans are restricted only to breast cancer patients with high risk of recurrence and to postoperative patients for the early detection of metastases during the follow-up study.

Genetic Control of Endogenous Murine Mammary Tumour Viruses Reinvestigated*

P. BENTVELZEN,† J. BRINKHOF† and J. J. HAAIJMAN‡

Abstract—*Milk samples of progeny mice from crosses between mouse strains which differ in the degree of release of endogenous murine mammary tumour virus (MuMTV) were tested for the presence of MuMTV antigens by means of the Sepharose bead immunofluorescence assay. The results indicated that as compared to the nonexpressor strain BALB/c, a single dominant gene controls the release of a MuMTV in the C3Hf strain. However, the low-cancer strain C57BL carries a dominant, epistatic gene which can inhibit virus release in the hybrid with C3Hf to a large extent. The GRS strain harbours a dominant gene which, in F1 hybrids of all mouse strains tested, causes the release of large quantities of a virus (MuMTV-P) which causes tumours at an early age. Other genetic factors control the release of a lesser oncogenic virus in the GRS strain. The animals tested for MuMTV antigens were subsequently forcibly bred for mammary carcinoma production. There is a good correlation between virus release at a young age and tumour development at a late age, but a substantial number of mice which were virus-negative nevertheless developed a mammary tumour.*

INTRODUCTION

GENETIC transmission of murine mammary tumour virus (MuMTV) was initially concluded from the observed genetic control of gamete-borne transmission of the virus in several mouse strains [1–5]. It was assumed that genetic information (germinal provirus, [6]) for a MuMTV would be present not only in those mouse strains which spontaneously release a gamete-borne MuMTV but also in low cancer strains. In the latter strains, expression, i.e. transcription of the germinal provirus, would be repressed. This view was substantiated by the finding that every mouse strain tested so far carried multiple copies of MuMTV homologous DNA, irrespective of virus expression and mammary carcinoma incidence [7–10], but only the high cancer strains would contain large amounts of MuMTV-RNA in various tissues [11].

From crosses between nonexpressor strains and MuMTV-releasing strains, it was deduced that single Mendelian factors control the expression of the virus [1–5, 12–15]. In the case of the peculiar mouse strain GRS, which produces tumours at a very early age under the influence of a genetically transmitted MuMTV [16], the conclusion of a single dominant gene controlling the release of the highly oncogenic virus was based mainly on the study of tumour incidences [1–5, 12, 13]. This conclusion has been seriously challenged [17–19], in particular on the basis of detection of viral antigens in the milk by means of a sensitive immunoassay.

Since the sensitive Sepharose bead immunofluorescence assay had been perfected [20, 21] and applied to the detection of oncoviral antigens [22, 23] in our laboratories, it was decided to reinvestigate the genetic control of the release of endogenous MuMTV with this method in addition to tumour detection.

Accepted 20 March 1978.

MATERIALS AND METHODS

Mice

The following mouse strains were used: 1. the high mammary cancer strains GRS and BALB/cfC3H. 2. the moderate mammary cancer strains C3Hf and BALB/c. 3. the low cancer strain C57BL.

Female mice, either inbred or hybrid, were caged at 4 months of age with a 3-month-old (C57BL × BALB/c) F1 male. Two weeks post-

partum the female was milked (0.25–0.5 ml) and the litter discarded. The defatted milk was stored at −30°C until tested in the immunoassay. The female was earmarked and then caged with two other females and a (C57BL ×BALB/c)F1 male. The cages were examined daily for litters, which were discarded. The males were replaced by a 3-month-old male every four months. The females were inspected twice a week for the presence of mammary tumours or other diseases. They were permitted to live out their life spans.

Virus

The standard strain of mammary tumour virus (MuMTV-S) [3] was isolated from BALB/cfC3H mammary tumours according to Westenbrink *et al.* [24]. This method is a modification of the technique developed by Calafat and Hageman [25]. In brief, ultrapellets of cell-free homogenates are first centrifuged on a discontinuous sucrose gradient and thereafter twice on a linear (20–50% w/w) sucrose gradient.

The endogenous, virulent MuMTV-O strain isolated from old BALB/c mice [26], had been kindly provided in 1972 by Dr. Ph. C. Hageman of the Netherlands Cancer Institute. After inoculation, a BALB/c colony which continuously transmits this virus through the milk and which develops a high incidence of mammary carcinomas at a young age was established. Virus was isolated from tumours as described above.

The so-called low oncogenic variant (MuMTV-L, [3]) was isolated from transplantable C3Hf mammary tumour lines. The virulent variant MuMTV-P was isolated from primary GRS tumours.

For bioassay, the virus was diluted in Hanks' balanced salt solution and 5 μg in 0.5 ml were then immediately injected into 4-week-old female BALB/c mice, which were then subjected to forced breeding [3].

Antiserum

A rabbit was immunized with 0.2 mg of purified MuMTV-S emulsified in complete Freund's adjuvant at multiple subcutaneous and intramuscular sites. This immunization was repeated two weeks later and the rabbit was bled two weeks thereafter. Antibodies to murine host materials were removed by immunoabsorbent column chromatography [27] using Sepharose-4B beads (Pharmacia, Uppsala, Sweden) coupled with either normal BALB/c mouse serum or normal BALB/c mammary gland extract.

In the Sepharose bead immunofluorescence assay [20–23], the antiserum was tested for reactivity with MuMTV, murine leukaemia virus, normal mouse serum, mouse mammary gland extract and ovalbumin. The antiserum proved to be satisfactorily specific.

An immunoglobulin fraction of the absorbed antiserum was prepared by DEAE-cellulose chromatography [28]. A portion of this fraction was coupled to Sepharose-4B beads according to March *et al.* [29]. Another portion of this fraction was labelled with fluorescein isothiocynate (FITC) [30].

Sepharose bead immunofluorescence assay for the detection of MuMTV antigens

The method is essentially the same as developed for C-type oncoviral antigens [22]. The Sepharose beads coupled with the antiserum to MuMTV was pipetted into wells of flat bottom microtitration plates (Cooke System, no. M220-24A, Greiner, Nürtingen, Germany). Each well contained 50 μl of a 1% (v/v) suspension.

The skimmed milk samples were diluted in such a way that they contained 0.5 mg protein per ml. The protein content was determined by the fluoram method [31]. The samples were then incubated with 0.3% Nonidet (NP40, Shell Oil Co., The Hague, The Netherlands). Two-fold dilutions of these milk samples (50 μl) in PBS were added to the wells along with beads coupled with antiserum. After 1 hr incubation, the beads were washed four times with PBS, using a homemade apparatus. They were then incubated for 1 hr with the FITC-conjugated antiserum fraction, which was diluted 50-fold in PBS with 2% hemoglobin.

Individual bead fluorescence was then measured with an inverted Diavert microscope (Leitz, Wetzlar, Germany) using a 25 × 0.50 water immersion objective. The microscope was equipped with an MPVI measuring device and a Ploemopak 2.2 incident light illuminator. The Volt meter (Hewlett Packard no. 3490, Palo Alto, California, USA), reading the photomultiplier (S20 cathode sensitivity) output was interfaced directly to a desk top programmable calculator (Hewlett Packard, no. 9821A) which immediately provided the average fluorescence and its standard error of ten beads per well.

The amount of viral antigens in milk samples was determined on the basis of a calibration curve obtained for purified MuMTV-S.

RESULTS

Mammary tumour incidences in mouse strains and their hybrids used in this investigation

For characterization with regard to mammary tumour development, relatively large numbers of animals from the various strains and their hybrids were forced bred. In addition, the efficacy of purified MuMTV preparations of different origin were compared in the susceptible BALB/c mouse strain.

It can be concluded from Table 1 that tumours appear extremely early in the GRS strain, which produces the genetically transmitted MuMTV-P. These lesions usually regress after parturition, but gradually become pregnancy-independent. Tumours appear somewhat later in the BALB/cfC3H strain, which carries exogenous MuMTV-S. These tumours sometimes show a partial regression after parturition, but during the next pregnancy they become fully autonomous.

The C3Hf mouse strain, which releases a lesser oncogenic MuMTV, shows a moderate tumour incidence (30%) at 18 months of age. Only one female of the C57BL strain, which does not seem to release a MuMTV, developed a mammary tumour. The BALB/c strain, which produces small amounts of the virulent MuMTV-O at a late age, develops a substantial number of tumours at 18 months of age like the C3Hf strain.

Infection of BALB/c mice with any of the MuMTV-strains results in a very high tumour incidence. The MuMTV-P strain isolated from GRS tumours is slightly less virulent than MuMTV-S and -O. The MuMTV-L strain isolated from C3Hf tumours is considerably less virulent, in that it induces tumours at a significantly later age. The incidence is surprisingly high, however.

All hybrids sired by a GRS male show an approximately 100% tumour incidence. The hybrid (BALB/c × GRS)F1 develops these lesions as early as does the parental GRS, while the hybrids of C3Hf or C57BL with GRS have a significantly later tumour age. In the two latter hybrids, tumours show a shorter period of pregnancy-dependency.

While the hybrid of C57BL and C3Hf has a tumour incidence comparable to that of the C3Hf strain, the combination of BALB/c and C3Hf results in a surprisingly high incidence (63%) as compared to the parental strains. The latter hybrid develops tumours at about the same age as C3Hf, whereas (C57BL × C3Hf)F1 shows tumours considerably later. The hybrid of BALB/c and the low cancer strain C57BL has a moderate tumour incidence like BALB/c, but neoplasms arise 7 months later on the average.

Immunoassay of milk samples for MuMTV antigens

When purified MuMTV preparations or tissue culture fluids were assayed with the Sepharose bead immunofluorescence assay, the lowest detectable amount of viral proteins was 0.3 ng per sample of 50 μl. Probably because of nonspecific binding of milk proteins to the beads, the sensitivity is considerably less for mouse milk: 5 ng per sample of 50 μl. The tested milk samples can be divided into three separate groups: (a) negative; (b) less than 5 μg MuMTV antigens per mg protein; (c) more than this amount. The incidences of the three groups for milk samples of the various mouse strains and their hybrids are given in Table 2.

The high cancer strains GRS and BALB/cfC3H have high levels of virus in their milk: the averages are 70 μg and 50 μg, respectively, per 1 mg milk protein. The C3Hf mouse strain produces considerably less: 10 μg on the average. The strains C57BL and BALB/c are negative for the virus.

The F1 hybrids produced by a GRS male had high levels of MuMTV proteins in their milk. Most (C57BL × C3Hf)F1 animals are MuMTV-negative, while all animals in the cross BALB/c × C3Hf are positive. They produce approximately twice as much MuMTV proteins as does C3Hf.

Except for one animal, the F1 hybrid of the "virus-free" mouse strains C57BL and BALB/c does not release MuMTV into the milk.

The results of the immunoassays of milk samples from progeny mice of the various series of crosses are presented in Table 3. The first five crosses concern the genetics of the release of MuMTV in the GRS strain and its hybrids. In all three crosses in which the C57BL strain is involved, incidences of MuMTV-positive milk samples are close to 50%. In those crosses in which the C57BL is not involved, the incidences are very much in excess of the anticipated 50%. However, when the incidences of the group with more than 5 μg are considered, they are around 50%, except for the cross ♀BALB/c × ♂(C3Hf × GRS)F1.

The next five crosses concern the genetics of release of MuMTV in the C3Hf strain and its hybrids. The incidences in the first

four crosses would be according to a single gene hypothesis: the difference would be that, in the case of BALB/c versus C3Hf, a dominant C3Hf gene would control virus release, while that gene seems to be recessive in the crosses involving the C57BL strain. From the cross BALB/c × (C57BL × C3Hf)F1 with its 20% incidence it seems that at least two genes are involved.

Tests for extrachromosomal male transmission of MuMTV

In the crosses involving GRS-F1 hybrid males, the females were mated only once to these males in order to avoid extrachromosomal male transmission of MuMTV [1, 2]. The females were then mated with a BALB/c male and allowed to raise a litter. In the meantime, they were milked once for immunoassay of MuMTV antigens. They were then subjected to forced breeding. The females of the litter sired by a BALB/c male were also tested for the presence of MuMTV antigens in their milk and afterwards subjected to forced breeding.

In cross No. 1, one C57BL female was shown to be infected on the basis of immunoassay. However, she did not develop a mammary tumour, but died of a lymphoreticular neoplasm at the age of 20 months. Of her (C57BL × BALB/c)F1 offspring, all three females proved to be positive for viral antigens in the milk. Two of them produced a mammary carcinoma at around 1 yr of age (11 and 13 months, respectively).

In cross No. 3, four BALB/c females proved to be antigen positive. Only two of them developed a tumour before one year of age, while the total mammary tumour incidence in this group was 28% with an average tumour age of 15.0±1.1 months. The offspring of these 4 females also proved to be infected on the basis of immunoassays and the fact that the majority of the progeny females produced a tumour before 1 yr of age.

In crosses 4 and 5 it was also found that not every infected BALB/c female developed an early mammary tumour. In cross No. 4, one infected female died from a lymphosarcoma at 16 months. In cross No. 5, one antigen positive female developed a mammary tumour at 19 months and one accidently drowned at the age of 15 months.

In crosses 4 and 5, some litters sired by a BALB/c male were positive with regard to MuMTV antigens in their milk as well as to early tumour development, whereas their mothers proved to be negative in both tests.

In conclusion, only 1% of the C57BL females seemed to be infected by a single mating with a GRS-hybrid male, whereas approximately 10% of the BALB/c females contracted the virus from their GRS-hybrid mates.

Mammary tumour development in mice assayed for MuMTV antigens

The mammary tumour incidences in forced bred females of the various inbred mouse strains and their F1 hybrids in relation to their MuMTV status is given in Table 5.

As compared to Table 1 in which considerably larger numbers of animals were used, the incidence and average tumour ages of the samples used in Tables 5 are not substantially different from those of the corresponding groups in Table 1.

Tumour incidences are significantly higher and tumour ages substantially lower in the classes in which MuMTV antigens can be detected at first lactation. There is also a slight difference in this respect between the low-MuMTV-releasers (less than 5 μg) and the high-MuMTV-releasers. For instance,

C57BL × BALB/c	38	16	24	100	19			18	23

*F1-hybrids were sired by the second indicated strain.

in the F1 hybrid BALB/c × C3Hf in the low-MuMTV class, only 33% of the animals develop a tumour at the relatively late age of 20 months, whereas in the high-MuMTV class, 86% of the animals contract the disease at the relatively early age of 14 months.

This picture becomes even more clear when tumour incidences and tumour ages are studied in the progeny of several crosses in relation to the MuMTV status at the first lactation period (Table 6). In every cross, tumour incidence is lower and tumour age higher in the so-called virus-negative groups. These groups with less than 5 μg of MuMTV antigens per 1 mg protein at first lactation also develop fewer tumours and at a later age than do the corresponding high-virus groups.

Especially in the first five crosses, which involve the GRS mouse strain, there is a striking difference in tumour age between the two groups with different amounts of MuMTV proteins in their milk. In 4 of these crosses, final tumour incidences are extremely high (more than 70%). It is noteworthy that the BALB/c mouse strain is involved in all of these cases.

DISCUSSION

The theory of genetic transmission of murine mammary tumour viruses originated in the purported single-genic control gamete-borne transmission of a virulent MuMTV in the GRS mouse strain [1–5]. The conclusion was based mainly on the incidence of palpable mammary tumours within a certain time period in a great variety of crosses involving the GRS mouse strain. By use of a rapid standardized tumour induction technique and an immunoassay for MuMTV antigens, van Nie and collaborators [12–14] concluded that indeed a single dominant gene of the GRS strain would cause release of large amounts of virus and early tumour development.

The theory has now been widely accepted, but its original basis—the single GRS gene associated with MuMTV transmission—has been seriously challenged [17–19]. In one study [18], the sensitive radioimmunoassay was used for the detection of MuMTV proteins in the milk. We employed the comparatively sensitive Sepharose bead immunofluorescence assay, the advantages of which have been discussed before [22]. After repeated absorption with nonviral materials, the antiserum proved to be sufficiently specific with this technique. No reactions were found with Rauscher murine leukaemia virus, normal BALB/c mouse serum or an extract of BALB/c lactating mammary gland. Specificity of the technique can also be concluded from the negative reactions of the C57BL and BALB/c milk samples. These strains are generally regarded to be negative for MuMTV in their milk. The technique is also sufficiently sensitive: the lowest detectable amount of MuMTV being 5 ng per sample of 50 μl.

In the crosses involving a GRS-hybrid male, there is a chance for nonchromosomal male transmission. We have therefore chosen a single mating of a female with such a male. It seemed that only one of the

C57BL females became infected. She subsequently transferred the virus via the milk to her offspring. Approximately 10% of the BALB/c females were infected by their GRS-hybrid mates. In the studies of Heston *et al.* [18, 19], neither milk-borne transmission nor extrachromosomal male transmission of MuMTV seemed to be controlled as in our study. This may partly account for the aberrant ratios of MuMTV-positives and tumour incidences, which do not seem to fit a single-gene postulate.

In our study in three crosses involving the GRS strain, incidences of MuMTV-positive milk samples which are close to 50%, as would be expected in case of a single gene were found. Van Nie *et al.* [12–14] have also tested second back cross generations and the results were consistent with the one-dominant gene postulate. They called this gene "Mtv-2".

However, in the BALB/c × (BALB/c × GRS)F1, the incidence of MuMTV-positive milk samples is greatly in excess of 50%. Extrachromosomal male transmission of the virus may account for a maximum of 10% of this excess, but probably less, as there is a good chance that progeny mice receive the virus directly from their father in a genetic way as well as indirectly via the milk from their infected mother.

The excess in BALB/c × (BALB/c × GRS)F1 can only be explained on the basis of more than one gene controlling release of a MuMTV. The virus-positive milk samples have been arbitrarily divided into two groups with 5 μg MuMTV protein per mg milk protein as a cut-off point. In the group above 5 μg, most animals contain excessively large amounts of viral antigens in their milk (82 μg ± 5). Tumours appear extremely early (7 months average) in this group. In the other group, a high tumour incidence (74%) is found, but tumours appear late (20 months). We conclude from this that, in this cross, a single dominant gene segregates, which causes release of large amounts of virus and early tumour development in approximately 50% of the back cross animals. In addition, a second gene which is associated with the release of small amounts of viral antigens and late tumour development manifests itself in this cross. This probably represents a virus other than the virulent MuMTV-P, causing pregnancy-dependent tumours.

Nandi and Helmich [17] made the reciprocal cross and by an elegant procedure

excluded virus transmission via the milk. From the incidences of mammary lesions (neoplasms and hyperplastic nodules) in the offspring before 1 yr of age, they concluded that two independently segregating dominant genes in the GRS strain would control the transmission of a MuMTV, or at least the production of mammary lesions.

We do find two distinct populations in the backcross of the GRS-hybrid to BALB/c: one developing tumours at an early age (7 months) and one producing mammary carcinomas at the average age of 20 months. In the study of Nandi and Helmich, the F1-hybrids of BALB/c and GRS have a 100% tumour incidence at 7 months of age. They found 75% at that age in the F2 generation. This is in agreement with a single-gene hypothesis; in the case of a two-gene hypothesis, a 94% incidence would be expected. In the back cross to BALB/c, they found a 53% incidence at 7 months, which is in accordance with the single-gene postulate; otherwise, 75% would be anticipated. At 12 months of age, they found a considerably higher incidence of mammary lesions. This may be partly due to the second gene, postulated by Van Nie *et al.* [14] and by us, which is associated with a lesser oncogenic virus. This MuMTV-strain might induce hyperplastic nodules at one year of age which will develop into tumours after a considerable length of time, like the nodules induced by MuMTV-L of the C3Hf mouse strain [32].

In the four first crosses involving the GRS strain (Table 3), the proportion of mice with large amounts of MuMTV antigens in their milk is close to 50%. The great majority of these mice develop tumours before one year of age. This finding supports the notion of a single dominant gene which causes the release of a great amount of virus and early tumour development in the GRS strain. The relatively high proportion of mice with small amounts of MuMTV antigens in the milk, as found in the back cross to BALB/c (cross No. 3), is not encountered in the four other crosses involving the GRS strain. Probably the BALB/c strain carries recessive genes which allow the expression of the second GRS mouse strain gene for another MuMTV.

The excess over 50% of MuMTV-positives (also in the high-virus category) in cross No. 5, BALB/c × (C3Hf × GRS)F1, can be explained by expression of the MuMTV-L of the C3Hf strain. In the latter strain, viral antigens are released in considerable amounts, although not as much as in the GRS strain. The presence of mice which only release MuMTV-L in the so-called high-virus category explains very high tumour incidence (91%) as well as the increased average tumour age (10 months). Since the incidence of virus-positives in this cross is not 100% as compared to the F1-hybrids of BALB/c with either C3Hf or GRS, it must be concluded that the GRS-gene controlling release of virulent MuMTV-P is not allelic to the C3Hf gene controlling release of MuMTV-L. No conclusion can be drawn about allelism between the second GRS gene controlling release of a lesser oncogenic MuMTV-strain and the C3Hf gene.

From the back crosses of (BALB/c × C3Hf)F1 to either parental strain, it can be concluded that a single dominant gene of the C3Hf strain causes release of MuMTV. This has been found earlier by Van Nie and Verstraeten [15], who called this gene "Mtv-1". The BALB/c strain, which does not release a MuMTV into the milk at an early age, has a similar tumour incidence and tumour age as the virus expressor C3Hf. In the F1-hybrids of these strains, tumours appear somewhat earlier and in a considerably higher incidence. This indicates the BALB/c strain to be rather susceptible to MuMTV-L, as was also found in bioassays (Table 1). In both back crosses, tumour development is enhanced and accelerated when large amounts of virus are released.

In the F1-hybrids of C57BL and C3Hf, expression of MuMTV is largely inhibited. The results of the back cross to C3Hf suggest that a single dominant C57BL gene inhibits the release of MuMTV-L to a large extent. From cross 10, BALB/c × (C57BL × C3Hf)F1, it can be concluded that the C57BL gene inhibiting MuMTV release segregates independently from the C3Hf gene "Mtv-1" which allows the production of MuMTV-L; otherwise, a 50% incidence of virus-positives would be expected. It must be assumed that the C57BL gene, which we propose to call "Imv" (Inhibitor of mammary tumour virus release), is epistatic to "Mtv-1". The latter gene cannot function in its presence. Possibly "Imv" also inhibits the expression of the second GRS strain gene which is associated with the release of small amounts of MuMTV.

Surprisingly, the hybrid (C57BL × C3Hf)F1 produces mammary tumours in approximately the same incidence as does the parental C3Hf, despite inhibition of MuMTV-expression at an early age. However, tumours appear at a considerably later age. In all crosses involving this hybrid (Nos. 8–10), there is some correlation between the presence of viral antigens in the milk at a young age and high tumour incidences and relatively young tumour age, but it is still noteworthy that a substantial number of tumours are produced in the so-called virus-negative categories. This also holds for several other virus-free groups in Tables 5 and 6.

It is known that the endogenous MuMTV-O is switched on at a late age in the BALB/c strain [26, 33]. Infectious virus can be recovered from 9% of spontaneous BALB/c mammary tumours [33] and small amounts of MuMTV antigens can be found in the majority of BALB/c tumours [15]. It is possible that, for instance, inhibition by the "Imv" gene breaks down on ageing in (C57BL × C3Hf)F1 leading to virus release and subsequent tumour production. An alternative possibility is the expression of only the gene for oncogenic transformation, called "mam", of the endogenous MuMTV. It must be kept in mind, however, that mammary tumours may develop without any involvement of an endogenous virus-gene.

Molecular hybridization studies indicated that several mouse strains contain multiple copies of the MuMTV genome in their normal cellular DNA [8–10]. The GRS strain contains an exceedingly high number of such copies [9–10]. We assume the "Mtv-2" gene to be associated with this excess in MuMTV proviral genomes; in other words that they are located in tandem at a single locus as has been postulated for RD114 and the protovirus for feline leukaemia virus in the domestic cat [34]. This cluster of proviral genomes is continuously transcribed without interference of any other cellular gene, giving rise to high virus titers and early tumour development.

The "Mtv-1" gene of the C3Hf allows continuous release of MuMTV-L, but does not induce the early appearance of the virulent MuMTV-O harboured by the BALB/c genome in the F1-hybrid with BALB/c. Reciprocally, BALB/c strain genes inhibit the expression of any of their own proviruses, but not affect the production of the endogenous MuMTV-L from C3Hf. We interpret these findings to mean that the germinal proviruses of MuMTV are controlled by closely linked regulatory genes. Only when in *cis*-position can they repress the neighbouring provirus. Such genes have no effect on proviruses at other sites in the mouse genome. In the C3Hf, such a gene would be mutated, giving rise to early virus release.

The "Imv" gene of the C57BL is epistatic to the "Mtv-1" gene of C3Hf and the gene(s) in the GRS are associated with a lesser oncogenic virus. It inhibits the expression of these viruses to a large extent. Position effect does not seem to play a role in the action of that gene; although not linked to "Mtv-1", it can interfere with its action. The "Imv" resembles the "I^e" gene in chickens [35], which is epistatic to the gene(s) allowing expression of group-specific antigens by the endogenous RAV-O virus. It remains to be investigated, however, whether the action of the "Imv" gene would be interference with the establishment of a somatic provirus.

Several mouse strains, derived from high-mammary cancer strains after removal of milk borne MuMTV-S spontaneously release a low-oncogenic MuMTV [36]. Probably the genes like "Mtv-1" allowing release of an endogenous virus also cause susceptibility to superinfection with MuMTV-S. It would be interesting to know whether such genes in other mouse strains are allelic to "Mtv-1".

The expression of low-oncogenic MuMTV in the other mouse strains is also inhibited by the C57BL genome in the respective F1-hybrids, most likely due to the "Imv" gene. Several other nonexpressor strains such as O20 and CBA inhibit the expression of MuMTV in F1-hybrids with C3Hf. It would be of interest to know whether the genes responsible for this phenomenon are allelic to "Imv" of the C57BL.

1. BACKGROUND AND INTRODUCTION

PROTOCOL 62761 of the Soft Tissue Cooperative Group is presently studying 2 combination chemotherapy regimens consisting of adriamycin, DTIC, cyclophosphamide and vincristine in patients with advanced soft tissue sarcoma. In the first arm (S_1) the four drugs are given simultaneously on day 1, while DTIC is continued during 5 days. In the second arm (S_2) adriamycin and DTIC are given simultaneously without cyclophosphamide and vincristine. The latter 2 drugs are alternated with the former 2 drugs every 4 weeks. The most active drugs in the treatment of soft tissue sarcomas are adriamycin and DTIC. The combination of these 2 drugs has proven to be more effective in soft tissue sarcoma than each of the 2 drugs given as a single agent. Vincristine and cyclophosphamide are quite ineffective in soft tissue sarcomas when given as single agents. Recently, *cis*-diammine-dichloro-platinum (*cis*-DDP) has proven to be effective in several solid tumors such as testicular carcinoma, ovarian cancer, bladder cancer and possibly in head and neck tumors as well [1–4]. The only data available on the effect of *cis*-DDP in soft tissue sarcoma consist of 5 available patients in a phase I study [2]. No response was observed in these patients. The Soft Tissue Sarcoma Group offers an excellent patient population to perform a phase II trial of *cis*-DDP in soft tissue sarcoma. This phase II study can be performed in patients who go off study in the protocol for advanced sarcoma (62761) and will give us information on the response rate of this tumor within 6 months from now. In case *cis*-DDP would prove to be active in soft tissue sarcoma our next step will be to initiate a protocol in advanced sarcoma including this drug in combination regimens. As all the investigators participating in the study for advanced soft tissue sarcoma are internists we feel that it is justified to introduce this toxic drug into the Soft Tissue Sarcoma Cooperative Group.

2. PURPOSE OF THE STUDY

(a) The main purpose will be to determine objective tumor response rate and duration of response to DDP in patients with advanced soft tissue sarcoma who have failed all treatment presently available.

(b) To determine the morbidity of *cis*-DDP treatment in this group of patients.

3. SELECTION OF PATIENTS

3.1 *Conditions for patient eligibility*

Patients with advanced soft tissue sarcoma who have failed on conventional treatment. This includes patients leaving protocols 62761 and 62771 because of progression and patients

*E.O.R.T.C. Soft Tissue Sarcoma Cooperative Group.

†This work was supported by Contract No. 1/CM/53840 from the National Cancer Institute, Bethesda, Maryland, U.S.A.

who are not eligible to enter 62761. The patient should have a measurable lesion with progression during the 4 weeks prior to treatment.

3.2 *Conditions for patient exclusion*

Patients 20 yr old or younger, patients above 70 yr and patients with abnormal kidney function: creatinine clearance below 80! Unfavourable, haematologic status; WBC below 3000/mm^3 and platelet count below 150,000/mm^3, cytostatic agents during the previous four weeks, performance status according to Karnofski under 50, central nervous system lesions, intercurrent infection and overt psychosis or marked senility.

4. DESIGN OF THE TRIAL

All patients will receive the same treatment schedule consisting of DDP in dextrose 5% infusion containing mannitol. The infusion will be given over 3 hr. If during the 1st course 100 mg/m^2 DDP is tolerated without toxicity, the dose will be increased to 120 mg/m^2 in the subsequent courses. This treatment will be repeated every 3 weeks. The response will be evaluated after the second course. If at 6 weeks there is tumor regression or no change, treatment will be continued until progression. If there is progression at 6 weeks the patient will go off study. Patients responding to treatment must be followed to progression and to death whenever possible.

5. THERAPEUTIC REGIMENS AND TOXICITY

5.1

Prior to the DDP infusion the patient should receive 1 l. of saline over a period of 4 hr. *Cis*-DDP 100 mg/m^2 will then be given in 1 l. dextrose 5% containing 37.5 g of mannitol over a 3 hr period. Diuresis should be maintained by giving an additional 3-liter saline infusion over the following 24 hr. In case the urine output is insufficient (<600 cm^3 per 6 hr) furosemide 20–40 mg/day should be added to the regimen. Thus, careful monitoring the urine output is essential! This treatment will be repeated every 3 weeks. If during the 1st course 100 mg/m^2 DDP is tolerated without toxicity the dose of DDP will be increased to 120 mg/m^2 in the subsequent course. The patient will be evaluated after 2 courses. The treatment will be continued until progression in case of no change or regression after 6 weeks. In case of progression at 6 weeks the patient will go off study.

5.2 *DDP toxicity*

The most important toxicity is renal failure. However, a good renal function prior to treatment and an adequate urine output during the 24 hr of treatment makes this complication unlikely [2, 5].

Auditory abnormalities consisting of a high pitch hearing loss may occur. Myelosuppression, reaching its nadir at day 10–14, is often seen but is not severe. Anaphylactic reactions are rare. Antiemetics should be given but are only slightly effective. In case of infectious complications following the treatment, gentamycin should be avoided whenever possible as there is probably a cumulative toxicity to the kidney. The same is true for damage which may be caused to the auditory nerve by gentamycin. In case gentamycin has to be given, never add cephalothin to this regimen as this combination is still more toxic to the kidney. Serious nephrotoxicity has been observed with this combination [6]. In case the serum creatinine increases during treatment to a level above 1.2 mg/100 ml the kidney function will, in most cases recover within 3 weeks. If, however, at 3 weeks the serum creatinine is still above 1.2 mg/100 ml the next dose should be postponed for a maximum of one week (4 weeks after previous dose). If at 3 weeks after the previous course the WBC count is below 3000 or the platelet count is below 150,000 the treatment should be postponed as well for 1 week. In case treatment has to be postponed for more than 1 week the patient should go off study due to toxicity.

6. REQUIRED CLINICAL EVALUATION, LABORATORY TESTS AND FOLLOW-UP

6.1

Age, sex, case history and duration of symptoms (specify), date of clinical and pathological diagnosis and how this was established, prior treatment (data and methods). The physical examination should include: height and weight, the Karnofski index and exact description and measurement of the measurable parameters.

6.2

The minimal laboratory studies required are: complete bloodcount creatinine clearance, liver function tests consisting of bilirubine, alkaline phosphatase, gammaglutamyl *trans*-peptidase, SGOT, SGPT and if possible cholinesterase. Furthermore, urinanalysis should be done. Because of the possible ototoxicity an audiogram should be performed prior to treatment as well. Radiological examination should include a chest X-ray and a skeletal survey. An isotopic bone scan is optional.

6.3

Follow-up. Before each treatment course the morbidity of the previous course should be registered. Furthermore, a clinical examination, blood investigations, and evaluation of the Karnofski index are required. An audiogram will be repeated after the second course. Any unexpected side effects of treatment should be reported immediately to the study coordinator. A clear description of the tumor response is required prior to the third course.

7. CRITERIA OF EVALUATION

Patients are considered evaluable if they have been treated with a minimum of 2 courses.

7.1 *Complete remission*

Disappearance of all symptoms and signs of soft tissue sarcoma for a minimum of 3 weeks.

7.2 *Partial remission*

Significant decrease in size in at least 50% of all lesions for a minimum of 3 weeks while the remainder are static. Such a decrease is defined as a reduction by 50% of the product of the two largest perpendicular tumor diameters. Changes in body chemistry and improvement in hemopoiesis cannot be construed as criteria of objective remission.

7.3 *Stable disease*

Less than 50% reduction in the product of largest perpendicular diameters of measurable lesions or less than 25% increase in any of the measurable lesions. No appearance of any new lesion.

7.4 *Progression*

Increase of more than 25% in the product of the largest perpendicular diameters of any lesion. Also, appearance of any new lesions regardless of the response of other lesions.

7.5 *Early death*

Death occurring during the first three weeks due either to tumor progression or drug toxicity.

8. REGISTRATION

A patient is registered after the local pathology review by telephoning to the E.O.R.T.C. Data Center, phone: Brussels: 538.65.33 or by telex 22.773 from 9.00 a.m. to 5.00 p.m., Monday–Friday. The following information is requested:

1. protocol number (62781),
2. name of the institution,
3. name of the patient,
4. histological type,
5. name of the responsible investigator.

9. SUBMISSION OF FORMS

All forms are to be sent in duplicate to the E.O.R.T.C. Data Center, Institut Jules Bordet, 1, Rue Héger Bordet, 1000 Bruxelles, Belgium.

The schedule for submission of forms is as follows:

1. *On-Study form*

Send within one week of the patient's entry on study, 1 page.

2. *Chemotherapy form*

Send after completion of each 2 cycles of DDP, 1 page.

3. *Flow-sheet*

The first flow sheet should be filled out prior to the first cycle of chemotherapy and sent with On-Study form. It should also be filled out at 6 weeks and thereafter every 12 weeks as long as the patient remains on-study. Also immediately upon progression, 1 page.

4. *Measurement form*

Send with on-study, at 6 weeks and every 3 weeks thereafter as long as the patient remains on-study. Also immediately upon progression.

5. *Summary form*

To be sent upon progression or death, whichever comes first.

10. STATISTICAL CONSIDERATIONS

The lowest limit of therapeutic activity considered to be of interest is a response rate of 20%. Twenty-nine patients will be entered on study and the drug rejected from further study if 3 or fewer responses are obtained. If no response have been obtained in the first 19 patients treated the study will be stopped. This plan insures that if the drug has a response rate of at least 25% the probability of rejecting the drug from further study is approximately 0.05.

11. ADMINISTRATIVE RESPONSIBILITY

This study is a joint effort among the investigators working in the E.O.R.T.C. Soft Tissue Sarcoma Cooperative Group. The secretary of the group will evaluate the clinical data of patients while the statistical analysis will be performed by Dr. Richard Sylvester. Dr. Sylvester can be reached at the Data Center.

The address of the Secretary Dr. H. M. Pinedo is: Oncology Unit, Department of Internal Medicine, University Hospital, Utrecht, The Netherlands. Telephone: 030-372202.

The Relationship Between Inflammatory Responses and WBP1 Tumour Cell Attachment to the Rat Omentum

J. A. GREEN* and A. E. WILLIAMS†

Department of Microbiology, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, England

WHILE much attention has been focussed on the inherent properties of neoplastic cells which confer invasiveness, the influences exerted on the process by the host have remained more obscure [1]. A close relationship between inflammatory responses and invasion by both normal cells (during pathological and morphogenetic processes) and neoplastic cells has been previously suggested [2]. During invasion of murine abdominal organs by ascites tumour cells certain regions of the viscera were invaded earlier than others and tumour cell adhesion and infiltration appeared to follow host responses to the tumour [3, 4]. Attachment to the abdominal wall appeared to be preceded by the breaking of mutual contact by the mesothelial cells and their exfoliation, resulting in the rapid adherence of tumour cells to the exposed membrane [5].

As a result of studies on the dissemination of ^{125}I-iodo-deoxyuridine labelled cells of the sublines of different malignancy of the WBP1 ascites tumour [6] after i.p. injection into black and white hooded rats, which demonstrated that more cells of each subline attached to the omentum than to any other organ or tissue, we undertook a study of the process in the light and scanning electron microscopes. Evidence is presented of the close link between inflammatory response and tumour cell attachment to the omentum.

Omenta were removed from groups of animals either without treatment or at intervals after i.p. injection of either 5×10^7 WBP1 cells in Tyrodes–gelatin–citrate medium or medium alone. The omenta were prepared either for observation in the SEM as described previously [7] with diffusion dehydration in acetone followed by critical point drying, or for histological examination by fixation in 10% formal saline containing 1% calcium chloride and staining 4 μm sections with haematoxylin and eosin.

By 8 hr after injection of tumour cells there was evidence in the SEM of a reaction in the surface of the taches laiteuses (Fig. 1) which did not occur after injection of medium alone. The smooth-surfaced mesothelial cells in many areas appeared to be breaking mutual contact, creating openings in the surface, and the number of cells attached to the surface was greater than normal. Many of the attached cells could have been WBP1 cells, having a diameter of 6 μm and a surface comprising closely packed microvilli, although some peritoneal cells from normal animals were similar in appearance. The mesothelium overlying adjacent adipose tissue appeared normal, with no evidence of cell attachment.

The appearance of the surface of the taches laiteuses then changed progressively, until at 24 hr after tumour injection these areas contrasted markedly with the mesothelium overlying adjacent adipose tissue (Fig. 2). The surface of the taches laiteuses comprised a mass of cells *ca.* 10 μm in diameter and smaller cells characteristic of WBP1 cells so that in many areas the mesothelium appeared to be entirely disrupted, whereas the mesothelium overlying surrounding adipose appeared normal, with no evidence of cell attachment.

Histological examination of omenta 24 hr after injection of tumour confirmed that characteristic WBP1 cells [8] were present at the surface of and within the taches laiteuses at

Accepted 23 January 1978.

†Teaching and Research Centre, Western General Hospital, Edinburgh EH4 2XU, Scotland.

this time. The mesothelium in these areas was difficult to recognise and there was evidence of an inflammatory response with an influx of polymorphonuclearcytes and some mast cells. Elsewhere the tissue appeared normal. After this time it was impossible to recognise the mesothelial surface of the taches laiteuses, tumour cells increased in evidence and the intensity of the inflammatory response increased progressively, with the appearance of large foci of the histiocytic cells characteristic of normal taches laiteuses. There was evidence of invasion of adipose tissue adjacent to some taches laiteuses by isolated WBP1 cells, until at 72 hr after tumour injection considerable invasion of adipose tissue had occurred. Even at this time the mesothelium overlying invaded and other adipose tissue still appeared normal with no evidence of tumour cell attachment.

We have clearly illustrated that tumour cell attachment is closely linked to the host inflammatory response. The breaking of mutual contact by the mesothelial cells created openings in the surface, perhaps exposing a more suitable surface for tumour cell attachment. That such a reaction was a prelude to attachment was strongly suggested by the fact that as the omentum is covered by the same continuous mesothelium there was no reason if this was not the case why tumour cells should not have attached to sites other than the taches laiteuses. The ensuing intense inflammatory response appeared to offer ideal opportunity for the establishment of tumour foci, and led to subsequent invasion of surrounding tissue. The inflammatory response, previously shown to cause differences in tumour cell attachment to various organs [3, 4] has in this case been shown to cause differences in cell attachment to different regions of the same organ.

Letters to the Editor

Acute Non-Lymphoblastic Leukemia

G. ROBUSTELLI DELLA CUNA, Q. CUZZONI, L. PAVESI and G. MARINI*

Divisione di Oncologia, Fondazione Clinica del Lavoro, Clinica Medica "A. Ferrata", Università di Pavia, 27100, Pavia, Italy*

THE MOST recent reports [1, 2] of two controlled clinical trials of chemoprophylaxis in early breast cancer have confirmed that adjuvant chemotherapy to radical mastectomy in primary breast carcinoma with positive axillary lymph nodes can improve the 3 yr relapse rate. Both single agent [3] and combination chemotherapy seem to be in general well tolerated, without any long term side effects such as drug related second malignancy [4]. Notwithstanding these successful results, many physicians have recommended caution since this approach should be still considered experimental [5–8]. The potential risk of a second drug-induced neoplasia is always present because alkylating agents, used in the above mentioned treatments, may be immunosuppressive and carcinogenic, facilitating the onset of a second malignancy.

This letter describes a case of acute promyelocytic leukemia arisen after prolonged adjuvant treatment with L-PAM, after surgery, for breast cancer.

Case report. A 39-yr-old premenopausal woman, who undervent radical mastectomy in February 1976 for a carcinoma of the right breast (T_2 N_{1b} M_0, estrogen and progesterone receptor negative) has been treated on out-patient basis with adjuvant chemotherapy (L-PAM: 0.15 mg/kg p.o. × 5 every six weeks for a total dose of 400mg) from March 1976 to January 1977 according to the protocol of Fisher *et al.* (1975) [3]. The woman, who stopped treatment with L-PAM in February 1977 because of severe leukothrombocytopenia (WBC 1800/mm^3, platelets 66,000/mm^3), was hospitalized in March 1977 for increasing anemia with fever and skin rushes. She appeared weak and pale, with petechiae over the arms, legs and abdomen.

A macular rush over the cheeks and left periorbital haematoma were also present. At the admission the blood picture was: HT: 20%, WBC: 10,900/mm^3 with a differential of 10% segmented neutrophils, 2% eosinophils, 0% basophils, 4% lymphocytes, 84% blasts. Platelets counts 120,000/mm^3. Two days later WBC rose to 14,000/mm^3 and platelets were 115,000/mm^3. Bone marrow aspirate was performed and marrow smears showed a differential of 78% blasts, 2% myelocytes, 2% metamyelocytes, 1% bands, 5% segmented neutrophils, 3% lymphocytes, 2% mature plasma cells, 3% basophilic normoblasts, 2% polichromatophilic normoblasts, 2% ortochromatic normoblasts. Cytochemical staining (PAS, peroxidase, naphtolASD-chloro-esterase, alpha-naphtil-esterase, naphtol-ASD-acetate-esterase with and without NAF) demonstrated both in peripheral blood and in bone marrow, blasts with marked positive reactions; a small percentage of these blasts were also blue toluidine positive. The coagulation parameters were: Plasma fibrinogen 0.03 g/ml (n. 0.20–0.40), fibrinogen degradation products (FDP) 84 μg (n. ≷ 8 μg), prothrombin activity 40% (n. 80–100%), plasma prothrombin time (Quick) 21 sec (n. 13–15 sec), plasma coagulation time (Howell) 5 min 05 sec (n. 1 min 30 sec–2 min 15 sec), partial thromoboplastin time (PTT) 55 sec (n. 35–45 sec). These clinical and laboratory findings allowed us to diagnose an acute promyelocytic leukemia with disseminated intravascular coagulation (DIC) [9–11]. Heparine and daunorubicine (40 mg/m^2 i.v.) were given for two days; unfortunately the woman died from massive

Accepted 22 February 1978.

cerebral haemorrhage a few days later. Permission for autopsy was not granted.

In our knowledge this is the first reported case of acute leukemia arisen after long-term adjuvant treatment with L-PAM for primary operable breast cancer. Obviously this case needs to be further confirmed and its incidence compared with the inherent susceptibility to development of leukemia in patients with breast cancer without treatment. Many papers [12–14] have described cases of acute leukemias after long-standing treatment with L-PAM for malignant (myeloma) and not malignant diseases. These leukemias have been variously classified : erithroleukemia, stem cell, myeloblastic, acute lymphatic, myelomonocytic and, in a few cases, promyelocitic leukemia.

From the haematological point of view, this report is interesting for the uncomon cytological type of leukemia induced by L-PAM. Moreover this observation cannot be neglected since it supports the fears of these clinicians [5–8] who have been warning the potential oncogenic risk of adjuvant chemotherapy. Our observation underline at least the importance of statements of Costanza [5] and British Breast Group [7] that chemoprophylaxis should not be considered a "standard procedure" and should not be used "electively in primary operable disease" until the ultimate value and drug related risk will be well known.

Heat Sensitivity of Rat Skin

Y. OKUMURA* and H. S. REINHOLD

Radiobiological Institute T.NO, Rijswijk (ZH) and Dept. of Experimental Radiotherapy, Medical Faculty of the Erasmus University, Rotterdam, The Netherlands

Abstract—*Experiments were conducted to determine the heat sensitivity of normal tissues. The rat skin was selected as a suitable model. After inflation of the rat subcutis with air, anaesthetized animals were placed in a heated water bath with the upper part of this air pouch exposed to the hot water. A total of* 502 *animals were treated with temperatures ranging from* 42 *to* 47°C *and exposure times of from* 12 *to* 240 min. *The intensity of damage was divided into* 6 *grades ranging from "no effect" to "maximum effect". The relationship between the exposure time to heat and the required temperature for isoeffect damage was determined and expressed as* $t = a \times b^T$, *with a value of* 0.51 *for* b(t = *exposure time;* T = *temperatures;* a = *constant). The synergistic effect of heat combined with X-irradiation was also studied. When animals were X-irradiated within* 6 hr *after heat treatment, the synergistic effect was evident, but disappeared after* 24 hr.

INTRODUCTION

INTEREST in the use of hyperthermia for cancer therapy has increased. Hyperthermic treatment has been performed and analysed experimentally as well as clinically and its enhanced effects when combined with irradiation and drugs have also been reported (for review, see [1–3]). Hyperthermia will very likely be applied as one of the methods of cancer treatment if some physical problems can be solved [4].

Damage to normal tissues cannot be neglected when hyperthermia is applied in cancer. Although effects on skin have been reported in the combination of irradiation and hyperthermia [5–7], analyses of the effect of hyperthermia alone are few. In this report, rat skin was selected as a suitable model and was treated hyperthermally with temperatures of from 42 to 47°C and with exposure times of from 12 to 240 min. The hyperthermic effects were analysed quantitatively with the RIDIT system [8]. The synergism of hyperthermia and irradiation effects on rat skin was also investigated.

Accepted 30 December 1977.
*Present address: Dept. of Radiation Biophysics, Atomic Disease institute, Nagasaki University School of Medicine, Sakamoto-machi, Nagasaki 852, Japan.

MATERIALS AND METHODS

Six to eight-week-old WAG/Rij male rats (approx. 120 g) were used in this study. In order to expose only skin, the following method was adopted. Animals were anaesthetized with nembutal injected peritoneally (0.1 ml per animal). The hair on the back was removed by clipping and 30 ml of air was injected subcutaneously at the site to form an air pouch [9]. The air pouch was immersed in heated water. The i.p. injection of nembutal kept the animals anaesthetized for about 1 hr. For prolonged heat treatments, additional i.p. injections with nembutal were usually required. The animals were supported by a lucite "raft", with the air pouches extended into the water through rectangular 30 × 50 mm holes. The temperature of the water was controlled within 0.1°C. After exposure to heat, the air was removed from the pouch. A separate series of experiments were performed in order to measure the temperature of the skin during the treatment by implantation of a thermister (UUA 35J3, Omega Engineering Inc., Conn.).

Irradiation with X-rays was carried out after the hyperthermic treatment. The animals were anaesthetized only during irradiation and the hyperthermic treatment. The intervals between hyperthermia and irradiation ranged from 0 to 72 hr. Irradiation

was performed with a 300 kV Phillips Muller X-ray machine; HVL 3 mm Cu; exposure dose rate about 380 rad per min.

Ten animals were used for each treatment group. A total of 502 animals were treated; 18 of the animals died during the initial phase of the anaesthesia. No animals were lost due to the hyperthermic treatment, as the body temperature remained at 38–39°C. The animals were observed for signs of damage twice weekly by three persons. Clipped hair of non-treated animals was regrown in one week. The hyperthermic damage was manifested during the first week and the maximum amount of damage was observed at the 2nd and 3rd weeks. Slight symptoms of damage were delay of hair growth and epilation of the skin. More severe was induration of the skin and the maximum effect was necrosis. At 4 weeks after the treatment, some recovery from the damage was observed in the group showing slight symptoms. Epilation of the skin was fully recovered at 6 weeks after the treatment, but the recovery from induration of the skin was not observed even at 8 weeks. When animals were treated with a high temperature and a long treatment time, which eventually produced induration of the skin, erythema appeared in one day after the treatment and this changed to dark-brown colored dots which were due to intracutaneous hemorrhage in 1 week. At the same time, edema appeared. This skin showed induration at 2 weeks. Induration of the skin is, therefore, the final step of erythema, haemorrhage and edema. In animals showing the maximal response, i.e. heavy induration and/or breakdown of skin, the entire skin surface involved became a nonviable, brittle scale which sloughed off during the healing process resulting in scar formation. As the maximum symptoms appeared at the 3rd week and did not change appreciably over one week, two sets of observations in this week were used for the analysis. The intensity of damage was divided into 6 grades ranging from "A" (no effect) to "F" (maximum effect) as shown in Table 2.

Table 1. *The values of* a *and* b *in equation* (1)

Grades	a	b
B	3.12×10^{14}	0.51
C	9.52×10^{14}	0.50
D+E	3.51×10^{14}	0.51

RESULTS

Temperature of skin

The temperature of skin was determined after the exposure to water of 44°C; this is shown in Fig. 1. After 5 min, it was 43°C and

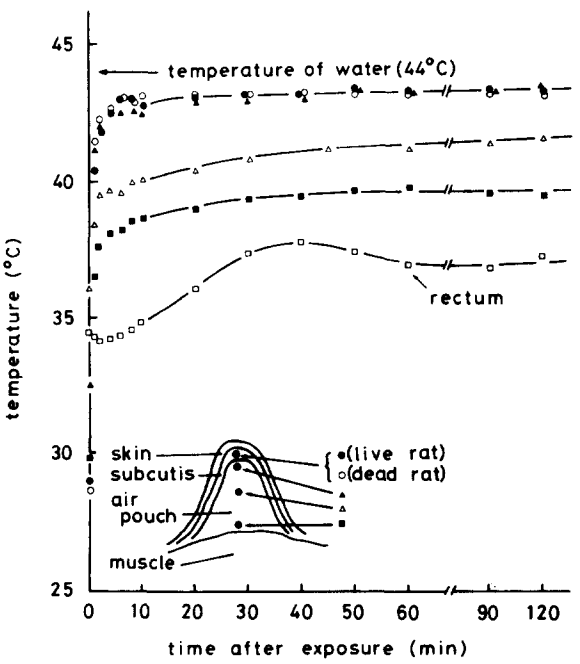

Fig. 1. *Temperature of the skin exposed to water of* 44°C. *The measured points are indicated on the cross-section of the air pouch.*

increased gradually to 43.3°C after 1 hr. As the increase in the temperature of the skin of dead animals showed the same pattern as that of live animals, the difference in temperature between the water and skin was due to the absorption of heat through the air of the pouch rather than blood flow. The temperature of the rectum reached 37°C in 30 min due to the absorption of heat, but the effects of heat on the body might be negligible.

Although the temperature of skin had increased to about 1°C below that of the water in 10 min, the exposure time was indicated from the time at which the air pouch was immersed in water and the temperature of treatment was taken as the temperature of the water in this work.

Relationship between temperature and exposure time

Animals were treated hyperthermally with water bath temperatures of 42–47°C with 1°C intervals and with exposure times of 12–240 min. In 50 observations of animals treated with 42°C for 240 min, 40 were scored as

grade "A", 9 as "B" and 1 as grade "C". The temperature of 42°C never produced damage greater than grade "C", even with the prolonged exposure time of 240 min. Total numbers of scores of the entire experiment were 383 as "A", 175 as "B", 154 as "C", 122 as "D", 109 as "E" and 511 as "F". These data were used for the determination of the relationship between temperature and exposure time for isoeffect. Obviously, the scores of the lower threshold, i.e. grade "A" (no effect) and the upper threshold, score "F" (maximum effect), cannot be used to obtain isoeffect lines. Therefore, only the "B", "C", "D" and "E" scores were used. As the frequencies of occurrence of symptoms of grades "D" and "E" were lower than those of other grades, the grades "D" and "E" were analysed as one grade. The relationship between the temperature and the required exposure time which produced damage of the same degree was obtained for grades "B", "C" and "D+E" and is shown in Fig. 2. The mean and its 95% confidence interval of exposure time producing each damage of grade are shown. The lines were drawn by the least squares method. The following relationship was observed between the temperature (T) and exposure time (t):

$$t = a \times b^{T} \qquad (1)$$

where a and b are constants. The value for a indicates the time in minutes at which the lines are extraporated to the temperature of 0°C and shows the position of the lines. The value for b indicates the slope of the lines. These values are shown in Table 1. The value for b was almost the same for three degrees of damage. The weighted mean value for b was 0.51.

Quantitative analysis of damages

Applying the RIDIT system designed by Bross [8], grades "A" to "F" were quantified according to the frequencies of occurrence of each symptom. In this system, the frequencies were used to derive a cumulative intensity scale from 0 to 1. The degrees of damage which are expressed by RIDIT are shown in Table 2.

The damages occurring hyperthermally are a function of both the temperature and the exposure time. As the treatment was performed with different temperatures and exposure times, all data were normalized to a 60-min exposure time by using the following equation derived from equation (1);

$$T = \frac{\log (60/t_0)}{\log b} + T_0 \qquad (2)$$

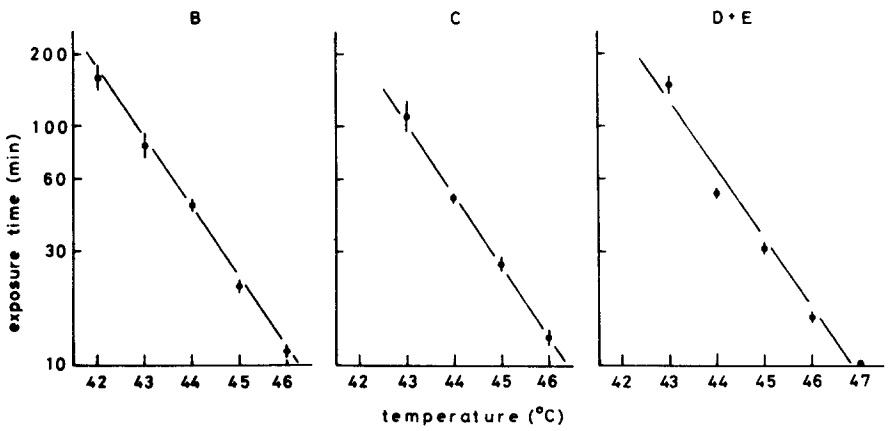

Fig. 2. Isoeffect curves for damage of grades "B", "C" and "D+E". The mean (solid circles) and its 95% confidence interval (vertical bars) of exposure time were calculated from the frequency of each damage at different temperatures.

where T_0 and t_0 are the temperature and exposure time, respectively, of one treatment condition to be normalized; T is an equivalent temperature of the condition for the 60-min exposure time. The results are shown in Fig. 3. The mean and its 90% confidence interval of temperature were obtained by average smoothing. Below 43°C, there was no damage; between 43 and 44°C, reparable damage occurred. When a temperature of more than 44°C was used, irreparable damage was produced.

To confirm the results shown in Fig. 3, additional experiments in which the intervals of temperature were less than 1°C were performed for a constant 60-min exposure. The

Table 2. Rat skin reaction after hyperthermic treatment

Grades	Symptoms	Degrees (RIDIT)
A. No effect	Normal skin	0.1317
B. Minimum effect	Delay of hair growth	0.3235
C. Slight effect	Slight epilation	0.4367
D. Obvious effect	Morderate epilation and/or slight induration	0.5316
E. Intense effect	Severe epilation and/or moderate induration	0.6110
F. Maximum effect	Heavy induration and/or break down of skin	0.8242

results are shown in Fig. 4. The curve in the figure is reproduced from Fig. 3. The experimental data are well fitted to the curve.

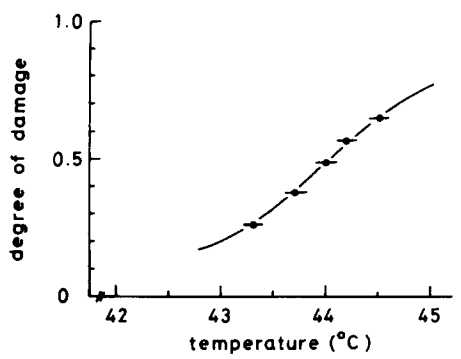

Fig. 3. Relationship of the degree of hyperthermic damage and equivalent temperature for a 60-min *treatment. The values for temperature were normalized to* 60 min *by means of equation* (2) *for all data and the mean and its* 95% *confidence interval of temperature were obtained by average smoothing.*

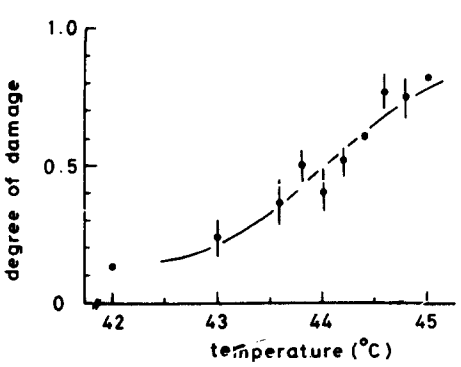

Fig. 4. Relationship of the degree of hyperthermic damage and indicated temperature for a 60-min *treatment time. The curve is from Fig. 3.*

This indicates that the relationship between the temperature and damage shown in Fig. 3 may be applied to any treatment within the range of 42–47°C when converted equivalently from one treatment schedule (T_1, t_1) to another treatment schedule (T_2, t_2) by using the following equations derived from equation (1):

$$T_2=\frac{\log\,(t_2/t_1)}{\log\,b}+T_1 \tag{3}$$

$$t_2=t_1 b^{(T_2-T_1)} \tag{4}$$

Hyperthermia combined with X-irradiation

Skin damage produced by hyperthermia alone or by a combination of hyperthermia and X-irradiation was scored at the 3rd week of treatment. Symptoms of X-irradiation and their RIDIT's are shown in Table 3. Figure 5 shows the degrees of damage produced by X-irradiation alone.

To determine the interval which produced or abolished a synergistic effect, animals were first treated hyperthermally at 44°C for 30 min, which corresponded to the treatment at 43°C for 60 min. This produced damage between grades "A" and "B" (Fig. 3). They were then X-irradiated with 2000 rad at different intervals. X-irradiation alone produced damage between grades "C" and "D" (Fig. 5). As additional hyperthermic treatment of such an exposure enhanced radiation-induced damage (data not shown), the damage produced by the combined treatments was analysed according to the symptoms shown in Table 3. The effect of combined treatment at different intervals is shown in Fig. 6. When X-irradiation was applied immediately after hyperthermic treatment, the maximum effect (moist desquamation of more than half of the treated area; grade "G") was observed. The damage was decreased with an increase in the interval between the treatments. This result agreed well with previous reports on tumor cells *in vivo* [6] and cultured cells [10], where the synergistic effect disappeared when the

interval was more than 8–12 hr. At an interval of 48 hr, the decreased effect was smaller than that induced by X-irradiation alone and thereafter returned to the X-irradiation level.

DISCUSSION

Previous studies on hyperthermic damage to normal tissues have been performed by exposing animal feet to heat and the damage to the skin examined [5, 6]. This system is too complicated for analysis of damage to normal tissues, because damage to the skin of the feet may result from damage of inner tissues as well. The system described in the present work is, in the author's opinion, preferable and more convenient, as it allows the treatment of the skin alone. As the temperature of treated skin was constant at about 1°C below that of water for live as well as dead animals, the diffusion of heat through blood flow must be negligibly small.

As the isoeffect curves were expressed according to equation (1), the hyperthermic dose for isoeffect is in proportion to t/b^T. The resulting value for b of 0.51 indicates that an increase in temperature of 1°C is equivalent to decreasing the exposure time by half and was consistent with values estimated from data of cultured cells and experimental tumors: 0.49 (Chinese hamster cells [11]), 0.53 (pig kidney cells [12]), 0.5 (sarcoma-180 in SWR mice [13]). This value corresponds with results of others [11] who suggested that it may be correlated with the activation energy of protein inactivation [11]; therefore, thermal damage to the skin might be due to inactivation of protein in cells constituting the skin.

The scoring systems for X-ray damage to the skin reported previously [14, 15] were designed to include a sufficient reliable relationship between the dose of X-rays and the degree of damage. The assignment of grades of damage was possible on the basis of long-standing experience in this field. The initial observation in the present experiments indicated that the peak reaction of the skin damage appeared at the 3rd week after the treatment and was of an entirely different aspect than X-ray damage. Therefore, the degree of the damage was quantified according to the frequencies of occurrence of damage for which the RIDIT system was chosen [8]. This system is preferable in situation

where one is faced with an entirely new set of symptoms [16]. In addition, precautions were taken to insure that the stimuli (i.e. the various combinations of exposure times and temperatures which make a "heat dose") were homogeneously distributed.

The mechanism of cell killing by hyperthermia differs from that of ionizing irradiation. For instance, cells which are in S phase or which are hypoxic are generally considered as being radiation-resistant, but sensitive to heat [11, 17–22]. Using both modalities at the same time is therefore of interest. A syngergistic effect on cell killing may indeed be observed when irradiation and hyperthermia are combined. However, the "therapeutic ratio" is not always increased. Robinson *et al.* [5], for instance, reported a therapeutic ratio of 2.1, but Thrall *et al.* [6] found a value of 0.79 under ambient conditions. The present finding that delay of the irradiation for one or two days (Fig. 6) has a slight protective effect on the skin indicates that it might be worthwhile to separate heat treatment and irradiation for some period of time. However, no information is yet available as to what extent this would influence tumor response.

Differences between Vinblastine and Vincristine in Distribution in the Blood of Rats and Binding by Platelets and Malignant Cells*

PETER W. GOUT, LYNDA L. WIJCIK and CHARLES T. BEER†

Department of Biochemistry and Cancer Research Centre, University of British Columbia, Vancouver, British Columbia, Canada, V6T 1W5

Abstract—*Tritium labeled vinblastine (VLB) and vincristine (VCR) were injected i.p. at a subacutely-toxic dose* (0.25 mg/kg) *into rats (Nb strain). In the first few hours the levels of VLB in the blood were substantially higher than those of VCR; subsequently, however, the levels of blood radioactivity in the case of VLB fell much more rapidly than those of VCR, reaching values well below the latter in* 8–10 hr. *There was a correlation between the different blood labeling profiles of the alkaloids and their binding by platelets—the carriers of a major proportion of the circulating alkaloids.*

In vitro, *platelets, cells isolated from alkaloid sensitive rat lymphomas and cultured L5178Y cells, all took up VLB much more rapidly than VCR; when restored to alkaloid free medium the cells readily released VLB but, in contrast, retained VCR tenaciously. In binding to cells, VLB and VCR have similar equilibrium association constants and are apparently bound to common receptors.*

It is suggested the preferential retention of VCR by cells may be an important factor underlying the greater toxicity and oncolytic potency of VCR.

INTRODUCTION

VINBLASTINE (VLB) and vincristine (VCR), cytotoxic alkaloids isolated from the plant *Catharanthus roseus* [1, 2], are used extensively in the treatment of certain types of cancer [3, 4]. The two compounds are very similar in structure (Fig. 1) and apparently also in their primary biological action. Thus the toxicity of VLB and VCR can in many cases be linked to disturbances in intracellular microtubular structures resulting from the binding of the alkaloids to a common target molecule, tubulin, the protein subunits from which microtubules are assembled [5–9]. In view of their structural and biological similarities it is of considerable interest that in their use as anticancer agents VLB and VCR differ markedly in their spectra of oncolytic activity, the dosages which are tolerated and the symptoms of toxicity they elicit. VLB, for example, is one of the more useful drugs for treating Hodgkin's disease but has only minimal effects against acute leukemia; VCR, on the other hand, is a valuable drug in the treatment of acute leukemia, particularly in children, and is also effective against certain lymphomas and neuroblastomas [3, 4]. VCR is substantially more toxic to the host than VLB (e.g. tolerated dose for adults: VCR, 25 μg/kg; VLB, 150 μg/kg). The main dose limiting factor in the use

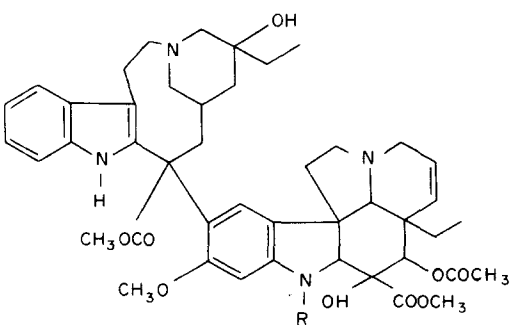

Fig. 1. Vinblastine, R=—CH_3; *vincristine, R*=—CHO.

Accepted 13 March 1978.
*This study was supported by the National Cancer Institute of Canada and the Medical Research Council of Canada.
†Research Associate, Medical Research Council of Canada.

of VCR is neurotoxicity which may be manifested as a severe neuropathy; the dose of VLB on the other hand is usually limited by its toxic effects on the hematopoietic system (e.g. bone marrow depression, leukopenia) [3, 4].

The biochemical and biological evidence presently available does not provide an explanation of the marked differences in the toxic and oncolytic properties of VLB and VCR. The differences may presumably arise from a number of variables, including the delivery of the administered alkaloids to the tissues and cells with which they interact, the alkaloid concentrations to which the tissues and cells are exposed, the transport of the alkaloids across the plasma membrane to intracellular receptors (e.g. tubulin) and the affinity of the receptors for the alkaloids. The identification and quantitation of the pharmacological, cytological and biochemical parameters which mediate the effects of the alkaloids may lead to a better understanding of their mechanisms of action and to an explanation of the differences between them. In the present study we have compared the pharmacokinetics of distribution of VLB and VCR in the peripheral blood of rats and the binding and release of the alkaloids by alkaloid sensitive cells. The cell types used have included blood platelets (which previous studies indicate may play a role in the transport of the alkaloids in the body [10, 11]) and cells isolated from a line of rat lymphomas which in their response to treatment with the alkaloids resemble certain human malignancies [12, 13]. Marked differences have been found between the two alkaloids both in the pharmacokinetics of their distribution in the blood and in their binding and release by cells. It is suggested that the differences in the cell binding properties of the alkaloids may account, at least in part, for some of the differences in their cytotoxic and oncolytic properties.

MATERIALS AND METHODS

Alkaloids

VLB sulfate and VCR sulfate were gifts from Eli Lilly & Co., Indianapolis, Ind., U.S.A.

Preparation of tritiated VLB and VCR

Tritiated VLB ([^{3}H]VLB) was prepared from VLB by proton exchange with tritiotrifluoroacetic acid and purified by procedures already described [11]. Tritiated VCR ([^{3}H]VCR) was prepared from VCR by the same method and purified by successive chromatography on columns of alumina and cellulose phosphate [10, 14]. The radiochemical purity of the tritiated alkaloids, based on co-chromatography with carrier compounds and isotopic dilution analysis, was: [^{3}H]VLB, 97.8%; [^{3}H]VCR, 95.0%. Their specific radioactivities were: [^{3}H]VLB, 1.4×10^9 dis/min/mg; [^{3}H]VCR, 1.6×10^9 dis/min/mg. The biological activity of the tritiated alkaloids, e.g. inhibition of cell replication, metaphase arrest in cultures of L5178Y cells, was the same as that of the corresponding non-radioactive compounds.

Rats

The animals used in this study were Nb strain rats bred in the animal colony of the Cancer Research Centre, University of British Columbia [15]. Male rats, wt 225 ± 25 g, were given i.p. injections of the tritiated alkaloids (0.25 mg/kg) dissolved in 1 ml of 0.9% NaCl solution.

Tumors

Lymphomas of the Node lymphoma No. 2 line were maintained by subcutaneous transplantation in the neck region of Nb strain rats. As reported elsewhere [13, 15] this lymphoma grows rapidly to give well defined masses with minimal necrosis and hemorrhage, and even when far advanced responds well to treatment with either VLB or VCR, regressing rapidly until no longer palpable. On a mg/kg basis VCR is 2–3 times more effective than VLB [13].

Blood sampling and fractionation

Blood was sampled from the tail or heart of the rats [10]. Blood plasma, WBC and RBC fractions were obtained by centrifuging citrated blood for 10 min at 4300 ***g*** in polyethylene tubing and separating the fractions by cutting the tubing with a razor blade as previously described [10, 11].

Preparation of platelet rich plasma

Platelet rich plasma (PRP) was prepared from heart blood of lightly etherized rats by the method of Aster and Jandl [16]. The blood (8 ml) was drawn into a 10 ml plastic syringe containing 1.6 ml of 0.15 M citrate (pH 4.6) as anticoagulant. After mixing, the citrated blood was expelled into a plastic centrifuge tube, allowed to stand

at room temperature for 20 min and then centrifuged for 15 min at 275 ***g***. The supernatant and WBC layer were removed with a siliconized pipette as one fraction which was then centrifuged for 5 min at 400 ***g*** to pack down erythrocytes and leukocytes. The supernatant was removed and used as "platelet rich plasma". The platelet count was $1.0 \pm 0.2 \times 10^6/mm^3$; red cell and leukocyte contamination was very low.

Preparation of cell suspensions from rat lymphomas

Rats bearing rapidly growing transplanted Node lymphomas (1.5–2.5 cm dia) were etherized and the tumors excised. Portions of the tumors, free of necrotic and hemorrhagic areas, were minced with scissors in a mixture of Hanks' balanced salt solution (6 vol) and calf serum (4 vol), buffered at pH 6.8 with citrate (0.015 M). The resulting suspension was filtered through stainless steel gauze to remove pieces of tumor tissue giving a suspension of cells which was usually contaminated with a substantial number of platelets. In view of the high affinity of platelets for VLB and VCR and the errors which might then arise in studying alkaloid-tumor cell binding, it was necessary to reduce platelet contamination to a minimum. This was done by repeated centrifugation (4–5 times) of the cells for 5 min at 300 ***g*** followed by resuspension of the cell pellet in fresh Hanks' salt solution–calf serum mixture. After the final centrifugation the cells were resuspended in Fischer's medium (Hyland, L.A., Calif., U.S.A.) containing calf serum (10%). This procedure gave a suspension of single refractile cells of which over 90% appeared to be viable on the basis of eosin exclusion; when the cell suspension was incubated with VLB at an antimitotic concentration (0.05 μg/ml) a high proportion of the cells accumulated at metaphase, indicating the presence of actively cycling cells.

Binding and release of tritiated alkaloids by platelets and tumor cells in vitro

Platelet rich plasma (*ca.* 10^9 platelets/ml), suspensions of cells isolated from rat lymphomas (*ca.* 15×10^6 cells/ml) and cultures of L5178Y mouse lymphoma cells [17] (*ca.* 5×10^6 cells/ml) were incubated at 37°C with [^{3}H]VLB and [^{3}H]VCR in stoppered siliconized glass vials rotating at 4 rev/min. At intervals throughout the incubation portions (*ca.* 100mg) of the suspensions were withdrawn into 7 cm lengths of polyethylene tubing (i.d. 0.066 in.). The tubes, sealed at one end, were centrifuged (7 min at 4300 ***g***) and the cell pellet separated from the supernatant by cutting the tubing immediately above the pellet [10, 11]. Both pellet and supernatant were radioassayed as described below. The pellet radioactivity was corrected for the small amount of supernatant radioactivity present in the pellet fraction; this correction was less than 5% of the radioactivity present in the supernatant.

When it was necessary to restore platelets to alkaloid free plasma, the suspensions were centrifuged for 20 min at 1700 ***g***, the supernatants carefully removed and the packed cells then gently resuspended in the original volume of alkaloid free, citrated plasma (pH 6.5). The radioactivity in the very small amount of supernatant retained in the pellet accounted for less than 2% of the total radioactivity in the pellet. Platelet losses during the procedure were low (less than 5%). When restoring tumor cells to alkaloid free medium, the cell suspensions were diluted with an equal volume of alkaloid free medium, centrifuged for 5 min at 300 ***g*** and the packed cells resuspended in the original volume of alkaloid free medium. Residual supernatant radioactivity accounted for less than 1% of the pellet radioactvity. Cell losses were small (less than 5%).

Radioassay methods

For the radioassay of blood, blood fractions, platelets, cells and supernatants, samples (up to 100 mg) were incubated in scintillation vials with 0.5 ml of 1N NaOH at 37°C for 24 hr and then if necessary decolorized with hydrogen peroxide [10]. Ten millilitres of PCS solubilizer (Amersham/Searle, Illinois, U.S.A.) containing 4% glacial acetic acid were then added to the vials and the radioactivity determined by liquid scintillation counting. Duplicate samples were counted to an accuracy of ±3% at the 95% confidence level and corrected for quenching.

The percentage of the radioactivity in a sample which was due to [^{3}H]VLB or [^{3}H]VCR was determined by isotopic dilution analysis as follows. A known amount of the sample was homogenized at pH 2–3 with a large known excess of purified carrier VLB or VCR. After removing small aliquots for assaying the total radioactivity in the sample, the alkaloid in the rest of the homogenate was extracted into benzene at pH 7 and then purified chromatographically using at least 3 systems. The latter

included elution from columns of alumina, cellulose phosphate or carboxymethyl cellulose using procedures already described [10. 11. 14] and also thin layer chromatography on alumina (Eastman Kodak No. 6063) run with acetone or ethylacetate/*iso*amyl alcohol (10:1) and on silica gel (Eastman Kodak No. 6060) run with acetone or ethylacetate/ethanol (1:1). In running the columns, multiple fractions were collected during the period when the carrier was leaving the column in order to verify that the radioactivity elution profile accurately matched that of the optical density [14]. The specific radioactivity of the recovered carrier alkaloid was determined from its radioactivity and u.v. absorption, and used to calculate the percentage of radioactivity in the original sample which was due to [^{3}H]VLB or [^{3}H]VCR.

RESULTS

Radioactivity in blood and blood fractions of rats given [^{3}H]*VLB and* [^{3}H]*VCR*

The levels and distribution of radioactivity in the peripheral blood of rats given single i.p. injections of [^{3}H]VLB and [^{3}H]VCR at a nonacutely-toxic dose (0.25 mg/kg) are shown in Fig. 2. The whole blood radioactivity profiles of the 2 alkaloids (Fig. 2A) have certain features in common. For example, in both cases the radioactivity appeared in the blood almost immediately after the injection, rose sharply to a peak value and then declined rapidly to much lower values. However, marked differences were also found: while the levels of radioactivity in the blood of rats given [^{3}H]VLB were initially substantially higher than those in the blood of rats given [^{3}H]VCR, in the case of VLB they fell much more extensively and after 8 hr were well below those in the blood of rats given [^{3}H]VCR.

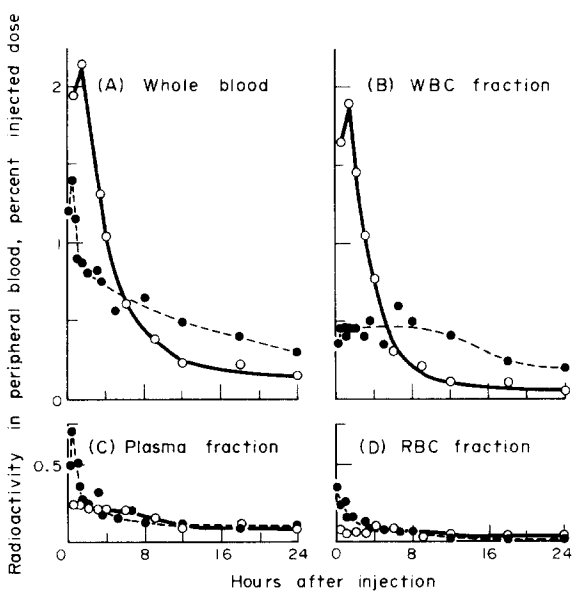

Fig. 2. Distribution of radioactivity in peripheral blood of rats given i.p. injections of [^{3}H]*VLB* (0.25 mg/kg; 3.5 × 10^8 dis/min/kg) *and* [^{3}H]*VCR* (0.25 mg/kg; 4.0 × 10^8 dis/min/kg). *Plasma, WBC and RBC fraction were obtained by centrifuging citrated tail blood samples at* 4300 *g* ("*Methods*"). *Radioactivity in whole blood* (*A*), *WBC fraction* (*B*), *plasma fraction* (*C*) *and RBC fraction* (*D*) *is expressed as percent of injected radioactivity, taking blood weight as* 7.5% *of body weight.* [^{3}H]*VLB*, ○——○, [^{3}H]*VCR*, ●--●. *Points are averages of results from at least* 3 *rats.*

A comparison of the labeling of the WBC fraction (Fig. 2B) shows that in the first few hours after the injection of [^{3}H]*VLB* this fraction was much more highly labeled than after the injection of [^{3}H]VCR. However, as time progressed this situation was reversed; in rats injected with [^{3}H]VLB the WBC radioactivity decreased sharply from its initial peak value, whereas in rats given [^{3}H]VCR the WBC radioactivity remained essentially constant for about 12 hr and thereafter declined only slowly. The labeling of the plasma fraction (Fig. 2C) was very similar for the 2 alkaloids except for a period of about 1 hr immediately after the injection. In this period the plasma radioactivity levels in the rats given [^{3}H]VCR were substantially higher than in those given [^{3}H]VLB. The levels of radioactivity in the RBC fraction (Fig. 2D) were very low except for a short period immmediately following the injection of [^{3}H]VCR; the temporary higher levels of [^{3}H]VCR radioactivity in this fraction are probably due to small amounts of entrapped plasma.

It can be seen from Fig. 2 that the WBC and plasma fractions together account for most of the radioactivity in the blood after the administration of either VLB or VCR. In the first 8–10 hr after injecting [^{3}H]VLB most of the circulating radioactivity was present in the WBC fraction. With VCR on the other hand, a substantial proportion of the circulating radioactivity was also present in the plasma, especially in the first few hours, but as time progressed most of the radioactivity was confined to the WBC fraction. It appears from the results that the differences betwen VLB and VCR in the labeling of the peripheral blood can to a major extent be accounted for by the labeling patterns of the WBC fraction.

It was shown by isotopic dilution analysis

("Methods") that, even 24 hr after the injection of [^{3}H]VCR, over 90% of the radioactivity in the WBC fraction was due to the unchanged alkaloid and furthermore using blood cell preparation methods [10], that as least 60% of the alkaloid in this fraction was associated with platelets. It appears therefore that platelets are the main cellular carriers of VCR in the peripheral blood of rats. We have already shown in a previous study [10] that in the peripheral blood, platelets are also the main cellular carriers of VLB.

Binding and release of [^{3}H]*VLB and* [^{3}H]*VCR by blood platelets* in vitro

Platelet rich plasma was incubated at 37°C with [^{3}H]VLB and [^{3}H]VCR at various concentrations. The binding of the alkaloids by platelets at 2 alkaloid concentrations is shown in Fig. 3. Very similar results were obtained at alkaloid concentrations up to 2 μg/ml. The lower concentration in Fig. 3 (0.05 μg/ml) is of the same order as that found in the plasma of rats given subacutely-toxic doses of VLB [13]. As found in a previous study [11], [^{3}H]VLB was rapidly taken up by platelets and in about 1 hr the amount of platelet bound alkaloid had reached a plateau. [^{3}H]VCR was bound by platelets at a much lower rate than VLB but eventually (after 8–10 hr) reached the same plateau as VLB at a given concentration. When the plateaus were reached, a substantial portion of the total alkaloid present had been taken up by the platelets, e.g. *ca.* 70 and 50% at alkaloid concentrations of 0.05 and 0.44 μg/ml, respectively. This demonstrates the marked ability of the platelets to concentrate the alkaloids from the plasma.

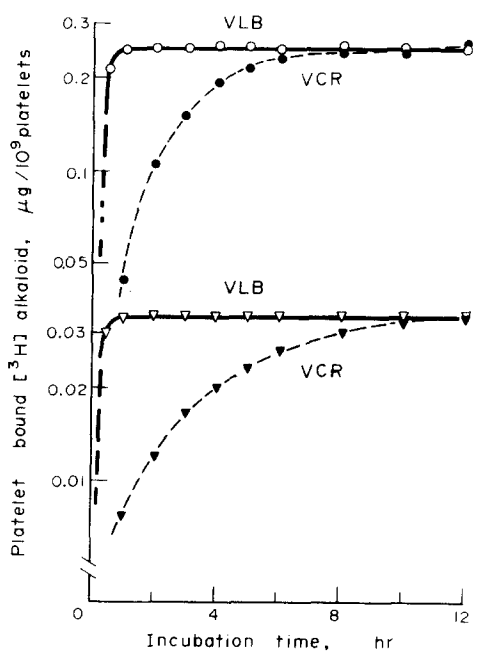

Fig. 3. Binding of [^{3}H]*VLB and* [^{3}H]*VCR by platelets* in vitro. *Aliquots of PRP containing* ca. 10^9 *platelets*/ml *were incubated at* 37°C *with* [^{3}H]*VLB* (0.44 μg/ml. ○——○; 0.05 μg/ml, ▽——▽) *and* [^{3}H]*VCR* (0.44 μg/ml. ●--●; 0.05 μg/ml, ▼--▼). *The amount of platelet bound alkaloid was determined at the times shown on centrifuged samples* ("*Methods*").

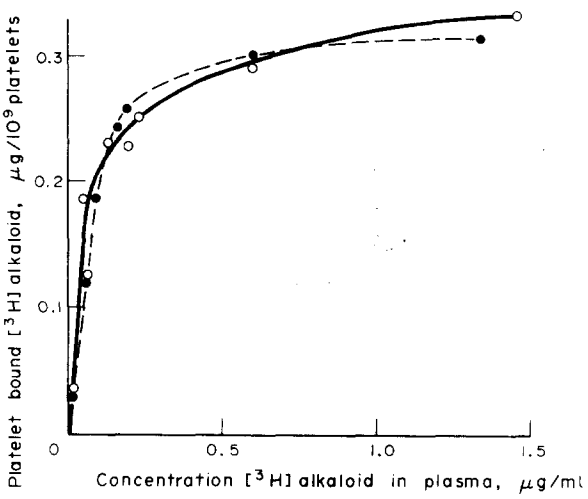

Fig. 4. Plots of amounts of [^{3}H]*VLB and* [^{3}H]*VCR bound at equilibrium by platelets vs concentrations of unbound alkaloid in the plasma. Aliquots of PRP* (*containing* 10^9 *platelets*/ml) *were incubated with the tritiated alkaloids at various concentrations. The amounts of platelet bound alkaloid and the alkaloid concentrations in the plasma were determined at intervals* ("*Methods*") *until equilibrium was established* (*usually within* 2 hr *for VLB and* 8–10 hr *for VCR; see Fig.* 3). *VLB*, ○——○; *VCR*, ●--●.

In Fig. 4 the amounts of alkaloid bound by platelets when a plateau had been reached (*ca.* 2 hr for VLB, 8–10 hr for VCR) are plotted against the concentrations of unbound alkaloid in the plasma. It can be seen that at the higher alkaloid concentrations the platelets became saturated with the alkaloids and also that over the entire concentration range the curves for VLB and VCR are essentially identical. Since the platelets bound equal amounts of VLB and VCR at saturation, it appears that the same number of binding sites are available for each alkaloid. Furthermore the close similarity in the curves indicates that the equilibrium association constants of the 2 alkaloids for the platelets are very similar.

When platelets which had taken up VLB and VCR were restored to alkaloid free plasma, there was a considerable difference in the ease with which the 2 compounds were released (Fig. 5). Platelets labeled with

[^{3}H]VLB readily released the alkaloid until equilibrium was once more established between the VLB bound by the platelets and that in the plasma (Fig. 5, upper panel). When resuspended for a second time in alkaloid free plasma, the platelets released

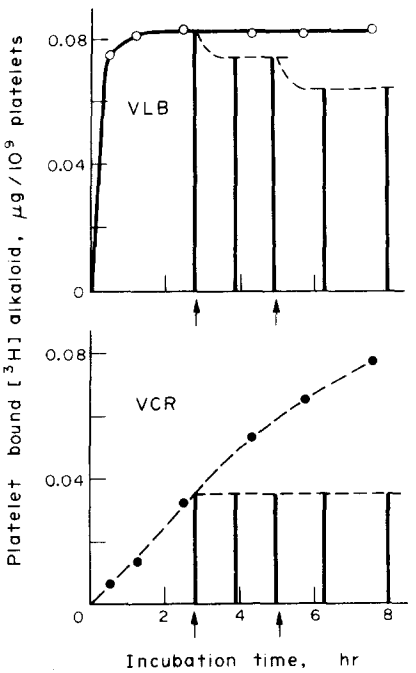

Fig. 5. Retention of [^{3}H]*VLB and* [^{3}H]*VCR by platelets on restoration to alkaloid free plasma. Aliquots of PRP were incubated at* 37°C *with* [^{3}H]*VLB* (0.11 μg/ml) *and* [^{3}H]*VCR* (0.11 μg/ml). *At intervals, samples were taken from the two suspensions for determination of the amounts of platelet associated alkaloid ("Methods"): VLB,* ○——○; *VCR,* ●--●. *After* ca. 3 hr (*1st arrow*) *platelets from a portion of each suspension were restored to alkaloid free plasma ("Methods") and the radioactivity retained by these platelets on further incubation was determined at* 2 *intervals (vertical bars,* hr 4 *and* 5). *At the time indicated by the 2nd arrow the platelets were once more resuspended in alkaloid free plasma and, after further incubation, again assayed for platelet associated alkaloid (vertical bars,* hr 6 *and* 8). *Platelet losses as a result of the manipulations were small (less than* 5%); *the results have been normalized for* 10^9 *platelets.*

a further amount of VLB, again establishing an equilibrium between bound and free alkaloid. The results indicate that the binding of [^{3}H]VLB by platelets is readily reversible, confirming conclusions reached in a previous study [11]. In contrast, platelets which had been labeled with [^{3}H]VCR released very little of the bound alkaloid when restored to alkaloid free plasma; even after a second resuspension in alkaloid free plasma and prolonged incubation the platelets retained essentially all the VCR initially bound (Fig. 5, lower panel).

Labeling of the WBC fraction in rats given i.v. injections of platelets prelabeled with [^{3}H]*VLB and* [^{3}H]*VCR*

The finding that platelets are the main cellular carriers of VLB and VCR in the peripheral blood of rats suggested that the differences in the labeling patterns of the WBC fractions in rats given the tritiated alkaloids (Fig. 2B) might be related to the differences in the alkaloid binding properties of platelets as found in the *in vitro* studies (Figs. 3 and 5). One aspect of this suggestion was investigated by giving rats intravenous injections of platelets which had been prelabeled *in vitro* with [^{3}H]VLB or [^{3}H]VCR and then determining the levels of radioactivity in the blood and its distribution among the blood fractions for 1–2 days. During this period essentially all the blood radioactivity was found to be concentrated in the platelet containing WBC fraction; the amounts of radioactivity in the plasma and RBC fraction were negligible. Figure 6 shows the percentage of injected radioactivity present in the WBC fraction of the rats, calculated on the basis that blood volume is 7.5% of body weight. In the first few min after the injection of platelets labeled with [^{3}H]VLB or [^{3}H]VCR, most of the injected radioactivity was in each case found to be present in the WBC fraction. Since the platelets were injected into the jugular vein and the blood was

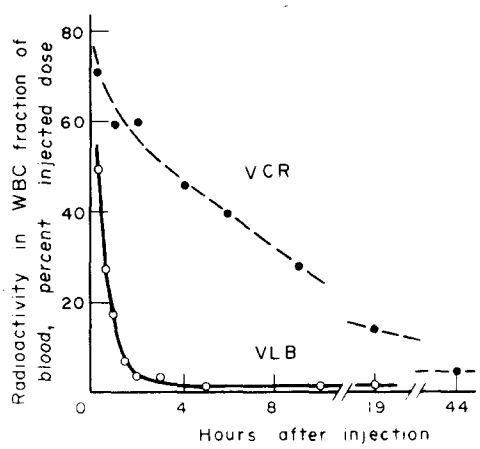

Fig. 6. Radioactivity of WBC fraction of peripheral blood of rats given i.v. injections of platelets prelabeled with [^{3}H]*VLB and* [^{3}H]*VCR. Platelets were prelabeled by incubating PRP at* 37°C *for* 3 hr *with* [^{3}H]*VLB* (0.3 μg/ml) *and* [^{3}H]*VCR* (0.9 μg/ml), *collected by centrifugation and resuspended in small volumes of alkaloid free plasma. Platelets* (ca. 3×10^9) *labeled with* [^{3}H]*VLB* (0.47 μg) *and* [^{3}H]*VCR* (0.48 μg) *were injected into the jugular vein of rats. The radioactivity in the WBC fraction of the total blood of the rats (calculated on the basis that blood weight is* 7.5% *of the body weight) is given as a percentage of injected radioactivity (means of* 2 *determinations). VLB,* ○——○; *VCR,* ●--●.

sampled from the tail, it appears that the platelets had been rapidly dispersed in the circulation. The rates at which the levels of WBC radioactivity (and hence also the levels of radioactivity in the blood) declined from their initial high values were markedly different for the 2 alkaloids. Thus after the injection of [^{3}H]VLB labeled platelets the WBC radioactivity declined very rapidly and within 2 hr only a few per cent of the injected radioactivity remained in the blood; in contrast, the levels of radioactivity in the WBC fraction after the injection of [^{3}H]VCR labeled platelets declined much more slowly and even after 10 hr over 25% of the injected radioactivity was still present in the circulation. It may be noted that the decline in the radioactivity of the WBC fractions will reflect not only the rates at which the [^{3}H]alkaloids are released from the platelets but also the loss of alkaloid labeled platelets from the circulation, e.g. as a result both of normal platelet turnover and the exchange of platelets in the circulation with those elsewhere in the body. On the assumption that the rate of platelet loss from the peripheral blood is the same for platelets labeled with [^{3}H]VLB as for platelets labeled with [^{3}H]VCR, it seems very probable that the difference between the 2 alkaloids in the decline of the WBC radioactivity (Fig. 6) is due largely to a ready release of VLB and a contrasting tenacious retention of VCR by platelets *in vivo*.

Binding and release of [^{3}H]*VLB and* [^{3}H]*VCR by tumor cells* in vitro

The binding and release of [^{3}H]VLB and [^{3}H]VCR by tumor cells *in vitro* was studied using suspensions of cells isolated from rat Node lymphomas and suspensions of cultured L5178Y mouse lymphoma cells. Figure 7 shows the labeling of the cells isolated from rat lymphomas when incubated with [^{3}H]VLB and [^{3}H]VCR at two concentrations, the lower of which (0.05 μg/ml) is in the range of that found in the plasma of rats given a therapeutically effective dose of VLB [13]. Both alkaloids were taken up by the cells from the medium at rates which for each alkaloid were proportional to its concentration. At a given alkaloid concentration, VLB was bound by the cells much more quickly than VCR. Thus, whereas the amount of [^{3}H]VLB bound by the cells reached a plateau in *ca.* 50 min, at least 5 hr elapsed before the amount of VCR bound approached a plateau. The

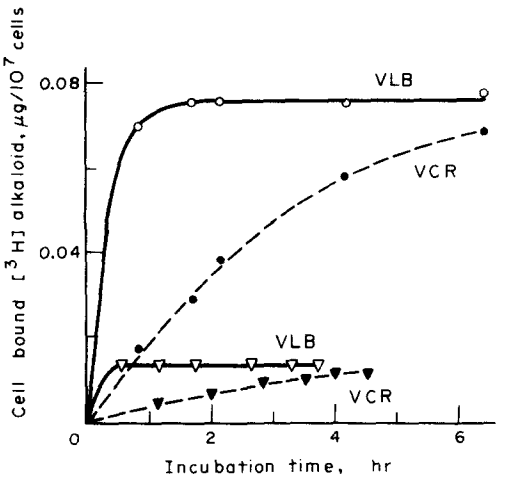

Fig. 7. Binding in vitro *of* [^{3}H]*VLB and* [^{3}H]*VCR by cells isolated from rat lymphomas. Aliquots of cell suspensions prepared from rat lymphomas* (ca. 15×10^6 *cells*/ml: "*Methods*") *were incubated at* 37°C *with* [^{3}H]*VLB* (0.46 μg/ml, ○——○; 0.05 μg/ml, ▽——▽ *and* [^{3}H]*VCR* (0.46 μg/ml, ●--●; 0.05 μg/ml, ▼--▼). *The amount of cell bound alkaloid was determined at the times shown on centrifugated samples* ("*Methods*").

amount of VCR eventually bound, however, quite closely approximated the amount of VLB bound at the same concentration. Isotopic dilution analysis showed that the cell associated radioactivity was due almost entirely to the unchanged alkaloids, e.g. after 5 hr incubation with the alkaloids, 85 and 95% of the cell bound radioactivity was due to [^{3}H]VLB and [^{3}H]VCR, respectively.

When isolated lymphoma cells, which had been prelabeled by incubation with [^{3}H]VLB and [^{3}H]VCR, were restored to alkaloid free medium and further incubated, they released the two alkaloids at markedly different rates. The results of a typical experiment are shown in Fig. 8. The cells which had been prelabeled with [^{3}H]VLB released a substantial amount of the cell bound alkaloid each time they were reincubated in fresh alkaloid free medium and after 6 such treatments the cells retained only 5% of the alkaloid initially taken up. In contrast, the cells prelabeled with [^{3}H]VCR released very little radioactivity after each reincubation in alkaloid free medium and even after 6 medium changes the cells retained over 75% of the [^{3}H]VCR originally bound. Figure 8 also shows that even if cells have initially taken up much more VLB than VCR, on lowering the extracellular alkaloid concentration VLB is released so readily that eventually the amount of VCR retained by the cells can greatly

exceed that of VLB. For example, although on incubation for 100 min with the [^{3}H]alkaloids, the tumor cells took up only one-third as much VCR as VLB, after 6 reincubations in alkaloid free medium they retained 6 times as much VCR as VLB.

Cultured L5178Y mouse lymphoma cells behaved very similarly to the cells isolated from the rat lymphomas with respect to the uptake and release of the tritiated alkaloids, i.e. [^{3}H]VLB was taken up quickly and readily released; [^{3}H]VCR was taken up slowly and released very slowly (data not included).

DISCUSSION

The present study has shown that VLB and VCR differ markedly both in the pharmacokinetics of their distribution in the peripheral blood of rats and in their binding by cells. The differences between the alkaloids in their uptake and release by cells seem to be particularly important since they appear to provide explanations not only of the differences in the pharmacokinetic distribution of the alkaloids, but also of some of the differences in the toxic and oncolytic properties of the alkaloids.

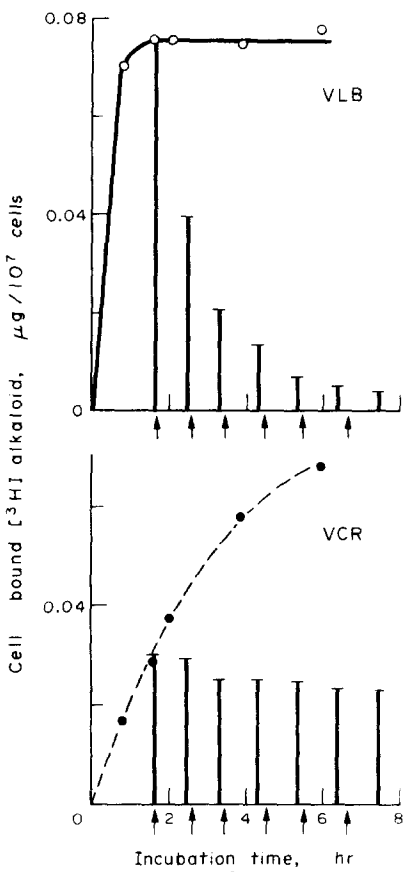

Fig. 8. Retention of [^{3}H]VLB and [^{3}H]VCR by isolated rat lymphoma cells on restoration to alkaloid free medium. Aliquots of cell suspensions prepared from rat lymphomas ("Methods") were incubated at 37°C with [^{3}H]VLB (0.46 μg/ml) and [^{3}H]VCR (0.46 μg/ml). The amounts of cell bound alkaloid were determined at intervals up to 6 hr (VLB, O——O; VCR, ●--●). After labeling the cells for 100 min a portion of each suspension was taken for determining the amounts of alkaloid retained by the cells when restored to alkaloid free medium ("Methods"). At each of the times indicated by the arrows the cells were resuspended in alkaloid free medium and incubation continued; the vertical bars indicate the amounts of alkaloid retained by the cells 50 min after each resuspension. The total loss in cell numbers resulting from the multiple resuspensions was less than 10%; the results have been normalized for 10^7 cells.

The marked differences observed in the pharmacokinetic distribution of VLB and VCR in the peripheral blood of rats (Fig. 2) can be correlated with differences in the alkaloid binding properties of blood platelets which, as shown in this and a previous study [10], are the main cellular carriers of VLB and VCR in the peripheral blood. It seems very likely, for example, that the high concentrations of VLB which are found almost immediately in the WBC fraction (Fig. 2B) and the comparatively low labeling of the plasma by [^{3}H]VLB (Fig. 2C) reflect the high rate at which platelets are able to concentrate VLB from the plasma, as found *in vitro* (Fig. 3). Furthermore, the higher levels of VCR initially found in the plasma and the relatively lower amounts of VCR in the WBC fraction are consistent with the lower rate at which platelets take up VCR as compared to VLB (Fig. 3). The rapid decline in the levels of VLB in the WBC fraction and the contrasting sustained levels of VCR in this fraction (Fig. 2B) can likewise be explained by the ease with which platelets release VLB and the tenacity with which they retain VCR, as found on restoration of labeled platelets to alkaloid free plasma *in vitro* (Fig. 5) and also *in vivo*, when platelets labeled with VLB and VCR were injected intravenously into rats (Fig. 6).

The marked differences between VLB and VCR in their rates of uptake and release by cells were found not only with blood platelets but also with cells isolated from rat lymphomas and cultured L5178Y mouse lymphoma cells. Thus all the cells took up VLB much more quickly than VCR (Figs. 3 and 7) and on restoration to alkaloid free medium readily released VLB but tenaciously retained VCR (Figs. 5 and 8). In view of the similarity in the alkaloid binding properties of cells of such diverse types as platelets (with no nucleus and comparatively simple metabolism) and replicating tumor cells, it seems likely that the mechanisms involved in the binding of the

alkaloids by cells—including their ability to differentiate between the 2 alkaloids—are common to a variety of cell types.

The use of platelets as comparatively simple models for studying the interaction of Vinca alkaloids with their cellular receptors has been indicated by a previous study [11] in which it was shown that in binding [^{3}H]VLB, platelets behave as if they have saturable receptors with a high affinity for the alkaloid; the displacement of platelet bound [^{3}H]VLB by non-radioactive VCR could tentatively be explained by a kinetic model in which VCR competed for the same binding sites as VLB but at a much lower rate. The present study, in which [^{3}H]VCR as well as [^{3}H]VLB has been used, provides strong support for this model. Thus it shows that even though, at a given alkaloid concentration, platelets may eventually take up as much VCR as VLB, they bind VCR at a much lower rate than VLB (Fig. 3). The finding that at saturation platelets bind equal amounts of each alkaloid, together with our previous observation that [^{3}H]VLB is displaced by VCR [11], strongly suggests that in platelets the 2 alkaloids do in fact have the same binding sites. In this connection it may be noted that Bleyer *et al.* [18] have concluded on the basis of competition studies that VLB and VCR have common binding sites in L1210 leukemia cells. It also appears that while VLB and VCR differ markedly in the rates at which they are taken up by platelets, they nevertheless have similar equilibrium association constants for platelets as indicated by the results in Figs. 3 and 4. VLB and VCR appear also to have very similar equilibrium association constants for cells isolated from rat lymphomas and for L5178Y cells, since, at a given alkaloid concentration, the cells eventually take up about the same amounts of each alkaloid (Fig. 7). It is of considerable interest that VLB and VCR should differ so markedly in their rates of uptake and release by platelets and tumor cells even though they have similar equilibrium association constants for the cells and apparently common receptors.

There is substantial evidence from other work that a major receptor for the biologically active Vinca alkaloids, including VLB and VCR, is "tubulin"—the protein subunits of cellular microtubules [5–7]. Although in the present study the specific nature of the cellular alkaloid receptors has not been investigated, it may be noted that exposure of the cells to the alkaloids resulted in pronounced disturbances in microtubular structures—indicative of tubulin–alkaloid interaction—i.e. disruption of the mitotic spindle in the tumor cells and of the circumferential bundle of microtubules in the platelets [10, 19]. The binding of VLB and VCR to isolated tubulin in certain respects resembles their binding to intact cells, e.g. both alkaloids have a high affinity for tubulin with association constants that are of the same order [20, 21] and they also appear to compete for the same binding sites on the tubulin [22, 23]. In spite of these similarities, however, the intact cells and tubulin differ markedly in the rates at which they bind VLB and VCR. Thus whereas VCR is bound much more slowly than VLB by platelets and tumor cells (Figs. 3 and 7), both alkaloids have been reported to bind rapidly to isolated tubulin, reaching equilibrium after only a few minutes incubation, at which point equal amounts of the compounds were bound [20]. This suggests that if the alkaloid binding properties of tubulin in intact cells are the same as *in vitro*, then the different rates at which VLB and VCR are taken up by cells are not determined primarily by differences in their binding to tubulin but are due instead to a rate controlling process which differentiates between the 2 alkaloids and which is not directly related to the interaction of the alkaloids with tubulin. It is tempting to speculate that the difference between VLB and VCR in their uptake (and possibly their release) by cells may stem from differences in the rates at which they are transported across the plasma membrane.

The pharmacokinetic distribution of VLB and VCR in the blood and the binding of the alkaloids by cells are, almost certainly, important variables mediating the toxic and oncolytic effects of these compounds. This raises the question of the extent to which *differences* in the latter are related to differences in the levels and distribution of VLB and VCR in the peripheral blood (Fig. 2). Although the levels of VCR in the plasma were for a short period substantially higher than those of VLB (Fig. 2C), it appears unlikely that during this period cells will accumulate even as much VCR as VLB in view of the lower rate at which they take up VCR. It is doubtful therefore if the transient higher levels of

VCR in the plasma account to a major extent for the greater toxicity and oncolytic potency of VCR. Regarding the transport of the alkaloids in the WBC fraction, it is possible that in the case of VLB the platelets may, as suggested elsewhere [11], play a role in the delivery of this alkaloid to tissues, in view of the readiness with which they take up and release VLB. On the other hand it is rather doubtful if platelets play a significant role in the delivery of VCR, in view of the tenacity with which they retain VCR. While the overall effect of the differences in the transport of VLB and VCR in the blood is not entirely clear, they do not appear to provide an adequate explanation of the differences in the toxic and oncolytic properties of the 2 alkaloids.

While, as indicated above, there is substantial evidence that the biological effects of VLB and VCR stem primarily from their binding to tubulin [5–9], the relatively minor differences in the interaction of the alkaloids with tubulin do not appear to account for the marked differences in the toxic and oncolytic properties of the compounds. In fact, Himes *et al.* [24] have suggested that the latter are likely to be determined by processes other than the interaction of VLB and VCR with tubulin *per se*, since the alkaloids not only have very similar tubulin binding properties but are also equally effective in inhibiting the polymerization of tubulin *in vitro*. From results in the present study it seems likely that at least a partial explanation of the greater toxicity and oncolytic potency of VCR may lie in the markedly greater tenacity with which cells retain VCR. Thus even though cells, on exposure to the alkaloids, may accumulate less VCR than VLB (e.g. as a result of the lower rate at which VCR is taken up), they will, in the face of falling extracellular alkaloid levels, retain VCR much longer and eventually in greater amounts than VLB (Fig. 8). It may be anticipated that when sensitive cells are exposed to the alkaloids for short periods, as may occur *in vivo*, VCR, as a result of its retention by cells, will continue to exert its toxic effects long after its extracellular levels have fallen to insignificant values; the effects of VLB on the other hand are likely to be less persistent in view of the readiness with which this alkaloid is released by cells when the extracellular alkaloid levels decline (Fig. 8). The differential in the retention of VLB and VCR by cells may assume special significance when asynchronously replicating cells are exposed to the alkaloids. Replicating cells are particularly sensitive to the alkaloids at mitosis and if briefly exposed to the compounds at less sensitive phases of the cell cycle, may retain much more VCR than VLB by the time they reach mitosis. VCR may also, in view of its more sustained retention by cells, have a more adverse effect than VLB on the recovery of cells from microtubular damage, perhaps accounting for its greater neurotoxicity.

In view of the readiness with which VLB is released by cells it may be expected that its toxic effects will be more dependent than those of VCR on the maintenance of elevated alkaloid levels in the immediate environment of cells. In this connection it is of interest that whereas, *in vitro*, cells isolated from rat lymphomas readily release VLB (Fig. 8), nevertheless in the animal the lymphoma has been found to retain the alkaloid long after the levels of VLB in the circulation had fallen to very low levels; it was suggested that the continuing presence of VLB in the tumor might be an important factor underlying the high sensitivity of the lymphoma to treatment with the alkaloid [13]. The mechanism of retention of VLB by the lymphoma *in vivo* is not yet known but may be related to the lymphoid character of the tumor tissue [13]. The difference in the retention of VLB *in vitro* by isolated cells and *in vivo* by the lymphoma raises the possibility that there may be more than one mechanism for maintaining elevated alkaloid levels in "target" tissues, e.g. retention by cells *per se* as found for VCR, and retention by virtue of some special property of the tissue as suggested for VLB in the lymphoma. The existence of alternative mechanisms could help to explain why VLB has a more limited spectrum of oncolytic activity than VCR, and why, for example, it is useful in the treatment of certain lymphomas (e.g. Hodgkin's disease, Nb strain rat lymphomas) but is much less effective than VCR in treating leukemias. Further studies on the mechanism of action of the Vinca alkaloids both at the cellular level and *in vivo* are clearly required.

Rapid Remission Induction in Adult Acute Non-Lymphoblastic Leukaemia*

D. DUBOVSKY, L. KERNOFF and P. JACOBS

The University of Cape Town Leukaemia Centre, Department of Haematology, Groote Schuur Hospital, Observatory, Cape 7925, *Republic of South Africa*

Abstract—*Nineteen out of* 40 *adults with acute non-lymphoblastic leukaemia attained complete remission. All these individuals had a neutrophil count greater than* 1 $\times 10^9$/1 *and a platelet count above* 100×9/1 *within an average of* 16 *days of completing a single* 5-day *course of cytotoxic chemotherapy comprising the epipodophyllotoxin VP*16–213, *cytosine arabinoside and adriamycin. This induction regimen offers an advantage where patients with acute leukaemia have to be treated in general medical wards without protected environments since the short neutropenic period permits early resolution of infection which remains the commonest cause of death during induction.*

INTRODUCTION

THE TREATMENT of acute non-lymphoblastic leukaemia has improved following the introduction of the drugs cytosine arabinoside and daunorubicin or its analogue adriamycin [1]. Although schedules for the administration of these agents vary they are given to achieve bone marrow aplasia which is generally accepted as a prerequisite for the regeneration of normal haematopoietic tissue and therefore complete remission [2]. During this aplastic period the patient is at risk of dying from haemorrhage and infection [3] and some workers, unable to justify this, have advocated using lower doses of antileukaemic drugs. However, such an approach has had an adverse effect on patient survival [4]. In specialised treatment centres aggressive induction regimens are administered to patients housed in reverse-barrier environments [5] and neutrophils [6] and platelet [7] transfusions are readily available. Such comprehensive supportive therapy is the major factor in determining patient recovery from the aplastic phase [5] but, unfortunately, these facilities are costly and not universally available.

In those hospitals where the physician is treating patients with acute leukaemia without the benefit of such specialised facilities a short pancytopenic period may be of advantage by limiting the interval during which they are at risk of dying from infection and haemorrhage. In this context we report our remission induction results obtained in 40 adults treated in a general hospital environment with a combination of the epipodophyllotoxin VP16–213, cytosine arabinoside and adriamycin.

MATERIALS AND METHODS

Forty consecutive previously untreated adults with acute non-lymphoblastic leukaemia were studied between January 1975 and July 1977 (Table 1). Variants such as smouldering leukaemia and blastic transformation of chronic granulocytic leukaemia were not included and no patient was excluded once treatment had commenced. Patients were treated in general medical wards and all received oral allopurinol, kanamycin and nystatin and were given frequent 0.2% Hibitane mouth washes. Pyrexia was, in the absence of a readily identifiable cause such as a recent transfusion, presumed to be due to infection and was treated with a combination of gentamycin, cephalothin and carbenicillin. Granulocytes obtained by filtration leucapheresis were

transfused if the temperature failed to respond to the antibiotics within 48 hr provided that the patient had an absolute neutrophil count less than $0.5 \times 10^9/l$. Platelets obtained by discontinuous centrifugation were transfused for active bleeding. The cytotoxic chemotherapy consisted of a combination of cytosine arabinoside (100 mg/m^2/day) for 5 days by continuous intravenous infusion, VP16–213 (60 mg/m^2/day) for the same 5 days by intravenous infusion over a 30-min period and adriamycin (40 mg/m^2) on day 6. Bone marrow aspiration and trephine biopsy were performed routinely 10 days after completing the course of treatment. If residual leukaemia was apparent in the marrow a second induction course was commenced using the same drug regimen. Patients shown to be aplastic received no further treatment until the bone marrow had regenerated and peripheral blood counts returned towards normal.

RESULTS

Twenty-eight of the 40 patients developed aplasia following a single course of therapy. Out of these 19 regenerated to complete remission (Group 1) and the other 9 died before regeneration had occurred (Group 2a). Of the remaining 12 patients, 5 had disease refractory to chemotherapy (Group 2b) and 7 died before the 10-day marrow examination and therefore could not be evaluated (Group 2c).

Group 1

Nineteen of the 40 patients (47.5%) entered complete remission having regenerated from their aplastic phase and all of these were under 50 yr of age. The average time to achieve an absolute neutrophil count of $1 \times 10^9/l$ or a platelet count of $100 \times 10^9/l$ following completion of the cytotoxic drugs was 16 days (range 6–29 days). Eighteen of these 19 (94.7%) developed sustained fever requiring antibiotics and white cell support. In 8 pyrexia was due to septicaemia with isolation of *Klebsiella* (4), *E. coli* (1), *staphylococcus* (2) and *streptococcus* (1). In the remaining 10 patients no organism was isolated from biological samples. However, 2 had a chest infiltrate on X-ray and 1 had unilateral hilar adenopathy with pleural effusion which was treated as tuberculosis.

Group 2a

Nine patients (22.5%) died following biopsy-proven aplasia. The mean time to death was 16 days (range 10–35 days).

Death was due to infection in 8 and to haemorrhage in 1. The mortality in this group was contributed to by the inclusion of 4 patients who were over the age of 50 yr and by 3 patients overtreated during the early stage of the study whilst experience was being accumulated with this treatment regimen.

Group 2b

Five patients (12.5%) had residual leukaemia after repeated courses of therapy in which 3 received 2 courses and 2 received 3 courses of the drugs. Four of the patients died and the fifth went on to successful syngeneic bone marrow transplantation. The mean time to death was 38 days (range 34–42 days). Our experience, therefore, suggests that if aplasia is not achieved after one course of treatment remission it is unlikely to be attained.

Group 2c

Seven deaths (17.5%) occurred before the tenth post-treatment day. Although blasts were no longer detectable in the peripheral blood, post mortem examinations were not obtained and accordingly these patient cannot be assigned to either of the above 2 sub groups.

DISCUSSION

The chemotherapy of acute non-lymphoblastic leukaemia remains largely empirical although it is based to some extent on data derived from animal models [8] and pharmacokinetic studies [9]. We have evaluated a 3-drug combination compromising the epipodophyllotoxin VP16–213, cytosine arabinoside and adriamycin. The VP 16–213 was incorporated because of its reported ability to potentiate the antitumour effects of cytosine [10]. Furthermore, we [11] and others [12] have shown it to be active against monocytic tumours and there is recent evidence [13] that a large population of these cells is present in the marrow of patients with acute myeloblastic leukaemia which is inapparent on examination of Romanovsky stained films. Since it has been suggested that cytosine arabinoside has the capacity to recruit cells into cycle [14] and lead to their synchronization [14] the adriamycin was administered at the completion of the cytosine infusion rather than at its commencement [15].

The time taken to achieve complete remission in adult acute non-lymphoblastic leukaemia varies widely and most investigators have reported the need to use more than one course of therapy. The MRC Working Party on Leukaemia in Adults [16] reported remission induction times for 5 different schedules to vary between 7 and 12 weeks. Glucksberg *et al.* [17] needed an average of 3 courses administered over 46 days to achieve complete remission in one group of patients and 1.4 courses given over 27 days in another. Wiernick [18] in 2 separate groups reported that at best 44% of patients achieving complete remission did so with a single course of therapy but the patient group as a whole required an average of 1.6 courses. Gale *et al.* [19] found that 35% of patients achieved complete remission with a single course with an average of 1.8 courses being needed.

In contrast, all our patients who achieved complete remission did so with a single course of chemotherapy with peripheral blood values rising in a time shorter than previously reported. It might have been anticipated that the short induction period would serve to reduce the incidence of infection. However, because this occurred early in the neutropenic phase no such benefit emerged and virtually all patients became infected. Nevertheless, this short period did have the advantage of decreasing the morbidity associated with infection since it is our experience and that of others [20] that final resolution of the infection only occurs once the bone marrow has regenerated.

The disparity between the number of patients who achieved aplasia and those going on to complete remission is accounted for by those (Group 2a) who died before their bone marrow had regenerated. Apart from the difference in age and the total white cell count at presentation (Table 1) these 2 groups did not differ in any other way particularly with respect to the incidence, duration and severity of infection. It is possible that the group of patients who died whilst aplastic may have survived had they been nursed in protected environments.

The poor response to treatment of individuals over the age of 50 has been noted [16] and was observed in our patients, reflecting the reduced tolerance of the elderly to the many consequences of septicaemia. An exception to this has been a recent report from Gale *et al.* [19]; here again, it is possible that access to protected environments may explain the difference.

We conclude that this 3-drug regimen has the advantage of rendering 70% of the patients aplastic with a single course of treatment with a short post-induction neutropenic phase. That some of these aplastic patients did not survive may reflect deficiencies inherent in treating adults with acute non-lymphoblastic leukaemia in general medical wards.

Quelamycin, a New Derivative of Adriamycin with Several Possible Therapeutic Advantages*

MARIO GOSÁLVEZ,† M. F. BLANCO,† C. VIVERO† and F. VALLÉS‡

†*Department of Experimental Biochemistry and* ‡*Department of Haemodynamics, Clínica Puerta de Hierro, Facultad de Medicina, Universidad Autónoma, Madrid, Spain*

Abstract—*Quelamycin is triferric doxorubicine, a metallic derivative of adriamycin made by chelation of adriamycin at neutral pH with three ferric irons. This new derivative appears to maintain considerable antitumor activity while having less general, hematologic and cardiac toxicity than adriamycin. In addition, quelamycin is absorbed by the intestine.*

INTRODUCTION

IT WAS previously reported [1, 2] that the antitumour antibiotic, adriamycin, inhibits the activity of the cardiac enzyme Na–K dependent adenosine triphosphatase and also inhibits cellular ion transport. It was then claimed that these effects could be the cause for the cardiotoxicity of the drug [1, 2]. The effects of adriamycin on the ATPase and on ion transport were counteracted by the presence of calcium [2] and, as adriamycin is known to be a potent chelating agent [3], we made the hypothesis that metallic derivatives of adriamycin made by chelation would not be cardiotoxic. The present report presents a new metallic derivative of adriamycin, triferric doxorubicine, which has been made chelating adriamycin with three ferric irons at neutral pH. This derivative which has been named quelamycin for its use in clinical trials, appears to show considerable antitumor activity in experimental animal tumors while it has less general, haematological and cardiac toxicity. Quelamycin seems, furthermore, to present new properties concerning its permeability because it is active by oral administration. A previous report containing part of these data appeared in an abstract [4].

MATERIALS AND METHODS

Isolation and assay of rabbit heart Na–K *ATPase*

The isolation and assay of rabbit heart Na–K ATPase was as described by Auditore and Murray [5] except that the freezing step was omitted. Four rabbit hearts were homogenized in 150 ml of a medium containing 0.25 M sucrose, 20 mM histidine, 5 mM EDTA and 0.1% deoxycholate (pH 7, 0°C). The homogenate was centrifuged at 9000 rev/min for 20 min. The supernatant free of mitochondria and nuclear debris was centrifuged at 52,000 ***g*** for 1 hr at 4°C. The supernatant was discarded and the pellet washed twice with 0.32 M sucrose plus 1 mM EDTA. This preparation had a mean Na–K-dependent ATPase activity of 0.2 μmole ATP/min/mg protein and amean sensitivity to ouabain of 50%. The enzyme activity was assayed after the incubation of the enzyme (0.1 mg/protein/ml) with the drug for 20 min in a shaking bath at 37°C. The incubation medium contained 80 mM imidazole, 3 mM Mg^+, 3 mM ATP, 140 mM Na^+ and 14 mM K^+ (pH 6.7). At the end of the incubation, samples were taken for the assay of inorganic phosphate. Phosphate was determined as described specifically for ATPase measurement by Post and Sen [6].

Incorporation of labelled thymidine

For incorporation studies of labelled thymidine, leukaemia L1210 cells were

harvested from the tumour samples by centrifugation at 600 *g* for 10 min at room temperature. The cell pellets were washed with 30 vol (30–60 ml) of a buffered electrolyte solution consisting of NaCl 117 mM, KCL 5.3 mM, NaH_2PO_4 1.1 mM, $NaHCO_3$ 26.2 mM, $CaCl_2$ 1.9 mM and $MgCl_2$ 1.0 mM (pH 7.45). Washed cells were resuspended in this solution (supplemented with 5 mM glucose) to a final concentration of 1.0×10^6 cells/ml. Samples of 1 ml of the cell suspension were preincubated at 37°C for 2 hr in the presence of the drug in a shaking bath. After this initial incubation, 1.0 μCi of thymidine-methyl^{3}H (2.0 Ci/mmole, New England Nuclear, Boston, Mass.) was added in 0.01 ml vol. The cell suspensions were incubated for 1 additional hr. After the second incubation, samples were chilled and the cells were immediately collected in 5 μm Millipore® filters and washed with 20 vol of ice cold 0.9% NaCl solution. The filters were placed in scintillation vials with 10 ml of aquasol scintillation mixture (New England Nuclear) and their radioactivities were measured in a Packard tri-carb model 3375 scintillation spectrophotometer. All experiments were done in duplicate with controls containing no antitumor drug.

Rat elctrocardiograms

Rat electrocardiograms were redorded with a Telco physiograph model B-52, essentially as described by the group of Zbinden [11]. Rats were unanesthetized but confined to a small animal holder. Needle electrode (26 gauge) was inserted into the skin using lead D as described by Grauwiler [7]. The paper speed was 10 cm/sec. Heart rate was monitored with a cardiotachometer coupled to the elctrocardiogram.

Animal treatments

The transplantation and evaluation of treatment of experimental animal tumours were made as described in the protocols used at the U.S. National Cancer Institute [8]. Tumours were obtained regularly from Dr. Abraham, Division of Cancer Treatment, U.S. National Cancer Institute, Bethesda. Lymphocytic leukaemia P388 was propagated in DBA/2 mice and transplanted for testing in BDF_1 mice (males, 20 ± 1.5 g), six animals per test group. The tumour transfer was done on day 7 by intraperitoneal injection of 0.1 ml diluted ascitic fluid containing 10^6 viable cells. Walker carcinosarcoma 256 in ascitic form was propagated in random bred albino Sprague–Dawley rats and transplanted for testing in random bred albino rats (Males, 60 ± 5 g), 6 animals per test group. The transfer was done on day 7 by intraperitoneal injection of 0.1 ml diluted ascitic fluid with 10^6 viable cells.

Ehrlich ascites tumour was propagated and transplanted for testing in Swiss mice (males, 20 ± 2 g), 6 animals per test group. The tumour transfer was done on day 9 by intraperitoneal injection of 0.1 ml diluted ascitic fluid with 10^6 viable cells. The tumours were treated intraperitoneally with adriamycin or quelamycin dissolved in water. The evaluation of antitumour activity was done by calculation of the median survival time from mortality distribution. Median Survival Time $= x + y/2$ where x is the earliest day when the cumulative number of deaths is $\geqq 3$ and y is the earliest day when the cumulative number of deaths is $\geqq 4$.

The LD_{50} of quelamycin and adriamycin was determined by intraperitoneal injection of a single dose with water as solvent in DBA/C57 F1 male mice (20 g of weight) with 7 days as observation period. A group of 20 mice was used for each dose.

RESULTS

Synthesis of quelamycin

For the synthesis of quelamycin (also called triferric doxorubicine or triferric adriamycin), it is necessary for each molecule of adriamycin in solution to chelate three atoms of ferric iron in the three bidentate ligands with high affinity at neutral pH. Thus, a good procedure for the synthesis is to join adriamycin in water at room temperature with three molar equivalents of ferric-chloride. Upon adding the iron, adriamycin changes its red colour to the black violet colour of ferric-adriamycin and the mixture is very acidic. The mixture is then neutralized slowly with NaOH to pH 7, under continuous agitation, to chelate the third iron with the amino sugar and the synthesis is completed. To avoid any excess of precipitated iron, it is convenient to filter the solution by a 0.2 μm Millipore® filter immediately upon neutralization. Quelamycin is only stable in solution for a few hours, because it tends to form polymers; thus, after filtration, it should be liophylized for storage as a dry powder which can be reconstituted by adding water. In the procedure of

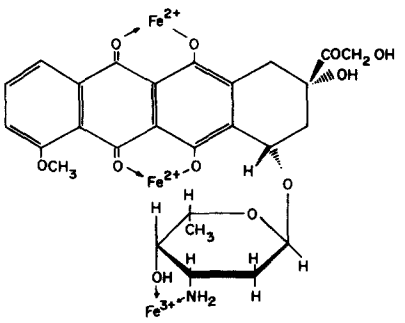

Fig. 1. Chemical structure of quelamycin.

liophylization, a quick freezing procedure is essential because polimerization is favoured by low temperature. The chemical structure of quelamycin is shown in Fig. 1. This structure was arrived at indirectly by determining the chelation sites of adriamycin at low iron concentration in neutral solutions of D_2O, using spectral analysis with an apparatus of nuclear magnetic resonance supplied with a computer averaging and summation system [10]. A maximum molecular weight of 700 was found by ultrafiltration indicating that over 99% of the chelate is in monomeric form [10]. As can be seen in Fig. 1, quelamycin has chelated the three irons in hexagonal and pentagonal rings of very high stability. Quelamycin remains undissociated in serum or tissue homogenates and is eliminated intact by urine after intravenous injection to the rabbit. Quelamycin is only slowly dissociated by heating in the presence of EDTA or oxalic acid.

Biochemical, biological and pharmacological effects of quelamycin

Figure 2 compares the effect of adriamycin and quelamycin on the activity of rabbit heart Na–K dependent ATPase. Adriamycin appears as a potent inhibitor of the enzyme while quelamycin does not have any effect. These experiments support the hypothesis that the counteracting effect of calcium in the effect of adriamycin in the enzyme [2] was due to its chelation by adriamycin. If the cardiotoxicity of adriamycin were due to its effects in the Na–K ATPase. quelamycin would behave as non-cardiotoxic.

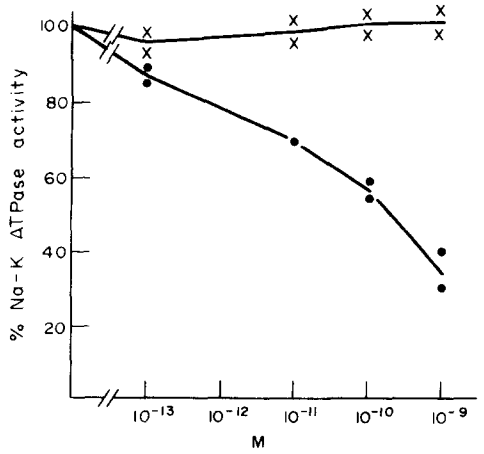

Fig. 2. Effects of increasing concentrations of quelamycin (crosses) and adriamycin (circles) on the activity of rabbit cardiac microsomal Na–K *ATPase.*

Figure 3 compares the average cardiac frequency and the QRS duration in the elctrocardiogram of groups of 5 rats treated with adriamycin and quelamycin. In the experiment of the lower part of the figure, the drugs were administered in a single intraperitoneal injection of 4 mg/kg daily,

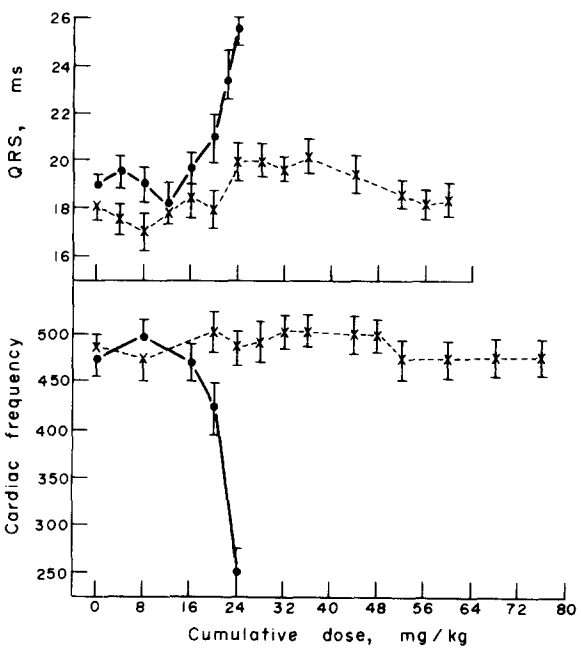

Fig. 3. Effects of cumulative doses of adriamycin (continuous line) and quelamycin (dotted line) on cardiac frequency and QRS widening in the rat electrocardiogram. Each point is the average value of 5 rats and the bar represents the standard error.

3 days per week. In the experiment of the upper part of the figure, the drugs were administered in a simple intraperitoneal injection of 2 mg/kg daily, 5 days a week for two weeks and then the dose was lowered to 1 mg/kg daily, 5 days a week. In both cases, when a cumulative dose of 24 mg/kg of adriamycin per rat was reached, the rats died, showing a great QRS widening and an intense bradicardia. In the groups treated with quelamycin, the rats reached much higher cumulative doses and survived without showing signs of electrocardiographic alteration. The observation was

continued for four months and no delayed cardiotoxocity appeared. In the group of rats treated with quelamycin, a QRS widening was found occasionally in individual rats. This widening later disappeared after a few days without further increasing when increasing the cumulative dose.

Aside from a decreased cardiotoxicity, quelamycin showed less general, haematological and digestive toxicity. Figure 4 (left graph) shows the mortality distribution of male mice of 20 g of weight (DBA/C57 F1 strain) after 7 days of a single intraperitoneal injection of adriamycin or quelamycin at different doses. Quelamycin has a LD_{50} of 45 mg/kg and adriamycin has a LD_{50} of 15 mg/kg. The right graph of Fig. 4 shows the variation in leucocyte count in dogs after the injection of 2 mg/kg of adriamycin or quelamycin. Each point is the average of the counts in two dogs. Quelamycin depresses the leucocyte count much less than does adriamycin.

considerable activity in the three tumour systems and quelamycin, due to its lower toxicity, could be used at higher doses.

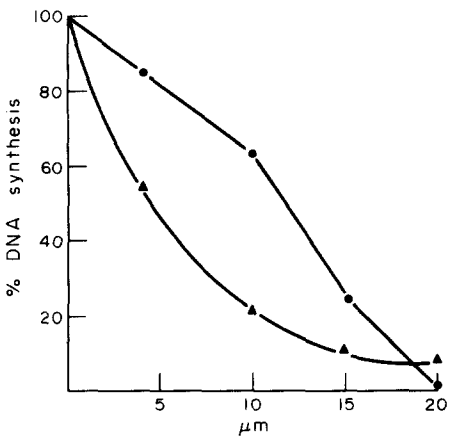

Fig. 5. Inhibition of DNA synthesis by increasing concentrations of quelamycin (circles) and adriamycin (triangles) as measured by uptake of tritiated thymidine in leukaemia 1210 cells. Each experimental point shows the average of three determinations.

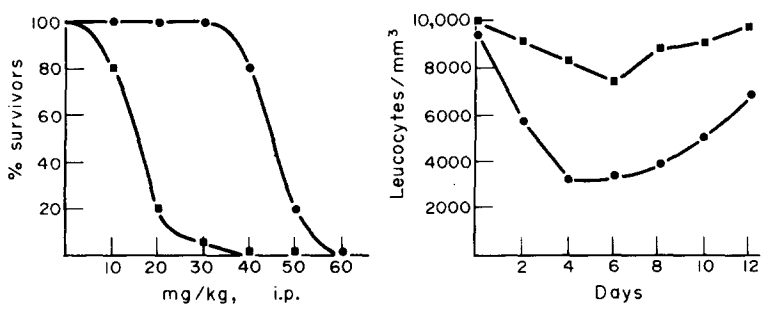

Fig. 4. (Left graph) Mortality distribution in mice after seven days of a single intraperitoneal injection of adriamycin (squares) or quelamycin (circles) at the indicated doses. (Right graph) Average leucocyte counts in the peripheral blood of two dogs in the days following a single intravenous injection of 2 mg/kg *of adriamycin (circles) or* 2 mg/kg quelamycin (squares).

While showing less toxicity, quelamycin maintained antitumour effect. Figure 5 shows the effect of adriamycin and quelamycin on the DNA synthesis of leukaemia L1210 cells as measured by uptake of tritiated thymidine. Both compounds appear as good inhibitors of DNA synthesis with similar potency. Table 1 illustrates the antitumour activity of quelamycin and adriamycin with a representative experiment in Ehrlich ascites tumours, Walker carcinosarcoma tumours and leukaemia P-388 tumours. Each experimental group consisted of six animals and the drugs were injected intraperitoneally at the indicated doses on day 1, 5 and 9 (P-388) or on day 1, 2, 3, 4 and 5 (Walker carcinosarcoma and Ehrlich ascites tumour) after transplantation. Both compounds showed

The antitumour activity of quelamycin and adriamycin varied considerably from experiment to experiment and this variation, in the absence of a large statistical study, precluded any conclusion about which drug shows more potent antitumour activity in each tumour. Figure 6 shows the leucocyte counts in peripheral blood in three cycles of administration of quelamycin in two dogs. The first and third cycles were of 4 mg quelamycin/kg using enterric-coated pills, and in the second cycle the same dose was administered by intravenous route. It can be observed that the bone marrow suppression is more complete with the intravenous dose but that there is considerable bone marrow depression activity with the pills. The pills were manufactured using

liophylized powder of quelamycin with 1% mannitol as support, using magnesium stearate and carboxymethyl cellulose as excipient and received a gastro resistant coat of acetylftalate of cellulose and dimethylftalate to pass through the stomach unaltered.

DISCUSSION

From our results, it appears that quelamycin is a derivative of adriamycin which maintains considerable antitumour effect while having less general, haematologic and cardiac toxicity. Our results in experimental tumours were obtained in a limited series of tumours and with a limited number of doses. To ascertain that quelamycin has equal antitumour potency to adriamycin milligram to milligram, it would be necessary to carry out larger studies. It is possible that, due to possible different permeability properties of quelamycin, the drug would show different activity in different tumours.

Quelamycin seems well tolerated over large cumulative doses from the electrocardiographic point of view. However, a transient QRS increase was noted in some animals. It is possible that Quelamycin could have been deprived of direct effects on cardiac contractility through lacking effect on the Na–K ATPase but would still have cardioactivity through neurological mechan-

isms at high doses, as is the case with other glycosides [12–14]. Nevertheless, to ascertain a lack of cardiotoxicity with quelamycin, a morphological study in the rabbit model cardiomyopathy [15] would be necessary; such studies are presently under way [16].

Quelamycin is active when administered orally but the haematological effect is less intense than with intravenous administration. The oral absorption could indicate permeability characteristics which would be suitable to cross the blood–brain barrier. Preliminary experiments have shown that quelamycin, when administered intravenously at high doses, crosses the blood–brain barrier in the rabbit but not in the mouse.

The apparent advantages of quelamycin over its parent compound, have prompted clinical studies in man. Presently, from a phase I clinical study carried out at the five major Madrid hospitals, it has been concluded that quelamycin had considerable antitumour activity and low toxicity. However, to ascertain the possible activity of quelamycin, the results of the ongoing phase II trial should first be completed.

Combination Chemotherapy of Malignant Glioma. Effect of Postoperative Treatment with CCNU, Vincristine, Amethopterine and Procarbazine

W.-D. HEISS, M. TURNHEIM and B. MAMOLI

Neurologische Universitätsklinik, Lazarettgasse, 14, A-1097 Vienna, Austria

Abstract—*A combination chemotherapy consisting of CCNU, vincristine, amethopterine and procarbazine (COMP-therapy) was studied in the postoperative treatment of malignant gliomas. Fifteen-day COMP-therapy series given* 10–20 days *after surgery and repeated at regular intervals increased the median recurrence-free interval to* 8.9 *months and the median survival time to* 10.7 *months. Both prolongations were significant when compared to the results in a control group not receiving postoperative chemotherapy (median recurrence-free interval:* 2.6 *months, median survival time:* 6.2 *months), in a group receiving postoperative CCNU-treatment* (3.5 *and* 6.5 *months, respectively), and to a group of patients treated with postoperative polychemotherapy* (4.7 *and* 8.0 *months, respectively). The only problematic side effect of COMP-therapy was neuropathy resulting from toxic vincristine-dosage.*

While nitrosoureas alone were not able to affect the length and the quality of survival, their combination with cell-cycle specific and other cell-cycle non-specific drugs improved the results in the therapy of primary malignant brain tumors.

INTRODUCTION

IN THE search for a more effective treatment of malignant glioma (glioblastoma, astrocytoma grades III–IV) combined modalities of surgery, radiotherapy and/or chemotherapy have been shown to be superior to surgical removal of the tumor alone. The median survival time for glioma patients with surgery only was between 4 and 6 months [1, 2]; extensive surgery and radiotherapy were able to prolong the median survival time [1–7], although this was not observed by all authors [8, 9]. Whereas some studies [1, 6, 9] showed that the addition of chemotherapeutic agents to the postoperative radiation therapy improves survival rates, others [2, 5, 7] did not find them to be significantly effective. Survival rates with postoperative chemotherapy alone were below those obtained with radiation therapy or combination of both [1, 2, 6, 7], but a high percentage of recurrent gliomas responded to a single drug [10–15, reviews in 16, 17] or combination chemotherapy [18–20]. The poor results with chemotherapy of gliomas were attributed to limited concentrations of drugs in the tumor cells due to the blood–brain-barrier [16, 21–23], a conclusion which has been recently questioned, however [24]. It has been shown previously [25] that a combination chemotherapy consisting of drugs not selected according to their ability to penetrate the blood–brain-barrier was superior to a monotherapy applying a single lipid soluble nitrosourea-derivative. This indicates that factors other than lipid solubility and the drug ability to penetrate into the normal brain must also be considered in the design of chemotherapeutic protocols. Such potentially effective factors include the route of administration and the combination of drugs. By application of several drugs in appropriate schedules sufficient amounts of effective agents might accumulate within the tumor cells. It was the purpose of this investigation to prove the efficiency of a combination of four antineoplastic drugs in postoperative treatment of malignant gliomas and to compare the results with those obtained under other protocols.

MATERIALS AND METHODS

Patients

The following drugs were selected for the combination chemotherapy (COMP) because they had previously proved to be effective in brain tumors (Table 1): 1-(2-chloroethyl)-3 cyclohexyl-1-nitrosourea (CCNU) is a cell-cycle non-specific lipophilic drug which readily penetrates into the brain tissue [26]. Its effectiveness on brain tumors has been reported repeatedly [13, 14, 27, 28]. Encouraging results with brain tumors have been obtained [15] with procarbazine, another cell-cycle non-specific compound which crosses the blood–brain-barrier [29].

Table 1. *COMP-protocol*

CCNU	100 mg/m^2 p.o.	1 day
Vincristine	1.4 mg/m^2 i.v.	1 + 8 day
Amethopterine	10 mg/m^2 i.m.	3, 7, 10 + 14 day
Procarbazine	100 mg/m^2 i.v.	2–15 day

Vincristine (VCR: Oncovin®), a cell-cycle specific drug which inhibits the cell division at metaphase, has been effective in some studies [10, 30, 31]; however, other authors do not consider it of value for the glioma therapy [32, 33]. Amethopterine (methotrexate), an S-phase specific drug, is taken up into neoplastic glial cells [34], but does not achieve high concentrations in normal brain tissue [35]. When given as intracarotid infusion [36], intrathecally [37] or intraventricularly [38], some effect upon gliomas could be seen.

The COMP-protocol, a combination chemotherapy employing CCNU, vincristine, methotrexate and procarbazine, was applied in 15-day series: the first series was initiated 10–20 days after surgery, the second and third in 6-week intervals thereafter, and the following cycles then were administered in 3-month intervals until recurrence of the tumor or death of the patient. When severe toxic side effects appeared treatment was modified or stopped. All patients received steroids (methyl-prednisolone, 20 mg/day) during the chemotherapeutic series and afterwards until the white blood count was normalized. When necessary, gastrointestinal side effects were treated, antibiotics were given and fluids and electrolytes were balanced.

Twenty-two consecutive patients suffering from malignant glioma (glioblastoma, astrocytoma grades III and IV, according to Kernohan *et al.* [39], received postoperative chemotherapy under the COMP-protocol. In all these cases as much as possible of the tumorous tissue was resected: specimens were obtained for histological and cytological examination. With a few exceptions autopsies were performed. If the biopsy-diagnosis was not confirmed by the postmortem histological examination, patients were excluded from the study. The patients underwent general and neurologic examinations before and regularly during the course of the COMP-protocol. EEG, brain scintigraphy, electroneurographic investigations and blood tests were performed at regular intervals. If necessary, cerebral angiography or computer tomography were undertaken.

In order to evaluate the effect of the COMP-therapy two criteria were used: (1) the survival time, the most clearly defined and most frequently used parameter; and (2) the time interval between surgery and recurrence of the tumor, which approximates the duration of "good" quality of life. This progression free interval was determined from clinical symptoms and/or occurrence of localized pathological isotope uptake in the scintigrams. Both criteria were compared with the results in groups of unselected patients treated previously under other protocols [25]. Those 55 patients also suffered from malignant gliomas diagnosed by the same neuropathologist without knowledge of the mode of further treatment. Sixteen patients who received conventional therapy—i.e. surgery only, or, in some cases, surgery plus irradiation—comprised the control group. Twenty four patients received 100 mg/m^2 CCNU in 6-week intervals following the operation. A third group of 16 patients were administered postoperatively a polychemotherapy (PChTh) described by Israel *et al.* [40]; the following cytotoxic agents were given in 1–4 consecutive 7-day cycles: procarbazine (125 mg i.v.) and 6-mercaptopurine (50 mg p.o.) daily; cyclophosphamide (300–500 mg i.v. infusion) on day 1, 3 and 5; 5-fluorouracil (250 mg i.v. infusion) on days 2, 4 and 6; amethopterine (5 mg i.m.) on day 1 and 4; vinblastine (5 mg i.v.) on day 7. These and the other patients received steroids (20 mg methyl-prednisolone) before and several weeks after surgery; steroids were also given intermittently to all patients when necessary during the latter course of their disease. In no case, neither under the COMP- nor under the other protocols, were steroids administered for a prolonged period of time in high dosages.

Table 2. Recurrence-free interval and survival time in months (median and range) of patients receiving postoperative COMP-therapy compared to patients under other protocols. Significant H-values of variance analysis are given ($P<0.01$)

	N	Age (yr)	Recurrence-free interval (months) median	range	Survival time (months) median	range
Controls	16	22–66	2.6	1.0– 9.0	6.2	1.0–11.4
CCNU	23	35–76	3.5	1.0–15.7	6.5	1.5–18.5
PChTh	16	18–69	4.7	2.5– 9.8	8.0	3.3–18.2
COMP	22	31–64	8.9	3.0–26.0	10.7	3.5–27.8
$\hat{H}$			15.96		12.84	

Survival times and recurrence-free intervals achieved under the different protocols were statistically evaluated by variance analysis using ranks (H-test of Kruskal and Wallis [41]). The results of the COMP-Therapy were compared to those of the control and of the CCNU group by the Wilcoxon rank sum test [42]; if necessary, the version of Gehan [43] was used.

RESULTS

Survival time

As shown in Table 2, the patients receiving postoperative COMP-therapy survived surgery by 3.5–27.8 months (median survival time 10.7 months). Six of these patients are still alive 9.5–27.5 months after surgery. The survival time is longer than the

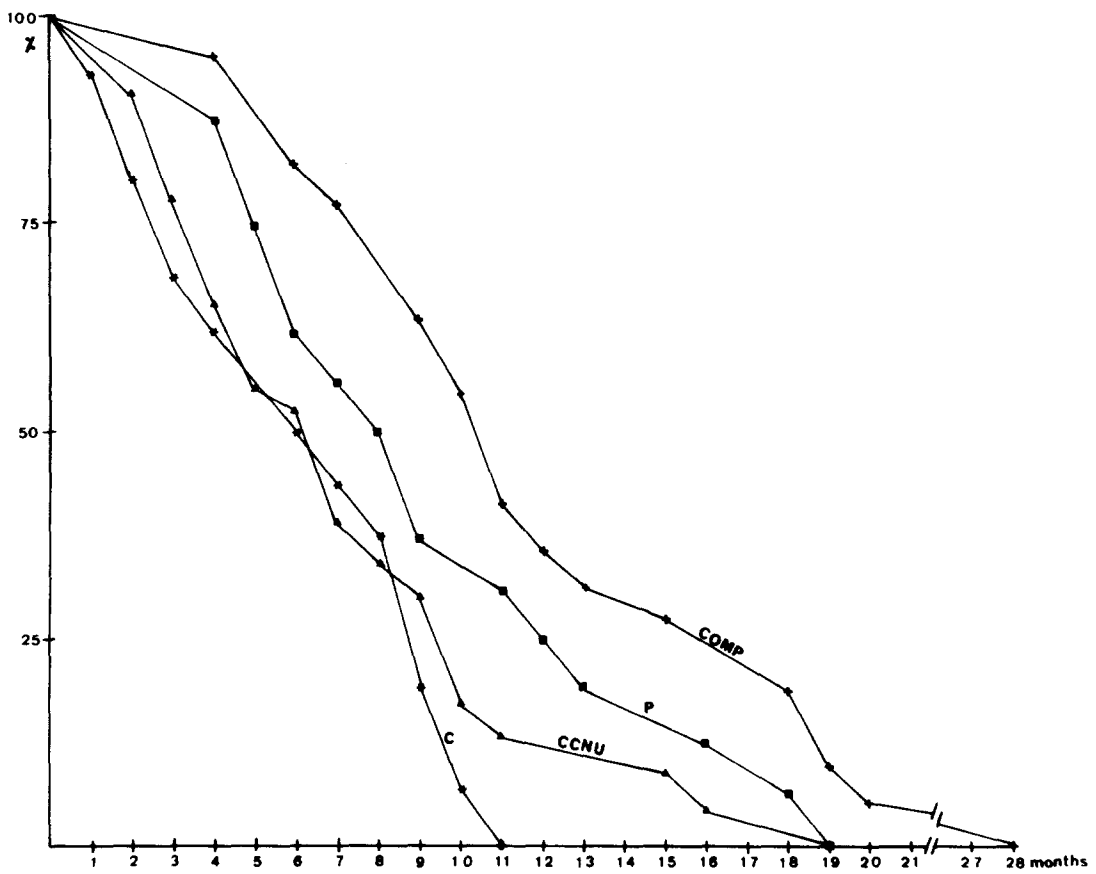

Fig. 1. Survival curves of patients under different protocols: C: control group, 16 patients; CCNU: 100 mg/m² every 6 weeks, 23 patients; P: polychemotherapy, 16 patients; COMP: COMP-therapy, 22 patients.

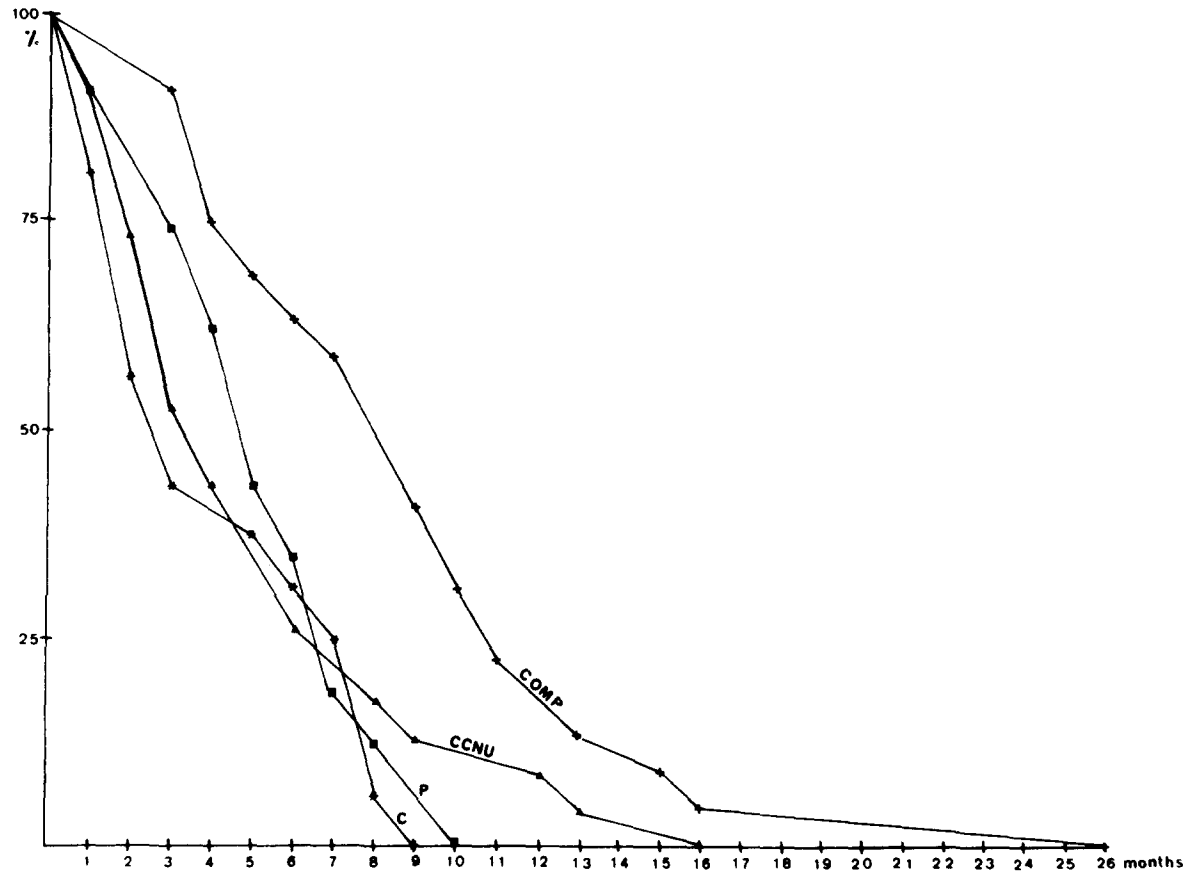

Fig. 2. Curves of recurrence-free intervals under different protocols. C: control group, 16 patients; CCNU: 100 mg/m² CCNU every 6 weeks, 23 patients; P: polychemotherapy, 16 patients; COMP: COMP-therapy, 22 patients.

survival times observed with the previously used protocols; this improvement shows up in the significant H-value from the variance analysis and in the survival curves of the patients (Fig. 1). The subsequent comparison of survival times in individual groups using Gehan's modification of the Wilcoxon-test showed significant differences of COMP-therapy to the control group ($z=3.2$, $P<0.01$) and to the group receiving CCNU only ($z=3.52$, $P<0.01$).

Recurrence-free interval

The recurrence-free intervals observed under COMP-therapy are also given in Table 2: they were between 3.0 and 26.0 months with a median of 8.9 months. Two patients included in the group were not suffering from recurrence 10.0 and 10.5 months after surgical removal of their glioma. Again, the recurrence-free intervals were significantly longer with the COMP-therapy than in the other protocols, proved by the high H-value and demonstrated in the curves of time intervals to recurrence (Fig. 2). Comparison of the groups showed significant differences of the COMP group to the control and to the CCNU group ($P<0.01$). The quality of the recurrence-free interval, i.e. the severity of neurologic deficits, was not used as a criterion for efficacy of the treatment, because the neurologic defects depend on the brain damage done by the tumor and surgery. Glioma patients with and without postoperative treatment reach their best clinical condition soon after surgery; its prolongation is the aim of the postoperative treatment.

Determination of recurrences

The patients underwent regular clinical neurological examinations; EEG and brain scintigraphy were performed at 4–6 weeks intervals. If neurologic symptoms developed or deteriorated, the patients were investigated immediately. In 8 patients brain scintigraphy confirmed recurrence of the tumor immediately after it was clinically suspected. In 2 patients a recurrence was indicated by clinical signs, but brain scintigraphy did not yet show a clear-cut localized isotope

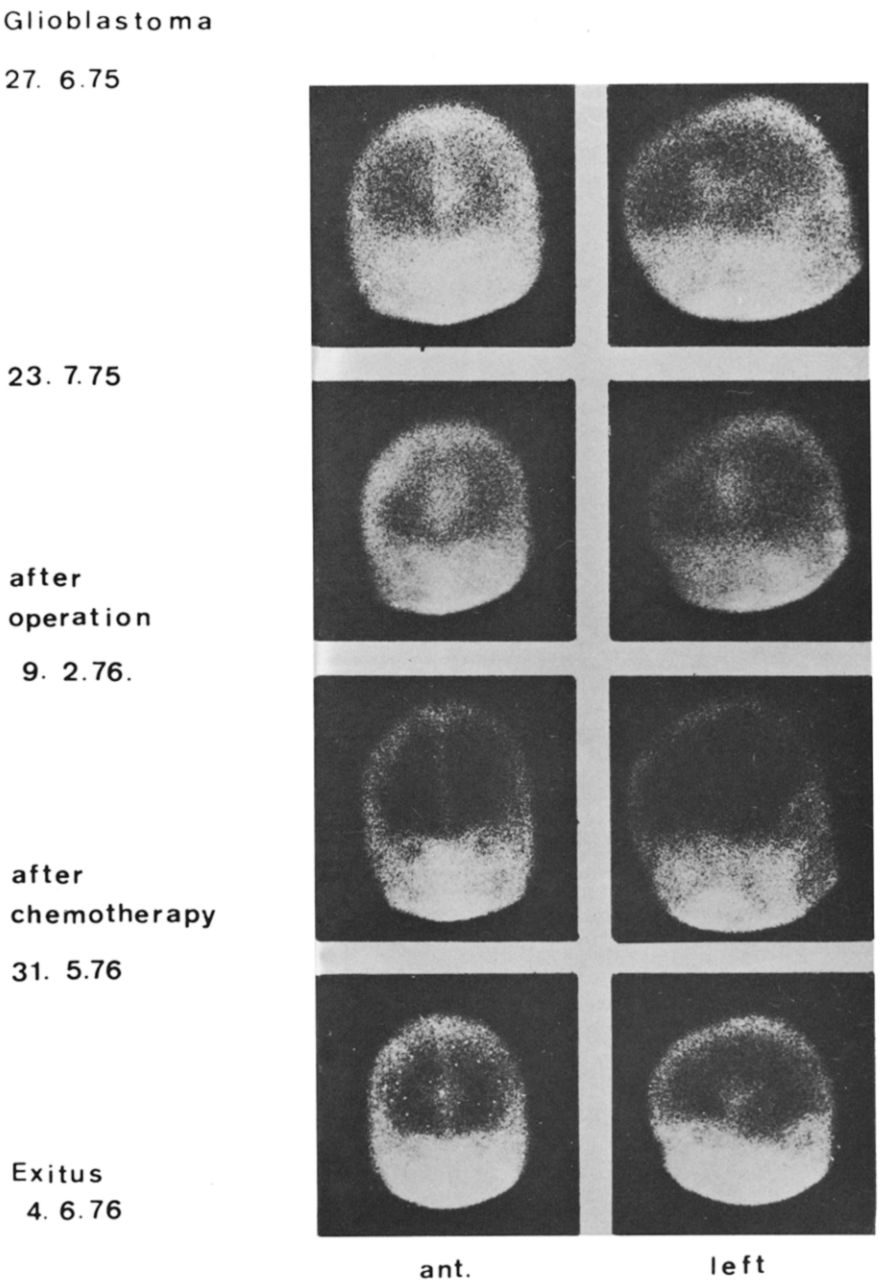

Fig. 3. Scintiphotograms of a patient suffering from butterfly-like glioblastoma. The tumor mass remaining after surgery disappeared during COMP-therapy, a recurrence showed up 3 months later and the patient died thereafter.

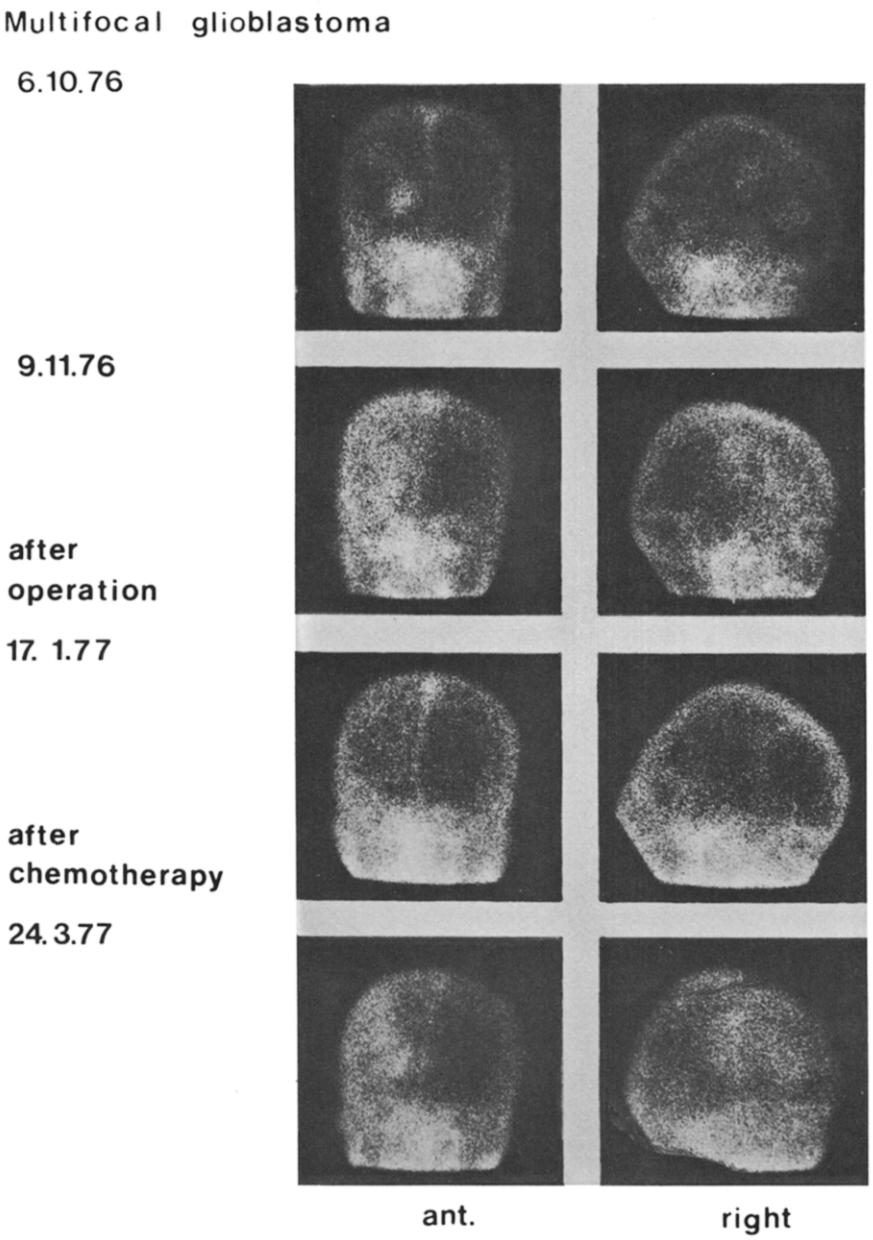

Fig. 4. Scintiphotograms of a patient with multifocal glioma. The frontal center was removed, the parieto-central tumor mass decreased during COMP-therapy. Recurrence occurred 3 months later.

uptake; scintigraphy was positive 2–3 weeks later. In 10 cases brain scintigraphy was positive before clinical signs indicated the recurrence: localized isotope uptake developed between 1 and 14 weeks before the condition of the patient deteriorated. Recurrence-free interval was defined as the time between surgery and the first evidence of a new or increased tumor-mass indicated by clinical deterioration or brain scintigraphy.

Brain scintigraphy could show the effect of therapy in those cases in which removal of the tumor was incomplete or, as in two cases with multifocal glioma, only one tumor could be excised. In such cases the region of increased isotope uptake caused by remaining tumorous tissue (Fig. 3) or by the second glioma center (Fig. 4) decreased its extension and intensity or disappeared completely. However, the effect of the therapy on these gliomas visualized by scintigraphy and expressed in clinical improvement did not last more than a few months.

Electroencephalography was not as effective in indicating recurrences; in 9 of 11 cases a focus was found shortly after the occurence of clinical or scintigraphical signs. In 2 patients EEG did not change markedly when tumor progression was evident from other sources.

Tumor recurrence was treated by surgery in 10 patients receiving postoperative COMP-therapy. The clinical condition of these patients was improved under further chemotherapy in 3 cases, the improvement lasting for 4 months in two cases and 6 months in one. In the other 7 cases tumor progression could not be delayed and these patients died soon thereafter. In the two cases with multifocal gliomas the second tumors were removed when they could not be further influenced by chemotherapy. In these cases as well surgical intervention had no effect on the clinical course.

Side effects

Gastrointestinal toxicity was the most consistently observed side effect. Gastrointestinal irritations—nausea and vomiting—were observed in more patients during the first few days of the COMP series; they could be suppressed by antiemetic drugs and usually disappeared after the 3rd day. All the patients complained of loss of appetite during the series.

Hematopoietic toxicity was frequently encountered: in most patients white blood cell counts lower than $3000/mm^3$ were seen after the individual COMP series, but the white blood cell counts usually recovered to above 4000 before the next series. In 7 instances white blood cells fell below $2000/mm^2$ with a specific depression of granulocytes (40% or below); as in the other cases bone marrow showed only slight toxic alterations and the counts improved with prolonged steroid therapy. Platelet depression was observed in most patients after the COMP series, but only in 3 instances were counts below $65{,}000/mm^3$. Neither infections nor bleeding were seen as a result of leukopenia or thrombocytopenia. Only a single case of transient depression of erythrocytes occurred. The transient hematopoietic toxicity was not considered as a contraindication to continued chemotherapy; in some instances the next series was postponed by 1–2 weeks until the counts reached normal values.

Increased serum enzymes indicating liver toxicity (alkaline phosphatase, transaminases) were observed in 10 cases, but the values usually returned to normal before the next series was started. Renal toxicity with increase in serum creatinine and urea for a few weeks was seen in only one case.

Neurotoxicity was the most severe side effect. All patients developed symptoms of peripheral neuropathy with loss of tendon reflexes, distal paresthesia, and, in few instances, transitory distal limb weakness; these symptoms were dependent upon the total dosage of VCR received. The neuropathy was objectified by electrophysiological investigation. Maximal motor nerve conduction velocity (NCV) of the right peroneal nerve and compound action potential (CAP) of the short digital extensor were measured: pathologic NCV values were recorded (Fig. 5) in 5 of 15 patients after 2–6 mg VCR; in 6 of 12 patients after 7–12 mg VCR; and in 10 of 12 patients after 13 mg or more VCR. In one case excitability of the peroneal nerve was completely lost after 16 mg VCR. The mean conduction velocity in the patients who received the respective total dosages of VCR were: 44 m/sec after 2–6 mg VCR, 41 m/sec after 7–12 mg VCR, 40 m/sec after 13–18 mg VCR, and 39 m/sec after more than 18 mg VCR. CAP was within the pathology range in 2 of 14 patients after 2–6 mg VCR, in 7 of 14 patients after 7–12 mg, in 7 of 11 patients after 13–18 mg and in 4 of 5 cases after more than 18 mg VCR. The mean values

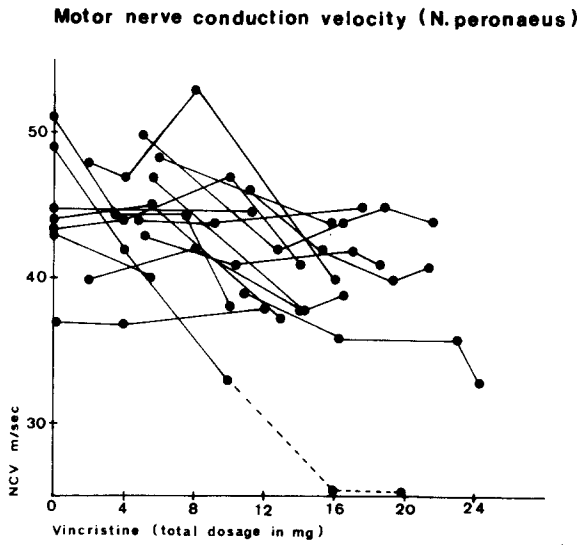

Fig. 5. Change of motor nerve conduction velocity (m/sec) *of the peroneal nerve of individual patients with increasing total vincristine dosage.*

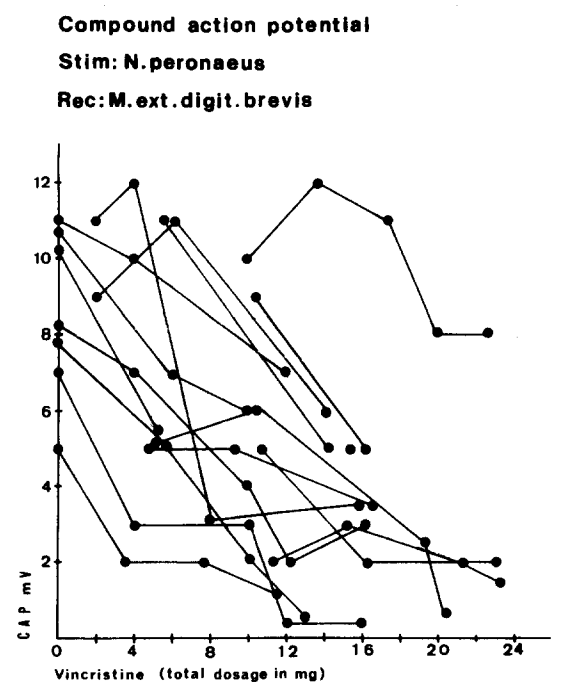

Fig. 6. Change of compound action potential (mV) *of M. ext. digit. brevis after peroneal nerve stimulation in individual patients with increasing total vincristine dosage.*

of the respective groups were 7.5 mV after 2–6 mg VCR, 4.6 mV after 7–12 mg VCR, 3.9 mV after 13–18 mg and 2.5 mV after more than 18 mg. The marked decrease of CAP compared to the slight alteration of NCV indicates a primary axonal neuropathy. In view of the electrophysiological alterations patients were not given more than 2 mg or half the original dosage, i.e. 0.7 mg/m^2 during the later COMP-series. By means of these controls and the consequent decrease in dosage, persistent clinically established neuropathies could be avoided.

DISCUSSION

After extensive experience with single-agent chemotherapy, especially for recurrent brain tumors [17], combined drug schedules and prophylactic treatment regimens must be tried to achieve substantial prolongation of survival time and improvement of quality of life during this time, as is now the case in the treatment of other malignancies [44, 45]. Due to the peculiarities of gliomas with respect to growth fraction and cell kinetics [46] the drug combinations must include both cell-cycle non-specific and cell-cycle specific agents in order to achieve a high tumor cell kill. Since the growth fraction increases secondarily to a decrease in tumor size after effective treatment, retreatment is necessary after a 3–4 week interval. Furthermore, removal of substantial parts of the glioma forces the remaining tumor cells into an active growth phase during which they are more susceptible to chemotherapy [47]. Therefore, chemotherapy was initiated in our cases 10–20 days after surgery, at a time when the tumor mass is minimal and the blood–brain-barrier is still disrupted. In consideration of tumor repopulation, the chemotherapeutic series were repeated twice after therapy-free intervals of 4 weeks, and, later, to avoid severe toxic side effects, after 10–11 week pauses. This regimen of therapy did not permit evaluation of the effect of chemotherapy by dividing the patients into "responders", "probable responders" and "non-responders" and calculating response rates [48]. The prerequisite of such an analysis, the continuous deterioration due to tumor regrowth, is not fulfilled. The effect of a therapy aimed at prevention of tumor regrowth can only be evaluated by comparing recurrence-free intervals and durations of survival with the same criteria achieved by different kinds of treatment.

In prospective randomized, concurrent, controlled clinical trials some regimens including chemotherapeutic agents [5–7] were tested.

Results obtained in consecutive and not concurrent studies are not devaluated by the method of their accumulation [49] as long as the patients in the different groups belong to the same population and are clinically and histologically examined by the same investigators, and as long as data from "historical" controls used agree with

those in the literature. In our study, the results with the COMP-therapy are compared to groups of patients investigated in the past: survival time and recurrence-free interval of the control group are in the range of those reported in the literature and of those obtained in a large follow-up study of glioblastoma patients surgically treated by the same neurosurgical team as ours [50]. Patients with and without postoperative radiotherapy were comprised in one group because of statistical reasons. This procedure was justified by comparable recurrence-free intervals and survival times of these patients. That the postoperative radiotherapy used in Vienna in the past could not improve survival time significantly was shown in the large groups of Grunert *et al.* [50]. The results obtained with post-operative CCNU monotherapy were not different from the controls, which is in accordance with previous reports [1, 2, 6, 7]. However, the polychemotherapy described by Israel *et al.* [40] slightly increased recurrence-free interval and duration of survival [25]. Compared to those protocols COMP-therapy had a significant effect not only on survival time, but also on the recurrence-free interval and, thereby, significantly prolonged the useful life-span for these patients. This prolongation of "good" quality of life, which was not combined to a prolongation of the time interval between recurrence of the tumor and the death of the patient, could not be due to the effect of steroids: patients in the other groups also received steroids; and a steroid effect on long-term survival could not be demonstrated with different administration schedules [51]. The significant improvement of quality and length of survival under COMP-protocol as compared to CCNU treatment suggests that other chemotherapeutic agents have to be added to nitrosoureas. The same was also indicated by the comparable results obtained with a combination of postoperative radiotherapy and nitrosourea-chemotherapy [1, 6, 9].

As in previous studies [48, 52] brain scintigraphy was the most reliable criterion in the detection of recurrences: by this method new tumor masses could be demonstrated in 10 cases before clinical signs indicated the recurrence, whereas clinical symptoms suggested a new tumor only in two cases with negative scintigrams. Computer tomography, which is also a reliable means for controlling therapeutic effects [53] has only been available for $1\frac{1}{2}$ yr and could not, therefore, be systematically evaluated for comparison to the previous protocols.

The toxic side effects of the COMP-therapy were less severe than with PChTh, during which strong bone marrow depression observed in a few cases necessitated the interruption of the treatment. There was no case in which the COMP-protocol had to be discontinued due to hematopoietic complications. The only drug the dosage of which had to be reduced in the latter course of therapy was vincristine: as described previously [32, 54–56] the toxic neuropathy of axonal origin is dependent on the total dosage of vincristine, but severe clinical symptoms may be avoided or are reversible when the drug is not administered further or when lower single doses are given. While vincristine-neuropathy was not a severe problem in our cases, it might be a limiting factor with substantial increase in the survival time.

In our experience COMP-therapy is the first postoperative treatment of glioma patients leading to a substantial improvement of good quality life. The still unsatisfactory results might be improved by changing the constituents of the combination, the dosage and the timing of administration of the individual drugs, and by combining chemotherapy with postoperative radiotherapy.

Abstract—*An immunization schedule that leads to the production of antimicrococcus antibodies of restricted electrophoretic heterogeneity in (female BALB/c × male DBA/2) F_1 mice (CDF_1) is described and commented on.*

Although mouse antimicrococcus sera agglutinate cultured L1210 cells in vitro, *micrococcus vaccinated mice never showed any anti-leukaemia immunoprotection. However, vaccinated mice, given booster doses of* 1 mg *heat-killed* Micrococcus lysodeikticus *on* days 4, 8 *and* 12 *after a tumour challenge of* 10^4 *cells, were considerably protected* ($P<0.001$) *and showed a* 92% *increase in mean life span over untreated controls, with* 57% *of long-term survivors, whereas unvaccinated mice, given* 1 *mg micrococcus injections on* days 4, 8 *and* 12, *showed a* 72% *increase in mean life span* ($P<0.001$), *but no long-term survivors were recorded.*

Our results underline the idea that, after establishment of tumour growth, the humoral antitumour immunity requires an adequate trigger of immunocompetent effector cells to be operationally effective.

INTRODUCTION

IN MAMMALS, the immune response to glycoprotein is predominantly directed at protein antigenic epitopes and not at the carbohydrate moiety [1].

Because of the similarity of the carbohydrate moiety of the serum glycoproteins and of the glycoproteins that function as cell surface receptors, it is likely that animals have acquired selective tolerance and recognize those polysaccharides as "self" antigens [2, 3]. However, when animals are infected or vaccinated with Gram-positive *Streptococci* [4], *Pneumococci* [5] or non-pathogenic *Micrococci* [6] that carry an analogous carbohydrate as a part of the bacterial cell wall, the elicited anti-carbohydrate immune response is abundant and often of restricted electrophoretic and structural heterogeneity (homogenous antibodies), a characteristic in common with the well studied myeloma proteins [7].

Rabbit antibodies against *Micrococcus lysodeikticus* (ATCC 4698) are of high titer (up to 40 mg/ml serum) [6] and are directed [8] either against the bacterium specific carbohydrate, called Perkins' antigen (a copolymer of glucose and *N*-acetyl-D-mannosaminuronic acid), or against the bacterial peptidoglycan built up by repeating units of *N*-acetyl-D-glucosamine, *N*-acetyl-D-muramic acid and a crosslinking peptide [9–11], and that has no adjuvant property for protein antigens [12].

Wikler [8] has shown that antimicrococcus antibodies are mostly directed against saccharides of the bacterial cell wall and can thus be compared with plant lectins [13]. Their interaction with mammalian cells is

Accepted 23 March 1978.

§To whom correspondence should be addressed.

however more selective than that of lectins as they bind to lymphocytes, to certain tumour cells, but not to erythrocytes [14, 15].

Since the antimicrococcus immunity is characterized by the presence of high titer antibodies of restricted heterogeneity and is subjected to an antigen-dependent clonal expansion, this study was undertaken in mice to investigate if *Micrococcus* prevaccinated mice are able to control the malignant proliferation of leukaemic murine L1210 cells.

MATERIALS AND METHODS

Micrococcus lysodeikticus

A suspension was made of lyophilized *Micrococcus lysodeikticus* (ML) (Worthington Biochem. Corporation) after repeated washings and centrifugations at 3000 ***g*** for 15 min at 4°C, in phosphate buffered saline (0.15 M NaCl–0.01 M potassium phosphate; pH = 7.3) = PBS buffer.

Bacillus Calmette-Guérin

One hundred milligrams containing vials of lyophilized Bacillus Calmette-Guérin (BCG) for scarification were purchased from the Pasteur Institute, Brussels. After recombination with the appropriate diluent and further dilution in Hanks' balanced salt solution, the suspension was kept at 4°C and used within two weeks.

Immunodiffusion

Two dimensional immunodiffusion was performed according to the method of Ouchterlony [16]. Precipitin lines formed at room temperature after 48 hr were stained.

Quantitative agglutination analysis

These were carried out in U shaped wells of Linbro agglutination plates (0.05 ml). The antiserum was mixed with 0.05 ml of phosphate buffered saline and consecutive twofold dilutions were made. After a preincubation period of 30 min at 37°C, 0.05 ml of the micrococcus suspension (2 mg/ml) was added and agglutination was scored after 2 hr at 37°C and expressed in $\log_2$ units.

Electrophoretic procedures

Cellulose acetate electrophoreses were carried out with a Beckman microzone cell model R200. Electrophoresis was carried out in barbital buffer (I = 0.075. pH = 8.6) for 20 min at 250 V at 4°C.

After staining with Ponceau S, the strips were destained with 5% acetic acid and scanned with a Vitatron modular Photometer with scanning accessory.

MICE AND TUMOUR

Mice

Inbred (BALB/c × DBA/2) F_1 animals were supplied by Charles River Breeding Laboratories. Those mice were stored at least for three weeks in an isolation room before we started experimenting. Female CDF_1 mice (female BALB/c × male DBA/2) F_1 animals weighing 19–23 g were used.

Tumour

L1210 lymphoid leukaemia was originally obtained from Mr. I. Wodinsky (Arthur D. Little, Inc., Cambridge, Mass.).

This tumour was maintained in DBA/2 mice by weekly intraperitoneal (i.p.) inoculation. L1210 cells were aspirated from DBA/2 mice and a suspension was made in Hanks' balanced salt solution: 10^4 cells in 0.1 ml solution were injected intraperitoneally to obtain the ascitic form of leukaemia. Animals were randomized into test groups and control groups.

For each survival experiment, 10–20 mice were used. The mean survival time ± the standard deviation of the treated mice and the control mice as well as the dosage and timing of each experiment are specified in the tables. Survivors on day 90 after tumour grafting were considered as long-term survivors and they are not used in the final evaluation of the mean survival time and the standard deviation (M.S.T. ± S.D.). A 25% increase in the mean survival time of treated mice over controls was considered significant and supported by a single tailed Student Fisher test.

Specific immunotherapy

Tumour cells were harvested from the peritoneal cavity of a DBA/2 mouse bearing a 7-day-old L1210 tumour (10^5 cells grafted on day 0) and grown without antibiotics as suspension cultures in Roswell Park Memorial Institute Medium 1640 (RPMI) supplemented with 10% heat-inactivated foetal calf serum. Tumour cells were routinely passaged every 48 hr as stationary cultures in Falcon 3024 flaks or grown exponentially in spinner cultures 48 hr before experimenting. Cultured cells were spun down and adjusted

to 5.10^7 cells/ml RPMI. After irradiation of 8000 rad (250 kV, 12 mA, 95 rad/min) by X-rays, 10^7 cells were grafted to CDF_1 mice.

RESULTS

1. *Natural antibodies to* Micrococcus lysodeikticus

The mammalian gut and part of the digestive tract are attractive loci for non-pathogenic Gram-positive as Gram-negative bacteria that constitute the "bacterial flora" and live in symbiosis with the mammalian host. Housing of these micro-organisms is immunologically restricted to the gut epithelium.

Since the cell walls of most of these bacteria contain carbohydrates or glycoproteins, we were not surprised to find positive agglutination patterns, presumably due to cross-reactions, with *Micrococcus* cells in 25 out of 25 tested sera of pre-immune rabbits at 4°C and 19 out of 25 pre-immune rabbits at 37°C.

Neither sera taken from 48 preimmune BALB/c mice, nor sera taken from 25 pre-immune C57 black/6j mice agglutinated *Micrococcus* cells at 37°C. However, in 17% of BALB/c mice and 4% of C57 black/6j mice, activity was detected at 4°C. These results strongly suggest that the cross-reacting protein acts as a cryoglobulin with low serum titer and low affinity as physiological temperature.

2. *Origin and evolution of the antimicrococcus immunity*

Previous studies in mice indicated that the immune response is higher when the vaccine is inoculated intraperitoneally [17].

One hundred and three CDF_1 mice were vaccinated with 0.15 mg heat-killed micrococcus cells (60°C for 30 min) once a week over 4 weeks.

They received three injections a week of 0.2 mg during weeks 10–14 and of 0.4 mg during weeks 24–29 and 31–36. Blood samples were taken from the retro-orbital plexus at different stages of the immunization period and their sera were subjected to cellulose acetate electrophoresis to check the presence of immunoglobulins of clonal dominance. The presence of antimicrococcus antibodies in the serum was detected by precipitation with lysozyme solubilized cell walls, in double diffusion (immunodiffusion). By quantitative agglutination with 2 mg/ml *Micrococcus* suspension, the serum antimicrococcus antibody titer of every bleeding was determined. This immunization schedule resulted in the production of antibodies of restricted heterogeneity and clonal dominance in 5% of the mice from week 25, 26% on week 30 and 33% on week 37, as seen in Fig. 1. As seen in Fig. 2, the mouse population first responded to the antigen with antibody titers resembling a binomial distribution (weeks 1–23) that shifts to an asymmetric curve on weeks 30–37. Antimicrococcus antibody titers of homogeneous responders were considerably higher (mean $\log_2$aggl. *Micrococcus* = 6.0) than non-homogeneous responder mice (mean $\log_2$aggl. *Micrococcus* = 2.0) on week 37.

3. In vitro *interaction of mouse antimicrococcus sera with L1210 or Ehrlich carcinoma cells*

Using a Leitz Orthoplan microscope, we found that fluorescein conjugated rabbit anti-micrococcus globulins bind to Ehrlich ascites cells [14] and that fixed (0.3% formaldehyde) carcinoma cells can be agglutinated by rabbit antimicrococcus sera. Controls with pre-immune immunoglobulins or sera were negative in both experiments.

Mice that were injected i.p. with L1210 cells preincubated with antimicrococcus gammaglobulins displayed an increase in mean life span, as compared to control mice that received the same dose of tumour cells incubated with the pre-immune gammaglobulins of the same rabbit [17].

Using a panel of mouse antimicrococcus sera of both homogeneous and non-homogeneous responders, we observed that immune sera of syngeneic mice, unlike pre-immune control sera or bacterium, agglutinate L1210 and Ehrlich carcinoma cells *in vitro*. As outlined in Table 1, agglutinations were performed according to the described quantitative agglutination procedure, using 10^7 cultured L1210 cells per ml and 5.10^6 Ehrlich carcinoma cells per milliliter as target suspensions.

4. *Tumour immunoprophylaxis exerted by the antimicrococcus immunity*

Part of the Micrococcus vaccinated CDF_1 mice were subdivided according to the presence in the serum of antibodies of clonal dominance into homogeneous and non-homogeneous responders on week 39. Both groups and a control group of unvaccinated mice were tumour challenged i.p. with 10^5

Quantitative agglutinations were performed at 37°C after a preincubation of 30 min.
Quantitative agglutinations were performed with cultured L1210 cells (10^7/ml) or Ehrlich carcinoma cells (5.10^6 cells/ml) at 37°C, as for the *Micrococcus* suspension.

in vivo grown L1210 cells. Another part of the vaccinated population and a control group received a graft of 5.10^3 leukaemic cells i.p. Vaccinated mice did not show any anti-tumour immunoprotection: for all graft dosages, the mean survival time of vaccinated mice is comparable to that of unvaccinated mice.

Since one could hypothesize that the anti-tumour subpopulation of antimicrococcus antibody (whose affinity for tumour cell epitopes is demonstrated by the agglutination test) is transiently present during the immunization period, a new experiment was devised.

Intact CDF_1 mice received i.p. three 0.1 mg injections a week on weeks 1–4, 0.2 mg on weeks 6–9, 0.3 mg on weeks 11–14, 0.4 mg on weeks 16–19 and finally 0.5 mg on weeks 20–24. On weeks 5, 10, 15, 20 and 25, a part of the vaccinated mice was withdrawn from the population, bled in the retro-orbital plexus and tested one week later for immunoprotection against 10^4 L1210 cells implanted intraperitoneally.

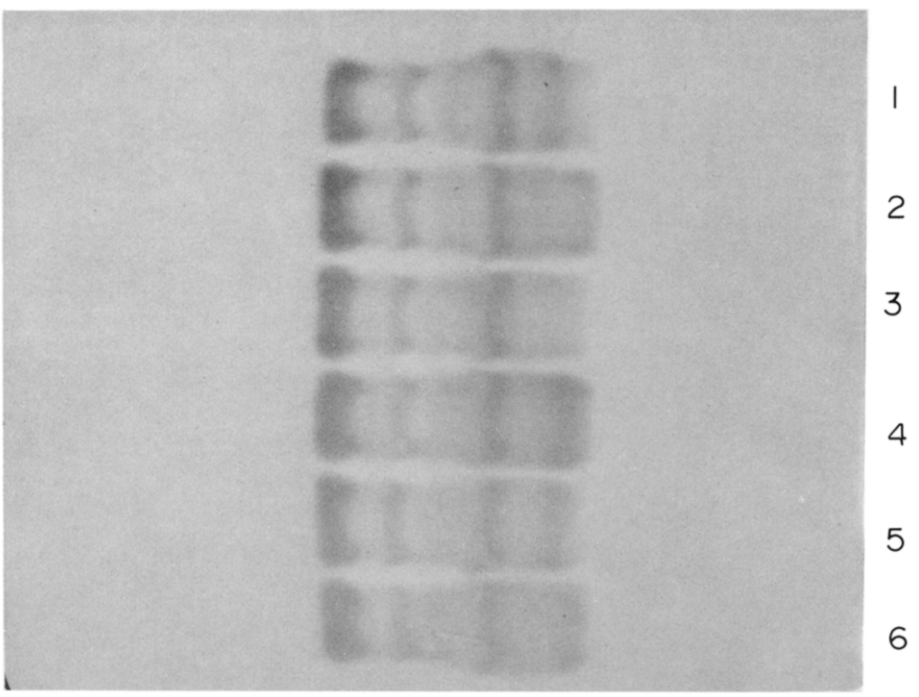

Fig. 1. *Microzone electrophoretic patterns of Micrococcus vaccinated* CDF_1 *mice. Cellulose acetate electrophoreses were carried out with a Beckman microzone cell model R*200. *Electrophoresis was carried out in barbital buffer (Ionic strength* $=0.075$, pH $=8.6$) *for* 20 min *at* 250 V. *The anode is to the left. Notice the presence of immunodominant (clonal dominant or homogeneous) antibodies in the immunoglobulin γ regions of sera* 1, 2, 4, 5 *and* 6 *as compared to pre-immune mouse serum* [3].

Although antimicrococcus antibodies were present from the fifth week in all tested mice, vaccinated mice were never offered a demonstrable anti-leukaemia immunoprotection.

After a rest period of 6 months, we have tested again the immunoprotective capacity of mice vaccinated with micrococcus for 36 weeks. During this period, the humoral antibacterial immune response had slowly decreased, as indicated by comparison of the agglutination patterns obtained from monthly bleedings in the retro-orbital plexus.

was continued by 1 mg injections on days 4, 8 and 12.

Prevaccinated mice that were boosted with micrococcus cells were considerably protected against tumour grafting. The mean life span was significantly ($P<0.001$) increased (M.S.T. = 21.67 days ± 0.58) over the control mice (M.S.T. = 11.3 days ± 0.60) and 57% of long-term survivors were recorded. *Micrococcus* injected on days 4, 8 and 12 in L1210 bearing and unvaccinated mice was unable to induce longterm survivors; yet, it induced an increase in mean survival time (M.S.T.

Table 2. Comparison of anti-L1210 immune protection of prevaccinated and unvaccinated CDF_1 mice treated with Micrococcus *or specific immunotherapy*

Schedule				Mice survival

− (control mice)	−	−	−	11.30 ± 0.60	100	0

CDF_1 mice were vaccinated with *Micrococcus lysodeikticus* during 36 weeks. After a rest period of six months, randomized mice were tumour challenged i.p. with 10^4 leukaemic L1210 cells. Some mice received 1 mg micrococcus injections on days 4, 8 and 12 after tumour grafting, others were treated by a single injection of 10^7 irradiated cultured L1210 cells, alone or in combination with 1 mg BCG or *Micrococcus*. 24 hr after tumour grafting, followed by 1 mg injections on days 4, 8 and 12. Mean survival time (M.S.T.) and the standard deviation (S.D.) of treated mice (T) over control mice (C) are listed and their ratio expressed in percentage (T/C%)
*Significance at $P<0.001$ level.

Micrococcus vaccinated and control mice received 10^4 cells i.p. on day 0. The protective effects of the vaccination with *Micrococcus*, eventually followed by booster injections after tumour challenge, of injection of irradiated cultured L1210 cells or of Bacillus Calmette-Guérin (B.C.G.), were investigated, as illustrated in Table 2.

Part of the vaccinated or control mice received i.p. 1 mg injections of *Micrococcus* on days 4, 8 and 12. Twenty-four hours after tumour challenge, part of vaccinated or control mice received i.p. 10^7 irradiated cultured L1210 cells, alone or mixed with 1 mg of Bacillus Calmette-Guérin (B.C.G.) or 1 mg of *Micrococcus* and the treatment

~19.44 days ± 1.24) as compared to control mice (M.S.T. ~11.3 days ± 0.60) ($P<0.001$). However, all other schedules were unsuccessful, as illustrated in Table 2.

DISCUSSION

In this paper we have studied the immunogenicity of the *Micrococcus*–antimicrococcus system in CDF_1 mice. An immunization schedule that leads to the production of antibodies of restricted electrophoretic heterogeneity and clonal dominance in those mice is described.

In contrast with rabbits where similar mg/kg dosages lead to the presence of homo-

geneous antibodies in the serum after eight weeks of active vaccination, we found that, in mice, immunoglobulins of clonal dominance appear no sooner than the 25th week.

Although Krause *et al.* [18] have demonstrated that the intravenous route is superior to other administration routes in the rabbit, mice were vaccinated intraperitoneally but we do not exclude that other routes may favourably influence the production of those particular immunoglobulins. It is worthy of note that the micrococcus vaccinated population responded to the antigen with antibody titers resembling a symmetric binomial curve until the 30th week. Thereafter, simultaneously with the appearance of antibodies of clonal dominance in the serum of some mice, the distribution curve seemed to be split into two areas: non-homogeneous responders tended to adhere to the low titer responder area, whereas homogeneous responders showed the highest antibody titers. Since L1210 cell membranes are coated with immunoglobulins *in vivo* [19], we decided to use "nude" tumour cells obtained from cell line cultures for the specific immunotherapy and *in vitro* tests. Unlike pre-immune sera, antimicrococcus sera were found to agglutinate non-fixed syngeneic leukaemic L1210 cells as Ehrlich carcinoma cells at physiological temperature.

Therefore we wanted to investigate if a similar binding on tumour cell epitopes due to a cross-reactive immunity might occur *in vivo* and consequently, if micrococcus vaccinated mice should be immunologically resistant to tumour grafting. In our experiments, neither mice producing antimicrococcus antibodies of restricted heterogeneity, nor non-homogeneous responding mice were immunologically protected against 10^5 or 5.10^3 L1210 leukaemic cells.

To exclude the possibility that the antitumor subpopulation of antimicrococcus is transiently present during the immunization period, we vaccinated a new population of intact mice and tested the antitumour immune resistance of those mice at different stages of the immunization period. Again, no anti-L1210 immunoprotection could be demonstrated in those vaccinated mice.

However, since we earlier demonstrated [17] that incubation of L1210 cells with rabbit antimicrococcus gammaglobulins and grafting those cells to intact mice led to the rejection of those incubated cells, unlike L1210 cells incubated with pre-immune globulins of the same rabbit, we hypothesize that the presence of the antimicrococcus antibody *per se* is insufficient to afford an effective immunoprotection. It is possible that the challenged mouse makes an immune response to the rabbit antibody on the surface of L1210 cells. This response could act as a trigger for the immunologic effector mechanisms. Such a trigger can be provided by the complement activating bacteria—*Micrococcus* [20] or Bacillus Calmette–Guérin [21]—and may be also offered by the structure of the Fc part of a xenogeneic antibody (rabbit). Indeed, evidence from multiple sources has been given that clinical as well as murine tumour (including L1210 [22] and Ehrlich carcinoma [23]) growth is accompanied by an impaired T cell function [24] and that mean survival time of skin grafts is considerably prolonged in tumour bearing animals [25]. Cell types known to function in antibody-dependent cellular cytotoxicity include Fc receptor bearing macrophages as well as B and T lymphocytes [26] and many of them, after activation, display membrane receptors for complement [27, 28].

Compatible with our assumption is the observation that booster doses of 1 mg *Micrococcus* to Micrococcus prevaccinated mice on days 4, 8 and 12 are able to induce 57% of long-term survivors cured on day 90 after grafting 10^4 L1210 cells intraperitoneally and to increase significantly ($P<0.001$) mean life span of vaccinated mice over control mice. However, mean life span of non-prevaccinated and Micrococcus treated mice was considerably increased ($P<0.001$) over control mice, but no long-term survivors were recorded. Neither prevaccinated mice given irradiated cultured L1210 cells alone or in combination with B.C.G. or M.L., nor unvaccinated mice given the same treatment were immunoprotected against tumour grafting.

It seems logical to assume that irradiated tumour cells (10^7) injected 24 hr after tumour grafting may compete with tumour grafted cells (10^4) for the antimicrococcus anti-tumour subpopulation *in vivo*, so that the immunoprotective effect is abolished.

It is important to mention that, in contrast to the experiments presented by Mathé [29], lyophilized B.C.G. vials were used in order to compare the activity of the bacterial with the activity generated by heat-killed *Micrococcus lysodeikticus* and furthermore, that mice were treated i.p.

In general, we conclude that the *Micrococcus*–antimicrococcus immunobacterial system is a promising anti-tumour system that, if adequately monitored, may afford a considerable immunoprotection against murine leukaemia tumour growth.

Abstract—*Daunomycin, an anti-tumor drug, the activity of which is known to be exerted mostly in the nucleus, was covalently attached to anti-tumor antibodies or to normal immunoglobulin. The attachment was accomplished either by direct linking or via a dextran bridge. All the conjugates retained a significant amount of their original drug activity. The capacity of these macromolecular conjugates to penetrate the malignant cell and the nucleus was examined. The compounds were found to be able to penetrate the cell membrane in the conjugated form. Daunomycin linked to anti-tumor antibodies entered the cell at a higher rate than daunomycin attached to normal Ig and daunomycin–dextran. In normal cells, no difference in uptake was observed between drug-immunoglobulin or drug-anti-tumor-antibody conjugates. Uptake studies with daunomycin conjugates, radioactively labeled by different methods, suggest that the drug is released from the complex after penetration into the cell but probably enters the nucleus as the free drug.*

INTRODUCTION

THE USE of antibodies [1–4] or other specific [5] and non-specific [3, 5, 6–10] macromolecules as carriers of anti-tumor drugs has been investigated by various groups throughout the last few years. The mode of action of these drugs requires their penetration into the cell and mainly into the nucleus, where they both intercalate and adlineate with nuclear DNA [11, 12]. We have used the anthracyclines daunomycin and adriamycin, linked to anti-tumor immunoglobulins or antibodies [13–15] as specific carriers to target cells, in an attempt to minimize the detrimental effect of these toxic drugs on normal cells. The covalently linked drug-antibody conjugates were shown to retain an appreciable amount of drug activity *in vitro*, and, as found recently, also *in vivo*.

We have since synthesized conjugates in which the linking of the anthracyclines to the antibody was not made directly but through a dextran bridge and thus obtained a high conjugation of the drug to the antibody.

We have attempted to clarify the mechanism of action of the conjugates of the drug with antibody or with immunoglobulin by testing the ability of these complexes to enter the cells. Previously it was shown that antibodies directed against the major histocompatibility locus are able to enter the cell and bind to the nucleus [16]. In this study, the uptake of radioactively labeled derivatives of the conjugates by tumor and normal cells and their nuclei was explored in correlation with their activity *in vitro*.

MATERIALS AND METHODS

Daunomycin–HCl (lot 33) was a gift from Farmitalia (Milano, Italy). Tritiated daunomycin (specific activity 14 Ci/mmole) was a gift from New England Nuclear (Mass., U.S.A.). Sodium boro[^{3}H]hydride (specific activity 293 mCi/mmole), and [5-^{3}H]uridine (specific activity 25 Ci/mmole) were purchased from the Radiochemical Centre (Amersham, England). [6-^{3}H]Thymidine (specific activity 4.5 Ci/mmole) was obtained

Accepted 20 February 1978.

from Nuclear Research Center, Dimona, Israel). Sodium borohydride was purchased from Merck (Schuchardt, Germany). Sodium periodate and mannitol were obtained from British Drug House (Poole, Englend). Biogel P-60 was purchased from Bio-Rad (Calif, U.S.A.).

Antibodies were prepared in goats against a soluble papain digest of a tumor cell membrane (Yac lymphoma carried out as a line in A/J mice) [17]. The antibodies were purified by the use of glutaraldehyde-fixed Yac Cells (10^7 cells/ml with 0.1% glutaraldehyde for 90 min at room temperature) as an immunoadsorbent and followed by elution with 2 M NaI (Merck, Darmstadt, Germany), by batch elution twice for 1 hr at 37°C. The normal goat immunoglobulins were precipitated from goat sera by 33% saturated ammonium sulphate.

Preparation of daunomycin conjugates

The binding of daunomycin to antibodies or to normal Ig was performed as previously reported [13], by oxidation of the sugar moiety of the daunomycin with periodate, linking it to the amino groups of the protein, followed by reduction of the Schiff bases with sodium borohydride. The only difference was that in the present study mannitol was added to the pure daunomycin in a ratio of 5/1. The oxidation of daunomycin in the absence of mannitol, even when the concentration of sodium borohydride was decreased from 0.1 to 0.02 M resulted in loss of solubility and lower yields.

The binding of daunomycin to dextran was performed by the use of periodate-oxidized dextrans [18]. The Schiff bases formed between the aldehyde groups on the oxidized dextran and the amino group on the sugar moiety of the drug after an overnight incubation at room temperature, were quantitatively reduced by sodium borohydride for stabilization of the binding.

Daunomycin–dextran-antibody or IgG

Oxidized dextran to which daunomycin had been linked (ratio of daunomycin to dextran 1:2) was incubated overnight with the immunoglobulin fraction or purified antibody preparation (Ig to dextran ratio 1:1) at 4°C and the resulting complex was reduced by $NaBH_4$ as above. Dextran-bound drug or Ab-dextran bound drug were separated from free drug by gel filtration on Biogel P-60. The conjugates were characterized as follows:

The daunomycin was determined by the absorbance at 495 nm, the antibody or Ig by absorbance at 280 nm (the absorbance of the drug at 280 nm was corrected for) and the dextran was quantitated by weight.

Each preparation was checked by thin layer chromatography for the presence of unbound daunomycin. The various conjugates contained between zero and 3.6% of its daunomycin in an unbound form.

Dialysis of the conjugates against 0.1 M acetate buffer at pH 4.2 resulted in release of 20–30% of the drug, indicating that the reduction was incomplete. However, it was impossible to use more drastic conditions for reduction, since this yields a product with damaged daunomycin as indicated by its decoloration.

The daunomycin content in the various preparations was determined to be as follows: daunomycin–antibody conjugates; 2–3 mole/mole; daunomycin–dextran conjugates; approximately 1 mole/mole (of dextran T-10, mol.wt 10,000); and in the daunomycin–dextran–antibody conjugates between 10 and 30 mole/mole antibody.

Determination of drug activity

Daunomycin activity was assayed by the inhibition of either uridine or thymidine incorporation. The drug or its conjugates were incubated with the tumor cells for a period of 2 hr. Either ^{3}H-uridine or ^{3}H-thymidine were then added for 1 hr at 37°C. The analysis of the incorporated nucleotide was performed as described for ^{3}H-uridine [13]. Overnight incubation (20 hr) of the drug or its conjugates in addition to ^{3}H-thymidine gave similar inhibition results to those obtained for the short incubation period.

^{3}H-labeling of daunomycin

In addition to tritiated daunomycin (New England Nuclear), daunomycin was labeled either by oxidizing its sugar moiety with periodate and then reducing the resulting aldehyde groups by NaB^3H_4, or by direct treatment with NaB^3H_4 without prior oxidation. The labeled preparations were checked by comparison of their chromatographic behaviour in TLC (in chloroform:methanol: water 13:6:1) to that of unmodified daunomycin. The R_F of the oxidized and reduced daunomycin was 0.66, that of the NaB^3H_4 treated material was 0.68 as compared to R_F 0.57 of cold daunomycin. The oxidized and reduced daunomycin lost an appreciable

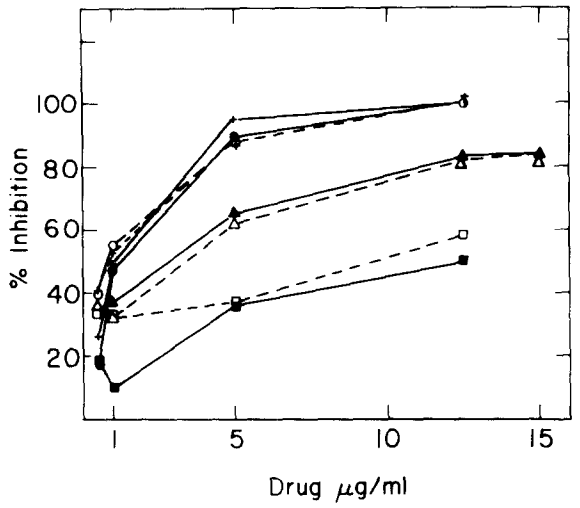

Fig. 1. Daunomycin and daunomycin–dextran activity determined by inhibition of ^{3}H-*uridine (broken line) and* ^{3}H-*thymidine (continuous line) incorporation. part of its drug activity, but the $NaBH_4$ treated compound was as active as the original daunomycin (Fig. 1).

The stability of the radioactive label was assessed by incubation of the labeled compounds at pH values 4.7 and 9.5, respectively, for 24 hr, after which the solutions were absorbed on a poropak Q column, and both efluent and eluent were monitored for radioactivity. Almost no loss in the radioactivity (~0.3%) was observed in acidic or neutral pH. Under basic conditions (pH 9.5) a loss of about 9% was obtained. These results show that the stability of the label in the daunomycin is quite high and should not interfere with the uptake experiments. This is true both when the label is in the sugar moiety (in the oxidized and reduced preparation) and when it is in the quinone ring or the keto side chain (in the reduced product).

Radioactive labeling of daunomycin–dextran and daunomycin–dextran–antibody conjugates

The conjugates were labeled with tritium by different procedures: (1) Tritiated sodium borohydride reduction of the Schiff bases formed during the binding process. (2) Preparation of the conjugates with tritiated daunomycin (catalytic exchange with ^{3}H gas). (3) Combined tritiated daunomycin and reduction by NaB^3H_4. The stability of the label was determined by dialysis of the compound against PBS for 6 hr and monitoring the radioactivity both inside and outside of the dialysis bag. The loss of radioactivity during the dialysis was approximately 4%. When the labeled conjugate was tested by TLC, the amount of radioactivity retained in the origin was about 70% of the total.

The cellular uptake of daunomycin and daunomycin conjugates

The uptake of daunomycin and its conjugates into cells, and their intracellular distribution, were tested by incubating 5×10^6 tumor or normal cells, with various concentrations of the radioactively labeled compounds, at 37°C and for several periods of time mostly up to 4 hr. At the termination of the incubation period the cells were washed extensively, and the extracellular unbound drug or drug-conjugates were counted. The cells were then incubated for 30 min in 1% Nonidet P40 at 4°C, followed by centrifugation (Sorvall 15,000 rev/min for 10 min). An aliquot (0.1 ml) of the supernatant, which included the fraction rich in cellular membranes and cytoplasmic contents, was counted. The pellets composed of the nuclei rich fraction were dispersed in 0.1–0.2 ml 1N NaOH and transferred into scintillation vials for counting. The scintillation fluid contained a mixture of toluene, tritone X-100 and 0.1 N HCl at a ratio of 6:3:1.

Testing the stability of daunomycin conjugates in the presence of cells

Yac cells (1×10^7) were incubated for various periods with radioactively labeled daunomycin conjugates. Incubation was followed by centrifugation. Aliquots of the supernatants were applied to columns of biogel P-60. The antibody-bound and the unconjugated drug were detected according to their elution position from the columns and quantitated by radioactivity and by optical density at 495 nm. The same tests were performed with the NP-40 supernatants of the postincubated washed tumor cells.

RESULTS

The activity of daunomycin and its various conjugates as measured *in vitro* is shown in Table 1 and Figs. 1 and 3. The activity was determined by inhibition of either ^{3}H-uridine or ^{3}H-thymidine incorporation. When daunomycin was directly linked to anti-Yac antibody or to normal Ig, an appreciable amount of its original activity was retained in the conjugates. Linking of daunomycin

Table 1. In vitro *activity of daunomycin and daunomycin-conjugates*

*Yac cells (10^6) were incubated for 2hr at 37°C in the presence of daunomycin or daunomycin-conjugates. Incorporation of [^{3}H]-uridine into cellular material precipitable by trichloroacetic acid was measured and expressed as per cent inhibition (100% of control culture containing no drug).

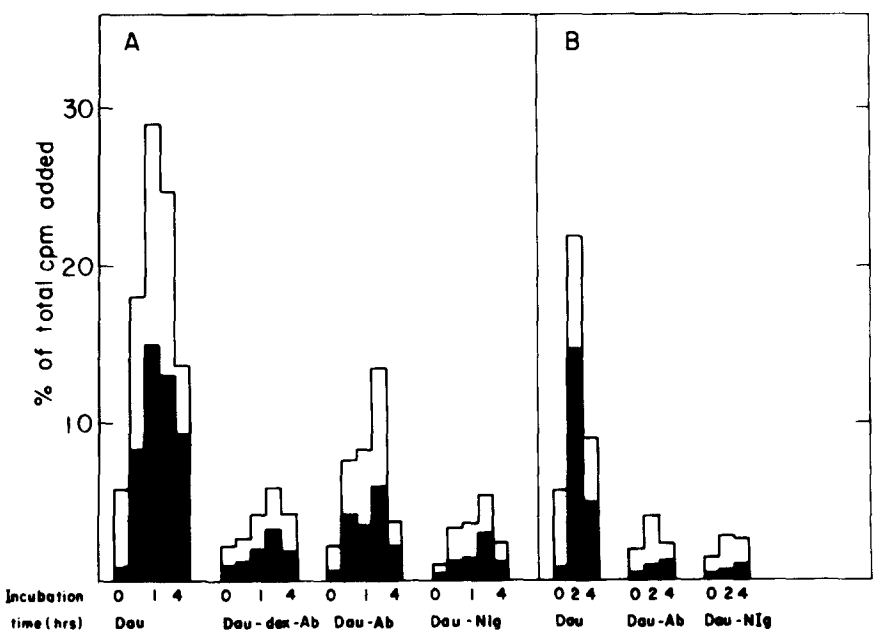

Fig. 2. *The* in vitro *uptake of daunomycin and its conjugates by Yac cells (A) and normal rat lymphocytes (B), measured as a function of time. Measurements of uptake were made at zero time and after* 0.5, 1, 2, 3 *and* 4 hr *following the addition of drug. The total drug accumulation in the cells is denoted by the open bars, whereas the nuclear incorporation by the shaded areas.*

to dextran resulted in a reduction of drug activity and when the dextran served as a bridge between the drug and anti-Yac a further decrease in the capacity to inhibit uridine and thymidine incorporation was observed. Daunomycin, in which the amino sugar was periodate-oxidized and reduced, also showed a decrease in activity, whereas the mere treatment by sodium borohydride had no apparent effect on the *in vitro* activity of the compound.

The uptake of daunomycin and its conjugates by Yac or normal cells (rat splenocytes) is depicted in Fig. 2A and B. It is expressed as % uptake of the total radioactivity added to a fixed number of cells. The distribution of daunomycin or daunomycin-conjugates in the membranes or the cytoplasm and its possible attachment to the nucleus was measured as a function of time of incubation. As can be seen, the free drug controls; daunomycin, oxidized and NaB^3H_4 reduced, or NaB^3H_4 treated, penetrated the cells very rapidly. Since the uptake assay was performed by centrifugation and washing at 0°C immediately after the addition of the drug, high intracellular levels of the free drug were observed at the zero point. Optimal levels of uptake was achieved at a drug concentration of 15–30 μg/ml, with a slight drop at 60 μg/ml. Uptake of the free drug reached a peak at 1 hr incubation, and declined after 3 hr. The accumulation of the drug in or on the

nuclei (shaded areas in the chart) paralled its uptake by the intact cell and amounted roughly to two thirds of the total cellular content.

^{3}H-daunomycin, prepared by catalytic exchange, behaved somewhat differently; i.e. most of the drug added (90% or more) penetrated the nucleus rapidly. In addition, no reduction in its uptake was noted after 3 hr and no decline in its uptake was observed at a concentration of 60 μg/ml.

Daunomycin–antibody conjugates labeled by NaB^3H_4 reduction, whether directly bound or via a dextran bridge, penetrated into the Yac cells and attached to their nuclei, although at a much lower rate than that of the free drug (Fig. 2A). As depicted by the results, daunomycin bound directly to antibodies entered the cells at higher levels than the drug bond, through dextran, to normal Ig. The optimal concentrations were similar to those obtained for free drug without an observed dependence on the amount of antibody in the preparation (the range of concentration tested with 1–3 mg/ml). Drug bound to antibody via the dextran bridge was taken up somewhat more readily at higher concentrations (60–80 μg/ml). The uptake of the bound substances proceeded at a slower rate than that of free drug, peaked at 2–3 hr and slightly decreased after 4 hr. Except for the decline after 4 hr, this corresponds well with the activities of the bound and free drug (Fig. 3). In assays of drug activity maximal levels are reached by the free drug after approximately 90 min, while longer incubation periods (up to 4 hr) are needed for daunomycin conjugate with either dextran or with antibodies via dextran for reaching their maximal potency. As is also depicted in Fig. 2, the accumulation of drug on the nuclei paralleled uptake by whole cells, comprising half to two thirds its value.

In normal non-related cells (rat splenocytes) the uptake of free drug was slightly lower than that by the tumor cells. The daunomycin conjugates with either anti-Yac antibodies or normal Ig (linked directly), were taken up at low rates (Fig. 2B) and did not differ from each other. This was expected, since these cells do not bind goat anti-Yac.

Daunomycin–dextran and daunomycin–dextran–antibody conjugates were tested for their stability in their intracellular and extracellular form. As can be seen from Table 2 both compounds preserve the conjugated form in the presence of cells up to 24 hr. After cell penetration an appreciable amount of free drug remains bound to the antibody dextran (70–75%) and to the dextran alone (43–44%) in the detergent supernatant. In each case the antibody in the conjugate adds to the stability of the complex.

The uptake of conjugates labeled at different positions in the complex is depicted in Fig. 4. In conjugates, whereby only the drug is radioactive, the label accumulates mostly (90%) in the nucleus. On the other hand, in conjugates labeled at the attachment

point between the drug and the macromolecules total radioactivity is divided between the cytoplasmic contents and the nucleus (only about half to two thirds in the latter). Similarly, when tritiated daunomycin was bound to dextran or to dextran-antibody, and the reduction was performed with tritiated sodium borohydride, radioactivity was similarly divided between cytoplasmic and nuclear fractions.

DISCUSSION

Daunomycin is known to react with polynucleotide compounds. The intercalation and adlineation of daunomycin and similar derivatives to DNA was established by various physico-chemical methods. Thus, the cellular activity of the drug is assumed to be mainly nuclear in nature, causing the unavailability of template DNA both to DNA and RNA polymerases [11, 12]. Whether this describes the full scope of the drug activity is not entirely clear. Various data and experimental observations seem to indicate that a wider spectrum of activities could be attributed to daunomycin, including undesirable effects such as cardiac toxicity and carcinogenesis [19], in addition to the observed beneficial effects, i.e. cytotoxicity to tumors. Antimitotic activity and cell destruction was observed with doses ineffective as inhibitors of macromolecular synthesis. In uptake studies most of the drug was accumulated in the nuclei and only a small amount in the mitochondria and microsomal fractions. However, chemical modifications, such as those shown by Israel *et al.* [20], showed that very active derivatives were mostly located in the cytoplasm [21] and not in the nucleus.

In the experiments carried out in this study tritium-labeled daunomycin and its conjugates were used. The stability of the label in all the compounds was checked in order to ensure that the extent of tritium exchange during the 4 hr required for uptake experiments, will not interfere with the experiments or affect their interpretation. The conjugates were found to be stable in the presence of cells during the experiment (Table 2).

The binding of daunomycin to various macromolecules affects its capacity to be taken up by the tumor cells and their nuclei (Fig. 2). Direct daunomycin–antibody conjugates were taken up more readily than those prepared via a dextran bridge. Both of the latter were taken up better than their controls, daunomycin–normal Ig and daunomycin–dextran (daunomycin–dextran was completely excluded from the cells in some preparations). In preliminary experiments with double labeled anti-Yac-daunomycin, where the anti-Yac was labeled by ^{125}I and the drug by ^3H-, both labels were found to be located on the nucleus.

The extent of label found on the nuclei amounted to 50–60% of the total intracellular drug content. The per cent of drug-conjugates taken up by the cells did not change appreciably with increasing concentrations. The uptake was more dependent on concentration with free tritiated daunomycin, similarly to observations of uptake with Hela cells [22]. Free drug uptake is maximal after 1 hr incubation and declines gradually after 3 hr. This is in agreement with results observed with L1210 and 3T12 cell lines [11, 13].

Daunomycin bound to anti-tumor antibodies was taken up more effectively by respective tumor cells than by normal rat splenocytes. With the normal cells no difference was observed between daunomycin–anti-tumor antibodies or daunomycin–immunoglobulin. These findings emphasize the contribution of the surface contact to the uptake by the cells.

No close correlation is observed between the uptake capacity and the inhibitory activity (Fig. 3). All conjugate types retained

a significant amount of the original drug activity. The daunomycin–dextran conjugate was a better inhibitor of nucleotide incorporation than daunomycin–dextran–antibody conjugates (Table 1). All conjugates prepared were at least as active as the free drug in the suppression of tumour development *in vivo*, and daunomycin–dextran and daunomycin–dextran–antibody were in many instances even better [24]. Thus, the cytotoxic activity of the conjugates is not directly related to the penetration of the conjugates into the cells.

The mechanism by which the covalently bound daunomycin conjugates exert their intracellular activity is probably similar to that believed to operate for the non-covalent daunomycin–DNA complexes. The first step in this process is pinocytosis, for which affinity of the complex to the cell surface plays an important role and facilitates the entrapment by the cells. Hence, daunomycin–dextran or daunomycin–dextran–Ig which have no surface affinity to either tumor or normal cells are taken up at lower levels than daunomycin linked to specific antibodies.

Daunomycin directly linked to antibody could be envisaged to enter the nucleus in the conjugate form, or, alternatively, it might be released from the carrier prior to its penetration into the nucleus. The different labeling methods used in our study suggest that the latter process takes place. When most of the radioactive label was in the dextran bridges between daunomycin and antibody, incorporation studies showed that about half of the incorporated radioactivity was found in the cytoplasm and only half to two thirds attached to the nucleus. On the other hand, when tritiated daunomycin was bound to the conjugate so that all the radioactivity was located on the drug, most of the label was found in the nucleus after 3 hr of incubation. When the two labeling methods were combined, uptake was again divided between cytoplasmic contents and nucleus (Fig. 4). Furthermore, linking daunomycin to antibodies by stable peptide bonds, such as direct coupling with carbodiimide between antibody and drug [13] or between an *N*-succinyl derivative of daunomycin coupled to the antibody via *N*-hydroxysuccinimide ester, no daunomycin activity could be demonstrated. The succinyl-daunomycin itself was as active as the original drug (unpublished results). Therefore, it seems that daunomycin, in order to convey its inhibitory activity, is released from its conjugates by acid or enzymatic hydrolysis. Further studies to elucidate the mechanism of action of daunomycin conjugates are in progress.

Abstract—*A pilot study has been carried out on the endocrine status of Hawaiian-Japanese, Japanese and British women. There were no striking differences between the three racial groups when ovarian and pituitary hormone levels were compared. British women had significantly higher plasma and urinary adrenal androgen levels and excreted more urinary corticosteroids than Japanese women: Hawaiian-Japanese women tended to have intermediate levels of these hormones. This effect of environment on endocrine status and its relationship to the risk of breast cancer is discussed.*

INTRODUCTION

WE HAVE been unable to find convincing differences between the endocrine status of normal British and Japanese women aged 16–70 yr that would account for the differences in the incidence of breast cancer between the two races [1–3]. The incidence of breast cancer in Hawaiian women of Japanese ancestry is now similar to that of Caucasians [4] as is that of Japanese immigrants to California [5]. If our results on Japanese and British women are correct, it might be expected that there would be no major differences in the endocrine function of women with Japanese ancestry in Hawaii and the pilot study reported in this paper is an examination of this thesis.

MATERIALS AND METHODS

Subjects

The women studied were divided into three menstrual groups according to menstrual status, pre-menopausal women were those aged 35 yr or more who were still menstruating regularly; "menopausal women" were those whose last menstrual period was more than 6 months but not more than $5\frac{1}{2}$ yr before the date of entry into the study, and "post-menopausal women" were those whose last menstrual period was more than $5\frac{1}{2}$ yr before entry into the study. Women taking steroidal contraceptives within a year of entry or with a history of endocrine or cardiovascular disease were excluded. All British and Japanese volunteers were obtained by personal contact and the Hawaiian-Japanese women were the wives of Japan-Hawaii Cancer Study cohort men, whose names were selected at random and asked to volunteer as study subjects.

The number of women, their mean ages, heights and weights are shown in Table 1. It can be seen that within a given menstrual category the mean and standard deviations of the ages are similar. The Hawaiian-Japanese on average are intermediate in height and weight to British and Japanese women. Both the Hawaiian-Japanese and Japanese women are significantly shorter than British women, although only the Japanese are significantly lighter than British women. There is no significant difference in either height or weight between Japanese and Hawaiian-Japanese women. Although the mean heights and weights for the three racial groups are similar, it could be argued that these figures could hide a disproportionate number of obese or thin women in any one group. Table 2 shows that this is unlikely since the mean body build (expressed as percentage of ideal body weight [6]), is similar in all groups studied.

Collection of blood and urine specimens

In pre-menopausal women the blood and urine was collected between the 16th and

Table 2. *Body-build characteristics*

Category	Pre-menopausal	Menopausal	Post-menopausal
British	99±13 (30)	105±14 (20)	105±12 (30)
Japanese	104±12 (28)	99±18 (19)	111±19 (35)
Hawaiian-Japanese	102±14 (13)	109±20 (21)	116±23 (20)

Results are expressed as (actual body weight divided by ideal body weight) ×100±S.D. Ideal body weight has been taken as height (cm)−100 (6). Figures in parentheses are the number of women in each group.

24th day of the menstrual cycle. On the first day of study, blood was taken into a heparinized container and plasma separated. In Britain and Japan blood was taken between 11.00 and 17.00 hr and in Hawaii at any time during the morning. Urine was collected for 3 days commencing on the 2nd day of study. After collection the urine and plasma were stored at −20°C. The Japanese and Hawaiian-Japanese specimens, packed in solid CO_2, were air freighted to London and arrived frozen. The samples were then stored at −20°C until analysed. Urine specimens having less than 0.7 g/24 hr of creatinine were discarded as being incomplete collections.

Assays

Plasma oestradiol and oestrone were determined using rabbit uterine cytosol in a modification of a method [7] described by Korenman *et al.* [8] in 1969. Plasma progesterone and urinary pregnanediol were measured using the methods of Swain [9] and Moore and Cooper [10] respectively. Urinary oestrogens were estimated by the method of Salokangas and Bulbrook [11] except that recovery was estimated by using tritium labelled steroids and corrected to 100%.

Plasma LH, FSH, TSH and prolactin were all measured by conventional double-antibody radio-immunoassay. The antiserum to FSH was kindly supplied by Dr. W. R. Butt and that to LH by The National Institutes of Health, Bethesda. Gonadotrophins for iodination were supplied by The Medical Research Council, (FSH, MRC 69/104; LH, MRC 71/53). The concentration of FSH and LH were expressed in terms of the MRC standards 68/39 (32.8 i.u./ampoule) and 68/40 (77 i.u./ampoule), respectively. The reagents and protocol for TSH and prolactin were kindly supplied by the National Pituitary Agency, National Institutes of Health, Bethesda.

Plasma dehydroepiandrosterone sulphate (DS) and androsterone sulphate (AS) were measured using gas–liquid chromatography

[12]. The concentration of plasma androstenedione was estimated by a radio-immunoassay method outlined previously [13]. The urinary 11-deoxy-17-ketosteroids (11-DKS), androsterone, aetiocholanolone and dehydroepiandrosterone were determined by the method of Bulbrook [14].

RESULTS

The amounts of ovarian and pituitary hormones in the blood of normal British, Japanese and Hawaiian-Japanese women are given in Table 3. Because of the large number of "*t*" tests performed only levels of $P<0.01$ are considered to be significant. The urinary oestrogen and progesterone metabolites are also shown. All results are expressed in geometric means (with the exception of the oestriol quotient [15]). The salient points emerging from the results in the table are that there are no differences between plasma and urinary oestrogens in pre-menopausal women in the three racial groups. The menopausal Hawaiians have a significantly higher plasma oestrone and lower progesterone than British or Japanese women and the urinary excretion of oestrone follows the same patterns as the plasma precursor. In post-menopausal Hawaiians the plasma oestradiol levels were significantly lower than in the other two groups. Oestriol quotients are not different.

The only differences found in the geometric mean levels of plasma LH was in the pre-menopausal group where the Hawaiian women had a significantly higher mean plasma LH level than the British women.

The geometric mean plasma FSH levels were similar for all racial groups except in the post-menopausal group where Japanese women had significantly lower levels than Hawaiian women.

Prolactin levels were similar in all three racial and menopausal status groups.

As far as TSH is concerned, the menopausal Hawaiian women show a significant increase in concentration compared to similar Japanese women.

Androgens

The geometric mean levels of plasma and urinary androgens are shown in Table 4.

Since the androgens are more highly age-related than menopausal-related, regressions of androgen levels on age were calculated.

The logarithms of the DS, AS, androstenedione and 11-DKS values were highly significantly correlated with age in all three racial groups, with the sole exception that in Hawaiian-Japanese women androstenedione did not correlate with age, almost certainly because of the small number of subjects.

When the age-adjusted means calculated from the best-fit line are compared, both Hawaiian-Japanese and British women have significantly higher levels of DS than Japanese women ($F=20.5$; $P<0.001$ and $F=13.0$; $P<0.001$ respectively). Conversely, the Hawaiians resemble the native Japanese in that their androstenedione levels are significantly lower than those in British women (British vs Japanese $F=24.0$, $P<0.001$; British vs Hawaiians, $F=14.6$, $P<0.001$).

The amount of 11-DKS excreted by the three groups is similar to the pattern for androstenedione in that the Japanese and Hawaiians excrete significantly less of these compounds than the British ($F=22.5$, $P<0.001$; $F=7.4$, $P<0.01$).

This trend was observed for both urinary androsterone and aetiocholanolone, although the difference in androsterone excretion between Hawaiians and British women was not significant.

Ratio of androsterone (5α) *and aetiocholanolone* (5β) *excretion*

The mean arithmetic ratio of androsterone to aetiocholanolone (5α/5β) is significantly lower in British women compared to Japanese women in all the age groups studied ($P<0.01$, <0.01 and <0.001 for pre-menopausal, menopausal and post-menopausal groups, respectively). This ratio for Hawaiian-Japanese women lies intermediate between the British and Japanese groups for all age groups (see Fig. 1) and is not significantly different from either race.

Urinary 17-hydroxycorticosteroids

The amount of 17-hydroxycorticosteroids excreted by British women was greater than that for Japanese in all menstrual groups, although the difference was only statistically significant between the pre-menopausal groups. The Hawaiian-Japanese excreted intermediate levels of 17-hydroxycorticosteroids.

DISCUSSION

In pre-menopausal Hawaiian women, the only difference noted was that the LH

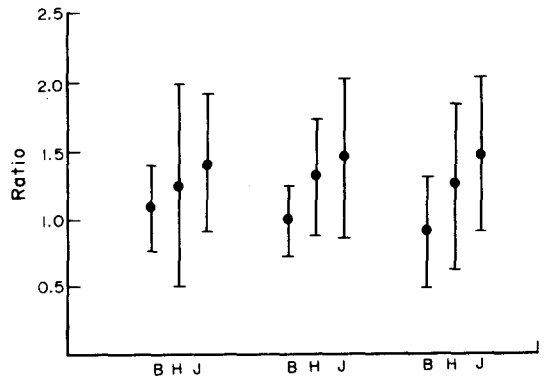

Fig. 1. The ratio of urinary androsterone (5α) to aetiocholanolone (5β) excretion in normal British, Japanese and Hawaiian-Japanese women. The mean±S.D. of the 5α/5β ratio for premenopausal, menopausal and postmenopausal British (B), Hawaiian-Japanese (H) and Japanese (J) normal women are shown from left to right, respectively.

levels were higher than those in British women. No differences were found in other ovarian or pituitary hormone concentrations in British, Japanese and Hawaiian-Japanese women. No pattern emerges that would enable us to relate endocrine status to the three different incidence rates: indeed, if ovarian and pituitary hormone levels were a determinant factor in the incidence of breast cancer, it would be predicted that the future rate in all 3 racial groups would be identical. It might be worth commenting on the fact that there are no differences in prolactin levels in the three groups since so much has been made of the importance of this hormone in carcinogenesis [16–18]. These results are in agreement with literature

DS, AS, and Δ-4 are plasma dehydroepiandrosterone sulphate, androsterone sulphate and androstenedione, respectively. 11DKS, A, Ae, DHA and 17-OHCS are urinary 11-deoxyketosteroids, androsterone, aetiocholanolone, dehydroepiandrosterone and 17-hydroxycorticosteroids, respectively. 5α/5β is the ratio of androsterone to aetiocholanolone.

in which the mean plasma prolactin levels in women with breast cancer have been shown to be similar to that in normal healthy controls [19–24]. Furthermore, abnormalities in plasma prolactin levels are not associated with such risk factors as age at first child, age at menarche, interval between first child and menarche, weight or family history [25]. However, Kwa *et al.* [25] and Henderson *et al.* [26] have reported abnormal prolactin levels associated with family history. There are also reports of abnormalities in nycthemeral rhythms in high risk groups [25, 27], but this has not been investigated so far in studies on geographical risk, and the design of the present study would not have permitted us to detect such an abnormality.

Turning to menopausal and post-menopausal Hawaiian-Japanese women, the characteristics of this group are an increased concentration of oestrone in urine and blood and an increased TSH level. Whether these differences reflect an alteration in the hormonal events of the menopause in Hawaiian women is not clear, but they appear to be unique to the Hawaiian women in that these hormone levels do not differ when British or Japanese women are compared.

In post-menopausal Hawaiians, plasma oestradiol was lower and plasma FSH higher than in British or Japanese women.

The differences in androgen status are very complex. On the one hand, plasma androstenedione and urinary 11-DKS and aetiocholanolone are significantly less in Hawaiian than in British women, and resemble those in Japanese women. However, plasma DS levels are significantly higher than those in Japanese women and resemble those of British women. Our conclusion is that environmental changes alter androgen status in a differential fashion. This is very unlikely to be solely due to changes in body-weight (see Table 1).

The measurement of ovarian and pituitary hormones in this pilot study reinforces the conclusions reached earlier—namely that levels of these hormones do not explain differences in incidence [1–3]. As for the androgens, the results are paradoxical. In British women, subnormal excretion of urinary androgen metabolites is associated with an increased risk of breast cancer [28–30]. In this study the converse is the case; higher plasma and urinary androgen levels are associated with an increased incidence rate. What is even more extraordinary is the finding that in both Japanese and Caucasian women a sub-normal excretion of androgen metabolites is associated with a poor prognosis [31–34] which implies that similar mechanisms operate in both races. It is still possible, therefore, that those Japanese and Hawaiians whose androgen levels are at the lower end of their respective normal ranges are at enhanced risk.

The impression from this pilot study is that changes of environment bring about some alterations in endocrine function, mainly in the androgens. For example, Westernization appears to be associated with a decrease in the $5\alpha/5\beta$ ratio, with an increase in plasma DS, but with no marked change in plasma androstenedione and in urinary 11-DKS. The changes in $5\alpha/5\beta$ ratio are of particular interest in that this is affected by thyroid function; the high and low ratios being associated with hyper- and hypothyroidism, respectively. Corticosteroid levels are lower in Japanese than in British women with the Hawaiians in an intermediate position.

But there is a striking similarity in the levels of the hormones regarded as classical carcinogens. The differences in incidence may therefore be due to factors other than hormones and these may be immunological [35–37] or an inter-relationship between androgen and corticosteroid levels and immune response [38, 39]. Before this conclusion is accepted, much more work is required on endocrine function in children and adolescents in all three races (since early events may be of great importance) and in a more thorough examination of the difference we have found at the menopause.

Variation in Expression of S_3 Antigen in Human Sarcoma Cell Lines: Influence of Passages and Medium on Generation of S_3*

JITENDER K. SETHI† and YASHAR HIRSHAUT

Sloan-Kettering Institute for Cancer Research, 425 E. 68th St., New York, New York 10021, U.S.A.

Abstract—*An antigen S_3, common to human sarcomas, has been detected by complement-fixation methods in sarcoma cell cultures (JNCI 57:489, 1976). Initial observations suggested that S_3 was present only during passages 1–3 and uniformly absent in older cell lines. This study was undertaken to determine the constancy of expression of S_3 in repeated passages in S_3-bearing cell lines. In addition, the influence of trypsinization and feeding on S_3 production were studied. Cell cultures prepared from 2 fibrosarcomas and chondrosarcoma were studied in detail in this regard. At each passage a sample was taken for cytological examination and another to determine whether S_3 was present. Expression of S_3 antigen was found to be extremely variable and no change in the distribution of cell types, morphologically identified, was noted, regardless of culture conditions and passage. The study confirms that S_3 antigen is most consistently expressed in early passages of human sarcoma cell lines and that this antigen may reappear in passages even if absent for as long as 4 serial passages. The variability of antigen production cannot be attributed to details of the trypsinization procedures used, the presence or absence of cell products in the medium used, or to the selection of specific cell types in the culture with the passage of time.*

INTRODUCTION

IN THE investigation of human tumor associated antigens, tissue culture cell lines have frequently served as the principal sources of antigen. Among the antigens which have been detected in cultured human cells are those related to melanoma [1, 2], sarcoma [3–8], Hodgkin's disease [9] and gliomas [10]. Unfortunately, in most instances antigen expression is quite variable. Often the antigen is expressed only for a short period, during a single passage or several early passages, and then seems to disappear. In this paper, our efforts to study antigen expression over a several month period in human sarcoma cell lines is reported. In this way, it was hoped to gain added insight into the basis for variation in tumor antigen expression under cultured conditions. For the purpose of this study the antigen assayed was S_3, a complement fixing antigen associated with cultures of human sarcomas [11]. Initial studies had suggested that S_3 was present only during the first three passages of sarcoma cell cultures and was absent in older established cell lines. Observations were made with repeated passages to determine the constancy of expression of S_3 in S_3-bearing cell lines. In addition, the influence of trypsinization and feeding on S_3 production were studied.

Accepted 19 April 1978.

MATERIALS AND METHODS

Tissue culture

Sterile tumor samples were obtained from patients undergoing surgery at the Memorial Hospital for Cancer and Allied Diseases, New York. The tissues on arrival at the laboratory were immeditaely processed for growth in tissue culture using RPMI-1640 with 20% heat inactivated filtered fetal calf serum. Details of techniques used to establish

cell cultures have been described in considerable detail elsewhere [12]. All cell lines were tested periodically for mycoplasma by Fogh's method [13] and any line found contaminated was discarded. Cultures were grown at 37°C and fed with fresh medium once every 3 weeks or more frequently if indicated by a marked increase in the acidity of the culture medium.

S_3 antigen assay

The micro-component fixation technique utilized to determine the presence of S_3 antigen in a cell line has previously been reported [11, 14]. In the present study, antigen preparations were made from cell lines during serial passages.

For preparation of S_3 antigen, confluent cells were harvested with sterile rubber policemen and placed in a 20% by volume cell suspension with phosphate buffer saline (PBS). The cells were then frozen and thawed 3 times after which they were sonicated (20 sec/ml) in 1 min bursts. Such preparations were stored at −70°C until use. These were tested with a standard set of unknown S_3 positive and negative sera obtained from sarcoma patients and normal individuals.

For the test, all dilutions were made with veronal buffer saline (VBS), pH 7.4. The sera were diluted with an equal volume of VBS and then inactivated at 56°C for 30 min. Sheep red blood cells (SRBC) were procured from New York City Department of Health. Amboceptor (Difco Laboratories, Inc. Detroit Mich.) was pretitered and freshly diluted for incubation with SRBC. Pooled titered human cord sera served as a source of complement. Each experiment included control wells of antiserum antigen and complement alone to which sensitized SRBC were added to show that none of the test components were themselves anticomplementary and that a positive reading denoted an antigen–antibody reaction.

Experimental modification of culture conditions

To examine the effect of passaging and growth conditions of S_3, cell cultures derived from two fibrosarcomas and one chondrosarcoma were transferred after either trypsinization or scraping and grown in RPMI-1640 with 20% inactivated calf serum. Then, half the cells handled by each method were fed at 2–3 week intervals by complete replacement of medium: the other half by replacement with 50% fresh medium. A sample was taken at each passage to check for S_3 activity and another sample for cytological examination. The experimental design for RFS-75 is illustrated in Fig. 1. Cell lines BCS-72 and LFS-98 were also processed in 4 batches the same way, up to passage 3 and 5 respectively.

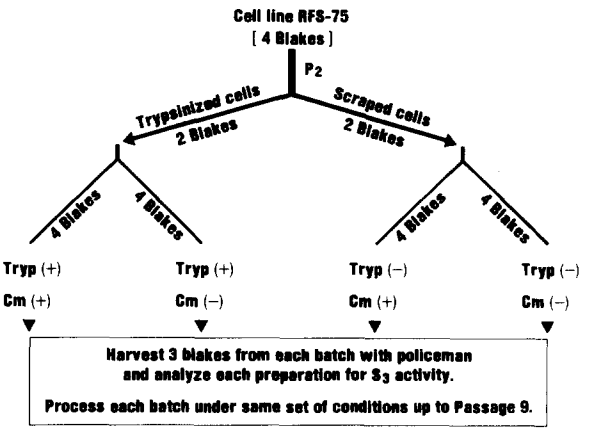

Fig. 1. Experimental design to examine effect of medium and subculturing conditions on S_3 expression. Tryp = trypsinization, Cm = conditioned medium.

Cytology

The fixation and staining techniques for cytological examination of tumor cell lines are described in detail elsewhere [15]. Briefly, the harvested cell pellet from each batch was suspended in 15 ml Earle's balanced salt solution and handled in two ways. The first was the monolayer technique, by which a few drops of the cell suspension were added to a large Leighton tube containing medium with 20% FCS. The cells were allowed to attach and grow on the surface of a glass slide placed in the tube. After incubation for 1–2 days, the cells were fixed in 70% ethyl alcohol and stained with Papanicolaou stain [16]. The second method was a smear technique. The remaining cell suspension was fixed by the addition of an equal volume of 70% ethyl alcohol.

After at least 24 hr fixation at room temperature the cell suspension was centrifuged for 15 min. The pellet was smeared on 4 or 5 albuminized microscope slides. These smears were then fixed in 80% ethyl alcohol for an hour prior to staining with Papanicolaou stain.

RESULTS

To date, 47 successful cultures have been initiated from 78 specimens available for tissue culture (60%). These lines have been

examined for S_3 activity over number of passages. As shown in Table 1, 21 lines (44%) were found to contain S_3 in at least one passage. The data for 13 cell lines studied for 3 or more passages for S_3 expression is given in Fig. 2. Of these 13 lines, 11 (85%) expressed S_3 antigen activity during the first 2 passages. By the third passage, only 8 lines were S_3 positive (61%) and in the fourth passage 5 of 10 lines tested showed similar activity (50%). All 5 cell lines retested during a fifth passage, that is, after being in cell culture for about 4 months, had initially been S_3 positive but were now negative. These were respectively 5 lines followed for 6 passages, 4 for 7 passages and 2 for 9 or more transfers. Of the 5 cell lines followed for 6 passages or longer, 3 remained S_3 negative. The exceptions were RFS-75 and KGS-116. Preparations from cell line RFS-75 during passages 6 and 5 did not show the presence of S_3 but did express the antigen again in passage 6, although it then disappeared. Cell line KGS-116 showed similar fluctuations in the expression of S_3. This antigen was present in passage 1, 2, 4, 9 and 11, but absent in intervening passages. Between passages 4 and 9, which were positive, there were four passages of the same line tested which showed no S_3 activity.

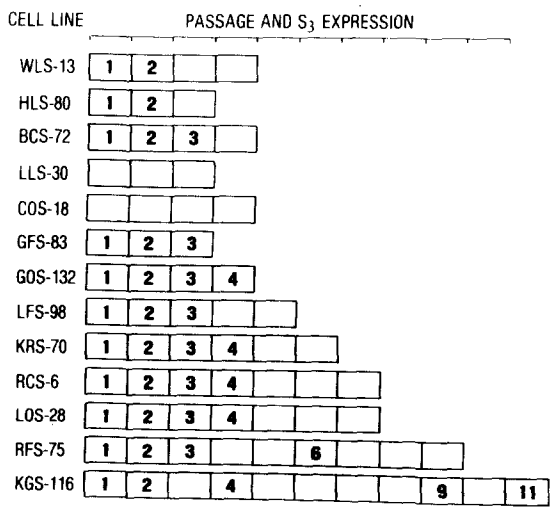

Fig. 2. Variation of S_3 expression with passage. Number denotes the passage in which S_3 was present.

When RFS-75 was studied according to the scheme in Fig. 1, trypsinization and the use of conditioned media both were found not to influence S_3 expression. Preparations from passages 3 and 6 were strongly antigen positive and material from passage 7 weakly positive under all 4 test conditions (Fig. 3). Of interest was the simultaneous appearance and disappearance of antigen in the separate culture bottles examined for S_3. In LFS-98, the antigen was expressed in all batches during passages 1 and 2,

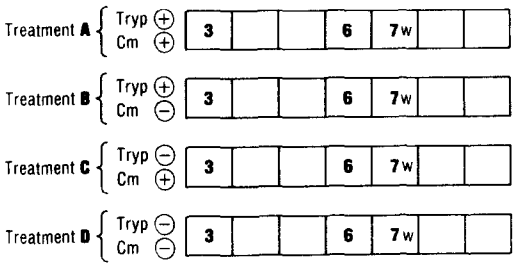

Fig. 3. Antigen expression in RFS-75. Tryp = trypsinization, Cm = conditioned medium, w = weak. Number denotes passage having S_3 activity.

but was completely absent in all cultures of subsequent passages up to passage 5. LFS-98 could not be grown beyond passage 5. Cell line BCS-72 also expressed S_3 antigen in all the 4 batches of passages 1 and 2, but absent in passage 3. Upon cytological examination, no changes in the distribution of cell type present in culture were observed which coincided with changes in antigen expression, conditions of transfers or passages (Fig. 4).

DISCUSSION

While this study confirms that S_3 antigen is most consistently expressed in early passages of human sarcoma cell lines, it also established for the first time that this antigen may reappear in passages even if absent for as long as 4 serial passages. The variability in antigen production cannot be attributed to details of the trypsinization procedures used, the presence or absence of cell products in the medium used, or to the selection of specific cell types in the cultures with the passage of time.

The inconsistent expression of human sarcoma associated antigens in cell lines derived from surgical tumor materials has previously been observed although not directly studied. Priori and co-workers [4] had detected a common sarcoma antigen in early passages only of two cultures of osteogenic sarcoma they tested. In previous work from this laboratory [3], S_1 production was seen to vary with passage although it tended, unlike S_3, to be more readily found in late passages. S_2, a fetal antigen studied in our laboratory [7] was also consistently expressed in early passages only. Moore *et al.* [6] have reported that 10 out of 14 sarcoma cell lines they examined were positive for a common antigen and that the expression of their antigen varied from passage to passage. Bloom [5] has shown that sensitivity of cultured sarcoma cells to the cytotoxic effects of allogeneic antibodies varies with the passage tested. Recently, Cornain *et al.* [2] observed fluctuations in production of melanoma associated antigens which they attributed to changes in culture conditions and growth rate of cells.

The results of present study make it clear that statements describing antigen expression *in vitro* as limited to specific passages or time periods in the life of a cell line cannot be accepted until a sufficient number of appropriate lines have been serially tested for long periods of time. Further, the conditions which determine optimal and consistent expression of tumor antigens in tissue culture systems remain to be defined. Finally, failure to detect an antigen in any single sample of cultured tumor cells should not be accepted as evidence that such a marker is not associated with these cells. If followed diligently, subsequent generations of the same cells may produce readily detectable quantities of antigen.

Epidemiologic Characteristics of Urinary System Tumors and Balkan Nephropathy in an Endemic Region of Bulgaria

I. G. NICOLOV, I. N. CHERNOZEMSKY, T. PETKOVA-BOCHAROVA, I. S. STOYANOV and I. I. STOICHEV

Institute of Oncology, Medical Academy, Sofia 1156, *Bulgaria*

Abstract—*In the endemic region of Vratza district, Bulgaria a close epidemiologic similarity was observed between endemic nephropathy (EN) and urinary tract tumors, in particular neoplasms of renal pelvis and ureter. They correlate geographically, affect more women as well as middle aged people, elicit very high incidence rates, reveal a tendency for familial aggregation of cases. In hyperendemic villages age-adjusted annual incidence rates per* 100,000 *were* 43.5 *in men and* 74.2 *in women for tumors of renal pelvis and ureter and* 38.7 *and* 24.6, *accordingly, for tumors of urinary bladder. Urinary tract tumors were often multiple, especially in patients with EN, and as a rule they originate from the uroepithelium. Among all patients with urinary system tumors (UST)* 27.3% *were also registered for EN while UST were found in* 6.5% *of the EN patients. In patients with concurrent occurrence of EN and UST nephropathy was first registered in* 51% *of the cases against in* 18% *for UST.*

The observed epidemiologic similarity between En and urinary tract tumors, their location in urinary system and the fact that they frequently combine is seen as a proof of a close etiologic and pathogenic relationship between the two diseases.

INTRODUCTION

ENDEMIC (Balkan) nephropathy (EN) is a progressive kidney disease observed so far in rural areas of Bulgaria, Yugoslavia and Rumania [1]. In these areas a frequent occurrence of urinary system tumors (UST) has also been encountered in recent years [2–4]. Although intensive investigations on both diseases have been carried out their etiology is not clear and is still a matter of speculation [5].

In this paper, following a report on the geographic correlation between EN and UST occurrence in Vratza district. Bulgaria [6], we present further evidence on their epidemiological correlation and concurrence in some of the patients. Parallel population studies on both disorders are at present unavailable.

MATERIALS AND METHODS

EN cases in Bulgaria have been registered in an area of around 1800 km^2 and a population of about 40,000 people. Our studies were carried out in 23 villages in the same area. The villages were divided into three groups on the basis of EN incidence rates in all endemic villages for the years 1965–1974: *Group A* included 8 villages with highest incidence of EN; *Group B*—7 villages with a moderate EN incidence; *Group C*—8 non-endemic villages, neighbouring the others. All groups of villages were comparable in size, sex distribution, social and working conditions of their population.

Information on EN has been collected from the files of patients registered at the Kidney Disease Clinic, Vratza District Hospital. Cancer cases were sought after a survey of the cancer notification forms, of medical registers in the villages, of medical records in the regional hospitals and in central urologic clinics. This preliminary information was reviewed carefully and cases confirmed on histologic, macroscopic, cytologic, radiologic and/or clinical evidence were analysed. The information on EN and UST was complemented by interviews of the patients or their relatives by members of our investigation team. Annual incidence rates of EN and UST in the years 1965–1974

Accepted 24 April 1978.

were age-adjusted against a standard world population [7]. Analyses on concurrent affection of people by both EN and UST were done on patients registered in the years 1965–1976. Papillomas and carcinomas of urinary tract were considered together, as it is generally accepted [8].

All quantitative data were evaluated statistically: differences between mean values were tested by the Student's *t*-test while the Chi-square test was used to evaluate the hypothesis of equal risk and a correlation analysis between incidences of EN and UST was made. Values of $P<0.05$ were considered significant [9].

RESULTS AND DISCUSSION

More than 2/3 of all EN patients, registered between 1965 and 1974 in the endemic area of Bulgaria, came from the villages in group A—463 cases and in Group B—182 cases. During the same period of time 185 cases with UST were registered in the studied villages. Their distribution by sub-sites, sex and domicile is given in Table 1. On this basis data on annual age-adjusted incidences, mean age and sex ratio of EN, tumors of kidney pelvis and ureter, and tumors of urinary bladder are represented in Table 2, while Fig. 1 illustrates the age distribution

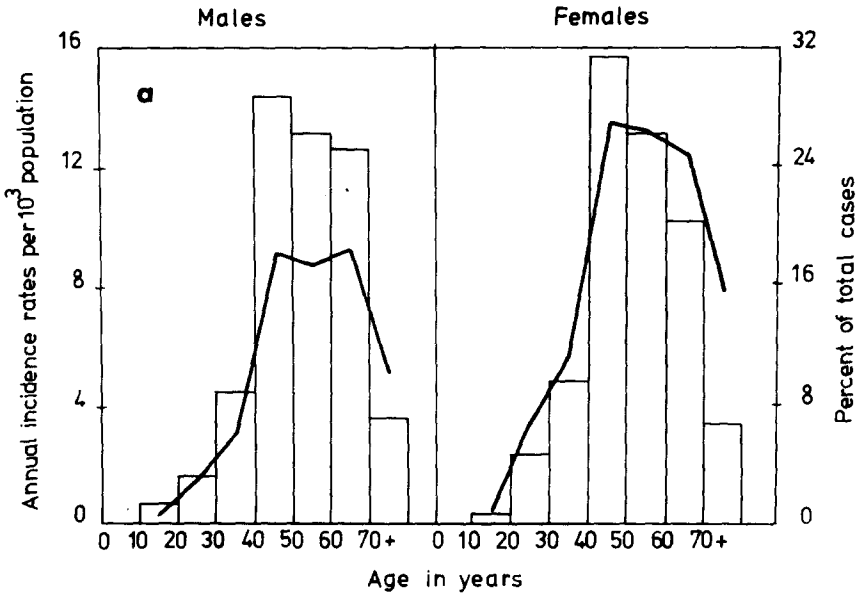

Fig. 1(a). Annual age-specific incidence rates (line) and percentage of distribution (columns) by age and sex of patients (a) with endemic nephropathy (EN).

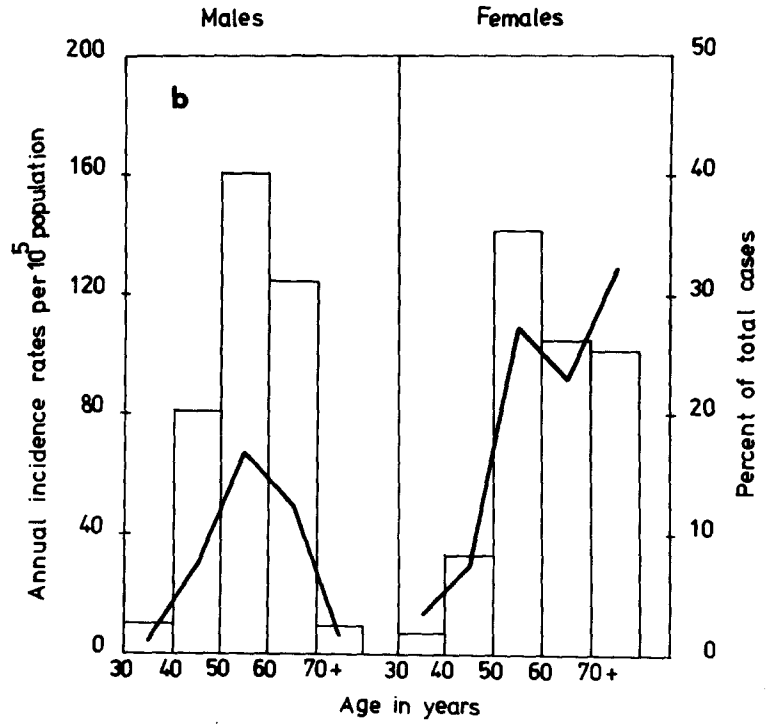

Fig. 1(b). with tumors of kidney, pelvis and ureter.

of the patients with this diseases. Histologically 85% of all urinary tract tumors were from the uroepithelium, 7% were squamous cell carcinomas and 8% were undifferentiated carcinomas.

The results show rather specific characteristics and an interesting relationship between EN and UST:

In the hyperendemic villages UST incidence is in the range of the most common neoplasms recorded for many world populations [8], whereas EN is the leading cause of deaths [6];

The sub-site distribution of UST shows a particularly high occurrence of tumors of kidney pelvis and ureter. Their annual

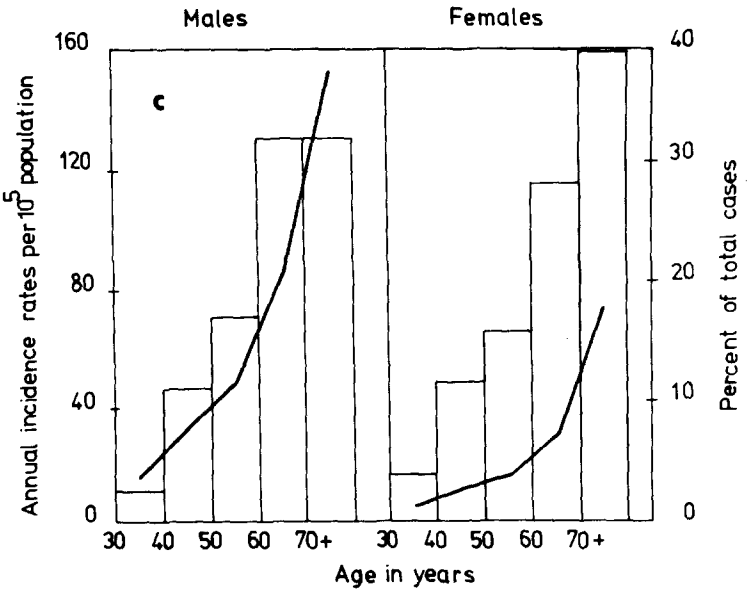

Fig. 1(c). with tumors of urinary bladder for the years 1965–1974. The patients with EN were registered in 8 hyperendemic villages (group A), whereas those with tumors, in 23 villages: 8, with highest incidence of EN; 7, with moderate incidence of EN and 8, with no EN incidence. All villages are situated in the endemic region of Vratza district (Bulgaria).

rates in males and females are 50 and 150 fold higher in comparison with the rest of the country [10–12]. The incidence of parenchyma-cell kidney tumors is close to that in the country as a whole, while urinary bladder neoplasms take an intermediate position. The data, obtained on a population survey, closely resemble observations made on clinical material in Bulgaria [2, 13] and Yugoslavia [3, 4].

It has to be emphasized that on a village basis of a village survey the incidence of EN and UST are highly correlated ($r=0.60$). The mean age of patients with EN as well as of patients with tumors of kidney pelvis and ureter is between 50 and 60 yr. Thus these tumors and even urinary bladder neoplasms affect younger people in the endemic region compared to such tumors outside the endemic area [8, 14–16]. The sex ratio indicates a definite tendency towards predominant affection of women in the area: in the case of urinary bladder cancers, men were more frequently affected but the differences are significant only in group B villages. In the case of tumors of kidney pelvis and ureter more women were affected in all groups although the differences between age-adjusted annual rates by sex are not significant. Nevertheless, in comparison with the existing data on sex ratio of these tumor sites outside the endemic area [8, 10, 14–16], women were relatively much more frequently affected, particularly those from the hyperendemic villages. And finally, EN incidence rates in women are significantly higher than those in men in all groups.

We have also observed multiple urinary tract tumors in some patients. There was a marked correlation between this multiplicity and EN incidence: 15% of the males and 33% of the females affected by UST in group A were with more than one site involved; in group B these cases were 4 and 18% accordingly, and in group C no such patients were observed. Most frequent combinations were tumors of the renal pelvis and ureter, followed by tumors of renal pelvis and bladder. It was also observed that multiple cancers were more frequently present in patients with EN for whom the relative risk of developing such cancers is more than twice as great than for patients with UST but without EN.

Another peculiarity of EN and UST in the endemic area is their concurrence in some patients. Analyses of this combination by sex and domicile are given in Table 3. We found a lower frequency of UST among EN patients in comparison with that published on clinical material. Bulgarian authors [2, 13] found a very high occurence of such neoplasms in EN patients at surgery or post mortem, whereas in the autopsy material of Belgrade clinics this combination

Table 3. Percentage distribution of patients with urinary system tumors (UST) and endemic nephropathy (EN) in relation to all registered for EN and UST patients from 15 villages of the endemic region of Vratza district (Bulgaria) for the years 1965–1976

*Group A—8 villages with highest incidence of EN.
Group B—7 villages with moderate incidence of EN.

was reported in only 10.5% of the cases [17]. Since our data was obtained from all registered EN cases the observed difference may be assigned to an asymptomatic course, at least for a certain period, of some papillomas of urinary tract in EN patients. Our material also shows that among all patients with tumors of renal pelvis and ureter EN was recorded in 34% of the males and in 36% of the females, against 12 and 29%, accordingly, among the patients with urinary bladder tumors, i.e. in males only EN is significantly more often combined with tumors of the renal pelvis. Finally, in patients with concurrent EN and UST, the nephropathy was registered first in 51% of the patients against 18% for UST. This may be related to various mechanisms, especially different durations of the asymptomatic period of both diseases.

Among the most specific epidemiologic features of EN and UST is a tendency for familial clustering of cases. This has been reported repeatedly for EN [18–20] and recently we have described multiple UST patients in families from the endemic area [21].

A hypothesis for common cause for EN and UST seems most plausible. The familial occurrence of EN and UST suggests their genetical determination but an analysis of the available material does not support such a conclusion [22]. Smoking habits should be also ruled out [23]. Another assumption is that some agent may impair the renal function and structure in people from the area and consequently small amounts of exogenous carcinogens or endogenous metabolites exert their carcinogenic action on the urothelium.

These alternative conclusions should highlight future research in the area.

Cell Migration and Energy Generating Metabolic Activities

H. D'SILVA,* B. P. GOTHOSKAR,* V. K. JAIN† and S. H. ADVANI‡

**Biophysics Division, Cancer Research Institute, Tata Memorial Centre, Parel, Bombay-400012, India, †Department of Biophysics, All India Institute of Medical Sciences, New Delhi 110 016, India and ‡Tata Memorial Hospital Tata Memorial Centre, Parel, Bombay 400 012, India*

Abstract—*We have used a "Capillary tube" migration system to investigate the migratory behaviour of peripheral leukocytes obtained from normal human donors and leukemic patients and its relationship to energy-generating metabolic activities.*

Using antimycin A (AA) and 2-deoxy-D-glucose (2-DG) as probes to disturb the metabolic activities that lead to energy production, our preliminary results indicate that the presence of AA (100–800 μg/ml) in the medium fails to influence the migration of normal and leukemic cells. On the other hand, 1–16 mM 2-DG—a potent inhibitor of glycolysis—causes a significant reduction in the migratory behaviour of the normal lymphocytes and lymphocytic leukemic cells. Myeloid cells show a lesser response to this drug. Simultaneous exposure of the cells to both AA (100μg/ml) and 2-DG (1–16 mM), however, results in an augmentation of the inhibitory effects in the case of the leukemic cells. Such an augmentation is particularly noticeable at all concentrations of 2-DG with leukemic lymphocytes.

INTRODUCTION

MIGRATION *in vitro* of leukocytes from human peripheral blood (PBL) has become a major area of physico-chemical and biological research in recent years. Several techniques [1–5] permit quantitative evaluation of the migratory behaviour of individual cells or a cluster of cells. Though simple in appearance, this activity is a complex *mechanical and chemical* phenomenon that involves a number of cellular components and environmental factors [6–9]. The *exquisite* sensitivity of this phenomenon to immunological influences has further attracted the attention of investigators involved in basic as well as applied sciences [10–18].

With the help of the capillary tube migration technique [4], we have been carrying out quantitative studies on the migratory behaviour of normal and malignant human PBL under various physiochemical and immunological environmental conditions. This cellular activity is an energy requiring process and hence is susceptible to chemicals or drugs that interfere with energy-generating metabolic reactions within the cells. In an effort to understand the energy-relationship underlying this activity, we have investigated the influence of some metabolic "probes" on the migratory behaviour of these cells. The present communication deals with data on human PBL migration under the influence of Antimycin A (AA), and 2-deoxy-D-glucose (2-DG), agents that are known to modify intracellular adenosine triphosphate (ATP) pools [19, 20].

Accepted 26 April 1978.

MATERIALS AND METHODS

Cells

Fifteen millilitre aliquots of peripheral blood were obtained from normal human donors and untreated patients with chronic myeloid leukemia (CML) or chronic lymphocytic leukemia (CLL). Additional samples were also obtained from CLL patients who showed blast crisis and had more than 80% blasts in the peripheral blood. Heparin (15 i.u./ml) was used as the anticoagulant.

Normal blood samples were allowed to sediment at 37°C for 60 min, the leukocyte rich supernatant was aspirated and the leukocytes washed twice with sterile normal saline. Purified granulocytes and lymphocytes were obtained with the use of a Ficoll–

Hypaque gradient [21]. Erythrocyte contamination, if any, was removed by subjecting the sample to 0.83% ammonium chloride shock. Final cell pellets were washed twice with normal saline and resuspended in a minimum volume of Eagle's minimal essential medium supplemented with 15% human AB serum (MEM).

Leukemic blood samples were allowed to sediment for 30 min and the supernatants rich in leukemic cells were aspirated. They were then washed twice with normal saline and resuspended in a small volume of MEM.

Leukocyte migration tests

The capillary tube method (1) was used for studying the migration of the leukocyte populations. Aliquots of cell suspension were taken up in 20 μl siliconized glass capillaries (Clay Adams) and sealed at one end with non toxic clay (Seal-Ease, Clay Adams). The sealed capillaries were placed in 13 × 100 mm plastic tubes and centrifuged at 200 ***g*** for 5 min at room temperature to sediment the cells. The volumes of the aliquots were *predetermined* so as to yield 5–6 mm high cell pellets in the capillaries. After cell sedimentation, each capillary was quickly cut slightly below (0.5 mm) the cell pellet–liquid interface and immediately anchored (in duplicate) to the inside edge of the standard plastic migration chamber with a spot of silicone grease. The chambers were then filled with medium alone (controls), or medium along with different concentrations of 2-deoxy-D-glucose (2-DG) or Antimycin A (AA) (experimental). In several experiments, the migration of the cells was studied in medium containing 100 μg/ml AA along with different concentrations of 2-DG. Sealing of the chambers, incubation at 37°C for 24 hr and measurement of the migration areas were carried out as previously reported [22]. Area of cell migration in the control medium was given a migration index (MI) of 1.00 and the effects of 2-DG and AA were expressed in terms of relative MI i.e.

$$\frac{\text{Mean area of migration of four replicates in the experimental chamber}}{\text{Mean area of migration of four replicates in the control chamber}}$$

Each experiment was carried out in duplicate and the samples tested came from 5 normal donors, 5 CML, 4 CLL and 3 CLL patients in blast crisis (Blasts > 80%). The preliminary experiments showed that the variation in the migration area of different types of human PBL in replicate chambers, was in the range of 2–5%. In the present studies, a difference of 10%, in the migration area (in the experimental chambers), was considered significant.

Chemicals

MEM was commercially obtained. Sterile AB serum was collected from normal human AB donors, and was inactivated at 56°C for 30 min before use. 2-deoxy-D-glucose (Serva Fein Biochemica Heidelberg) was dissolved in sterile saline to yield a 100 mM stock solution. Antimycin A, an antibiotic substance produced by *Streptomyces kitazawaensis*, (obtained from Sigma), was dissolved in distilled ethyl alcohol (1 mg/ml). Both the stock solutions were further diluted with the medium to yield the required concentrations.

RESULTS

Antimycin A is a respiratory inhibitor which blocks the electron transport chain [23]. This drug when tested in a range from 100 to 800 μg/ml, did not show a consistent pattern of effect on the migratory behaviour of normal or either type of leukemic cells. Though slight fluctuations in the values of MI (from 0.90 to 1.20) were seen, these had no relationship with the concentrations of AA used in the medium (Fig. 1).

2-DG, a glucose analogue has been reported to be an efficient inhibitor of glycolysis in tissue slices [19] and cell suspensions [27]. In our studies, the 2-DG influence on all the cell types except the CLL blasts, was investigated in 5 separate experiments. In contrast to AA, the presence of 2-DG in the medium inhibited the migratory behaviour of all the cell types studied. Results presented in Fig. 2 show that (a) the inhibitory effect is a function of concentration of 2-DG and (b) amongst the cell types studied, the order of susceptibility seems to be blast cell > CLL cells > normal leukocytes > CML cells.

Figures 3, 4 and 5 depict the modification of 2-DG effects by the simultaneous presence of 100 μg/ml AA, observed in 5 separate experiments. Whereas unfractionated normal leukocytes did not show any significant augmentation of 2-DG effects in the presence of AA (Fig. 3), the myeloid (Fig. 4) and

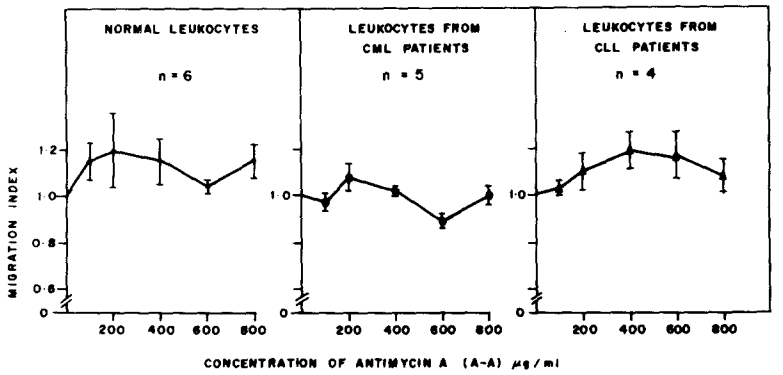

Fig. 1. Migration of different types of leukocytes in the presence of antimycin A (A-A) (mean ± S.E.).

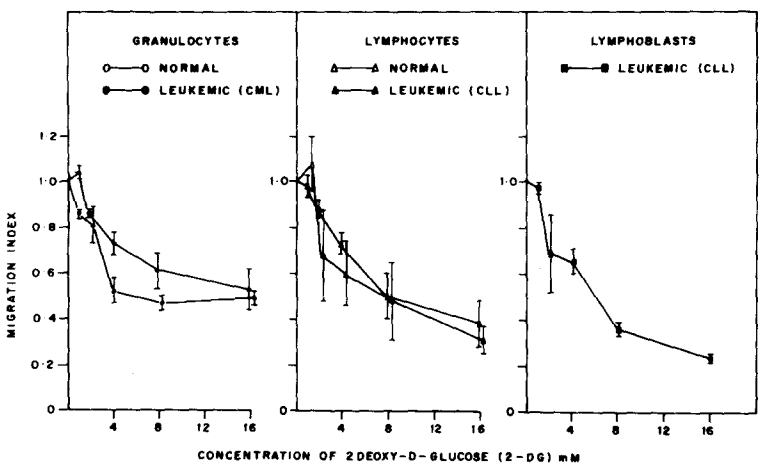

Fig. 2. Migration of different types of leukocytes in the presence of 2-deoxy-D-glucose (2-DG) (mean ± S.E.).

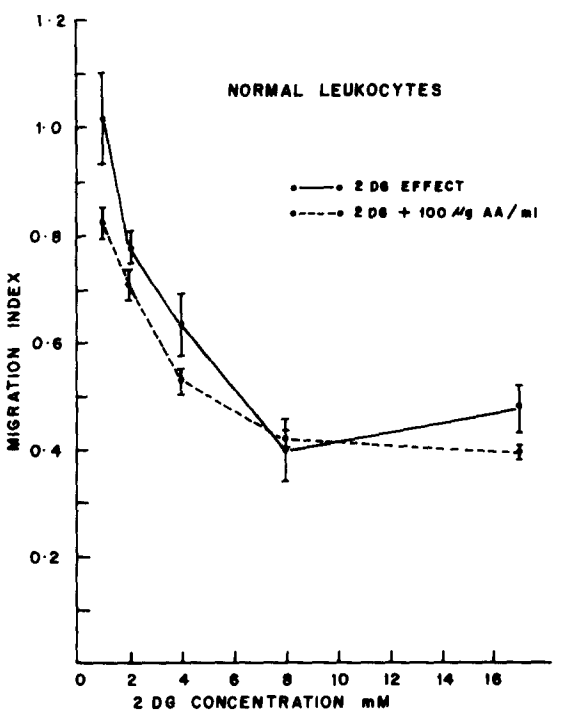

Fig. 3. Modification of the migration-inhibitory effect of 2-deoxy glucose (2DG) by antimycin A (AA).

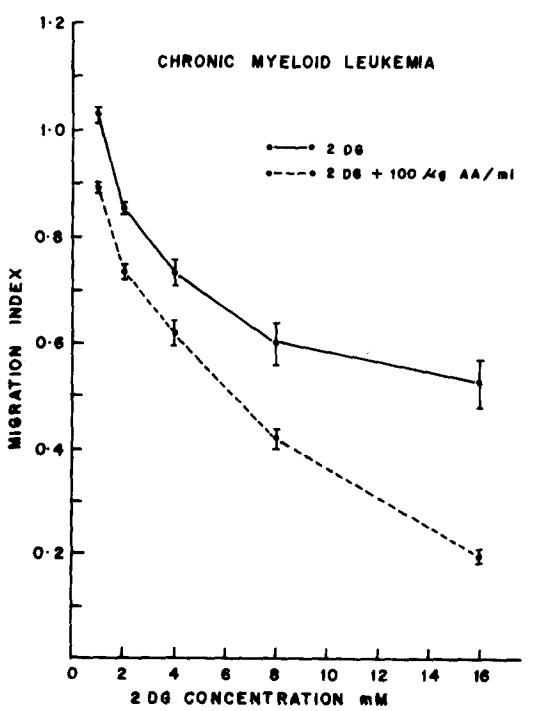

Fig. 4. Modification of the migration-inhibitory effect of 2-deoxy glucose (2 DG) by antimycin A (AA).

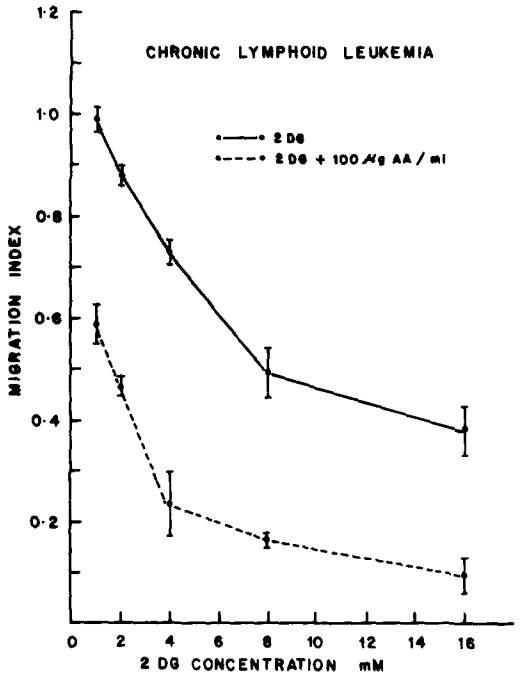

Fig. 5. Modification of migration-inhibitory effect of 2-deoxy glucose (2 DG) by antimycin A (AA).

lymphoid (Fig. 5) types of leukemic cells exhibited a clearly enhanced susceptibility to 2-DG in the presence of AA. This was particularly noticeable for CLL lymphocytes even at 1 mM 2-DG concentration (shift of M.I. Value from 0.98 to 0.59).

DISCUSSION

There have been several investigations concerning the metabolic differences in normal and leukemic blood cells. Attempts have been made to distinguish lymphocytes and granulocytes, normal and leukemic, on the basis of their cytochemical reactions [24], aerobic and anaerobic glycolysis [25–27] and respiratory rates [27, 28]. These studies indicate that normal lymphocytes and granulocytes have an energy metabolism similar to their leukemic counterparts [28]. Further, such studies have also shown the predominance of glycolytic activity in leukocytes [29] as judged from a cellular susceptibility to 2-DG.

Our results indicate that the capillary tube migration system can be used to assess the differential effects of metabolic probes, random motility of leukocytes providing a rapid, reliable and reproducible indicator. These results from leukocyte migration in the presence of 2-DG fall in line with the past evidence. The higher susceptibility of migration of the lymphoid cell types to 2-DG also agrees with the finding that lymphocytic cells have a high rate of anaerobic glycolysis [29] and presumably depend on this primarily for their energy requirements.

The flexibility of leukocyte energy metabolism is well known, since blocking of respiration has been reported to cause an increase in glycolysis and vice versa [30]. Augmentation of 2-DG mediated migration-inhibition in the presence of AA—respiratory inhibitor—indicates the prevention of such a shift so as to make the cells more susceptible to the glucose analogue. The CLL lymphocytes show such augmentation even with the lowest 2-DG concentration used, in spite of the presence of 5 mM glucose in the medium.

Metabolic blocking of the glycolytic pathway [30–33] has been reported to affect leukocyte functions like phagocytosis and permeability. Results presented here indicate leukocyte migration also to be a sensitive indicator of similar metabolic disturbances.

Correlation Between Immunosuppression to Tumorigenesis. 1. Humoral Immunosuppressing Factor

ANWAR A. HAKIM

Departments of Surgery and Physiology, Division of Surgical Oncology, College of Medicine, University of Illinois at the Medical Center, 180 Longwood Drive, Kankakee, Illinois 60901, U.S.A.

Abstract—*Factors that alter cellular immunity, macrophage and lymphoid cell functions can be obtained from sera of animals bearing proliferating tumors. Rats bearing syngeneic mammary adenocarcinoma (R 3230) AdCa) and CFW mice bearing syngeneic spontaneous mammary adenocarcinoma have been examined. Peritoneal macrophages and spleenocytes cytotoxicity against tumor cells, and the effect of serum on incorporation of ^{3}H-thymidine into normal spleenocytes DNA in response to phytohemagglutinin (PHA) were assessed at time intervals during tumour growth.*

1. *If drawn early, during the* 1st *to the* 6th *week, after s.c. injection of tumor cells enhanced, but if drawn later,* 7th *to expiration week, the serum suppressed the response of normal spleenocytes to PHA.*

2. *Macrophages and spleenocytes from normal animals had no effect, those from animals bearing a subcutaneous progressively growing syngeneic tumor enhanced proliferation, whereas those from animals immunized against the tumor were cytotoxic against syngeneic tumor cells.*

3. *Cell-free supernatants harvested from mixed cultures at ratios between* 10:1 *to* 8.3×10^3 *of normal spleenocytes, or spleenocytes from immune animals to syngeneic tumor cells enhanced, whereas supernatants from mixed cultures of spleenocytes of tumor-bearing animals to syngeneic tumor cells suppressed the response of normal spleenocytes to PHA.*

4. *Cell-free supernatants harvested from mixed cultures at* $1:10^4$ *ratio of syngeneic tumor cells with spleenocytes of animals early (during the* 1st *to* 4th *week) after s.c. injection of tumor cells enhanced, but those from mixed cultures of cells suppressed the response of syngeneic normal spleenocytes to PHA.*

INTRODUCTION

BLOOD from patients and animals bearing tumors contain several factors that modify the response of the host to a growing neoplasm. The relation between these factors and tumor burden could be of diagnostic and prognostic value, and warrant further investigations.

Immunosuppression accompanies tumor growth in both patients and animals [1–4], and immunosuppressive factors impair immunocompetence as measured by decreased reactivity of host's lymphocytes to mitogenic stimulation [5–8]. Cytotoxic activity of blood lymphocytes from cancer patients for cultured cells derived from human tumors has been considered to be indicative of the presence of a tumor-host response [9, 10]. "Blocking factors" also have been demonstrated in several host-tumor systems [11].

Many cancer patients and tumor-bearing animals, at least in the early stage of the tumor proliferation, possess "potentiating" [12–14] activities which render the infiltrating lymphocytes capable to stimulate rather than suppress proliferation of tumor cells [15]. These activities are mediated by immunoglobulins [16], antigens shed from cell membrane [17, 18] or tumor-specific antigen–antibody complexes [19, 20].

To be of clinical value, the factors by which humoral and cellular immunity control the rate of tumor proliferation must be quantitatively related to tumor burden. The present studies examine the *in vivo* correlation between humoral immunosuppression immunostimulation and cell-mediated cytotoxicity to tumor burden. They demonstrate a correlation between the presence of immuno-

stimulating–immunosuppressing agents in cell-free supernatants harvested from *in vitro* mixed cultures of spleenocytes with syngeneic tumor cells. The pattern of immunostimulation–immunosuppression depended on the source and ratio of spleenocyte to tumor cells.

MATERIALS AND METHODS

Animals and tumors

Inbred female CFW white mice, 6–8 weeks old, from our colony, were used. The syngeneic mouse tumor studied was a mammary adenocarcinoma (CFW-AdCa) that arose spontaneously in our CFW colony. It was maintained for 35 generations by serial s.c. inoculation of 1×10^4 living cells suspended in 0.2 ml of Hanks' basal salt solution (HBSS).

Inbred female Fischer rats, 12–16 weeks old, from our colony, were used. The tumor was DMBA-induced mammary adenocarcinoma (R 3230 AdCa). It was maintained for 27 generations by serial s.c. inoculation of 1×10^8 living cells suspended in 0.5 ml of HBSS. The injection site was palpated for the presence of tumor every two days, and growth rates were measured with a caliper.

Target cell cultures

CFW-AdCa and R3230 AdCa monolayers were established *in vitro* as described under condition TC "a" [19]. After treatment of the excised tumors with collagenase (10 μm/ml) supplemented with 1000 μm of deoxyribonuclease/ml (DNAase I Sigma) the cells were washed twice. They were subcultured *in vitro* for 3–4 passages before use. The cell lines were constantly tested for tumorigenicity.

One hundred percent of syngeneic animals injected s.c. with 1×10^5 cultured tumor cells developed tumors resembling the primary tumors in their growth pattern and histological characteristics.

Sera from immune and tumor-bearing mice and rats

Different groups of tumor-bearing mice and rats, injected with 1×10^4 CFW-AdCa (or 1×10^8 R3230 AdCa) were bled on the 2nd, 6th, 9th, 12th, 15th, 17th, 22nd, 27th, 34th and 45th day after isograft. CFW-AdCa or R3230 AdCa hyperimmune sera were obtained from CFW mice or Fischer rats injected 4 times at weekly intervals with 5×10^5 neuraminidase-treated and glutaraldehyde-fixed tumor cells [20]. All the sera were heat inactivated at 56°C for 30 min and stored in separate vials at −20°C until required. The sera were diluted 1:5 with Eagle's minimum essential medium (MEM) and filtered through 0.22 μm Millipore® filters before use.

Preparation of spleenocytes

Spleens from normal, tumor-bearing and immune animals were dissected at time intervals, minced with sterile forceps, and gently teased through a 80-gauge sterile stainless steel screen. The cells were washed 3 times in HBSS, suspended in Eagle's MEM supplemented with 15% fetal calf serum (FCS) and incubated 24 hr in cotton stoppered tissue culture bottles at 37°C in a humidified atmosphere of 5% CO_2 and 95% sterile air [21]. The non-adherent cells were collected, washed 3 times in HBSS, and suspended in Eagle's MEM at a concentration of 5×10^5 viable cells/ml. Cellular viability assessed by trypan blue exclusion, was greater than 95% in all experiments.

Macrophage cultures

Macrophages were obtained from normal CFW mice or rats, CFW mice or rats bearing a progressively growing subcutaneous CFW-AdCa or R3230 AdCa, or from CFW-AdCa or R3230 AsCa mice or rats immunized against the syngeneic tumor. Two millilitres (or 10 ml) thioglycollate was injected i.p. into each mouse (or each rat) and 4–5 days later, the animals were sacrified and their peritoneal exudate cells (PEC) were harvested by being washed with HBSS containing 2 units heparin/ml. The cells were centrifuged and resuspended in Eagle's MEM; 1×10^7 cells were plated in 100×20 mm plastic Petri dishes and placed in a humidified 37°C incubator containing 5% CO_2 atmosphere.

Five days after the i.p. injection with thioglycollate, the harvested PEC consisted of about 85% large, vacuolated mononuclear cells with typical macrophage morphology. The remaining 13–15% consisted of lymphocytes and some granulocytes. Washing the non-adherent cells with Eagle's MEM 1 hour after initial plating in culture dishes removed the lymphocytes. Granulocytes are short-lived cells and were removed when adherent PEC cultures were refed on the 5th culture day [22], at that time, all the remaining adherent cells were capable

of phagocytizing carbon [23], had the typical macrophage morphology and were used in the present studies.

Biological activities of cell-free supernatants and sera

The various non-adherent cells from the spleen cell cultures described earlier were added to tumor cell cultures at a ratio of 10^3:1, approximately 1×10^6 tumor cells per flask in 20 ml of Eagle's MEM. After 24 hr incubations, the supernatants from the mixed cultures and from incubations containing the non-adherent cells or the tumor cells each alone (control) were collected, centrifuged at 6000 ***g*** for 10 min and passed through a 0.22 nm Millipore® filter. The cell-free supernatants were then tested as follows:

(*a*) *Macrophage activation.* The supernatants were added to 4-day old cultures of macrophages from syngeneic normal, tumor-bearing or immunized animals. After 48 hr, the macrophages were collected, washed with Eagle's MEM and harvested with the aid of a soft, wide-tipped rubber policeman. Cell counts and viability were determined, they were suspended in cold HBSS, then examined for cytotoxic activity against syngeneic tumor cells.

(*b*) *Effects on response of normal spleenocytes to phytohemagglutinin (PHA).* Spleenocytes were obtained from syngeneic normal mice or rats. They were passed through sterile cotton-wool columns and eluted with Eagle's MEM. After 3 washings, the cells were counted and viability assessed by the Trypan blue dye.

In culture tubes, aliquots of 10^5 normal spleenocytes in 1 ml of Eagle's MEM supplemented with 15% FCS plus 100 u/ml penicillin, 100 μg/ml streptomycin and 1 mM glutamine. All tubes except the unstimulated control contained 10 μg of purified PHA. Experimental tubes contained aliquots of supernatants equivalent to 10 μg protein. Additional control tubes contained a concentration of reference pooled normal mouse or rat serum equal to the greatest concentration of experimental protein tested. The tubes were then maintained in a 5% CO_2 humidified environment at 37°C for 50 hr then pulsed by the addition of 1 μCi of ^{3}H-thymidine for 18 hr. Before harvesting, viability of the cells was reassessed. In these experiments viability did not differ in control or experimental groups. The cultures were harvested and DNA synthesis was determined as previously described [24].

The data were computed as percentage of suppression (−) or stimulation (+).

$$\% \text{ Suppression} = \frac{\text{Cpm experimental tubes with PHA} - \text{Cpm control tubes without PHA}}{\text{Cpm control tubes with PHA} - \text{Cpm control tubes without PHA}} \times 100$$

(*c*) *Quantitative assay of cell-mediated cytotoxicity* in vitro. Tumor cells growing *in vitro* at confluency were labeled for 24 hr with 0.25 μCi of ^{51}Cr per ml of Eagle's medium. Before the assays, the cultures were washed with HBS to remove all unbound radioactive material. The labeled tumor cells were harvested by short trypsinization (0.25% trypsin for 1 min) and suspended in the supplemented Eagle's MEM.

Routinely, single-cell suspension of target cells were mixed with macrophages (or spleenocytes) at various ratios and rotated for 1 hr on a platform at room temperature, plated in culture dishes and incubated for 5 days. Twenty-four hours after plating, the cultures were refed, on day 5 they were washed twice with HBSS to remove all radioactivity not associated with adherent, presumably viable target cells. The adherent cells were lysed with 1 ml of 0.5 N NaOH and washed twice with HBSS. The lysate and the HBSS washes were combined and radioactivity was monitored in a gamma counter. Each sample was counted three times for 5 min and percentage cytotoxicity was computed.

$$\% \text{ Cytoxicity} = \frac{\text{Cpm in adherent cells alone} - \text{Cpm in tumor cells with macrophages}}{\text{Cpm in adherent cells alone}} \times 100$$

RESULTS

Briefly, the present studies were aimed to identify the biological activities of agent(s) released as a result of tumor cell proliferation. The first groups of experiments were performed to determine whether s.c. injection of syngeneic tumor cells will produce activities which alter lymphoid tissue, i.e. spleenocytes functions.

1. *Stimulation-suppression of the response of syngeneic spleenocytes to phytohemagglutinin (PHA) with serum from animals isografted with mammary adenocarcinoma*

In agreement with earlier results [28], PHA stimulated the incorporation of ^{3}H-

(+) is stimulation. (−) suppression.
Control spleenocytes were exposed to the same experimental conditions using Eagle's medium in place of the serum used.

thymidine into lymphocytes and spleenocytes. The magnitude of this effect varied with the type of cells and was influenced by several factors added to the incubation medium. Therefore, aliquots of serum drawn at zero and at time intervals from animals injected with mammary adenocarcinoma cells were examined.

(a) Correlation between tumor size and effect of serum drawn from rats isografted with R3230 AdCa on response of normal syngeneic spleenocytes to PHA. After inoculation of R3230 AdCa cells into syngeneic unconditioned rats, the serum drawn during the early period, between 0 and 30th day, enhanced whereas, sera drawn at later periods reduced the response of normal syngeneic spleenocytes to PHA. The data summarized in Table 1, indicate a correlation between the serum suppressing effect and tumor size. Stimulation was observed with serum drawn from time zero and increased to a peak between the 10th and 20th day. At later period it progressively decreased to nil. Sera obtained between the 30th to expiration day produced suppression which progressively increased. During this latter period, the tumor grew to reach approximately 60 mm in diameter.

(b) Correlation between tumor size and effect of serum drawn from CFW-mice isografted with CFW-AdCa cells on response of normal syngeneic spleenocytes to PHA: After inoculation of CFW-AdCa into syngeneic unconditioned CFW-mice stimulation

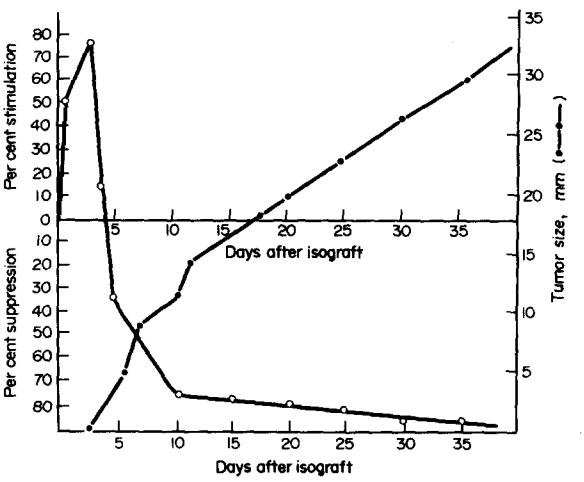

Fig. 1. Effect of murine serum on syngeneic murine spleenocytes response to phytohemagglutinin during tumor growth. Response to phytohemaglutinin (—○—○—), Tumor size in mm (—●—●—).

was observed with serum drawn from zero time, increased to peak between 3rd and 4th day, and decreased to nil on the 5th day. On the fourth day all the animals had palpable nodules of approximately 2 to 3 mm in diameter. Sera obtained between the 5th day to expiration day suppressed the response of normal syngeneic spleenocytes to PHA. During the latter period tumor grew progressively from 2.5 to 33 mm in diameter. The data depicted from the two curves in Fig. 1 indicate correlation between the serum suppressing activity and tumor size.

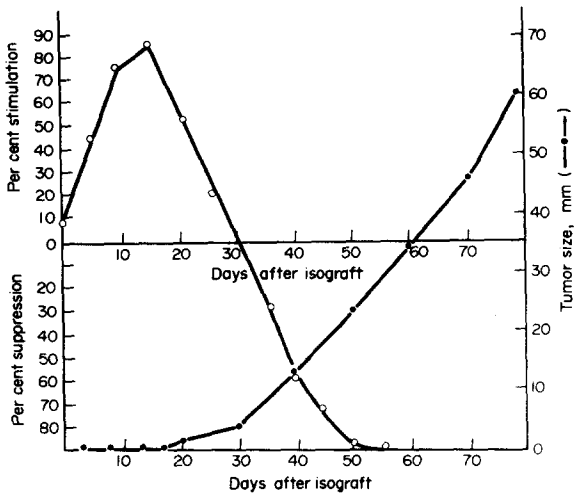

Fig. 2. Effects of rat serum on response of syngeneic spleenocytes to phytohemagglutinin (PHA) during tumor development. Response to PHA (○—○) and tumor size in mm (●—●).

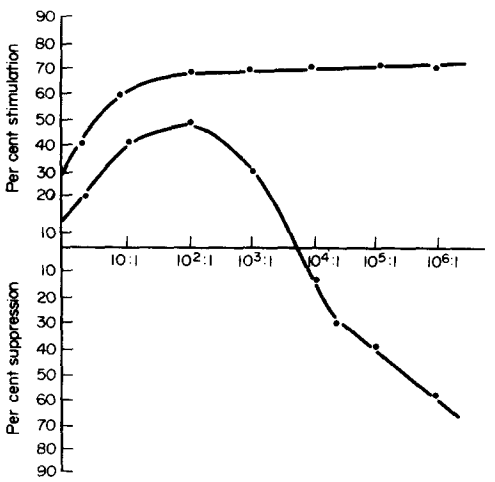

Fig. 3. Effect of supernatants from mixed cultures at various ratios of syngeneic rat spleenocytes to R3230 AdCa tumor cells on response of normal syngeneic spleenocytes to phytohemagglutinin. R3230 AdCa cells with spleenocytes from (A) tumor-bearing and (B) immunized rats.

(c) Correlation between tumor size and effect of serum drawn from rats isografted with R3230 AdCa on response of normal syngeneic spleenocytes to PHA. The data summarized by the two curves in Fig. 2, indicate a correlation between the serum suppressing effect and tumor size. Stimulation was observed with sera obtained from time zero and increased to peak between 15th and 20th day and decreased to nil on the 29th day. Data obtained after the 30th day suppressed mitogenic stimulation of normal syngeneic spleenocytes. During this latter period, the tumor grew progressively from 3 to 60 mm in diameter.

2. *Stimulation–suppression of the response of syngeneic spleenocytes to PHA with cell-free supernatants from mixed cultures of sensitized spleenocytes and syngeneic tumor cells*

To establish the origin of serum stimulating–suppressing activities, normal, sensitized spleenocytes and tumor cells, each alone and mixed cultures were incubated at 37°C in 5% CO_2 atmosphere for 5 days. Cell-free supernatants from mixed cultures of spleenocytes from normal syngeneic animals and R3230 AdCa cells had no effect, if harvested from mixed cultures at low ratios (10:1 to 10^3:1) spleenocytes from syngeneic rats bearing progressively growing tumors and R3230 AdCa cells, the supernatants enhanced, but from higher ratios (10^4:1 to 10^6:1) inhibited the response of normal syngeneic spleenocytes to PHA (curve A, Fig. 2). Cell-free supernatants harvested from mixed cultures of spleenocytes from immunized animals with R3230 AdCa cells enhanced (curve B, Fig. 3) the response of normal syngeneic spleenocytes to PHA. The magnitude of the effect varied with the ratio of spleenocytes to tumor cells. Not shown in the figure, supernatants from cultures of spleenocytes alone had no effect, whereas supernatants from cultures of R3230 AdCa cells alone produced weak but statistically significant ($P<0.005$) suppression of the response of normal syngeneic spleenocytes to PHA. Not reported here, similar patterns were obtained with cell-free supernatants from mixed cultures of spleenocytes from CFW-mice bearing progressively growing CFW-mammary AdCa.

Therefore, these experiments demonstrated that cell-free supernatants from mixed cultures of sensitized spleenocytes, i.e. spleenocytes from immunized animals (at all ratios) and from animals bearing progressively growing tumors (at low ratios), with syngeneic tumor cells stimulated the response of normal syngeneic spleenocytes to PHA ($P<0.001$). Since supernatants from cultures of the spleenocytes had no effect, but supernatants from cultures of tumor cells alone had statistically significant suppressing activity, it is suggested that the suppressing agent(s) may be released by the tumor cells. The origin of the stimulating agent(s) must await further studies.

3. *Evolution of cell-mediated cytotoxic activities against mammary adenocarcinoma*

Cytotoxic activity of lymphoid cells from hosts bearing neoplasms for cultured cells

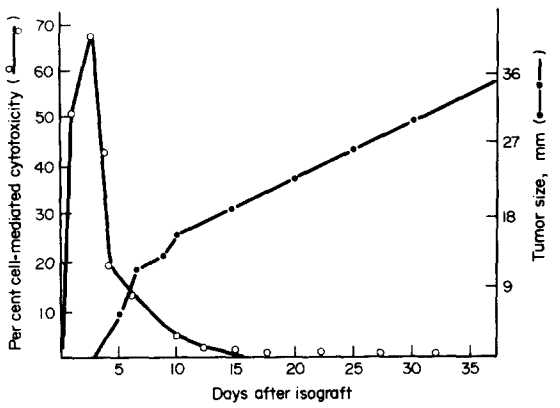

Fig. 4. Evolution of cell-mediated cytotoxicity against R3230 AdCa. Spleenocytes were taken from tumor-bearing rats at time intervals during the progressive growth of the adenocarcinoma. Each reading represents the average of 4 separate determinations. The variation between the determinations varied less than 5% with a $P<0.001$.

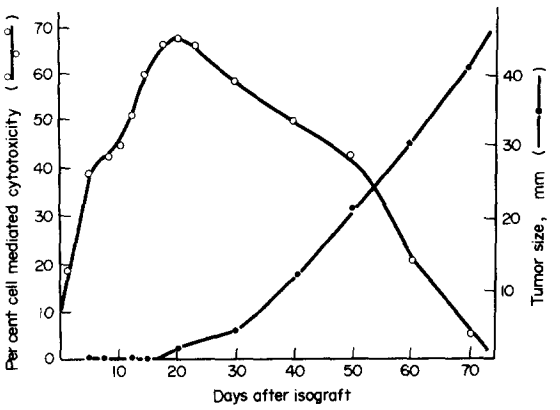

Fig. 5. Cell-mediated cytotoxicity against CFW-AdCa cells. Spleenocytes were taken from tumor-bearing syngeneic animals at time intervals during the progressive growth of the tumor in CFW-mice. Each point represents the average of 4 separate determinations. The variation between each determination varied less than 5% with a $P<0.001$.

derived from the host tumor indicate the presence of a tumor-associated host response. The following experiments are aimed at the evolution of cell-mediated cytotoxicity directed against syngeneic tumor cells during growth of the tumor.

(a) Cell-mediated activity against rat mammary R3230 AdCa cells: the results depicted by curve "a" Fig. 4, indicate that before inoculation of the tumor cells, normal syngeneic spleenocytes possessed statistically significant 10% ($P<0.05$) cytotoxic activity against R3230 AdCa. This cytotoxicity increased to reach a peak between the 19th and 21st day after isograft, then decreased to a very low level. In these experiments solid tumors became palpable between the 19th and 21st day after injection of the tumor cells (curve b, Fig. 3) a period where maximum cytotoxic activity was attained. Spleenocytes from either normal or R3230 AdCa-bearing rats had no effect against murine CFW-AdCa cells.

(b) Cell-mediated cytotoxic activity against murine mammary CFW-AdCa cells. The data presented by curve "a" Fig. 4, indicated that before isograft normal syngeneic spleenocytes had statistically non-significant cytotoxic activity against CFW-AdCa cells. This cytotoxic activity increased sharply after s.c. injection of CFW-AdCa cells to reach a peak on the 3rd day, then decreased to nil on the 16th day. Solid tumors became palpable on the 3rd or 4th day after the isograft (curve b, Fig. 5), it is the period at which maximum cytotoxicity was observed. The size of the tumor increased progressively to reach 20 mm in diameter on the 16th day, where spleenocytes became non-effective against syngeneic CFW-AdCa cells. Spleenocytes, either from normal or from CFW-AdCa-bearing animals had no effect against R3230 AdCa.

Therefore, the magnitude of spleenocyte cytotoxic activities correlate inversely with the size of the tumors. It is suggested that if tumor size continues to increase at the peak value of cytotoxic activity, it is indicative of failure of the host cell-mediated immunity to interfere with the growth of the tumor.

4. *Correlation between serum blocking and suppressing activities with tumor size*

The patterns of serum immunostimulation–immunosuppression, and spleenocyte cytotoxic activity showed direct correlation between suppression and tumor size and an inverse relation with spleenocyte cytotoxic activities. The following experiments examine the relation between serum "blocking" activities and tumor size. The data summarized in Table 2, indicated a correlation between number of tumor cells isografted with tumor size. The changes in tumor size were accompanied with changes in both serum "blocking" and suppressive activities. The magnitude of increase in serum blocking or suppressive activities varied directly with number of tumor cells injected.

Therefore, these experiments showed patterns of serum biological activities which accompanied progressive growth of the tumor. Although the patterns suggest similarities between serum "blocking" and suppressive activities, the data do not permit differentiation of the two serum activities. Whether

Table 2. Correlation between tumor size, serum blocking and suppressive activities

Number of tumor cells injected	Days after injection	Tumor size (mm)	Serum blocking activity (%)	Serum suppressive activity* (%)

*(+) indicates stimulation. (−) indicates suppression. The above data represent the average±S.D. of six separate experiments.

caused by the same or different agent(s), the results indicated that the serum activities reflect changes in tumor size.

5. *Correlation between macrophage functions and tumor size*

Macrophages play a role in the control of tumor development, but specificity of the reactions involved is at present unclear. Whether from normal CFW-mice or from rats, peritoneal macrophages had statistically non-significant effects on response of syngeneic spleenocytes to PHA. On the other hand, macrophages from tumor-free immune animals enhanced, whereas macrophages from hosts bearing progressively growing tumors suppressed the response of normal syngeneic spleenocytes to PHA. The data summarized in Table 3, indicated that the magnitude of suppression varied also with number of inoculated tumor cells and time after isograft. Macrophage suppressing activities correlated with the number of cells in the isograft and with tumor size. It is suggested that during progressive tumor development, macrophages suppress spleenocyte functions. The present data do not permit any conclu-

Table 3. Macrophage activities and tumor size

Tumor (animal)	Days after tumor cell inoculation	Tumor size (mm)	Macrophage suppression (−) or stimulation (+) (%)
CFW-mice normal	—	—	+ 5±0.7

	9	—	44±4.2	−52±4.9	−61 ±5.8
	18	—	12±1.2	−23±1.9	−29 ±2.3
	38	—	5±0.5	−13±1.0	−17 ±1.7

The above data represent the average±S.D. of six separate experiments where 4 animals per group were used.
*The tumors were removed on day 36, after tumor cell inoculation.
†The tumors were removed on day 43, after tumor cell inoculation.

sion on quantitative correlation between serum and macrophage suppressing activities. The effect of tumor growth on other macrophage functions are under investigation.

6. *Reversibility of tumor-induced patterns by surgical removal of tumor mass*

Preceding experiments showed that serum suppressing and "blocking" activities, cell-

mediated cytotoxicity and macrophage-mediated suppression all varied with tumor size, the following experiments examine reversal of these patterns by removal of the tumor. The data in Table 4 showed that serum "blocking" activities increased, the initial serum and macrophage-stimulating activities changed to suppressing activities during tumor development. On the 36th and 42nd day after isograft, the tumors were removed surgically from both the AdCa-bearing mice and rats, respectively. After surgery, serum "blocking", and serum and macrophage suppressing activities decreased.

Therefore, these experiments demonstrated that surgical removal of the tumor reversed the patterns of serum and macrophage suppressing–stimulating activities. Whether the progressive growth of the tumor is the cause of the changes in the serum and macrophage activities, or the changes in these activities permitted and caused tumor progressive development must await further in progress studies.

DISCUSSION

Both CFW-AdCa in mice and R3230 AdCa in rats are hormone-regulated mammary adenocarcinomas. CFW-AdCa is also of moderate antigenicity [25] which yielded antigenic cell membrane fraction that was not found in the membrane fractions from normal mammary cells [26]. *In vivo* growth rate of this tumor was influenced by changes in the host immune reactivity, i.e., the serum from tumor-bearing animals enhanced, whereas the serum from immune animals retarded the growth of CFW-AdCa in syngeneic animals. Thus proliferation of CFW-AdCa in syngeneic unconditioned host was influenced by the host's immunological mechanisms.

Depending on the period after isograft, the serum from CFW-AdCa-bearing mice or R3230 AdCa-bearing rats caused stimulation and suppression of the response of normal syngeneic spleenocytes to PHA. This investigation supports the hypothesis, originally suggested by Prehn [13, 29, 30], of a dual effect of the immune response to a tumor transplant. Spleenocytes from normal mice were unable to stimulate target cell growth *in vitro* at low ratios of lymphoid cells to target cells (100:1). However, spleenocytes from CFW-mice or rats bearing the mammary adenocarcinoma for 5 days exhibited both stimulatory and inhibitory activities (unpublished preliminary observations). From the *in vivo* studies of Ilfeld *et al.* [31], Treves *et al.* [32], Carnaud *et al.* [33] and Small and Trainin [34], it would appear that stimulation and inhibition of tumor growth are mediated by different subpopulations of T-cells. However, the role of macrophages and B-cells in either phenomenon cannot be excluded. Fiddler [35, 36] found that cell-mediated immunostimulation depended on direct lymphoid cell-target cell contact. However, at least in the effect on the response of spleenocytes to PHA, our results indicated involvement of soluble factor(s). Cell-free supernatants from cultures of spleen cells [37] and peripheral blood leukocytes [38] exhibited both enhancing and cytotoxic effects on the DNA synthesis and division of target cells *in vitro*. Further, Shearer *et al.* [39, 40] have demonstrated humoral stimulation of tumor cell growth *in vitro* mediated by heterologous antibody.

Spleenocyte cytotoxic activities against syngeneic tumor cells, were detected early after inoculation of viable tumor cells and decreased sharply at later periods where the tumors were progressively growing. These results could be considered indicative, at least in the early period, of the presence of tumor-associated host response [9, 10], and in the latter period of the overwhelming mechanisms of the tumor. Although at low level, animals with greater tumor diameter maintained statistically significant ($P<0.001$) cell-mediated cytotoxic activity. Francois *et al.* [41] found that cell-mediated cytotoxicity disappeared entirely after 21 days, whereas Ladolfo *et al.* [42] reported that cytotoxic effector cells were present, although at low levels. The correlation between development of mammary adenocarcinoma and cytotoxicity is in agreement with reports in several tumor systems in which cytotoxic peak was detectable between 8 and 15 days after challenge [43–53]. The significance of the appearance of these peaks is not well understood. In some host-tumor systems cellular reactivity appears to be directly related to tumor size [46–49], it is quite possible that the peak of cellular activity is related to a general pattern of cytotoxic lymphocyte or other cellular activation.

In both CFW-AdCa and R3230 AdCa systems, other serum activities appear to be directly related to tumor size. For example at periods where the tumors became greater than 5 mm in diameter, the shift from serum

stimulating to suppressing activity was accompanied with appearance of serum "blocking" activity. Both, serum suppressing and "blocking" activities continued to increase until the animals expired. These two activities could be related to an increase of free or antibody-complexed membrane antigens shed by growing tumors [51–53]. It is possible that the suppressive activity may gradually become excessive, thus blocks the stimulating as well as the "arming" activity [54]. Further studies are in progress examining the possibility of the same compound acting as an immunosuppressive and as a "blocking" agent.

Macrophages may play a role in the control of tumor development. For example, a depression of a variety of macrophage functions resulted in an increased incidence of neoplasia and conversely, stimulation of various activities enhanced resistance to neoplastic disease [55]. Macrophages have been shown to influence blastogenesis in the mixed lymphocyte reactions (MLR). However, depending upon experimental conditions and animal species, blastogenesis may be enhanced or depressed by macrophages [56–58]. In the present studies, macrophages from either mice bearing CFW-AdCa or rats bearing R3230 AdCa suppressed response of normal syngeneic spleenocytes to PHA.

Transient Bleomycin-Induced Thrombocytopenia. A Clinical Study

P. HILGARD*† and D. K. HOSSFELD

Westdeutsches Tumorzentrum, Innere Universitätsklinik (Tumorforschung), Hufelandstrasse 55, D-4300 Essen 1, Federal Republic of Germany

Abstract—*The combination chemotherapy with vinblastine followed by a 5 day continuous infusion of bleomycin resulted in a transient decrease of the peripheral platelet count in all patients investigated. A significant bone marrow toxicity as a cause of thrombocytopenia could not be demonstrated. A detailed coagulation analysis, including fibrinogen turnover studies in one patient, confirmed the absence of intravascular coagulation as the cause for increased platelet consumption. Since no direct effects of bleomycin on blood platelets could be found, it is concluded that platelets are sequestrated in lung capillaries due to drug-induced early endothelial damage.*

INTRODUCTION

BLEOMYCIN is an antibiotic produced by a strain of streptomyces verticillus which has a broad spectrum of antiviral and antibacterial activity [1]. The drug was also shown to inhibit the growth of various transplanted animal tumours [2]. Bleomycin was found to be clinically effective in a variety of malignancies, predominantly squamous cell carcinomas [3]. As bleomycin is relatively little myelotoxic, it was incorporated into many chemotherapeutic regimens. In testicular cancers the combination of bleomycin with vinblastine is highly effective, resulting in total response rates of approximately 75% [4].

In our hospital, stage II testicular carcinomas were treated with a combination of vinblastine and bleomycin according to the schedule suggested by Samuels *et al.* [4]. Bleomycin is given over a 5-day period as a continuous intravenous infusion. Regularly after initiation of the therapy we observed a significant decrease of the peripheral platelet count. The present communication describes this phenomenon, and investigations to elucidate the pathogenesis of the bleomycin-induced thrombocytopenia are presented.

MATERIALS AND METHODS

Patients

Five patients were studied (age range: 22–38 yr) who had a semiorchidectomy with subsequent abdominal lymphadenectomy. In all patients the malignant disease was limited to the abdominal lymph nodes (stage II).

Treatment

Vinblastine was given on days 1 and 2 in a dose of 0.2 mg/kg/day followed by a continuous bleomycin infusion of 30 units/24 hr throughout days 2–6.

Laboratory tests

All tests were performed before and daily after initiation of the therapy. Red cells, leucocytes and blood platelets were determined using routine laboratory techniques. Plasma fibrinogen, prothrombin time (PT), partial thromboplastin time (PTT), thrombin time (TT), reptilase time (RT) and factor VIII activity were measured according to standard procedures [5]. Factor XIII was estimated using the method of Bohn and Haupt [6]. Fibrin degradation products were studied in serum samples by the staphylococcal clumping test (SCT), the results being expressed as the exponents of the basis two [7].

Accepted 25 April 1978.

Fibrinogen turnover

In one patient the plasma half life ($t/2$) of ^{125}I-fibrinogen was determined during bleomycin therapy. Commercially available ^{125}I-fibrinogen (Radiochemical Centre, Amersham, U.K.) was used. Venous blood samples were taken every 12 hr after injection of the tracer and the fibrinogen $t/2$ was determined according to the method described by Bradley and Hickman [8]. The average mean $t/2$ had been previously established in 5 patients with acute leukaemia in complete remission and had been found to be 3.8 days (range: 3.0–4.9 days).

Bone marrow biopsy

In three patients the bone marrow was examined before and 7 days after initiation of the treatment. To compare the bone marrow composition before and after therapy unbiasedly, the bone marrow smears were coded.

In vitro *studies*

The blood platelets of two thrombocytopenic patients 5 days after initiation of the treatment were resuspended in normal, blood group identical plasma and incubated for 3 hr at 37°C. Similarly, platelets from two normal healthy donors were incubated in the plasmas of treated patients. The original platelet rich plasma served as a control. All platelet counts in the various samples were adjusted to $7 \times 10^4/mm^3$. Platelet counts of the samples were performed at various time intervals and finally a thrombelastogram was recorded after addition of calcium chloride to the plasmas.

Platelet rich plasma of two healthy control persons was incubated with different concentrations of bleomycin, ranging from 15 to 0.5 μg/ml, over a period of 1 hr, and platelet counts were performed at regular time intervals. Finally, thrombelastographic tracings were carried out after addition of calcium chloride to the plasmas. An equal volume of normal saline was added to the control samples.

RESULTS

Figure 1 shows the course of the platelet counts throughout the time of observation before and after therapy. Two to three days after initiation of the treatment a significant decrease of blood platelets was noted in all patients. The pattern of the leucocyte count during that period is given in Fig. 2. Leucopenia occurred 2 days after initiation of the therapy. No significant changes of the red cell count were observed. The plasma fibrinogen values before and during treatment are presented in Fig. 3. The

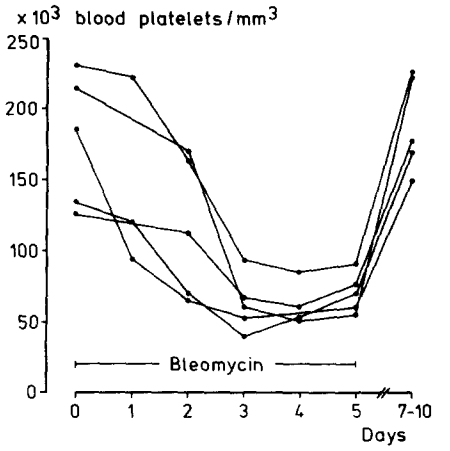

Fig. 1. Peripheral platelet counts in 5 patients during a 5 day continuous infusion of bleomycin.

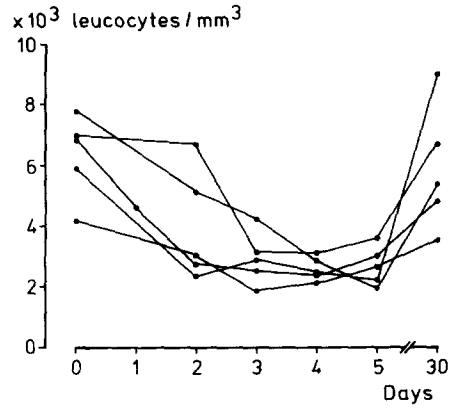

Fig. 2. Leucocyte count in 5 patients during a 5 day continuous infusion of bleomycin.

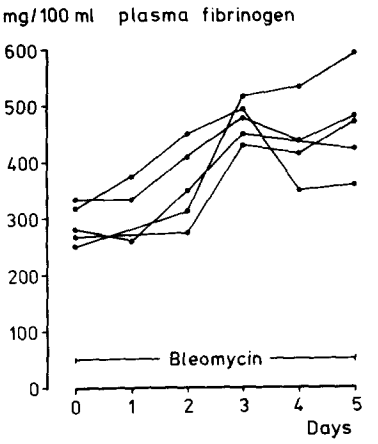

Fig. 3. Plasma fibrinogen levels in 5 patients during a 5 day continuous infusion of bleomycin.

fibrinogen levels increased concomitantly with the platelet decrease. Table 1 gives the mean values of the other coagulation data throughout the period of bleomycin treatment. There was no overall change of these parameters during treatment. Each laboratory value during treatment was subjected to a statistical analysis (analysis of variance) and compared to the pretreatment values. No significant changes could be elaborated in any of the parameters under investigation.

Table 1. Mean values of coagulation data of 5 patients during a 5 day continuous infusion of bleomycin (PT = Prothrombin time, PTT = Partial thromboplastin time, TT = Thrombin time, RT = Reptilase time, SCT = Staphylococcal clumping test)

	PT (%)	PTT (sec)	TT (sec)	RT (sec)	FVIII%	FXIII%	SCT (titre)
	mean	mean	mean	mean	mean	mean	mean
Day 0	96	45	18	16	100	120	4.8
Day 1	97	43	17	16	100	120	5.0
Day 2	73	42	18	15	100	114	4.6
Day 3	96	50	18	15	100	112	4.4
Day 4	97	42	18	17	100	106	4.2
Day 5	98	40	17	16	100	108	4.4
Normal range	75–100	35–52	17–21	14–18	80–100	80–120	3.0–6.0

The plasma half life of ^{125}I-fibrinogen in one patient during bleomycin therapy was found to be 4.1 days, indicating a normal survival of the clottable protein (normal range: $t/2 = 3.0$–4.9 days).

The bone marrow examinations in 3 patients before and after treatment revealed an obvious decrease of the cellularity in only one patient. A relative increase with a left shift of the granulopoesis and a decrease of the erythropoesis were seen in all patients. The morphology of the megakaryocytes appeared unaltered after therapy. By counting the number of megakaryocytes per slide under low power, a reduction was noted in one patient only.

Neither normal platelets resuspended in patients plasma nor platelets from bleomycin treated patients resuspended in normal plasma showed any numerical alterations throughout the incubation period. No gross evidence for a functional impairment of the platelets was observed in the thrombelastograms after recalcification of the platelet rich plasmas. Negative findings were also recorded when normal platelets were incubated with various amounts of bleomycin and compared to the corresponding control samples.

DISCUSSION

The main haematological feature in the 5 patients during bleomycin treatment was the significant decrease of circulating blood platelets 2–3 days after initiation of the continuous infusion. An identical phenomenon was seen in all patients subsequently subjected to this treatment. Since vinblastine is myelotoxic, thrombocytopenia could be attributed to the preceding injection of vinblastine. The simultaneous decrease of the white cells in our patients could suggest such a mechanism. However, although leukopenia is a frequent complication after vinblastine therapy, thrombocytopenia is a rare event [9]. Furthermore, if a platelet life span of 8–10 days [5] is taken as a basis for kinetic considerations, it is unlikely that the transient decrease of the peripheral platelet count by more than 50% within 2–3 days is a result of bone marrow damage. The bone marrow examinations carried out 7 days after initiation of the treatment support this assumption since no striking numerical or morphological alterations of the megakaryocytes could be seen.

If decreased platelet production is not the cause for the thrombocytopenia, an increased peripheral destruction has to be considered. Clinically, disseminated intravascular coagulation (DIC) is a major factor in the pathogenesis of increased platelet consumption. However, detailed coagulation studies in our patients did not reveal any laboratory evidence for DIC, on the contrary, a normal plasma fibrinogen turnover almost rules out this condition. Based on the *in vitro* studies it appears unlikely that bleomycin or any derivative thereof damages platelets directly in the circulation.

Among the toxicities of bleomycin, pulmonary lesions are clinically most important. The pathogenesis of pulmonary fibrosis, which according to a survey of 808 patients occurs in approximately 11%, is not fully understood [10]. After initiation of bleomycin treatment

in mice changes in the vascular endothelium of pulmonary capillaries have been demonstrated [11]. In contrast to previous investigations in humans, recently Burkhardt *et al.* [12] described a high incidence of intrapulmonary microthrombi after bleomycin treatment, suggesting that the activation of the clotting mechanism represents an initial step in the development of bleomycin-induced pulmonary toxicity. It has to be taken into account, however, that this study is based on autopsies, and antemortal pulmonary microemboli are a frequent observation in patients dying from chronic diseases [13]. The direct interrelation between bleomycin treatment and intrapulmonary microthrombi remains to be established.

From our data it can be concluded that bleomycin does not induce a hypercoagulable state, yet early endothelial damage in lung capillaries could lead to increased platelet sequestration at this site. Ultrastructural studies have clearly demonstrated that platelet aggregation can occur without fibrin formation at sites of endothelial damage, even before morphological alterations of the endothelium become visible [14]. It is conceivable that the peripheral platelet decrease after initiation of bleomycin treatment is an expression of such a mechanism. The concomitant increase of the plasma fibrinogen would favour this hypothesis, since tissue damage is frequently associated with an increase of the fibrinogen level [15]. Whether the observations described here are of any pathogenetic importance for the subsequent development of pulmonary fibrosis remains unknown. Experimental studies employing platelet aggregation inhibitors could possibly shed some light on the interaction of blood platelets, vascular endothelium and lung fibrosis after bleomycin treatment.

Enrichment of *Helix pomatia* (HP) Lectin Binding Variant from the TA3St Mouse Ascites Tumor by Repeated Column Selection*

ULLA HELLSTRÖM,† STEN HAMMARSTRÖM† and GEORGE KLEIN‡

†*Department of Immunology, University of Stockholm, S* 106 91 *Stockholm, Sweden and* ‡*Department of Tumor Biology, Karolinska Institutet, S* 104 01 *Stockholm* 60, *Sweden*

Abstract—*TA3 is the ascites form of a mouse mammary carcinoma in strain A/Sn. It exists in two forms, the immunosensitive TA3St and the immunoresistant TA3Ha. The two lines also differ with regard to their ability to bind* Helix pomatia *A hemagglutinin (HP). We have attempted to select an immunoresistant subpopulation of TA3St by repeated enrichment of HP positive cells on HP-Sepharose columns. TA3St cells were passed through HP-Sepharose and the bound cells were eluted with the competitive hapten,* N*-acetyl-*D*-galactosamine* (D-*GalNAc*). *The eluted cells were reinoculated into syngeneic A/Sn mice, grown to ascites, harvested and again passed over a HP-Sepharose column in the same way. Following several selective cycles of this type, the* HP^+ *enriched cell fractions were further amplified by inoculating* 1–50 *cells into A/Sn mice. Subpopulations containing a high frequency of* HP^+ *cells were chosen for further column selections. We have successfully enriched* HP^+ *TA3St cells to* 95–100% *by this procedure. However, the selected variants had more weakly binding HP-receptors (low* K_{app} *and weak staining by HP-FITC) than the approximately* 5% HP^+ *cells in the original TA3St cell population or TA3Ha cells. They also differed from TA3Ha by remaining immunosensitive and by maintaining an unchanged H-2*^{a} *expression.*

INTRODUCTION

TA3St and TA3Ha are two serially transplanted ascites tumor lines, originating from the spontaneous mammary adenocarcinoma TA3 of strain A (H-2^a) origin [1–3]. The two sublines differ in H-2 antigen expression and in homotransplantability. TA3St grows only in syngeneic mice and has a high expression of H-2^a antigens (=immunosensitive) whereas the TA3Ha subline grows progressively across the H-2 barrier and sometimes even in rats and hamsters [1]. It has a low H-2 antigen expression (=immunoresistant) [4, 5].

Previously, the two lines have been compared with regard to a number of biological and biochemical characteristics, summarized in Table 1.

*This work was supported by Public Health Service Research Grant No. 5R01 CA 14054-05, the Swedish Cancer Society and the Swedish Natural Science Research Council Grant No. B 3485-007.

Table 1. *Summary of some characteristics of TA3Ha and TA3St ascites tumor lines*

Characteristic	Tumor TA3Ha	TA3St
Growth in allogeneic mice	Yes	No
H-2^a antigen expression	Low	High
Susceptibility to humoral (anti H-2^a) cytotoxicity	No	Yes
Surface morphology	Smooth	Rough
Electrophoretic mobility	Fast	Slow
Con A agglutinability*	–	+
HP-receptors	Many	Few†
VG-receptors‡	Many	Few
Epiglycanin	Yes	No
Chromosomes	Near-diploid	Hypo-teraploid

Data from Friberg, [1, 2]; Friberg and Lilliehöök, [4]; Friberg and Hammarström, [9]; Codington, [8]; Codington *et al.* [6].

*Note that the number of surface receptors for Con A is the same for both tumor lines [9].

†Approximately 90% of the cells are HP receptor negative (see Table 2).

‡VG = *Vicia graminea* lectin.

The TA3Ha subline contains large amounts of a surface glycoprotein (epiglycanin) and large numbers of carbohydrate residues capable of combining with *Helix pomatia* A hemagglutinin (HP) and *Vicia graminea* lectin (VG). TA3St is low in epiglycanin, HP- and VG-receptors. Furthermore, the TA3Ha subline expresses very little H-2^a antigen, compared to the TA3St line. It has been postulated that the low expression of H-2^a on TA3Ha is related to the presence of the epiglycanin that would mask the H-2^a antigen [5]. This implies that the immunoresistance of this line is due to the same masking mechanism. It has been demonstrated that VG binds to the epiglycanin and that this substance is responsible for all, or almost all, of the binding to TA3Ha cells [6]. From considerations of the carbohydrate specificity of HP [7] the proposed chemical structure of the epiglycanin [8] as well as of the abundancy of epiglycanin and HP receptors on the TA3Ha cells it seems likely that HP similarly detects the epiglycanin on TA3Ha cells.

The present study was undertaken to gain more information about the immunoresistance phenomenon. We departed from our observation that TA3St cells were heterogenous with respect to HP-binding. While the majority ($\geqq 90\%$ of the cells) were HP negative, a small but variable fraction (5–10%) were HP positive by direct immunofluorescence with FITC-HP [9]. We have attempted to select an immunoresistant subpopulation of TA3St by repeated enrichment of HP positive cells on HP-Sepharose columns. This was done by passing TA3St cells through HP-Sepharose and eluting the bound cells with the competitive hapten, *N*-acetyl-D-galactosamine (D-GalNAc). The eluted cells were reinoculated into syngeneic A/Sn mice, grown to ascites, harvested and again passed over a HP-Sepharose column in the same way. Following several selective cycles of this type, the HP^+ enriched cell fractions were further amplified by inoculating 1–50 cells into A/Sn mice. Subpopulations containing a high frequency of HP^+ cells were chosen for further column selections. At intervals, selected and control cell populations were also tested for transplantability to foreign mouse strains and also for their ability to adsorb anti H-2^a antibodies.

We have successfuly enriched HP^+TA3St cells to 95–100% by this procedure. However, the selected variants had more weakly binding HP-receptors (low K_{app} and weak staining by HP-FITC) than the HP^+ cells in the original TA3St cell population or TA3Ha cells. They also differed from TA3Ha by remaining immunosensitive and by maintaining an unchanged H-2^a expression.

MATERIALS AND METHODS

Cell types

The history of TA3Ha and TA3St, two ascites sublines of a spontaneous mammary carcinoma that arose in a female strain A-mouse has been published together with the details of tumor maintenance [1, 3]. Table 1 summarizes some of their relevant properties.

TA3Ha/A.CA Cl. 3B AAA14-21, TA3Ha/A.CA Cl. 7 AAC10 and TA3Ha/A.CA Cl. 11 AAB16-24 are isoantegenic variant sublines of somatic cell hybrids, obtained by the fusion of $TA3HaB^{imp-}$ (an 8-AG resistant, HGPRT deficient, *in vitro* maintained subline of TA3Ha) with A.CA fibroblasts [3]. All hybrid lines were designated according to a system described by Friberg *et al.* [10]. The number following the initial three letters which designate the mouse genotype and individual cell line, represents the number of passages in A/Sn mice.

Originally, the hybrids were low malignant, but they threw off high malignant segregants following chromosome loss. These were reselected in syngeneic A × ACA F_1 hosts. Subsequently, H-2^f loss variants were selected by transfer to strain A mice and serial propagation in the ascites form [3, 10, 11].

Initially, the transplantability of the strain A compatible TA3Ha/ACA variants was restricted to syngeneic strain A mice and its cells had a normal H-2^a antigen expression [10, 11]. However, after 10–20 generations in A/Sn mice the sublines derived from clones 3B and 7 became allotransplantable and showed a decreased H-2^a expression in parallel [12].

The subline derived from clone 11 was only weakly allotransplantable and showed an almost normal H-2^a expression [12].

While these studies were in progress, an allotransplantable variant appeared spontaneously in a strain A mouse, inoculated with TA3St. This variant, designated as "TA3ST/NS" (non-specific) was also compared with the main lines with regard to HP-binding capacity.

Helix pomatia A hemagglutinin (HP) was purified by affinity chromatography on insolubilized hog blood group A+H substance [13].

It is a hexavalent carbohydrate binding protein with the following carbohydrate binding specificity (specificity range:

α-D-GalNAc > β-D-GalNAc ~ α-D-GNAc > β-D-GNAc > α-D-Gal) [7].

HP-receptor positive cells (HP^+ cells) were detected by direct membrane immunofluorescence. Fluoresceine isothiocyanate (FITC) conjugated HP was used. The F/P molar ratio was 7:14. $0.25–0.5 \times 10^6$ tumor cells were incubated with 0.1–15 μg FITC-HP in Tris buffered Hanks' solution (TH) containing 0.02% NaN_3 for 30 min at 4°C, washed with TH + NaN_3 and mounted in 50% glycerol . At least 200 cells were counted.

For binding studies HP was labelled with Na [^{125}I] (specific activity < 14 mCi/μg I) using the chloramine T procdeedure as described [14]. In the binding experiments a constant number of cells ($0.1–1.0 \times 10^6$) were incubated with increasing amounts of [^{125}I]-HP in a total volume of 2.7 ml phosphate buffered saline, pH 7.3 (PBS) containing 0.2% human serum albumin (HSA) and 0.02% NaN_3. The cells were kept in slow vertical rotation for 2 hr at 20°C. The binding data were treated according to Scatchard's derivation of the law of mass action [15]. The specificity of the binding and immunofluorescence was checked by the addition of D-GalNAc (positive control) and D-Glc (negative control).

Cell fractionation on HP-sepharose columns

Immunoadsorbent purified HP was conjugated to CNBr-activated Sepharose 6MB particles (Pharmacia Fine Chemicals AB, Uppsala, Sweden) as earlier described [15]. Columns (0.9 × 15 cm) supplied with a 85 μm net, containing 3 ml swollen gel (1.5 mg HP/ml) were utilized. Tumor cells ($100–150 \times 10^6$) were applied to the columns and allowed to penetrate the gel. The cells were then incubated for 15 min in the gel. Non-adherent cells were washed off with 150–200 ml PBS containing 0.2% HSA. Bound cells were then eluted with 50 ml of PBS–HSA containing 3–5 mg D-GalNAc/ml. In some experiments the gel was then suspended in PBS–HSA + D-GalNAc and transferred to a test tube. The beads were allowed to settle and remaining cells in the supernatant were recovered. Cells recovered in this way amounted to about 5% of added cells. The specificity of the elution step was checked by the use of D-Glc instead of D-GalNAc. No cells (< 2%) were eluted with D-Glc.

Allograft tests

Undiluted ascitic fluid, 0.1 ml, containing approximately 10^7 ascites tumor cells, was inoculated intraperitoneally into syngeneic strain A mice, and into the following foreign genotypes: ABY (H-2^b), ASW (H-2^s), ACA (H-2^f), DBA/2 (H-2^d), CBA (H-2^k), C57Bl and C57leaden (H-2^b) and C3H (H-2^k). Mice were observed for tumor development during 2 months.

Absorption tests

An identical number of washed cells of each cell line at 7 serial dilutions ($400–6.3 \times 10^4$ cells) and controls, in triplicate, were incubated at 37°C for 45 min with A.CA anti H-2^a-antiserum (diluted 1:8 in RPMI medium containing 10% calf serum). After centrifuging down the cells, an aliquot of each supernatant solution was tested. Absorption was calculated from the cytotoxic action in the presence of guinea pig complement, compared to unabsorbed antisera, against normal A/Sn lymph node target cells, as previously described [3].

RESULTS

HP-receptors on different TA3-sublines

Table 2 summarizes the results of immunofluorescence and HP binding experiments. The percentage of HP positive cells and the average number of HP-receptors/cell was determined for different TA3-sublines. As shown earlier [9] all TA3Ha cells were strongly HP positive and contained large numbers of HP-receptors. Most TA3St cells were HP negative but there was a small, variable (4–13%) HP positive fraction. The average number of HP-receptors/cell was $0.2–0.6 \times 10^6$. When recalculated on the basis of the number of immunofluorescence positive cells (4–13%) *n*-values of $2–15 \times 10^6$ were obtained. These values are generally lower than those obtained for TA3Ha cells ($20–30 \times 10^6$).

We have also tested the strain A-compatible isoantigenic variants of three independently fused TA3Ha/ACA fibroblast hybrids (clones 3B, 7 and 11, for further nomenclature see footnote to Table 2). All three hybrid sublines were 90–100% HP positive and contained

relatively large numbers of HP-receptors ($n = 3–14 \times 10^6$). The number of receptors and the percentage of strongly positive cells varied slightly on repeated tests of the same variant sublines. This variation did not appear to be related to the time of harvest of the ascites tumor cells 8–19 days after inoculation). Generally the variant sublines contained slightly fewer HP-receptors/cell than the TA3Ha line.

$TA3HaB^{imp-}$, an 8-AG resistant, HGPRT negative subline was tested both *in vivo*, in the ascites form and *in vitro*. There was an interesting difference in the number of HP-receptors. While both *in vivo* and *in vitro* cultivated cells were 100% HP positive the *in vivo* line contained about 5 times more receptors/cell than the *in vitro* line.

The spontaneously arising allotransplantable variant of TA3St, obtained in the course of this study and designated TA3St/NS, was also tested. As seen in Table 2, only a small fraction of the cells were HP positive and the number of receptors was low.

Origin of HP positive TA3St cells

The question arose whether HP positive cells of the TA3St subline were tumor or host cells. This was approached by a cytotoxic selection experiment (Table 3). TA3St cells were grown in A × ASW F_1 mice and in A/Sn mice. Ascites cells were harvested and exposed to an A anti ASW antiserum and rabbit complement. This can be expected to kill the host cells derived from the A × ASW F_1 but not the A/Sn mice. A/Sn and ASW lymphocytes were treated in the same way as controls. The antiserum killed the ASW lymphocytes and a significant fraction of the cells harvested from A × ASW F_1 mice inoculated with TA3St. Ascites cells harvested from A/Sn mice and control A/Sn lymphocytes were not killed. The percentage of HP positive cells was the same (5–6%) in the antiserum treated ascites cell populations harvested from both hosts, indicating that the HP positive cells were tumor cells. This is also in line with earlier studies, showing that peritoneal lymphoid cells from A/Sn and A × C3H mice were not stained by FITC-HP [9].

Purification of HP⁺ TA3St cells

HP-receptor containing TA3St cells were enriched by the selection procedure summarized in Table 4. Briefly, TA3St cells were applied to a column charged with HP, covalently bound to Sepharose 6MB particles. After washing with medium, bound cells were eluted with the competitive sugar

‡A statistical average of one cell was inoculated into A/Sn mice i.p. and the resulting ascites tumor was harvested.

§NT not tested.

¶These cells were from HP-Sepharose column No. 19 (D-GalNAc eluted fraction). The cells were passaged in A/Sn mice and frozen. Five months later the cells were inoculated in A/Sn mice and the resulting ascites tumor was used.

hapten D-GalNAc. Eluted cells were passaged i.p. in A/Sn mice and the fractionation procedure was repeated. After 7 consecutive column fractionations and mouse passages a cloning experiment was performed. A statistical average of 1 D-GalNAc eluted cell per mouse, obtained from HP-column 7, was injected into a series of A/Sn mice. An ascites tumor grew out in one out of 25 inoculated mice only (25% HP^+ cells). These cells were fractionated on two HP-Sepharose columns (88% HP^+ cells) and subjected to a second cloning. Growth was obtained in one out of 5 mice (40% HP^+ cells). These cells were used for further column selection experiments (Table 4). Table 4 shows that the percentage of HP positive cells increased gradually during the selection procedure, reaching 90–100% HP^+ cells after 17 column fractionations and mouse passages. There are three points of interest. (1) The efficiency of each fractionation procedure was relatively low. Only a 2–3 fold enrichment of HP^+ cells was obtained in the sugar eluted fraction at its best. On the other hand, HP^+ cells were efficiently depleted from the cell population, provided the columns were not overloaded. (2) Only weakly stained HP^+ cells were enriched by the column selection procedure. Somewhat surprisingly the strongly stained cells were actually lost. Calculation of the recovery of the HP-marker (positive and strongly positive) in 5 experiments showed that 70–80% of the HP^+ cells were recovered in the various fractions passed, D-GalNAc-eluted and mechanically eluted in presence of D-GalNAc). In contrast only 25–35% of the strongly positive cells were recovered. Inspection of the beads after mechanical elution showed that they were free of cells. (3) Passage of the eluted cells in A/Sn mice (6–13 days) decreased the percentage of HP^+ cells, as a rule.

Properties of HP^+ TA3St cells

Figure 1 shows the binding of radiolabelled HP to untreated and to HP^+ enriched TA3St cells at different stages of the selection procedure. Biphasic binding curves were obtained with the HP^+ enriched TA3St cells, reflecting the presence of strong and weak HP-binding receptors. Weak HP-binding receptors could not be demonstrated in the original TA3St cell population. After 19 consecutive HP-Sepharose selections when the cells were 100% HP positive (see Table 4), the number of strong and weak HP-binding receptors per cell was 1.2×10^6 and 3.2×10^6, respectively. The K_{app} for the interaction between HP and strong binding receptors on the HP^+ enriched TA3St cells was similar to the value for the interaction between HP and the original TA3St cells.

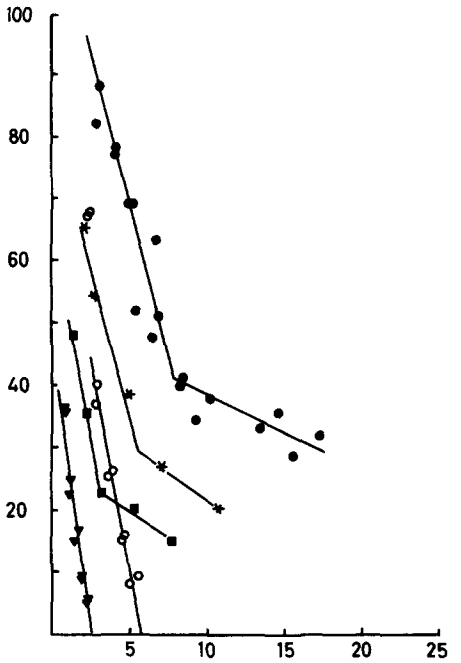

Fig. 1. Binding of [^{125}I]-labelled HP to TA3St cells of generation 224 (▼——▼) *and* 217 (○——○), *respectively and to* D-*GalNAc eluted TA3St cells after* 11 (■——■). 13 (*——*) *and* 19 (●——●) *fractionations on HP-Sepharose columns, respectively see Table* 4). *Abscissa:* $\frac{r}{[H]} \times 10^{-12}$. *Ordinate:* $r \times 10^{-5}$.

The K_{app} for the interaction between HP and weak binding receptors was approximately one tenfold lower. It may therefore be concluded that the fractionation procedure has selected a new population of TA3St cells characterized by a relatively large number of weak HP-binding receptors. These cells could not be demonstrated in the original TA3St tumor either by immunofluorescence or by HP-binding (Table 2 and Fig. 1).

Repeated passage of HP^+TA3St cells in A/Sn mice without intermittent column fractionation led to the gradual loss of cells with weak HP-binding receptors (Table 5). After 12 passages the frequency of HP^+ cells had decreased to 23%. This cell population gave a nearly monophasic binding curve, showing the presence of strong binding sites and only few weak binding sites. It may therefore be concluded that the TA3St cell population obtained by the column selection procedure described above (Table 4) has reverted back to a cell population with

HP-binding characteristics similar to those of the original TA3St cells. This reversion was characterized by loss of cells with weak HP-binding receptors. Cells with strong HP-binding receptors occurred in about the same proportion in both the column selected —and reverted cell populations and in the original TA3St population.

Allograft tests

In view of the fact that the highly HP-reactive TA3Ha cell population grows apparently without limitations in allogeneic mice, we have tested various HP^+ enriched TA3St cell populations for their ability to grow in allogeneic mice. The cells were tested after the following selection steps: HP-Sepharose column No. 6 + mouse passage ($HP^+ = 7\%$), column No. 13 + mouse passage ($HP^+ = 47\%$), column No. 16 + mouse passage ($HP^+ = 67\%$), column No. 17 + mouse passage ($HP^+ = 86\%$), column No. 20 + mouse passage ($HP^+ = 77\%$), column No. 22 + mouse passage ($HP^+ = 81\%$), column No. 23 + mouse passage ($HP^+ = 100\%$), column No. 24 + mouse passage ($HP^+ = 100\%$) and HP-Sepharose column No. 19 + 5 mouse passages ($HP^+ = 100\%$) (c.f. Tables 4 and 5). Altogether we have inoculated 8 A/Sn, 10 ABY, 8 ACA, 10 ASW, 9 DBA/2, 6 C57leaden, 6 C3H, 10 C57Bl, 8 CBA and 10 C57Bl × DBA/2 F_1 hybrid mice. All strain A mice died with progressively growing tumors. Occasional temporary growth was seen in a few ABY, DBA/2 and C3H mice but these invariably regressed. No growth was seen in any of the other allogeneic hosts and none of them died with tumors, under an observation period of more than 2 months.

Absorption tests

HP^+ enriched TA3/Stockholm cell populations were also tested for their ability to bind anti-H-2^a antibodies, in comparison with TA3St och TA3Ha cells, as described previously [3].

Altogether 4 absorption experiments were carried out against an ACA antiA serum, tested against normal A lymphocytes as targets. There was no significant difference in the absorbing capacity of TA3St and the HP^+ enriched population.

DISCUSSION

These data show that it was possible to select, from TA3St cell populations, HP-binding cell fractions by a series of HP-column binding and elution sequences. However, the HP-binding properties of the selcted HP^+ TA3St line differed considerably from the TA3Ha line. The findings are schematically summarized in Table 6.

Biologically, the selected variants did not correspond to TA3Ha because they failed to grow in foreign strains of mice after homotransplantation and remained unchanged with regard to the absorbing capacity for anti-H-2^a antibodies. This suggests that the membrane changes responsible for the high HP binding do not necessarily involve the masking of H-2^a antigenic sites. As a subsequent step, we

Table 6. Schematic summary of HP-binding, allotransplantability and H-2^a expression

Cell line	HP-receptors strong	HP-receptors weak	Allotransplantability	H-2^a expression
TA3St	2–10%	—	–	high
HP^+TA3St	2–10%	>90%	–	high
TA3Ha	100%	—	+	low

intend to select allotransplantable TA3St sublines by forced passage through foreign strains, to see whether this biological selection leads to the appearance of epiglycanin positive variants with high HP-binding capacity and reduced H-2^a antigen expression.

Effect of Human and Mouse Interferon and of Polyriboinosinic Acid·Polyribocytidylic Acid on the Growth of Human Fibrosarcoma and Melanoma Tumors in Nude Mice

E. DE CLERCQ, J. GEORGIADES,† V. G. EDY§ and H. SOBIS

Rega Institute for Medical Research, University of Leuven, B-3000 Leuven, Belgium

Abstract—*Human leukocyte interferon, human fibroblast interferon, mouse interferon and an interferon inducer, polyriboinosinic acid·polyribocytidylic acid (poly(I)·poly(C)), were examined for their effect on the growth of two human tumor cell lines in athymic nude mice. The human tumor cell lines were derived from a fibrosarcoma (designated HT-1080) and a nonmelanotic melanoma (designated A-375). Repeated doses of* 5 mg/kg *of poly(I)·poly(C), administered every other day starting* 1 day *after tumor cell inoculation, caused a significant inhibition of tumor growth. On the contrary, human (leukocyte or fibroblast) interferon and mouse interferon, at doses up to* 5×10^6 units/kg, *did not affect the growth of either of the two human tumor cell lines tested.*

INTRODUCTION

CONGENITALLY athymic (nude) mice accept for their lifetime skin grafts from mammals (cat, human), birds (chicken), reptiles (lizards) and amphibians (frogs) [1, 2]. They also support the growth of a variety of human tumor cells. Both primary human tumors, e.g. malignant melanoma [3] and lung carcinoma [4] and permanent cell lines derived from human tumors, e.g. melanoma [5–7], HeLa [8], mammary carcinoma [9], colon carcinoma [10] and neuroblastoma [11] have been transplanted successfully to nude mice. Even after long-term serial transplantation in nude mice, these malignant tumors retain their original cytological and histological appearance [12], although Aubert *et al.* [5] noted ultrastructural and biochemical changes in human malignant melanoma cell lines which had been transplanted into nude mice. The human tumor-nude mouse system has been advocated as a suitable model for *in vivo* screening of sensitivity of human tumors to chemotherapeutic agents [13].

We have been able to maintain in nude mice the growth of two established human tumor cell lines, a fibrosarcoma (designated HT-1080) and a nonmelanotic melanoma (designated A-375). These tumor systems were chosen to evaluate the antitumor potentials of interferon and poly(I)·poly(C). Both human interferon and mouse interferon were examined for antitumor activity. We reasoned that if interferon exerted a direct cytotoxic (or cytostatic) effect on the tumor cells, human interferon but not mouse interferon would prove to be effective. If, however, the antitumor effect of interferon were mediated by the host cells (e.g. lymphocytes or macrophages), one might expect mouse interferon but not human interferon to be effective. *In vitro* and *in vivo* interferon generates several biological responses some of which may seem compatible with a direct

§Present address: Theodor Kocher Institut, 3009 Bern, Switzerland.

inhibitory effect on tumor cell growth while others point to a host-mediated rejection of the tumor cells. For example, interferon inhibits the multiplication of leukemic cells under steady-state conditions [14]. It enhances the expression of cell surface antigens [15], including the expression of histocompatibility antigens on lymphoid cells [16, 17]. Furthermore, interferon has been shown to increase the specific cytotoxicity of sensitized lymphocytes for allogeneic target tumor cells [18] and to stimulate the phagocytic activity of peritoneal macrophages [19, 20].

By virtue of its interferon inducing capacity and several other activities, in particular a direct inhibitory effect on macromolecule (DNA, RNA and protein) synthesis [21–23], poly(I)·poly(C) might also be expected to exhibit an antitumor action in the human tumor-nude mouse system. Poly(I)·poly(C) has recently been found to suppress the growth of mouse L-929 tumor cells in nude mice [24]. This antitumor effect of poly(I)·poly(C) may have resulted from a direct cytotoxic action of the double-stranded RNA on the tumor cells. Poly(I)·poly(C) has indeed been shown to selectively block macromolecule synthesis of tumor cells [25].

MATERIALS AND METHODS

Mice

Athymic nude (*nu/nu*) mice of NMRI background were bred according to breeding scheme IV of Giovanella and Stehlin [26]. They were kept in stainless steel cages, in conventional conditions, at an ambiant temperature of 25°C and a relative humidity of 80%. Other characteristics of our nude mouse strain have been dealt with previously [24].

Interferon preparations

Human leukocyte interferon was kindly provided by Dr. K. Cantell (Central Public Health Laboratories, Helsinki, Finland). The human leukocyte interferon had a specific activity of 10^6 U per mg protein.

Human fibroblast interferon was prepared essentially as described by Billiau *et al.* [27], except that the final medium contained 6 mM Hepes (*N*-2-hydroxyethyl piperazine), 13 mM tricine (*N*-Tris–hydroxymethyl-methyl glycine) and 1% (v/v) pasteurized human plasma protein fraction (Belgian Red Cross). Two human fibroblast interferon preparations were employed. The first preparation had a specific activity of 2×10^5 U/mg protein and was used in these animals which were treated with interferon at 5×10^5 u/kg (10^4 U per mouse). The second preparation, which had been purified by adsorption chromatography on controlled pore glass [28], had a specific activity of 2×10^6 U/mg protein and was used in these animals which were treated with interferon at 5×10^6 U/kg (10^5 U per mouse).

Mouse interferon was induced in L-929 cells by Newcastle disease virus. It was prepared according to a modification of the procedure described by Knight [29]. The specific activity of the mouse interferon preparation amounted to 6×10^5 U/mg protein.

Interferon titers

For human leukocyte interferon, the titers are expressed in terms of the Human Interferon Research Standard B (MRC 69/19). For human fibroblast interferon such standardization is not applicable, since human fibroblast and leukocyte interferons show different dose–response curves [30, 31]. Therefore, human fibroblast interferon titers are expressed in laboratory reference units. Mouse interferon titers are expressed in terms of the Mouse Interferon Reference Standard G 002-904-511 (NIH).

Poly(I)·poly(C)

Poly(I)·poly(C) was prepared by mixing equal volumes of the homopolymer solutions of poly(I) and poly(C), both purchased from P-L Biochemicals (Milwaukee, Wisconsin) and dissolved in Dulbecco's PBS (phosphate buffered saline) at 1 mg/ml. Aliquots of the poly(I)·poly(C) stock solution were stored at −20°C and thawed prior to use.

Tumor cell lines

The fibrosarcoma HT-1080 cell line was established by Rasheed *et al.* [32] from the fibrosarcoma of a 35 yr old Caucasian man who died without having received chemotherapy or radiotherapy.

The melanoma A-375 cell line was provided by Dr. P. T. Allen (National Cancer Institute, Fort Detrick, Frederick, U.S.A.).

The HT-1080 and A-375 cell lines were maintained in polystyrene culture bottles in Eagle's minimal essential medium supplemented with non-essential aminoacids, tricine

and 10% heat-inactivated (90 min at 56°C) fetal calf serum. The cells were subcultured weekly by trypsinization at a 1–10 split ratio.

Histological and ultrastructural examination

For histological studies the tumors were fixed in formol, embedded in paraffin and stained with erythrosin-hematoxylin (or Gordon–Sweets to visualize reticulin). For ultrastructural studies, tumor specimens were fixed in glutaraldehyde, postfixed with osmium tetroxide, stained with uranyl acetate, dehydrated and embedded in araldide. Thin sections were cut with an OMU 2 Reichert ultramicrotome, stained with lead hydroxide and examined by a Zeiss 95 electron microscope.

Tumor cell inoculation

The antitumor activity of interferon and poly(I)·poly(C) was assessed with fibrosarcoma HT-1080 and melanoma A-375 tumors which had been passed previously onto nude mice. To this end, the tumors were harvested from the mice and after trypsinization, the tumor cells were resuspended in serum-free Eagle's minimal essential medium. The tumor cells were then injected subcutaneously with a 22 G 1 1/4 needle in the dorsum of 22 day old *nu/nu* mice. The HT-1080 cells were injected at 3×10^6 cells/0.1 ml/mouse whereas the A-375 cells were injected at 1.2×10^6 cells/0.1 ml/mouse.

Interferon treatment

The interferon preparations (mouse interferon as well as human fibroblast or leukocyte interferon) were injected intraperitoneally to the nude mice at either of the following dosage regimens: (i) 10^4 U per mouse (*ca.* 5×10^5 U/kg) on alternate days from the first till the 23rd day after tumor cell inoculation, or (ii) 10^5 U per mouse (*ca.* 5×10^6 U/kg) on alternate days from the first till the 9th day after tumor cell inoculation. The interferon doses employed in our studies are comparable to those which are generally feasible in man and exceed those (3×10^6 interferon units per person) which are now being administered to patients with osteogenic sarcoma [33, 34].

Poly(I)·poly(C) treatment

Poly(I)·poly(C) was injected intraperitoneally at 100 μg per mouse (*ca.* 5 mg/kg) on alternate days from the first till the 9th or 23rd day after tumor cell inoculation. The latter treatment regimen has been shown previously [24] not to impair the normal life span of nude mice and may be considered equivalent to the poly(I)·poly(C) dosage that has been employed in preliminary studies in human tumor patients [35, 36].

Measurements of tumor size

Length and breadth of the tumors were measured once weekly with slide calipers. The third dimension of the tumors could not be determined accurately. Tumor size is presented as the square root of the tumor area (calculated in mm^2).

Statistical analysis

Differences in tumor size between two groups at a given time were assessed by Student's *t*-test.

RESULTS

Effect of interferon and poly(I)·poly(C) on fibrosarcoma HT-1080 tumor growth in nude mice

Tumors developed at the inoculation site of the cells, grew as single encapsulated masses with spherical, ellipsoid or rectangular form and displayed the same growth pattern in male and female mice. Spontaneous regression was not observed. Tumor development did not hamper the animal's activity or hasten its death. Tumor growth was local. There was no evidence of macroscopic metastases.

On histological examination the tumor appeared to be composed of poorly differentiated cells with large nuclei and prominent nucleoli. Silver staining revealed the presence of reticulin fibers. On electron microscopic observation, collagen fibrils were found outside the cells. The cytoplasm of the cells contained filaments which may be identified as protocollagen fibrils.

Neither human (leukocyte or fibroblast) interferon nor mouse interferon, administered intraperitoneally at 10^4 U per mouse on alternate days, starting one day after tumor cell inoculation, had an appreciable effect on tumor growth (Fig. 1). Under the same conditions, poly(I)·poly(C), administered at 100 μg per mouse, caused a marked inhibition of tumor development. The average tumor sizes ($\sqrt{mm^2}$) recorded at day 43, that is 21 days after tumor cell inoculation, were 19.0 for group I (human leukocyte interferon), 17.0 for group II (human fibroblast interferon), 16.2 for group III (mouse

interferon), 3.6 for group IV [poly(I)·poly(C)] and 16.3 for group V (PBS control). While differences in tumor size between the control (group V) and groups I, II and III were not significant, tumor sizes of mice which had been treated with poly(I)·poly(C) (group IV) significantly differed from tumor sizes of control mice (group V) ($P<0.001$).

At the dosage regimen at which poly(I)·poly(C) was employed, there was no evidence of a deleterious effect on the general health (body weight) of the animals. When the poly(I)·poly(C) injections were stopped, there was no burst of tumor growth. The tumors grown in poly(I)·poly(C)-treated mice and the tumors grown in untreated mice did not reveal any histological or ultrastructural differences.

As neither human interferon nor mouse interferon exerted an inhibitory effect on HT-1080 tumor growth when injected at 10^4 U per mouse, additional experiments were performed in which both mouse and human interferon were administered at 10^5 U per mouse. This treatment was initiated one day after tumor cell inoculation and continued every other day until the ninth day after tumor cell inoculation, when it became apparent that even at 10^5 U per mouse human interferon as well as mouse interferon failed to affect HT-1080 tumor growth (Fig. 2). The average tumor sizes ($\sqrt{mm^2}$) recorded at day 34, that is 12 days after tumor cell inoculation, were 11.0 for the group of mice treated with human fibroblast interferon, 11.1 for the group of mice treated with mouse interferon and 10.7 for the

control (PBS) group. Five consecutive doses of 100 μg of poly(I)·poly(C) administered at 1, 3, 5, 7 and 9 days after tumor cell inoculation sufficed to reduce the average tumor size (measured at the 12th day after tumor cell inoculation) from 10.7 (control) to 5.4 ($P<0.001$) (Fig. 2).

As the lack of antitumor activity of human interferon might have been attributed to an abnormally rapid clearance (or inactivation) or human interferon in the bloodstream of nude mice, interferon titers were measured in the blood of HT-1080 tumor-bearing mice which had received multiple intraperitoneal injections of either human (fibroblast) interferon or mouse interferon (10^5 units/mouse) or poly(I)·poly(C) (100 μg/mouse) (regimen as explained in the legend to Fig. 2). Comparable serum interferon titers, amounting to approximately 1000 units/ml, were obtained within 2–8 hr following the fifth injection of poly(I)·poly(C) or of human and mouse interferon (data not shown), suggesting that the inability of human interferon to inhibit HT-1080 tumor growth in the nude mouse could not be attributed to an unusually rapid disappearance of human interferon from the blood. Injection of mouse interferon to nude mice resulted in the appearance of serum interferon activity with the species specificity of mouse interferon, and injection of human interferon gave rise to serum interferon activity with the species specificity of human interferon. It is noteworthy that upon injection of poly(I)·poly(C) only mouse interferon was detected in the bloodstream; human interferon might have been found if the transplanted HT-1080 tumor cells participated in the production of interferon.

Effect of interferon and poly(I)·poly(C) on melanoma A-375 tumor growth in nude mice

The growth patterns demonstrated by the melanoma A-375 tumors was essentially the same as that of the fibrosarcoma HT-1080 tumors, except that tumors grew at a slower pace. Also, melanoma tumors assumed a predominantly spherical form.

Histological examination of the tumor revealed the presence of pleomorphic cells, numerous mitotic figures, but no melanin. Premelanosomes were detected upon electron microscopic observation. Melanization was incomplete as could be expected from an aggressive melanoma.

One day after they had been inoculated with the melanoma tumor cells, the mice were submitted to the same interferon treatment as employed for the fibrosarcoma HT-1080 cell-bearing mice. As shown in Fig. 3, both human interferon, whether leukocyte or fibroblast, and mouse interferon failed to affect tumor growth. Poly(I)·poly(C), however, brought about a partial reduction of tumor size. The average tumor sizes ($\sqrt{\text{mm}^2}$) recorded at day 43, that is 21 days after tumor cell inoculation, were 9.5 for group I (human leukocyte interferon), 10.4 for group II (human fibroblast interferon), 10.7 for group III (mouse interferon), 6.1 for group IV [poly(I)·poly(C)] and 10.0 for group V (PBS control). The tumor sizes of groups I, II and III did not significantly differ from that of the control (group V). However, differences in tumor size between the control group and group IV (which had been treated with poly(I)·poly(C)) were significant at $P<0.001$.

DISCUSSION

In mice, poly(I)·poly(C) has been shown to inhibit the growth of a variety of transplanted murine tumors, e.g. L-1210 leukemia [37], reticulum cell sarcoma [38], malignant melanoma [39] and mammary carcinoma [40]. These inhibitory effects have recently been extended to L-929 tumor cell growth in nude mice [24] and are further extended, in the present report, to two human tumor cell lines transplanted to nude mice. The two cell lines tested were a fibrosarcoma (designated HT-1080) and a nonmelanotic melanoma (designated A-375). Upon subcutaneous inoculation of 1 or 3×10^6 tumor cells, single, well-defined tumor masses developed at the sites of inoculation. Repeated doses of 100 μg of poly(I)·poly(C) (5 mg/kg), administered intraperitoneally on alternate days starting 1 day after tumor cell inoculation, effectively inhibited tumor growth. When tested under the same conditions, no inhibition of tumor growth was obtained with poly(I)·poly(s^2C), a thioketo analogue of poly(I)·poly(C) (41), kindly provided by Dr. K. Reuss (E. Merck, Darmstadt) (data not shown). Human interferon and mouse interferon, administered at 10^4 or 10^5 per mouse (5×10^5 or 5×10^6 U/kg), also failed to affect tumor growth.

Yet, mouse interferon preparations have been reported to inhibit the growth of several murine transplantable tumors and to increase the survival of the tumor-inoculated mice [42–45]. These mouse interferon preparations were particularly effective when intimate contact between tumor cells and interferon occurred, i.e. in mice which received both the tumor cells and the interferon preparations by the intraperitoneal route [42, 44]. However, interferon has also been shown to inhibit the growth of a solid malignant tumor (Lewis lung tumor) and to prevent the development of pulmonary metastases in experiments in which the tumor cells were inoculated subcutaneously and interferon was administered by the intravenous route [43]. In these conditions as well as in ours, no direct contact between tumor cells and interferon was achieved. Whereas interferon blocked tumor cell proliferation in the one case [43], it failed to do so in the other (see Figs. 1–3).

The antitumor activity demonstrated by poly(I)·poly(C) in the nude mouse may be ascribed to a direct cytotoxic action of the drug on tumor cell metabolism. Both HT-1080 fibrosarcoma cells and A-375 melanoma cells proved particularly susceptible to the cytostatic effects of poly(I)·poly(C) [as monitored by (^{3}H-methyl) thymidine incorporation] when the cells were plated *in vitro* in the presence of the double-stranded RNA (data to be published). The lack of antitumor activity of mouse interferon in the human tumor-nude mouse system may be interpreted to mean that in our test conditions the host-mediated resistance to the heterotransplant is not greatly affected by the exogenous administration of mouse interferon. To explain the lack of antitumor activity of human interferon, a variety of reasons could be considered, including the relatively rapid appearance and development of the tumors upon inoculation of the tumor cells (see Figs. 1–3). *In vitro*, both HT-1080 fibrosarcoma and A-375 melanoma cells were sensitive to the anti-proliferative effects of human (fibroblast and/or leukocyte) interferon (data to be published), so that their lack of antitumor activity *in vivo* could not be rationalized in terms of an abnormal resistance of the tumor cells to the "anticellular" effects of interferon.

The fact that neither human interferon nor mouse interferon exerted an inhibitory effect on tumor growth in our human tumor-nude mouse systems could obviously be attributed to the relatively low doses of interferon employed (5×10^5–5×10^6 U/kg). It should be pointed out, however, that these doses approach or even exceed those which would seem technologically feasible in human beings and that similar interferon doses have been found effective in inhibiting the growth of methylcholanthrene-induced tumors in mice [46].

It should be recognized that malignant human tumors when transplanted into nude mice generally grow as sharply circumscribed nodules, do not break through their compression capsules and do not metastasize. In this sense, they do not express their malignant potential in the environment of the nude mouse. This rather "benign" behaviour of human tumors transplanted into nude mice may eventually explain why interferon, unlike poly(I)·poly(C), failed to suppress tumor growth. One may indeed speculate that interferon predominantly acts by inhibiting spread of the tumor cells and formation of metastases. Therefore, any potential antitumor effects of interferon would go unnoticed if the host itself prevents metastasis.

Acknowledgements—Our thanks are due to Prof. A. Billiau and Ir. J. Van Damme for the supply of human fibroblast interferon, to Dr. K. Cantell for the supply of human leukocyte interferon and to Prof. P. De Somer for stimulating discussions.

Cyclophosphamide Pretreatment Reduces the Toxic Effect of High Dose Melphalan on Intestinal Epithelium in Sheep

J. L. MILLAR,* T. A. PHELPS,* R. L. CARTER† and T. J. McELWAIN‡

**Division of Biophysics*, †*Division of Histopathology*, ‡*Division of Medicine*, *Institute of Cancer Research and Royal Marsden Hospital, Clifton Avenue, Belmont, Sutton, Surrey SM2 5PX, United Kindom*

WE HAVE investigated binary combinations of cytotoxic drugs in mice which have less than the expected toxicity on normal tissues such as bone marrow [1–3], urothelium [2] and intestinal epithelium [3]. A priming dose of cytotoxic drug is given, followed by an interval, and then a large dose of either the same or a different cytotoxic drug. Very often the amount of drug that can be given in the large dose exceeds that which would normally be fatal to the mouse. The time interval between treatments is critical and varies from 2 to 4 days depending on the drugs used and the tissue(s) at risk.

Evidence has been presented [2, 3] that tumour tissue is not spared by drug combinations that spare normal tissues, and drugs used in this way have increased the therapeutic index. It was therefore important to see if a drug combination of this sort spared tissues in a large mammal such as the sheep, and to establish the optimum timing between priming dose and challenge dose. Sheep were chosen as they were readily available from local farms and the two drugs investigated were cyclophosphamide and melphalan as these have been extensively investigated [2, 3].

Barren ewes, kept for the duration of the experiment in a purpose built animal house, ranged in weight between 49 and 58 kg. Cyclophosphamide (cyclophosphamide monohydrate, Koch-Light Ltd.) was dissolved in saline; melphalan (Alkeran, Burroughs Wellcome Co.) was first dissolved in 1 ml of 2% acid alcohol and then in buffered diluent provided by the manufacturers. Both drugs were given i.v. as single injections. Cyclophosphamide, 10 mg/kg was always given first and followed at a variable time interval by melphalan, 3 mg/kg. The animals were killed 4 days after the melphalan with pentobarbitone (Expiral, Abbott Lab. Ltd.) and an immediate autopsy was performed. Blocks of tissue were taken at standard points in the duodenum, jejunum, ileum and ascending colon, fixed in 10% formol saline and processed for routine microscopy. Morphological changes in the intestinal mucosa were scored on a semi-quantitive 0 to 3 scale.

The effect of different time intervals between cyclophosphamide pretreatment and the dose of melphalan on the intestinal mucosa are summarised in Table 1. Histological examination of the gut epithelium in animals treated with melphalan alone (last column) indicated that few normal elements remained 4 days after this large dose of melphalan. With cyclophosphamide given 2 days before melphalan, the mucosal damage appeared to be even more severe. If, however, an interval of between 5 and 9 days was left between cyclophosphamide pretreatment and high dose melphalan, mucosal damage was much less pronounced, with the optimum when cyclophosphamide treatment preceded melphalan by 7 days.

Peripheral blood counts, measured at the time of killing (Table 2), indicated that the total leukocyte count fell less in animals pretreated with cyclophosphamide 7 days before melphalan.

Although no convincing explanation of the underlying mechanism has been established, the ability of a priming dose to reduce the

Table 1. *Changes in intestinal mucosa in sheep treated with a sequence of* 10 mg/kg *cyclophosphamide* (*CY*) *and* 3 mg/kg *melphalan* (*M*) *given at different time intervals. Symbols above the diagonal lines refer to villi, below the lines to crypts*

Tissue	CY given 2 days before M	CY given 5 days before M	CY given 7 Days before M	CY given 9 Days before M	M Alone
Duodenum	+ + / + +	+ + + / + +	+ + / +	+ + + / + +	+ / +
Distal jejunum	0 / +	+ / + +	+ + + / + +	+ / +	0 / +
Distal ileum	0 / 0	+ / +	+ + + / +	+ + + / +	0 / +
Ascneding colon	/ + +	/ + + +	/ +	/ + +	/ 0

Changes in villi, small intestine:
0 = Completely absent.
+ = Flat with epithelial covering.
+ + = Raised with some epithelial covering.
+ + + = Condition approaching that seen in untreated control animals.

Changes in crypts, small intestine and large intestine:
0 = Completely absent.
+ = Dilated with incomplete epithelial lining.
+ + = Intact but abnormal.
+ + + = Condition approaching that seen in untreated control animals.

Table 2. *Effect of varying the timing between* 10 mg/kg *cyclophosphamide* (*CY*) *and* 3 mg/kg *melphalan* (*M*) *on the peripheral leukocyte counts in sheep*

	Treatment					
	Normal	CY given 2 days before M	CY given 5 days before M	CY given 7 days before M	CY given 9 days before M	M alone
24 hr after melphalan	8800 ± 809	N.D.	N.D.	4500 ± 312	N.D.	6357 ± 121
96 hr after melphalan		387 ± 137	1284 ± 149	2505 ± 100	865 ± 74	557 ± 63

Counts ± S.E./mm^3.
N.D. = Not done.

toxicity of a large dose of melphalan has been shown to operate in bone marrow in mice [3] and rats [4] and in the intestinal epithelium in mice [3] and sheep. This phenomenon is clearly not species or tissue specific, though the mechanisms may be different depending on the tissue.

If the phenomenon occurs in man, the timing and dosage will almost certainly be closer to that for sheep than for rats or mice, and it is unlikely that the timing for gut sparing in man will involve an interval of less than 5 days. Gut sparing would be the major objective in man since protection of the bone marrow is less of an advantage in centres where adequate support can be given during the period of drug-induced pancytopenia.

Experimental tumour systems studied so far [2, 3] have not been spared by binary drug combinations which spare normal tissues. Tumour cells presumably lack some of the

control mechanisms of normal renewal tissues and they may not have the capacity to alter their biochemical or proliferative behaviour after a priming dose of drug. By administering drugs in ways which reduce the toxicity of these drugs to normal critical tissues, larger doses may be given and an improvement in anti-tumor effect obtained.

Impairment of Inflammatory Reactions in Tumour-Bearing Mice as Measured by Evans Blue Extravasation*

J. AMICE, L. DAZORD and L. TOUJAS

Service D'Immunologie et d'Immunothérapie, Centre Régional Anticancéreux, F 35 000 Rennes, France

MANY authors have reported diminutions of skin reactions of delayed type hypersensitivity in cancer patients, sometimes in relation with the prognosis of the disease. Some investigations suggest that this effect could result from an impairment of the non-specific step of the response rather than from a failure in the function of antigen-reacting cells. Johnson *et al.* [1] observed that cancer patients with diminished responses to the hapten DNCB had a parallel diminution of inflammatory reactions against Croton oil, a non-antigenic irritant substance. Likewise, Bernstein *et al.* [2], in cancer bearing guinea pigs, found a diminution of skin tests after local administration of non-specific irritant or of specific recall antigens. However, immune cells responded normally *in vitro*: antigen-stimulated blood lymphocytes underwent blast transformation and synthetized skin reactive factor.

In the present work, inflammatory reaction was measured in mice, at different times after implantation of a solid tumour. The vascular component of the inflammatory reaction provoked by the intradermic injection of Freund adjuvant oil was measured, using a quantitative Evans blue test. The alterations recorded seemed related with the size of the tumour. However, as a strong hyperplasia of spleen and liver took place during tumour growth, we wondered whether this generalized inflammation could play a role in the diminution of the local inflammatory response to Freund adjuvant.

Female B6 D2 mice, 6 per group, were tested 1–4 weeks after i.m. graft of 10^6 Lewis tumour cells. For the test, 10 μl oil of Freund incomplete adjuvant (DIFCO) were injected in both ear pinnas. Twenty-four hours later, the mice received i.p. 0.2 ml of a 2.5 p. 100 Evans blue solution. Diazo dyes which bind plasma protein have been widely used to quantify capillary permeability [3] especially in inflammatory reactions [4]. Four hours after Evans blue injection, under ether anaesthesia, 30 μl blood were collected from the retroorbitary sinus, added to 2 ml saline and centrifuged. Then the animals were killed, tumour diameter and spleen weight measured. From each ear, the inflammatory site was removed with a punch biopsy. The skin disks thus obtained were dissolved in 2 ml Soluene 100 (Packard) within 90 min at 60°C. Blood supernatants and Soluene solutions, both containing Evans blue, were analyzed by spectrophotometry respectively at 605 and 615 nm.

As shown on Table 1, the decrease of Evans blue extravasation at the inflammatory site was significant from the 14th day after tumour graft. On the 28th day, the amount of dye per ear was 3 times lower than in the control. This diminution could not be ascribed to a parallel decrease of dye haemoconcentration. On the contrary Evans blue was more abundant in the blood of tumour bearing mice. The decrease in inflammatory response was roughly parallel with the increase in size of the tumour and of the lymphoid organs, here expressed through the spleen weight. The histological examination of spleen and liver did not show any malignant metastasis but only non specific proliferation of mononuclear cells.

Accepted 26 April 1978.

Table 1. Inflammatory reaction measured by Evans blue extravasation during the growth of Lewis tumour

Days after tumour graft	μg Evans blue ± S.E.		Tumour diameter ± S.E. (mm)	Spleen weight ± S.E. (mg)
	At inflammation site	Per 30 μl blood		
7	8.8 ± 2.7	12.9 ± 3.6*	2.7 ± 0.5	121 ± 22*
14	6.8 ± 2.7*	14.4 ± 2.0*	5.8 ± 1.3	187 ± 47*
21	5.0 ± 2.8*	13.8 ± 4.6*	13.5 ± 2.1	419 ± 34*
28	3.2 ± 1.3*	12.6 ± 2.4*	18.9 ± 1.5	706 ± 126*
Control (no tumour)	9.4 ± 2.5	10.0 ± 1.2	–	83 ± 15

*Significantly different from control groups at Student's *t*-test.

The mechanisms by which the presence of a tumour can provoke a diminution of inflammatory response may be discussed. Products synthetized from tumour cells in culture have been shown to inhibit the chemotaxis of inflammatory cells towards inflammation sites [5]. On the other hand tumour growth was shown to be often accompanied by inflammatory reactions developing either locally in contact with tumour cells [6] or at distance, giving rise to a stimulation of the reticuloendothelial system [7]. Several authors have described interactions between inflammatory foci located in different parts of the body: the previous induction of an inflammation was shown to diminish the response to the ensuing inoculation of irritant material [8, 9]. The intravenous injection of bacterial organisms inducing granulomatous reactions was shown to impair the present Evans blue test (in preparation). Thus, the inflammatory reactions associated to tumour growth could be sufficient to diminish the skin response against an inflammatory agent. Interactions between two distant inflammatory processes could result from a competition for the use of common cells or soluble mediators. Moreover, antinflammatory substances have been extracted from inflammatory exudates (reviewed in [10]). Such factors would represent a regulatory process of inflammation which, in the present case, would have overflowed from the local reaction and extended to the whole body.

Assessment of Response to Therapy in Advanced Breast Cancer

A Project of the Programme on Clinical Oncology of the International Union against Cancer, Geneva, Switzerland

J. L. HAYWARD* (Chairman),* R. D. RUBENS (Secretary),* P. P. CARBONE,† J.-C. HEUSON,‡ S. KUMAOKA§ and A. SEGALOFF||

**Imperial Cancer Research Fund, Breast Cancer Unit, Guy's Hospital, London, United Kingdom, †Division of Clinical Oncology, Wisconsin Cancer Clinical Centre, University Hospital, Madison, U.S.A. ‡Institut Jules Bordet, Centre des Tumeurs de L'Universite Libre de Bruxelles, Belgium, §National Cancer Centre Hospital, Tokyo, Japan and ||Richard W. Freeman Research Institute, Alton Ochsner Medical Foundation, New Orleans, U.S.A.*

In 1977, a project of the programme on clinical oncology of the UICC published a system of guide-lines recommended for use in clinical trials designed to assess the objective response of locally advanced or metastatic mammary cancer to treatment [1–6]. Since then it has become apparent that the rules for defining duration of remission are not entirely clear. In particular, patients achieving a complete objective regression may have, additionally, a period when only in partial regression. The following amendments to the original publications have been agreed.

Categories of response

Objective regression. (i) Complete response. The disappearance of all lesions determined by two observations not less than 4 weeks apart. (ii) Partial response. Fifty per cent or more decrease in measurable lesions and unequivocal improvement in evaluable but non-measurable lesions with no new lesions developing, determined by two observations not less than 4 weeks apart.

No change and progressive disease. These categories remain as defined previously.

Duration of response

It is recommended that: (1) The period of "overall response" be from the date of start of treatment to the date of first observation of progressive disease. (2) The period of "complete response" be from the date complete response was first recorded to the date of first observation of progressive disease. (3) In those patients who just achieve a "partial response", only the period of overall response should be recorded.

Thus, in patients achieving a complete objective remission the duration of this complete response should be distinguished from the longer overall response recorded in these cases.

Accepted 27 April 1978.

Announcements

THE SECOND INTERNATIONAL CONFERENCE ON THE ADJUVANT THERAPY OF CANCER

The Second International Conference on the Adjuvant Therapy of Cancer will be held in Tucson, Arizona 28–31 March, 1979, under the sponsorship of the Cancer Center Division of the University of Arizona. Drs. Sydney E. Salmon and Stephen E. Jones will serve as Conference Co-Chairmen. Abstract forms are now available; the deadline for submission of abstracts (prepared in the format of AACR/ASCO) is 1 December, 1978. For abstracts forms or further information, contact:

Dorothy Baker,
Conference Coordinator,
Cancer Center Division,
University of Arizona,
Tucson, Arizona 85724,
602-626-6044.

WORKSHOP ON CLONING HUMAN TUMOR STEM CELLS

A practical workshop on soft agar cloning methods for human tumor stem cells will be held at the University of Arizona, College of Medicine, in Tucson, 3–5 January, 1979, under the sponsorship of the Cancer Center Division. The workshop will be presented by Drs. Sydney E. Salmon, Anne Hamburger, David S. Alberts, Ronald N. Buick and colleagues.

Further information may be obtained by writing to the Cancer Center Division, University of Arizona, Health Sciences Center, Tucson, Arizona 85724, or by phoning Dr. Ronald Buick at (602) 626-6408.

EUROPEAN ORGANISATION FOR RESEARCH ON TREATMENT OF CANCER (E.O.R.T.C.)

Second Breast Cancer Working Conference, Experimental and Clinical Aspects, in Copenhagen, Denmark, 31 May–2 June, 1979.

Program Committee: H. T. Mouridsen, T. Palshof, J. Daehnfeldt and E. Engelsman.

The scientific program of the Conference will include recent experimental findings and clinical studies in primary and advanced breast cancer.

The Conference will include lectures by leading authorities, panels of invited guestspeakers and free communications. The number of participants is limited to 250 and dead line for registration is 15 March, 1979.

Please address inquiries to:
H. T. Mouridsen and T. Palshof,
Finseninstitute,
49 Strandboulevarden,
DK-2100 Copenhagen Ø,
Denmark.

Telephone: (01) 26 08 50, ext. 342.

RADIATION BIOLOGY IN CANCER RESEARCH

"Radiation Biology in Cancer Research" will be the topic of the 32nd annual Symposium on Fundamental Cancer Research to be held in Houston at the Shamrock Hilton Hotel 27 February–2 March, 1979. Subjects to be covered include responses at low doses; targets and effects; delayed effects in tissues; tissue effects not definitely attributable to cell killing; tumor biology; and potential applications of radiobiology to radiotherapy. Co-chairmen: Dr. H. Rodney Withers and Dr. Raymond E. Meyn.

For additional information: Stephen C. Stuyck, M. D. Anderson Hospital and Tumor Institure, Houston, Texas 77030, (713) 792-3030.

Perspectives in Cancer Research

The Comparative Epidemiology of Selected Neoplasms Between Dogs, Cats and Humans. A Review

HOWARD M. HAYES, JR.

Environmental Epidemiology Branch, National Cancer Institute, 3C07 Landow, Bethesda, MD 20014, *U.S.A.*

THERE are a multitude of factors implicated in the etiology of cancer. Singly or in combination, determinants such as viruses, genetic susceptibility, alterations of endocrine metabolism, and exposures to solar radiation, X-radiation, certain chemicals, radioactive elements, inorganic substances, foods and drugs have been identified [1]. Yet, there is considerably more research to be done. Who is at risk for cancer, when and why? Some of the answers may lie in gaining new knowledge about disease processes in lower animals.

Proof of the kinship in the etiology of animal and human cancer is easily demonstrated by the work of Holsti and Ermala [2]. These investigators attempted to induce lung cancer in mice by painting their oral mucosa with tobacco tar. Rather than producing tumors of the lung, they induced carcinomas of the urinary bladder. The association of tobacco usage and subsequent bladder cancer in humans has now been established and quantified [3, 4].

The study of spontaneous occurring neoplasms in animals has recently gained further impetus. With the identification of excessive mortality rates of particular human cancers in specific U.S. counties [5], it now makes it possible to pursue the epidemiology of the lesion in similarly exposed pets. Dogs and cats which are kept as pets could be an ideal sentinel for monitoring the effects of low-level environmental contaminants. Pets share their owner's environment except for work-related exposures and tobacco usage. These two confounding variables presently bias many human surveys.

This review concerns the epidemiology of canine and feline neoplasms of the testis, ovary, mammary gland, urinary bladder, kidney, thyroid gland, chemoreceptor system, brain and blood–lymphatic system. Comparisons will be drawn between the human and veterinary epidemiology when possible.

TESTIS

The mortality rate from testicular neoplasms has doubled in men in the last 20 yr [6]. This lesion is now the leading cause of cancer death in the U.S. among men between the ages of 25 and 29 [5]. These neoplasms are second in hospital prevalence in the dog [7], but are very rare in the cat.

Men and dogs share many of the epidemiologic features of testicular tumors; the primary exception is the different frequency of occurrence of certain cell-types. Embryonal carcinomas and teratomas predominate in children and seminomas in adults, but Sertoli cell and interstitial cell tumors in humans are quite rare [6]. In the dog, seminomas, Sertoli cell tumors, and interstitial cell tumors occur with about equal frequency; teratomas have been unreported [7].

Several canine breeds have been identified with an excessive risk of one or more cell-types of testis including the Boxer, Weimaraner, Shetland Sheepdog and German Shepherd dog. What is intriguing is that the factor(s) responsible for the familial risk in Boxers expressed itself in three different tumor cell-types, whereas in the Weimaraner, just two cell-types were present excessively, and in the Shetland Sheepdog and German Shepherd dog only one cell-type [7]. In about half of the infrequent familial aggregates of testicular

neoplasia in man, more than one tumor cell-type was exhibited [8].

Other factors besides inheritance must play a large role in testicular tumorigenesis. There is some evidence to suggest that environmental exposures associated with rural or urban living contribute to the origin of seminomas in man [9–12]. Unfortunately, comparative data for dogs are not presently available.

Cryptorchism has long been recognized as a contributing factor to testicular neoplasia. Whether the etiology of the tumor(s) is founded only upon the dysgenetic gonad or is also the result of the inguinal and intra-abdominal environment is debatable [8]. Cryptorchid dogs have an estimated risk for testis tumors 13.6 times that of normal dogs [7]. In cryptorchid men, the relative risk has been estimated to be 14 by Mostofi [6] and 8.8 by Morrison [13]. However, tumor cell-types associated with the defect are different in each species. Among cryptorchid men, seminomas are the major cell-type [6, 13], while seminomas and Sertoli cell tumors share about equal risk in cryptorchid dogs [7]. Interstitial cell tumors have not been observed with cryptorchism in humans and only very rarely in dogs.

The Shetland Sheepdog has been proposed as an appropriate canine model for further research into testicular maldescent and tumorigenesis [7]. This breed has a predilection for the occurrence of each independent factor [7, 14], plus the concomitant occurrence of both [7].

OVARY

Ovarian malignancies represent 5% of the cancers diagnosed in U.S. women. Epithelial neoplasms account for about 75% of the U.S. incidence of ovarian cancer in white females [15]. Second most frequent are granulosa-theca cell tumors. In the largest canine study yet presented, epithelial neoplasms accounted for 60% and granulosa-theca cell tumors 27% of the classifiable ovarian tumors [16]. Overall, ovarian neoplasms are infrequently seen in the dog and cat.

Epithelial ovarian cancers, as a group, show consistently increasing incidence with age through 75 yr in women. In contrast, the incidence rates for malignant granulosa-theca cell tumors present two relatively static levels of occurrence with 45 yr being the age when risk increases [15]. Similarly in dogs, risk increases strikingly with age for bitches with epithelial ovarian tumors. Those with granulosa-theca cell tumors have a generally constant risk between 4 and 15 yr of age, followed by an increase [16].

There is a strong histologic similarity between ovarian neoplasms in dogs and those in women with the exception of granulosa-theca cell tumors. These tumors show considerably more morphological variation in bitch dogs than in women. This finding led Willis [17] to suggest that granulosa-theca cell tumors and epithelial ovarian tumors in the dog may share a common etiology. However, his hypothesis is not consistent with the reported epidemiology of the lesion [16].

There is little evidence of a familial association of ovarian neoplasms in women [18]. However, the incidence of ovarian cancer is much higher in white than black women. The difference here is attributed to the much higher incidence of epithelial ovarian cancer in whites over 45 yr of age than experienced by blacks [19]. Inheritance plays only a small role, at most, in the etiology of the canine lesion as the Pointer is the only breed identified with high risk for ovarian cancer [16].

The pathogenesis for spontaneous ovarian tumors in humans and animals is obscure. Suspected causes among women include hormonal imbalances and environmental carcinogens. Lingeman, in her treatise on human ovarian cancer [18], suggests the latter as the most prominent cause of the lesion, although few definitive clues exist. Unfortunately, the presently known epidemiologic features of canine ovarian cancer shed no new light on etiology [16]. Yet, the bitch dog does appear to be a suitable model for testing suspected ovarian carcinogens in women because of the similarities of the disease in both subjects.

MAMMARY GLAND

Tumors of the mammary gland are the most common neoplasm in the female dog but are infrequent in the cat [20]. The ratio of female to male dogs with the lesion is about 50:1, which is about the same ratio in people [21]. The distribution of mammary cancer by age in bitch dogs appears similar to that in women, using Lebeau's [22] dog-years to human-years formula [23].

Histologically, feline mammary carcinomas are more readily recognized as malignant than those from the dog. But occasionally in the cat, and often in the dog, mammary carcinomas are not uniform in histologic ap-

pearance. As in women, it appears that a correlation exists in cats between the histologic grading of malignancy and prognosis [24].

A relationship between tumor risk and parity in the bitch dog has been disputed [23, 25–27]. Schneider *et al.* [23] have reported a significant sparing effect for mammary cancer occurs in the bitch dog that had an oophorectomt prior to $2\frac{1}{2}$ yr of age. Studies of human breast cancer show that (1) risk increases with the age of the mother at giving first birth, (2) women under 30 yr of age who complete a full term pregnancy have less cancer risk than nulliparous women, although cancer protection is generally not enhanced by additional births [21], and (3) oophorectomy in women under 40 yr of age has a protective effect against the later development of breast cancer [28].

Familial factors do play a role in the etiology of the tumor. Female relatives of women with breast cancer have 2–3 times the risk for the lesion than the general population [21]. The increased risk is especially evident in the patient's children [29, 30].

In dogs, an excessive risk for mammary cancer has been identified in four canine breeds—Miniature Poodle, English Setter, German Shorthair Pointer and Pointer; it is important to note that the Pointer breed is also at high risk for ovarian cancer [18]. The occurrence of both cancers has been linked in some human families [31].

More investigation is needed to delineate factors possibly affecting canine and feline mammary cancer (i.e., obesity, the precursor effect of benign mammary neoplasms). Yet, there appears to be ample reason to use the dog and cat as models for research.

URINARY BLADDER

In the U.S. bladder cancer accounts for 4.3% of the incidence of all malignancies in humans [15]. In dogs, it represents 1% of the hospital prevalence of cancer [32], but is much rarer in cats [20]. Transitional cell carcinoma is the most common cell-type diagnosed in people [33] and dogs [32].

Four canine breeds (Scottish Terrier, Shetland Sheepdog, Collie, Beagle) show a marked propensity for the malignancy [32]. There is little evidence for an inheritance role in humans, although two families have been identified with an unusual aggregation of bladder tumors [34, 35]. One characteristic investigated in the living members of these families was their level of urinary tryphophan metabolites, a suspected cause of bladder cancer [33]. The similarities in the tryphophan metabolism between humans and dogs [36, 37] suggest that further studies using high-risk breeds of dogs could be helpful.

Female dogs have been detected with 1.5 times the risk of male dogs ($P<0.05$) for the tumor [32]. This sex differential probably occurs because of the infrequent urination, on a daily basis, by the female dog as compared to the male [38]. Urine-borne carcinogenic agents thus would have longer exposure to the bladder epithelium in the female than the male dog.

The sex risk is reversed in humans [15]. About one-tenth of the incidence of bladder cancer in men is reportedly associated with cigarette smoking [4, 39] and occupational exposures to chemicals, e.g., aromatic amines [33].

Recent canine trials indicate a dose–time relationship can also exist in the etiology. The total dose of carcinogen required to produce tumors is considerably less if given in small amounts over an extended period of time [40]. The latent period has been as long as 10 yr in some trials. Yet, once carcinogenesis has been initiated, removal of the exposure does not inhibit the growth of the tumor [41]. The overall low frequency of bladder cancer in dogs is consistent with a low dose response to general environmental exposures over an extended period of time [32].

It has been proposed that canine bladder cancer should be made a reportable disease in the U.S. [32]. Increasing case counts over time would possibly identify geographic areas where emerging environmental hazards to humans are now present.

KIDNEY

Very little is known about the etiology of renal carcinoma in animals and man. Wynder [42], in a review about the human lesion, proposed nutritional factors, e.g., animal fats and cholestoral, as a possible cause.

The epidemiology of feline renal carcinoma has been described. However, the recent description of canine renal carcinoma indicates an epidemiology very similar to that in humans [43].

Renal carcinoma accounts for 2% of human cancer in the U.S. [15]. In the dog, the tumor represents slightly less than 1% of

diagnosed malignancies. In neither species are genetic determinants conspicuous, although both men and male dogs are at increased risk for the lesion [15, 43]. And further, the male risk by age of canine renal carcinoma resembles the pattern of risk in men [43].

The reason for the male predominance of human renal carcinoma is obscure. Environmental factors are suggested by the rising incidence among American men, but not among women [44] and call for further studies into the role of tobacco, nutrition and occupational determinants. However, these factors cannot account for the male excess in dogs (and similar trends in sex ratio with age) and suggest the influence of host susceptibility, including the endogenous production or metabolism of sex hormones. This scenario is consistent with the evidence of remission in some human patients if treated with progesterone [45, 46].

THYROID GLAND

Endocrine malignancies compose 1.4% of all human cancers in the U.S. [15], 3.7 and 0.9% of the diagnosed cancers in dogs and cats [20]. Carcinoma of the thyroid is the predominant lesion among endocrine cancers. An environmental influence, linked with endemic goiter, has been disputed as an etiologic factor in human beings [47] and dogs [48]. X-radiation, a well-known etiologic agent for the human lesion [49], has not been implicated in the spontaneous neoplasia of the gland in domestic animals [48].

The morbidity and mortality from thyroid cancers is about $2\frac{1}{2}$ times greater in women than in men [5, 47]. Statistically, the diagnostic frequency in dogs shows no sex differential [48]. Familial aggregates of medullary thyroid carcinoma, singularly or in combination with other endocrine abnormalities, have been reported in man [50]. In dogs, breed predispositions for thyroid carcinoma have been detected in Boxers, Golden Retrievers and Beagles [48]. However, medullary thyroid carcinoma rarely occurs in dogs [51].

The excess risk among Boxer dogs is thought to be partly due to the anomalous follicular patterns commonly seen in their thyroid glands. More interesting may be the finding of excessively high risk among the Beagle breed. Investigators have reported an unexplained high prevalence of thyroiditis in several Beagle colonies used in laboratory research [52, 53]. This type of thyroiditis is indistinguishable from Hashimoto's thyroiditis in man [54], which may predispose man to thyroid carcinoma [55–58]. Follow-up studies of Beagles with thyroiditis could clarify this relationship.

Certain other primary neoplasms have been identified in humans and dogs as occurring in association with thyroid carcinoma. One is a syndrome called multiple endocrine adenomatosis, type 1, which is a dominantly inherited constellation of tumors composed of adenomas and carcinomas of several endocrine organs, plus occasionally multiple lipomas [48, 59–61]. Another syndrome is one that involves tumors of the thyroid and chemoreceptor system (chemodectomas) [62–63].

CHEMORECEPTOR SYSTEM

The chemoreceptor system consists of numerous morphologically similar glomera located throughout the body. In people, the larger clusters of cells have been named the glomus jugulare, glomus pulmonale, aortic body and carotid body.

Although the function and mode of action is not completely understood, the aortic and carotid bodies have been shown to be responsive to changes in the oxygen and carbon dioxide tensions, pH, and temperature of the circulating blood [64]. These bodies can initiate an increase in the depth, minute volume and rate of respiration via parasympathetic innervation. Also, via the sympathetic nervous system, they can increase the heart rate and elevate the arterial blood pressure. The human and canine chemoreceptor systems are quite similar.

Chemodectomas are uncommon in humans and dogs and very rarely occur in cats. In people, they occur twice as often in the carotid body than other sites [65]. Conversely, about 80% of the chemodectomas in dogs are located at the aortic body [63]. Chemodectomas, regardless of location however, are histologically indistinguishable. There is usually no correlation between histologic appearance of this tumor and its malignancy potential [66].

The number of human chemodectomas observed in each sex has been about the same with one exception; Peruvians who live in the Andes experience a 6-fold excess among women [65, 67]. In dogs, males have about 2 times the prevalence of females [68]. In neither humans nor dogs are the reasons for this sex differential known. However, an association of seminomas and interstitial cell tumors in con-

junction with canine chemodectomas has been reported [63, 69].

Some of the determinants in the etiology of chemodectomas are known. Genetic factors have been implicated, by familial aggregations, in about 8% of the lesions in people [67, 70]. Further, chronic hypoxia seems to be implicated, at least among the Peruvians living at high altitudes [65].

In dogs, only breeds of brachycephalic English Bulldog family (i.e., Boxer, Boston Terrier) have been detected with significantly high risk [68]. These breeds frequently have soft tissue anomalies of the oral and nasal cavities which restrict and impede respiration [71, 72]. Yet, other brachycephalic breeds, such as the Pekingese and Pug, show no affinity for chemodectomas. Thus, for Bulldog breeds, a genetic predisposition plus an aggravation of respiratory distress may be necessary factors responsible for the tumorigenesis of their chemoreceptor system [68].

BRAIN

Intracranial neoplasms have held a special interest for researchers over many centuries. Irrespective of the tumor's behavior (benign or malignant), these neoplasms have an insidious effect caused by the increase in intracranial pressure due to tissue displacement.

The annual age-adjusted incidence of brain tumors in humans is about 5 per 100,000 in the U.S. [15]. These tumors are rare in domestic animals with the exception of the dog [73]. Gliomas, astrocytomas, and glioblastomas are the predominant tumor types of the brain in adult humans and dogs. Medulloblastomas predominate in children. Little is known about the types of brain tumors that occur in puppies.

The age distribution in humans is bi-phasic. The childhood peak is under 10 yr of age and the adult peak is 64–69 yr [15]. The peak risk in dogs occurs between 10 and 14 yr of age [73], the median of which approximates the second peak in humans [22]. White men have more brain tumors than white women, however no sex differential is evident in U.S. blacks [15]. No sex risk has been noted in dogs [73].

The etiology of naturally occuring brain tumors is obscure. An association of reticulum cell sarcoma in the human brain following renal transplant and immunosuppression has been observed [74]. In dogs, gliomas have been induced with Rous sarcoma virus [75].

Familial excesses for astrocytomas have been reported in people [76, 77]. In dogs, only breeds of English Bulldog ancestry show high risk [73]. As mentioned before, this composite dog family commonly have soft tissue anomalies of the nose and mouth which may result in chronic hypoxia.

Chronic hypoxia in humans can be a stimulus for fibrillary gliosis in the neonatal and infantile brain [78], the severity of which appears to be correlated with the length of time of prolonged hypoxia [79]. Gliosis may be a precursor of gliomas and other related tumors. Or, the conditions may share a common etiology (i.e., chronic hypoxia), since the entire spectrum of nodular and diffuse gliosis, gliomatosis, astrocytomas, and glioblastoma has been concurrently observed in people [80–82].

BLOOD–LYMPHATIC SYSTEM

Tumors of the hematopoietic system are the most common neoplasms diagnosed in cats and rank fourth in occurrence in dogs. The leukemia–lymphoma complex ranks first in cats and dogs for the percentage of malignancies [20]. Leukemia accounts for about half of the incidence of cancer in children under 5 yr of age. Lymphomas account for about 3% of the cancers in the same age group. Each lesion represents 3.25% of the annual age-adjusted incidence of cancer in the U.S. [15]. The age distribution of feline lymphosarcoma is biphasic [83] and similar in age pattern to human leukemia [15].

Lymphoid tumors constitute most of the hematopoietic neoplasms in dogs and cats, and lymphosarcoma is the most common form of malignancy of the system. It should be noted that the term "leukemia" in the veterinary literature has often been used as a general term to represent, in fact, lymphosarcoma. Histologically, lymphosarcoma in the dog and cat are similar and resemble the disease in man.

The Boxer [84–86] and English Pointer [86] have been identified with significantly high risk for canine lymphosarcoma. No sex-specific features are evident in the dog [86]. Unlike feline lymphosarcoma, transmission of the canine disease has been unsuccessful with cell-free distillates of the tumor [87].

Lymphosarcoma is the most prevalent malignant tumor in cats. No breed predisposition has been established. Although, males appear

to have a 2-fold risk compared with females [83].

The etiology of the feline lesion is a C-type RNA virus [88], commonly referred to as feline leukemia virus (FeLV). FeLV has been transmitted by cat-to-cat contact in the laboratory [89]. This is also the likely mode of transmission in the general population [90]. The errant and often hostile instincts of the male (non-castrated) cat to other male cats may subject them to sufficient cat-to-cat contact that could explain their 2-fold risk for FeLV infection.

Feline lymphosarcoma has been associated with at least one other infectious disease, feline infectious anemia (FIA). FIA is caused by an infection with Hemobartonella felis, a protozoan, and can result in severe anemia.

Cats with acute clinical expression of FIA have 12 times the risk of development of feline lymphosarcoma as matched controls [91]. The exact association between FIA and feline lymphosarcoma or between severe anemia and subsequent lymphosarcoma is unclear [92]. As in experiments with rats and mice [93, 94], severe anemia may trigger clinical lymphosarcoma in the cat. However, the causal organisms of FIA and FeLV could, in some way, be linked. Similar to lymphosarcoma, FIA appears to be naturally transmitted by cat-to-cat contact; male cats have a 2.5 fold risk for acute clinical disease [95].

Evidence has been presented to show FeLV can cross species barriers. Newborn and young puppies inoculated with FeLV will develop lymphosarcoma [96, 97]. Of great importance is the fact that FeLV will replicate in human cells [98, 99]. Many studies have evaulated the possibility of cat-to-human transmission of FeLV; none have shown the FeLV is a hazard to man [100].

CONCLUSIONS

Recent data about the epidemiologic features of 9 different tumor sites in dogs and cats have been reviewed. Far more information is generally known about cancer that occurs in dogs than in cats. The epidemiologic features for canine tumors at most organ sites show marked similarity to those in humans. Although, the frequency of particular cell-types at some organs often differs. The similarities in risk by age and sex should encourage further research to determine which cancers in the dog are correlated with environmental factors that affect human beings. Identification and monitoring the frequency of these canine cancers may provide a prognostic resource about subsequent environmentally influenced cancer in human beings.

Abstract—*The spatial distribution of oxygen removal rate, Q_R, has been measured in the Lewis lung carcinoma at intervals up to* 10 days *after a single exposure to* 2000 rad ^{137}Cs *γ-rays and also in untreated tumours allowed to grow to different sizes. The measured patterns of Q_R were compared with the histological structure of the tissue. There was a good correlation between Q_R and the distribution of viable and necrotic tissue within the tumour and Q_R towards the centre of large necrotic zones was as low as* 10% *of that of viable regions. A large increase in the proportion of necrotic tissue was observed in irradiated tumours particularly in the central region and this occurred during a period when the total volume remained approximately constant. Because of the increased necrosis, the distribution of oxygen utilization and the pattern of future growth both differed in irradiated tumours from those of untreated tumours of the same size. Following irradiation the average Q_R for central regions decreased to about* 30% *of the control level at* 5 days *and then showed a slow increase. The decrease in average Q_R was mainly a result of the increased proportion of necrosis. The Q_R of viable tissue alone showed much less change following irradiation although it was reduced to* 80% *of the control value at* 5 days.

INTRODUCTION

THE RATE of oxygen removal by a tissue, defined as the ratio of the rate of oxygen uptake per unit volume to the oxygen solubility of the tissue [1], is an important parameter of tissue oxygenation which, with the oxygen diffusion coefficient controls the total distance of penetration of oxygen into the tissue from capillaries. Significant spatial variations in oxygen removal rate have been demonstrated within a number of different tissues and have shown some correlation with regions of distinct histological appearance, such as for example the cortex and medulla of rat kidney and the viable and necrotic zones of an experimental tumour [2]. In addition, variation in oxygen removal rate may also occur within regions of tumour tissue having a uniform histological appearance.

In tumours which have been irradiated a number of factors may combine to produce changes in the oxygen removal rate. A transient change in oxygen removal rate may occur during the reorganization of a tissue containing a large number of cells killed by radiation as dead cells or cellular fragments are cleared from the tumour via the vasculature and the tissue is repopulated by surviving cells. Major alterations in the structure of a tumour, such as the formation of necrosis, which may result from radiation damage may be associated with less transient changes in the oxygen removal rate. Hence, changes in the distribution of oxygen removal rate in irradiated tumours can only be fully interpreted if changes in tumour structure are also taken into account. A detailed study of this kind should lead to an improved understanding of the role of tissue oxygen uptake rate in the response of tumours to fractionated radiation schedules, and the hypothesis that changes in oxygen uptake rate are a significant factor in the reoxygenation of tumours containing radioresistant hypoxic cells [3, 4] can be investigated.

A study of the effect of irradiation on the

Accepted 2 May 1978.

oxygen removal rate of the rat fibrosarcoma, SSB1a, has been reported previously [5]. The method has now been used for the Lewis lung carcinoma in the mouse. The properties of the Lewis lung carcinoma have been found to differ from those of the SSB1a fibrosarcoma both in terms of changes in the oxygen removal rate and changes in the tumour structure produced by exposure to radiation. These changes are discussed in terms of cellular processes occurring within the irradiated tissue of the two tumours.

MATERIALS AND METHODS

1. *Experimental procedure*

The method for measuring the distribution of the rate of oxygen removal in tissue has been described in detail previously [1]. A sample of recently excised tissue is mounted in a Perspex cuvette with a plane cut surface pressed against a 12 μm polythene membrane. The sample is pre-equilibrated with pure carbon monoxide for 5 min to saturate any haemoglobin in the tissue. It is then placed in a measuring chamber where it is allowed to equilibrate with a gas of known oxygen tension. The cuvette is then brought into contact with the plane end of a multicathode polarographic electrode which cuts off the oxygen supply to the respiring tissue and the rate of oxygen removal in a small zone of tissue adjacent to each cathode is calculated from the time course for the change in surface oxygen tension. The complete measuring system is installed in a temperature controlled cabinet maintained at 25°C.

2. *The definition of oxygen removal rate*

The technique measures the oxygen removal rate, Q_R in units of mmHg/sec, defined as the ratio of the rate of oxygen uptake to the oxygen solubility per unit volume of tissue and calculated from the equation

$$Q_R = \frac{\pi P_o}{8} \cdot \left(\frac{k}{i_o}\right)^2 \qquad [1]$$

where P_o is the partial pressure in mmHg of the equilibrating gas, k is the slope of the cathode current time course plotted against the square root of time and i_o is the intercept of this curve on the current axis. Time is measured from the moment of contact between the electrode and cuvette. Q_R is integrated over a tissue zone approximating to that of a cylinder of radius and length about 300 μm situated perpendicularly to the tissue surface [6]. Ninety-one concurrent measurements of Q_R are derived from separate cathodes positioned in a hexagonal array with 500 μm spacing. A computer is used to process the data and, by interpolation between individual data points, to plot a map of the distribution of Q_R within the total area of approximate diameter 5 mm sampled by the electrode (for example, Figs. 7 and 8).

3. *Treatment of tissue samples*

A special method is used for processing the tissue samples so that the structure can be compared exactly with the measured distribution of Q_R [2]. The tissue surface is held flat throughout the stages of fixation and wax embedding and the sample is sectioned within about 100 μm of this surface. The position of the electrode during the measurement is recorded by indian ink markers placed in the tissue. A grid consisting of a hexagonal array of points is placed over the tissue section so that the positions corresponding to individual cathodes can be located (Figs. 7 and 8).

The Lewis lung carcinoma was maintained by serial transplantation in C57Bl/10 male mice. At about 10 days after transplantation the tumours reached a mean diameter of 8.5–9.5 mm (measured parallel to the skin: the depth perpendicular to the skin was usually less than this) which was the standard size for irradiation. The tumours were irradiated by two opposed caesium-137 sources and were excised at appropriate times subsequently. Non-irradiated tumours at the standard size were used for controls. The tissue cuvettes held samples up to 8.5 mm diameter. In tumours of larger diameter it was necessary to select an area of appropriate size from the cross section of the cut tumour. This could be either in the centre of the tumour or in an eccentric position tangential to one edge which gave a more even distribution between viable tumour tissue and the necrosis which was increased towards the centre.

4. *Scoring of histological structure*

The structure of the Lewis lung carcinoma is that of patches of viable tissue interspersed with necrosis. A scoring system was devised to characterise the tissue structure in the neighbourhood of each cathode measuring position. Each point on the grid placed over the tissue section was centred in turn in the 500 μm diameter field of view of the microscope. The diameter of the field of view was

chosen to somewhat exceed the size of the zone corresponding to the measurement of Q_R to allow for any slight inaccuracies in the lining up of the grid and the original electrode position. The tissue viability was scored as a proportion of the area within each field of view according to the scale:

V > 95% viable tissue.
IV > 75% viable tissue.
III—25–75% viable tissue.
II < 25% viable tissue.
I < 5% viable tissue.

Non-necrotic tissue had a different appearance at certain times after irradiation from that in non-irradiated tissue due to the presence of nuclear fragments and many large multinucleate cells (Figs. 4 and 5). It was still distinguishable from the necrotic areas which contained cellular fragments and frequently zones of haemorrhage.

5. *Accuracy of the measurement* Q_R

The use of a cuvette membrane can introduce an error into the measurement of Q_R the size of which is a function of the ratios of the oxygen diffusion constant and the solubility between the membrane and the tissue. The error has been estimated to be less than 15% for most tissues [6] but can be assessed for a given tissue by comparing measurements made with and without a cuvette membrane.

Measurements on 4 Lewis lung carcinomas with differing Q_R distributions following equilibration with 50% O_2 and made with and without a 12 μm polythene membrane are given in Fig. 1. There is a small shift to lower Q_R values particularly at the highest Q_R values but this is estimated to be less than 15%. The difference between the means of the distributions is certainly less than 15%.

It has also been calculated that for a polythene membrane the error in Q_R is relatively independent of the value of Q_R itself [6]. Comparisons of relative Q_R values will therefore be significant even for differences of less than 15% for distributions measured within individual tumours and for differences between tumours of the same line. Some caution may be appropriate in interpreting differences between control and irradiated tumours since it is not known if a change in either the tissue diffusion constant or solubility for oxygen is produced. Some of the variation in Q_R within individual tumours could be due to variation either in the tissue oxygen diffusion constant which would affect the error on the estimate of Q_R, or in the oxygen solubility which would affect both the error in Q_R and the absolute value of Q_R. However, there is little information as yet about small scale variation in the oxygen diffusion parameters of tissues.

RESULTS

1. *Change in average* Q_R *in tumours exposed to* 2000 rad

The average change in Q_R for tumours exposed to 2000 rad Cs γ-rays is presented in Fig. 2. An average value for each tumour over the total area sampled was obtained by averaging 91 individual values from a single measurement. These values were again averaged within groups of similarly treated tumours to give the overall means and standard errors shown in the figure. The number of tumours in each group, shown in the figure, was at least 5 in most cases. The average Q_R values are for samples taken from both central and off-centre regions of the tumours and represent the accumulated results of more than one series of experiments. The measurements for central regions were made following equilibration with air whereas the off-centre samples were equilibrated with 50% O_2 to give a slight increase in accuracy for the measurement of Q_R in the areas containing a high proportion of viable tissue. The mean tumour volumes are also shown in Fig. 2. The tumour volumes remained rather constant during the first 6 days after exposure to 2000 rad except perhaps for a small increase in volume up to day 3. After the sixth day the tumours started to regrow but in an irregular fashion as indicated by the increase in the standard errors of the mean values. At later times the tumours tended to ulcerate so that measurements were not made after the tenth day.

There was a large difference between Q_R measurements for central and off-centre tumour areas. The Q_R for central areas decreased sharply to reach a minimum at day 5 of about 30% of the control value and then started to increase slowly. The Q_R for off-centre sampling areas decreased during the first 3 days to reach a plateau level at about 75% of the control level.

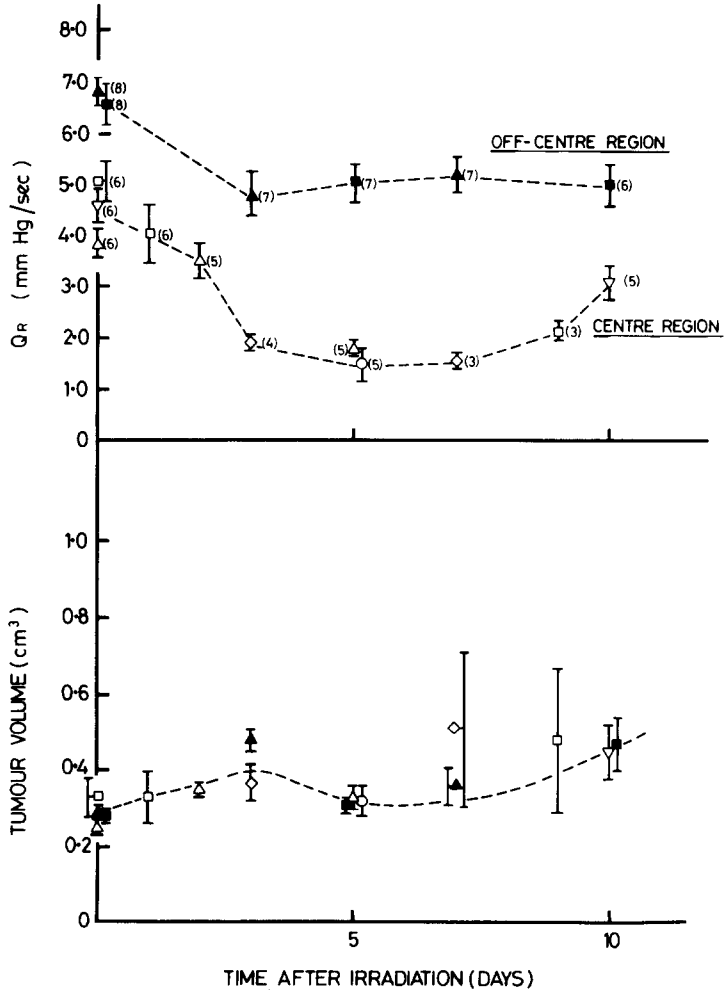

Fig. 2. The average Q_R *for central and off-centre regions and the tumour volume at various times after exposure to* 2000 rad. *The points represent the means and standard errors of the average* Q_R *values for the numbers of tumours indicated in brackets. Different symbols represent different batches of tumour implants.*

The large differences between the Q_R of central and off-centre samples are due to the greater proportion of necrotic tissue in the central samples (see No. 3 of Results). Similarly the smaller difference between the control levels for central and off-centre samples is due to the smaller amount of necrosis in the control tumours.

2. *Change in average* Q_R *in untreated tumours*

The mean Q_R for similar groups of untreated tumours was measured at selected times after reaching the standard irradiation size. The measurements were made on central sampling areas following equilibration with air and are shown together with changes in tumour volume in Fig. 3.

The tumour volume increased by about a factor 3 in 6 days during which time the mean Q_R decreased to about 50% of the control level. The change in Q_R was not as rapid or as large as that in irradiated tumours (Fig. 2) in which the volume did not change.

3. *Comparison of* Q_R *of irradiated tumours with histological structure*

Although the tumour volumes remained almost constant during the first 7 days after exposure to 2000 rad major changes in tumour structure took place during this time. These were assessed from a series of histological preparations of complete tumour cross sections. In control tumours, at the standard irradiation size, the proportion of necrosis was less than 5% of the total tumour area but this was increased to 30% in tumours which had been irradiated 7 days earlier. The proportion of necrosis was somewhat less than this in tumours sampled at later times after irradiation. At 7 days, the time of maximum necrosis, the viable tissue in the tumour was mainly confined to a shell round the periphery. At later times the tumours showed evidence of patchy regrowth with zones of viable tissue and necrosis rather randomly intermixed.

The Q_R was measured on batches of tumours sampled at 3, 5, 7 and 10 days after

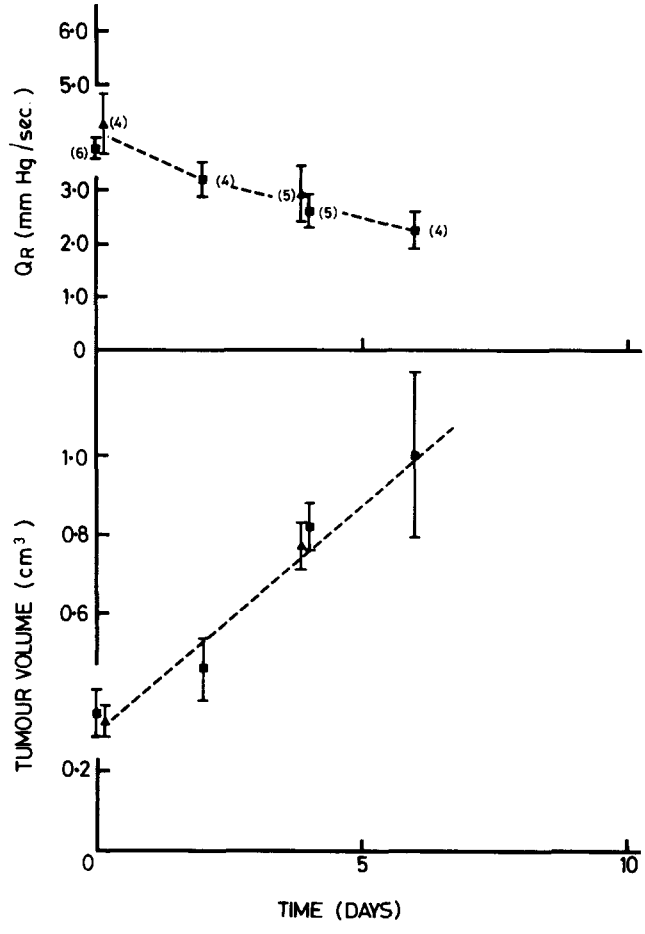

Fig. 3. The average Q_R *for central regions and the tumour volume for untreated tumours at various times after reaching the standard irradiation size. The points represent the means and standard errors of the average* Q_R *values for the numbers of tumours indicated in brackets. Different symbols represent different batches of tumour implants.*

2000 rad and histological sections were produced which showed the area sampled by the electrode. The areas of tissue beneath individual cathode positions were classified in terms of the proportional content of viable tissue according to the scale given in the methods (No. 4, Materials and Methods). The zones which were classified as viable contained many radiation-damaged cells at 3 and 5 days after irradiation (Fig. 5) but by 10 days the damaged cells had disappeared and the viable areas resembled those of control tumours (Fig. 4).

For each tumour the Q_R values corresponding to a given score for the viability index were averaged and the mean Q_R values for each viability index were averaged between all tumours in the group to give an overall mean and standard error. If a tumour had 5 or less values of Q_R for a given viability index this was not included in the mean for the group, but this only occurred for indices of I or II in control tumours where the proportion of necrosis was low. The results, shown in Fig. 6, were from the same batches of tumour that gave the mean Q_R values shown in the upper of the two curves in Fig. 2 for sampling from off-centre tumour regions. The Q_R of totally viable areas scored as V was found to be more than three times that of totally necrotic areas scored as I, and intermediate viability indices corresponded to intermediate values of Q_R.

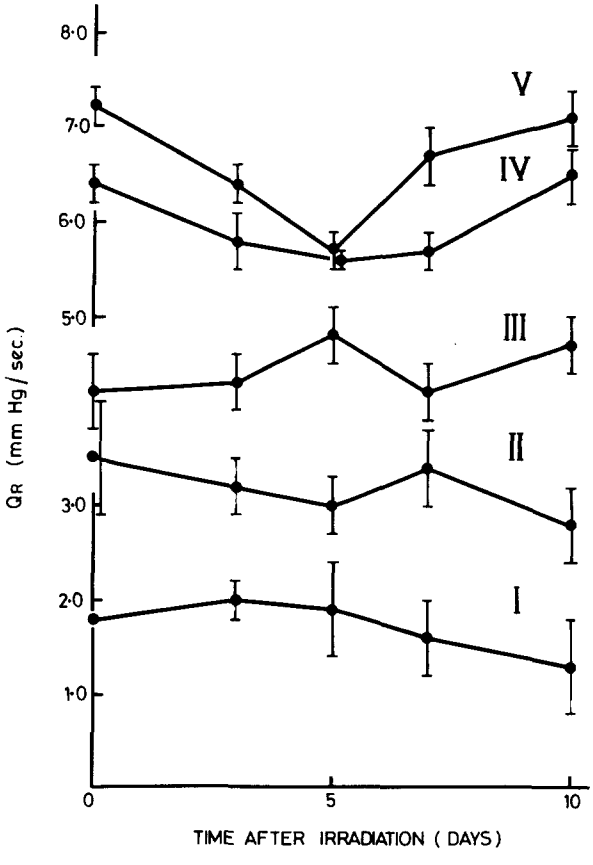

Fig. 6. Values of Q_R *for regions of viability indices* I–V *at various times after exposure to* 2000 rad. *The points represent the means and standard errors of the average* Q_R *values for each index for a group of tumours.*

Areas with a viability index of V were the only ones in which Q_R showed a significant change with time after irradiation. The Q_R decreased to 80% of the control level 5 days after irradiation and then increased almost completely back to the control level by day 7. Although the mean Q_R of areas with index I did not change significantly there was a clear tendency for Q_R to be less than 0.8 mmHg/sec towards the centre of the large necrotic zones which were found in tumours sampled at the later times after irradiation. In these cases the Q_R varied by more than a factor of 10 between the wholly viable areas and the centres of necrotic areas. An example of this is shown in Fig. 8 where the Q_R distribution for an area of tumour, sampled 10 days after exposure to 2000 rad and containing a large necrotic area, is compared with a photograph of the tissue section with a superimposed grid marking the area sampled by the electrode during the measurement. A similar diagram showing the Q_R distribution and corresponding histological structure for a control tumour is given in Fig. 7.

DISCUSSION

The Lewis lung carcinoma has been described as an anaplastic epidermoid tumour with a marked tendency to become haemorrhagic [7]. Small tumours usually have a rather uniform appearance but an increasing proportion of necrosis in larger tumours can lead to the restriction of intact tissue to thin shells surrounding zones of non-proliferating cells and to ulceration through the skin. The proportion of necrosis within the tumour is somewhat lower in tumours which become closely attached to the skin during growth. The increase in the proportion of necrotic tissue in larger tumours is associated with a reduced growth rate and with some changes in the kinetics of cellular proliferation [8, 9]. Areas of haemorrhage often develop in the neighbourhood of necrotic zones and may be caused by the deficient structure of many of the blood vessels. For example vascular spaces without an intact endothelial lining are found in the periphery of the tumour and these allow blood to come into direct contact

with tumour cells [10]. Haemorrhage in the tumour periphery may in addition result from leakage of blood through the open ends of new capillaries which are formed in response to an angiogenic stimulus [11].

By relating the patterns of Q_R to the histological structure of the Lewis lung carcinoma it has been possible to establish the separate Q_R values for different types of region within the tumour. The Q_R of necrotic zones was found to be appreciably less than that of viable zones but nevertheless significantly above zero (Fig. 6). There was a gradient in Q_R across larger necrotic zones and towards the edges of these zones functional respiratory enzymes and substrates were evidently retained. The necrotic zones, therefore, continued to contribute to the total tumour demand for oxygen. If radiation resistant hypoxic cells are considered to be located in zones at the boundary of necrotic regions, a non-zero Q_R of the necrotic zone would produce a gradient in oxygen tension across the hypoxic layer. This could limit the effectiveness of attempts to improve the tissue oxygenation, by for example breathing oxygen at high pressure, around points towards the venous end of the circulation where the increase in capillary oxygen tension may be small. The non-zero Q_R of necrotic zones also precludes the possibility that these zones could act as stores of oxygen which could damp out fluctuations in tissue oxygen tension produced by circulatory variations in the oxygen supply.

The changes in structure induced by irradiation of the Lewis lung carcinoma were different from those observed in the rat fibrosarcoma, SSB1a [5]. The structure of the fibrosarcoma remained unchanged for the first ten days after exposure to 2000 rad and acellularity of the tumour core only developed when the tumour started to regrow. Irradiation of the Lewis lung carcinoma resulted in the formation of a predominantly central region of necrosis during the period of growth delay when the total tumour volume remained approximately constant. The proportion of necrosis reached a maximum at about 7 days after irradiation when it was considerably greater than in untreated tumours of the same size. The changes in Q_R also differed between the two tumours. The minimum in the Q_R for viable tissue occurred at 3 days after irradiation for SSB1a and 5 days for the Lewis lung carcinoma. The Lewis lung carcinoma showed more visible evidence of damage than SSB1a with the presence of nuclear fragments and many large multinucleate cells. It was perhaps surprising that the changes in Q_R were not greater than those in SSB1a. It must be deduced that the cell fragments and abnormal cells which were found in non-necrotic regions classified with a viability index of V at 3 and 5 days after irradiation had an almost normal capacity for respiration and that a considerable proportion of the respiratory enzymes from lysed cells were retained within the tumour for several days and continued to utilise oxygen.

The marked increase in necrosis towards the centre of the irradiated Lewis lung carcinoma would seem to indicate that the tissue in the tumour core is more sensitive than that at the edge to either a direct or an indirect effect of radiation. Two possibilities can be considered: (1)—that the cells in the centre are more sensitive to the direct effect of radiation and that a certain level of killing corresponds to the formation of necrosis, (2)—an indirect mechanism, which is triggered by the local radiation damage to act at some time after the irradiation, produces necrosis of the central region.

If the first of the possible causes is considered, necrosis could result when the surviving fraction is reduced to a low level where surviving cells are too few in number to be noticed. It seems unlikely, however, that any cells could survive in the extreme necrotic conditions which are observed. A co-operative effect could be envisaged, whereby when the surviving fraction is low enough, the large number of damaged cells are toxic to the few remaining survivors so that all cells within the necrotic region eventually lyse. An increased sensitivity of central cells in a tumour is apparently contrary to the conventional view that radiation resistant hypoxic cells are preferentially distributed towards the centre. An increased radiation kill of central cells could perhaps result from a mechanism similar to that reported by Hahn [12] for Chinese Hamster cells *in vitro* where the capacity for the repair of sublethal damage was reduced for cells in stationary growth phase. However, in the Lewis lung carcinoma even hypoxic cells seem to have a considerable capacity for the repair of sub-lethal damage [13].

The second possible cause for increased necrosis in the centre of an irradiated tumour could be vascular insufficiency associated with inadequacy in the capacity for the removal of cellular debris. Although central blood vessels have generally been observed to have an intact endothelium in contrast to some

peripheral vessels [10] the spacing of the central vessels may be too great for the cellular damage to be dealt with or the blood flow may be reduced or cease altogether following the irradiation.

It is accepted that microscopic features of tumour structure on the scale of intercapillary distances play an important role in the determination of radiosensitivity particularly by influencing the number and distribution of hypoxic cells. The studies on both the fibrosarcoma, SSB1a and the Lewis lung carcinoma indicate that the responses of tumours to irradiation may also depend on larger scale features of the structure. If it is assumed that necrotic areas do not contain any viable cells, it follows, for either of the two causes of necrosis postulated above, that at the time of the formation of necrosis some cells must die in addition to those that were killed by the direct action of radiation. In addition to modifying the effect of the initial radiation exposure, the increased necrosis is likely to alter the capacity of the tumour for regrowth and the sensitivity to subsequent fractionated irradiations. The relevance of such macroscopic changes in tumour structure has often been ignored particularly in studies which have assessed the radiation response of tumours from changes in gross volume alone.

Indirect evidence for a change in the oxygen uptake of irradiated tumours has been considered in an earlier paper [5]. The present results confirm the conclusion reached then, that a change in oxygen uptake is not likely to contribute to the early reoxygenation of hypoxic zones in tumours during the first few days after irradiation. Furthermore, it is now apparent that if changes in oxygen uptake are of significance in later reoxygenation, the timing of such changes will differ for different tumour lines.

Acknowledgements—We wish to thank Dr. Noel Evans for many helpful suggestions and constructive criticisms. We are also grateful to Michael Rogers for making histological preparations of the specimens, to Dr. Peter Bryant for useful discussion of the results and to Dr. Tessa Sadler of the Department of Surgery of the Royal Postgraduate Medical School for supplying the tumour.

Tumour Immunoprophylaxis Exerted by the Antimicrococcus Immunity II. Influence on the Proliferation of Murine Plasmacytoma (MOPC 173) and Ehrlich Carcinoma Cells*

RENÉ VERLOES,† GHANEM ATASSI,‡ PATRICK DUMONT‡ and LOUIS KANAREK†

†*Laboratorium voor Chemie der Proteinen, Vrije Universiteit Brussel, Instituut voor Moleculaire Biologie, Paardenstraat* 65, *B*-1640 *Sint-Genesius-Rode, Belgium and* ‡*Service de Médecine Interne et Laboratoires d'Investigation Clinique Henri Tagnon* (*Section de Chimiothérapie Expérimentale*), *Centre des Tumeurs de l'Université Libre de Bruxelles, Rue Héger-Bordet* 1, *B*-1000 *Bruxelles*

Abstract—*The influence of the micrococcal vaccine on the proliferation of normal immunocompetent and neoplastic plasma* (*MOPC* 173) *and of carcinoma* (*Ehrlich ascites*) *cells is studied.*

BALB/c mice and CDF_1 *mice, hypervaccinated with* Micrococcus Lysodeikticus, *developed significantly* ($0.001 < P < 0.005$) *lower primary immune responses against sheep erythrocytes and also displayed impaired secondary immune responses.*

Administration of Bacillus Calmette-Guérin could partially restore the immunologic potential of vaccinated mice as measured by the capability of mice to answer with primary or secondary immune responses to sheep erythrocytes but did not increase immunoresponsiveness of normal mice sensitized at nearly optimal antigenic dose.

Switching on a secondary antimicrococcus immune response after grafting 200,000 *Ehrlich carcinoma cells in the peritoneum of BALB/c mice resulted in a* 30% *increase in mean life span over control mice. However, mice hyperimmunized for months with* Micrococcus lysodeikticus *were offered the strongest immunoprotection and we found* 67% *of mice surviving to day* 90 *whereas the other vaccinated but tumour bearing animals showed a* 29% *increase in life span over control mice.*

Similarly, we demonstrated that 44% *of BALB/c mice, hyperimmunized for months, were able to reject a tumour challenge of* 200,000 *grafted MOPC* 173 *plasmacytoma cells, whereas the other micrococcus vaccinated but tumour bearing animals died with a* 26% *increase in mean survival time over control mice.*

INTRODUCTION

HYPERVACCINATION of rabbits with Gram-positive bacteria, such as *Streptococcus* [1, 2], *Pneumococcus* [3] or non-pathogenic *Micrococcus* (American Type Culture Collection 4698) stimulates the production of high titer of anticarbohydrate antibodies of restricted heterogeneity, as seen by electrophoresis (monocomponent banding immunoglobulins = M spike) and sequence analysis (homogeneous antibodies) [4]. The occurrence of those antibodies is in close analogy with the well studied [5] monoclonal immunoglobulins produced by rapidly proliferating benign plasma cells or malignant myelomas.

Antimicrococcus producing cell clones are subjected to an antigen-dependent clonal proliferation and it is common to find decreasing serum antibody levels, returning to very low levels, when vaccination is stopped.

Extensive research regarding the antibody nature of monoclonal myelomatous immunoglobulins has very clearly demonstrated, as pointed out by Waldenström [6], that "there

Accepted 10 May 1978.

*This work was supported by Contracts No. N01-CM-57040 and No. N01-CM-53840 entered into with the National Cancer Institute, Bethesda, Maryland, U.S.A. and by a special grant from the Belgian government (Fonds voor Onderling Overlegde Akties) and from the "Fonds voor Kollectief Fundamenteel Onderzoek".

is no question about the fact that anti-streptolysin and antistaphylolysin are the two most common monoclonal antibodies that are found in myeloma". But no definite role had been proposed for the true antigenic properties of those monoclonal immunoglobulins, nor is there any conclusive evidence for the role of *Streptococcus* or *Staphylococcus* in the genesis of this malignancy or in the control or maintenance of myelomatous cellular proliferation.

However, Collins and Wust clearly demonstrated that antibodies to group A *Streptococcus pyogenes* polysaccharide cross-react with tumour polysaccharides of an SV40 transformed hamster cell line and that up to 50% of the animals were offered an effective antitumour immunoprotection, when pre-vaccinated with *Streptococcus* [7].

In general oncology, it is common to find poor antibody responses and increased liability to infection associated with advanced clinical or murine cancer [8–10].

Since (multiple) myeloma growth as macroglobulinemia is often accompanied by a generalized immunosuppression [11, 12], this study was undertaken to examine if the antimicrococcus immunity, characterized by the production of oligoclonal antibody responses of high titer, may influence the expression of immune responses in vaccinated mice and if this antibacterial immunity may affect murine plasmacytoma (MOPC 173) or carcinoma (Ehrlich ascites) tumour growth.

Since antimicrococcus antibodies are directed against the bacterium specific carbohydrate (Perkins' antigen) or against the peptidoglycan [13] containing glucose and *N*-acetyl-D-glucosamine which are also specific ligands for lectins such as Concanavalin A [14] and since those antibodies bind to lymphocytes and to certain tumour cell types, but not to erythrocytes [15], they are believed to act on cells in a way similar to lectins, but with a greater discriminatory capacity.

Consequently, since lectins such as Concanavalin A are mitogenic *in vitro* [16] but were shown to be immunosuppressive *in vivo* [17], we had an additional stimulus to check the influence of the antimicrococcus immunity on immune and neoplastic cell proliferation.

The immune capacity of mice was tested by analysing the humoral immune response to sheep and horse erythrocytes injected at different stages of the immunization period. Syngeneic (inbred) mice respond to those cellular antigens with sharply resembling antibody titers of high magnitude. In contrast to the plaque forming technique, developed by Jerne, this experimental system measures the direct expression of humoral immunity and does not require animals to be killed, allowing research on the evolution of the immune response.

MATERIALS AND METHODS

Micrococcus lysodeikticus

A suspension was made of lyophilized *Micrococcus lysodeikticus* (Worthington Biochem. Corporation) after repeated washings and centrifugations at 3000 ***g*** for 15 min at 4°C, in phosphate buffered saline (0.15 M NaCl–0.01 M potassium phosphate; pH = 7.3) = PBS buffer. Micrococcus cells were heat-killed by incubating the suspension at 60°C for 30 min and used within one week.

Bacillus Calmette-Guérin

One hundred milligrams containing vials of lyophilized Bacillus Calmette-Guérin (B.C.G.) for scarification were purchased from the Pasteur Institute, Brussels. After reconstitution with the appropriate diluent and further dilution in Hanks' balanced salt solution, the suspension was kept at 4°C and used within two weeks.

Erythrocytes of sheep and horse

Ten milliliter samples of sterile, heparinized sheep or horse blood were purchased from the Pasteur Institute, Brussels and stored upon delivery in Alsever solution at 4°C.

Horse red blood cells (HoRBC) or sheep red blood cells (SRBC) were washed five times with PBS buffer and centrifuged at 300 ***g*** for 15 min. They were diluted in PBS buffer and counted in a Thoma cell haemacytometer.

Quantitative agglutination analyses

These were carried out in U shaped wells of Linbro agglutination plates. One twentieth of a milliliter of the antiserum was mixed with 0.05 ml of phosphate buffered saline and consecutive twofold dilutions were made. After a preincubation period of 30 min at 37°C, 0.05 ml of the SRBC or HoRBC (10^8 cells/ml) were added and the agglutination was scored after 2 hr at 37°C and expressed either in $\log_2$ units or by the reciprocal of the highest active dilution.

Electrophoretic procedures

Cellulose acetate electrophoreses were carried out with a Beckman microzone cell model R200.

Electrophoresis was carried out in barbital buffer (I=0.075, pH=8.6) for 20 min at 250 V at 4°C.

After staining with Ponceau S, the strips were destained with 5% acetic acid and scanned with a Vitatron Modular Photometer with scanning accessory.

Mice and tumours

Mice. Inbred (BALB/c mice × DBA/2)F_1 animals were supplied by Charles River Breeding Laboratories, Calco, Italy.

Those mice were stored at least for 3 weeks in an isolation room before we started experimenting. Female CDF_1 mice (BALB/c female × DBA/2 male)F_1 animals, weighing 19–23 g, were used. BALB/c mice were originally obtained from the T.N.O., Rijswijk, The Netherlands, fed and watered *ad libitum*. Either male mice weighing minimum 19 g or female mice weighing at least 18 g were used.

Tumours. An hyperdiploid line of the Ehrlich ascites tumour was obtained from Dr. Maisin (Belgium). This tumour has been transplanted for years by Mr. A. Cordier in inbred BALB/c mice, by weekly passage of 10^7 tumour cells to intact mice.

Ehrlich cells were aspirated from BALB/c mice and diluted in phosphate buffered saline. One tenth of a millilitre of the suspension was injected intraperitoneally (i.p.) to obtain the ascitic form of the carcinoma. Animals were randomized into test groups and control groups.

The IgG_{2a} secreting plasmacytoma 173 (MOPC 173) was kindly provided by Dr. A. Paraf (France) and weekly passaged to inbred BALB/c mice by grafting 10^6 cells to intact BALB/c mice.

Animals were randomized into test and control groups. For each experiment, ten to twenty mice were used. Mean survival time ± the standard deviation of the treated mice and the control mice (M.S.T. ± S.D.) as well as dosage and timing of each experiment are specified in the tables. Survivors on day 90 after tumour grafting were considered as long-term survivors and were eliminated from the final calculations of the mean survival time.

RESULTS

1. *Effect of hypervaccination with* Micrococcus lysodeikticus *on a primary immune response in BALB/c mice*

Previous studies in mice have demonstrated that the immune response is higher when the vaccine is injected intraperitoneally [18].

Inbred BALB/c mice were vaccinated three times a week i.p. with heat-killed *Micrococcus lysodeikticus* and received 0.05 mg per injection on weeks 1 and 2 and 0.1 mg on weeks 3 and 4, 9–14 and 19–24. They received intraperitoneally three 0.2 mg injections a week on weeks 29–31.

The capability of vaccinated mice to answer to a challenge of sheep erythrocytes was tested on weeks 16 and 33. Vaccinated and control mice were inoculated intraperitoneally with 2.10^8 SRBC and bled in the retro-orbital plexus on the fourth day. The serum anti-SRBC and antimicrococcus response was quantitatively determined by agglutination with 10^8 SRBC/ml or 2 mg/ml micrococcus suspension. As illustrated in Fig. 1, micrococcus vaccinated BALB/c mice

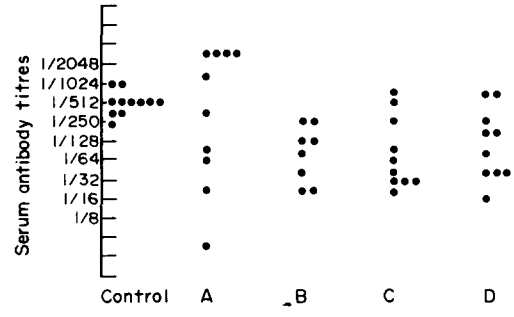

Fig. 1. Effect of hypervaccination with Micrococcus lysodeikticus *on the primary anti-SRBC response of BALB/c mice. BALB/c mice were hyperimmunized with heat-killed micrococcus vaccinated mice and control mice were determined. cinated and control mice was tested on weeks* 16 (*A*) *and* 33 (*B, C, D*) *by measuring the primary immune response to* 2.10^8 *sheep erythrocytes injected on day* 0. *Four days later, mice were bled and individual serum anti-SRBC antibody titers of micrococcus vaccinated mice and control mice were determined. Immune responses of groups B* ($P<0.001$), *C* ($P<0.001$) *and D* ($P<0.005$) *were significantly depressed.*

displayed lower anti-SRBC responses than control mice and this was more pronounced when testing on week 33 ($0.001<P<0.005$).

2. *Influence of hypervaccination on a primary response in BALB/c mice*

Intact BALB/c mice were injected with 2.10^8 SRBC on days 0, 2 and 4 and showed a strong primary immune response, as quantitatively measured by the serum agglutination titer of bleeding on day 8. Mice were randomized into test and control groups. Test group mice were vaccinated with heat-killed *Micrococcus* 3 times a week intraperitoneally and received 0.1 mg injections on weeks 1–4 and 9–12, 0.2 mg on

weeks 14–17 and 19–22 and 19–22, 0.4 mg on weeks 24–27 and 29–32 and 0.5 mg on weeks 34–37 and 39–42.

In Fig. 2, the evolution of a primary anti-SRBC response of test group and control mice bled and quantitated at different stages of the immunization period is produced.

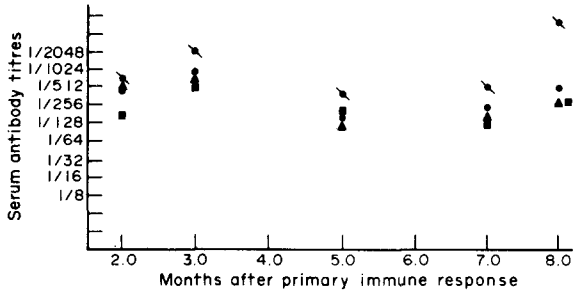

Fig. 2. Effect of hypervaccination with Micrococcus lysodeikticus *on the expression of a primary and secondary anti-SRBC response in BALB/c mice. Four groups of* 10 *BALB/c mice were primed with* 2.10^8 *SRBC and* 30 *of them were vaccinated thereafter with heat-killed* micrococcus lysodeikticus. *The expression of a primary anti-SRBC immune response is followed during hypervaccination with* Micrococcus *and compared to unvaccinated control mice (●) Eight months after priming with SRBC, Micrococcus vaccinated (▲, ■, ●) and unvaccinated control mice were boosted i.p. with* 5.10^8 *SRBC. Mean serum anti-SRBC antibody titers of this secondary immune response of vaccinated (▲, ■, ●) and control mice (●) are presented.*

Eight months after priming with SRBC, the animals were boosted i.p. with 5.10^8 cells after 44 weeks of vaccination. They were bled 4 days later and their sera were analysed for quantitative agglutinations with *Micrococcus* and SRBC. Whereas a primary anti-SRBC response switched on *before* hyperimmunization of BALB/c mice with *Micrococcus* is rather unaffected during hypervaccination, the secondary anti-SRBC response of vaccinated mice displays considerably lower anti-SRBC titers than PBS treated control mice, as illustrated in Fig. 2.

There was no direct correlation between the individual magnitude of the anti-SRBC and the antimicrococcus antibody serum titer (not shown).

3. *Effect of hyperimmunization with* Micrococcus lysodeikticus *on a primary immune response in* CDF_1 *mice*

One hundred and three intact CDF_1 mice were vaccinated once a week with 0.15 mg of heat-killed *Micrococcus* over 4 weeks. They received three 0.2 mg injections a week on weeks 10–14 and three 0.4 mg injections a week on weeks 24–29 and 31–36. Blood samples were taken from the retro-orbital plexus at different stages of the immunization period and mouse sera were subjected to cellulose acetate electrophoresis to check the presence of immunoglobulins of clonal dominance.

The serum antimicrococcus antibody titer of every bleeding was determined by quantitative agglutination with 2 mg/ml *Micrococcus* suspension. This immunization schedule resulted in the production of antibodies of restricted electrophoretic heterogeneity and clonal dominance in 5% of the mice from week 25, 26% on week 30 and 33% on week 37. Absorption of the sera with micrococcus cells results in the disappearance of electrophoretic homogeneity and precipitation with soluble cell wall antigen (immunodiffusion).

A primary anti-sheep-erythrocyte antibody response was tested after 22 weeks (before the first appearance of immunoglobulins of clonal dominance in the serum) and 36 weeks of hypervaccination. Two weeks after the last micrococcus vaccination, 2.10^8 sheep erythrocytes were inoculated intraperitoneally. As indicated in Fig. 3, CDF_1 mice vaccinated for 22 weeks and those vaccinated for 36 weeks and subdivided into non-homogeneous and homogeneous responding mice showed a depression of the primary anti-SRBC response ($P<0.001$). There was no direct correlation with the quantitative anti-micrococcus antibody titer (not shown).

Fig. 3. Influence of the antimicrococcus immunity of homogeneous and heterogeneous responder CDF_1 *mice on the primary immune response to sheep erythrocytes.* CDF_1 *mice were hyperimmunized with* Micrococcus lysodeikticus *according to an immunization scheme that leads to the production of homogeneous antibodies. Individual antibody titers of a primary anti-SRBC response of micrococcus vaccinated mice (A and B) and unvaccinated mice, tested on week* 24, *are listed.*

Antibody titers of homogeneous (C) and heterogeneous (D) responder mice, answering to SRBC with a primary immune response on week 38 *are compared with control mice.*

Immune responses of mice of groups A, B, C, and D were significantly depressed ($P<0.001$).

4. *Reversibility of the immunosuppression*

In the preceding experiment, we have tested the immunologic capacity of vaccinated CDF_1 mice, two weeks after the last injection of *Micrococcus*. This precaution was taken to insure that an immune response against sheep or horse erythrocytes should not suffer from competitive recruitment of appropriate immunocompetent and bystander cells, a phenomenon called "antigenic competition". We assumed that a rest period of two weeks is long enough for immune mice to clean up the last micrococcus cells and to recover from the injections. Since horse and sheep erythrocytes induce high humoral immune responses in mice and do not cross-react with each other, they were used as indicator systems to test the mouse immune responsiveness.

However, when the CDF_1 mice that were hyperimmunized for 36 weeks were tested after a rest period of 6 months, we found again a dramatically decreased primary anti-sheep erythrocyte immune response, even in those mice where the antimicrococcus antibody had disappeared from the serum, as seen in Table 1. Again, there was no

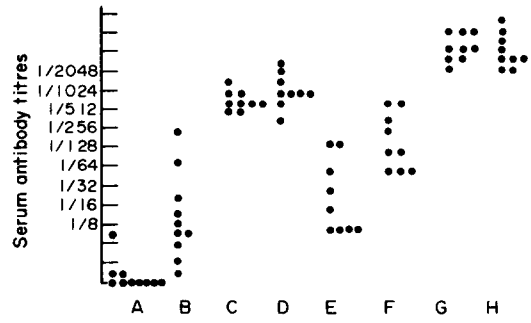

Fig. 4. Influence of B.C.G. administration on primary and secondary immune responses of micrococcus lysodeikticus hypervaccinated mice. CDF_1 mice were hypervaccinated with Micrococcus lysodeikticus *for 36 weeks, followed by a rest period of 6 months. Then, mice immunoresponsiveness was tested. Individual antibody titers of vaccinated (V^+) and unvaccinated (V^-) mice responding to 2.10^8 horse erythrocytes (H^+) with 1 mg B.C.G. (B^+) or without B.C.G. (B^-) are presented. Both primary (A–D) and secondary (E–H) immune responses are listed: A and $E = V^+$, H^+, B^-; B and $F = V^+$, H^+, B^+; C and $G = V^-$, H^+, B^+; D and $H = V^-$, H^+, B^-. Immune responses of groups A, B, E, and F were significantly depressed ($P < 0.001$).*

responses of normal mice sensitized with a near optimal antigenic dosage.

We conclude that, in micrococcus vaccinated mice that show an impaired response against new cellular antigens, the immunosuppression

Table 1. Comparison of the antimicrococcus antibody titer with the anti-SRBC antibody titer of a primary immune response in hypervaccinated mice

Micrococcus vaccinated mice						Control mice

9	5	6	6.5	4.5	1.5	0	10

CDF_1 mice were hyperimmunized with *Micrococcus lysodeikticus* for 36 weeks, followed by a rest period of 6 months. Then, vaccinated mice and controls of the same age were injected with 2.10^8 sheep erythrocytes (SRBC) i.p. on day 0. Mice were bled on day 4 and the anti-SRBC titer of each mouse was compared to the antimicrococcus antibody titer and expressed in $\log_2$ agglutination units.

direct correlation with the quantitative anti-micrococcus antibody titer (regression $r = 0.011$). Similarly, we found that the administration of 1 mg of Bacillus Calmette-Guérin (B.C.G.) simultaneously with 2.10^8 horse erythrocytes could partially restore the immunoresponsiveness of CDF_1 mice as reflected by a primary and a secondary response anti-HoRBC response listed in Fig. 4, but was unable to amplify anti-HoRBC may be partially reversed by the administration of an additional macrophage and T cell stimulator such as B.C.G. [19].

5. *Immunoprophylaxis of the antimicrococcus immunity on the proliferation of Ehrlich carcinoma and plasmacytoma (MOPC 173) cells.*

We previously demonstrated that anti-micrococcus antibodies of rabbit and mice agglutinate Ehrlich ascites cells *in vitro* [20].

In a first experiment, BALB/c mice were immunized one injection a week (40 μg given subcutaneously) for 4 weeks. On weeks 7, 9 and 11, the animals received three injections a week.

Vaccinated mice received a tumour graft 4 months later and the randomized mouse population was divided into two groups: one group was boosted with 400 μg of heat-killed *Micrococcus* administered on days 1, 4 and 7 after tumour grafting, whereas the second group of prevaccinated mice was untreated. As illustrated in Table 2, BALB/c mice implanted (day 0) Ehrlich cells and mean survival time (M.S.T. = 29.0 days ± 8.2) of the other vaccinated but tumour bearing mice was considerably extended (M.S.T. = 22.4 dayss ± 3.1) over control mice. However, only 7% of long-term survivors were recorded 90 days after grafting i.p. 2,000,000 Ehrlich cells.

In a last experiment, we have tested the immunoprophylactic capability of an antimicrococcus immunity on the proliferation of plasmacytoma (MOPC 173) cells.

BALB/c mice were hyperimmunized with

Table 2. Effect of prevaccination with Micrococcus lysodeikticus *on murine ascites tumour growth*

Number	Tumour + dose	Micrococcus vaccinated mice Mean survival time (T) ± standard deviation (days)	Control mice Mean survival time (C) ± standard deviation (days)	T/C%	Number of cured mice vs total of micrococcus vaccinated mice
A EAT	200,000 cells	19.9 ± 2.7	20.1 ± 2.0	99	0/9 (0%)
B EAT	200,000 cells	26.1 ± 12.0	20.1 ± 2.0	130	1/9 (11%)
C EAT	200,000 cells	29.0 ± 8.25	22.4 ± 3.1	129	8/12(67%)

A and B: BALB/c mice immunized with one injection a week (50 μg given subcutaneously) for 4 weeks. On weeks 7, 9 and 11, animals received 3 injections a week. Vaccinated mice received a tumour graft 4 months later and some were boosted (B) with 400 μg given subcutaneously on days 1, 4 and 7 after tumour grafting.
C, D, E: BALB/c mice were vaccinated according to an immunization schedule that yields the production of homogeneous antibodies.

that had earlier shown a primary immune response did not develop any immunoprotection against 200,000 intraperitoneally implanted Ehrlich carcinoma cells. We assume that Ehrlich tumour bearing mice might be unable to recall sufficient antimicrococcus memory T cells, even in the case of shared epitopes. Micrococcus vaccinated mice, repeatedly boosted with 400 μg of heat-killed bacteria given subcutaneously on days 1, 4 and 7 after tumour grafting, displayed a significant increase in mean life span (M.S.T. = 26.1 days ± 12.0) over control mice (M.S.T. = 20.1 days ± 2.0). Then, mice were hyperimmunized i.p. for months with *Micrococcus* according to an immunization scheme described under paragraph 1 and tumour challenged on week 34.

As outlined in Table 2, BALB/c mice were given the highest immunoprotection by hypervaccination with *Micrococcus lysodeikticus:* on day 90 after tumour grafting, 67% of these mice were cured after a tumour challenge of 200,000 intraperitoneally heat-killed *Micrococcus lysodeikticus* i.p. according to the immunization scheme described under paragraph 2. On week 45, they received a tumour challenge of 200,000 plasmacytoma cells (MOPC 173) in the mouse peritoneum. As represented in Table 2, micrococcus vaccinated mice considerably resisted to a challenge of this rapidly growing neoplasm and 44% of the animals were cured on day 90, whereas the other vaccinated but tumour bearing mice displayed an increase in mean life span (M.S.T. = 13.9 days ± 2.2) over unvaccinated control mice (M.S.T. = 11.0 days ± 1.5).

DISCUSSION

In this paper, we report on the effect of hypervaccination with *Micrococcus lysodeiktikus* and its influence on the proliferation of murine immunocompetent cells and neoplastic plasma and of carcinoma cells.

By the expression of both primary and secondary humoral immune responses against sheep or horse erythrocytes, the immunologic potential of mice was measured and analysed at different stages of the immunization period. We present evidence that, depending on the immunization schedule, BALB/c mice hyperimmunized for months with *Micrococcus* displayed lower anti-SRBC responses than control mice and this is far more pronounced when mice were tested on week 33 than on week 16, as seen in Fig. 1. ($0.001 < P < 0.005$).

Figure 2 clearly shows the evolution of a primary immune anti-SRBC response during a hypervaccination schedule and demonstrates that, as compared to PBS treated animals, micrococcus vaccinated mice show an impaired secondary immune anti-SRBC response. Anti-SRBC responses of CDF_1 mice vaccinated with *Micrococcus lysodeikticus*, according to an immunization scheme that leads to the production of antibodies of restricted electrophoretic heterogeneity and clonal dominance, were dramatically depressed when tested on week 22 (before the first appearance of clonal dominant immunoglobulins in the mouse serum) and week 38 ($P < 0.001$).

Both anti-SRBC responses of homogeneous and non-homogeneous responder mice were considerably lower ($P < 0.001$) than those of control mice and we were unable to find a direct correlation with the antimicrococcus antibody titer.

This immunosuppression, generated by vaccination with heat-killed *Micrococcus lysodeikticus*, was still present after a rest period of 6 months even in those mice where the antimicrococcus antibody had disappeared from the serum (Table 1). However, we also observed that administration to those mice of 1 mg of Bacillus Calmette-Guérin together with horse erythrocytes could partially restore the immune responsiveness of vaccinated mice, as illustrated in Fig. 4. Both the bacterium and the antimicrococcus antibody may possibly account for the immunosuppression.

We previously demonstrated that rabbit antimicrococcus antisera may agglutinate lymphocytes of different species and certain tumour cell types but not erythrocytes [15], which was confirmed by others [21] who demonstrated that fluorescent rabbit anti-micrococcus antibodies induce spots and cap formation on lymphocytes of the peripheral blood and predominantly on T cells. Up to now, we ignore if this binding leads to an overstimulation, suppression or elimination of the target cell.

Alternatively, we may think that the bacterium itself may depress the immunological potential of certain lymphoid cell types in the same way as dextrans, levans [22] and pneumococcal polysaccharides [23] and that repeated administrations may induce a long-lasting reduced ability to proliferate of particular subpopulations that are required to function in the network of cellular reactions that build together an adequate immune response.

Compatible with this plausible model is the observation that CDF_1 mice hypervaccinated for five months with *Micrococcus lysodeikticus* showed an impaired anti-SRBC immunity when SRBC was inoculated intraperitoneally but were still able to build an almost normal immune response when SRBC was injected intravenously (unpublished observation).

In a third model, we may think that the antimicrococcus immunity, directed against carbohydrates such as glucose and *N*-acetyl-D-glucosamine, may selectively lead, in a way similar to lectins such as Concanavalin A, to the *in vivo* production of suppressor T cells that, whether localized or generalized, may inhibit immunologic responses [24]. However, it is worthy of note that CDF_1 mice that were hypervaccinated for months with *Micrococcus lysodeikticus* and displayed dramatically decreased immunologic responses did not have a shortened life span as compared to control mice (unpublished observation).

In a last set of experiments, we clearly demonstrated that switching on a secondary immune antimicrococcus response results in a considerable increase in mean life span of vaccinated mice over control mice bearing Ehrlich ascites tumour. When hyperimmunized for months with *Micrococcus lysodeikticus*, mice were given the strongest immunoprotection and we found 67% of cured mice on day 90 after grafting 200,000 cells, whereas the other vaccinated but tumour bearing animals showed a 29% increase in mean life span (M.S.T. = 29.0 days ± 8.2) over control mice (M.S.T. = 22.4 days ± 3.1).

The immunoprotection was severely reduced by grafting 2,000,000 Ehrlich cells to the vaccinated mice and resulted in 7% of cured mice on day 90 after tumour grafting, as outlined in Table 2. Our results show that immunosuppression occurs when

the number of grafted cells is less than 10^5 tumour cells.

Similarly, we demonstrated that BALB/c mice hyperimmunized for months with *Micrococcus lysodeikticus* were protected against a tumour challenge of 200,000 grafted plasmacytoma cells: 44% of long-term survivors were cured on day 90 and the other vaccinated but tumour bearing mice died with an increase in mean survival time (M.S.T. = 13.9 days ± 2.2) over control mice (M.S.T. = 11.0 days ± 1.5), as listed in Table 2.

With those results, we show that the antimicrococcus immunity itself obtained through hyperimmunization can be sufficient to control the proliferation of murine plasmacytoma (MOPC 173) and carcinoma (Ehrlich) cells.

This is in sharp contrast with our data obtained with the L1210 system where we clearly demonstrated [20] that booster injections were required for the antimicrococcus immunity to be operationally effective against this murine leukaemia.

Since Ehrlich ascites carcinoma (fatal tumor dose for 100% of the animals = 1000 cells) and MOPC 173 plasmacytoma (fatal tumour dose for 100% of the animals = 10,000 cells) are slightly immunogenic, whereas L1210 leukaemia is poorly immunogenic [15] (tumour dose 100% = 1–10 cells), we assume that the immunogenicity of carcinoma and plasmacytoma is sufficient to trigger enough effector cells that, in collaboration with the antimicrococcus immunity, lead to an effective immunity, whereas insufficient recruitment by the poorly immunogenic L1210 cells requires additional effector cell triggering. Those results provide additional evidence that the micrococcus vaccine might be successfully used to inhibit nascent neoplastic cell proliferation.

Pregnancy β_1 Glycoprotein and Chorionic Gonadotrophin in the Serum of Patients with Trophoblastic and Non-Trophoblastic Tumours*

K. D. BAGSHAWE,† R. M. LEQUIN,‡ PH. SIZARET§ and YU. S. TATARINOV¶

†*Department of Medical Oncology, Charing Cross Hospital, London, United Kingdom,* ‡*Radioimmunoassay Laboratory, Department of Obstetrics and Gynaecology, Sint Radboudziekenhuis, Nijmegen, The Netherlands, Centre International de Recherche sur le Cancer,* 150 *Cours Albert-Thomas, Lyon, France and* ¶*Department of Biochemistry and Immunochemical Laboratory for Research in Malignant and Embryonal Tissues,* 2*nd Moscow Medical Institute, Moscow, U.S.S.R.*

Abstract—*Measurements of the concentration of the pregnancy associated beta$_1$ globulin, B_1SP_1, and human chorionic gonadotrophin (hCG) in sera from patients with hydatidiform mole, invasive mole, choriocarcinoma, malignant teratoma and various non-trophoblastic tumours have been made in a multi-centre study by radioimmunoassay. Estimations of B_1SP_1 and hCG in different laboratories correlated to a degree consistent with the conditions of the study. The correlation between B_1SP_1 and hCG values in patients with gestational trophoblastic tumours was not close and that in patients with malignant teratomas was poor. Values for hCG were usually higher than those for B_1SP_1, suggesting that, in general, hCG is likely to be the more useful and consistent marker. HCG values* > 3000 ng/ml *were always associated with detectable levels of B_1SP_1. The possibility that B_1SP_1 measurements have a place in detecting minimal residual disease states, has not, however, been excluded by the present study. Elevated values of B_1SP_1 were not found in a small group of patients with non-trophoblastic tumours.*

INTRODUCTION

A PREGNANCY associated beta-globulin has been identified in the sera of pregnant women by an antiserum against pregnancy [1, 2] and against a protein fraction of placenta [3]. It ia referred to here as B_1SP_1. The biological function of this glycoprotein has not yet been defined but it has been localised in both normal and malignant trophoblastic cells [4–6] and in some non-trophoblastic tumours [7]. Oestrogen-binding [8] and immunosuppressive properties [9] have been described.

Trophoblast synthesizes several polypeptides and one of these, human chorionic gonadotrophin (hCG) is widely used as the basis of pregnancy tests. Quantitative estimations of this hormone are used to monitor hydatidiform mole, invasive mole, choriocarcinoma and trophoblast-like elements found in malignant teratomas [10]. Two other trophoblastic polypeptides, human placental lactogen (hPL) and placental alkaline phosphatase (PAP) have been identified in the sera of some patients with trophoblastic tumours but as markers for trophoblastic tumours they have proved inferior to hCG. It is relevant that both hPL and PAP are characteristic of the trophoblast of late pregnancy whereas hCG and B_1SP_1 are both produced in relatively large amounts by early pregnancy trophoblast [11–13]. Since hCG shares some antigenic determinants with pituitary luteinizing hormone (LH), assay specificity depends on using antisera directed at the B sub-unit of hCG ([14]. B_1Sp_1 is not known to have an analogue in the normal non-pregnant adult and it therefore offers the potential of more specific detection of minimal residual tumour.

Accepted 9 March 1978.

*This study was organised by the International Agency for Research on Cancer, Lyon, France.

In the present study we have made a preliminary comparison of B_1SP_1 and hCG as markers for trophoblastic and some non-trophoblastic tumours.

MATERIALS AND METHODS

Four laboratories participated in the study and for the present report are designated A, B, C, D. Samples of sera were collected in the hospitals associated with the participating laboratories and stored at −20°C until transported in the frozen state to the W.H.O. laboratory at Lyons. The samples were then thawed, aliquoted, coded and returned frozen to the participating laboratories. The sources of sera, on which both B_1SP_1 and hCG measurements were made, are shown in Table 1.

Table 1.

Gestational trophoblastic tumours*	83
Malignant teratoma†	23
Non-trophoblastic tumours‡	23
Normal female blood-donors	20
Positive controls (late pregnancy sera)	11
	160

*Includes hydatidiform mole, invasive mole, choriocarcinoma.
†Includes embryonal carcinoma, teratocarcinoma, seminoma.
‡Includes fibromyoma and carcinomas of cervix and endometrium.

Estimations of β_1SP_1 were made in laboratories A & B; estimations of hCG by β-subunit assay were made in laboratories C & D. The estimations reported here were all made by radioimmunoassays but no attempt was made to use common reagents or reference materials or to standardise methods.

Laboratory A used Behringwerke Standard β_1SP_1 for reference standards and for isotopic labelling. The anti-β_1SP_1 serum was raised in rabbits and a 2-stage incubation system was employed.

Laboratory B prepared its own β_1SP_1 from pooled pregnancy sera and compared this with Behringwerke Standard. It used a rabbit anti-β_1SP_1 with a 2-stage incubation in the second antibody precipitation method. Both laboratory A and B expressed results as ng/ml.

Laboratory C and laboratory D used their own laboratory purified preparations of hCG prepared from pregnancy urine sources for isotopic labelling with ^{125}I and as laboratory standards.

Laboratory C expressed its results in weight of laboratory standard and laboratory D in terms of the 2nd International Reference Preparation of hCG. Both laboratories C and D used double antibody methods but laboratory C employed a 2-stage incubation whereas laboratory D used a one stage incubation with pre-precipitated antisera, the first antisera in each case being of rabbit origin.

The amount of sera available did not allow all laboratories to obtain results on all the specimens but at least one result for each polypeptide was obtained on the samples reported here. The effect of freezing and thawing the samples on estimations in the participating laboratories was not studied.

RESULTS

β_1SP_1

The limit of sensitivity in laboratories A and B were 3 ng/ml and 2 ng/ml respectively. Observed values ranged from the limit of sensitivity up to 1500 ng/ml and 37,000 ng/ml respectively. The mean values for all specimens examined was 109 ng/ml in laboratory A and 49 ng/ml in laboratory B. The coefficient of correlation between these laboratories was 0.919 (paired T value 1.62 for 59 degrees of freedom).

The mean values for patients with gestational trophoblastic lesions in the two laboratories were 309 and 138 ng/ml (correlation coefficient 0.914) and for malignant teratomas the mean values were 37 and 16 ng/ml (correlation coefficient 0.916). The mean values for normal female blood donors were <4 ng/ml. For patients with non-trophoblastic tumours the mean values did not differ significantly from the normal controls <4 ng/ml.

hCG

The lower limits of the working range in the laboratories for this study were 4 ng/ml in laboratory C and 10 m.i.u. in laboratory D. Values observed ranged from the lower limit of the working range to 410,000 ng/ml and 560,000 mi.u./ml respectively. Mean values were 17,495 ng/ml and 51,565 mi.u./ml The coefficient of correlation between the laboratories was 0.693 (paired T value −2.32 for 76 degrees of freedom). The mean values for patients with gestational trophoblastic

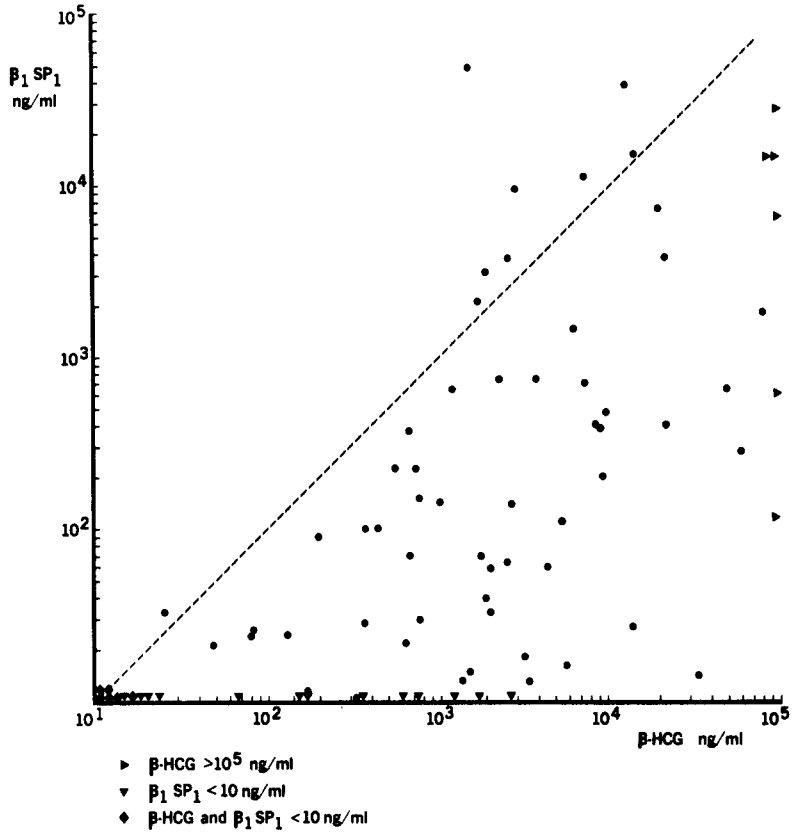

Fig. 1. Relationship between serum β-HCG and $\beta_1 SP_1$ in patients with gestational trophoblastic tumours.

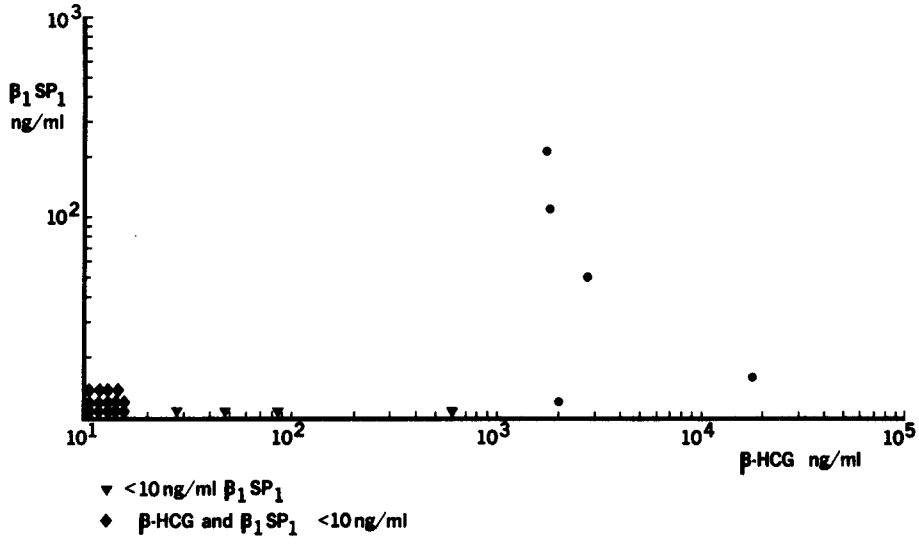

Fig. 2. Relationship between serum β-HCG and $\beta_1 SP_1$ in patients with teratocarcinoma and other gonadal tumours.

tumours were 40,583 ng/ml and 119,384 mi.u./ml (correlation coefficient 0.651) and for malignant teratomas were 415 ng/ml and 119. mi.u./ml (correlation coefficient 0.993). For normal blood donors the means were <4 ng/ml and <10 mi.u./ml respectively. For non-trophoblastic tumour patients the mean values did not differ significantly from the normal controls in laboratory D but were marginally higher in laboratory C.

Correlation between $\beta_1 SP_1$ and hCG

The mean ratio hCG/B_1SP_1 for all samples was 4.3/1.0; for gestational tumours it was 14.6/1.0 and for malignant teratoma it was 113.3/1.0. The correlation between estimated concentrations of the two substances in the same specimens (using the data from laboratories B and C only) in gestational trophoblastic tumours was 0.281 and for malignant teratomas was 0.164 (see Figs. 1 and 2).

In the group with gestational tumours there were 2 samples where hCG was not detected in either laboratory but low levels of B_1SP_1 (3–10 ng/ml) were detected. There were 2 samples where B_1SP_1 was not detected but low levels of hCG were recorded. In 9 instances the concentration of B_1SP_1 exceeded the concentrations of hCG but in 63 instances hCG concentration exceeded B_1SP_1 (Fig. 1).

Estimates of the two substances in the sera of patients with malignant teratoma gave widely differing correlation coefficients; for laboratories B and C the coefficient was 0.164 (22 degrees of freedom) and for laboratories B and D it was 0.657 (14 degrees of freedom). In no cases did the B_1SP_1 value exceed the hCG concentration and in no instance was B_1SP_1 detected in the absence of hCG. In 4 cases hCG was detected in the absence of B_1SP_1 (Fig. 2).

DISCUSSION

It is well known that when assays are performed in different laboratories using different assay techniques, reagents and standards, wide variations are likely in the numerical values observed and that the correlation between results may be poor. Such studies may however reveal broad patterns of agreement. The correlation between estimates in the B_1SP_1 laboratories in the study was satisfactory but that between the hCG laboratories was less so except in the case of malignant teratomas where the correlation was good.

The present data indicate that hCG values are generally higher than B_1SP_1 values in the sera of patients with active gestational trophoblastic tumours and malignant teratomas. The metabolic half-lives of these substances are probably similar, that is about 30–50 hr, [15, 16], so the differences are likely to reflect different rates of synthesis and secretion. The values of both hCG and B_1SP_1 in the sample of patients with non-trophoblastic tumours revealed no significant elevations above control values but the sample was small and firm conclusions would be unwarranted.

Although hCG values were generally higher than those of B_1SP_1, suggesting that hCG is likely to remain the most useful marker for choriocarcinoma, there were, nevertheless, few samples where B_1SP_1 was undetectable and in 2 instances B_1SP_1 was detected but hCG was not. In order to determine whether B_1SP_1 measurements might, for instance, reveal minimal residual disease not detected by hCG measurements further studies will be required. It is also necessary to determine whether the relationships of the two substances have prognostic implications. There were no instances where a high level of one marker was associated with undetectable levels of the other although B_1SP_1 values <10 ng/ml were sometimes found with hCG values in the range of 50–5000 ng/ml. It seems clear that although B_1SP_1 and hCG are probably synthesized by the same cells dissociation in their respective rates of synthesis or metabolism takes place.

Acknowledgements—We wish to thank Dr. H. Bohn for supplies of β_1 glycoprotein and antisera. We also wish to thank our laboratory colleagues for their participation in this Study, in particular Dr. Frances Searle, Mr. L. H. Elvers, Mr. G. Hiemstra, Miss Nicole Martel and Dr. A. V. Sokolov.

The paper was prepared for publication by K. D. Bagshawe, who wishes to acknowledge the statistical advice of Dr. K. D. McCrae.

Oestrogen Receptors and Peripheral Serum Levels of Oestradiol-17β in Patients with Mammary Carcinoma*

N.-O. THEVE,† K. CARLSTRÖM,‡ J.-Å. GUSTAFSSON,§ S. GUSTAFSSON,¶ B. NORDENSKJÖLD,|| H. SKÖLDEFORS† and Ö. WRANGE§

†*Department of Surgery* II *and* ‡*The Hormone Laboratory, Department of Obstetrics and Gynaecology, Sabbatsberg Hospital, Stockholm, Sweden;* §*Department of Chemistry* I, *Karolinska Institutet, Stockholm, Sweden;* ¶*Department of Clinical Chemistry and* ||*Radiumhemmet, Karolinska sjukhuset, Stockholm, Sweden*

Abstract—*Oestradiol receptors were determined by isoelectric focusing in cytosol from breast cancer tissue from* 12 *pre- and* 70 *postmenopausal patients. Simultaneous determination of the peripheral serum levels of oestradiol-*17β *was carried out in the* 12 *premenopausal and* 57 *of the postmenopausal patients. At oestradiol-*17β *levels below* 150 pM *the receptor values ranged from below* 0.01 *to* 7.19 fmole *bound* [^{3}H] *oestradiol-*17β/μg *of DNA. At oestradiol-*17β *levels above* 150 *pM only low receptor values* (<0.25 fmole *bound* [^{3}H] *oestradiol-*17β/μg *of DNA) were recorded. The results indicate an influence of the endogenous oestrogen on the receptor assay probably due to blockade of the hormone binding site. It is proposed that an endocrine evaluation of the patient should be performed together with the oestrogen receptor assay.*

INTRODUCTION

THE DETERMINATION of oestrogen receptors in breast cancer tissue can now be considered as an established tool for the selection of therapeutic regimens [1, 2]. Forty to sixty % of the receptor positive tumours are reported to respond favourably to different kinds of endocrine therapy, while the corresponding figure for receptor negative tumours is about 5% [1]. It is therefore important to know the factors influencing the receptor assay. It has been reported that oestrogen receptor positive tumours are more frequent among postmenopausal patients [1] and it is well known that the production and peripheral levels of oestrogens decrease dramatically during the menopause. This indicates an effect of endogenous oestrogen on the results of the receptor assay. Furthermore, a relation between high plasma levels of oestradiol-17β and low binding of [^{3}H]-oestradiol-17β in slices of human breast cancer tissue has been reported by Maass *et al.* [3] although very few patients with high oestrogen levels were included in that study. Sakai and Saez [4] have recently reported a positive correlation between high plasma levels of oestrogens and the degree of saturation of the receptor in breast cancer tissue.

In order to further investigate the influence of endogenous oestrogen upon the results of oestrogen receptor assays and endocrine treatment, we have determined free oestrogen receptors in breast cancer tissue from pre- and postmenopausal patients using a newly developed technique based on isoelectric focusing [5]. The receptor values have been correlated to the patient's age and the peripheral serum levels of oestradiol-17β.

MATERIALS AND METHODS

Clinical material

The clinical material consisted of 82 patients with histologically confirmed breast cancer. Twelve of the subjects were premenopausal and 70 postmenopausal. Oestrogen receptor analysis was performed in all patients and peripheral serum levels of oestradiol-17β were determined in the 12 premenopausal subjects and in 57 of the postmenopausal subjects.

Accepted 26 April 1978.
*This investigation was supported by grants from Cancerföreningen i Stockholm (to J.-Å. G.) and from Riksföreningen mot Cancer (to B. N.).

Determination of oestrogen receptors

Surgical biopsies were performed and immediately transferred to the laboratory in ice cold saline. They were trimmed free from fat and normal tissue and analyzed immediately or frozen at −70°C. Fresh or rapidly thawed carcinomas were mixed and suspended in three volumes of ET-buffer (10 mM Tris–HCl pH 7.4; 1.5 nM disodium-EDTA) containing 7.5 nM [^{3}H]oestradiol-17β at 0°C for 30 min. After that the mince was homogenized, further incubated at 0°C for 45 min and centrifugated. The supernatant was subjected to limited trypsin digestion at 10°C for 30 min and the receptor content was determined by isoelectric focusing in slabs of polycrylamide gel. The procedure summarized above is described in detail in a previous communication [5]. The DNA content in the homogenate was determined according to Burton [6] and the results were expressed as fmole bound [^{3}H]oestradiol-17β per μg of DNA.

Determination of serum oestradiol-17β

The determination of oestradiol-17β in peripheral serum was performed after ether extraction by radioimmunoassay using anti-oestradiol-17β-6 (carboxymethyl oxime) bovine serum albumin. This antibody cross reacts to 11% with oestrone [7].

RESULTS

According to a previous study from this group [8] tumours with receptor values less than 0.2 fmole/μg DNA were not associated with clinically significant response to tamoxifen therapy and thus regarded as negative in this respect. Of the 82 patients studied 25 had oestrogen receptor values less than 0.2 fmole/μg DNA. Ten of the twelve pre-menopausal subjects were included in this group. The age of all patients ranged from 26 to 83 yr and the oestrogen receptor values are listed according to the patient's age in Fig. 1. In Fig. 2 the oestrogen receptor values are listed according to the peripheral serum levels of oestradiol-17β. Oestradiol-17β-values exceeding 150 pM are only associated with oestrogen receptor values less than 0.25 fmole/μg DNA.

DISCUSSION

The results of the present investigation confirm the tendency to low binding of [^{3}H]oestradiol-17β at high peripheral

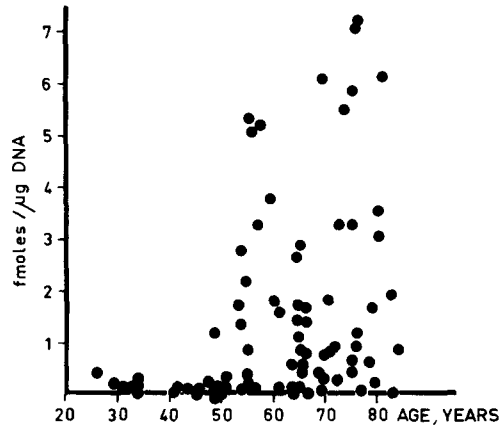

Fig. 1. Oestrogen receptor values in breast cancer tissues listed according to the patients age.

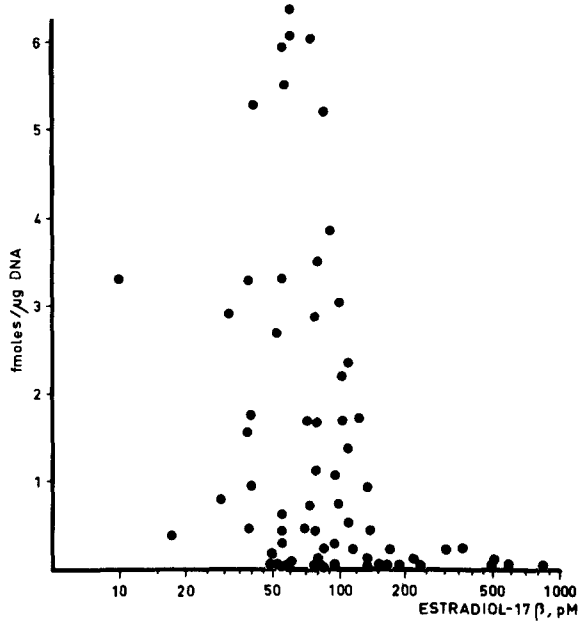

Fig. 2. Oestrogen receptor values in breast cancer tissues listed according to serum oestradiol-17β.

oestrogen values shown by Maass *et al.* [3]. This is not unexpected since a fraction of the receptors occupied by endogenous hormone will be located in the nuclei. Similar results can also be extracted upon re-examination of the data presented by Sakai and Saez [4]. When they plotted their receptor values against the plasma levels of oestrone + oestradiol-17β no clear tendency was found in this respect. If one, however, plots their receptor values against the levels of oestradiol-17β only, a clear tendency to low receptor values at high oestradiol-17β levels (above 150 pM) can be demonstrated. It should be pointed out

that the plasma levels of unconjugated oestrone presented by Sakai and Saez and the oestrone/oestradiol-ratios which can be calculated from their data by far exceed the corresponding figures given by other authors for healthy subjects as well as for breast cancer patients [9–13]. Methodological factors might therefore explain the lack of tendency when the plasma levels of oestrone + oestradiol-17β was used by Sakai and Saez as an endocrine parameter.

Fishman *et al.* have recently studied the relationship between cytosol oestradiol-17β receptors and the oestrogen content in human breast cancer tissue [14]. They claimed no relation between high oestrogen content and low receptor measurements. However, no data concerning their patients were presented. It is well known that women with low peripheral oestrogen levels can show high as well as low receptor values (Fig. 2). This wide range of receptor values may reflect differences between tumour cells with regard to receptor levels and/or cellular heterogenity of the tumours, i.e. different amounts of receptor-containing cells in different tumours [2]. Another reason may be differences in the oestrogen metabolism in the tumours, especially in the formation of oestradiol-17β from other oestrogens [4]. Such metabolic differences may, however, be of less significance at higher oestrogen levels due to the large amounts of available oestradiol-17β. Garola and McGuire [15] have recently shown that increased peripheral levels of oestradiol-17β due to exogenous administration caused a pronounced decrease in the cytosol receptor values in DMBA induced mammary tumours in the rat. Concomitantly a corresponding increase in the nuclear receptor values was observed. This experiment clearly demonstrates the influence of peripheral oestrogen levels upon the results of the cytosol receptor assay.

From the present results it can be concluded that an endocrine evaluation of the patient should be carried out together with the receptor assays. Exchange studies and assay of the nuclear receptor may be of value at least in premenopausal patients. In the endocrine evaluation the oestrogen metabolic pattern in the tumour tissue may give information of importance for evaluation of the receptor assay. Studies on this topic are in progress in our laboratories and the results will be published elsewhere.

Abstract—*We can follow in culture the spontaneous neoplastic transformation of one epithelial cell strain derived from normal rat liver and determine, by comparison with other liver cell strains, the divers modifications which appear before or during transformation.*

A decrease in adhesiveness seems to be one of the first manifestation. Increase in saturation density, ability to grow in soft agar and acquisition of tumorigenicity appear much later.

Moreover, in contrast to the other cell strains, in this transformed cell strain, some enzymatic activities were increased and tyrosine aminotransferase was induced by dexamethasone.

INTRODUCTION

THE DEVELOPMENT of the hepatic cell culture system is important in the assay of potentially carcinogenic drugs and for studies on the mechanism of cell transformation. Since the report by Berry and Friend on differentiated normal hepatocytes purified after perfusion with collagenase [1], a number of investigators have shown that isolated parenchymal cells do not proliferate *in vitro* and do not give rise to clones of liver epithelial cells [2–4]. By contrast, some authors have obtained epithelial cell strains from normal liver by other procedures [5–9]. Generally, these cells do not closely resemble hepatocytes, being structurally simpler, they appear to stem from hepatic cell types that proliferate quickly in culture. These cells, often fail to show hepatocyte-like biochemical properties [10] such as tyrosine aminotransferase (TAT) which have been chosen as a hepatic marker for its response to glucocorticoids. On the other hand, adult liver contains specific "markers" such as the isozymes aldolase B and pyruvate kinase L. Isozymes are multiple molecular forms, genetically determined; they may have different properties, but they have the same action on the principal substrates and seem to represent a high degree of differentiation. In several pathological conditions, especially in neoplastic tissues, and in primary hepatocyte cultures, modifications of the liver isozymic pattern have been reported [11–17].

Moreover, certain proteins have been found in normal liver of different animals which inhibit the cell growth of cultures [15] and tissues, especially adult liver growth after a partial hepatectomy [16]. These authors report this "inhibitory factor" as specific to liver tissue and as being present in a small amount in hepatoma [15]. Its presence has not yet been investigated in hepatic cell strains.

Malignant conversion *in vitro* of cultured liver cells has often been induced or accelerated by treatment with chemical carcinogens or oncovirus but few reports concern spontaneous transformations of liver cells *in vitro*. The detection of malignant conversion *in vitro* of epithelial cells is more difficult than for fibroblasts. This is because little alteration appears in the cell morphology. However growth and functional changes and neoplastic properties can also occur during transformation. Since a number of variations from

Accepted 25 April 1978

one clone to another have been reported with the same line, and from one cell line to another in different induced malignant transformations *in vitro*, it is interesting to analyze the gradual changes which occur during "spontaneous" transformation.

The purpose of the present paper is

(a) to describe the principal cytological, growth and functional changes which gradually appear in different isolated epithelial cell strains derived from normal livers when they spontaneously transform in culture;

(b) to compare the changes of each parameter at sequential passages;

(c) to compare their new characteristics to those of a hepatoma cell strain.

MATERIALS AND METHODS

I. *Cell strains and culture conditions*

The cell strains F_I, F_{II}, F_{III} were initiated from normal liver of 10-day old Fischer or Commentary rats. The Williams' procedure was employed using 0.25% trypsin and the sequential passage of primary cultures to achieve an elimination of fibroblasts [8]. The cells were grown in Williams' medium supplemented with 15% fetal bovine serum, glutamine (0.293 g/l) and antibiotics (neomycin 0.05 g/l, streptomycin 0.05 g/l, penicillin 200,000 U/l).

Hepatoma cells LF derived from transplantable tumour. This tumour originated from a hepatoma induced in Commentry rats by a carcinogen, dimethylaminoazobenzene (DAB). The cell strain was initiated by consecutive dissocations with 0.25% trypsin solution. The cells were grown in MEM medium with 20% bovine serum (56°C heat inactivation) and supplemented with glutamine and antibiotics as above. The main difference between the two media is that Williams' medium contains more aminoacids, vitamins and ions (Zn, Cu, Fe, Mn) than MEM and that Williams' medium is supplemented with fetal calf serum instead of calf serum.

II. *Preparation of samples for assays*

To investigate the "inhibitory factor" in the cell strains, monolayers of cells were washed 3 times with PBS and scraped from the dishes with a rubber policeman, suspended in PBS and counted with the coultronic Coulter (F'). The cell suspensions were lysed by sonication for 45 sec and the lysates were centrifuged at 5000 rev./min for 10 min. The supernatant was filtered on a 0.45 μ Millipore® filter.

For the enzyme studies, we used a cell extract supernatant obtained by detaching the cells with 0.25% trypsin solution, washing them in PBS, followed by freezing and thawing 3 times and centrifuging at 12,000 rev/min for 10 min.

Morphological changes were observed by light and electron microscopy using routine preparation methods.

Neoplastic transformation was demonstrated *in vitro* by the growth of colonies in soft agar [17]. It was confirmed by tumour production *in vivo* after intraperitoneal injection of about 2×10^6 cells into syngeneic newborn rats.

III. *Enzyme and protein assays*

Enzymes were assayed by the following methods: aldolase, Sibley and Lehninger's [18]; pyruvate kinase, Bücher and Pfleiderer's [19]; lactate dehydrogenase, Wroblevski and Ladue's [20]; glucose-6-phosphate dehydrogenase, Beutler's [21]; tyrosine aminotransferase, Granner and Tomkin's [22]. Enzymatic activities were expressed in International units (i.u.) per g of protein. Total proteins were measured by the Lowry procedure [23].

For the electrophoretic studies, the pyruvate kinase isozymic pattern was resolved by isoelectrofocusing using Vesterberg's method.[24] with some modifications [25]. Aldolase isozymes were separated by the electrophoretic method of Penhoët *et al.* adapted to starch gel [26].

The "inhibitory activity" of the cell extracts was defined by their effect at different dilutions on the cell growth of the hepatoma cell strain LF, during 24 hr of incubation. Results are expressed in per cent of growth inhibition compared to the controls.

RESULTS

I. *Growth and morphological characteristics of the hepatic epithelial cell strains during the first passages*

Many cell strains have been successfully established in our laboratory using successive trypsination. Three of them shown in Table I were studied: F_I and F_{II} were initiated from Fischer rats, and F_{III} from Commentry rats. They divided slowly and reached confluency several weeks after seeding. Thereafter, for subcultures, when 10^5

Table 1. *Rat liver and hepatoma cells cultures*

Cell strains >30th passage	Origin	Rat strain	Morphology	Plating* efficiency (average) %	Colony† forming cells in soft-agar average %	Tumor production‡ No. rats with tumors / No. inoculated rats
F_I	Normal liver	Fisher	Epithelial	27	0.16	12/15
F_{II}	Normal liver	Fisher	Epithelial	2	0	0/10
F_{III}	Normal liver	Commentry	Epithelial	29	0	0/20
LF	Hepatoma	Commentry	Epithelial	51	0.23	18/20

*0.25–1 × 10^3 cells seeded/plate (average 5–10 plates).
†5 × 10^4 cells seeded/plate (average 3 plates—colonies counted 12 days after plating).
‡2–3 × 10^6 cells inoculated (0.2 ml i.p./newborn rat).

cells/ml were seeded in 6 cm^2 dishes, confluency was reached after 4–5 days of culture.

During the first passages, their mode of growth was a flattened epithelial shape and cells had a very high adhesion to the substrate on which they grew and to their neighboring cells (Fig. 1). Tight junctions between the cells were seen by ultrastructural studies.

II. *Spontaneously-transformed liver cell strains and hepatoma in culture: growth and morphological characteristics*

In contrast to the F_{II} and F_{III} cell strains which still conserve some normal characteristics, one of the strains studied F_I (Table 1) on the 30th passage, in normal conditions, appeared to present some evidence of neoplastic transformation.

F_I cells gave rise to colonies in soft-agar similar to the hepatoma strain LF. In addition, intraperitoneal injection of 2–3 × 10^6 cells into syngeneic newborn rats gave rise to carcinomas in 80% of the animals at the different stages studied: 31st, 37th, 48th passages. However, the development of tumours was always very slow (4–9 months) in comparison to hepatoma cells which needed, in the same conditions, 10 days to produce tumours at each passage studied (18th to 500th). The histological studies of the nodular granulations obtained with F_I cells showed some aspects of tumour cells from little-differentiated hepatoma. By contrast, injection of LF hepatoma gave rise to tumors with the characteristic trabecular morphology of hepatoma. Using ultrastructural studies, no evidence of viral and PPLO particles was observed in F_I, F_{II}, F_{III} and LF cells.

One of the first manifestations of the transformation of F_I cells was a decrease of their high adhesion: it was progressively easier to detach the cells from their substrate by trypsin action through the 18th to the 30th passage. Gradual overlapping in the culture also occurred very early (near the 13th passage), but the cells remained epithelioid, and never piling up as LF hepatoma cells (Fig. 2). In both these strains, F_I and LF, there was a marked decrease in mutual cell contact. These cells had many prominent surface microvilli and no tight-junctions were observed by microscopic studies.

Increase of the protein/cell ratio by a factor of 3 in the cell strain F_I was the same as in the hepatoma LF. This ratio remained unchanged in F_{II} and F_{III} cells and.these cell strains still conserved an apparent normal aspect.

Nevertheless, in comparison to F_{II} cells which did not change, the adhesiveness of F_I and F_{III} cells decreased progressively. In addition, the generation time appeared strongly reduced and the saturation density was increased by a factor 4 for F_I on the 132nd passage and by a factor 3 for F_{III} on the 66th passage. However they had not yet reached the high saturation density of LF hepatoma cells, which increased by a factor 8 on the 91st passage. Confluency was complete earlier for F_I and LF (after 2–3 days of culture instead of 4–5 days for F_{III}).

However, in spite of the transformation shown above for F_{III}, these cells never produced colonies in soft-agar even on the 65th passage and did not give rise to tumor in rats after intraperitoneal injection (43rd

passage). It was the same for the F_{II} cell strain studied which are still on the 40th passage. But, we have observed that using Williams' medium instead of MEM medium even the neoplastic LF hepatoma cell strain fails to grow in soft agar.

Thus, if the F_I cell strain shows evidence of spontaneous neoplastic transformation, the F_{III} cells strain appears to be in the process of transforming. For F_{II}, which still keeps some of the normal aspect of liver cells, we think that it could be transformed later like the others.

The isozymic pattern was the same in all the cell strains studied. Pyruvate kinase L (liver type) was absent and the K type (kidney and fetal type) was the only one seen during the cell growth and at confluency. Electrofocusing showed that the two subbands of the K form, M_2 and M_4 were present, M_2 being the most predominant (Fig. 3). For aldolase, hybrids ac were found (A is the muscle and fetal type; C is found in brain and in fetal liver). The specific form of adult liver, B type, was never seen in any of the strains studied (Fig. 4).

Table 2. Enzymic activities (in i.u./g *of protein) of normal and transformed cells*

	Normal hepatocytes	Epithelial cells F_{III}	Epithelial cells F_{II}	"Spontaneously" transformed epithelial cells F_I	Hepatoma cells LF
Pyruvate kinase	120	185	402	770	625
Aldolase	19	8.5	17	23	127
Lactico-dehydrogenase	2590	690	643	772	7800
Glucose-6-phosphate Dehydrogenase	60	66	240	270	560
Tyrosine amino-transferase	15	0.25	0.3	0.3	0.5

III. *Enzyme activities and specific characteristics of liver-cell strain during their spontaneous transformation*

The activity of pyruvate kinase, aldolase, glucose-6-phosphate dehydrogenase, shown in Table 2, appeared to be increased in the spontaneously transformed cells F_I in comparison to F_{II} and no evident increase was observed for F_{III}. The lacticodehydrogenase activity was very high in all cases, especially in LF hepatoma cells.

Induction of TAT by adding 10^{-5}M dexamethasone to the F_I cell medium was observed after 18 hr of action. Specific activity of TAT, was increased 2–5 times in the F_I cell strain. By contrast, no TAT induction was observed with F_{II} and F_{III} strains.

Table 3 shows that different concentrations of the F_I cell-strain extracts during its 16 first passages, inhibited the cell growth as did extracts of rat liver. But no inhibitory effect was observed after the 34th passage

Table 3. Inhibition of cell growth after 24 hr *of action of adult rat liver extracts and of cell strain F_I extracts at different passages*

Concentration of extracts* —in mg of liver/ml medium for liver extracts —in 10^6 cells/ml medium for cell extracts	Inhibition of cell growth in culture in % by extracts of: Adult rat liver	Cell strain F_I at different passages 15th	16th	34th	45th	116th

(when the neoplastic transformation appeared) even with high extract concentrations. Moreover, the inhibitory effect was never found with extracts of LF hepatoma cells *in vitro*, or *in vivo*, even at very high concentrations. We have previously shown that arginase which is known to be present in normal liver but absent in hepatoma, is not the inhibitory factor of liver extracts [15].

DISCUSSION

Most studies of transformation *in vitro* concern fibroblastic cell lines. Some of the morphologic criteria often used to score for transformation of these cells in culture, cannot be applied to epithelial cultures.

Few studies have reported spontaneous transformation of rat liver epithelial cells.

In 1965, Katsuta *et al.* [27] obtained neoplastic transformation by stress in the "nagisa" zone; later Sato *et al.* (1968) [28], Oshizo *et al.* (1972) [29], Allen and Yipe *et al.* (1976) [30] also described spontaneous transformations of these cells, Borek (1972) [31] obtained transformation by nutritional stress alone.

Weinstein *et al.* (1975) [32], Karasaki *et al.* (1976) [7] reported viral particles in their neoplastic "spontaneous" transformed cells.

In this present study, we can follow the spontaneous transformation of different independently isolated epithelial cell strains derived from normal rat liver, and we define the frequency and the sequential appearance of modifications which generally occur during neoplastic or non-neoplastic transformation.

"Normal" epithelial liver cells in culture were flat, strongly adhering to their substrate and their neighboring cells; they grew as monolayer without overlapping. When they spontaneously transformed, we always observed as in neoplastic cells an early decrease of their adhesiveness to the substrate as noted by Sanford *et al.* [33], a progressive overlapping and an increase in microvilli as Allen *et al.* [30]. Our results concerning degree of saturation density agree with those of Borek [31] and Weinstein *et al.* [32]. However, differences between one strain and another appeared: if the F_{III} cells, (transformed but not yet neoplastic) show no piling-up, we can observe as for neoplastic F_I cells, a decrease of adhesiveness and a net increase of saturation density, but at a later passage than for F_I.

Thus, in agreement with Sandorf *et al.* [7], it seems that a high growth rate does not necessarily indicate a neoplastic conversion in the cells.

The changes of the specific activities of the studied enzymes which appeared, especially in F_I and LF cell strain, could not represent an early event of transformation since no significant difference appeared between the "normal" F_{II} strain and the "transforming" F_{III} strain. In the same way, Karasaki *et al.* [35] recently reported no ATPase activity at the time the cell strains studied became tumorigenic.

Ability to grow in soft-agar has been reported by many authors, providing a simple and objective method of scoring for neoplastic transformed epithelial cells. It is well known that only the tumorigenic cells grow in soft agar. We have verified that the F_I strain and the LF hepatoma strain which could induce tumors by injection into newborn rats could grow in soft agar. However, this last test could not represent an early event of transformation since no colonies were produced in agar by the F_{III} strain. In addition, we have observed that with Williams' medium, instead of MEM medium, the LF neoplastic hepatoma cell strain fails to grow in agar. It shows the importance of components of medium or of serum in the growth of the culture in soft agar. Eagle *et al.* [36] also reported that a neoplastic transformed kidney-cell strain, which normally produced tumors, did not grow in soft agar. Schaeffer and Polifka [37], also noted that, while cells produced tumors, there was no growth in agar. Thus, it seems that a negative test of growth in soft agar does not provide evidence of a non-transformed state of the F_{III} cells strain.

"Spontaneously" transformed epithelial F_I and F_{III} cell strains remained different from the LF hepatoma cell strain, which showed the highest saturation density and piling-up. The increase of specific activities of different enzymes, especially LDH, appeared higher in LF hepatoma cells than in F_I or F_{III} cells. In addition, when these LF cells were injected into rats, tumors were always produced in a short time with the characteristics of differentiated hepatoma. For the F_I cell strain, the tumorigenic properties were present but tumors appeared much later and were not so differentiated. They were not yet present for F_{III}.

It could be supposed that the differences observed between the different liver-cell strains studied, and also between the spontaneous liver-transformed epithelial cells and

hepatoma cells in culture, represented different steps in carcinogenesis. Ability to grow in agar and tumorigenic properties could be the late and progressively acquired characteristics of transformation.

The parenchymal origin of these epithelial cells has to be discussed. Epithelial cells prepared from normal rat, could have been derived from either the liver parenchyma or from bile duct epithelium. Since it is difficult to distinguish them in culture, the demonstration of liver specific, biochemical functions in these cultured cells could be theoretically the best marker for the origin of these cells.

Specific aldolase B and pyruvate kinase L isozymes were absent in all our cell strains studied before and after transformation. But, there are no published evidence, except Chessebeuf's data [38], that non-tumorigenic epithelial cell strains initiated from normal rat liver conserve similar specific adult liver functions. Consequently in our systems, these enzymes cannot be used either as a "marker" of epithelial cells or as a test of neoplastic transformation.

Some authors have reported a protein "inhibitory factor" as specific to normal liver tissue. Evidence for its presence has been shown in the F_I cell strain. It disappears thereafter with occurrence of transformation. However, further studies are required to determine whether or not the transformation and/or cell growth play a role in the disappearance of this hepatic specific "inhibitory factor".

The inducibility of TAT by corticoids has been reported by a number of investigators, as a parenchymal specific property. This property is conserved in many hepatoma cell strains. Weinstein *et al.* [32] did not find it in normal epithelial cells strains. Assays with F_I, F_{II}, and F_{III} strains indicated that the F_{II} and F_{III} strains lacked dexamethasone-inducible tyrosine aminotransferase but that this enzyme could be induced in neoplastic transformed F_I cells.

It seems that under the culture conditions the lack of homeostatic regulators such as hormonal and immunologic controls, the state of continued growth and aging can undergo different modifications and loss of functions. We have reported that addition of hydrocortisone hemisuccinate to the medium is required for the maintenance of hepatocytes in culture [3]. This observation was recently confirmed by Laishes and Williams [39] who suggest that complex media may have to be devised to maintain functioning epithelial cells in culture.

What does "spontaneous" neoplastic transformation mean? It seems, for Weinstein *et al.* [32], that viral particles found in a hepatoma cell and in a spontaneous transformed cell strain, might play a causative or cofactor role in the induction of hepatomas. However, in our systems, using ultrastructural studies, no evidence for oncogenic virus or PPLO particles was seen; they could not be involved in the spontaneous transformation. In addition, a difference in the susceptibility in rat strains could not be involved either, since the transformed F_I and F_{III} cell strains came from two different strains (Fischer and Commentry) and the "normal" F_{II} cell strain from the Fischer strain, as did F_I. There is perhaps, an effect due to the calf serum used in our cultures. It is well known that some components of calf and horse serum, as compared with fetal calf serum, accelerate neoplastic transformation [35].

But it appears that we can still say now, like Hayflick [40], that "spontaneous" only means that we are ignorant of the cause.

Growth of Canine Lymphosarcoma in X-Irradiated and Non-Irradiated Athymic (Nude) Mice*

D. R. MORGAN,† L. N. OWEN and D. E. ONIONS‡

Department of Veterinary Clinical Medicine, University of Cambridge, Madingley Road, Cambridge, United Kingdom

Abstract—*Lymphosarcoma cells from 8 dogs failed to grow in Nude mice. Following whole-body X-irradiation of Nude mice cells from another canine lymphosarcoma grew successfully and were subsequently transplanted to both irradiated and non-irradiated Nude mice. When injected subcutaneously large infiltrating tumours grew and metastasised widely.*

INTRODUCTION

MANY solid human tumours have been transplanted into Nude mice (Nu) as has Burkitt's lymphoma [1] but Nu mice rarely developed tumours after i.m., i.p. or s.c. inoculations of other human lymphomas. Intracranial hetero-transplantation of various non-Burkitt lymphomas however yielded 90% "takes" [2].

Canine osteosarcoma, mammary carcinoma and melanoma have been successfully transplanted [3]. A canine mast cell leukaemia was transmitted as an ascites tumour [4].

In mice it has been shown that a majority of BALB/c lymphoid tumours grow at a significantly reduced rate in BALB/c Nu mice when compared with growth in BALB/c mice [5]. Irwin *et al.* [6] were not able to transplant bovine lymphosarcoma in Nu mice unless whole body irradiation had been previously given.

In the present experiments canine lymphosarcoma failed to grow in Nu mice but was successfully transplanted into X-irradiated Nu mice. Further passages grew both in irradiated and non-irradiated animals.

Accepted 17 May 1978.

*This study was supported by the Medical Research Council, Leukaemia Research Fund and the Wellcome Foundation.

†Present address: University of London, King's College Biochemistry Department, Strand, London WC2.

‡Present address: University of Glasgow Veterinary School, Bearsden Road, Bearsden, Glasgow.

MATERIALS AND METHODS

Lymphosarcoma

Eleven dogs histologically diagnosed as multicentre lymphosarcoma, one of which was also leukaemic, had one entire lymph node, usually either the prescapular or popliteal excised under anaethesia. Tumour tissue was chopped into 1–2 mm fragments using crossed scalpels and was then sieved through a 50 μm stainless steel mesh using Hanks' balanced salt solution. Viability of cells harvested in this way is usually >70% as assessed in trypan blue exclusion tests.

Nu mice

The mice were obtained from the Medical Research Council, Carshalton 5 yr ago and have been kept as a closed colony under barrier-maintained conditions [7]. Mice used in the experimemts were between 8 and 12 weeks of age. Whole body X-irradiation when given was from a Marconi Radiotherapy machine (250 K/V 15 Ma, Thoreus filter 0.44 mm SN +0.25 mm CU +1 mm Al). Lymphosarcoma cells were injected 4–24 hr after irradiation.

Transplantation

Cells from each tumour were injected into one to four mice dependent on availability of animals. In first transplant experiments a total of 28 mice were injected. The usual route of injection was s/c over the back but 9 mice were injected i/p.

The number of cells injected was usually 10^7–10^8.

In the lymphosarcoma successfully transplanted into X-irradiated Nu mice further transplants were made using a similar technique to that used with the primary tumour. Four passages were made using a total of 12 irradiated and 12 non-irradiated mice.

Tissue culture

Aliquots of freshly prepared cell suspensions were placed in RPMI 1640 medium supplemented with 20% foetal calf serum and incubated at 38°C.

RESULTS

In 20 non-irradiated mice injected with lymphosarcoma cells from 8 dogs no tumour growth was detected. Most mice lived between 90 and 330 days following the injection but 6 mice lived 37–62 days only.

Two mice which had received 700R whole body X-irradiation and lymphosarcoma cells died 4 days later. Two other similarly irradiated mice injected with a different lymphosarcoma died after 7 days. Two mice receiving 300 rad and 2 mice receiving 500 rad were later injected s/c with lymphosarcoma cells from a 5 yr old female Alsation. Tumour growth was apparent 3 weeks later and developed into a large subcutaneous mass.

In further passages both into X-irradiated and non-irradiated mice growth occurred in both irradiated and non-irradiated mice after the second passage. Because of the diffuse nature of the tumours spreading subcutaneously measurements of growth rate were not possible but no obvious differences in the growth in irradiated and non-irradiated animals occurred. Tumours reached a weight of 5 g without ulceration within 6 weeks by the fourth passage and regression was not seen in any of the mice injected.

In the third and later s/c passages tumour was also found to have invaded the peritoneum and metastases were found in the axillary lymph nodes, lungs, kidney and heart.

Histologically the lymph node from the original dog showed complete loss of normal architecture and was replaced by a sheet of closely packed lymphoid cells with some lymphoblastic types. Mitotic figures were common (Fig. 1). The transplanted tumour showed similar features both in the subcutaneous mass and at distant sites (Fig. 2). Cells in primary cultures and cultures from transplanted tumour remained viable *in vitro* for a few days only and long-term cultures were not established.

DISCUSSION

It is generally recognised that there is a resistance to the growth of lymphomas in Nu mice when compared with other tumours. Various hypotheses as to why this occurs have considered the possible effects of tumour inhibition by macrophages, lack of some growth factor, residual T cell activity [8–10] or the role of natural tumour antibodies [11].

Campanile *et al.* [12] have reported data indicating a relatively strong radioresistant transplantation resistance against allogeneic tumour cells in Nu mice. They were not able to determine to what extent this resistance is related to the Hh system or to natural cytotoxicity or to other immunological factors.

Warner *et al.* [5] in their studies on inhibition of growth of lymphoid tumours in syngeneic Nu mice have put forward an explanation that these mice have increased levels of non T cell immunity to certain virus associated lymphoid tumours. Their results correlate the *in vitro* lytic activity of haematopoietic cells from Nu mice with the *in vivo* growth pattern of various virus and non-virus associated tumours.

The article by Warner *et al.* [5] refers specifically to murine tumours. Protection against transplantation of xenogeneic lymphoid tumours may be due to natural killer cells directed at interspecific glycoprotein (gp70) determinants or other interspecific oncornaviral antigen determinants expressed on these cells. Wecker *et al.* [13] have shown that gp70 can be expressed in the absence of complete virus expression and can also be found on normal murine lymphoid cells that have been activated immunologically. Burkitt's lymphoma suspect for Herpes viral aetiology is easily transplantable and Marek's disease of proven Herpes viral aetiology has been transplanted into Nu mice [14]. This is in contrast to bovine lymphosarcoma of known oncornaviral aetiology. The belief that natural killer cells may be directed in the manner described gives further support for an oncornaviral aetiology of canine lymphosarcoma.

In our cases of transplanted lymphosarcoma there were widespread tumour deposits following subcutaneous inoculation and it appears

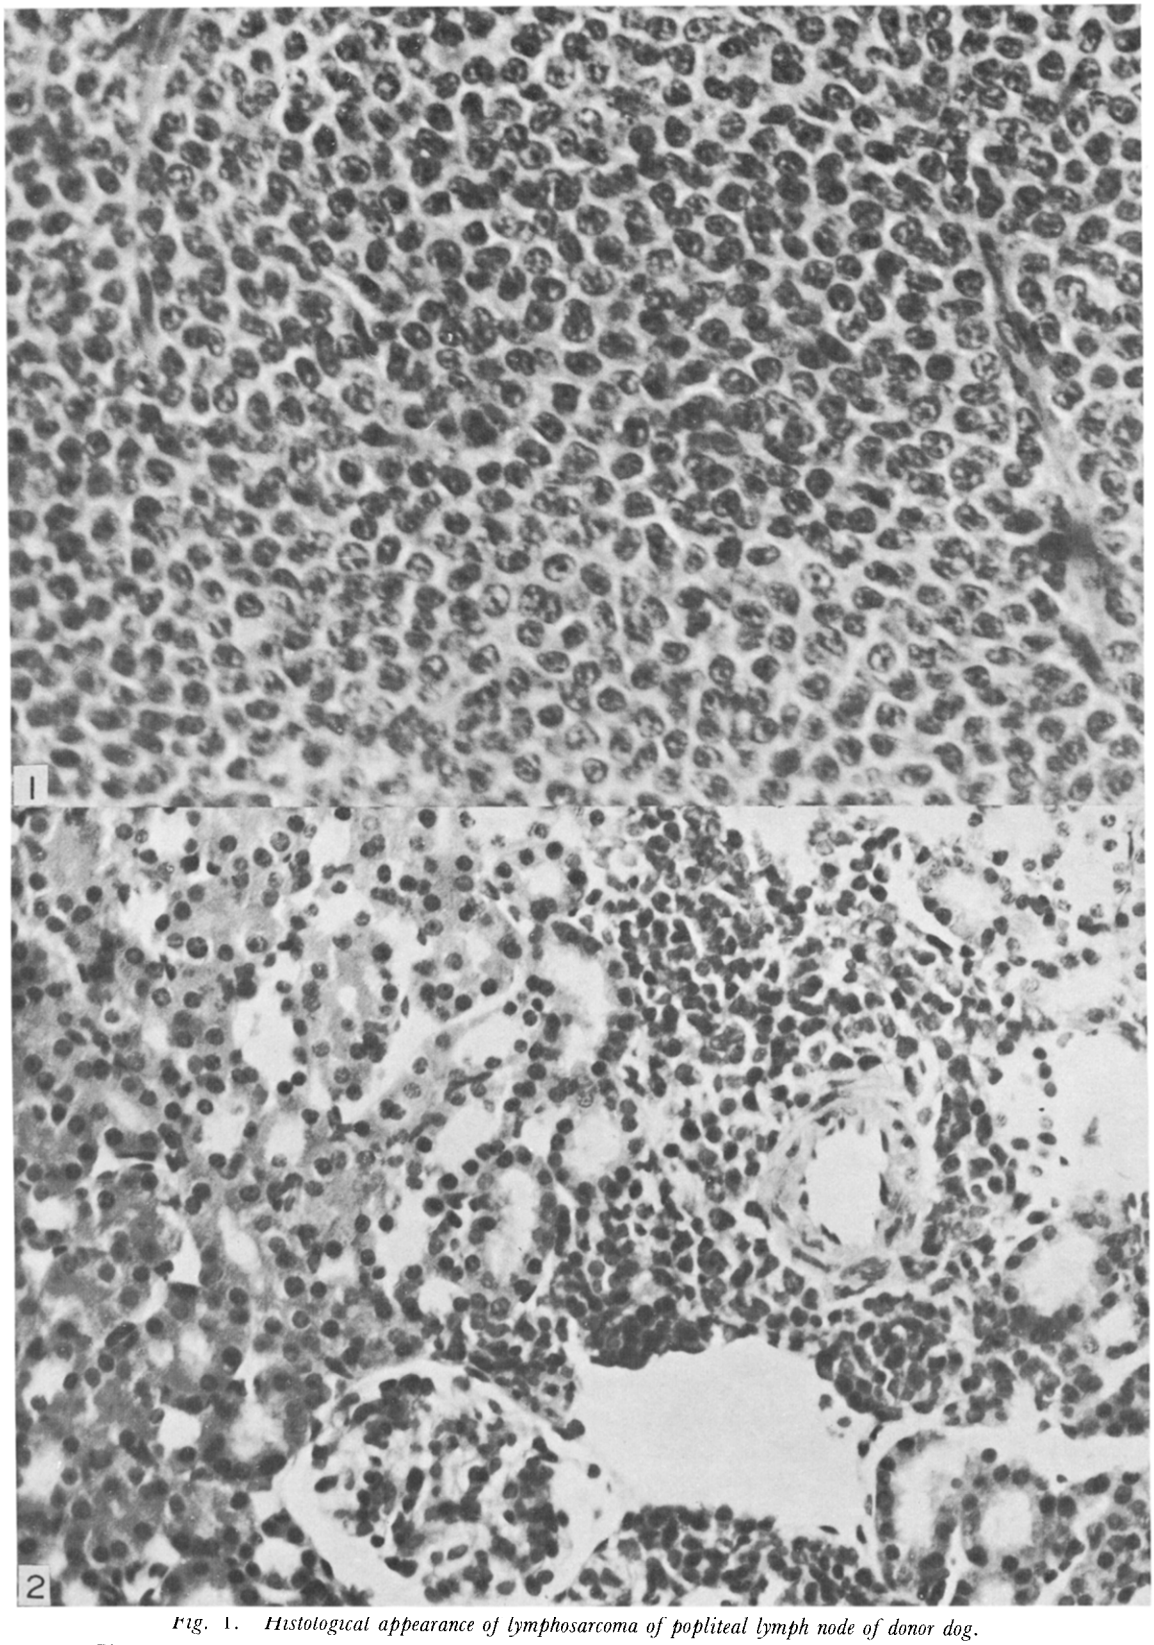

Fig. 1. Histological appearance of lymphosarcoma of popliteal lymph node of donor dog.

Fig. 2. Lymphosarcoma in kidney of Nu mouse injected s/c with lymphosarcoma cells—fourth passage. Tumour was also found in the lungs and heart.

likely that this was true metastatic spread. Metastasis is rare in tumours transplanted into Nu mice. In the lymphomas described by Epstein *et al.* [2] which were injected intracranially 2 of 21 showed extra cranial spread. Nodular lesions developed 7–8 months after implantation but they resembled diffuse mixed histiocytic and lymphocytic leukaemia rather than the original Hodgkins cases. They contained foci of cells which reacted positive with anti-human immunofluorescent reagents.

Price *et al.* [15] and others have reported the recovery of murine xenotropic type C viruses from cell cultures of hetero-transplanted human tumours in Nu mice. Epstein *et al.* [2] have considered the possibility that these viruses may enhance the growth potential of human lymphoid cells in Nu mice. Only limited E.M. studies have been made on our transplanted canine lymphosarcoma tumours and no viral particles seen but C type particles have been found in transplanted canine osteosarcoma tumours.

Preliminary Evaluation of a Phase I Clinical Study of Quelamycin

H. CORTÉS, J. VICENTE, L. BAENA, J. OTERO and M. GOSÁLVEZ

Clínica 1° de Octubre, Fundación Jiménez Díaz, Instituto Nacional de Oncología and Clínica Puerta de Hierro, Madrid, Spain

Abstract—*We have performed a preliminary evaluation of a phase* I *clinical trial of quelamycin (triferric adriamycin) with* 20 *patients. Quelamycin has appeared to have a good general tolerance, the main toxicity being characterized by leucopenia and alopecia. The maximum dose was* 225 mg *equivalent*/m^2 *and the drug produced* 4 *objective responses out of* 16 *evaluable patients.*

INTRODUCTION

QUELAMYCIN is triferric doxorubicin, a metallic derivative of adriamycin made by chelation of adriamycin with three ferric ions at neutral pH [1, 2]. A preclinical evaluation of quelamycin indicates that this derivative has less general, hematological and cardiac toxicity than adriamycin while it maintains similar antitumor action [1–4]. This report presents the preliminary evaluation of a phase I clinical trial with quelamycin carried out in Madrid by the Oncological Group of Work formed by the clinical oncologists of the six major Madrid hospitals.

MATERIALS AND METHODS

Quelamycin was synthesized by Dr. M. Gosálvez and was liophylized and sterilized by Montedison Farmaceutica, S.A. (Barcelona) in vials of 25 mg equivalent of activity to be reconstituted with 10 ml of water for intravenous injection. The vials were used within the first 6 months after the manufacturing date and the injection of the drug was performed slowly and directly into the vein. One milligram equivalent of quelamycin is the quantity of triferric adriamycin (1.25 mg) which has the same activity in inhibiting DNA synthesis as 1 mg of adriamycin. Each milligram equivalent of quelamycin, upon the dissociation of the chelate by heating with EDTA, yields 1 mg of adriamycin [4].

Patients

Patients with histologically confirmed advanced cancer, not amenable to conventional treatment, were eligible for inclusion in the study. All patients were recognized to have a life expectancy of $\geq$12 weeks and a Karnofsky performance status of $\geq$30%. Patients were admitted to the study if they had no other chemotherapy for 8 weeks previously or radiotherapy for 12 weeks previously and if they had not previously received adriamycin. All patients had received prior chemotherapy. Other requirements included adequate cardiac (normal EKG) and renal function (BUN 25 mg/100 ml), serum bilirubin of less than 1.5 mg/100 ml) serum glutamic oxaloacetic transaminase (SGOT) of less than 100 i.u., pretreatment white blood cells wbc and platelet counts in excess of 5000 and 100,000 cells/mm^3, respectively. Physical examination, determination of wbc, differential, platelet, reticulocyte counts and electrocardiograms were performed weekly. Every three weeks SGOT, BUN, creatinine, bilirubin, serum iron and X-rays were performed. Bone marrow aspiration was performed initially and when indicated. Tumor measurements using the product of the greatest horizontal and the greatest vertical diameter were obtained weekly or biweekly. In assessing tumor responses, objective response was considered when the patient had a dimunition of $\geq$50% of tumoral masses. Subjective

Accepted 10 May 1978.
Reprint requests to: Dr. Mario Gosálvez, Bioquimica Experimental, Clínica Puerta de Hierro, San Martin de Porres, 4, Madrid-35, Spain.

response was considered when the patient had a dimunition of more than 25% but less than 50% of tumoral masses. Stable disease was considered when the tumor progression arrested.

The starting dose based on preclinical toxicology studies [4] was in all cases 75 mg equivalent/m^2 of body surface area given as a direct, slow, intravenous injection. Doses were repeated every three weeks and were escalated according to individual hematological tolerance which was very variable. A minimum wbc of 3000/mm^3 was required before starting the next dose. If with the first dose the nadir of neutrophils was not less than 1500 cells/mm^3, the second dose was increased to 125 or 150 mg equivalent/m^2. If doses of 150 mg/m^2 were tolerated with a nadir of more than 1500 leucocytes/mm^3, the following dose was escalated to 200 or 225 mg equivalent/m^2.

RESULTS

Of the 20 patients who entered into the study, all were evaluable for toxicity and 16 for antitumor effect; the other 4 received only one cycle of therapy and later either died or rejected treatment, or the evaluation was insufficient. Immediately following the dose of quelamycin, all patients had vomiting and nausea, 4 patients mentioned a metallic after-taste and 7 patients had fever (37–39°C) and chills. In 4 patients the urine was red consequently to the drug. All patients had variable neutropenia which was maximal on the 14th day after the injection of quelamycin and was dose related (Table 1) and not cumulative. Only one case showed thrombocytopenia (75,000 platelets/mm^3). Alopecia was observed in 12 cases and was complete in all after the second dose. No other toxicity was observed. No alteration of any biochemical parameter including enzymes and iron in serum was observed. In spite of the fact that three patients surpassed cumulative doses of quelamycin superior to 500 mg equivalent/m^2 (600, 750 and 1700 mg equivalent/m^2 respectively), no electrocardiographic (EKG done weekly) or clinical signs of cardiotoxicity were observed in any of the patients at any of the doses. The patient that reached 1700 mg equivalent/m^2 died of tumoral progression and at necropsy no histological signs of cardiomiopathy were observed in the heart.

The signs of toxicity were always reversible and no case of death due to the medication was encountered. Although the primary purpose of the study was to study the toxicity, antitumoral objective responses (Table 2) were observed in 4 cases. The antitumoral action of quelamycin was evident from the very first dose of 75 mg equivalent/m^2 and did not apparently increase with the augmentation of the dose. The longest period of treatment reached was 7 months in an epidermoid lung carcinoma that maintained a subjective response all throughout.

DISCUSSION

It is evident that quelamycin can be administered as a single dose every three weeks at doses of 150 mg/m^2 without causing severe bone marrow suppression. However, there is a factor of variable individual tolerance to the drug and there were cases in which doses of 75 mg/m^2 caused bone marrow suppression and there was a case in which, with doses of 225 mg/m^2, the bone marrow effect was moderate. In spite of the very advanced state of all neoplastic

Table 1. *Hematological toxicity*

			Nadir of neutrofiles		
Dose	No. cycles	No. patients	Superior value	Inferior value	Mean ± S.D.
75 mg/m^2	24	20	7330	582	3029 ± 1646
125 mg/m^2	5	3	2890	1200	1798 ± 699
150 mg/m^2	9	9	2021	528	1335 ± 528
225 mg/m^2	5	2	1985	50	982 ± 409

Table 2. Tumoral responses

Diagnosis		Number of cases	Objective response	Subjective response	Stable disease	Progressive disease

Maxilar epidermoid carcinoma		1				1
Resistant breast cancer		1			1	
		16	4	2	1	9

patients subjected to treatment, a good general tolerance to quelamycin was evident either immediately or delayed.

Quelamycin showed tumoral response in 4 cases. These effects are an indication that quelamycin has antitumoral action, but we can not conclude from our limited data whether its antitumor effect is equal or superior to the antitumor effect of adriamycin. Similarly, there is not yet sufficient data to ascertain a lower cardiotoxicity with quelamycin. However, if the relation of antitumor potency of quelamycin with adriamycin were equivalent mg–equivalent to mg, quelamycin could represent an advantage because it is three times less acute dose limited than adriamycin. It is, on the other hand, noteworthy that, among the responses, there was a colon carcinoma and an anaplastic lung carcinoma (large cells), two kinds of tumors that, in our hands, are resistant to adriamycin.

In Vitro Effects of Methotrexate, 5-Fluorouracil, Cyclophosphamide and Vincristine Sulphate on the Metabolism of Induced Mammary Cancers in Rats*

W. de LOECKER† and G. van der SCHUEREN‡

†*Afdeling Biochemie, Department Humane Biologie and*
‡*Centrum voor Gezwelziekten, Fakulteit Geneeskunde, Katholieke Universiteit te Leuven, B-3000 Louvain, Belgium*

Abstract—*In function of concentrations* 0.001–100.0 μg *methotrexate added to the incubation medium, the* [2-^{14}C]*glycine incorporation into the proteins of experimental mammary cancer tissue of rats became progressively reduced. Only the highest concentrations of methotrexate reduced the* [1-^{14}C]α*-aminoisobutyric acid uptake by the cells.*

In the present in vitro *system, 5-fluorouracil only inhibited the* [6-^{3}H]*thymidine incorporation into DNA without affecting either glycine incorporation or the* α*-aminoisobutyric acid uptake. Cyclophosphamide impaired the glycine incorporation into the proteins as well as the thymidine incorporation into DNA in function of increasing amounts added, while the highest concentrations applied resulted in an increased* α*-aminoisobutyric acid uptake by the cells.*

With vincristine sulphate addition to the incubating tumour-slices, glycine incorporation and α*-aminosoisobutyric acid uptake were reduced which was particularly noticeable at the highest dose levels.*

INTRODUCTION

HORMONAL treatment and chemotherapy of advanced and metastatic breast cancer by a combination of different antineoplastic agents resulted in important tumour regression [1–3]. In the mean time considerable progress has been made in the understanding of the mechanism of action by which the different agents affect the normal and the tumour cells [4, 5].

Apart from the established knowledge of methotrexate and 5-fluorouracil effects on thymidylate synthetase and of vincristine and vinblastine sulphate on the depolymerisation of spindle microtubules, the alkylating action of cyclophosphamide and the generally accompanying cytotoxic effects of most of these compounds are still not sufficiently understood.

In an attempt to approach some of the problems concerning the mechanism of action, the *in vitro* effects of methotrexate, 5-fluorouracil, cyclophosphamide, and vincristine sulphate, on the metabolism of experimental mammary carcinoma of rats, have been examined.

MATERIALS AND METHODS

Adult female locally inbred Sprague–Dawley rats, weighing 180–200 g were fed on an *ad libitum* Purina Chow diet and having free access to pure drinking water were each treated over a period of 5 weeks with a weekly stomach intubation of 0.5 ml solution of 7.12-dimethylbenz(a)anthracene (DMBA) (Fluka) 1% in olive oil [6].

Tumours appeared along the mammary lines from the sixth week after the treatment was completed. Mammary tumours measuring at least 1 cm and up to 3 cm in diameter were excised, freed from connective tissue and fat and cut in slices with a Stadie–Riggs microtome. Samples of 200 mg wet weight were placed in Erlenmeyer flasks and

incubated in 5 ml Krebs–Ringer bicarbonate buffer, pH 7.2, previously gassed with 95% O_2–5% CO_2, for 1 hr in a shaking waterbath at 37°C. The incubation medium contained radioactive labelled precursors as well as progressively increasing doses of various anti-neoplastic agents. The addition of 1 μCi [2-^{14}C]glycine (sp. act. 10 mCi/mmole) to the medium allowed to follow the incorporation into the proteins. The effects on DNA synthesis were evaluated by the addition of 10 μCi [6-^{3}H]thymidine (sp. act. 10 Ci/mmole) to the medium.

By the incubation with 2 μCi [1-^{14}C] α-aminoisobutyric acid (AIB) (sp. act. 58 mCi/mmole) (Radiochemical Centre, Amersham, England) some aspects of transport mechanism and cell membrane integrity were examined [7].

Methotrexate (Lederle), 5-fluorouracil (Roche Products), cyclophosphamide (Mead Johnson Co.), and vincristine sulphate (Eli Lilly & Co.), were applied in concentrations of 0.001, 0.01, 0.1, 1.0, 10.0 and 100.0 μg in 5 ml buffer.

After the incubation with [2-^{14}C]glycine and [6-^{3}H]thymidine, 10 ml ice-cold 20% trichloroacetic acid (TCA-British Drug Houses. AR grade) were added to the Erlenmeyer flasks to precipitate the proteins. The denatured proteins were twice washed with 5 ml TCA 5% and subsequently twice heated for 15 min in 5 ml TCA 5% at 90°C to extract the nucleic acids. After incubation with [1-^{14}C] α-aminoisobutyric acid, the reaction was interrupted by the addition of 20 ml ice-cold physiological saline solution to the medium, followed by two more washes of 10 ml saline, to remove extracellular labelling. The protein precipitates after incubation with [2-^{14}C] glycine and the dried down hot TCA extracts after [6-^{3}H] thymidine incubation as well as the tumour tissue after [1-^{14}C] α-aminoisobutyric acid incubation, were dissolved in 3 ml of hydroxyde of hyamine-10-X (Packard Instrument Co.) by heating overnight in a waterbath at 60°C.

After the addition of 15 ml scintillator liquid to the hyamine solutions, the radioactivity was counted in a Liquid Scintillation Spectrometer (720 series—Nuclear Chicago) [7]. The incorporated radioactivity was expressed as DPM per 100 mg protein.

Standard errors of the mean and Student's *t*-test were calculated. The protein contents of the different tumours were determined colorimetrically [8]. The tumours used were histologically analysed.

RESULTS

Histological analysis of the different mammary tumours used revealed a complex adenocarcinoma type structure with some secretory characteristics.

The protein content of these cancers varied

between 85 and 110 mg/g of wet weight.

Methotrexate treatment inhibited the [2-^{14}C] glycine incorporation into the proteins in function of the dose level applied. The smallest methotrexate dose used 0.001 μg reduced the incorporation by 28.0% ($P<0.01$) while 100 μg methotrexate resulted in a glycine incorporation of only 35.0% ($P<0.001$) of the non-treated control samples (Fig. 1a). The [6-^{3}H] thymidine incorporation into DNA amounting to 25,800±749 dpm/100 mg protein for the control samples was not affected by methotrexate treatment. Only the highest concentrations of 10.0 μg and 100.0 μg methotrexate reduced the [1-^{14}C] α-aminoisobutyric acid uptake by the cells respectively by 29.0% ($P<0.01$) and by 48.6% ($P<0.001$) (Fig. 1b).

With 5-fluorouracil treatment only the [6-^{3}H] thymidine incorporation into DNA became depressed, reaching 80.8% ($P<0.01$) of the control values with 0.01 μg and 70.1% ($P<0.001$) with 100.0 μg while the [2-^{14}C] glycine incorporation and the [1-^{14}C] α-aminoisobutyric acid uptake were not significantly affected (Fig. 2). Cyclophosphamide, 0.01 μg decreased the [2-^{14}C] glycine incorporation into the proteins by 28.2% ($P<0.01$) reaching a maximal inhibition with 10.0 and 100.0 μg when only 59.4% ($P<0.001$) of the control values were incorporated (Fig. 3a). Even with a low dose of 0.001 μg, a significant 15.7% ($P<0.01$) inhibition of the [6-^{3}H] thymidine incorporation into DNA was observed, reaching 22.9% ($P<0.001$) with the highest dose levels (Fig. 3b). A dose level of 10.0 μg cyclophosphamide increased the [1-^{14}C] α-aminoisobutyric acid uptake into the cells by 53.5%($P<0.01$) while with 100.0 μg the uptake was even more than doubled to 211.0% ($P<0.001$) of the controls (Fig. 3c). Vincristine sulphate treatment affected

the [2-^{14}C] glycine incorporation with 0.1; 1.0; 10.0 and 100.0 μg by a reduction of 21.7% ($P<0.001$), 40.0% ($P<0.001$), 45.7% ($P<0.001$) and 48.2% ($P<0.001$) without effect on the [6-^{3}H] thymidine incorporation into DNA (Fig. 4a). The [1-^{14}C] α-aminoisobutyric acid uptake was inhibited with 1.0 μg by 33.7% ($P<0.01$) with 10.0 μg by 53.0% ($P<0.001$) and with 100.0 μg by 79.8% ($P<0.001$) (Fig. 4b).

DISCUSSION

The absolute values of precursor incorporation sometimes differ considerably from one batch of tumour tissue to another which depends on the structure and the differentiation of the tissue leading to varying amounts of protein content. As the effects on incorporation increase almost linearly for up to 6 hr in function of incubation time, it is assumed that drug as well as radioactive precursors penetrate the tumour cells homogeneously.

Methotrexate inhibits thymidylate synthetase probably by interfering with the enzyme stabilisation as well as dihydrofolate reductase. As tetrahydrofolate becomes depleted a reduction of folate dependent purine and protein synthesis occurs [9–11]. Thymidine and deoxyadenosine are known to reverse the toxicity of methotrexate which does not affect the *in vitro* incorporation of [6-^{3}H] thymidine into the DNA chain [12]. The [1-^{14}C] α-aminoisobutyric acid uptake by the cells being reduced by the highest methotrexate levels used seems due to a toxic effect on membrane transport mechanism, which accentuates the inhibition of [2-^{14}C] glycine incorporation into the proteins already affected by the tetrahydrofolate depletion which interferes with glycine metabolism [13–15].

The inhibitory effect of 5-fluorouracil on thymidylate synthetase should be reduced or even neutralized by the addition of thymidine to the incubation medium [12, 16]. However the *in vitro* [6-^{3}H] thymidine incorporation into DNA becomes progressively reduced in function of the added 5-fluorouracil dose which may be explained by a competitive incorporation of this base analogue into DNA eventually through mutagenesis leading to pathological gene transcription. This effect confirmed by the incubation of the tissue with 5-fluoro [6-^{3}H] uracil, is also occurring in RNA where it is only considered to be of secondary importance [17].

The glycine incorporation into the proteins continues unchanged in spite of increased 5-fluorouracil treatment which implies the pre-existing messenger RNA to be responsible for the immediate protein synthesis in the presence of an intact membrane system. The alkylating cyclophosphamide is now considered to be converted in the liver by a microsomal oxydase system to 4-hydroxycyclophosphamide and its tautomeric aldophosphamide which through further still uncertain transformations may lead to several not yet recognised active forms [18, 19]. The cytotoxic effect of cyclophosphamide however may be produced by conversions in the tum-

ourcell itself[5]. This cytotoxic activity, although unexplained and not further explored in this study, seems responsible for the inhibition on the thymidine incorporation into DNA and on glycine incorporation into the proteins, while the increased α-aminoisobutyric acid content in the cells is most probably due to a destructive effect on the membrane structure leading to an easier passage of amino acids into the cells [20]. The metaphase arresting compounds, vincristine sulphate and vinblastine sulphate are rapidly taken up by the cells where they attach to the microtubule proteins leading to destruction of the mitotic s spindle [21–24]. In the cell they produce cytoplasmic vesicles which line up along the membranes [25]. In these short term *in vitro* experiments the observed effects of vincristine sulphate cannot be explained by the inhibitory activity on mitosis. Thymidine incorporation into DNA is not even affected. The incorporation of glycine into proteins seems related to the precipitation of certain cellular proteins as well as to an inhibition of the cellular membrane transport system which results in a decreased amino acid uptake into the cells [26].

Apart from the expected effects of the examined antineoplastic agents on protein and DNA synthesis, an important effect on the membrane integrity and transport function becomes apparent when mammary cancer cells are incubated with the highest dose levels of methotrexate, cyclophosphamide and vincristine sulphate. This membrane effect greatly contributes to the inhibition of protein synthesizing activity observed in these *in vitro* systems.

Abstract—*Increased risk of breast cancer in pre-menopausal women correlates with sub-normal plasma progesterone values in the luteal phase of the menstrual cycle and a sub-normal excretion of urinary androgen metabolites. Plasma oestradiol values do not vary with risk. In post-menopausal women, plasma oestradiol and progesterone levels are not related to risk.*

INTRODUCTION

THERE are a number of well-known factors related to risk of breast cancer, such as age at menarche, age at first child, family history and previous breast disease. A sub-normal excretion of urinary androgen metabolites has also been found to be correlated with an increased risk of the disease [1, 2].

The relation of each of the factors to the subsequent development of breast cancer has been examined in a prospective study carried out in Guernsey over the last 16 yr. Each factor, taken singly, was significantly correlated with risk [3]. Recently, a mathematical model has been constructed in which a logistic model for the probability of developing breast cancer has been combined with a Wiebull distribution for the time of diagnosis, so that the joint influence of all the above variables on subsequent risk could be estimated [4]. Five risk groups were delineated; the lowest estimated probability of developing breast cancer was 0.010: the highest was 0.224. These estimates were calculated for women in Guernsey for whom a determination of the amount of urinary aetiocholanolone was available (1498 of the 5000 women who took part in the prospective trial). It so happened that 765 of the 1498 women had provided a specimen of blood in a second prospective trial and it was possible, therefore, to assign a risk category to each of these blood donors. A variety of hormone assays were then carried out on the plasma samples to see whether endocrine function was related to the various degrees of risk. This paper deals with plasma oestradiol and progesterone in pre- and post-menopausal women.

Accepted 26 May 1978.

MATERIALS AND METHODS

1. *Subjects*

Urine specimens were obtained from 5000 normal women in Guernsey between 1961 and 1965. Between 1966 and 1976, a further 5000 volunteers gave a 50 ml sample of blood between 13.00 and 22.00 hr. This was taken into a heparinized vacutainer: the plasma was separated by centrifugation and stored at −20°C until required for analysis. All volunteers filled in a detailed questionnaire concerning reproductive history, previous and current diseases and drug history.

The five risk categories for the 1485 women in the 1961–1965 Guernsey study are shown in Table 1, with the estimated probabilities of developing breast cancer. The number of women in each class from whom blood was obtained is also given.

Pre-menopausal women were considered to be in the luteal phase of their menstrual cycle if their blood samples were obtained after at least six-tenths (rounded up to

the nearest whole number) of their cycle had elapsed. In the case of a woman with a 28 day cycle, this would mean a blood collection on or after the 17th day: in a woman with a 24 day cycle, a blood sample on day 15 was accepted. Only women who stated that they had regular cycles were accepted and only cycles between 24–36 days in length were taken.

Approximately 80% of the subjects had cycles in the range of 28 days ± 2 days. As a second check that no bias had been introduced by the above definition of the luteal phase, the mean time between obtaining the blood and the date of the subsequent cycle was calculated. These means were 4.4, 6.0, 6.7 and 6.8 days for risk groups 0–3 respectively.

Women were defined as being in the follicular phase of their cycle if the blood was obtained between days 1 and 14. However, in 14 of these women, values of plasma progesterone in excess of 3 ng/ml were found between days 9 and 14. These women were re-classified as being in the luteal phase of their cycles, on the assumption that they had had a short follicular phase. The age and menstrual cycle characteristics of the women studied are shown in Table 2.

Post-menopausal women were defined as those who had not menstruated for at least 6 months and aged over 50 yr. Menopausal women were not included. Blood samples were not analysed if any of the volunteers were on drugs known to affect endocrine function, (e.g. contraceptive steroids, hormone replacement therapy, thyroid hormones), if menstrual cycles fell outside the limits already defined, or if information on cycles or menopause was missing. Such bloods numbered 379 of the 765 samples available.

Table 1. Risk characteristics

Risk group	Family history	Log aetio	Age menarche	Age 1st birth	Estimated probability	No. of blood samples available: Age 30–49	No. of blood samples available: Age ≧50
0	0	0	0	0	0.010	24	7
	0	0	1	0	0.019		
	0	1	0	0	0.022	85	43
1	1	0	0	0	0.021		
	0	0	0	1	0.028		
	0	1	1	0	0.043		
	1	0	1	0	0.042		
	1	1	0	0	0.047	93	53
2	0	0	1	1	0.054		
	0	1	0	1	0.060		
	1	0	0	1	0.059		
	1	1	1	0	0.090		
	0	1	1	1	0.116	35	44
3	1	0	1	1	0.113		
	1	1	0	1	0.125		
4	1	1	1	1	0.224	1	1

Risk groups 0–4 are women with 0–4 risk factors positive. A zero denotes a favorable state: 1 denotes a positive risk factor. The two women in risk group 4 have been included in risk group 3 in all subsequent tables. Log aetio refers to the lorarithms of the amount of aetiocholanolone excreted, expressed in μg/24 hr.

Table 2. Age and menstrual cycle characteristics of women in the four risk groups

Risk group	N	Mean age	Mean cycle length	Mean day follicular phase	Mean day luteal phase
0	24	39.8 ± 4.6	27.1 ± 3.0	8.6 ± 4.2	21.9 ± 4.5
1	85	39.2 ± 3.7	27.0 ± 2.0	6.8 ± 3.5	19.6 ± 4.4
2	93	40.1 ± 4.5	27.2 ± 1.9	7.7 ± 4.0	18.8 ± 4.0
3	36	41.8 ± 5.0	27.7 ± 2.3	6.9 ± 4.3	19.0 ± 4.3

The means are shown with standard deviations.

Since differential rejection of blood specimens in particular groups could lead to bias, the percentage of rejected specimens in each risk group was calculated for pre-menopausal women. For groups 0–3, the percentages were 30, 31, 27 and 31. In groups 0, 1 and 2 the reasons for rejection were similar but in the highest risk group significantly more blood samples were rejected because of irregular menstrual cycles or previous hysterectomies.

2. *Analytical methods*

Plasma oestradiol-17β was measured by radioimmunoassay using antisera to oestradiol conjugated through the 6 position to B.S.A. and used at a final dilution of 1:50,000. The basic assay technique was that described by Korenman *et al.* [5]. The coefficients of variation ranged from 16% at 10–50 pg/ml to 13% at 101–450 pg/ml. Recoveries averaged 78%. The sensitivity of the method was 6 pg/ml. Plasma progesterone was measured by the method of Swain [6].

RESULTS

1. *Plasma progesterone in pre-menopausal women*

The means of the logarithms of the plasma progesterone values are shown in Table 3. There are no apparent differences between the plasma concentrations in the two age groups 30–39 and 40–49. All statistical comparisons have therefore been carried out on the total groups.

There is a diminution in both the mean follicular phase and luteal phase progesterone levels with increasing risk. This is not significant in the follicular phase but in the luteal phase, the mean progesterone level is significantly lower in risk group 3 compared to that in risk group 0 ($t=2.18$: $P<0.05$).

The relation between declining progesterone levels and increasing risk of breast cancer is shown in Fig. 1. Levels of progesterone of less than 3 ng/ml in the luteal phase of the cycle have been taken to indicate anovulatory cycles. It can be seen that the proportion of such cycles in relation to ovulatory cycles increases as risk increases, and it is this that accounts for the difference between the mean levels. If only ovulatory cycles are considered, then there are no

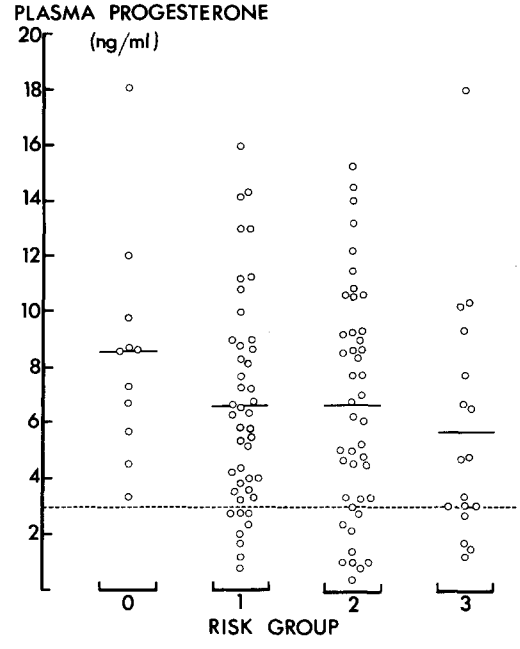

Fig. 1. Plasma progesterone values for women in the luteal phase, in risk groups 0–3. Points above the horizontal dashed line indicate presumed ovulatory cycles (more than 3 ng/ml). The solid horizontal bars show the arithmetic means.

The results are expressed as the means of the logarithms of the plasma oestradiol values (pg/ml plasma × 10) ± standard deviation.

Table 5. Mean of logarithms of plasma progesterone and oestradiol levels in post-menopausal risk groups

	Risk group 0	1	2	3
Progesterone	1.075±0.324 (7)	1.182±0.333 (26)	1.170±0.422 (41)	1.136±0.402 (30)
Oestradiol	1.449±0.138 (7)	1.522±0.201 (42)	1.467±0.228 (43)	1.453±0.215 (33)

The units are as in Tables 4 and 5.

differences in progesterone levels in the four risk groups. The proportion of anovulatory cycles is 0, 18, 20 and 24% for risk groups 0–3 respectively. Since it is possible to ascribe an individual risk level to each woman (see Table 1), a regression of the logarithms of the progesterone concentration on risk level was calculated and found to be significant in the luteal phase ($r = -0.211$, $P < 0.05$, $n = 117$).

There is no significant association between risk and levels of progesterone in the follicular phase although the trend is in the same direction as in the luteal phase.

2. *Plasma oestradiol in pre-menopausal women*

When age groups 30–39 and 40–49 yr are taken together there are no significant differences between the means in the four risk groups in either the follicular or luteal phase of the menstrual cycle. In the age group 30–39 yr, however, the mean plasma oestradiol level is significantly greater in risk group 1 than in group 0 ($t = 2.686$, $P < 0.02$), but this effect is not duplicated in the 40–49 group.

There is no significant relationship between individual risk levels and plasma oestradiol levels. This result is unaltered if the data are re-analysed after removal of all anovulatory cases. The results are summarized in Table 4.

3. *Plasma progesterone and oestradiol in post-menopausal women*

The means of the logarithms of the progesterone and oestradiol values in post-menopausal women in the four risk groups are given in Table 5. There are no significant differences between the mean levels of these plasma steroids in the four groups. There is no significant correlation between individual risk levels, plasma progesterone or plasma oestradiol values.

4. *Relation of corpus luteal deficiency to single risk variables*

The design of this study was not appropriate for determining whether a single risk factor correlated with a particular endocrine abnormality. Nevertheless, an approximation may be obtained by calculat-

Table 6. Number of women with ovulatory or anovulatory cycles in association with given risk factors

Risk factor	Ovulatory	Anovulatory	(%)
Menarche before 14th birthday	54	21	(28)
Menarche, other	38	4	(10)
1st baby after 24th birthday	63	16	(20)
1st baby, other	29	9	(24)
Family history, positive	12	7	(37)
Family history, negative	80	18	(18)
Aetiocholanolone, less than 1 mg/24 hr	6	6	(50)
Aetiocholanolone, other	86	19	(18)

ing the number of anovulatory cycles which are associated with a given favourable or unfavourable factor, ignoring other factors that may be present. The results are shown in Table 6.

Anovulatory cycles are found more commonly in women with an early menarche, a family history of breast cancer, or a sub-normal excretion of aetiocholanolone, than in women with none of these factors, but only in the last instance is the distribution significantly abnormal ($X=6.5$, $P<0.02$).

The reality of the association between a sub-normal excretion of aetiocholanolone and anovulatory cycles is supported by the finding that in the entire population of pre-menopausal women (i.e. ignoring risk levels) there is a significant association between plasma progesterone levels in the luteal phase of the cycle and the excretion of aetiocholanolone in the urine ($r=0.231$, $P<0.02$, $n=117$).

This relationship is carried largely by risk groups 2 and 3 (which are characterized by a substantial proportion of women having a sub-normal excretion of aetiocholanolone). In risk group 2 the data are: $r=0.339$, $P<0.05$, $n=44$; and in risk group 3: $r=0.613$, $P<0.01$, $n=17$.

The relationship is not found in the follicular phase of the cycle or in post-menopausal women.

DISCUSSION

Sherman and Korenman [7] have made a persuasive case that inadequate corpus luteal function may provide an endocrine setting favourable for the development of mammary carcinoma. Our results support this view and indicate that increasing risk of breast cancer in pre-menopausal women is correlated with a diminished production of progesterone in the luteal phase of the menstrual cycle in the face of normal levels of oestradiol.

As far as other studies on high-risk groups are concerned, Sitruk-Ware *et al.* [8] have shown that women with benign breast disease have a significantly lower level of plasma progesterone in the luteal phase of the cycle compared with controls. Conversely, a prospective study carried out by the Royal College of General Practitioners shows that the incidence of benign breast disease diminishes as the content of progestagen in steroid contraceptives increases [9].

Once breast cancer is diagnosed, there is evidence that the same pattern of luteal insufficiency can be found. Grattarola [10] showed that only 17% of his patients with breast cancer had a secretory endometrial pattern indicative of ovulation, compared with 68% in normal women. Kodama *et al.* [11] have recently reported that Japanese patients with breast cancer have a sub-normal excretion of four steroids which vary with the phase of the menstrual cycle (one of which was pregnanediol). Swain and her colleagues found an increased incidence of luteal insufficiency in patients with advanced breast cancer but did not find this in patients with the early disease [12]. These results are not in agreement with those of the Manchester group [13, 14] who found raised levels of plasma oestradiol and progesterone in patients with benign and malignant breast disease. Their series did not apparently contain any women with anovulatory cycles, which is unexpected since these are common even in the normal population [15].

Anovulatory cycles or luteal insufficiency may not be the only critical factors associated with risk. There is at least an indication that early menarche is associated with luteal dysfunction (Table 6). A relationship between age at menarche and subsequent ovarian

function is implied by reports that women with a late menarche have a disproportionate incidence of amenorrhoea after using steroidal contraceptives [16].

Also, while a sub-normal excretion of androgen metabolites is a feature of the luteal abnormality in the high risk group, the androgen abnormality may not be a feature of anovulatory cycles in low risk groups. It may be that both factors contribute to high risk.

In the post-menopausal women in the Guernsey study, nothing remarkable was found. There may be a heavy bias in this group since the risk levels were calculated by Farewell [4] using data obtained from 48 women who subsequently developed breast cancer and these were predominantly pre-menopausal. It is not at all clear whether the risk factors used in the Farewell model would be useful in women well past the menopause.

The Guernsey prospective studies were originally designed to investigate the possible relationships between urinary and plasma hormones and the aetiology of breast cancer, but in the last few years the emphasis has shifted towards the identification of high-risk groups for periodic breast screening. The question therefore arises whether corpus luteal insufficiency would be a "useful" risk factor. One quite striking finding is that the women with a sub-normal excretion of urinary aetiocholanolone are predominantly those who, five years later, were shown to have a luteal deficiency. This implies that the abnormality is not sporadic but may occur in the majority of menstrual cycles in women at high risk. It also indicates that measurement of plasma progesterone and of urinary aetiocholanolone may give the same prognostic information but it may be possible to check this point when a sufficient number of the 5000 volunteers who gave a blood sample in 1965–1976 eventually develop breast cancer.

If a deficiency in the luteal phase secretion of progesterone does turn out to be an important determinant of risk, the correlation of such an abnormality might be possible.

The Interaction of Hydrocortisone, Interferon and the Epstein–Barr Virus in Lymphoid Cells*

MICHÈLE LEYRITZ† and JEAN H. JONCAS†‡

†*Department of Microbiology and Immunology, University of Montreal and* ‡*Pediatric Research Center, Ste-Justine Hospital, Montreal, Quebec, Canada H3T 1C5*

Abstract—*Thirty-two human lymphoid cell lines of various origins were treated with hydrocortisone (HC) 20 μg/ml for* 3 days *and examined for cell viability, increase in the percentage of EBV antigen-positive cells, and interferon synthesis. Burkitt's lymphoma (BL) cell lines* (6/9) *under the effect of HC were characterized by a decrease in cell viability, increase in the percentage of EA antigen-positive cells, and poor interferon response in contrast to lymphoblastoid cell lines derived from the peripheral blood of normal individuals* (0/14) *or patients with infectious mononucleosis* (0/4). *The enhancement in the expression of EBV–EA as shown by the increase in the percentage of EA antigen-positive cells following HC was exclusively seen in BL cell lines* (6/9). *This effect could be blocked by phosphonoacetic acid (PAA). In contrast the effect on cell viability could not be inhibited by PAA but was abolished by pretreatment of the cells with interferon.*

INTRODUCTION

HYDROCORTISONE (HC) is used by clinicians for a variety of purposes. Its mechanism of action is complex and is still incompletely understood [1]. Hydrocortisone, like other steroid hormones, appears to control gene expression and protein synthesis following its binding to specific cytoplasmic receptors [2]. It can also affect lymphoid cell viability.

Human lymphoid cells are more corticosteroid-resistant than mouse lymphoid cells [3]. Differentiated cells are usually more resistant to corticosteroids than undifferentiated or blast cells [3]. Even though RNA and DNA synthesis have recently been shown to be inhibited by corticosteroids *in vitro* in both normal peripheral B and T human lymphocytes [4], mature lymphoid cells from the peripheral blood of normal individuals are generally corticosteroid-resistant, whereas leukemic lymphoblasts are more corticosteroid-sensitive [5]. Although the presence and relative number of receptors are not the only factors responsible for sensitivity to glucocorticoids [6, 7], it has been noted that there is a greater number of glucocorticoid receptors on human lymphoblasts, particularly null lymphoblasts, from lymphoblastic leukemia than on normal peripheral lymphocytes [8].

The Epstein–Barr virus is a Herpes virus with a very narrow host range. The human B lymphocyte is virtually the only cell known to support the *in vitro* replication of this virus. Its replication, even in the B lymphocyte, is usually restricted to the expression of an early nuclear antigen, EBNA. Occasionally, the expression of the virus genome can go on to the synthesis of another antigen, the early cytoplasmic antigen, EA, either spontaneously or following induction with IUdR or BUdR. Rarely does replication go on to the synthesis of the viral capsid antigen, or to the production of complete virus particles [9].

Like other Herpes viruses, the Epstein–Barr virus seems to persist in a latent state in the host following infection [10]. Under appropriate conditions, the culture of *peripheral blood lymphocytes* from a large percentage of EBV antibody positive individuals, will result in the establishment of permanent lymphoid cell lines containing the EB virus genome and expressing EBNA. The culture of the *Burkitt's lymphoma* cells will also yield permanent lymphoid cell lines positive for the EB virus genome and expressing EBNA. A few exceptional lymphoid cell lines either T or

B will be free of EBV and EBNA negative [11, 12]. Reactivation of EBV as a result of immunosuppressive measures, or following administration of HC, might therefore occur and possibly lead to clinically apparent or significant disease. Strauch *et al.* [13] have reported the presence of EBV in the throat washings of approximately 50% of renal transplant patients under immunosuppression, suggesting reactivation of EBV since the prevalence of oral excretion in normal individuals is only approximately 10–20%. In a similar study we found a prevalence of 40% for EBV excretion in throat washings of renal transplant patients [14].

We have also reported that, *in vitro*, HC could adversely affect cell viability, with an enhancement of the expression of the EBV–EA and VCA antigens, and a delayed interferon response in 2 out of 6 lymphoblastoid cell lines containing the EBV genome [15]. These two cell lines were derived from BL cells. The four unresponsive cell lines were characterized by no altered cell viability, no enhancement of the expression of the EBV antigens, and a brisk interferon response. The purpose of the present paper is to summarize the results of studies done on 32 lymphoid cell lines of various origins showing different response patterns to HC according to the origin of the cell line tested.

MATERIALS AND METHODS

Leukocyte culture

Heparinized whole blood was separated on Ficoll–Hypaque (density 1.078) by centrifugation at 370 ***g*** for 20 min. The layer of lymphocytes thus obtained was resuspended in RPMI 1640 medium and washed by centrifuging the suspension at 370 ***g*** for 10 min. The suspension was washed twice and resuspended in RPMI 1640 medium containing 20% fetal calf serum. The concentration of cells per ml was adjusted to 10^6. One sample was then used for the HC test (test on fresh lymphocytes and another sample used to establish a lymphoblastoid cell line (spontaneous establishment). Cord blood cell lines were obtained from José Menezes. Establishment of these cell lines was obtained as described [11]. Lymphoma cell lines were obtained from various workers. All the cell lines were maintained in Falcon plastic bottles in suspension cultures with RPMI 1640 medium supplemented with 10–20% fetal calf serum and antibiotics readjusting the cell concentration to $2–3 \times 10^5$ with fresh medium twice a week.

The HC test

The fresh cells or the cell lines to be tested were divided into two aliquots before each experiment, one serving as control, the other being put in contact with 20 μg (4×01^{-5}M) of HC/ml (Solu cortef) for 3 days.

A dose–response curve had been done in our previous study [15]. This amount of HC produced a near maximal response for two of the parameters studied and a maximal response for the third, cell viability. It is approximately 100 times the physiologic concentration. Each experiment was done in triplicate.

The cell concentration used in all experiments was 10^6 cells/ml. The cells were incubated at 37°C and samples were taken at 1, 2 and 3 days after the addition of HC to do viable cell counts by the trypan blue dye exclusion method and to stain the cells for the EBV antigens by indirect immunofluorescence (IF) using an EA + VCA + serum, an EA − VCA + serum, and an EA − VCA − serum as control [16]. The titer of infectious virus in the supernatant of cultures with and without pretreatment of the cells with HC, was measured by the inhibition of Raji cell colony formation by EBV described by Rocchi *et al.* [17], as modified by Menezes *et al.* [11]. The supernatant of samples of 10^6 cells with and without HC was also examined by electron microscopy (EM). It was centrifuged at low speed to remove cell debris. The supernatant thus obtained was centrifuged at 80,000 ***g*** for 1 hr. The pellet was resuspended in acetate buffer and examined by EM after negative staining as described elsewhere [15]. Finally, the interferon titer in the whole culture after a 3-day incubation was measured by a micromethod previously reported [18], using Sindbis virus and human embryo fibroblasts. Control and test cultures were done in triplicate and each experiment was repeated twice.

Viral inhibitors

Phosphonoacetic acid (PAA), an inhibitor of Herpes virus DNA polymerase, was kindly supplied by Abbott Laboratories and it was used at the concentration of 50 μg/ml of RPMI 1640 culture medium. This concentration of PAA was shown in previous studies [19], to block EBV–DNA replication without being toxic to the cells. Exogenous interferon (10^6 units/ml) was a gift of Hans Strander and Kari Cantell. It was used, as in our previous studies [15], in amounts of 10^1–10^3 units/ml of RPMI 1640 culture medium. Cells were incubated with interferon for a period of 24 hr before the HC test was performed.

Table 1. *The effect of hydrocortisone* (20 μg/ml) *on lymphoblastoid cell lines after an incubation period of three days*

Group	Response pattern	Cell lines obtained from (N–PB), (CB), (BL–T)	Number of cell lines with Decrease in viability*	Increase in EA/VCA Ag's*	Detectable interferon titer* (units/0.1 ml)

RESULTS AND DISCUSSION

The overall results show that decrease in cell viability, enhanced expression of the viral genome, and interferon production can occur independently, following the addition of HC (Table 1 and Fig. 1).

Cell viability

Cell viability of EBV genome negative lines (BJA-B, a BL derived B lymphoid cell line, and MOLT 4, a leukemia derived T cell line), and of fresh lymphocytes from certain individuals (3 out of 5), could be decreased when treated with HC, suggesting a direct cellular effect of HC. More specifically, the percentage of E rosette-forming cells dropped significantly following HC treatment of the fresh lymphocytes from 58 to 33% ±2%.

Interferon

Interferon also could be induced by HC in fresh lymphocytes from certain individuals (3 out of 5 cases), suggesting that HC could have a direct effect on interferon production. Titers were usually less than 50 units/0.1 ml as compared to more than 100 units/0.1 ml following Sendai virus, another interferon inducer.

In the cell lines (Table 1) there seems to be an inverse correlation between the decrease in cell viability and the interferon response. When there is an effect on cell viability there is no interferon response and vice versa. We have also confirmed our previous finding [15] that exogenous interferon will prevent the adverse effect of HC on cell viability in HR1K. Similarly, addition of interferon (100 and 1000 units/ml) to a suspension of fresh lymphocytes treated with HC also prevented the effect of the hormone on cell viability. These three observations are probably different aspects of the same phenomenon. The significance of these unexpected findings are presently under study.

EBV antigens

In HR1K, an EBV producer BL-derived cell line, it was found that the antigen induced by the addition of HC was the early antigen (EA) (Fig. 1). There was an apparent increase of 1 $\log_{10}$ in virus titer. The addition of phosphonoacetic acid for 10 days prevented the effect of the hormone, added on the 7th day, on the expression of EBV–EA, but not on cell viability, thereby further dissociating the effect

of HC on the expression of the viral genome from its cellular effect. The number of cells on day 10 in the control and in the PAA treated samples rose to 3.1×10^6 cells $\pm 1.2 \times 10^5$ cells whereas, in the HC and HC+PAA treated samples it rose only to 2×10^6 cells $\pm 1.5 \times 10^5$ cells. The percentage of EA positive cells in the HC+PAA treated sample (2%), did not differ from that found in the control PAA treated sample (2.6%) but was significantly higher ($P<0.05$) in the HC treated sample (13%) showing that PAA could prevent the increase in EA positive cells caused by HC. In contrast, as noted also in our previous study [15], exogenous interferon (100 and 1000 units/ml) could not prevent this increase in EA positive cells although, as mentioned before, it prevented the adverse effect on cell viability, again dissociating the effect of HC on cell viability from its effect on the viral genome.

Response patterns to HC

The Burkitt's tumor cell lines were characterized by an absent or delayed interferon response, a decrease in cell viability and an increase in the number of EA positive cells following HC *in vitro* (BL-T pattern). In contrast, EBV–EA or EA–VCA positive cell lines derived from the peripheral blood (PB) of 14 normal individuals (N–PB pattern), 4 patients with infectious mononucleosis, and the EBV-transformed *marmoset* lymphoblastoid cell line B95-8 (not shown), a well-known EBV-producer cell line, did not show this decrease in viability, or increase in the percentage of EA-positive cells. However, all these LCL showed a brisk interferon response, following HC, when interferon was not already present in the culture (Table 1). A few exceptions to the BL–T pattern (3/9) were noted among the group of BL cell lines. We are now investigating the possibility that these cell lines were derived from "normal" lymphoid cells within the tumor mass rather than from the tumor cells themselves by doing karyotype analysis and studies of other markers of lymphoma cell lines as done by Nilsson and Ponten [12] who differentiated "lymphoma" cell lines as monoclonal and heteroploid among other characteristics from "lymphoblastoid" cell lines which were polyclonal and diploid. Alternatively, the lack of effect on viability by HC in 3 of the 9 BL cell lines could be the result of spontaneous or acquired resistance to HC, a phenomenon occasionally observed [7].

The EBV-transformed cord blood (CB) cell lines responded to HC by a decrease in cell viability (3/5) but no increase in the number of EA-positive cells in contrast to the responder BL cell lines, again showing that the effect of HC on cell viability can be dissociated from its effect on EBV-EA. It is interesting to note that HC does not have an enhancing effect on EA in the B95-8 cell line, a well-known EBV transformed and EBV-producer cell line, similar to HR1K in many respects, but derived from the peripheral blood of a normal marmoset in contrast to HR1K which is a lymphoma cell line derived from a Burkitt's tumor. The increase in the percentage of EA positive cells in lymphoma cell lines following HC may suggest a different control of the expression of EBV–EA in lymphoma derived cells, and could explain the characteristic EA antibody response of Burkitt's tumor patients. It is of interest in this respect that patients with ataxia telangiectasia, who share with Burkitt's lymphoma patients an increased susceptibility to developing lymphoma and a chromosome 14 anomaly, also show a high prevalence of EBV–EA antibodies [20]. Cell lines from the peripheral blood of these patients are being obtained and will be studied for their response to HC.

Finally, the different response pattern of lymphoma cells to HC noted in our *in vitro* study, in contrast to that of presumably normal cells, is generally consistent with the observations made by the other workers [3, 5, 6] and with the observed sensitivity of most lymphoid tumor cells *in vivo* to the lethal effect of glucocorticoids.

Acknowledgements—The authors are grateful to Gilbert Lenoir, Guy De Thé and Werner Henle for providing some of the Burkitt lymphoma cell lines used.

Radiobiological Hypoxia of a Transplanted Rat Tumour and the Effect of Treatment with Cyclophosphamide*

BRYAN DIXON,† JAMES V. MOORE‡§ and HELEN SPEAKMAN‡

†*Radiobiology Department, Regional Radiotherapy Centre, and* ‡*Radiotherapy Department, University of Leeds, Leeds LS16 6QB, United Kingdom*

Abstract—*Isologous tumours, 8–10 mm in diameter, of the 37th–40th generation spontaneous adenocarcinoma LMC_1 have been grown subcutaneously in 150–200 g female Wistar rats and irradiated with ^{60}Co γ-rays before or 1, 4, 7 or 10 days after intraperitoneal injection of 150 mg/kg of cyclophosphamide (CP).*

Dose–response curves for delay in growth of the tumour given aerobic or hyperbaric (HBO) irradiation alone were biphasic and, above 15 Gy (AIR) and 20 Gy (HBO), their response was governed by a component of hypoxic cells. One day after CP the response of the tumour to aerobic irradiation was the same as when rendered hypoxic by clamping 15 min prior to treatment indicating that only hypoxic tumour cells survive in animals treated with drug. Three days later hypoxia is reduced by reoxygenation, but the hypoxic fraction is still significantly higher than before treatment with CP. Only by 7 and 10 days had the hypoxic fraction of clonogenic cells been reduced to a level characteristic of the untreated tumour.

Even though at 4 days after giving drug the hypoxic component of cells was significantly larger than normal for rats breathing air, no resistant component was found in the tumour response for HBO irradiation. This suggests that processes leading to the reoxygenation of a tumour after an initial treatment with drug may themselves permit an enhanced effect of subsequent HBO irradiation.

INTRODUCTION

THE USE of cytotoxic drugs as adjuvants to radiotherapy offers a potential therapeutic advantage in improved control of primary tumours. Thus doses of cytotoxic agents tolerated by the host may be used to kill a large proportion of cells in the tumour prior to irradiation [1, 2]. However, many such agents are less effective against non-proliferating than against cycling populations of cells [3]. Some at least of the non-proliferating cells in solid tumours may also be hypoxic [4], so that unless reoxygenation occurs in the conditions prevailing after drug treatment, subsequent irradiation will have a less than optimal effect. We have examined the response of an experimental tumour whilst subjected to elevated, normal or reduced conditions of oxygenation, to irradiation alone or after pre-treatment by the cycle-active alkylating agent cyclophosphamide (CP). This tumour contains a clonogenic cell population relatively resistant to the action of the drug [2] and has a hypoxic fraction, measured by cell assay *in vitro* of approximately 18% [5]. The present experiments employed the endpoint of delay in the macroscopic growth of the tumour [6].

MATERIALS AND METHODS

Tumours of the 37th–40th transplant generations of the rat adenocarcinoma LMC_1 [7] were implanted subcutaneously in the flank of female 150–200 g Wistar rats of John's strain, using the method of Thomlinson [8]. Animals were assigned randomly to treatment groups when their tumours first reached a mean diameter of 8–10 mm, as determined by ca-

liper measurements. After treatment they were caged in groups of 6, allowed food and water *ad libitum* and their tumours measured daily.

Cyclophosphamide ('Endoxana'; Ward Blenkinsop, Bracknell) was injected intraperitoneally at a standard dose of 150 mg/kg of body weight. This dose reduces the surviving fraction of clonogenic cells in the tumour to about 3% [2] and also results in a less than two-fold change in tumour volume over the first 10 days after treatment [5].

Rats were immobilised for irradiation by intraperitoneal injection of 65 mg/kg of sodium amylobarbitone ('Amytal'; Lilly, Basingstoke) and immediately after treatment were given 0.8 mg/kg of 'Megimide' (Nicholas, Slough) to facilitate recovery from the hypnotic. Tumours were irradiated locally with ^{60}Co γ-rays at a dose-rate of approximately 1.90 Gy/min, the rats lying within a pressure chamber [6]. When treated with the rats breathing hyperbaric oxygen (HBO, 4 At abs) or air, the tumour lay unsupported in the irradiation beam. Tumours were made artificially hypoxic by occluding the blood supply to the tumour with a 'U' shaped clamp applied 15 min prior to irradiation of rats breathing air. All irradiations were given as single doses. In rats treated first with CP, irradiation of the tumour in air or under hypoxia was carried out 1, 4, 7 or 10 days later. Irradiation in HBO was also used at 4 days after CP treatment.

After treatment the time taken for each 8–10 mm tumour to grow to an average diameter of 25 mm was measured. The difference in mean times taken by tumours in treated and untreated groups of rats constitutes the growth delay. The *rates* of regrowth of tumours treated by irradiation alone and those in rats given CP before irradiation has previously been shown to be the same [5].

RESULTS

After irradiation alone, the growth delay for tumours treated when clamped increased progressively with dose, while the growth delay data for tumours irradiated in rats breathing air or HBO were biphasic (Fig. 1). Data for doses up to and including 20 Gy (HBO) and 15 Gy (air) could be fitted by redrawing the dose response curve for irradiation under hypoxic conditions assuming oxygen enhancement ratios of 3.0 and 2.7 respectively (curves A and B, Fig. 1). With larger doses given in either condition, delay data were consistent with the response curve for hypoxic tumours

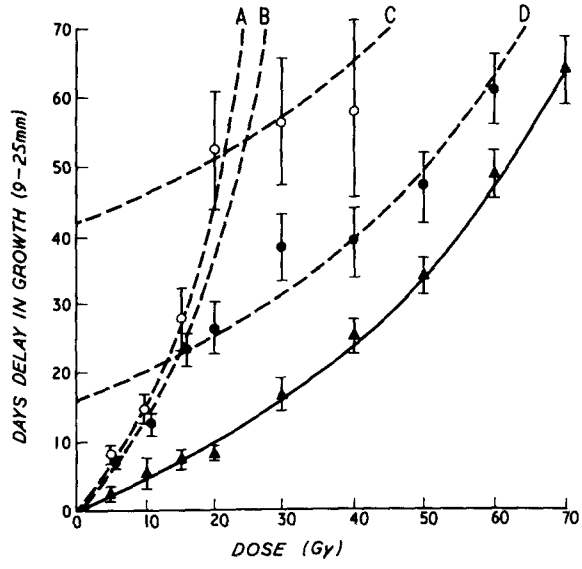

Fig. 1. Radiation dose–response for LMC$_I$ in rats before treatment with CP. ▲ hypoxic; ● aerobic; ○ HBO. Mean delays ±2 S.E., 4–6 rats per treatment group. Hypoxic curve fitted free-hand, curves A–D fitted as described in text.

when this was displaced vertically upward, to an extent greater for irradiation in HBO (Curve C, Fig. 1) than in air (Curve D, Fig. 1).

The delay in growth of LMC$_I$ tumours following injection of rats with 150 mg/kg CP alone was 12.8 ± 0.3 days. When this mean value was subtracted from the total delay obtained for tumours irradiated when clamped, but 1, 4, 7 or 10 days after treatment of the rats with drug, the delays due to the irradiation did not differ significantly from those for hypoxic tumours in rats not given CP (Fig. 2). After CP and with irradiation

given in *aerobic* conditions at day 1, the growth delay of the tumours due to irradiation was also consistent with the radiation dose response curve for *hypoxic* tumours in rats not previously treated with drug (Fig. 3).

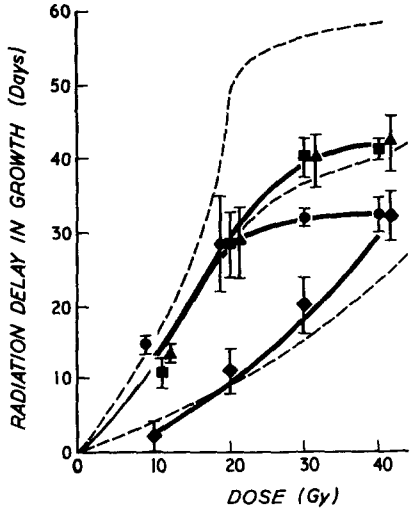

Fig. 3. Dose–response for LMC_I irradiated in air after treatment of rats with CP: ◆ 1 day; ● 4 days; ■ 7 days *or* ▲ 10 days *previously. Five to six rats per treatment group. Mean delays* ±2 S.E. *Dashed curves as in Fig. 2.*

However, 4 days after CP, a biphasic curve for irradiation in air was restored but the delays due to 30 and 40 Gy remained significantly less than the corresponding delays for aerobic irradiation alone ($P>0.01$). By 7 and 10 days after CP, the tumour response to all doses of aerobic irradiation was the same as for tumours in rats that had not been treated previously with drug.*

When tumours were irradiated in untreated hosts breathing HBO, a residual resistant component was revealed at high dose (Fig. 1). Four days after CP when the resistant component in air breathing rats is even higher than normal, this residual component could not be shown in the radiation response of tumours when treated in HBO, none having yet regrown after 30 or 40 Gy more than 150 days after treatment (Fig. 4).

DISCUSSION

The shapes and positions of curves for delay in tumour growth (Figs. 1–4) are believed to be determined mainly by the relative sensitivities of clonogenic cells within a population, rather than the absolute size of that population. Thus Thomlinson [10] found that for the Fibrosarcoma RIB_5 40 min after 35 Gy with the tumour clamped (for RIB_5C reducing the clonogenic cell population by approximately 10^3 [11]) the delay data obtained for second doses given in air were changed little from that for aerobic irradiation of previously untreated tumours. We have found also that the delay curves for LMC_I tumours irradiated at 5 mm diameter either clamped or in air, (Moore, unpublished) resemble closely those treated at 9±1 mm (Fig. 1). It seems valid then, to determine changes in the proportion of hypoxic cells by shifts in the growth delay curves for tumours even though the total number of cells may alter with time after an initial treatment, as occurs for LMC_I in the days following injection of CP [2]. Thus for rats treated with CP and where all the clonogenic cells within the tumour had been made uniformly resistant to radiation by clamping, little change was encountered in the position and shape of the dose–response curve for growth delay determined at any of the chosen intervals after treatment with drug.

The delay data for tumours irradiated under aerobic conditions does however reveal differences dependent upon the time elapsed after giving drug. Notably, at 1 day after CP the response to radiation was almost indistinguishable from that for a tumour in which

*Radiation doses greater than 40 Gy were in general not given to CP treated animals since the combined delay in tumour growth permitted an increased incidence and more widespread development of metastases [9].

all cells had been made hypoxic by clamping (Fig. 3). A similar shift has been observed for the tumour RIB_5 when second doses of radiation were given 40 min after a first dose sufficient to destroy all the well-oxygenated cells [10]. However for LMC_I the effect persisted much longer; the data indicated that the proportion of hypoxic cells had still not been reduced by reoxygenation to pretreatment value even 4 days after CP. That alkylating agents may preferentially spare hypoxic clonogenic cells has been shown recently for the KHT sarcoma treated with nitrogen mustard [1]. The phenomenon however, is not universal; the proportion of hypoxic cells in the B16 melanoma was unchanged when assayed 2 hr after CP [12]. In the cases where the proportion of hypoxic cells among survivors is raised, as for LMC_I, the rate of reoxygenation may vary between tumour types, as it does after a dose of radiation [13]. The LMC_I tumour has a relatively low Cell Loss Factor of 0.3 [7] and after 150 mg/kg CP but before regrowth occurs, its volume never regresses below that on the day of treatment [2]. It is unlikely then, that the type of reoxygenation seen for the C_3H mammary carcinoma which is rapid and complete [12], would occur in LMC_I, which in this respect more closely resembles the very slowly reoxygenating osteosarcoma described by van Putten [14].

In the light of these observations, the extent to which HBO enhanced the effect of the larger doses of radiation given 4 days after CP, is puzzling (Fig. 4). In rats not treated with CP, irradiation in HBO revealed a residual proportion of hypoxic cells (Fig. 1). That reduced competition for oxygen from sterilized tumour cells in rats treated with CP would enable this hypoxic component to reoxygenate is reasonable but the same argument holds for tumours in rats breathing air where the hypoxic component is larger than normal four days after CP (Fig. 4). However at this time reoxygenation is still in progress and normal levels of tumour hypoxia are not attained until 7–10 days (Fig. 3). Thus, the situation prevailing after treatment with CP is in contrast to that before, when the oxygen concentration of critical cells is decreasing and hypoxia is a transient state leading to cell death and necrosis. On this basis, factors operating in favour of reoxygenation of the tumour after CP treatment also may favour the more efficient oxygenation of erstwhile hypoxic cells during irradiation in HBO.

Apart from this apparent enhanced effect of HBO irradiation 4 days after CP, which requires further studies at other time intervals, the results of these experiments clearly indicate that the systemic use of drug before local radiotherapy under aerobic conditions may either prejudice local control of the tumour (i.e. at 1 and 4 day intervals for LMC_I) or at best (7–10 days) have little or no synergistic effect. From the clinical standpoint the therapeutic optimum, i.e. a reduction in the hypoxic fraction below a level characteristic of the untreated tumour, was not achieved. If this depends ultimately upon a reduction of tumour volume and a diminution of inter-capillary distances this is not achievable with LMC_I using single doses of other chemotherapeutic agents e.g. Methotrexate, Thiotepa and Adriamycin (Dixon, unpublished). Doses of CP greater than 150 mg/kg result in an unacceptable mortality, and though this may be avoided by the use of a split dose, actual regression of the LMC_I tumour does not occur [15].

Acknowledgements—We are grateful to Tenovus for their financial support (J.V.M.) and to Professor C. A. Joslin for advice and encouragement. We are especially indebted to Dr. R. H. Thomlinson for the use of the experimental HBO chamber, Mr. J. Mouncey of the Yorkshire Regional Medical Physics Unit for assistance with the irradiation dosimetry and Mrs. J. Haines for secretarial assistance.

Breast Cancer: The Error of the Exponential

E. ALLAN

Christie Hospital and Holt Radium Institute, Withington, Manchester, England

Abstract—*Survival curves for patients with breast cancer have been studied. A significant deviation from the exponential was found, and it has been shown instead that a log normal type of distribution of survival times is responsible for the shape of the survival curve. Conclusions drawn from acceptance of the exponential are therefore in error, whereas conclusions drawn from the log normal type of distribution are compatible with clinical observations and lead to the acceptance of the concept of biological predeterminism.*

INTRODUCTION

FASHIONABLE views concerning the behaviour of breast cancer emanate from the the demonstration of an apparent exponential survival curve for those patients dying from their disease [1]. It is said that this indicates that the process of dying from carcinoma of the breast is random, that the probability of dying from cancer is constant and that the number of patients dying during equal periods is a fixed proportion of those that were alive at the beginning of the period.

It would follow from this hypothesis that breast cancer is incurable in the sense that the last cancer cell cannot be eliminated from the body. This signifies that all breast cancers metastasise and that these metastases are held in a dormant state by general or local tissue immunological control. Breakdown of immunity then occurs as a random event and the metastases then grow and eventually cause the death of the patient. However, it is postulated that temporary control of the tumour may be achieved by hormone or chemotherapy administration and survival therefore prolonged [2].

However, Boag [3] investigated the distribution of survival times for patients dying from cancer at several sites. He found a continuous unimodal distribution with a skew to the right. A logarithmic transformation of the variate made the distribution approximately normal. He therefore described this as being of log normal distribution. Data collected from a number of different centres all yielded histograms that were essentially similar in form. He considered that this indicated that if the treatment had not been successful in eradicating the tumour completely, the length of survival must be dependent principally on the growth rate of the tumour remnants and not upon the form of treatment used. Boag also concluded that a log normal distribution indicated that a proportion of patients were cured of their disease, since at the end of 10 yr a group of patients were still alive and symptom free, and the group was too large to be fitted into the tail of the log normal distribution. However, a short follow up time left the distribution of survival times for breast cancer patients in some doubt.

Although the exponential survival curve and that obtained from the log normal distribution of survival times are similar in appearance when drawn on a semi log scale, they are in fact separate, statistically identifiable curves. Different, irreconcilable concepts of the natural history of breast cancer stem from the acceptance of each of these curves. In this paper an attempt has been made to identify the correct form of the survival curve for breast cancer patients.

MATERIALS AND METHODS

An investigation has been made into the distribution of survival times of 363 patients dying from breast cancer. These were women who presented with disease confined to the breast or associated with mobile homolateral axillary lymph nodes such that it was possible

Accepted 25 May 1978.

to remove all macroscopic disease by simple or radical mastectomy. None of the patients had clinical evidence of distant metastases at presentation, but investigations were limited to a chest X-ray and an X-ray to exclude bone metastases if pain was present. The 363 patients comprised the sum total registered at the Christie Hospital during 1955 who conformed to these criteria. Survival has been calculated from the time of the initial surgical operation.

RESULTS

The distribution of survival times (Fig. 1) was found to be unimodal with a skew to the right, similar to that found by Boag [3]. When a semi log plot of the survival curve is made (Fig. 2), it is found that there is a shoulder corresponding to the first 12 months. Campos [1] has suggested that the shoulder represents the time required for a tumour to reach a size that will kill the host and that the curve becomes exponential after this. When the author's curve is inspected with the first 12 months excluded, it is found that there is a tendency for the curve to be convex downwards. However, this deviation from the exponential is not statistically significant.

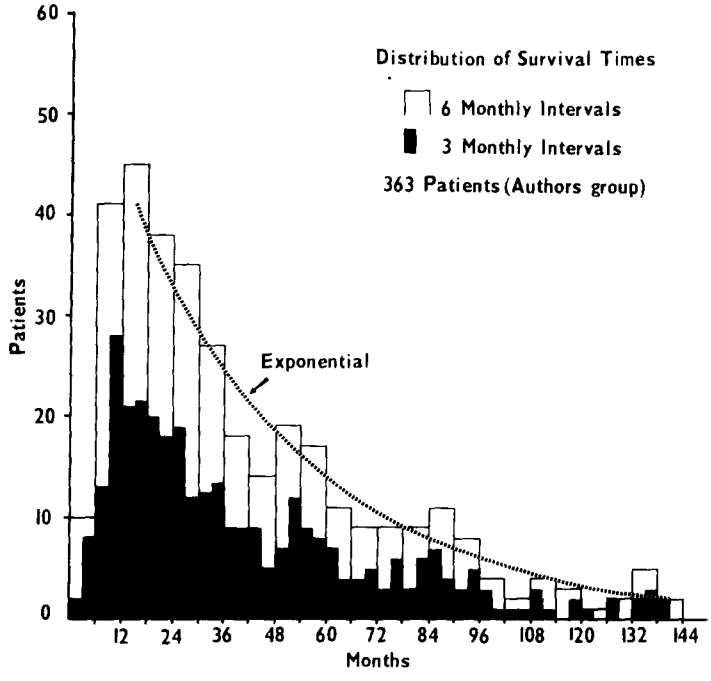

Fig. 1. Histogram showing distribution of survival times (author's group of patients).

DISCUSSION

Although the author's curve with the first 12 months excluded showed no significant deviation from the exponential, the question must be asked: Is this part of the curve truly exponential, or is the curve not exponential and are there too few patients to make the deviation statistically significant? In an attempt to answer this question a survival curve, obtained from the literature for 4304 breast cancer patients, has been studied [4] (Fig. 2). This deviates from the exponential in a similar manner to the curve derived from the author's group of patients and the deviation is statistically significant (Kolmogorov–Smirnov Test $P \ll 0.001$). However, if the patients in this large published series are not homogeneous, the underlying survival distribution may still be exponential. The group has therefore been divided into those having histologically positive and those having negative axillary nodes. The survival curves for both subgroups are a very poor fit to the exponential ($P \ll 0.001$).

There is, therefore, no doubt that the survival curve for breast cancer patients has been mistakenly identified as being of an exponential form. The reason for this is that when the curve is derived from a small number of patients the deviation from the exponential

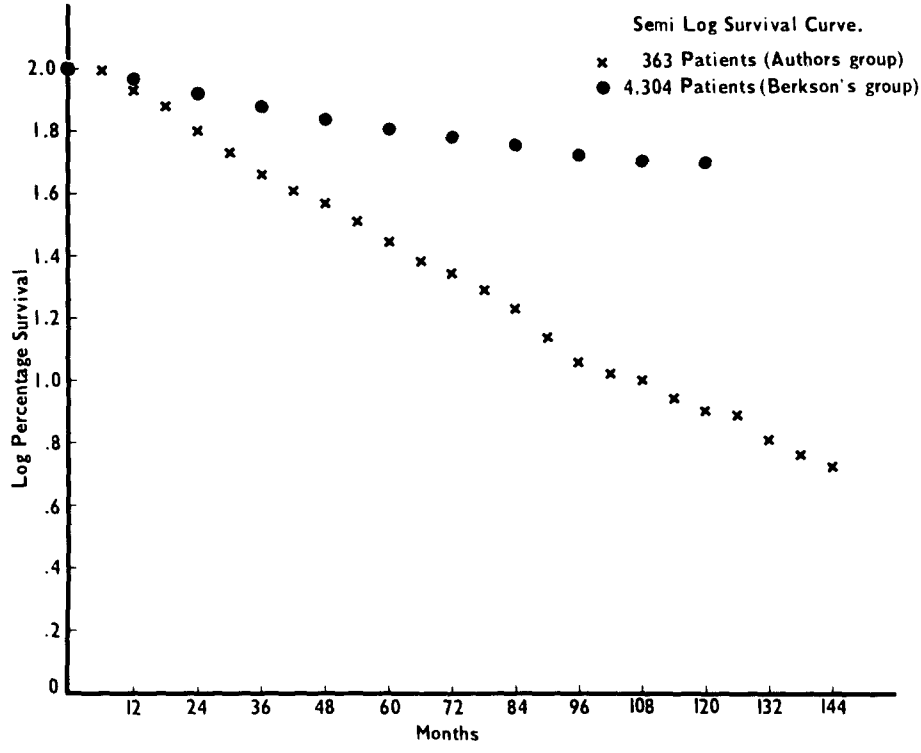

Fig. 2. Semi log survival curve (author's and Berkson's group of patients).

will not reach significant values. When a curve derived from large numbers of patients is considered, a statistically significant deviation from the exponential becomes apparent. The form of the survival curve must result instead from a continuous unimodal distribution of survival times with a skew to the right, similar to that described by Boag. However, when large numbers of patients dying from cancer at various sites are considered, there is a significant deviation from the log normal [5], and it is probable that the distribution does not accurately correspond to any specific statistical model. Therefore, for the rest of this article, the term log normal type will be used when referring to the observed distribution.

The rest of this discussion is hypothesis regarding the significance of the error of the exponential. Since the observed distribution approximates to the log normal model. Boag's conclusions are considered.

The validity of Boag's contention that the length of survival must be dependent principally on the growth rate of the tumour is first investigated. It has been shown that cancers grow in most cases for most of the time in an exponential manner, and that death occurs at approximately the 45th doubling, when a critical mass of tumour is present [6–9]. It would therefore be expected that a relationship exists between growth rate and duration of survival. Four papers published in the literature confirm this.

1 and 2. Tumour growth rate and duration of survival are directly proportional [10, 11].

3. There is a log normal type of distribution both of survival and of tumour growth rates [12].

4. When tumours are induced in mice using ultra-violet light, the intervals required for the cancers to appear formed a log normal type of frequency distribution [13].

It is thus apparent that the log normal type of distribution of survival times has been produced by a log normal type of distribution of tumour growth rates, and therefore that survival in those patients not cured depends principally on the growth rate of the tumour.

Boag's conclusion that a cured group of patients can be identified statistically is now considered. If this conclusion was valid this would indicate that there is a group of patients with breast cancers which fails to metastasise. There are three observations which appear to support this concept.

1. If a survival curve is drawn for a group of patients suffering from breast cancer, after 15 yr, the curve is almost parallel to that constructed for a healthy group of women of similar age distribution. This indicates that most patients with breast cancer are cured if they have survived 15 yr [14].

2. A constant metastatic pattern is found in

unselected groups of breast cancer patients [15–17]. This implies a random distribution of clinically observed metastases within the limitations of constant factors in individual patients. This must result from a random distribution, implantation and growth of metastasising tumour fragments within the limitations of constant mechanical factors and is incompatible with the concept of intermittent or selective immunological control. Therefore, if metastases fail to appear clinically, the primary tumour has failed to metastasise.

3. When ^{51}Cr labelled cancer cells were injected into mice [18], it was found that the cells lodged in the organs so as to produce the subsequently observed metastatic pattern. It was also found that the cells passed rapidly through the organs which were rarely the site of metastases. Most of the cancer cells eventually died in transit in the blood stream before lodging in any organ and were finally broken down in the liver and spleen. This observation implies that when cancer cells lodge in organs a constant proportion of them will give rise to clinically apparent metastases. Therefore, if clinical metastases fail to appear the primary tumour has failed to produce metastasising cells capable of implantation in the tissues or alternatively has done so in insufficient numbers to produce clinical metastases.

It has been shown that when metastases develop they have almost all been initiated during the preclinical phase of the parent tumour [10]. There thus seems little doubt, that the conclusions drawn from the log normal type of distribution, that some patients with breast cancer are cured, may be explained by postulating that some cancers do not shed their cells or alternatively shed very few cells into the blood stream.

The log normal type of distribution of survival times is produced by a log normal type of distribution of tumour growth rates. Therefore, patients who have tumours which metastasise may have slowly or rapidly growing tumours. It may therefore be expected that there is no correlation between metastatic potential and tumour growth rate [19]. The validity of this supposition is now examined.

In a previous paper by the author [17] it was demonstrated that patients with a long latent interval had slowly growing tumours. These must represent the extreme end of the skew of a log normal type distribution. However, most of the patients developed widespread metastases and died from their disease.

Patients with poorly differentiated tumours have lower survival rates than those with better differentiated tumours [4]. It is pertinent to enquire whether this is because poorly differentiated tumours have a high metastatic potential or because they have a faster growth rate. Four observations provide the answer to this question.

1. When a group of breast cancer patients having a long latent interval was assessed, it was found that anaplastic tumours did not differ in growth rate from better differentiated tumours [17].

2. It has been shown that the histological pattern is similar whether a group of tumours show clinical evidence of metastases after 1–2 yr or after a latent interval of 5 yr [15].

3. It has been demonstrated that patients with anaplastic tumours develop local recurrence twice as frequently as those with better differentiated tumours [20].

4. Tumour doubling time is not related to the degree of tumour differentiation [8].

There is, therefore, little doubt that the degree of tumour differentiation is an indication not of tumour growth rate but of metastatic potential.

It has been reported [21] that a characteristic cellular morphology can be identified in tumours recurring more than 10 years after the initial treatment, i.e. slowly growing tumours [16]. On the basis of this a typing system has been devised which does not correlate with other histological classifications but shows good correlation with survival. This typing system would therefore appear to give an indication of tumour growth rate.

CONCLUSION

Acceptance of the exponential function of the survival curve has led to a misunderstanding of the natural history of breast cancer. A realisation of the log normal type of distribution leads us to the acceptance of the concept of biological predeterminism [22]. When the first cancer cell forms the outcome of the disease is determined. Non-metastatic breast cancer is curable. When metastases have occurred, there is no evidence that host immunity or treatment significantly alters survival.

Acknowledgements—My thanks to Mr. M. Palmer for invaluable help with statistics, to Mr. R. Schofield for the figures, to Dr. E. Sherrah-Davies for helpful criticism and advice and to Mrs. A. Hurst, who typed the manuscript.

VM26 (NSC-122819): A Clinical Study in Advanced Cancer of the Lung and Ovary*

MICHAEL K. SAMSON, LAURENCE H. BAKER, ROBERT W. TALLEY and ROBERTO J. FRAILE†

Department of Oncology, Wayne State University School of Medicine, Detroit, Michigan 48201, *U.S.A.*
Division of Oncology, Henry Ford Hospital, Detroit, MI 48202, *U.S.A.*

Abstract—*Fifty-five evaluable patients with advanced carcinoma of the lung* (25 *squamous*, 19 *adeno*, 11 *small cell*) *and* 16 *patients with advanced adenocarcinoma of the ovary were treated with VM*26 *in a phase* II *study. Only one response was noted, a partial* (>50%) *remission in squamous cell cancer of the lung for* 8+*months. The drug was well tolerated with minimal nausea, vomiting, anorexia and alopecia. Myelosuppression was infrequent in patients not previously treated with chemotherapy and usually tolerable in patients previously treated. Orthostatic hypotension, hepatotoxicity and peripheral neuropathy were not observed. On the basis of this report VM*26 *does not appear to demonstrate any significant antitumor effect in advanced cancer of the lung and ovary.*

INTRODUCTION

PODOPHYLLOTOXIN derivatives have been studied since the late 1940's for evidence of clinical antitumor activity. Two new semisynthetic derivatives have been recently developed by Sandoz Laboratories: VM26, 4′-demethyl 1-0-[4,6-0-0(2-thenylidene)-β-D-glucopyranosyl] epipodophyllotoxin (NSC-122819), and VP16-213, 4′-demethyl-1-0[4,6-0(ethylidene)-β-D-glucopyransosyl] epipodophyllotoxin (NSC-141540).

In cell cultures exposed to VM26 and VP16-213 metaphase arrest has been shown, but unlike the parent compound podophyllotoxin, microtubular alterations have not been demonstrated. A premitotic block preventing entry of cells into mitosis appears to be the predominant mechanism of action [1, 2, 3]. Additionally, these drugs cause inhibition of thymidine incorporation [4, 5, 6]. Both compounds are active in Ehrlich ascites, Walker carcinosarcoma, Sarcoma 37 and 180, and several murine leukemias including L1210 [7, 8, 9]. Both drugs demonstrate schedule dependency in the latter system.

VP16-213 has undergone more extensive clinical evaluation [10]. Antitumor activity has been observed in acute nonlymphocytic leukemia, Hodgkin's and non-Hodgkin's lymphoma, ovarian carcinoma and small cell carcinoma of the lung [11–18]. VM26 has been studied by the European Organization for Research of Treatment of Cancer (E.O.R.T.C.) in various solid tumors and responses were noted in Hodgkin's and non-Hodgkin's lymphoma, bladder and breast carcinoma [19]. Other tumor types were not represented by a sufficient number of patients to assess drug activity. Another report documents responses in intracranial neoplasms [20].

We initiated a broad phase II study of VM26 in various solid tumors in 1976 and our results in lung and ovarian cancer are the subjects of this report.

MATERIALS AND METHODS

Patient eligibility

All patients entered on the study had histologically proven advanced squamous cell, small cell undifferentiated (oat cell) or adenocarcinoma of the lung, or adenocarcinoma of

Accepted 18 April 1978.
*This investigation was supported by National Cancer Institute Contract N01-CM-67105.
†The authors wish to acknowledge the contribution of Sheila Mitchell for her invaluable assistance in the preparation of this manuscript.

the ovary. The patients were informed as to the investigational nature of the study and all gave written consent in accordance with our institutional policy. There were no age restrictions. Other criteria for eligibility included the following: a life expectancy of at least 6 weeks; no prior chemotherapy with a podophyllotoxin derivative; measurable disease outside a concurrently or previously irradiated site; initial white blood cell count $>3000/mm^3$ and platelet count $>100{,}000/mm^3$; adequate renal function as defined by a serum creatinine $\leqq 1.5$ mg% and BUN $\leqq 25$ mg%; adequate liver function as defined by a SGOT < twice upper limits of normal and total bilirubin <2.0 mg%; and no previous chemotherapy within the past 28 days and evidence of hematologic recovery from that therapy.

On study evaluation

Patients were evaluated while receiving therapy with serial CBCs, chest roentgenograms, liver and renal function tests and tumor measurement. A two week survival on therapy constituted an adequate trial.

Treatment protocol

VM26, supplied by the National Cancer Institute, Bethesda, Maryland, U.S.A. in 10 mg/ml, 5 ml ampoules, was diluted in at least 5 vol of sodium chloride injection U.S.P. or 5% dextrose in water and administered in an established IV line over 30 min to 1 hr. Good risk patients received an initial dose of $30\ mg/m^2$ daily × 5 every 3–4 weeks while poor risk patients with prior extensive radiation therapy and/or chemotherapy were started at $20\ mg/m^2$ daily × 5 every 3–4 weeks. Subsequent doses of VM26 were adjusted to nadir blood counts and patient tolerance. Dose escalation was encouraged in the absence of myelotoxicity.

Definitions of response

Complete remission was defined as the disappearance of all clinical evidence of active tumor for a minimum of 4 weeks together with a disappearance of all tumor-related symptoms. Partial remission was defined as >50% decrease in the sum of the products of the largest perpendicular diameters of all measured lesions lasting at least 4 weeks in the absence of significant increase in any one lesion or the appearance of new lesions. Progressive disease was defined as unequivocal increase of any measured lesion or the appearance of new lesions.

Patients. Seventy-seven patients (37 men, 40 women) were entered onto the study. Six patients were considered early death; that is, they died within 14 days of initiation of therapy from tumor-related causes and were inevaluable for toxicity or response. Additional patient characteristics with respect to age, Karnofsky performance status, and the nature of prior treatment are outlined in Table 1.

Table 1. Patient characteristics

Tumor	No. of pts entered	Male	Female	No. of pts evaluable	Age (mean, range)	Karnofsky performance status (mean, range)	Prior therapy: Chemotherapy	Prior therapy: Radiotherapy	Prior therapy: Both	Prior therapy: None
Lung										
Squamous cell carcinoma	28	21	7	25	60, 35–78	68, 40–90	1	13	6	8

Ovary, adenocarcinoma	16		16	16	58, 40–75	71, 40–90	12	0	4	0
Totals	77	37	40	71						

RESULTS

Antitumor activity

Of the 71 evaluable patients in all tumor categories only one partial response was observed in a patient with squamous cell carcinoma of the lung. The duration of this response was 8+ months. Of significance was the lack of response in small cell carcinoma of the lung and adenocarcinoma of the ovary.

Toxicity

Non-hematologic toxicity could be evaluated in 71 patients and consisted of nausea in 8% of patients, vomiting in 5% and alopecia in 7%. Nausea and vomiting were consistently mild to moderate in nature and easily controlled with anti-emetics. Peripheral neuropathy, hepatoxocity and hypotension were not observed.

Hematologic toxicity and days to nadir by dose level through three course (mean number of courses of therapy per patient=3) is described in Tables 2 and 3, separated by the presence or absence of prior chemotherapy. There did not appear to be any cumulative myelosuppression nor any time delay in administering subsequent courses of therapy. Significantly more leukopenia (wbc $<3000/mm^3$ in 27% of evaluable courses) and thrombocytopenia (platelets $<100,000/mm^3$ in 18% of evaluable courses) was observed in those patients who had received prior chemotherapy ($P<0.01$). There was one drug-related death from sepsis in a

patient with small cell carcinoma of the lung whose white blood cell count was 0.17 $\times 10^3/mm^3$ and platelet count 26,000/mm^3 at the time of his demise.

DISCUSSION

VM26 was administered to 55 evaluable patients with advanced carcinoma of the lung (25 squamous, 19 adenocarcinoma, 11 small cell) and to 16 patients with ovarian carcinoma.

Only one objective response was observed in squamous cell carcinoma of the lung.

The drug appeared to be well tolerated with minimal nausea and vomiting and tolerable myelotoxicity.

The lack of response is disappointing particularly in small cell carcinoma of the lung and adenocarcinoma of the ovary where VP16-213, an analog of VM26, has shown evidence of activity in several reports, and is presently an integral part of many first line drug combinations in these tumor categories. One may question the dose and schedule of drug administration that was chosen in this study, but in view of the poor response rate it would be difficult to justify alternate treatment schedules in future studies in these tumor types. Furthermore, a prospective randomized trial comparing VM26 and VP16-213 would offer little additional information since the advantage of VP16-213 over VM26 at least in small cell carcinoma of the lung would appear to be obvious.

Other solid tumors are currently being evaluated and will be the subject of another report.

Letter to the Editor

Adriamycin in Ovarian Cancer Patients Resistant to Cyclophosphamide

GIORGIO BOLIS,* MAURIZIO D'INCALCI,†‡ FAUSTA GRAMELLINI* and COSTANTINO MANGIONI*

**I Clinica Ostetrica e Ginecologica dell'Università di Milano, Italy and †Istituto di Ricerche Farmacologiche 'Mario Negri', Via Eritrea, 62-20157 Milan, Italy*

INTRODUCTION

In the management of ovarian cancer patients at stages III and IV a consistent benefit can be obtained by the use of alkylating agents. Melphalan (L-PAM) and Cyclophosphamide (Cy) are widely used because of their relatively low toxicity. About 50% of patients obtain benefit for periods of about 1 yr from these drugs [1, 2]. It is however clear that a second line of therapy must be available for both non responders and relapsing patients.

Despite its structural and pharmacological differences from the family of alkylating agents adriamycin (AMD) was found active on ovarian cancer [3, 4]. These data together with previous conflicting reports of its activity as second line therapy [3, 5] led us to test its activity in a homogeneous population of patients previously treated with a protocol consisting of Cy low doses.

PATIENTS AND CRITERIA FOR THE STUDY

The study comprises 38 patients, median age 53 (27:73), life expectancy more than 3 months, performance status >70, with ovarian cancer stages III, IV previously treated with surgery and cyclophosphamide (Cy) (100 mg/day p.o.); 12 had relapsed after response to Cy and 26 were non-responders; in the latter group 9 were stationary and 17 in progression.

The regimen employed was: ADM 60 mg/m^2 by rapid i.v. injection every 3 weeks. Response was evaluated as ≧50% regressions; progression as ≧50% of measurable masses of new lesions, no change as less than 50% variation in the size of the original lesions. All the patients were evaluated after 3 cycles of ADM.

RESULTS

The table reports the response and survival in groups of patients divided according to their previous response to CY. Out of the 38 patients entering the study only 3 responded to ADM (7.89%, confidence limits for $P=0.05$ 1.66–21.38). The median survival of the 9 patients with a stationary,

Table. Response to ADM

Status after Cy therapy	Second line treatment

Progression after response	12	2	0	10
Stationary	9	0	9	0
Progression	17	1	0	16
Total	38	3	9	26
Survival (months)		8 (4–11)	11 (6–17)	4 (2–10)

Accepted 3 May 1978.
‡To whom reprint requests should be addressed.

slow growing tumour was longer (11 months, 4–15) than responding patients (8 months, 6–17) and obviously much higher than patients in progression (4 months 2–10). Five patients are still alive: in one of them, after a partial response it became possible to remove the residual tumour surgically and this patient is alive with no evidence of disease after 15 months. One patient is alive with no change at 4 months and 3 patients are in progression at 3, 3 and 4 months respectively.

The treatment was generally well tolerated and never required admission to hospital. Hematological toxicity was observed in 25% of the women; mean WBC was 3200/mm^3 (1200–6000) mean platelets 130,000 (40,000–420,000), nausea vomiting and alopecia occurred in all cases. No patient suffered cardiac toxicity.

DISCUSSION

Our results indicate that ADM has scant effect in ovarian cancer patients resistant to Cy. This result is not in contrast with the encouraging results obtained with ADM as first line chemotherapy [3, 4, 6], but confirms previous data on its low efficacy as second line therapy [3, 5] in a population resistant to a low dosage of Cy which might be expected to include patients sensitive to more aggressive therapy.

No statistical differences can be found among all the results in the literature and in fact in series of about 40 patients the percentage of response would have to be at least 35–40% to reach a statistically significant level. That ovarian cancer patients resistant to first line chemotherapy do not respond to other treatments has been demonstrated with many drugs such as 5FU [5], high dose MTX [7], high dose Cy [8, 9], *cis*-diamminodichloroplatinum (*cis*-DDP) [10]. It could however be argued that 5FU and MTX have poor activity even in first line therapy and that Cy and *cis*-DDP may develop cross resistance with the alkylating drugs given in first instance. The finding however that ADM behaves in the same manner leads to the hypothesis that ovarian cancer in patients who respond to chemotherapy may have some different features from the ones that show immediate or secondary resistance.

Certainly other causes may contribute to making response improbable such as the size of the tumour, its growth rate, or circulatory efficiency in resistant tumours.

To conclude, it seems that, in the management of ovarian cancer, very little can be gained by sequential treatments, and that better efforts may be expected by improving the first therapeutic attack.

Rotenone: A Possible Environmental Carcinogen?

MARIO GOSÁLVEZ and JUAN J. DÍAZ-GIL

Bioquimica Experimental, Clinica Puerta Hierro, Universidad Autónoma, Madrid, Spain

IN A PREVIOUS paper [1] we reported that the respiratory inhibitor rotenone induces a high incidence of mammary fibroadenomas in the albino rat. In a second report [2] we pointed out that rotenone was also inducing the tumors when administered orally. We now report information about the uses of rotenone as an insecticide, pesticide and piscicide which may induce the consideration of this compound as an environmental carcinogen.

Initially [1] we mentioned the use of rotenone as an insecticide in small quantities because the Section of Agricultural Plagues of the Spanish Ministry of Agriculture evaluated the world consumption of rotenone extrapolating for the world population the low Spanish consumption. Further investigations through various state agencies in the United States and an exhaustive bibliographic search in the not readily available literature revealed, however, that:

1. There is a massive consumption of rotenone as an insecticide in superindustrialized countries, especially in the U.S., Great Britain, Sweden, Denmark, Finland, Israel, Canada and Norway. The United States does not produce all rotenone needed for its consumption and must import substantial quantities of rotenone yearly. A minimum of ten million pounds of rotenone and rotenone products (cube and derris powder) were imported in the U.S. in 1950. The importation of rotenone diminished since then, reaching one million pounds in 1972. The total yearly consumption of rotenone in the U.S. presently is estimated at 15 million pounds.
2. Rotenone is used in the U.S. mainly as an agricultural insecticide and as a piscicide. The use as an agricultural insecticide is small, presently in fields (mainly fruit) but, however, is massively used in private household gardens of the American home [3, 4]. As a piscicide, rotenone is used for total killing or for selective killing in lakes, rivers, fisheries, water reservoirs and water plants [5–9]. Through this use, rotenone contaminates drinking water. The concentration of rotenone in drinking water is not available at present but it is enough to cause a characteristic odor and taste [5, 6].
3. Rotenone is also used in the U.S.A. for parasitic controls in cats, dogs and cows but with this use no ingestion of rotenone by humans is foreseen.

Figure 1 depicts the uses of rotenone and its possible ways of arrival to the human female in the U.S.A. The ingestion in consumed fresh or cooked vegetables grown in private household gardens and the ingestion with drinking water are considered the main possible environmental hazards. In Table 1 an experiment is shown in which we have investigated the content of rotenone in green beans cultivated in winter in our laboratory under household garden conditions, using a commercial insecticide containing rotenone. The treated beans contained from 14 to 58 μg of rotenone per gram of beans when ready to be cooked. This amount is well within the order of magnitude of the carcinogenic potency of rotenone (0.1 mg of rotenone daily during 30 days is enough to cause tumours in the rat).

As rotenone is carcinogenic in the rat at very low doses by oral administration and the ingestion of rotenone by humans in substantial amounts, it is more than a possibility, we believe, that rotenone could possibly be considered as an environmental carcinogen. Such a consideration, however, would not guarantee that rotenone is a causative agent of the human mammary tumors in the absence of well founded epidemiological studies.

Accepted 14 June 1978.

Table 1. *Content of rotenone in green beans treated with rotex* 2.5

	Beans	Leaves	Stems	Roots
Control plants	N.D.	N.D.	N.D.	N.D.
Experiment A	58	850	N.D.	N.D.
Experiment B	14	420	N.D.	N.D.

N.D.: Not detectable.
The numbers express micrograms of rotenone per wet weight of plant material. Each experiment is the average of the data obtained from two flowerpots. Rotex 2.5 is a Spanish brand (Grima Laboratories, Valencia, Spain) of insecticide containing 2.5% rotenone. The beans were cultivated in Madrid (Spain) during the winter months, exposed to the sun, air and rain and were collected at a size of 5–10 cm. The plants in experiment A received, in the last two months of growth, three pulverizations with Rotex 2.5, one every 15 days. The plants in experiment B received two pulverizations, one every 30 days. The plants were sprayed according to norms for the use of Rotex 2.5 in agriculture. The determination of the rotenone content was made by gas chromatography as previously described [7] except that we included a previous purification of the chloroform extracts in thin layer chromatography [9].

Although an epidemiological study of rotenone in household gardens and mammary tumor incidence would be highly desirable, this may be perhaps an impossible study since most individuals would not remember what pesticide they used in their garden 10, 20 or 30 yr ago. The purpose of this report is to call to the attention of the scientific community and state organizations with interest in possible environmental hazards to the fact that rotenone is a rat carcinogen by oral route and which is possibly reaching the human female in certain countries in substantial amounts.

Publishing & Advertising Offices Headington Hill Hall, Oxford, OX3 0BW (Oxford 64881)
Subscription rates (1978) (including postage and insurance) $160.00 per annum for libraries, research establishments and all other multiple-reader institutions.
Specially reduced rates to individuals. In the interests of maximising the dissemination of the research results published in this important international journal we have established a two-tier price structure. Individuals, whose institution takes out a library subscription, may purchase a second or additional subscription for personal use at the much reduced rate of $30.00 per annum. Twelve issues, published monthly. All subscription enquiries should be addressed to the Subscription Fulfillment Manager, Journals Division, Pergamon Press, Headington Hill Hall, Oxford.
