COMPARATIVE STUDIES OF THE COORDINATION MODE IN COMPLEXES OF COPPER WITH ASPARAGINE AND COPPER WITH ASPARTIC ACID IN SOLUTION AND SOLID STATE

LECHOSLAW LOMOZIK* and ANNA WOJCIECHOWSKA

Faculty of Chemistry, Adam Mickiewicz University, Grunwaldzka 6, 60-780 Poznan, Poland

(*Received* 18 *December* 1987; *accepted after revision* 13 *June* 1988)

Abstract—^{1}H NMR, ^{13}C NMR and IR studies have been employed to compare the mode of coordination of Cu complexes with DL-asparagine (Asn) and Cu with DL-aspartic acid (Asp) in solution and in isolated solid complexes: $Cu(Asn)_2$, $[Cu(Asn)(OH)(H_2O)_2]$, $K_2[Cu(Asp)_2]\cdot 2H_2O$, $Ba[Cu(Asp)_2]\cdot 2H_2O$ and $Ba[Cu(Asp)(OH)(H_2O)_2]_2$. It was found for DL-asparagine that only the carboxyl group participates in the coordination in complexes with Cu in solution at pH = 5, whereas carboxyl and amine groups participate in coordination at pH = 9. In the solid complex of Asn with Cu: Cu(Asn), the coordination was found to take place through the carboxyl, amine and amide groups, and in the complex $[Cu(Asn)(OH)(H_2O)_2]$ through carboxyl and amine groups. In the case of DL-aspartic acid it was found that carboxyl groups participate in the coordination of complexes with Cu in solution at pH = 5, whereas carboxyl and amine groups participate in the coordination at pH = 9. In the solid complexes of Asp with Cu: $K_2[Cu(Asp)_2]\cdot 2H_2O$ and $Ba[Cu(Asp)(OH)(H_2O)_2]_2$ coordination takes place through both the carboxyl and amine groups. Identical coordination in solution and in the solid state was found in hydroxo complexes of both investigated ligands with Cu.

Intensive studies of metal complexes in biological systems have been conducted in recent years.[1–3] The molecular weight of groups functioning as ligands in these systems is of the order of thousands, and the metal is only a minor constituent of them. Therefore, it is necessary to conduct investigations on much simpler models such as, for example, complexes of amino acids and peptides with metals. Such complexes are a source of information for better understanding of the laws governing biological systems. The reactions occurring in living organisms proceed mainly in solution, but data concerning the structure of the given complexes, in terms of the bond length and coordination mode, are frequently obtained in crystallographic studies of the crystals. Any conclusions drawn about the complexes in solution on the basis of results obtained for solids runs the risk of interpreting the data erroneously. It is incorrect to assume, prior to any experiments, that the coordination mode in the solids is identical with that in solution, especially as experiments of this type have proved that in many cases the model obtained for the solid complex is not identical to that existing in solution.[4–7] Copper plays a crucial role in systems of this type.[8]

In the present study we attempted to compare the results obtained in coordination mode studies of the complexes of copper with DL-asparagine and copper with DL-aspartic acid in aqueous solution and in isolated solid complexes. The results obtained are of particular significance for estimating the role of the metal and its coordination compounds in the processes occurring in living organisms.

EXPERIMENTAL

DL-asparagine (Asn) and DL-aspartic acid (Asp) by Reanal (Hungary), which were chromatographically pure, were used in the study. Copper perchlorate was obtained by dissolving cupric

*Author to whom correspondence should be addressed.

oxide in concentrated $HClO_4$, followed by crystallization. The following deuterated compounds were used in spectroscopic studies: D_2O (IBJ, Poland), DCl (PAN), NaOD (Veb-Berlin-Chemie). Samples for ^1H NMR, ^{13}C NMR and IR studies were prepared by dissolving copper perchlorate and DL-asparagine (DL-aspartic acid) in D_2O. The pH measurements were carried out on a pH-meter PHM-26 Radiometer and corrected according to the formula pD = pH + 0.40.[9] DL-asparagine and DL-aspartic acid concentrations in the samples were 0.20 and 0.50 M, respectively. The metal to ligand ratio was 1 : 50 in ^1H NMR and ^{13}C NMR studies, and 1 : 2 in IR investigations. ^1H NMR spectra were recorded on a BS-467 Tesla spectrometer with DSS as the internal standard, ^{13}C NMR spectra on a JEOL Fx 90 QFT spectrometer with dioxan as the internal standard. IR spectra were recorded on a Perkin–Elmer 180 spectrometer. All the IR spectra were performed for deuterated (the ligands were recrystallized three times from heavy water) and undeuterated ligands so that their results could be interpreted unambiguously. IR spectra of solid compounds were recorded within the range 4000–400 cm^{-1} as KBr discs, and within the range 700–200 cm^{-1} as CsBr discs.

Preparation of complexes

$Cu(Asn)_2$. This compound was prepared using a method similar to that described in ref. 10 (cupric acetate was substituted by cupric perchlorate). Analysis for $Cu(Asn)_2$: Found: N, 17.4; C, 29.5; H, 4.3. Calc.: N, 17.2; C, 19.4; H, 4.3.

$[Cu(Asn)(OH)(H_2O)_2]$. This was obtained by dissolving 0.03 mole of DL-asparagine and 0.005 mole of $Cu(ClO_4)_2$ in water. The solution was brought to pH = 9. The complex was precipitated with acetone, rinsed with absolute ethanol and dried in a desiccator over P_4O_{10} at room temperature. Navy blue crystals of the complex were obtained. Analysis for $[Cu(Asn)(OH)(H_2O)_2]$: Found: N, 11.1; C, 19.6; H, 4.8. Calc: N, 11.4; C, 20.0; H, 4.9.

$K_2[Cu(Asp)_2]\cdot 2H_2O$. This compound was prepared applying a method similar to that used for $Cu(Asn)_2$. (The method described in ref. 10 was modified by neutralizing the reaction mixture to pH = 7 by means of KOH.) Analysis for $K_2[Cu(Asp)_2]\cdot 2H_2O$: Found: N, 6.4; C, 21.4; H, 3.1. Calc: N, 6.4; C, 21.7; H, 3.2.

$Ba[Cu(Asp)_2]\cdot 2H_2O$. This compound was prepared employing a method described in ref. 11. Analysis for $Ba[Cu(Asp)_2]\cdot 2H_2O$: Found: N, 5.6; C, 19.5; H, 2.8. Calc: N, 5.6; C, 19.2; H, 2.8.

$Ba[Cu(Asp)(OH)(H_2O)_2]_2$. This was obtained by dissolving 0.015 mole of DL-aspartic acid and 0.003 mole of $CuSO_4$ in water. $Ba(OH)_2$ was added to the solution until pH = 13 was reached. CO_2 was passed through the mixture to precipitate the excess Ba^{2+}. After filtering off the precipitate, the complex was precipitated with dioxan. A light blue precipitate was obtained. The complex was air dried at 50°C. Analysis for $Ba[Cu(Asp)(OH)(H_2O)_2]_2$: Found: N, 4.4; C, 14.9; H, 3.8. Calc: N, 4.4; C, 15.1; H, 3.8.

RESULTS AND DISCUSSION

It follows from our earlier studies[12] as well as from the literature on Cu/Asp and Cu/Asn complexing equilibria (Table 1) that the following complexes arise in the systems: Cu(Asp), $Cu(Asp)_2^{2-}$, $Cu(HAsp)^+$, $Cu(Asp)(OH)^-$ and $Cu(Asn)^+$, $Cu(Asn)_2$, $Cu(Asn)(OH)^-$.

In order to determine the coordination mode in Cu complexes with DL-aspartic acid and DL-asparagine in solution, ^1H NMR, ^{13}C NMR and IR studies were carried out at pH = 5 and 9. At pH = 5 (as evidenced by our earlier observation[12]) predominant forms in the systems mentioned above

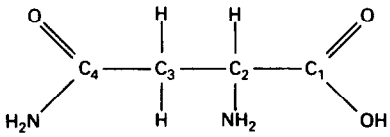
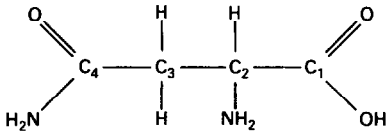
Asn+Cu	pH = 9	112.105	−16.271	−28.051	114.476	4.00	3.08

are the complexes of the ML and ML_2 type, whereas at pH = 9 the ML(OH) hydroxo complexes dominate. At pH = 5 in the ^1H NMR spectrum of DL-aspartic acid with Cu (Table 2), the signals of protons at C_2 and C_3 are shifted, and in the ^{13}C NMR spectrum (Table 2) shifts are exhibited by the atoms C_1, C_4 (the greatest shifts) and C_2, C_3 (almost identical shifts), see structure below.



The above data indicate the coordination via both carboxyl groups of DL-aspartic acid at pH = 5, and 9 via both the carboxyl groups and amino group [in the ^1H NMR spectrum the shift of proton signals at C_2 and C_3 has been observed and also in the ^{13}C NMR spectrum the shift of signals coming from C_1, C_2, C_3, C_4 has been recorded (Table 2)]. The above conclusions were confirmed by IR studies (Table 3). In the IR spectrum of DL-aspartic acid with Cu, the signals from carboxyl groups are shifted towards lower frequencies, thus both carboxyl groups participate in the coordination.[19] The decay of the signal at 1627 cm^{-1} arriving from the $-C(\overset{+}{N}H_3)COO^-$ group in the spectrum of DL-aspartic acid with copper at pH = 9 (Table 3) also proves the coordination through nitrogen. In the ^1H NMR spectrum of DL-asparagine with copper at pH = 5, the proton signal at C_2 is shifted, though no shift of the proton signal is observed at C_3. Thus, it can be concluded that the carboxyl group participates in the coordinatiom with Cu, which is also supported by the data obtained from ^{13}C NMR spectra (Table 2), see structure below.



The absence of a proton signal shift at C_3 in the ^1H NMR spectrum at pH = 5 and relatively small shifts at C_2 and C_3 in the ^{13}C NMR spectrum let us conclude that the amide group, carbonyl oxygen as well as the amine group do not take part in the coordination. At pH = 9, DL-asparagine is coordinated with Cu through the carboxyl and amine groups. The value of the C_4 shift calculated from the ^{13}C NMR spectrum (Table 2) excludes the coordination by the amide group and the oxygen atom of the carbonyl group in this system. IR studies confirm the above conclusions (Table 4).

To obtain information about the coordination mode of DL-asparagine and DL-aspartic acid with Cu in the solid state, the following solid complexes

Table 3. IR spectra of Asp and Asp+Cu^{II} (cm^{-1}), (D_2O solution; CaF_2 cells)

System		$-COO^-$	$>C(\overset{+}{N}H_3)COO^-$
Asp	pH = 5	1583	1614
Asp+Cu	pH = 5	1556	1575
Asp	pH = 9	1592	1627
Asp+Cu	pH = 9	1585	

Table 4. IR spectra of Asn and Asn+Cu^{II} (cm^{-1}), (D_2O solution; CaF_2 cells)

System		$-COO^-$	$-C(=O)-NH_2$
Asn	pH = 5	1622	1640
Asn+Cu	pH = 5	1609	1640
Asn	pH = 9	1591	1632
Asn+Cu	pH = 9	1578	1632

were synthesized: $Cu(Asn)_2$, $[Cu(Asn)(OH)(H_2O)_2]$, $K_2[Cu(Asp)_2]\cdot 2H_2O$, $Ba[Cu(Asp)_2]\cdot 2H_2O$, as well as $Ba[Cu(Asp)(OH)(H_2O)_2]_2$ and their IR spectra were recorded. The recorded spectra were referred to the spectrum of the ligand alone. In the spectrum of the $Cu(Asn)_2$ complex (Table 5), the shift of the peak of the carboxyl group shows evidence of its participation in coordination with Cu. The amide group (peak shift), as well as the amine group ($—NH_2$ signal shift and disappearance of the $—NH_3$ peak in the spectrum of the complex) also participate in the coordination (Fig. 1). The carboxyl group coordinates with the metal through one oxygen of the carboxyl group (the carboxyl group signal shifts to higher frequencies). Additional peaks in the far-IR appearing in the spectrum of the complex prove coordination through oxygen and nitrogen (Fig. 2).

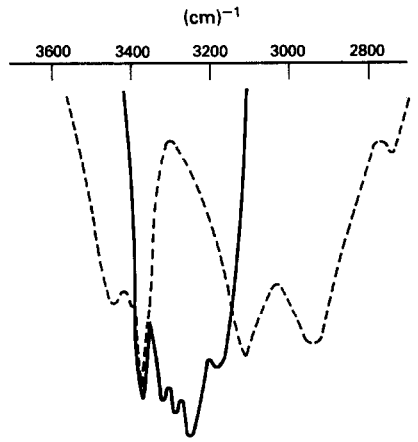


Fig. 1. IR spectra of: —— $Cu(Asn)_2$; --- $Asn\cdot H_2O$ (solid state in KBr, 3600–2800 cm^{-1}).

In the spectrum of the $[Cu(Asn)(OH)(H_2O)_2]$ complex (Table 5), the peak from the amide group remains at the unchanged position but it is broadened by the signal from H_2O (Fig. 3; compare with Fig. 1, where the amide and amine groups participate in coordination). The amine group of asparagine participates in the coordination (the peak from $—\overset{+}{N}H_3$ does not appear). The carboxyl group signal shifts, which indicates that the carboxyl group takes part in the complex formation and also the participation of both oxygens. The peak due to H_2O is located at higher frequencies than that ascribed to hydrated complexes, which indicates that water takes two positions in the metal's inner coordination sphere.[20,21]

The complex ions of DL-aspartic acid with copper were obtained as potassium and barium salts. In the IR spectrum of the complex $K_2[Cu(Asp)_2]\cdot 2H_2O$ in comparison with the spectrum of the ligand alone, a shift of the carboxyl group signal is observed. Thus, the coordination in this complex takes place through the oxygens of the carboxyl groups. The

amine group also participates in the coordination, which was also confirmed by the studies in the far-IR (Table 6). An identical method of coordination was observed for the complex $Ba[Cu(Asp)_2] \cdot 2H_2O$ (Table 6). The coordination has been found to take place in the $Ba[Cu(Asp)(OH)(H_2O)_2]_2$ complex through the oxygens of the carboxyl groups and through the amine group. The participation of water in the coordination has also been found (Table 6).

In the IR spectra of $Cu(Asn)_2$, $K_2[Cu(Asp)_2] \cdot 2H_2O$ and $Ba[Cu(Asp)_2] \cdot 2H_2O$ complexes two new peaks have been recorded in the far IR, although they were not observed in the spectra of the ligands (Fig. 2, Tables 5 and 6). These peaks are due to the formation of metal–nitrogen and metal–oxygen bonds. On the basis of the above data and the symmetry rules[20–23] it can be concluded that the double complexes yielded occur in the *trans* configuration. For the synthesis of the complexes, DL-asparagine and DL-aspartic acid were used. The results obtained for complexes of both ligands with Cu are in agreement with the previous obser-

vation[20,24] according to which the complexes formed from the racemic amino acids adopt a *trans* structure.

In the analysis of the structure of the complexes of asparagine with copper in aqueous solution and solid state, fundamental differences have been observed, particularly for complexes occurring in solution at pH = 5. In the case of asparagine, the amide and amine groups do not participate in the coordination in solution at such pH conditions, whereas their participation in the coordination is observed in the solid complex $Cu(Asn)_2$. In solution, where solvent molecules compete with the ligand, at pH = 5 the $—NH_3$ group does not participate in the coordination and the free place in the metal's coordination sphere is taken by a water molecule. The same is true of the amide group. In the solid state both groups participate in the coordination. The $Cu(Asn)_2$ complex was the only solid complex obtained in our studies that was weakly water-soluble. This weak solubility may be due to the coordination through the amide group. This conclusion is also supported by the fact that the other type of the isolated complexes, $[Cu(Asn)(OH)(H_2O)_2]$, where the amide group does not participate in the coordination, is characterized by very good solubility in water.

In complexes of aspartic acid, differences have also been observed for complexes in solution (at pH = 5) and solid state. In the complexes in solution, coordination through the amine group has not been detected, whereas in solid complexes coordination takes place by participation of the amine. An identical coordination in solution and in the solid state has been determined for hydroxo complexes. For both asparagine and aspartic acid the carboxyl and amine groups participate in the coordination. In all of the isolated solid complexes the coordination number is six. Differences in the structure of coordination compounds in the solid state and in solution that have been found in the present study point to the necessity of taking this fact into consideration when results concerning solids are to be employed to determine the coordination mode of complex compounds in solution. Problems of this type are often encountered in studies on coordination compounds of metal ions with biomolecules when one tries to obtain correct information on the role of the metal in living organisms. Accurate conclusions can only be drawn after conducting experiments with a full awareness of the possible errors.

ESR STUDY OF SOME COPPER(II) COORDINATION COMPOUNDS WITH SUBSTITUTED BIGUANIDINES—I

R. K. RAY

Department of Chemistry, Rama Krishna Mission Vivekananda Centenary College, Rahara-743186, 24-Parganas (North), West Bengal, India

(*Received* 21 *April* 1988; *accepted* 16 *June* 1988)

Abstract—Copper(II) complexes of substituted biguanides have been studied by ESR spectroscopy in water, in their polycrystalline form and in the corresponding nickel(II) complex matrix. In aqueous solution, nine nitrogen superfine lines on the higher field $3/2 \leftrightarrow 3/2$ copper hyperfine splitting component is indicative of four equivalent or nearly equivalent nitrogen atoms surrounding the copper(II) ion. α'^2 values indicate that like biguanide, 1-amidino-O-alkylureas, β-phthalocyanine and tetraphenylporphine, substituted biguanides and their protonated forms are equally strong-field ligands. The evaluation of the covalency parameters indicate that the unpaired electron of copper(II) spends about 36% of its time in the nitrogen donor sites of the ligands.

The structure of four-coordinated metal biguanide complexes has become a subject of varied interest. Based on chemical tests Ray and Saha[1] have suggested structure **I** (shown in Fig. 1) which was accepted by Kunchur and Mathew[2,3] after X-ray studies. From UV spectral data Sen[4] proposed another structure **II** (shown in Fig. 2) and from the NMR and X-ray diffraction pattern Creitz *et al.*[5] established structure **III** (shown in Fig. 3) for the bis(biguanide)nickel(II) chloride dihydrate.

The electron spin resonance (ESR) technique can be employed to detect the nature of the coordinating

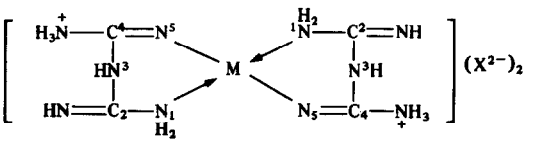

Fig. 1. Structures of bis(biguanide)metal(II) (M^{II} = Cu^{II}, Ni^{II}) halides (X = Cl, Br, I).

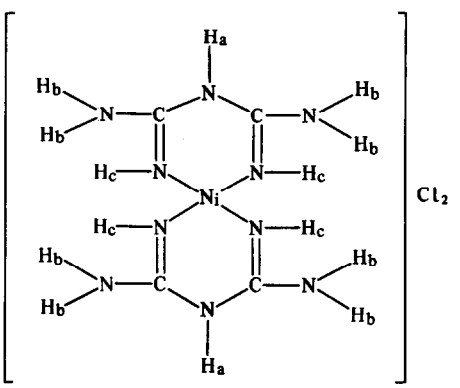

Fig. 3. Structure of bis(biguanide)nickel(II) chloride.

atoms in copper(II) complexes since the Spin Hamiltonian parameters obtained can be used to establish the metal–ligand bond nature. As few ESR studies of copper(II) biguanide complexes have appeared in the literature[6–8] and the bonding sites for the biguanide ligand are not unambiguous, we

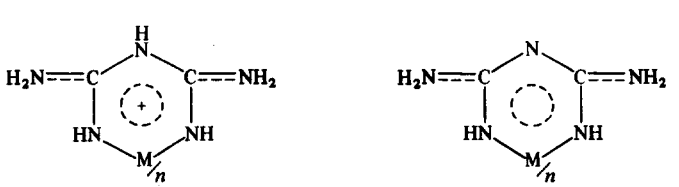

Fig. 2. (a) Biguanide complex. (b) Neutral metal biguanide complex.

undertook an investigation of the ESR and optical spectra of some copper(II) biguanide complexes in order to establish the extent of covalency in the metal–ligand interaction. While this work was in progress a brief ESR report of some copper(II) dibiguanide complexes was communicated.[9]

EXPERIMENTAL

Bis(substituted biguanide)copper(II) dichloride and bis(substituted biguanide)nickel(II) dichloride were prepared following published procedures.[1] Dehydration of $Cu(X\text{-}big)_2 \cdot nH_2O$ and $Ni(X\text{-}big)_2 \cdot nH_2O$ (X = CH_3-, C_2H_5-, etc., n = 1, 2, 3) was accomplished by heating the complexes *in vacuo* at about 70°C for 3 days. The stoichiometry of the complexes was confirmed by carbon, hydrogen, nitrogen and metal analyses.

Copper(II)-doped nickel $(X\text{-}big)_2$ was prepared by adding about 4% of $Cu(X\text{-}big)_2 \cdot 2.5H_2O$ to $Ni(X\text{-}big)_2 \cdot 3H_2O$ dispersed in 8 M aqueous sodium hydroxide. The mixture was well stirred, filtered, then washed with water and ethanol, air dried and finally dehydrated.

Electronic spectra (Nujol) were recorded by using a Cary 14 spectrophotometer at Wright State University, Dayton, OH, U.S.A., and ESR spectra were obtained on a Varian V4502-12X band spectrometer at the Instituto Chimico Policattedra, Universita di Cagliari, Italy.

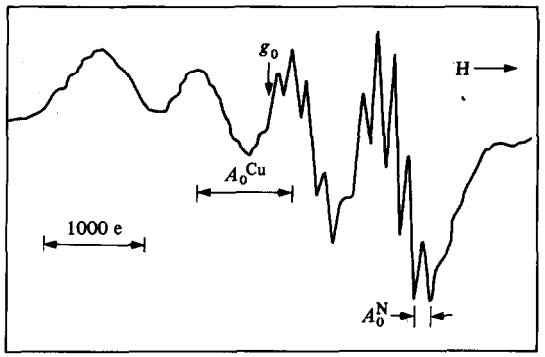

Fig. 4. Aqueous solution ESR spectrum of $[Cu(Me\text{-}bigH)_2]Cl_2$, frequency = 9.421 kMc.

RESULTS AND DISCUSSION

From the ESR spectrum, in aqueous media (Fig. 4), of bis(methyl biguanide)copper(II) chloride the average g-value (g_0), the isotropic hyperfine constant (A_0^{Cu}) and the isotropic ligand hyperfine structure constant (A_0^N) were determined. Other parameters $g_\parallel$, $g_\perp$, $A_\parallel^{Cu}$ and $A_\perp^{Cu}$ were measured from the anisotropic spectra of powdered magnetically dilute solids[10] (Fig. 5, Table 1). The ligand superfine structure components were observed but assignments of the components is not straightforward as the principal axes of the superfine tensor are not necessarily the same as those of the hyperfine tensor. The ESR spectra of all the complexes in solution show nine nitrogen super hyperfine com-

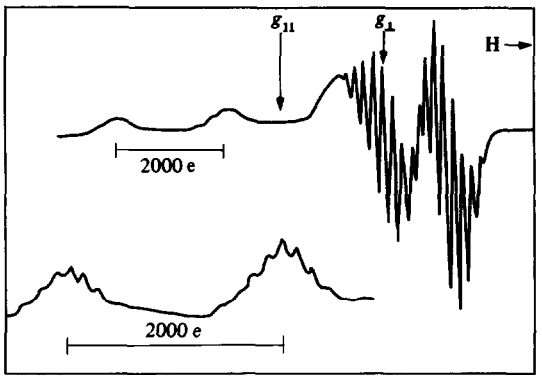

Fig. 5. ESR spectrum of $[Cu(Me\text{-}bigH)_2]Cl_2$ in $[Ni(Me\text{-}bigH)_2]Cl_2$: polycrystalline sample. In the lower left-hand side of the figure the low field $A_{\parallel}^{Cu}$ hyperfine components are shown enlarged by a factor of 10. Frequency = 9.518 kMc.

ponents indicating four equivalent or nearly equivalent nitrogen donor atoms surrounding the copper(II) ion with a $[CuN_4]$ chromophore. This is consistent with the single crystal X-ray studies.[2,3] These results are quite comparable to those of $[Cu(big)_2]$ and $[Cu(AMU)_2]$ (big-H = biguanide; AMUH = 1-amidino-O-methyl urea), both the ligands are strong field in character.[12,13] The electronic spectra of bis(ligand) copper(II) salts show typical absorption bands at 20,410 cm^{-1} in the solid state and at 19,230 cm^{-1} in aqueous medium which suggests a square planar $[CuN_4]$ chromophore.[14] Other square planar $[CuN_4]$ chromophores appear in bis(biguanide) copper(II) (19,230 cm^{-1} in water and 20,410 cm^{-1} in the solid state), bis(phenyl biguanide) copper(II) (18,200 cm^{-1} in water), (ethylene dibiguanide) copper(II) (19,230 cm^{-1} in water), bis(ethylene diamine) copper(II) (18,200 cm^{-1} in water), tetrakis(benzimidazole) copper(II) (19,000 cm^{-1}, solid phase).[15-18]

Taking into account the ESR spectral characteristics and the square-planar geometry as evidenced by the electronic spectra, one can consider that the copper(II) ion in these complexes is in a tetragonal field. The corresponding antibonding wave functions are[19-22]

$$\psi_{B1g} = \alpha d_{x^2-y^2} - \alpha'(-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_x^{(3)} - \sigma_y^{(4)})/2$$

$$\psi_{B2g} = \beta_1 d_{xy} - \beta_1'(p_y^{(1)} + p_x^{(2)} - p_y^{(3)} + p_x^{(4)})/2$$

$$\psi_{A1g} = \alpha_1 d_{z^2} - \alpha'(\sigma_x^{(1)} + \sigma_y^{(2)} - \sigma_x^{(3)} - \sigma_y^{(4)})/2$$

$$\psi_{E1g} = \begin{cases} \beta d_{xz} - \beta'(p_z^{(1)} - p_z^{(3)})/2^{1/2} \\ \beta d_{yz} - \beta'(p_z^{(2)} - p_z^{(4)})/2^{1/2}. \end{cases}$$

Where α, β_1 and β are the coefficients which express the covalent character of the σ-bonding in-plane and out-of-plane π-bonding, respectively and the other symbols have their usual significance. These coefficients can be obtained from the relations which connect them with the spin Hamiltonian parameters for the axial symmetry.[23-25]

$$g_{\parallel} = 2.0023 - \frac{8\lambda_0\alpha\beta_1}{\Delta E_{xy}} \times \left\{\alpha\beta_1 - \alpha'\beta_1 S - \alpha'(1-\beta_1^2)^{1/2}\frac{T(n)}{2}\right\}$$

$$g_{\perp} = 2.0023 - \frac{2\lambda_0\alpha\beta}{\Delta E_{xz}} \times \left\{\alpha\beta - \alpha'\beta S - \alpha'(1-\beta^2)^{1/2}\frac{T(n)}{\sqrt{2}}\right\}.$$

Where α and α' were obtained using nitrogen superfine splittings. λ_0 ($= -828$ cm^{-1}) is the spin–orbit coupling constant for the free copper(II) ion and $T(n)$ was set equal to 0.333.[22] ΔE_{xy} and ΔE_{xz} are the electronic transition energies $^2B_{2g} \leftarrow {}^2B_{1g}$ and $^2E_g \leftarrow {}^2B_{1g}$, respectively.

The σ bonding parameter $(\alpha_N')^2$ was calculated from A_0^N and used to calculate α_N^2 using $\alpha^2 - 2\alpha.\alpha' S + \alpha'^2 = 1$, where S ($= 0.093$) is the integral overlap.[22] $\alpha_N'^2$ ($= 0.36$) indicates that the unpaired electron spends about 36% of its time in the nitrogen donor sites of biguanide ligands. In Table 2, the $\alpha_N'^2$ values (roughly the measure of the extent of electron delocalization) show that both biguanide and substituted biguanide anions and their protonatd forms are strong field ligands and they are placed slightly below the CN^- ion in the spectrochemical series.[12]

The in-plane σ-covalency parameter α_{Cu}^2 was calculated using a simplified expression:[22]

$$\alpha_{Cu}^2 = \frac{-A_{\parallel}}{0.036} + (g_{\parallel} - 2.002) + \frac{3}{7}(g_{\perp} - 2.002) + 0.04.$$

The α_{Cu}^2 values (0.80–0.85) account for the fraction of the unpaired electron density located on the copper(II) ion. The reported α_{Cu}^2 values of copper(II)–β-phthalocyanine and tetraphenylporphine complexes are 0.80 and 0.82.[26,27]

In D_{4h} symmetry the g values for the copper(II) ion with the $^2B_{1g}$ ground state can be expressed[28,29] as

$$g_{\perp} = 2.002 - 2k_{\perp}^2\lambda_0/\Delta E_{xz}$$

and

$$g_{\parallel} = 2.002 - 8k_{\parallel}^2\lambda_0/\Delta E_{xy}$$

from which orbital reduction factor k and G values were evaluated using the relation

$$G = \frac{g_{\parallel} - 2.002}{g_{\perp} - 2.002} = \frac{4k_{\parallel}^2\Delta E_{xy}}{k_{\perp}^2\Delta E_{xz}}.$$

The G values for the present complexes are found

[Cu(AMU)$_2$]	Ni^{II} complex	3.26	0.50	0.71	0.35	0.69	0.81	0.70	1.05	20.41	23.53

to be less than 4 ($G = 2.92$–3.35) as expected for a non-ionic compound, which means the ligands under study are strong field in nature. The reported G values of tetraphenylporphine copper(II) and phthalocyanine copper(II) are 2.77 and 3.69, respectively.[26,27]

The in-plane and out-of-plane metal π-bonding coefficients β_1 and β are obtained from the expressions:[28,30]

$$\alpha^2\beta^2 \cong (g_{\perp} - 2.002)\Delta E_{xz}/1656\,\text{cm}^{-1}$$

$$\alpha^2\beta_1^2 \cong (g - 2.002)\Delta E_{xy}/6624\,\text{cm}^{-1}.$$

The uncertainty involved in the assignment of ΔE_{xz} and $g_{\perp}$ as obtained from polycrystalline samples[10,13] usually precludes a reliable estimate of the out-of-plane π-bonding parameter β^2. However, in cases where ΔE_{xz} are not known accurately, a 20% error in ΔE_{xz} values causes only about a 5% error in β.[22] Likewise, $\beta^2 = 1$ indicates total ionic character and $\beta^2 = 0.5$ a total covalent character of the in-plane π-bonding.[22] For the present complexes, $\beta^2 = 0.71$–0.77, indicating a pronounced covalent character.

METAL VAPOUR SYNTHESIS OF ZERO-VALENT NICKEL PHOSPHINE COMPLEXES AND THEIR CHARACTERIZATION BY ^{31}P NMR SPECTROSCOPY

KEITH J. FISHER and ELMER C. ALYEA*

Guelph-Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, Guelph, Ontario, Canada N1G 2W1

(*Received* 3 *May* 1988; *accepted* 21 *June* 1988)

Abstract—A series of $Ni[P(p\text{-}X\text{—}C_6H_4)_3]_4$ complexes has been synthesized by the cocondensation of Ni atoms with various solvents at 77 K, followed by warm-up to room temperature in the presence of the excess *para*-substituted triphenylphosphine. The complexes show a linear correlation between the coordination chemical shift, $\Delta\delta(^{31}P)$, and both the pK_a of the phosphine ligands and the Hammett sigma function of the *para*-substituent. The ditertiary phosphine complexes $Ni(Ph_2P(CH_2)_nPPh_2)_2$ ($n = 1$–4), also prepared by metal vapour synthesis, display the expected ^{31}P chemical shift "chelate ring" effect for the $n = 2$ case.

Zero-valent nickel complexes of phosphines and phosphites have been extensively studied.[1,2] General syntheses utilize displacement of an organic ligand such as cyclopentadiene or cyclooctadiene from its nickel complex or reduction of a nickel(II) complex with $NaBH_4$, AlR_3, Zn dust or excess ligand; however, the metal vapour technique has been employed for a few $Ni(PR_3)_4$ complexes.[3] The importance of steric effects in determining the exchange equilibria among phosphorus ligands in these complexes as well as the ease of substitution of CO from $Ni(CO)_4$ led Tolman to the cone angle concept for describing the bulk of phosphorus donor ligands.[4–6] Tolman observed that electronic effects strongly influenced the rate constants for ligand dissociation from $Ni(PR_3)_4$.[5]

In initiating metal vapour synthesis (MVS) in our laboratory, we have explored the experimental conditions for the formation of zero-valent nickel–phosphine complexes. Particular interest was focussed on *para*-substituted triarylphosphines to allow a correlation of ^{31}P chemical shifts for the $Ni[P(p\text{-}X\text{—}C_6H_4)_3]_4$ complexes with parameters that reflect the electronic effects of the *para*-substituent.

EXPERIMENTAL

A Torrovap MVS system was employed to cocondense nickel atoms with various solvents. Typically, *ca* 0.4 g of Ni were evaporated using the electron gun source and a pressure of less than 10^{-5} torr, with about 100 cm^3 of the solvent being codeposited on the inner wall of the 5 dm^3 rotating flask, which was immersed in a liquid dinitrogen bath. Following the cocondensation, normally requiring about 2 h, the reaction flask was allowed to warm until the matrix melted. The solvated metal solution was syphoned into a receiving flask held at 77 K. The flask was filled with dinitrogen and removed from the MVS system. All or portions of these solutions of solvated nickel atoms were reacted with excess phosphine ligands at various temperatures (see text) to produce the nickel(0) phosphine complexes.

All solvents were dried using standard procedures and degassed before use by freeze–pump–thaw cycles. Dinitrogen was dried and deoxygenated by passage over heated BTS catalyst. Samples for NMR spectral measurements were sealed in 10 mm tubes due to the dioxygen sensitivity of some of the complexes. ^{31}P NMR spectra were recorded at ambient temperature on a Bruker WH-400 spectrometer in the FT mode using 85% H_3PO_4 as external standard.

RESULTS AND DISCUSSION

As briefly mentioned in early MVS reports, $Ni(PR_3)_4$ complexes are readily prepared by cocondensing nickel atoms with various solvents at 77 K and adding excess phosphine ligands. Allowing for the loss of approximately 40% of the evaporated Ni atom that deposits on the electron focussing shield, conversion of solvated Ni atoms to $Ni(PR_3)_4$ is essentially quantitative if the phosphine ligands are added at or only slightly above 77 K. Suitable solvents used in our experiments included toluene, toluene/10% dimethoxyethane, acetone, methylcyclohexane and methylcyclohexane/20% dimethoxyethane. Of these solutions, only that of toluene/10% dimethoxyethane still showed the production of a small amount of $Ni(PR_3)_4$ when warmed to 253 K before addition of the phosphine ligand. Klabunde and coworkers[7] have shown earlier that toluene solutions of Ni atoms decompose to Ni metal if allowed to warm above 193 K. We observe that if Ni atoms are cocondensed with toluene containing norbornadiene the resultant brown, clear solution appears stable at room temperature, and reacts with dppe to give $Ni(dppe)_2$. The red solution obtained by codepositing Ni atoms with methylcyclohexane containing indene at 77 K is also stable at room temperature and does not react with PPh_3 or dppe. The nature of the solution species, probably $Ni(indene)_2$, is under further investigation. Similarly, we note that the dark brown solution obtained by evaporating Ni atoms into an acetone solution containing acetylacetone is stable at room temperature. Reaction of this solution occurs with both PPh_3 and dppe to give paramagnetic species of yet unknown structure; in the presence of dioxygen rather than phosphine, $Ni(acac)_2$ is isolated in 86% yield.

^{31}P NMR spectral data for the six $Ni[P(p\text{-}X\text{—}C_6H_5)_3]_4$ complexes prepared in this study by MVS are compiled in Table 1. Only $Ni[P(C_6H_5)_3]_4$ was studied previously, with Tolman[4] reporting that no detectable ^{31}P resonance was observed for a saturated solution of the complex in toluene, even with excess $P(C_6H_5)_3$ being added. This type of behaviour, with fast exchange and extensive dissociation according to the equation

$$NiL_4 \rightleftharpoons NiL_3 + L \qquad (1)$$

was later contrasted with that exhibited by other nickel(0) phosphine and phosphite complexes.[5] Our data, obtained in toluene solutions in the presence of excess phosphine, indicates that $Ni[P(C_6H_5)_3]_4$ shows an extreme in this type of behaviour. All of the other substituted phenylphosphine complexes give readily detected ^{31}P resonances even in the presence of only a slight excess of the phosphine.

A plot of the coordination chemical shift $\Delta\delta(\delta NiL_4 - \delta L)$ with the basicity of the phosphine, given by pK_a, is shown in Fig. 1 for the six com-

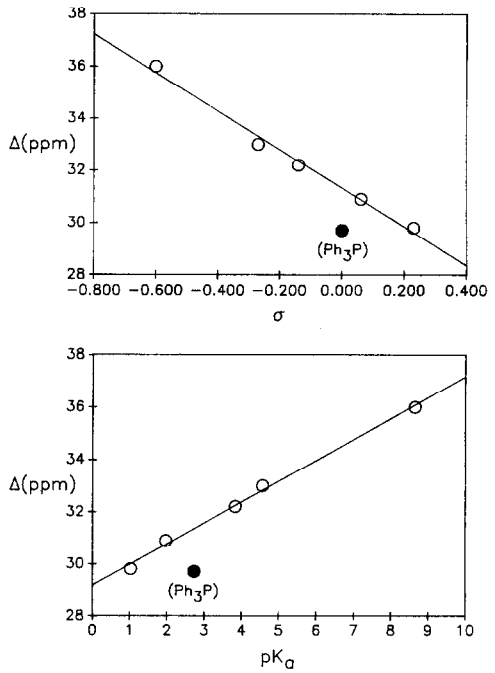

Fig. 1. Correlations of ^{31}P data with pK_a and σ_p for substituted triphenylphosphine nickel(0) complexes.

plexes; also shown is a plot of $\Delta\delta$ with the Hammett sigma function of the *para*-substituent on the phenyl group. Since the triarylphosphines are sterically similar ($\theta = 145°$),[6] the two correlations were expected to demonstrate the differing electronic properties of the ligands. As expected, a good correlation was found between increased $\Delta\delta$, i.e. more deshielding of P, and the increased basicity of the triarylphosphine. The departure of the data for $Ni[P(C_6H_5)_3]_4$ from the correlation is attributed to the greater rate of exchange and degree of dissociation, which would lead to a smaller $\Delta\delta$ due to an averaging of ^{31}P signals. The apparent lower dissociation for the $[p\text{-X—}C_6H_5)_3P$ (X = Cl, F) complexes is noteworthy and may be indicative of enhanced d_π–d_π Ni—P back-donation due to the electronegative substituents. Regardless of this possibility, what is nevertheless clear from our ^{31}P NMR data is that the chemical shifts observed for this series of $Ni[P(p\text{-X—}C_6H_5)_3]_4$ complexes directly reflect the σ-bonding ability of the substituted triarylphosphine ligands.

^{31}P NMR spectral data for the four $Ni[Ph_2P(CH_2)_nPPh_2]_2$ (n = 1–4) complexes prepared in this MVS study are given in Table 2. The $\Delta\delta$ values are near 30 ppm for three of the complexes (n = 1, 3 and 4), i.e. similar to those found for the $Ni[P(p\text{-X—}C_6H_5)_3]_4$ complexes as well as the closer analogue, $Ni(PMePh_2)_4$. The $Ni(dppe)_2$ complex, however, shows the expected anomalous behaviour well documented for ditertiary phosphine complexes having five-membered chelate rings.[8] The ring contribution in this case, by comparison to the chemical shift value for $Ni(PMePh_2)_4$, the closest monodentate analogue, is 36 ppm.

SYNTHESIS AND AIR STABILITY OF MIXED LIGAND LANTHANIDE ORGANOMETALLICS INVOLVING BOTH INDENYL AND CYCLOPENTADIENYL LIGANDS

ZHOU ZHENNAN,* WU ZHONGZHI, DU BAOHU and YE ZHONGWEN

Institute of Organic Chemistry, Anhui Normal University, Wuhu, China

(*Received* 3 *May* 1988; *accepted* 21 *June* 1988)

Abstract—By the reaction of Cp_2LnCl (Cp = C_5H_5; Ln = Sm, Dy, Ho, Er, Yb) with IndNa (Ind = C_9H_7), five new organolanthanides containing Cp and Ind groups have been synthesized. Comparing their air stability by exposure to air, we found these complexes were more stable in air than the corresponding Cp_3Ln, and their relative stability increased with a decrease of the metal ionic radii. All the complexes were characterized on the basis of their analytical and spectral data.

Tricyclopentadienyl and triindenyl organolanthanides have been presented previously in the literature,[1,2] but literature involving both cyclopentadienyl (Cp) and indenyl (Ind) mixed ligand organolanthanides have not been reported as yet. In this paper, we report the synthesis of five new mixed ligand organolanthanides by the following equation:

$$Cp_2LnCl + IndNa \xrightarrow[RT]{THF} Cp_2Ln(Ind)(THF) + NaCl$$

$$Ln = Sm^{I}, Dy^{II}, Ho^{III}, Er^{IV}, Yb^{V}.$$

These new complexes were characterized by elemental analysis (Table 1), IR (Table 2) and mass spectroscopy (Table 3), and their air stability was compared as follows.

RESULTS AND DISCUSSION

By the reaction of Cp_2LnCl (Ln = Sm, Dy, Ho, Er, Yb) with IndNa in THF at room temperature, five new organolanthanides have been synthesized. Elemental analysis data (Table 1) on all complexes were consistent with the formulation $Cp_2Ln(Ind)(THF)$. These complexes contained one solvated THF molecule which could not be removed under vacuum at room temperature. All the complexes were soluble in THF and ether but were only sparingly soluble in benzene, *n*-hexane and other hydrocarbon solvents.

Complexes I–V were characterized by IR and MS spectroscopy. All complexes in Table 2 exhibited a characteristic absorption of the aromatic C—H vibrations of C_5 and C_6 rings at 3000–3100 cm^{-1} and 700–850 cm^{-1}. In addition, an aliphatic C—H stretching vibration was observed between 2800 and 3000 cm^{-1}. This indicated the presence of a σ-metal-to-carbon bonding in all complexes.[3–5] In the mass spectra (see Table 3), the molecular ion peaks and main resulting ion fragment peaks were all shown. Based on the above results, we could clearly demonstrate that the five new mixed ligand organolanthanides were positively obtained. Since the metal–indenyl complexes[6–9] showed a remarkable similarity in structure to their cyclopentadienyl homologues, the structure of complexes I–V could not yet be elucidated from IR and MS.

Almost all the organolanthanides were sensitive to air and moisture. The coordinated unsaturation of the lanthanide complexes may be one of the important factors for their instability. Recently, the method of using bulky ligands to decrease the coordinated unsaturation of the organolanthanides has become favourable for the stabilization of lanthanide–carbon bonds.[10–12] The synthesis of the five new complexes reported in this paper could actually be regarded as substituting one Ind group for one Cp group of Cp_3Ln. Since the steric volume of the Ind group was bigger than the Cp group, the coordinated unsaturation of the new complexes decreased; the mixed ligand complexes should be

Table 1. Analytical and other physical data for complexes I–V

Complex		Colour	M.p. (°C)[a]	Yield (%)	Elemental analysis[b] %Ln	%C	%H
$Cp_2Sm(Ind)(THF)$	(I)	Yellow–orange	115	80	32.2 (32.6)	59.1 (58.8)	5.4 (5.5)
$Cp_2Dy(Ind)(THF)$	(II)	Pale yellow	112	45	33.9 (34.3)	57.6 (57.5)	5.3 (5.2)
$Cp_2Ho(Ind)(THF)$	(III)	Yellow	126	50	34.2 (34.5)	57.3 (57.2)	5.2 (5.4)
$Cp_2Er(Ind)(THF)$	(IV)	Pink	125	55	34.5 (34.4)	57.0 (56.8)	5.2 (5.3)
$Cp_2Yb(Ind)(THF)$	(V)	Deep green	200[c]	30	35.3 (35.2)	56.3 (56.1)	5.1 (5.5)

[a] Melting points were determined in sealed argon-filled capillaries.
[b] Elemental analysis results were obtained on a Yanaco-MT-2 analyser. The elemental analysis data for Ln were obtained by a published method.[3] Found values are given in parentheses.
[c] Decomposition temperature.

more stable than their corresponding homogeneous ligand complexes (Cp_3Ln).

In order to compare the stability of Cp_3Ln and Cp_2LnInd, five known complexes of Cp_3Ln (THF) of an identical metal were also synthesized according to the literature method.[1] The two different kinds of complexes (mixed and homogeneous) were exposed to air (temperature = 20°C, relative humidity = 78%). When their colour changed or major characteristic absorption peaks in the IR disappeared, it was considered an indication of the decomposition of the complexes. The exposure time recorded for the complexes to decompose was specified as a criterion for their relative stability.

We found that the order of their relative stability was

(i) $Cp_2LnInd > Cp_3Ln$,
(ii) $Cp_2YbInd > Cp_2ErInd > Cp_2HoInd > Cp_2DyInd > Cp_2SmInd$.

From the above order, it was obvious that:

(i) by replacing one Cp group from Cp_3Ln with an Ind group, the new complexes would be more stable.

Table 2. IR spectral data[a] for complexes I–V (4000–200 cm^{-1})

Complex		Main absorptions (cm^{-1})

$Cp_2Yb(Ind)(THF)$	(V)	3080(w), 3065(m), 2925(m), 2853(m), 1605(m), 1480(m), 1445(s), 1390(m), 1300(m), 1210(w), 1055(w), 1011(s), 914(m), 845(m), 777(s), 765(s), 724(s), 250(w).

[a] The IR spectra were recorded on a Perkin–Elmer 983(G) spectrometer as Nujol or fluorocarbon oil mulls.

Table 3. Mass spectra data[a] for complexes I–V

Complex		Main peaks (m/e)[b]
M=Cp_2Sm(Ind)(THF)	(I)	397(M—THF), 332(M—Cp—THF), 282(M—Ind—THF), 267(M—2Cp—THF), 152(Sm), 115(Ind), 72(THF), 65(Cp)
M=Cp_2Dy(Ind)(THF)	(II)	409(M—THF), 344(M—Cp—THF), 294(M—Ind—THF), 279(M—2Cp—THF), 164(Dy), 115(Ind), 72(THF), 65(Cp)
M=Cp_2Ho(Ind)(THF)	(III)	410(M—THF), 345(M—Cp—THF), 295(M—Ind—THF), 280(M—2Cp—THF), 165(Ho), 115(Ind), 72(THF), 65(Cp)
M=Cp_2Er(Ind)(THF)	(IV)	411(M—THF), 346(M—Cp—THF), 296(M—Ind—THF), 281(M—2Cp—THF), 166(Er), 115(Ind), 72(THF), 65(Cp)
M=Cp_2Yb(Ind)(THF)	(V)	419(M—THF), 354(M—Cp—THF), 304(M—Ind—THF), 289(M—2Cp—THF), 174(Yb), 115(Ind), 72(THF), 65(Cp)

[a] MS spectra were recorded on VG ZAB-HS mass spectrometer.
[b] MS data are given for the isotopes ^{152}Sm, ^{164}Dy, ^{165}Ho, ^{166}Er, ^{174}Yb, the peak patterns correspond to theoretical values based on the natural abundance of isotopes.

(ii) The air stability of these new complexes increased with decrease of the metal ionic radii. These results agreed well with our previous report.[13]

Based on the above conclusions, the method of using steric bulky ligands to stabilize the coordinated unsaturation complexes was usually successful.

EXPERIMENTAL

All operations were performed in an atmosphere of prepurified argon using Schlenk techniques or in a glove-box. All solvents were refluxed and distilled over blue sodium benzophenone or finely divided $LiAlH_4$ under argon immediately prior to use. The reactants, Cp_2LnCl[14] and IndNa,[2] were prepared according to the literature methods. Indene was distilled in a commercial reagent and the 182°C distillate was collected.

General method of the synthesis of complexes I–V

A 60 cm^3 THF solution of 3 mmol of Cp_2LnCl was placed in a Schlenk flask and an equivalent amount of sodium indenide was added. The reaction mixture was allowed to stir at room temperature for 24 h. After the NaCl was removed from the reaction mixture by centrifugation, the resulting solution was concentrated *in vacuo* to about 20 cm^3. By addition of 50 cm^3 of *n*-hexane, a solid precipitated out which was recrystallized twice from THF/*n*-hexane and was dried *in vacuo* to obtain the product.

Yields, analyses and physical properties of all five complexes are listed in Table 1.

SOME LANTHANIDE CHLORIDE COMPLEXES OF PYRIDINALDAZINE AND PYRROLALDAZINE SCHIFF BASES*

MAHMOUD M. DAWOD, FAWWAZ I. KHALILI and AFIF M. SEYAM†

Department of Chemistry, University of Jordan, Amman, Jordan

(*Received* 3 *May* 1988; *accepted* 21 *June* 1988)

Abstract—Lanthanide chloride complexes with pyridinaldazine (PAA) and pyrrolaldazine (PyAA-H_2): $[Ln(L)Cl_2(H_2O)_n]Cl \cdot mH_2O$, where Ln = Ce, Nd, Sm, Yb; L = PAA, PyAA-H_2; $n = 2, 4$; $m = 0, 1, 2, 3.5$, have been prepared by the reaction of the corresponding lanthanide chloride with PAA or PyAA-H_2 ($YbCl_3 \cdot 6H_2O$ with PyAA-H_2 gave the 2:1 complex, $[Yb_2(PyAA)Cl_4(H_2O)_4] \cdot 2H_2O$) and characterized by spectral data, electrical conductance, magnetic susceptibility, thermal and elemental analysis.

A variety of Schiff base complexes with trivalent lanthanides have been reported over the last few years.[1] Pyridinaldazine (PAA) has been shown to produce metal complexes with a variety of different stoichiometries.[2,3] While there is some information about transition metal complexes with PAA and PMK (2-pyridylmethylketazine),[3,4] little is known about lanthanide complexes with the PMK ligand.[5] In this paper we wish to report the synthesis and characterization of some lanthanide chloride complexes of PAA and PyAA-H_2.

EXPERIMENTAL

Physical and analytical measurements

Proton magnetic resonance (^{1}H NMR) spectra were recorded on a Varian T-60A spectrometer in methanol-d_4. Chemical shifts are reported relative to internal $Si(CH_3)_4$. IR spectra were recorded on a Perkin–Elmer (577) spectrometer as KBr discs or Nujol mulls pressed between two NaCl discs or two polyethylene sheets. Conductivity measurements were carried out using a 10^{-3} M solution in methanol on a Philips PW 9509 digital conductivity meter at 25°C. Magnetic susceptibility measurements were carried out using Evans' method[6] with methanol as a solvent. Diamagnetic corrections for the ligands were calculated using Pascal's constants. UV–vis. spectra were recorded on a Beckman Du-7 spectrophotometer. Thermogravimetric analyses (TGA) were recorded on a Mettler TG 10A TA processor using a Mettler TG-50 thermobalance. Microanalyses were performed by Dr Franz Pascher from the Ellen Pascher Microanalysis laboratory, Bonn, F.R.G. Metal analyses were determined by titration with EDTA[7] after decomposition of the sample with HNO_3. The titration method was confirmed by analyses of the metals as the corresponding oxide. Chloride was determined gravimetrically as AgCl.[8]

Materials and methods

All synthetic procedures were performed under a dinitrogen atmosphere in Schlenk-type glassware using normal benchtop Schlenk techniques,[9] or in a dinitrogen filled glove-box. Acetone (previously distilled over $CaCO_3$), diethyl ether, tetrahydrofuran (previously distilled from Na/K benzophenone), methanol (previously distilled over Mg) were used. Commercially obtained pyridine-2-carboxyaldehyde (Fluka) was purified as in the literature,[10] pyrrole-2-carboxyaldehyde (BDH) was purified by stirring over active carbon in methanol; $CeCl_3 \cdot 6H_2O$, $NdCl_3 \cdot 6H_2O$, $SmCl_3 \cdot 6H_2O$ (Fluka), $YbCl_3 \cdot 6H_2O$ (K & K) were used without further purification. The ligands PAA and PyAA-H_2 were prepared according to Stratton's method.[2]

The complexes were prepared by the following general procedure using the appropriate stoichiometries for the ligand and the metal salt.

[a] Starting temperature 45°C.

To a stirred solution of the metal salt (2.38 mmol) in a mixture of methanol–acetone (1 : 4), a solution of the ligand (2.38 mmol) in a mixture of methanol–diethyl ether (1 : 10) was added. The reaction mixture was stirred for 1 h in the case of PAA and overnight in the case of PyAA-H_2, to give the complex as a precipitate. The complex was filtered, recrystallized from a mixture of methanol–acetone–diethyl ether (1 : 3 : 5), washed with acetone and diethylether and dried *in vacuo* over P_4O_{10} at room temperature for three days.

RESULTS AND DISCUSSION

The new lanthanide complexes were synthesized by the reaction

$$LnCl_3 \cdot 6H_2O + L \longrightarrow [Ln(L)Cl_2(H_2O)_n]Cl \cdot mH_2O$$

where Ln = Ce, Nd, Sm, Yb; L = PAA, PyAA-H_2; n = 2,4; m = 0, 1, 2, 3.5. Work-up procedure involved filtration and crystallization; yields were generally high (60–73%). The complexes gave satisfactory analytical data (Table 1). The complexes are air-stable, hygroscopic, usually yellow coloured microcrystalline solids, soluble in methanol and ethanol, partially soluble in tetrahydrofuran and acetone, slightly soluble in diethyl ether but hydrolyzed in water. Elemental analysis show that the ratio of the metal-to-ligand in the complexes is 1 : 1 except in complex **VIII** where the ratio is 2 : 1.

Magnetic data (Table 1) indicate that these complexes have magnetic moments which are close to the theoretical values for the Ln^{3+} [11] and agree well with those for other lanthanide complexes.[12,13] They suggest that there is no metal–metal interaction or spin–spin coupling.

TGA data (Table 1) show that water of hydration is lost around 100°C and helps in assigning the number of water molecules of hydration in these complexes. Conductivity data (Table 2) show that these complexes behave as 1 : 1 electrolytes in methanol except for complex **VIII** which is a non-electrolyte.

^{1}H NMR (Table 2) of the complexes synthesized in this study show that the resonances are broad and shifted down field; this phenomenon is common in paramagnetic systems.[14] The presence of methanol in complex **III** was confirmed by ^{1}H NMR after hydrolyzing the complex in D_2O and a singlet at δ 3.3 ppm was observed which corresponds to methyl protons of methanol. Other complexes did not show any singlet corresponding to methyl protons of methanol after hydrolysis in D_2O.

UV–vis. data (Table 2) show that the electronic spectra of the complexes are dominated by ligand absorption bands with a hyperchromic effect. The domination of the ligand absorption bands could be related to the high absorption coefficient of the ligands as compared to the Ln^{3+} ions which masks any splitting of the band.[12]

IR spectroscopy is useful for probing the structure of Schiff base complexes.[3,4] IR data (Table 3) for the complexes **I**–**VII** show a distinct splitting of the C=N group stretching bands and of the ring breathing vibrational bands characteristic of the tridentate ligand. The ligand is coordinated through the nitrogens of the two rings and one nitrogen of the C=N groups. For complex **VIII**, the ring breathing region and the pyrrole N—H vibrational bands suggest that the ligand in this binuclear complex is coordinated in a tetradentate fashion as the

dianion, $PyAA^{2-}$. This is because of the smaller radius of Yb^{3+} in comparison to other lanthanides and the presence of a dinegative charge on $PyAA^{2-}$, that prefers a *trans, trans* configuration,[3] a dinuclear complex was formed. However, neutral PAA forms a mononuclear complex with Yb^{3+}.

Therefore, suggested formulae (Table 1), based on spectral data, electrical conductance, magnetic susceptibility, thermal and elemental analysis, show that, in complexes **I–IV**, **V–VII** and **VIII**, the coordination number is nine, seven and six, respectively, and this is expected for the lanthanides.[15]

(*Received* 24 *August* 1987; *accepted after revision* 4 *July* 1988)

Abstract—The preparation of the new phosphine–amine ligand $HN(CH_2CH_2CH_2PMe_2)_2$ via radical addition of dimethylphosphine to diallylamine is described. Some simple coordination chemistry with Ni, Pd and Pt is also reported.

The investigation of functionalized phosphines and their use to construct and stabilize polynuclear transition metal compounds has undergone significant development in recent years.[1,2] The unusual combination of class A and class B donor atoms in these ligands leads to interesting structural types and reactivity of their complexes, which is potentially useful, e.g. in homogeneous catalysis.[3] Potentially terdentate linear amine phosphine compounds containing tertiary alkyl phosphine functions are rare and there are only a few previous examples of complexes of such ligands.[4] Similar ligands containing aryl phosphine donors are scarcely better studied.[5] We herein describe the straightforward and direct synthesis of the new terdentate ligand $[(CH_3)_2PCH_2CH_2CH_2]_2NH$, (PNP), from diallylamine and dimethyl phosphine and its coordination behaviour with group VIII transition metals. We report the preparation and characterization of complexes $(MCl_2PNP)_n$, where M is nickel(II), palladium(II) and platinum(II).

EXPERIMENTAL

The phosphine ligand was prepared and handled under vacuum or inert atmospheres. All solvents were degassed by nitrogen purge or freeze–thaw cycles immediately prior to use. Dimethylphosphine[6] and Zeise's dimer $[PtCl_2(C_2H_4)]_2$[7] were prepared according to literature methods, other reagents were purchased and used as obtained. NMR spectra were recorded on a Bruker WM360 instrument operating at 360.13 (^1H), 90.53 (^{13}C) and 145.80 MHz (^{31}P). IR spectra were obtained with a Perkin–Elmer 783 spectrometer, electronic spectra with a Pye Unicam Lamda 5 spectrophotometer and magnetic susceptibility measurements were on a Johnson Matthey Equipment Magnetic Susceptibility Balance. Microanalyses were obtained within this department.

Preparation of PNP

Into a nitrogen filled stainless steel autoclave (300 cm^3) was placed diallylamine (10 g, 0.103 M.), dimethylphosphine (15.7 g, 0.253 M.), α,α′-azobisisobutyronitrile (25 mg) and hexane (120 cm^3). The autoclave was sealed and held at 100°C for 20 h. The resultant solution was transferred to distillation apparatus where the solvent and unreacted volatile materials were removed under reduced pressure. The product was distilled to yield PNP, 10.5 g (48%) as a colourless liquid (b.p. 95–100°C, 0.5 mm).

Preparation of $NiCl_2$(PNP)

To a solution of $NiCl_2 \cdot 6H_2O$ (474 mg, 2 mmol) in ethanol (15 cm^3) was added PNP (442 mg, 2 mmol) with stirring. The resulting red–brown solution was stirred for a further 6 h. Ethanol was removed *in vacuo*, the residue was extracted into dichloromethane (20 cm^3), filtered and evaporated to dryness yielding a purple powder that was washed with hexane (20 cm^3) and diethylether (20 cm^3) and dried *in vacuo*. The yield was essentially quantitative.

*Author to whom correspondence should be addressed.

Preparation of [$PdCl_2$(PNP)]

To a solution of Na_2PdCl_4 (596 mg, 2 mmol) in ethanol (20 cm^3) was added PNP (442 mg, 2 mmol) with stirring. After 2 h, the yellow solution was evaporated to dryness and the yellow residue extracted into dichloromethane (20 cm^3), filtered and evaporated *in vacuo*. The yellow powder was washed with hexane (20 cm^3), diethylether (20 cm^3) and dried *in vacuo*. The yield was quantitative.

Preparation of [$PtCl_2$(PNP)]

To a solution of $[PtCl_2(CH_2{=}CH_2)]_2$ (294 mg, 0.5 mmol) in dichloromethane (25 cm^3) was added PNP (221 mg, 1 mmol) and the solution stirred for 12 h. The solvent was removed *in vacuo* and the residue extracted into ethanol (20 cm^3), filtered to remove traces of unreacted starting material and evaporated to dryness. The white powder was washed with hexane (20 cm^3) and dried *in vacuo*. The yield was essentially quantitative.

RESULTS AND DISCUSSION

Ligand synthesis

The synthesis of PNP relies on the ready addition of P—H functions across C=C double bonds. There are numerous reports of P—H addition to allylic phosphines[8] such that this is an established method for the preparation of oligophosphines. Similarly allylamine has been coupled with diphenylphosphine to yield $Ph_2P(CH_2)_3NH_2$.[9] We have extended this approach to the addition of two mole equivalents of dimethylphosphine to diallylamine catalysed by AIBN. The reaction requires a significant excess of $HPMe_2$ in order to maximize formation of the desired product. If less $HPMe_2$ is used, significant proportions of the lower boiling monophosphine $Me_2PCH_2CH_2N(H)C_3H_5$ (as determined by ^1H NMR) may be isolated. Polymerization does not appear to compete with product formation at any appreciable rate when the reaction is performed in hydrocarbon solvent, since very little residue is left upon distillation of the diphosphine. The yield of the reaction compares favourably with yields reported for similar reactions.[8,9] The diphosphineamine ligand is effectively characterized by elemental analysis, Table 1, and IR and NMR spectroscopies, Table 2.

Complex formation

When PNP is added to ethanolic solutions of $NiCl_2 \cdot 6H_2O$ and Na_2PdCl_4, a dichloromethane solution of $(Cl_2PtC_2H_4)_2$ complex formation occurs and powders may be isolated in each case. Since the compounds have not been obtained crystalline, purification is by washing only. However, elemental analyses correspond well to the formula MCl_2(PNP) (M = Ni, Pd, Pt). Analytical data for the complexes are summarized in Table 1.

The conductance data indicate that the complexes behave as non-electrolytes in dichloromethane. The poor solubilities of the complexes in suitable solvents precludes the determination of molecular weights by cryoscopy.

Of interest are comparisons of the X-ray powder photographs of these complexes. The patterns for the nickel and palladium complexes are virtually identical to each other but very different to that for the platinum complex. Thus, the nickel complex appears isostructural with the palladium complex, but not with the platinum complex. Since the purple

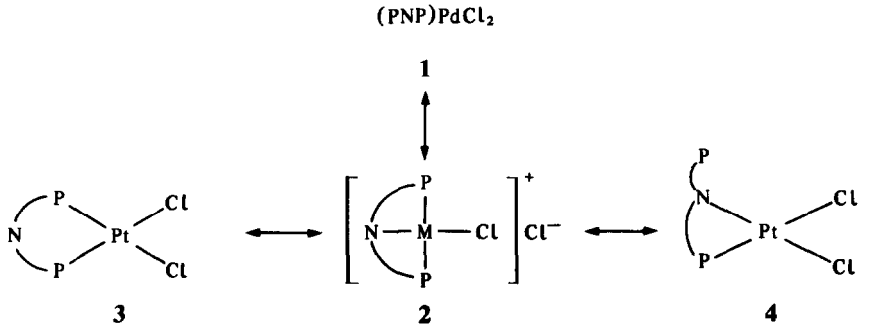
[b] IR: neat for PNP, in Nujol for Pd^{II}, Ni^{II} and Pt^{II} complexes.

nickel(II) complex is paramagnetic and a non-electrolyte in solution, a square-planar configuration at the metal is precluded. A five-coordinate structure would be consistent with the data since similar magnetic and spectral (electronic) properties have been reported previously for NP_2X_2 (X = halide) donor sets.[10] Five coordination for palladium is also precedented, although in our case conductance measurements indicate the compound to be essentially a non-electrolyte in dichloromethane but a weak electrolyte in nitromethane. Again, this behaviour has previously been reported for similar complexes[10] and may be interpreted in terms of an equilibrium between five-coordinate **1** and a square-planar cation **2** as indicated in Scheme 1.

The bonding in the Pd and Pt compounds may be inferred from a combination of $^{31}P[^1H]$, $^{13}C[^1H]$, ^1H NMR and IR spectroscopies (Table 2). Coordination of phosphorus to Pd^{II} and Pt^{II} commonly results in a downfield shift of between 10–50 ppm in the $^{31}P[^1H]$ NMR. Both the spectra display two broad singlets due to coordinated phosphorus atoms and may be due to fluxional processes involving exchange of free for coordinated phosphorus and/or displacement of nitrogen by free phosphorus as indicated in Scheme 1. The platinum complex is presumably square-planar. The intermediate values of conductance in nitromethane again indicate a possible equilibrium between structures **3** or possibly **4** and the cation **2** as shown in Scheme 1. The two resonances in the ^{31}P NMR spectrum of this compound are presumably indicative of a slow exchange (on the NMR timescale) between two of the proposed structures, most likely **2** and **3** since no resonance due to an uncoordinated phosphine is observed.



Scheme 1. Possible structures and solution behaviour for the palladium and platinum complexes. In **2**, M = Pd, Pt. $\frown$ = $-(CH_2)_3-$.

Abstract—Polyoxomolybdates, monomeric chelated(O,O) oxomolybdenum(VI) and monomeric halogenooxomolybdenum(V) complexes reacted in alcohols with phenylhydrazine to yield dinuclear complexes of the following formulae noted (**1**), (**2**), (**3**), and (**4**): $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(C_6H_5CONHO)\}_2]$, $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(OR)(C_6H_5NHNH_2)\}_2]$, $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OR)(C_6H_5NHNH_2)\}_2]$ and $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_2H_5)(C_2H_5OH)\}_2]$; **a**: R = CH_3; **b**: R = C_2H_5; **c**: R = C_3H_7. **1b** crystallized in the triclinic space group $P\bar{1}$ $a = 9.728(3)$, $b = 11.154(1)$, $c = 12.720(2)$ Å, $\alpha = 97.92(1)°$, $\beta = 106.40(2)°$, $\gamma = 106.56(2)°$, $V = 1233$ Å^3, $Z = 1$. Refinement was based on 2549 reflections and converged at $R = 0.06$. **2a** crystallized in the monoclinic space group $P2_1/n$, $a = 11.404(2)$, $b = 11.998(1)$, $c = 16.778(4)$ Å, $\beta = 108.56(1)°$, $V = 2176$ Å^3, $Z = 2$. Refinement was based on 2481 reflections and converged at $R = 0.024$. Mixed crystals containing **2a** and **3a** in the same unit cell (70:30) are isomorphous with **2a**, $a = 11.443(3)$, $b = 11.826(4)$, $c = 16.785(4)$ Å, $\beta = 108.45(2)°$, $V = 2155$ Å^3, $Z = 2$. Refinement was based on 2623 reflections and converged at $R = 0.049$. **3c** crystallized in the triclinic space group $P\bar{1}$, $a = 9.534(3)$, $b = 12.057(2)$, $c = 12.751(3)$ Å, $\alpha = 98.90(1)°$, $\beta = 96.37(2)°$, $\gamma = 112.50(2)°$, $V = 1314$ Å^3, $Z = 1$. Refinement was based on 1615 reflections and converged at $R = 0.053$. **4** crystallized in the monoclinic space group $C2/m$, $a = 10.495(3)$, $b = 18.792(4)$, $c = 11.115(3)$ Å, $\beta = 101.91(1)°$, $V = 2145$ Å^3, $Z = 2$. Refinement was based on 1238 reflections and converged at $R = 0.055$. All these structures consist of discrete dinuclear units containing *cis*-bisdiazenido moieties $[Mo(C_6H_5N_2)_2]^{2+}$ bridged by two alkoxo groups. Molybdenum achieves six coordination either with a chelating bidentate ligand as in **1** or with two unidentate ligands as in **2**, **3** and **4**. A unique feature of **2** and **3** is the occurrence of phenylhydrazine and phenyldiazenido in the same coordination sphere.

*Authors to whom correspondence should be addressed.

In view of the perceived analogies of isopolymetalates to metal oxide surfaces, the coordination chemistry of these species with small organic molecules is of current interest.[1] A number of organooxygen[2] and organonitrogen[3] derivatives of high valent polyoxomolybdates are known for which we have a continued interest. Zubieta *et al.* have recently reported the reaction of isopolymolybdates with phenylhydrazine yielding tetranuclear, hexanuclear, or octanuclear species, depending on reaction conditions.[4] Jeannin and co-workers have reported the reactions of $[MoO_2(acac)_2]$ with phenylhydrazine and acetamidoxime yielding, respectively, a dinuclear bis(phenyldiazenido)molybdenum complex[5] and a nitrosylmolybdenum(II) complex.[6] We report here the reactions of phenylhydrazine with various Mo^{VI} and Mo^{V} oxo complexes yielding dinuclear bis(phenyldiazenido)molybdenum complexes of the following types: $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(C_6H_5CONHO)\}_2]$, (**1**); $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(OR)(C_6H_5NHNH_2)\}_2]$, (**2**); $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OR)(C_6H_5NHNH_2)\}_2]$, (**3**); $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_2H_5)(C_2H_5OH)\}_2]$, (**4**); **a**: R = CH_3; **b**: R = C_2H_5; **c**: R = C_3H_7. The synthesis and the X-ray structure of one of these complexes (**2a**) were recently reported by Zubieta *et al.*[7]

EXPERIMENTAL

Materials

Acetylacetone, benzohydroxamic acid and phenylhydrazine are commercially available. $(NBu_4)_2[Mo_6O_{19}]$,[8] α-$(NBu_4)_4[Mo_8O_{26}]$[9] and $[MoO_2(acac)_2]$[10] were prepared according to literature procedures. $(NEt_4)[MoOCl_4(H_2O)]$ and $(NH_4)_2[MoOBr_5]$ were prepared by reducing MoO_4^{2-} in concentrated hydrochloric or hydrobromic acid and adding $(NEt_4)Cl$ or NH_4Br.[11] $[MoO_2(C_6H_5CONHO)_2]\cdot CH_3OH$ was prepared from $[MoO_2(acac)_2]$ and PhCONHOH following a general procedure described by Murray and coworkers.[12]

Synthesis of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OEt)(C_6H_5CONHO)\}_2]$ (**1b**)

$[MoO_2(C_6H_5CONHO)_2]\cdot CH_3OH$ (0.40 g, 0.92 mmol) was dissolved in C_2H_5OH (10 cm^3) and $C_6H_5NHNH_2$ (0.5 cm^3, 5.1 mmol) was added. A deep purple colour developed immediately and dark violet microcrystals of $[\{Mo(C_6N_2)_2(\mu\text{-}OC_2H_5)(C_6H_5CONHO)\}_2]\cdot 2C_2H_5OH$ (**1b**) began to deposit within 1 h. They were filtered off after 12 h, washed with C_2H_5OH and air dried. Yield: 0.35 g (71%). Found; C, 51.4; H, 4.8; N, 13.3. Calc. for $C_{46}H_{54}N_{10}Mo_2O_8$: C, 51.8; H, 5.1; N. 13.1%. The crystallization was slower when the reactant concentrations were lowered but keeping the same $C_6H_5NHNH_2$/Mo ratio; crystals of a suitable size for X-ray work were obtained in this way. $[\{Mo(C_6H_5N_2)(\mu\text{-}OCH_3)(C_6H_5CONHO)\}_2]\cdot 2CH_3OH$ (**1a**) was prepared similarly to **1b** but with CH_3OH. Found: C, 49.8; H, 4.5; N, 14.1. Calc. for $C_{42}H_{46}N_{10}Mo_2O_8$: C, 49.9; H, 4.6; N, 13.9%.

Synthesis of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OCH_3)(OCH_3)(C_6H_5NHNH_2)\}_2]$ (**2a**)

The preparation of **2a** has been given by Hsieh and Zubieta.[7] Two other methods are reported hereunder.

Method 1. From $(NBu_4)_4[Mo_8O_{26}]$ *or* $(NBu_4)_2[Mo_6O_{19}]$. A large excess of $C_6H_5NHNH_2$ (20 cm^3, 0.20 mol) was added to $(NBu_4)_4[Mo_8O_{26}]$ (1.1 g, 0.5 mmol) in MeOH (50 cm^3). The resulting mixture was stirred at room temperature for 15 min during which time all the solid dissolved, and a purple–red colour developed. Well-shaped purple–black crystals of **2a** separated upon standing. The crystals were filtered off after 3 days, washed with CH_3OH and air-dried. Successive crops were collected over a period of 10 weeks. Yield: 1.2 g (62%, based on Mo). Found: C, 50.4; H, 5.1; N, 17.6; Mo, 19.6. Calc. for $C_{40}H_{48}N_{12}Mo_2O_4$: C, 50.4; H, 5.1; N, 17.6; Mo, 20.1%.

The reaction of $(NBu_4)_2[Mo_6O_{19}]$ (0.5 g, 0.36 mmol) with various amounts of $C_6H_5NHNH_2$ (from 0.15 cm^3 up to 10 cm^3) in CH_3OH (25 cm^3) was also studied at room temperature. A crystalline precipitate was formed within a few days. Its chemical analysis and IR spectroscopic study showed that pure $(NBu_4)_2[Mo_4O_8(OCH_3)_2(C_6H_5N_2)_4]$ was obtained for low $C_6H_5NHNH_2$/Mo ratios while essentially pure **2a** separated for high ratios. Mixtures of these two diazenido complexes were obtained for intermediate cases.

Method 2. From $[MoO_2(acac)_2]$. This synthesis was analogous to that used for $[\{Mo(C_6H_5N_2)_2(acac)(\mu\text{-}OCH_3)\}_2]$[5] but a larger $C_6H_5NHNH_2$/Mo ratio was used: 10 cm^3 of $C_6H_5NHNH_2$ and 0.65 g (2 mmol) of $[MoO_2(acac)_2]$ in 40 cm^3 of CH_3OH. The product collected after 2 days was spectroscopically identical with that obtained from method 1. Yield: 0.3 g, 31%.

Synthesis of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OC_2H_5)(OC_2H_5)(C_6H_5NHNH_2)\}_2]$ (**2b**)

An excess of $C_6H_5NHNH_2$ (5 cm^3, 51 mmol) was added to $(NH_4)_2[MoOBr_5]$ (1.1 g, 2 mmol) in

C_2H_5OH (100 cm^3) and the mixture was stirred at room temperature for 15 min. The colour changed from red–brown to purple–red and **2b**, purple–black crystals, slowly separated upon standing. Yield: 0.8 g, 79%. Found: C, 51.8; H, 5.6; N, 16.5. Calc. for $C_{44}H_{56}N_{12}Mo_2O_4$: C, 52.4; H, 5.6; N, 16.7%.

Synthesis of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OC_3H_7)(OC_3H_7)(C_6H_5NHNH_2)\}_2]$ **(2c)**

This synthesis was performed analogously to method 2 for **2a**. A large excess of $C_6H_5NHNH_2$ (20 cm^3) was added to $[MoO_2(acac)_2]$ (0.65 g, 2 mmol) in 1-propanol (25 cm^3) and the mixture was stirred for 10 min at room temperature. A dark purple crystalline solid began to deposit after several weeks; it was filtered off after 3 months and washed with 1-propanol and ether. Yield: 0.55 g, 52%. Found; C, 54.2; H, 6.1; N, 15.6. Calc. for $C_{48}H_{64}N_{12}Mo_2O_4$; C, 54.1; H, 6.1; N, 15.8%.

Synthesis of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OR)(C_6H_5NHNH_2)\}_2]$ (**3a**: R = CH_3; **3b**: R = C_2H_5)

$C_6H_5NHNH_2$ (5 cm^3, 51 mmol) was added to $(NEt_4)[MoOCl_4(H_2O)]$ (1 g, 2.5 mmol) and the mixture was refluxed for 1 h. The resulting purple suspension was filtered and the filtrate was allowed to stand at room temperature yielding single crystals within 2 days. The IR spectra of the precipitate and of crystals were nearly identical and both samples were shown to be mixtures of **2a** and **3a**. Moreover it was shown by X-ray diffraction that **2a** and **3a** actually form mixed crystals, i.e. the unit cell contains both **2a** and **3a**. Analysis of a crystalline sample calculated for a mixture of 65% of $C_{40}H_{48}N_{12}Mo_2O_4$ and 35% of $C_{38}H_{42}N_{12}Cl_2Mo_2O_2$: C, 49.4; H, 4.8; N, 17.6; Cl, 2.6; Mo, 20.1. Found: C, 48.7; H, 4.8; N, 178.6; Cl, 2.6; Mo. 20.0%. This ratio was suggested by the chemical analysis and by the X-ray structure determination. Similar results were obtained if the whole reaction was carried out at room temperature.

Attempts to prepare **3b** similarly by the reaction of $C_6H_5NHNH_2$ with $(NEt_4)[MoOCl_4(H_2O)]$ in C_2H_5OH either at room temperature or under reflux yielded mixtures of **2b** and **3b**.

Synthesis of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OC_3H_7)(Cl)(C_6H_5NHNH_2)\}_2]\cdot 2C_3H_7OH$ **(3c)**

The synthesis was performed following a modification of the method used for **3a** and **3b**. $C_6H_5NHNH_2$ (4 cm^3) was added to $(NEt_4)[MoOCl_4(H_2O)]$ (0.5 g) suspended in 1-propanol (50 cm^3). The resulting mixture was stirred at room temperature for 5 h; the solution was purple and a grey–white precipitate separated. It was filtered off and was identified as $C_6H_5NHNH_2HCl$ by IR spectroscopy. Large dark purple needles were recovered from the mother solution after standing for 48 h at room temperature. Yield: 0.28 g, 39%. Found: C, 51.1; H, 5.4; N, 15.1; Cl, 5.9; Mo, 17.0. Calc. for $C_{48}H_{66}N_{12}Cl_2Mo_2O_4$: C, 50.7; H, 5.8; N, 14.8; Cl, 6.2; Mo, 16.9%.

Synthesis of $[\{Mo(C_6H_5N_2)_2Cl)(\mu\text{-}OEt)(EtOH)\}_2]$ **(4)**

$(NBu_4)_2[Mo_4O_8(C_6H_5N_2)_4]$[4a] (1.0 g, 0.66 mmol) was dissolved in CH_3CN/CH_2Cl_2 (10 cm^3/10 cm^3) and an excess of 12 N HCl (0.5 cm^3, 6.0 mmol) was added. Dark violet crystals of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OEt)(EtOH)\}_2]$ **(4)** deposited after standing for 3 weeks at room temperature. Yield: 0.39 g (74%). Found: C, 48.1; H, 5.1; N, 13.8. Calc. for $C_{32}H_{42}N_8Cl_2Mo_2O_4$: C, 48.4; H, 5.3; N, 14.1%.

X-ray structures

Crystals were mounted on glass fibers with epoxy cement and were studied by precession and Weissenberg methods. Cell constants and data collection were measured at room temperature with Mo-K_α radiation (λ = 0.71069 Å) on an Enraf–Nonius CAD4 diffractometer equipped with a graphite monochromator. Unit cell dimensions were determined by a least-squares fit of the setting angles of 25 reflections. Data were corrected for Lorentz and polarization effects and an empirical absorption correction based upon Ψ-scan was applied. Structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares using CRYSTALS program package.[13] Neutral atom form factors including anomalous dispersion were taken from *International Tables*.[14] Extinction was corrected. Crystallographic data are summarized in Table 1. Only specific points are quoted below for each case.

1b—Hydrogen atoms were included in refinement as fixed contributions. Carbon and oxygen atoms of the solvent molecule were constrained with the usual bond distances and with an overall isotropic thermal parameter; solvent hydrogen atoms were omitted.

2a—This structure was solved first by Hsieh and Zubieta[7] and independently by Jeannin and coworkers. Results are in agreement.

Mixed crystals of **2a** and **3a**—During refinement, it became apparent that the coordination site *trans* to $C_6H_5NHNH_2$ was disordered, being occupied either by a methoxo group or by a chlorine atom,

indicating mixed crystals; occupancy factors converged to 0.72 and 0.31, and were fixed at 0.7 and 0.3 in the final refinement. Hydrogen atoms were located on a difference Fourier map and all but five were refined with an overall isotropic thermal parameter. Only the hydrogen atoms of the terminal OCH_3 groups were omitted.

3c—The centrosymmetric dinuclear unit $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_3H_7)(C_6H_5NHNH_2)\}_2]$ was easily located and refined; however refinement revealed high thermal motion with temperature factors ranging from 5 Å^2 for molybdenum up to 22 Å^2 for the terminal carbon atom of the propanolato bridge which contains an unusually short C—C distance. This could arise from disorder or from departure from centrosymmetry. Attempts to refine in non-centrosymmetric $P1$ space group were not successful. The propanolato bridge was loosely constrained in further refinement. Hydrogen atoms were included as fixed contributions. Then at this stage, a difference Fourier series revealed weak diffuse residual peaks located around the inversion centre (1/2, 1/2, 1/2) suggesting the presence of solvent. The disorder was not solved. The best decrease of R was obtained with six carbon atoms introduced with 0.5 occupancy so that R dropped from 8.5 to 5.3. Despite these difficulties the structure of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_3H_7)(C_6H_5NHNH_2)\}_2]$ seems reliable in view of its comparison with those of **2a**, **3a** and **4**.

4—The general conditions of data collection and the methodologies used in this structure were similar to those employed for structures **1b**–**3a**, except that data were collected on a Nicolet R3m diffractometer and the SHELXTL[13b] program package was used in the structure solution and refinement. The choice of the centric space group $C2/m$ yielded a centrosymmetric binuclear unit $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_2H_5)(C_2H_5OH\}_2]$ with the Mo, Cl, O(2), and C(3) atoms located on the mirror plane through $y = 0$. The oxygen atom O(1) and the methylene carbon C(1) of the bridging ethoxy group are located on the two-fold axis through $x = 0.5$, $z = 0.5$. As a consequence of this disposition of the binuclear unit, C(4) of the terminal ethoxy group is disordered about the mirror plane while C(2) of the bridging ethoxo group is disordered about the two-fold axis. Refinement in the acentric space group $C2$ produced no significant improvement in the residuals and resulted in temperature factors of 18–21 Å^2 for the terminal carbon atoms. The centric alternative $C2/m$ was assumed to be the correct choice.

Atomic positional and thermal parameters for **1b**, **2a**, mixed **2a**–**3a**, **3c** and **4**, and complete listings of bond angles and distances are available as supplementary material and from authors. Selected interatomic distances and bond angles showing a comparison between those five compounds are listed in Table 2.

Spectral measurements

IR spectra were determind as KBr or RbI pellets with a Perkin–Elmer 597 spectrophotometer. Absorption spectra were obtained with a Beckman 5240 spectrophotometer.

RESULTS AND DISCUSSION

Some general trends of the reaction of phenylhydrazine with Mo^{VI} oxo-compounds can be inferred from our synthetic work and from the work of other groups,[15,16] although reaction conditions are not strictly identical since phenylhydrazine hydrochloride was sometimes used by other groups and triethylamine was sometimes added to the reaction mixture:

—the main products of $C_6H_5NHNH_2$ reaction with polyoxomolybdates in alcohols are the tetranuclear species, $[Mo_4O_8(OR)_2(C_6H_5N_2)_4]^{2-}$,[4a] and dinuclear compounds, $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(OR)(C_6H_5NHNH_2)\}_2]$, depending on the $C_6H_5NHNH_2$/Mo ratio; aside from these compounds two complexes with different stoichiometries, $[Mo_8O_{26}(C_6H_5N_2)_6]^{4-}$[4d] and $[Mo_4O_{10}(OCH_3)_2(C_6H_5N_2)_2]^{2-}$[4c] have been characterized by Zubieta and co-workers;

—the reaction of $C_6H_5NHNH_2$ with $[MoO_2L_2]$ complexes yields dinuclear species $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)L\}_2]$ or $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OR)(C_6H_5NHNH_2)\}_2]$ when L is an (O,O)-chelate; this contrasts with the behaviour of (N,O)-, (N,S)-, and (S,S)-chelates which yield mononuclear $[Mo(C_6H_5N_2)_2L_2]$ complexes.[15,16] Compounds **1** are only slightly soluble in common solvents. Complexes **2** and **3** are more soluble, especially in chlorohydrocarbon solvents, but these solutions were found to be relatively unstable, even if dry solvents were used.

The IR spectra of complexes **1**, **2**, **3** and **4** show the characteristic pattern of singly-bent diazenido ligands in the range 1480–1650 cm^{-1}.[4a,15c,17,18] The visible absorption spectra of these complexes in solution are characterized by an intense band at *ca* 520 nm ($\varepsilon = 8 \times 10^{-4}$ mol^{-1} dm^3 cm^{-1} per Mo). These features are typical of the *cis*-$[Mo(C_6H_5N_2)_2]^{2+}$ unit.[4a]

The IR spectra of **2** and **3** show weak bands at 3220 and 3380 cm^{-1} assigned to ν(N—H). However, clear characterization of the hydrazine ligand by ^{1}H NMR in $CDCl_3$ was hampered by

rather low solubility and by some instability of the solutions as mentioned above.

The IR spectrum of **3** shows a band at *ca* 290 cm^{-1} which is not present in the spectrum of **2** and is therefore assigned to stretching ν(Mo—Cl) consistently with published data.[19]

The molecular structures of the centrosymmetrical dinuclear complexes of **1b**, **2a**, **3a**, **3c** and **4** are shown in Figs 1, 2, 3, 4 and 5. All complexes contain the $[\{MO(C_6H_5N_2)_2(\mu\text{-}OR)\}_2]^{2+}$ unit which has already been found in a number of compounds.[4a,5] In this unit, the molybdenum atom is ligated to two bridging alkoxo and two phenyldiazenido groups; it achieves six coordination either by a chelating bidentate ligand as in **1**, or by two unidentate ligands as in **2**, **3** and **4**. In the first case, the geometry around molybdenum is forced by the chelate ring. In the second case, two different geometries are conceivable according to whether the unidentate ligands are mutually *cis* or *trans*. However, only the latter has been ever found. As a consequence of the *trans* influence of the phenyldiazenido, the bridge is dissymmetrical for **1** while it is nearly symmetrical for **2** and **3**.

The overall geometry of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OC_2H_5)(C_6H_5CONHO)\}_2]$ is similar to that of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OCH_3)(acac)\}_2]$ while those of complexes **2**, **3** and **4** are similar. In **4** the Mo—O(2) distance 2.113(4) Å is outside the range for terminal alkoxides;[20] it clearly indicates that the ligand is ethanol.

A unique feature of compounds **2** and **3** is the occurrence of phenylhydrazine and phenyldiazenido ligands in the same coordination sphere. There was no example of this kind of molybdenum complexes until the recent report

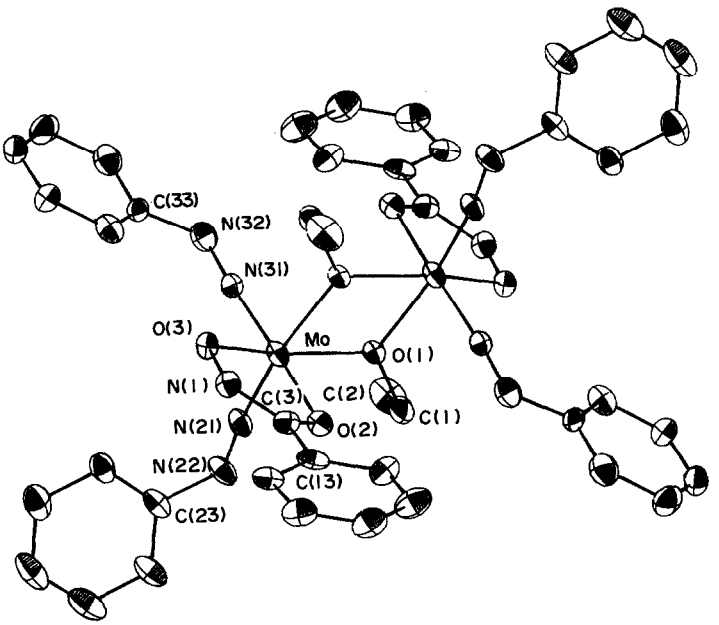

Fig. 1. Molecular structure and labelling scheme for $[Mo(C_6H_5N_2)_2(\mu\text{-}OC_2H_5)(C_6H_5CONHO)\}_2]$ (**1b**) with 20% thermal ellipsoids.

of Hsieh and Zubieta about the structure of **2a**.[7] This **2a** structure is the archetype of a new family of complexes with the general formula $[\{Mo(C_6H_5N_2)_2X(\mu\text{-}OR)(C_6H_5NHNH_2)\}_2]$ (X = OR, Cl; R = CH_3, C_2H_5, n-C_3H_7...) which are readily formed when polyoxometalates, monomeric oxomolybdenum(VI), or monomeric halogenomolybdenum(V) complexes are treated with an excess of phenylhydrazine in ROH. The vanadium complex $[VCl_2\{C_6H_5(CH_3)N_2\}\{C_6H_5(CH_3)NNH_2\}]^+$ is the only other case of a complex containing hydrazine residues in more than one protonated state which was obtained by reacting a metal compound with a substituted hydrazine.[21] Compounds **2** and **3** also appear to be the first molybdenum complexes where end-on hydrazine coordination is crystallographically supported; this coordination is likely to occur in complexes

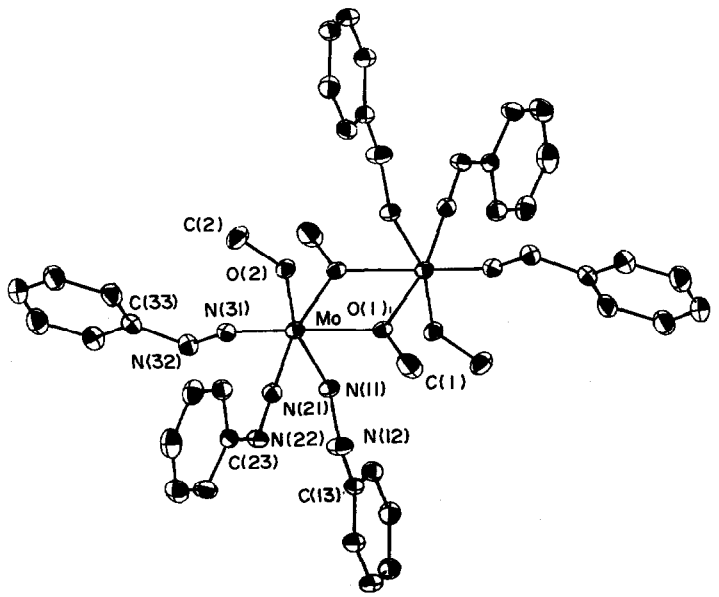

Fig. 2. ORTEP drawing of $[\{Mo(C_6H_5N_2)_2(\mu\text{-}OCH_3)(OCH_3)(C_6H_5NHNH_2)\}_2]$ (**2a**) with 20% thermal ellipsoids.

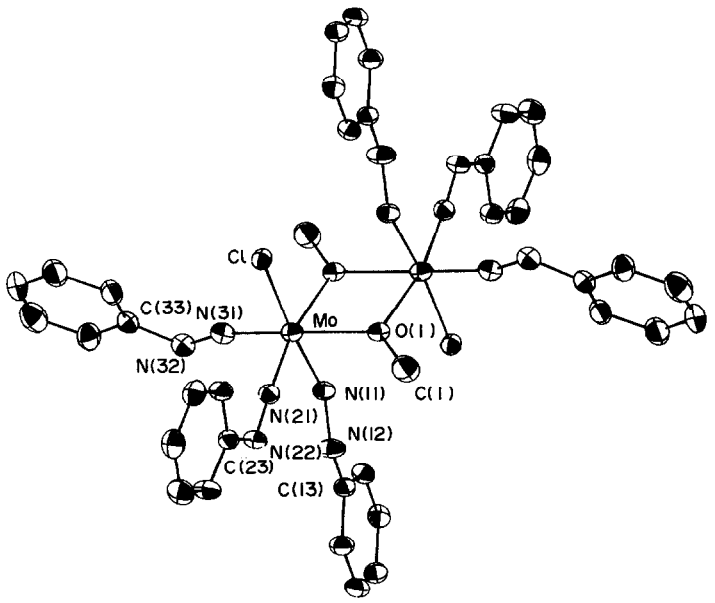

Fig. 3. ORTEP drawing of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OCH_3)(C_6H_5NHNH_2)\}_2]$ occurring in mixed crystals (**2a**/**3a**) with 20% thermal ellipsoids.

such as $[Mo(CO)_5(C_6H_5NHNH_2)]$[22] and $[Mo(\eta^5\text{-}C_5H_5)I_2(NO)(C_6H_5NHNH_2)]$[23] studied by IR spectroscopy. The occurrence of neutral phenylhydrazine in **2** and **3** is consistent with electron count requirements; it is also supported by the appearance of NH_2 and NH hydrogen atoms in Fourier maps, their successful refinement, and the Mo—NH_2—NH—C_6H_5 geometry: the Mo—N and N—N distances 2.267(3) and 1.423(4) Å in **2a** are indicative of single bonds. The environment of the NH_2 nitrogen atom is roughly tetrahedral and the configuration about the N—N bond is *gauche*.

The geometry of the *cis*-$[Mo(C_6H_5N_2)_2]^{2+}$ unit ensures maximum π-interaction between the diazenido ligand π^*-orbitals and the molybdenum t_{2g} orbitals.[24] This is supported by the

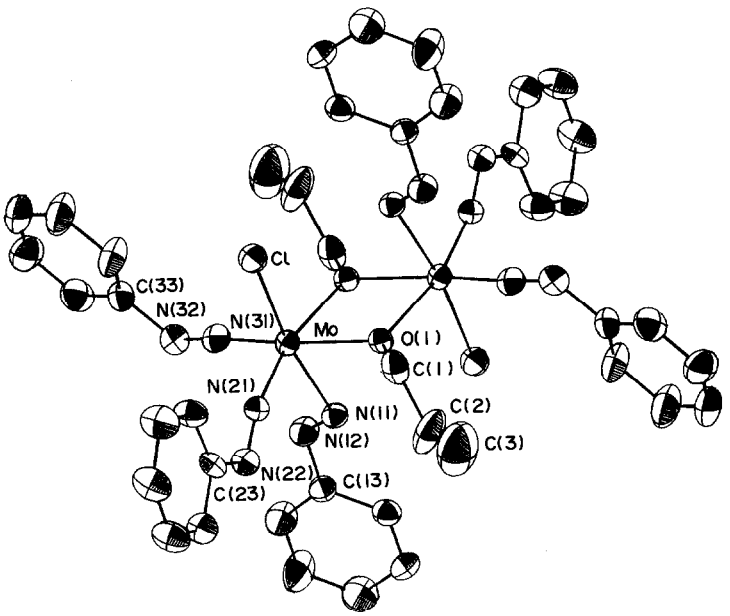

Fig. 4. ORTEP drawing of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_3H_7)(C_6H_5NHNH_2)\}_2]$ (**3c**) with 15% thermal ellipsoids.

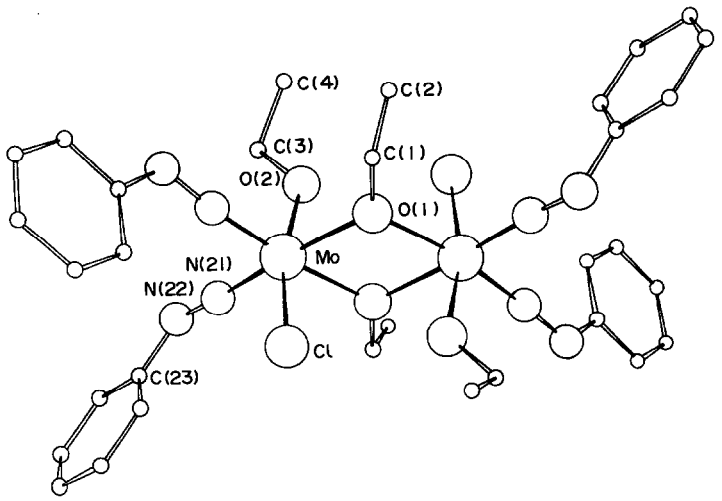

Fig. 5. Perspective drawing of $[\{Mo(C_6H_5N_2)_2Cl(\mu\text{-}OC_2H_5)(C_2H_5OH)\}_2]$ (**4**).

short Mo—N(diazenido) distances (1.82 Å average) and the wide angle of the Mo—N—N unit for the diazenido ligand (169° average).

Although there is obviously no π requirement for the phenylhydrazine ligand, its phenyl ring is not far from being coplanar with one diazenido ligand in both **2a** and **3c**; however the orientation of this phenyl ring in **3a** and **3c** with respect to the rest of the molecule is different while both $C_6H_5N_2$ groups are similarly orientated in both compounds.

Structural features of the benzohydroxamate ligand in **1b** are very similar to those of the hydroxamate ligand in $[MoO\{(CH_3)_2NO\}(C_6H_5CONHO)(C_6H_5CONO)]$[25] and in other hydroxamatomolybdenum complexes.[26] In **1b** crystals, an intermolecular hydrogen bond stretches between the NH group and the ethanol oxygen atom (N(1)···O(4) = 2.82(1) Å; N(1)—H(1)—O(4) = 153.3°).

Compounds **1**, **2**, **3** and **4** contain the $[Mo(C_6H_5N_2)_4(\mu\text{-}OR)_2]^{2+}$ unit which proves to be a robust core able to ligate various types of other ligands.

γ-PHENOXYBUTANOIC ACIDS AND THEIR METAL(II) COMPLEXES. THE CRYSTAL STRUCTURES OF 4-(4-CHLOROPHENOXY)BUTANOIC ACID, 4-(2,4-DICHLOROPHENOXY)BUTANOIC ACID, DIAQUABIS [4-PHENOXYBUTANOATO]NICKEL(II), AND COBALT(II) AND DIAQUABIS[4-(4-CHLOROPHENOXY)BUTANOATO]NICKEL(II)

(*Received* 18 *May* 1988; *accepted* 4 *July* 1988)

Abstract—The crystal structures of the complexes diaquabis[4-(phenoxy)butanoato] nickel(II) (**1**), diaquabis[4-(4-chlorophenoxy)butanoato]nickel(II) (**2**) and the acids 4-(4-chlorophenoxy)butanoic acid (**3**) and 4-(2,4-dichlorophenoxy)butanoic acid (**4**) have been determined using X-ray diffraction techniques. The yellow complexes **1** and **2** are isomorphous and isostructural and have distorted octahedral MO_6 stereochemistry with two slightly asymmetric bidentate carboxylate groups [Ni—O, 2.062, 2.181(2) Å, (**1**) and 2.068, 2.175(2) Å, (**2**)] and two waters [Ni—O, 2.021(1) Å, (**1**) and 2.016(2) Å, (**2**)]. The planar conformation of the acids **3** and **4** is retained in the complexes **1** and **2**.

Three known pale green six-coordinate nickel(II) complexes with phenoxyalkanoic acids[1–3] have stereotypical octahedral stereochemistry about the metal. The coordination comprises four waters and two oxygens from *trans*-related unidentate carboxylate groups. This is contrary to the early contention[4] that the nickel(II) carboxylates are invariably dimeric or polymeric. The yellow nickel(II) complexes are usually square-planar[5] but no examples with this stereochemistry are known among the nickel(II) carboxylates. Therefore, the structures of the yellow crystalline complexes which form readily with aqueous nickel(II) and (4-phenoxy)butanoic acid [PBAH] and 4-[4-chlorophenoxy)butanoic acid [PCBAH] [complexes (**1**) and (**2**)] were of particular interest. In addition, the comparative conformational features of the free acids and the coordinated ligands were of interest. The structures of 4-(4-chlorophenoxy) butanoic acid [PCBAH] (**3**) and the commercial herbicide 4-(2,4-dichlorophenoxy)butanoic acid, [2,4-DB][6] (**4**) are also reported.

EXPERIMENTAL

Preparations

The phenoxybutanoic acids were synthesized from ethyl 4-bromobutanoate and the appropriate phenol, using the general procedure of Synerholm and Zimmerman.[7] Metal complexes were prepared by reacting 50% aqueous ethanolic solutions of the acids with nickel or cobalt carbonate as previously described.[8] Partial evaporation (room temperature) of the filtrates yielded yellow crystals of the nickel complexes with 4-(phenoxy)butanoic acid, $[(Ni(PBA)_2(H_2O)_2]$ (**1**), and 4-(4-chlorophenoxy) butanoic acid, $[Ni(PCBA)_2(H_2O)_2]$ (**2**). The red cobalt(II) complex with 4-(phenoxy)butanoic acid, $[Co(PBA)_2(H_2O)_2]$ (**1a**), was confirmed as isomorphous with **1** from single crystal X-ray

diffraction photographs, while elemental analysis and IR spectra of **1**, **1a** and **2**, (obtained as Nujol mulls on a Jasco IR-810 recording spectrometer) indicated that all three were structurally similar.

Crystals of 4-(4-chlorophenoxy)butanoic acid (**3**) and 4(2,4-dichlorophenoxy)butanoic acid (**4**) were obtained from a mixture of toluene and chloroform.

Crystal data, X-ray data and structure refinement

Table 1 lists information about unit cell parameters, data acquisition and structure refinement for compounds **1**, **2**, **3** and **4**. Data were collected either at room temperature (293 K) (**1** and **2**) or at low temperature (173 K) (**3** and **4**) on a Nicolet R3m four-circle diffractometer, using graphite monochromatized Mo-K_α radiation ($\lambda = 0.7107$ Å). Structures were solved by either the heavy-atom method (**1** and **2**) or direct methods (**3** and **4**) using the SHELX-76 set of programs.[9] Refinement was by blocked-matrix least-squares with all heavy atoms anisotropic. Hydrogens were located from difference-Fourier syntheses and were included in the respective refinements with both positional and isotropic thermal parameters refined. No corrections were made for absorption or extinction.

Neutral atom scattering factors were used.[10] Final atomic coordinates (including hydrogens), anisotropic thermal parameters, intraligand bond distances and angles, and observed and calculated

structure factors and IR spectra are available from the Editor or the authors.* Bond distances and angles about the coordination spheres for complexes 1 and 2 are given in Table 2.

DISCUSSION

Complexes 1, $[Ni(PBA)_2(H_2O)_2]$, and 2, $[Ni(PCBA)_2(H_2O)_2]$, are isomorphous and isostructural. The MO_6 stereochemistry in each is very distorted octahedral (Fig. 1) with molecular two-fold symmetry coincident with crystallographic symmetry. The coordination polyhedron comprises two waters [Ni—Ow, 2.021(2) Å, (1); 2.016(2) Å, (2)] and four oxygens from two slightly asymmetric bidentate carboxylate groups of the two γ-phenoxybutyrate ligands [Ni—O, 2.062, 2.181(2) Å, (1); 2.068, 2.175(2) Å, (2)]. This bidentate chelate complexing mode was previously unknown among the nickel(II) carboxylates. Examples having undistorted $[NiO_2(Ow)_4]$ octahedral stereochemistry, involving unidentate carboxyl groups are known; nickel(II) phenoxyacetate tetrahydrate,[1] nickel(II) acetate tetrahydrate[11,12] and nickel(II) formate dihydrate.[13] However, in the latter complex, the $[NiO_2(Ow)_2]$ unit is extended into a polymer structure via a second $[NiO_6]$ centre which involves six different carboxylate groups.

In contrast, zinc carboxylates, including phenoxyalkanoates and the analogous phenylthioalkanoates, having $MO_4(Ow)_2$ stereochemistry and crystallographic two-fold symmetry, are relatively well known.[8,14] These complexes, with only one exception (zinc acetate dihydrate[15]), all show considerable asymmetry in the bidentate carboxylate groups, ranging up to 2.03, 2.52 Å for zinc salicylate dihydrate.[16] These examples represent complexes of the *trans*-[M(bidentate)$_2$(unidentate)$_2$] type having small normalized bidentate "bite", which degenerate to skew-trapezoidal bipyramidal stereochemistry.[17] With complexes 1 and 2, the bidentate "bites" of the carboxyl groups are 2.17 Å (1) and 2.17 Å (2), which compare with 2.23 and 2.23 Å for the uncomplexed acids 4-(4-chlorophenoxy)butanoic acid (3) and 4-(2,4-dichlorophenoxy)butanoic acid (4), respectively. This is considerably shorter than the O···O distance found in normal carboxyl groups and results in a significant contraction in the O—C—O

*Atomic coordinates have also been deposited with the Cambridge Data Centre.

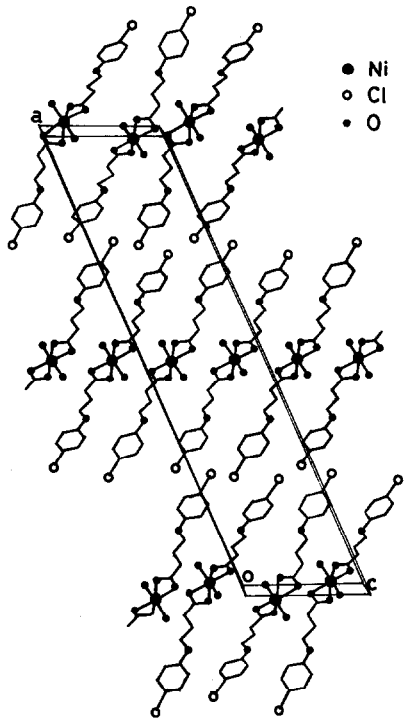

Fig. 2. Packing of complexes **1** and **2** in the unit cell.

bond angle of the group [118.5(2)° (**1**); 118.6(2)° (**2**), compared to 123.3(2)° (**3**) and 123.3(1)° (**4**)].

The monomeric complexes pack in the unit cell (Fig. 2) with only two intermolecular associations involving the coordinated water, Ow—O(10)′, [2.75 Å, (**1**) and 2.72 Å, (**2**)], and Ow—O(11)′ [2.77 Å, (**1**) and 2.78 Å, (**2**)]. Intramolecular stabilization results from longer associations between Ow(1) and O(11) [2.92 Å (**1**); 2.91 Å (**2**)]. The normally unassociated phenoxyalkanoate side-chains retain their preferred planar conformation (Table 3).

The isomorphism (single crystal X-ray preliminary photographs, chemical analysis and IR spectra), has been confirmed for the cobalt(II) complex, $[Co(PBA)_2(H_2O)_2]$ (**1a**). Although this phenomenon has not previously been observed for Ni and Co complexes with the phenoxyalkanoic acids, a number of cases of isomorphism involving other first transition series metal complexes have been described (Mn^{II}, Co^{II},[18] Co^{II}, Zn^{II}[19]). The inference is that like the Ni^{II} complexes (**1**) and (**2**), this Co^{II} complex is also very unusual since previous examples of these metal complexes with phenoxyalkanoic acids have been regular octahedral.

Acids and ligand conformation

The γ-phenoxyalkanoic acids (**3**) and (**4**) form centrosymmetric hydrogen bonded cyclic dimers [O···O, 2.62 Å (**3**) and 2.66 Å (**4**)], similar to most phenoxyalkanoic acids.[19] The oxybutanoic acid side-chains are essentially planar (Figs 3, 4), which is consistent with the observations for the phenoxyethanoic acids with no steric effects from 2,6-

Abstract—X-ray absorption spectra for molybdenum(V) in hydrochloric acid solutions were measured and their XANES and EXAFS were analysed. The μ-oxo dimer of Mo^V was detected in 4.5–6.0 M HCl solutions. The Mo—Mo bond length in the dimer is 2.94–3.06 Å and the Mo—O—Mo angle is *ca* 104–111°.

For the Mo^V species in hydrochloric acid solution several investigations have been carried out by the means of magnetic susceptibility,[1] spectrophotometry,[2,3] ESR spectroscopy[4,5] and others.[6,7] These studies indicated that in highly acidic solutions (> 8 M HCl) the major dissolved species is a paramagnetic monomer of $MoOCl_5^{2-}$. When the acidity of the solution is decreased, dimerization occurs to produce a paramagnetic μ-oxo dimer of $Mo_2O_3Cl_8^{4-}$ (in 5–6 M HCl). A further decrease of the acidity results in a diamagnetic dimer having di-μ-oxo $Mo_2O_4^{2+}$ core. The $MoOCl_5^{2-}$ in solution shows spectral and magnetic properties essentially identical to those of the salts of M_2MoOCl_5 [M = NH_4^+, pyH^+, Cs^+, etc.],[8,9] indicating that the structure of $MoOCl_5^{2-}$ in solution remains almost the same as those in solids. For $Mo_2O_4^{2+}$, the spectral data indicate the structural similarity in solids and solutions.[3] The schematic illustrations of the structures for $MoOCl_5^{2-}$ and $Mo_2O_4^{2+}$ are shown in Fig. 1.

For $Mo_2O_3Cl_8^{4-}$, there have been few reports concerning its structure. Colton and Rose[12] reported the synthesis of $[(C_2H_5)_4N]_4[Mo_2O_3Cl_8]$. Its spectral data were usually associated with di-μ-oxo dimers of $Mo_2O_4^{2+}$ and not μ-oxo species.[7] It has also been reported that this synthesis was difficult to reproduce.[13] Therefore, there are some limitations to investigating the structure of the μ-oxo dimer of $Mo_2O_3Cl_8^{4-}$ in solution by comparing with the structure of $Mo_2O_3Cl_8^{4-}$ in solid crystals.

Extended X-ray absorption fine structure (EXAFS) has been useful to analyse various materials having no long-range order, such as amorphous compounds, metal complexes in enzymes and in solutions.[14] Cramer *et al.*[15] have already investigated the EXAFS for Mo^V in 3 M HCl solution and reported that the structure of the dissolved Mo^V species is similar to that of $Mo_2O_4^{2+}$ shown in Fig. 1. In the present work the

structure of μ-oxo dimer of $Mo_2O_3Cl_8^{4-}$ is investigated by analysing its X-ray absorption near edge structure (XANES) and EXAFS and by comparing with those for other Mo^V samples.

EXPERIMENTAL

$BaMo_2O_4(C_2O_4)_2 \cdot 5H_2O$,[16] $Mo_2O_3[S_2CN(C_2H_5)_2]_4$,[17] $Mo_2O_3(S_2COC_2H_5)_4$,[17] $(NH_4)_2MoOCl_5$[18] and Mo^V in HCl solutions[19] were prepared according to the literature. Mo^V solutions were deaerated by bubbling pure nitrogen through them. The concentrations of Mo^V were adjusted to 0.12 M and were determined by spectrophotometry and cerium(IV) titration.[20] Other chemicals were of guaranteed reagent grade and were used without further purification.

X-ray absorption spectra were obtained with the EXAFS apparatus of the 2.5 GeV storage ring from Photon Factory at Tsukuba. Photon energy was calibrated by using a pre-edge peak of sodium molybdate, $Na_2MoO_4 \cdot 2H_2O$ at 20007.0 eV. Other conditions were the same as those reported previously.[21]

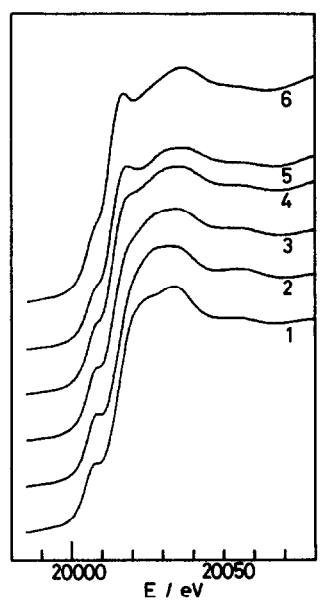

Fig. 2. Mo-K-edge XANES spectra for the Mo^V samples. (1) $BaMo_2O_4(C_2O_4)_2 \cdot 5H_2O$; (2), (3), (4) and (5) are for 0.12 M Mo^V in 3.0, 5.4, 6.0 and 8.0 M HCl, respectively; (6) $(NH_4)_2MoOCl_5$.

RESULTS AND DISCUSSION

K-edge XANES spectra of Mo^V taken for various samples are shown in Fig. 2. For $BaMo_2O_4(C_2O_4)_2 5H_2O$ (Ba-salt) a pre-edge peak is observed at 20008.7 eV. This pre-edge peak is assigned to a 1*s*–4*d* transition.[22] The pre-edge peak for Mo^V in HCl solution is observed clearly, when c_{HCl}, the concentration of HCl, is less than 5 M. However, in more acidic solutions the peak is obscured due to the red shift of the absorption edge. The coordination of the chloride ion may cause a shift of the edge, which is indicated by the result of EXAFS analysis described later in this paper. In HCl solutions molybdenum(V) complexes are involved in dimer(diamagnetic)–dimer (paramagnetic)–monomer(paramagnetic) equilibria and their core units are represented generally as follows:[7,23]

$$\underset{(\geqslant 8\text{ M HCl})}{2MoO^{3+}} \rightleftharpoons \underset{(5\text{–}6\text{ M HCl})}{\begin{matrix} Mo_2O_3^{4+} \\ + \\ 2H^+ \end{matrix}} \rightleftharpoons \underset{(3\text{ M HCl} \geqslant)}{\begin{matrix} Mo_2O_4^{2+} \\ + \\ 2H^+ \end{matrix}}$$

The intensities of the pre-edge peak in 1.2–5 M HCl solutions change little and correspond to the presence of one Mo=O bond (it is known that the intensity of the pre-edge peak correlates with the number of Mo=O bonds per molybdenum atom[21]). This result agrees with the fact that the dissolved species have one Mo=O bond per mol-

ybdenum atom. The threshold energy, E_0 (which was determined from the position of the half height of the absorption edge at around 20040 eV; in this method experimental errors for E_0 are within about $\pm$ 0.2 eV), for various Mo^{V} samples are listed in Table 1. The values of E_0 in HCl solutions of less than 3 M where major species contain the $Mo_2O_4^{2+}$ unit are close to that for Ba-salt. As c_{HCl} is increased the value of E_0 is decreased. In 5–6 M HCl solutions where the $Mo_2O_3^{4+}$ unit is present,[2] the value of E_0 varies from 20013.6 to 20012.3 eV. The solid samples of $Mo_2O_3[S_2CN(C_2H_5)_2]_4$ and $Mo_2O_3(S_2COC_2H_5)_4$, containing the $Mo_2O_3^{4+}$ unit, also have the value of 20012.4 and 20013.4 eV, respectively. In an 8 M HCl solution where the major species is considered to contain the unit of MoO^{3+}, the XANES spectrum and the value of E_0 are very close to those for $(NH_4)_2MoOCl_5$ (NH_4-salt).

EXAFS Fourier transforms (FT) for various Mo^{V} samples are shown in Fig. 3. In the FT, the corrections for the phase shift and the back-scattering amplitude were performed by using the parameters for the Mo—O bond given by Teo and Lee[24] (in this method experimental errors for bond distances are within about $\pm$ 0.02 Å). In the EXAFS FT for the Ba-salt, two distinct peaks are observed at 1.75 and 2.56 Å. The peak at 1.75 Å may correspond to both Mo—O_b (bridging oxygen atom) and Mo—O_t (terminal oxygen atom) (1.88 and 1.93 Å for Mo—O_b and 1.70 Å for Mo—O_t were reported[11]), in fact, also for Mo^{VI} compounds peaks for Mo—O_b and Mo—O_t are not observed separately by EXAFS.[21] The peak at 2.56 Å corresponds to Mo—Mo and this value agrees with that obtained by X-ray diffraction analysis.[11] In HCl solutions of less than 3 M the structures of the dissolved Mo^{V} species remain the same as that for $Mo_2O_4^{2+}$, for their EXAFS FT are almost the same as that for Ba-salt, as already reported by Cramer *et al.*[15] The increase in concentration of HCl brings about an appearance of a peak at about 2.3 Å (in > 4.5 M HCl), indicating the coordination of chloride ions to the molybdenum atom. In 5.4 M HCl, a distinct peak appears at 2.99 Å, and this is assigned to the Mo—Mo bond distance of the $Mo_2O_3^{4+}$ unit, as this peak is observed in the 4.5–6 M HCl solutions where the Mo^{V} species of $Mo_2O_3Cl_8^{4-}$ is considered to be present.[2] In an 8 M HCl solution peaks corresponding to Mo—Mo bonds disappear and peaks for Mo=O (1.67 Å) and Mo—Cl (2.36 Å) bonds are observed. These results are also observed for the NH_4-salt, indicating that $MoOCl_5^{2-}$ is present as the major species in 8 M HCl solution.

The numbers of coordinating oxygen, chlorine and molybdenum atoms, N_O, N_{Cl}, $N_{Mo(a)}$ (for the $Mo_2O_4^{2+}$ unit) and $N_{Mo(b)}$ (for $Mo_2O_3^{4+}$), respectively, for the Mo^{V} species in HCl solutions of various concentration are estimated by using the relation, $hR^2 = PN$, where h is the peak height in FT, R is the bond length and P is the proportional

5.4	1.73	1.06	2.25	1.12	2.63	0.61	2.99	0.39
5.6	1.71	1.01	2.27	1.62	2.66	0.50	3.02	0.33
6.0	1.69	1.05	2.36	2.46	2.74	0.47	3.06	0.28
6.5	1.64	0.97	2.37	3.63	2.82	0.44	—	—
8.0	1.67	1.00	2.36	4.00	—	—	—	—

constant.[25] In this case the root–mean–square relative deviation (RMSRD) of R is assumed to be constant. This assumption leads to the experimental errors for N within about $\pm 7\%$. The reference samples used to determine the value of P were $MoOCl_5^{2-}$ (in 8 M HCl) for N_O and N_{Cl}, and $Mo_2O_4^{2+}$ (in 1.2 M HCl) for N_{Mo}. The values of R and N determined are listed in Table 2. In these analyses values for N are averaged ones for each molybdenum atom and therefore, not for each species. In HCl solutions of less than 3 M where the Mo^V dimer containing the $Mo_2O_4^{2+}$ unit is mainly present, the values of N_O are nearly one, i.e. it is equal to the number of Mo—O_t bonds, although the peaks at about 1.74–1.78 Å also have the character of the two Mo—O_b bonds. In 1.2–8 M HCl solutions the value of N_O remains nearly one and this result is in agreement with the structures of three major units that have one Mo—O_t bond per molybdenum atom. For the coordination of the chloride ion, the value of N_{Cl} increases when c_{HCl} is increased above 5 M HCl (in 4.5 M HCl a shoulder for Mo—Cl is observed at around 2.3 Å). For an 8 M HCl solution the value of N_{Cl} is four implying that four chlorine atoms which are *cis*-directed to the terminal oxygen are taken into consideration, that is, the value of N_{Cl} in Table 2 does not contain any information of the chlorine atom *trans*-directed to the terminal oxygen.

For the dimer ($Mo_2O_4^{2+}$)–dimer($Mo_2O_3^{4+}$)–monomer(MoO^{3+}) equilibria, concentrations of each species were determined from the values of $N_{Mo(a)}$ and $N_{Mo(b)}$, and fractions, [Mo^V in each species]/[total Mo^V] ([] denotes the concentration of the monomer), were calculated in HCl solutions of various concentration. The results are shown in Fig. 4. These results are in agreement with those obtained by spectrophotometric measurements.[2] That is, the peak at about 2.94–3.06 Å in 4.5–6 M HCl solutions can be assigned undoubtedly to the Mo—Mo bond in the $Mo_2O_3^{4+}$ unit. As shown in Fig. 4 the fraction for $Mo_2O_3^{4+}$ is less than *ca* 0.4 and this result is also in agreement with that reported previously.[2,4]

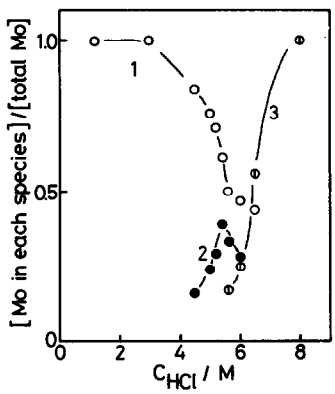

Fig. 4. Dependence of [Mo^V in each species]/[total Mo^V] on c_{CHl}. (1) $Mo_2O_4^{2+}$; (2) $Mo_2O_3^{4+}$; (3) MoO^{3+}.

The distance for Mo—Mo in the $Mo_2O_3^{4+}$ unit was determined to be 2.94–3.06 Å in 4.5–6 M HCl while its Mo—O_b distance cannot be determined precisely by the FT method as described above. However, assuming that the Mo—O_b distance is 1.86 Å, which is the averaged Mo—O_b value obtained from the literature for $Mo_2O_3(S_2COC_2H_5)_4$,[26] $Mo_2O_3[S_2CN(C_3H_7)_2]_4$[27] and $Mo_2O_3[S_2P(OC_2H_5)_2]_4$[28] (these species have linear μ-oxo bridges), it is concluded that the dimer containing the $Mo_2O_3^{4+}$ unit has a bent Mo—O—Mo bond with an angle of *ca* 104–111°. Blake *et al.*[26] deduced by molecular orbital considerations that if the $Mo_2O_3^{4+}$ unit has a linear μ-oxo bridge, the two Mo=O bonds in paramagnetic $Mo_2O_3^{4+}$ are present in different planes in order to avoid the three-centred *d–p–d* interaction. In this study, it is revealed that the paramagnetic dimer containing the $Mo_2O_3^{4+}$ unit in

HCl solution has a bent μ-oxo bridge, however, the two different Mo=O bonds may also be present in different planes in order to avoid a direct interaction between the Mo atoms in order to keep its paramagnetic character.

Acknowledgements—The authors thank Drs Tadashi Matsushita and Masaharu Nomura of the National Laboratory for High Energy Physics (K.E.K.) for their help with the X-ray absorption measurements.

KINETIC STUDIES OF THE OXIDATION OF DIAQUA-BIS(PICOLINATO)COBALTATE(II) BY PERIODATE

AHMED A. ABDEL-KHALEK

Chemistry Department, Faculty of Science, Cairo University, Beni-Suef City, Egypt

(*Received* 18 *February* 1988; *accepted after revision* 4 *July* 1988)

Abstract—A kinetic study of the oxidation of the bis complex of pyridinecarboxylic acid (picolinic acid) with cobalt(II), $[Co(pc)_2(H_2O)_2]$ (pc = picolinate), by periodate in an acetate medium has been performed. The kinetics obeyed the rate law $d[Co^{III}]/dt = (k'_2+k_3[CH_3COO^-])[Co^{II}(pc)_2(H_2O)_2][IO_4^-]$. An inner-sphere mechanism is proposed. An argument based on isokinetic correlations among activation parameters for the oxidation of a series of some cobalt(II) complexes, including the picolinato complex, is presented in support of a common mechanism for these reactions.

Periodate oxidations (IO_4^- products) are believed to proceed via an inner-sphere mechanism.[1–8] Its oxidation of organic substrates are specific when direct bonding of I^{VII} to e.g. OH, NH_2 etc. in the 1,2 positions with the formation of a cyclic intermediates.[1] An inner-sphere mechanism was proposed for iodide oxidation where an oxygen atom transfer with the formation of HOI as an intermediate was invoked.[2] Further support for this mechanism could be drawn from reactions of this oxidant with transition metal complexes. It was found that periodate readily oxidizes either labile complexes or inert complexes possessing at least one potential bridging ligand. In the oxidation of iron(II), stopped-flow traces clearly showed the formation and decomposition of an intermediate.[3] Intermediate cobalt(III) products, which are indicative of Co—O—IO_3 bond formation, were also identified spectrophotometrically in periodate oxidations of cobalt(II) complexes of edta[4] (ethylenediaminetetraacetate), hedta[5] (N-2-hydroxyethylethylenediaminetriacetate), edda[5] (ethylenediaminediacetate) and nta[6] (nitrilotriacetate). A common mechanism for the oxidation of these cobalt(II) complexes by periodate is proposed and supported by an excellent isokinetic relationship between ΔH^* and ΔS^* values for these reactions.[6] The initial cobalt(III) product was not observed in the case of oxidation of cdta (*trans*-1,2-diaminecyclohexanetetraacetate) by periodate because the rate of ring closure is faster than that of oxidation.[7] In the oxidation of chromium(III) by periodate, the hydroxo species is the reactive ion, with the hydroxide acting as the bridging ligand.[8]

In particular we have chosen the pyridinecarboxylic acids, supported by the fact that some properties of the respective complexes are influenced by the position and number of functional groups.

In the present study we report our findings on the oxidation of $[Co(pc)_2(H_2O)_2]$ by IO_4^-.

EXPERIMENTAL

Reagents

Reagent grade picolinic acid, sodium metaperiodate, cobalt nitrate hexahydrate, sodium acetate, sodium nitrate and glacial acetic acid were used without further purification. A stock solution of periodate was made up by weight and wrapped with Al foil to avoid photochemical decomposition.[9] A cobalt(II) nitrate solution was standardized with edta volumetrically. A stock solution of the sodium salt of picolinic acid was prepared by weighing the acid form and neutralizing with the appropriate amount of sodium hydroxide. The $[Co(pc)_2(H_2O)_2]$ was made up just before the kinetic run by mixing cobalt(II) and ligand solutions in the concentration ratio 1 : 2.3 to ensure complete formation. At lower ratios the oxidation is very difficult and a yellow precipitate always formed, which is similar to the precipitate obtained on mixing cobalt(II) and periodate. Solutions of sodium acetate and sodium

nitrate were made up by weight and those of acetic acid by dilution, and standardized against sodium hydroxide solution.

Oxidation products

The stoichiometry of the reaction can be represented by eq. (1).

$$2[Co^{II}(pc)_2]+IO_4^- \longrightarrow 2[Co^{III}(pc)_2]^+ + IO_3^- \quad (1)$$

where IO_4^- represents the total periodate. The ratio of [Co^{III} complex] produced to [IO_4^-] initially present was 2.00 ± 0.05.

The UV–vis. absorption spectra of the products from the oxidation of $[Co^{II}(pc)_2(H_2O)_2]$ by IO_4^-, in the absence and presence of acetate ions, were recorded on a Unicam SP8000 spectrophotometer. The maxima and molar absorption coefficients of the acetate-free cobalt(III) product at pH 4.0 were $\varepsilon_{max}^{535} = 174$ and $\varepsilon_{max}^{382} = 290$ $dm^3\ mol^{-1}\ cm^{-1}$.[10] In acetate medium these values were $\varepsilon_{max}^{533} = 204$ and $\varepsilon_{max}^{382} = 305\ dm^3\ mol^{-1}\ cm^{-1}$. The molar absorbance of the cobalt(III) product, in acetate buffer, varies with acetate ion concentration.

Kinetic measurements

A Unicam SP8000 spectrophotometer, equipped with a thermostatted cell holder, was used to monitor the reaction. The reactants in buffer solutions in the two compartments of an indented flask, were thermostatted for about 20 min. These were thoroughly mixed and quickly transferred to an absorption cell. The formation of the cobalt(III) complex was followed at 530 nm where the absorption is maximal at the pH of the reaction. Pseudo-first-order conditions were maintained in all runs by using a large excess of periodate concentrations (more than ten-fold) over that of $[Co^{II}(pc)_2(H_2O)_2]$. The pH of the reaction was measured on a Radiometer digital pH meter model PHM62. The ionic strength was maintained by using the appropriate amounts of sodium nitrate solution.

RESULTS

The UV–vis. absorption spectrum of the product from the oxidation of $[Co^{II}(pc)_2(H_2O)_2]$ by periodate gave only the final product $[Co^{III}(pc)_2(H_2O)_2^+]$. This is in contrast to what was found in oxidations of cobalt(II) complexes of edta,[4] hedta, edda,[5] and nta,[6] where intermediate cobalt(III) products were identified spectrophotometrically.

The kinetics of $[Co^{II}(pc)_2(H_2O)_2]$ oxidation by periodate were studied over the pH range 4.05–5.15, ionic strength 0.50 M and temperatures 20, 25, 30 and 35°C over a range of periodate and complex concentrations.

Plots of $\ln(A_\infty - A_t)$ vs time were linear up to $\geqslant 80\%$ of the reaction where A_∞ and A_t are absorbances at infinity and time t, respectively. Pseudo-first-order rate constants, obtained from the slopes of these plots using a linear least-squares program, are collected in Table 1. The constancy of k_{obs}, at a

fixed periodate concentration, pH, ionic strength and temperature over a range of complex concentration, is in agreement with a first-order dependence on $[Co^{II}(pc)_2(H_2O)_2]$.

The rate of the reaction was found to be directly proportional to the concentration of IO_4^-. The results in Table 1 show that k_{obs} varies linearly with $[IO_4^-]$ according to eq. (2).

$$k_{obs} = k_2[IO_4^-]. \quad (2)$$

The dependence of the reaction rate on pH was investigated over the range of pH 4.05–5.15. It was found that the change of k_{obs} with a change in pH value is not consistent over one unit of pH increase. It was decided to examine whether the apparent pH dependence arises from a mechanistic path or a medium effect. Kinetic runs were then carried out at constant pH and ionic strength using different acetate ion concentrations. The results in Table 2 and Fig. 1 show that k_2 depends on acetate ion

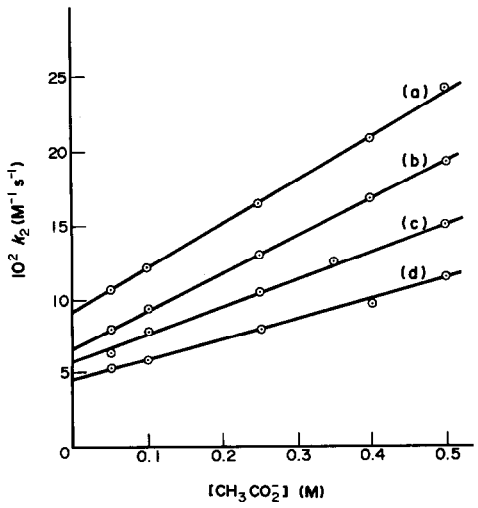

Fig. 1. Dependence of k_2 on $[CH_3CO_2^-]$ at (a) 35.0, (b) 30.0, (c) 25.0, (d) 20.0°C.

Table 3. Variation of acetate-dependent rate constant k'_2 and acetate-dependent rate constant k_3 with temperature

T (°C)	$10^2k'_2$ ($M^{-1}s^{-1}$)	$10k_3$ ($M^{-2}s^{-1}$)
20.0	4.7±0.6	1.3±0.3
25.0	5.9±0.5	1.8±0.7
30.0	6.9±0.4	2.5±0.6
35.0	9.2±0.7	2.9±0.8

concentration. This dependence can be described by eq. (3) at the temperature used.

$$k_2 = k'_2 + k_3[CH_2COO^-]. \quad (3)$$

From these results, the rate law for the oxidation of $[Co^{II}(pc)_2(H_2O)_2]$ by IO_4^- in acetate medium is given by eq. (4).

$$d[Co^{III}]/dt = (k'_2 + k_3[CH_3COO^-])[Co^{II}(pc)_2(H_2O)_2][IO_4^-]. \quad (4)$$

The values of k'_2 and k_3, collected in Table 3, at the temperature used, were obtained from the intercepts and the slopes, respectively, of Fig. 1. Enthalpies of activation associated with k'_2 and k_3, ΔH_2^* and ΔH_3^*, were calculated from a linear least-squares fit to the Eyring equation to be 30±2.5 and 40±2 kJ mol^{-1}, respectively. The corresponding entropies of activation ΔS_2^* and ΔS_3^* were calculated as −160±8 and −126±8 $JK^{-1}\,mol^{-1}$, respectively.

A plot of ΔH^* against ΔS^* for the oxidation of cobalt(II) complexes of hedta, edda, edta, and nta with periodate[6] is repeated, including values of ΔH^* and ΔS^* for the oxidation of $[Co^{II}(pc)_2(H_2O)_2]$, Table 4, as shown in Fig. 2. This plot reveals a

good isokinetic correlation among the activation parameters for these complexes.

DISCUSSION

Oxidation of $[Co^{II}(pc)_2(H_2O)_2]$ by periodate gave different cobalt(III) products in the absence and presence of the acetate ion. This indicates different cobalt(II) reactive species, the most likely species being $[Co^{II}(pc)_2(H_2O)_2]$ and $[Co^{II}(pc)_2(CH_3CO_2)(H_2O)]^-$. Coordination of the acetate ion to $[Co^{II}(pc)_2(H_2O)_2]$, prior to oxidation by IO_4^-, seems to be supported by the change in the spectrum of the cobalt(II) complex observed on addition of the acetate ion.

An inner-sphere mechanism is proposed for both the acetate-dependent and -independent pathways and may be represented by eqs (5)–(10)

$$[Co^{II}(pc)_2(H_2O)_2]+CH_3CO_2^- \underset{K_1}{\rightleftharpoons} [Co^{II}(pc)_2(CH_3CO_2)(H_2O)]^- + H_2O \quad (5)$$

$$[Co^{II}(pc)_2(H_2O)_2]+IO_4^- \underset{K_2}{\rightleftharpoons} [(pc)_2(H_2O)Co^{II}-OIO_3]^- \quad (6)$$

$$[Co^{II}(pc)_2(CH_3CO_2)(H_2O)]^- + IO_4^- \underset{K_3}{\rightleftharpoons} [(pc)_2(CH_3CO_2)Co^{II}-OIO_3]^{2-} \quad (7)$$

$$[(pc)_2(H_2O)Co^{II}-OIO_3]^- \xrightarrow[k_1]{H_2O} [Co^{III}(pc)_2(H_2O)_2]^+ + I^{VI} \quad (8)$$

$$[(pc)_2(CH_3CO_2)Co^{II}-OIO_3]^{2-} \xrightarrow[k_2]{H_2O} [Co^{III}(pc)_2(CH_3CO_2)(H_2O)]+I^{VI} \quad (9)$$

$$2I^{VI} \longrightarrow IO_4^- + IO_3^- . \quad (10)$$

The rate law derived from the above mechanism, assuming that K_1, K_2 and K_3 are small, is

$$\text{rate} = (k_1K_2+k_2K_1K_3[CH_3CO_2^-])[Co^{II}(pc)_2(H_2O)_2][IO_4^-]. \quad (11)$$

From a comparison of eqs (4) and (11) one obtains $k'_2 = k_1K_2$ and $k_3 = k_2K_1K_3$. The fact that acrilonitrile was polymerized seems to support the suggestion of the presence of a free radical I^{VI} in the reaction mechanisms.

The periodate ion is capable of acting as a ligand, as evidenced from its coordination to copper(III)[11] and nickel(IV).[12] Periodate oxidation of $[Co^{II}(pc)_2(H_2O)_2]$, like that of cdta,[7] did not show the formation of an initial cobalt(III) product. This may be due to the oxidation process being outer-sphere, and hence only $[Co^{III}(pc)_2(H_2O)_2]^+$ was produced. Alternatively, the oxidation process may be inner-sphere, but because the rate of conversion of the initial cobalt(III) product to the final product is faster than that of the oxidation process, the initial cobalt(III) product was not observed. The second alternative is consistent with an inner-sphere mechanism that is generally proposed for periodate oxidations.

The small changes in rate constants for the cobalt(II) complexes of hedta, edda, edta, nta and pc, see Table 4, may arise from parallel changes in ΔH^* and ΔS^* values. These changes lead to only small changes in ΔG^*, and for such a closely related series a common mechanism is supported.[13] This mechanism consists of periodate ion coordination to the cobalt(II) complex in a step preceding the rate-determining intramolecular electron transfer within the precursor complex.

SYNTHESIS AND SPECTROSCOPIC CHARACTERISTICS OF BIS-[DIMETHYL(PHENYL)SILYLMETHYL]PLATINUM(II) COMPLEXES WITH NITROGEN DONOR LIGANDS

BERNARDETA C. ANKIANIEC and G. BRENT YOUNG*

Inorganic Chemistry Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 26 *May* 1988; *accepted* 6 *July* 1988)

Abstract—A series of bis-[dimethyl(phenyl)silylmethyl]platinum(II) complexes, $LPt(CH_2SiMe_2Ph)_2$ with bidentate, N-heteroaromatic ligands (L = 2,2′-bipyridyl; 4,4′-dimethyl-2,2′-bipyridyl; 4,4′-di-*t*-butyl-2,2′-bipyridyl; 2,2′-bipyrimidyl; 2,2′-bipyrazyl; 1,10-phenanthroline; 4,7-diphenyl-1,10-phenanthroline; 3,4,7,8-tetramethyl-1,10-phenanthroline and 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) have been synthesized by the displacement of the diolefin from $(cod)Pt(CH_2SiMe_2Ph)_2$ or $(nbd)Pt(CH_2SiMe_2Ph)_2$, or by the displacement of the thioether from $[Pt(CH_2SiMe_2Ph)_2(\mu\text{-DMS})]_2$ (cod = cycloocta-1,5-diene; nbd = [2.2.1]bicyclohepta-2,5-diene; DMS = dimethyl sulphide). These new derivatives have been characterized by electronic, IR and NMR (^1H and ^{13}C) spectroscopy. Also reported is the synthesis and spectroscopic characterization of an isolable bis-pyridine analogue, *cis*-$(py)_2Pt(CH_2SiMe_2Ph)_2$.

Organo-transition metal compounds play crucial roles in various organic reactions mediated by transition metals. Understanding the behaviour of transition metal alkyl (or aryl) complexes is therefore fundamental to the elucidation of such metal-promoted processes.[1] A common thermolytic pathway favoured by many organometals is hydrogen transfer, most frequently from a β-carbon site, though α-hydrogen abstractions and metallations at more remote (γ- or δ-) sites have emerged recently. In addition to such intramolecular C—H activations, there have been several instances of intermolecular H-transfer from "inert" hydrocarbons.[2]

Following from our recent studies of neophyl† platinum(II) derivatives,[3] our aim is to explore in more detail the reactivity controls on aromatic C—H activation. Complexes containing the sila-neophyl† group have received scant attention.[4] Here, we describe the synthesis and spectroscopic characteristics of a series of bis(sila-neophyl) platinum(II) complexes, $LPt(CH_2SiMe_2Ph)_2$ [L = cycloocta-1,5-diene (cod); [2.2.1]bicyclohepta-2,5-diene (nbd); 2,2′-bipyridine (bipy); 4,4′-dimethyl-2,2′-bipyridine (Me_2bipy); 4,4′-di-*t*-butyl-2,2′-bipyridine (Bu^t_2bipy), 2,2′-bipyrimidine (bipym); 2,2′-bipyrazine (bipyz); 1,10-phenanthroline (phen); 4,7-diphenyl-1,10-phenanthroline (Ph_2phen); 3,4,7,8-tetramethyl-1,10-phenanthroline (Me_4phen); 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (Me_2Ph_2phen)]. We also report the synthesis and characterization of a relatively inert bis(pyridine)platinum(II) complex—*cis*-$(py)_2Pt(CH_2SiMe_2Ph)_2$. Relatively few dialkylplatinum(II) derivatives containing pyridine as a ligand have been reported[5–7] although several diaryl complexes have emerged.[5,8]

† Neophyl = 2-methyl-2-phenylpropyl; sila-neophyl = dimethyl(phenyl)silylmethyl.

EXPERIMENTAL

General and instrumental

Elemental analyses were carried out by Imperial College Microanalytical Laboratories. NMR spectra were recorded on Brüker WM250 (^1H, 250.13 MHz; ^{13}C, 62.9 MHz) and Jeol FX90Q (^1H, 89.55 MHz) spectrometers. IR data were collected on a Perkin–Elmer 683 instrument as 4% KBr dispersions and electronic spectra were recorded on a Shimadzu UV-160 spectrometer.

All reactions were carried out under argon, using

standard anaerobic techniques.[9] All apparatus was flame-dried before use. Solvents were distilled under nitrogen prior to use; diethyl ether and *n*-hexane from sodium/benzophenone, toluene from sodium.

Chloromethyldimethylphenylsilane (sila-neophyl chloride) and 2,2′-bipyrimidyl were used as supplied by Lancaster synthesis. Chloromethyldimethylchlorosilane supplied by Lancaster synthesis was stored under argon, but used without further purification. 2,2′-Bipyridyl, 4,4′-dimethyl-2,2′-bipyridyl, 1,10-phenanthroline, 4,7-diphenyl-1,10-phenanthroline, 3,4,7,8-tetramethyl-1,10-phenanthroline, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, cycloocta-1,5-diene, [2.2.1]bicyclohepta-2,5-diene and dimethyl sulphide were all used as supplied by Aldrich Chemical Company. Pyridine was supplied by Rose Chemicals and distilled under argon from sodium hydroxide prior to use. A sample of 4,4′-di-*t*-butyl-2,2′-bipyridyl was synthesized by a modified procedure.[10] The precursors (cod)$PtCl_2$,[11] (nbd)$PtCl_2$[5] and $(DMS)_2PtCl_2$[12] were prepared using published methods.

Preparation of chloromethyldimethylphenylsilane[13]

A solution of PhMgBr (167 mmol) in diethyl ether (200 cm^3) was slowly added dropwise to $ClCH_2SiMe_2Cl$ (22 cm^3, 167 mmol) in diethyl ether (50 cm^3). Upon stirring, the initially colourless solution gradually turned pale yellow and a white precipitate of magnesium halides was evolved. After addition of PhMgBr was complete, the mixture was refluxed for 24 h. The resulting stirred suspension was cooled to −15°C and hydrolysed by dropwise addition of degassed saturated ammonium chloride solution (100 cm^3). The pale yellow ethereal layer was separated and the aqueous phase washed with diethyl ether (3 × 20 cm^3). The ether extracts were combined, dried over magnesium sulphate and decolourized with activated charcoal to give an almost colourless solution. Removal of the diethyl ether *in vacuo* afforded a pale yellow oil of the crude product. Distillation under reduced pressure gave sila-neophyl chloride (22.6 g, 122 mmol, 77%, b.p. 114°C/10 mm Hg) as a colourless liquid. (^1H NMR $\delta \equiv 0.32$ ppm—CH_3, 2.85 ppm—CH_2, 7.14–7.47 ppm—C_6H_5.)

Preparation of bis(sila-neophyl)(cycloocta-1,5-diene)platinum(II)

To a stirred suspension of (cod)$PtCl_2$ (1.85 g, 4.94 mmol) in diethyl ether (30 cm^3) at −25°C a solution of $PhMe_2SiCH_2MgCl$[4a] (16 mmol) in diethyl ether (30 cm^3) was added dropwise. The mixture was allowed to reach room temperature and stirred for a further 16 h, during this time magnesium chloride was evolved, forming a white precipitate in a dark yellow solution. The stirred suspension was cooled to −25°C and hydrolysed dropwise with degassed saturated ammonium chloride solution (30 cm^3). On reaching ambient temperature the yellow ethereal layer was separated and the aqueous phase washed with diethyl ether (3 × 10 cm^3). The ether extracts were combined, dried over magnesium sulphate and decolourized with activated charcoal to give a colourless solution. Removal of the solvent *in vacuo* gave a white crystalline solid which was recrystallized from the minimum amount of hexane (10 cm^3) to afford large colourless prisms of the product. (Yield: 2.38 g, 80%.) IR: 3065w, 3045sh, 3020sh, 3010sh, 3000w, 2950m, 2920w, 2890w, 2870w, 2855w, 2840sh, 1590vw, 1518w, 1488w, 1475w, 1460w, 1428m, 1410sh, 1385vw, 1375vs, 1340w, 1315w, 1305w, 1262m, 1242s, 1190vw, 1000w, 995w, 980m, 950m, 895vw, 865m, 810vs,br, 780s, 765s, 750m,sh, 740s, 730s, 700s, 680sh, 632m, 550m, 475s, 390s, 370m.

Preparation of bis(sila-neophyl)([2.2.]bicyclohepta-2,5-diene)platinum(II)

A solution of $PhMe_2SiCH_2MgCl$ (14 mmol) in diethyl ether (40 cm^3) was added dropwise at −78°C to a stirred suspension of (nbd)$PtCl_2$ (1.6 g, 4.5 mmol) in diethyl ether (20 cm^3). The mixture was gradually warmed to room temperature and then stirred for a further 16 h. The stirred suspension was then cooled to −25°C and hydrolysed with saturated ammonium chloride solution (20 cm^3). The ethereal layer was separated and the aqueous phase washed with diethyl ether (5 × 10 cm^3). The ether extracts were combined, dried over $MgSO_4$ and decolourized with activated charcoal to give an almost colourless solution. Filtration, washing the $MgSO_4$ with diethyl ether (2 × 20 cm^3) and removal of the solvent *in vacuo* gave an off-white solid, which was recrystallized from the minimum amount of hexane (3 cm^3) to give white needles of the product. (Yield: 1.85 g, 70%.) (Nbd)$Pt(CH_2SiMe_2Ph)_2$ decomposes slowly at room temperature over a period of several days, hence all samples were stored at −20°C. IR: 3060w, 3048w, 3039sh, 3020vw, 3003w, 2988sh, 2966w, 2925sh, 2902sh, 2887w, 2842w, 1482w, 1431sh, 1422m, 1419sh, 1371w, 1359w, 1333vw, 1308m, 1258m, 1239m, 1189w, 1156vw, 1104s, 1064w, 1030w,br, 997vw, 988w, 977w, 961w, 949w, 932w, 920vw, 905vw, 832s, 808s,br, 790m, 753m, 748m, 744m, 736m, 724sh, 715m, 698s, 683m, 628m, 560w, 468m, 385m.

Preparation of tetrakis(sila-neophyl)-bis-(μ-dimethylsulphide)diplatinum(II)

A solution of sila-neophyllithium[4b] (3.9 mmol) in hexane (30 cm^3) was added, dropwise to a stirred suspension of $(DMS)_2PtCl_2$ (0.51 g, 1.3 mmol) in diethyl ether (30 cm^3) at −20°C. The mixture was gradually warmed to room temperature and stirred for a further 8 h. The stirred suspension was cooled to −20°C and hydrolysed with saturated ammonium chloride solution (30 cm^3). The ethereal layer was separated and the aqueous phase washed with diethyl ether (2 × 15 cm^3). The ether extracts were combined, dried over $MgSO_4$ and decolourized with charcoal. Removal of the solvents *in vacuo* gave a yellow–brown oily residue. Trituration with either hexane or toluene afforded the product as a white powder. (Yield: 0.4 g, 55%.) The solid decomposes at room temperature over a period of several hours and was stored at −20°C. IR: 3058w, 3040vw, 3016vw, 2944w, 2917w, 2877vw, 2860w, 2833w, 1484w, 1422m, 1419sh, 1408wm, 1259vw, 1250w, 1237m, 1106s, 1024wm, 997wm, 981s, 970w, 943w, 825s,br, 810sh, 803s,br, 768m, 763sh, 732s, 717m, 699s, 688sh, 650vw, 621w, 552w, 469m, 382wm, 366m.

Preparation of cis-*bis(sila-neophyl)-bis-(pyridine) platinum*(II)

(cod)Pt(CH_2SiMe_2Ph)$_2$ (0.2 g, 0.33 mmol) was dissolved in excess pyridine (15 cm^3, *ca* 186 mmol) and stirred at 60°C for 24 h to give a pale yellow solution. Excess pyridine was removed *in vacuo* to give a pale yellow semi-crystalline solid, which was dissolved in diethyl ether (2 cm^3) and *n*-hexane was added dropwise (0.5 cm^3). Cooling the solution to −20°C afforded small pale yellow plates of the product. (Yield: 0.19 g, 85%.) IR: 3073w, 3055w, 3028vw, 3018vw, 3000vw, 2978wm, 2942wm, 2927w, 2117w, 1601m, 1482m, 1448s, 1428m, 1361vw, 1352vw, 1264wm, 1238m,br, 1209w, 1192w, 1163w, 1109s, 1107sh, 1068m, 1047w, 1023w, 1014w, 1009w, 978sh, 976w, 957w, 838s, 813vs, 786m, 760s, 732vs, 700vs, 689sh, 640w, 632w, 580w, 475wm, 458w, 388m, 303w.

Preparation of bis(pyridine)-1-platina-3-silaindan

(py)$_2$Pt(CH_2SiMe_2Ph)$_2$ (0.1 g, 0.2 mmol) was dissolved in toluene (8 cm^3) and left at ambient temperature for 4 days. Removal of toluene *in vacuo* afforded a yellow–brown oily residue which was recrystallized from diethyl ether (1 cm^3) and hexane (0.5 cm^3) to give the product as a pale yellow crystalline solid. (Yield: 0.07 g, 91%.) IR: 3105w, 3074wm, 3065wm, 3048m, 2994w, 2950m, 2896wm, 2861wm, 2831wm, 1602s, 1568s, 1480m, 1463m, 1447vs, 1385w, 1244s,br, 1217m, 1155vw, 1109w, 1077s, 1069s, 1044m, 1026s, 977wm, 957w, 833vs,br, 759s, 743s, 695s, 664w, 637wm, 563wm,br, 502w, 438w, 406vw.

Preparation of bis(sila-neophyl)(2,2′-bipyridyl) platinum(II)

2,2′-Bipyridyl (0.5 g, 3.2 mmol) and (cod)Pt(CH_2SiMe_2Ph)$_2$ (0.2 g, 0.32 mmol) were dissolved in the minimum amount of toluene (15 cm^3) and the solution stirred at 60°C for 5 days. Excess ligand was removed by washing with saturated $FeSO_4$(aq) solution. The toluene extracts were dried over $MgSO_4$ and filtered. Concentration of the solution to *ca* 2 cm^3, dropwise addition of *n*-hexane (1 cm^3) to effect crystallization and cooling to −20°C afforded large orange needles of the product. (Yield: 0.22 g, 78%.) IR: 3060w, 3048vw, 3005vw, 2970w, 2798vw, 2863w, 2839w, 1601wm, 1487w, 1469m, 1444m, 1426m, 1385wm, 1310w, 1260w, 1238m, 1231sh, 1156w, 1108s, 1023w, 994w, 980vw, 958w, 950w, 943w, 833s, 812s, 769wm, 756s, 739m, 723m, 702s, 680wm, 630w, 568w, 472m, 426w, 370wm.

Preparation of bis(sila-neophyl)(4,4′-dimethyl-2,2′-bipyridyl)platinum(II)

(Nbd)Pt(CH_2SiMe_2Ph)$_2$ (0.2 g, 0.34 mmol) and Me_2bipy (0.063 g, 0.34 mmol) were dissolved in toluene (10 cm^3) and stirred at 60°C for 21 days to give an orange–red solution. Concentration of the resulting solution to *ca* 2 cm^3, followed by dropwise addition of *n*-hexane (1 cm^3) and cooling to −20°C gave orange needles of the product. (Yield: 0.2 g, 87%.) IR: 3093vw, 3062vw, 3043vw, 2015vw, 2972w, 2895sh, 2874w, 2860w, 2836w, 2574s, 1552m, 1487w, 1450w, 1427m, 1406s, 1377m, 1363sh, 1262w, 1238m, 1190vw, 1158vw, 1139vw, 1109s, 1080w,sh, 1020w, 1010w,br, 999w, 967vw, 950w, 940sh, 832s, 816s, 803s, 770m, 750s, 740s, 719s, 704s, 693wm, 687wm, 663wm, 630w, 576wm, 476m, 447w, 390vw, 371m.

*Preparation of bis(sila-neophyl)(4,4′-di-*tert*-butyl-2,2′-bipyridyl)platinum*(II)

[Pt(CH_2SiMe_2Ph)$_2$(μ-DMS)]$_2$ (0.16 g, 0.14 mmol) and Bu$^t_2$bipy (0.08 g, 0.3 mmol) were dissolved in toluene (10 cm^3) and left at ambient temperature for 4 days giving a deep orange–red solution. Excess Bu$^t_2$bipy was removed by washing with $FeSO_4$(aq). Concentration of the solution to *ca* 2

cm^3, followed by dropwise addition of *n*-hexane (0.1 cm^3) and cooling to −20°C yielded orange crystals of the product. (Yield: 0.21 g, 96%.) IR: 3077w, 3038w, 2959w, 2931sh, 2888m, 2863m, 2837m, 1610s, 1588sh, 1492w, 1495sh, 1478s, 1465sh,br, 1423m, 1418s, 1364m, 1333vw, 1312w, 1298w, 1280vw, 1259m, 1234s, 1200w, 1155vw, 1127sh, 1119sh, 1104s, 1018w, 1009wm, 997w, 902wm, 956w, 948w, 939w, 910vw, 898w, 882m, 847sh, 830vs, 810s, 769s, 757w, 734s, 717s, 698s, 678wm, 629w, 617vw, 600wm, 577w, 553w, 531vw, 490vw, 470m, 420vw, 370wm, 304w.

Preparation of bis(sila-neophyl)(2,2′-bipyrimidyl) platinum(II)

(cod)Pt(CH_2SiMe_2Ph)$_2$ (0.34 g, 0.56 mmol) and 2,2′-bipyrimidyl (0.20 g, 1.26 mmol) were dissolved in toluene (15 cm^3) and stirred at 60°C for 10 days to give a dark red solution. Excess bipym was removed by washing with $FeSO_4$(aq). Concentration to *ca* 2 cm^3, following by dropwise addition of *n*-hexane (2 cm^3) and cooling to −20°C afforded wine red hexagonal crystals of the product. (Yield: 0.28 g, 77%.) IR: 3093vw, 3062vw, 3043vw, 2915vw, 2972w, 2895sh, 2874w, 2860w, 2836w, 1574s, 1552m, 1487w, 1450w, 1427m, 1406s, 1377m, 1363sh, 1262w, 1238m, 1190vw, 1158vw, 1139vw, 1109s, 1080w,sh, 1020w, 1010w,br, 998w, 967vw, 950w, 940sh, 832s, 816s, 803s, 770m, 750s, 740s, 719m, 704s, 693wm, 687wm, 663wm, 630w, 576wm, 476m, 447w, 390vw, 371m.

Preparation of bis(sila-neophyl)(2,2′-bipyrazyl) platinum(II)

[Pt(CH_2SiMe_2Ph)$_2$(μ-DMS)]$_2$ (0.13 g, 0.12 mmol) and bipyz (0.04 g, 0.25 mmol) were dissolved in toluene (8 cm^3) and left at room temperature for 4 days to give a purple solution. Excess ligand was removed by washing with $FeSO_4$(aq). Concentration of the solution to *ca* 2 cm^3, addition of *n*-hexane (1 cm^3) dropwise and cooling to −20°C gave magenta rods of the product. (Yield: 0.13 g, 87%.) IR: 3059w, 3011w, 2956wm, 2940vw, 2892vw, 2847m, 2828m, 1582m, 1576sh, 1487w, 1480vw, 1463wm, 1422m, 1409s, 1392sh, 1306w, 1268m, 1258w, 1247w, 1237m, 1177m, 1166m, 1158sh, 1108s, 1069w, 1062w, 1059w, 1017vw, 996w, 985vw, 953vw, 942wm, 919vw, 827vw, 808s, 769s, 740s, 713s, 700m, 688sh, 680sh, 659wm, 627w, 571w, 472m, 368wm.

Preparation of tetrakis(sila-neophyl)(μ-2,2′-bipyrimidyl)diplatinum(II)

[Pt(CH_2SiMe_2Ph)$_2$(μ-DMS)]$_2$ (0.2 g, 0.18 mmol) and 2,2′-bipyrimidyl (0.03 g, 0.18 mmol) were dissolved in toluene (8 cm^3) and left at ambient temperature for 4 days. The initially colourless solution turned dark red after 5 min and dark green after 15 min. After 1 h fine needles began to precipitate. The solid was filtered and recrystallized from acetone (15 cm^3) to give dark green needles of the product. (Yield: 0.19 g, 97%.) IR: 3060w, 3040vw, 3016vw, 2990vw, 2945m, 2920sh, 2890sh, 2863wm, 2837w, 1422s, 1403s, 1256wm, 1237s, 1194w,br, 1106s, 1028w, 1011w, 996w, 956w,br, 829vs, 805vs,br, 787wm, 718m, 738m, 728s, 717m, 698s, 685sh, 624sh, 611vw, 631wm, 501w, 470m, 382m, 367w.

Preparation of bis(sila-neophyl)(1,10-phenanthroline)platinum(II)

(cod)Pt(CH_2SiMe_2Ph)$_2$ (0.25 g, 0.42 mmol) and 1,10-phenanthroline (0.15 g, 0.83 mmol) were dissolved in toluene (10 cm^3) and stirred at 60°C for 8 days forming an intense orange–red solution. Excess phen was removed by washing with a freshly prepared aqueous $FeSO_4$ solution (5 × 30 cm^3) until the washings were colourless. Concentration of the organic layer to *ca* 2 cm^3 and addition of *n*-hexane (2 cm^3) yielded large red plates of the product. (Yield: 0.23 g, 82%.) IR: 3065w, 3020vw, 3000sh, 2965w, 2950w, 2883w, 2850vw, 2840w, 1497vw, 1490vw, 1450vw, 1425m, 1415w, 1386w, 1320vw, 1300vw, 1265wm, 1240m, 1205vw, 1192w, 1110m, 1015wm, 960wm, 955sh, 910vw, 840s, 815s, 778m, 769wm, 740m, 722m, 705m, 680w, 577w, 478w, 375w.

Preparation of bis(sila-neophyl)(3,4,7,8-tetramethyl-1,10-phenanthroline)platinum(II)

(cod)Pt(CH_2SiMe_2Ph)$_2$ (0.35 g, 0.58 mmol) and 3,4,7,8-tetramethyl-1,10-phenanthroline (0.2 g, 0.85 mmol) were dissolved in toluene (20 cm^3) and stirred at 60°C for 14 days. The resulting orange solution was washed with $FeSO_4$(aq), concentrated to *ca* 2 cm^3 and *n*-hexane (1 cm^3) was added to give long orange needles of the product. (Yield: 0.32 g, 76%.) IR: 3072w, 3056w, 3025vw, 3002vw, 2961sh, 2957m, 2935sh, 2894w, 2878m, 2837m, 1520w, 1491w, 1443sh, 1428s, 1396sh, 1365w, 1340vw, 1322w, 1303w, 1268m, 1240s, 1112s, 1019m, 980vw, 967w, 952m, 917w, 870w, 839vs, 813vs, 772s, 743s, 726s, 703s, 691sh, 681m, 632w, 587sh, 572w, 540w, 480m, 374m, 333w, 308w.

Preparation of bis(sila-neophyl)(4,7-diphenyl-1,10-phenanthroline)platinum(II)

(cod)Pt(CH_2SiMe_2Ph)$_2$ (0.23 g, 0.38 mmol) and 4,7-diphenyl-1,10-phenanthroline (0.235 g, 0.71

mmol) were dissolved in toluene (20 cm^3) and stirred for 28 days at 60°C to give a dark orange–red solution. Excess ligand was removed by washing with $FeSO_4$(aq). Concentration of the solution to *ca* 3 cm^3 and addition of *n*-hexane (2 cm^3) gave vermillion red rods of the product. (Yield: 0.31g, 99%.) IR: 3060w, 3086vw, 3010vw, 2970w, 2894vw, 2875w, 2858w, 2838w, 1630w, 1595w, 1560w, 1515vw, 1494w, 1487w, 1446w, 1437w, 1423m, 1417wm, 1395w, 1384wm, 1320vw, 1298vw, 1262m, 1242m, 1237m, 1227w,sh, 1189vw, 1156w, 1100s, 1076sh, 1029wm, 1020wm, 1010wm, 998wm, 962wm, 952wm, 944w, 924vw, 910w, 848s, 831s, 812s, 770s, 765s, 740s, 720m, 703s, 633wm, 620sh, 582w, 571wm, 555wm, 500w, 475m, 372wm.

Preparation of bis(sila-neophyl)(2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline)platinum(II)

$[Pt(CH_2SiMe_2Ph)_2(\mu\text{-DMS})]_2$ (0.15 g, 0.13 mmol) was dissolved in toluene (10 cm^3) and Me_2Ph_2phen (0.1 g, 0.27 mmol) was added. The mixture was left at room temperature for 3 h and then the solvent removed *in vacuo* to give an orange–red oily residue, which was extracted into *n*-hexane (3×15 cm^3). Evaporation of the solvent yielded a dark orange microcrystalline solid of the product. This may be further recrystallized from toluene (1 cm^3) and *n*-hexane (0.5 cm^3). Cooling to −20°C affords vermillion crystals of the product. (Yield: 0.18 g, 80%.) IR: 3062w, 3043w, 3003vw, 2962m, 2881wm,br, 1622wm, 1569wm, 1543w, 1513vw, 1483wm, 1438wm, 1425m, 1400w, 1385w, 1262s, 1104s,br, 1026s,br, 806vs,br, 771m,sh, 729m, 700s, 642w, 631wm, 577w, 537vw, 494w, 479wm, 468wm, 386m,br.

RESULTS AND DISCUSSION

(a) *Synthesis*

A variety of bis(sila-neophyl)platinum(II) compounds can be isolated in good yields using methods similar to those previously employed for analogous bis-alkyl and bis-aryl platinum(II) complexes.[3,14–18] Metathetical displacements of diene from $(cod)Pt(CH_2SiMe_2Ph)_2$ or $(nbd)Pt(CH_2SiMe_2Ph)_2$, or displacement of the thioether from $[Pt(CH_2SiMe_2Ph)_2(\mu\text{-DMS})]_2$ by nitrogen donor ligands produces $LPt(CH_2SiMe_2Ph)_2$. These substitutions are characteristically slow; sila-neophyl complexes are qualitatively more inert to diene displacement than their neophyl analogues.[3] Conversion is generally complete in 5–30 days at 60°C in toluene. Excess of the nitrogen donor ligand (2–15-fold) accelerates the reactions. Usually, the residual free ligand can be separated readily from the organometallic product by extraction into aqueous ferrous sulphate solution as $[Fe(L)_3]^{2+}$.

All of the complexes $LPt(CH_2SiMe_2Ph)_2$ are air-stable and, unlike pale yellow $(py)_2Pt(CH_2SiMe_2Ph)_2$, are brightly coloured crystalline solids. All have satisfactory elemental analyses (Table 1). ^1H and ^{13}C NMR, IR and electronic spectroscopy are discussed below. Most of these complexes rapidly decompose in toluene solutions exposed to air. In addition, they react with chlorocarbon solvents. Chloroform and dichloromethane were avoided as recrystallization solvents.

Table 1. Analytical data for bis(sila-neophyl)platinum(II) complexes

Compound	Colour	Found (Calculated) C%	H%	N%
$(cod)Pt(CH_2SiMe_2Ph)_2$	Colourless	51.7(51.9)	6.3(6.4)	
$(nbd)Pt(CH_2SiMe_2Ph)_2$	White	51.1(51.3)	5.9(5.8)	
$[Pt(CH_2SiMe_2Ph)_2(\mu\text{-DMS})]_2$	White	42.9(43.2)	5.7(5.8)	
$(py)_2Pt(CH_2SiMe_2Ph)_2$	Pale yellow	51.8(51.6)	5.6(5.6)	4.3(4.3)
$(py)_2Pt(CH_2SiMe_2C_6H_4)$	Pale yellow	45.1(45.5)	4.6(4.4)	5.7(5.6)
$(bipy)Pt(CH_2SiMe_2Ph)_2$	Orange	51.7(51.7)	5.3(5.3)	4.3(4.3)
$(Me_2bipy)Pt(CH_2SiMe_2Ph)_2$	Orange	53.1(53.1)	5.5(5.6)	4.1(4.1)
$(Bu^t_2bipy)Pt(CH_2SiMe_2Ph)_2$	Orange	57.1(56.7)	6.7(6.6)	3.6(3.7)
$(bipym)Pt(CH_2SiMe_2Ph)_2$	Maroon	48.2(47.9)	4.9(4.9)	8.6(8.6)
$(bipyz)Pt(CH_2SiMe_2Ph)_2$	Magenta	48.0(47.9)	4.9(4.9)	8.9(8.6)
$[Pt_2(CH_2SiMe_2Ph)_4(\mu\text{-bipym})]$	Dark green	46.1(46.1)	5.1(5.1)	4.8(4.9)
$(phen)Pt(CH_2SiMe_2Ph)_2$	Red	53.5(53.5)	5.0(5.1)	4.1(4.2)
$(Ph_2phen)Pt(CH_2SiMe_2Ph)_2$	Vermillion	61.2(61.1)	5.0(5.1)	3.4(3.4)
$(Me_4phen)Pt(CH_2SiMe_2Ph)_2$	Orange	55.9(55.9)	5.8(5.8)	3.7(3.8)
$(Me_2Ph_2phen)Pt(CH_2SiMe_2Ph)_2$	Vermillion	62.5(62.6)	5.9(5.7)	3.3(3.2)

(b) *Spectroscopic studies of bis(sila-neophyl) platinum*(II) *complexes*

(i) *Conventions.* The numbering system follows that for the neophyl and platinaindan analogues (Fig. 1).[3] The phenyl carbon attached (or potentially attached) to the platinum is labelled C_2, while the alkyl-substituted carbon is designated C_1. Also shown in Fig. 1 are numerical conventions for the nitrogen donor ligands.

Throughout the discussion, peaks which show a coupling to ^{195}Pt ($I = 1/2$, 34% abundant) are denoted by $\delta(J)$; where δ is the chemical shift (ppm) and J is the observed coupling constant (Hz) to ^{195}Pt. Such multiplets are termed "triplets" ("t") to distinguish them from binomial 1:2:1 triplets.

(ii) ^1H *NMR* (*Table* 2). ^1H NMR spectroscopy provides very useful characteristics. A doubled doublet at low field (δ 7.6–7.9 ppm) is particularly diagnostic of the coordinated sila-neophyl skeleton. The platinum-bound methylene hydrogens generate 1:4:1 "triplets" and $^2J_{Pt-H}$ for these protons is in the range 88–101 Hz. The ^{195}Pt-"satellites" of these signals are noticeably broader in complexes with nitrogen donor ligands in comparison with (cod)Pt(CH_2SiMe_2Ph)$_2$ (Fig. 2). This phenomenon appears more pronounced for phenanthroline ligands than for those of the bipyridyl family. It is attributed to enhanced relaxation of the ^{195}Pt nuclei by quadrupolar ^{14}N.[8,22] A related effect has been observed in the ^1H NMR spectrum of H_3CHgI, in which $^2J_{Hg-H}$ is not observed due to rapid relaxation of ^{199}Hg by ^{127}I.[19] General broadening of ^1H NMR signals has been noted occasionally as

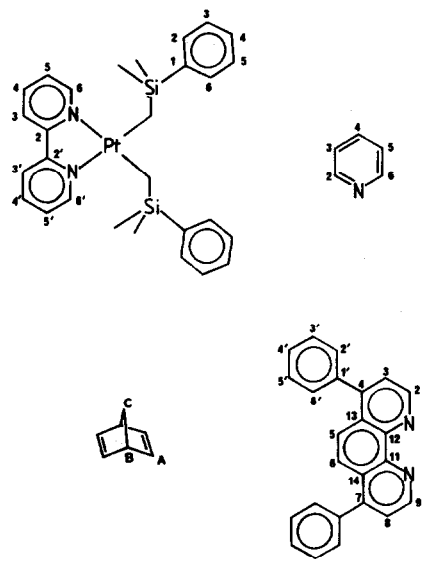

Fig. 1. Conventions employed for bis(sila-neophyl) platinum(II) complexes.

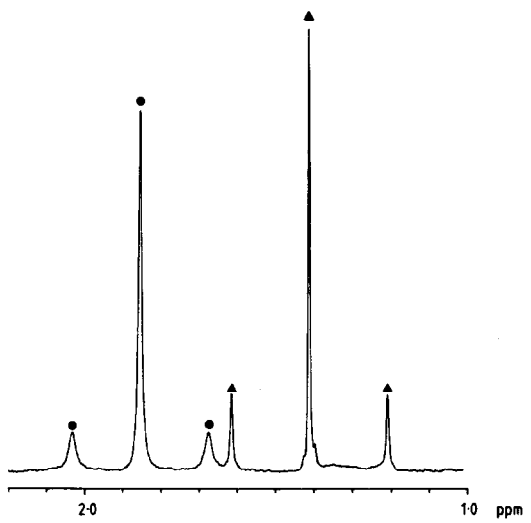

Fig. 2. Satellite broadening in the Pt–methylene resonance of (Ph$_2$phen)Pt(CH_2SiMe_2Ph)$_2$. ● = [Ph$_2$phen)Pt (CH_2SiMe_2Ph)$_2$; ▲ = (nbd)Pt(CH_2SiMe_2Ph)$_2$.

a characteristic of N-coordination[20] but although some effect can be detected for the central resonance, it is not as pronounced as that in the Pt-satellites. Resonances assigned to the neutral ligands are largely as expected and the values of $^3J_{Pt-H}$ for the protons adjacent to the nitrogen atoms are about 20 Hz.

Compared with bis(neophyl)platinum(II) complexes,[3] hydrogens in both the Si-bound methyl groups and the Pt-bound methylene groups resonate, as expected, at higher fields due to the proximal silicon. Among the aromatic hydrogens the doubled doublet of H_2 is generally downfield of that in the corresponding bis-neophyl complex. In addition, the values of $^2J_{Pt-H}$ are marginally higher than those of bis(neophyl) compounds (Fig. 3), in accord with a greater *s*-character in the Pt—C—H skeleton (*vide infra*).

(iii) ^{13}C *NMR* (*Table* 3). All the bis(sila-neophyl) compounds have been characterized by their $^{13}C\{^1H\}$ NMR spectra. Most are very complicated by the number and variety of aromatic carbons present.

The compounds LPt(CH_2SiMe_2Ph)$_2$ all show marked coordination shifts for both Si—CH_3 and aryl carbon atoms relative to Me_3SiPh (Tables 4 and 5). In accord with the general trends observed previously for $PhMe_2Si(X)$,[21] magnitudes of coordination shifts ($\Delta\delta$) are in the order $C_1 > C_4 > C_2 > C_3$; the chemical shifts of *meta*-carbon atoms in monosubstituted benzenes are least affected by changing the substituents. In all cases C_1 and C_2 are shifted downfield relative to Me_3SiPh, and C_3 and C_4 upfield. A downfield shift

[a] Positive sign indicates downfield shift.
[b] Negative sign indicates upfield shift.
[c] Obscured by solvent.

for C_2 indicates that LPt(R) is electron withdrawing (relative to H). The silicon-bound methyl carbons also display downfield coordination shifts, again reflecting that LPt(R)CH_2^- is more electron withdrawing than a methyl group. In general though, the coordination shifts do not display a marked variation with changing L, suggesting that the inductive properties of the metal fragment is rather insensitive to L. Relatedly, $^3J_{Pt—C}$ for the sila-neophyl group changes little as L varies.

The magnitude of $^1J_{Pt—C}$ for the sila-neophyl derivatives is characteristically *ca* 200 Hz smaller than that for the neophyl analogue.[3,18] We have observed this trend elsewhere[22] in related systems and have attributed it to the reduced ability of silylmethyl groups to concentrate carbon 2*s*-character into the Pt—C bond, in accord with the propositions of isovalent hybridisation,[23] assuming, reasonably, that Fermi contact contributions to *J* predominate.[24]

Comparison of (cod)Pt(CH_2SiMe_2Ph)$_2$ with (cod)Pt(CH_2CMe_2Ph)$_2$ (Fig. 3) suggests that there is a correspondingly variable response from Pt in the extent to which it commits the 6*s* orbital to the two mutually *trans* bonds to carbon. While $^1J_{Pt—C}$ for the alkyl group increases from 710 to 897 Hz from the silicon to the carbon analogue, $^1J_{Pt—C}$ for the η^2-alkene decreases correspondingly from 43 to 65 Hz. In the neophyl complex, platinum is diverting less 6*s* character towards its η^2-M—C bond and more to its η^1-M—C interaction, presumably in response to the greater 2*s* contribution to Pt—C bonding by the metal-bound carbon of neophyl. Neophyl, by the usual criteria, exercises a stronger bond-weakening *trans*-influence than sila-neophyl.[25] We are evaluating bond strength variations in these complexes by other (thermochemical, diffractometric) techniques.

Notably $^1J_{Pt—C}$ for (cod)PtMe_2[26] has the intermediate value of 773 Hz (H has electronegativity intermediate between C and Si). $^2J_{Pt—H}$ varies in the same sense as $^1J_{Pt—C}$ in accord with these prop-

ositions. $^1J_{C-H}$ is expected also to be greater for the neophyl methylene group but has not been measured for any of these complexes.

(iv) *IR spectroscopy*. IR data for this series of compounds is listed in the Experimental. Absorption characteristics of bis(sila-neophyl) complexes arise mainly from the phenyl and silicon–carbon vibrations. Those at *ca* 1600 cm^{-1} and 1470–1430 cm^{-1} are aryl C—C vibrations. The strong peaks at 760–750 cm^{-1} and 710–700 cm^{-1} are out-of-plane C—H bending modes typical of five adjacent phenyl hydrogens. The peak at 1240–1230 cm^{-1} is a symmetric CH_3 deformation and the two strong bands at 860–830 cm^{-1} and 815–810 cm^{-1} are assigned to Si—C stretching modes. The strong band at 1110–1105 cm^{-1} is a characteristic X-sensitive band. In addition, the band near 580 cm^{-1} may be attributed to a Pt—C stretching mode.

(v) *Electronic spectroscopy* (*Table* 6). The electronic spectra of $LPt(CH_2SiMe_2Ph)_2$ (where L = neutral nitrogen donor ligand) are particularly characterized by two absorptions attributed to metal–ligand charge-transfer (MLCT) $d\pi \rightarrow \pi^*$ transitions and have been employed as a measure of relative electronic effects of such ligands.[15,17] The more energetic of the two is often obscured by the more intense ligand $\pi \rightarrow \pi^*$ transitions in the near-UV. The lower energy absorption can always be observed and hence has been a gauge of the energy differences between the ($d\pi$) HOMO of the metal and the (π^*) LUMO of the ligand. The energy of λ_1 increases in the order: μ-bipym < bipyz < bipym < Ph_2phen < Me_2Ph_2phen < phen ≃ bipy < Me_2bipy ≃ Bu^t_2bipy < Me_4phen.

The lower MLCT energies for the bipyz and bipym complexes relative to the bipy analogue is consistent with the generally observed reduction in complexes of N-bonded heteroatomatic ligands with electronegative ring atoms or substituents.[27] The LUMO for bipym is proposedly lower in energy than for bipy, resulting in a smaller separation from the $d\pi$ orbitals of platinum. Similarly, the higher energy of this absorption for Me_2bipy and Bu^t_2bipy complexes (relative to bipy) is explained by the electron-releasing substituent raising the energy of the LUMO. The phenanthroline ligands, with their increased conjugation, might be expected to exhibit lower energy absorption relative to bipy. Ph_2phen (in which conjugation can be further augmented by suitable orientation of the phenyl substituents) does give rise to a relatively minor reduction in energy of the π^* orbitals but phen and bipy exhibit similar absorption energies. For the dinuclear complex, $[Pt_2(CH_2SiMe_2Ph)_4(\mu\text{-bipym})]$, the absorption occurs at considerably longer wavelengths than for the mononuclear analogue. This phenomenon, which has been noted previously,[17] is believed to be due to the presence of a relatively high energy, largely non-bonding HOMO, spanning both metals in the binuclear complex.

The energy of the MLCT bands exhibited solvatochromism as observed for related comlexes.[13] On changing from acetone to dichloromethane, fairly small bathochromic shifts were observed for the bipy and the various phenanthroline complexes, while the bipym (both mono and bis-bidentate) and bipyz complexes displayed significant energetic lowering of the absorption (15–18 nm). In toluene, on the other hand, all the complexes displayed significant shifts. The energy of the λ_1 absorption, in general, was lowered by 15–25 nm with the exception of $(bipyz)Pt(CH_2SiMe_2Ph)_2$, where a smaller shift (7 nm) was observed. It has been suggested that direct interaction with the metal centre is responsible for the solvatochromic shifts of MLCT bands in closely related bis-dialkylplatinum(II) complexes.[28]

Comparing the electronic spectra of cor-

Table 6. Electronic spectra of bis(sila-neophyl)platinum(II) complexes

Complex	λ_{max} (nm) Actone	CH_2Cl_2	Toluene
$(bipy)Pt(CH_2SiMe_2Ph)_2$	475.5	478.0	504.0
$(Me_2bipy)Pt(CH_2SiMe_2Ph)_2$	467.5	468.0	497.5
$(Bu^t_2bipy)Pt(CH_2SiMe_2Ph)_2$	465.5	468.5	497.0
$(bipyz)Pt(CH_2SiMe_2Ph)_2$	525.0	541.0	548.0
$(bipym)Pt(CH_2SiMe_2Ph)_2$	487.5	505.5	528.5
$[Pt_2(CH_2SiMe_2Ph)_4(\mu\text{-bipym})]$	591.5	616.5	624.0
$(phen)Pt(CH_2SiMe_2Ph)_2$	475.0	475.0	500.5
$(Ph_2phen)Pt(CH_2SiMe_2Ph)_2$	485.0	489.5	506.0
$(Me_4phen)Pt(CH_2SiMe_2Ph)_2$	429.0	432.5	468.5
$(Me_2Ph_2phen)Pt(CH_2SiMe_2Ph)_2$	479.0	482.0	504.0

responding bis(neophyl) complexes revealed no significant differences in the relative electronic effects of the ligands, suggesting that the ligands confer similar electronic environments in both types of complexes. Thus, the different reactivity of sila-neophyl and neophyl derivatives probably do not originate with the electronic influence of the ancillary ligand.

(c) *Thermolytic behaviour of bis(sila-neophyl) platinum*(II) *complexes*

Qualitatively, bis(sila-neophyl) complexes are more substitution inert than the related dineophyl analogues, higher temperatures are required for the displacement of the diolefin by the nitrogen donor ligand. Preliminary investigations indicate that sila-neophyl complexes with bidentate N-donor ligands are also more thermolytically inert than the corresponding neophyl complexes, as no detectable metallacyclization occurs in toluene solutions up to 140°C. Toluene solutions of $(py)_2Pt(CH_2SiMe_2Ph)_2$ at ambient temperature (or above) do rearrange to the corresponding platinasilaindan. We are currently investigating the thermal behaviour of these and related bis-hydrocarbyl platinum(II) complexes.

Acknowledgements—We thank Dick Sheppard and Sue Johnson for high field NMR measurements and Steve Black for a sample of 4,4′-di-*tert*-butylbipyridyl. The award of a studentship by the SERC (to B.C.A.) is gratefully acknowledged. We are also indebted to Johnson Matthey for continuous support via generous loans of platinum and to the SERC, Royal Society and the University of London Central Research Fund for equipment grants in support of our work.

THE ADSORPTION OF TUNGSTEN(VI) ON ACTIVATED CARBON FROM 1.0 M Na(H)Cl SOLUTION

J. J. CRUYWAGEN* and A. T. PIENAAR

Department of Chemistry, University of Stellenbosch, Stellenbosch, 7600 South Africa

(*Received* 2 *June* 1988; *accepted* 6 *July* 1988)

Abstract—The adsorption of tungsten(VI) onto activated carbon has been investigated as a function of pH_c in the range 2.0–6.5 at constant ionic strength (1 M NaCl) and temperature (25°C). The tungsten concentration was varied from 5×10^{-4} to 2×10^{-2} M. Adsorption is very strong at $pH_c < 4.5$ and depending on equilibrium conditions, loadings of ~ 2.8 mM W^{VI} per g activated carbon can be obtained. Computer treatment of distribution data led to an adsorption model, similar to that proposed (J. J. Cruywagen and H. F. de Wet, *Polyhedron* 1988, **7**, 547) for molybdenum(VI), comprising mainly dimeric species and small amounts of monomeric species. The chemisorption is explained in terms of complexation of tungsten(VI) with basic oxygen atoms at the surface of the activated carbon. Adsorption constants of tungsten and molybdenum correlate well with complex formation constants of tungsten and molybdenum with oxalate and citrate.

It is known that tungsten(VI)[1] and molybdenum(VI)[2–4] are strongly adsorbed by activated carbon from acid solution. Very recently it has been shown that the adsorption behaviour of molybdenum can be explained quantitatively in terms of the adsorption of mononuclear and dimeric species of which the latter predominates.[4] Very little has been published about the adsorption of tungstate onto activated carbon. Work aimed at the separation of tungsten has been carried out under non-equilibrium conditions and the data have been interpreted qualitatively in terms of the adsorption of polyanions.[1] In view of the results obtained for molybdenum[4] an equilibrium study of the adsorption of tungsten is of special interest. A comparison of the adsorption models for the two systems could provide some further insight into the mechanism of adsorption of molybdate and tungstate onto activated carbon. The strong adsorption of molybdenum(VI) species has been rationalized in terms of chemical bonding with basic oxygen atoms available at the surface of the activated carbon. If similar coordination of tungsten(VI) by oxo groups in the structure of the activated carbon takes place, the relative tendencies of tungsten and molybdenum to adsorb should parallel those of complex formation with ligands such as oxalate and citrate; stability constants for these complexes are available. With these considerations in mind the present investigation of the adsorption of tungsten onto activated carbon (as a function of both tungsten concentration and pH) has been carried out under conditions similar to those of the previous molybdenum study.[4]

EXPERIMENTAL

Materials and solutions

Analytical grade chemicals and water obtained from a Milli-Q system were used for the preparation of all solutions. Sodium tungstate and sodium chloride solutions were prepared from the recrystallized salts and standardized gravimetrically as described previously.[5] Hydrochloric acid was standardized indirectly against potassium hydrogen phthalate by titration with sodium hydroxide. Granular peat based activated carbon (Chemviron, type BPL) of particle size 0.5–2.0 mm was used in the adsorption experiments. The carbon was soaked for a week in a concentrated acid solution (10 M HCl; 1 M HF) to remove soluble ash components, iron and other metal ions.[6] It was washed, first with 1 M HCl and then repeatedly with distilled water to remove the acid. The carbon was dried at 110°C.

pH_c Measurements

The free hydrogen ion concentration, h, was determined by measuring the potential (to $\pm$ 0.2 mV) with a T & C Model 1002 Research pH meter. A Ross combination electrode (supplied by Orion Research) with a 3 M KCl internal filling solution was used. The relationship between the measured potential E (in mV) and the hydrogen ion concentration at 25°C is given by the equation

$$E = E^0 + 59.16\,pH_c \qquad (1)$$

where $pH_c = -\log h$. E^0 was determined by titration of a 1.0 M NaCl solution with 0.10 M HCl, which was 0.90 M with respect to NaCl.

Adsorption measurements

A known mass of carbon (usually $\sim$ 0.25 g) was equilibrated with 50 cm^3 of sodium tungstate solution in a well stoppered polythene tube by slow mechanical shaking for seven days in a water bath at 25°C. In the case of molybdenum adsorption on activated carbon it has been shown that a period of seven days was sufficient for adsorption equilibrium to be established. Preliminary adsorption experiments carried out with a 1.0 mM tungstate solution at $pH_c \sim 2$ likewise showed that the tungstate concentration in the liquid phase remains practically constant after an equilibration period of six to seven days. Time dependent reactions that occur in dilute tungstate solutions, acidified to a degree of protonation $Z > 1.2$, became very slow after about a week[7] and did not seem to have any effect on the establishment of adsorption equilibrium for the experiments pertaining to the two lowest concentrations (cf. Discussion below). The tungstate solutions were 1.0 M with respect to sodium chloride and for each series of experiments at a given tungsten(VI) concentration, the hydrochloric acid concentration was varied to obtain pH_c values in the range 2–6 after equilibration. The initial tungstate concentrations for the various adsorption experiments were 0.5, 1.0, 5.0, 10.0 and 20.0 mM. For comparison purposes an adsorption experiment was also carried out with a 1.0 mM molybdate solution under the same conditions. Due to the very strong adsorption of tungsten (and molybdenum) on activated carbon, the amount adsorbed could be obtained with sufficient accuracy from the difference between the initial and equilibrium concentration in the aqueous phase.

The tungsten concentration in the aqueous phase was determined colorimetrically using a Varian Cary 210 spectrophotometer. The excellent Tiron method for the colorimetric determination of molybdenum[8] has been slightly adapted for the determination of tungsten. Maximum absorbance of the tungsten(VI) tiron complex occurs at $\sim$ 320 nm, but the wavelength of 340 nm was chosen because of the very sharp increase in absorption of tiron itself at wavelengths < 340 nm. A small increase in absorption ($\sim$ 3%) takes place during the first 4 h after the reagents have been mixed and then remains constant for several hours. The molar absorption coefficient, ε, at 340 nm then has the value 9400 $cm^{-1}\,M^{-1}$.

RESULTS AND DISCUSSION

The results of adsorption experiments at various tungsten(VI) concentrations are shown in Fig. 1 as plots of the logarithm of adsorption (mmol W^{VI} per g activated carbon) against equilibrium pH_c. It is seen that the adsorption increases with an increase in initial tungstate concentration. At a given pH_c in the range 2–4 the adsorption is proportional to the initial tungstate concentration up to $\sim$ 5.0 mM. Adsorption is very strong and at $pH_c = 2.3$, for example, about 97% of the tungstate in the aqueous phase is adsorbed. Although the percentage adsorption decreases with further increase in tungstate concentration it is still rather high at 20.0 mM, namely $\sim$ 70% at $pH_c = 2.3$. Also represented in Fig. 1 are results for the adsorption of molyb-

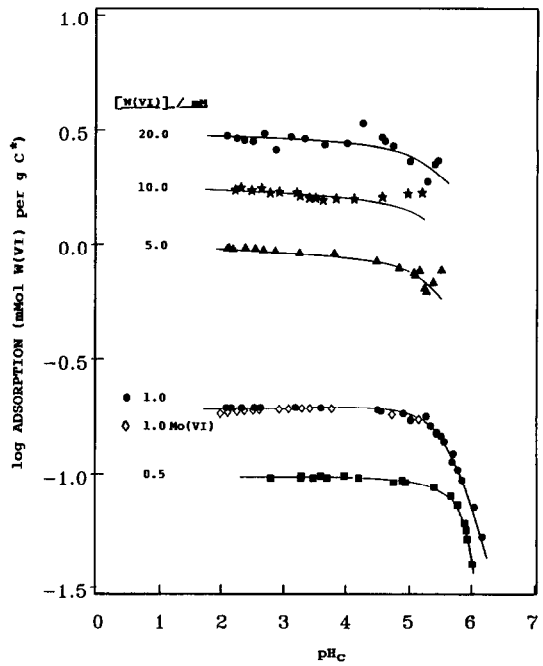

Fig. 1. Adsorption of tungsten(VI) [and molybdenum(VI)] by activated carbon from a 1.0 M Na(H)Cl solution, as a function of pH_c, at various tungsten concentrations.

denum(VI) at a concentration of 1.0 mM, from which it can be seen that the adsorption behaviour of the two metals is very similar at this concentration. At a much higher concentration, adsorption of tungsten is somewhat weaker than that reported for molybdenum.[4] At $pH_c = 2.5$ and initial concentration of 20.0 mM, for instance, the amount of tungsten adsorbed is 2.85 mmol g^{-1} compared to 3.00 mmol g^{-1} in the case of molybdenum. This result is consistent with the interpretation (put forward for the molybdenum system) that adsorption of polyanions is insignificant. At high concentration the percentage of polyanions in the aqueous phase increases and since the polyanions of tungsten(VI) are more stable than those of molybdenum(VI), adsorption of tungsten will be weaker. For the heptanuclear polyanions, $W_7O_{24}^{6-}$ and $Mo_7O_{24}^{6-}$ for example, the values for $\log\beta_{7,8}$ are 65.2 and 52.8, respectively.[5,9]

The variation in the distribution of tungsten between the activated carbon and aqueous solution, as a function of pH_c, for the experiments at the two lowest concentrations are shown in Fig. 2. It is seen that maximum distribution occurs at $pH_c \sim 3.4$ for the experiment with a tungsten concentration of 0.5 mM and decreases sharply with an increase in pH_c. For the experiment at 1.0 mM concentration the maximum appears at a slightly lower pH_c and the distribution at the maximum is somewhat higher.

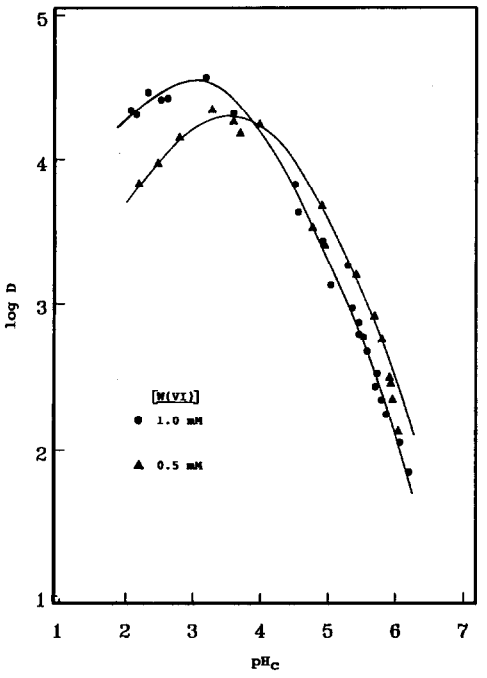

Fig. 2. Distribution of tungsten(VI) between activated carbon and a 1.0 M Na(H)Cl solution as a function of pH_c at initial concentrations of 0.5 and 1.0 mM. The curves are calculated from the constants given in Table 1.

These distribution curves resemble those for the adsorption of molybdenum.[4] It therefore seemed worthwhile to attempt a quantitative interpretation of the distribution curves in terms of the adsorption model derived for molybdenum.

The tungsten system, however, is much more complicated and quantitative treatment of the data is difficult because of the lack of information about equilibria for $Z > 1.2$. Because of slow reactions the polyanions are poorly characterized and some are described only in terms of symbols such as ψ, X and Y.[10,11] For this reason only the lowest concentrations could be used for the calculations and by making some simplifying approximations a satisfactory interpretation of the data could be obtained. Also, the distribution curves for the higher concentrations showed too many irregularities to justify quantitative treatment.

Equilibria and calculations

For the molybdenum adsorption system it has been shown that molybdate is bound to the carbon mainly in the dimeric form and that relatively small amounts of the monomeric species $[HMoO_4]^-$ and $Mo(OH)_6$ also adsorb.[4] Assuming similar behaviour for tungsten, the overall adsorption equilibria (in 1 M NaCl medium) are represented by the equations

$$2WO_4^{2-} + 3H^+ + C^* \rightleftharpoons HW_2O_7^-(ads) \quad (2)$$

$$WO_4^{2-} + H^+ + C^* \rightleftharpoons HWO_4^-(ads) \quad (3)$$

$$WO_4^{2-} + 2H^+ + C^* \rightleftharpoons W(OH)_6(ads) \quad (4)$$

where C* represents the activated carbon. The concentrations of the adsorbed species are expressed in terms of mmol tungsten(VI) adsorbed per g of activated carbon. For very small amounts adsorbed it is a good approximation to assume a constant activity for the activated carbon. The overall adsorption constants are than given by

$$K_{2,3} = [HW_2O_7^-(ads)]/[WO_4^{2-}]^2[H^+]^3 \quad (5)$$

$$K_{1,1} = [HWO_4^-(ads)]/[WO_4^{2-}][H^+] \quad (6)$$

$$K_{1,2} = [W(OH)_6(ads)]/[WO_4^{2-}][H^+]^2. \quad (7)$$

The distribution of tungsten between the solid and liquid phases is given by

$$D = \{2[HW_2O_7^-(ads)] + [HWO_4^-(ads)] + [W(OH)_6(ads)]\}/B \quad (8)$$

where B is the total tungsten concentration in solution after equilibration and by substitution using eqs (5)–(7) gives the expression

$$D = (2K_{2,3}b^2h^3 + K_{1,1}bh + K_{1,2}bh^2)/B \quad (9)$$

where,

$$b = [WO_4^{2-}].$$

The equilibria for the various possible protonation and condensation reactions of tungstate can be presented by the general equation

$$pWO_4^{2-} + qH^+ \rightleftharpoons (WO_4^{2-})_p(H^+)_q. \quad (10)$$

Formation constants for the species are denoted by $\beta_{p,q}$, for example $\beta_{7,8}$ for the polyanion $[W_7O_{24}]^{6-}$. For brevity, species will occasionally be described by the stoichiometric coefficients p and q, i.e. (7,8) for $[W_7O_{24}]^{6-}$. The total tungsten concentration, B, in the solution is given by

$$B = b + \sum p\beta_{pq}b^p h^q. \quad (11)$$

For $Z < 1.2$, equilibria are established rapidly and formation constants for the following polyanions have been reported for the ionic medium 1.0 M NaCl:[5] $[W_6O_{20}(OH)_2]^{6-}$, $[W_7O_{24}]^{6-}$, $[HW_7O]_{24}^{5-}$, $[H_2W_{12}O_{42}]^{10-}$. At very low tungsten concentrations, such as those pertaining to the aqueous phase after equilibration, the monomeric species $[HWO_4]^-$ and $W(OH)_6$ must be taken into account. Equilibrium constants reported for these species under somewhat different conditions, i.e. ionic strength 0.1 and temperature 20°C were used.[10] To make provision for slow equilibria at $Z > 1.2$, formation constants were used that had been obtained from potentiometric measurements of acidified tungstate solutions aged for seven days.[7] A reaction model that gave a satisfactory description of the potentiometric data for the aged solutions comprised the four polyanions mentioned above and two additional species, namely $[H_2W_7O_{24}]^{4-}$ and $[W_8O_{26}]^{4-}$ for which the values of the equilibrium constants were $\log\beta_{7,10} = 76.30$ and $\log\beta_{8,12} = 90.20$.

Computer treatment of data

The variation in distribution with change in pH_c, expressed in terms of the various tungstate species, is given by the following equation

$$D = \sum pK_{pq}b^p h^q/(b + \sum p\beta_{pq}b^p h^q). \quad (12)$$

The experimental points on the distribution curve (log values) were fitted to eq. (12) using the non-linear least-squares program *BMDPAR*.[12] The free $[WO_4]^{2-}$ concentration, b, at each point was calculated from the total tungsten concentration in a subroutine by iteration according to Newton's method.[13]

The calculations were started using the data of the experiment at the lowest concentration (0.5 mM) for which the proportions of polyanions in the solution are the smallest. In the first computer run, adsorption of mononuclear species was neglected and despite the uncertainties about the identity of some polyanions, and also of some of the formation constants introduced into eq. (12), a reasonable fit of the theoretical curve on the experimental points was obtained. The fit could be improved by adding the two mononuclear species as additional adsorbing species. The same result was obtained for calculations using data for the experiment at a tungsten concentration of 1.0 mM. Computations carried out on the assumption that either only mononuclear species or some polyions e.g. a hexa- or heptanuclear species adsorb, resulted in a totally unacceptable fit. From these results it may be concluded that for the pH_c range and concentrations investigated, tungsten is adsorbed mainly in the dimeric form. Significant adsorption of the monomeric species, $[HWO_4]^-$ and $W(OH)_6$, occurs only at $pH_c > 5.5$ and $pH_c < 3.0$, respectively (Fig. 3).

In the case of the molybdenum adsorption system some formation constants could be calculated which agreed well with values obtained by other methods. Several more runs were therefore done in an attempt to extract some useful information about tungsten(VI) equilibria from the distribution data at concentrations of 0.5 and 1.0 mM. Because of the very strong adsorption and extremely low concentrations of tungsten in the aqueous phase the accuracy of the data does not justify extensive model testing. It was found, however, that the fit could be improved by introducing a dimeric cation similar to that characterized in the case of molybdenum.[14] A dimeric tungsten anion analogous to $[HMo_2O_7]^-$ on the other hand was not accepted; the formation constant refined to an insignificant small value. Next, constants of species occurring in relatively high concentrations in the aqueous phase ($\sim 50\%$) were treated as unknowns, i.e. $\beta_{1,2}$, $\beta_{7,9}$ and $\beta_{8,12}$. Because of convergence problems not all these constants could be treated simultaneously as unknown parameters together with the three adsorption constants. By fixing the values of either two, three or four constants in turn, new values for all constants were calculated with concommitant improvement of the fit; the (8,12) species, however, was rejected.

The results of the computer treatment of the distribution data are summarized in Table 1. The values listed for the constants are those that resulted in the best fit for each of the distribution curves. (Constants for other species were fixed on literature values.) The agreement between the values for $\log K_{2,3}$, $\log\beta_{1,2}$ and $\log\beta_{2,5}$ for the two experiments

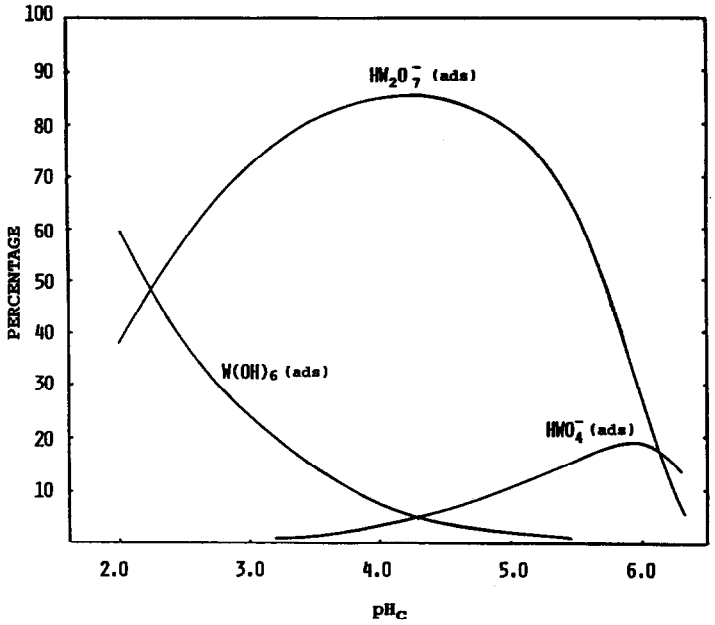

Fig. 3. Concentration of adsorbed species, expressed as a percentage of the total amount of tungsten(VI) adsorbed, as a function of pH_c. The curves are calculated for an initial concentration of 1.0 mM using average values of the adsorption constants.

Table 1. Values obtained for adsorption (K_{pq}) and formation (β_{pq}) constants from the computer treatment of the distribution data at initial tungsten(VI) concentrations of 0.5 and 1.0 mM. Error limits are estimated values

	0.5 mM	1.0 mM
$\log K_{1,1}$	8.2±0.5	7.9±0.5
$\log K_{1,2}$	11.8±0.5	12.6±0.5
$\log K_{2,3}$	22.9±0.3	22.8±0.3
$\log \beta_{1,2}$	8.3±0.2	8.2±0.2
$\log \beta_{2,5}$	23.1±1.0	22.8±1.0
$\log \beta_{7,10}$	77.0±1.0	76.0±1.0

is good. In addition to the satisfactory fit of the theoretical curves on the experimental points the agreement between the values for $K_{2,3}$ is very strong evidence for the dimeric nature of the predominant adsorbed species. Because of the much weaker adsorption of the monomeric species the values of $K_{1,1}$ and $K_{1,2}$ could not be determined with great accuracy. The differences between the values for these constants therefore reflect experimental inaccuracies, but it might also be an indication of some deficiencies in the assumed reaction model of the aqueous phase. Good agreement, however, was obtained between the present values for $\log \beta_{1,2}$ (8.2 and 8.3) and that reported previously (8.1).[10] Also reasonable is the agreement between the values now calculated for $\log \beta_{7,10}$ (76.0 and 77.0) and that obtained from potentiometric measurements[7] of aged (seven days) tungstate solutions ($\log \beta_{7,10} = 75.8$). Although the existence of a (7,10) polyanion, $[H_2W_7O_{24}]^{4-}$, has not been postulated before in the literature, its inclusion serves well to obtain an adequate description of the aqueous phase equilibria. The existence of such an ion does not seem unreasonable in view of the experimental evidence recently obtained for the heptanuclear tungsten(VI) polyions (7,8) and (7,9).[5,15,16] The value of $\log \beta_{7,10} = 76 \pm 1$ is acceptable if compared with $\log \beta_{7,8} = 65.19$ and $\log \beta_{7,9} = 69.96$.[5]

This is the first time that evidence for a (2,5) tungsten(VI) species has been obtained and a value for its formation constant was determined. Again it is difficult to assess the probability of the existence of this species from the present data. Its inclusion, however, does improve the fit and a similar dimeric molybdenum(VI) cation has been characterized.[14] The value of $\log \beta_{2,5} = 23$ for the tungsten species is significantly higher than the values obtained for the molybdenum cation, $\log \beta_{2,5} = 18.4$ and 19 pertaining to a 3 M $NaClO_4$ medium.[14,17] This difference is consistent with the greater stability of condensed tungsten species; compare for example the values of the formation constants of $[W_7O_{24}]^{6-}$ and $[Mo_7O_{24}]^{6-}$ in a 1.0 M NaCl medium, namely $\log \beta_{7,8} = 65.2$ and 52.8, respectively.[5,4]

The adsorption model

A satisfactory description of the tungsten(VI) adsorption data at low concentrations in the pH_c

range 2–6 is afforded in terms of a model comprising a dimeric and two monomeric species. This model also worked quite well for the adsorption of molybdenum, for which it had been tested for concentrations up to 10 mM.[4] It is interesting to compare the adsorption constants of the different tungsten and molybdenum species. Stronger adsorption of tungsten(VI) onto activated carbon is indicated by greater adsorption constants for each of the tungsten species, namely $\log K_{1,1} \sim 8.0$ and 6.4, $\log K_{1,2} \sim 12.2$ and 10.5, $\log K_{2,3} \sim 22.9$ and 19.8.

The explanation advanced for the strong adsorption of molybdenum(VI) on activated carbon in terms of chemical bonding to basic surface oxygen atoms,[4] analogous to complex formation of oxalate,[18] citrate,[19] lactate,[20] etc. seems to be equally well suited for tungsten(VI). A strong driving force for the chemisorption reaction would be the gain in bond energy when the coordination spheres of molybdenum(VI) and tungsten(VI) are expanded from four to six. Relatively large negative ΔH values have been measured for the complexation reactions of molybdate[18,19] and tungstate[21] with oxalate and citrate; in such complexes molybdenum(VI) and tungsten(VI) are usually octahedrally coordinated.[22–24]

When the formation constants for dinuclear complexes of tungstate[21] and molybdate[18] with oxalate are compared it is seen that the tungsten complex is more stable, which corresponds with the stronger adsorption of tungsten compared to that of molybdenum (cf. $K_{2,3}$ values above):

	$\log \beta$
$2WO_4^{2-} + 5H^+ + 2C_2O_4^{2-} \rightleftharpoons [W_2O_5(C_2O_4)_2(OH)H_2O]^{3-}$	32.8
$2MoO_4 + 5H^+ + 2C_2O_4^{2-} \rightleftharpoons [Mo_2O_5(C_2O_4)_2(OH)H_2O]^{3-}$	31.8.

Also, if the formation constants for the citrate complexes of molybdenum[19] and tungsten[21] are compared it is found that the values are greater for tungsten than for molybdenum:

	$\log \beta$	
	Mo^{VI}	W^{VI}
$MO_4^{2-} + Cit^{3-} + H^+ \rightleftharpoons [MO_3Cit]^{4-} + H_2O$	8.25	10.14
$MO_4^{2-} + Cit^{3-} + 2H^+ \rightleftharpoons [MO_3HCit]^{3-} + H_2O$	15.08	17.08
$MO_4^{2-} + Cit^{3-} + 3H^+ \rightleftharpoons [MO_3H_2Cit]^{2-} + H_2O$	19.7	21.6.

Also noteworthy are the comparable differences between the molybdenum and tungsten constants for complexation and adsorption, respectively. This consistency between the adsorption and complexation constants for the two metals supports the interpretation of the adsorption behaviour in terms of surface complex formation.

COMPLEXATION AND INTRAMOLECULAR ALKYLATION OF BIPYRIDYL LIGANDS BY $Zr(OAr)_2R_2$ ($R = CH_3$, CH_2Ph) COMPOUNDS

LISA M. KOBRIGER, ANNE K. McMULLEN, PHILLIP E. FANWICK and IAN P. ROTHWELL†

(*Received* 20 *April* 1988; *accepted* 13 *July* 1988)

Abstract—Addition of the α-di-imine ligands 2,2′-bipyridine (bipy), 4,4′-dimethyl-2,2′-bipyridine (4,4′-Me_2bipy) or 1,10-phenanthroline (phen) to the bis-alkyls $Zr(OAr\text{-}2,6Bu^t_2)_2(R)_2$ ($OAr\text{-}2,6Bu^t_2$ = 2,6-di-*tert*-butylphenoxide; $R = CH_3$, CH_2Ph) results in the formation of two types of product. In the case of the dimethyl substrate a simple adduct such as $Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2(bipy)$ is generated. However, with dibenzyl the products obtained are the result of an intramolecular alkylation of the α-di-imine ligands. Spectroscopic data confirm the asymmetric nature of the ensuing alkylated heterocycles. A single crystal X-ray diffraction study on $Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2$(4,4′-bipy) confirmed the stoichiometry and showed a very crowded coordination sphere about the six-coordinate metal centre with the two *trans* methyl groups being severely bent towards the bipyridine chelate rings.

The ability of neutral donor ligands such as ethers, tertiary phosphines, amines and nitrogen heterocyclic compounds to coordinate to and stabilize the homoleptic alkyls of the high valent early *d*-block, lanthanide and actinide metals has been well recognized for some time.[1–3] However, recent developments have shown that pyridine based ligation can sometimes undergo further reactions subsequent to coordination to the metal. Hence, Erker has shown that treatment of (η^4-butadiene)$ThCp^*_2$ with pyridine led to the formation of an η^3-allyl thorium compound resulting from attack at the α-carbon of the pyridine ring.[4] Recent work on the chemistry of early *d*-block metal η^2-acyls has also shown that pyridine heterocycles are candidates for undergoing carbon–carbon bond forming reactions subsequent to coordination. Hence, treatment of the di-alkyls $(ArO)_2MR_2$ (OAr = 2,6-di-*tert*-butylphenoxide; M = Zr, Hf; $R = CH_3$, CH_2Ph) with CO in the presence of pyridine leads to the high yield formation of α,α-disubstituted pyridine–dimethoxide ligation.[5] A pathway involving stepwise attack of intermediate η^2-acyl groups on the pyridine ring is envisioned. Work by Tilley *et al.* has shown similar reactivity for η^2-sila–acyl ligands. Preliminary mechanistic data is consistent with a pathway involving nucleophilic attack of the metal–acyl group at the α-carbon of the pyridine ring followed by a facile 1,2-hydrogen shift to generate the observed α-substituted pyridinemethoxide linkage.[5,6] The alkylation of pyridine and bipyridine substrates by alkyl–lithium reagents is a well documented process and is used extensively in the synthesis of 2-alkylpyridines and *ortho*-alkylated bipyridines and phenanthrolines.[7]

In this paper we wish to report the intramolecular alkylation of bipyridyl ligands by zirconium alkyls of the type $Zr(OAr\text{-}2,6Bu^t_2)_2(R)_2$. Structural studies on a six-coordinate adduct of stoichiometry $Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2$(bipy) strongly suggests that steric crowding is important in inducing the alkylation.

RESULTS AND DISCUSSION

The two, pale yellow di-alkyls, $Zr(OAr\text{-}2,6Bu^t)_2M_2$[8] and $Zr(OAr\text{-}2,6Bu^t)_2(CH_2Ph)_2$[9] form deep yellow–orange solutions in benzene or toluene on addition of 2,2′-bipyridine (bipy). In the cases of the dimethyl, reaction with one equivalent

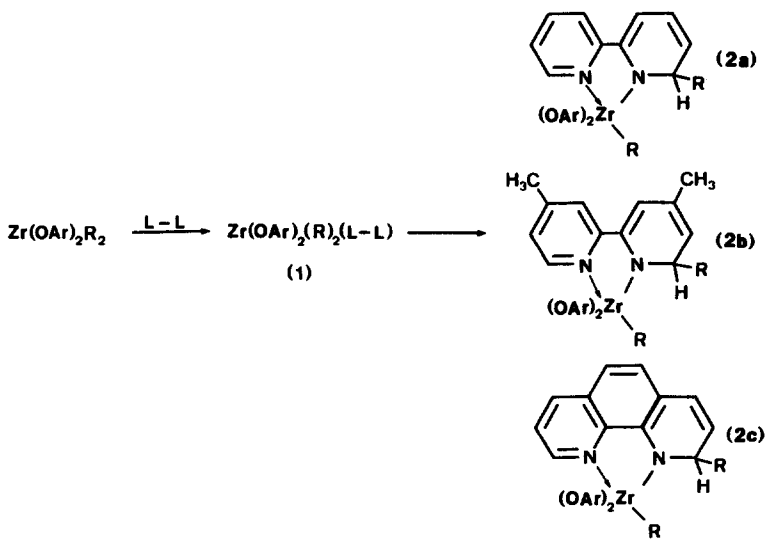
leads to orange products of stoichiometry $Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2(bipy)$ (**1a**) or $Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2(4,4'\text{-}Me_2bipy)$ (**1b**), which can be recrystallized from toluene on cooling as large orange blocks. The ^1H NMR of **1** is found to be broad at ambient temperatures and concentration dependent. We interpret this observation as being due to a rapid equilibrium of the type shown:

$$Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2 + bipy \rightleftharpoons Zr(OAr\text{-}2,6Bu^t_2)_2(Me)_2(bipy). \quad (\mathbf{1b})$$

Apart from these changes, solutions of **1a** or **1b** in hydrocarbon solvents are stable for weeks at room temperature.

In contrast, addition of one equivalent of bipy or $4,4'\text{-}Me_2bipy$ to the dibenzyl $Zr(OAr\text{-}2,6Bu^t_2)_2(CH_2Ph)_2$ results in initially orange solutions which lighten to a pale yellow over a period of an hour. During this time dramatic changes in the ^1H NMR spectrum take place. Although it is possible to isolate pure materials of stoichiometry "$Zr(OAr\text{-}2,6Bu^t_2)_2(CH_2Ph)_2(bipy)$" from the reaction, the spectroscopic data is consistent with a more complex formulation in which intramolecular transfer of a benzyl group to one of the bipy or phenanthroline α-carbon atoms has occured (Scheme 1). A similar alkylation product can also be obtained using 1,10-phenanthroline. In this case the initially orange solution of the intermediate adduct is replaced by an intense red solution containing product **2c** (Scheme 1).

The ^1H and ^{13}C NMR spectra of the three alkylation products, **2**, contain certain similar features. Particularly informative are the series of multiplets that appear in the region δ 3.0–6.5 ppm in the ^1H NMR spectra. These well-resolved, sharp signals are highly characteristic of pyridyl rings which have undergone 1,2-addition reactions,[7,10] in this case of a $Zr—CH_2Ph$ function. Comparison of the spectra of the bipy, 4,4'-bipy and phen derivatives of **2** allows an unequivocal assignment of these resonances. The characteristic doublet due to the *ortho*-proton of the non-alkylated pyridyl rings is also present in the δ 8.0–8.5 ppm region. The other aromatic proton resonances in the δ 6.5–7.5 ppm region are too difficult to resolve for accurate assignment. The diastereotopic methylene protons of the two benzyl groups, one of which has been transferred to the pyridyl ring are also observed as AB patterns in the δ 2.5–3.5 ppm region at low temperatures. The remaining proton resonances, those of the *tert*-butyl groups of the aryloxide ligands appear at ambient temperatures as three, broad resonances of intensity 2:1:1. The asymmetry induced in the bipyridyl ligands on alkylation at one of their faces means that non-equivalent aryloxide groups should ensue in any static structure that one can envisage. This is consistent with the observed spectra, except that it also appears that restricted rotation about one of the aryloxide, Zr—O—Ar bonds is taking place, presumably for steric reasons, resulting in non-equivalent *tert*-butyl groups. Similar restricted rotation of 2,6-di-*tert*-butylphenoxide ligands has been previously well documented.[11] However, although the low temperature limiting spectra are consistent with the expected structure of these molecules, the high temperature ^1H NMR spectra contain some puzzling features. At all temperatures from -60 to $+80°C$ the resonance due to the protons attached to the



Scheme 1.

alkylated pyridyl system remain sharp and well resolved. However, as the temperature is raised the AB patterns of the two benzyl groups broaden and collapse into two singlets at the expected weighted average of the low temperature AB patterns. No exchange of benzyl groups appears to be occurring on the NMR time scale. Although the equilibration of the diastereotopic benzyl protons at higher temperatures is indicative of some fluxional process taking place, it is very difficult to see how this can be occurring for the benzyl group attached to the pyridyl ring. At all temperatures this group should remain diastereotopic as long as carbon–carbon bond breaking processes are ruled out. Similarly the aryloxide *tert*-butyl groups broaden, coalesce and appear as a broad singlet at 80°C in the ^{1}H NMR spectrum. At the present time we have no totally satisfactory explanation for these observations. The alkylated bipyridyl ligands might very well be expected to undergo rapid dissociation and recoordination of the undisrupted pyridine ring. A process such as this would explain the exchange of non-equivalent aryloxide ligands but again could not account for the high temperature singlets for the benzyl ligands. In the ^{13}C NMR spectrum the two α-carbon single atoms of the non-equivalent benzyl groups are observed as resonances at $\approx \delta$ 50 and $\approx$ 70 ppm.

Unfortunately it was not found possible to obtain single crystals of the alkylation products, **2**, suitable for crystallographic study. However, suitable crystals of the dimethyl adduct **1b** were obtained and subjected to a structural analysis. The solid state structure of **1b** is shown in Fig. 1, while Table 1 contains some pertinent bond distances and angles. The molecule can be seen to contain a six-coordinate zirconium atom with a coordinate geometry considerably distorted from octahedral. The Zr—OAr, Zr—CH_3 and Zr—N(pyridyl) distances appear well into the normal range reported for related groups bound to Zr^{IV},[8,12] The distortions of the coordination sphere from octahedral are certainly significant in view of the observed alkyl transfer seen to take place in the benzyl complexes. The angle between the bulky *cis*-aryloxide groups is opened up to 107.9(1)°. Meanwhile the methyl groups, which in an idealized geometry would be mutually *trans* are both bent towards the 4,4′-Me_2bipy ligand to give a CH_3—Zr—CH_3 angle of only 144.2(2)°. The heterocyclic chelate generates only a modest 67.3(1)° bite at the metal. The structure can be envisaged in terms of the 4,4′-Me_2bipy ligand trying to squeeze between the two methyl groups in a tetrahedral $Zr(OAr\text{-}2,6Bu^t_2)_2(CH_3)_2$ molecule, with the bulky aryloxide ligands sterically resisting the opening up of the CH_3—Zr—CH_3 angle. In the structurally characterized bis-benzyl, $Zr(OAr\text{-}2,6Bu^t_2)_2(CH_2Ph)_2$, O—Zr—O and C—Zr—C angles of 116.2(2) and 110.0(3)°, respectively, were observed.[9] The severe

crowding present in this molecule is also evident in the distortions clearly seen in the aryl rings of the OAr-2,6Bu$^t_2$ groups (Fig. 1). The inability of the alkyl groups to "back away" from the incoming bipyridyl ligands presumably is the reason that alkyl transfer occurs. The lack of observed alkylation by the dimethyl over its benzyl counterpart may be a consequence of the even greater steric crowding present in the intermediate [Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_2$Ph)$_2$(bipy)]. However, thermodynamic considerations such as the fact that L$_n$M—CH$_2$Ph bonds are typically weaker than L$_n$M—CH$_3$ bonds may be an important consideration.[13]

EXPERIMENTAL

The bis-alkyls Zr(OAr-Bu$^t_2$)$_2$(CH$_3$)$_2$[8] and Zr(OAr-Bu$^t_2$)$_2$(CH$_2$Ph)$_2$[9] were synthesized as previously reported. The heterocyclic compounds 2,2′-bipyridine (bipy), 4,4′-dimethyl-2,2′-bipyridine (4,4′-Me$_2$bipy) and 1,10 phenanthroline (phen) were obtained commercially and dried by melting under a dynamic vacuum of 10^{-2}–10^{-3} torr for 20–30 min. ^{1}H and ^{13}C NMR spectra were obtained using a Varian Associates XL-200 spectrometer while microanalyses were performed in-house at Purdue.

Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_3$)$_2$(bipy) (**1a**)

Although ^{1}H NMR spectra of 1 : 1 mixtures of Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_3$)$_2$ and bipy in benzene-d$_6$ showed the presence of a new compound, recrystallization from such solutions sometimes yielded mixtures of starting materials as well as **1a**. The best results for obtaining pure crystalline **1a** was found to be cooling a mixture of the dimethyl and bipyridine (2 equiv) in toluene whereupon large orange blocks of product were obtained. Found: C, 68.2; H, 8.2; N, 4.0. Calc. for ZrC$_{40}$H$_{56}$N$_2$O$_2$: C, 68.8; H, 8.2; N, 4.1%. ^{1}H NMR (C$_6$D$_6$, 30°C): δ 1.62 (s, OAr-*Bu$^t_2$*); 1.87 (s, Zr—CH$_3$); 8.61 (d, 2,2′-H).

Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_3$)$_2$(4,4′-Me$_2$bipy) (**1b**)

An essentially identical procedure to that used for **1a** above yielded **1b** as very large orange blocks. Found: C, 70.1; H, 8.4; N, 3.7. Calc. for ZrC$_{42}$H$_{60}$N$_2$O$_2$: C, 70.4; H, 8.4; N, 3.9%. ^{1}H NMR (C$_6$D$_6$, 30°C): δ 1.59 (s, OAr-*Bu$^t_2$*); 1.86 (s, Zr—*CH$_3$*); 2.15 (s, 4,4′-*Me$_2$*bipy); 8.50 (d, 2,2′-H).

Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_2$Ph)(bipy-CH$_2$Ph) (**2a**)

The addition of bipy (1 equiv) to a solution of Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_2$Ph)$_2$ in toluene results in the formation of a dark orange solution after 4 h. Addition of hexane to the solution results in the precipitation of the product as small yellow microcrystals. Found: C, 74.0; H, 7.7; N, 3.4. Calc. for ZrC$_{52}$H$_{64}$N$_2$O$_2$: C, 74.3; H, 7.7; N, 3.3%. ^{1}H NMR (−30°C, C$_6$D$_5$CD$_3$): δ 1.03 (s), 1.34 (s), 1.76 (s, ratio of 1 : 1 : 2, OAr-Bu$^t_2$); 2.58, 2.68 (AB pattern, *CH$_2$*Ph); 2.94, 3.39 (AB pattern, *CH$_2$*Ph); 3.45 (broad triplet, 4′-H); 4.16 (dd, 3′-H); 5.24 (d, 5′-H); 6.01 (t, 2′-H); 8.22 (d, 2-H); 6.5–7.3 (m, other aromatics). ^{13}C NMR (C$_6$D$_6$, 30°C): δ 46.9 (bipy-*C*H$_2$Ph); 72.2 (Zr—CH$_2$Ph); 32.9, 32.5, 31.98 (OAr-2,6Bu$^t_2$).

Zr(OAr-2,6Bu$^t_2$)$_2$(CH$_2$Ph)(4,4′-Me$_2$bipy-CH$_2$Ph) (**2b**)

An identical procedure to that used to prepare **2a** only now using 4,4′-Me$_2$bipy yielded **2b** as small yellow–orange plates. Found: C, 74.4; H, 8.3; N, 3.3. Calc. for ZrC$_{54}$H$_{70}$N$_2$O$_2$: C, 74.7; H, 7.9; N, 3.2%. ^{1}H NMR (−30°C, C$_6$D$_5$CD$_3$): δ 1.07 (s), 1.38 (s), 1.76 (s, ratio of 1 : 1 : 2, OAr-2,6Bu$^t_2$); 2.58, 2.62 (AB pattern, *CH$_2$*Ph); 3.00, 3.40 (AB pattern, *CH$_2$*Ph); 1.21 (s), 1.78 (s, 4,4′-*Me$_2$*); 4.09 (dd, 3′-

H); 5.25 (d, 5′-H); 5.95 (d, 2′-H); 6.5–7.5 (m, other aromatics).

$Zr(OAr\text{-}2,6Bu^t_2)_2(CH_2Ph)(Phen\text{-}CH_2Ph)$ (2c)

Obtained as deep red microcrystals by an essentially identical procedure using phen instead of bipy. Found: C, 76.5; H, 7.5; N, 4.2. Calc. for $ZrC_{54}H_{64}N_2O_2$: C, 75.0; H, 7.5; N, 3.2%. ^1H NMR (−30°C, $C_6D_5CD_3$): δ 0.90 (s), 1.39 (s), 1.80 (s, 1:1:2 ratio, OAr-2,6Bu^t_2); 2.84, 2.92 (AB pattern, CH_2Ph); 3.10, 3.35 (AB pattern, CH_2Ph); 6.32 (dd, 2′-H); 4.29 (dd, 4′-H); 3.91 (m, 3′-H); 8.51 (d, 2-H); 6.5–7.7 (m, other aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 49.5 (phen-CH_2Ph); 74.1 (Zr—CH_2Ph).

Crystallographic studies

Crystal data and data collection parameters are contained in Table 2. The procedures used in the data collections are those typically used by the Purdue Crystallographic Center and have been reviewed.[14] All non-hydrogen atoms were refined anisotropically while the positions for hydrogen atoms were calculated assuming idealized geometry and a bond distance of 0.95 Å. For methyl groups, one hydrogen was located in a difference Fourier map, its position idealized and the remaining positions calculated. The three intensity standards were measured after every 5000 s of beam time and showed no decay. An extinction correction was not applied.

LIGAND REACTIVITY IN 2,2′-BIPYRIDINE COMPLEXES; CHARGE EFFECTS UPON REACTIONS WITH BASE

EDWIN C. CONSTABLE

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 21 *March* 1988; *accepted* 13 *July* 1988)

Abstract—^{1}H and ^{13}C NMR studies indicate that the 2,2′-bipyridine ligands in $[Rh(bipy)_3]^{3+}$ (bipy = 2,2′-bipyridine) salts are in a different electronic environment to those in $[Ru(bipy)_3]^{2+}$ salts. The rhodium(III) cation undergoes a rapid and specific deuteration reaction upon treatment with solutions of $Na[OCD_3]$ in CD_3SOCD_3/CD_3OD. Exchange occurs rapidly at H_6 and more slowly at H_3. These observations are interpreted in terms of a separability of σ- and π-bonding contributions to the metal–ligand interaction.

It is well established that ligand reactivity may be modified upon coordination to a metal ion.[1–5] Particular interest has centred on the reactions of pyridine and oligopyridine complexes which are among the commonest components of both homogeneous and heterogeneous systems for solar energy photoconversion. The reactivity of oligopyridine complexes has been the subject of some controversy.[6–11] It has been noted that the σ- and π-components of the metal–ligand interaction are separable and opposed in complexes with π-acceptor ligands.[12–17] A number of years ago, we reported a novel deuterium exchange reaction associated with coordinated 2,2′-bipyridine ligands in solutions of $[Ru(bipy)_3]^{2+}$ salts.[18] Other workers have confirmed these results[19–21] and extended the observations to $[Os(bipy)_3]^{2+}$ salts.[21] More recently it has been demonstrated that $[Ru(terpy)_2]^{2+}$ salts undergo analogous reactions, and that the relative rates of reaction at the central and terminal pyridyl rings preclude a pathway involving cyclometallated intermediates.[22] We have now extended these observations to complexes of 2,2′-bipyridine and 2,2′:6′,2″-terpyridine with other metals, and report herein our studies of $[Rh(bipy)_3]^{3+}$ salts.

EXPERIMENTAL

^{1}H and ^{13}C NMR spectra were recorded on Bruker WM250 or AM400 spectrometers. Electronic spectra were recorded on a Pye–Unicam 8800 spectrophotometer.

Relaxation measurements were made using the inversion recovery technique. Measurements were made using degassed 20 mM solutions of the ruthenium or rhodium complexes in CD_3SOCD_3. In each case, ten different τ values ranging from 0.05 to 7 s were used for the experimental data sets. Deuteration studies were made using 10 mM solutions of $[Rh(bipy)_3][PF_6]_3$ in 1:1 CD_3SOCD_3/CD_3OD. Solutions of $Na[OCD_3]$ in CD_3OD were prepared by the reaction of weighted amounts of sodium metal with CD_3OD.

Rhodium trichloride trihydrate was used as supplied (Johnson Matthey); 2,2′-bipyridine (Aldrich) was recrystallized under nitrogen before use.

Tris(2,2′-*bipyridine*)*rhodium*(III) *hexafluorophosphate*

A solution of $[Rh(bipy)_3]Cl_3$ in aqueous ethanol was prepared as described by Lehn,[23] and treated with a 2 M excess of aqueous $[NH_4][PF_6]$. The yellow precipitate ws collected by filtration and recrystallized from ethanol–acetone to give yellow plates of $[Rh(bipy)_3][PF_6]_3$.

RESULTS AND DISCUSSION

The ^{1}H NMR chemical shifts and associated T_1 relaxation times for 20 mM solutions of $[M(bipy)_3]^{n+}$ (M = Ru, $n = 2$; M = Rh, $n = 3$) in CD_3SOCD_3 are presented in Table 1. We have previously reported the use of relaxation measurements in the assignment of the NMR spectra of coordinated 2,2′-bipyridine ligands.[24] The spectrum of the rhodium complex was fully assigned on the basis of a COSY experiment.

Table 1. ^{1}H NMR chemical shift values (δ) and relaxation times (T_1, s) for CD_3SOCD_3 solutions of $[M(bipy)_3][PF_6]_n$ (20 mM, M = Ru, $n = 2$; M = Rh, $n = 3$)

	Ru		Rh		
	δ	T_1 (s)	δ	T_1 (s)	$\Delta\delta^a$
H_3	8.40	0.41	9.04	0.45	0.64
H_4	8.17	0.72	8.57	0.79	0.40
H_5	7.53	0.66	7.79	0.72	0.26
H_6	7.73	0.88	7.85	0.90	0.12

$^a\Delta\delta = \delta(Rh) - \delta(Ru)$.

The spectrum of the rhodium(III) complex closely resembles that of the corresponding ruthenium(II) compound. The most noticeable feature is the downfield shift of H_3 with respect to the free ligand, and the origins of this effect in the conformational changes resulting from the adoption of a *cis* conformation of the ligand upon coordination have been discussed.[5,24-27] A comparison of the chemical shifts of the rhodium(III) complex with those of the ruthenium(II) complex reveals the expected downfield shift for all the resonances in the tripositive cation. The $\Delta\delta$ values are also listed in Table 1 and are of some interest.

The crystal and molecular structures of the cations $[Rh(bipy)_3]^{3+}$ and $[Ru(bipy)_3]^{2+}$ reveal the two ions to possess extremely similar structures;[28,29] the M—N distances and all other molecular parameters in the two are the same within experimental error. Any differences in ground state and reactivity properties will thus be due to the difference in charge between the two ions. The similarity in the T_1 relaxation times is further evidence that the structures and solute–solvent interactions of the two complexes are similar. A simple electrostatic model for the metal–ligand interaction would predict the greatest deshielding to occur close to the metal, i.e. at H_6. The relationship between the ^{1}H NMR chemical shift and electron density at a directly bonded carbon atom has been established for aromatic molecules, and is expected to hold for molecules as closely related as the rhodium(III) and ruthenium(II) cations.[30] The $\Delta\delta$ values decrease in the order $H_3 > H_4 > H_5 > H_6$, with a remarkably small shift in $\Delta\delta$ of 0.12 associated with H_6. The net deshielding is a function of the *total* electron density at each site, which includes contributions from both σ- (electron withdrawing) and π- (electron releasing) components. These results are in general accord with those previously reported for $[M(NH_3)_5py]^{n+}$ (M = Ru, $n = 2$; M = Rh, $n = 3$)[21,32] and with the predictions of the electroneutrality principle;[33] indeed, the efficiency of the back-donation at quenching the charge build-up at the six-position is remarkable. These results provide a quantitative measure of the efficiency of d(or p)–π^* back-donation in isoelectronic d^6 ions. As expected, the higher positive charge on the rhodium(III) centre results in a greater polarization of the ligand, and also results in a contraction of the $4d$ and $5p$ orbitals involved in the back-donation. Thus the rhodium ion is *less* able to compensate for the *larger* positive charge build-up in the ligand. The net effect is as we observe; the reduced back-donation from the rhodium only acts effectively to prevent charge build up at the site of highest positive charge closest to the metal (i.e. at the six position). These results are consistent with quantum chemical studies at various levels of sophistication which have been reported for these systems.[14-17]

The ^{13}C NMR spectra of the complexes exhibit similar changes, and values of δ and $\Delta\delta$ are listed in Table 2. Once again, these are consistent with effective back-donation reducing the charge build-up at C_6. The pattern of $\Delta\delta$ values is similar to that observed in the $[M(NH_3)_5py]^{n+}$ complexes mentioned earlier.[31,32] Specifically, C_2 and C_6 undergo upfield shifts on passing from the ruthenium(II) to the rhodium(III) complexes; this is exactly the opposite to that expected in the absence of back-donation.

Treatment of a CD_3SOCD_3 solution of $[Rh(bipy)_3]$

Table 2. ^{13}C NMR chemical shift values (δ) for CD_3SOCD_3 solutions of $[M(bipy)_3][PF_6]_n$ (20 mM, M = Ru, $n = 2$; M = Rh, $n = 3$)

	Ru	Rh	
	δ	δ	$\Delta\delta^a$
C_2	156.6	154.5	−2.1
C_3	124.5	126.8	+2.3
C_4	137.9	143.1	+5.2
C_5	127.8	130.4	+2.6
C_6	151.2	150.9	−0.3

$^a\Delta\delta = \delta(Rh) - \delta(Ru)$.

$[PF_6]_3$ with $Na[OCD_3]$ in CD_3OD resulted in the immediate formation of a deep brown solution. The ^1H NMR spectrum of this solution exhibited 12 separate resonances, four of which could be assigned to free 2,2′-bipyridine. Upon the addition of CF_3COOD, the solution changed colour to yellow and the resonances due to the free ligand broadened (presumably due to fast protonation–deprotonation equilibria) and a spectrum containing eight sharp resonances was obtained.

Treatment of solutions of $[Rh(bipy)_3][PF_6]_3$ in 1 : 1 CH_3SOCH_3/CH_3OH with $Na[OCH_3]$ resulted in no change in the electronic spectrum. However, rapid changes in the ^1H NMR spectrum of a solution of the complex in 1 : 1 CD_3SOCD_3/CD_3OD occurred upon the addition of $Na[OCD_3]$ at 40° (Fig. 1). Upon the addition of $Na[OCD_3]$ the intensity of the δ 7.85 doublet (H_6) diminishes. Associated with this process, the triplet at δ 7.79 collapses to a doublet. Under the reaction conditions described, the exchange of H_6 is complete within 25 min, after which period a noticeable reduction in the signal for H_3 occurs, with a concommittant collapse of H_4 from a triplet to a doublet. The exchange of H_3 and H_6 is virtually complete after 1 h; after prolonged reaction times further exchange occurs at H_5 and the signal for H_4 is observed as a singlet at δ 8.57.

The behaviour reported above is in marked contrast to that previously reported for the corresponding osmium(II) and ruthenium(II) complexes, in which the fastest exchange is observed at H_3.[18–22] Whilst these observations are in accord with our initial predictions of a large inductive charge build-up at C_6, they are not consistent with the ^1H NMR shift data which indicates effective back-donation at this site.

A number of mechanisms for the proton–deuteron exchange reaction have been proposed, including cyclometallation at C_3, addition–elimination at C_4 and an acid–base reaction giving a metal-stabilized pyridyl anion. The involvement of cyclometallated intermediates has been eliminated previously,[22] and the present observation of exchange at H_6 effectively confirms this. If we assume a common mechanism for the exchange at H_3 and H_6 we may effectively preclude addition–elimination reactions, since the π-centred mesomeric effects at C_4 (for exchange of $H_{3,5}$) and C_5 (for exchange of H_6) are different and opposite. This leaves a simple acid–base reaction involving methoxide acting as a base rather than a nucleophile.

Under the conditions of the reaction (40°C, excess $Na[OCD_3]$), deprotonation is expected to lead to the thermodynamic anion (although the *kinetic* product will be the C_3 anion, since the parent acid bears the greatest positive charge at this site). Thus, H_6 is the most acidic proton in the ion, although C_6 is the site that shows least change in total electron density. However, C_6 is the position which shows the greatest change in σ electron density as a result of polarization by the metal ion. In the anion, we may regard the negative charge as being localized in an in-plane sp^2 orbital, which is most sensitive to the charge distribution within the σ-bonded framework, and only affected by the net charge to a lesser

Fig. 1. ^1H NMR spectra of $[Rh(bipy)_3][PF_6]_3$ (30 mM, 1 : 1 CD_3SOCD_3/CD_3OD) in the presence of $Na[OCD_3]$ (400 mM) at 40°C.

extent. In other words, the higher positive charge on the rhodium(III) stabilizes the pyridyl anion regardless of any other π-bonding changes which are occurring.

In conclusion, this study has given a considerable amount of information regarding metal–ligand interactions in pyridine complexes. The proton–deuterium exchange reaction in 2,2′-bipyridine complexes proceeds by an acid–base mechanism rather than by nucleophilic attack upon the coordinated ligand. The use of total charge densities in predicting the reactivities of coordinated ligands can only be expected to give reasonable results in the case of π-innocent systems. The balance of σ- and π-components in the metal–ligand interaction may be used to effectively tune the reactivity of coordinated ligands at various sites.

Acknowledgements—I should like to thank the Royal Society for a grant towards the purchase of a spectrophotometer and Johnson Matthey plc for the loan of rhodium trichloride and ruthenium trichloride. I also with to thank Drs Malcolm Gerloch and Antony Stone for helpful discussions.

(*Received* 23 *May* 1988; *accepted* 20 *July* 1988)

Abstract—The new compound $[VOCl_2(MeCN)_2(H_2O)]$ has been prepared and characterized by elemental analysis, and IR and ESR spectroscopies. This compound is a versatile starting material for a wide range of complexes, in particular for those of the general formula $[VOCl_2L_2]$. As an illustration of the chemistry of $[VOCl_2(MeCN)_2(H_2O)]$, several complexes have been prepared where L = Ph_3PO, tetramethylurea, imidazolidine-2-thione and 1,3-dimethylimidazolidine-2-thione, and these have been characterized by elemental analysis; UV–vis, IR, and ESR spectroscopies; and for L = 1,3-dimethylimidazolidine-2-thione (dmit), by X-ray crystallography. $[VOCl_2(dmit)_2]$ crystallizes in the orthorhombic space group *Pnn*2, with $a = 9.9684(6)$, $b = 10.4631(9)$ and $c = 8.5624(6)$ Å, and $Z = 2$. The molecule has square-pyramidal coordination geometry, with the thiourea ligands *trans* to each other. This is the first example of a crystal structure of a vanadium(IV)–thiourea complex.

The synthesis of coordination complexes containing the $VOCl_2$ moiety can be hampered by the lack of suitable starting materials.[1] Herein, we report the simple preparation of such a starting material which is soluble in polar media, namely $[VOCl_2(MeCN)_2(H_2O)]$. As an illustration of its chemistry, two thiourea complexes of the type $[VOCl_2L_2]$ have been prepared from it and characterized by UV-vis, IR and ESR spectroscopies, and by elemental analysis. In addition, the X-ray crystal structure of one complex of this type, where L = 1,3-dimethylimidazolidine-2-thione (dmit), has also been determined. Whereas urea complexes of vanadium(IV) are well known and have been thoroughly studied,[2] the corresponding thiourea complexes have not been well characterized previously. Consequently, the present report of the structural characterization of $[VOCl_2(dmit)_2]$ is the first example of a vanadium(IV)–thiourea crystal structure.

EXPERIMENTAL

Materials and instrumentation

A 50% w/v aqueous solution of $VOCl_2$ was obtained from BDH; reagent grade MeCN was dried by distillation from P_4O_{10}; reagent grade $SOCl_2$ was used as received from Fisons; imidazolidine-2-thione was obtained from Aldrich; 1,3-dimethylimidazolidine-2-thione was prepared by the method of Maier.[3]

Analyses were carried out by the University of Manchester Microanalytical Laboratory. IR spectra in the region 600–4000 cm^{-1} were recorded for samples mulled in liquid paraffin and held between NaCl plates on a Perkin–Elmer Model 297 spectrophotometer. UV-vis spectra were recorded for samples dissolved in MeCN and contained in matched silica cells of 1 cm pathlength on a Perkin–Elmer Model 402 spectrophotometer. ESR spectra were obtained on fluid solutions of the compounds in CH_2Cl_2 at room temperature at X-band frequencies with a Varian 112 spectrometer.

Preparation of $[VOCl_2(MeCN)_2(H_2O)]$

An aqueous solution of $VOCl_2$ (50% w/v, 15 cm^3) was evaporated to a dark green paste and triturated with 5 cm^3 of $SOCl_2$, yielding a pale blue solid. Excess $SOCl_2$ was removed by decantation and evaporation under reduced pressure, and the residue dissolved in 25 cm^3 of MeCN. This blue solution was then evaporated to dryness, and the resulting dark blue paste triturated a second time with 5 cm^3 of $SOCl_2$, to give a dark brown solid. Excess $SOCl_2$ was again removed by decantation and evaporation under reduced pressure. To the residue, 50 cm^3 of MeCN was added, whereupon a green solution was formed from which a bright blue precipitate of $[VOCl_2(MeCN)_2(H_2O)]$ appeared on standing. This solid was isolated by filtration, washed with MeCN, and dried *in vacuo*. The product was stored in a Schlenk tube under dry dinitrogen. Found: C, 19.0; H, 3.4; N, 10.9; Cl, 30.7; V, 21.4. $C_4H_8Cl_2N_2O_2V$ requires C, 20.2; H, 3.4; N, 11.8; Cl, 29.8; V, 21.4%.

Preparation of $[VOCl_2$(1,3-*dimethylimidazolidine-2-thione*$)_2]$

The preparations of the thiourea complexes were identical, and one representative example is given. $[VOCl_2(MeCN)_2(H_2O)]$ (0.78 g, 3.3 mmol) was dissolved in MeCN (15 cm^3), and to this solution 1,3-dimethylimidazolidine-2-thione (0.83 g, 6.4 mmol) in MeCN (10 cm^3) was added with stirring. The solution immediately turned bright green. After stirring the reaction mixture for 15 min, the solution was evaporated to dryness, yielding a pale green, microcrystalline powder.

Crystals suitable for examination by X-ray diffraction were obtained by recrystallizing the crude product from dry MeCN in air, protected by a $CaCl_2$ guard tube. Found: C, 29.0; H, 5.1; N, 13.4; Cl, 18.0; V, 13.0. Calc. for $C_{10}H_{20}Cl_2N_4O_2S_2V$: C, 30.2; H, 5.06; N, 14.1; Cl, 17.8; V, 12.8%.

Crystal structure determination

Crystal data. $C_{10}H_{20}Cl_2N_4OS_2V$, $M = 398.27$. Orthorhombic, $a = 9.9684(6)$, $b = 10.4631(9)$, $c = 8.5624(6)$ Å, $V = 893.06$ Å^3 (refined from 32 reflections with $20° \leqslant 2\theta \leqslant 40°$), Cu-$K_\alpha$ radiation, ($\lambda = 1.54184$ Å), space group *Pnn*2 (No. 34), $Z = 2$, $D_x = 1.488$ g cm^{-3}. Crystal colour: green. Crystal size: $0.19 \times 0.26 \times 0.43$ mm. $F(000) = 410$, $\mu = 9.71$ mm^{-1}.

Data collection and reduction.[4] The crystal was mounted in a capillary tube. Siemens AED2 diffractometer, ω–θ scan mode, temperature = 295 K. A total of 4095 reflections were measured with $3° \leqslant 2\theta \leqslant 130°$, yielding 790 unique, non-extinguished reflections, of which the 733 reflections having $F > 4\sigma_c$ (σ_c based on counting statistics) were deemed observed and used for structure solution and refinement. The intensities of three reflections were monitored during data collection and a correction for the *ca* 4% decay observed was applied. Data were also corrected for Lorentz and polarization effects, including effects of the monochromator, and a semi-empirical absorption correction was applied. Transmission factors ranged from 0.024 to 0.083.

Structure solution and refinement.[5] Direct methods. Refined by least-squares with all non-hydrogen atoms anisotropic, minimizing $\Sigma w(|F_o|-|F_c|)^2$, where $w^{-1} = \sigma^2(F) = \sigma_c^2(F)+6-49G+117G^2-3S-S^2-20GS$ and $G = F_0/F_{max}$ and $S = \sin\theta/\sin\theta_{max}$.[6] Hydrogen atoms were included subject to the following constraints: C—H = 0.96 Å, H—C—H = 109.5°, $U(H) = 1.2U_{eq}(C)$. Final discrepancy indices were $R = 0.0452$ and $R' = 0.0445$. The final difference-synthesis showed no peaks greater than 0.31 nor less than −0.28 e Å^{-3}. Selected bond lengths and interbond angles are given in Table 1.

RESULTS AND DISCUSSION

The partial dehydration of aqueous solutions of $VOCl_2$ with $SOCl_2$ followed by treatment with aceto-

nitrile gives a good yield of the hygroscopic blue complex $[VOCl_2(MeCN)_2(H_2O)]$. Previous workers[1,7] have prepared the fully dehydrated complex $[VOCl_2(MeCN)_2]$, but that preparation requires the isolation of a very reactive intermediate product, $VOCl_2$, which is then treated with acetonitrile. The present synthesis is faster, can be carried out in one reaction vessel and yields a material which can be used to prepare a wide range of $VOCl_2$ adducts. For example, we have used $[VOCl_2(MeCN)_2(H_2O)]$ to prepare the previously known complexes $[VOCl_2(tmu)_2]$[8] (tmu = tetramethylurea) and $[VOCl_2(Ph_3PO)_2]$[9] in addition to the thiourea complexes mentioned below. Despite the presence of one mole equivalent of H_2O per mole in $[VOCl_2(MeCN)_2(H_2O)]$, it may still be used (in dry solvents) to prepare hydrolytically sensitive materials, such as the thiourea complexes prepared in this study. Thus, it has greater synthetic utility than might be expected at first sight.

The identity of $[VOCl_2(MeCN)_2(H_2O)]$ was confirmed by elemental analysis and IR and ESR spectroscopies. In the IR spectrum of the material, five principal bands were observed and assigned as follows: 3300 (br, OH stretch); 2320, 2300 (CN stretches); 1620 (OH bend); 990 cm^{-1} (V=O stretch).

$[VOCl_2(MeCN)_2(H_2O)]$ reacts with thiourea and its cyclic derivatives such as imidazolidine-2-thione (ethylenethiourea) to give complexes of the type $(VOCl_2L_2]$, where L is the thiourea. We were successful in crystallizing one of these adducts, where L = 1,3-dimethylimidazolidine-2-thione, to give crystals suitable for an X-ray crystal structure determination. $[VOCl_2(dmit)_2]$ has square-pyramidal coordination geometry about vanadium (Fig. 1). In the crystal, the molecule occupies a position of 2/*m* crystallographic symmetry, with the two-fold axis passing through the V=O bond, and the chlorine and sulphur atoms lying in the mirror plane. This situation gives rise to disorder in the crystal structure, since the V=O bond may point in either a positive or negative direction with respect to the normal to the mirror plane. Similar types of disorder have been found before.[10]

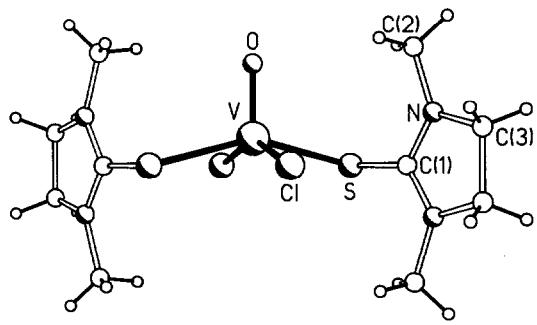

Fig. 1. Molecular structure of $[VOCl_2(dmit)_2]$.

The dimensions of the $VOCl_2$ fragment (Table 1) are unremarkable when compared to other adducts of this type.[8,9] However, the V—S distance of 2.424(1) Å is rather long in comparison to some other mean V—S bond lengths such as V—S(thiolate) = 2.378 Å,[11] V—S(dithiolene) = 2.337 Å[12] and V—S(dithiocarbamate) = 2.402 Å.[13] This may be due in part to the different charges on the sulphur-containing ligands, but it could also relate to the observation by ESR spectroscopy, (*vide infra*) that at least two species are formed when $[VOCl_2L_2]$, L = imidazolidine-2-thione or 1,3-dimethylimidazolidine-2-thione, is dissolved in CH_2Cl_2. The long V—S bond may indicate that it is relatively weak, allowing the thiourea ligands to dissociate in solution. There are two significant changes in the dimensions of the thiourea ligand itself on coordination. Firstly, the C=S bond length increases from 1.673(5) Å in the free ligand[14] to 1.728(4) Å in the complex and secondly, the C—N bond length decreases from 1.342(5) and 1.334(5) Å in the free ligand to 1.311(4) Å in the complex.

The IR spectra of the complexes in the region 4000–600 cm^{-1} contained bands due to the thiourea ligands and bands due to the V=O stretching mode. V—S and V—Cl vibrational modes appear below 600 cm^{-1}. The V=O stretching wavenumbers for

Compound	$\nu_{V=O}$ (cm^{-1})	λ_{max} (nm)	ε(dm^3 mol^{-1} cm^{-1})
$[VOCl_2(imdt)_2]$	998	720	46
$[VOCl_2(dmit)_2]$	1002	730	43

the complexes studied are given in Table 2. The UV-vis spectra of the solutions formed by dissolving the thiourea complexes in MeCN are unremarkable, being dominated in the visible region by a broad band in the red region. The UV-vis peak maxima positions and extinction coefficients are given in Table 2.

ESR spectra of the complexes measured at X-band frequencies in solution in CH_2Cl_2 indicated the presence of two ESR-active species, with average g and A values as shown in Table 3. These species probably arise from dissociation of thiourea ligands from the complex in solution, since addition of an excess of the appropriate thiourea ligand causes a change in the relative intensities of the signals from the two species. There is precedent for the dissociation of neutral sulphur donor ligands from early transition metal complexes: for example, Ph_3PS was found to dissociate from the $MoOCl_3$ moiety in complexes of the type $[MoOCl_3L]$.[18] Comparing the relatively large $\bar{g}$ values and relatively small $\bar{A}$ values found in the ESR spectra of these thiourea complexes with the similar values found for other sulphur donor ligand complexes, and with the different values found for typical oxygen donor ligand complexes (Table 3), it is clear that the data are consistent with the retention of at least some sulphur donor ligation in solution, despite the evidence for ligand dissociation.

THE COORDINATION CHEMISTRY OF SILYL–SULPHURDIIMIDES

RAY JONES, DAVID J. WILLIAMS, PAUL T. WOOD and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

(*Received* 6 *June* 1988; *accepted* 20 *July* 1988)

Abstract—Reaction of $RNSNSiMe_3$ (R = Me_3Si, 'Bu, *p*-$O_2NC_6H_4S$-) with $PtCl_2$(dppe) gives, in the case of R = *p*-$O_2NC_6H_4S$-, [Pt($NSNSC_6H_4NO_2$)$_2$(dppe)]. Reaction of $(Me_3Si)_2N_2S$ (**1**) or Bu'$NSNSiMe_3$ (**4**) with $Pt(C_2H_4)(PPh_3)_2$ gives Pt$(NSNR)_2(PPh_3)_2$ (R = Me_3Si or 'Bu). The X-ray structure of *p*-$O_2NC_6H_4SNSNSiMe_3$ reveals an essentially coplanar arrangement of the aryl and SNSN fragments. The bond lengths in the S_2N_2 chain are more closely related to those in $S_2N_2^{2-}$ ligands than those in $S_2N_2H^-$ ligands. The X-ray crystal structure of [Pt($NSNSC_6H_4NO_2$)(dppe)] (**5**) confirms the expected *cis* square-planar coordination of the platinum by the chelate phosphine and two *p*-$O_2NC_6H_4SNSN^-$ ligands. Of the atoms in the S—N ligand only the terminal nitrogen atoms lie in the platinum coordination plane. The rest of these ligands are essentially planar with their backbones *trans*-axial and approximately normal with respect to the PtN_2P_2 plane.

There have been several reports[1] on the coordination properties of sulphurdiimides, RNSNR, but it was only quite recently that the use of a silyl sulphurdiimide, $(Me_3Si)_2N_2S$ (**1**), in the preparation of the σ-bonded diimido complex *cis*-Pt$(NSNSiMe_3)_2(PPh_3)_2$ (**2**) was described.[2] Here we report full details of the preparation of **2** together with the results of our investigations into the reactivity of substituted silyl diimides $RNSNSiMe_3$ [R = *p*-$O_2NC_6H_4S$- (**3**), 'Bu, (**4**)]. As part of these studies we have characterized *p*-$O_2NC_6H_4SNSNSiMe_3$ (**3**) and the platinum complex Pt$(NSNSC_6H_4NO_2)_2(PPh_3)_2$ (**5**) by X-ray crystallography. The geometry of the S_2N_2 group in **3** is compared with that of the related $S_2N_2H^-$ and $S_2N_2^{2-}$ ligands.[3–5]

EXPERIMENTAL

All procedures were carried out under an inert atmosphere (Ar or N_2) unless stated otherwise. Solvents were dried before use; CH_2Cl_2 was distilled from CaH_2; diethyl ether, tetrahydrofuran (THF), toluene and *n*-hexane were distilled from sodium–benzophenone. ^{31}P-{^1H} NMR spectra were obtained using a JEOL FX90Q spectrometer operating at 36.21 MHz and are referred to external 85% H_3PO_4. IR spectra were recorded using a PE 683 as pressed KBr discs or Nujol mulls. Elemental analyses were performed by the microanalytical service at Imperial College.

The compounds, *cis*-[$PtCl_2(PR_3)_2$], were obtained from $PtCl_2$COD whilst $MCl_2(CH_3CN)_2$ (M = Pd, Pt) and $Pt(C_2H_4)(PPh_3)_2$ were prepared by standard methods.[6–8] Bis(trimethylsilyl)sulphurdiimide and *p*-$O_2NC_6H_4SNSNSiMe_3$ were prepared by adaptation of the literature methods.[9,10] *t*-$BuNSNSiMe_3$ was obtained[11] from the reaction of *t*-BuNSO with $(Me_3Si)_2NLi$.

p-$O_2NC_6H_4SNSNSiMe_3$ (3)

Bis(trimethylsilyl)sulphurdiimide (2.66 g, 0.013 mol) was dissolved in dichloromethane (75 cm^3) and cooled in an ice bath. To this stirred solution was added over 30 min, *p*-$O_2NC_6H_4SCl$ (2.46 g, 0.013 mol) in dichloromethane (60 cm^3). During this time the solution changed colour from pale yellow to red–orange. The solvent was removed *in vacuo* and the resulting solid was extracted with hexane (80 cm^3) which upon cooling to −20°C gave the product as pale orange–yellow needles. Yield

1.1 g, 29%. Found: C, 37.8; H, 4.4; N, 14.5. Calc.: C, 37.6; H, 4.6; N, 14.6%. Crystals suitable for X-ray analysis were obtained by slow crystallization from a hexane solution.

$Pt(NSNSiMe_3)_2(PPh_3)_2$

$(Me_3Si)_2N_2S$ (0.3 cm^3, 0.28 g, 1.3 mmol) was added to a solution of $Pt(C_2H_4)(PPh_3)_2$ (1.0 g, 1.3 mmol) in benzene (25 cm^3). The reaction was stirred at room temperature for 2 h and then all volatile material was removed under reduced pressure to give a yellow solid which was triturated with hexane, redissolved in benzene (20 cm^3) and filtered through Celite. The volume of benzene was reduced to *ca* 10 cm^3 and 20 cm^3 of *n*-hexane were added. The product crystallized as pale yellow plates. Yield 0.32 g, 50%. $^{31}P-\{^1H\}$: $\delta = 11.76$, $^1J(Pt—P) = 3098$ Hz. IR: $\nu(NSN)_a$ 1167, $\nu(NSN)_s$ 1022w, $\delta(NSN)$ 835br cm^{-1}. Found: C, 50.4; H, 4.6; N, 5.3. Calc.: C, 51.2; H, 4.9; N, 5.7%.

$Pt(NSN^tBu)_2(PPh_3)_2$

Me_3SiNSN^tBu (0.1 g, 0.13 mmol) and $Pt(C_2H_4)(PPh_3)_2$ (0.51 g, 0.056 mmol) were stirred together in toluene (5 cm^3) for 2 h. The solvent was removed *in vacuo* and the product extracted into *n*-hexane (2×20 cm^3). The hexane was reduced to *ca* 5 cm^3 and cooled (−20°C) to give the product. Yield 11 mg, 9%. $^{31}P-\{^1H\}$: $\delta = 11.76$, $^1J = 3101$ Hz. Found: C, 53.0; H, 5.2; N, 5.4. Calc.: C, 52.9; H, 5.0; N, 5.7%.

$Pt(NSNSC_6H_4NO_2)_2(dppe)$

$PtCl_2(dppe)$ (0.024 g, 0.03 mmol) and p-$O_2NC_6H_4SNSNSiMe_3$ (0.077 g, 0.16 mmol) were stirred together in chloroform for 1 month. After this time the solvent was removed *in vacuo* and the remaining solid extracted with benzene (10 cm^3). Addition of hexane (10 cm^3) gave the product as a red precipitate. Crystals suitable for X-ray analysis were obtained by slow diffusion of hexane into a benzene solution. Yield 25 mg, 70%. Found: C, 44.7; H, 3.7; N, 7.1. Calc. for $[Pt(NSNSC_6H_4NO_2)_2(dppe)\cdot C_6H_6]$: C, 44.7; H, 3.9; N, 7.1%. $^{31}P-\{^1H\}$ ($CDCl_3$): $\delta = 33.43$ ppm, $^1J(Pt—P) = 3130$ Hz.

$Pd(HNSNSC_6H_4NO_2)Cl_2$

A solution of p-$O_2NC_6H_4SNSNSiMe_3$ (0.3 g, 1 mmol) in benzene (5 cm^3) was added to a solution of $PdCl_2(PhCN)_2$ (0.4 g, 1 mmol) in benzene (80 cm^3). On mixing, the solution became cloudy and after stirring for 1 week an orange–brown precipitate was formed together with a lightening of the solution from red to orange. The solid was filtered off, washed with hexane (3×10 cm^3) and dried *in vacuo*. Yield 0.3 g, 75%. Found: C, 16.7; H, 1.5; N, 10.4. Calc.: C, 18.4; H, 1.3; N, 10.7%.

$C_9H_{13}N_3O_2S_2Si$ (**3**). $M = 287.4$, triclinic, $a = 5.839(4)$, $b = 11.574(6)$, $c = 11.598(10)$ Å, $\alpha = 111.84(5)$, $\beta = 110.08(6)$, $\gamma = 100.00(5)°$, $U = 691$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.39$ g cm^{-3}. Yellow air-stable irregular polyhedron, crystal dimensions $0.1 \times 0.1 \times 0.1$ mm. $\mu(Cu\text{-}K_\alpha) = 43$ cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 300$.

$C_{38}H_{32}N_6O_4P_2PtS_4$ (**5**). $M = 1022.0$, monoclinic, $a = 16.760(4)$, $b = 17.581(6)$, $c = 27.517(9)$ Å, $\beta = 90.73(2)°$, $U = 8107$ Å^3, space group $P2_1/c$, $Z = 8$ (two crystallographically independent molecules), $D_c = 1.68$ g cm^{-3}. Red–orange air-stable irregular polyhedron, crystal dimensions $0.15 \times 0.1 \times 0.2$ mm. $\mu(Cu\text{-}K_\alpha) = 96.0$ cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 4047$.

Data collection and processing for **3** *and* **5**

Nicolet R3m diffractometer, ω-scan method, ($2\theta \leqslant 116°$ for **3** and 100° for **5**), graphite monochromated Cu-K_α radiation, 1843 and 8322 independent measured reflections of which 1273 and 6655 were considered observed [$|F_o| > 3\sigma(|F_o|)$] for **3** and **5**, corrected for Lorentz and polarization factors. For both **3** and **5** empirical absorption corrections based on 360 azimuthal scans were applied.

Structure analysis and refinement for **3**

The structure was solved by direct methods and the non-hydrogen atoms refined anisotropically. The methyl groups were refined as rigid bodies, the positions of all the other hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters, [$U(H) = 1.2U_{eq}(C)$] and allowed to ride on their parent carbons. Refinement was by block-cascade full-matrix least-squares to give $R = 0.069$, $R_w = 0.068$ ($w^{-1} = \sigma^2(F) + 0.00093F^2$) ($R = \Sigma[|(F_o - F_c)|]/\Sigma|F_o|$). The maximum residual electron density in the final ΔF map was 0.37 e Å^{-3}. The mean and maximum shifts/error in the final refinement cycle were 0.012 and 0.057, respectively. Computations were carried out on an Eclipse S140 computer using the *SHELXTL* program system.[12]

Structure analysis and refinement for **5**

The structure was solved by the heavy-atom method and all non-hydrogen atoms refined aniso-

tropically. Refinement (for two separate data collections on different crystals) showed the structure to be subject to severe anisotropic thermal motion in all of the aryl rings in both independent molecules. This disorder/anisotropic thermal motion could not be resolved into alternate partial occupancy orientations so refinement was terminated at $R = 0.115$.

RESULTS AND DISCUSSION

Sulphur diimides are known to coordinate in a variety of ways.[1] With organic substituents such as 'Bu or Ph the complexes are bonded through one or both nitrogen atoms except in those cases where fragmentation to RNS complexes occurs. We have investigated the reactivity of $(Me_3Si)_2N_2S$ and $RNSNSiMe_3$ [R = 'Bu, *p*-$O_2NC_6H_4S$ (**3**)] with simple metal phosphine halides and with $Pt(C_2H_4)(PPh_3)_3$ since the Si—N bond is relatively weak particularly in comparison to the Si—Cl bond. It was hoped that this would provide a rational synthetic route to diimido complexes. The formation of **3** from **1** [eq. (1)] is a typical example of the reactivity of this molecule.

$$(Me_3Si)_2N_2S + p\text{-}O_2NC_6H_4SCl \rightarrow p\text{-}O_2NC_6H_4SNSNSiMe_3 + Me_2SiCl. \quad (1)$$

Elimination of Me_3SiCl provides the driving force for the reaction although it should be noted that a significant side product is the insoluble bis compound RSNSNSR and **3** is only obtained in *ca* 30% yield.

The X-ray structure of **3** (Fig. 1, Table 1) reveals a planar S_2N_2 chain [maximum deviation from the mean plane 0.007 Å for S(1)] which is rotated slightly with respect to the aromatic ring (C(2)—C(1)—S(2)—N(2) torsion angle 5°). The bond distances and angles within the S_2N_2 chain closely resemble those in the metallacycle $Pt(S_2N_2)(PMe_3)_2$,[13] but are markedly dissimilar from those in $[Pt(S_2N_2H)(PMe_2Ph)_2]BF_4$[4] (Table 2).

Of particular interest is the packing arrangement adopted by **3** in the crystal (Fig. 2). The molecules form infinite parallel stacks along the crystallographic *a* direction with their planes inclined. The interplanar separation between the S_2N_2 groups is 3.75 Å; the closest contact is C(1)—S(1)′ 3.65 Å. Within each stack, the S(1)—N(2) bond of one molecule lies over the aryl ring of the next.

Reaction of **1**, **3** or **4** with *cis*-$[PtCl_2(PR_3)_2]$ ($PR_3 = PPh_3$, PEt_3, PMe_2Ph and 1/2dppe) does not proceed as hoped except in the case of treatment of $PtCl_2$(dppe) with **3**, which gives $Pt(NSNSC_6H_4NO_2)$(dppe) (**5**). The latter product was characterized by IR, NMR and X-ray crystallography, however, it is not obtained via a smooth, simple reaction. The reaction takes 1 month at room temperature in chloroform and is insensitive to more vigorous conditions (e.g. reflux in toluene). ^{31}P NMR spectra were taken at time intervals during the course of the reaction. Thus after 1 week, the spectrum consists of *ca* 25% unreacted starting material, 25% of **5** and a third compound **6** with $\delta = 35.1$ ($^1J = 3014$ Hz), $\delta = 38.0$ ($^1J = 3798$ Hz) and $^2J(^{31}P—^{31}P) = 9$ Hz. For comparison, **5** has $\delta = 33.4$ and $^1J = 3130$ Hz and **2** has $\delta = 11.76$ ppm and $^1J = 3098$ Hz. It has been proposed[16] that

in $Pt(PPh_3)_2(PhNSNPh)$ (**7**) the diimide coordinates assymmetrically in an edge-on fashion through one N=S bond. In the ^{31}P NMR of **7** the ^{31}P—^{195}Pt coupling constants are 3368 and 4320 Hz and $\delta = 17.4$ ppm (both ^{31}P resonances). Since both **5** and **6** involve a different phosphine to **2** and **7** direct comparison of δ values is not possible but the coupling constants are quite dissimilar. The most plausible structure for intermediate **6** is $PtCl(dppe)(NSNSC_6H_4NO_2)$.

The X-ray structure of **5** (which has been briefly reported elsewhere[17]) although of limited precision because of disorder/thermal anisotropy problems reveals (Fig. 3) square-planar coordination of the platinum by the chelate phosphine and two anionic *p*-$O_2NC_6H_4SNSN^-$ ligands. Each of the independent molecules has approximate non-crystallographic C_2 symmetry about an axis bisecting the N—Pt—N and P—Pt—P angles. The *p*-$O_2NC_6H_4SNSN^-$ ligands are essentially planar with a *syn,syn* conformation about the N_2S group as might be expected from recent calculations.[18] In contrast to **2** the backbones of the *cis* diimido ligands are *trans*-axial relative to the coordination plane of the platinum with resulting pseudo-octahedral coordination of the Pt^{II} atom by the distal S_2N_2 sulphur atoms. The apical Pt···S contacts for both independent molecules are 3.19, 3.44, 3.25 and 3.37 Å. The mean inclination of the Pt···S vectors to the PtP_2N_2 plane is *ca* 60°.

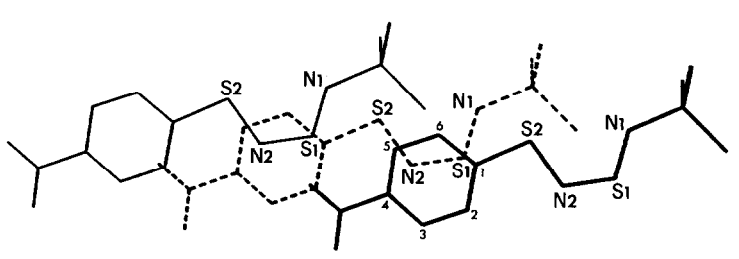

Fig. 2. Viewed parallel to the S_2N_2 plane showing the continuous stepped stacking of lattice translated molecules of (**3**) in the crystal. Uppermost molecule is shown heavy, middle dashed and lower light.

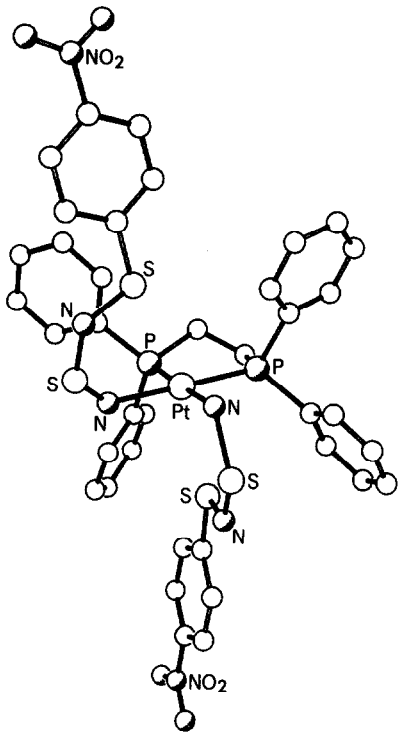

Fig. 3. The X-ray crystal structure of $Pt(NSNSC_6H_4NO_2)_2(PPh_3)_2$ (**5**).

The similarity of the ^1J values for **2** and **5** is as expected if the R group in $RNSN^-$ is only of marginal importance but we do not believe this to be the case. It should be noted[13,14] that in $[Pt(S_2N_2H)(dppe)][PF_6]$ the phosphorus *trans* to nitrogen has $\delta = 38.6$ ppm and $^1J = 3162$ Hz whilst in $Pt(S_2N_2)(dppe)$ the signal is at $\delta = 41.1$ and has $^1J = 2784$ Hz. We would have expected that the $S_2N_2^{2-}$ complex would have been more directly comparable with the p-$O_2NC_6H_4SNSN^-$ complex as was the case with $Pt(S_2N_2)(PPh_3)_2$ and **2**. It thus seems likely that changing from $R = Me_3Si$ to p-$O_2NC_6H_4S$ and from PPh_3 to dppe has mutually opposed effects on the magnitude of ^1J resulting in **2** and **5** fortuitously having remarkably similar parameters. This observation serves to underline the difficulties in making use of ^{31}P NMR data in an empirical fashion!

$Pt(C_2H_4)(PPh_3)_2$ reacts smoothly with the bis-silyldiimide to give $Pt(NSNSiMe_3)_2(PPh_3)_2$. With Me_3SiNSN^tBu the reaction appears clean by NMR but the product $[Pt(NSN^tBu)_2(PPh_3)_2$ (**8**)] is extremely soluble and could only be isolated in low yield. **3** gives a mixture of products which, to date, we have been unable to separate. The structure of **2** has been established by X-ray crystallography. It consists of a square-planar Pt^{II} with *cis* σ-bonded $NSNSiMe_3$ ligands.[15] Comparison of the ^{31}P NMR of **2** and **3** reveals almost identical chemical shifts and coupling constants as expected.

Reaction of $PdCl_2(PhCN)_2$ with **3** gives a complex with a microanalysis corresponding to $PdCl_2(HNSNSC_6H_4NO_2)$ (**9**). The IR spectrum of **9** is significantly different from both the starting material and the simple σ-bonded complexes (Table 3). Apart from the variation in frequency of the ν(NSN) vibrations the most obvious feature is the presence of bands due to NH. We speculate that **9** contains an edge-on coordinated $HNSNSC_6NO_2$ ligand.

Abstract—The cyanate–copper(II) complexes $[Cu(terpy)(NCO)_2] \cdot nH_2O$ ($n = 0$, 1) have been synthesized and characterized by spectroscopic techniques and analytical data. The crystal structure of the hydrated complex has been determined by X-ray diffraction methods. The compound crystallizes in the space group $P\bar{1}$ with $a = 8.684(3)$, $b = 9.485(6)$, $c = 10.774(7)$ Å, $\alpha = 83.58(5)$, $\beta = 87.21(4)$, $\gamma = 68.44(3)°$, $U = 851(2)$ Å^3; $Z = 2$, $D_m = 1.63(4)$, $D_x = 1.62$ g cm^{-3}, μ(Mo-K_α) = 14.3 cm^{-1}, $F(000) = 402$, $T = 293$ K. The structure was refined to $R = 0.055$ ($R_w = 0.055$). The centrosymmetric dimeric structure consists of two $[Cu(terpy)(NCO)_2] \cdot H_2O$ units, which are linked through hydrogen bonds between the cyanate groups and the water molecules. The coordination sphere of the copper(II) ion is approximately regular square pyramid. The half-field absorption in the $\Delta M_s = 2$ region of the powdered X-band ESR spectra has been observed for the dimeric compound.

2,2′:6′,2″-terpyridine (terpy) is a tridentate rigid "quasi planar" ligand that forms complexes with divalent 3*d* transition ions.[1] The coordination chemistry of terpy includes two kinds of complexes: the bis-terpyridine complexes corresponding to ratio of metal to terpy 1:2, which are always discrete molecules[2–5] and the mono-terpyridine complexes (ratio 1:1) which can give rise to mononuclear[6–14] and polynuclear species.[15–17]

In previous papers, we have reported the synthesis and characterization of a wide set of five-coordinate compounds of the formulation $[Cu(terpy)X_2]$ (X = coordinating anion: halide or pseudohalide).[18–20] These complexes are discrete molecules, with the copper(II) ion bonded to three N-atoms of the tridentate ligand and the two X^- ions, or by one X^- and one H_2O molecule as in the nitrite complex.[7] Some mononuclear species exhibit an unusual symmetry in which the coordination polyhedron of the copper(II) ion shows a C_{2v} symmetry.[19,20]

On the other hand, the ability and adaptability of the cyanate ligand as a bridging one is well estab-

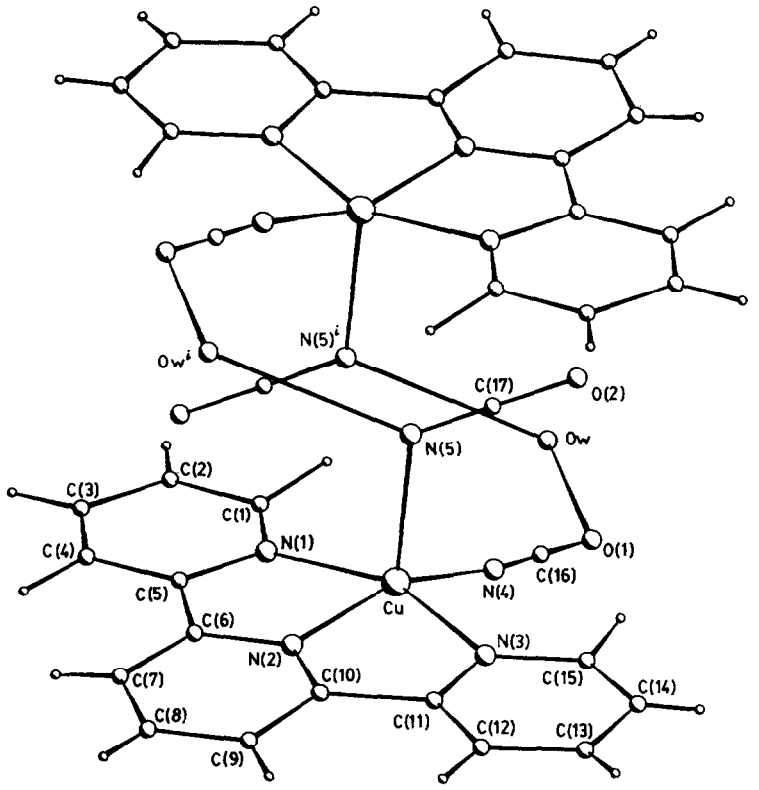

Fig. 1. Molecular structure of the $[Cu(terpy)(NCO)_2]_2 \cdot 2H_2O$ complex showing the atom numbering.

lished.[21–25] In order to know the behaviour of this ligand in the complexes of the type $[Cu(terpy)X_2]$, we decided to carry out a study of the $[Cu(terpy)(NCO)_2] \cdot nH_2O$ ($n = 0, 1$) compounds.

RESULTS AND DISCUSSION

Figure 1 shows a perspective view of the dimeric complex $[Cu(terpy)(NCO)_2]_2 \cdot 2H_2O$, with the detailed labelling of the atoms, and Fig. 2 shows a stereoscopic view of the unit cell. Significant bond distances and angles are given in Table 1.

The centrosymmetric dimeric structure consists of two $[Cu(terpy)(NCO)_2] \cdot H_2O$ units, which are linked through hydrogen bonds between the cyanate groups and the water molecules. The coordination sphere of the copper(II) ion is better described as a distorted square pyramid. The basal positions are occupied by the three nitrogens of the terpyridine ligand (Cu—N(1), N(2), N(3); 2.046(6), 1.957(6), 2.043(7) Å, respectively) and one N-cyanate group (Cu—N(4), 1.904(7) Å). The apical site is occupied by the other N-cyanate ligand (Cu—N(5) = 2.188(7) Å). The average value of

i = $1-x, 1-y, 1-z$.

the angles N_{apical}—Cu—N_{basal} is 98(3)°, while the *trans*-basal angles, N(1)—Cu—N(3) and N(2)—Cu—N(4) are 156.8(2) and 159.1(3)°, respectively. The basal atoms are coplanar within ±0.067 Å and the copper(II) ion is displaced 0.29 Å from the mean plane. The terpy ligand is planar within ±0.04 Å. Because of the rigidity of the terpyridine rings the angles N(2)—Cu—N(1) and N(2)—Cu—N(3) deviate from 90° by about 11° and the Cu—N(2) bond length is smaller than Cu—N(1),N(3) by ≈ 0.1 Å.

The simultaneous presence of "end-on" and "end-to-end" bonds in the cyanate groups of the $[Cu(terpy)(NCO)_2]_2 \cdot 2H_2O$ compound is one remarkable structural feature. Both NCO groups are practically linear [angles N(4)—C(16)—O(1) and N(5)—C(17)—O(2), average value 179(1)°]. The copper(II) ion is nearly in the plane defined by the N(4), C(16) and O(1) atoms of the equatorial cyanate (the Cu—N(4)—C(16)—O(1) torsion angle is 6.9°) and, is clearly out of the plane defined by the N(5), C(17) and O(2) atoms of the apical cyanate (the Cu—N(5)—C(17)—O(2) torsion angle is 85.9°). This fact explains the shortening of the Cu—N(4) bond length, which is 0.284 Å shorter than that obtained for the Cu—N(5) bond. This suggests that there is more π-donor character in the Cu—N(4) bond, which is in agreement with the shorter N(4)—C(16) bond length (1.142(10) Å) than N(5)—C(17) (1.170(11) Å). The CO distance is practically similar in both cyanate groups (average value, 1.21(1) Å).

In the dimeric compound, each water molecule forms intramolecular hydrogen bonds with both the O(1) atom of the basal-cyanate group (Ow···O(1), 2.910(55) Å) and the N(5)^{i} atom of the apical-cyanate ligand belonging to the other half of the dimer (Ow···N(5)^{i}, 2.868(65) Å). The intradimeric copper–copper distance is 6.759(1) Å.

The distortion of the coordination polyhedron from trigonal bipyramid ($\Delta = 0$) towards a regular square pyramid ($\Delta = 1$) was calculated by quantification of the Muetterties and Guggenberger description.[26,27] The value thus obtained for the title compound ($\Delta = 0.80$) indicates a topology near to regular square pyramid. A similar result is observed using Kepert's model based on an interligand repulsion approach.[28]

The interest of the IR spectra of the $[Cu(terpy)(NCO)_2] \cdot nH_2O$ ($n = 0, 1$) complexes lies mainly in the bands due to the NCO groups. For the hydrated compound, the first feature is the well defined splitting of the bands due to the ν_{as} vibration at 2250, 2230 and 2180, 2170 cm^{-1}, which is in good agreement with the presence of two different cyanate ions bonded to the water molecules. The symmetric stretching vibration ν_s is at 1340 cm^{-1}, in the range of N-bonded cyanates. The splitting observed in the bending mode, δ, 600, 610 and 630 cm^{-1} appears in complexes containing bridging-bonded NCO groups.[21–25] For the water molecule, the stretching, bending and rotation vibrations appear at 3580, 3400; 1660 and 480 cm^{-1}, respectively. The IR spectrum of the anhydrous compound $[Cu(terpy)(NCO)_2]$ exhibits bands corresponding to ν_{as} at 2230, 2220 cm^{-1}; ν_s at 1355 cm^{-1} and δ at 625, 615 cm^{-1}, which suggest the presence of terminally N-bonded cyanate groups in this complex.[21–25]

Some IR and structural data for cyanate–terpyridine complexes are given in Table 2. In good agreement with other cyanate complexes given in the literature,[21–25] it can be seen that: (i) the stretching vibration ν_{as} appears in the range 2250–2200 cm^{-1} when the MNC angle approaches 180°, and the CN distance is short, indicative of a C≡N triple bond; (ii) for the compounds where the MNC angle approaches 120° and the CN distance tends towards what would be expected for a C=N double bond, the ν_{as} vibration is in the range 2220–2100 cm^{-1}; (iii) the splitting of the bending vibration (δ) in the complexes containing terminally bonded NCO

Table 2. Some IR and structural data for the cyanate–terpyridine complexes

In compound 1, the N-cyanate groups are related by the binary axis. Compounds 2 and 5 show bridged [M—N(CO)—M] and terminal [M—NCO] cyanate ligands, respectively.

[a] This band is obscured by the nitrate group.

(only 10 cm^{-1} or less) is shorter than that observed in the compounds with bridged NCO ligands.

The X-band ESR spectra of polycrystalline samples of the [Cu(terpy)(NCO)$_2$]$_2$·2H$_2$O compound show axial-type signals which remain unchanged from room temperature down to 125 K. Figure 3(a) shows the ESR spectrum at 125 K.

The values $g_{\parallel} = 2.249 > g_{\perp} = 2.096 > g_0 = 2.0023$ point towards a mainly copper(II) $d_{x^2-y^2}$ orbital ground state.[6] This result agrees with the regular square pyramidal geometry of the [CuN$_5$] coordination polyhedron. Likewise, in the ESR spectrum the appearance of a weak absorption corresponding to the $\Delta M_s = 2$ forbidden transition can be noted at "half-field" values ($\approx$ 1600 G). This signal implies a magnetic interaction between the copper(II) ions of the dimeric compound. From the ESR spectrum, the distance "r" between the two copper(II) ions interacting in the dimeric compound has been calculated. The expression, relative intensity = (intensity of $\Delta M_s = 2$/total intensity of $\Delta M_s = 1$) = Ar^{-6} $(9.1/\nu^2)$ (where ν is the spectrometer operating frequency in G Hz, and $A = 21 \pm 2$ is a calculated parameter) was used.[29] The value obtained, $r = 6.5$ Å, fits nicely to the crystallographically determined (Cu—Cu^i = 6.759(1) Å).

The ESR spectra of the anhydrous compound [Cu(terpy)(NCO)$_2$] show a *o*-rhombic resolution for the "g"-tensor, which is not modified at 125 K, $g_1 = 2.270$, $g_2 = 2.132$, $g_3 = 2.036$ [Fig. 3(b)]. This result indicates a deviation of the geometry of the coordination polyhedron from the regular square pyramid towards the trigonal bipyramid. The absorption corresponding to the $\Delta M_s = 2$ transition is not observed.

In the visible region, the reflectance electronic spectrum of the [Cu(terpy)(NCO)$_2$]$_2$·2H$_2$O complex exhibits one broad unresolved band centred around 14000 cm^{-1}. We tentatively assigned this band to the non-resolved transition $B_1 \rightarrow B_2$, E in C_{4v} symmetry.[6] The covalence factor (K) has been calculated from the ESR and reflectance measurements.[6] The value obtained ($K = 0.76$) is slightly greater than that calculated for the chlorinated compound [Cu(terpy)Cl$_2$]·nH$_2$O ($n = 0$, 1), with a similar regular square pyramidal geometry.[6] This fact is possibly due to the higher π-donor character of the Cu—NCO bonds in the cyanate complex.

EXPERIMENTAL

Synthesis

Solutions of terpy (0.121 g, 0.52 mmol) in ethanol (10 cm^3) and Cu(NO$_3$)$_2$·3H$_2$O (0.123 g, 0.52 mmol)

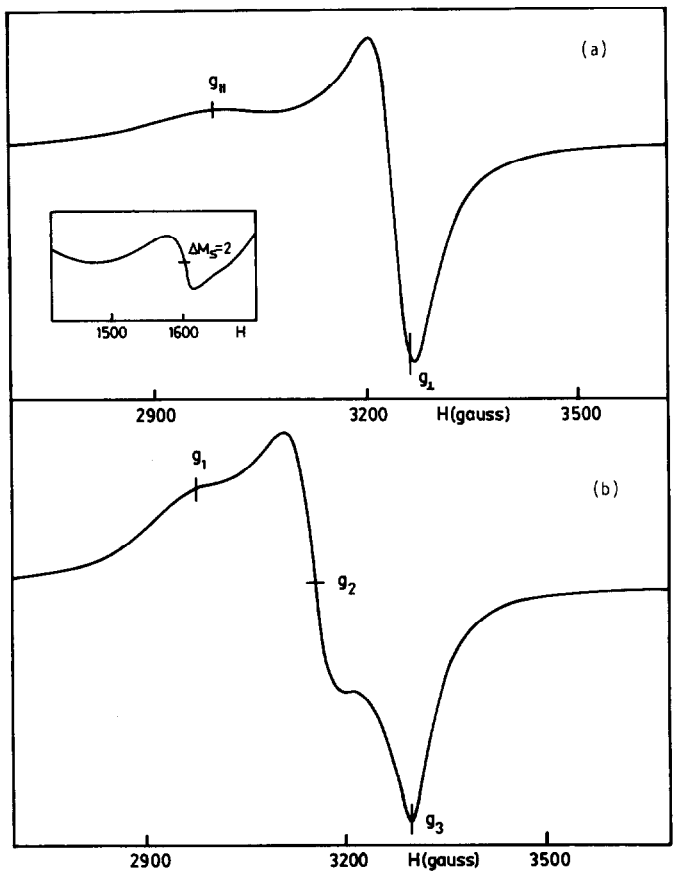

Fig. 3. X-band ESR spectra (125 K) of powdered samples of the (a) $[Cu(terpy)(NCO)_2]_2 \cdot 2H_2O$ and (b) $[Cu(terpy)(NCO)_2]$ complexes.

in water (10 cm^3) were mixed with stirring. A green microcrystalline solid was obtained immediately by addition of the KNCO pseudohalide (0.117 g, 1.44 mmol) dissolved in water (5 cm^3). The solid was filtered and washed with water and diethyl ether. Crystallization from a saturated water–acetone (1 : 2) mixture of the product gave green crystals. Found: C, 50.9; H, 3.2; N, 17.2. $[Cu(C_{15}H_{11}N_3)(NCO)_2] \cdot H_2O$ requires: C, 51.1; H, 3.3; N, 17.5%. The thermogravimetric analysis indicates the presence of one water molecule per copper(II) ion. The anhydrous compound was obtained by dehydration of the $[Cu(terpy)(NCO)_2] \cdot H_2O$ at 55°C. Found: C, 53.5; H, 2.8; N, 18.3. $[Cu(C_{15}H_{11}N_3)(NCO)_2]$ requires: C, 53.6; H, 2.9; N, 18.4%.

Crystal structure determination

A single crystal of dimension $0.3 \times 0.15 \times 0.015$ mm was used for data collection. Formula weight 398.5, triclinic, $P\bar{1}$; $a = 8.684(3)$, $b = 9.485(6)$, $c = 10.774(7)$ Å, $\alpha = 83.58(5)$, $\beta = 87.21(4)$, $\gamma = 68.44(3)°$ and $U = 851(2)$ $Å^3$; $Z = 2$, $D_m = 1.63(4)$, $D_x = 1.62$ g cm^{-3}, μ(Mo-K_α) = 14.3 cm^{-1}, $F(000) = 402$, $T = 293$ K. The density was measured by flotation in a bromoform–acetone mixture.

Intensity data were collected at room temperature on an Enraf–Nonius CAD 4 automatic four-circle diffractometer using the $\omega/2\theta$ scan technique with Mo-K_α ($\lambda = 0.7107$ Å, graphite monochromated) radiation. Cell dimensions were taken from least-squares refinements of 25 reflections ($2 \leqslant 2\theta \leqslant 19°$). A total of 3054 independent reflections ($\theta < 25°$, $-10 \leqslant h \leqslant 10$, $-11 \leqslant k \leqslant 11$, $0 \leqslant l \leqslant 12$) were collected with three orientation standard reflections measured every 50 reflections and one intensity standard reflection every 3600 s. The variation in the intensity of this standard reflection was within 1.6%. A total of 1605 reflections were considered observed with $I \geqslant 2.5\sigma(I)$ and included in the refinement. The intensity data were corrected for Lorentz polarization factors. Absorption effects were neglected.

Direct methods, *MULTAN84*,[30] were used to locate 20 of 26 non-H atoms. The remaining non-H atoms were found by Fourier syntheses. All H

atomic sites, minor H of the water molecule, were located by subsequent difference Fourier maps but not refined. The structure was refined by full-matrix least-squares techniques with *SHELX 76*.[31] The function minimized was $\Sigma\omega[|F_o|-|F_c|]^2$ where the weights ω were taken as $\omega = [\sigma^2|F_o|+K|F_o|^2]^{-1}$, where $K = 0.001500$. The atomic scattering factors were taken from ref. 32. The final agreement factors R and R_ω reached, respectively, 0.055 and 0.055 for all observed reflections. Maximum and minimum electron densities in the final difference map were 0.53, -0.38 e Å^{-3}.

Physical measurements

Water was determined thermogravimetrically using a Perkin–Elmer TGS-1 thermobalance. The IR spectra (KBr pellets) were recorded on a Perkin–Elmer 1430 spectrophotometer. The diffuse reflectance electronic spectrum on solid powder was registered using a Perkin–Elmer Lambda-9 US/VIS/NIR spectrophotometer. A Brucker ER 200tt spectrometer equipped with a standard low-temperature device, operating at X-band calibrated by a NMR probe for the magnetic field and a HP 5342 A frequency counter for the microwave frequency, was used to record the ESR powder spectra of the complexes at different temperatures.

COMPLEXES OF RUTHENIUM(II) WITH THE MONO-OXIMES OF 1,2-NAPHTHOQUINONE: X-RAY CRYSTAL STRUCTURE OF BIS(1,2-NAPHTHOQUINONE 1-OXIMATO)DIPYRIDINE RUTHENIUM(II)

JOHN CHARALAMBOUS,* WILLIAM C. STOTEN and KIM HENRICK

Department of Applied Chemistry and Life Sciences, The Polytechnic of North London, Holloway, London N7 8DB, U.K.

(*Received* 12 *April* 1988; *accepted* 25 *July* 1988)

Abstract—The ruthenium(II) complexes $Ru(nqo)_2$ [nqoH = 1,2-naphthoquinone 1-oxime (1-nqoH) or 1,2-naphthoquinone 2-oxime (2-nqoH)] were prepared by the interaction of the quinone oxime with hydrated ruthenium(III) chloride. Reaction of the chloride with the sodium salts of the oximes in ethanol or acetic acid afforded complexes of the type $Na[Ru(nqo)_3]$ and $Ru(nqo)_2(nqoH)$, respectively. The complex $Ru(nqo)_2$ reacted with pyridine or triphenylphosphine to give 1:2 adducts but showed no tendency to react with hydrochloric acid. The adduct $Ru(1\text{-}nqo)_2(py)_2 \cdot 1.5py$ was characterized by X-ray crystallography.

RESULTS AND DISCUSSION

Complex formation between ruthenium salts and 1,2-naphthoquinone 1-oxime (1-nqoH) and 1,2-naphthoquinone 2-oxime (2-nqoH) (the abbreviation nqoH will be used to denote both 1-nqoH and 2-nqoH) in aqueous media has been known for some time and it has been successfully used for the spectrophotometric determination of ruthenium.[1–3] Although the species arising from these systems have not been isolated, characterized, or otherwise studied to any significant extent, they have been generally formulated as ruthenium(III) complexes.[4,5] As a continuation of our studies of complexes derived from 1,2-quinone mono-oximes,[6–9] we now report on the reactions of hydrated ruthenium trichloride with the mono-oximes of 1,2-naphthoquinone or their sodium salts and the characterization and study of the ruthenium(II) complexes arising from them. We also report on the crystal and molecular structure of the complex bis(1,2-naphthoquinone 1-oximato)di(pyridine)ruthenium(II). Several ruthenium(II) oximic complexes have previously been obtained from the reaction of the oxime with dichlorotris(triphenylphosphine)ruthenium(II).[10]

The complexes $Ru(1\text{-}nqo)_2$ and $Ru(2\text{-}nqo)_2$ were obtained from the reaction of ruthenium(III) chloride with the sodium salt of the respective 1,2-naphthoquinone mono-oxime in aqueous tetrahydrofuran. Reaction in ethanol using 3 mol equiv. of the sodium salts afforded complexes of the type $Na[Ru(nqo)_3]$, whereas in acetic acid complexes of the type $Ru(nqo)_2(nqoH)$ resulted. The formulation of the products of the above reactions as ruthenium(II) complexes is indicated by their diamagnetic character. The formation of ruthenium(II) complexes in the reactions involving ruthenium(III) chloride and the naphthoquinone oximes or their sodium salts reflects the high ligand-field effect and π-acceptor properties of quinone oximato ligands. Ruthenium(II) complexes have also been obtained from the reactions of ruthenium(III) chloride with triphenylphosphine,[11] dipyridine,[12] 1,10-phenanthroline[13] and sodium thiocarbamates[14] which are ligands also noted for their strong ligand-field effect and π-acceptor properties. In contrast, reactions of the ruthenium(II) chloride with the weaker ligand field species acetylacetone,[15] edta[16] and ethylene diamine[17] lead to ruthenium(III) complexes unless a strong reductant is present: e.g. zinc. Reduction of the metal is also observed in reactions involving iron(III) mono-oximes of 1,2-naphthoquinone.[18] However, in these cases iron(III)

*Author to whom correspondence should be addressed.

complexes $Fe(nqo)_3$ accompany the iron(II) products.

The complexes $Ru(nqo)_2$ did not react with hydrochloric acid whereas the complexes $Ru(nqo)_2(nqoH)$ did exhibit some degree of decomposition to give $Ru(nqo)_2$ and the protonated ligand. The inertness of the complexes $Ru(nqo)_2$ towards hydrochloric acid parallels that of the corresponding rhodium(III) chelates,[9] and contrasts the facile acidolysis of first row transition metal complexes of the quinoneoximic ligands.[19]

Pyridine and triphenylphosphine reacted with the complexes $Ru(nqo)_2$ to give the adducts $Ru(nqo)_2(LB)_2$ (LB = py or Ph_3P). Significantly, the reaction with triphenylphosphine did not lead to deoxygenation of the naphthoquinoneoximic ligand or reduction of the metal. This behaviour contrasts with that of first row transition metal complexes of quinone-mono-oximes which generally undergo deoxygenation of the ligand and/or reduction of the metal on treatment with triphenylphosphine.[6,20] However, similar resistance towards the phosphine is shown by the complexes $Rh(nqo)_3$,[9] and can be accounted for by the Ru^{II} and Rh^{III} low-spin d^6 configuration.

All the complexes $Ru(nqo)_2$, $Ru(nqo)_2$, $Ru(nqo)_2(nqoH)$ and $Na[Ru(nqo)_3]$ are diamagnetic suggesting a low-spin d^6 configuration. Their IR spectra show strong absorptions at 1540–1610 cm^{-1}, characteristic of chelated quinoneoximato ligands. The complexes of the type $Ru(nqo)_2(nqoH)$ also exhibit bands at *ca* 2800 cm^{-1} in accord with the presence of a protonated nqoH ligand. The UV–vis spectra of all the complexes show intense charge-transfer absorptions at 530–580 and 615–645 nm which tail into the visible region. In general the spectra show very close similarity to those reported earlier for ruthenium quinone oximic complexes erroneously formulated as ruthenium(III) species.[2–5] Thermal gravimetric analysis (Table 1) on the pyridine adducts showed that pyridine is lost quantitatively at *ca* 260°C to give $Ru(nqo)_2$ which decomposes at *ca* 300°C.

Crystal and molecular structure of $Ru(1\text{-}nqo)_2(py)_2$

Crystal data. $C_{30}H_{22}RuN_4O_4 \cdot 1.5(C_5H_5N)$. The crystals were obtained by slow crystallization from pyridine–acetone. Triclinic, $P\bar{1}$, $a = 16.321(4)$, $b = 11.519(4)$, $c = 9.354(5)$ Å, $\beta = 102.22(3)°$, $U = 1646.90$ Å, $D_c = 1.22$ g cm^{-3}, $Z = 2$. A crystal of size $0.81 \times 0.18 \times 0.18$ mm was used in the data collection. Data were collected in the θ-range 3–25° with a scan width of 0.8°, on a Philips PW1100 four-circle diffractometer using graphite monochromated Mo-K_α radiation. The structure was solved and refined using 4030 unique reflections [$I > 3\sigma(I)$] out of 4114. The coordinates of the metal atom were deduced from a Patterson synthesis, and the remaining non-hydrogen atoms were located from subsequent difference-Fourier syntheses. The hydrogen atoms were located in a difference-Fourier synthesis calculated using data with $\sin\theta < 0.35$ and were included in the structure factor calculations but were not further refined. Ru, N and the carbonyl O atoms were assigned anisotropic thermal parameters in the final cycles of full-matrix refinement which converged at $R = 0.0505$, with weights of $w = 1/\sigma 2F_o$. The bond lengths and the angles are listed in Tables 2 and 3, and the atomic numbering is explained in Fig. 1.

As with other 1,2-quinone oximato complexes of *d*-block metals the chelate ring in bis(1,2-naphthoquinone 1-oximato)di(pyridine)ruthenium(II) is five-membered. The bond lengths in the chelate ring

agree well with results for other 1,2-naphthoquinone oximato complexes and the short C(3)—C(4) bond lengths provide additional evidence for the quinone oximic character.[20–22] The NO groups of the two chelating ligands are in a *cis* arrangement whereas in other related complexes, e.g. $Cu(1\text{-nqo})_2(Me_2CO)_2$,[21] the arrangement is *trans*.

EXPERIMENTAL

IR and UV–vis spectra were recorded with Pye–Unicam SP 2000 and 1200 spectrophotometers,

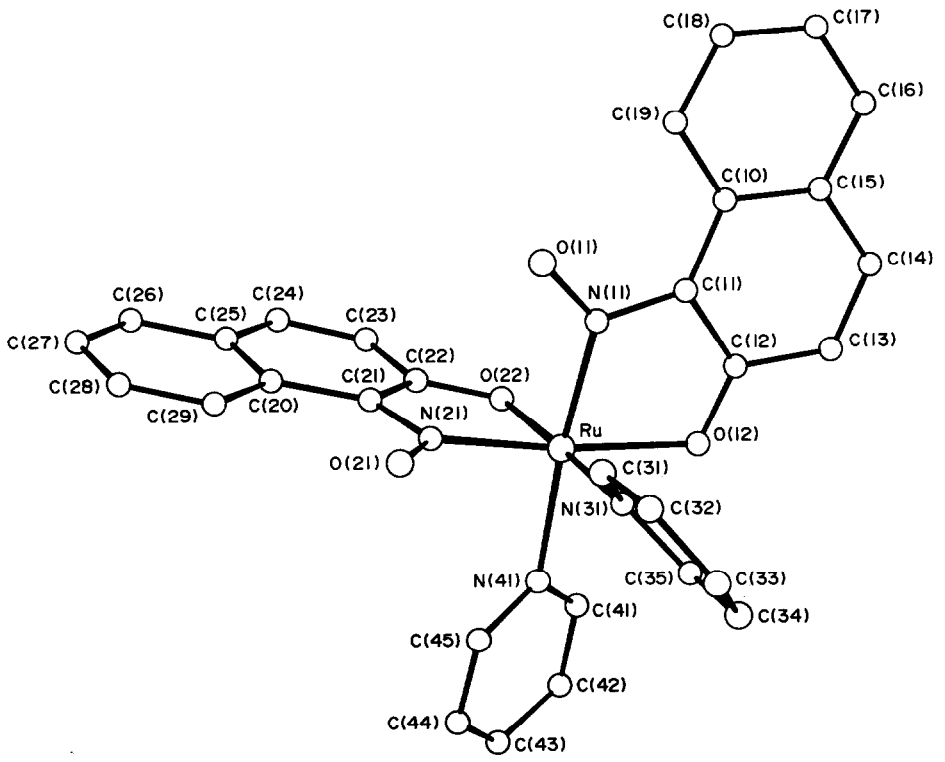

Fig. 1. Structure of $Ru(1\text{-nqo})_2(py)_2$.

respectively. Magnetic measurements were made at room temperature using a Gouy balance equipped with a permanent magnet of 3600 Oe. Thermal gravimetric measurements were made using a Stanton HT-SM thermobalance, programmed for a linear rise between 20–400°C at a rate of 4.5°C min^{-1}. A downward flow of nitrogen (5 dm^3 h^{-1}) was maintained. Hydrated ruthenium(III) chloride, $RuCl_3 \cdot 2H_2O$, was provided by Johnson Matthey.

Reaction of hydrated ruthenium(III) *trichloride with the sodium salts of the mono-oximes of* 1,2-*naphthoquinone in aqueous THF*

A solution of hydrated ruthenium(III) chloride (1.21 g, 5 mmol) in water (50 cm^3) was added to a stirred suspension of sodium 1,2-naphthoquinone 1-oximate (1.96 g, 10 mmol) in a 1:1 water–THF mixture (100 cm^3) with stirring. After 4 h the mixture was filtered to give purple–brown bis(1,2-naphthoquinone 1-oximato)ruthenium(II) (2.18 g, 98%). (Found: C,53.6; H, 2.7; N, 6.1; Ru, 22.4. $C_{20}H_{12}N_2O_4Ru$ requires: C, 53.6; H, 2.7; N, 6.3; Ru, 22.7%.)

Similarly, sodium 1,2-naphthoquinone 2-oximate gave brown bis(1,2-naphthoquinone 2-oximato)ruthenium(II) (2.10 g, 92%). (Found: C, 53.8; H, 2.4; N, 6.0; Ru, 22.6. $C_{20}H_{12}N_2O_4Ru$ requires: C, 53.6; H, 2.7; N, 6.3; Ru, 22.7%.)

Reaction of hydrated ruthenium(III) *chloride with sodium* 1,2-*naphthoquinone mono-oximates in ethanol*

A solution of hydrated ruthenium(III) chloride (2.08 g, 8.5 mmol) in ethanol (100 cm^3) was added to a solution of sodium 1,2-naphthoquinone oximate (5.8 g, 27 mmol) in ethanol (150 cm^3) and heated under reflux for 24 h. After cooling, filtration gave purple sodium tris(1,2-naphthoquinone 1-oximato)ruthenate (II) (4.89 g, 89%). Found: C, 55.8; H, 3.0; N, 6.4; Na, 3.5; Ru, 16.1. $C_{30}H_{18}N_3NaO_6Ru$ requires: C, 56.2; H, 2.8; N, 6.6; Na, 3.6; Ru, 16.1%.)

Similarly, sodium 1,2-naphthoquinone 2-oximate gave blue sodium tris(1,2-naphthoquinone 2-oximato)ruthenate(II) (2.14 g, 81%). (Found: C, 56.1; H, 2.7; N, 6.5; Na, 3.5; Ru, 15.7. $C_{30}H_{18}N_3NaO_6Ru$ requires: C, 56.2; H, 2.8; N, 6.6; Na, 3.6; Ru, 16.1%.)

Reaction of hydrated ruthenium(III) *chloride with sodium* 1,2-*naphthoquinone mono-oximates in acetic acid*

A solution of hydrated ruthenium(III) chloride (2.08 g, 8.5 mmol) in dilute acetic acid (30%, 50 cm^3) was added to a solution of sodium 1,2-naphthoquinone 1-oximate (5.85 g, 27.5 mmol) in glacial acetic acid (250 cm^3) and the mixture was heated under reflux for 24 h. Filtration gave blue–violet bis(1,2-naphthoquinone 1-oximato)(1,2-naphthoquinone 1-oxime)ruthenium(II). (Found: C, 57.9; H, 3.0; N, 6.7; Ru, 16.2. $C_{30}H_{19}N_3O_6Ru$ requires: C, 58.3; H, 3.1; N, 6.8; Ru, 16.2%.)

Similarly, sodium 1,2-naphthoquinone 2-oximate gave blue bis(1,2-naphthoquinone 2-oximato)(1,2-naphthoquinone 2-oxime)ruthenium(II) (79%). (Found: C, 57.9; H, 2.9; N, 6.9; Ru, 16.5. $C_{30}H_{19}N_3O_6Ru$ requires: C, 58.3; H, 3.1; N, 6.8; Ru, 16.2%.)

Reaction of $Ru(1\text{-}nqo)_2(1\text{-}nqoH)$ *and* $Ru(2\text{-}nqo)_2(2\text{-}nqoH)$ *with dilute hydrochloric acid*

Bis(1,2-naphthoquinone 1-oximato)(1,2-naphthoquinone 1-oxime)ruthenium(II) (0.62 g, 1 mmol) was heated in dilute hydrochloric acid (10%, 100 cm^3) for 6 h. Filtration of the mixture yielded bis(1,2-naphthoquinone 1-oximato)ruthenium(II) (0.45 g, 99%) (identified by TLC and IR) and 1,2-naphthoquinone 1-oxime (0.16 g, 99%) (identified by TLC and IR).

Similarly, bis(1,2-naphthoquinone 2-oximato)(1,2-naphthoquinone 2-oxime)ruthenium(II) gave (1,2-naphthoquinone 2-oximato)ruthenium(II) (97%) (identified by TLC and IR) and 1,2-naphthoquinone 2-oxime (91%) (identified by TLC and IR).

Attempted reactions of $Ru(1\text{-}nqo)_2$ *or* $Ru(2\text{-}nqo)_2$ *with concentrated hydrochloric acid*

$Ru(1\text{-}nqo)_2$ or $Ru(2\text{-}nqo)_2$ (*ca* 0.50 g) was recovered in *ca* 99% yield after being heated with concentrated hydrochloric acid (20 cm^3) for 7 days.

Reaction of $Ru(1\text{-}nqo)_2$ *and* $Ru(2\text{-}nqo)_2$ *with pyridine*

Bis(1,2-naphthoquinone 1-oximato)ruthenium (II) (0.45 g, 1 mol) was stirred in pyridine (50 cm^3) at 20°C for 4 h. Removal of the solvent at 60°C/35 mm Hg gave bis(1,2-naphthoquinone 1-oximato)di(pyridine)ruthenium(II) (0.61 g, 99%). (Found: C, 59.6; H, 3.4; N, 9.4; Ru, 17.1. $C_{30}H_{22}N_4O_4Ru$ requires: C, 59.7; H, 3.6; N, 9.3; Ru, 16.7%.)

Similarly, bis(1,2-naphthoquinone 2-oximato)ruthenium(II) gave violet bis(1,2-naphthoquinone 2-oximato)di(pyridine)ruthenium(II) (97%). (Found: C, 60.1; H, 3.6; N, 9.1; Ru, 16.8. $C_{30}H_{22}N_4O_4Ru$ requires: C, 59.7; 3.6; N, 9.3; Ru, 17.1%.)

Reaction of $Ru(1\text{-nqo})_2$ *and* $Ru(2\text{-nqo})_2$ *with triphenylphosphine*

Bis(1,2-naphthoquinone 1-oximato)ruthenium (II) (0.5 g, 1.1 mmol) and triphenylphosphine (1.1 g, 4 mmol) were heated under reflux in THF (50 cm^3) for 7 days. Filtration of the mixture afforded bis(1,2-naphthoquinone 1-oximato)bis (triphenylphosphine)ruthenium(II) (0.72 g, 69%). (Found: C, 70.4; H, 3.9; N, 2.7; P, 6.2; Ru, 10.5. $C_{56}H_{42}N_2O_4P_2Ru$ requires: C, 69.3; H, 4.3; N, 2.9; P, 6.5; RU, 10.5%.)

Similarly, bis(1,2-naphthoquinone 2-oximato) ruthenium(II) gave bis(1,2-naphthoquinone 2-oximato)bis(triphenylphosphine)ruthenium(II) (85%). (Found: C, 70.0; H, 4.1; N, 2.8; P, 5.9; Ru, 10.8. $C_{56}H_{42}N_2O_4P_2Ru$ requires: C, 69.3; H, 4.3; N, 2.9; P, 6.5; Ru, 10.5%.)

PEROXO COMPLEXES OF Zr^{IV}, Th^{IV}, W^{VI} AND U^{VI} IONS STABILIZED BY MULTIDENTATE ORGANIC LIGANDS

M. T. H. TARAFDER* and A. A. M. ANWARUL ISLAM

Department of Chemistry, University of Rajshahi, Rajshahi, Bangladesh

(*Received* 29 *June* 1988; *accepted* 25 *July* 1988)

Abstract—Several new peroxo complexes of zirconium, thorium, tungsten and uranium containing organic ligands, ethylenediaminetetraacetic acid and succinic acid, have been prepared. The complexes have the compositions $[M(O_2)(H_2edta)]$, $[M'(O)(O_2)(H_2edta)]$ and $[M''(O_2)(scac)\cdot 2L]$ (H_2edta = dianion of ethylenediaminetetraacetic acid; scac = dianion of succinic acid; M = Zr^{IV} and Th^{IV}; M′ = W^{VI} and U^{VI}; M″ = Zr^{IV} and Th^{IV}; L = $OPPh_3$ or $OAsPh_3$), respectively. The present complexes were found to be very stable and inert towards oxidation. The size of the metals as well as the electronic nature of the auxiliary ligands (L) influence the mode of coordination of the peroxo moiety. The frequency of the ν_1 mode of the $M(O_2)$ grouping decreases with an increase in the atomic numbers of metals in a particular group and in donor strength of the ancillary ligands used.

The study of the chemistry of peroxo complexes has advanced rapidly in the last decade due to developments in the application of such complexes as oxidants in synthetic organic chemistry.[1–9] The reactivity of metal peroxides depends on the nature of other auxiliary ligands used. Peroxo complexes containing monodentate and bidentate auxiliary ligands were found to undergo oxygen transfer reactions to various substrates,[1–9] however, those containing tridentate ligands have been found to be very stable and inert towards oxidation reactions.[6,7,10] We are interested to extend such a study with new peroxo complexes of different elements of Group 4A and 6A containing ethylenediaminetetraacetic acid and succinic acid as quadridentate and bidentate ligands, respectively. The synthesis and properties of peroxo complexes of titanium(IV),[11] niobium(V) and tantalum(V)[12] containing $edta^{2-}$ have been reported. However, reports on the peroxo complexes of zirconium, thorium, tungsten and uranium containing $edta^{2-}$ and $scac^{2-}$ as ancillary ligands are lacking. We present here the synthesis of these complexes and their possible attempted oxygen transfer reactions. An attempt has also been made to study the effect of the size of the metal ions and the electronic nature of auxiliary ligands ($OPPh_3$ and $OAsPh_3$) on ν_1(O—O) modes of the complexes in their IR spectra.

EXPERIMENTAL

Physical measurements

IR spectra (as KBr discs) were recorded with a Pye–Unicam SP3-300 IR spectrophotometer. Conductivities of 10^{-3} M solutions of the complexes in dimethyl sulphoxide (DMSO) were measured at 25°C using a WPA CM35 conductivity meter and dip-type cell with platinized electrodes.

Reagents

All chemicals used were reagent grade and were used as supplied by Merck.

Analyses

Zirconium,[7] thorium,[6] tungsten[9] and uranium[5] were determined gravimetrically. Carbon and hydrogen analyses were done by Mikroanalytisches Labor Pascher, Germany.

Preparation of complexes

General method for the preparation of the complexes $[M(O_2)(H_2edta)]$ (M = Zr^{IV} *and* Th^{IV} *and* $[U(O)(O_2)(H_2edta)]$ (**1**, **2** *and* **4**). $M(NO_3)_4\cdot 6H_2O$ (M = Zr^{IV} or Th^{IV}) or $UO_2(NO_3)_2\cdot 6H_2O$ (0.005 mol) was dissolved in water (20 cm^3) to which a solu-

tion of $Na_2edta \cdot 2H_2O$ (disodium sodium salt of edta) (0.005 mol) in the same solvent (25 cm^3) and 30% H_2O_2 (20 cm^3) were added successively. The precipitate was filtered and washed with water and ether, and dried *in vacuo* over P_4O_{10}.

Preparation of $[W(O)(O_2)(H_2edta)]$ (**3**). A suspension of WO_3 (0.015 mol) in 30% H_2O_2 (70 cm^3) was stirred overnight at 45–50°C. This was filtered and to the clear filtrate was added a solution of Na_2edta (0.015 mol) in water (50 cm^3). The mixture was stirred while cooling at the same time in an ice-salt bath. A yellow precipitate appeared, which was washed successively with water and ether, and dried *in vacuo* over P_4O_{10}.

General method for the preparation of the complexes $[M(O_2)(scac) \cdot 2L]$ ($M = Zr^{IV}$ *or* Th^{IV}; scac = *dianion of succinic acid*; $L = OPPh_3$ *or* $OAsPh_3$) (**5–7**). A solution of $M(NO_3)_4 \cdot 6H_2O$ (0.004 mol) in water (20 cm^3) was added to a solution of succinic acid (0.004 mol) in methanol (20 cm^3). A solution of L (0.008 mol) in methanol (25 cm^3) was then added to the above mixture followed by the addition of 30% H_2O_2 (20 cm^3). The product was filtered, washed successively with water and ether, and stored.

Attempted reactions of **1** *and* **2** *with allyl alcohol and of* **4** *and* **5** *with triphenylphosphine and triphenylarsine, respectively*

Refluxing of **1** with allyl alcohol in a 1 : 1 molar ratio in tetrahydrofuran (THF) medium for 48 h failed to produce any reaction. **1** was recovered unchanged.

Refluxing of **2** with allyl alcohol in the presence of a large excess of 30% H_2O_2 in dioxane medium for 48 h at 90°C also failed to produce any reaction. **2** was recovered unchanged.

Refluxing of **4** and **5** with equimolar quantities of triphenylphosphine and triphenylarsine, respectively in THF for 48 h also failed to produce any reaction. **4** and **5** were recovered unchanged.

RESULTS AND DISCUSSION

The analytical data of the complexes are given in Table 1. The molar conductance values indicated that all of the complexes were non-electrolytes in DMSO indicating that the anions are covalently bonded in all the cases. These data are consistent with six-fold coordination of Zr^{IV} and Th^{IV} complexes, while the W^{IV} and U^{VI} complexes are seven-coordinated.

IR spectral data are shown in Table 2. The H_2edta^{2-} behaves as a quadridentate dinegative ligand coordinating at the two amino nitrogens and the two carboxylate anions. IR spectra of **1–4** indicate the presence of two kinds of carboxo groups. Complexes **1–4** show ν(C=O) bands at around 1600 cm^{-1}—lower than the free ligand value, indicating carboxylate binding in the complexes. However, these complexes also show bands at $\sim$ 1665 cm^{-1} as expected for the free carbonyl group in Na_2edta molecule (Table 2). In addition, a broad band at 3400–3520 cm^{-1} does persist in the spectra of **1–4** dried *in vacuo*, indicating the presence of —OH groups in the coordinated $edta^{2-}$ ion also. Further, the presence of M—N bonds in **1–4** are evident from the appearance of ν(M—N)[5–9] modes at 265–320 cm^{-1} in the far-IR spectra of the complexes. Complexes **5–7** display ν(C=O) bands at 1635–1650 cm^{-1}, significantly lower than the free ligand (Table 2) value which indicates coordination by the carboxylate anions. The ν(O—H) observed for the free $scacH_2$ molecule disappears upon coordination in **5–7** revealing that succinic acid is a bidentate dinegative ligand coordinating through both carboxylate anions. Further support for M—O′ (O′ = oxygen in organic ligand) bonding in **1–7** is apparent from the ν(M—O′) modes at 380–425 cm^{-1} (Table 2) in the far-IR spectra of the complexes.[5–9] The complexes **3** and **4** display ν(M=O) modes at 955 and 910 cm^{-1}, respectively.[4–9]

The metal peroxo grouping gives rise to three IR-active vibrational modes. These are predominantly

[a] Relative band intensities are denoted by vs, s, m, w, sh and br, meaning very strong, strong, medium, weak, shoulder and broad, respectively. E stands for P and As.

O—O stretching (ν_1), the symmetric M—O stretch (ν_2) and the antisymmetric M—O stretch (ν_3). The characteristic ν_1(O—O) modes of **1**–**7** appear at 800–860 cm^{-1}. There is a decrease in ν_1 upon passing from zirconium complexes (**1** and **5**) to the thorium complexes (**2**, **6** and **7**). Again, in the case of the peroxo complexes of the elements from group 6A, there is a decrease in ν_1 upon passing from the tungsten complex (**3**) to the corresponding uranium complex (**4**). The present data, thus clearly reveal that for the $M(O_2)$ grouping, the ν_1 modes decrease with an increase in the atomic numbers of metals in a particular group. In the present examples, the ν_3 and ν_2 modes appear at 630–695 and 570–635 cm^{-1}, respectively. Complexes **6** and **7** show a decrease in ν(P=O) of 72 and 70 cm^{-1}, respectively, compared to the free ligand value (1192 cm^{-1}),[13] suggesting coordination by the oxygen of $OPPh_3$. Complex **7** shows a decrease in ν(As=O) of 20 cm^{-1} from the free ligand value (880 cm^{-1}),[14] indicating coordination by the oxygen of $OAsPh_3$. For **6** and **7**, the ν_1 mode appears at lower frequency in the arsenic compound (**7**, 800 cm^{-1}) compared to that in the phosphorus analogue (**6**, 830 cm^{-1}). It is argued that ν_1(O—O) in the peroxo complexes is decreased by replacing a given ligand by one which is a stronger donor.[4,5] We have previously reported that the oxygen in the arsine oxide is more negative, and values of 2.45×10^{-10} and 1.78×10^{-10} esu were obtained for arsine oxide and phosphine oxide, respectively.[8] This points to a greater polarity in the case of arsine oxides and hence ≡As—O is a stronger donor than ≡P—O. This causes a weaker coulombic interaction in the Th^{4+}—O_2^{2-} moiety for compounds containing $OAsPh_3$. This argument seems to account for the lower ν_1 value observed for **7** than for **6**.

Reactivity

The present peroxo complexes were found to be very stable and were not explosive. To explore the reactivity of the present peroxo complexes toward olefins and other substrates, **1** and **2** were allowed to react with allyl alcohol. These compounds failed to oxidize allyl alcohol even when refluxing at 90°C was continued for 48 h. Compounds **4** and **5** were also inert towards phosphine and arsine. These negative results outline the enhanced stability of the metal peroxo moiety in the presence of quadridentate and bidentate dinegative chelating ligands which precludes oxygen transfer reactions. The present findings also demonstrate that the chelate action derived from bidentate, dinegative ligands equals that of the quadridentate ligand used. We also observed similar behaviour for various peroxo complexes containing tridentate ligands.[5–7,10]

OXIDATION OF NICKEL(II) BIS(SALICYLALDIMINE) COMPLEXES: SOLVENT CONTROL OF THE ULTIMATE REDOX SITE

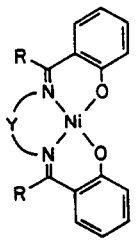
KENNETH A. GOLDSBY,* JEAN K. BLAHO and LISA A. HOFERKAMP

Department of Chemistry, The Florida State University, Tallahassee, FL 32306-3006, U.S.A.

(*Received* 1 *July* 1988; *accepted* 15 *August* 1988)

Abstract—The oxidation of nickel(II) bis(salicylaldimine) complexes has been examined by cyclic voltammetry. The complexes are reversibly oxidized in strong donor solvents, but in weak donor solvents, they are oxidatively polymerized at the electrode surface. A ligand–radical coupling mechanism involving the phenolic portion of the salicylaldimine chelate is proposed, and the solvent dependence is explained in terms of the solvent's ability to stabilize the nickel(III) oxidation state relative to ligand-localized oxidation.

Transition metal bis(salicylaldimine) complexes have received much attention as synthetic dioxygen carriers[1] and as catalysts for the oxidation of organic molecules.[2] Although the oxidation of transition metal bis(salicylaldimine) complexes has been extensively investigated,[3,4] oxidation of the salicylaldimine chelate itself has not been addressed. Herein we report that nickel(II) bis(salicylaldimine) complexes of the type shown in structure I† are oxidatively polymerized in poor donor solvents which



Ia: R = H; Y = CH_2CH_2

Ib: R = H; Y = o-C_6H_4

Ic: R = Me; Y = CH_2CH_2

cannot stabilize the nickel(III) oxidation state relative to ligand-localized oxidation. The oxidative polymerization of these complexes demonstrates a previously unrecognized mode of ligand-localized redox chemistry for the salicylaldimine chelate.

The nickel(II) bis(salicylaldimine) complexes used in these studies were synthesized by standard literature procedures.[5] As previously reported by Kapturkiewicz and Behr for [Ni(H-sal$_2$en)],[4] the nickel(II) bis(salicylaldimine) complexes gave reversible voltammograms in good donor solvents such as pyridine (DN = 33.1),‡ dimethylsulphoxide (DN = 29.8), and N,N-dimethylformamide (DN = 26.6). The electrochemical behaviour observed in weak donor solvents, however, was considerably more complex. For example, initial scan voltammograms of the nickel(II) complexes in acetonitrile (DN = 14.1) showed two distinct oxidations in the potential range 0.8–1.2 V *vs* SSCE, followed by a single reduction of lesser current intensity. Subsequent scans between 0.5 and 1.4 V resulted in rapid current enhancement of the cathodic wave and the appearance of a new anodic wave which grew rapidly at the expense of the initial oxidations (Fig. 1). The increase in current observed with each new scan is indicative of oxidative polymerization of the redox active species to give surface-modified electrodes.[6] With continued scanning, an *insoluble* orange film formed on the electrode surface, which is also consistent with polymer formation. Oxidative polymerization of the nickel(II) salicylaldimine complexes also occurred

*Author to whom correspondence should be addressed.

† The abbreviated names, [Ni(R-sal$_2$Y)], are derived from structure I where Y is en (ethylenediamine, CH_2CH_2) or phen (*o*-phenylenediamine, *o*-C_6H_4).

‡ DN refers to the Gutmann Donor Number[8] for that solvent.

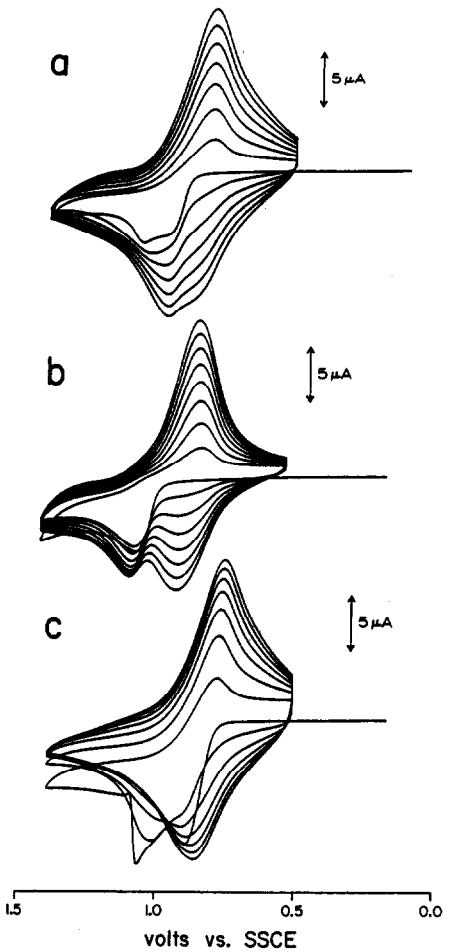


Fig. 1. Cyclic voltammograms showing oxidative polymerization of the nickel(II) bis(salicylaldimine) complexes at a platinum disc electrode in 0.1 M n-Bu_4NPF_6/CH_3CN: (a) 3×10^{-4} M [Ni(H-sal$_2$en)]; (b) 3×10^{-4} M [Ni(H-sal$_2$phen)]; (c) 1×10^{-3} M [Ni(Me-sal$_2$en)]. Scan rate = 100 mV s^{-1}.

in acetone (DN = 17.0) and methylene chloride (DN $\simeq$ 0) electrolyte solutions. The presence of nickel in these films was confirmed by energy-dispersive spectroscopy of the electrode surfaces.[7] Furthermore, visible spectra of films obtained on indium(tin) oxide coated glass electrodes showed broad spectral features characteristic of the nickel(II) bis(salicylaldimine) complexes.

The solvent dependence observed for the oxidative polymerization of the nickel(II) bis(salicylaldimine) complexes can be understood in terms of the solvent's role in governing the ultimate site of oxidation. In strong donor solvents, the oxidation of square planar nickel(II) complexes to nickel(III) occurs with a concomitant increase in coordination number as the higher oxidation state is stabilized by axial ligation. The degree to which axial ligation can stabilize the higher oxidation state of the metal is determined by the donating ability of the solvent.[8] For [Ni(H-sal$_2$en)], this relationship is reflected in the solvent dependence of the [Ni(H-sal$_2$en)]$^{+/0}$ couple.[4] For ligand systems where ligand-localized oxidations are also accessible, it has been shown that the ultimate site of oxidation is determined largely by the solvent's ability to stabilize nickel(III) through axial ligation.[9] In this respect, it is important to note that the bis(salicylaldimine) ligands, H_2(R-sal$_2$Y), are irreversibly oxidized at potentials about 200 mV higher than the corresponding [Ni(R-sal$_2$Y)] complexes. Consequently, the following mechanism can be proposed for the solvent dependent oxidative polymerization of the nickel(II) bis(salicylaldimine) complexes: in good donor solvents, Ni^{II} is oxidized to Ni^{III}. In more weakly donating solvents, however, the nickel(III) oxidation state is not stabilized relative to ligand oxidation, and oxidative polymerization occurs via a ligand–radical coupling mechanism. Electrochemical studies of unsymmetrical nickel(II) Schiff base complexes suggest that the initial site of oxidation is metal-localized, followed by rapid internal electron transfer to give ligand-oxidized species.[10]

The oxidative carbon–carbon coupling of phenols is known to occur by a radical coupling mechanism;[11] therefore, it seems reasonable that oxidative polymerization of nickel(II) bis(salicylaldimine) complexes occurs by an analogous mechanism involving the phenolic portion of the salicylaldimine chelate. As a test for this coupling mechanism, the complexes shown in structure **II–IV** were synthesized* and examined by cyclic voltammetry. It is well known that alkyl substitution at the *ortho* and *para* positions inhibits the oxidative coupling of phenols at these sites.[11] Consistent with the radical coupling mechanism proposed here, the cyclic voltammogram of **II** shows two distinct oxidations, but no evidence for polymerization at the electrode. Furthermore, polymerization occurs for **III** but not for **IV**, which is reasonable given the steric hindrance expected for *ortho–ortho* coupling of the nickel(II) bis(salicylaldimine) complexes and the greater radical electron density at the *para* carbon.[11]

In summary, the oxidative electrochemical behaviour of nickel(II) bis(salicylaldimine) complexes is governed by the solvent's ability to stabilize nickel(III) relative to ligand-localized oxidation. In

*These complexes were prepared by standard procedures[5] and characterized by ^{13}C NMR spectroscopy and chemical ionization mass spectroscopy. The precursor methyl-substituted salicylaldehydes were synthesized by a literature method.[12]

weak donor solvents, the nickel(II) bis(salicylaldimine) complexes are oxidatively polymerized via a ligand–radical coupling mechanism, suggesting that the possibility of ligand redox reactions must be included when considering the potential oxidative decomposition pathways for other metal salicylaldimine complexes. The properties of the surface modified electrodes prepared in this manner will be the subject of a future manuscript.

HETEROLEPTIC POLYPYRAZOLYLBORATE DERIVATIVES OF THE LANTHANIDE IONS. THE SYNTHESIS OF TROPOLONATE COMPLEXES AND THE X-RAY CRYSTAL STRUCTURE OF $[Yb\{HB(C_3N_2H_3)_3\}_2\{OC_7H_5O\}]$

MICHAEL A. J. MOSS and CHRISTOPHER J. JONES*

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham, B15 2TT, U.K.

(*Received* 3 *May* 1988; *accepted* 15 *August* 1988)

Abstract—The air- and moisture-stable complexes $[Ln\{HB(C_3N_2H_3)_3\}_2\{O_2C_7H_5\}]$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Tb, Yb, Lu, Y), have been prepared and characterized. The molecular structure of the ytterbium complex reveals a distorted square antiprismatic coordination geometry around the eight-coordinate Yb^{3+} ion. The tropolonate ligand occupies a position which links the two approximately square faces of the coordination polyhedron.

The tripodal ligand hydrotrispyrazol-1-ylborate,[1] L^-, forms homoleptic complexes of formula $[LnL_3]$ (Ln represents a lanthanide element or yttrium) with trivalent lanthanides.[2] The complexes of the smaller lanthanide ions were found to be soluble in organic solvents but those with Ln = La–Gd were not. A structural study of the ytterbium complex[3] has shown that two of the ligands are tridentate while the third is bidentate giving an overall coordination number of eight. The observed coordination geometry was unusual with bicapped trigonal prismatic (BCTP), a dodecahedral (Dod) or square antiprismatic geometry (SAP) usually being preferred.

In a study of heteroleptic complexes containing the $\{LnL_2\}^+$ moiety, we have prepared compounds of the formula $[LnL_2(acac)]$ (acacH = pentane-2,5-dione) which contain a uninegative bidentate co-ligand. Powder X-ray diffraction studies have shown that the complexes $[LnL_2(acac)]$ could, like $[LnL_3]$, by divided into two structural classes. Thus, the group from Ln = La–Dy were structurally distinct from the Ln = Ho–Lu group. The compounds with $X = acac^-$ and Ln = Ce or Yb were structurally characterized by single crystal X-ray diffraction techniques.[4] These studies revealed a substantial distortion of the BCTP geometry in the complex structure on going from Ce^{3+} to the smaller Yb^{3+} ion. Having established the sensitivity of the coordination geometry on metal ion size in the series $[LnL_2(acac)]$, we were interested to investigate the effect of co-ligand chelate ring size on the structure and properties of these systems. We have now prepared a series of complexes using the tropolonate ligand (trop) which can form a five-membered chelate ring in $[LnL_2X]$ as opposed to the six-membered ring formed with X = acac.

The reaction of Ln^{3+} salts with L^- and tropolone (tropH), in water at pH > 7 proceeded smoothly to precipitate $[LnL_2(trop)]$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Tb, Yb, Lu, Y), in high yield.† All the derivatives were air- and moisture-stable and those with Ln = Nd, Sm, Eu, Tb, Yb and Lu were freely soluble in CH_2Cl_2 whilst those of the larger ions, Ln = La, Ce and Pr, were not. Thus in the case of the tropolonate complexes an intermediate situation prevails in that not all the complexes are sol-

* Author to whom correspondence should be addressed.

† All the new compounds have been fully characterized by ^1H NMR, IR and MS. All give satisfactory elemental analyses for C, H and N.

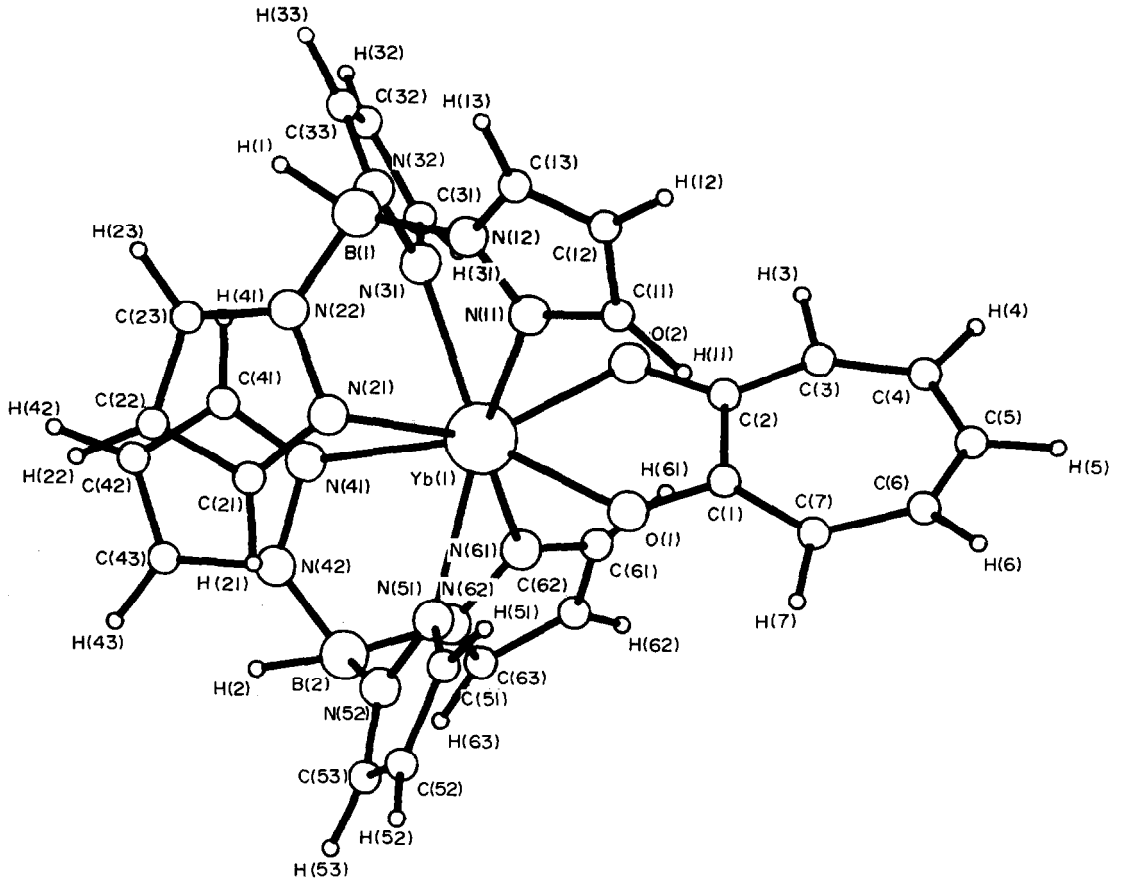

Fig. 1. The molecular structure of $[Yb\{HB(C_3N_2H_3)_3\}_2(C_7H_5O_2)]$ showing the numbering of atoms other than C and H. Selected bond distances and angles: Yb—O(1) 2.222(9), Yb—O(2) 2.267(8), Yb—N(11) 2.501(10), Yb—N(21) 2.482(11), Yb—N(31) 2.425(12), Yb—N(41) 2.548(10), Yb—N(51) 2.439(11), Yb—N(61) 2.474(11); O(1)—Yb—O(2) 69.2(3), N(11)—Yb—N(21) 69.1(3), N(21)—Yb—N(31) 80.5(4), N(31)—Yb—N(11) 74.7(4), N(41)—Yb—N(51) 79.2(4), N(51)—Yb—N(61) 74.3(4), N(61)—Yb—N(41) 73.5(4).

uble in CH_2Cl_2, unlike the $[LnL_2(acac)]$ series (Ln = La–Lu) which are all soluble. However, solubility is maintained over a wider range of cation radius than for the tris complexes, $[LnL_3]$. Like their $[LnL_2(acac)]$ counterparts, the soluble $[LnL_2(trop)]$ complexes were found to be non-rigid on the NMR timescale, only three pyrazolyl proton environments being observed in $CDCl_3$ solution.

In order to structurally characterize a representative of this new series of heteroleptic complexes a single crystal X-ray diffraction study of $[YbL_2(trop)]$ has been carried out.*

$YbL_2(trop)$ is an eight-coordinate monomer as shown in Fig. 1. The coordination geometry is best described as square antiprismatic, although it is on the geometric reaction pathway from SAP to BCTP. Interestingly, the bidentate ligand in $[YbL_3]$ and $[CeL_2(acac)]$ spans one edge of a square, whereas in this structure the tropolonate ligand spans between the two squares. This is, to our knowledge, the first structural characterization of the tropolonate ligand bound to a lanthanide ion.

* *Crystal data.* $C_{25}H_{25}B_2N_{12}O_2Yb$, $M = 720.2$. Orthorhombic, $a = 9.280(2)$, $b = 17.840(8)$, $c = 19.393(2)$ Å, $U = 3211$ Å^3, $Z = 4$, $D_c = 1.48$ g cm^{-3}, space group $P2_12_12_1$ (No. 19), Mo-K_α radiation ($\lambda = 0.7107$ Å, $\mu = 28$ cm^{-1}). Data were collected on a CAD4 diffractometer at the Crystallography Unit, Universities of Aston and Birmingham. 5961 reflections were measured ($2 < 2\theta < 55°$), giving 2813 unique reflections with $I > 2.5\sigma I$ after merging ($R = 0.0434$). The structure was solved using conventional heavy-atom methods on the merged data. In the final stages of full-matrix least-squares refinement, unmerged data were used.

The final model, shown in Fig. 1, refined to $R = 0.0613$ and R_w $\{[\Sigma w(|F_o|-|F_c|)^2]^{1/2}\} = 0.0652$. The refinement of the other enantiomer converged to a model with $R = 0.069$ and $R_w = 0.074$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

The results described here show that only a small structural change occurs when acac is replaced by trop in $[YbL_2X]$. However, the replacement of acac by trop does have a significant effect on the solubility properties of the heteroleptic $[LnL_2X]$ (X = acac or trop) complexes of the early lanthanides. The replacement of trop by bidentate L similarly has a marked effect on the solubility properties of complexes with the lanthanide ions in the middle of the series. The effect of further reducing the chelate ring size of the co-ligand X in these systems is currently being investigated using carboxylate co-ligands.

HYDROGENATION OF ALDEHYDES WITH AN IRIDIUM(I)–PERCHLORATO COMPLEX

CHONG SHIK CHIN,* SUNG CHUL PARK and JUN HO SHIN

Department of Chemistry, Sogang University, CPO Box 1142, Seoul 121-741, Korea

(*Received* 29 *June* 1988; *accepted* 15 *August* 1988)

Abstract—The iridium(I)–perchlorato complex, $Ir(ClO_4)(CO)(PPh_3)_2$ catalyses the hydrogenation of aldehydes to alcohols at 25°C under atmospheric pressure of hydrogen.

While various metal complexes have been reported to show catalytic activities for the hydrogenation of aldehydes and ketones to alcohols,[1–4] catalytic hydrogenation of a carbonyl group with iridium complexes is less well known[5] and no report has been made on the hydrogenation with iridium complexes at room temperature under atmospheric pressure of H_2. In this paper we wish to report the catalytic hydrogenation of aldehydes to the corresponding alcohols in the presence of $Ir(ClO_4)(CO)(PPh_3)_2$ (**1**)[6] at 25°C under atmospheric pressure of H_2.

*Author to whom correspondence should be addressed.

Although no hydrogenation products were detected in the reaction of *trans*-$C_6H_5CH{=}CHCHO$ (**2**) with H_2 in the presence of **1** in neat **2**,[7] $C_6H_5CH_2CH_2CHO$ (**3**) was observed by increasing the concentration of **1** and employing an appropriate amount of solvent at 25°C under atmospheric pressure of H_2; and **3** is further hydrogenated to $C_6H_5CH_2CH_2CH_2OH$ (**4**) when the pressure of H_2 is increased (see Table 1). This observation led us to examine the hydrogenation of aldehydes to alcohols in the presence of **1** (Table 1).

Hydrogenation of more substituted aldehydes is slower than that of less substituted aldehydes and practically no hydrogenation products were

Table 1. Hydrogenation of aldehydes (3.0 mmol) with $Ir(ClO_4)(CO)(PPh_3)_2$ (0.1 mmol) in $CDCl_3$ (2.0 cm^3) at 25°C under hydrogen (P_{H_2} = 1 atm) for 5 h

Substrate	Product	Yield (%)	Remarks

$CH_3(CH_2)_3CHO$	$CH_3(CH_2)_3CH_2OH$	58	
$CH_3CH{=}CHCHO$	$CH_3(CH_2)_2CH_2OH$	22	
	$CH_3(CH_2)_2CHO$	48	
$CH_2{=}C(CH_3)CHO$	$CH_3CH(CH_3)CHO$	63	
$(CH_3)_2CHCHO$			No reaction
C_6H_5CHO	$C_6H_5CH_2OH$	15	
$C_6H_5CH_2CH_2CHO$	$C_6H_5CH_2CH_2CH_2OH$	10	
$C_6H_5CH{=}CHCHO$[a]	$C_6H_5CH_2CH_2CHO$	47	
	$C_6H_5CH_2CH_2CH_2OH$	100	P_{H_2} = 3 atm
	[$C_6H_5CH_2CH_2CHO$	28	P_{H_2} = 3 atm for 3 h
	$C_6H_5CH_2CH_2CH_2OH$]	78	
$(CH_3)_2CO$	$(CH_3)_2CHOH$	1	

[a] Hydrogenation of $C_6H_5CH{=}CHCHO$ was not observed when the concentration of $Ir(ClO_4)(CO)(PPh_3)_2$ was considerably low in neat aldehydes.[7] Also see text.

observed in the reactions of ketones (see Table 1); this fact is readily understood by the steric effect of the substituents on the interaction between the metal and the carbonyl group.

It is already known that complex **1** reacts with **2** and *trans*-$CH_3CH{=}CHCHO$ (**5**) to give $[IrL(CO)(PPh_3)_2]ClO_4$ (L = **2**, **5**) where **2** and **5** are coordinated through the oxygen atom but not through the π-system of the olefinic group, and the reaction of $[IrL(CO)(PPh_3)_2]ClO_4$ with H_2 in the presence of excess **2** or **5** produces only $Ir(H)_2(ClO_4)(CO)(PPh_3)_2$ (**6**).[7] In this study, it has been found that the reaction of **6** with aldehydes under nitrogen produces alcohols, e.g. 0.5 mmol of **6** with 2.5 mmol of C_6H_5CHO in 2.0 cm^3 of $CDCl_3$ under nitrogen at 70°C for 5 h produced 0.2 mmol of $C_6H_5CH_2OH$. Accordingly, a dihydrido(aldehyde)iridium(III) complex (**7**) is suggested as the intermediate for the hydrogenation [see eq. (1)]. A dihydrido metal complex, $LnM(H)_2(O{=}CR_2)$, analogous to **7** was previously suggested as the intermediate in the hydrogenation of carbonyl compounds to alcohols.[8] It should be noted that no iridium complexes of saturated aldehydes have been isolated from the reactions of **1** and saturated aldehydes.

$$Ir(H)_2(ClO_4)(CO)(PPh_3)_2 \xrightarrow{RCHO} \underset{(6)}{} \quad [Ir(H)_2(OCHR)(CO)(PPh_3)_2]ClO_4 \xrightarrow[-RCH_2OH]{H_2} (6). \qquad (1)$$

OXIDATIVE ADDITION OF 1,4-DIISOPROPYL-1,4-DIAZABUTADIENE TO HEXAKISISOPROPOXYDIMOLYBDENUM (M≡M). $Mo_2(OPr^i)_6(Pr^iNCHCHNPr^i)$ AND $Mo_2(OPr^i)_5(Pr^iNCHCHNPr^i)_2$

MALCOLM H. CHISHOLM,* KIRSTEN FOLTING, JOHN C. HUFFMAN and J. J. KOH

(*Received* 22 *August* 1988; *accepted* 22 *August* 1988)

Abstract—Addition of $Pr^iNCHCHNPr^i$ (1 equiv) to hydrocarbon solutions of $Mo_2(OPr^i)_6$ (M≡M) leads to formation of the black crystalline compound $Mo_2(OPr^i)_6(Pr^iNCHCHPr^i)$ (I), which has been shown to contain a reduced diimine ligand (2−) and an oxidized $(Mo{=}Mo)^{8+}$ centre, Mo—Mo = 2.539(2) Å, supported by a pair of bridging OPr^i ligands. The local coordination geometry about each Mo atom corresponds to a distorted tbp and the $Pr^iNCH{=}CHNPr^i$ ligand is chelated to one metal atom through axial and equatorial bonds.

Double bonds between metal atoms are relatively rare in the chemistry of multiple bonds between metal atoms.[1,2] Attempts to synthesize $(M{=}M)^{8+}$ containing compounds by oxidative addition reactions involving $M_2(OR)_6$ compounds have almost invariably led to $(M{-}M)^{10+}$ compounds, e.g. in their reactions with halogens,[3] alkyl- or benzylhalides,[4] *ortho*-quinones[5] and α-diketones.[6] Indeed, only the addition of Pr^iOOPr^i to $Mo_2(OPr^i)_6$ (M≡M) led to the clean conversion of a M—M triple bond to a double bond, eq. (1).[3]

$$Mo_2(OPr^i)_6(M{\equiv}M) + Pr^iOOPr^i \rightarrow Mo_2(OPr^i)_8(M{=}M). \quad (1)$$

We describe here our discovery of the second reaction in which a M—M triple bond is transformed to a double bond, namely, the reaction shown in eq. (2).

$$Mo_2(OPr^i)_6(M{\equiv}M) + Pr^iNCHCHNPr^i \xrightarrow[\text{hexane}]{22^\circ C} Mo_2(OPr^i)_6(Pr^iNCH{=}CHNPr^i). \quad (2)$$

We were intrigued by the notion that Diels–Alder type cyclo-addition reactions might be operative for M—M triple bonds and 1,3-butadienes. When we found that for M = Mo and R = Pr^i there was no apparent reaction with 1,3-butadiene we turned our attention to the reaction between 1,4-diaza-1,3-butadiene recognizing that the formation of Mo—N bonds might be thermodynamically more favourable. 1,4-Diaza-1,3-butadiene ligands (α-diimines), RN=CH—CH=NR, have been shown to exhibit a diverse coordination chemistry.[7]

The addition of $Pr^iNCHCHNPr^i$ (1 equiv) to hydrocarbon solutions of $Mo_2(OPr^i)_6(M{\equiv}M)^8$ leads to an immediate reaction.† Black crystals, $Mo_2(OPr^i)_6(Pr^iNCHCHNPr^i)$ (I) were obtained by cooling the concentrated mother liquor to −15°C. Crystal data for I at −160°C: $a = 9.696(6)$, $b = 19.517(14)$, $c = 19.202(12)$ Å, $\beta = 114.51(2)^\circ$, $Z = 4$, $d_{calc} = 1.375$ g cm^{-3} and space group $P2_1/c$. A total of 5092 reflections were collected using Mo-K_α, $6^\circ \leqslant 2\theta \leqslant 45^\circ$, of which 4362 were unique. The structure was solved by using the 3562 reflections that had $F > 3.0\sigma(F)$ and a combination of direct methods (MULTAN) and Fourier methods leading to the residuals: $R(F) = 0.0359$ and $R_w(F) = 0.0367$. All the hydrogen atoms were located in a difference Fourier, computed after initial

refinement of the heavy atoms. The refinement was completed using anisotropic thermal parameters on non-hydrogen atoms. A ball-and-stick drawing of the molecule is given in Fig. 1 and selected bond distances and angles in Table 1.*

Compound **I** has a Mo—Mo distance of 2.539(2) Å, closely similar to that seen in $Mo_2(OPr^i)_8$, 2.523(1) Å.[9] The Mo—N distances, 1.959(4) and 2.078(4) Å are much shorter than the N-to-Mo distances in $Mo_2(OPr^i)_6(py)_2$, Mo—N = 2.32(1) Å (av)[10] and are similar to those seen in $Mo(NMe_2)_4$, 1.93(1) Å (av),[11] and $W(NMe_2)_6$, 2.03(1) Å.[12,13] The C(16)—C(17) distance, 1.350(8) Å, is short comparable to the C—C double bond distance in ethylene, 1.34(1) Å.[14] Collectively, the structural data are indicative of a $(Mo{=}Mo)^{8+}$ unit supported by a pair of bridging OPr^i ligands and a reduced, 2−, $Pr^iN{-}CH{=}CH{-}NPr^i$ ligand. The local coordination about each metal atom approximates that of a trigonal bipyramid and the two halves of the molecule share a common axial–equatorial edge. The $Pr^iNCHCHNPr^i$ ligand behaves as a chelate to one metal atom. Presumably this is preferred to spanning the Mo—Mo bond because the formation of a five-membered ring is favoured relative to a six-membered ring.

Compound **I**, like $Mo_2(OPr^i)_8$, is fluxional in solution and reactive. It behaves as a coordinatively unsaturated molecule and even reacts further with $Pr^iNCHCHNPr^i$ to give, by elimination of Pr^iO, a paramagnetic compound $Mo_2(OPr^i)_5(Pr^iNCHCHNPR^i)_2$ (**II**). Based on preliminary structural data compound **II** contains two reduced, 2−, $Pr^iNCH{=}CHNPr^i$, ligands and a central Mo_2^{9+} moiety (Mo—Mo = 2.71 Å) supported by three bridging OPr^i ligands.[15]

The present finding suggests that, by suitable choice of R and R′, reactions between $M_2(OR)_6(M{\equiv}M)$ and R′NCHCHNR′ may afford access to a series of M—M double bonded compounds, $M_2(OR)_6(R'NCH{-}CHNR')$, for both molybdenum and tungsten. Further studies are in progress.

A DIIRON–DITUNGSTEN CLUSTER SUPPORTED BY CARBONYL AND ALKOXIDE LIGANDS: $Fe_2W_2(OPr^i)_6(CO)_5(py)$

MALCOLM H. CHISHOLM,* JOHN C. HUFFMAN and J. J. KOH

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 22 *August* 1988; *accepted* 22 *August* 1988)

Abstract—From the reaction between $W_2(OPr^i)_6(py)_2(M{\equiv}M)$ and $Fe_2(\mu\text{-}S_2)(CO)_6$ in hexane at room temperature the first heteronuclear mixed alkoxide–carbonyl cluster $Fe_2W_2(\mu_3\text{-}S)_2(OPr^i)_6(CO)_5(py)$ has been obtained and structurally characterized. The central planar distorted rhomboidal Fe_2W_2 unit is capped by $\mu_3\text{-}S^{2-}$ ligands. There are two Fe—W bonds, in addition to Fe—Fe and W—W bonds.

It is now well established that polynuclear metal carbonyl complexes $M_x(CO)_y$ may be attached to metal oxide supports with retention of the essential framework of the M_x cluster and in certain cases catalytic activity of the supported cluster has been studied.[1] In these types of systems the support–cluster interaction is relatively innocent and the advantages that may result are derived from either mechanical considerations (the ease of handling of the catalyst, substrate/separations) or because the life of the catalyst may be enhanced due to the reduction in intermolecular reactions between clusters. There are, however, other types of interactions that can be envisaged between a metal oxide support and a carbonyl cluster that are non-innocent in nature. Two plausible and potentially common modes of reaction involve (i) redox reactions and (ii) the formation of M—M′ bonds between the metal atoms of the carbonyl cluster and those of the support.

Our work with metal alkoxides, whose structures often mimic those found for metal oxides,[2] led us to examine the reactivity between certain molybdenum and tungsten alkoxide clusters and carbonyl clusters of the later transition elements. We describe here our first results in this area, namely the synthesis and the structural characterization of the product formed in the reaction between $W_2(OPr^i)_6(py)_2(M{\equiv}M)$[3] and $Fe_2(\mu\text{-}S_2)(CO)_6$.[4] Our choice of reactants was made on the basis of (i) the well established chemistry of each of the dinuclear compounds, (ii) the obvious potential for a redox-active interaction, (iii) the substitutional lability of $W_2(OPr^i)_6(py)_2$, which dissociates pyridine in solution, and (iv) the fact that dinuclear compounds provide the simplest of clusters upon which to test the hypothesis.

Alkane solutions of $W_2(OPr^i)_6(py)_2$ and $Fe_2(\mu\text{-}S_2)(CO)_6$ (1 : 1 stoichiometry) reacted at room temperature to yield dark solutions from which a black crystalline product was obtained by concentration of the solution and cooling to *ca* −15°C. The crystals were collected by filtration and dried *in vacuo* to yield 35% based on 1 : 1 stoichiometry. The ^1H NMR spectrum revealed the presence of six different OPr^i ligands, together with resonances due to pyridine. The IR spectrum suggested the presence of only terminal CO ligands and the existence of a molecule having little if any symmetry. It was readily apparent that an assignment of molecular structure was not going to be possible based on spectroscopic data and a suitable crystal was selected for an X-ray diffraction study.†

A ball-and-stick drawing of the $Fe_2W_2(OPr^i)_6$

*Author to whom correspondence should be addressed.

†Cell dimensions at −158°C: $a = 19.069(6)$, $b = 9.460(2)$, $c = 24.458(7)$ Å, $\beta = 120.87(1)°$, $Z = 4$, $d_{calc} = 1.959$ g cm^{-3} and space group *Aa*. Of 2732 reflections collected (Mo-K_α, $6° \leqslant 2\theta \leqslant 45°$), 2491 reflections were unique and the 2324 having $F > 3.0\sigma(F)$ were used in the refinement. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were not located but were included in the final model as idealized fixed atom contributors with d(C—H) = 0.95 Å. Final residuals are $R(F) = 0.041$ and $R_w(F_o) = 0.042$. Listings of programs and general operating procedures have been published.[5] Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Centre.

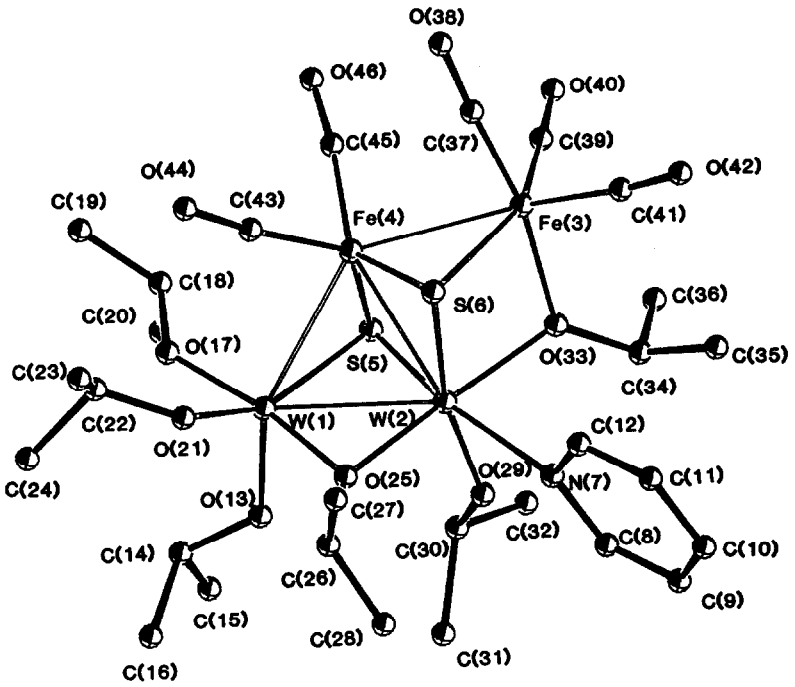

Fig. 1. A ball-and-stick drawing of the $Fe_2W_2(\mu_3\text{-}S)_2(OPr^i)_6(CO)_5(py)$ molecule showing the atom numbering scheme.

$(CO)_5(py)$ molecule is shown in Fig. 1. There is a central planar rhomboidal Fe_2W_2 core with adjacent Fe_2 and W_2 atoms. A μ_3-sulphido ligand caps each W_2Fe and Fe_2W triangle above and below the Fe_2W_2 plane. The formation of $Fe_2W_2(OPr^i)_6(CO)_5(py)$ occurs according to the stoichiometry shown in eq. (1) with the liberation of one equivalent of pyridine and carbon monoxide.

$$W_2(OPr^i)_6(py)_2 + Fe_2(\mu\text{-}S_2)(CO)_6 \rightarrow Fe_2W_2(OPr^i)_6(CO)_5(py) + py + CO. \quad (1)$$

The $(W{\equiv}W)^{6+}$ centre in $W_2(OPr^i)_6(py)_2$ acts as a reducing agent towards the μ-S_2^{2-} ligand in the generation of two S^{2-} ligands which together with loss of CO generate unsaturation at the iron atoms. The latter is compensated for by the formation of (i) an alkoxide bridge to Fe(3) and (ii) M—M bonds between: W(1)—Fe(4) = 2.699(3) and W(2)—Fe(4) = 2.648(4) Å. The W(2) to Fe(3) distance which is spanned by the μ-OPr^i ligand is 3.148(3) Å, a non-bonding distance.

The W—W distance, 2.714(1) Å and the Fe—Fe distance, 2.648(4) Å, are indicative of M—M single bonds.

The product of reaction (1) may be viewed as arising from the following hypothetical reaction pathway. (1) The $(W{\equiv}W)^{6+}$ centre reduces the S_2^{2-} ligand to give $(W{=}W)^{8+}$ and two S^{2-} groups. (2) Loss of CO, formally from Fe(3), generates a carbene-like metal centre that adds across the $(W{=}W)^{8+}$ group to generate a $(W{-}W)^{10+}$ moiety bridged by both sulphur and iron atoms. This results in a pseudo-octahedral geometry about each W atom and the 18-electron rule is satisfied for both Fe atoms as a result of W—Fe, Fe—Fe and Fe–ligand bonding which includes the use of an alkoxide bridge from a neighbouring W centre.

The present finding suggests that reactions between early transition metal alkoxides and later transition metal carbonyl clusters may provide access to a new class of heteronuclear clusters with multi-functional sites for reactivity. Further studies are in progress.

DOUBLE BONDS BETWEEN MOLYBDENUM ATOMS SUPPORTED BY DIMETHYLAMIDO LIGANDS: $Mo_2(NMe_2)_4(OR)_4$ COMPOUNDS, WHERE R = 4-METHYLCYCLOHEXYL AND DIISOPROPYLMETHYL

MALCOLM H. CHISHOLM,* CHARLES E. HAMMOND and JOHN C. HUFFMAN

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 22 *August* 1988; *accepted* 22 *August* 1988)

Abstract—Hydrocarbon solutions of $Mo(NMe_2)_4$ and the alcohols, ROH (2 equiv) (where R = 4-methylcyclohexyl and diisopropyl) react to give compounds of empirical formula $Mo(NMe_2)_2(OR)_2$ which are dimeric both in solution and in the solid-state. The derivative for R = 4-methylcyclohexyl has a crystallographically imposed centre of inversion and a central planar $Mo_2(\mu\text{-}N)_2$ moiety: Mo—Mo = 2.5431(5) Å. The local geometry about each Mo atom corresponds to a distorted trigonal bipyramid and the two halves of the molecule are joined along a common equatorial–axial edge.

Though molybdenum shows a remarkable propensity to form multiple bonds (Mo—Mo), well characterized compounds where $n = 2$ are very rare.[1] We report here our discovery of a new class of Mo≡Mo bonded compounds of formula $Mo_2(NMe_2)_4(OR)_4$ and our structural characterization of one example, namely that where R = 4-methylcyclohexyl.

Molybdenum in its +4 oxidation state forms a series of monomeric compounds of formula MoL_4, where L = NMe_2,[2,3] $P(C_6H_{11}^{cy})_2$,[4] SBu^t[5] and OBu^t.[6] The compounds where L = NMe_2,[3] $P(C_6H_{11}^{cy})_2$[4] and SBu^t[5] are diamagnetic and have been structurally characterized, whereas the *tert*-butoxide, which is not structurally characterized is paramagnetic. The diamagnetism of the MoL_4 compounds (L = NMe_2, $P(C_6H_{11}^{cy})_2$ and SBu^t) can be understood in terms of ligand-to-metal π-bonding. All attempts to attain a suitably crystalline sample of a monomeric $Mo(OR)_4$ compound for an X-ray study have thus far proved unsuccessful. However, during attempts to prepare a monomeric compound of formula $Mo(NMe_2)_{4-x}(OR)_x$ suitable for an X-ray study, we discovered the formation of compounds of empirical formula $Mo(NMe_2)_2(OR)_2$ that were diamagnetic. We show here they are diamagnetic because of Mo—Mo double bond formation.

Hydrocarbon solutions of the highly air-sensitive compound $Mo(NMe_2)_4$ react with ROH (2 equiv), where R = 4-methylcyclohexyl and diisopropylmethyl ($CHPr^i_2$), to give dark solutions from which dark purple–brown crystals can be obtained in *ca* 30–40% yield.

The compound where R = 4-methylcyclohexyl was examined in an X-ray study.[7] (Crystal data at −142°C: $a = 10.083(1)$, $b = 11.623(1)$, $c = 9.637(1)$ Å, $\alpha = 111.10(1)°$, $\beta = 100.53(1)°$, $\gamma = 74.62(1)°$, $Z = 1$, $d_{calc} = 1.349\ g\ cm^{-3}$ and space group $P\bar{1}$. Final residuals are $R(F) = 0.0255$ and $R_w(F) = 0.0279$.]† A ball-and-stick drawing of the centrosymmatic molecule is shown in Fig. 1.

There is a central planar $Mo_2(\mu\text{-}N)_2$ unit with Mo—Mo = 2.5431(5) Å similar to the few other characterized d^2–d^2 $(Mo{=}Mo)^{8+}$-containing compounds.[8] The coordination about each Mo atom

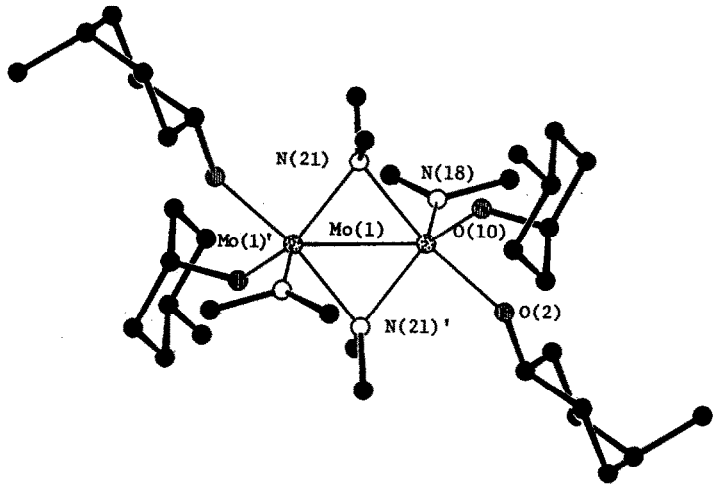

Fig. 1. A ball-and-stick drawing of the centrosymmetric molecule $Mo_2(NMe_2)_4(OC_6H_{10}^{cy}\text{-}4\text{-}Me)_4$ showing the atomic numbering scheme. Selected bond distances (Å) and angles (°) are as follows: Mo—Mo = 2.5431(5), Mo(1)—O(2) = 1.990(2), Mo(1)—O(10) = 1.966(2), Mo(1)—N(18) = 1.919(2), Mo(1)—N(21)′ = 2.096(2), Mo(1)—N(21) = 2.168(2); O(2)—Mo(1)—O(10) = 82.36(7), O(2)—Mo(1)—N(18) = 98.52(8), O(2)—Mo(1)—N(21) = 160.40(8), O(2)—Mo(1)—N(21)′ = 86.70(8), O(10)—Mo(1)—N(18) = 117.67(9), O(10)—Mo(1)—N(21) = 78.27(7), O(10)—Mo(1)—N(21)′ = 141.78(8), N(18)—Mo(1)—N(21) = 93.11(9), N(21)—Mo(1)—N(21)′ = 106.79(7), Mo(1)—N(21)—Mo(1)′ = 73.21(7).

corresponds to a distorted trigonal bipyramid and the two halves of the molecule are joined along a common equatorial–axial edge.

The structure is similar to that seen for $Mo_2(OPr^i)_8$[9] and it is of particular interest to see that in the present structure there is a preference for the NMe_2 groups to bridge rather than the alkoxide ligands. This may result from steric factors that allow the NC_2 blades to occupy the bridging positions with a minimum degree of internal congestion. The terminal NMe_2 ligands occupy equatorial sites with Mo—N distances of 1.92(1) Å comparable to those in monomeric $Mo(NMe_2)_4$, which implies a significant degree of Mo—N double bond character. Also worthy of mention is that the axial bonds (terminal Mo—O and bridging M—N) are longer than their equatorial counterparts—a feature previously seen in $Mo_2(OPr^i)_8$.[9] The structure is similarly related to that of $[Zr(NMe_2)_4]_2$ recently reported in this journal.[10] The Zr-to-Zr distance of 3.704(1) Å in the d^0–d^0 $M_2(\mu\text{-}NMe_2)_2$-containing compound compared to the d^2–d^2 distance, 2.54 Å, in the present compound emphasizes the significance of metal–metal bonding. Indeed, one might well wonder why $Mo(NMe_2)_4$ does not adopt a dinuclear structure $Mo_2(NMe_2)_8$ having a Mo—Mo double bond. Apparently there must be a subtle interplay between maximizing M–N π-bonding and maximizing M—M bonding that favours, in the case of $Mo(NMe_2)_4$, the monomer.

Variable temperature ^1H NMR studies on the $Mo_2(NMe_2)_4(OR)_4$ compounds (R = 4-methylcyclohexyl and diisopropylmethyl) indicate that a dimeric structure is maintained in solution. Specifically there are distinct signals associated with the terminal and bridging NMe_2 ligands even at room temperature. At low temperatures there is evidence for the presence of two isomers which can reasonably be formulated as *syn* and *anti* isomers as shown in Fig. 2. Presumably at higher temperatures a turnstyle operation involving the terminal ligands exchanges the axial–equatorial bonds and leads to *syn* ⇄ *anti* isomerization. Further studies are in progress.

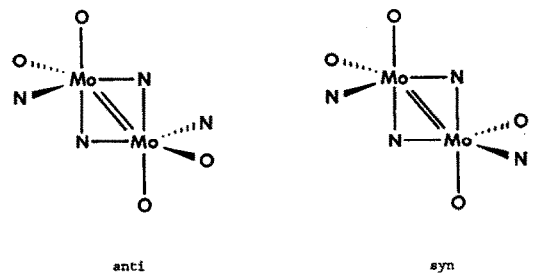

Fig. 2. *Syn* and *anti* isomers of the $Mo_2(NMe_2)_4(OR)_4$ compounds.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry, Pb—organolead Compounds, part 1. Tetramethyllead. Published by Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science. 8th Edn. Springer, Berlin, 1987. ISBN 3-540-93560-6, XII + 194 pp. DM 896.

Few compounds receive the accolade of having a book devoted to them, but this volume of Gmelin is exclusively about tetramethyllead. Few chemists, even organometallic chemists will have handled it directly, but all will have made indirect use of it because its importance lies in its use as an antiknock agent for internal combustion engines.

Here is indeed all that you ever wanted to know about tetramethyllead; the literature is covered up to the end of 1986.

A compilation of reports and monographs on tetramethyllead, starting in the 1920s and listed chronologically, occupies the first 55 pages. This includes analytical methods, toxicology, applications and environmental aspects.

The preparation of the compound is then covered in 40 pages (which include 638 references). The principal methods are the reaction of a Grignard reagent, or of methyllithium or other methylmetallic compounds with lead(II) chloride, or the reaction of a lead–sodium alloy with methyl chloride, or the electrolysis of methylmagnesium chloride using a sacrificial lead anode.

Methods of analysis, spectroscopy and physical properties are thoroughly covered. there is a thorough treatment (35 pages) of chemical reactions, and sections on physiological properties and toxicity, on uses, and on tetramethyllead in the environment.

The presentation and printing is of Gmelin's usual impeccable standard.

(*Received* 23 *December* 1987; *accepted* 6 *July* 1988)

Abstract—Several high-spin Fe^{III} complexes of the type $Fe(HL)Cl_2$ and Fe(L)Cl (HL = monoanion of terdentate NNO ligand and L = dianion of quadridentate ONNO ligand, respectively), based on the condensation products of S-methylisothiosemicarbazide and different aromatic 2-hydroxy-aldehydes, have been prepared and characterized by elemental analysis, conductivity and magnetic measurements, IR and electronic spectra, as well as by cyclic voltammetry. For all solid complexes a pentacoordinated structure is proposed, while in DMF solutions hexacoordination is suggested. Differences in some physico-chemical properties, arising from structural changes in the coordinated ligand, are discussed.

In our previous paper[1] we described the synthesis and some physico-chemical and voltammetric characteristics of different types of mono- and bis-(ligand) chelate complexes with the terdentate salicylaldehyde semi-, thiosemi- and S-methyl-lisothiosemicarbazones. Here, we present the analogous data for two novel mono(ligand) Fe^{III} complexes with 5-nitrosalicylaldehyde S-methyl-isothiosemicarbazone (H_2L^1) and 2-hydroxy-1-naphthaldehyde S-methylisothiosemicarbazone (H_2L^2) of general formula $Fe(HL)Cl_2$ (HL = monoanionic form of the terdentate ligand), as well as for several complexes of the type Fe(L)Cl, where L = the dianionic form of quadridentate ligands S-methyl-1,4-bis(arilydene)isothiosemicarbazide, viz.

EXPERIMENTAL

Chemicals and methods

For all syntheses only the Merck $FeCl_3$ or $FeCl_3 \cdot 6H_2O$ reagent grade were used. Other chemicals for syntheses were also of p.a. quality but of a different make.

The voltammetric, conductometric and spectrophotometric measurements were carried out in freshly distilled N,N-dimethylformamide (DMF). The salts used as supporting electrolytes (tetrabutylammonium perchlorate (TBAP) and lithium chloride) were used after recrystallization. The C, H, N analysis procedure and magnetic susceptibility measurements have been described earlier.[2]

The air-dried samples were used for all measurements except voltammetry and spectrophotometry; in the latter case the samples were dried at 110°C.

The apparatus and procedure for conductivity measurements, IR spectrometry, UV–vis. spectrophotometry and voltammetry have been described earlier.[1] In voltammetric experiments a glassy carbon disc served as the working electrode and an aqueous SCE as the reference electrode, and

all potentials were reported against the latter electrode.

Synthesis of ligands

The S-methylisothiosemicarbazones were obtained by the reaction of stoichiometric amounts of a hot aqueous solution of S-methylisothiosemicarbazidehydrogen iodide[3] and an alcoholic solution of the corresponding aldehyde. After neutralization of the mixture with aqueous $Na_2CO_3 \cdot 10H_2O$ solution, the light yellow crystals of the ligands obtained were filtered off and washed with water (to a negative reaction on I^-) and finally with EtOH. Yield: 70–90%.

Synthesis of complexes

$Fe(HL^1)Cl_2$. The mixture of 0.56 g (2 mmol) of H_2L^1 and 0.40 g (2.5 mmol) of $FeCl_3$ (anhydrous) was heated for 5 min with 10 cm^3 of absolute EtOH. The black crystals, formed in the brown solution during 1 h, were filtered off and washed with EtOH and Et_2O. Yield: 0.40 g.

$Fe(HL^2)Cl_2 \cdot 0.5EtOH$. To 30 cm^3 of the hot ethanolic solution of H_2L^2 (0.50 g, 2 mmol) was added 10 cm^3 of ethanolic solution of $FeCl_3 \cdot 6H_2O$ (0.67 g, 2.5 mmol). The obtained mixture was heated for about 5 min to dissolve the ligand completely. The needle-like crystals which formed in the green solution after 10 h of crystallization were filtered off and washed with EtOH and Et_2O. Yield: 0.50 g.

Fe(L)Cl (L = L^3, L^7, L^8, L^9). The mixture of $Fe(HL)Cl_2$ (HL = HL* = monoanion of salicylaldehyde S-methylisothiosemicarbazone or HL^1 or HL^2) (2 mmol) and of the corresponding aldehyde (2.5 mmol) in MeOH (20 cm^3) was heated under reflux for 1–1.5 h. After 5 h, the brown crystals obtained were filtered off and washed with MeOH and Et_2O. Yield: 40–50%.

Fe(L)Cl (L = L^4, L^5, L^6). A mixture of 2 mmol of S-methylisothiosemicarbazone of the corresponding aldehyde, 2.5 mmol of the same aldehyde and 2.5 mmol of $FeCl_3$ (anhydrous) in 10 cm^3 of absolute EtOH was refluxed for 2–3 h. After several hours the precipitated crystals were filtered off and washed with EtOH and Et_2O. Yield: 30–35%.

RESULTS AND DISCUSSION

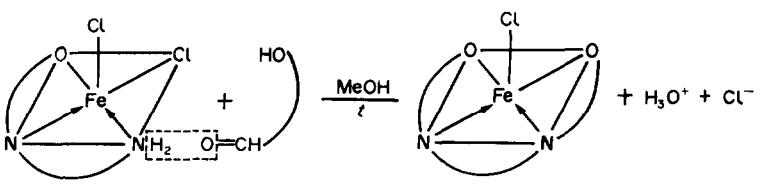
Syntheses and general characteristics of complexes

The synthesis of $Fe(HL^*)Cl_2$ was accomplished by the reaction of warm ethanolic solutions of Fe^{III} chloride and the ligand.[4] In the same way we prepared the new Fe^{III} complexes with H_2L^1 and H_2L^2, described here. The three complexes served as the basis for the synthesis of the corresponding complexes with quadridentate ligands (H_2L^3, H_2L^7–H_2L^9).

The condensation reaction involving the NH_2 group of the terdentate S-methylisothiosemicarbazone and the C=O aldehyde group of the corresponding aldehyde, carried out in warm methanolic solutions of these complexes, yielded the complex with a quadridentate ONNO ligand (Scheme 1).

Because the other dichloro-(S-methylisothiosemicarbazonato)-ferrum^{III} complexes are hard to crystallize, the corresponding Fe(ONNO)Cl complexes were synthesized by a direct template reaction, i.e. by the reaction of S-methylisothiosemicarbazone and the corresponding aldehyde in the presence of the Fe^{III} ion as template. It was observed that the best results are achieved using anhydrous $FeCl_3$ and absolute ethanol as solvent.

It should be mentioned that this template reaction was first discovered in the synthesis of Ni^{II}, Cu^{II} and VO^{II} complexes, which was carried out in a water–ethanol medium, in the presence of a base (NaOH, KOH or NH_3).[5] The attempts to synthesize some analogous Fe^{III} complexes under the same reaction conditions were unsuccessful. However, using non-aqueous solvents in the presence of different organic bases (pyridine, N,N-dimethylformamide, benzimidazole), Gerbeleu and coworkers.[6] were able to prepare the complexes with H_2L^3, H_2L^4, H_2L^6 and H_2L^7. The crystallization time required was one to several days and the yields were 23–85%. However, we have shown that the Fe^{III} complexes of this type may be obtained in



Scheme 1.

satisfactory yield in a much shorter time and in the absence of organic bases. This may be achieved either by direct syntheses using $FeCl_3$ (anhydrous), S-methylisothiosemicarbazone of an aldehyde and the corresponding aldehyde in absolute EtOH, or by the reaction of $Fe(HL)Cl_2$ and the corresponding aldehyde in commercial MeOH.†

All the complexes isolated are black or dark brown crystalline substances (Table 1) which are stable up to 300°C. The exception is $Fe(HL^2)Cl_2$ which melts at 255°C.

The complexes are soluble in DMF and Me_2CO but less soluble in MeOH and EtOH. Complexes of the Fe(L)Cl type are also sparingly soluble in Et_2O and $CHCl_3$, whereas the $Fe(HL)Cl_2$ complexes are insoluble in these solvents. None of the complexes are soluble in water.

The effective magnetic moments (Table 1) are characteristic for the high-spin Fe^{III} complexes. This means that the ligands involved belong to the low-strength ligand field group. However, it has been reported[7] that a similar ligand, 3-hydroxy-2-naphthaldehyde thiosemicarbazone, forms a low-spin Fe^{III} complex.

Geometric configuration of complexes

The molecular structures of some representatives of both types of complexes have been already reported. Thus, the X-ray analysis of $Fe(HL)Cl_2$ (HL = monoanion of the terdentate NNO 2-hydroxyacetophenone S-methylisothiosemicarbazone) showed that it has a trigonal bipyramidal configuration involving the chelate ligand and both chloride ions.[8] On the basis of spectral and magnetic measurements, a square pyramidal structure was ascribed to $Fe(HL)Cl_2$ (HL = the monoanion of the terdentate ONS, 3-hydroxy-2-naphthaldehyde thiosemicarbazone).[7] Finally, X-ray analysis showed that $Fe(L^3)Cl$ forms a square pyramid with the chloride atom at the apex.[9]

On taking into account the IR data and the analogy between the above complexes and those described here, it can be concluded that the latter also have a pentacoordination structure. Thus, the IR spectra of all S-methylisothiosemicarbazones contain, in the region 3500–3000 cm^{-1}, three bands viz. a strong high-frequency band at 3450 ± 20, a weak narrow band at 3290 ± 30 and a broad low-

† Various reaction conditions are the cause of differences in composition of the present and previously reported complexes. Therefore, in ref. 6 the complexes $Fe(L^4)Cl$, $Fe(L^6)Cl$ and $Fe(L^7)Cl \cdot 0.5MeOH$ were isolated as crystallosolvates with 0.5DMF, 0.5THF and 1EtOH · 1DMF, respectively.

frequency band of medium intensity at 3100 ± 40 cm^{-1}, corresponding to $\nu_a(NH)$, $\nu_s(NH)$ and $\nu(OH)$, respectively. Furthermore, the $\nu(OH)$ band disappears, which indicates coordination of the deprotonized OH group of the phenolic hydroxyl. On the other hand, the spectrum of $Fe(HL^1)Cl_2$ contains only one broader band (the maximum at 3320 cm^{-1}) which can be ascribed to the $\nu(NH)$ vibrations (in the non-complexed ligand: $\nu_a(NH) = 3440$, $\nu_s(NH) = 3280$ cm^{-1}). The maxima of the $\nu(NH)$ bands in the spectrum of $Fe(HL^2)Cl_2$ are not clearly defined, which may suggest the presence of relatively strong hydrogen bonds. In any case, the position of the $\delta(NH_2)$ band in the spectra of the non-coordinated ligand (1625 cm^{-1}) and its shift of 25 cm^{-1} towards lower energies upon coordination, indicates the involvement of the nitrogen atom of the NH_2 group in the above two complexes. (It should be mentioned that a terdentate NNO character of the H_2L^1 ligand was confirmed by X-ray analysis of its complex with Cu^{II}.[10]) In the IR spectra of the Fe(L)Cl complexes there are no characteristic $\nu(NH)$ bands, which suggests that the condensation reaction of S-methylisothiosemicarbazone and the corresponding ligand took place. Finally, a very strong band from the azomethine group, $\nu(-CH=N-)$, appearing in the spectrum of S-methylisothiosemicarbazone at about 1630 cm^{-1}, is also shifted after coordination towards lower energies by *ca* 35 cm^{-1}.

The molar conductivities (Table 1) of the DMF solutions of both mono- and dichloro complexes are significantly lower than those expected for the 1:1 type of electrolyte in this solvent (65–90 Ω^{-1} mol^{-1} cm^2).[11] Therefore, it is clear that the chloride ions are also involved in coordination. It should be noticed that the conductivity of the solution does not change even after 24 h, which can be referred to the relative strength of the Fe—Cl bond. Another support of the coordination of chloride is the presence of a band of variable intensity at 350 cm^{-1} belonging, most probably, to the $\nu(Fe—Cl)$.[12]

On the basis of all the above, a pentacoordinated structure can be ascribed to all of the complexes isolated. However, none of the two possible coordination polyhedra can be preferentially ascribed to the $Fe(HL)Cl_2$ complexes. On the other hand, all the data indicate that the Fe(L)Cl complexes may have a tetragonal pyramidal structure, with the chelate ligand at the bases and the chlorine atom at the apex. In DMF solution, however, an octahedral structure, which is most common for Fe^{III} complexes, may be formed on account of coordination of a solvent molecule in the other axial position.

Electronic spectra

The electronic spectra of all complexes with quadridentate ligands are generally quite similar (Table 2). One common feature is the absence of absorption bands in the visible region which would correspond to *d–d* transitions. Another characteristic is the appearance of two main bands in the region 20,400–33,300 cm^{-1}. The lower broad band in the 21,700–23,250 cm^{-1} region, which after the addition of an excess of Cl^- (LiCl) shifted by about 500–1000 cm^{-1} towards higher wavelengths, corresponds to the $d–\pi^*$ interactions in the complex. The one or two ill-defined bands around 26,300 cm^{-1} appear at the foot of the main band whose maximum occurs in the range 29,400–33,300 cm^{-1}. On the basis of its position and the corresponding value of ε (30,000–40,000), this band can be ascribed

Table 2. Electronic spectral data for Fe^{III} complexes in DMF

[d] Broad peak.

to the π–π^* interactions of the ligand. An exception is the spectrum of Fe(L^7)Cl which, instead of one, exhibits three strong ill-separated bands. Since the addition of Cl^- (LiCl) causes significant changes (two unequal well separated maxima at 27,470 and 31,540 cm^{-1} are obtained), it can be supposed that the introduction of another Cl^- on coordination induces some changes in the electronic configuration of the ligand containing the *p*-NO_2 group. On the other hand, this region of the spectra for other complexes is not affected by the addition of chloride, which indicates the absence of any significant electronic interaction between the coordinated Cl^- and the organic ligand.

The DMF solutions of the complexes with terdentate ligands absorb very strongly only in the narrow region of 27,000–34,500 cm^{-1}. So, the *d–d* interactions are also excluded. However, because the ligand itself absorbs very strongly in this region, it is not quite clear whether the bands at about 27,700 cm^{-1} belong exclusively to the d–π^* transitions or whether there is an overlap with the π–π^* bands. The bands at $\lambda > 30{,}700$ cm^{-1} belong most probably to the intraligand electronic transitions (π–π^*). Addition of Cl^-(LiCl) produces changes in the whole absorption range, which is a consequence of structural alterations of the complex species in the solution.

Voltammetric studies

Complexes with terdentate ligands. Since the appearance of cyclic voltammograms of these complexes is greatly influenced by the supporting electrolyte, the discussion will be given accordingly.

Perchlorate medium (TBAP): in the presence of an inert supporting electrolyte such as TBAP, several Fe^{III} complex species of different composition may be present in solution. As a result, the cyclic voltammograms contain several ill-separated one-electron peaks representing the reduction of the complex. At about 0.0 V the complex $[FeCl_x(DMF)_y]^{(3-x)+}$ ($x \leqslant 4$, $x+y=6$) is reduced, whereas the peaks at more negative potentials (up to -1.1 V) can be ascribed to the reduction of $[Fe(HL)Cl_x(DMF)_y]^{(2-x)+}$ ($x+y=3$), and $[Fe(HL)_2]^+$. All the reduction peaks have their oxidation counterparts. If, however, the potential limit is set sufficiently negative, a multielectron irreversible reduction of the ligand itself is observed in the region of -2.0 to -2.5 V. In the case of the complex containing the 5-NO_2–salicylaldehyde moiety, the additional reduction peaks observed in the range -1.2 to -1.8 V may be explained by the presence of an electrophilic substituent in the benzene ring.

These complexes can be oxidized in two or three steps in the potential region $+0.5$ to $+1.6$ V. The processes are followed by irreversible chemical reactions of the complex decomposition.

Chloride medium (LiCl): in contrast to the above, the cyclic voltammograms of the complexes in the presence of LiCl exhibit three well-defined one-electron reduction peaks (I–III) and the corresponding oxidation counterparts (I′–III′) (Fig. 1). The voltammetric behaviour of these complexes is quite similar to that of salicylaldehyde S-methylisothiosemicarbazone, whose cyclic voltammogram is given in the inset. Therefore, the same dimeric formula $[Fe(HL)_2][FeCl_4]$[1] can be ascribed to these complexes. Furthermore, one HL^- in the $[Fe(HL)_2]^+$ can be replaced by three Cl^- ions, so that the species reacting at the potentials of peaks I and II are $[FeCl_4]^-$ and $[Fe(HL)Cl_3]^-$, respectively; peak III represents the reduction of $[FeL_2]^-$, formed by a specific chemical reaction after the reduction at peak II.[13]

General voltammetric characteristics of these complexes are presented in Table 3. As evident from its potentials, the I/I′ couple represents a quasi-reversible process with no chemical complications. The controlled-potential electrolysis at peak I gives 1 mole of electrons per mole of reactant taken as the dimer. Another mole of electrons is consumed in the reduction at peaks II and III, half of it at each potential. This result confirms the specific nature of the chemical reaction by which $[Fe(HL)Cl_3]^-$ is transformed into $[FeL_2]^-$.[13] The $\Delta E/\Delta \log v$ slope of -30 to -50 mV, observed at low sweep rates,

is also support of the presence of an irreversible chemical reaction. It should be noticed that the difference in current function of peak I and the sum of current functions of peaks II and III may be mainly the consequence of different diffusion coefficients of the reacting species.

The potentials of peaks II and III do not practically depend on the nature of the ligand containing an unsubstituted aldehyde. On the other hand, the introduction of an electrophilic substituent (p-NO_2) into the benzene ring makes the electron transfer much easier (the potentials of both peaks are more positive by about 200 mV).

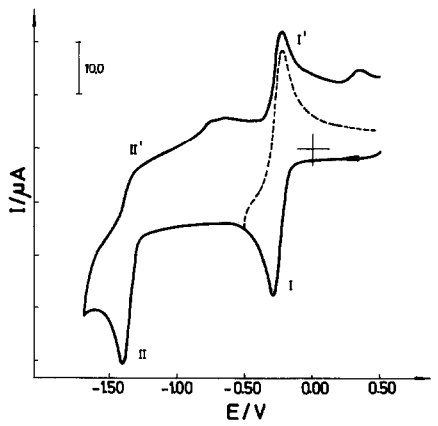

Fig. 2. Cyclic voltammograms for $Fe(L^3)Cl$; 0.1 mol dm^{-3} LiCl. GC electrode, 0.20 V s^{-1}.

Complexes with quadridentate ligands. Unlike those described above, these complexes generally exhibit the same voltammetric behaviour in both the electrolytes used.[14] [Fe(L)Cl(DMF)], the main complex species in the presence of TBAP, is transformed into $[Fe(L)Cl_2]^-$ when Cl^- is present in excess in the solution. As a result, the corresponding peak potentials are about 50 mV more negative.

Chloride medium (LiCl): all the complexes are reduced in two one-electron processes (peaks I and II; peaks I′ and II′ being the oxidation counterparts) as shown in Fig. 2.

The process (I/I′) has the characteristics of a quasi-reversible electron transfer, accompanied by a slow irreversible chemical reaction of first order (the $\Delta E/\Delta \log v$ is about −20 to −30 mV at $v < 0.10$ V s^{-1}). The ratio $I_{p(I')}/I_{p(I)} \approx 1$ at $v \geqslant 0.02$ V s^{-1} is obtained for all complexes with the exception of $Fe(L^5)Cl$ and $Fe(L^7)Cl$. In the voltammograms of these complexes, and especially that of $Fe(L^7)Cl$, an increase in the sweep rate produces a slight decrease of $I_{p(I)}$, an increase of the half-peak width, and an increase of the slope $\Delta E/\Delta \log v$ to −60 mV. At the same time, peak I′ exhibits no complications. Since this behaviour is not observed in the presence of TBAP, the kinetic complications may be ascribed to the Cl^- introduced into the other axial position in the complex. Obviously, a stable electronic configuration, after the electronation of a species containing two strong electrophilic groups (—NO_2) at the *para* position with respect to the phenolic oxygen, i.e. the Fe^{III} central atom, and in the presence of Cl^- at both axial positions, can be obtained only after reorganization of the molecule. Hence, at low sweep rates, the kinetic complications are apparently not reflected on the recorded curve.

The reduction at peak II is a quasi-reversible process followed by a fast irreversible chemical reaction of second-order. Peak II′ normally appears at $v > 1$ V s^{-1} and increases with increasing v until the ratio $I_{p(II')}/I_{p(II)}$ approaches unity. At the same time the peak shifts in the positive direction with $\Delta E/\Delta \log v \approx 10$ mV. The irreversible chemical reaction following the reduction of the complex is probably the complex decomposition giving rise to

several peaks at more positive potentials than peak II′. After the two-electron electrolysis (either directly at peak II, or stepwise at peak I and II), the complex cannot be reoxidized because of a strong blocking of the GC electrode by complex decomposition products.

Some voltammetric characteristics of the complexes are presented in Table 4. The differences in peak potentials for different complexes indicate that the introduction of an electrophilic substituent into the benzene ring facilitates transfer of the first, and especially of the second electron, thus suggesting that the reduction of the complex is predominantly of the ligand type.

Abstract—The complexes, $Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2]X(L)$ (X = Cl, L = Ph_3P; X = I, L = pyrazine) have been prepared by reaction of PtX_2(dmen) (dmen = N,N-dimethylethane-1,2-diamine) with $TlO_2CC_6F_4H$-*p*, C_6F_5H and L in hot 2,6-dimethylpyridine (dmpy), and are considered to have L *trans* to —NMe_2. The pyrazine complex was also obtained in very low yield from an analogous synthesis in 1,4-dioxan. Reaction of $PtBr_2$(dmen) with $TlO_2CC_6F_4H$-*p* and C_6F_5H in 2,6-dimethylpyridine without an added ligand gave a low yield of $Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2](O_2CC_6F_4H\text{-}p)$(dmpy).

The decarboxylation reaction of $PtCl_2$(en) (en = ethane-1,2-diamine) with thallous pentafluorobenzoate in pyridine unexpectedly yields the diorganoamidoplatinum(II) complex, $Pt[N(p\text{-}HC_6F_4)CH_2]_2(py)_2$,[2,3] rather than $Pt(C_6F_5)_2$(en) [cf. the decarboxylation synthesis of $Pt(C_6F_5)_2$(2,2′-bipyridyl)[4]]. Analogous complexes, $Pt[NRCH_2]_2(py)_2$ (e.g. R = C_6F_5, *p*-BrC_6F_4, 2,3,5-$F_3C_6H_2$) have been prepared by reaction of $PtCl_2$(en) with thallous 2,3,5,6-tetrafluorobenzoate and an appropriate fluorocarbon, RF.[3] These syntheses can be extended to give N,N-dimethyl-N′-polyfluorophenylethane-1,2-diaminato(1−)platinum(II) complexes $Pt[NRCH_2CH_2NMe_2]X(py)$ (X = Cl, Br or I; e.g. R = *p*-HC_6F_4, C_6F_5 or *p*-ClC_6F_4) by reacting PtX_2(dmen) (dmen = N,N-dimethylethane-1,2-diamine) with thallous pentafluorobenzoate (for R = *p*-HC_6F_4) or with thallous 2,3,5,6-tetrafluorobenzoate and the appropriate fluorocarbon RF in pyridine.[1,5] Besides providing a new route to organoamidometallics, the reactions yield ethane-1,2-diaminatoplatinum(II) complexes which are moisture stable in contrast with the behaviour of simpler complexes, e.g. $Pt(NHCH_2CH_2NH_2)_2$.[6] Up to this stage, a limitation of the CO_2 elimination syntheses is that the neutral ligand, L, in the organoamidometallic products $Pt[NRCH_2]_2L_2$ and $Pt[NRCH_2CH_2NMe_2]X(L)$ is restricted to solvents suitable as decarboxylation media, viz. pyridine and some substituted pyridines.[1–3,5] In an attempt to overcome this, we have examined decarboxylation reactions in 2,6-dimethylpyridine (which has steric inhibition of coordination) and 1,4-dioxan (oxy donors give less stable Pt complexes) in the presence of added ligands.

RESULTS AND DISCUSSION

Reaction of PtX_2(dmen) with thallous 2,3,5,6-tetrafluorobenzoate and pentafluorobenzene in the presence of triphenylphosphine (X = Cl) or pyrazine (pyz) (X = I) in 2,6-dimethylpyridine (dmpy)

* For part II, see ref. 1.

†Author to whom correspondence should be addressed.

resulted in substantial decarboxylation and the formation of the organoamidoplatinum(II) complexes, **1a** and **1b** in low yield.

$$PtX_2(dmen) + TlO_2CC_6F_4H\text{-}p + C_6F_5H + 2L \text{ (or } L + dmpy) \rightarrow TlX + p\text{-}H_2C_6F_4 + CO_2 + LHF \text{ (or dmpyHF)} + Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2]X(L) \quad (1)$$

1a X = Cl; L = Ph_3P

1b X = I; L = pyz.

Extensive purification of the products was needed (see Experimental) and this was a major cause of the low yields (see also ref. 3). An attempt to carry out reaction (1) (L = pyz, X = I) in 1,4-dioxan resulted in much less decarboxylation than in 2,6-dimethylpyridine and gave a very low yield of **1b**. The complex [Pt(dmen)pyz($O_2CC_6F_4H$-*p*)]I was obtained in substantial yield (although in only very low yield after purification), reflecting the incomplete decarboxylation. Thus, use of sterically hindered or weakly donating ligands enables the synthesis of $Pt[N(R)CH_2CH_2NMe_2]X(L)$ complexes where L ≠ decarboxylation solvent.

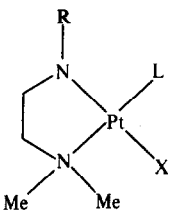
The decarboxylation reaction of $PtBr_2$(dmen) with thallous 2,3,5,6-tetrafluorobenzoate and pentafluorobenzene in 2,6-dimethylpyridine without an added ligand gave less carbon dioxide than reaction (1) and a very low yield of an impure organoamidoplatinum complex, **2**.

$$PtBr_2(dmen) + 2TlO_2CC_6F_4H\text{-}p + C_6F_5H + 2dmpy \rightarrow 2TlBr + CO_2 + p\text{-}H_2C_6F_4 + dmpyHF + Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2] \quad (2)$$

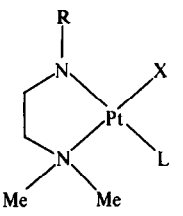
(2) $(O_2CC_6F_4H\text{-}p)(dmpy)$. (2)

The formation of **2** rather than $Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2]Br(dmpy)$ (**1c**) is surprising in view of the use of a 1 : 1 mole ratio of platinum complex : thallium salt and the outcome of (1) and similar reactions (see Introduction) in pyridine and other substituted pyridines.[1,5] Since decarboxylation is incomplete (41%), substantial unreacted thallous 2,3,5,6-tetrafluorobenzoate is available to convert **1c** into **2**.

The constitution of **1a** and **1b** as organoamidoplatinum(II) complexes follows from the observation of parent ions in their mass spectra (Experimental), the absence of ν(NH) IR absorption or N*H* proton resonances and ^{19}F NMR resonances similar to those of other 2,3,5,6-tetrafluorophenylethane-1,2-diaminato(1— or 2—)platinum(II) complexes, e.g. $Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2]X(py)$ [X = Cl (**1d**) or I (**1e**)][1] or $Pt[N(p\text{-}HC_6F_4)CH_2]_2(py)_2$.[3] Both **1a** and **1b** have intense IR absorption characteristic (see examples in refs 1,3,4,7) of ν(CF) of a *p*-HC_6F_4 group. There are two possible isomers (**A** or **B**) for $Pt[N(R)CH_2CH_2NMe_2]X(L)$ complexes.



A



B

Crystal structures of **1d** and $Pt[N(C_6F_5)CH_2CH_2NMe_2]I_{0.63}Cl_{0.37}(py)$[1] and unit cell data for $Pt[N(C_6F_5)CH_2CH_2NMe_2]I(py)$[1] (**1f**) show that these complexes have structure **A**. Other reported $Pt[N(R)CH_2CH_2NMe_2]X(L)$ complexes have spectroscopic data, particularly ^3J(PtH) coupling constants, similar to those of crystallographically characterized compounds and are also considered to have structure **A**.[1] Complex **1b** has $^3J[PtH(NMe_2)]$ and ^3J[PtH(pyz)] coupling constants and a ν(PtI) frequency (Experimental) similar to those of **1e** (30, 38 Hz, and 171 cm^{-1}, respectively) and **1f** (31, 38 Hz, and 164 cm^{-1}, respectively), hence structure **A** (R = *p*-HC_6F_4, X = I, L = pyz) is likely. Recently, a second isomer (hence structure **B**) of $Pt[N(p\text{-}HC_6F_4)CH_2CH_2NMe_2]Cl(py)$ has been isolated and has $^3J[PtH(NMe_2)]$ of 38 Hz and ^3J[PtH(py)] of 26 Hz.[8] For **1a**, the $^3J[PtH(NMe_2)]$ coupling constant (20 Hz) is much smaller than those (av. 31 Hz) of **1b** and **1d–f**,[1] indicating[9,10] that the ligand *trans* to NMe_2 has a stronger *trans* influence than pyridine or pyrazine and hence[9] is triphenylphosphine rather than chlorine. Furthermore, ^4J(HP) coupling is observed for the N*Me*$_2$ and C*H*$_2$NMe$_2$ resonances and not the C*H*$_2$N(*p*-HC_6F_4) resonance. Since coupling of hydrogen to *trans* phosphorus donor atoms is usually larger than to *cis* donor atoms,[11] structure **A** (R = *p*-HC_6F_4, L = Ph_3P, X = Cl) rather than **B** is indicated. In addition, ν(Pt—Cl) of **1a** is in good agreement with that (313 cm^{-1})[1] of **1d**, and ^3J[PtH(C*H*$_2$NR)] is near the average value (32 Hz) observed for reported complexes with structure **A**.

Identification of **2**, which was not obtained pure, is based on observation of a parent ion in the mass spectrum, and detection, assisted by substituent chemical shift data,[1,3,12] of the dmpy, *p*-$HC_6F_4CO_2$, and N(*p*-HC_6F_4)$CH_2CH_2NMe_2$ ligands by ^1H and ^{19}F NMR spectroscopy (Experimental). A pair of IR bands at 950 and 940 cm^{-1} is attributable to ν(CF)

of the two p-HC_6F_4 groups, whilst the separation (311 cm^{-1}) between the $\nu(CO_2)$ frequencies (Experimental) is much greater than that (205 cm^{-1})[13] of sodium 2,3,5,6-tetrafluorobenzoate, indicative[14] of unidentate carboxylate coordination. Of the PtH coupling constants useful in structural diagnosis, only ^3J[PtH(CH_2NMe_2)] of 31 Hz could be resolved. This is slightly larger than the average (27 Hz) for several compounds with structure **A**,[1] but it is still probably more consistent with 2,6-dimethylpyridine rather than carboxyl (weak *trans* influence[9]) *trans* to CH_2NMe_2. For the complex Pt(dmen)(pyz)(p-$HC_6F_4CO_2$)I (obtained from the preparation of **1b** in dioxan), PtH coupling establishes coordination of the neutral ligands and the separation (245 cm^{-1}) between the $\nu(CO_2)$ frequencies suggests unidentate carboxylate coordination. Thus, iodide is probably ionic, although there are examples of ionic polyfluorobenzoates with separations somewhat greater than those of the corresponding sodium salts.[4,15] The ^3J[PtH(NMe_2)] and ^3J[PtH(pyz)] coupling constants (Experimental) are consistent with pyrazine *trans* to NMe_2.

The ease of the decarboxylation reactions (1) and (2) increases with added ligands (L) in the sequence L = none < pyz < Ph_3P. On the basis of the proposed reaction path for other decarboxylation syntheses of organoamidoplatinum(II) complexes,[1-3] reactions (1) and (2) probably involves initial formation of [Pt(dmen)L_2]X($O_2CC_6F_4H$-p) (L = dmpy, pyz or Ph_3P) (**3**), decarboxylation with hydrogen abstraction from the NH_2 group giving [Pt($NHCH_2CH_2NMe_2$)L_2]X (**4**), nucleophilic attack of the amido nitrogen of **4** on C_6F_5H giving [Pt[N(p-HC_6F_4)$CH_2CH_2NMe_2$]L_2]X, and, for reaction (1), displacement of L *trans* to the amido nitrogen by halide ions giving **1a** and **1b**. The extent of formation of **3** in a pre-rate determining equilibrium depends on the nucleophilicity of L (dmpy- < pyz < Ph_3P towards Pt).[16] Isolation of [Pt(dmen)(pyz)($O_2CC_6F_4H$-p)]I from the synthesis of **1b** in dioxan indicates incomplete formation of **3** (L = pyz, X = I), inhibiting the rate of decarboxylation.

EXPERIMENTAL

General

Microanalyses were carried out by the Australian Microanalytical Service, Melbourne. Carbon dioxide was determined gravimetrically as barium carbonate. Decarboxylation was monitored using a small volume barium hydroxide trap additional to the main trap, and reactions were terminated when carbon dioxide evolution slowed significantly. Spectroscopic methods are given in Part I.[3] Listed IR bands of Nujol and hexachlorobutadiene mulls are restricted to those of medium or greater intensity for the region 4000–650 cm^{-1}, except for platinum–halogen stretching frequencies. Proton chemical shifts are in ppm downfield from internal Me_4Si, and ^{19}F chemical shifts in ppm upfield of internal $CFCl_3$. The solvent was $(CD_3)_2CO$ unless indicated otherwise. Listed mass spectra are restricted to ions above m/z 300, the base peak being m/z 58, $C_3H_8N^+$, in all cases. For platinum-containing ions, only the most intense peak [containing ^{195}Pt or ^{231}(PtCl)] is given for each cluster which showed the correct isotope pattern. Visible spectra are for ethanol solutions in the range 350–700 nm.

Solvents and reagents

2,6-Dimethylpyridine (EGA) was refluxed over and distilled from potassium hydroxide pellets, refluxed over aluminium trichloride (14 g/150 cm^3) for 3 h and then distilled, and finally refluxed over $BF_3 \cdot OEt_2$ (4 cm^3/120 cm^3) followed by distillation and storage under nitrogen. Other solvents were purified as described previously.[1,3] Polyfluoroaromatics were from Bristol Organics, pyrazine from EGA, and triphenylphosphine from BDH. Preparations of thallous 2,3,5,6-tetrafluorobenzoate[17] and dihalogeno(N,N-dimethylethane-1,2-diamine)platinum(II) complexes[1] have been given. Nitrogen was purified by passage through a BASF R3/11 catalyst and molecular sieves.

Decarboxylation reactions in 2,6-dimethylpyridine or 1,4-dioxan

2,6-Dimethylpyridine (or dioxan) was added by syringe to the solid reagents in a Schlenk flask which had been purged with nitrogen. Pentafluorobenzene was then added. The reaction mixture was heated under nitrogen which was passed into a barium hydroxide trap. After reaction, the reaction mixture was evaporated to dryness under vacuum (10^{-3} mm), and the residue was washed with petrol (usually b.p. 60–85°C) to remove traces of solvent and extracted with acetone or ether. The solution was filtered to remove thallous halide and evaporated to dryness. Subsequent purification is given below.

Attempted synthesis of bromo(2,6-dimethylpyridine)[N,N - dimethyl - N′ - (2,3,5,6 - tetrafluorophenyl)ethane - 1,2 - diaminato(1−)]platinum(II). Dibromo(N,N-dimethylethane-1,2-diamine)platinum(II) (0.80 mmol), thallous 2,3,5,6-tetrafluorobenzoate (0.80 mmol) and pentafluorobenzene (45 mmol) in 2,6-dime-

thylpyridine (10 cm^3) were heated at 100–115°C for 1 h giving carbon dioxide (41%). The solid from acetone extraction was washed with petrol (b.p. 60–85°C) and extracted with ether. Addition of petrol and evaporation gave a few yellow crystals of 2,6-dimethylpyridine[N,N - dimethyl - N′ - (2,3,5,6 - tetrafluorophenyl)ethane - 1,2 - diaminato(1−)] (2,3,5,6 - tetrafluorobenzoato)platinum(II) (**2**) (3%). ^{19}F NMR: −139.7, m, 2F, F3,5 ($HC_6F_4CO_2$); −144.1, m, 2F, F2,6 ($HC_6F_4CO_2$): −144.7, m, 2F, F3,5 (HC_6F_4N); −150.6, m, 2F, F2,6 (HC_6F_4N). ^1H NMR: 2.62, t, ^3J(HH) 5 Hz, with satellites ^3J(PtH) 31 Hz, 2H, CH_2NMe_2; 3.00, s, 8H, Me_2N and $CH_2N(C_6F_4H)$; 3.29, s, 6H, Me (dmpy); 6.39, tt, ^3J(HF) 11 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4N; 7.10, d, ^3J(HH) 8 Hz, 2H, H3,5 (dmpy); 7.37, tt, ^3J(HF) 10 Hz, ^4J(HF) 7 Hz, 1H, $HC_6F_4CO_2$; 7.56, t, ^3J(HH) 8Hz, 1H, H4 (dmpy). Some weak impurity resonances were also present. IR: 1655s and 1640s [$\nu_{as}(CO_2)$], 1610s, 1584m, 1494vs, 1460s, 1336vs [$\nu_s(CO_2)$], 1178s, 1168s, 1133s, 1075m, 1063m, 950s, 940s, 896m, 850m, 800m, 773s and 718s cm^{-1}. Mass spectrum: *m/z* 730 [5%, M^+]; 623 [1, $(M—dmpy)^+$]; 536 [1, $(M—HC_6F_4CO_2H)^+$]; 534 [1, $Pt(C_{10}H_8F_4N_2)dmpy^+$]; 495 [2, $Pt(HC_6F_4CO_2)dmpy^+$]; 478 [2, $Pt(C_7H_2F_4N)dmpy^+$]; 427 [3, $Pt(C_{10}H_8F_4N_2)^+$]; 359 [1, $Pt(HC_6F_4NH_x)^+$]; 344 [1, $Pt(HC_6F_4)^+$], 301 [3, $Pt(C_7H_8N)^+$]. The ether insoluble residue contained a substantial amount of the products, and the ^{19}F NMR spectrum showed five different *p*-HC_6F_4 groups to be present.

b - *Chloro* - c(N),d(N′) - [N,N - *dimethyl* - N′ - (2,3,5,6 - *tetrafluorophenyl)ethane* - 1,2 - *diaminato* (1−)]-a-*triphenylphosphineplatinum*(II) (**1a**).

Dichloro(N,N - dimethylethane - 1,2 - diamine)platinum(II) (1.0 mmol), thallous 2,3,5,6-tetrafluorobenzoate (1.0 mmol), pentafluorobenzene (18.0 mmol) and triphenylphosphine (2.0 mmol) in 2,6-dimethylpyridine (10 cm^3) were heated at 115°C for 20 min giving carbon dioxide (95%). The solid from ether extraction was recrystallized from ether–petrol (b.p. < 40°C) and twice from toluene–petrol at −28°C giving yellow crystals (15%), m.p. 207–208°C (Found: C, 46.5; H, 3.6; F, 10.5; N, 3.8. $C_{28}H_{26}ClF_4N_2PPt$ requires C, 46.2; H, 3.6; F, 10.4; N, 3.9%.) ^{19}F NMR: −144.6, m, 2F, F3,5; −150.5, m, 2F, F2,6. ^1H NMR: 2.39, m, ^3J(HH) 5 Hz, ^4J(HP) 2 Hz, 2H, CH_2NMe_2; 3.01, d, ^4J(HP) 3 Hz, with satellites ^3J(PtH) 20 Hz, 6H, NMe_2; 3.34, t, ^3J(HH) 5 Hz, with satellites ^3J(PtH) 35 Hz, 2H, $CH_2N(C_6F_4H)$; 6.11, tt, ^3J(HF) 11 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4; 7.29–7.43, m, 9H, H3,4,5 (Ph_3P); 7.62–7.69, m, 6H, H2,6 (Ph_3P). Visible spectrum: 424 nm (ε = 570). IR: 3050m, 2945m, 2928m, 1627m, 1585m, 1489vs, 1468m, 1451s, 1435s, 1421m, 1264m, 1169m, 1160m, 1101s, 1094vs, 1021m, 998s, 939m, 926s, 886m, 817m, 780m, 744s, 706s, 697vs, 691vs, 312s [ν(PtCl)] cm^{-1}. Mass spectrum: *m/z* 728 [4%, M^+]; 514 [1, $Pt(C_{21}H_{22}NP)^+$]; 456 [1, $Pt(C_{18}H_{14}P)^+$]; 378 [1, $Pt(C_{12}H_8P)^+$].

c(N),d(N′)-[N,N-*Dimethyl*-N′-(2,3,5,6-*tetrafluorophenyl)ethane* - 1,2 - *diaminato*(1−)] - b - *iodo* - a - *pyrazineplatinum*(II) (**1b**).

(i) *In* 2,6-*dimethylpyridine*: diiodo(N,N-dimethylethane-1,2-diamine)platinum(II) (1.0 mmol), thallous 2,3,5,6-tetrafluorobenzoate (1.0 mmol), pyrazine (5.0 mmol) and pentafluorobenzene (18.0 mmol) in 2,6-dimethylpyridine (10 cm^3) were heated at 105–110°C for 1 h giving carbon dioxide (72%). The solid from acetone extraction was washed with ethanol (5 cm^3) to remove dark impurities. Ether extraction, filtration, evaporation to dryness, and recrystallization from ether/petrol (b.p. 60–85°C) gave an orange solid, which was dissolved in pyridine (2 cm^3) and precipitated by the addition of water.* After vigorous shaking, the precipitate was collected and recrystallized from ether–petrol (b.p. < 40°C) at 0°C, yield 10%, m.p. 176°C (Found: C, 26.1; H, 2.3; F, 12.0; N, 9.2. $C_{14}H_{15}F_4IN_4Pt$ requires C, 26.4; H, 2.4; F, 11.9; N, 8.8%.) ^{19}F NMR ($CDCl_3$): −142.9, m, 2F, F3,5; −150.6, m, 2F, F2,6. ^1H NMR ($CDCl_3$): 2.51, t, ^3J(HH) 5 Hz, 2H, CH_2NMe_2; 3.20, s with satellites ^3J(PtH) 32 Hz, 6H, NMe_2; 3.26, m, 2H, $CH_2N(C_6F_4H)$; 6.25, tt, ^3J(HF) 10 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4; 8.27, dd, ^3J(HH) 3 Hz, 2H, H3,5 (pyz); 8.58, d, ^3J(HH) 3 Hz with satellites ^3J(PtH) 41 Hz, 2H, H2,6 (pyz). Visible spectrum: 416 nm ($\varepsilon = 1.8 \times 10^3$). IR: 1634m, 1576m, 1493vs, 1461vs, 1450vs, 1419s, 1278m, 1152m, 1128m, 1053m, 935vs, 888m, 810m, 171w [ν(PtI)] cm^{-1}. Mass spectrum: *m/z* 637 [0.7%, M^+]; 557 [0.3, $(M—pyz)^+$]; 430 [0.3, $(M—pyz—I)^+$]; 427 [0.2, $Pt(C_{10}H_8F_4N_2)^+$].

(ii) *In* 1,4-*dioxan*: similar amounts of the first three reagents from (i) and pentafluorobenzene (45 mmol) in dioxan (10 cm^3) were heated at 100°C for 1.5 h giving carbon dioxide (37%). The product from acetone extraction was similarly extracted with ether and the resulting solid recrystallized from a minimum of ether at 0°C giving **1b** (3%), m.p. 170°C (dec.) (Found: C, 26.7; H, 2.4; F, 12.1; N, 8.8%) with spectroscopic properties in agreement with those from synthesis (i). The dark ether-insoluble residue was washed with tetrahydrofuran (20

* Dissolution in pyridine converts any $(pyz)_2PtI_2$ or $(dmpy)_2PtI_2$ into water-soluble $[py_4Pt]I_2$.

cm^3) and recrystallized from acetone–petrol (65–80°C) with activated charcoal to give white (N,N-dimethylethanc-1,2-diamine)pyrazine(2,3,5,6-tetrafluorobenzoato)platinum(II) iodide (4% cf. *ca* 50% prior to recrystallization), m.p. > 230°C (dec.) (Found: C, 26.8; H, 2.2; N, 7.6. $C_{15}H_{17}F_4IN_4O_2Pt$ requires C, 26.4; H, 2.5; N, 8.2%.) ^{19}F NMR: −140.6, m, 2F, F3,5; −144.6, m, 2F, F2,6. ^1H NMR: 3.00, br s (PtH satellites incompletely resolved), 4H, CH_2; 3.19, s, with satellites ^3J(PtH) 32 Hz, 6H, NMe_2; 7.22, tt, ^3J(HF) 10 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4; 7.34, br s, 2H, NH_2; 8.69, m, 2H, H3,5 (pyz); 9.16, m with satellites ^3J(PtH) 37 Hz, 2H, H2,6 (pyz). IR: 3068m, 1608 and 1602vs [$\nu_{as}(CO_2)$], 1490vs, 1419m, 1360s [$\nu_s(CO_2)$], 1335m, 1237m, 1171m, 1017m, 942s, 841m, 819m, 783m, 756s, 713m cm^{-1}. No platinum containing ions were observed in the mass spectrum. The presence of iodine was established by qualitative tests.

FORMATION OF GOETHITE FROM FERRIHYDRITE AT PHYSIOLOGICAL pH UNDER THE INFLUENCE OF CYSTEINE

R. M. CORNELL* and W. SCHNEIDER

Laboratorium für anorganische Chemie, ETH-Zentrum, CH-8092 Zürich, Switzerland

(*Received* 11 *March* 1988; *accepted* 13 *July* 1988)

Abstract—The presence of L-cysteine at L-cysteine: Fe ratios $\geqslant 0.2$ causes ferrihydrite ($5Fe_2O_3 \cdot 9H_2O$) to transform rapidly to goethite [α-FeO(OH)] in the pH range 7.5–9 and at temperatures between 25–70°C. L-Cysteine is the first example of an organic ligand that directly promotes the formation of goethite; all organic ligands studied previously, suppressed the transformation of ferrihydrite to goethite.

L-Cysteine is a reducing ligand which exhibits associative interactions with interfacial iron sites of ferrihydrite. It appears to act by converting these sites to more labile sites thus facilitating the transformation to goethite, possibly in conjuction with enhanced dissolution of ferrihydrite.

The presence of phosphate or silicate species stabilized ferrihydrite and reduced the goethite promoting effect of cysteine.

The implications of these results for biomineralization of iron oxides is considered. It is suggested that the crystals of goethite found in the teeth of limpets (*Patella vulgata*) may have formed via activated reorganization of ferrihydrite, rather than by oxidatively induced hydrolysis of a ferrous precursor.

Ferrihydrite is a poorly ordered ferric oxyhydroxide which with time transforms into the thermodynamically more stable crystalline compounds, goethite [α-FeO(OH)] and haematite (α-Fe_2O_3). These oxides form by separate pathways.[1,2] Formation of goethite involves dissolution of ferrihydrite followed by reprecipitation of goethite in solution, whereas haematite arises via a solid state transformation within the particles of ferrihydrite. As these mechanisms are competitive, reaction conditions that promote haematite are unfavourable for goethite formation and *vice versa*. At pH 7–8 the solubility of ferrihydrite is at a minimum and supersaturation with respect to goethite is very low. In this pH range precipitation of goethite is slow enough for haematite to be the predominant transformation product.

Foreign ions can determine which reaction pathway predominates and investigations of the various effects of different ions have provided interesting details of the transformation mechanisms. The influence of organic ligands such as carboxylic and hydroxy carboxylic acids[3,4] and also simple sugars[5] has been studied intensively. One reason for this interest is that these ligands possess the same functional groups as those found in the organic matrix in which bioinorganic goethite is precipitated and thus might shed some light on the mechanisms by which biomineralization is achieved. All organic ligands studied to date suppressed formation of goethite from ferrihydrite and in some cases, actively promoted haematite formation.[6] These results appeared to suggest that biomineralization of goethite could not involve a ferrihydrite precursor.

Recently, we extended our investigations to another organic ligand, L-cysteine. This ligand is of interest because it is a powerful reducing agent and so might be expected to promote dissolution of ferrihydrite at physiological pH.

We report here the complete and rapid transformation of ferrihydrite to goethite at pH 7.5–8.5 in the presence of L-cysteine. This is the first example of an organic ligand that promotes the formation of goethite from ferrihydrite. Two specific aims of this investigation were (1) to determine the

*Author to whom correspondence should be addressed.

effect of various levels of cysteine on the kinetics and the products of the reaction and (2) to consider whether cysteine could overcome the stabilizing effect on ferrihydrite of ions such as silicate and phosphate. A further aim was to consider the significance of these results for the biomineralization of goethite.

EXPERIMENTAL

Ferrihydrite was precipitated from ferric nitrate solution with 1 M KOH and the pH adjusted to between 7.5–8.5 with bicarbonate buffer solution. Enough L-cysteine to give a final concentration of between 10^{-3}–10^{-1} M (L : Fe = 0.1–10) was then added to the freshly precipitated ferrihydrite; most experiments were carried out using 2×10^{-3} M cysteine. As cysteine is readily oxidized, a fresh stock solution was prepared just before each experiment. The suspensions (1 g ferrihydrite/dm^3) were held in closed polypropylene bottles and aged in the dark (to avoid photochemical decomposition of cysteine) for up to 48 h. Several suspensions were aged at 25 or 40°C, but the majority were held at 70°C to facilitate comparison with earlier studies. No attempt to exclude air was made as the main aim of this work was to investigate the effect of cysteine on the transformation under standard conditions. Additional experiments were performed in which L-cysteine was replaced by D-penicillamine, cysteamine or glycine. In a further series of experiments, phosphate or silicate, as well as cysteine were added to the system. All chemicals were analytical grade (Fluka).

The kinetics of the reaction were followed by taking subsamples during the reaction and dissolving unconverted ferrihydrite using a 30 min extraction with 0.4 M HCl. The acid–oxalate extraction method of Schwertmann[7] could not be used in the present work because the combination of cysteine and oxalate led to complete reductive dissolution of all the solid phases (including goethite) in the system. Preliminary experiments showed that the acid treatment adopted provided a satisfactory separation of the crystalline and amorphous iron hydroxides. The extent of the transformation was expressed as the ratio, Fe_A/Fe_T, where Fe_A is the acid soluble material (i.e. unconverted ferrihydrite) and Fe_T is the total iron in the system. Analysis for Fe was carried out using atomic absorption spectroscopy (AAS).

The crystalline product of the transformation was washed and dried at 50°C. X-ray powder diffraction (XRD) patterns were obtained using a Guinier–Enraf camera (Mk IV) with Fe-K_{α_1} radiation. Where the reaction product consisted of a mixture of goethite and haematite, the proportion of each was estimated by comparison with a series of standards made by mixing known amounts of synthetic goethite and haematite. The 110 and 111 XRD lines of goethite and the 102 peak of haematite were used for comparison.

Transmission electron micrographs were obtained using a Hitachi H-600 electron microscope operating at 100 kV. For TEM examination the samples were dispersed in twice distilled water with ultrasonic treatment and a drop of suspension evaporated to dryness on a carbon coated bronze grid. Elemental analysis for C, N, H and S was carried out by the microanalytical department.

The interaction between cysteine and iron oxides was followed using pulse polarography (Polaroid E 506 metrohm polarograph). Suspensions of cysteine and either ferrihydrite or goethite (0.1 g/100 cm^3, pH 8) were equilibrated for 1 min, 2 or 24 h at 25°C, centrifuged and the level of cysteine in the supernatant liquid found by polarography. Standard solutions of cysteine (pH 8) were also prepared for calibration purposes: the cysteine peak was observed at −0.51 V. Goethite (BET surface area 70 m^2 g^{-1}) was prepared by ageing ferrihydrite at pH 12.5 and 70°C for 48 h.

RESULTS AND DISCUSSION

Reaction products

These depended on the ratio of cysteine to iron in the system (Table 1). In the absence of cysteine (control system), ferrihydrite transformed entirely to haematite in the pH range 7–9. Addition of 10^{-3} M cysteine (L : Fe = 0.1) led to a product which XRD showed to consist only of haematite. TEM, however, indicated the presence of some tiny crystals of goethite (1–2%). Seeding the system with 6% goethite raised the amount of goethite in the product to around 30%, whereas seeding the control system did not promote goethite formation.

Doubling the concentration of cysteine in the

Table 1. Effect of cysteine concentration on the transformation products of ferrihydrite, pH 8, 70°C, 24 h

L : Fe	Product
0	Haematite
0.1	Haematite + trace goethite
0.2	Goethite
0.4	Goethite
1.0	Goethite
10.0	Cystine + 10 Å phase

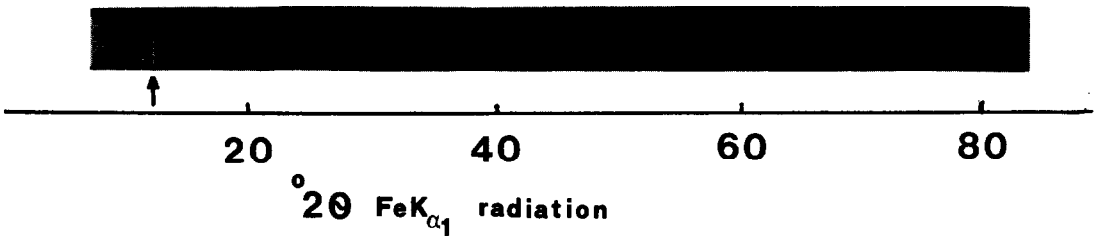

Fig. 1. X-ray powder diffraction pattern of the 10 Å intermediate formed at cysteine: Fe = 10.0. The arrow indicates the 10 Å XRD line.

system (L : Fe = 0.2) caused ferrihydrite to transform entirely to goethite in a few hours at both 70 and 40°C. At room temperature the transformation took 48 h. With higher levels of cysteine (up to 10^{-2} M), goethite was again the only solid end product. The organic end product (cystine) remained in the supernatant liquid.

A large excess of cysteine (L : Fe = 10) led to the formation, within 24 h, of a mixture of cysteine and a dark iron compound. The latter compound was washed, dried and X-rayed. It gave a well-defined, reproducible XRD pattern with a characteristic line at 10 Å (Fig. 1). This XRD pattern did not correspond to that of any previously recorded iron oxide or hydroxide. However, elemental analysis of the compound showed that it was not an iron–cysteine compound such as Fe^{II}cysteine$(H_2O)_{1.5}$ or $Na_2Fe^{II}(cysteine)_2H_2O$ reported by other workers.[8] Less than 2% C, N or S was present: probably some organic material was adsorbed on the surface of the precipitate. This compound (henceforth referred to as the 10 Å phase) may be a mixed valence Fe hydroxide. Its identification is not a major issue as the emphasis in the present investigation is on the formation of goethite at much lower cysteine: Fe ratios (0.2) at which this compound does not form.

Progress of the transformation

Upon addition of 2×10^{-3} M cysteine the ferrihydrite darkened, probably as a result of formation of a mixed valence Fe^{II}–Fe^{III} surface. XRD analysis of subsamples taken at intervals during the transformation showed that for a system with L : Fe = 0.2, the only crystalline phase present was goethite. TEM examination of subsamples showed a mixture of goethite crystals and an amorphous phase. Goethite formed as acicular crystals around 3000 Å in length. These crystals had poorly developed terminal faces, probably as a result of interference in growth by adsorbed ligand.

The stage during the transformation at which cysteine was added determined the proportion of goethite in the reaction product (Table 2). Addition of 2×10^{-3} M cysteine at increasingly later stages after precipitation led to an increase in haematite formation at the expense of goethite. Addition of cysteine to ferrihydrite that had been aged (pH 8) at 70°C for 4 h produced no goethite. The ferrihydrite was still X-ray amorphous and completely oxalate soluble. Nevertheless, the structural rearrangement foreshadowing haematite nucleation must have been underway already, producing a more structured, more stable material. Addition of a high enough level of cysteine to this structured material led to formation of some goethite (Table 2).

Table 2. Effect on the reaction product of stage of addition of cysteine to ferrihydrite, pH 8, 70°C

[Cysteine] (M)	Time of ageing before cysteine addition (h)	Product
2×10^{-3}	0	Goethite
	1	Goethite
	2	Haematite + 10% goethite
	4	Haematite
4×10^{-3}	2	Goethite + 10% haematite
	4	Goethite + 50% haematite

Kinetics

The transformation of ferrihydrite into crystalline goethite was complete at 70°C and with $0.2 \leqslant L : Fe \leqslant 1.0$ within 10 h. Typical plots of the extent of transformation vs time are shown in Fig. 2. These kinetic curves consisted of an initial induction period followed by a faster transformation stage and are similar to those observed for transformations carried out at pH 12 in the absence of cysteine.[9]

With 10^{-3} M cysteine in the system the transformation was retarded to some extent. The lowest

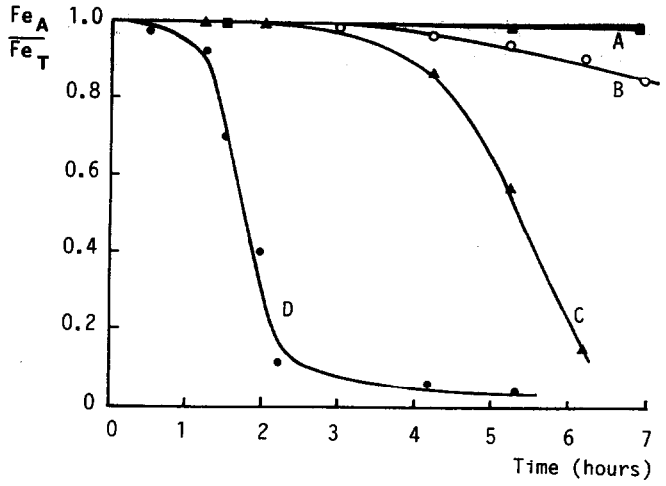

Fig. 2. Fe_A/Fe_T as a measure of the degree of transformation of ferrihydrite into goethite vs time: (A) control, (B) with 10^{-3} M cysteine, (C) with 10^{-2} M cysteine and (D) with 2×10^{-3} M cysteine; pH 8, 70°C. Fe_A = acid extractable iron, Fe_T = total iron in the system.

level of cysteine needed to effect complete transformation into goethite (2×10^{-3} M) markedly accelerated the overall transformation by reducing the induction period from 4–5 h to 30 min. The induction period is the time needed to increase the supersaturation with respect to goethite above the critical level needed for formation of nuclei.[9] Once this had been achieved, the transformation proceeded at a rate of 10^{-2} min^{-1}. This is an order of magnitude higher than the rate constant for the transformation (in the absence of cysteine) at pH 12, indicating that cysteine has accelerated the overall reaction. As the level of cysteine increased from 2×10^{-3} to 10^{-2} M, the induction period gradually increased and the rate of the subsequent transformation decreased (Fig. 2).

At 40°C (physiological temperature) and with 2×10^{-3} M cysteine, the transformation was complete within 7 h. Experiments at 25, 40 and 70°C showed that the transformation had an activation energy of 30.1 KJ mol^{-1}.

Interaction of cysteine with iron oxides

After contact with ferrihydrite at pH 8 and 25°C for 1 min, a solution of cysteine showed polarographic peaks at −0.51, −0.63 and −0.94 V. The two latter peaks are due to the presence of cystine[10] and were missing from solutions of cysteine to which ferrihydrite had not been added. The ability of soluble ferric species to catalyse oxidation of cysteine is well documented[11] and the present results show that solid ferric hydroxides have the same ability.

Oxidation of cysteine was initially very rapid, but decreased as the level of cysteine in the system fell. With 2×10^{-3} M cysteine present, initially around 90% thiol was oxidized almost at once, but after a further 2 h, some cysteine was still present in solution.

Ottow[12] showed that low redox potentials (−350 mV) alone had only a very slight reductive effect on stable Fe–oxides: to achieve a significant reduction, *adsorption* of the reducing ligand was necessary. Clearly the first step in the interaction must involve adsorption of cysteine on ferrihydrite. Adsorption is followed by reduction of surface ferric sites and desorption into solution of a cysteine free radical. The free radicals combine in solution to produce the disulphide (cystine). A similar mechanism is considered to operate during mobilization of iron from ferritin by thiols.[13] In the present work, cysteine was always oxidized to a large extent at once, regardless of the level originally added (always $\geqslant 10^{-3}$ M). However, with low cysteine: Fe ratios (0.1) ferrihydrite appeared to be more or less unaffected: only as the L: Fe ratio increased was ferrihydrite as well as cysteine altered.

Oxidation of cysteine was slower for goethite than for ferrihydrite. With 2×10^{-3} M cysteine equilibrated with goethite, there was a 50% drop in the level in solution after 2 h. The lower reactivity of goethite is the result of its more structured surface, not the lower surface area. With sufficient goethite to provide a surface area equivalent to that of ferrihydrite, the extent of oxidation at any stage was still far less than with ferrihydrite. This is expected on thermodynamic grounds.

Comparison with probe ligands

Cysteine has three functional groups, namely $RCOO^-$ ($pK_1 = 1.9$), RS^- ($pK_2 = 8.3$) and RNH_2 ($pK_3 = 10.8$). A comparison of the effect of cysteine on the formation of goethite with that of probe ligands with different combinations of functional groups (Table 3) indicated that cysteine owes its goethite promoting ability to adsorption on ferrihydrite through the sulphedral group.

Penicillamine which differs from cysteine mainly in that two hydrogen atoms adjacent to the sulphedral group are replaced by two methyl groups, has a much lower goethite inducing effect. Apparently, steric hindrance by the methyl groups reduces the extent to which coordination to the surface iron through the sulphedral groups takes place.

Only haematite formed in the presence of 10^{-2} M glycine, whereas with the same level of cysteamine ($NH_2CH_2CH_2SH$), the reaction product was 100% goethite (Table 3). Besides confirming the crucial role of the sulphedral group, these observations indicate that the role of the carboxylate groups is simply to assist surface coordination.

Interaction of cysteine with stabilized ferrihydrite

A phosphate or silicate stabilized ferrihydrite (L : Fe = 0.1) remained unchanged for weeks in the presence of between 2×10^{-3} and 10^{-2} M cysteine, regardless of whether cysteine was added before or after the addition of stabilizing ligand to ferrihydrite. With L : Fe = 0.1, all phosphate or silicate in the system is adsorbed to give a monolayer of adsorbed species on the ferrihydrite surface.[14] Cysteine does not displace these inorganic ligands even when present in a 10-fold excess. On the other hand, phosphate or silicate could displace adsorbed cysteine.

These observations provide support for the assumption that adsorption of cysteine on ferrihydrite preceeds any oxidation–reduction reactions.

Interactions of cysteine with ferrihydrite leading to goethite

Unlike all other ligands investigated previously, cysteine directly promotes the transformation of ferrihydrite to goethite. Cysteine induced the formation of goethite at pH 7.5–8.5 by converting the interfacial iron sites of ferrihydrite (by the binding of sulphedral groups and concurrent electron transfer) to more labile sites (local complexes) than those in the normal ferrihydrite structure.

In the system in which goethite forms most rapidly (L : Fe = 0.2), the ratio of cysteine to iron is not high enough to ensure complete reductive dissolution of ferrihydrite. Only a fraction of the ferric ions are reduced : this is sufficient, however, to convert parts of ferrihydrite into dark, mixed valence Fe^{II}–Fe^{III} hydroxide domains which are probably related to the green rusts. No crystalline material apart from goethite was detected by TEM or XRD indicating that the mixed valence precursor is very poorly ordered as expected according to the concept of activated sites mentioned above. This activation leads to far more rapid formation of goethite in solution. The system is saturated with oxygen and hence ferrous ions produced by interaction of ferrihydrite with cysteine would be reoxidized readily.

Table 3. Effect of different ligands on the transformation products of ferrihydrite, pH 8, 70°C, 24 h

	Ligand	[L] (M)	Product
Cysteine	$HSCH_2CHNH_2COOH$	10^{-2}	Goethite
		2×10^{-3}	Goethite
Penicillamine	$HS{-}\underset{\displaystyle CH_3}{\overset{\displaystyle CH_2}{\overset{|}{\underset{|}{C}}}}{-}NH_2COOH$	10^{-2}	Goethite + 10% haematite
Cysteamine	$NH_2CH_2CH_2SH$	2×10^{-3}	Goethite
		10^{-2}	Goethite
Glycine	NH_2CH_2COOH	10^{-2}	Haematite

The transformation can be summarized as:

$$\text{ferrihydrite} + RSH \rightarrow Fe^{II}_x Fe^{III}_y \text{hydroxide} + \tfrac{1}{2}RSSH + \tfrac{1}{2}H^+ \rightarrow \text{goethite}.$$

Although with L : Fe = 0.1 some cysteine is oxidized, insufficient Fe^{II} is produced to solubilize ferrihydrite to any extent and haematite formation is far more competitive than that of goethite. As seeding with goethite promotes goethite formation, however, the presence of cysteine must have led to a slight increase of solubility over that of pure ferrihydrite (where seeding with goethite has no effect).

Fischer[15] showed that at pH 6–7, Fe^{II} can promote formation of goethite by reductively dissolving ferrihydrite. At least 10 ppm Fe^{II} was required. We have found that low levels (2×10^{-3}–4×10^{-3} M) of Fe^{II} lead to goethite formation, but far more slowly than do equivalent concentrations of cysteine. We conclude that in our systems the ferrous ions produced do not reductively dissolve ferrihydrite: instead interaction with cysteine, which includes partial reduction, leads to formation of a new type of more labile iron site or mixed valence compound.

The most important feature of this investigation is the ability of cysteine to promote the transformation of ferrihydrite to goethite. Details of all the reactions involving cysteine and iron, particularly those in solution, have not been established. The results of other authors permit some suggestions as to possible reactions to be made. With L : Fe $\geqslant$ 1.0, qualitative analysis indicated that ferrous species were immediately released into solution. The supernatant liquid, however, had a red–violet tinge which is consistent with oxidation of a bis ferrous cysteine complex by molecular oxygen. This tinge fades with time, owing to autoreductive decomposition of the ferric cysteine complex to cystine and ferrous cysteinate.[16] The violet–red colour could be regenerated by shaking the solution with air and the cycle continued until all the thiol was reduced to the disulphide. This cycle was confined to the early stage (first hour) of the transformation reaction.

Despite the production of ferrous ions, no magnetite (Fe_3O_4) formed in these systems. With 4×10^{-3} M ferrous ions in the system and in the *absence* of cysteine, magnetite formed together with goethite. Earlier studies have shown that addition of other divalent ions such as Mn[17] and Cu[18] to ferrihydrite at M^{II} : Fe^{III} ratios greater than 0.2, led to the formation of a spinel phase: the essential step is interaction of the divalent ion with the ferrihydrite surface. With high levels of cysteine in the system this pathway is bypassed because ferrihydrite is rapidly converted into another compound. Magnetite cannot form in systems with lower levels of cysteine because the ratio of Fe^{II} produced to Fe^{III} in the system does not attain the threshold ratio of 0.2.

Implications for the biomineralization of goethite

Well-formed acicular crystals of goethite develop in the mature teeth of the limpet (*P. vulgata*) in a few days.[19] The mechanism by which goethite forms in these teeth at neutral pH has not been established. It seems probable that the organic matrix of chitin and protein in which the goethite grows and also the presence of inorganic ions such as phosphate and silicate should direct the transformation.

Mann *et al.*[19] considered that as formation of goethite from ferrihydrite requires temperatures of 60–70°C and pH $\geqslant$ 11 to proceed at a significant rate, formation of goethite in limpets' teeth probably involved oxidation of ferrous solutions, rather than transformation of ferrihydrite. Earlier results[4,5] which showed that organic ligands suppress formation of goethite from ferrihydrite appeared to support this hypothesis.

We now suggest an alternative mechanism for biomineralization of goethite. Our present results show that low levels of a reducing organic ligand can induce rapid formation of goethite at neutral pH and 40°C. This mechanism may also operate in limpet teeth. Mann *et al.* showed that besides goethite, the teeth contain large deposits of amorphous ferric hydroxide.[19] There is more amorphous material in immature than in mature teeth suggesting that a transformation may have occurred. In these teeth goethite crystals were mainly located in the cusp, whereas amorphous material associated with high levels of Si and P was concentrated at the base of the tooth. The distribution of these phases is in line with our results which showed that high levels of Si or P stabilized ferrihydrite against interaction with cysteine. Before examination of the mineralized component of these teeth, Mann *et al.*[19] removed the organic material, hence the presence of sulphur groups has not been reported. Identification of the proteins present in the organic material would be of interest and could help to confirm whether a reductive transformation of ferrihydrite could occur in the teeth.

A further point of interest is why goethite forms in the teeth of limpets and magnetite develops in chiton (*Polyplacophora*) teeth.[20] In both types of teeth amorphous ferric hydroxide has been detected. Our studies using synthetic systems show that reduction of ferrihydrite by an organic ligand

produced goethite, whereas interaction with a divalent cation leads to magnetite or a spinel. If the amorphous material in these teeth is the precursor of the crystalline phase, these observations suggest that the composition of the crystalline phase depends simply on the nature of the foreign species in the local environment.

(*Received* 11 *February* 1988; *accepted* 13 *July* 1988)

Abstract—The title compounds were studied by measuring their magnetic susceptibilities up to 4.2 K and by use of their IR, ligand field and ESR spectra. Distorted octahedral structures are ascertained for both compounds, the $C(CN)_3$ or $N(CN)_2$ groups having a bidentate bridging function. Spin exchange coupling takes place in both compounds, being both antiferromagnetic and ferromagnetic in nature, the latter appears to prevail at low temperatures.

The preparation of the compounds CuX_2L_2, where $X = N(CN)_2$, $C(CN)_3$ and L = pyrazole or its derivative, has recently been published.[1,2] The low temperature magnetic measurements combined with IR, ligand field and ESR spectra showed that in $Cu\{N(CN)_2\}_2(pz)_2$ infinite arrays of Cu^{II} atoms joined by bridging dicyanamide ligands propagate a weak but noticeable magnetic exchange interaction.[1] In other CuX_2L_2 complexes according to their spectral properties bridging X ligands are also present.[2] To investigate the influence of these bridges on the magnitude and kind of exchange interaction occurring, we measured the temperature dependence of the magnetic susceptibilities of $Cu\{C(CN)_3\}_2(tmpz)_2$ and $Cu\{N(CN)_2\}_2(tmpz)_2$ (tmpz = 3,4,5-trimethylpyrazole) which had been ascertained to possess sub-normal room-temperature magnetic moments.[2] Moreover, spectroscopic methods were also employed with a view to complete the picture.

EXPERIMENTAL

The compounds under investigation were prepared as described elsewhere.[2] IR spectra (4000–400 cm^{-1}) were recorded on a Perkin–Elmer 180 spectrophotometer using KBr pellets. FIR (400–50 cm^{-1}),[3] electronic[4] and ESR spectra,[5] as well as magnetic susceptibilities in the range 4.2–290 K,[5] were measured as given in the cited papers.

RESULTS AND DISCUSSION

IR spectra

The pseudohalide vibrations in the IR spectra were assigned by comparison with the spectra of trimethylpyrazole[6] and $C(CN)_3^-$ or $N(CN)_2^-$;[7] the data are listed in Table 1.

For $Cu\{C(CN)_3\}_2(tmpz)_2$ the $\nu(C{\equiv}N)$ values in the regions of about 2245 and 2195 cm^{-1} indicate,[7,8] unambiguously, a bidentate function of the tricyanmethanide ligands, Cu—NC·C·(CN)·CN—Cu. In the case of $Cu\{N(CN)_2\}_2(tmpz)_2$ the issue is less clear on account of the $\nu(C{\equiv}N)$ number and spread. After comparing the $\nu(C{\equiv}N)$ values with those for many other $M\{N(CN)_2\}_2L_2$ complexes (M = Cu, Ni, Co; L = a pyrazole or pyridine type ligand) with pseudooctahedral configurations,[1,2,4] where the $\nu(C{\equiv}N)$ values range between *ca* 2265–2240 and 2190–2140 cm^{-1},

[d] Broad band with a complex splitting.

the bidentate bridge dicyanamide ligands may be taken as being quite acceptable.

In the far-IR region, strong bands between *ca* 305–245 cm^{-1} are tentatively assigned to the Cu—N stretching vibrations. These frequencies corroborate the symmetric bridging of the pseudo-halide groups through their cyanide nitrogens.[4,9] The absorptions that occur for both complexes at *ca* 95 cm^{-1} belong most likely to the stretches of the long Cu—N bonds in axial direction,[3] although they may also be due to a vibration of the free tmpz.[6]

Ligand field and ESR spectra

The position of the ligand field band maxima and the low wavenumber shoulders (Table 2) are in agreement with a distorted octahedral arrangement of donors around the Cu^{II} atoms,[10] having in the case of $Cu\{N(CN)_2\}_2(tmpz)_2$ a weaker tetragonal distortion.[11]

The compound, $Cu\{C(CN)_3\}_2(tmpz)_2$, at room temperature and $Cu\{N(CN)_2\}_2\cdot(tmpz)_2$ at 77 K (Fig. 1) show tetragonal ESR spectra with g values (Table 2) indicating a $d_{x^2-y^2}$ ground state.[10] The room temperature ESR spectrum of $Cu\{N(CN)_2\}_2(tmpz)_2$ consists of an asymmetric single line. According to the G parameters slightly below four, the g values are practically unaffected by the exchange coupling present[10] (see below).

Magnetism

Selected variable-temperature magnetic data for both compounds are listed in Table 3. The temperature dependences of the reciprocal magnetic susceptibilities obey the Curie–Weiss law (Fig. 2); however, the Weiss constants calculated for the low and high temperature regions are different from each other, and also from the overall Weiss constants (Table 4).

exhibits a sub-spin value which remains constant, 1.56 ± 0.02 BM, within the range 16–290 K; at lower temperatures the μ_{eff} values moderately increase. For $Cu\{N(CN)_2\}_2(tmpz)_2$, the μ_{eff} value above 100 K is also somewhat sub-spin and constant: 1.65 ± 0.01 BM. Below this temperature, the magnetic moments increase considerably and reach 1.95 BM at 4.2 K. The χ_M^{corr} T values increase from 0.344 to 0.374 $cm^3\ mol^{-1}$ K in the temperature range

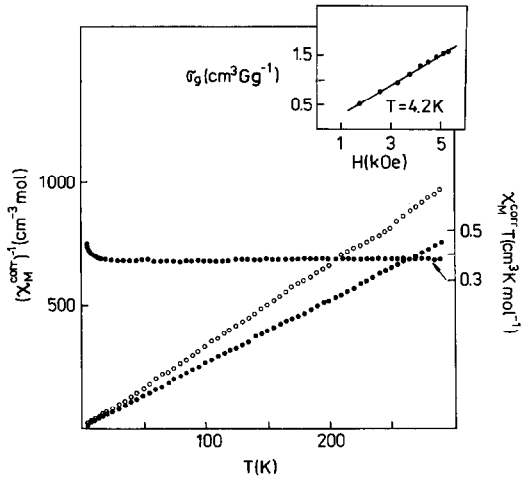

Fig. 2. Plots of $(\chi_M^{corr})^{-1}$ vs T for $Cu\{C(CN)_3\}_2(tmpz)_2$ (○) and $Cu\{N(CN)_2\}_2(tmpz)_2$ (●), χ_M^{corr} T vs T and σ_g vs H for $Cu\{N(CN)_2\}_2(tmpz)_2$.

measured (Fig. 2). The dependence of the specific magnetization, σ_g, against field strength, H, at 4.2 K is a straight line, so that the ferromagnetic admixture effect can be excluded.

The attempt to explain the experimental function $\chi_M^{corr} = f(T)$ for $Cu\{C(CN)_3\}_2(tmpz)_2$ by approximation to the two-dimensional model of a square-planar antiferromagnet[12] was made,

$$\chi_M = \frac{N_A g^2 \mu_B^2}{4kT}\left(1+\frac{2}{x}+\frac{2}{x^2}+\frac{1.333}{x^3}+\frac{0.250}{x^4}+\frac{0.4833}{x^5}+\frac{0.003797}{x^6}\right)^{-1}$$

[a] RT = room temperature.

where $x = kT/|J|$. The g_{av} value obtained from the ESR spectrum was used as a constant in the process of fitting data. The exchange parameter, $|J|$, is 0.57 cm^{-1}, which is also very small and with respect to the relatively high ERR value (for definition see ref. 5) of 5.73×10^4, no particular significance can be assigned to it. For $Cu\{N(CN)_2\}_2(tmpz)_2$ with even more complicated magnetic behaviour, the experimental susceptibility data were not fitted to any model of magnetic interaction.

It is very probable that both compounds by mutual assistance of pseudohalide bridges and sterically influential tmpz molecules possess complex three-dimensional structures, in which we are dealing with weak antiferromagnetic and ferromagnetic couplings. The common effect of both is the averaging and relative constancy of the magnetic moments. At lower temperatures, the changes of μ_{eff} suggest the ferromagnetic coupling is predominant, especially in $Cu\{N(CN)_2\}_2(tmpz)_2$. Structural crystallographic data are necessary for detailed understanding of these unusual magnetic properties but only polycrystalline powder materials are available at present.

CONCLUSIONS

The results entered in the paper prove that both compounds under study have complex polymeric structures with pseudohalide bridges mediating magnetic interaction between the Cu^{II} atoms. This interaction is both antiferromagnetic and ferromagnetic in nature, and results in averaging the magnetic moments which are, except with low temperatures, almost invariable. At low temperatures the magnetic moments increase thus indicating a strengthening ferromagnetic interaction.

CLEAVAGE OF THE TETRAMERIC PALLADIUM(II) COMPLEX $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ WITH NUCLEOPHILES. X-RAY CRYSTAL STRUCTURES OF THE PRODUCTS *TRANS*-$[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$ AND $[Pd_2(PPr^n_3)_2Cl_2(NO_2)_2]$

G. BRUNO,* S. CAMPAGNA, M. CUSUMANO, A. GIANNETTO and V. RICEVUTO

Dipartimento di Chimica Inorganica e Struttura Molecolare, Salita Sperone 31, Vil.S.Agata, 98016 Messina, Italy

(*Received* 20 *May* 1988; *accepted* 20 *July* 1988)

Abstract—The tetrameric complex $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ readily reacts with the nucleophiles NO_2^- and Cl^- to give a variety of palladium(II) square-planar complexes of PPr^n_3. A scheme for these reactions is proposed. The crystal structures of *trans*-$[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$, obtained by reaction of the tetramer with $[As(C_6H_5)_4]NO_2$, and of $[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$, obtained by reaction of the tetramer with the bridged complex $[Pd_2(PPr^n_3)_2Cl_4]$ have been determined by single crystal X-ray diffraction: (**1**) $[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$, $M_r = 777.45$, orthorhombic, $P2_12_12_1$, $a = 17.723(2)$, $b = 14.890(1)$, $c = 13.178(1)$ Å, $V = 3477.7(5)$ Å^3, $Z = 4$, $D_x = 1.48$ Mg m^{-3}, λ(Mo-K_α) = 0.71069 Å, $\mu = 0.78$ cm^{-1}, $F(000) = 1584$, $T = 293$ K, $R = 0.053$ for 1710 independent reflections with $I > 3\sigma(I)$. (**2**) $[Pd_2(PPr^n_3)_2Cl_2(NO_2)_2]$, $M_r = 696.2$, monoclinic, $P2_1/n$, $a = 13.665(2)$, $b = 7.855(1)$, $c = 13.704(2)$ Å, $\beta = 101.4(1)$, $V = 1441.8(4)$ Å^3, $Z = 4$, $D_x = 1.60$ Mg m^{-3}, λ(Mo-K_α) = 0.71069 Å, $\mu = 0.74$ cm^{-1}, $F(000) = 704$, $T = 293$ K, $R = 0.030$ for 1993 independent reflections with $I > 3\sigma(I)$.

We have recently shown[1] that by reaction of the bridged complex $[Pd_2(PPr^n_3)_2Cl_4]$ with $NaNO_2$ in methanol the tetrameric compound $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ is obtained. In this species an approximate square of Pd atoms is joined together by nitro–nitrito bridges; a nitro group and a tri-*n*-propylphosphine complete the coordination. This complex is very labile and is promptly cleaved, in different solvents, by nucleophiles to give various square-planar complexes of PPr^n_3. In this paper we describe the reaction of $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ with the nucleophiles Cl^- and NO_2^- and report the crystal structure of one of the products of the reaction with the latter nucleophile, *trans*-$[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$, and of the complex $[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$ obtained by reaction of the tetramer with $[Pd_2(PPr^n_3)_2Cl_4]$.

EXPERIMENTAL

The preparation of $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ has already been reported.[1] $[Pd(PPr^n_3)(NO_2)_3]$ $[As(C_6H_5)_4]$ was obtained by reacting $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ in methanol, in the presence of $[As(C_6H_5)_4][NO_3]$ in a ratio of 1 : 10, with a large excess of $NaNO_2$. The solution was stirred for 1 h and the solvent evaporated off. The residue, after washing several times with water, was crystallized from methanol–diethyl ether.

$[Pd_2(PPr^n_3)_2Cl_4]$. The tetrameric compound $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$, dissolved in methanol, was treated with a large excess of LiCl. The resulting solution was left under magnetic stirring for 24 h and the solvent was evaporated off. The solid residue was washed with water and crystallized from cold ethanol.

The complexes *trans*-$[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$, $[Pd(PPr^n_3)(NO_2)Cl_2][As(C_6H_5)_4]$ and $[Pd(PPr^n_3)Cl_3][As(C_6H_5)_4]$ were prepared by reacting $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$ with $[As(C_6H_5)_4][NO_2]$, in the appropriate ratio in methanol. The resulting solution was stirred for 1 h and the solvent evaporated off. The residue was dissolved in CH_2Cl_2 and the product was precipitated as a crystalline solid by the addition of diethyl ether.

$[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$ was obtained as a crystalline solid by reacting the tetramer with $[Pd_2$

*Author to whom correspondence should be addressed.

$(PPr^n_3)_2Cl_4]$, in methanol, in a ratio of 1:2. LiCl, NaCl and $NaNO_2$, as well as all the solvents used, were of reagent grade.

UV–vis spectra were recorded using a Perkin–Elmer Lambda 5 spectrophotometer. IR spectra in the range 250–4000 cm^{-1} were recorded as Nujol mulls on a Perkin–Elmer 783 spectrometer. Conductivity measurements were carried out with a Radiometer CDM3 conductivity bridge.

Diffraction data, for **1** and **2**, were collected on a Siemens–Stoe Four Circle diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Accurate unit cell dimensions and crystal orientation matrices were obtained from least-squares refinement of 2θ, ω, χ and ψ values of 20 strong reflections in the range $14 < 2\theta < 24°$. Three standard reflections were monitored periodically during the course of the data collection as a check of the crystal stability, and these varied by less than 3% for both compounds. Of 3800 and 3950 independent reflections measured by the ω–2θ scan technique, in the range $3 < 2\theta < 50$, 1710 and 1993 ($R_{int} = 0.022$, 0.018) having net intensity $I > 3\sigma(I)$ were used in the solution and refinement of the structure. Corrections for Lorentz and polarization effects were made, but not those for absorption ($\mu = 16.3$ and 15.5 cm^{-1}). Both the structures were solved by using standard Patterson methods. The Fourier difference synthesis phased with the heavy-atom positions allowed the location of the non-hydrogen atoms in **1** and **2**. Full-matrix least-squares refinement of the models was carried out by minimizing the function $\Sigma w(|F_o|-|F_c|)^2$. The weighting scheme used in the last refinement cycles were $w = 0.7186/[\sigma^2(F_o)+0.005366F_o^2]$ for **1** and $w = 0.6979/[\sigma^2(F_o)+0.001878F_o^2]$ for **2**, which showed reasonable consistency in a test of $w\Delta^2$ for data sectioned with respect to both F_o and $\sin\theta/\lambda$. Anisotropic temperature factors were introduced for all non-hydrogen atoms; in compound **1** the phenyl rings of the triphenylarsine cation were refined as rigid groups and restricted to their normal geometry (D_{6h} symmetry; $d_{C-C} = 1.395$ Å) by using the group refinement procedure. Each ring was assigned an individual isotropic thermal parameter. Hydrogen atoms were added at calculated positions and included in the structure factor calculations with a common thermal parameter ($U = 0.06$ Å^2). Both models reached convergence with $R = [\Sigma|F_o|-|F_o|]/\Sigma|F_o| = 0.053$ and 0.030 $wR[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.056$ and 0.036 for **1** and **2**, respectively. Scattering factors for non-hydrogen atoms were taken from ref. 2 and for hydrogen atoms from ref. 3. Anomalous dispersion corrections for Pd, Cl and P atoms were taken from ref. 4.

Reversing the sign of the imaginary anomalous scattering component for **1**, which has the non-centrosymmetric space group $P2_12_12_1$, increased R from 0.053 to 0.071. This difference is highly significant, and therefore the model has the correct absolute configuration.

All calculations were performed with the *SHELX 76*[5] and *PARST*[6] set of programs on the IBM 4341 computer at the "Centro di Calcolo dell' università di Messina". Atomic coordinates, anisotropic temperature factors and calculated and observed structure factors are available as supplementary material. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

On addition of excess nitrite or chloride to a methanol or dichloromethane solution of $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$, an immediate reaction occurs as shown by the large spectral variation, in the UV region, associated with the process. However, when using NaCl or LiCl as the nucleophile only the starting complex is recovered if the solvent is evaporated off. The reaction product in the case of NO_2^-, $[Pd(PPr^n_3)(NO_2)_3]^-$, can be obtained in the solid state as a pure compound, providing the nucleophile/complex ratio is $\geqslant 4$, in the presence of a bulky counter ion such as $[As(C_6H_5)]^+$. When the nucleophile is Cl^-, various substances are obtained as a function of the chloride concentration. Thus, when the chloride/complex ratio is 4 only $[Pd(PPr^n_3)(NO_2)_2Cl]^-$ forms in solution; with a large excess of chloride (over 100-fold with respect to the complex) either $[Pd(PPr^n_3)Cl_3]^-$ or the chloro-bridged complex $[Pd_2(PPr^n_3)_2Cl_4]$ are the reaction products. The former, as well as $[Pd(PPr^n_3)(NO_2)_2Cl]^-$, precipitates in the presence of $[AS(C_6H_5)_4]^+$; the latter substance is obtained, using LiCl or NaCl as the nucleophile, when the solvent is evaporated off. Intermediate Cl^- concentrations lead to a mixture of variously substituted complexes of PPr^n_3 including a substance which precipitates in the presence of $[As(C_6H_5)_4]NO_3$ and can be formulated, on the basis of elemental analysis, as $[Pd(PPr^n_3)(NO_2)Cl_2][As(C_6H_5)_4]$. In this compound, the two chlorides most likely occupy mutual *cis* positions; the IR spectrum (Nujol mull) shows in fact two stretching frequencies at 265 and 329 cm^{-1} assignable to the Pd—Cl *trans* and *cis*, respectively, to phosphine.[7] In addition, reaction of a 1:1 ratio of this complex and PPr^n_3 does not lead to *trans*-$[Pd(PPr^n_3)_2Cl_2]$ as expected if NO_2 were *trans* to

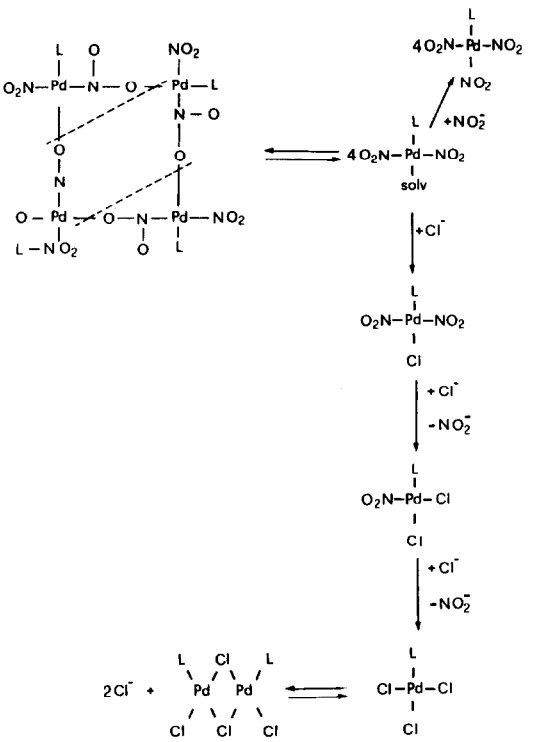
phosphine but to $[Pd(PPr^n_3)_2ClNO_2][As(C_6H_5)_4]$. The IR spectrum of this product shows a stretching frequency Pd—Cl at 285 cm^{-1} characteristic of Cl *trans* to phosphine[7] and only one Pd—P stretching frequency at 425 cm^{-1} as expected for phosphines *trans* to each other.

The IR spectrum of $[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$ exhibits a band at 285 cm^{-1} attributable to Pd—Cl with the chloride *trans* to phosphine. This type of structure has been conclusively confirmed by X-ray analysis of the substance. The structure of $[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$ has also been established by single crystal determination. On the basis of the nature of the reaction products a possible reaction scheme is predicted in Scheme 1.

The existence of an equilibrium between the tetramer and a solvo-species is supported by the conductivity data. A methanol solution of the tetramer (1×10^{-4} M) exhibits a molar conductance of about 9 $\Omega^{-1}\,cm^2\,M^{-1}$ which is unexpected for a neutral complex.[8]

By reacting the tetramer with the bridged complex $[Pd_2(PPr^n_3)_2Cl_4]$, $[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$ is obtained:

$$[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4] + 2[Pd_2(PPr^n_3)_2Cl_4] \rightarrow 4[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]. \quad (2)$$



Scheme 1.

The structure of $[Pd_2(PPr^n_3)_2(NO_2)_2Cl_2]$ has also been established by single crystal determination.

Molecular structure of $[Pd_2(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$ **(1)**

The crystal structure of **1**, depicted in Fig. 1 with the atomic labelling, consists of a discrete

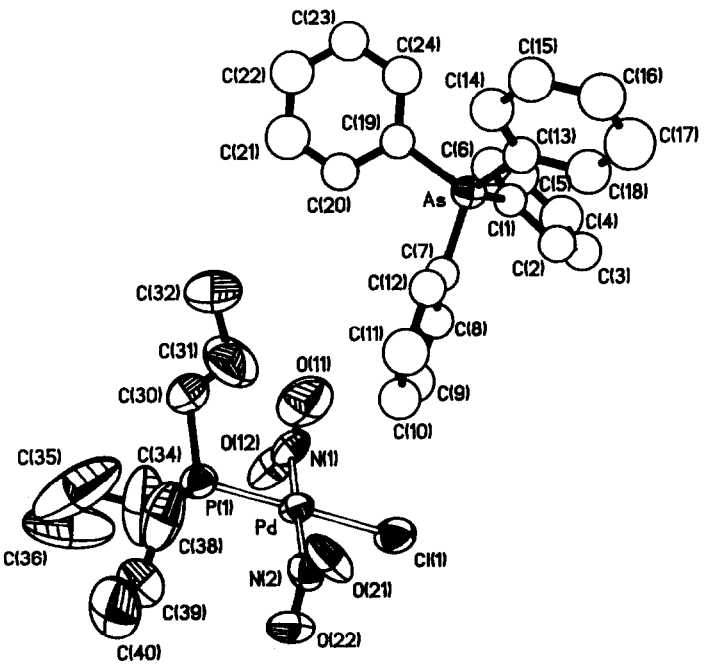


Fig. 1. Molecular structure of *trans*-$[Pd(PPr^n_3)(NO_2)_2Cl][As(C_6H_5)_4]$.

anion, in which the metal atom is fully coordinated, and separated from the cation $[As(C_6H_5)_4]^+$ by normal van der Waals interactions. Bond distances and angles are reported in Table 1. The local anion geometry is, as expected, square-planar slightly distorted as the atom-to-plane deviations are all lower than 0.02 Å. The two nitrogen atoms of the nitro groups *trans* to each other form an angle [N(1)—Pd(1)—N(2)] of 178.1(6)°. Both the Pd(1)—N(1) and Pd(1)—N(2) bond distances are comparable (2.037(19) and 2.007(18) Å) with the corresponding values in $[Pd(PPr^n_3)(NO_2)_3][As(C_6H_5)_4]$[9] and other nitro complexes.[10,11] The geometry of the nitrite groups is characterized by N—O distances (mean 1.16(3) Å) and the O—N—O angle of 122.6(2)°. In addition, the planes of the nitrite groups are nearly perpendicular to the coordination plane, being rotated by 88.7(9) and 91.9(8)° with respect to it. The Pd(1)—P(1) bond distance of 2.243(6) Å is comparable with the corresponding value of 2.262(6) Å in $[Pd(PPr^n_3)(NO_2)_3][As(C_6H_5)_4]$[9] and 2.248(4) Å in $[Pd_4(PPr^n_3)_4(NO_2)_4(ONO)_4]$[1] and is much lower than the value of 2.327(3) Å in $[Pd_2(PPr^n_3)_2(NCS)(SCN)_2(\mu\text{-CN})]$[11] where the two phosphines are mutually *trans*. The Pd(1)—Cl bond distance of 2.347(5) Å is slightly lower than the value of 2.359(1) Å found for Pd—Cl *trans* to $As(C_6H_5)_3$ in *cis*-$[Pd(SNNMe_2)(As(C_6H_5)_3)Cl_2]$[12] and is significantly longer than the value of 2.300 Å mediated over a series of Pd—Cl bonds[13] where two chlorine atoms are *trans* to each other.

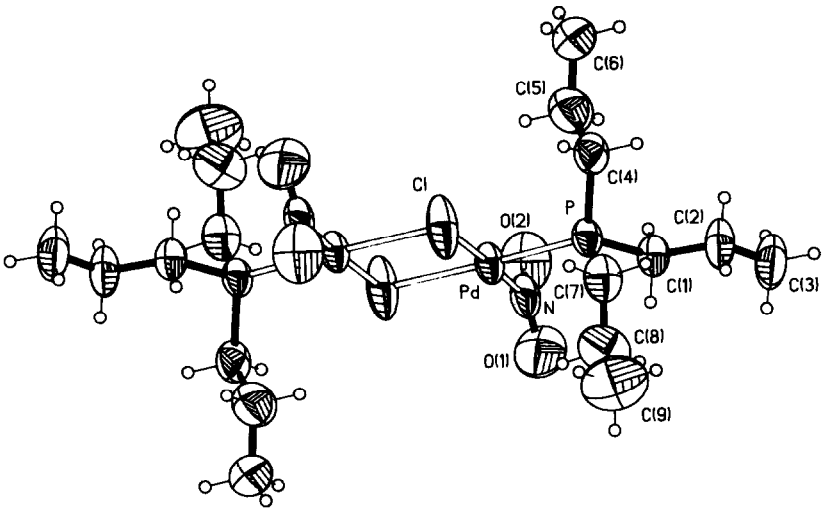

Fig. 2. Molecular structure of $[Pd_2(PPr^n_3)_2Cl_2(NO_2)_2]$.

As—C bond distances (mean value 1.865 Å) and other structural features of $[As(C_6H_5)_4]^+$ and of PPr^n_3 are as usual and require no special comment.

Molecular structure of $[Pd_2(PPr^n_3)_2Cl_2(NO_2)_2]$ (**2**)

The crystal structure of **2** with atomic labelling is depicted in Fig. 2. Bond distances and angles are reported in Table 2. The crystal of compound **2** consists of packing of discrete dimeric molecules $[Pd_2(PPr^n_3)_2Cl_2(NO_2)_2]$ separated by normal van der Waals contacts. Each metal atom is surrounded by a P atom from the PPr^n_3 ligand, an N-bonded nitrite group and two unsymmetrical *cis* chlorine atoms in a planar configuration. The two Pd—Cl bond distances are 2.316(1) and 2.417(1) Å; the latter value refers to a Pd—Cl *trans* to PPr^n_3. The Pd—P bond distance of 2.232(1) Å is at the lower limit found for this type of bond. The two palladium atoms are connected together at a distance of 3.420 Å. The dihedral angle between the two coordination planes is only 1.30(7)°. The P(1)—Pd—Cl(1) and P(1)—Pd—Cl(1′) bond angles are 90.25(4) and 177.58(4)°, respectively. The Pd—N bond distance is 1.979(4) Å slightly shorter than the corresponding values for **1**. Furthermore, the nitro group plane is rotated by 86.0(3)° with respect to the coordination plane. This orientation seems to be the usual one in the absence of steric overcrowding. In the PPr^n_3 ligand the P—C bond distances are as expected and range from 1.797(5) to 1.812(5) Å. The other bond lengths and angles within this ligand, as well as the relatively large thermal motion of the propyl chain, are as usual.

2-QUINALDINATE CARBONYL COMPLEXES OF RHODIUM(I) WITH SUBSTITUTED TRIARYLPHOSPHINE LIGANDS

J. V. HERAS,* M. CANO, M. A. LOBO and E. PINILLA

Departamento de Química Inorgánica, Facultad de Ciencias Químicas, Universidad Complutense, 28040-Madrid, Spain

(*Received* 16 *October* 1987; *accepted* 25 *July* 1988)

Abstract—A number of square-planar rhodium(I) complexes [Rh(N⁀O)LL′] [L,L′ = CO; L = CO, L′ = P(X—C_6H_4)$_3$ (X = 4-CH_3O, 4-CH_3, 3-CH_3, 2-CH_3, 4-F, 4-Cl)], containing 2-quinaldinate (C_9NH_6—COO^-) as monoanionic N⁀O bidentate have been synthesized by means of the reaction [Rh(quin)(NBD)]+CO → [Rh(quin)(CO)$_2$]+NBD [NBD = norbornadiene (bicyclo-2,2,1-hepta-2,5-diene)], or alternatively by reaction of [Rh(acac)(CO)$_2$] with 2-quinaldinic acid. Only one of the carbonyl groups in the [Rh(quin)(CO)$_2$] could be substituted by triarylphosphine ligands and complexes of the type [Rh(quin)(CO) P(X—C_6H_4)$_3$]] were obtained in all cases. The square-planar monocarbonyl complexes were isolated in one or two isomeric forms depending on the π-acceptor properties of the phosphine ligand present. Using excess of triarylphosphine the new pentacoordinated compounds [Rh(quin)(CO)[P(X—C_6H_4)$_3$]$_2$] were obtained and two isomeric forms were separated in most cases.

It is well known that the dicarbonylic complexes of the type [Rh(N⁀O)(CO)$_2$] [(N⁀O) = anionic chelate, N⁀O donor ligand] react with neutral ligands (L) such as PPh_3 or $AsPh_3$ to give the monocarbonyl derivatives [Rh(N⁀O)(CO)(L)].[1–6] In these reactions,

$$[Rh(N\frown O)(CO)_2] + L \rightarrow [Rh(N\frown O)(CO)(L)] + CO,$$

two isomers are possible, but only one has been isolated in all the cases investigated.

The crystallographic results for one series of the above monocarbonyl complexes indicated that the nitrogen atom of the chelate ring has a larger *trans*-influence than that of the oxygen atom.[7–10]

On the other hand, in complexes of the type [Rh(quin)(CO)$_2$] and [Rh(β-diketonate)(CO)$_2$] it has been observed that two carbonyl groups are substituted by triphenylphosphite to form the corresponding bis-triphenylphosphite complexes.[11–13] This fact is explained by Leipoldt and co-workers[13] by the formation of two very strong Rh—P bonds as a result of the largest π-acceptor properties of the triphenylphosphite.[14]

Although in the above examples, the two carbonyl groups can be substituted, in recent work Leipoldt suggested that the [Rh(quin)(CO)$_2$] complex only yields the monosubstituted complex in their reactions with triphenylphosphine.[13] It is reasonable to think that the formation of mono- or disubstituted species is clearly dependent on the nature of the P-donor ligands.[13,15]

Based on these considerations, we set out to investigate the reactivity of the [Rh(quin)(CO)$_2$] dicarbonyl complex[1] with triarylphosphine ligands of different π-acceptor capacity, P(X—C_6H_4)$_3$ (X = 4-CH_3O, 4-CH_3, 3-CH_3, 2-CH_3, 4-F, 4-Cl). A stoichiometric molar ratio of phosphine/complex or an excess of these ligands has been employed in all cases.

RESULTS AND DISCUSSION

[Rh(quin)(NBD)] *and* [Rh(quin)(CO)$_2$] *complexes*

Reaction of the dimeric rhodium(I) complex, [RhCl(NBD)]$_2$, in benzene with an equimolar amount of 2-quinaldinic acid (Hquin) in the presence of sodium carbonate, gave rise to a break of the chlorine bridges in the dimeric compound, and an orange solid was isolated from the reaction

*Author to whom correspondence should be addressed.

medium. The new compound has been characterized on the basis of the analytical and spectroscopic data as [Rh(quin)(NBD)] (**I**).

The bubbling of carbon monoxide through a dichloromethane solution of this complex caused the displacement of the coordinated diolefin yielding the dicarbonyl derivative [Rh(quin)$(CO)_2$] (**II**) according to eq. (1):

$$[Rh(quin)(NBD)] + 2CO \rightarrow [Rh(quin)(CO)_2] + NBD. \quad (1)$$

Both compounds (**I**) and (**II**) are air-stable and non-electrolytes in acetone solutions (10^{-3} M), and they were obtained in high yields. The analytical data were consistent with the formulation proposed (Table 1).

The red–orange dicarbonylic derivative, which has been previously described,[1,13] can be also isolated by reaction of the [Rh(acac)$(CO)_2$] complex with an excess of Hquin.

The IR spectrum (Table 2) in the solid state of the [Rh(quin)(NBD)] complex shows one very strong ν_{as}(COO) band at 1640 cm^{-1}. This band appears in the same range of frequencies as that observed for the [Rh(pyc)(NBD)] complex, for which a bidentate N,O coordination is proposed.[6] Additionally, the bands which appear at 1310 and 717 cm^{-1} are assigned to the presence of the NBD ligand.[16]

The IR spectrum of the dicarbonyl derivative is in accord with that described by Ugo *et al.* for the same compound.[1]

The ^{1}H NMR spectrum of [Rh(quin)(NBD)] shows two multiplet peaks centred at δ = 1.35 and 4.4 ppm, which are attributed, respectively, to $>CH_2$ and $>CH+>CH$ protons of the NBD ligand; two multiplet peaks at δ = 8.4 (H^1) and 8–7.4 (H^2–H^6) ppm are attributed to the 2-quinaldinate ligand.

Table 1. Analytical data, physical properties and yields for the four-coordinated complexes

$[Rh(quin)(CO)[P(X—C_6H_4)_3]]$ (X = 4-CH_3O, 4-CH_3, 3-CH_3, 2-CH_3, 4-F, 4-Cl)

Addition of triarylphosphine ligands to a dichloromethane solution of $[Rh(quin)(CO)_2]$ in a 1:1 molar ratio gave monocarbonyl compounds of the type $[Rh(quin)(CO)[P(X—C_6H_4)_3]]$.

The new complexes are air-stable at room temperature, soluble in CH_2Cl_2 or $CHCl_3$ and moderately soluble in other polar solvents. The analytical data, Table 1, were consistent with the formulations proposed.

The IR spectra (Table 2) of the solid compounds show one band in the 1662–1658 cm^{-1} region assigned to $\nu_{as}(COO)$ of the carboxylic group. This band is not significantly shifted with respect to the initial compounds and it is characteristic of a bidentate N,O coordination of ligands of the type pyridincarboxylate.[17–19]

On the other hand, a very strong absorption band in the 1972–1955 cm^{-1} region has been assigned to the $\nu(C{\equiv}O)$ of the carbonyl group. This band appears to be split when the phosphine ligands are $P(4\text{-}F—C_6H_4)_3$ and $P(4\text{-}Cl—C_6H_4)_3$, and it can be attributed either to solid state effects or to the presence of two isomeric forms.

In the cases in which one $\nu(C{\equiv}O)$ vibration is observed, it can be reasonably assumed that the only isomer is obtained with the phosphine *trans* to the heterocyclic nitrogen, due to the strong *trans* effect of this atom. This is in agreement with the results of structure determinations on [Rh(oxine)(CO)(PPh_3)], [Rh(oxine)(COD)], [Rh(Sal—NR)(PR_3)] and [Rh(pyc)(CO)(PPh_3)].[7–10] All the compounds show characteristic IR absorptions of the coordinated phosphine ligand.[20]

A correlation between $\nu(C{\equiv}O)$ and the basicity of the triarylphosphine ligands can be observed, and an increase in the basicity of the triarylphosphine causes a shift in the $\nu(C{\equiv}O)$ towards lower frequencies.

The ^{31}P NMR spectra of the complexes containing *p*-substituted triarylphosphine ligands have been registered (Table 2). Different behaviour is also observed depending on the phosphine ligands. Thus, in the cases in which X = 4-CH_3O or 4-CH_3, only one doublet appears at δ = 38.61 ppm, J = 168.14 Hz and δ = 40.89 ppm, J = 168.46 Hz, respectively. However, when X = 4-F, 4-Cl, two doublets with the same J(Rh—P) (Table 2) were observed. It is reasonable to attribute this to the presence of two isomeric forms. On the other hand, it is remarkable that the two doublets have the same intensity when X = 4-F and a very different intensity (1:6) when X = 4-Cl.

The above $\nu(C{\equiv}O)$ and J(Rh—P) data support the formation of square-planar rhodium(I) compounds.[5]

It is noteworthy that the isomers are observed only in the cases in which the substituted triarylphosphine ligands show the strongest π-acceptor properties. In these cases, the *σ–trans* effect of the nitrogen relative to the oxygen of the 2-quinaldinate ligand does not seem significantly different. This fact has also been reported by Leipoldt and co-workers in the [Rh(quin)$[P(O—C_6H_5)_3]_2$] complex.[13] Thus, the two isomers observed in our compounds are attributed to the substitution in the $[Rh(quin)(CO)_2]$ of the carbonyl group *trans* to the nitrogen or oxygen atom, respectively. Unfortunately, we have not been able to separate these isomers.

$[Rh(quin)(CO)[P(X—C_6H_4)_3]_2]$ (X = 4-CH_3O, 4-CH_3, 3-CH_3, 4-F, 4-Cl)

New compounds of the type [Rh(quin)(CO)$[P(X—C_6H_4)_3]_2$] have been isolated when the complexes $[Rh(quin)(CO)[P(X—C_6H_4)_3]]$ or [Rh(quin)$(CO)_2$] were allowed to react with the triarylphosphine ligands in a 1:1 or 1:2 molar ratio, respectively. However, different behaviour was observed with $P(2\text{-}CH_3—C_6H_4)_3$ and in these reactions only the square-planar $[Rh(quin)(CO)[P(2\text{-}CH_3—C_6H_4)_3]]$ species was obtained. It is possible that the steric characteristics of this ligand may prevent an increase in the coordination.

All the $[Rh(quin)(CO)[P(X—C_6H_4)_3]_2]$ complexes investigated in this work, with exception of the $[Rh(quin)(CO)[P(4\text{-}CH_3O—C_6H_4)_3]_2]$ derivative, were obtained in two isomeric forms, "a" and "b", in the solid state (Table 3). The solids isolated are diamagnetic, of moderate to good stability, soluble in solvents such as CH_2Cl_2 or $CHCl_3$ and moderately soluble in acetone, EtOH, MeOH etc.

Table 3 lists some identifying properties of the solid isomers. It was found, in solution, that all the solid "a" and "b" present a more or less quick evolution towards the square-planar compounds, and in all the cases after 24 h these species can be precipitated from their solutions.

The IR spectra of the solid "a" and "b" isomers in the carbonyl stretching region show in all cases one single strong $\nu(C{\equiv}O)$ absorption without splitting or shoulders (Table 3). These bands are shifted to lower frequencies with respect to the tetracoordinated starting compounds (Table 2). This fact is consistent with an increase in the electronic density of the rhodium atom caused by the coordination of a new phosphine ligand. It is remarkable that this shift is more enhanced in the "a" than the "b" sets. The sequence of their values is again in

[a] Freshly prepared solutions.

[b] Values in parentheses refer to spectra of [Rh(quin)(CO)[P(X—C_6H_4)$_3$]] parent compounds.

agreement with the basicity of the phosphine ligand.

A significant trend was also observed for the —COO stretching modes of the carboxylate group of the 2-quinaldinate ligand. In all cases the decrease in ν_{as}(COO) and the increase in ν_{sym}(COO) with respect to the parent compounds may be significant of a new interaction occuring through the oxygen of the —C=O group which was uncoordinated in the square-planar parent compounds. These modifications are also different in the "a" and "b" series and the highest values of $\Delta\nu(COO) = \nu_{as} - \nu_{sym}$ are found in the compounds of type "a".

The position of the antisymmetric stretching carbonyl band at *ca* 1610 cm^{-1} for the "b" isomers is very similar to that observed in other pyridine carboxylate complexes[17,19] for which a bidentate or bridge O,O coordination is suggested in the solid state.

On the other hand, in most of the examples of 2-pyridincarboxylate complexes a coordination involving terminal and/or bridging carboxylate groups and the pyridine nitrogen atom was observed. However, when terminal carboxylate groups are present the ν_{as}(COO) appears at values higher than 1660 cm^{-1}.

For the above considerations a monodentate coordination through only one oxygen is ruled out for our compounds, and it is suggested that the 2-quinaldinate ligand is coordinated through one oxygen of the carboxylate group and possibly through the heterocyclic nitrogen. Additional interactions, which are higher for "b" than for "a" isomers, through the other carboxylic oxygen are also

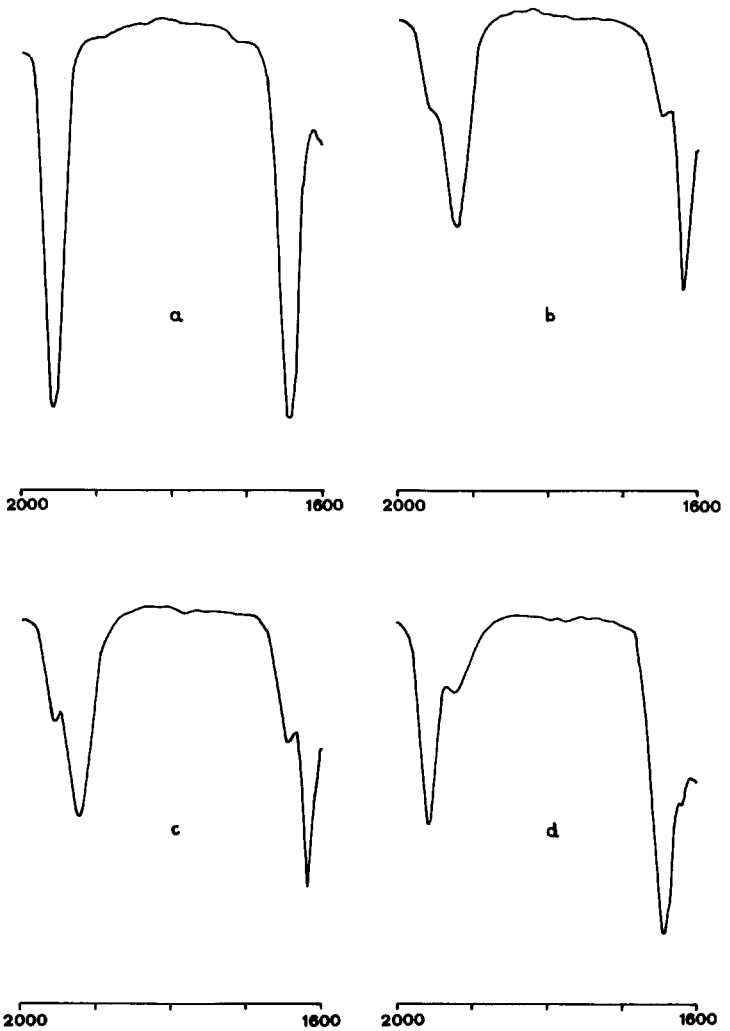

Fig. 1. IR spectra (2000–1600 cm^{-1}) in CH_2Cl_2 solution of (a): [Rh(quin)(CO)[P(4-CH_3O—C_6H_4)$_3$]$_2$]; (b): [Rh(quin)(CO)[P(4-CH_3O—C_6H_4)$_3$]$_2$] in fresh solution; (c): [Rh(quin)(CO)[P(4-CH_3O—C_6H_4)$_3$]$_2$] after 3 h; (d): [Rh(quin)(CO)[P(4-CH_3O—C_6H_4)$_3$]$_2$] after 20 h.

possible and they are consistent with the values of the ν_{as}(COO) frequencies. This is also supported by the appearance of new bands at 346–352 cm^{-1} (Table 3) tentatively assigned to ν(M—O) vibrations.[19,21,22]

In contrast, the IR spectra in CH_2Cl_2 solutions were the same for the "a" and "b" isomers of each phosphine ligand. In all cases the pattern of the bands in carbonyl stretching region showed one strong sharp absorption with a shoulder [Table 3, Fig. 1(b)]. The shoulders were identical in position to the ν(C≡O) bands in the parent tetracoordinated monocarbonyl compounds (Table 3) and their intensities increased with time [Fig. 1(c) and (d)].

Similar behaviour was observed in the stretching carboxylate ν(COO) region. In all cases when the IR were registered a few minutes after the solutions were prepared, two bands at *ca* 1660 and 1630 cm^{-1} were observed. The first band was in the same position as that of the ν_{as}(COO) of the square-planar compounds [Rh(quin)(CO)[P(X—C_6H_4)$_3$]] (Table 3). An increase in the intensity of the former together with a decrease in the latter bands was observed with time [Fig. 1(c) and (d)], and after 24 h only the characteristic bands of the starting tetracoordinated complexes were present [Fig. 1(a)].

The above considerations indicate that the compounds [Rh(quin)(CO)[P(X—C_6H_4)$_3$]$_2$] present two isomeric forms "a" and "b" in the solid state but in CH_2Cl_2 solution only one is detected and this is transformed towards the tetracoordinated starting materials.

It is probable that the new compounds present in the solid state have a five-coordinate geometry, but there are many possible isomeric forms for it and unfortunately characterization by X-ray diffraction has not been possible because attempts to crystallize the compounds caused conversion to the square-planar tetracoordinated [Rh(quin)(CO)[P(X—C_6H_4)$_3$]].

The ^{31}P NMR spectra for the "a" and "b" isomers [Rh(quin)(CO)[P(4-F—C_6H_4)$_3$]$_2$] recorded in $CDCl_3$ solutions for 10 min, present only one broad peak at δ = 43.73 ppm, which is not split by coupling with the ^{103}Rh atom. This fact can also be explained if an interchange process has been occurring. The signal is slightly shifted with time but in none of the cases was Rh—P coupling observed. After 20 min, the spectra show a broad signal at δ = 26.84 ppm which is approximately in the average position of the square-planar species and the free phosphines ligand. After 5 h, this signal was not modified.

We think that in solution the [Rh(quin)(CO)[P(X—C_6H_4)$_3$]$_2$] species are transformed into the square-planar complexes according to eq. (2):

$$[Rh(quin)(CO)[P(X—C_6H_4)_3]_2] \rightleftharpoons [Rh(quin)(CO)[P(X—C_6H_4)_3]] + P(X—C_6H_4)_3 \quad (2)$$

and that a fast interchange process may exist between the free and coordinated phosphine ligands.[15]

EXPERIMENTAL

C, H, N analyses were carried out by Elemental Micro-Analyses Ltd Laboratories, Amberley, Beaworth, Devon, U.K. IR spectra in the 4000–200 cm^{-1} region were recorded on Perkin–Elmer 325 and 1300 spectrophotometers using KBr discs and dichloromethane solutions. The ^{1}H NMR spectrum was recorded on a Perkin–Elmer R-12 apparatus at 90 MHz. The ^{31}P NMR spectra were recorded on a Varian FT-80A apparatus at 200 MHz. Conductance measurements were performed in acetone solutions (approx 10^{-3} M) with a Philips PR9500 conductimeter.

[Rh(quin)(NBD)]

A stoichiometric amount of 2-quinaldinic acid (Hquin) was added to a benzene suspension of the [RhCl(NBD)]$_2$ complex. After the addition of an excess of Na_2CO_3 and stirring for 12 h at room temperature the reaction mixture was filtered. The orange solid was dissolved in dichloromethane, the Na_2CO_3 was filtered off and the complex precipitated by addition of cold Et_2O; it was recrystallized from CH_2Cl_2–Et_2O, washed with Et_2O and vacuum-dried (Yield 75%).

[Rh(quin)(CO)$_2$]

Method (*a*). Carbon monoxide was bubbled through a solution of the [Rh(quin)(NBD)] complex in CH_2Cl_2 at room temperature for 1 h. The colour of the solution changed from yellow to orange. The red–orange complex was precipitated by the addition of Et_2O, recrystallized from CH_2Cl_2–Et_2O and vacuum-dried.

Method (*b*). An excess of 2-quinaldinic acid was added to an acetone solution of [Rh(acac)(CO)$_2$]. Immediately, the colour of the solution changed from yellow to red–orange. After 1 h stirring the addition of water gave rise to the quantitative precipitation of the red–orange dicarbonyl compound, which was filtered off, washed with water and vacuum-dried (Yield 98%).

[Rh(quin)(CO)[P(X—C_6H_4)$_3$]] (X = 4-CH_3O, 4-CH_3, 3-CH_3, 2-CH_3, 4-F, 4-Cl)

The addition of P(X—C_6H_4)$_3$ to a solution of [Rh(quin)(CO)$_2$] in CH_2Cl_2, in a 1 : 1 stoichiometric ratio, caused evolution of CO and the colour changed from orange to yellow. The solution was stirred for about 18 h, and then cold *n*-hexane was added and the faint yellow precipitate that appeared was separated by filtration. After concentration of the solution under reduced pressure the solid compounds were obtained; they were filtered off, recrystallized from CH_2Cl_2–*n*-hexane and vacuum-dried.

[Rh(quin)(CO)[P(X—C_6H_4)$_3$]$_2$] (X = 4-CH_3O, 4-CH_3, 3-CH_3, 4-F, 4-Cl)

A solution of [Rh(quin)(CO)$_2$] (100 mg, 0.3 mmol) in 20 cm^3 of dichloromethane was added to 0.6 mmol of the phosphine ligand (X = 4-CH_3O, 212 mg; X = 4-CH_3, 3-CH_3, 183 mg; X = 4-F, 190 mg; X = 4-Cl, 220 mg).

When the phosphine ligand was P(4-F—C_6H_4)$_3$ the solution was stirred for 30 min, then 5 cm^3 of *n*-hexane were added and a light orange precipitate ("b"-isomer) was obtained. This was filtered off, washed with *n*-hexane and vacuum dried. The solution was concentrated and a light yellow solid ("a"-isomer) was obtained and separated by the same procedure.

For the phosphine ligand, P(3-CH_3—C_6H_4)$_3$, a fast reaction occurred. After the addition of hexane (40 cm^3), filtration and concentration of the solution, a light yellow solid was obtained, which was filtered off, washed with *n*-hexane and vacuum-dried ("a"-isomer). Hexane was added to an acetone solution of the "a"-isomer and an orange solid ("b"-isomer) was separated by an analogous procedure to the above.

When the phosphine ligands employed were P(4-CH_3—C_6H_4)$_3$ and P(4-Cl—C_6H_4)$_3$, the reactions in dichloromethane–*n*-hexane (40 cm^3) yielded the simultaneous precipitation of the "a" and "b" isomers. In the first case (X = 4-CH_3), a reaction temperature of 0°C was necessary and the reaction occurred instantaneously. The separation of the two forms was possible by treatment of the mixture with benzene–*n*-hexane (1 : 3) or *n*-hexane–dichloromethane (6 : 1), to give an orange ("b"-isomer) or yellow ("a"-isomer) precipitate, respectively. These were filtered off and vacuum-dried. In the second case (X = 4-Cl), the reaction time was 20 min; the isomer mixture was treated with *n*-hexane–dichloromethane (6 : 1) or acetone–*n*-hexane (1 : 3), and the "b" or "a" isomers were respectively isolated by concentration of the solutions, which we than filtered off and vacuum-dried.

In the reaction with P(4-CH_3O—C_6H_4)$_3$ only the "a"-isomer was obtained and this reaction occurred instantaneously. The addition of *n*-hexane gave rise to precipitation of a yellow solid, which was isolated as in the above cases.

COMPLEXATION OF IRON(II) WITH 3-HYDROXYIMINOPENTANE-2,4-DIONE (Hinaa)

ANTHONY R. BUTLER,* ADRIANNE M. CALSY and CHRISTOPHER GLIDEWELL

Department of Chemistry, The University, St. Andrews, Fife KY16 9ST, Scotland, U.K.

(*Received* 16 *March* 1988; *accepted* 15 *August* 1988)

Abstract—Iron(II) reacts with Hinaa (3-hydroxyiminopentane-2,4-dione) in the pH range 6.80–7.58 to give a complex ion of composition $[Fe(inaa)_3]^-$. NMR evidence suggests that it is the *fac* isomer. A kinetic study, using stopped-flow spectrophotometry, demonstrated that the rate of formation of the complex depends upon $[inaa^-]^3$. Therefore, the rate-determining step must be cyclization of the *third* $inaa^-$ ligand.

It has been known[1] for a number of years that 3-hydroxyiminopentane-2,4-dione [(1), otherwise named isonitrosoacetylacetone and abbreviated to Hinaa] forms highly coloured complexes with some transition metals. More recently,[2,3] this has been exploited as a means of extracting metal ions from aqueous solution. Also the reaction of **1** with iron(II) to give a blue complex has been used as a method of assay[4] for iron(II) in the presence of iron(III), with which **1** has no reaction.

RESULTS AND DISCUSSION

There is some disagreement in the literature concerning the structure of the blue complex. It has been described[2–4] as the neutral species $Fe^{II}(inaa)_2$, consistent with its solubility in organic solvents. However, Ablov and Zubarev[5] formulated this product as $Na[Fe^{II}(inaa)_3]$, containing octahedral low-spin iron(II), on the basis of elemental analysis (for Fe and N), the observed diamagnetism, and its behaviour as a 1:1 electrolyte in methanol solution. Our elemental analysis confirms the identity of our product with that of Ablov and Zubarev, while the observation of sharp NMR spectra confirms the diamagnetism of the iron, which must therefore be present as low spin iron(II). The structure of the $[Fe(inaa)_3]^-$ ion can be deduced with a measure of certainty by comparison of its spectroscopic data with those of related complexes. Cobalt(III) forms a complex with Hinaa which is the octahedral neutral species $Co^{III}(inaa)_3$. IR spectra (Table 1) and ^1H NMR spectra have established[6] that here $inaa^-$ is a bidentate ligand, bound to the metal through the oxime nitrogen and the oxygen of one carbonyl group. Two neutral complexes have been isolated,[7,8] from the reaction of palladium(II) with Hinaa, of identical composition, $Pd(inaa)_2$. Again IR and ^1H NMR spectroscopy have established that they are *cis* and *trans* isomers in which chelation of $inaa^-$ is the same as that in $Co(inaa)_3$. Table 1 shows the principal IR frequencies and ^1H chemical shifts of the iron(II) $inaa^-$ complex, together with those of $Co(inaa)_3$ and $Pd(inaa)_2$ for comparison. The close similarities suggest that the binding in $[Fe(inaa)_3]^-$ is the same as that in $Co(inaa)_3$ and $Pd(inaa)_2$, i.e. as in **2**. However, ion

2 can exist in two isomeric forms, *fac* and *mer* **3** and **4**. The two methyl groups of each ligand are in different environments (see **2**) and will give rise to two signals in the ^{1}H NMR spectrum. In the form $[Fe(inaa)_3]^-$ it is only the *fac* isomer which has the three ligands equivalent. The ^{1}H NMR spectrum of $[Fe(inaa)_3]^-$ in DMSO has signals (2.10 and 2.50 ppm) corresponding to only two methyl groups with no evidence of splitting, consistent with the complex existing as the *fac* isomer. This is the preferred form for the related ligands violurate (**5**) and isonitrosomalamide (**6**) in the salts ammonium tris(violurato)ferrate(II)[9] and potassium tris (isonitrosomalamido)ferrate(II),[10] established by X-ray crystallography.

The conversion of $[Fe(H_2O)_6]^{2+}$ into $[Fe(inaa)_3]^-$ must occur by stepwise replacement of water as a ligand and we investigated the kinetics of reaction in order to ascertain the rate-determining step. The appearance of the absorbance at 600 nm due to $[Fe(inaa)_3]^-$ on mixing an aqueous solution of an Fe^{II} salt with an alkaline solution of Hinaa occurred on the stopped-flow time scale. The kinetics of reaction were examined under pseudo first-order conditions with $inaa^-$ in excess over Fe^{2+}. Because of the possibility that changes in pH could affect the reaction rate the reaction mixture was buffered using Hinaa as its own buffer. For this a solution of Hinaa was partially neutralized with NaOH to give a buffer based on the conjugate acid–base pair Hinaa–$inaa^-$. From the measured pH of this buffer and the known[11] pK_a of Hinaa, we calculated the $inaa^-$ concentration in each solution. This was further varied by dilution of the buffer with 0.50 M KCl solution; this changed [$inaa^-$] but not the pH. The buffer was placed in one arm of a stopped-flow spectrophotometer, while the other contained 5×10^{-4} M iron(II) sulphate. On mixing, the absorbance at 600 nm, due to $[Fe(inaa)_3]^-$, appeared in a first-order manner and from this the pseudo first-order rate constant (k_{obs}) was calculated. The results are displayed in Table 2. A plot k_{obs} is curved but monotonic; at identical values of [$inaa^-$] the pH has essentially no effect on the value of k_{obs} and so we conclude that it is [$inaa^-$] rather than the pH, which controls the rate of complexation. Curvature in the plot of k_{obs} against [$inaa^-$] suggests a dependence at a power greater than unity and, in fact, a plot of k_{obs} against [$inaa^-$]^3 is linear with no intercept (Fig. 1). This is consistent with the slow step being substitution of water by the *third* $inaa^-$ ligand, with the previous two substitutions being equilibrium processes (Scheme 1).

Table 2. Kinetic data[a] for the reaction of $inaa^-$ and iron(II)[b] at 25°C

[a] I = 0.25 M.
[b] $[Fe^{2+}] = 2.5 \times 10^{-4}$ M.

The irreversible step (k_3 in Scheme 1) is not, of course, a single process. It can be broken down into three steps: (a) formation of complex **9**, (b) ligation by one end of the bidentate ligand $inaa^-$ with loss of one water molecule to give **10**, and (c) a second ligation with displacement of the final water molecule (Scheme 2). Step (a) is unlikely to be anything but fast. Also, it does not seem likely that (b), loss of the fifth water ligand to form complex **10**, will be slow as comparable reactions typically have rates

of the same order of magnitude as solvent exchange for labile species. Complexes in which some water ligands have been replaced are also generally subject to inductive labilization. Thus, we deduce that loss of the sixth water ligand and ring closure of $inaa^-$, k_c, is the rate-determining step. A similar scheme has been proposed[12] for the formation of $Fe(L)_3^{2+}$, where L is 1,10-phenanthroline or 2,2′-bipyridyl, from Fe^{2+} and the ligand in acid solution.

A notable feature in the formation of $[Fe(inaa)_3]^-$ is the change of spin state of iron during reaction; $Fe(H_2O)_6^{2+}$ is a d^6 high spin complex, and therefore kinetically labile, but as a diamagnetic species[5] $[Fe(inaa)_3]^-$ is a low spin, kinetically inert complex. By analogy[13] with the examples of $[Fe(phen)_2(H_2O)_2]^{2+}$ and $[Fe(phen)_3]^{2+}$, it is probable that the change to a low spin, diamagnetic complex occurs after complexation by the third $inaa^-$ ligand.

Although $inaa^-$ forms complexes with cobalt and palladium as well as iron(II) it was not possible to detect complex formation with ruthenium, nickel, copper, manganese or vanadium. Likewise, no reaction between iron(II) and 4-hydroxyimino-2,2,6,6-tetramethylheptane-3,5-dione in alkaline solution was detected, probably for steric reasons.

Scheme 2.

EXPERIMENTAL

Hinaa (**1**)[14] and 4-hydroxyimino-2,2,6,6-tetramethyl-3,5-dione[15] were made by literature methods. Sodium acetate (30 mmol) was added to a solution of $FeCl_2$ (10 mmol) and Hinaa (30 mmol) in water (20 cm^3). After heating at 45–50°C under an atmosphere of nitrogen for 30 min the resulting dark blue crystals were filtered off and washed several times with cold water. Found: C, 38.2; H, 3.8; N, 8.9. $Na[Fe(inaa)_3]$, $C_{15}H_{18}FeN_3NaO_9$ requires: C, 38.9; H, 3.9; N, 9.1%.

For the kinetic studies a Hi-Tech stopped-flow spectrophotometer was used. A solution containing Hinaa–$inaa^-$ was placed in one syringe and a solution of iron(II) in the other. The ionic strength was set at 0.25 M by the addition of KCl.

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, U.K.

(*Received* 25 *July* 1988; *accepted* 15 *August* 1988)

Abstract—The μ-alkylidyne dimetal complexes $[MFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ (M = Cr, Mo, or W) react with elemental sulphur or selenium yielding the heterobimetallic compounds $[MFe(\mu\text{-}\eta^2\text{-}ECC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ (E = S, Se). The complexes $[MFe(\mu\text{-}\eta^2\text{-}ECC_6H_3Me_2\text{-}2,6)(\mu\text{-dppm})(\mu\text{-CO})(CO)_2(\eta\text{-}C_5H_5)]$ (E = S, M = Cr or Mo; E = Se, M = W; dppm = bis(diphenylphosphino)methane) are obtained by treating the species $[MFe(\mu\text{-}\eta^2\text{-}ECC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ with dppm. The reaction between $[MoFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$ and selenium affords the μ_3-selenide complex $[MoFe_2(\mu\text{-}CC_6H_4Me\text{-}4)(\mu_3\text{-Se})(CO)_7(\eta\text{-}C_5H_5)]$.

Reactions between transition metal–alkylidene compounds and chalcogens often lead, via carbon–chalcogen bond formation, to complexes in which chalcoaldehyde or chalcoketone groups ligate a single metal centre,[1] or bridge metal–metal bonds.[2] This methodology has allowed the stabilization of the labile species $CH_2{=}E$ (E = S, Se or Te) within the coordination sphere of a metal ion.[1c,3]

The corresponding chemistry of alkylidyne–metal complexes has been less extensively studied as yet, however, parallels are emerging. Thus the osmium complex $[OsCl(\equiv CC_6H_4Me\text{-}4)(CO)(PPh_3)_2]$ reacts with chalcogens to give the compounds $[OsCl(\eta^2\text{-}ECC_6H_4Me\text{-}4)(CO)(PPh_3)_2]$ (E = S, Se or Te).[4] In contrast, the molybdenum and tungsten alkylidyne complexes $[M(\equiv CR)L_2(\eta\text{-}C_5H_5)]$ (M = Mo, R = CH_2Bu^t L = CO or $P(OMe)_3$; M = W, R = C_6H_4Me-4, L = CO) and $[W(\equiv CMe)(CO)_3\{H_2B(pz)_2\}]$ ($H_2B(pz)_2$ = dihydrobis(pyrazol-1-yl)borate) react with sulphur or selenium to give, respectively, the compounds $[Mo(\eta^2\text{-}E_2CCH_2Bu^t)L_2(\eta\text{-}C_5H_5)]$ (L = CO, E = S or Se; L = $P(OMe)_3$, E = S), $[W(\eta^2\text{-}E_2CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (E = S or Se)[5a] and $[W(\eta^2\text{-}S_2CMe)(CO)_3\{H_2B(pz)_2\}]$.[5b] In these syntheses there was no direct evidence for the intermediacy of mononuclear molybdenum or tungsten compounds containing η^2-ECR (E = S or Se, R = CH_2Bu^t, Me or C_6H_4Me-4) fragments. Thioacyl ligands exist, however, in the products $[MFe(\mu\text{-}\eta^2\text{-}SCC_6H_4Me\text{-}4)(CO)_5L]$ (M = Mo, L = η-C_5H_5 or $HB(pz)_3$ {hydrotris(pyrazol-1-yl)borate}; M = W, L = η-C_5Me_5) (**1**) of reactions between sulphur and the dimetal compounds $[MFe(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_{n+2}L]$ (M = Mo, n = 4, L = η-C_5H_5;[6a] n = 3, L = $HB(pz)_3$;[6b] M = W, n = 3, L = η-C_5Me_5),[6c] and in the complex $[WFe_2(\mu_3\text{-}\eta^2\text{-}SCMe)(CO)_8(\eta\text{-}C_5H_5)]$ (**2**), obtained by treating $[WFe_2(\mu_3\text{-}CMe)(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$ with sulphur.[7]

It was observed[7] that the latter reaction also affords the compound $[WFe_2(\mu\text{-CMe})(\mu_3\text{-S})(CO)_7(\eta\text{-}C_5H_5)]$ (**3a**), and that this μ_3-sulphido complex is formed when (**2**) is refluxed in THF (tetrahydrofuran). Interestingly, the reaction between selenium and $[WFe_2(\mu_3\text{-CMe})(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$ requires more vigorous conditions than that involving sulphur, and consequently the μ_3-selenido complex (**3b**) is the only isolable product. It seems likely, therefore, because of the ready conversion of (**2**) into (**3a**), that compound (**3b**) also forms via an intermediate μ_3-SeCMe complex akin to (**2**). Similarly, the compounds $[WFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$ and $[WFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-dppm})(\mu\text{-CO})(CO)_6(\eta\text{-}C_5H_5)]$ (dppm = $Ph_2PCH_2PPh_2$) react with sulphur or selenium to give the complexes (**3c**), (**3d**), (**4a**) and (**4b**), respectively.[7] It is probable that these products are also formed via species similar to (**2**) containing μ_3-η^2-ECC_6H_4Me-4 (E = S or Se) ligands. Thus the overall reaction is one in which bond formation occurs between the alkylidyne group and the chalcogen, but this is followed by

breakage of this bond with transfer of the alkylidyne ligand to an edge bridging site on the metal triangle.

In this paper we report the synthesis of several complexes in which μ-η^2-$ECC_6H_3Me_2$-2,6 groups span bonds between iron and chromium, molybdenum or tungsten. The new compounds were obtained from reactions between sulphur or selenium and the unsaturated 32 valence electron species $[MFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ (M = Cr, Mo or W).[8]

RESULTS AND DISCUSSION

The reaction between $[WFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ and sulphur in diethyl ether at room temperature affords in high yield the red complex $[WFe(\mu\text{-}\eta^2\text{-}SCC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ (**5a**), characterized by the data given in Tables 1 and 2. Similar reactions between sulphur and the compounds $[MFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ (M = Mo or Cr) yield the analogous molybdenum– and chromium–iron complexes (**5b**) and (**5c**), respectively. The products (**5a**)–(**5c**) are similar to the previously obtained dimetal species (**1**).[6] Moreover, the structure of (**1a**) was established by X-ray diffraction.[6a] It is noteworthy that the IR spectra of (**5a**) and (**5b**) in the carbonyl stretching region are very similar to those of (**1a**) and (**1c**). Thus for (**1c**),[6c] bands occur at 2039, 1975, 1964 and 1900 cm^{-1}, to be compared with those in the spectrum of (**5a**) (Table 1) at 2046, 1985, 1968 and 1902 cm^{-1}.

The ^1H and ^{13}C-$\{^1H\}$ NMR spectra of the compounds (**5a**)–(**5c**) show the expected signals (Table 2) for the formulations proposed. Thus whereas in the ^{13}C-$\{^1H\}$ NMR spectra of the precursors $[MFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ resonances for the μ-$CC_6H_3Me_2$-2,6 nuclei occur at δ 391.8 (W), 407.4 (Mo) and 438.5 ppm (Cr), these diagnostic signals for an alkylidyne–carbon nucleus are absent in the spectra of (**5a**)–(**5c**). However, in the spectra of (**5a**) and (**5c**) signals at δ 127.6 and 112.6 ppm, respectively, are assigned to the μ-$SCC_6H_3Me_2$-2,6 nuclei. No peak due to the bridgehead carbon was observed in the spectrum of (**5b**), probably due to an insufficiently concentrated solution for this weak signal to be observed. In the ^{13}C-$\{^1H\}$ NMR spectra of the related species (**1a**) and (**1c**) the resonances due to the ligating carbon of the thioacyl groups occur at δ 113.4[6a] and 95.6 ppm,[6c] respectively. The corresponding peak in the spectrum of the homonuclear dimetal complex $[Fe_2(\mu\text{-}\eta^2\text{-}SCC_{10}H_{15})(NO)(CO)_4(PPh_3)]$ occurs at 144.6 ppm.[9] Evidently these signals cover a wide range of chemical shifts.

(7c)	W	Se

In the CO region of their $^{13}C-\{^{1}H\}$ NMR spectra the compounds (**5a**)–(**5c**) show three peaks; two signals being due to the CO groups ligating the W, Mo or Cr atoms, and one being due to the $Fe(CO)_3$ fragment. The CO ligands of the latter evidently undergo rapid intramolecular site exchange on the NMR time-scale, a common property for this group.

An interesting feature of the reactions which afford (**5a**)–(**5c**) is the absence of any product containing the μ-$C(C_6H_3Me_2$-2,6)C(O)S fragment. The reaction between $[MoFe(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_6(\eta\text{-}C_5H_5)]$ and sulphur yields, in addition to (**1a**), the complex $[MoFe\{\mu\text{-}C(C_6H_4Me\text{-}4)C(O)S\}(CO)_5(\eta\text{-}C_5H_5)]$ (**6a**).[6a] Moreover, there is some evidence for the formation of the related species (**6b**), simultaneously with (**1b**), in the reaction between $[MoFe(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_5\{HB(pz)_3\}]$ and sulphur.[6b] The products (**6**) are assumed to form via attack of sulphur on an intermediate in which a μ-$C(C_6H_4Me$-4)C(O) ligand bridges the molybdenum–iron bonds. Dimetal compounds with μ-ketenyl groups have been implicated, or even in some instances isolated, in several reactions of carbonyl complexes containing bridging alkylidyne groups.[10]

As mentioned earlier, reactions between elemental selenium and the compounds $[WFe_2(\mu_3\text{-}CR)(\mu\text{-}CO)(CO)_8(\eta\text{-}C_5H_5)]$ (R = Me or C_6H_4Me-4) afford, respectively, the capping μ_3-selenido complexes (**3b**) and (**3d**), and no direct evidence of the existence of products containing μ-SeCR groups was obtained.[7] In contrast, the dimetal compounds $[MFe(\mu\text{-}CC_6H_3Me_2$-2,6)$(CO)_5(\eta\text{-}C_5H_5)]$ (M = W, Mo or Cr) react slowly with selenium in diethyl ether at room temperature to give the complexes $[MFe(\mu\text{-}\eta^2\text{-}SeCC_6H_3Me_2$-2,6)$(CO)_5(\eta\text{-}C_5H_5)]$ [M = W (**5d**), Mo (**5e**) and Cr (**5f**)], respectively. Data characterizing these products are given in Tables 1 and 2, from which it is evident that (**5d**)–(**5f**) are the selenium analogues of (**5a**)–(**5c**).

In the synthesis of (**5d**)–(**5f**) use of a low power ultrasound bath significantly decreased the time required for completion of the reaction, with no decrease in the yield. Moreover, because the preparation of the precursors $[MFe(\mu\text{-}CC_6H_3Me_2$-2,6)$(CO)_5(\eta\text{-}C_5H_5)]$ from the alkylidyne complexes $[M(\equiv CC_6H_3Me_2$-2,6)$(CO)_2(\eta\text{-}C_5H_5)]$ (M = W, Mo or Cr) proceeds in high yield,[8] it was possible to prepare (**5d**)–(**5f**) directly in a one-pot reaction from the mononuclear metal alkylidyne compounds. In this procedure, a second equivalent of

$[Fe_2(CO)_9]$ was employed to facilitate the removal of CO as $[Fe(CO)_5]$.

A feature common to the ^1H and $^{13}C-\{^1H\}$ NMR spectra of (**5a**)–(**5f**) is the presence of peaks indicating the chemical inequivalence of the two methyl groups of the $C_6H_3Me_2$-2,6 fragment. These molecules have no element of symmetry and, accordingly, diastereotopic Me group environments exist, even if rapid rotation about the μ-EC—C($C_6H_3Me_2$-2,6) bond occurs. This is distinct from the situation with the precursors $[MFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_5(\eta\text{-}C_5H_5)]$ which possess time-averaged mirror symmetry about the M(μ-C)Fe planes, and hence the Me_2-2,6 group gives rise to one resonance in both the ^1H and $^{13}C-\{^1H\}$ NMR spectra.[8]

Treatment of (**5b**) with dppm in toluene at reflux temperatures (*ca* 110°C) affords, after *ca* 48 h, the dimetal compound $[MoFe(\mu\text{-}\eta^2\text{-}SCC_6H_3Me_2\text{-}2,6)(\mu\text{-dppm})(\mu\text{-CO})(CO)_2(\eta\text{-}C_5H_5)]$ (**7a**) in high yield. Alternatively, complex (**7a**) may be obtained by treating $[MoFe(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(\mu\text{-dppm})(\mu\text{-CO})(CO)_2(\eta\text{-}C_5H_5)]$ (**8**) in toluene with sulphur; it being necessary to reflux the mixture for reaction to occur. Although only moderate yields of (**7a**) are obtained by this route, it is noteworthy that several other compounds containing dimetallacyclopropene ring structures, such as (**8**), react with sulphur with metal–metal bond cleavage to give the aforementioned mononuclear molybdenum or tungsten complexes $[M(S_2CR)(CO)_2(\eta\text{-}C_5H_5)]$ (M = Mo or W, R = C_6H_4Me-4). These dimetal species include $[MoMn(\mu\text{-CR})(CO)_4(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4Me)]$, $[Mo_3(\mu\text{-CR})_2(CO)_6(\eta\text{-}C_5H_5)_2]$[11] and $[WZr(\mu\text{-CR})(\mu\text{-}\sigma:\eta^2\text{-CO})(CO)(\eta\text{-}C_5H_5)_3]$.[12] Evidently the presence of the μ-dppm ligand in (**8**) prevents metal–metal bond rupture.

The compounds $[MFe(\mu\text{-}\eta^2\text{-}ECC_6H_3Me_2\text{-}2,6)(\mu\text{-dppm})(\mu\text{-CO})(CO)_2(\eta\text{-}C_5H_5)]$ [M = Cr, E = S (**7b**); M = W, E = Se (**7c**)] were prepared by treating (**5c**) with sulphur, and (**5d**) with selenium, respectively, in refluxing toluene. The data characterizing (**7a**)–(**7c**) (Tables 1–3) indicate that all three compounds are structurally similar. The IR spectrum in the carbonyl region for each compound reveals three bands, the absorption near 1800 cm^{-1} indicating the presence of a semi-bridging CO group. This feature is reflected in the $^{13}C-\{^1H\}$ NMR spectra (Table 2), since the relatively deshielded resonances at δ 251.3 (**7a**), 264.6 (**7b**) and 238.7 ppm (**7c**) may be assigned to this group. Moreover, these signals occur as doublets due to coupling with one ^{31}P nucleus. Peaks due to the μ-$ECC_6H_3Me_2$-2,6 nuclei could not be assigned in the spectra; these resonances are probably hidden under the many signals for the Ph and C_6H_3 moieties. The $^{31}P-\{^1H\}$ spectra (Table 3) each showed the expected two resonances, occurring as doublets [*J*(PP) *ca* 90 Hz]. The PFe signal occurs in the range δ 47.2–51.4 ppm, but the chemical shifts for the PM (M = Cr, Mo or W) resonances are more variable (δ 19.2–80.5 ppm), being increasingly deshielded in the order W < Mo < Cr. Not surprisingly the data for (**7a**) and (**8**) are very similar.

Interestingly, the compounds (**5d**)–(**5f**) are recovered unchanged after refluxing toluene solutions for several hours, and there was thus no evidence for C—Se bond cleavage leading to products with μ-Se and μ-$CC_6H_3Me_2$-2,6 groups. Two electron μ-selenido ligands are known in bimetallic chemistry,[13–15] as well as four electron μ_3-selenido groups in trimetallic systems.[7,16] The stability of the tetrahedrane M · Se · C · Fe cores in the compounds (**5d**)–(**5f**) may be due to the special properties of the bulky $C_6H_3Me_2$-2,6 substituent, since we have observed several examples of unusual structural phenomena associated with this group.[8,17] However, the thermal stability of (**5d**)–(**5f**) may be due to other factors discussed below.

As mentioned earlier, the trimetal compounds $[WFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$ and $[WFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-dppm})(\mu\text{-CO})(CO)_6(\eta\text{-}C_5H_5)]$ react with selenium to yield the compounds (**3d**) and (**4b**), respectively, via a pathway believed to involve the intermediacy of species containing μ_3-η^2-$SeCC_6H_4Me$-4 groups.[7] Unfortunately, the corresponding tungsten–diiron compounds with capping μ_3-$CC_6H_3Me_2$-2,6 fragments do not form,[8] and so whether or not with selenium they afford products with μ_3-η^2-$SeCC_6H_3Me_2$-2,6 ligands, or whether complexes with μ_3-Se and μ-$CC_6H_3Me_2$-2,6 groups, are produced, cannot be determined. To complete the earlier studies[7] we have investigated the reaction between selenium and $[MoFe_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(\mu\text{-CO})(CO)_8(\eta\text{-}C_5H_5)]$. In diethyl ether at room temperature, these reagents afford the μ_3-selenido complex $[MoFe_2(\mu\text{-}CC_6H_4Me\text{-}4)(\mu_3\text{-Se})(CO)_7(\eta\text{-}C_5H_5)]$ (**3e**). The spectroscopic data for (**3e**) (Tables 1 and 2) are very similar to those of (**3d**). Thus (**3e**) shows in its IR spectrum CO bands at 2057, 2015, 1995, 1977, 1954 and 1854 cm^{-1}, to be compared with those in the spectrum of (**3d**) at 2053, 2011, 1989, 1973, 1951 and 1862 cm^{-1}. A resonance at δ 344.5 ppm in the $^{13}C-\{^1H\}$ NMR spectrum of (**3e**) is diagnostic for the presence of a μ-CC_6H_4Me-4 nucleus bridging two metal centres. The corresponding peak in the spectrum of (**3d**) occurs at δ 318.5 ppm.[7]

The formation of (**3e**) under such mild conditions, compared with those required for the synthesis of (**3d**), necessitating heating the reagents in THF, is surprising. If, as seems likely, (**3d**) and (**3e**) form via intermediates structurally similar to

Table 1. Analytical[a] and physical data for the complexes

[a] Chemical shifts (δ) in ppm, coupling constants in Hz. Measurements at ambient temperatures, in $CDCl_3$ unless otherwise indicated.
[b] ^{1}H decoupled, chemical shifts are positive to high frequency of $SiMe_4$.
[c] Signal for bridgehead μ-C nucleus not observed.
[d] In CD_2Cl_2.

Table 3. ^{31}P NMR data[a]

Compound	$^{31}P(\delta)$
(**7a**)	51.4 [d, FeP, J(PP) 96], 44.3 [d, MoP, J(PP) 96]
(**7b**)	80.5 [d(br), CrP, J(PP) 85], 47.2 [d(br), FeP, J(PP) 85]
(**7c**)	48.9 [d, FeP, J(PP) 90], 19.2 [d, WP, J(PP) 90, J(WP) 76]
(**8**)	53.3 [d, FeP, J(PP) 93], 39.9 [d, MoP, J(PP) 93]

[a] ^1H decoupled, chemical shifts (δ) in ppm to high frequency of 85% H_3PO_4 (external), coupling constants in Hz. Measurements at room temperature, in CD_2Cl_2. No corrections made for roof effects.

(**2**), but containing μ_3-η^2-$SeCC_6H_4Me$-4 groups, it may be that Se—C (or S—C) bonds cleave more readily when E—CR fragments occupy triply bridging sites on a metal triangle, rather than when they are part of a tetrahedrane structure as in the compounds (**5**).

EXPERIMENTAL

All experiments were carried out under nitrogen using Schlenk tube techniques. Solvents were rigorously dried before use. Light petroleum refers to that fraction of b.p. 40–60°C. IR spectra were measured with Nicolet MX10 and MX5 FT spectrometers, and NMR spectra were recorded with JNM FX 90Q, GX 270 and GX 400 instruments. The compounds [M(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (M = W, Mo or Cr) were prepared as described previously,[8] as was the complex [$MoFe_2(\mu_3$-CC_6H_4Me-4)$(\mu$-CO)$(CO)_8(\eta$-$C_5H_5)$].[18] The chalcogens used were in the form of resublimed sulphur and grey selenium. The compound [$MoFe(\mu$-$CC_6H_3Me_2$-2,6)$(\mu$-dppm)$(\mu$-CO)$(CO)_2(\eta$-$C_5H_5)$] (**8**) was synthesized by the method used to obtain the tungsten analogue.[8] The compound [$MoFe(\mu$-$CC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (1.50 g, 3.16 mmol) and dppm (1.21 g, 3.16 mmol) were stirred in Et_2O (100 cm^3) for 20 min. Solvent was removed *in vacuo* and the residue dissolved in CH_2Cl_2 (3 cm^3) and light petroleum (12 cm^3) and chromatographed on a water-cooled column (3 × 30 cm) packed with alumina. Eluting with the same solvent mixture removed a small amount of starting material which was discarded. The second and major green fraction which was eluted was concentrated under reduced pressure to *ca* 5 cm^3 and cooled to *ca* −78°C (dry ice) to afford the product (**8**) as dark green *microcrystals* (1.86 g), characterized by the data given in Tables 1–3.

Preparation of the complexes [$MFe(\mu$-η^2-$ECC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (M = W, Mo *or* Cr; E = S *or* Se)

The preparations of the compounds (**5**) were similar and hence only details of two syntheses are given.

(i) A Et_2O (50 cm^3) solution of [$WFe(\mu$-$CC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (0.50 g, 0.88 mmol) and sulphur (0.05 g, 1.60 mg atom) was stirred for 4 h, and then volatile material was removed *in vacuo*. The residue was dissolved in a mixture of CH_2Cl_2 (6 cm^3) and light petroleum (4 cm^3) and chromatographed on a water-cooled Kieselgel column (*ca* 3 × 30 cm), eluting with the same solvent mixture. The major red eluate was collected, and the solvent was reduced in volume *in vacuo* to *ca* 6 cm^3. Cooling to *ca* −78°C afforded red *microcrystals* of [$WFe(\mu$-η^2-$SCC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (**5a**) (0.86 g).

The compounds [$MFe(\mu$-η^2-$SCC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] [M = Mo (**5b**, 0.41 g) or Cr (**5c**, 0.44 g)] were similarly prepared from [$MFe(\mu$-$CC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (M = Mo or Cr), respectively.

(ii) A suspension of [W(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (0.50 g, 1.85 mmol) and [$Fe_2(CO)_9$] (1.42 g, 3.9 mmol) in Et_2O (75 cm^3) was stirred for 15 h. The solvent and resultant [$Fe(CO)_5$] (**CAUTION**) were removed *in vacuo*. The residue was treated with selenium (0.20 g, 2.50 mg atom) and Et_2O (75 cm^3), and the mixture was stirred for 15 h. Solvent was removed *in vacuo*, and the residue extracted with a mixture of CH_2Cl_2 (6 cm^3) and light petroleum (14 cm^3). The extracts were chromatographed on a water-cooled Kieselgel column (*ca* 3 × 30 cm), eluting with the same solvent mixture. Initial eluates containing iron carbonyl were discarded, and the major orange fraction was collected. Solvent was reduced in volume *in vacuo* to *ca* 4 cm^3, and the solution was cooled to −78°C to yield orange *microcrystals* of [$WFe(\mu$-η^2-$SeCC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] (**5d**) (0.42 g).

Similar treatment of [M(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (M = Mo or Cr) gave the compounds [MFe(μ-η^2-$SeCC_6H_3Me_2$-2,6)$(CO)_5(\eta$-$C_5H_5)$] [M = Mo (**5e**, 0.46 g) or Cr (**5f**, 0.52 g)], respectively.

Preparation of the complexes [MFe(μ-η^2-$ECC_6H_3Me_2$-2,6)(μ-dppm)(μ-CO)$(CO)_2(\eta$-$C_5H_5)$] (M = Mo *or* Cr, E = S; M = W, E = Se)

(i) A representative synthesis was as follows. A toluene (20 cm^3) solution of (**5b**) (0.10 g, 0.20 mmol) and dppm (0.08 g, 0.20 mmol), contained in a Schlenk tube fitted with a high-pressure stopcock, was heated at 110°C in an oven for 48 h. After cooling to room temperature, solvent was removed *in vacuo*. The residue was dissolved in a mixture of Et_2O (10 cm^3) and light petroleum (10 cm^3), and the solution was chromotographed on a water-cooled Kieselgel column. Elution with the same solvent mixture removed an orange–red eluate, which was concentrated *in vacuo* to *ca* 3 cm^3. Cooling to −78°C afforded orange *microcrystals* of [MoFe(μ-η^2-$SCC_6H_3Me_2$-2,6)(μ-dppm)(μ-CO)$(CO)_2(\eta$-$C_5H_5)$] (**7a**) (0.16 g).

Similar treatment of (**5c**) with sulphur, and (**5d**) with selenium, afforded the compounds [CrFe(μ-η^2-$SCC_6H_3Me_2$-2,6)(μ-dppm)(μ-CO)$(CO)_2(\eta$-$C_5H_5)$] (**7b**) (0.14 g) and [WFe(μ-η^2-$SeCC_6H_3Me_2$-2,6)(μ-dppm)(μ-CO)$(CO)_2(\eta$-$C_5H_5)$] (**7c**) (0.15 g), respectively.

(ii) A THF (50 cm^3) solution of (**8**) (0.14 g, 0.17 mmol) and sulphur (0.05 g, 1.6 mg atom), contained in a Schlenk tube fitted with a high-pressure stopcock, was heated at 70°C in an oven for 5 days. After cooling to room temperature, solvent was removed *in vacuo*, and the residue was dissolved in a mixture of Et_2O (4 cm^3) and light petroleum (16 cm^3) and chromatographed on a water-cooled Kieselgel column (*ca* 2 × 50 cm). The column was eluted with a mixture of Et_2O and light petroleum (1:1). The initial brown–yellow eluate was discarded. Further elution with Et_2O–light petroleum (8:1) removed an orange fraction. Solvent was removed from the latter *in vacuo*, and the residue was crystallized from hexane (5 cm^3) at −78°C to afford orange *microcrystals* of [MoFe(μ-η^2-$SCC_6H_3Me_2$-2,6)(μ-dppm)(μ-CO)$(CO)_2(\eta$-$C_5H_5)$] (**7a**) (0.11 g).

Synthesis of the compound [$MoFe_2$(μ-CC_6H_4Me-4)(μ_3-Se)$(CO)_7(\eta$-$C_5H_5)$]

A Et_2O (50 cm^3) solution of [Mo(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] (0.32 g, 1.00 mmol) and [$Fe_2(CO)_9$] (0.78 g, 2.20 mmol) was stirred at room temperature for 15 h. All volatile material was removed *in vacuo* (**CAUTION** [$Fe(CO)_5$]) leaving [$MoFe_2$(μ_3-CC_6H_4Me-4)(μ-CO)$(CO)_8(\eta$-$C_5H_5)$][18] as the residue. The latter was dissolved in Et_2O (50 cm^3) and treated with selenium (0.20 g, 2.50 mg atom), the mixture being stirred for 72 h. Solvent was removed *in vacuo*, and the residue was extracted twice with a mixture of CH_2Cl_2 (6 cm^3) and light petroleum (14 cm^3). The combined extracts were chromatographed on a water-cooled alumina column (*ca* 3 × 30 cm). Elution with the same solvent mixture gave a dark brown fraction from which solvent was removed *in vacuo*. The residue was crystallized from hexane (5 cm^3) at −78°C to give brown *microcrystals* of [$MoFe_2$(μ-CC_6H_4Me-4)(μ_3-Se)$(CO)_7(\eta$-$C_5H_5)$] (**3e**) (0.26 g).

POTENTIOMETRIC STUDIES ON THE MIXED LIGAND COMPLEXES IN SOLUTION: M^{II}–TETRACYCLINE–GLYCINE SYSTEMS

MAHMOUD A. GHANDOUR, H. A. AZAB,* AHMED HASSAN and A. M. ALI

Department of Chemistry, Faculty of Science, Asiut University, Asiut, Egypt

(*Received* 11 *July* 1988; *accepted* 15 *August* 1988)

Abstract—The interaction of Be, Mg, Ca, Sr and Ba ions with tetracycline was followed by pH-metry and stability constants were determined for the chelates containing 1 : 1 ratio of ligand to metal ion at $t = 25°C$ and $\mu = 0.1$ mol dm^{-3} ($NaNO_3$), for the above mentioned metals except Be where 1 : 1 and 2 : 1 complexes were detected. The protonation constants of tetracycline were also determined under the same conditions. The stability constants of the 1 : 1 complexes formed decrease in the order Be > Mg > Ca > Sr > Ba. Potentiometric equilibrium measurements have been made under the same conditions for the interaction of tetracycline and Be, Mg, Ca, Sr, Ba, Cu and Zn with the biologically important secondary ligand (glycine) in a (1 : 1 : 1) ratio. The $\Delta \log K$ values

$$[\Delta \log K = \log k^{M(TC)}_{M(TC)(gly)} - \log K^{M}_{M(gly)}]$$

were interpreted on the basis of statistical considerations and the nature of species formed in solution.

Among the most important broad-spectrum antibiotics are the members of the tetracycline family. The phenomenon of complex formation between tetracycline analogues and various cations is well documented.[1–12] Metal ion complex formations are among the prominent interactions in nature,[13–15] and the glycine residue is an important and versatile binding site of protein while tetracycline is equally important as an antibiotic. For an improved understanding of the driving forces leading to mixed-ligand complexes in biological systems, ternary complexes of the type M^{II}–TC–glycine, where M = Ca, Mg, Cu or Zn, have been investigated to determine the stability constants of the complexes formed. Although Be, Sr and Ba interactions with tetracycline and/or glycine are of little interest, since these metal ions are not normally present in the human body, these systems were studied for comparison.

EXPERIMENTAL

Calvin–Bjerrum's technique as adopted by Irving and Rossotti[16] was used to determine the protonation constants of the ligands (tetracycline and glycine) and formation constants of the metal complexes at 25°C in aqueous solutions.

pH Measurements were carried out on a Corning 601A precision research ionalyzer digital pH meter. During the titrations, oxygen-free nitrogen was bubbled through the solution. The electrode system was calibrated in terms of hydrogen-ion concentrations instead of activities. Thus, all constants determined in this work are concentration constants. The solutions of Mg, Ca, Sr, Ba, Cu and Zn (AR, BDH) as nitrates were prepared and titrated complexometrically by EDTA. AR beryllium sulphate solution was prepared and standardized as recommended. Tetracycline was obtained as the hydrochloride and used without purification as fresh solutions in bidistilled water.

In the binary systems studied, the following solutions were titrated potentiometrically against standard carbonate-free sodium hydroxide (0.1 mol dm^{-3}) solution:

(a) 0.01 mol dm^{-3} HCl,

(b) **(a)** + 0.01 mol dm^{-3} tetracycline hydrochloride,

(c) **(b)** + 2.5×10^{-3} mol dm^{-3} metal nitrate solution.

*Author to whom correspondence should be addressed.

In ternary systems studied, numerous titrations of different M^{II}/tetracycline and/or glycine mixtures in 1:1:1 molar ratio (1×10^{-3} mol dm^{-3}, for each) were performed. The solutions titrated can be represented according to the following scheme:

HCl (**a**);
HCl + tetracycline (**b**);
HCl + tetracycline + M^{II} (**c**);
HCl + glycine (**d**);
HCl + glycine + M^{II} (**e**);
HCl + tetracycline + glycine + M^{II} (**f**).

The total volume was adjusted to 50 cm^3 by adding double-distilled water in each case. The titrations were performed at 25°C and $\mu = 0.1$ mol dm^{-3} ($NaNO_3$).

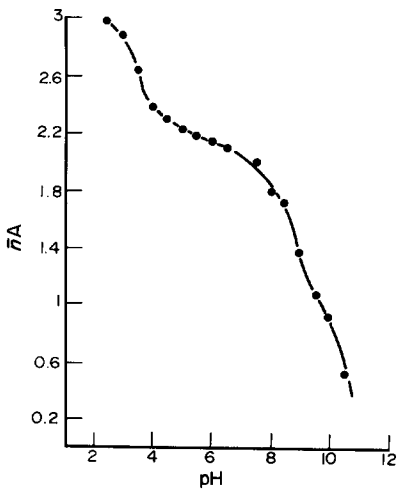

Fig. 2. Proton–tetracycline formation curve.

RESULTS AND DISCUSSION

Representative titration curves are shown in Fig. 1. The values of $\bar{n}_A$ as determined by the method of Irving and Rossotti[16] were compiled from the titration data using solutions (**a**) and (**b**). Calculations of proton ligand association constants were carried out by plotting a graph of $\bar{n}_A$ against pH (Fig. 2). The values of log K_1^H, log K_2^H and log K_3^H (the first, second and third proton association constants of tetracycline, respectively) are the pH values corresponding to $\bar{n}_A = 0.5$, 1.5 and 2.5, respectively. The values of log K_1^H, log K_2^H and log K_3^H (Table 1) agree quite well with those previously reported.[4]

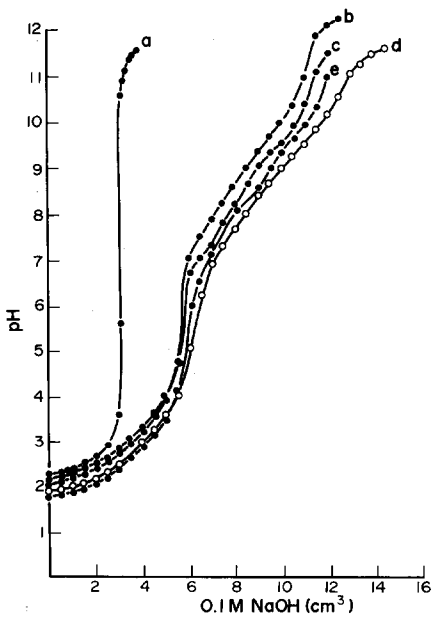

Fig. 1. Titration curves of (a) 0.01 M HCl + 0.1 M $NaNO_3$, (b) mixture (a) + 0.01 M tetracycline hydrochloride, (c) mixture (b) + 2.5×10^{-3} M Ba^{2+}, (d) mixture (b) + 2.5×10^{-3} M Be^{2+} and (e) mixture (b) + 2.5×10^{-3} Mg^{2+} with 0.1 M NaOH; total volume 50 cm^3.

The titration curves of the metal–ligand solutions (**c**) are well separated from the ligand solution (**b**) (Fig. 1.) Thus, replacement of H^+ ions is due to complexation. From these titration curves, $\bar{n}$ (average number of ligand molecules attached per metal ion) and pL (free ligand exponent) values were calculated.[16] The $\bar{n}$ values were plotted against the corresponding pL values to get the formation curves of the metal complexation equilibria. The formation curves are shown in Fig. 3. From these formation curves, the values of stability constants listed in Table 1 were determined using the half-integral method.[16] Only 1:1 ligand/metal complexes were formed between Mg, Ca, Sr and Ba ions and tetracycline. Be reacts with tetracycline to give 1:1 and 2:1 ligand/metal complexes. In particular Be may well display different titration and formation curves (cf. Figs 1 and 3) support to the formation of hydroxo complexes.

For alkaline earth metal ions studied, the stability constants of the 1:1 complexes formed with tetracycline decrease in the order of "ionic potential" (or polarizing power), which is defined as formal charge/ionic radius. Thus, the corresponding stability constants decrease in the order: Be > Mg > Ca > Sr > Ba.

Figures 4, 5 and 6 represent typical titration curves for the different M^{II}–TC–glycine systems studied. It is observed that the M^{II}–TC titration curve (c) diverges from TC curve (b) at different pH values (pH ~ 3.2 for Mg, pH ~ 2.6 for Cu and pH ~ 4.5 for Zn) denoting the formation of M^{II}–TC binary complexes. For the titration curves of the ternary systems studied, one observes that the (c, f) however overlap with each other at lower pH values in case of Mg and Cu, while that for Zn is

Cation	$\log K_1^H$	$\log K_2^H$	$\log K_3^H$	M(TC) $\log K_1$	M(TC) $\log k_2$	M(gly) $\log K_1$	$\log K^{M(TC)}_{M(TC)(gly)}$	$\log B^{M}_{M(TC)(gly)}$	$\Delta \log K$
H^+	10.46	8.50	3.36	—	—	—	—	—	—
Be				9.50	3.9	6.80	3.80	13.30	−3.00
Mg				8.40	—	3.30	4.20	12.60	+0.90
Ca				7.90	—	4.60	4.10	12.00	−0.50
Sr				7.10	—	3.20	3.80	10.90	+0.60
Ba				4.00	—	3.50	3.80	7.80	+0.30
Cu				8.60	—	7.00	4.60	13.20	−2.40
Zn				4.30	—	5.90	9.00	13.30	+3.10

well separated. This indicates the formation of Zn–TC–glycine at lower pH values which may be considered as evidence for the formation of a protonated tetracycline mixed ligand complex.

The stability constants of the ternary metal ion complexes containing tetracycline and glycine were calculated for eq. (1) from the data obtained from potentiometric pH titrations:

$$M(TC) + gly \rightleftharpoons M(TC)(gly), \quad (1)$$

$$K^{M(TC)}_{M(TC)(gly)} = \frac{[M(TC)(gly)]}{[M(TC)][gly]}$$

[$I = 0.1$ mol dm^{-3} ($NaNO_3$); 25°C]. Similarly, the constants of the binary complexes (eqs 2 and 3) were also determined

$$M + TC \rightleftharpoons M(TC), \quad (2)$$

$$K^{M}_{M(TC)} = \frac{[M(TC)]}{[M][TC]}$$

$$M + gly \rightleftharpoons M(gly), \quad (3)$$

$$K^{M}_{M(gly)} = \frac{[M(gly)]}{[M][gly]}$$

It is assumed, for convenience, that complexation of the secondary ligand (glycine) starts after the complete formation of the M^{II}/tetracycline 1:1

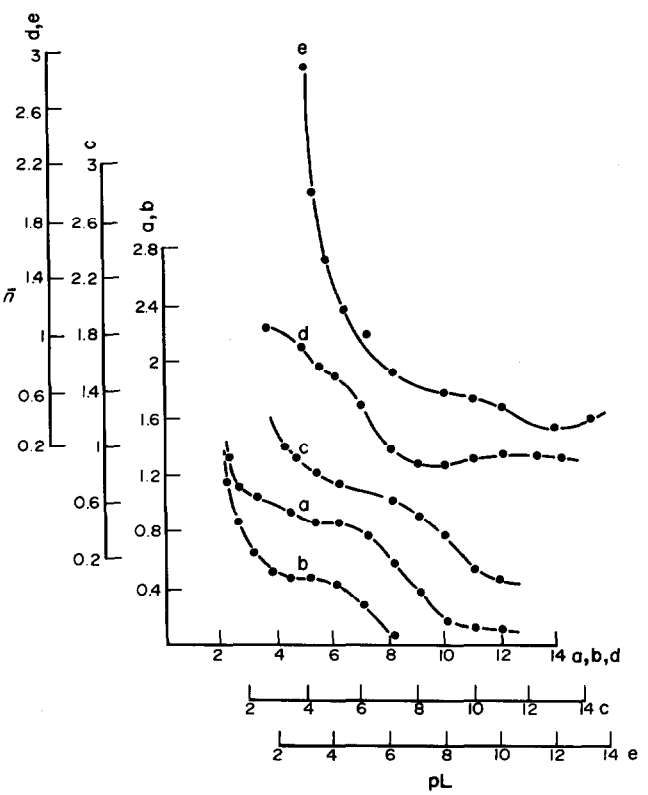

Fig. 3. Alkaline earth metal ion–tetracycline formation curves, (a) Mg^{2+}–TC, (b) Ba^{2+}–TC, (c) Ca^{2+}–TC, (d) Sr^{2+}–TC and (e) Be^{2+}–TC.

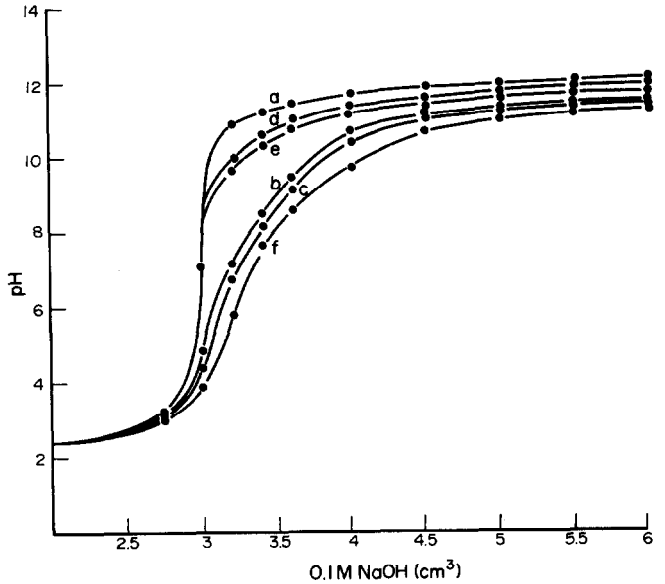

Fig. 4. Titration curves for the Mg^{II}–TC–glycine system.

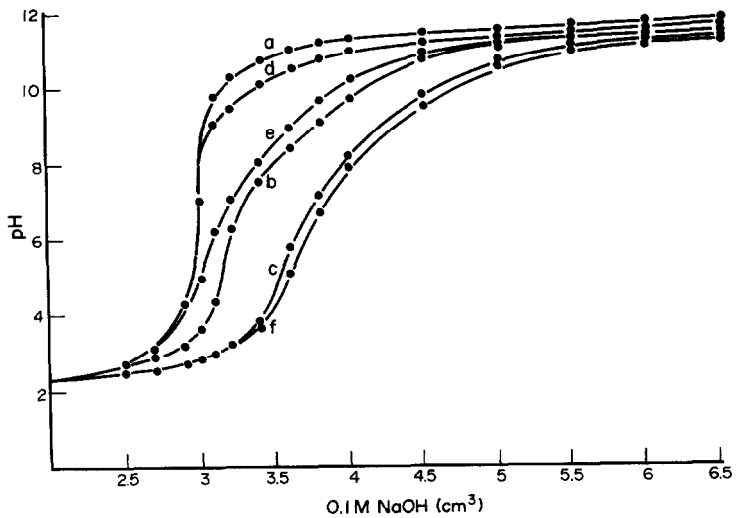

Fig. 5. Titration curves for the Cu^{II}–TC–glycine system.

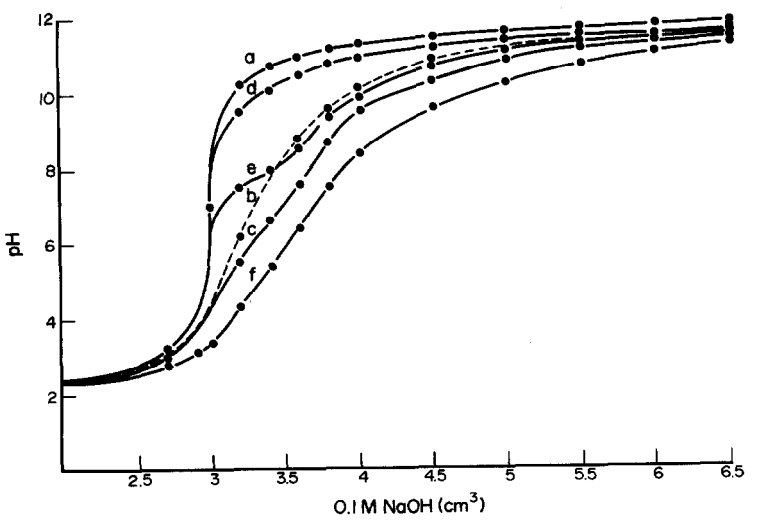

Fig. 6. Titration curves for the Zn^{II}–TC–glycine system.

complex. Thus, the overall stability constant $\beta^{M}_{M(TC)(gly)}$ may be represented by eq. (4):

$$M + TC + gly \rightleftharpoons M(TC)(gly), \qquad (4)$$

$$\beta^{M}_{M(TC)(gly)} = \frac{[M(TC)(gly)]}{[M][TC][gly]} = K^{M(TC)}_{M(TC)(gly)} \times K^{M}_{M(TC)}.$$

At the experimental pH values used in the calculation in this work the interfering effects of hydroxo complexes are negligible. Thus, the secondary ligand, glycine, combines with the binary 1 : 1 metal/tetracycline complex in a similar manner to its interaction with aquated metal ions in solutions. The horizontal distance between curves (c) and (f) can be measured and used for the calculation of $\bar{n}_{mix}$ (average number of secondary ligand molecules associated with one [M(TC)] ion). The equation used for the calculation of $\bar{n}_{mix}$ will be the same as in the original paper[16]

$$\bar{n}_{mix} = \frac{(V_f - V_c)[N^0 + E^0 + T^0_L(y - \bar{n}_H)]}{(V_0 + V_c)\bar{n}_H T^0_M}. \qquad (5)$$

In eq. (5), T^0_M is the concentration of [M(TC)] which is equal to the concentration of M^{II} used; y = number of dissociable protons of glycine ($y = 1$); values of $\bar{n}_H$, for the secondary ligand at different pH values, were calculated from the amino acid formation curve. All other symbols have their usual meanings. From the values of $\bar{n}_{mix}$ so obtained, free secondary ligand exponent, pL'_{mix} was calculated using the equation,

$$pL'_{mix} = \log\left(\frac{\sum_{n=0}^{j} \beta^H_n \left(\frac{1}{10^B}\right)^n}{T^0_L - \bar{n}_{mix} T^0_M} \times \frac{V_0 + V_f}{V_0}\right), \qquad (6)$$

where

β = second formation constant value of glycine,
B = the pH-meter reading.

The second formation constant of glycine was determined from the titration curves (a, d) using the Rosotti and Irving formula.[16] The obtained value (9.70) is in a good agreement with literature value.[17] The stability constants determined in this work for Mg, Cu or Zn complexes of glycine, agree well with literature values.[18,19] The disagreement found for the values of Ba, Ca or Sr complexes of glycine, may be attributed to the different ionic strengths and methods used for determination.[18,20] The stability constants of the Cu and Zn complexes of tetracycline agree with the values found in literature.[2]

Formation curves corresponding to the various mixed ligand M^{II}–TC–glycine systems were obtained by ploting $\bar{n}_{mix}$ vs pL'_{mix}. Representative results are shown in Fig. 7. The corresponding formation constants $\log K^{M(TC)}_{M(TC)(gly)}$ obtained by the average value method are reported in Table 1. $\Delta\log K$, defined by eq. (7), is a measure of the stability of the ternary complexes with respect to

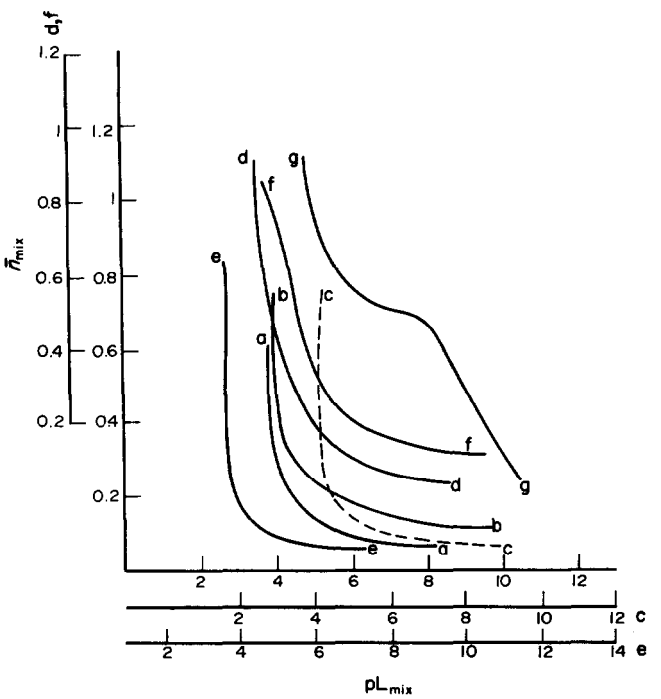

Fig. 7. M^{II}–TC–glycine formation curves (a) Be^{II}, (b) Mg^{II}, (c) Ca^{II}, (d) Sr^{II}, (e) Ba^{II}, (f) Cu^{II}, (g) Zn^{II}.

the binary complexes,

$$\Delta\log K = \log K^{M(TC)}_{M(TC)(gly)} - \log K^{M}_{M(gly)}. \quad (7)$$

In the case of M^{II}–TC–glycine systems, where M^{II} = Mg, Ca, Sr or Ba, $\Delta\log K$ is found to be slightly positive or negative (Table 1) in accordance with statistical expectations.[21] In the ternary complex systems, the two oxygen atoms of the phenolic B-diketone moiety of the tetracycline molecule form σ-bonds with the metals. In addition to this there exists a tendency for a $M \rightarrow O$ π-interaction due to back donation of electrons from the metal π-orbital to the vacant delocalized π-orbital over the phenolic B-diketone moiety of the tetracycline molecule. As a result of this back donation the concentration of electrons around the metal ion in M^{II}–TC does not increase significantly and the electronegativity of the metal ion in this species remains almost the same as in the aquated metal ion. This justifies the small values of $\Delta\log K$. The strong covalent bond formed between Be and the tetracycline molecule may disfavour the formation of the ternary complex Be–TC–glycine. The $\Delta\log K$ value for this system is negative in accordance with the statistical considerations[14] where the statistical, steric and electrostatic factors result in a lower stability constant for the 1:1:1 metal/ligand complexes as compared with those for the binary systems.

The higher stability constant of Zn–TC–glycine ternary complex compared with the binary system may be attributed to the difference in the nature of the species formed in solution. The Zn–TC–glycine system involves a protonated binary species MHTC in acidic medium whereas the Cu ions form a ternary complex through the interaction with the neutral binary species MTC with the secondary ligand. The Zn–TC–glycine system is more stable due to extra hydrogen bonding of the proton with oxygen atom of the secondary ligand molecules.

Tetracycline hydrochloride LH_3^+ Cl^-, has three sites and the protons may be dissociated from these sites in proportions which vary with the degree of neutralization. These sites are shown in Fig. 8 as the amide system (A), the phenolic B-diketone moieties (B) and (B′), and the dimethyl-ammonium cation (c): The first dissociation constant pK_1^H is generally attributed to site (A).[22,23] Stephens *et al.*[22] have assigned the second and the third dissociation constants, pK_2^H and pK_3^H, to site (C) and the combined (B) and (B′) system, respectively, while Lesson *et al.*[23] reverse these assignments in the case of protonated tetracycline, considering a complete dissociation scheme for all. Sachan[5] suggested that pK_2^H is due to system (B). Doluisio and Martin[1] concluded that the chelation occurs through the co-ordination of the nitrogen atom of the dimethylamino group at C_4 and the oxygen atom of the hydroxyl group either at C_3, or at C_{12_a}. On the basis of absorption spectra, Conover[24] concluded that the normal site for metal binding by tetracycline is the enolized B-diketone group at C_{11} and C_{12}, i.e. group (B′) in Fig. 8. According to Baker and Brown,[25] on the basis of reflectance spectra, the dimethylamino group does not take part in the co-ordination, and the chelation is through oxygen atoms, probably in system (A). Sachan[5] concluded that the co-ordination sites of the TC are the oxygen atoms of system (B).

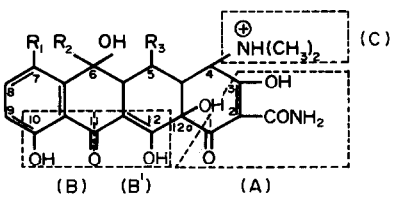

Fig. 8.

Thus, there is lack of agreement as to the assignment of the site of co-ordination. The following considerations may be suggested.

(a) Albert[26] pointed out that only the functional group having a dissociation constant of approximately 7.0 undergoes ionization when chelation takes place.

(b) The presence of an OH group at C_3 suggests that the complexation of metal ions with TC should be independent of pK_1^H, and consequently the complexing species should not be LH_2.[6]

(c) Covalent forces, rather than electrovalent forces, are dominating in the phenol–B-diketone system and in the dimethyl ammonium group between O and H atoms at C_{10} and between N and H atoms at C_4, respectively.[4] From these we may assume that the complexation of alkaline earth metal ions as well as Cu and Zn with tetracycline takes place through the pK_2^H value of the antibiotic, and that the complexing species were LH^- for these systems. Formation of Zn–TC–glycine complex which starts at lower pH values may take place through the pK_1^H value of tetracycline and the complexing species may be LH_3^+. Considering that metal complexation may be involved in the antibacterial activity[27–29] and that the phenolic group in tetracycline[30] is responsible for part of its antibacterial activity, then that may be considered as a further support for our conclusion.

SPECTROPHOTOMETRIC STUDY OF THE COMPLEXATION EQUILIBRIA AND THE DETERMINATION OF PALLADIUM(II) WITH 4-(5′-METHYL-3′-ISOXAZOLYLAZO)-RESORCINOL

J. P. PÉREZ TRUJILLO,* Z. SOSA and J. J. ARIAS*

Department of Analytical Chemistry, University of La Laguna, 38204 La Laguna, Spain

(*Received* 15 *July* 1988; *accepted* 15 *August* 1988)

Abstract—The complexation equilibria between Pd^{II} and 4-(5′-methyl-3′-isoxazolylazo)-resorcinol (MIAR) have been studied and the existence of the species PdH_2R^{2+}, $PdHR^+$, PdR and $PdOHR^-$ have been established; the acid dissociation constants for the first three are $pK_{121a} = 2.65 \pm 0.16$, $pK_{111a} = 7.09 \pm 0.15$ and $pK_{101a} = 9.57 \pm 0.20$. The ternary complex Pd^{II}–MIAR–hexamine has also been studied. A new method for the determination of 0.4–4.0 ppm Pd ($\varepsilon = 1.8 \times 10^4$ l mol^{-1} cm^{-1}) has been developed and applied to samples of hydrogenation catalysts.

Hetero-azo phenols based on pyridine and thiazole have been widely used as reagents for palladium[1–3] although in most cases little attention has been given to the study of the corresponding equilibria in solution. However, the system Pd^{II}–4-(2-pyridylazo)-resorcinol (PAR) has been investigated in some detail.

Thus, Busev and Ivanov[4] detected the formation of two complexes, a green one extractable into ethyl-acetate and formed in 0.35–5 M sulphuric acid medium, and a red one formed at pH 7. Flaschka and Hicks[5] showed that the green complex can only be extracted in the presence of chloride ions. Saxena *et al.*[6] indicated that as least three complex species are formed: at pH 2.0 an unstable green 1 : 1 species, and at pH 3.7–5.0 and 5.6–12.2, two red complexes with a stoichiometry of 1 : 1 and 3 : 2, respectively, these complexes change their colour and/or composition as a function of the pH. Yotsuyanagi *et al.*[7] studied the acid–base equilibria among the different complexes and establishing the existence in solution of four 1 : 1 species: a green one $[Pd(H_2R)H_2O]^{2+}$ at pH < 4, a cationic red species $[Pd(HR)H_2O]^+$ and a neutral red species $[Pd(R)H_2O]$ in the pH region 4–7, and an anionic red species $[Pd(R)OH]^-$ at pH > 8, attributing the spectral changes to proton dissociation from the *o*- and *p*-hydroxyl groups and the molecule of water bonded to the forth coordination site of the square planar structure of the Pd^{II} complexes.

On the other hand, Vostova and Sommer[8] investigated the complexation equilibria of Pd^{II} with various hetero-azo derivatives, one of which was TAR.

In the present work, a study of the complexation equilibria in the system Pd^{II}–MIAR by spectrophotometric methods is presented with a view to contribute to the knowledge of the chemistry of palladium with hetero-azo compounds.

EXPERIMENTAL

4-(5′-Methyl-3′-isoxazolylazo)-resorcinol (MIAR), 10^{-3}M solution in absolute ethanol.[9] Standard 10^{-2} M solution of palladium perchlorate, prepared from the chloride by perchloric acid treatment, and standardized by AAS. The ionic strength, *I*, of the solution was kept constant at 0.1 M ($NaClO_4$). Hexamine–perchloric acid buffer solution, pH 6.5.

Analytical reagent grade chemicals and demineralized water were used throughout with no further purification.

The pH measurements were made with a radiometer PHM64 digital pH-meter with glass–calomel combination electrode. Absorption measurements were made with a Hitachi Perkin–Elmer 200 recording spectrophotometer provided with 1-cm matched quartz cells. A selecta vibromatic mechanical shaker was used. Measurements were made at 25 ± 0.1°C. Calculations were made on a Digital VAS/VMX 11/780 (V.4.0) computer.

Extraction—spectrophotometric determination of palladium

To the solution under study, containing 4–40 μg of palladium, 4 cm^3 of 10^{-3} M MIAR and 1 cm^3 of pH 6.5 hexamine–$HClO_4$ buffer solution were added and made up to 10 cm^3 with demineralized water. This solution was shaken with 10 cm^3 of chloroform for 45 min, centrifuged, and the absorbance of the organic layer at 490 nm was measured against a reagent blank.

Determination of palladium in hydrogenation catalysts

A 0.50 g sample of the catalyst was dissolved by treatment with perchloric acid, nitric acid, aqua regia or EDTA, according to the catalyst support, heating if necessary. The solution was diluted and made up to volume with 1 M perchloric acid in a 100 cm^3 standard flask. An aliquot was analysed for palladium according to the procedure described previously.

RESULTS AND DISCUSSION

Complexation equilibria in the Pd^{II}–MIAR system

Pd^{II} and MIAR react to give different colours according to the C_{Pd}/C_R ratio and the pH of the medium. Thus, in equimolar solutions (Fig. 1) a green colour is formed at pH < 3, and has an absorption maximum at 427 nm; at pH > 3, the colour is red, with an absorption band at 465–495 nm, which continuously increases in height as the acidity of the medium is decreased. In solutions containing excess of MIAR (Fig. 2) the colour is yellow, with a maximum at 365 nm and an absorption band centred at 495 nm at pH < 4.5; at pH 6–9 two new maxima appear, at 380 and 440 nm that coalesce as the pH increases, to give way at pH 11 to a well-defined maximum at 460 nm.

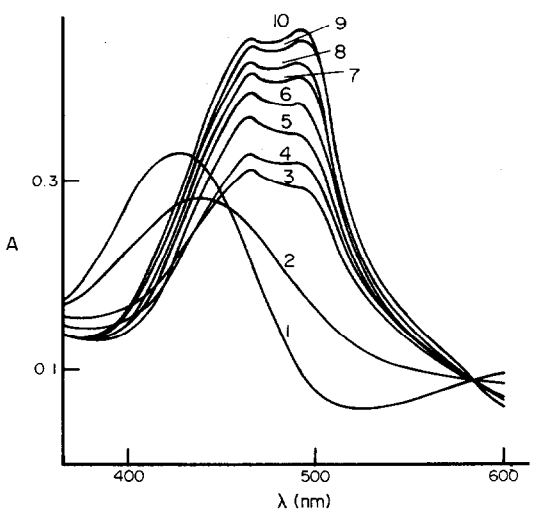

Fig. 1. Absorption spectra of the system Pd^{II}–MIAR; $C_R = C_M = 2 \times 10^{-5}$ M; $I = 0.1$ M ($NaClO_4$); 20%(v/v) ethanol–water, pH (1) 0.93; (2) 2.58; (3) 3.58; (4) 4.50; (5) 5.70; (6) 7.25; (7) 8.54; (8) 9.52; (9) 10.52; (10) 11.08.

The absorbance (A)–pH curves obtained at 427, 440, 450 and 495 nm for different C_{Pd}/C_R ratios (Fig. 3) confirm the existence of different species in solution, depending on the pH and the C_{Pd}/C_R ratio.

Determination of the stoichiometry by the continuous variations and mole ratio methods, applied at pH 1.0, 4.2, 7.2 and 9.5 and at 427, 440 and 495 nm, indicate the presence of 1:1 and 1:2 Pd/R complexes.

Accordingly it can be assumed that the variation of the absorbance observed in the pH region 1–4 for $C_{Pd}/C_R = 1$ corresponds to the acid–base equilibrium between the green and red Pd/R 1:1 species, and the progressive increase in absorbance at pH > 6 may be due to deprotonation and/or hydrolysis of the red species. The change in absorbance at pH 1.5–3.5 when excess of reagent is present ($C_{Pd}/C_R = 1:2$) is observed only at 495 nm (curve 4) and is analogous to that observed for $C_{Pd}/C_R = 1$, but is of lesser magnitude; the change is even smaller $C_{Pd}/C_R = 0.1$. This can be interpreted as

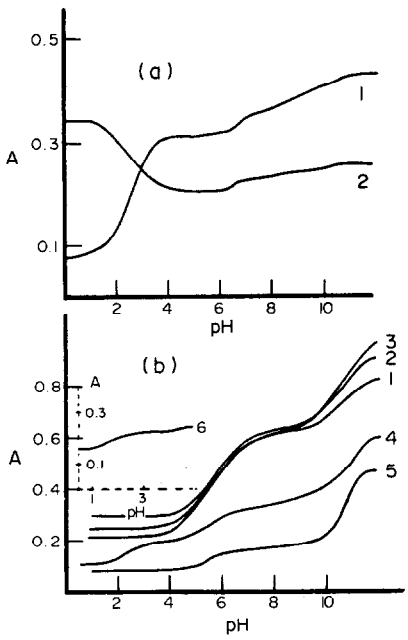

Fig. 3. Absorption–pH curves for the system Pd^{II}–MIAR (a) $C_R = C_M = 2 \times 10^{-5}$ M; $I = 0.1$ M ($NaClO_4$); 20%(v/v) ethanol–water. λ = (1) 495 nm; (2) 427 nm. (b) $C_R = 2C_M = 4 \times 10^{-5}$ M; $I = 0.1$ M ($NaClO_4$); 20%(v/v) ethanol–water. λ = (1) 427 nm; (2) 440 nm; (3) 450 nm; (4) 495 nm; (5) reagent, $\lambda = 440$ nm; (6) $C_R = 10C_M$, $\lambda = 495$ nm.

due to the presence of complexes with 1 : 1 and 1 : 2 Pd/R stoichiometry, when the reagent is in excess, while for the $C_{Pd}/C_R = 1$ only complexes of 1 : 1 Pd/R stoichiometry exist.

The simultaneous presence of species with different stoichiometry in solutions with excess of reagent makes the study of the corresponding equilibria practically impossible either by graphical or numerical calculation methods. Therefore, only the study of the A–pH curves obtained for the equimolar ratio and in excess of palladium has been undertaken in this work.

Assuming that the transition between the green and red 1 : 1 species is caused by an acid–base equilibrium, the method of Sommer *et al.*[10] for graphical analysis of the A–pH curves was used, to calculate the transition constant, from which $pK_a = 2.70 \pm 0.13$ is calculated and it is deduced that one proton is released during the transition from the green to the red species. The non-existence of well-defined zones in the rest of the A–pH curve makes its graphical analysis impossible.

The A–pH curve for the equimolar solution was next analysed by applying the LETAGROP–SPEFO program[11,12] for which the curve was divided into two steps: the first at pH 1–4.5, corresponding to the green–red transition, and the second at pH 5–12. The results in Table 1, indicate that for the first step the best fit with the experimental data is obtained when a single proton is interchanged, and for the second step when two protons are successively interchanged. The data obtained in the joint analysis of the entire experimental A–pH curve are also included in Table 1.

All the above leads to the conclusion that in the pH region 1–12, in equimolar solutions, the system Pd–MIAR presents three acid–base equilibria and four complex species related to each other by the following equilibria:

Table 1. Values of U,[a] $\sigma(A)$[b] and pK_a for the different species calculated by the LETAGROP–SPEFO method

Species	U	$\sigma(A)$	pK_a	ε (l mol^{-1} cm^{-1})	
			$1 < pH < 4.5$	$\lambda = 427$	490

in accordance with Yotsuyanagi.[7]

Equilibria in the system Pd^{II}*–MIAR–hexamine*

In equimolar solutions of MIAR and Pd^{II} with excess of hexamine (2%) present, the formation at pH < 3 of a green complex (λ_{max} = 430 nm) is observed. At pH 3–9 the colour changes to red, with an absorption band at 465–495 nm, which decreases slightly in intensity at pH > 9. In excess of reagent, C_{Pd}/C_R = 1:2 (2% hexamine), a green colour is observed at pH 1, with an absorption band at 360–430 nm, and the colour changes to red as the acidity of the medium is decreased; at pH 4 there is a maximum at 365 nm and a band at 465–495 nm which coincides with that of the complex formed in equimolar solution; at pH > 9 a new maximum appears at 460 nm, which at pH > 12 coincides with that of the binary complex in the absence of hexamine.

The absorbances are independent of ionic strength when this is $> 10^{-2}$ M, and decrease according to nature of the anion of the electrolyte employed for this purpose in the sequence $ClO_4^- > NO_3^- > Cl^- > Br^-$.

The *A*–pH curves (Fig. 4) show a transition in the pH region 1.5–4.5, analogous to observed in the absence of hexamine (Fig. 3) and the fact that the spectra when reagent excess is present do not indicate the formation of new species points to the transition of the green ternary complex to the red one with loss of the *o*-OH proton of the reagent and to the presence of hexamine molecules co-ordinated to Pd(II), hindering the formation of 1:2 Pd/R complexes. At Ph > 10 and equimolar reactant ratio, a slight decrease in absorbance is observed, attributable to the dissociation of the proton of the *p*-OH group. The formation of hydroxylated species is hindered by the hexamine molecule bonded to the fourth co-ordination site in the square planar Pd^{II} complex. In contrast, when reagent excess is present a sharp increase in absorbance appears which does not correspond to the absorbance sum for the ternary complex and the excess of reagent. Since, moreover, at these pH values the spectra coincide with those of the binary complex, it is thought that deprotonation of the *p*-OH group of the ternary compound, ionization of the excess of reagent and transition between the ternary complex and the 1:2 Pd/R binary complex, occur simultaneously.

The stoichiometry, determined by the usual methods, at pH 4.2 and 7.2 and at 470 and 490 nm (2% hexamine), indicates a 1:1 Pd/R ratio. However, the number of molecules of hexamine forming part of the complex could not be established, it being found only that a 50-fold excess of hexamine with respect to the palladium present is necessary for the absorbance readings to reach a plateau. However, the co-ordinating possibilities of Pd^{II} point to the possible formation of a 1:1:1 Pd/R hexamine complex.

In accordance with the above it can also be assumed that the variation in absorbance that is produced in the first step of the *A*–pH curves is caused by an acid–base equilibrium between the green and red ternary complexes, of the type:

$$Pd(H_2R)(\text{hexamine}) \underset{\text{green}}{\overset{K_t}{\rightleftharpoons}}$$

$$Pd(H_yR)(\text{hexamine}) + qH^+, \quad (y = 2-q).$$
$$\text{red}$$

Analysis of these *A*–pH curves by the method of Sommer *et al.* gave a mean value of $pK_t = 2.75 \pm 0.02$. The application of the LETAGROP–SPEFO program to the experimental data affords the best fit for the system formed by the species $Pd(H_2R)$(hexamine) and Pd(HR)(hexamine) with release of a proton, and $pK_t = 2.70 \pm 0.03$ ($U = 0.270 \times 10^{-3}$; $\sigma = 0.003$). A comparison with the data included in Table 1 shows the good agreement of the data obtained here for K_t with the value for the binary complex, which seems to indicate that the molecule of hexamine

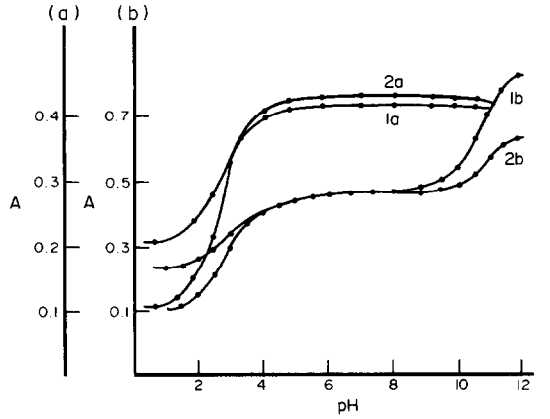

Fig. 4. Absorption–pH curves for the system Pd^{II}–MIAR–hexamine. I = 0.1 M ($NaClO_4$); 20%(v/v) ethanol–water; |hexamine| = 2%. (a) $C_R = C_M = 2 \times 10^{-5}$ M; (b) $C_R = 2C_M = 4 \times 10^{-5}$ M; λ = (1) 470 nm; (2) 490 nm.

co-ordinated to palladium in the ternary complex influences the first transition equilibrium.

Because the variation in the absorbance in the second step of the A–pH curve for Pd/R = 1 was very small, neither graphical nor numerical analysis was applied to it.

Extraction of the red Pd–*MIAR–hexamine complex into chloroform*

With a view to increasing the sensitivity and/or selectivity of the determination of palladium with MIAR, it seemed worthwhile to combine formation of the complexes with their extraction into organic solvents.

Preliminary tests has indicated that both free reagent and ternary complex were extractable with different organic solvents, chloroform giving better and more stable absorbance readings after 45 min of mechanical shaking. Neither the 1 : 1 nor the 1 : 2 Pd/R complexes are extracted, but form precipitates at the interphase. In any case, the ternary complex must be formed in the aqueous phase and then extracted into chloroform, since if a solution of MIAR in chloroform is used as the extractant the kinetics of the process is so slow that the method would not be of any practical interest.

The wavelength of the absorption maximum and the value of the absorbance of the spectra in organic phase are dependent on the anion of the inert electrolyte. The absorbance decreases in the sequence $ClO_4^- > NO_3^- > Cl^- > Br^-$. Using 0.1 M $NaClO_4$ as inert electrolyte the Pd–MIAR–hexamine complex shows an absorption maximum at 490 nm and is extracted in the pH range 4–9 (Fig. 5) coinciding with the region of predominance of the species $[Pd(HR)(hexamine)]^+$ in the aqueous phase. The presence of ethanol (4–20%) in the aqueous medium is necessary in order to facilitate the extraction.

The stoichiometry of the extracted species determined by the usual methods, at pH 6.5 and 490 nm,

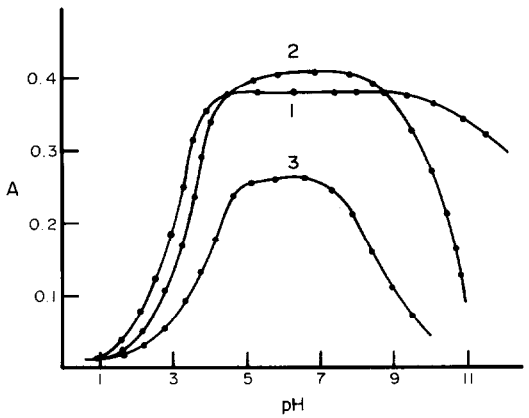

Fig. 5. Extraction curve for the system Pd^{II}–MIAR–hexamine as a function of the pH of the homogeneous phase. $I = 0.1$ M ($NaClO_4$); 10%(v/v) ethanol–water; $\lambda = 490$ nm; (1) $C_R = C_M = 2 \times 10^{-5}$ M, |hexamine| = 2%; (2) $C_R = 5C_M = 1 \times 10^{-4}$ M, |hexamine| = 2%; (3) $C_R = C_M =$ |hexamine| $= 2 \times 10^{-5}$ M.

indicates a 1 : 1 Pd/R ratio. However, the number of molecules of hexamine forming part of the complex could not be established, it being found only that a 20-fold excess of hexamine with respect to the palladium present is necessary for the absorbance reading to reach a plateau.

In accordance with the above information it can be assumed that the extracted species is the ionic couple:

$$[Pd(HR)(hexamine)]^+ClO_4^-.$$

Spectrophotometric determination of palladium

Table 2 presents a summary of the characteristics of the spectrophotometric methods developed, based on (a) the formation of the yellow complex $[Pd(HR)_2]$ in homogeneous medium; (b) the formation of the ternary complex $[Pd(HR)(hexamine)]^+$ in homogeneous medium and (c) the extraction of the latter into chloroform. As can

Table 2. Characteristics of the different methods developed for the determination of palladium

Species	pH	λ_{max} (nm)	ε (l mol^{-1} cm^{-1})	Beer (ppm)	Ringbom (ppm)
$Pd(H_2R)$	1	485	8500	0.42–6.3	2.13–5.3
$[Pd(HR)U]^a$	7.2	490	20,700	0.20–4.2	0.85–4.2
$[Pd(HR)U]^b$	6.5	490	18,300	0.40–4.0	0.85–3.8

U: Hexamine.

[a] Homogeneous phase.

[b] Extraction into chloroform.

be observed the extractive–spectrophotometric method not only maintains the sensitivity of the method based on the formation of the ternary complex in homogeneous solution, which turn is twice as sensitive as the method based on the formation of the binary yellow complex.

The statistical study, for the extractive-spectrophotometric method, carried out on ten samples, each containing 2.13 ppm of Pd^{II}, gave 2.123 ppm as the mean value, 0.016 ppm as the standard deviation and 0.5% as the relative error ($P = 0.05$).

The effect of several ions on the determination of 2.13 ppm palladium, was studied by application of the recommended procedure. The criterion for interference was a deviation of more than 2% between the palladium concentration found and that taken. The ions F^-, Cl^-, Br^-, SCN^-, Cd^{2+}, Ca^{2+}, Mg^{2+}, La^{3+} and Zn^{2+} can be present up to 100:1 $C_x:C_{Pd}$ ratio, Ba^{2+} and Al^{3+} up to 25:1; Ru^{3+}, Pt^{2+} and Au^{3+} up to 1:1 and Cu^{2+}, Co^{2+} and Ni^{2+} interfere even in the 1:1 ratio, but can be present in 50:1 ratio when the spectrophotometric method at pH 1 is used.

The method developed was applied to the determination of palladium in samples of hydrogenation catalysts: Pd–asbestos (4.26% Pd), Pd–carbon activo (4.56% Pd), Pd–$CaCO_3$ (5.14% Pd), Pd–Al_2O_3 (4.60% Pd) and Pd–$BaSO_4$ (3.88% Pd) with recoveries of 4.23, 4.34, 5.03, 4.75 and 3.99%, respectively, as mean values of three determinations.

η^3-ALLYL COMPLEXES OF MOLYBDENUM—IV.* PREPARATION AND CRYSTAL STRUCTURES OF SOME SUBSTITUTED-CYCLOPENTADIENYL MOLYBDENUM ALLYL DERIVATIVES

O. ANDELL,† R. GODDARD, S. HOLLE, P. W. JOLLY,‡ C. KRÜGER and Y. H. TSAY

Max-Planck-Institut für Kohlenforschung, D-4330 Mülheim a. d. Ruhr, F.R.G.

(*Received* 13 *July* 1988; *accepted* 25 *August* 1988)

Abstract—A series of substituted-cyclopentadienyl molybdenum allyl derivatives has been prepared by reacting $(\eta^3\text{-}C_3H_5)_3MoCl$ with substituted-cyclopentadienyl and -indenyl alkali metal salts. In general, the isolated products are of the type $Cp'Mo(\eta^3\text{-}C_3H_5)_2$ and in three cases this has been confirmed by crystal structure determinations. Spectroscopic evidence suggests that at low temperatures compounds have the composition $Cp'Mo(\eta^3\text{-}C_3H_5)_2(\eta^1\text{-}C_3H_5)$ are also formed. The reaction with potassium fluorenyl is anomalous: the NMR spectra and a crystal structure determination show that the product (η^3-fluorenyl)Mo $(\eta^3\text{-}C_3H_5)_3$, contains four η^3-allyl groups bonded unsymmetrically to the metal atom.

The dormancy in the chemistry of tetra(η^3-allyl) molybdenum was interrupted after *ca* twenty years with the isolation of $(\eta^3\text{-}C_3H_5)_3MoCl$ (**1**) from the reaction with gaseous HCl in pentane at $-70°C$ [eq. (1)] and this compound has been used to prepare a series of η^3-allyl molybdenum complexes.[1–3]

One of the more interesting reactions studied has been that with sodium cyclopentadienide from which the paramagnetic complex $CpMo(\eta^3\text{-}C_3H_5)_2$ (**2**) could be isolated and its structure and electron deformation density determined by X-ray methods.[4]

$$(\eta^3\text{-}C_3H_5)_4Mo \xrightarrow[-C_3H_6]{HCl} \underset{\mathbf{1}}{(\eta^3\text{-}C_3H_5)_3MoCl} \xrightarrow[-NaCl/[C_3H_5]]{NaCp} \underset{\mathbf{2}}{CpMo(\eta^3\text{-}C_3H_5)_2} \quad (1)$$

Although these results have considerably extended the chemistry of the allyl molybdenum system, the compounds have proved rather unreactive, (**2**), in particular, (in contrast to the related chromium compound)[5] shows no remarkable reactivity in either stoichiometric or catalytic reactions. There are two obvious approaches for improving the situation—the introduction of substituents either into the cyclopentadienyl ring or the allyl group. Here we report the synthesis of a series of substituted-cyclopentadienyl and -indenyl molybdenum allyl complexes and a subsequent publication will be devoted to their reactions.

RESULTS AND DISCUSSION

The substituted-cyclopentadienyl and -indenyl molybdenum allyl compounds shown in Table 1 have been prepared in 60–80% yield by reacting $(\eta^3\text{-}C_3H_5)_3MoCl$ (**1**) with the appropriate alkali metal salt in THF at *ca* $-30°C$. With a few exceptions (see below), the products are of the type $Cp'Mo(\eta^3\text{-}C_3H_5)_2$ e.g. [eq. (2)].

(2)

The compounds are in general orange–red solids and are thermally stable at room temperature. The anticipated and observed paramagnetism (one unpaired electron, Table 1) prevented the use of NMR-spectroscopy to obtain useful structural information and since it was not clear how the indenyl system would bond to the metal (η^3-, η^5- or even η^6- situations are conceivable), we have undertaken crystal structure determinations of the compounds containing the 2-methylindenyl, 2-methoxyindenyl and 5,6-dimethoxyindenyl groups: in all cases the indenyl derivative is bonded in an η^5- manner (see discussion below).

The product of the analogous reactions between $(\eta^3\text{-}C_3H_5)_3WCl$ and CpNa is $CpW(\eta^3\text{-}C_3H_5)_2C_3H_5$ and contains both η^1- and η^3-allyl groups and, moreover, this compound shows no tendency to react further with loss of an allyl group.[6] This apparent difference in the behaviour of the molybdenum and tungsten systems (which we attribute to a difference in the strength of the M—C bonds involved) encouraged us to study the reactions involving molybdenum at even lower temperatures and indeed spectroscopic evidence suggests that initially a species is generated which contains an η^1-allyl group. For example, by carrying out the

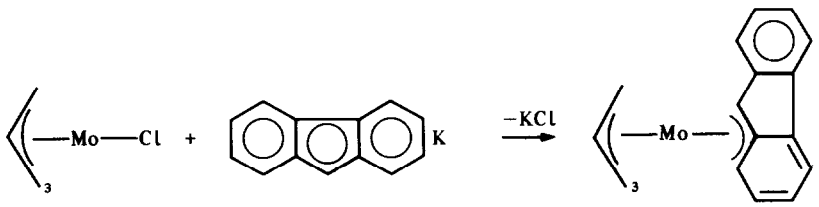
reaction with indenyl–lithium in ether at −78° and washing the product repeatedly with pentane at −78°C, it is possible to obtain a small amount of a relatively insoluble red–violet material whose IR spectrum (KBr, −78°C) suggests the presence of an η^1-allyl group ($\nu_{C:C}$1640, 910 cm^{-1}) while the ^{1}H-NMR spectrum (D_8-THF, −78°C) although not completely interpretable is that of a diamagnetic species and shows absorptions compatible with the presence of a vinyl group ($\delta_{HC:}$ *ca* 5.9–5.8 m,br, 4.3 d, 4.1 dd; for comparison, the vinyl protons in (t-$C_4H_9C_5H_4$)W(η^3-C_3H_5)$_2C_3H_5$ are found at 5.68 m, 4.33 d and 4.23 dd ppm[6]). Similar absorptions are observed in the low temperature IR spectra of the products of the reaction with t-$C_4H_9C_5H_4Li$ ($\nu_{C:C}$1635, 908 cm^{-1}) and CpLi ($\nu_{C:C}$1640, 912 cm^{-1}) and are absent from the spectra of the related Cp$Mo(\eta^3$-$C_3H_5)_2$ and (indenyl)$Mo(\eta^3$-$C_3H_5)_2$ species.

In the case of the reaction with 5,6-dimethoxyindenyl lithium, the IR spectrum and elemental analysis indicate that the major component containing an η^1-allyl group ($\nu_{C:C}$1622, 905 cm^{-1}) is stable at room temperature and here repeated washing has also enabled a sample to be isolated whose ^{1}H-NMR spectrum suggests the presence of a vinyl group ($\delta_{HC:}$ 5.9–5.8 m,br, 4.26 d, 4.13 d) although the broadness of the signals suggests contamination by paramagnetic material (the structure of what is presumably the minor component, viz. (η^5-5,6-dimethoxyindenyl)$Mo(\eta^3$-$C_3H_5)_2$, is presented below). The elemental analysis of the product of the reaction with 2-phenylindenyl lithium suggests that this compound should also be formulated as (2-phenylindenyl)$Mo(C_3H_5)_3$ in agreement with the observed diamagnetism. Unfortunately, we were unable to prepare sufficient of this compound for an NMR-spectoscopic study or to obtain suitable crystals for an X-ray diffraction study so that we cannot decide whether this compound should be formulated as (η^3-2-phenylindenyl)$Mo(\eta^3$-$C_3H_5)_3$ (see the fluorenyl compound discussed below) or (η^5-2-phenylindenyl)$Mo(\eta^3$-$C_3H_5)_2C_3H_5$. The analytical data for the product of the reaction with 1-$CyCH_2$indenyl lithium lies between that expected for tris-allyl and bis-allyl systems, so that presumably a mixture of the two species is formed.

To summarize, with the exception of the 2-phenylindenyl and 5,6-dimethoxyindenyl derivatives mentioned above, the main product of the reaction between (η^3-$C_3H_5)_3MoCl$ and the substituted-cyclopentadienyl or -indenyl derivatives at *ca* −30° are the paramagnetic compounds of the type Cp′$Mp(\eta^3$-$C_3H_5)_2$ while at −78° these are contaminated with Cp′$Mo(\eta^3$-$C_3H_5)_2C_3H_5$ systems.

The reaction with fluorenyl potassium takes a different course: a purple, diamagnetic compound is formed which has the composition (fluorenyl)$Mo(\eta^3$-$C_3H_5)_3$. The crystal structure determination (see below) and the NMR spectral data (see Experimental) indicate that the fluorenyl group is acting as an η^3-organic ligand and that the molecule, in addition, contains three η^3-C_3H_5-groups [eq. (3)].



(3)

All fifteen H-atoms of these three groups are magnetically inequivalent indicating that they are asymmetrically bonded to the metal atom. Particularly remarkable in the ^{1}H-NMR spectrum is the difference in the chemical shifts of the *meso*-H-atoms: two have "normal" values of *ca* 4 ppm whereas one experiences a high field shift to 0.22 ppm. We assign this signal to the *meso*-H-atom which lies above the fluorenyl plane (H-21, see crystal structure). The allylic H-atoms of the fluorenyl group give rise to a singlet at 6.14 ppm (9′) and a doublet at 4.35 ppm (1′) while the remaining fluorenyl H-atoms are assigned to four doublets and three triplets lying between 8.35 and 7.05 ppm.

CRYSTAL STRUCTURE DETERMINATIONS

The molecular structure of three substituted-indenyl molybdenum derivatives viz. (η^5-2-methylindenyl)$Mo(\eta^3$-$C_3H_5)_2$ **(I)**, (η^5-2-methoxyindenyl) $Mo(\eta^3$-$C_3H_5)_2$ **(II)** and (η^5-5,6-dimethoxyindenyl)$Mo(\eta^3$-$C_3H_5)_2$ **(III)**, as well as of (fluorenyl)$Mo(\eta^3$-$C_3H_5)_3$ **(IV)** have been determined by single crystal X-ray diffraction methods and are shown in Figs 1 and 2. Selected bond distances and bond angles and interplanar angles are summarized in Tables 1 and 2.

The molybdenum atom in the three substituted-indenyl derivatives is bonded to the five membered ring in an η^5-manner. In the case of the 5,6-dimethoxyindenyl derivative, the unit cell contains two

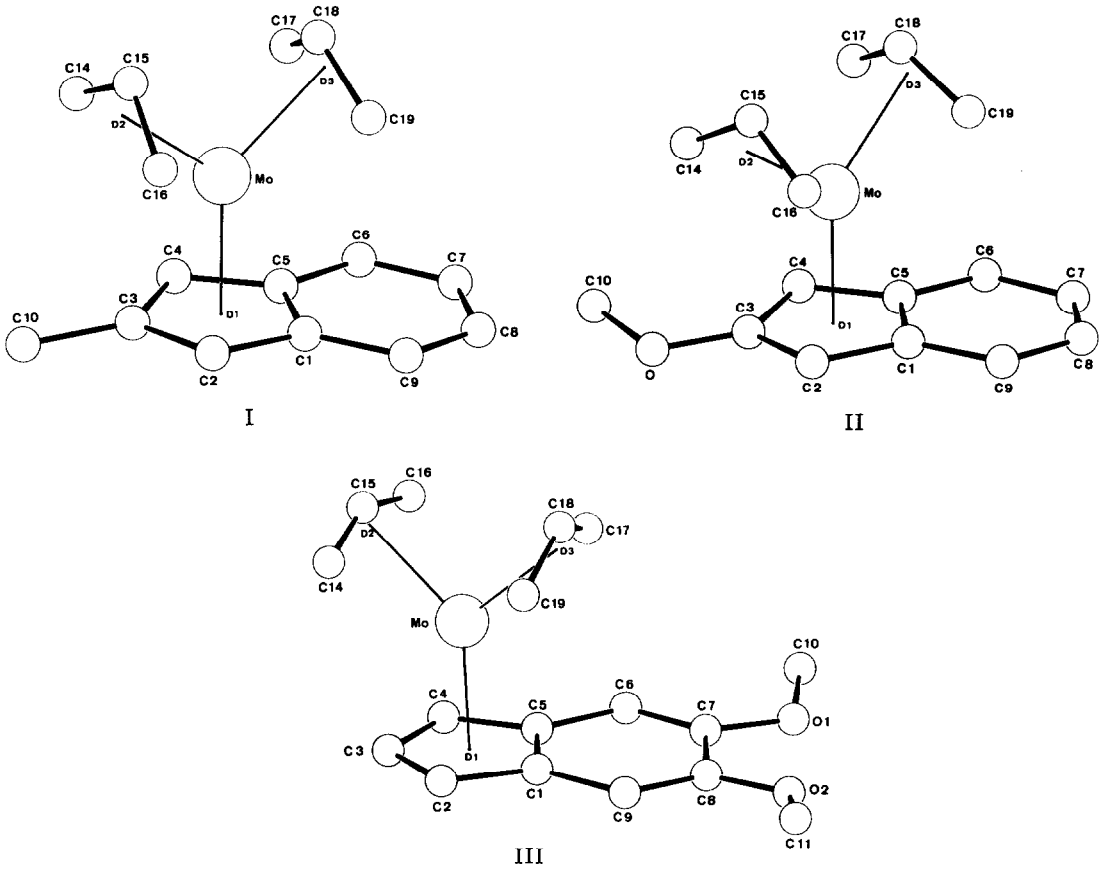


Fig. 1. The molecular structures of $[(\eta^5\text{-2-methylindenyl})Mo(\eta^3\text{-}C_3H_5)_2]$ (**I**), $[(\eta^5\text{-2-methoxyindenyl})Mo(\eta^3\text{-}C_3H_5)_2]$ (**II**) and $[(\eta^5\text{-5,6-dimethoxyindenyl})Mo(\eta^3\text{-}C_3H_5)_2]$ (**III**).

independent molecules but the poor quality of the data (Table 2) precludes any further discussion. The structure of the 2-methylindenyl and 2-methoxyindenyl derivatives are similar to that observed for $(\eta^5\text{-}C_5H_5)Mo(\eta^3\text{-}C_3H_5)_2$[2] with the metal lying in a trigonal planar environment. The allyl groups are arranged in a non-parallel, *cis*-configuration with the *meso*-C-atoms directed away from the metal.

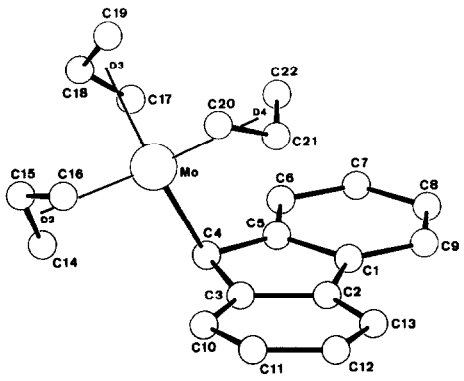

Fig. 2. The molecular structure of $[(\text{fluorenyl})Mo(\eta^3\text{-}C_3H_5)_3]$ (**IV**).

Table 2. Angles between planes

	I	II	III		IV
allyl(a)/C*p*	72.2	75.5	79.6	94.9	58.8
allyl(b)/C*p*	76.1	76.4	91.5	79.3	52.2
allyl(c)/C*p*	—	—	—	—	32.0
allyl(a)/allyl(b)	25.7	28.2	14.1	18.9	36.0
allyl(a)/allyl(c)	—	—	—	—	44.9
allyl(b)/allyl(c)	—	—	—	—	62.0

allyl(a): C14,C15,C16; allyl(b): C17,C18,C19; allyl(c): C20,C21,C22; Cp: C1—C5.

The angles between the allyl planes (25.7° for **I**, 28.2° for **II**) are similar to that observed for $(\eta^5\text{-}C_5H_5)Mo(\eta^3\text{-}C_3H_5)_2$ (25.6°).

The four organic ligands in $(\text{fluorenyl})Mo(\eta^3\text{-}C_3H_5)_3$ are arranged in an essentially tetrahedral manner around the central metal atom. The fluorenyl group is bonded asymmetrically to molybdenum [Mo—C(4) 2.342(2), Mo—C(3) 2.611(2) and Mo—C(10) 2.856(3)] indicating considerable rehybridization towards an η^1-allyl situation.

EXPERIMENTAL

All experiments were carried out under argon using anhydrous and oxygen-free solvents. $(\eta^3\text{-}C_3H_5)_3MoCl$ was prepared according to Benn *et al.*[3] The following compounds were prepared by published procedures: MeC_5H_4Na,[7] $i\text{-}C_3H_7C_5H_4Na$,[7] $t\text{-}C_4H_9C_5H_4Na$,[8] Me_5C_5Tl,[9] indenylNa,[10] 2-Me-indenylLi,[11] 2-MeO-indenylLi,[12] 2-Ph-indenylLi,[13] 5,6-dimethoxyindenylLi[14] and fluorenylK.[15] ^1H NMR spectra were recorded on a Brucker WH 400 instrument and mass spectra using a Varian CH 5 with ^{98}Mo as the standard. Microanalyses were carried out by Dornis and Kolbe, Microanalytical Laboratory, Mülheim a. d. Ruhr.

$[(\eta^5\text{-}t\text{-}C_4H_9C_5H_4)Mo(\eta^3\text{-}C_3H_5)_2]$

A solution of *t*-butylcyclopentadienyl lithium (1.23 g, 9.6 mmol) in monoglyme (80 cm^3) was added to a stirred suspension of $(\eta^3\text{-}C_3H_5)_2MoCl$ (2.15 g, 8.5 mmol) in THF (50 cm^3) at $-35°$ over a period of 30 min and stirred at this temperature for a further 18 h. The solvent was evaporated at room temperature and the orange–brown residue extracted with pentane. The pentane-extract was filtered through Avicel, evaporated and the solid residue recrystallized from hexane at $-35°C$ to give the compound as red–orange crystals. Yield 1.89 g (75% theory). The analytical data is summarized in Table 3.

$[(\eta^5\text{-}MeC_5H_4)Mo(\eta^3\text{-}C_3H_5)_2]$

Prepared as above from methylcyclopentadienyl lithium in THF at $-30°C$ and purified by vacuum sublimation (70°C/10^{-4} mmHg).

$[(\eta^5\text{-}i\text{-}C_3H_7C_5H_4)Mo(\eta^3\text{-}C_3H_5)_2]$

Prepared as above from *i*-propylcyclopentadienyl sodium in THF at $-35°C$.

$[(\eta^5\text{-}Me_5C_5)Mo(\eta^3\text{-}C_3H_5)_2]$

Prepared as above from pentamethylcyclopentadienyl thallium in THF at -78 to $-10°C$.

$[(\eta^5\text{-}indenyl)Mo(\eta^3\text{-}C_3H_5)_2]$

Prepared as above from indenyl lithium or sodium in THF or ether at $-35°C$.

$[(\eta^5\text{-}2\text{-}methylindenyl)Mo(\eta^3\text{-}C_3H_5)_2]$

Prepared as above from 2-methylindenyl lithium in THF at -78 to $-30°C$.

[c] (η^5-organyl)Mo(η^3-C_3H_5)$_3$ compound.

[(η^5-2-*methoxyindenyl*)Mo(η^3-C_3H_5)$_2$]

Prepared as above from 2-methoxyindenyl lithium in THF at −78 to −15°C.

[(η^5-2-*phenylindenyl*)Mo(C_3H_5)$_3$]

Prepared as above from 2-phenylindenyl lithium in THF at −78°C.

[(η^5-1-$CyCH_2$*indenyl*)Mo(C_3H_5)$_n$] (n = 2, 3)

Prepared as above from 1-$CyCH_2$indenyl lithium in THF at −30°C.

[(η^5-5,6-*dimethoxyindenyl*)Mo(C_3H_5)$_3$]

Prepared as above from 5,6-dimethoxyindenyl lithium in THF at −78 to −25°C.

[(η^3-1,9,10-*fluorenyl*)Mo(η^3-C_3H_5)$_3$]

Fluorenyl potassium (3.0 g, 14.6 mmol) was added to a stirred suspension of (η^3-C_3H_5)$_3$MoCl (3.6 g, 14.3 mmol) in THF (300 cm^3) at −78°C over a period of 2 h and stirred for a further 18 h. The solvent was evaporated and the dark purple residue extracted with pentane at 5°C, the pentane-extract was filtered through Avicel at 5°C, the solvent evaporated at −35°C and the residue recrystallized twice from hexane to give the compound as small purple crystals. Yield 2.2 g (40% theory).

Crystal structure determination

A detailed description of the experimental procedure has been reported previously.[16] Crystal data for I–IV are summarized in Table 4.

Acknowledgments—O.S.A. thanks the Swedish Board for Technical Development for the award of a stipendium. R.G., C.K. and Y.H.T. were responsible for the crystal structure determinations. We thank Dr A. Rufińska and B. Gabor for interpreting the NMR-spectra of (η^3-$C_3H_5)_3$(η^3-fluorenyl)Mo and Dr K. Seevogel and B. Waßmuth for interpreting the low temperature IR spectra.

ADDUCTS OF COORDINATION COMPOUNDS—XIV.* THE NATURE OF POULENC'S SILVER BROMIDE, "$[Rh(py)_4Br_2Ag]Br_2$"

R. D. GILLARD,† SIMON H. MITCHELL and DYFRIG J. THOMAS

Department of Chemistry, University of Wales, P.O. Box 912, Cardiff CF1 3TB, Wales, U.K.

(*Received* 29 *July* 1988; *accepted* 25 *August* 1988)

Abstract—The 1 : 1 adducts of silver bromide with the complex salts *trans*-$[M(py)_4X_2]Br$ (py = pyridine; M = Rh, X = Br—Poulenc's compound; M = Rh or Ir, X = Cl—newly synthesized compounds) are salts, *trans*-$[M(py)_4X_2](AgBr_2)$, of the dibromo-argentate(I) ion (ν_3 at *ca* 240 cm^{-1}), rare in solid species.

Large cations like tetraphenylarsonium and phosphonium (Ph_4E^+; Ph = C_6H_5; E = P or As) containing flat aromatic substituents on a central atom are commonly used to precipitate anions. Pyridine based cations often precipitate unusual anions. For example, [diquat] bromide treated with bromine yields[2] $[diquat](Br_3)_2$ and the paraquat salt of the InI_3^{2-} ion is stable.[3] In a similar way, cations *trans*-$[RhL_4X_2]^+$ (L = an N-heterocycle like pyridine, X = chloride or bromide) form salts with common anions (like halide or nitrate) which themselves readily give rise to adducts with a surprising range of substances. Many of the adducts have interesting or unusual components.

Among those which have been studied are several (chiefly of the dibromo–pyridine cation above, abbreviated to B here) initially discovered[4] by Poulenc. These include: $[B](NO_3)HNO_3$, a hydrogen dinitrate; $[B](NO_3)AgNO_3$, a dinitrato-argentate(I)—these two types form the subject of the previous paper[1] in this series; $[B](H_5O_2)Br_2$,[5] and [B]BrAgBr, formulated by Poulenc as *trans*-$[Rh(py)_4Br(BrAg)]Br_2$, a possible structure again supported recently.[6] Our present note reformulates the last as the dibromoargentate(I), only the second example of such a solid salt. We have also made the analogous chlororhodium and chloroiridium(III) compounds, by precipitation. For completeness, the many other adducts, solvates and the like, including salts of trihalide ions, may be mentioned.

The interactions via chloride or bromide ions, of silver(I) with rhodium(III) or iridium(III) are of particular interest, because of the much-used but ill-understood "rhodium effect" and "iridium effect" on the speed of photographic emulsions (usually achieved technically[7] by adding simple or complex halides of these platinum metals to the precipitating emulsion of silver halide).

RESULTS AND DISCUSSION

Poulenc obtained[4] his adduct *trans*-$[Rh(py)_4Br_2](AgBr_2)$ in rather low yield while trying to remove bromide coordinated to rhodium(III) by precipitation. We find that the same product may be obtained in high yield by a much simpler scheme (1):

$$trans\text{-}[Rh(py)_4Br_2]Br + (AgBr_2)^- \longrightarrow trans\text{-}[Rh(py)_4Br_2](AgBr_2). \quad (1)$$

This reaction of *trans*-$[Rh(py)_4Br_2]Br \cdot 6H_2O$ with AgBr dissolved in saturated aqueous potassium bromide by either of the two methods was successful.

(1) An aqueous or 25% (v/v) aqueous ethanol solution of the complex was added to and rapidly mixed with the aqueous KBr–AgBr solution. *Trans*-$[Rh(py)_4Br_2]AgBr_2$ immediately precipitates as an orange–yellow powder.

(2) *Trans*-$[Rh(py)_4Br_2]Br$ ground with the aqueous KBr–AgBr solution changes rapidly to a fine powder of the product.

The analogous (and isomorphous) salts of iridium(III) and of dichlororhodium(III) were made by the first method. All three compounds decompose

in water because of the insolubility of silver bromide.

$$[M(py)_4X_2](AgBr_2) \longrightarrow AgBr\downarrow + [M(py)_4X_2]^+_{(aq.)} + Br^-_{(aq.)}.$$

The IR spectrum of *trans*-$[Rh(py)_4Br_2](AgBr_2)$ is very similar to that of its parent *trans*-$[Rh(py)_4Br_2]Br \cdot 6H_2O$. There is one new band at 240 cm^{-1}. This probably arises from the Ag—Br_2 asymmetric stretch $\nu_3(\Sigma_u^+)$. There is a general paucity of data[6,8] on Ag—Br modes. The careful study[8b] of $[N(CH_3)_4][AgX_2]$ dissolved in tri(*n*-butyl)phosphine oxide by Waters and Basak placed the IR active $\nu_3(\Sigma_u^+)$ mode of $AgBr_2^-$ at 253 cm^{-1}. Bottger and Geddes[8c] isolated solid salts of the stoichiometry $[E(CH_3)_4](AgBr_2)$ (E = N or P), but their vibrational spectra strongly suggested that the anions were made up by linked AgX_4 tetrahedra, and certainly did not contain linear two-coordinate silver ions.

IR spectra are recorded in Table 1.

Similarly, for the new iridium compound, *trans*-$[Ir(py)_4Cl_2](AgBr_2)$, the spectra confirm the presence of pyridine (1650, 776, 709 cm^{-1}) and the presence of a pyridine–Ir bond (339 cm^{-1}). The only notable difference between the parent and adduct is again the absorption (which we assign as ν_3) at 238 cm^{-1} of the adduct.

The solubility of silver halides in aqueous silver salts and aqueous halides is well known and understood. The relevant stability constants[6,11] indicate that the chief species in excess of *aqueous* halide X^- are AgX_2^- (while compounds like $(NH_4)_2AgBr_3$ may be made, for example in methylethyl ketone, they are insensitive to light). A simple method[12] of making large crystals of silver chloride depends on the slow reversal of (2).

$$HCl + AgCl \rightleftharpoons \text{“}H[AgCl_2]\text{”}. \qquad (2)$$

So the anion AgX_2^- (X = halide) has long been recognized[13] as a solution species, but in the solid state there are few examples.[14] Poulenc's compound has been proposed[15] as a further example, without structural work. It is the last of those remarkable adducts which were originally reported[4] by Poulenc to be dealt with in this series (cf. *trans*-$[Rh(py)_4Br_2](H_5O_2)Br_2$,[5] *trans*-$[Rh(py)_4Br_2][H(ONO_2)_2]$[1,16] and *trans*-$[Rh(py)_4Br_2][Ag(ONO_2)_2]$).[1]

In the first established example[14] of a linear silver dibromide anion, $[Au(dtc)_2]AgBr_2$, the silver atom is linearly coordinated by bromine and lies on a special position in the lattice. There is[17] an analogous but not isomorphous gold compound, containing linear $AuBr_2^-$.

Besides $AgBr_2^-$, there are a small number of monomeric linear cationic AgX_2^+ or anionic AgX_2^- complexes (X = NH_3,[18,19] py[20] and NCO[21]), so this structure for $AgBr_2^-$ is not too unexpected. However it is much rarer than would be thought in view of its common occurrence in solution.

Instead of the two coordinated linear dihaloargentate(I) structures expected from solution studies, distorted tetrahedral coordination of silver by hal-

[a] For crystal structure see ref. 9.

[b] Our methods produced powders. In view of the aqueous insolubility of the compounds, it may be necessary to employ a different solvent system to prepare crystals. AgX_2^- is stable[10] in DMSO, which might be suitable.

[c] The chloride analogue *trans*-$[Rh(py)_4Cl_2](AgCl_2)$ could not be prepared by our present methods, so a different solvent system might also be needed.

[d] $\nu_3(\Sigma_u^+)$ of linear $[AgBr_2]^-$.

ide is common in the solid state. The tetrahedra may be paired, sharing edges ($[Ag_2I_6^{4-}]$),[22] or linked together to form chains, either single AgX_2^- (X = Br or I)[23] and AgI_3^{2-},[24] or double $Ag_2I_3^-$ [25,26] and $Ag_3I_4^-$ [27] (but this last one also has a silver atom occupying an octahedral hole between each pair of double tetrahedra). One other arrangement is found: a polymer of edge-sharing trigonal bipyramids (AgX_2^-, X = Cl[28] or Br[29]).

None of the known silver halide–silver nitrate double salts contains a simple linear X—Ag—X sequence. Usually the silver and halide form a polymeric structure, and there are several distinct types of silver atoms. In the few cases where an almost linear sequence *is* found, there is always nitrate also coordinated to the silver.[30–32]

In view of the frequent similarity (diagonal relationship) between S^{2-} and Br^-, the existence[33] of the linear ion AgS_2^{3-} containing two coordinated silver (isoelectronic with $AgCl_2^-$) in the salt Na_3AgS_2 is interesting. Nevertheless, salts of linear $AgBr_2^-$ are extremely rare, and it is interesting that Poulenc's salt precipitates this monomeric anion.

EXPERIMENTAL

IR spectra were measured in Nujol mulls, and X-ray photographs used Cu-K_α radiation and 6 h exposure.

trans-$[Ir(py)_4Cl_2]Cl \cdot 6H_2O$

A known synthesis[9] was used, substituting commercial iridium trichloride for K_3IrCl_6. $IrCl_3$ (0.507 g) dissolved in water (18 cm^3), with pyridine (6.5 cm^3) and ethanol (3 cm^3) was heated (steam bath) for 20 min. The solution was made acid (conc. HCl) and cooled in ice. The yellow crystals which formed were collected and crystallized from water. Yield 56%. An aqueous solution (4.52×10^{-5} M) showed peaks at 255.8 and 195.7 nm. The former had a molar extinction coefficient, ε, of 20,974, close to Jørgensen's value[34] (which confirms the presence of 4 mol of pyridine per iridium).

trans-$[Ir(py)_4Cl_2](AgBr_2)$

To 30 cm^3 of saturated aqueous KBr, $AgNO_3$ solution was added until the first sign of a permanent precipitation: saturated KBr was added dropwise until the precipitate just disappeared. This was now a saturated KBr/AgBr solution containing silver(I) chiefly as $[AgBr_2]^-$ (see text). *trans*-$[Ir(py)_4Cl_2]Cl$ (0.256 g) was dissolved in water (30 cm^3) by gentle warming. The KBr/AgBr solution was mixed with this solution and left in the dark for 1 h. The precipitate was washed thoroughly with saturated KBr solution, to remove any traces of solid AgBr; it was then washed with water. The precipitate was dried in a desiccator over conc. H_2SO_4. Yield = 0.253 g (72%).

The adduct (0.0729 g, 8.61×10^{-5} mol) was boiled in water for 20 min in the dark. The silver bromide formed was collected and washed with water, ethanol and finally ether, then weighed (0.01588 g, 8.41×10^{-5} mol).

trans-$[Rh(py)_4Cl_2](AgBr_2)$

Saturated KBr/AgBr was added to a solution of *trans*-$[Rh(py)_4Cl_2]Cl$ (0.3141 g/30 cm^3). A yellow precipitate immediately formed. This was collected and washed throughly with saturated KBr solution, then with water. The powder was dried in a desiccator over conc. H_2SO_4. Yield = 0.3314 g (73.6%). An X-ray powder diffraction photograph was taken (Cu-K_α radiation for 6 h).

Poulenc's compound: trans-$[Rh(py)_4Br_2](AgBr_2)$

Poulenc's original method[4] and the precipitation were used. The products from both reactions were washed with saturated aqueous KBr to remove AgBr, then with water and finally ethanol. The yield by method (2) is 93.8%. Found: C, 28.7; H, 2.3; N, 6.3. Calc. for $C_{20}H_{20}AgBr_4N_4Rh$: C, 28.4; H, 2.4; N, 6.6%.

COMMUNICATION

REACTION OF SOLID SODIUM HYDRIDE WITH SOLID AMMONIUM THIOCYANATE IN HMPA–TOLUENE:* AN ESR SPECTROSCOPIC INVESTIGATION AND CRYSTAL STRUCTURES OF THE TWO PRODUCTS OF THE REACTION, $[(NaNCS \cdot HMPA)_2]_\infty$ AND $(NaNCS \cdot 2HMPA)_2$

DONALD BARR, MICHAEL J. DOYLE, SIMON R. DRAKE, PAUL R. RAITHBY, RONALD SNAITH† and DOMINIC S. WRIGHT

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 11 *August* 1988; *accepted* 24 *August* 1988)

Abstract—Reaction of solid NH_4SCN with solid NaH and HMPA (1 : 1 : 2 molar ratios) in toluene produces two complexes, $(NaNCS \cdot HMPA)_n$ (**1**), which has an S···Na-linked polymeric structure ($n = 2\infty$) with a repeat dimeric unit of form $SCN \cdot Na(\mu_2\text{-}HMPA)_2Na \cdot NCS$, and $(NaNCS \cdot 2HMPA)_n$ (**2**), which is a discrete symmetrical dimer ($n = 2$) with two μ_2-HMPA ligands and with terminal HMPA and NCS^- ligands (one of each per Na centre) arranged *trans*; the reaction appears to proceed via an electron-transfer mechanism, radical species having been detected by ESR spectroscopy.

A previous communication[1] noted the reaction of solid NH_4SCN with Bu^{n}Li and 2HMPA [O:P(NMe$_2$)$_3$] in toluene, and presented ESR spectroscopic evidence that formation, via numerous colour changes, of the product, $(HMPA)_2Li \cdot (\mu_2\text{-}HMPA)_2 \cdot Li(NCS)_2$, involved the intermediacy of radicals. An earlier report[2] had shown that NH_4 Hal solids (Hal = Cl, Br, I) also react with Bu^{n}Li in the presence of various Lewis bases, L (e.g. HMPA, TMEDA, PMDETA), to give complexes of the type $(LiHal \cdot xL)_n$. Here we show that such syntheses of alkali metal complexes are not limited to lithium, nor is the source of the metal restricted to a solution of an organometallic. Thus, solid NH_4SCN reacts rapidly with solid NaH and 2 equiv of HMPA, in toluene, giving two products, $NaNCS \cdot HMPA$ (**1**) and $NaNCS \cdot 2HMPA$ (**2**); a similar reaction, but with Na metal replacing NaH, gives **2** alone. In the crystal, **1** is polymeric, with dimeric $(SCN)Na \cdot (\mu_2\text{-}HMPA)_2 \cdot Na(NCS)$ units linked by NaNCS···Na interactions, while **2** is a discrete dimer, also having a central $Na(\mu_2\text{-}HMPA)_2Na$ ring but with a terminal NCS^- and a (further) terminal HMPA ligand attached, in a *trans* manner, to each Na. An ESR spectroscopic study has shown that radicals are involved in these reactions.

Addition of HMPA (3.58 g, 20 mmol) to a mixture of NH_4SCN (0.76 g, 10 mmol) and NaH (0.24 g, 10 mmol) solids in toluene (12 cm^3) at room temperature gave an immediate blue coloration. Vigorous gas evolution occurred forthwith, the colour changing to turquoise, then green, then (after *ca* 30 min) pale yellow; at this final stage, no solids remained. The solution was warmed and further toluene (10 cm^3) added before filtration. Cooling to 25°C afforded cubic crystals of $NaNCS \cdot HMPA$ (**1**). After further filtration, addition of hexane (18 cm^3) to the filtrate, followed by refrigeration, gave finely faceted crystals of $NaNCS \cdot 2HMPA$, **2**.‡§

* The synthetic routes described are the subjects of a preliminary patent (British Patent Application No. 8724662) filed by the Associated Octel Co. Ltd, U.K.

† Author to whom correspondence should be addressed.

‡ Yield of **1**, 29% relative to NH_4SCN taken; m.p. 149°C. Yield of **2**, 57%; m.p. 67–68°C. Satisfactory analyses (±0.2% of calculated values for C, H, N, Na, P) were obtained for **1** and **2**.

§ The direct syntheses of **1** and **2** have been reported, by dissolution of NaSCN in methanol or acetone, followed by addition of HMPA, then evaporation. Crystals isolated had melting points of 150–151 and 76–77°C, respectively.[3]

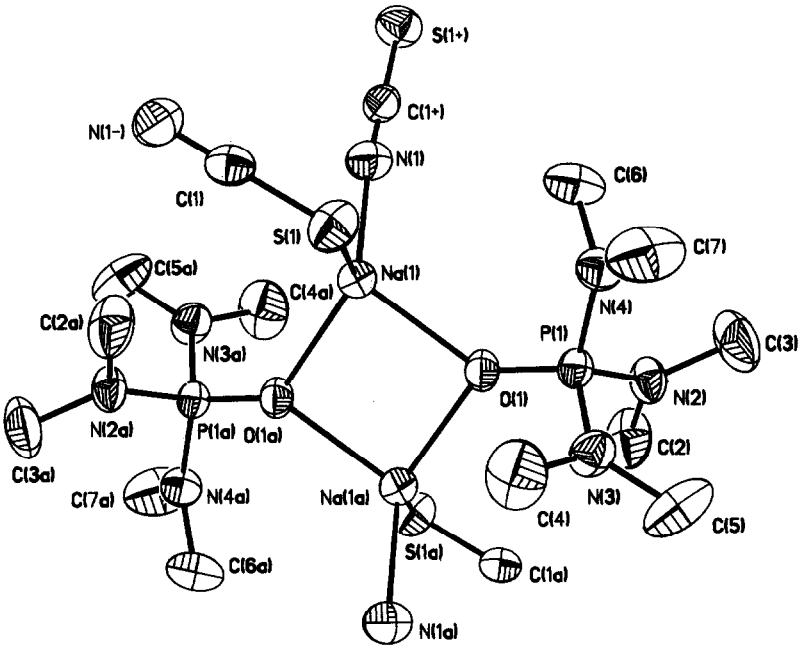

Fig. 1. The molecular structure of **1** showing the atom numbering scheme. Hydrogens have been omitted for clarity and the thermal ellipsoids represent the 30% probability level.

This latter product (but not **1**) was also obtained (in 75% yield) by reacting Na metal with NH_4SCN(s) and 2HMPA in toluene: this mix also initially gave a blue, then blue–green colour, but the reaction was much slower, a pale yellow solution resulting after stirring at 25°C for 1.5 days.

The crystal structures of both products have been determined.* The 1 : 1 complex, **1** (Fig. 1) is polymeric and has, as its central repeat unit, a $Na(\mu_2$-HMPA$)_2Na$ dimeric ring with alternating Na—O distances of 2.295(3) and 2.322(3) Å (cf. data in ref. 1). Each Na^+ is attached also, within the dimer, to a linear NCS^- ligand [Na—N, 2.328(4) Å; $Na\widehat{N}C$, 173.7(3)°; $\widehat{NCS}$, 179.6(4)°], and the S-ends of such ligands link four such dimers together in infinite 2D layers [Na···S, 2.895(2) Å; Na···$\widehat{SC}$, 101.6(2)°]. Such a bifunctional mode for thiocyanate has only been observed once before for alkali metal derivatives, in the 1D polymeric structure of $(LiSCN \cdot TMEDA)_\infty$.[4] The crystal structure of **2** contains, in contrast, *discrete* dimers (Fig. 2), again with bridging HMPA ligands [average Na—O, 2.336(3) Å], but now with each Na completing its four-coordination, in a *trans* manner, with a linear NCS^- ligand [Na—N, 2.348(6) Å; $Na\widehat{N}C$, 160.0(3)°; $\widehat{NCS}$, 179.4(5)°] and with an oxygen-attached HMPA ligand [Na—O, 2.239(4) Å]; clearly then, the additional HMPA molecules (one per Na) in **2** have served to replace the Na···SCN interdimer contacts apparent in **1**. Complexes **1** and **2** are the first structurally characterized NaSCN complexes in which L is not a macrocyclic ligand;[5] these (crowns etc.) lead to monomers, with or without Na···NCS contacts, so that **2** is the first oligomer (a dimer) of this kind, and **1** the first polymer (itself accrued through dimers).

The colours seen during the reaction of NH_4SCN(s) and 2HMPA with NaH(s) in toluene, giving **1** and **2**, have been investigated. As background, binary mixtures of NH_4SCN(s)+2HMPA, NH_4SCN(s)+NaH(s), and NaH(s)+2HMPA in toluene were examined: no colours were observed,

*Crystal data for **1**: $C_{14}H_{36}N_8Na_2O_2P_2S_2$, $M = 520.55$, monoclinic, space group $P2_1/c$ (No. 14), $a = 10.794(2)$, $b = 8.500(2)$, $c = 15.776(3)$ Å, $\beta = 106.65(2)°$, $V = 1386.7(5)$ Å^3, $D_c = 1.246$ g cm^{-3}, $Z = 2$, $F(000) = 552$, λ(Cu-K_α) = 1.5418 Å, μ(Cu-K_α) = 33.51 cm^{-1}; 2195 measured intensities ($2\theta_{max} = 116°$), 1567 unique with $F > 3\sigma(F)$. Structure solved by direct methods and refined by blocked-cascade least-squares to $R = 0.051$ and $R_w = 0.054$.

Crystal data for **2**: $C_{26}H_{72}N_{14}Na_2O_4P_4S_2$, $M = 878.96$, triclinic, space group $P\bar{1}$ (No. 2), $a = 10.044(1)$, $b = 11.715(2)$, $c = 12.002(2)$ Å, $\alpha = 105.63(1)$, $\beta = 96.49(1)$, $\gamma = 113.08(1)°$, $V = 1212.4(3)$ Å^3, $D_c = 1.203$ g cm^{-3}, $Z = 1$, $F(000) = 472$, λ(Cu-K_α) = 1.5418 Å, μ(Cu-K_α) = 27.60 cm^{-1}; 3616 measured reflections ($2\theta_{max} = 116°$), 2750 unique with $F > 3\sigma(F)$. Structure solved by direct methods and refined by blocked-cascade least-squares to $R = 0.060$ and $R_w = 0.067$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

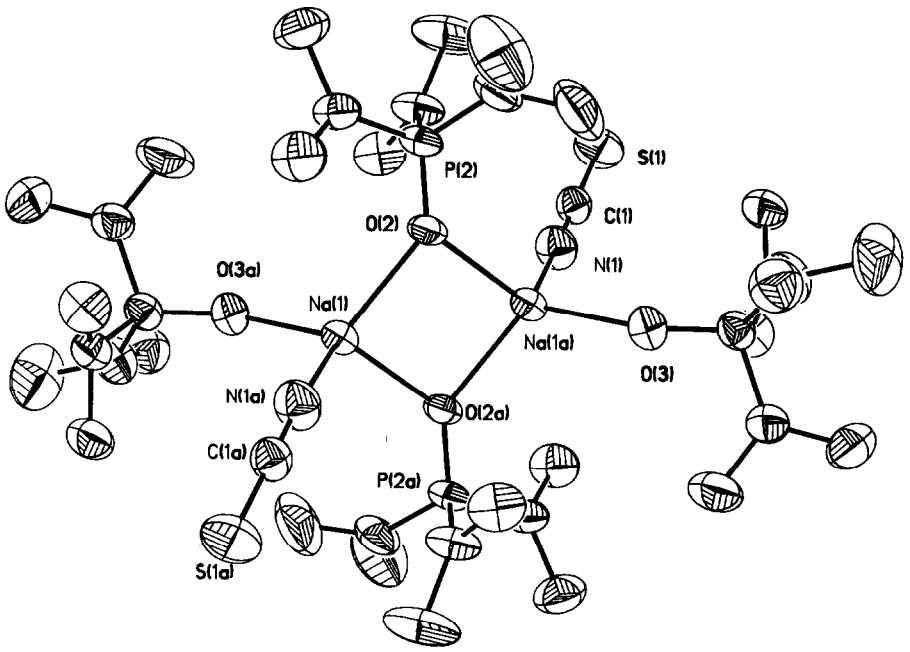

Fig. 2. The molecular structure of **2** showing the atom numbering scheme. Hydrogens have been omitted for clarity and the thermal ellipsoids represent the 30% probability level.

neither were there any apparent reactions or discernible dissolutions of solids. Thus, all *three* reactants [NH_4SCN(s), NaH(s), 2HMPA] in toluene are needed to afford reaction/a blue colour. ESR spectra were obtained on this blue-coloured reaction mixture over the temperature range −269 to −100°C and some typical spectra are shown in Fig. 3.

At −269°C, three signals seem apparent [Fig. 3(a)]. However, microwave power saturation measurements reveal that the highest field resonance in fact consists of two signals [Fig. 3(b)];[6] thus, there are two types of radicals present, giving rise to four signals. The first three of these (from low to high field) have g tensors which occur at precisely the same fields ($g_1 = 2.026$, $g_2 = 2.009$, $g_3 = 1.980$ and $g_{av} = 2.005$) as the signals obtained from the NH_4SCN(s)–Bu^{n}Li–2HMPA reaction system in toluene,[1] which were attributed to a thiocyanate-based radical, e.g. $(SCN)_2^-$. As observed previously, the line widths and line shapes of the three g tensors are temperature dependent over the temperature range −269 to −100°C, and diminish slowly with progressive warming. Also as in that lithium system, all three reactants [NH_4SCN(s), NaH(s), 2HMPA] must be present here, otherwise these three signals (and the blue colour) are not observed: the implication is that HMPA-assisted electron-transfer from Na(H) to SCN^- occurs. The fourth, low intensity signal, $g = 1.975$, is also found in the ESR spectra of any binary system containing NaH(s) [i.e. for NaH(s)+NH_4SCN(s) or

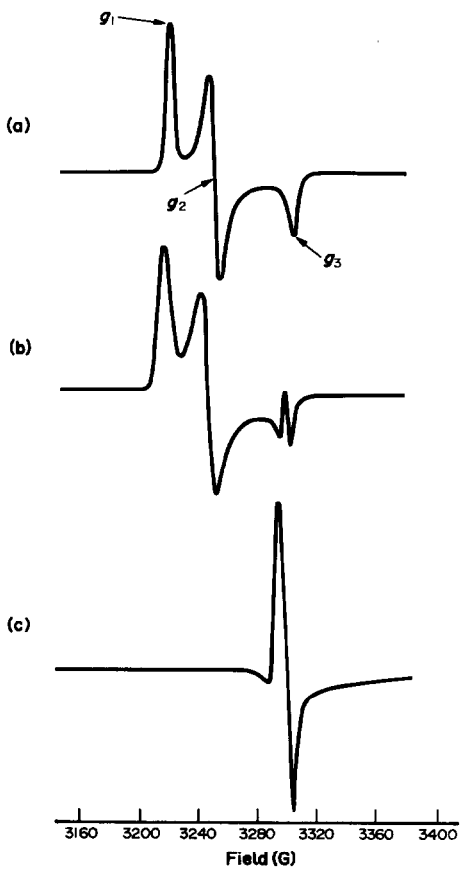

Fig. 3. ESR spectra recorded at −269°C on (a) a frozen toluene solution of the NH_4SCN(s)–NaH(s)–2HMPA reaction mixture, at a power of 5 mW; (b) the same system at 50 mW; (c) solid NaH at 10 mW.

NaH(s)+2HMPA, both in toluene, but not for NH_4SCN(s)+2HMPA], and indeed in those of NaH(s) in toluene and of NaH(s) alone [Fig. 3(c)]; it can thus be ascribed to an impurity, as yet unidentified, in the commercially supplied NaH.

1. HOMONUCLEAR STRUCTURAL OVERVIEW

The oxo group, formally considered as O^{2-}, is an extremely versatile ligand. It is capable of binding as a terminal group to a metal (M=O) (4 electron donor) or bridging 2, 3, 4 or 5 metal atoms. In the latter situations it acts as a 4, 6 or 8 electron donor, respectively. Bridging oxygens are designated as (μ-O) (for dinuclear bridging), (μ_3-O), (μ_4-O) or (μ_5-O). A variety of oxo bridging modes (Fig. 1) have been identified for such bridging between transition metal ions including several where

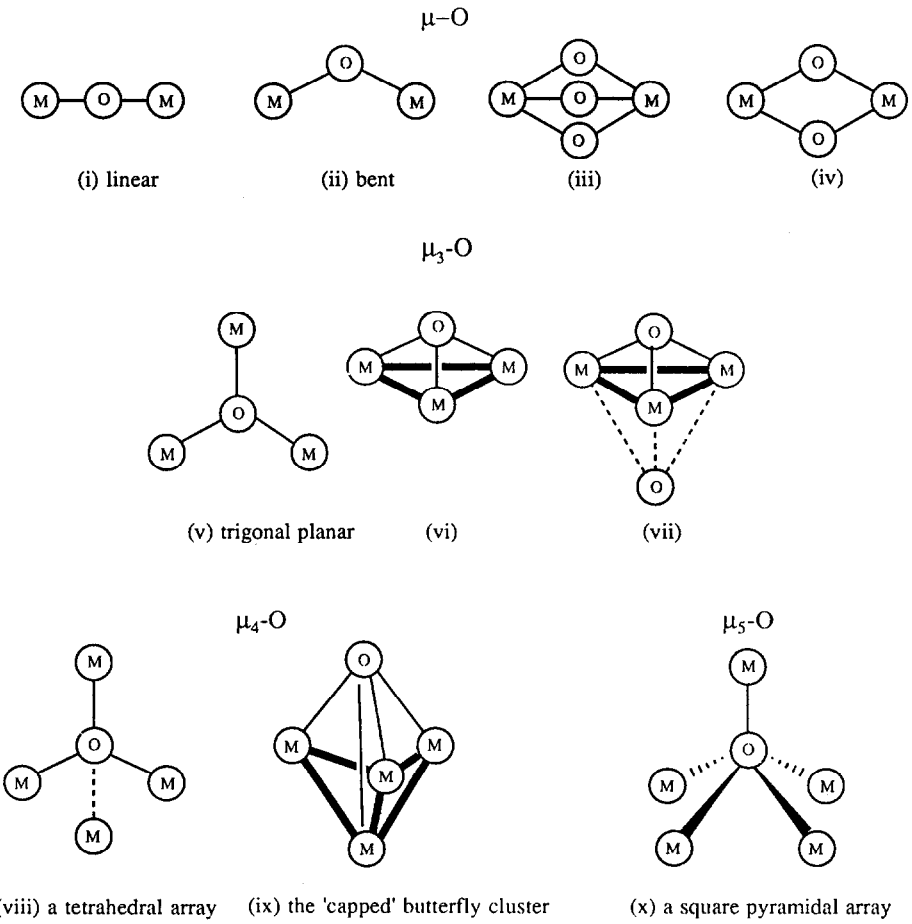

Fig. 1. Oxo bridging mode.

oxygen behaves as a "capping" ligand and lies above a metal–metal bonded cluster of metal atoms. Depending on the metal, further oxygen atoms may be bound as terminal groups.

Homonuclear oxo-bridged species are predominantly formed by metals in groups 4–8, i.e. the triads from Ti, Zr, Hf to Fe, Ru, Os, examples being known for each of the 15 elements involved.

Earlier general reviews on oxo compounds by Griffith[1] and Jezowska-Trzebiatowska[2] listed many of the early structure determinations which established bonding modes (i)–(v), while Murray[3] (Fe^{III}) and Stiefel[4] (Mo^{V}) gave accounts of the oxo bridging compounds of these two elements. Holm[5] has recently presented a further substantially updated, selective catalogue of oxo-bridged compounds of types (i)–(iv) as an accompaniment to his detailed review of metal-centred oxygen atom transfer. This review will be primarily concerned with complexes containing a single oxygen linked to two or more metals and only brief mention will be made of compounds having more than one oxygen atom linking two metals [structural types (iii) and (iv)].

1.1 *Structure and bonding considerations*

A collection of representative structural data for mono-oxo-bridged complexes is given in Table 1. The metals range in electron configuration from d^0 to d^5. No complexes having unsupported M—O—M bridges have been characterized for metals having d^n configurations greater than d^5. Linear (180°) or "almost" linear (173–180°) M—O—M linkages predominate amongst (μ-O) complexes. Exceptions are found for d^0 (Ti^{IV}) and especially d^5 (Fe^{III}, Ru^{III}). Iron(III) oxo-bridged complexes are known with FeOFe angles in the range 139–180° with the majority having angles $<180°$. Oxo complexes of Mo^{V} and Re^{V} also contain non-bridging terminally bound oxo groups whose distances from the metal are notably shorter than the bridging M—O distances in line with

their formulation as M=O bonds. The bridging distances are generally some way between these values for M=O links and "pure" single bond M—O links where these have been identified indicating some degree of double bond character in the bridging bonds.

A molecular orbital treatment was first applied to the RuORu system in $[Ru_2^{IV}OCl_{10}]^{4-}$ in a now classical paper by Dunitz and Orgel[38] which considered the Ru—O linkages to be made up of σ-

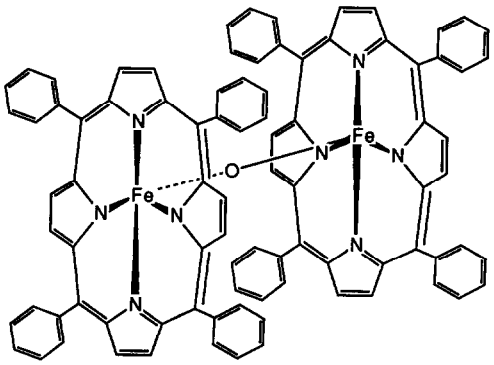
[a] Two crystallographically distinct $Mo_2O_3(Et_2dtc)_4$ units are found in the crystal of symmetry C_i and C_2.

and π-bonding components. This basic method has been extended and subsequently applied to other $[M_2OCl_{10}]^{4-}$ [2,39] ions, $[Cr^{III}(NH_3)_5]_2O$[40] and, bridged metalloporphyrins[41] where the bridging atoms may be O, N or C. The π-bonding, antibonding and non-bonding orbitals concerned may be represented as $(e_u^b)[(b_{2g})(b_{1u})(e_g)](e_u^*)$ where the exact ordering of b_{2g}, b_{1u} and e_g levels may vary with changes in the metal and the nature of the ligands attached to it. The linearity and diamagnetism of $[Ru_2^{IV}OCl_{10}]^{4-}$ are accounted for by the accommodation of eight ruthenium and four oxygen electrons in the configuration $(e_u^b)^4[(b_{2g})^2(b_{1u})^2(e_g)^4](e_u^*)$ while the room temperature paramagnetism of the linear, mixed valence complex $[Re_2^{IV/V}OCl_{10}]^{3-}$ ($3.75\mu_B$ at 293 K) is in agreement with the configuration[39] $(e_u)^4[(e_g)^3(b_{2g})^1(b_{1u})^1](e_u^*)^0$ with very close spacing of the e_g, b_{2g} and b_{1u} orbitals. A similar relative ordering of the levels [40] but with a greater energy separation between e_g and two closely grouped b_{2g}, b_{1u} levels can qualitatively account for the low magnetic moment [42] observed for the $d^3 \cdot d^3$ complex $\{[Cr(NH_3)_5]_2O\}^{4+}$ ($1.8\mu_B$ at 293 K and virtual decrease to zero at 125 K), viz. $(e_u)^4[(e_g)^4(b_{2g})^1(b_{1u})^1](e_u^*)^0$.

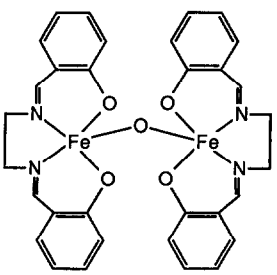
Jezowska-Trzebiatowska[26] appears to have first suggested limitation to the formation of stable linear M—O—M compounds to metals having d^n electron configurations in the range $n = 0$–5 in line with the MO picture of bonding in the M—O—M unit. This requires a maximum of 12 electrons to fill all π-bonding and non-bonding orbitals, i.e. up to d^4 metal configurations, while for d^5 metal ions, electrons must enter the π-antibonding level (e_u^*) with consequent destabilization of the linear π-bond structure, forcing a bent configuration on the resulting molecule. This is in line with the range of MOM angles found for Fe_2O systems. Higher numbers of d electrons (d^6, d^7, d^8, d^9) would only be accommodated in higher level antibonding orbitals with increased destabilization of the oxo bridge, again in line with the virtual absence of such compounds amongst the metals of groups 9–12.

Tatsumi and Hoffman[41] have greatly extended this approach to compare the bonding requirements of model $[Fe(N_4)]_2X$ systems where X = O, N or C. They have reiterated the critically important role played by M—O π-bonding in stabilizing MOM linkages and showed how the bond angle in FeOFe compounds, where π-antibonding levels would have to be occupied in the linear MO concept, can vary over a wide range in order to maximize what π-bonding component can be generated and to minimize occupancy of M—O π^*-antibonding levels. They concluded that the angle found for a given $[Fe(L)]_2O$ complex would be decided largely by the extent of intermolecular interaction between the ligands attached to Fe. Thus, in $[Fe(TPP)]_2O$ (**1**) where the bulky, "flat", inflexible porphyrins will interact quite considerably with each other, the bond approaches linearity at 174°, whereas the quadridentate open-chain ligand $salen^{2-}$ in $[Fe(salen)]_2O$ (**2**) can reduce intermolecular contacts by having the bulky bridging groups arranged in a *trans* fashion about the FeOFe links allowing the FeOFe angle to be considerably reduced to *ca* 140°. Clearly, the presence of other unbounded solvent molecules in the crystal can alter the angle due to packing effects for this molecule. Ruthenium(III) oxo compounds also containing d^5 ions show similarly bent bonds (Table 1).

With systems having d^1 or d^2 metals (Mo^V, Re^V) there should be no bar to linearity in MOM links and this situation is commonly found (Table 1). However, these metals may also have additional

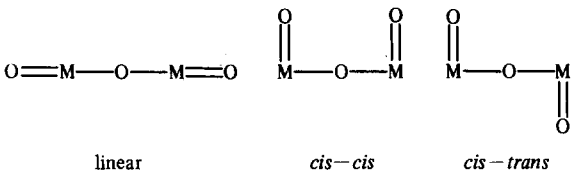


[(TPP)Fe]$_2$O (1).

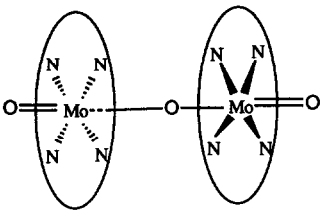


[Fe(salen)]$_2$O (2).

terminal oxo groups attached and the possibility of several different structural forms then arises.† The linear structure (3) has been found for each Re_2O_3 compound so far examined, while both *cis–cis* and *cis–trans* forms have been determined for Mo_2O_3 derivatives.[4] The linear form of $[Mo^VO(TPP)]_2O$[10] is the only example of this arrangement structurally proved for Mo in (6). The



(3) (4) (5)



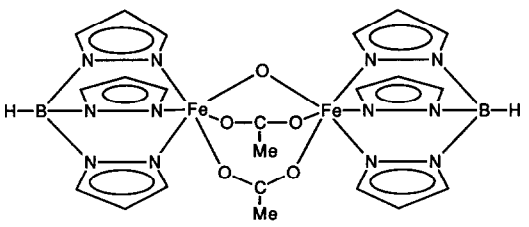
$[Mo^V(O)(TPP)]_2O$ (6).

Mo^V oxo-porphyrin complex is also found to be paramagnetic[44] at room temperature whereas the other oxo-bridged complexes of Mo^V are diamagnetic.[4] A *cis*-dioxo array in Mo^{VI} derivatives is also commonly found rather than a *trans* arrangement because such structures allow oxygen to participate in the most favourable π-interactions with the metal. It has been argued[41] that the structure resulting for a given complex will result from a balance between the minimal M d_π–O p_π antibonding interaction which favours a linear OMOMO array, and maximum π-bonding favouring a *cis* (or *cis–trans*) arrangement. The extent of π-bonding between O and M increases as the number of *d* electrons decreases since a larger number of empty *d* orbitals becomes available for interaction with O p_π electrons. Indeed, the remarkable compound $Nb_2O_3(TPP)_2$,[10,41] a d^0 system, has all three O atoms bridging between both Nb atoms [Fig. 1(iii)] and utilizing a maximum number of *d* orbitals for π-bonding.[45] The linearity of $Mo_2O_3(P)_2$[41] would appear to result from the inflexible planar structure of the porphyrin which, with a *cis*-oxo array, would constrain the single *d* electron of each Mo to orbitals involving increased M—O π^*-antibonding character. Other types of ligand so far examined are apparently flexible enough to allow minimization of this type of interaction. Metals having the d^2 configuration, Re^V and Tc^V, are predicted to have linear O=M—O—M=O arrangements since the increased number of *d* electrons will reduce the M—O π-interaction still further and increase the antibonding component in a *cis* arrangement.

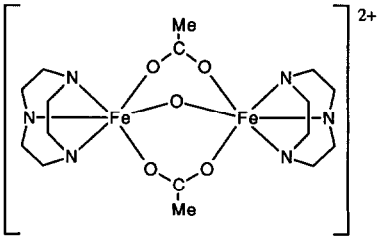
1.2. *"Supported" oxo bridging*

Iron forms oxo-bridged complexes with great facility and a wide variety of ligands. Such compounds are involved in a variety of processes in biological systems either with porphyrin groups coordinated to the metal, i.e. haem compounds,[46] or with non-haem type coordination. In particular, the non-haem oxygen-carrying haemerythrin proteins found in certain invertebrates appear to contain Fe—O—Fe units to which a molecule of oxygen can be coordinated reversibly.[47]

Lippard[48] (7) and Wieghardt[49] (8) have separately developed model compounds for the hae-



$[(HBPz)Fe^{III}(\mu\text{-}CH_3COO)]_2O$ (7).



$\{[(TACN)Fe^{III}(\mu\text{-}CH_3COO)]_2O\}^{2+}$ (8).

† A fourth structural form with the M=O linkages mutually at right-angles (the "skew" form) can exist, but no examples of such a configuration are known.

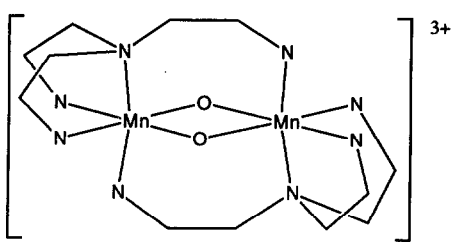
merythrin core which contain Fe—O—Fe units "supported" by carboxylato bridges and having a tridentate ligand capable of coordinating in the "*fac*" mode to each metal ion. Similar supported oxo-bridged groupings, $[M_2O(CH_3COO)_2]^{2+}$, have been prepared for Ti^{IV},[50] V^{III},[51] Mn^{III} [52] and Os^{IV}.[53] The acetate bridged oxo complexes are extremely stable species. They are related to the well known "basic acetate" complexes of Fe^{III} and other trivalent metals discussed below (Table 3) representing, as it were, a single bridged segment of the trinuclear species.

Manganese oxo complexes have also received increasing attention in recent years because of the key role played by that element in the photosynthetic water oxidation–oxygen evolution cycle.[54] There is believed to be a requirement for two or four Mn atoms for each photosystem II centre and this group or aggregate can cycle through a range of oxidation states. EXAFS and ESR data have indicated that O and N are nearest neighbours to manganese in the metalloprotein unit.[55] A series of mono- and dioxo-bridged Mn complexes have been prepared for modelling purposes. The majority are dimanganese dioxo-bridged compounds, most of which can be obtained in several of the possible valence state combinations $Mn^{III}(O)_2Mn^{III}$, $Mn^{III}(O)_2Mn^{IV}$, $Mn^{IV}(O)_2Mn^{IV}$.

Wieghardt *et al.*[52b] have shown that a dinuclear Mn^{II} hydroxy–aceto-bridged complex $\{[LMn^{II}(\mu\text{-}CH_3COO)]_2(\mu\text{-OH})\}^+$ can be oxidized first to an oxo-bridged dimanganese(III) ion $\{[LMn^{III}(\mu\text{-}CH_3COO)]_2(\mu\text{-O})\}^{2+}$ then to the mixed oxidation state ion $\{[LMn^{III}(\mu\text{-}CH_3COO)](\mu\text{-O})[LMn^{IV}(\mu\text{-}CH_3COO)]\}^{3+}$ and finally the Mn^{IV} dinuclear complex. The Mn—(μ-O) distances in the III/IV complex are equal within the experimental accuracy of the X-ray diffraction study but disorder among the ClO_4^- ions of the complex examined may have limited the ability to distinguish between the two oxidation states. The Mn^{III}/Mn^{IV} ions were shown to be coupled antiferromagnetically with the spin-exchange constant $J = -80\ cm^{-1}$ whereas the Mn^{III}/Mn^{III} compound displayed ferromagnetic coupling[52a] with $J = +18\ cm^{-1}$. A comproportionation constant of 7×10^8 was obtained from redox potential measurements for the reaction between the Mn^{III}/Mn^{III} and Mn^{IV}/Mn^{IV} complexes which forms the mixed valence complex Mn^{III}/Mn^{IV}.[52b] Structural data are presented in Table 2. Differences between Mn^{III}—(μ-O) and Mn^{IV}—(μ-O) distances have been observed in the bpy-[56] and tren-containing complexes indicating localization of the valence centres. The tren complex has arms of the ligands bridging between the metal ions and a di-(μ-O) bridge[59] (**9**).



$[Mn^{III}Mn^{IV}(tren)_2(\mu\text{-O})_2]^{3+}$ (**9**).

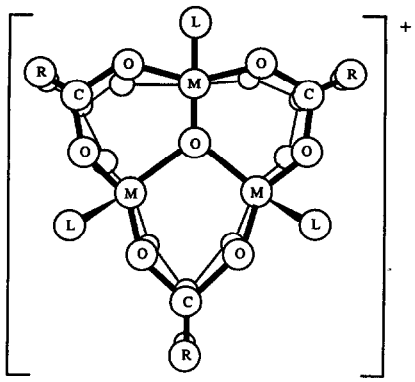
[a] M—O–carboxylate, averaged distances.
[b] μ_3-O is 0.24 Å from the Fe_3 plane.

No established experiment using any of the model complexes described has successfully oxidized water in homogeneous solution, but a report has been made[60] of O_2 evolution from H_2O when the complex $[(bpy)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(bpy)_2](ClO_4)_3$ is suspended in water in the presence of the powerful oxidant Ce^{IV}. The heterogeneous physical conditions were thought to mimic the actual photosynthetic site more clearly than a homogeneous system.

1.3 *The* (μ_3-O) *trigonal structure*

The planar trinuclear oxo structure [Fig. 1 (v)] of D_{3h} symmetry is structurally well established[61] as the central unit in a series of carboxylato-bridged ions of general formula $[M_3(\mu_3\text{-}O)(RCOO)_6L_3]^+$, M = Cr, Fe, V, Co, Mn, Rh; R = CH_3 (the "basic" acetates) and a wide range of other carboxylates; L = H_2O, pyridine or substituted pyridines, tetrahydrofuran (**10**) (Table 3). Ruthenium[78,79] and Ir[80]

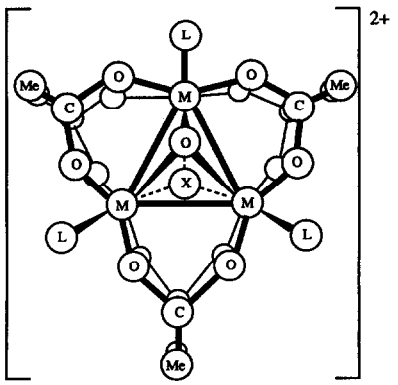


$[M_3(\mu_3\text{-}O)(\mu\text{-}RCOO)_6L_3]^+$ (**10**).

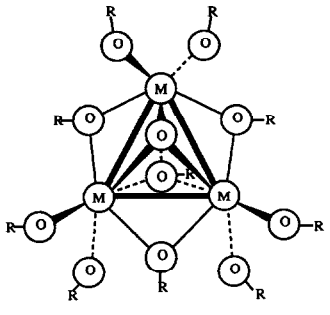
complexes have also been prepared but not structurally characterized. This structure is also found for mixed valence neutral compounds having the formal oxidation state distribution of $[M^{III}_2M^{II}(\mu_3\text{-}O)(CH_3COO)_6L_3]$ M = Fe, Cr, V, Mn, Ru, at least in most "room temperature" structure determinations, indicating either that full electron delocalization has occurred, rapid electron transfer between metal sites is taking place or the $M^{III}_2M^{II}$ triangular arrays are disordered in the crystal so as to produce a randomized distribution of metal centres with different oxidation states. This matter is addressed as part of the discussion of related heterotrinuclear oxo compounds in Section 4.4.

There is practical interest in such trinuclear oxo complexes since several are known to be catalysts for various processes. Thus, $[Ru_3(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3][CH_3COO]$[81] catalyses olefin hydrogenation in DMF solution in the presence of H_2, through formation of $[HRu_3(O)(CH_3COO)_5(DMF)_3]^+$, or isomerization of terminal olefins in the absence of H_2. Only one Ru atom appears to be involved. $[Fe^{III}_2Fe^{II}(\mu_3\text{-}O)(CH_3COO)_6py_3]$, and several heteronuclear analogues (Fe_2CO, Fe_2Mn, Fe_2Ni) catalyse[82] the reduction of aromatic nitro compounds by a mercaptoethanol; $[Co_3(\mu_3\text{-}O)(CH_3COO)_5(OH)py_3]^+$ and $[Co_3(\mu_3\text{-}O)(CH_3COO)_6py_3]^+$ are catalyst[69] precursors for the autoxidation of aromatic hydrocarbons.

A distinct group of complexes derived from Mo, W and Nb has a similar molecular formula to those of the "basic acetates" of the trivalent metal ions, viz. $[M_3(\mu_3\text{-}O)(\mu_3\text{-}X)(RCOO)_6L_3]^{2+}$, but a different structure. The work of Bino and Cotton[88] has elucidated the unique structural feature of these compounds which is based on a metal–metal bonded equilateral triangle of metal atoms with an oxygen placed above the triangle, bonding to all three metal atoms (**11**). A second oxygen or an alkylidyne group, CCH_3, can occupy the analogous μ_3-bridging position on the opposite side of the triangle. Two carboxylato groups bridge each pair of metal atoms and a final trio of ligands such as water, THF or even further monodentate carboxylate groups are coordinated to the metals. A generalized treatment of the bonding in these molecules has been given.[101] Comparative structural data are given in Table 4. A variation in structural type is found in complexes having single alkoxide groups bridging each pair of metal atoms in the equilateral triangle with two monodentate alkoxide groupings coordinated to each metal (**12**).[98–100] An extension of the MO treatment used for the carboxylato compounds has provided a basis for the redox behaviour shown by such molecules.[102]



$[M_3(\mu_3\text{-}O)(\mu_3\text{-}X)(\mu\text{-}CH_3COO)_6L_3]^{2+}$ (**11**).



$[M_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6]$ (**12**).

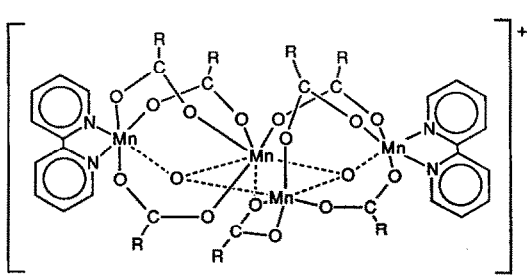
1.4 *Polymetal clusters with* (μ-O) *and* (μ_3-O) *bridging*

Polynuclear Fe^{III} oxo-bridged species with $Fe_2(\mu\text{-O})$ or $Fe_3(\mu_3\text{-O})$ bridging units are known with four, six, eight or 11 Fe atoms in the cluster unit, the Fe—O—Fe linkages generally being supported by other bridging units such as hydroxide, alkoxide, carboxylate or polyamine. The present status of this biologically important field has been reviewed by Lippard,[83] one of its major contributors. The $[Fe_{11}O_6(OH_6)(PhCOO)_{15}]^-$ anion has magnetic, spectroscopic and structural properties similar to those of the poly-iron core of ferritin, the iron storage protein. There is speculation as to whether Fe_{11} oxo-bridged units are basic to the structure of the protein.[84]

Similarly high nuclearity Mn oxo complexes have been formed when "basic manganese acetates", containing Mn^{III} or $Mn_2^{III}Mn^{II}$, $Mn_3(\mu_3\text{-O})$ units react with various bridging ligands. Examples of such compounds are $[Mn_4(\mu_3\text{-O})_2(RCOO)_7(bpy)_2]^+$ [85] (**13**) from the reaction of $[Mn_3(\mu_3\text{-O})(RCOO)_6L_3]^{0/+}$ with bipyridine (L = py, H_2O; R = CH_3, Ph), $[Mn_4(\mu_3\text{-O})(\mu_3\text{-Cl})(HIm)(CH_3COO)_3Cl_5]$[86] and $[Mn_9(\mu_3\text{-O})_2(PhCOO)_8(sal)_4(salH)_2(py)_4]$[87] (salH represents salicyclic acid). This latter complex essentially consists of two $Mn_4(\mu_3\text{-O})_2$ units of comparable pyramidal structure to others already described, and containing Mn^{III} ions, coordinated to a central Mn^{II} via bridging salicylate ions (**13**).



$[Mn_4(\mu_3\text{-O})_2(\mu\text{-RCOO})_7(bpy)_2]^+$ (**13**).

The Mn_4O_2 complexes can undergo oxidation processes to yield a variety of states reminiscent of the naturally occurring photosystem II aggregates of four Mn ions.[85]

The magnetic properties of the Mn_4 species indicate extensive antiferromagnetic coupling[85,86,87] between Mn ions in these complexes, most probably in pairs which in turn couple more weakly with each other. Ferromagnetic coupling between such pairs is given as an explanation of the temperature dependence of magnetic susceptibility of the (μ_3-Cl) bridged complex.[86]

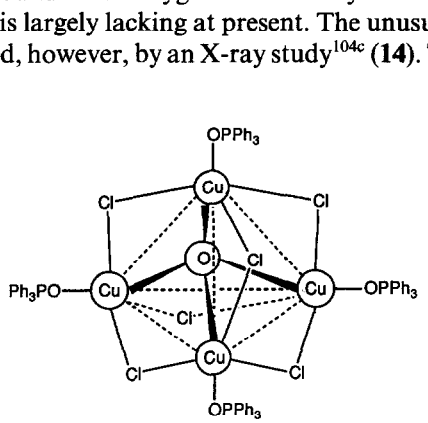
1.5 *Oxo bridging in groups* 9–12

Although a number of oxo or oxo-bridged compounds of the remaining transition elements (groups 9–12, triads Co, Rh, Ir to Zn, Cd, Hg) have been proposed, structures authenticated by X-ray studies are rare. This situation is in line with the prediction of instability in M_2O systems when M has more than five *d* electrons to be allocated to the non-bonding and antibonding molecular orbitals of such systems.[26] Thus, for Co, the complex[69] $[Co_3(\mu_3\text{-}O)(CH_3COO)_5(OH)py_3]^+$ has been shown to have the trinuclear "basic acetate" structure (**10**) and is the only Co complex demonstrated to contain Co—O—Co linkages by a structural study. This contrasts with the ability of dioxygen to coordinate, often reversibly, to a wide range of Co^{II} complexes forming essentially Co^{III}–superoxo ($Co^{III} \cdot O_2$) or bridged peroxo($[Co^{III}]_2O_2$) complexes.[103]

The compound $Co_4O((CH_3)_3CCOO)_6$ has been proposed on spectroscopic grounds[104a] to have an oxygen ion bridging four Co^{II} ions, a type of structure authenticated by X-ray structural studies for Be^{II} and Zn^{II} "basic acetate" complexes of the general formula $M_4(\mu_4\text{-}O)(CH_3COO)_6$.[104b] This consists of a tetrahedral array of metal ions bonded by an O^{2-} ion at the centre of the tetrahedron with the metal ions linked by carboxylate bridges along the six edges of the tetrahedron.

Complexes of other elements in these latter groups, of low oxidation state (Ni^0, Pt^0, Ir^I, Rh^I), also react with dioxygen, usually giving peroxo type species by oxidative addition.[103b]

The reactions of Cu^I compounds with oxygen are in many cases believed to form oxo-bridged species but structural evidence is largely lacking at present. The unusual (μ_4-O) Cu^{II} species $[Cu_4(\mu_4\text{-}O)(OPPh_3)_4Cl_6]$ has been defined, however, by an X-ray study[104c] (**14**). The copper-containing oxygen

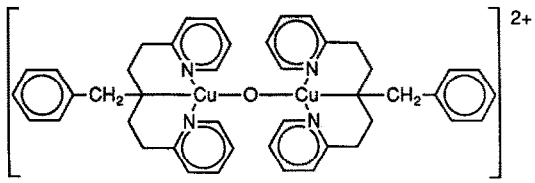


$[Cu_4(\mu_4\text{-}O)(OPPh_3)_4(\mu\text{-}Cl)_6]$ (**14**).

carrier haemocyanin which is found in certain molluscs and arthropods may contain a μ-oxo $Cu_2^{II}O$ linkage, and efforts to prepare compounds to model this system have been made.[105]

Examples of complexes considered to contain such linkages and formed by the reaction of Cu^I complexes with molecular oxygen include $[Cu^{II}(phen)Cl]_2O$[106a] and $\{[Cu^{II}(PBA)]_2O\}(PF_6)_2$[106b] (PBA = bis[2(2-pyridyl)ethyl]benzylamine) while $[Cu^{II}HB(3,5\text{-}Me_2Pz)_3]_2O$[107a] ($HB(3,5\text{-}Me_2Pz)_3^-$ is the 3,5-dimethylpyrazolylborate anion) has been formed by the reaction of iodosyl benzene with $[Cu^IHB(3,5\text{-}Me_2Pz)_3PPh_3]$. This complex is reported to react further with H_2O_2 to give a peroxo-bridged dimer.[107b]

None of these types of complexes have yet been authenticated by an X-ray structure study and their constitutions have been proposed on the basis of microanalyses together with a variety of other evidence, including reaction with PPh_3[106a,107a] to form $OPPh_3$ and reduction to the Cu^I starting complex, low magnetic moments[106b,107] or ESR spectra[106a] indicating magnetic coupling between Cu^{II} ions and molecular ion observation in a field desorption mass spectrum.[107]



$\{[Cu^{II}(PBA)]_2O\}^{2+}$ (**15**).

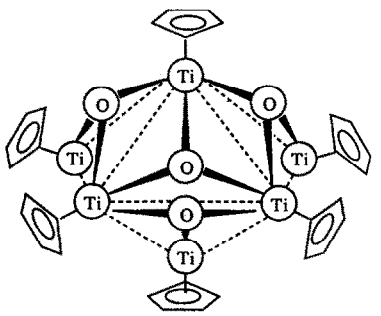
$\{[Cu(PBA)]_2O\}(PF_6)_2$ (**15**) reacts with H_2O[106b] to give the dihydroxy-bridged compound $\{[Cu(PBA)OH]_2\}(PF_6)_2$ which has been structurally characterized. This hydroxy dimer also has a low magnetic moment indicating magnetic coupling between two metal centres.

Direct reaction in methanol of $Cu^{II}Cl_2$ and the triaza-macrocycle N,N′,N″-trimethyl-1,4-triazacyclononane (MACN) is also postulated to form an oxo-bridged complex[108] with a further bridging water molecule. The structural study of this complex was prevented by oxygen disorder in the bridge. It shows antiferromagnetic behaviour over a temperature range.

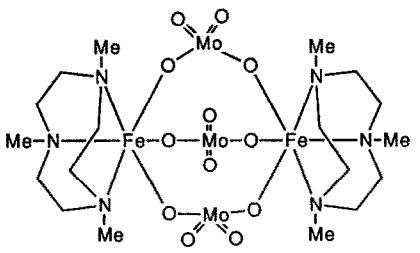
1.6 *Oxo bridging in organometallic compounds*

Increasing interest has been shown in recent years in the preparation of metal cluster oxo compounds which have organometallic groups attached to the metals, particularly carbonyl and cyclopentadienyl groupings. Oxygen has been shown to be capable of bridging two or three metals in such low valent compounds. An example of a (μ_3-O) complex being the $[Fe_3(CO)_9(\mu_3\text{-}O)]^{2-}$ anion which has the oxygen-capped structure (vi) in Fig. 1. It also promotes the formation of metal oxo-bridged cluster systems, e.g. $[CpTi]_6(\mu_3\text{-}O)_8$ (**16**). An extensive review of such compounds has been made.[109] The term "organometallic oxides" has been used to describe these compounds,[109b] the phrase being particularly apt with regard to the mixed metal systems derived from the reactions of polyoxometallates with organometallic cations, e.g. $[CpTi(Mo_5O_{18})]^{3-}$,[110] $\{[Cp_2U]_2(\mu\text{-}K_2O\text{-}TiW_5O_{19})_2\}^{4-}$.[111] Their synthesis and study is directed towards providing a better understanding of the mechanisms of catalysis of organic reactions on metal oxides and may lead to the production of new catalytic materials.

Polyoxometallate anions may also be bound to complex cations forming heteronuclear oxo-bridged species, e.g. $[Fe_2(MACN)_2Mo_3O_{12}]$[112] (**17**). This potentially very large group of heteronuclear oxo complexes will not be reviewed in this report because of space limitations.



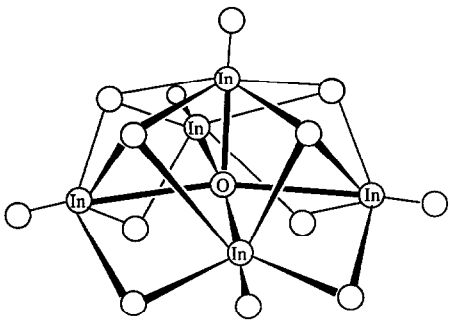
$(CpTi)_6(\mu_3\text{-}O)_8$ (**16**).



$[Fe_2^{III}(MACN)_2Mo_3O_{12}]$ (**17**).

1.7 (μ_5-O) *compounds*

Although (μ_5-O) compounds of transition metals have not yet been reported, there are two other polymetallic systems containing lanthanide or main group metals which have been shown by X-ray diffraction studies to contain a single oxygen coordinated to five metal ions in a square-pyramidal array. These are the alkoxy-bridged complexes $(\eta^5\text{-}C_5H_5\text{-}Y)_5(\mu\text{-}OCH_3)_4(\mu_3\text{-}OCH_3)_4(\mu_5\text{-}O)$[113a] and $In_5(\mu\text{-}O^iPr)_4(\mu_3\text{-}O^iPr)_4(O^iPr)_5(\mu_5\text{-}O)$ (**18**).[113b] The Y and Yb analogues of the latter complex have



$In_5(\mu\text{-}O^iPr)_4(\mu_3\text{-}O^iPr)_4(O^iPr)_5(\mu_5\text{-}O)$ **(18)**.

also been prepared.[113b] These remarkable compounds represent further potentially very useful examples of soluble "polymetallic oxides". The bonding arrangements in the $(C_5H_5\text{-}Y)(\mu_5\text{-}O)$ complex have been compared with those in polyboranes.

It may now be anticipated that analogous $(\mu_5\text{-}O)$ bound transition metal complexes will be identified in due course along with a wider range of main group species.

2. FORMATION OF HOMONUCLEAR OXO-BRIDGED COMPOUNDS

The widespread occurrence of homonuclear μ-oxo compounds would suggest that heteronuclear analogues would also be known in considerable numbers. However, relatively few compounds having an authenticated M—O—M′ linkage have been known until the last few years, no doubt because routes for the directed synthesis of such linkages have not been sought until recently. It is pertinent, therefore, to briefly review the methods used for preparing homonuclear species. Although precise mechanisms of formation are scarcely known for any of the methods used, they may be conveniently grouped under the headings Reduction, Oxidation and Olation–Oxolation, the last term indicating formation of an oxo group by deprotonation of a hydro group.

2.1 *Reduction processes*

The well studied decahalo compounds $[M_2OX_{10}]^{4-}$ (M = Ru^{IV}, Os^{IV}, Re^{IV}, W^{IV}) containing linear MOM have been prepared[1,2] by reduction of an oxide, e.g. $Ru^{VIII}O_4$, or oxometallate anion, e.g. $W^{VI}O_4^{3-}$ in halic acid solutions. $(lig)_2OMo^{V}OMo^{V}(lig)_2$ complexes with various bidentate ligands are also prepared by reduction of $Mo^{VI}(O)_2(lig)_2$[115] complexes with reagents such as dithionite, PPh_3, etc., although direct reaction with $MoCl_5$ can also give the oxo complexes. The reaction of PPh_3 in excess with $Mo^{VI}(O)_2(dtc)_2$ complexes forms mono-oxo Mo^{IV} complexes, $MoO(dtc)_2$.[116]

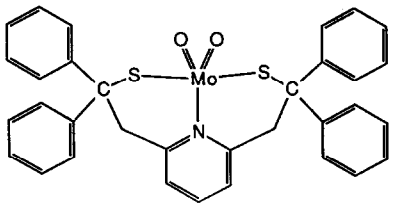
$$(dtc)_2Mo^{VI}(O)_2 + PPh_3 \longrightarrow (dtc)_2Mo^{IV}O + OPPh_3. \quad (1)$$

Many Mo^{V} oxo-bridged complexes have been found to undergo disproportionation in solution to Mo^{VI} and Mo^{IV} species.[115b,117–119] This reaction has usually been recognized by the failure of the UV–vis spectrum of an oxo-bridged complex to obey Beer's law. Redox reactions between the Mo^{VI} and Mo^{IV} compounds[117b] have also been shown to form oxo-bridged Mo^{V} compounds, presumably via an inner sphere electron transfer mechanism involving an initial $OMo^{VI}{=}O \rightarrow Mo^{IV}O$ transition state.

$$(dtc)_2Mo^{VI}(O)_2 + OMo^{IV}(dtc)_2 \longrightarrow [(dtc)_2Mo^{V}O]_2O. \quad (2)$$

Such a reaction is presumably involved in the formation of oxo-bridged Mo^{V} complexes when reducing agents react with $Mo^{VI}(O)_2$ complexes.

Measurements of the kinetic (Table 5) and thermodynamic (Table 6) parameters for a number of these reactions have been made. It has been shown by Berg and Holm[120] that the formation of an oxo-bridged complex by such a reaction can be prevented when the ligand attached to Mo is sufficiently bulky to inhibit the approach of two Mo centres to a distance appropriate for oxo bridge formation, even though electron transfer may take place **(19)**.



$Mo^{IV}(O)_2$(DMEpy) (**19**).

$(L)_2Mo(O)OMo(O)(L)_2$ complexes (L = anions of 8-quinolinol or acetylacetone)[116,121] have been prepared by the reduction of the corresponding Mo^{VI} species, but disproportionation of these complexes has not been detected. Indeed, the $Mo^{IV}O$ complexes containing these ligands have not so far been prepared even by oxygen abstraction using PPh_2Et.[116] $[Mo^{V}O(acac)_2]_2O$ does not appear to be reduced by common reagents although the 8-quinolinol product does. A $Mo^{IV}O$ complex could not be isolated, however.[121]

2.2 *Oxidation processes*

(a) *Dioxygen.* Oxo-bridged $(ML)_2O$ compounds of the transition metals Fe, Cr, Mn and Ru have been prepared with porphyrin (Fe^{III},[122] Cr^{III},[123] Ru^{IV}[23,124]) or phthalocyanine ligands (Fe^{III},[125] Mn^{III}[21,126]) by reaction of the M^{II}(lig) complex with molecular oxygen in solution. Many other Fe^{II}[3,29] and a few Cr^{II}[18] complexes have been found to react similarly with oxygen but many reactions of Cr^{II}[127] and Mn^{II}[128] complexes with oxygen have resulted in impure oxo–hydroxy species being formed. Since the heat of reaction with air or pure oxygen is often sufficient to cause visible decomposition of the complexes in a number of cases, oxidation with very low concentrations of oxygen in solution may aid in the isolation of new compounds.

The oxidative reaction of Fe(P) porphyrins with oxygen has been studied extensively because of its relevance to the reversible oxygen-carrying functions of haem proteins where μ-oxo formation is prevented.[129]

The following overall sequence has been proposed.

$$(P)Fe^{II} + O_2 \rightleftharpoons (P)Fe^{III}(O_2) \xrightleftharpoons{(P)Fe^{II}} (P)Fe^{III}—O—O—Fe^{III}(P) \quad (3)$$

$$(P)Fe^{III}—O—O—Fe^{III}(P) \longrightarrow 2(P)Fe^{IV}O \quad (4)$$

$$(P)Fe^{IV}O + Fe^{II}(P) \longrightarrow (P)Fe^{III}—O—Fe^{III}(P). \quad (5)$$

Most of the intermediate species have been identified only by spectral or other means, their high reactivity making isolation difficult or impossible. Thus, La Mar *et al.*[131] have presented ^1H NMR evidence for the formation of the peroxo-bridged species (P)FeO—OFe(P) and $(P)Fe^{IV}O(B)$ complexes at low temperatures (< 193 K). Formation of "ferryl" $Fe^{IV}O$ complexes is facilitated by the presence of a heterocyclic base (B). It has further been shown that $(P)Fe^{III}—O—Fe^{III}(P)$ is formed when $Fe^{II}(P)$ is reacted with such an $Fe^{IV}O$ species at low temperatures.[130,132] Holm[5] has provided an extensive summary of the work on identification of $Fe^{IV}O$ species.

The critical step involving fission of the O—O linkage has had little direct experimental support until recently when Groves and Watanabe[133] presented kinetic and spectral studies on the decomposition of the peroxo linkage in an acylperoxy Fe^{III} porphyrin leading to formation of an $Fe^{IV}O$ porphyrin cation radical.

In the overall reaction leading to oxo-bridged species two additional pathways have been suggested for the decomposition of the proposed peroxy dinuclear system viz.

$$(P)Fe^{III}—O—O—Fe^{III}(P) \longrightarrow (P)Fe^{III}—O—Fe^{III}(P) + O_2 \quad (6)$$

$$(P)Fe^{III}—O—O—Fe^{III}(P) + 2Fe^{II}(P) \longrightarrow (P)Fe^{III}—O—Fe^{III}(P). \quad (7)$$

Evidence for each route[131] was obtained at temperatures above $-30°C$, indicating that the overall reaction may well proceed by a variety of paths.

The reaction of Cr^{II} porphyrin complexes with molecular oxygen leads to the formation of $[Cr^{III}(P)]_2O$ compounds when the supply of oxygen is limited.[134] In the presence of excess oxygen stable $Cr^{IV}O(P)$ complexes are formed in striking contrast to the highly reactive $Fe^{IV}O(P)$ species. The overall reaction sequence for the formation of $Cr^{IV}O(P)$ is considered to be the same as that proposed for Fe^{II} reactions.[123]

$$(P)Cr^{II} + O_2 \rightleftharpoons (P)Cr^{III}(O_2) \xrightleftharpoons{(P)Cr^{II}} (P)Cr^{III}—O—OCr^{III}(P) \quad (8)$$

$$(P)Cr^{III}—O—O—Cr^{III}(P) \longrightarrow 2(P)Cr^{IV}O \quad (9)$$

$$(P)Cr^{IV}O + Cr^{II}(P) \rightleftharpoons (P)Cr^{III}—O—Cr^{III}(P). \quad (10)$$

The existence of the equilibrium in reaction (10) has been demonstrated by spectroscopic means[134] and $[Cr(P)]_2O$ complexes prepared by direct reaction of $Cr^{IV}O(P)$ and $Cr^{II}(P)$ compounds.[123]

Spectroscopic evidence for the existence of the superoxide precursor $Cr^{III}(P) \cdot O_2$ has been obtained from the reaction of solid $Cr^{II}(TPP)(py)_2$ with dry oxygen.[135] The oxygen compound, when dissolved in toluene, is converted to $Cr^{IV}O(TPP)$.[123]

A careful magnetic and spectroscopic study of the reaction between oxygen and solid $Cr^{II}(Pc)$[136] indicated the likely formation of a dimeric $[Cr(Pc)]_2O_2$ compound thought to contain Cr^{IV} entities rather than being a peroxo-bridged Cr^{III} compound. Earlier attempts to react $Cr^{II}(Pc)$ with oxygen in solution had led to the formation of mixtures of hydroxy-containing $Cr^{III}(Pc)$ products[136] rather than a clearly defined oxo-bridged compound.

Mn^{II} porphyrins show reversible reactions with molecular oxygen at low temperatures but do not yield oxo-bridged or other identified oxo compounds at higher temperatures.[137,138] The presence of Lewis bases can prevent any reaction occurring between $Mn^{II}(P)$ and oxygen because of preferential coordination of the base molecules to Mn^{II}.[137] Manganese(II) phthalocyanine, however, reacts readily in the presence of pyridine to form an oxo-bridged compound having further molecules of pyridine coordinated to each Mn^{III} ion.[21] The early complications experienced in defining the nature of the product[139] formed when oxygen reacted with $Mn^{II}(Pc)$ appear to relate to the adventitious presence of water in many reactions which led to the formation of Mn—OH species and impure samples of the oxo-bridged complex.

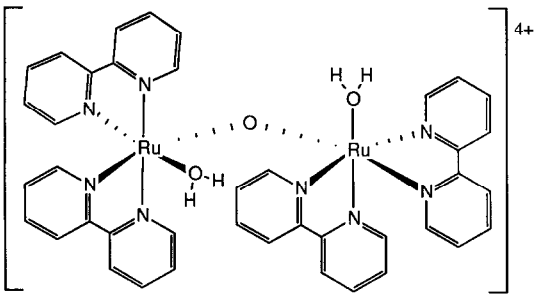
Many Co^{II} complexes including porphyrin derivatives react reversibly with dioxygen to form

(P)Co^{III}–superoxo species[103] as well as the dinuclear peroxo compounds

$$Co^{II}(L)+O_2 \rightleftharpoons Co^{III}(L)\cdot O_2 \overset{Co^{II}(L)}{\rightleftharpoons} (L)Co^{III}—O—O—Co^{III}(L). \quad (11)$$

There have been no reported instances where a μ-oxo compound has been detected as the by-product of such reactions.

The action of oxygen on the ions $[Ru^{II}(lig)_2Cl\cdot S]^{+}$[247](lig = bipyridyl, 1,10-phenanthroline) or $[Ru^{II}(NH_3)_5\cdot S]^{2+}$[248] (S = acetone) results in the formation of the oxo-bridged Ru^{III} species[37a] $\{[Ru^{III}(lig)_2Cl]_2O\}^{2+}$ and $\{[Ru^{III}(NH_3)_5]_2O\}^{4+}$. Boiling solutions of the bpy and phen chloro complexes in the presence of Ag^+ ions converts them to the aqua complexes $\{[Ru^{III}(lig)_2H_2O]_2O\}^{4+}$. Water in turn can be replaced by NO_2^-[247] or pyridine[249] giving $\{[Ru^{III}(lig)_2L]_2O\}^{2+}$ (L = NO_2^-, pyridine). The unsymmetrically substituted complex $\{[Ru^{III}(lig)_2py]O[Ru^{III}(lig)_2H_2O]\}^{4+}$ has also been obtained.[249] Structural studies on $\{[Ru^{III}(bpy)_2H_2O]_2O\}(ClO_4)_4$[37a] and $\{[Ru^{III}(bpy)_2NO_2]_2O\}(ClO_4)_2$[37b] have revealed bent RuORu bonds (Table 1) (**20**). The group of Ru^{III} complexes



$\{[Ru(bpy)_2H_2O]_2O\}^{4+}$ (**20**).

have low magnetic moments[247,248] in the range 1.7–18 μ_B per Ru atom. The variation of susceptibility with temperature of $\{[Ru^{III}(bpy)_2NO_2]_2O\}(PF_6)_2$ indicates[247] strong magnetic coupling between the Ru ions via the bridging O^{2-} ions. The data is adequately accounted for by use of the Bleaney–Bowers expression having the coupling constant $2J = -173$ cm^{-1} and $g = 2.48$. The phen analogue has $2J = -119$ cm^{-1} and $g = 2.29$. ESR signals have not been observed for the compounds.

The complexes show UV–vis spectra having quite different features to those shown by normal monomeric Ru^{III} bpy and phen complexes which display weak bands related to *d–d* transitions. In particular, the oxo-bridged compounds each show an intense absorption band in the region of 630–670 nm with $\varepsilon = ca\ 20\times10^3$, a feature found for a number of MOM bonded compounds having delocalized electronic bonding systems. Such a view of the bonding in these complexes is also considered to account for the magnetic coupling.

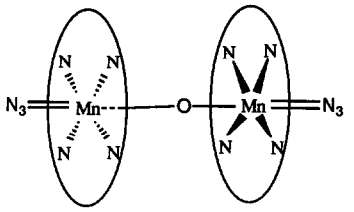
A particular feature of the complexes is their ability to undergo oxidation[37a,248] in a number of stages to give a range of higher oxidation state compounds including a number with mixed oxidation states, e.g. $Ru^{III}ORu^{IV}$, $Ru^{IV}ORu^{V}$ and $Ru^{V}ORu^{V}$. The $Ru^{IV}ORu^{IV}$ species is generally not observed, however, and appears to undergo ready disproportionation to $Ru^{III}Ru^{IV}$ and $Ru^{V}Ru^{V}$ ions. The redox chemistry of the complexes is notably dependent on pH and the higher oxidation state systems have been characterized as containing terminal oxo groups attached to Ru, derived by loss of protons from water molecules, e.g. $\{[Ru^{V}(bpy)_2O]_2O\}^{4+}$.

The ions $\{[Ru^{III}(bpy)_2H_2O]_2O\}^{4+}$ and $\{[Ru^{III}(bpy)_2py]O[Ru^{III}(bpy)_2H_2O]\}^{4+}$ are found to act as catalysts in the oxidation of water to oxygen when Ce^{IV} ions are added to aqueous solutions containing these ions.[37a,250] The exact oxidation states of the species involved in the final oxygen evolution step are not established with certainty but must involve Ru^{IV}/Ru^{V} systems. The possibility has been considered that O_2 could arise by combination of the terminal oxygen atoms believed to be attached to Ru in the Ru^{V} type compounds. However, such a mechanism is thought unlikely because of the estimated distance apart of the oxygens, based on the coordinated water positions established by X-ray studies.[37a] ESCA measurements have supported a delocalized electronic con-

figuration for the compounds since the mixed valent complexes $\{[Ru^{III}(bpy)_2Cl]O[Ru^{IV}(bpy)_2Cl]\}(PF_6)_3$[247] and $\{[Ru^{III}(NH_3)_5]O[Ru^{IV}(NH_3)_5]\}(ClO_4)_5$[248] show equivalent Ru centres.

A mixed valent Os analogue of these complexes has been prepared, $\{[Os^{III}(bpy)_2H_2O]O[Os^{IV}(bpy)_2OH]\}^{4+}$.[251] The spectral properties are similar to those of the Ru complexes in that an intense band is found at *ca* 600 nm, its position being pH dependent. The number of accessible redox couples is considerably greater for this system than for Ru, extending from Os^{II}—O—Os^{II} to Os^{V}—O—Os^{V}.

(b) *Oxo-transfer reagents.* Oxo-bridged compounds have resulted from the reaction of oxo-transfer reagents such as iodosyl benzene (PhIO) with metal porphyrins. The reactions most probably involve a comproportionation reaction. Thus, $Mn^{III}(TPP)\cdot N_3$ reacts with PhIO to yield the Mn^{IV} compound $N_3\cdot(TPP)Mn^{IV}OMn^{IV}(TPP)\cdot N_3$[20] (**21**). The initial reaction is expected to form



$[Mn^{IV}(TPP)N_3]_2O$ (**21**).

$Mn^{V}O(TPP)\cdot N_3$ which could then react via an inner sphere bridged transition state with further $[Mn^{III}(TPP)]^+$ to give the Mn^{IV} product.

$$N_3\cdot(TPP)Mn^{III}\overset{e}{\frown}O{=}Mn^{V}(TPP)\cdot N_3 \longrightarrow N_3\cdot(TPP)Mn^{IV}{-}O{-}OMn^{IV}(TPP)\cdot N_3. \quad (12)$$

$Cr^{III}(TPP)Cl$ forms the highly reactive $[Cr^{V}O(TPP)]^+$ on reaction with PhIO,[140] but the eventual product is $Cr^{IV}O(TPP)$ rather than the readily oxidized $[Cr^{III}OCr^{III}]$ intermediate.

Various nitrogen oxides or RNO species have also been found valuable reagents in transferring oxygen to organometallic substrates. The molecularity of the oxo-bridged organometallic clusters which form can vary with the choice of the amine oxide. Thus[141]

$$\begin{array}{l} C_5H_5NO\ \ [CpV(\mu_3\text{-}O)]_4 + [CpV]_6(\mu_3\text{-}O)_8 + (Cp)_5(O)V_6(\mu_3\text{-}O)_8 \\ \quad + \\ (Cp)_2V \nearrow\searrow \\ \quad + \\ (CH_3)_3NO\ \ \{(Cp)_5V_6(\mu_3\text{-}O)_8\}_2\{(\mu\text{-}O)_2(CpV)(N(CH_3)_3)_2\} + [CpV]_6(\mu_3\text{-}O)_8. \end{array} \quad (13)$$

The oxo-bridged aqua ion $\{[Cr^{III}(H_2O)_5]_2O\}^{4+}$ has been reported to form in low yield (*ca* 4%) when $[Cr((H_2O)_6]^{2+}$ ions react with 1,4-benzoquinone.[252a] $[Cr(H_2O)_6]^{3+}$ and several Cr–hydroquinone complexes are also formed in major amounts in the reaction. The ions are separable by ion exchange. The "oxo" ion has an absorption spectrum showing three sharp, intense peaks in the near-UV region very reminiscent of the bands shown by $\{[Cr(NH_3)_5]_2O\}^{4+}$, a complex whose linear CrOCr bridge has been characterized by a crystallographic study.[17] Electronic transitions within the linear π-bonded CrOCr segment have been identified as the source of this spectral feature. The ion $\{[Cr(H_2O)_5]_2O\}^{4+}$ undergoes rapid hydrolysis[252b] in acid solution to yield the hexaqua ion $[Cr(H_2O)_6]^{3+}$; the kinetics of the reaction have been interpreted as showing that two alternate pathways can be used, one of which (the major) is acid dependent. The rate is also catalysed by a large number of cations including alkali metal ions and $[Cr(H_2O)_6]^{3+}$, and by perchlorate ions. It has been suggested that the acid dependent path involves an initial protonation of the oxo group with the resultant hydroxo-bridged species remaining linear and only slowly converting to the expected "bent" CrOHCr form which is rapidly hydrolysed to $[Cr(H_2O)_6]^{3+}$. The half-life of acid hydrolysis is 70 min in 1.0 M $HClO_4$ at 25°C. The ammine complex $\{[Cr(NH_3)_5]_2O\}^{4+}$ is not susceptible to rapid hydrolysis at room temperature and studies have been carried out at 55°C to obtain reasonable rates.[253]

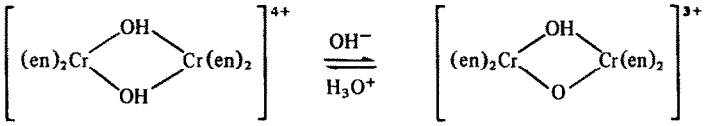
The reaction of molecular oxygen with $[Cr(H_2O)_6]^{2+}$ has been reported[254a] to form a dihydroxo bridged species $\{[Cr(H_2O)_4OH]_2\}^{4+}$, a distinction between this ion and the oxo compound having

the same charge $\{[Cr(H_2O)_5]_2O\}^{4+}$ having been drawn on the basis of $H_2{}^{18}O$ exchange studies.[254b] The crystal structure of the tosylate of this ion has also been reported by Marty and co-workers[255] establishing CrOHCr angles of 101°. This group has also established the existence of polychromium ions linked by hydroxy groups rather than oxo bridges.[256] The studies on $\{[Cr(NH_3)_5]_2O\}^{4+}$ and $[(NH_2)_5Cr(OH)Cr(NH_3)_4H_2O]^{5+}$ have established (a) the linearity of the CrOCr bridge[17] and the bent nature of the Cr(OH)Cr linkage ($168 \pm 5°$)[17] and (b) the existence of strong magnetic coupling in the oxo complex leading to a notable lowering of the magnetic moment per Cr, compared to little or no coupling in the hydroxy-bridged complex which shows a moment only slightly smaller than the spin-only value for a d^3 ion ($\mu_{eff} = 3.44\mu_B$).

The analogous monohydroxo-bridged complex ion[257] $\{[Cr(H_2O)_5]_2OH\}^{5+}$ which is formed from the dihydroxy compound in strong acid solution has a moment of $3.45\mu_B$. The dihydroxo complex has $\mu_{eff} = 3.74\mu_B$.

Acid hydrolysis of the monohydroxy-bridged species has been reported to be slow ($t_{1/2}$ *ca* 6 days in 2 M acid), indicating a relatively stable species, and this fact is difficult to reconcile with the hydrolytic instability of the oxo compound reported by Holwerda and co-workers.

An example of an oxo–hydroxo bridged species has been provided by Springborg and Toftlund[258] who reported that the dihydroxy-bridged ion $\{[Cr(en)_2OH]_2\}^{4+}$ is converted to an oxo-bridged species in strong alkali [see eq. (14)].

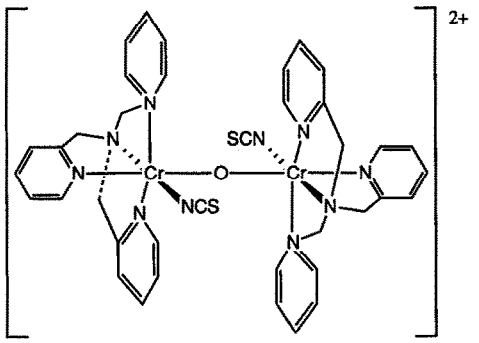


(14)

The oxo-hydroxo complex was isolated as a perchlorate salt. The diol compound has a pK_a of 12 at 0°C.

Conversion of the aqua Cr^{III} hydroxo complexes to oxo-bridged species is not feasible by use of OH^- since condensation to higher nuclearity $[Cr(OH)]_n$ species occurs as the pH is raised.

Holwerda and co-workers[18b] have recently shown that NCS^- converts a dihydroxy-bridged Cr^{III} complex to a mono-oxo-bridged complex in boiling water (**22**).



$\{[Cr^{III}(tmpa)NCS]_2O\}^{2+}$ (**22**).

(c) *Formation of metal–metal bonded* M_3O *species*. The formation of M_3 triangular metal–metal bonded arrays for M = Mo, W with O capping on either one or both sides and carboxylate anions bridging each pair of metal atoms (Table 4), results from the reactions of Mo(W) hexacarbonyls with mixtures of the free acid and anhydride.[142] The μ_3-bridging group X may be O, or an alkylidyne (CCH_3), the latter presumed to be formed by reduction of an acetate group.[92b] The complexes must generally be separated from other accompanying products by ion-exchange chromatography. Niobium analogues of these compounds are prepared from the metal–metal bonded complex $Nb_2Cl_6(Me_2S)_3$. The source of the oxygen atom has generally not been determined but may arise from the air since the reactions were seldom performed under oxygen-free conditions.

One reaction has been devised for the directed synthesis of oxo-bridged, "triangulo" compounds having alkoxy groups bridging the metal pairs. This involves a comproportionation[98,99] reaction between triply bonded $Mo(OR)_6$ species and oxo Mo^{VI} compounds.

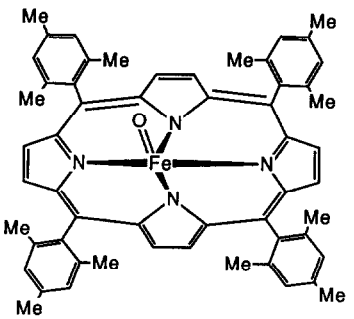
$$(RO)_3Mo{\equiv}Mo(OR)_3 + Mo(O)(OR)_4 \longrightarrow Mo_3(\mu_3\text{-}O)(OR)_{10} \quad (15)$$

2.3 *Olation and oxolation reactions*

Iron(III) oxo complexes in particular can be formed by reactions which appear to proceed via Fe—OH intermediates[3] participating in an olation or more specifically an "oxolation" reaction

$$Fe{-}OH + HO{-}Fe \longrightarrow Fe{-}O{-}Fe + H_2O. \quad (16)$$

Synthetic procedures either use aqueous solutions of Fe^{III} aqua ions in which Fe—OH entities are prevalent even at pHs below seven or non-aqueous solutions of complexes containing groups such as Fe—Cl which can be replaced by the addition of OH^-. Direct structural evidence for the Fe^{III}—OH group in coordination complexes is not extensive but several examples where OH groups bridge Fe^{III} ions have been reported.[143] $Fe^{II}(P)$ complexes containing *meso*-tetramesitylporphyrin or *meso*-tetrakis(2,4,6-trimethoxy)phenylporphyrin give $Fe^{III}(P)OH$ compounds[144a,b] on reaction with oxygen, instead of the more usual oxo-bridged products. The hydroxy compounds also result from the reaction of OH^- ions with $Fe^{III}(P)Cl$. They are high spin Fe^{III} compounds and can be readily distinguished from oxo-bridged species by this property, together with their ^1H NMR and ESR spectra, which are both typical of $Fe^{III}(P)X$ compounds. Their IR spectra are also typical of hydroxy containing species with broad absorptions *ca* 3400 cm^{-1} and no evidence for the 850 cm^{-1} peak which is normally observed as an antisymmetric vibration of the FeOFe linkage. The bulky substituents may be considered to prevent a sufficiently close approach of "Fe—OH or Fe—O" species which could result in Fe—O—Fe bridge formation. Reduction of this steric restraint by use of Fe porphyrins containing *meso*-tetrakis(3,4,5-trimethoxyphenyl)porphyrin or the tetrapentafluorophenyl derivative allows mixtures of Fe(P)OH and $[Fe(P)]_2O$ complexes to be observed in solution.[144b] Tetramesitylporphyrin has been found to stabilize the formation of $(P)Fe^{IV}O$[144c] by preventing the sufficiently close approach of an $Fe^{II}(P)$ molecule to allow the redox reaction $Fe^{IV}O + Fe^{II} \rightarrow Fe^{III}OFe^{III}$ to occur (**23**).



$Fe^{IV}(O)(TMesP)$ (**23**).

The trinuclear compounds $[M_3(\mu_3\text{-}O)(\mu\text{-}RCOO)_6(H_2O)_3]^+$ ($M = Fe^{III}$, Cr^{III}, Mn^{III}, V^{III}, Rh^{III}, Ru^{III}, Ir^{III}, Os^{III})[78,79,80] have also been prepared by reacting M^{III} salts with excess carboxylate ions in aqueous solution. Acetate has been the most common anion employed but a range of other carboxylates is entirely possible. The formal mixed valent compounds $Fe_2^{III}Fe^{II}$, $Cr_2^{III}Cr^{II}$, $Mn_2^{III}Mn^{II}$, etc. (Table 3) are also prepared by mixing appropriate amounts of metal salts of the different oxidation states. The mechanism by which the final M_3O unit is formed has not been the subject of a detailed study but a plausible route would involve the initial formation of M—O—M species, supported by carboxylate bridges, to which a further M^{III} unit can add, rather like protonation of an oxo group. Such reactions have been considered by Lippard[83] as contributing to the formation of poly $Fe^{III}O$ clusters.

The mixed valence $[Ru_3(O)(CH_3COO)_6(PPh_3)_3]$[77] and the cationic Co^{III} complex[80] are prepared by similar aqueous procedures but using "Ru^{II} acetate" and Co^{II} acetate, so that oxidation processes must also be involved here.

3. PHYSICAL PROPERTIES OF OXO-BRIDGED COMPOUNDS

A number of measurements other than a direct X-ray structure determination have some value in indicating whether an oxo-bridged structure may exist in a new complex isolated for the first time.

3.1 *Magnetic susceptibilities*

Magnetic moments, lower than the "spin-only" values appropriate to the constituent metal ions, are generally observed for oxo-bridged complexes. Many such complexes are diamagnetic. The variation of magnetic susceptibility with temperature of these paramagnetic complexes, also in the main, is found to show antiferromagnetic behaviour. The spin coupling effect is demonstrated by a representative selection of compounds collected in Table 7 showing the experimental magnetic

Table 7. M—O—M stretching frequencies and magnetic moments of oxo-bridged complexes

	Compound	$\nu_{as\ MOM}$ (cm^{-})	$\nu_{M=O}$ (cm^{-1})	μ_{eff}^{a} (μ_B/metal ion)	μ_S	Reference

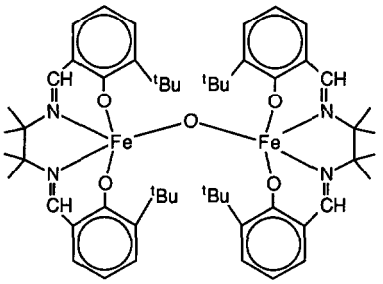
[a] Measurements all reported at or near to 293 K.
[b] Not defined.

moments measured at or close to 293 K (considered as "room temperature") together with the "spin-only" values of their magnetic moments per metal ion, i.e. assuming absence of magnetic coupling. As described earlier, a description of the bonding in the MOM unit using a molecular orbital approach and considering σ- and π-bonding between metal *d* and oxygen *p* orbitals has provided an appropriate way of defining ground state electronic configurations for a number of linear MOM systems, particularly where diamagnetism is encountered. A more widely applicable approach when studying magnetic properties *per se* has been to treat the magnetic susceptibility as arising from an exchange interaction between a series of metal ions without the need to define a mechanism for the exchange process. The procedure requires definition of a spin Hamiltonian, in the simplest form being

$$\mathscr{H} = -2\Sigma J_{ij} S_i S_j,$$

with J_{ij} being an exchange integral between metal centres i and j having a negative value for antiferromagnetic interaction between the centres and positive for ferromagnetic interaction. An expression for the molar susceptibility for the system can then be defined using the Van Vleck equation. The theoretical treatment has been termed the Heisenberg–Dirac–Van Vleck or HDVV method. The general theoretical approach has been described.[3,61,145] It has been found to provide a good fit for experimental data for many Fe_2O systems[3,145] and the Cr_2O complex $\{[Cr(NH_3)_5]_2O\}^{4+}$.[42] The mechanism for exchange is best considered as a "super-exchange" process involving participation of the metal *d* orbital interaction with the *p* orbitals of oxygen.

Iron(III) compounds remain the most accurately studied complexes of any oxo complexes showing exchange coupling.[3] Holm and co-workers[146] have examined the influence of FeOFe angle on extent of coupling by comparing the two complexes $[Fe(salen)]_2O$ and $[Fe(3\text{-}^tBusaltmen)]_2O$ (**24**)



$[Fe(3\text{-}^tBusaltmen)]_2O$ (**24**).

which contain very similar ligands although the bulky substituents of the latter compound can prevent too much bending of the FeOFe linkage. The extent of coupling as measured by the *J* values increases as the bond angle increases, although the differences are small (Table 8). This is in line with the bonding picture for such compounds which shows a reduced Fe—O π-interaction as the bond departs from linearity.[41] The $[Fe(3\text{-}^tBusaltmen)]_2X$ (X = O, S) compounds have very similar bond angles and this allows the conclusion to be drawn that coupling through S is greater than through O.

The nature of the ligand attached to the metal will also influence the extent of coupling and an attempt has been made to gauge the influence of peripheral substituents on the magnetic coupling in a series of substituted tetraphenylporphyrin $[Fe(P)]_2O$ compounds[147] (Table 8). The variation in substituent was from electron withdrawing $CF_3C_6H_4$ and C_6F_5 groups to the electron donating $CH_3O \cdot C_6H_4$. It was argued that the extent of FeOFe coupling should increase as the core size of the porphyrin ring increases because this would allow greater attraction for axial ligands by the metal. The core size of the porphyrin ring would be predicted to increase as the electron donating capacity of substituents on the *meso*-phenyl rings increased. Detailed crystallographic data is not yet available to be considered along with the magnetic evidence but the increase in *J* values followed an increase in the electron releasing property of the substitution, i.e. *J* increases in the order $4\text{-}CF_3C_6H_4 < C_6H_5 < 4\text{-}MeOC_6H_4$.

[a] The various (TXP) abbreviations represent the dianions of *meso*-substituted tetraaryl porphyrins, the aryl groups being phenyl (TPP), 4-methoxyphenyl (T(4-MeOP)P), 4-trifluoromethylphenyl (T(4-CF_3P)P), pentafluorophenyl (TPFPP).

[b] Derived from ^{13}C NMR measurements.

The pentafluorophenyl complex shows a similar J value to that of the 4-$CH_3OC_6H_4$ complex based on solid state magnetic data. Values of J obtained from ^{13}C paramagnetic shift data, however, while in good agreement with solid state data for the other compounds studied, gave an appropriately lower coupling constant for the C_6F_5 complex. The difference between the two sets of data for this compound may relate to some major stereochemical difference between the pentafluorophenyl derivatives and the remaining complexes.

Trinuclear (μ_3-O) complexes such as the triangular $[M_3O(CH_2COO)_6(L)_3]^+$ species (M = Fe^{III}, Cr^{III}, Mn^{III}) also show magnetic coupling between the metal centres. The crystallographically confirmed D_{3h} symmetry for the arrangement of three Fe^{III} or Cr^{III} ions in these complexes leads to a spin Hamiltonian[145] having a single coupling constant to describe the interaction of the ions

$$\mathscr{H} = -2J(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_2 \cdot \hat{S}_3 + \hat{S}_1 \cdot \hat{S}_3).$$

Expressions derived for the variation of magnetic susceptibilities with temperature from 300 to below 100 K for both Fe_3O and Cr_3O acetato complexes have not been completely successful in simulating the experimental data, the deviations being greatest at the lowest temperatures.

Improvements in the fit of such expressions have been produced by a variety of approaches[149] including assuming (a) an isosceles triangular array of the metal ions rather than equilateral[145] for which the spin Hamiltonian may be represented as

$$\mathscr{H} = -2J(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_2 \cdot \hat{S}_3) - 2J'(\hat{S}_3 \cdot \hat{S}_1);$$

(b) the existence of two different forms of the compound at low temperatures; (c) inter-trimer exchange coupling; and (d) dynamic distortion of the structure of the complex,[149] i.e. allowing each M^{3+} ion to vary its distance from the other two ions rapidly, a process termed "fast fluxionality". The idea that different forms of the complex may exist in the same crystal gains support from heat capacity measurements which have disclosed that a phase transition occurs[150] in $[Cr_3(\mu_3\text{-}O)(CH_3COO)_6H_2O]Cl \cdot 6H_2O$ at low temperatures due to reorganization of the solvate water molecules. While time resolved optical spectroscopic studies have shown that there are two different Cr_3O complexes[151] present in crystals of that complex which can take part in excitation energy transfer processes.

The magnetic properties of the Mn^{III} (μ_3-O)acetato-bridged compound (L = py) have been studied[76] using the same basic theoretical approach[145] assuming three equivalent Mn^{III} ions arrayed in an equilateral triangular array around oxygen. The antiferromagnetic interaction is considerably weaker for $Mn_3^{III}O$ than $Fe_3^{III}O$ and comparable to that in the $Cr_3^{III}O$ system. ($-J = 10.2$ cm^{-1} (Mn_3O); 11 cm^{-1} (Cr_3O, L = H_2O);[214] 30 cm^{-1} (Fe_3O, L = H_2O)[214]) and this has been related[76] to the greater occupancy of d_{z^2} orbital directed towards the bridging O^{2-} ion in Fe^{III} d^5 systems than for Cr^{III}, d^4 or Mn^{III}, d^3. Since the overall exchange process is considered to be a super-exchange interaction via oxygen, a larger interaction is possible with occupancy of the d_{z^2} metal orbitals.

Interaction via the carboxylato bridges or by direct M···M interaction is not considered to contribute to the process[145] of magnetic coupling in any of these M^{III} compounds.

3.2 *Vibrational spectra*

Vibrations of a linear MOM unit of D_{4h} symmetry give rise to a Raman active symmetric vibration frequency and asymmetric stretching and bending vibrations in the IR spectral region. A bent MOM array of C_{2v} symmetry will give rise to asymmetric, symmetric and bending vibrations active both in the IR and Raman regions. Recent accurate Raman measurements on the linear $[M_2OCl_{10}]^{4-}$ ions have identified frequencies for each type of vibration (Table 9) for a number of these complexes. The ν_{as} and ν_s values lie in the frequency ranges suggested earlier for such types of vibrations (ν_{as} 750–900 cm^{-1}; ν_s 200–500 cm^{-1}) but the bending modes are found at much higher frequencies (400–450 cm^{-1}) than had earlier been suggested.[2b]

In many of the presently known homonuclear complexes the presence of organic ligands provides a multitude of additional bands and this has made clear-cut identification of the various frequencies more difficult and rather subjective. ^{18}O labelling has been applied in only a few cases with effect. More often than not broad sections of the spectrum of the labelled compound show increased or decreased intensities rather than single, identifiable bands.

Metals which also have terminal oxygen atoms attached, e.g. $Mo^{V}O$, $V^{V}O$ provide a source of further M—O vibrations and allocations of such vibrations have been made for Mo=O vibrations[153] on the basis of comparison of ^{18}O labelling studies on $MoO_2(LL)_2$, $MoO(LL)_2$, $Mo_2O_3(LL)_4$ and $Mo_2O_4(LL)_2$ compounds (LL represents dithiocarbamates and other S_2 chelating ligands). Related data for the $[M_3O(RCOO)_6L_3]^+$ cations (M = CR, Fe, Mn, Ru, Rh) have been reported.[154] Some data are shown in Table 10.[18]O-Substituted $[Fe_3(^{18}O)(CH_3COO)_6py_3]^+$ has been examined to enable assignments to be made of both in-plane ($\nu_{as\,Fe_3O}$) and out-of-plane (δ_{s,Fe_3O}) vibrations of the oxo unit.[155]

3.3 ^{17}O *NMR*

Direct observation of a bridging oxygen atom or distinguishing it from a terminal oxygen in the same molecule by some means has an obvious importance in initial studies of a potentially oxo-bridged

complex. In principle, ^{17}O NMR measurements provide such a means, chemical shifts being expected to differ for each type of oxygen. Despite the complications of detecting the nucleus due to its large nuclear spin ($I = 5/2$) and electronic quadropole moment, the use of the technique has been extended since the advent of Fourier transform techniques applied to NMR spectroscopy.[156] The need to produce ^{17}O labelled species for examination requiring use of the expensive isotope has also been removed, or at least reduced, with the advent of higher frequency spectrometers. The technique has been used extensively by Klemperer in studies on the diamagnetic polyoxometallates and mixed-metal compounds containing such anions.[157] It does not give an advantage, however, to studies on paramagnetic complexes. Chemical shift values for some oxo-bridged complexes are given in Table 11.

Table 11. ^{17}O NMR resonance spectra of oxo-bridged complexes. Chemical shift values for selected compounds

[a] Measurements are downfield from external $H_2{}^{17}O$.

3.4 *Optical electronic spectra*

The UV–vis spectra of oxo-bridged complexes do not, in general, show outstanding features that indicate the presence of an oxo bridge. However, some cases exist, particularly for linear MOM species, where distinct spectral features have been recognized and related to transitions in the electronic framework encompassing the MOM linkage. Thus, the distinct dark purple colours of $[Mo^{V}O]_2O$ dithiocarbamate compounds have been associated with intense absorptions in the region of 500–520 nm.[4] Such absorptions appear to be characteristic of the Mo—O—Mo linkage and have been suggested to arise from transitions involving an antibonding level of the three centre Mo—O—Mo linkage.[158]

Absorptions around 500 nm, associated with dark colours, appear to correlate generally with M—O—M linear configurations since such absorption bands have been observed for a number of complexes of different metals and attached ligands. Thus the V^{V} complex containing 8-quinolinolato ligands (Q^-), $[Q_2V^{V}O]_2O$, is also reported to have a very dark colour and its solution shows a similar absorption around 550 nm.[159] $\{[Re^{V}O(CN)_4]_2O\}^{4-}$ also has an intense purple colour[152] with an absorption at 540 nm.

The series of iso-structural halide compounds $[M_2OX_{10}]^{n-}$ ($M = Ru^{IV}$, Os^{IV}, Re^{IV}, W^{IV}; X = Cl, Br; $n = 4$) and the mixed valence species $[Re_2OCl_{10}]^{3-}$ having linear MOM arrangements, also display strong charge-transfer bands around 500 nm giving rise to the dark colours of the compounds. The bands have been assigned to $e_u^* \leftarrow e_g$ transitions of the π-electron systems of these MOM linkages.[152] For these ions the transition is in resonance with the symmetric stretching vibration for the MOM unit.

The $[M_3(\mu_3O)(CH_3COO)_6L_3]^+$ complexes of Fe^{III} and Cr^{III} have absorption spectra with general features resembling those of the metal ions in fields approaching octahedral symmetry.[160] Absorption bands are observed, however, which show enhanced intensities that can be linked with the exchange interactions in such molecules which result in their reduced magnetic moments.

4. HETERONUCLEAR OXO-BRIDGED COMPOUNDS

Interest in obtaining heterobinuclear oxygen-bridged compounds to model biologically important systems containing two metal components or the surfaces of heteronuclear oxide catalysts has resulted in the preparation of a variety of such materials in recent years. Since the spread of elements and the types of complexes involved is still relatively small, it is convenient to arrange the discussion by the method of synthesis used for each class of μ-oxo compounds.

4.1 *Bridging by oxo groups as Lewis bases*

An oxo group bound to a metal is normally represented as M=O leaving two lone pairs of electrons associated with oxygen. Holm[5] has recognized that stable M=O groupings are restricted to metals having oxidation states of IV or greater and electron configurations in the range d^0–d^4, i.e. for transition elements in groups 4–8.

Depending on the electron density available on the oxygen atom in (L)M=O compounds, a donor–acceptor reaction could take place with an appropriate electron deficient partner to produce an oxo-bridged product

$$(L)M{=}O + M'(L') \longrightarrow (L)M{=}O \longrightarrow M'(L'). \qquad (17)$$

The two bond distances M—O and M′—O would be expected to differ considerably (M=O < M′ ← O) and the oxidation states of M and M′ would be unaltered.

The extent to which the M=O oxygen can act as a Lewis base will be influenced by the extent of further π-bonding to the metal involving an oxygen electron pair to form an M≡O structure, as envisaged by Ballhausen and Gray[161] in their molecular orbital treatment of bonding in VO^{2+}. They concluded that the remaining oxygen lone pair would occupy an sp_σ type hybrid orbital of largely s character which would thus show little capacity to bond to other Lewis acids.

Nevertheless, a number of heterobinuclear compounds have been obtained, with d^0 M=O systems apparently behaving as Lewis bases (Table 12).

Table 12. The oxo group as a Lewis base

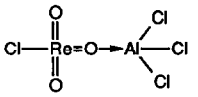
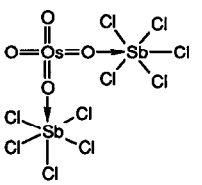
$[V^{IV}O(EDDA)]$			$[(EDDA)V{=}O{-}Ru(NH_3)_5]^{2+}$		166

Direct reaction between the oxyhalide ReO_3Cl or OsO_4 and Lewis acid halides such as $AlCl_3$, $SbCl_5$ or $NbCl_5$ in CCl_4 solution results in the isolation of compounds denoted as μ-oxo compounds[162] (**25**). No structural data is available to confirm these structures but shifts in IR spectral bands due to Re—O stretching frequencies were interpreted as a consequence of Re—O—M bond formation. In the absence of X-ray data the possibility of halide bridging Re—Cl—Al, however, cannot be completely ruled out.

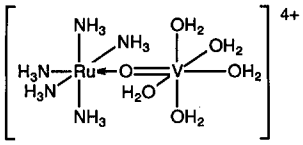




$ClO_2Re{=}O{-}AlCl_3$, $O_2Os(OSbCl_5)_2$ (**25**).

Similar types of complexes have been reported to form between $M(VI)O \cdot X(neopentyl)_3$ (M = Mo, W; X = Cl, Br, OR) and a range of Lewis acids (Table 12), Mo^{IV}—O—M coordination being again indicated by shifts in the M=O stretching frequencies.[163] A number of these compounds are excellent catalysts for olefin metathesis whereas the parent oxo complexes are not.[167] The production of a greater electron deficiency at the metal following coordination of an appropriate Lewis acid is suggested to facilitate reductive ($W^{VI} \rightarrow W^{IV}$) α-elimination processes to form carbenes for reaction with olefins.

A more elaborate study of the stable, dark green product isolated from the reaction between $[Ru(NH_3)_5H_2O]^{2+}$ and VO^{2+} ions in water[165] in the absence of air has been made. It is considered



$[(NH_3)_5Ru{-}O{=}V(H_2O)_5]^{4+}$ (**26**).

to be the bridged species $[(NH_3)_5Ru^{II}OV^{IV}(H_2O)_5]^{4+}$ (**26**). A further complex isolated in the presence of SO_4^{2-} ions, was assigned the formula $[(NH_3)_5RuOV(H_2O)_4SO_4]SO_4$. The former complex ion shows a characteristic intense absorption at 378 nm ($\varepsilon = 1.3 \times 10^4$ M^{-1} cm^{-1}) with a weaker band at 625 nm ($\varepsilon \sim 2 \times 10^3$ M^{-1} cm^{-1}) which accounts for the colour of the complex. Similar spectral bands are observed for other $[Ru(NH_3)_5L]^{2+}$ species where L is a π-bonding ligand such as CO. $[Ru(NH_3)_5H_2O]^{2+}$ shows only weak absorptions in its UV–vis spectrum, transitions being Laporte forbidden in such a spin paired d^6 system. The complex does not dissociate when nitrogen is passed through the solution indicating that the strength of the VO → Ru bond is sufficient to resist competition from molecular nitrogen which is known to bind readily to Ru^{II} as $[Ru(NH_3)_5N_2]^{2+}$. This observation allowed a lower limit of 10^7 to be set for the stability constant of the RuOV complex. An IR stretching frequency at 975 cm^{-1} has been assigned to the V=O stretching frequency which in $[VO(H_2O)_n]^{2+}$ has a value[168] of 1000 cm^{-1}. The Ru portion of the complex is oxidized to $[Ru(NH_3)_5OH]^{2+}$ when a solution in water is exposed to oxygen.

The complex might be considered as $Ru^{II}OV^{IV}$ or $Ru^{III}OV^{III}$ depending on whether or not a redox reaction had occurred. The ESR spectrum of the solid compound gave $g = 1.98$, very close to the value for d^1 V^{IV} in $[VO]SO_4$ but with a line width approximately twice that of the vanadyl salt. A more detailed treatment of the ESR spectrum has not subsequently been attempted but this is necessary to resolve the question of localization of the electron.

The same μ-oxo compound can also be formed by reaction between $[Ru^{III}(NH_3)_5Cl]^{2+}$ and V_{aq}^{3+}, but kinetic studies disclosed that a preliminary redox stage occurs involving primarily V^{3+} ions (as $[VO]^+$ or $[V(OH)_2]$) thus:

$$[Ru(NH_3)_5Cl]^{2+} + [VO(H_2O)_x]^+ \longrightarrow [Ru(NH_3)_5H_2O]^{2+} + [VO(H_2O)_x]^{2+} + 2H^+ + Cl^- . \tag{18}$$

The bridge-forming reaction can then take place

$$[Ru(NH_3)_5H_2O]^{2+} + [VO(H_2O)_x]^{2+} \longrightarrow [(NH_3)_5Ru^{II}OV^{IV}(H_2O)_5]^{4+} . \tag{19}$$

Comparison of rate constants and activation parameters for $[Ru^{II}(NH_3)_5H_2O]^{2+}$ reacting by a second-order process with $[VO(H_2O)_x]^{2+}$ and other ligands such as N_2 or pyridine which show similar kinetic characteristics, led to the conclusion that the bridging reaction is essentially an SNI ligand substitution process with H_2O being displaced by VO^{2+} considered as an incoming ligand.

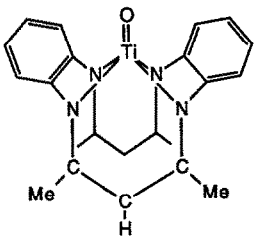
A MO bonding scheme has been proposed[165] for the RuOV system which treats VO^{2+} as similar to dinitrogen. The single unpaired electron expected for the $Ru^{II}OV^{IV}$ formulation is allotted to a non-bonding orbital on vanadium.

The high stability to dissociation of the RuOV system is thus ascribed to Ru···O···V π-bonding with d_{xz} and d_{yz} orbitals of Ru having the correct energies and symmetries to overlap with E-type empty orbitals of VO^{2+}, just as with N_2.

Similar types of $[(NH_3)_5RuOV(L)]^{(4-n)+}$ complexes are formed in solution when $[(NH_3)_5Ru(H_2O)]^{2+}$ reacts with VO^{2+} complexes of EDTA ($n = 4$), HEDTA ($n = 3$) and EDDA ($n = 2$).[166] The compounds each show the distinctive green colour observed for the $RuOV_{aq}$ complex due to charge-transfer bands close to 605 nm (ε = *ca* 1.2×10^4) assigned to $d_{xy}(B_2)Ru \rightarrow \pi^*(E)VO^{2+}$ transitions. They also each possess a further intense band *ca* 390 nm (ε = *ca* 1.2×10^4) similar to the aqua complex, arising from $\pi_b(E)Ru^{2+} \rightarrow \pi_a^*(E)VO^{2+}$ transitions. ESR spectra indicate the presence of V^{IV} in each case. Formation of the complexes is strongly pH dependent in contrast to the formation of the aqua compound, and particular pH ranges have been prescribed for each

complex. All are fully formed, however, at pHs > 4.5. A further distinction from the vanadium aqua complex $[(NH_3)_5RuOV_{aq}]^{4+}$ lies in the fact that each RuOV–polydentate chelate complex will undergo an overall intramolecular electron transfer reaction at low pH leading to the formation of Ru^{III} and V^{III} products. The oxo-bridged complexes, however, can be regenerated from such solutions under pH-jump conditions.[166] The kinetic parameters indicating that this reaction proceeds by an inner sphere reaction, contrast with the Ru^{III} and V^{III}_{aq} reaction which gives the $Ru^{II}OV^{IV}$ complex by an outer sphere redox process.[165] A mechanism involving a hydroxy-bridged intermediate Ru^{III}—OH—V^{III}(L) is suggested.

In the first study that has produced X-ray structural data for donor–acceptor oxo bridging, Yang and Goedken[164] isolated compounds from the reaction of the macrocyclic titanyl complex $Ti^{IV}O$(DBAT) (**27**) with a variety of transition metal compounds in which Ti=O → M linkages

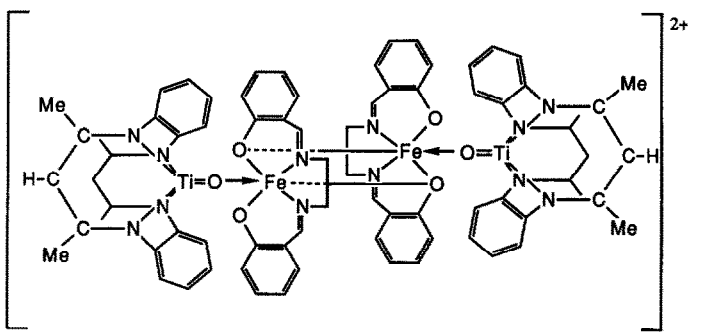


$Ti^{IV}O$(DBAT) (**27**).

were proposed. The empirical formulae of the compounds are given in Table 12, together with IR data purporting to represent asymmetric stretching frequencies for Ti—O—M bonds.

In each of these compounds the TiO group is behaving as a ligand coordinating to the second metal. No oxidation state change has occurred. TiO(TPP) apparently does not react to form such a range of complexes, indicating a smaller Lewis basicity for the oxygen in the metalloporphyrin.[164]

An X-ray structural study of the [(DBAT)TiOFe(salen)]$^+$ cation (**28**) isolated as the $[B(Ph)_4]^-$



[(DBAT)Ti^{IV}=O—Fe^{III}(salen)]$_2$[BPh_4]$_2$ (**28**).

salt showed it to contain the expected Ti—O—Fe linkage. In addition, the heterobinuclear ion was dimerized by bridging between Fe atoms and salicylaldimine oxygen atoms on two neighbouring [Fe(salen)]$^+$ units. This structural arrangement has also been found for [Fe(salen)Cl]$_2$.[169]

The Ti—O—Fe link is bent (161.6 Å) as are other Ti—O—Ti and Fe—O—Fe systems (Table 1). The Ti—O bond distance (1.701(6) Å) is shorter than is found in homobinuclear Ti—O—Ti systems, in line with considerable residual Ti=O character in the link. The Fe^{III}—O linkage (1.935(6) Å) however, is longer than in [Fe(salen)]$_2$O and other Fe_2O compounds, again in line with the nature of the bonding mode proposed for the complex.

4.2. (μ-O) *Formation by ester elimination*

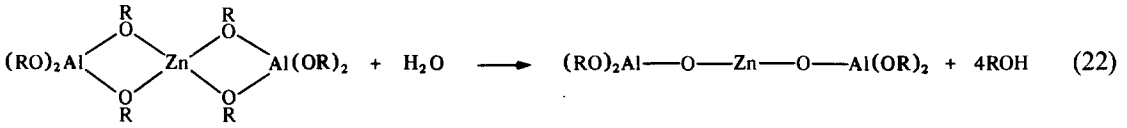
Silyl acetates have been shown to react[170] with metal alkoxides (M = Ti, Zr, Ta, Fe, V) with elimination of esters and formation of metal alkylsiloxides.

$$M(OR)_m + xR'_3SiO_2CCH_3 \longrightarrow (RO)_{m-x}M{-}(O{-}SiR'_3)_x + xROOCCH_3. \quad (20)$$

Similarly, titanium alkoxides react with titanium carboxylates to eliminate esters forming TiOTi linkages and the application of this reaction has been patented.[171] A related reaction between aluminium alkoxides and zinc acetate has been used by Osgan and Teyssié[172] to produce a complex considered to contain AlOZnOAl linkages. The reaction has been extended to other metal acetates of Cr^{II}, Mn^{II}, Fe^{II}, Co^{II} and Mo^{II}.[173,174]

$$2(RO)_3Al + M(OOCCH_3)_2 \longrightarrow (RO)_2Al{-}O{-}M{-}O{-}Al(OR)_2 + 2ROOCCH_3. \quad (21)$$

The general method reported involves heating a stoichiometric mixture of $Al(OR)_3$ and M^{II} acetate (2:1) in an inert solvent such as decalin at temperatures above 200°C. An alternative process[175] involves controlled hydrolysis of mixed Al—M alkoxides $[(RO)_3Al]_2M(OR)_2$, the so-called Meerwein complexes. This reaction would formally release an alcohol.

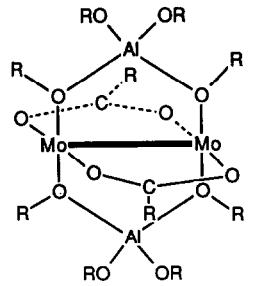


(22)

The "high temperature" synthetic route is said[172] to have other side reactions occurring and complete analytical purity of the products was seldom achieved. Certain of the complexes, notably the $(AlO)_2Zn$ species,[172,176] were found to be soluble catalysts for the polymerization of epoxides,[172] oxiranes[176] and cyclic esters[177] and the preparation and use of a number of these materials have been the subject of patent coverage.[178] The "Osgan–Teyssié" catalysts, however, are reported to be very sensitive to the presence of polar impurities in a reaction mixture and this has retarded their commercial use.[179]

Alkyl–alkoxy aluminium derivatives have been employed[179] to produce $[R_2AlO]_2Zn$ type species which show greater resistance to decomposition. A relatively limited amount of detailed synthetic information, spectroscopic or other data has been reported for the compounds and no structural determination has been made. The existence of Al—O—M bonding is inferred from the stoichiometry of the elimination of esters in the initial formation reactions. The compounds are said to be very soluble in most organic solvents, particularly hydrocarbons, and show degrees of association, measured cryoscopically, varying with the solvent and bulk of the alkoxide group[173,174] (Table 13). The presence of ^{i}Pr and ^{t}Bu groups leads to lower degrees of association, as does use of benzene as solvent. Surprisingly, a number of complexes are reported not to vary their level of association with concentration.[173] This was considered to indicate the existence of thermodynamically stable polynuclear species. The most widely applicable catalysts contain Al and Zn and have been allotted the molecular formula $\{[(RO)_2AlO]_2Zn\}_4$ in benzene solution. The complex of formula $[(^iPrO)_2AlO]_2Mo$ is not associated in benzene.[173] Its proton decoupled ^{13}C NMR spectrum measured in deuterated toluene, however, shows resonances at $\delta = 26.0$ and 28.4 corresponding to two different CH_3 groups, and at $\delta = 63.6$ and 69.2 due to the CH groups. These results have been taken to indicate the presence of bridging alkoxide groups as well as terminal ones, and indicate that association must occur in this solvent though not in benzene. The mass spectra for the compounds show ions corresponding to $M(OAl)_2$ fragments with varying numbers of alkoxide groups attached.

A Mo complex prepared by "thermal condensation" in decalin between equimolar quantities of $[Mo^{II}(CH_3COO)_2]_2$ and $Al(O^iPr)_3$[180] has been subjected to X-ray structural study[181] and found to resemble the parent Mo^{II} acetate. Its formal molecularity may be represented as $(\mu\text{-}OOCCH_3)_2$



$[Mo(\mu\text{-}CH_3COO)(\mu\text{-}O^iPr)_2Al(O^iPr)_2]_2$ (**29**).

$Mo_2[(\mu\text{-}O^iPr)_2Al(O^iPr)_2]_2$ (**29**). The Mo atoms are metal–metal bonded and bridged by two acetato groups and the oxygen atoms of four alkoxide groups in pairs. There is no single oxo Mo—O—Al linkage. The complex is described as orange in colour whereas the supposed Mo—O—Al products are said to be deep red or green.[173] The orange compound absorbs oxygen irreversibly from the air until a molar ratio Mo/O_2 of 1 is reached. The product generates acetone slowly over a period of some hours.[180]

The green Fe^{II} complexes, $[(RO)_2AlO]_2Fe$, prepared by heating Fe^{II} acetate and $Al(OR)_3$ at 500°C in decalin under argon (R = ^{n}Bu, ^{i}Pr, ^{i}Bu), are reported[182] to react reversibly with molecular oxygen in heptane solution to form the red complexes $\{[(RO)_2AlO]_2Fe\}_2O_2$. The starting compounds are octameric in heptane while the final complexes are monomers. Their empirical formulae were determined by volumetric oxygen uptake and cryoscopic molecular weight measurements. Oxygen can be removed by refluxing in *o*-dichlorobenzene. The oxygen-containing complexes have iron as

Table 13. Oxo bridging by ester elimination—formation of $(RO)_2Al—O—M^{II}—O—Al(OR)_2$ complexes[173]

A = benzene; B = cyclohexane.

[a] Other complexes referred to in ref. 173 are said to be based on Ni^{II}, Fe^{III}, Cr^{III} or Ti^{IV} linked to $OAl(OR)_2$ or $OSnR_3$ groups; but no details of their properties are given.

[b] $\bar{\eta}$ = degree of association measured cryoscopically.

[c] Mean degree of association varies with concentration.

Fe^{III}, determined by an EDTA titration, the oxygen presumably being considered to be the peroxo group O_2^{2-}. ESR measurements detecting the presence of Fe^{III} at 298 K ($g = 2.3$) were also made in order to prove that the oxygen reaction is fully reversible. The overall reaction is represented as

$$\frac{2}{n}\{[(RO)_2AlO]_2Fe^{II}\}_n + O_2 \underset{450\ K}{\overset{298\ K}{\rightleftharpoons}} \begin{array}{c}(RO)_2AlOFe^{III}OAl(OR)_2\\ |\\ O\\ |\\ O\\ |\\ (RO)_2AlOFe^{III}OAl(OR)_2\end{array} \tag{23}$$

The ESR signal of the solid "peroxo" complex changed little in intensity over the temperature range 77–320 K and the authors suggest this indicates ferromagnetic behaviour.

The reaction is extremely interesting since reversible oxygen carriage by Fe^{II} species other than "blocked" porphyrins is relatively rare. Further studies have not been reported on these complexes but they would repay re-investigation, with attention being given to their magnetic behaviour. Neither magnetic nor visible spectra data have been reported for the Fe, Co or Cr compounds as initially synthesized and nothing can be said with certainty about their oxidation states or stereochemistries.

The high temperature conditions said to be necessary to prepare the complexes and the occurrence of other unspecified side reactions do not appear conducive to obtaining pure compounds. However, the reaction forming a M—O—M′ linkage appears attractive as a synthetic route and would repay further study, particularly if the elimination of an ester can be accomplished between single entities.

$$(Lig)M—OR + (Lig')M'—OOCR' \quad (Lig)M—O—M'(Lig') + R\cdot OOCCR'. \tag{24}$$

4.3 *Inner sphere electron transfer formation of* (μ-O) *links*

Just as homobinuclear μ-oxo compounds can be formed by redox reactions of the comproportionation type, so too should heterobinuclear μ-oxo species. The conditions necessary to form such compounds call for an oxo group, coordinated to one metal ($A^x{=}O$), to be capable of forming an "inner sphere" oxo-bridged complex with a second metal (B^y) across which an electron can transfer.

$$(L)A^xO + B^y(L') \longrightarrow (L)A^x{=}O{-}{-}{-}B^y(L') \longrightarrow (L)A^{x-1}—O—B^{y+1}(L'). \tag{25}$$
$$\qquad\qquad\qquad

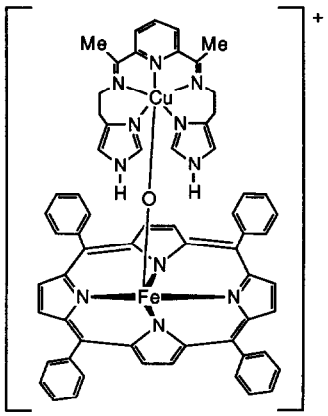
It contains two haem-Fe and two Cu centres and its function appears to require an initial reaction of dioxygen with an Fe–Cu pair.[183] The pair of haem and Cu sites has been found to show strong antiferromagnetic coupling when the enzyme is fully oxidized or in its "resting state" and this led to the suggestion that an Fe—X—Cu bridge can be established where X is an oxo group.[184] Homobinuclear μ-oxo complexes are generally found to show such magnetic coupling and this property could also be expected for a heterobinuclear Fe—Cu bridged intermediate. The magnitude of exchange coupling has been estimated to be large ($-J > 200\ cm^{-1}$) with an $S = 2$ ground state.[186] However, other small molecules or ions such as the imidazolato[185a] or mercapto[185b] have been suggested as bridging units.

Initial attempts[187] to mimic the structural requirements which cause the strong coupling in the oxidase were made by appending "strapping" groups from the porphyrin ring system which coordinates Fe^{III}, while Cu^{II} was held in the "strap". Any oxygen in a bridging mode was anticipated to arise, "serendipitously". Antiferromagnetic coupling, however, was small and in no case was it possible to determine clearly whether O^{2-} or another ligand accepted the bridging site.[187] A further attempt by Chang *et al.*[188] involved a porphyrin for coordinating Fe, to which was attached a thiazole sulphide "strap" linked via pyrrole rings intended to provide a more flexible coordination site for a Cu^{II} ion. Flexibility in coordination stereochemistry was considered important for Cu^{II} so that appropriate orbitals could align with those of Fe to allow magnetic coupling.[187,188] The product had an analytical composition corresponding to $FeCu(P)(O)(H_2O)(CH_3COO)L$. The compound appeared stable to solution in CH_2Cl_2 and recovery by evaporation. An IR spectral band at 880 cm^{-1} was assigned to be a M—O—M′ asymmetric stretching vibration. The magnetic susceptibility versus temperature data down to *ca* 4 K could be fitted to a simplified Van Vleck equation assuming interaction between a high spin Fe^{III} ($S = 5/2$) ion and a Cu^{II} ($S = 1/2$). The two states ($S = 2, 3$) resulting from this coupling are separated by $-3J = 132 \pm 5\ cm^{-1}$, a relatively small value compared with the coupling measured in the oxidase.

Wilson and co-workers[189] attempted a more fundamental redox reaction to form an Fe^{III}—O—Cu^{II} bridge by reacting $Fe^{IV}O(TPP)$ [formed at $-78°C$ in pyridine by reaction of oxygen with $Fe^{II}(TPP)$] with a pentadentate Cu^{I} complex—known to bind molecular oxygen reversibly in solution although not form an oxo-bridged Cu^{II} species. The reaction was expected to be

$$Fe^{IV}O(TPP) + Cu^{I}(Lig)^{+} \longrightarrow [(TPP)Fe^{III}—O—Cu^{II}(Lig)]^{+}. \quad (27)$$

The product (**30**) was isolated as a $[BF_4]^-$ salt. Preparation of the ^{18}O labelled complex by using



$[(TPP)Fe^{III}(\mu\text{-}O)Cu^{II}(Lig)]^{+}$ (**30**).

$Fe^{IV}{}^{18}O(TPP)$ showed that IR bands previously observed at 890.2 and 872.8 cm^{-1} in the [Fe^{III}—^{16}O—Cu^{II}] product and assigned to the asymmetric stretching mode were missing in the ^{18}O labelled complex, and a new peak at 880.5 cm^{-1} had appeared. The complementary band expected was possibly not distinguishable because of other ligand absorptions in the region where it would be expected to appear, although increased absorbance was noted in the area around 847.7 cm^{-1}. These results supported the existence of an Fe—O—Cu structure for the complex.

The magnetic susceptibility of the complex showed a decrease from $\mu_{eff} = 4.23$ at 298 K to 3.95 at 10 K. The complex was ESR silent at 10 K. The Mössbauer spectrum consisted of a doublet having $\delta(Fe^{\circ}) = 0.23$ mm s^{-1} and $\Delta E_Q = 2.06$ mm s^{-1} at 136 K. The authors considered these results to indicate strong antiferromagnetic coupling, however, but the $S = 1$ ground state resulting differed from the $S = 2$ state of the natural cytochrome *c* oxidase.

Other Fe–porphyrin–Cu complexes incorporating imidazolate[190] or sulphur[191] bridging have failed to produce complexes showing the strong antiferromagnetic coupling of the natural product and, although further examples of well authenticated Fe—O—Cu type systems have not been reported, oxo bridging as the coupling mode in the enzyme still appears plausible.

$Cr^{IV}O(P)$ *as an oxidant.* The direct synthesis of a series of heterobinuclear μ-oxo complexes having Cr^{III} as one component in the bridge has been accomplished using $Cr^{IV}O$ porphyrin complexes as oxidants and a variety of Fe^{II},[192] Mn^{II},[193] $Mo^{IV}O$[194,195] or $V^{IV}O$[196] complexes as reductants.

$Cr^{III}OFe^{III}$ *compounds.* Reaction occurs rapidly at room temperature in toluene or THF solution between $Cr^{IV}O(P)$ and various Fe^{II} complexes in the absence of moisture and oxygen. The range of donor atom sets in the Fe complexes studied has been N_4, O_2N_2, S_2N_2, O_2N_3, $(S_2)_2$ (Table 14).

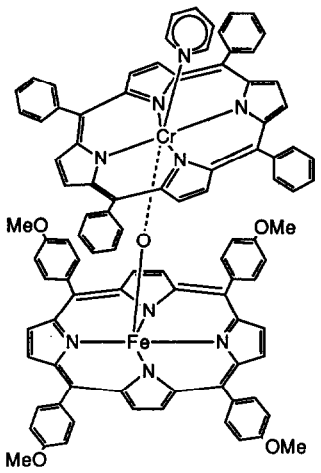
$$Cr^{IV}O(P) + Fe^{II}(Lig) \longrightarrow (P)Cr^{III}—O—Fe^{III}(Lig). \quad (28)$$

Only one X-ray diffraction study and that of limited accuracy has been made so far[192b] on any of these compounds, because of difficulties in obtaining adequate crystals. This study of the mixed porphyrin complex (py)(TPP)CrOFe(TMP), which also had a pyridine molecule coordinated to Cr, was of lower accuracy than necessary to define bond distances with high accuracy ($R = 0.149$) because of the presence of unresolved extraneous solvent. However, the essential structural features of the molecule have been indicated (**31**), the Cr and Fe centres being identifiable by the nature of



(py)(TPP)Cr^{III}(μ-O)Fe^{III}(TMP) (**31**).

the *meso*-aryl substances attached to them. The CrOFe linkage is essentially linear (178(2)°) while the two rings are rotated by 32(1)° with respect to each other in order to accommodate the sets of aryl rings.

The three CrOCr compounds that have been structurally characterized each have linear Cr_2O units (Table 1) while $[(TPP)Fe]_2O$ also has an almost linear Fe_2O arrangement. The flexible nature of FeOFe linkage systems and their angular dependence primarily upon interligand repulsions coupled with the predicted preferred linear arrangement of $d^3 \cdot d^3$ Cr_2O systems (see Section 1) suggests that in these mixed complexes the CrOFe array will normally be close to linear even when Fe^{III} is not coordinated by a porphyrin or similarly bulky ligand.

The complexes are generally stable in solution in toluene or $CHCl_3$ in the absence of moisture or air. In the presence of oxygen $Cr^{IV}O(P)$ can be detected spectroscopically together with the appropriate $(Lig)Fe^{III}OFe^{III}(Lig)$, indicating that some disproportionation must occur

$$(P)Cr^{III}OFe^{III}(Lig) \longrightarrow Cr^{IV}O(P) + Fe^{II}(Lig) \quad (29)$$

allowing further reaction with oxygen to take place.

$$4Fe^{II}(Lig) + O_2 \longrightarrow 2(Lig)FeOFe(Lig). \quad (30)$$

Water also slowly attacks the compounds leading to formation of the species defined as "$Cr^{III}(P)$" hydroxo complexes, whilst Fe_2O complexes can generally be isolated from such mixtures.[123]

The phthalocyanine complex (TPP)CrOFe(Pc) also gives CrO(P) and $[(Pc)Fe]_2O$ when exposed to air in toluene.[192b] However, a different behaviour is observed when the heteronuclear oxo complex is allowed to react with oxygen in pyridine solution. $Fe(Pc)(py)_2$ and the pyridine adduct of $[(TPP)Cr]_2O$ were initially detected by their visible spectra and the CrOCr compound slowly converted to $(py)Cr^{IV}O(TPP)$ with time.

Ercolani *et al.*[197] have shown that $[Fe(Pc)]_2O$ is converted to $Fe(Pc)(py)_2$ in the presence of excess pyridine and $[(P)Cr]_2O$ may be formed from a comparable reaction with (TPP)CrOFe(Pc), giving both $Cr^{II}(TPP)py_2$ and $Fe^{II}(Pc)(py)_2$. $Cr^{II}(TPP)$ is known to react with oxygen more slowly in pyridine than toluene,[123] thus allowing the intermediate CrOCr complex to be detected.

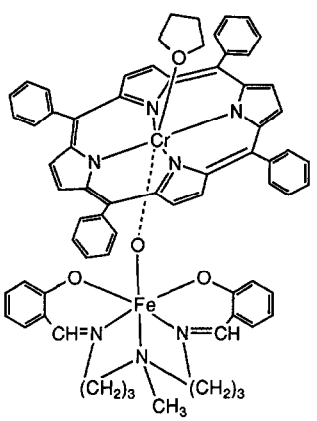
A number of complexes can be isolated[192b,193] containing a mole of water when recrystallized in the presence of moist air, although solutions left exposed for some hours will show decomposition. IR spectral evidence was not always found for the presence of the molecule, although microanalytical data appeared to indicate its presence. In view of the crystallographic identification of pyridine coordinated to Cr in (py)(TPP)CrOFe(TMP) and the spectroscopic evidence for various donors coordinating to other CrOFe species (see below), the formulae of a number of the compounds have been reported as having water coordinated to the Cr ion.

Visible spectra: the complexes with porphyrin ligands coordinated to both Cr and Fe[192] show only one major Soret absorption band in the 422–427 nm region with log ε values ranging from 4.96 to 5.36 in benzene. Two less intense bands occur near 560 and 600 nm. This pattern is found even though dissimilar porphyrins are coordinated to each metal.

A point of inflection near 400 nm occurs in each spectrum. Chromium(II) and Fe^{II} homonuclear oxo complexes have Soret bands at 412 and 407 nm, respectively, while Cr^{III}(P)Cl shows its major absorption at 447 nm and Fe^{III}(P)Cl at 417 nm. The single Soret bands observed in the heterobinuclear oxo complexes presumably represent envelopes for transitions involving both Cr(P) and Fe(P′) species. The single (P)CrOFe(Pc) complex reported shows bands that could be associated with each segment of the molecule, a Soret type band at 431 nm and a "phthalocyanine" major peak at 699 nm. Complexes with the Fe–salicylaldimines and –dithiocarbamate[193] ligands have spectra dominated by the Cr^{III} porphyrin segments (Cr(TPP) in the complexes reported) showing a Soret band at *ca* 437 nm with the corresponding two further peaks at *ca* 560 and 600 nm. The Soret bands are more symmetrical than those for the mixed Fe/Cr prophyrin derivatives.

The UV–vis spectra of all these complexes vary in the presence of Lewis bases, indicating further coordination can occur.[192–194] The structural identification of (py)(TPP)CrOFe(TMP) which was obtained from a toluene–pyridine solution with excess pyridine present, points to coordination of bases being more favourable at Cr^{III} than Fe^{III} in those heteronuclear oxo complexes. Indeed, neither $[Fe(TPP)]_2O$[198] nor $[Fe(salen)]_2O$[30b] appear able to coordinate Lewis bases.

Measurements of equilibrium exchange constants have been made by a standard spectroscopic technique[195] for the reaction of several nitrogenous Lewis bases with the complex (THF)(TPP) CrOFe(salmah) in THF solution (Table 15) (**32**). The Fe complex being six-coordinate, any



(THF)(TPP)Cr^{III}(μ-O)Fe^{III}(salmah) (**32**).

base coordination process is expected to occur at the Cr^{III} centre.

$$\text{(THF)(TPP)CrOFe(salmah)} + \text{B} \rightleftharpoons \text{(B)(TPP)CrOFe(salmah)} + \text{THF}. \qquad (31)$$

Highly hindered Lewis bases such as 2- and 2,6-substituted pyridines fail to show evidence for coordination even when in very large excess (B/Cr, 10^4), while the ability of other bases to coordinate increases with basic strength of the amine just as has been observed for reactions of such bases with Cr(TPP)Cl.[199] The heterocyclic base 1-methylimidazole was also found to bind more strongly than

Table 15. The binding of Lewis bases to (TPP)CrOFe (salmah) at 25°C[196]

Base	Log K ($\pm$0.1)
	Solvent: THF
py	2.3
4-pic	2.6
3,5-lut	2.7
1Me-Im	4.5
sec-$BuMH_2$	3.4
pip	3.2
H_2O	1.8
	Solvent: toluene
THF	2.2
py	4.8

py = pyridine; 4-pic = 4-picoline; 3,5-lut = 3,5-lutidine; 1Me-Im = 1-methyl-imidazole; pip = piperidine; THF = tetrahydrofuran.

would be indicated by its pK_a value. Significant ligand → metal π-bonding has been suggested to account for this anomaly.[199]

The complex (H_2O)(TPP)CrOFe(salmah) was used in the studies and comparisons of its spectra in pure toluene and in toluene–THF mixtures indicated that at the concentrations used (10^{-5}–10^{-6} M), water had either completely dissociated (in toluene) or been displaced by THF. The addition of further high concentrations of water to such THF solutions allowed a determination of the log K value for the H_2O–THF exchange (Table 15).

However, a second slow reaction occurs in aq. THF which could be followed by observing the growth of a new intense band at 448 nm due to the formation of the imperfectly characterized Cr(TPP) "hydroxy species".[123]

Measurements in toluene for the reaction

$$\text{(TPP)CrOFe(salmah)} + \text{B} \rightleftharpoons \text{B(TPP)CrOFe(salmah)} \qquad (32)$$

showed that the affinities of Cr^{III} for the THF and pyridine are similar to those of the metal in Cr(TPP)Cl. The log K value for the addition of 1-methylimidazole in toluene was too large to be measured by the spectroscopic technique employed, but it could be estimated as log $K = 6.6$ from the sum of the 1-MeIm–THF exchange constant (log $K = 4.4$) and the THF binding constant in toluene (2.2). Attempts to obtain a measure of the binding of water to (TPP)CrOFe(salmah) in toluene were hampered by the hydrolysis reaction. An approximate value can be estimated from the log K values for the H_2O–THF exchange reaction and the THF binding constant viz. log $K_{H_2O} = 4.0$.

The spectral changes upon addition of pyridine to THF solutions of (THF)(TPP) CrOFe(Pyrdtc)$_2$ and (THF)(TPP)CrOMn(salah) are consistent with coordination only to Cr^{III}. The values of log K only differ slightly from that for pyridine coordinating to (TPP)CrOFe(salmah).

IR spectra: bands attributable to CrOFe stretching frequencies have been reported for (P)CrOFe(P′) complexes in the region of 845 cm^{-1} and assigned to an asymmetric CrOFe stretching vibration (Table 14). The identification of the band at 842.5 cm^{-1} in (TPP)CrOFe(TPP) was supported by ^{18}O labelling experiments.[192b] A variety of ligand bands in the 800–900 cm^{-1} region have made it impossible to detect comparable frequencies in the Fe(Pc) and other Fe(Lig) systems.

^1H *NMR spectra*:[192b] the various types of protons associated with each of the porphyrins coordinated to either Cr or Fe can be detected in the ^1H NMR spectra of the paramagnetic (P)CrOFe(P′) complexes. The relatively sharply defined resonances for each type of proton in the Fe–porphyrin moiety occur at positions very close to those recorded for the homonuclear complexes (P′)

FeOFe(P′)[200] though with some minor variations in the breadth of peaks. Similarly, other broad resonance peaks allocated to composites of *meso*-phenyl protons can be observed at positions very close to those for porphyrin protons in Cr(P)Cl complexes. Resonances due to pyrrole β-hydrogens cannot be detected in these latter molecules but they are believed to contribute a broad resonance appearing at *ca* 40 ppm in the oxo complex. The similarities in the chemical shifts between the Fe_2O and CrOFe species imply that the effective electron spin at the Fe atoms in both types of complexes is the result of similar strong magnetic coupling. The paramagnetic shifts for uncoupled ($S = 5/2$) Fe^{III} porphyrin complexes such as Fe(P)Cl species are much larger because of dipolar and contact contributions.

Mössbauer spectra: zero field Mössbauer spectra of the CrOFe complexes (except for (TPP) $CrOFe(Et_2dtc)_2$) show single quadrupole split doublets at each temperature examined. Isomer shift and quadrupole splitting parameters are presented in Table 16 together with data for some homobinuclear Fe_2O compounds and other Fe^{II} and Fe^{III} complexes for comparison.

The data are consistent with the Fe^{III} centres being high-spin ($S = 5/2$). The spectra of the compounds like other Fe_2O species do not show the magnetic broadening at 77 K observed for mononuclear Fe^{III} ($S = 5/2$) complexes. This has been ascribed[192b] to rapid spin relaxation within the $S' = 1$ state of the CrOFe compounds, leading to a predicted broadening at higher temperatures where some excited states may be occupied. Iron(III) oxo complexes with tetradentate ligands attached and an overall five-coordinate array about Fe^{III} generally have quadrupole splitting values less than 1 mm s^{-1}. The larger value found for the salmah complex[201e] where Fe has six-fold coordination suggests a larger electronic field gradient for the compound. Similar values of ΔE have been observed for other six-coordinate ($S = 5/2$) Fe^{III} oxo complexes $[enH_2][\{Fe(HEDTA)\}_2O]$[201c] and $[Fe(salen)(Im)_2]PF_6$.[201d] Detailed Mössbauer or magnetic measurements are not available for $[Fe(salmah)]_2O$. By contrast, the complex having a five-coordinate, presumably square pyramidal array about Fe^{III}, (TPP)CrOFe(salen), shows similar values of δ and ΔE to those in $[Fe(salen)_2]_2O$.

[a] Measured relative to α-Fe at room temperature.

The complexes containing dithiocarbamate groups show different features to the other heterobinuclear complexes. The pyrrolidyl complex shows a large quadrupole splitting, the value being close to the range typically observed by five-coordinate $Fe(dtc)_2X$ (X = halide) compounds.[201b] Iron has a spin quartet ground state in such complexes. Homobinuclear oxo-bridged Fe–dithiocarbamates have not so far been described. The diethyldithiocarbamate compound obtained exhibits two quadrupole doublets indicating two inequivalent iron sites. The relative intensities of the quadrupole pairs varied with temperature (T) and with different preparations of the complex despite the samples showing excellent microanalytical data. The inner pair reduces in intensity by comparison with the outer as T is lowered. The isomer shifts of the doublets are in the region generally associated with Fe^{III} dithiocarbamate derivatives.[201h] The large ΔE observed for the main (outer) quadrupole pair is similar to that for the pyrrolidyl species and other five-coordinate $Fe(dtc)_2X$[201b] compounds, while the smaller quadrupole splitting of the inner doublet corresponds to a value in the range normally found for neutral six-coordinate $Fe(dtc)_3$ compounds.[201b] However, the variation of the relative intensities of the Mössbauer peaks with temperature and the constancy of microanalytical data indicates the phenomenon is not due to $Fe(dtc)_3$ impurity. "Spin-crossover" effects can be eliminated as a cause for two species since complexes showing magnetic spin equilibria show only one Mössbauer doublet,[201h] the "cross-over rate" being shorter than the lifetime of the ^{57}Fe excited state. A peak due to the presence of a small amount of THF in the mass spectrum of $(TPP)CrOFe(Et_2dtc)_2$ suggests that the explanation is due to the occurrence of small amounts of the THF adduct $(TPP)CrOFe(Et_2dtc)_2THF$ which causes Fe to achieve six-coordination. Some $Fe(Et_2dtc)_2X \cdot THF$, incorporated in the main product $Fe(Et_2dtc)_2X$ when the parent complex is recrystallized from THF, has also been found to give rise to two doublets in the Mössbauer spectrum of the latter complex.[201g] The inner doublet has a small quadrupole splitting similar to those found with six-coordinate Fe–dtc compounds. Because of the large molecular weight of the heteronuclear complex, amounts of THF considerably less than 1 mole per mole of complex would not readily be detected by microanalysis.

Magnetic susceptibilities: at room temperature, $Cr^{III}OFe^{III}$ heterobinuclear μ-oxo complexes show magnetic moments considerably reduced below the values expected for molecules containing uncoupled $S = 3/2$ 5/2 centres (Table 14). The variation of magnetic moment and susceptibility with temperature has been studied for a number of compounds from 300 to 4 K at which temperature μ_{eff} has decreased to values of the order of 2.8 BM. This behaviour is consistent with the presence of moderately strong antiferromagnetic coupling in all the complexes studied.

A simple Heisenberg–Van Vleck isotropic coupling model leading to the expression

$$\chi'_m = \frac{N\beta^2 g^2}{kT} \frac{2\exp(-9x)+10\exp(-7x)+28\exp(-4x)+60}{3\exp(-9x)+5\exp(-7x)+7\exp(-4x)+9}$$

with $\chi = J/kT$, was found to adequately reproduce the experimental data above 25 K for the porphyrin complexes (P)CrOFe(P').[192b] It leads to an $S' = 1$ ground state for the complexes with $J = ca. -150\ cm^{-1}$ (Table 17). A sharp decrease in μ_{eff} below 25 K, however, was observed for each of the complexes studied whether with Fe(P), Fe(salmah)[203] or $Fe(Et_2dtc)_2$[203] moieties, which could not be accommodated by this treatment. Such sharp decreases in μ_{eff} at low temperatures have also been observed in other heteronuclear systems with a variety of bridging ligands including

Table 17. Magnetic coupling parameters for (P)CrOFe(L) compounds

M(X, Y)M′ dibridged species contained in compartmental ligands.[202] The effect has been explained either by assuming superposition of weak interdimeric antiferromagnetic coupling or zero field splitting, or both effects acting simultaneously.

The experimental data for CrOFe compounds containing Cr^{III}(P) moieties linked to various Fe(L) systems have been found to be fitted by the Hamiltonian

$$\mathscr{H} = -2J\hat{S}_1\hat{S}_2 + D_1(\hat{S}_{1z}^2 - 1/3S_1^2) + D_2(\hat{S}_{2z}^2 - 1/3S_2^2) + g_1\beta\hat{H}\hat{S}_1 + g_2\beta\hat{H}\hat{S}_2$$

which includes single zero field splitting terms for each metal (Fe^{III} being taken as having $S = 5/2$ and Cr^{III}, $S = 3/2$). The parameters obtained for the compounds are shown in Table 17. The magnitude of the coupling constant J is notably larger for the (P)CrOFe(P′) complexes than the (P)CrOFe(salmah) complexes, the only non-porphyrin derivatives so far studied.[203] The two axial ligands coordinated to Cr^{III} and completing six-fold coordination for that element in the (P)CrOFe(salmah) compounds appear to have little influence on J values.

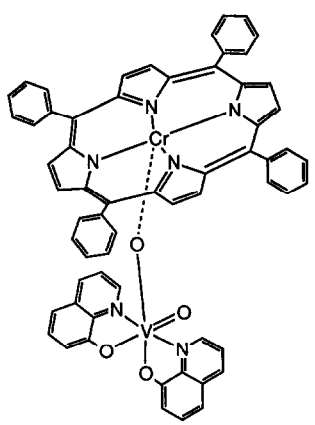
$Cr^{III}OM$ *compounds* (M = Mn^{III}, $V^{V}O$, $Mo^{VI}O$)

The pentadentate complex Mn^{II}(salah) is reported to react with oxygen to give first, peroxo-bridged complexes (salah)MnO—OMn(salah), which can then react further in an unknown manner with excess oxygen.[204]

$Cr^{IV}O$(TPP) reacts with both Mn^{II}(salah) and Mn^{II}(salmah) to give products characterized as μ-oxo species,[193] analogous to the Fe compounds (Table 14). The visible spectra of the compounds are again dominated by the porphyrin contribution. A clear IR spectral identification of a CrOMn asymmetric stretching frequency could not be made.

The room temperature magnetic moments of the proposed $CrOMn^{III}$ complexes are reduced from the spin-only values expected for an $S = 3/2$, $S = 2$ system (Table 14). The considerable decrease of the Mn(salah) complex value with temperature is indicative of antiferromagnetic coupling between the metal centres. Attempts to fit a simple Heisenberg–Van Vleck coupling model for an $S = 3/2$, $S = 2$ dimer to the data have only been successful if the g value is assumed less than 1.9.[195] However, theoretical considerations suggest g should be in the range 1.9–2.0.

The V^{IV} quinolinol complex $V^{IV}O(Q)_2py$, which has been shown to give the homobinuclear oxo-bridged complex $[(Q)_2V^{V}O]_2O$ upon reaction with oxygen,[205,9] has been found to react with $Cr^{IV}O$(TPP), giving a complex characterized as the oxo-bridged species (py)(TPP)Cr^{III} $OV^{V}(O)(Q)_2$[195] (**33**). Since the V atom has a coordination number of six, the pyridine molecule will be attached to Cr.



(TPP)$Cr^{III}(\mu$-O)V^{V}(O)$(Q)_2$ (**33**).

CrO(TPP) also reacts with $V^{IV}O(acac)_2$ to yield a similar oxo-bridged complex formulated as (TPP)$Cr^{III}OV^{V}$(O)$(acac)_2$[196] although the parent V^{IV} complex is inactive towards molecular oxygen. The ESR spectra of both the presumed oxo-bridged complexes in frozen CH_3CN–DMF solutions under N_2 display weak, broad bands at *ca* $g = 4.4$ arising from the d^3 Cr^{III} metal centre. There is

complete absence of a strong signal at *ca* $g = 2.0$ which would indicate a V^{IV}, d^1 centre. This confirms that a redox reaction has occurred and supports the allocation of μ-oxo structure. The magnetic moments of the complexes at 293 K are both *ca* 3.83 BM as expected for a spin-free Cr^{III}–V^{V} d^3–d^0 system. The quinolinato complex showed Curie–Weiss behaviour over the entire range 300–4.2 K.

The complexes display medium intensity IR bands at *ca* 940 cm^{-1} which are assigned to the stretching frequencies of terminal V—O_t groups.[110,205] Strong bands at *ca* 850 cm^{-1} in each complex are assigned to asymmetric CrOV vibrations. ^{18}O Labelling of the bridging O, by use of $Cr^{18}O(TPP)$ to prepare $(TPP)Cr^{18}OV(O)(acac)_2$, resulted in a greatly reduced intensity of the band at 850 cm^{-1}, but porphyrin ligand absorptions in the 800–700 cm^{-1} region prevented clear recognition of the $Cr^{18}OV$ frequency.[195] Increased absorption was observed, however, in the region near 800 cm^{-1}.

Just as $Mo^{IV}O(dtc)_2$ derivatives have been shown to react with $Mo^{VI}(O)_2(dtc)_2$ to form homonuclear oxo-bridged complexes,[117b] $Mo^{IV}O(Et_2dtc)_2$ and $Mo^{IV}O(Pyrdtc)_2$ correspondingly react with $Cr^{IV}O(TPP)$ to form complexes believed to contain $Cr^{III}OMo^{V}$ linkages.[194,195] Thus

$$Cr^{IV}O(TPP) + Mo^{IV}O(Et_2dtc)_2 \longrightarrow (TPP)Cr^{III}OMo^{V}O(Et_2dtc)_2. \quad (33)$$

This same complex can also be formed by a Cr^{II}–Mo^{VI} reaction[195]

$$Cr^{II}(TPP) + Mo^{VI}(O)_2(Et_2dtc)_2 \longrightarrow (TPP)Cr^{III}OMo^{V}(Et_2dtc)_2. \quad (34)$$

The compounds are purple in colour, dissolving to give red–green solutions in most polar organic solvents. The imido complex $Mo^{IV}(N—p\text{-tol})(Pyrdtc)_2$[206] also reacts to give a compound assigned a μ-oxo configuration (TPP)Cr—O—Mo(N—*p*-tol)(Pyrdtc)$_2$. A homobinuclear μ-oxo complex, $[(dtc)_2Mo(N—p\text{-tol})]_2O$, has been formed[206] by reaction of $Mo^{VI}(O)(N—p\text{-tol})(Et_2dtc)_2$ with the Mo^{IV} imido derivative and an oxo bridge, rather than imido bridge formulation assigned on the grounds that the final complex did not show an IR band in the region expected for terminal Mo=O viz. 980–920 cm^{-1}; strong bands in this region being associated with a *cis* arrangement of terminal and bridging oxygens.[153]

The two CrOMo compounds derived from $Mo^{IV}O(dtc)_2$ complexes each show a weak, broad IR band at *ca* 925 cm^{-1} but this band is absent in the complex derived from the organoimido complex. ^{18}O Labelling experiments were not able to verify this assignment conclusively.[195] Preparation of 40% ^{18}O labelled $(TPP)CrOMo(^{18}O)(Et_2dtc)_2$ gave a sample whose IR spectrum only showed broadening of the weak band at 925 cm^{-1}. A similar broadening of a porphyrin band at 890 cm^{-1} was also observed which is in the region expected for Mo—^{18}O terminal vibrations. "Weak" rather than "strong" absorptions have been observed for terminal M=O stretching frequencies in $[MoO(TPP)]_2O$,[207a] $[Re^{V}O(Et_2dtc)_2]_2O$[207b] and $Re_2O_3py_4Cl_4$[208] where the M_2O_3 units are in a linear, *trans* array, O=M—O—M=O.

Whether the CrOMo(O) species have such a linear arrangement (CrOMo=O) cannot be answered in the absence of a structural study, but steric resistance from the porphyrin ring might encourage such organization as in the $[MoO(TPP)]_2O$ complex.

The magnetic moments for these complexes at 293 K are only slightly less than expected for a Cr^{III} ($S = 3/2$), Mo^{V} ($S = 1/2$) complex (Table 14). The decrease in the magnetic moments of these species at low temperatures suggests weak antiferromagnetic coupling is taking place. This is in contrast to the strong coupling in homobinuclear d^1 $[(dtc)_2MoO]_2O$ complexes which are diamagnetic. The linearly arranged oxygens in $[MoO(P)]_2$ (P = TPP, OEP) are considered to contribute to the paramagnetism ($\mu_{eff} = 1.48$ BM per Mo) found in these complexes. The dithiocarbamate complexes have *cis* arrangements of the terminal and bridge oxygens which allows overlap of the appropriate ground state orbitals on the Mo atom to produce the strong coupling observed, whereas the linear arrangement of terminal and bridge oxygens prevents this overlap.[41]

The relatively weak coupling observed in the heterobinuclear compounds and the weak IR CrOMo stretching frequency identified may also indicate a linear CrOMo=O array in these compounds.

$Mo^{V}OFe^{III}$ and $Mo^{V}OMn^{III}$ compounds. Several Fe^{II} complexes have been found capable of reducing $Mo^{VI}(O)_2(Et_2dtc)_2$ in THF to form μ-oxo complexes[193] $(Et_2dtc)_2Mo^{V}(O)Fe^{III}(Lig)$ (Table 14). The characteristic doublet at 910 and 877 cm^{-1} in the IR spectrum arising from the MoO_2 combination in the starting complex is no longer observed in the products. A band at 933 cm^{-1} was assigned to the terminal Mo=O bond which should remain in the bridged compound, but no clearly defined absorption could be identified for an MoOFe vibration. The magnetic moments for the

complexes at 293 K are notably lower than the spin-only value appropriate for a Mo^{V} ($S = 1/2$), Fe^{III} ($S = 5/2$) system and indicate magnetic coupling exists in this complex.

Evidence that the complexes dissociate in solution was found in the observation that both $Mo(O)_2(Et_2dtc)_2$ and Fe(salmah) were slowly precipitated when hexane was added to a solution of $(Et_2dtc)_2Mo(O)OFe$(salmah) in acetone. Furthermore, on attempting recrystallization of $(Et_2dtc)_2Mo(O)OFe$(salen) from acetone the compound Fe^{III}(salen)(Et_2dtc) was isolated,[195] indicating some considerable degree of lability associated with the Mo segment.

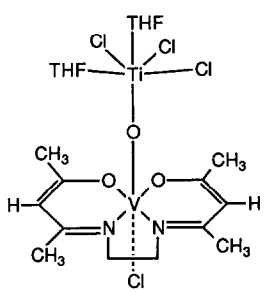
Reactions attempted between $Mo(O)_2(Et_2dtc)_2$ and Mn^{II}(salmah) or $Mn^{II}(Et_2dtc)_2$ have given rise to products analysing as $(Et_2dtc)_2Mo(O)Mn(Lig)$ species.[193] The doublet in the IR spectrum, due to the MoO_2 unit, was no longer present in the products and a clearly defined peak due to the terminal Mo=O linkage could not be detected. The magnetic moments of analytically pure samples were comparable to the spin-only values for systems containing Mn^{III} ($S = 2$), Mo^{V} ($S = 1/2$) centres, indicating little coupling was involved. The complexes also dissociated in solution with slow evaporation of a solution of the $Mn(Et_2dtc)_2$ product yielding $Mn^{III}(Et_2dtc)_3$. It has been reported[209] that $Mn^{II}(Et_2dtc)_2$ forms $Mn^{III}(Et_2dtc)_3$ when solutions are exposed to air. These types of complexes need further investigation to determine whether antiferromagnetic behaviour can be observed with different ligands.

In an attempt to produce MoOFe or MoOCr complexes which might show greatly increased resistance to dissociation, redox reactions were attempted using $Mo^{VI}(O)_2(L)_2$ (L = acac, 8-quinolinato) since the Mo^{V} oxo-bridged homobinuclear complexes containing these ligands show little or no detectable dissociation.[116] However, no reaction could be observed with Fe^{II}(L) (L = salah, $(Et_2dtc)_2$) or Cr^{II}(TPP).[195] Such differences in oxidative behaviour between Mo^{VI} dithiocarbamates and the corresponding acetylacetone or 8-quinolinol compounds have been reported for reactions involving oxidations of hydrazines, tertiary phosphines and alcohols.[210]

The formation of heterobinuclear oxo complexes of Mo and Fe has been claimed[211] from the reaction of a compound described only as "Fe^{III} molybdate" with several dithiocarbamates including Et_2dtc^{-} and 8-quinolinol in a mixture of 7 M HCl and acetic acid. The formulae of the complexes which were reported to precipitate from solution were represented as $FeMoO_2(Lig)_4H_2O$. The complex of similar formula having Lig = Et_2dtc, prepared by the redox method, would be totally decomposed in the presence of an HCl–CH_3COOH mixture, or indeed excess H_2O alone.[195] The magnetic moment of the Et_2dtc^{-} complex was reported to be 2.95 BM at room temperature and similarly low values were observed for the other dithiocarbamates examined. The 8-quinolinol complex, however, was said to show a high moment of 6.93 BM, larger even than the spin-only value of 6.16 BM, calculated for a Mo^{V} ($S = 1/2$), Fe^{III} ($S = 5/2$) system. The presence of an FeOMo linkage was suggested on the basis of an IR absorption band at 640 cm^{-1} unrelated to other data.

Whatever the nature of these compounds, it is unlikely that they contain a simple FeOMo linkage as postulated to result from the redox route. If the compounds are pure, they may relate to mixed-metal polyoxometallate complexes.

A $V^{IV}OTi^{IV}$ *compound.* A rather unusual reaction involving oxidation of only one metal reagent has been reported by Floriani and co-workers[212] who found that $V^{IV}O$(acen) reacted with $TiCl_3(THF)_3$ at $-70°C$ to produce the bridged compound $(Cl)(acen)V^{IV}OTi^{IV}(Cl)_3(THF)_2$ (**34**). At the temperature of refluxing THF, reductive deoxygenation occurs to yield $(Cl)V^{III}$(acen).



$[Cl(acen)V^{IV}(\mu\text{-}O)Ti^{IV}Cl_3(THF)_2]$ (**34**).

A plausible route for the formation of the oxo-bridged complex as an intermediate in the overall deoxygenation process has been proposed which involves an initial donor–acceptor complex formation followed by intermolecular Cl transfer.

The bridging VO distance (1.937(6) Å) is notably longer than in other VOV complexes (Table 1) while the TiO distance is shorter, at 1.691(6) Å, than in other homobinuclear TiOTi systems. The VOTi angle 169.1(3)°, is said[212] to indicate virtual *sp* hybridization, which could account for the short TiO linkage on the basis of some multiple character in the bond. An IR band at 835 cm^{-1} was suggested as arising from vibration in such a TiO band.

4.4 *Heterotrinuclear* (μ_3-O) *complexes*

$[M_2M'(\mu_3\text{-O})(CH_3COO)_6L_3]$ *compounds*. Mixed-metal hydroxy acetates of Fe^{III} with various divalent transition metal ions were reported[213] before the constitution of the "basic acetate" complexes $[M_3(\mu_3\text{-O})(CH_3COO)_6L_3]^{n+}$ was recognized and were allotted somewhat misleading polynuclear compositions. The true nature of such complexes as analogues of the (μ_3-O) bridged compounds was realised by Blake and co-workers.[214]

Mixed-metal analogues of the trinuclear oxo complexes $[M_3(\mu_3\text{-O})(RCOO)_6L_3]^{n+}$ have now been prepared for the combinations $Fe_2^{III}M^{II}$,[214a,215] ($n = 0$; M^{II} = Mg, Mn, Co, Ni, Zn); $Cr_2^{III}M^{II}$,[215,214b] ($n = 0$; M^{II} = Mg, Fe, Co, Ni); $Cr^{III}Fe^{III}M^{II}$,[214b] ($n = 0$; M^{II} = Mn, Co, Ni, Fe); with R = CH_3 and L = H_2O, py. Fe_2^{III} Cr^{III} and $Cr_2^{III}Fe^{III}$ complexes with acetato[215,216] or O—O bonded glycine[217–219] molecules are known as well as a $Ru_2^{III}Rh^{III}$[220] acetato complex ($n = 1$ and L = H_2O or py) for these M_3^{III} mixed-metal systems.

The complexes have been synthesized by reacting appropriate molar ratios of metal salts (perchlorate, nitrate, halide) in aqueous solution in the presence of a large excess of a carboxylate salt. Many of the oxo compounds are insoluble in the medium and precipitate as the aqua complexes (L = H_2O), a number of complexes also containing water of crystallization. The coordinated water is replaced by pyridine on recrystallization of the aqua compound from that solvent. $Cr_2^{III}M^{II}$ complexes have generally been formed by using Cr^{II} acetate as a reagent, although Cr^{III} Fe^{III} compounds have been prepared by interaction of Cr^{III} and Fe^{III} salts. The heterotrinuclear complexes $Fe^{III}Cr^{III}M^{II}$[214b] have been prepared by addition of Cr^{II} acetate to the corresponding $Fe_2^{III}M^{II}$ preformed complex. The $Ru_2^{III}Rh^{III}$[220] complex was separated from Ru_3^{III} and Rh_3^{III} species by ion-exchange chromatography from the reaction mixture produced by interaction of substitution-inert Rh^{III} and Ru^{III} halides in hot aqueous or methanolic acetic acid containing a source of acetate ions. The $Rh_2^{III}Ru^{III}$ complex was not detected.

The related series of mixed valence, homotrinuclear complexes may be appropriately considered together with these heteronuclear compounds, since their properties might be expected to relate to hetero species of similar valence distribution. Complexes having the formal oxidation state distribution $[M_2^{III}M^{II}(\mu_3\text{-O})(CH_3COO)_6L_3]$ (L = H_2O, pyridine or a substituted pyridine) have been structurally characterized for the combinations $Fe_2^{III}Fe^{II}$, $Cr_2^{III}Cr^{II}$, $Mn_2^{III}Mn^{II}$, $V_2^{III}V^{II}$, $Ru_2^{III}Ru^{II}$ (Table 3). The complexes usually have solvent associated, e.g. benzene, or additional molecules of L in the lattice.

X-ray structural studies of $[Fe^{III}Cr_2^{III}(\mu_3\text{-O})(CH_3COO)_6(H_2O)_3]X$ species (X = $[FeCl_4]^-$,[216] NO_3^- [221]) while confirming the similarity of the structure to those of the Fe_3^{III} and Cr_3^{III} compounds, were unable to distinguish between the individual metal ions and a statistical distribution of ions in the crystal was indicated.

Indeed, some doubt was cast[216] on whether the earlier compound[221] studied was a truly mixed-metal complex on the grounds that the reported red colour of the complex examined was appropriate to the homotrinuclear Fe_3O compound. The sample examined in the later study[216] was almost black in colour and was separately shown to contain Fe and Cr ions in the same molecular unit by an electrochemical procedure. The M—O bond distances were comparable with those found for the Cr_3O complex. The $Fe_2^{III}Cr^{III}$ glycinate[217] complex, however, shows an ordered arrangement in the crystal. Refinement of the crystallographic data, assuming the metal sites were each filled by Fe^{III} ions, resulted in a considerably higher temperature factor for one atom, presumably indicating the Cr site. The cations within the unit cell are arranged so that the Cr—(μ_3O) bonds are aligned indicating the existence of magnetic ordering. The non-bonded M···M distances are very similar

Table 18. Vibrational spectra (cm^{-1}) of mixed valent and heterotrinuclear complexes $[Fe_2M'(\mu_3\text{-}O)(\mu\text{-}CH_3COO)_6L_3]$[223]

M′	L	$\nu_{as(M_2M'O)}$	$\nu_{as(M_2M'O)}$	$\delta_{s(M_2M'O)}$

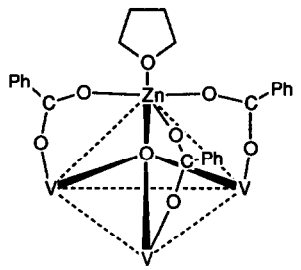
to those in the Cr_3 and Fe_3 systems with only slight variations being detected between the Cr—O and Fe—O distances.

The M^{III}—O and M^{II}—(μ_3-O) bond distances should differ in a molecule containing the formal oxidation states $M_2^{III}M^{II}$ "trapped" in a $[M_3(\mu_3\text{-}O)(CH_3COO)_6L_3]$ structure. The three metal ions would surround the central O^{2-} ion, lying at the vertices of an isosceles triangle. The site symmetry at the oxygen would then be C_{2v} rather than D_{3h} as in the M_3^{III} systems. Structural studies on a variety of such mixed valence complexes have failed to discern any difference between the three metal ions except in the case of $[Mn_2^{III}Mn^{II}(\mu_3\text{-}O)(CH_3COO)_6(3\text{-}Cl\text{-}py)_3]$ where the three Mn ions form an isosceles triangular array indicating the position of an Mn^{II} ion (Table 3). In other cases, the apparent equivalence of the metal sites, judged by the structural evidence, indicates either a rapid electron transfer between the metal ions, possibly via the central oxygen, or a bonding array of M_3O in which the metal and oxygen electrons are delocalized and are accommodated in molecular orbitals embracing the entire cluster. Such a delocalization has been described for the $Ru_2^{III}Ru^{II}$ complex to account for its diamagnetism.[77] A third possibility is that there is a statistical distribution of $M_2^{III}M^{II}$ units thoughout the crystal, making each metal position appear equivalent. Mössbauer spectral studies on the $Fe_2^{III}Fe^{II}$ species, $[Fe_2^{III}Fe^{II}(\mu_3\text{-}O)(CH_3COO)_6L_3]S$ (L = pyridine, 4-Et-py, S = L);[72] (L = 4-Me-py, S = benzene),[71] have shown that both Fe^{III} and Fe^{II} sites can be detected at low temperatures (to 11 K), quadrupole split doublets being observed in the intensity ratios 2:1, Fe^{III}/Fe^{II}. As the temperature is increased, changes in the relative intensities and positions of the doublets occur until, at *ca* 300 K, only a single averaged spectrum is observed. X-ray diffraction studies show equivalence of the Fe sites at room temperature. A sufficiently rapid electron transfer process is considered to be occurring at room temperature that oxidation state differences between the Fe ions cannot be detected by processes having the longer time scales of X-ray diffraction or Mössbauer spectroscopy.[222]

The temperature at which electron transfer becomes sufficiently rapid to "equilibrate" the metal ions in the solid state has been shown to depend on the nature of the non-coordinated solvent molecules co-crystallized with individual complexes, and not solely on the overcoming by thermal motion of the thermal barrier to electron transfer.[71]

No single crystal X-ray structural studies have yet been reported for any of the $Fe_2^{III}M^{II}$ or $Cr_2^{III}M^{II}$ complexes, but a number[215] have been shown by X-ray examination to form rhombohedral crystals with one molecule per unit cell and to be isomorphous with $[Mn_2^{III}Mn^{II}(\mu_3\text{-}O)(CH_3COO)_6py_3]$.[74] This complex shows equivalent Mn centres and thus indicates that the heterotrinuclear complexes are disordered with the divalent metal ion randomly occupying one of the three equivalent metal sites.

A unique octanuclear mixed metal complex, $[V^{III}Zn^{II}(\mu_4\text{-}O)(C_6H_5COO)_3(THF)]_4$, has been structurally identified by Cotton *et al.*[246] It was prepared under argon by reaction of the double salt $[V_2Cl_3(THF)_6]_2[Zn_2Cl_6]$ with benzoate ions in THF. The complex may be viewed as containing a tetrahedral grouping of V atoms with a Zn ion capping each face of the tetrahedral array, with a



$[V^{III}Zn^{II}(\mu_4\text{-O})(\mu\text{-}C_6H_5COO)_3(THF)]_4$, view of a ZnV_3O unit (**35**).

μ_4-O atom inside each V_3Zn pyramid about 2.0 Å from each metal ion (**35**). The benzoate carboxylato groups bridge each of the 12 V–Zn pairs and the THF molecules coordinated to each Zn complete the five-fold trigonal bipyramidal coordination around these ions. The V ions are effectively octahedrally coordinated. The V ions are more closely packed (V ··· V) at 2.965(4) Å than in the V_3O carboxylato complexes (3.3 Å, Table 3), probably because of the bonding by the oxo bridges.

The $M_4(\mu_4\text{-O})$ unit is also known in the "basic" acetato structures[104b] of $[M_4(\mu_4\text{-O})(CH_3COO)_6]$, (M = Be^{II}, Zn^{II}).

The source of oxygen in the V_4Zn_4 compound is unknown. Molecular oxygen was supposedly excluded from the reaction mixture and H_2O is thought unlikely since the complex decomposes further on exposure to air or moisture. Abstraction from a carboxylate group has been suggested.

Vibrational spectra: Cannon and co-workers[223] have examined the M_3—O vibration modes by IR spectroscopy to try to establish the "true" molecular symmetry of $Fe_2^{III}Fe^{II}$ systems. The procedure was to compare the spectra of mixed-metal valence compounds with corresponding mixed-metal complexes, necessarily of C_{2v} symmetry. In C_{2v} symmetry, the asymmetric vibration associated with the $Fe_2M^{II}(\mu_3\text{-O})$ unit would be split into two components, A_1 and B_2. Such bands have been assigned[223] for a range of $[Fe_2M^{II}(\mu_3\text{-O})(CH_3COO)L_3]$ complexes (Table 18). The assignments for the Fe_2Ni compound were defined with the aid of ^{18}O substitution for the $(\mu_3\text{-O})$.[224] The frequencies were found to increase in the order Mn < Co < Ni, i.e. of increasing crystal field stabilization and dissociative stability. These assignments have allowed the allocation of the related bands in $[Fe_2^{III}Fe^{II}(\mu_3\text{-O})(CH_3COO)_6L_3]$ compounds at room temperature, supporting the existence of discrete Fe^{III} and Fe^{II} centres, detectable on the time scale appropriate to molecular vibrations.[223]

Magnetic susceptibilities: the magnetic susceptibilities of a series of the mixed-metal oxo-acetate complexes $Cr_2^{III}M^{II}$, $Fe_2^{III}M^{II}$ (M = Ni, Mn, Mg) have been studied between 295–4.2 K.[215] The data have been fitted to the isotropic Hamiltonian

$$\mathcal{H} = -2\Sigma_{ij}J_{ij}S_iS_j + \mu_B\Sigma_i g_i S_i H$$

Table 19. Magnetic data for heterotrinuclear complexes[214] $[M_2M'(\mu_3\text{-O})(\mu\text{-}CH_3COO)_6L_3]^{+/0}$

M_2	M′	L	$-J_{12}$ (cm^{-1})	$-J_3{}^a$ (cm^{-1})
Cr^{III}	Cr^{III}	H_2O	11(1)	
Cr^{III}	Co^{II}	py	27(2)	
Cr^{III}	Ni^{II}	py	26(2)	47(2)
Fe^{III}	Fe^{III}	H_2O	30(3)	
Fe^{III}	Mg^{II}	py	62(3)	
Fe^{III}	Mn^{II}	py	64(3)	21(1)
Fe^{III}	Ni^{II}	py	73(3)	33(2)
Fe^{III}	Ni^{II}	H_2O	71(3)	31(3)

[a] $-J_{13} = -J_{23} \equiv -J_3$.

defining the interaction of the three magnetic ions in the cluster with each other and the applied field H. With $S_1 = S_2$, $g_1 = g_2$ and $J_{13} = J_{23}$ (written as J_3) it is given the form

$$\mathscr{H} - 2J_{12}S_1S_2 - 2J_3S_{12}S_3 + \mu_B[g_1S + (g_3 - g_1)S_3] \cdot H$$

where $S_{12} = S_1 + S_2$ and $S = S_{12} + S_3$.

The values of the coupling constants are shown in Table 19 for the combinations whose experimental data were fit. It is noteworthy that the J_{Fe-Fe} and J_{Cr-Cr} values in the heterotrinuclear series are approximately twice their values in the homotrinuclear compounds and almost independent of the nature of M^{II}, an indication that coupling proceeds via the oxygen atom as the main superexchange pathway. The in-plane p orbitals of the oxygen are seen as particularly effective in facilitating exchange.

The $Cr_2^{III}Fe^{II}$ complex data could not be adequately fitted to the Hamiltonian, possibly because of spin–orbit coupling in the Fe^{II} ground state.[215]

The complete sequence of mixed $Cr^{III}_{3-x}Fe^{III}_x(\mu_3\text{-O})$ bridged trinuclear carboxylato complexes has been prepared[219] with the N-protonated glycinato ion bridging via its carboxyl group, as defined by structural studies[217] on $[Fe_2Cr(\mu_3\text{-O})(H^+NH_2CH_2COO)_6(H_2O)_3](ClO_4)_7$. The magnetic susceptibilities of the four complexes Cr_3, Fe_3, Cr_2Fe and Fe_2Cr have been studied down to 80 K together with that of the mixed valence derivative $[Fe_2^{III}Fe^{II}(\mu_3\text{-O})(H^+NH_2CH_2COO)_6(H_2O)_3]Cl_6$. Attempts were made to fit the data to a susceptibility expression which would allow that the three metal ions in each compound occupied the vertices of an isosceles triangle and not an equilateral array. This involved the use of a factor representing the ratio of two integrals such that $J_{12} = J_{23} = \alpha J_{13}$. Both the values of α and J were varied in order to obtain the best fit with the experiment. For Cr_3 and Cr_2Fe complexes, best fits were obtained with $\alpha = 1$ indicating close approximation to an equilateral triangular configuration for the metal ions, whereas best fits for the Fe_3 complex data were obtained when the α-value was 0.7 indicating that something less than an equilateral triangle fitted the structure. The Fe_2Cr complex appeared somewhat insensitive to the arrangement of the metal atoms. The $Fe_2^{III}Fe^{II}$ compound showed the most extreme influence of shape and the best fit was obtained when the complex was considered as a binuclear Fe_2^{III} species with virtually no contribution from the Fe^{II} ion being necessarily included. This could suggest a considerable degree of spin localization exists in this complex in contrast to most other $Fe_2^{III}Fe^{II}$ species so far examined.

Electronic spectra: the replacement of one trivalent ion in $[M_3(\mu_3\text{-O})(CH_3COO)_6L_3]^+$ by a divalent M^{II} ion reduces the ligand field around each remaining M^{III} ion, and shifts to lower frequencies are observed for *d–d* transitions associated with the Cr^{III} and Fe^{III} ions.[214b,215] This reduction in ligand field and its effect on absorption spectra contrasts with the increased M^{III}—M^{III} magnetic exchange observed,[215] which is suggested to be related to increased M^{III}—O—M^{III} π-bonding. The spectral transitions due to individual M^{II} ions have been allocated for a number of the systems.[215] The $Cr^{III}Fe^{III}M^{II}$ complexes are purple in colour, contrasting with the less intense green of most $Cr_2^{III}M^{II}$ and $Fe_2^{III}M^{II}$ complexes prepared. The colour appears to be associated with a band at *ca* 19,000 cm^{-1}.[215] Comparison with the spectra of Cr_3^{III} and Fe_3^{III}, and the mixed systems $Cr_2^{III}Fe^{III}$ and $Cr^{III}Fe_2^{III}$ show that intense bands are found at 18,600 and 25,500 cm^{-1} for the $Cr_2^{III}Fe^{III}$ complex (which has a purple–red colour) which do not correspond to bands in the spectra of Cr_3^{III} or Fe_3^{III}. The $Cr^{III}Fe_2^{III}$ complex is red–brown in colour and shows less well defined absorptions, having a spectrum somewhat akin to a super position of Cr_2Fe and Fe_3 spectra, although the intensities of bands are greater than for a simple mixture of species. The Cr_3 and Fe_3 complexes are green and olive-green, respectively.

A reason for this colour difference between the mixed-metal and homotrinuclear systems is suggested to involve simultaneous (Cr^{III}, Fe^{III}) double excitations.[214]

Other spectral studies on $M_2^{III}M'^{III}$ *complexes*: the $[Ru_2Rh(\mu_3\text{-O})(CH_3COO)_6L_3]^+$ (L = H_2O or pyridine) complexes[220] show ^{13}C and ^1H NMR resonances for the methyl groups of the acetate bridging groups in the ratio of 1 : 2 integrated intensities, providing unambiguous evidence that the isosceles triangular Ru_2RhO configuration occurs. X-ray photoelectron spectra of the complexes show small but detectable differences in the Ru $3d_{5/2}$ binding energies between the Ru_3 and Ru_2 complexes.

Metal–metal bonded $M_3(\mu_3\text{-O})$ *and* $M_3(\mu_3\text{-O})_2$ *compounds.* Mixed-metal acetato bridged compounds containing metal–metal bonded triangular arrays of Mo_2W and MoW_2, with (μ_3-O) groups "capping" the triangular arrays, have been prepared[225] by an adaptation of the reduction process used in making the homotrinuclear compounds. This involved reduction of mixtures of sodium tungstate and molybdate with Zn in acetic anhydride. A mixture of the W_3, Mo_2W and W_2Mo cations $[M_3(\mu\text{-O})_2(CH_3COO)_6(H_2O)_3]^{2+}$ was formed and separated by cation exchange chromatography. The time of the separation procedure was reported to last one month! Chemical identification of the clusters was carried out by ^1H NMR spectroscopy in D_2O. The homotrinuclear Mo_3 and W_3 compounds show one sharp CH_3 singlet, while the M_2M' species each show two CH_3 resonances with the intensity ratio of 2 : 1. Although a full structure determination has not been completed, lattice parameters for the mixed MoW complexes are very similar to those of the Mo_3 complex, indicating statistical disorder for the Mo_2W and W_2Mo units in the crystal. X-ray photoelectron spectra of the four complexes Mo_3, W_3, Mo_2W and W_2Mo have been used to determine binding energies for Mo 3*d*, W 4*d* and W 4*f* electrons.[226] The various values show successive decreases in energy in the sequence Mo_3, Mo_2W, MoW_2W_3, although the separations between the various electron levels (e.g. Mo $3d_{3/2}$, Mo $3d_{5/2}$) are essentially constant and larger than for the Ru_2Rh, non-metal–metal bonded compound.[220] The changes have been related to a charge shift along the metal–metal bonds, reflecting greater electronegativity of the Mo^{IV} state over the corresponding W state. The structural evidence indicates that the M—M bond lengths do not change greatly along the whole series from Mo_3, Mo_2W, W_2Mo to W_3. ^{183}W and ^{95}Mo NMR spectra have also been recorded for the complexes.[227]

The redox reaction devised by Chisholm and co-workers[100] has been applied to the directed synthesis of Mo_2W mixed-metal species.

$$(RO)_3Mo^{III}{\equiv}Mo^{III}(OR)_3 + OW^{VI}(OR)_4 \longrightarrow Mo_2^{IV}W^{IV}(\mu_3\text{-O})(OR)_{10}. \quad (35)$$

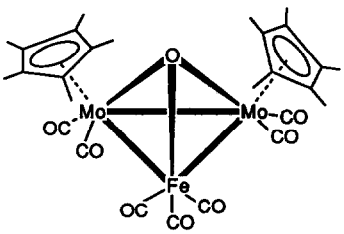
The compound $Mo_2W(\mu_3\text{-O})(O^iPr)_{10}$ is isomorphous with the Mo_3 complex and has a disordered arrangement of Mo and W atoms. The reaction involving $W_2(OR)_6$ and $OMo(OR)_4$ did not yield the W_2Mo complex cleanly, $W_3(\mu_3\text{-O})(OR)_{10}$ being obtained in the largest yield. A plausible explanation[100] for this involves the oxo-transfer reaction

$$Mo(O)(O^iPr)_4 + W_2(O^iPr)_6 \longrightarrow MoW(O^iPr)_6 + WO(O^iPr)_4 \quad (36)$$

being favoured, followed by reaction of $WO(O^iPr)_4$ with $W_2(O^iPr)_6$. The interesting reaction may have a much wider scope than production of oxo-bridged complexes since a variety of $MX(OR)_4$ species may well be used. Mixed-metal complexes with an alkylidene cap have been prepared by reaction of $Mo_2(OR)_6$ with $(RO)_3W{\equiv}CMe$,[228] but attempts to prepare mixed Nb, Ta and Mo, W compounds with (μ_3-OR) capping groups have not been successful.[100]

5. HETERONUCLEAR ORGANOMETALLIC OXO-BRIDGED COMPOUNDS

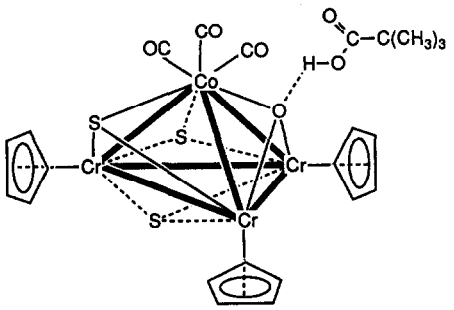
There is only a relatively small number of heteronuclear oxo-bridged organometallic compounds yet known, no doubt related to the lack of synthetic procedures for preparing them. Several compounds have been reported amongst mixed-metal carbonyl derivatives where oxygen has been inserted into the cluster fortuitously, it would appear, in each case. Thus, an attempt to add the coordinatively unsaturated organometallic species $Fe(CO)_4$, produced *in situ* by photolysis of $Fe_2(CO)_9$, to the Mo≡Mo triple bond in $Mo_2(C_5Me_5)_2(CO)_4$, gave the μ_3-O bonded cluster $(C_5Me_5)_2Mo_2Fe(\mu_3\text{-O})(CO)_7$[229] (**36**). The source of oxygen was shown to be dioxygen and an im-



$(C_5Me_5)_2Mo_2Fe(\mu_3\text{-O})(CO)_7$ (**36**).

proved synthetic method which involved pretreatment of the mixture of reactants with dioxygen before irradiation commenced was devised.

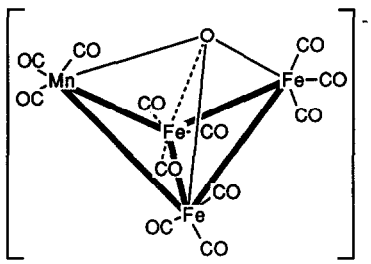
$(CpCrSC(CH_3)_3)_2S$ has been found to react with $Co_2(CO)_8$ in benzene in the presence of pivalic acid to give the paramagnetic material $Cp_3Cr_3(\mu_3\text{-}S)_3(\mu_3\text{-}O)Co(CO)_3 \cdot Me_3CCOOH$[230] (**37**). Again,



$(Cp)_3Cr_3(\mu_3\text{-}S)_3(\mu_3\text{-}O)Co(CO)_3(Me_3C \cdot COOH)$ (**37**).

the source of oxygen is unclear. The structure consists of an isosceles triangle of Cr atoms bonded to a sulphur atom. The bridging oxygen atom links two Cr and the Co atoms and is attached to the shorter Cr—Cr bond. The $Co(CO)_3$ group is weakly bound to the oxygen and two further sulphur atoms which, in turn, are triply bridging to two Cr atoms and the Co.

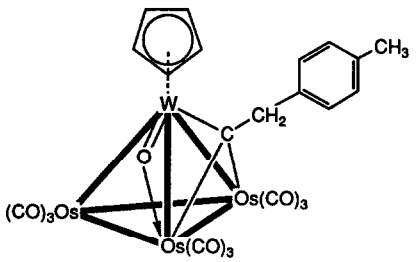
One compound has been reported in which oxygen bridges four metals viz. $[(PPh_3)_2N][Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]$—a "butterfly oxo cluster"[231] (**38**). The complex is formed by reaction of the



$[Fe_3Mn(CO)_{12}(\mu_4\text{-}O)]^-$ (**38**).

$(\mu_3\text{-}O)$-capped ion[232] $[Fe_3(\mu_3\text{-}O)(CO)_9]^{2-}$ containing a triangle of metal–metal bonded Fe atoms with $[Mn(CO)_3(CH_3CN)_3][PF_6]$ in acetone. The $Mn(CO)_3$ unit may be thought of as adding to an $Fe_2(\mu_3\text{-}O)$ face of the Fe_3O group. The count of 62 cluster valence electrons achieved by assuming oxygen provides six electrons makes this molecule comparable with the molecular orbital descriptions of similarly shaped butterfly carbides. The M—O distances are short, averaging 1.89(2) Å. The complex decomposes under CO in acetone over several hours, giving CO_2 and Fe compounds of lower nuclearity. This type of reaction may account for the relative rarity of oxo-bridged metal carbonyls compared to carbido and nitrido species.

A number of heteropolynuclear carbonyl cluster compounds containing bridging oxo ligands are known where the oxygen bridge has been formed by the breakdown of an oxygen-containing group in a precursor molecule. Thus, heating the tetranuclear acylcarbonyl $(Cp)WOs_3(CO)_{11}$ $(\mu_3\text{-}\eta^2\text{-}C(O)CH_2C_6H_4CH_3)$, which contains a lengthened and hence "activated" CO bond, causes the C—O bond to break with formation of the μ-oxo alkylidyne complex $(Cp)WOs_3(CO)_9(\mu\text{-}O)$ $(\mu_3\text{-}C \cdot CH_2C_6H_4CH_3)$[233] (**39**). The shorter length of the W—O (1.812(7) Å) bond compared to the

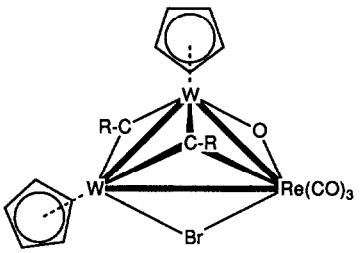


$(Cp)WOs_3(CO)_9(\mu\text{-}O)(\mu_3\text{-}C \cdot CH_2C_6H_4CH_3)$ (**39**).

Os—O bond (2.169(8) Å) and even to W—O in the parent compound (2.150(10) Å) strongly suggests the donor–acceptor mode W=O → Os for this oxo bridge. The nearly coplanar arrangement of WOs_3 atoms in the parent has changed to a pseudo-tetrahedral array in the oxo-bridged product. The W—O—Os angle (80°) is still, however, similar to that in the parent. Pyrolysis of the complex in toluene or reaction with H_2 does not affect the oxo group.

A second example[234] of a W—O—Os bridge has resulted from reaction of Me_3NO with the acetylene complex $CpWOs_3(CO)_{10}(\mu_3\text{-}\eta^2\text{-}C_2H_2)H$ yielding $CpWOs_3(CO)_8(\mu\text{-}O)(\mu_3\text{-}\eta^2\text{-}C_2H_2)H$. The bonding mode is again W=O → Os as evidenced by the metal–oxygen distances (W—O 1.76(8) Å and Os—O 2.200(8) Å). The oxo group is almost coplanar with the WOs_2 plane. Similar oxo-bridged WOs_3 units have been found in $CpWOs_3(CO)_9(\mu\text{-}O)(\mu\text{-}CHCH_2C_6H_4Me)(\mu\text{-}H)$ and $CpWOs_3(CO)_9(\mu_2\text{-}C{=}CHC_6H_4Me)(\mu\text{-}H)$. Such edge-bridging oxygens are implicated in the dissociation of CO molecules in the Fischer–Tropsch reaction but had been assumed previously to be bound symmetrically to a pair of metal atoms.

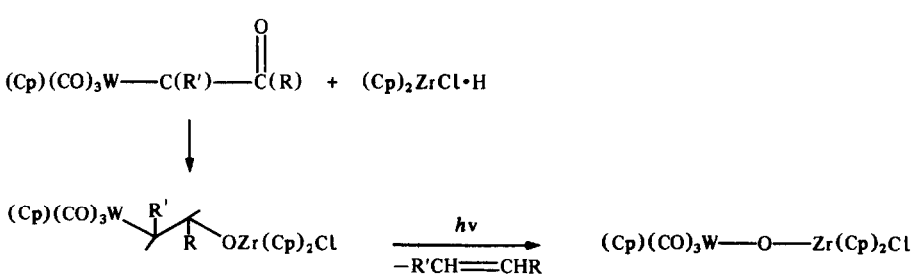
Aerial oxidation of the heterotrimetallic complex $(Cp_2)_2ReW_2(\mu\text{-}Br)(\mu\text{-}CR)(\mu\text{-}CO)(CO)_3$ (R = *p*-tolyl) gives an oxo-bridged species,[235] $(Cp_2)_2ReW_2(\mu\text{-}Br)(\mu\text{-}O)(\mu\text{-}CR)(\mu_3\text{-}CR)(CO)_3$ (**40**), in which



$(Cp)_2ReW_2(\mu\text{-}Br)(\mu\text{-}O)(\mu\text{-}CR)(\mu_3\text{-}CR)(CO)_3$ (**40**).

oxygen replaces a bridging CO ligand between W and Re and the capping tolylmethylidyne group becomes bound more asymmetrically to the ReW_2 triangle than in the parent. This is because of a considerable increase in the Re—C bond distance (μ-C—Re 2.248(12)–2.515(20) Å). The ReOW angle is necessarily small (93.7(6)°).

Oxo bridging results from the extrusion of an alkene from the oxo-alkyl bridge in the W—Zr heterobinulcear complex formed as follows,[236]

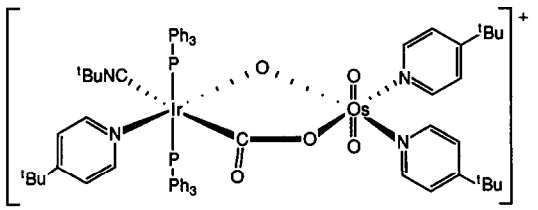


(37)

The ZrOW linkage is virtually linear (175.7°) but asymmetric with the WO bond (2.065 Å) longer than ZrO (1.871 Å).

The IR spectrum contains a broad absorption at 789 cm^{-1} which is shifted to 750 cm^{-1} on ^{18}O substitution at the bridge. The ^{17}O NMR spectrum shows a single resonance at $\delta = 194$, well beyond the range of homobinuclear species containing oxo bridging. This suggests a reduced degree of π-bonding between oxygen and one of the two metals, presumably W. The bridge is left intact when the complex reacts with PMe_3 or acetylenes, substitution taking place at W, or with LiMe, when the (Zr)—Cl atom is replaced. Acetyl chloride, however, converts the oxo-bridged compound to the acetate $(Cp)(CO)_3W(O_2CCH_3)$ and Cp_2ZrCl_2.

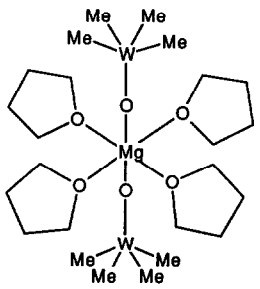
A redox reaction occurs between Vaska's compound $Ir(PPh_3)_2CO \cdot Cl$ and OsO_4 in the presence of heterocyclic bases at −78°C to give an Ir^{III}—O—Os^{VI} species[237] which also possesses a uniquely bridging CO_2 molecule formed *in situ* by an oxygen from OsO_4 reacting with the CO molecule (**41**).



$[(4\text{-}^t\text{Bupy})(^t\text{BuNC})(PPh_3)_2Ir(\mu\text{-}CO_2)(\mu\text{-}O)Os(O)_2(4\text{-}^t\text{Bupy})_2]^+$ (**41**).

Methylation at the exocyclic oxygen of the bridging CO_2 unit can occur and the structure of the resulting molecule has been obtained. The Os—O—Ir angle is 120.6(4)°.

Molecules in which "anionic" oxo-organometallic species are bound to Mg^{2+} have been prepared by the reaction of Mg mono- and bifunctional alkyls with Mo^{VI} or W^{VI} oxo-halides $(MOCl_4)$[238–240] or $[Me_3NH][ReO_4]$.[241,242] A series of THF solvated compounds having Mg—O—M^V bonding, have been characterized by X-ray structural studies viz. $(THF)_4Mg(OWMe_4)_2$[240] (**42**), $(THF)_4Mg(OReMe_4)_2$,[241] $(THF)_4Mg\{OW[(2\text{-}CH_2C_6H_4)_2]_2\}_2$[239] and $(THF)_4Mg\{OW[C_6H_4(CH_2)_2]_2\}_2$.[238]

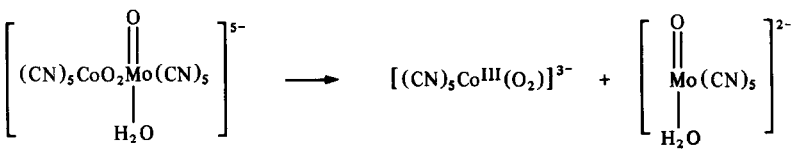


$Mg(THF)_4(OW^VMe_4)_2$ (**42**).

The M—O bond distances are comparable to M^V—O in μ-oxo homonuclear species. The Mo and W compounds are paramagnetic[240] as befits d^1 compounds and have ESR spectra at 98 K in toluene appropriate for square-pyramidal compounds having $S = 1/2$; whereas the d^2 Re^V species are diamagnetic. Long range magnetic dipole–dipole interaction between the two W atoms causes splitting of the peaks. LiMe also reacts to form $LiOMR_4$ compounds.[240] Methyl ^1H resonances are not observed at room temperature for the $LiOReMe_4$ compound, but at lower temperature a broad peak appears which condenses to a sharp singlet at δ 3.12 ppm at −60°C. The reason for this unusual behaviour is uncertain but is suggested[240] to perhaps be related to an unusually short spin–lattice relaxation time through coupling with the quadrupolar isotopes ^{185}Re and ^{187}Re having $I = 5/2$.

6. HETEROBINUCLEAR PEROXO SPECIES

In the light of the extensive chemistry of peroxo-bridged metal compounds (particularly that of Co^{III}) it might be expected that a range of heteronuclear peroxo M—O_2—M′ complexes would be accessible. Only one such compound appears to have been reported by Arzoumanian *et al.*[243] Thus, $K_5[(CN)_5Co^{III}O_2Mo^{VI}(O)(Cl)(CN)_5]$ is formed by passing oxygen through an aqueous solution containing Co^{II}, Mo^{V} and KCN. The Mo=O linkage gave an IR band at 918 cm^{-1} while the peroxide ligand was associated with a band at 893 cm^{-1} and was analysed by titration with Ce^{IV}. The complex readily exchanged Cl for H_2O and in solution under an oxygen atmosphere the complex $[Mo(O)(O_2)(CN)_4]^{2-}$ was produced.[244] The peroxo group in this latter complex was shown by ^{18}O labelling experiments to be derived from the gaseous oxygen in the reaction vessel and was not transferred from the initial dimetallic compound.[244] This indicated dissociation into a Co^{III} superoxo species followed by reaction with gaseous oxygen[245] to give $[(O_2)Mo(O)(CN)_4]^{2-}$ and a cyano free radical. This was inferred to have been formed by the subsequent detection of the tetracyanoethylene radical anion from its ESR spectrum in the reaction mixture. It was presumably formed by reaction of CN˙ with the solvent CH_2Cl_2.[245]



(38)

The initial thought[244b] that this particular reaction might have implications for catalytic systems is not realistic, in terms of O_2 transfer, but the study of the reactions of Co^{III}–superoxo species with the other oxidizable metal substrates may well result in other CoO_2M bridged systems being isolated.

salen	N,N′-ethane-1,2-diylbis(salicylideneiminate)(-2)
salah	N,N′-4-azaheptane-1,7-diylbis(salicylideneiminate)(-2)
salmah	N,N′-4-methyl-4-azaheptane-1,7-diylbis(salicylideneiminate)(-2)
salphen	N,N,′-benzene-1,2-diylbis(salicylideneiminate)(-2)
TACH	the tri-imido ion of 1,5,9,13-tetraazacyclohexadecane
TACN	1,4,7-triazacyclononane
tmpa	tris(2-pyridylmethyl)amine
TPyEA	tris(2-pyrazol-1-ylethyl)amine
tren	tris(2-aminoethyl)amine
tsalen	N,N′-ethane-1,2-diylbis(thiosalicylideneiminate)(-2)
T—P	5,10,15,20-tetraaryl substituted porphyrinates thus:
TCP	tetra-4-chlorophenyl
TFP	tetra-4-fluorophenyl
TMP	tetra-4-methoxyphenyl
TMesP	tetra-2,4,6-mesityl
TPP	tetraphenyl
TTP	tetra-4-tolyl
TXP	tetra-3-5-xylyl

KINETICS AND MECHANISM OF AQUATION REACTIONS OF DIHALO-, DIACETONITRILE- AND BROMOACETONITRILE-(3,3′,3″-TRIAMINOTRIPROPYLAMINE)COBALT(III) PERCHLORATE

SALAH S. MASSOUD* and RONALD M. MILBURN

Department of Chemistry, Boston University, Boston, MA 02215, U.S.A.

(*Received* 1 *May* 1988; *accepted* 21 *June* 1988)

Abstract—The octahedral cobalt(III) complexes with the tripodal quadridentate amine, 3,3′,3″-triaminotripropylamine [trpn = $N(CH_2CH_2CH_2NH_3)_3$], $[Co(trpn)Cl_2]ClO_4$, $[Co(trpn)Br_2]ClO_4$, $[Co(trpn)F_2]ClO_4 \cdot 3/2H_2O$, $[Co(trpn)(CH_3CN)_2](ClO_4)_3$ and $[Co(trpn)(CH_3CN)Br]BrClO_4$ have been synthesized. The acid hydrolysis of $[Co(trpn)Cl_2]^+$ and the rate of bromide substitution in $[Co(trpn)(CH_3CN)Br]^{2+}$, clearly demonstrate the extreme lability of these complexes. The aquation of $[Co(trpn)F_2]^+$ ion was examined in both neutral and acidic medium. In neutral aqueous medium, the primary aquation determined at 25°C and $\mu = 0.5$ M, gave $k_1 = 1.28 \times 10^{-3}$ s^{-1}, $\Delta H_1^\ddagger = 12.8$ kcal mol^{-1} and $\Delta S_1^\ddagger = -28.9$ cal K^{-1} mol^{-1}, while for the secondary aquation step (25°C and $\mu = 1.0$ M) the acid-independent pathway gave $k_2 = 1.4 \times 10^{-4}$ s^{-1}, $\Delta H_2^\ddagger = 21.3$ kcal mol^{-1} and $\Delta S_2^\ddagger = -4.7$ cal K^{-1} mol^{-1}. The acid hydrolysis of $[Co(trpn)(CH_3CN)_2]^{3+}$ was studied over the pH range 1–4 and the temperature range 8–20°C. The hydrolysis proceeds in two consecutive steps:

$$[Co(trpn)(CH_3CN)_2]^{3+} \xrightarrow{k_1} [Co(trpn)(CH_3CN)(H_2O)]^{3+} \xrightarrow{k_2} [Co(trpn)(H_2O)_2]^{3+}.$$

Analysis of the kinetic data gave $k_1 = 1.2 \times 10^{-2}$ s^{-1} (20°C), $\Delta H_1^\ddagger = 16.0$ kcal mol^{-1} and $\Delta S_1^\ddagger = -12.7$ cal K^{-1} mol^{-1}, and $k_2 = 2.38 \times 10^{-3}$ s^{-1} (20°C), $\Delta H_2^\ddagger = 14.9$ kcal mol^{-1} and $\Delta S_2^\ddagger = -19.4$ cal K^{-1} mol^{-1}. The results of the kinetics of these substitution reactions are discussed in relation to data for the other tetraamine cobalt(III) complexes.

The complexes of cobalt(III) with the tripod quadridentate ligand 3,3′,3″-triaminotripropylamine [trpn = $N(CH_2CH_2CH_2NH_2)_3$] dramatically enhance the rate of hydrolysis of ATP[1-3] (ATP = adenosine-5′-triphosphate) in comparison to the unpromoted hydrolysis. They appear to be very valuable for "model system" studies of the metal ion effect on non-enzymatic reactions, which are related to similar biologically important processes.

Complexes of the tripod tetraamine, 2,2′,2″-triaminotriethylamine [tren = $N(CH_2CH_2NH_2)_3$] have been extensively studied, and the subject has been reviewed.[4] Use of this ligand led to the preparation of either five-coordinate[5] or *cis*-octahedral complexes.[6] The addition of another CH_2 group into each ethylene bridging chain of tren produces the more flexible trpn ligand, which allows the formation of tetrahedral, trigonal bipyramidal or octahedral complexes.[7-9] Also, in many species of octahedral tetraamine complexes, the *cis*/*trans* isomerization complicates the study. This problem is avoided by using the trpn ligand, for which the fifth and sixth coordination sites are fixed and forced to be in the *cis* position.

It has been suggested that replacement of five-membered ethylenediamine (en) with six-membered trimethylenediamine (tn) rings causes marked labilization in some cobalt(III) complexes.[10] Thus the combined effects of marked labilization associated with the six-membered ring systems and the absence of *cis* ⇌ *trans* isomerization in Co(III)–trpn systems offer a unique opportunity to gather significant

information about metal-ion catalysed reactions.[1-3]

Since no kinetic data were available for the cobalt(III)–trpn systems and in order to gain more insight into the mechanism of the substitution reactions in these complexes, we have decided to study the acid hydrolysis of the complex ions $[Co(trpn)F_2]^+$, $[Co(trpn)Cl_2]^+$, $[Co(trpn)Br_2]^+$, $[Co(trpn)(CH_3CN)_2]^{3+}$ and $[Co(trpn)(CH_3CN)Br]^{2+}$.

EXPERIMENTAL

Synthesis of the complexes

The complexes $[Co(trpn)Cl_2]ClO_4$, $[Co(trpn)Br_2]ClO_4$, $[Co(trpn)F_2]ClO_4 \cdot 3/2H_2O$, $[Co(trpn)(CH_3CN)_2](ClO_4)_3$ and $[Co(trpn)(CH_3CN)Br]BrClO_4$ were prepared as previously described in our recent report.[11]

Electronic spectra and rate data were recorded using a Cary 210 spectrophotometer. pH measurements were made with an Orion Research pH meter model 601 A fitted with a combination electrode.

Kinetic measurements

All rate measurements were made spectrophotometrically at an appropriate wavelength, where a large difference between the molar absorptivities for the reactants and products exists. In each kinetic run, an equilibrated solution (H_2O, aqueous $HClO_4$ solution or equal volumes of 0.20 M $HClO_4$ and CH_3CN) was added to a thermostated volumetric flask containing a weighed sample of the complex together with $NaClO_4$ (for adjusting the ionic strength). The addition was made quickly and with vigorous swirling. Then, the solution was transferrred into a thermostated 1 cm quartz cell, where the rate of hydrolysis was monitored spectrophotometrically with time.

Acid hydrolysis of the $[Co(trpn)X_2]^+$ *ion* (X = F, Cl, Br). The acid hydrolysis of $[Co(trpn)Cl_2]^+$ ion (5 mM) in 0.1 M $HClO_4$ at 25°C and $\mu = 0.5$ M was measured by following the absorbance change vs time at 530 nm. The primary aquation of $[Co(trpn)F_2]^+$ ion (3 mM) in neutral aqueous medium was followed at 368 nm. The secondary aquation was measured in 0.09–1.1 M $HClO_4$ and the reaction was examined at 368 nm, as well as at 338 nm.

Acid hydrolysis of the $[Co(trpn)(CH_3CN)_2]^{3+}$ *ion.* In a typical experiment a weighed sample of the complex, $[Co(trpn)(CH_3CN)_2](ClO_4)_3$ (7.85 mg) in a thermostated volumetric flask, was treated with an aqueous solution (pH 1.0–4.0) equilibrated at the same temperature to give a solution of concentration 2.5 mM of the complex. Hydrolysis was monitored at 510 nm.

Acid hydrolysis of the $[Co(trpn)(CH_3CN)Br]^{2+}$ *ion.* A weighed sample of $[Co(trpn)(CH_3CN)Br]ClO_4$ complex was dissolved in aqueous acetonitrile solution (equal volumes of 0.20 M $HClO_4$ and CH_3CN) to give a 2.5 mM solution of the complex. The rate of the reaction was followed over the temperature range 4–35°C, by measuring the absorbance change at 500 nm.

Ion exchange procedures

These were carried out with Bio-Rad cation exchange resin (A.R., AG 50 W-X8, 100–200 mesh, in the H^+ form). A jacketed column (12 × 1.2 cm) was used and cold water was circulated through the jacket. The neutral solutions of $[Co(trpn)F_2]^+$ were allowed to undergo the primary aquation for ~ 45 min (~ $5t_{1/2}$ at 25°C) and were then charged onto the column. The column was washed with deionized–distilled water until the washings appeared neutral. The collected washings were than titrated with standardized $Th(NO_3)_4 \cdot 4H_2O$ using sodium alizarin as an indicator.[12] It is important to note that runs with NaF (Gold label from Aldrich) confirmed that F^- could be recovered quantitatively from the ion exchange column.

RESULTS AND DISCUSSION

Structural aspects

A series of cobalt(III)-trpn complexes has been prepared and isolated.[11] The isolated complexes under investigation are presented in Scheme 1. The visible spectral data of these complexes summarized in Table 1, are consistent with the *cis*-octahedral geometry.[11,13]

In an attempt to find a suitable solvent in which the aquation of $[Co(trpn)X_2]^+$ (X = F, Cl, Br) could be studied, it was observed that DMF, THF and CH_3CN reacted with the complex. The product of the reaction $[Co(trpn)Br_2]ClO_4$ with acetonitrile has been separated out and characterized; $[Co(trpn)(CH_3CN)Br]BrClO_4$. Such a complex is sparingly soluble in acetonitrile and it does not react further to produce the corresponding diacetonitrile, even with prolonged reflux. On the other hand, the reaction of $[Co(trpn)(H_2O)_2](ClO_4)_3$ with acetonitrile afforded the $[Co(trpn)(CH_3CN)_2](ClO_4)_3$ complex.

Acid hydrolysis kinetics

$[Co(trpn)X_2]^+$ (X = Cl *or* Br). In acid medium the complex ions $[Co(trpn)Cl_2]^+$ and $[Co(trpn)Br_2]^+$

were found to hydrolyse very rapidly. The complete conversion of these ions to the diaqua, $[Co(trpn)(H_2O)_2]^{3+}$, occurred within a few minutes. Attempts to find a suitable non-aqueous solvent, in which the aquation could be studied, failed and therefore, we were unable to investigate the primary aquation step in these complexes. However, an attempt was made to obtain an estimate for the rate of the second aquation for $[Co(trpn)Cl_2]^{+}$ ion, by dissolving $[Co(trpn)Cl_2]ClO_4$ in aqueous 0.1 M $HClO_4$ at 25°C, and following the absorbance change at 530 nm. In this way, we were able to observe a part of the conversion of $[Co(trpn)(H_2O)Cl]^{2+}$ to $[Co(trpn)(H_2O)_2]^{3+}$. The estimated half-life for this change is ~ 125 s, which corresponds to a rate constant $k_2 \simeq 5.5 \times 10^{-3}$ s^{-1}. On the other hand, the conversion of the dibromo species to the diaqua was too fast to be followed.

However, it is interesting to compare the result of the acid hydrolysis of the $[Co(trpn)Cl_2]^{+}$ ion with other similar tetraamine species $[CoN_4Cl_2]^{+}$ (N_4 = non-replacable monodentate or polydentate amine). The results collected in Table 2 for the secondary aquation in these systems, clearly demonstrate the extreme lability of the trpn system relative to the other tetraamines. Briefly, the rate of the second chloride substitution decreases in the order: trpn > tn_2 > tren ⩾ en_2.

Table 2. The secondary acid hydrolysis rate constant of the $[CoN_4Cl_2]^{+}$ ion at 25°C

N_4	k_2 (s^{-1})	Relative rate	Reference
cis-en_2	1.6×10^{-6}	1	14
trans-tn_2	2.14×10^{-4}	135	10
tren	2.38×10^{-6}	1.5	15
trpn	~ 5.5×10^{-3}	~ 3400	This work

Aquation of $[Co(trpn)F_2]^{+}$. In neutral aqueous medium, the hydrolysis of the $[Co(trpn)F_2]^{+}$ ion led to spectral changes with a very small shift of the lowest energy *d–d* band maxima to lower wavelengths. The spectral scans displayed an isosbestic point at 580 nm, which was maintained throughout the reaction. The final spectral trace gave λ_{max} at 368 nm with ε = 62 M^{-1} cm^{-1}, which is different from that observed for the diaqua species (Table 1). The stoichiometry of the reaction can be repre-

sented by eq. (1):

$$[Co(trpn)F_2]^+ + H_2O \xrightarrow{k_1} [Co(trpn)(H_2O)F]^{2+} + F^- \quad (1)$$

Evidences for this reaction stoichiometry include the following: (i) the isosbestic point at 580 nm remained during the course of the reaction, (ii) the final spectral scans showed no appreciable change over a period of 90 min, (iii) pseudo-first-order kinetics were observed for at least 3 half-lives, (iv) titration of the released fluoride ion with standardized thorium(IV) nitrate gave an average of 1.04 ± 0.06 mol of F^- released/mol of complex (see Experimental).

First-order rate constants were calculated from the slopes of the linear plots of $\ln(A_\infty - A_t)$ vs time. The rate data are listed in Table 3. The activation parameters ($\Delta H^\ddagger$ and $\Delta S^\ddagger$) were evaluated by linear least-squares analysis of Eyring graphs ($\ln k_1/T$ vs $1/T$; k_1 is the primary hydrolysis rate constant and T is the absolute temperature). These values are $\Delta H_1^\ddagger = 12.8 (\pm 0.5)$ kcal mol^{-1} and $\Delta S_1^\ddagger = -28.9 (\pm 1.5)$ cal K^{-1} mol^{-1}.

The hydrolysis of $[Co(trpn)F_2]^+$ ion was also conducted in acid medium over the concentration range 0.1–1.1 M of $HClO_4$. The spectral scans displayed a new isosbestic point at 425 nm with the disappearance of the former one observed at 580 nm. Furthermore, the final spectral trace was consistent with the formation of the well characterized $[Co(trpn)(H_2O)_2]^{3+}$ ion.[11] The first spectral scan recorded after 3 min (time taken to dissolve the complex) gave molar absorptivities in the range 63–67 M^{-1} cm^{-1} at 368 nm. It was apparent, that in acidic medium the rate of the primary aquation of the $[Co(trpn)F_2]^+$ ion had occurred very quickly, probably during the time of dissolution, i.e. the spectral scans refer to the secondary aquation step, which was found to be acid-catalysed.

The pseudo-first-order rate constants for the secondary aquation of $[Co(trpn)F_2]^+$ ion, measured at various $[H_3O^+]$ concentrations and at different temperatures are presented in Table 4. The observed pseudo-first-order rate constants (k_{obs}) calculated at 368 and 338 nm were in agreement to within 6%, confirming the assumption that no other side reactions are complicating the study.

0.708	8.62	16.87	29.65	46.52
1.0619[b]	13.78			

[a] Ionic strength maintained with $NaClO_4$.
[b] $\mu = 1.1$ M in this case.

The plots of k_{obs} vs $[H_3O^+]$, shown in Fig. 1, gave straight lines with a positive intercept at $[H_3O^+] = 0$. The non-zero intercept indicates the presence of a reaction pathway, which is independent of the hydrogen ion concentration. The other pathway depends on the hydrogen ion concentration, and presumably involves a rapid reversible acid–base pre-equilibrium, where the protonated form of the complex is more labile than the unprotonated form. This can be represented by the following mechanism:

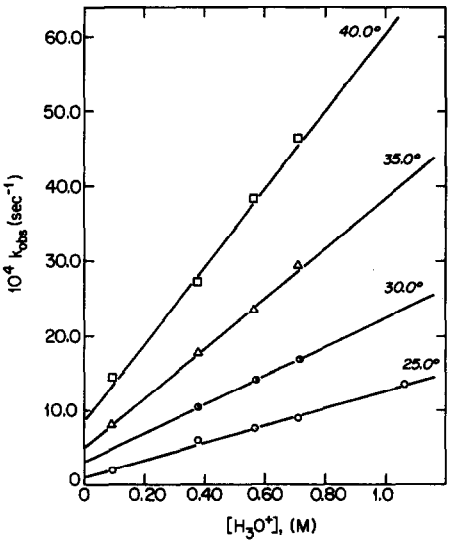

Fig. 1. The dependence of the pseudo-first-order rate constant on the hydrogen ion concentration for the secondary acid hydrolysis of $[Co(trpn)F_2]^+$ (3 mM) at different temperatures: (○) 25.0°C, (◑) 30.0°C; (△) 35.0°C; (□) 40.0°C.

$$[Co(trpn)(H_2O)F]^{2+} + H_3O^+ \underset{}{\overset{K_{eq,fast}}{\rightleftharpoons}} [Co(trpn)(H_2O)FH]^{3+} + H_2O \quad (2)$$

$$[Co(trpn)(H_2O)F]^{2+} + H_2O \xrightarrow{k_2} [Co(trpn)(H_2O)_2]^{3+} + F^- \quad (3)$$

$$[Co(trpn)(H_2O)FH]^{3+} + H_2O \xrightarrow{k'_2} [Co(trpn)(H_2O)_2]^{3+} + HF \quad (4)$$

where K_{eq} is the equilibrium constant for the protonation reaction 2, and k_2 and k'_2 are the rate constants for reactions 3 and 4, respectively. Under pseudo-first-order conditions of constant hydrogen ion concentration, combination of eqs (2)–(4) leads to the rate law given by eq. (5).

$$-\frac{dC_t}{dt} = k_{obs}C_t = \frac{k_2 + k'_2K_{eq}[H_3O^+]}{1 + K_{eq}[H_3O^+]}C_t \quad (5)$$

where C_t represents the total concentration of the monofluoro complex in both protonated and unprotonated forms. When $K_{eq}[H_3O^+] \ll 1$, eq. (5) is reduced to:

$$k_{obs} = k_2 + k'_2K_{eq}[H_3O^+]. \quad (6)$$

This latter expression fits the data, as is shown by the straight lines obtained from a plot of k_{obs} vs $[H_3O^+]$ (Fig. 1). The least-squares slopes and intercepts, corresponding to the values of k'_2K_{eq} and k_2, respectively, are given in Table 5.

The activation parameters corresponding to k_2 and k'_2K_{eq} were obtained from linear Eyring plots over the range 25.0–40.0°C. For the acid-independent path (k_2), the activation parameters are $\Delta H_2^{\ddagger} = 21.3(\pm 0.7)$ kcal mol^{-1} and $\Delta S_2^{\ddagger} = 4.7(\pm 2)$ cal K^{-1} mol^{-1}, while for the acid-catalysed path (k'_2K_{eq}), the parameters are $\Delta H^{\ddagger} = 19.2(\pm 0.4)$ kcal mol^{-1} and $\Delta S^{\ddagger} = -7.7(\pm 1.2)$ cal K^{-1} mol^{-1}.

The observed rate constant for the second aquation of $[Co(trpn)F_2]^+$, at a given hydrogen ion concentration at 25°C and $\mu = 1.0$ M, can be calculated by the expression:

$$k_{obs}(s^{-1}) = 1.40 \times 10^{-4} + (1.07 \times 10^{-3})[H_3O^+]. \quad (7)$$

Table 5. Values of k_2 and k'_2K_{eq} at various temperatures for the secondary aquation of $[Co(trpn)F_2]^+$ ($\mu = 1.0$ M)

Temperature (°C)	$10^4 k_2$ (s^{-1})	$10^3 k'_2K_{eq}$ (s^{-1} M^{-1})
25.0	1.40	1.07
30.0	3.14	1.94
35.0	4.70	3.47
40.0	8.80	5.24

Although for the acid-independent pathways the ratio of $k_1/k_2 \simeq 10$, the reaction in neutral aqueous medium did not show the second hydrolysis step. This might be attributed to the presence of an equilibrium between the monoaqua and the diaqua species; i.e.:

$$[Co(trpn)(H_2O)F]^{2+} + H_2O \rightleftharpoons [Co(trpn)(H_2O)_2]^{3+} + F^-.$$

A related result has been obtained for the hydrolysis of $[Cr(tren)F_2]^+$ where, in both basic and acidic solutions, the release of a second fluoride was not observed.[16] It might be expected that the removal of ligands which retain some basicity, even when coordinated, would be acid catalysed, as in the case of most metallic complexes containing the oxalate,[17] cyanide[18] and fluoride ion.[19–23] Comparing the rate constants for the primary acid-independent hydrolysis for the series *cis*-$[CoN_4F_2]^+$, reveals that k_1 (s^{-1}) decreases in the order trpn (1.3×10^{-3}) $\gg$ tren[23] (9.0×10^{-6}) > en$_2$[19] (3.0×10^{-6}). The large labilization induced by the trpn ligand compared to the tren ligand may be attributed to the much lower $\Delta H^{\ddagger}$ value [$\Delta H^{\ddagger}_{trpn} - \Delta H^{\ddagger}_{tren} = -9.5$ kcal mol^{-1}]. The entropy of activation favours the tren system [$-T(\Delta S^{\ddagger}_{trpn} - \Delta S^{\ddagger}_{tren}) = +6.7$ kcal mol^{-1}], but this is not sufficient to offset the large difference in $\Delta H^{\ddagger}$.

Acid hydrolysis of $[Co(trpn)(CH_3CN)_2]^{3+}$. The kinetics of aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$ ion was studied in the pH range 1–4 and over the temperature range 8–20°C. The spectral changes for the acid hydrolysis is shown in Fig. 2. A careful inspection of these curves suggests that three species are involved in the reaction, namely $[Co(trpn)(CH_3CN)_2]^{3+}$ (A), $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$ (B) and $[Co(trpn)(H_2O)_2]^{3+}$ (C). The former and latter complexes have been isolated and characterized.[11] For the kinetic measurements the wavelength chosen was 510 nm. During the first part of the reaction, two isosbestic points at 531 and 417 mm, were observed and the lower energy *d–d* band (λ_{max}) shifted gradually from 498 nm to 510(± 2) nm. Then, during the second part of the reaction, this band moved to 530(± 2) nm. Also, the isosbestic points moved to 537 and ~410 nm, respectively, and the final spectrum corresponds to the diaqua species. Thus, the overall reaction can be represented by eq. (8).

$$[Co(trpn)(CH_3CN)_2]^{3+} \xrightarrow{H_2O} [Co(trpn)(H_2O)_2]^{3+} + 2CH_3CN. \quad (8)$$

For two consecutive irreversible first-order reactions:[24]

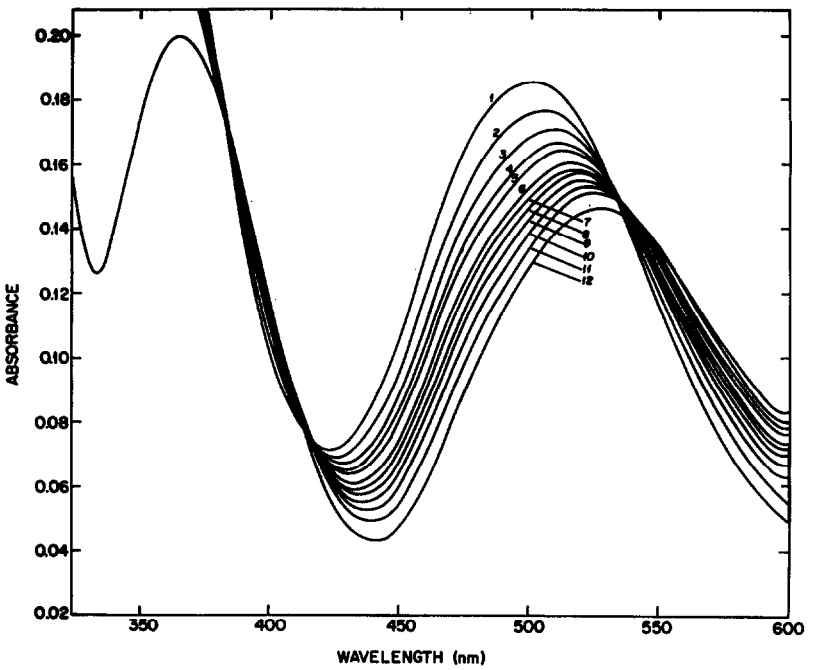

Fig. 2. Spectral changes during the aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$ (2.5 mM) in aqueous medium (pH = 4.0), at 11.5°C as a function of time [curve no., time (min)]: 1, 2.0; 2, 3.5; 3, 5.0; 4, 6.5; 5, 8.0; 6, 10.0; 7, 11.5; 8, 14.0; 9, 17.0; 10, 22.0; 11, 33; 12, 50.

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \tag{9}$$

it can be shown that the concentration of the species A, B and C at any time t, are given by:

$$[A] = [A]_0 e^{-k_1 t} \tag{10}$$

$$[B] = \frac{[A]_0 k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}) \tag{11}$$

$$[C] = [A]_0\left\{1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right\}. \tag{12}$$

The absorbance A_t at any time t, for a 1 cm cell, is given by eq. (13)

$$A_t = \varepsilon_a[A] + \varepsilon_b[B] + \varepsilon_c[C]. \tag{13}$$

Also it is not difficult to show that:[25]

$$A_t - A_\infty = a_1 e^{-k_1 t} + a_2 e^{-k_2 t} \tag{14}$$

where $A_\infty = \varepsilon_c[A]_0$, the absorbance at infinite time. $[A]_0$ is the initial complex concentration, a_1 and a_2 are composed of rate constants k_1 and k_2, and the molar absorptivities ε_a, ε_b and ε_c for the species A, B and C, respectively.

Figure 3 shows a typical plot of ln $(A_t - A_\infty)$ vs t for the acid hydrolysis of the $[Co(trpn)(CH_3CN)_2]^{3+}$ ion. From the straight-line portion of this curve, the first-order rate constant for the slow reactions (k_2) was obtained. When the logarithm of the difference between the extrapolated straight-line portion and the experimental curve was plotted vs time (Fig. 3), the rate constant of the more rapid reaction (k_1) was obtained. The rate constants k_1 and k_2 are collected in Table 6.

The activation parameters were evaluated from the linear plots of $\ln k_1/T$ and $\ln k_2/T$ vs $1/T$. For the fast step $\Delta H_1^\ddagger = 16.0(\pm 2.0)$ kcal mol^{-1} and $\Delta S_1^\ddagger = -12.7(\pm 6.0)$ cal K^{-1} mol^{-1}, while for the slow step $\Delta H_2^\ddagger = 14.9(\pm 2.0)$ kcal mol^{-1} and $\Delta S_2^\ddagger = -19.4(\pm 6.0)$ cal K^{-1} mol^{-1}. Over the temperature range examined, the rate of the first aquation is only about four times greater than that of the second aquation. Also, the aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$ is independent of pH over the range 1.0–4.0 (Table 6).

Table 6. The rate constants for the aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$ in acidic medium and at different temperatures

Temperature (°C)	pH	$10^3 k_1$ (s^{-1})	$10^3 k_2$ (s^{-1})
8.3	4.0	3.31	0.88
11.5	4.0	5.17	1.16
16.0	4.0	7.59	1.91
20.0	4.0	11.3	2.59
20.0	2.5	12.8	2.36
20.0	1.0	11.9	2.38

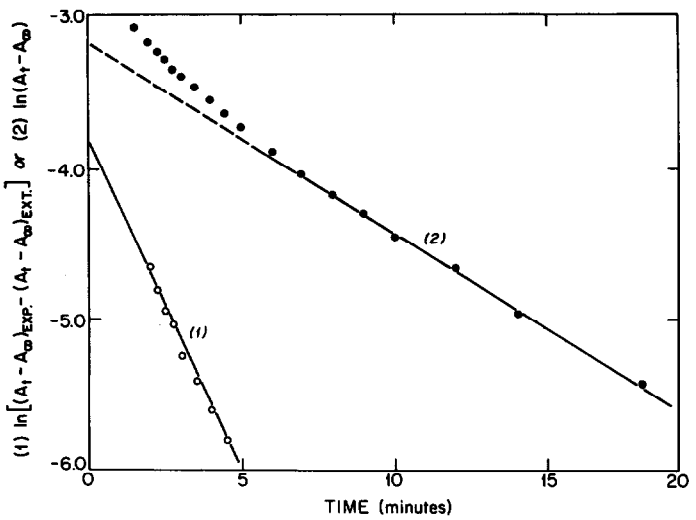

Fig. 3. Plot of the experimental data for the aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$ in acidic aqueous medium (pH = 4.0) at 16.0°C, λ = 510 nm.

The pK_1 for the acid dissociation constant of the coordinated water in $[Co(trpn)(H_2O)_2]^{3+}$ is 4.8 (25°C and $\mu = 0.1$ M).[26] This value led us to expect that the corresponding pK of $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$ would not be less than 5.0. Therefore, the species formed during the acid hydrolysis of the $[Co(trpn)(CH_3CN)_2]^{3+}$ ion would not be complicated by the presence of hydroxo–acetonitrile species as shown from the data in Table 6. Similar behaviour has been found during the aquation of the *cis*-$[Cr(C_2O_4)_2(DMSO)_2]^-$ ion[27] and the $[Co(NH_3)_5(CH_3CN)]^{3+}$ ion.[28]

However, it might be noted that metal complexes of organic nitriles of the formula $[ML_5(RCN)]^{3+}$ ($M = Co^{III}$, Cr^{III}, Rh^{III}; $L = NH_3$, H_2O; $RCN = CH_3CN$, C_6H_5CN) are known for a number of kinetically inert metal ions[29–31] and show kinetic stability towards simple aquation, the complexes hydrolyse to the corresponding carboxamide in neutral and alkaline solutions.[32,33] Therefore, the rapid aquation of the $[Co(trpn)(CH_3CN)_2]^{3+}$ ion is surprising in view of the normal kinetic inertness of the above mentioned nitrile complexes.

The spectrum of the intermediate, $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$, was calculated using the kinetic data (k_1 and k_2), the molar absorptivities (ε_a and ε_c) and eqs (10)–(13). The calculations were made at an optimum time in order to have a high concentration of the intermediate. An approach of this type was first made in studying the hydrolysis of the $[Cr(en)_3]^{3+}$ ion[34] and in other systems.[27,35] The result of this calculation is depicted in Fig. 4, together with the visible spectra of $[Co(trpn)(CH_3CN)_2]^{3+}$ and $[Co(trpn)(H_2O)_2]^{3+}$ ions. It is interesting to note that the position of the lower energy *d–d* band (λ_{max}) is shifted to longer

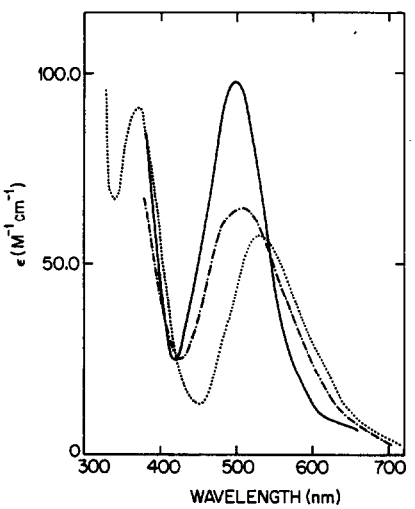

Fig. 4. Absorption spectra of (——) $[Co(trpn)(CH_3CN)_2]^{3+}$ in acetonitrile, (····) $[Co(trpn)(H_2O)_2]^{3+}$ in aqueous 0.1 M $NaClO_4$ (pH ~ 4) and (–·–·–) $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$ (calculated) in aqueous medium (pH 4.0).

wavelength with reducing ligand field. i.e. diacetonitrile → monoaquaacetonitrile → diaqua species. The calculations reveal that the $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$ ion has λ_{max} at 510 nm with $\varepsilon = 66.3$ $M^{-1}\,cm^{-1}$.

Aquation of the $[Co(trpn)(CH_3CN)Br]^{2+}$ *ion.* Due to the extreme lability of the $[Co(trpn)Br_2]^+$ ion towards acid hydrolysis, it was very difficult to extract quantitative information about its rate of aquation. The lack of suitable solvent for $[Co(trpn)Br_2]ClO_4$ ruled out the use of stopped-flow technique. Therefore, we considered the hydrolysis of $[Co(trpn)(CH_3CN)Br]^{2+}$, which in

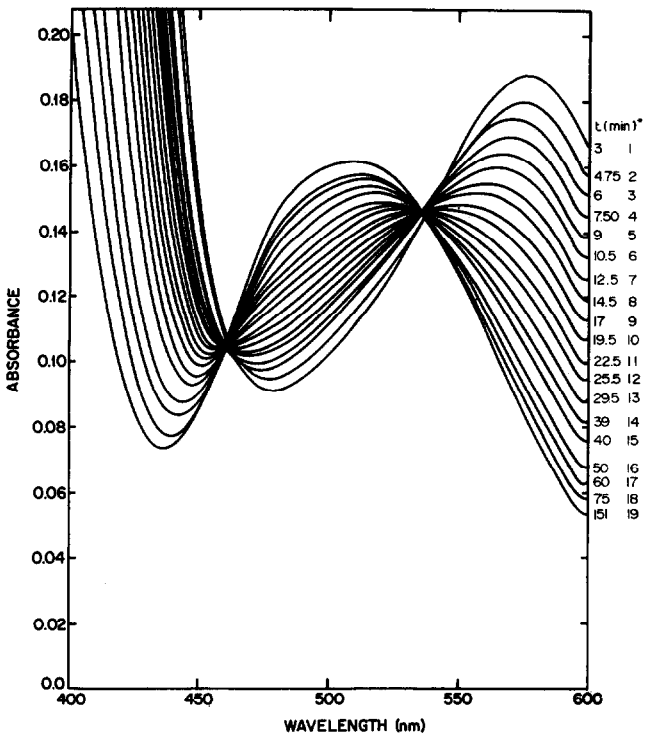

Fig. 5. Spectral changes of $[Co(trpn)(CH_3CN)Br]^{2+}$ (2.5 mM) in 50% (by volume) aqueous 0.2 M $HClO_4$ and CH_3CN solution at 13.7°C as a function of time.

principle should not differ too much from the hydrolysis of the $[Co(trpn)(H_2O)Br]^{2+}$ ion.

When the hydrolysis of $[Co(trpn)(CH_3CN)Br]^{2+}$ was carried out in acidic aqueous medium, the kinetics were complicated due to the small difference in the reactivity of $[Co(trpn)(CH_3CN)Br]^{2+}$ and $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$ towards aquation, i.e. the rate of bromide replacement by water in $[Co(trpn)(CH_3CN)Br]^{2+}$ was very close to the rate of replacement of acetonitrile in the primary product of the hydrolysis; $[Co(trpn)(CH_3CN)(H_2O)]^{3+}$. To overcome these difficulties, the hydrolysis of $[Co(trpn)(CH_3CN)Br]^{2+}$ was conducted in aqueous acetonitrile solution, where the second step in the reaction is suppressed.

The kinetics for $[Co(trpn)(CH_3CN)Br]^{2+}$ were studied in a mixed solvent containing equal volumes of 0.20 M $HClO_4$ and CH_3CN. The spectral scans as a function of time, shown in Fig. 5, indicate that more than one step is involved in the reaction. These curves clearly show the pronounced deviation from the isosbestic point at 536 nm, particularly at the beginning of the reaction. Moreover, the final spectral trace for the reaction gave an absorption band λ_{max} at 510(±2) nm. The intensity of this band varies with the H_2O : CH_3CN volume ratio, implying the presence of an equilibrium mixture in the products. At low temperatures (4–14°C), the plots of $\ln(A_\infty - A_t)$ vs time show a deviation from linearity. The first-order rate constants k_a and k_b for the fast and slow reaction, respectively, were evaluated as described before for the aquation of $[Co(trpn)(CH_3CN)_2]^{3+}$. These values are tabulated in Table 7. Thus, the reaction of $[Co(trpn)(CH_3CN)Br]^{2+}$ in aqueous acetonitrile solution can be represented by:

$$[Co(trpn)(CH_3CN)Br]^{2+} + H_2O \xrightarrow{k_a} [Co(trpn)(CH_3CN)(H_2O)]^{3+} + Br^- \quad (15)$$

$$[Co(trpn)(CH_3CN)(H_2O)]^{3+} + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [Co(trpn)(H_2O)_2]^{3+} + CH_3CN. \quad (16)$$

The rate constant k_b depends on k_2 and k_{-2}, and the equilibrium position between the aquaacetonitrile and the diaqua species [eq. (16)].

Eyring plots yielded $\Delta H^\ddagger = 18.1(\pm 0.6)$ kcal mol^{-1} and $\Delta S^\ddagger = -6.6(\pm 2.0)$ cal K^{-1} mol^{-1} for the fast reaction and $\Delta H^\ddagger = 17.0(\pm 0.55)$ kcal mol^{-1} and $\Delta S^\ddagger = -13.2(\pm 1.5)$ cal K^{-1} mol^{-1} for the slow reaction. These data reveal that the rate of the first step is only ~ four times greater than the rate in the second step. This difference in rate appears to arise from the small difference in the entropy of activation between the two steps.

Table 7. Pseudo-first-order rate constants (k_a and k_b) for the reaction of $[Co(trpn)(CH_3CN)Br]^{2+}$ in 50% aqueous (0.20 M $HClO_4$)–acetonitrile solutions

Temperature (°C)	$10^3 k_a$ (s^{-1})	$10^3 k_b$ (s^{-1})
4.30	1.21	0.32
7.80	1.52	0.46
11.60	2.92	
13.70	3.42	0.81
20.5		1.84
25.0		3.04
28.0		3.55
32.0		5.51

The rate of replacement of the Br^- ion in $[Co(trpn)(CH_3CN)Br]^{2+}$ with H_2O ($k \simeq 1.17 \times 10^{-2}$ s^{-1} at 25°C) is probably not much different than the rate of the second aquation of $[Co(trpn)Br_2]^+$. This rate is about twice that for replacement of Cl^- ion in $[Co(trpn)(H_2O)Cl]^{2+}$. The same observation has also been found for the aquation[10] of $[Cotn_2(H_2O)Br]^{2+}$ relative to $[Cotn_2(H_2O)Cl]^{2+}$. Furthermore, the rate of aquation of $[Co(trpn)(CH_3CN)Br]^{2+}$ reflects the extreme lability of these complexes due to the trpn ligand. For example, the relative rate of replacement of the bromide ion by water in the tetraamine–cobalt(III) complexes $[Co(tren)(H_2O)Br]^{2+}$:[36] $[Cotn_2(H_2O)Br]^{2+}$:[10] $[Co(trpn)(CH_3CN)Br]^{2+}$ is 1:165:3560.

In conclusion, some comments must be considered: (i) the reactivity of the tetraamine–cobalt (III) complexes can be enhanced or retarded by modifying the nature of the amine ligand(s); (ii) the replacement of the five-membered rings ($N_4 = en_2$ or tren), and even the six-membered rings ($N_4 = tn_2$) with the tripod trpn ligand causes marked labilization in tetraaminecobalt(III) complexes; (iii) the reactivity towards substitution reactions in the dihalotetraamine–cobalt(III) complexes decreases in the order trpn > tn_2 > tren > en_2.

The high lability of the $Co(trpn)^{3+}$ species is believed to be associated, at least in part, with the flexibility of the six-membered ring system (in contrast to the much less flexible five-membered amine rings $Co(en)_2^{3+}$ and $Co(tren)^{3+}$). Such flexibility is likely to contribute to the ease of forming the transition state by a mechanism which is primarily dissociative in nature.[10] Furthermore, the complexes of $Co(trpn)^{3+}$ represent a compromise between a system with fixed *cis* geometry and a fully labile species. These features might be of great importance in some biological processes such as the dephosphorylation of ATP.[1-3]

SYNTHESIS AND CHARACTERIZATION OF SOME NEW ORGANOMETALLIC COMPLEXES OF NICKEL(II) CONTAINING TRIMETHYLPHOSPHINE

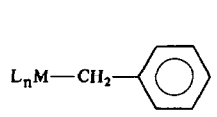
ERNESTO CARMONA,* MARGARITA PANEQUE and MANUEL L. POVEDA

Departamento de Química Inorgánica e Instituto de Ciencias de Materiales, Universidad de Sevilla-CSIC, 41071-Sevilla, Spain

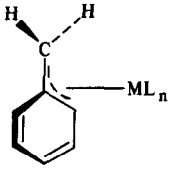
(*Received* 31 *May* 1988; *accepted* 6 *July* 1988)

Abstract—$[Ni(cod)_2]_2$ (cod = 1,5-cyclooctadiene) oxidatively adds $C_6H_5CH_2Cl$ in the presence of 1 or 2 equiv of PMe_3 affording $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ or *trans*-$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$, respectively. Variable temperature NMR studies carried out with a mixture of these two complexes indicate that both are involved in a fast equilibrium which interchanges the two types of benzylic ligands. The above mentioned compounds decompose in the presence of excess PMe_3 with the formation of $[NiCl_2(PMe_3)_3]$, $[Ni(PMe_3)_4]$ and the reductive elimination product $(C_6H_5CH_2)_2$. In addition, the synthesis and spectral characterization of the new complexes *trans*-$[Ni(C_6H_5)X(PMe_3)_2]$ (X = Cl, Br), *trans*-$[Ni(2,4,6\text{-}C_6H_2Me_3)X(PMe_3)_2]$ (X = Cl, Br) and $[(\eta^5\text{-}C_5H_5)Ni(2,4,6\text{-}C_6H_2Me_3)(PMe_3)]$, are also described.

It is well known that the benzyl ligand, $C_6H_5CH_2$, can adopt a variety of coordination modes (which include the alkyl-type coordination, **A**, as well as the pseudoallylic η^3-bonding, **B**) and that the adoption of a particular coordination mode is strongly



A



B

influenced by the nature of the ML_n fragment to which the benzyl group is bonded. While η^1-interactions are commonly found among transition metal–benzyl complexes,[1] relatively few η^3-structures are known[2] and for nickel only a few examples have been reported to date, among them the η^3-*o*-methylbenzyl derivative, $[Ni(\eta^3\text{-}CH_2C_6H_4\text{-}o\text{-}Me)Cl(PMe_3)]$, recently prepared in our laboratory.[3]

As an extension of this and previous work concerning the chemistry of nickel alkyl and acyl complexes,[4] we now report the formation of η^1- and η^3-benzyl complexes of the compositions $[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) and $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ (**2**), that of the aryl derivatives $[NiX(Ar)(PMe_3)_2]$, [Ar = C_6H_5, X = Cl (**3a**); X = Br (**4a**); Ar = 2,4,6-$C_6H_2Me_3$ (mesityl), X = Cl (**5**); X = Br (**6**)] and $[Ni(\eta^5\text{-}C_5H_5)(2,4,6\text{-}C_6H_2Me_3)PMe_3]$ (**7**) and their reactions with CO to afford the acyl compounds $[NiX(\eta^1\text{-}COR)(PMe_3)_2]$, [R = $CH_2C_6H_5$, X = Cl (**1b**); R = C_6H_5, X = Cl (**3b**); X = Br (**4b**)]. Variable temperature NMR studies on the benzyl complexes, **1a** and **2**, have been carried out, and are also reported.

RESULTS AND DISCUSSION

Synthesis and spectroscopic characterization of the benzyl complexes trans-$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) *and* $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ (**2**)

The room temperature reaction of the dichloride, $[NiCl_2(PMe_3)_2]$, with *ca* 2 equiv of $Mg(CH_2C_6H_5)Cl$, produces a brown suspension from which a brown crystalline material can be obtained after work-up. Spectroscopic studies reveal the presence of a mixture of the benzyl derivatives *trans*-$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) and $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ (**2**). In addition to these products, formation of a very dark, sparingly soluble

*Author to whom correspondence should be addressed.

crystalline species is sometimes observed. The latter displays an IR absorption at 3580 cm^{-1}, which indicates the presence of hydroxo ligands, and this, together with the similarity in colour, solubility and other properties with those found for the recently prepared *o*-methylbenzyl compound $[Ni_3(CH_2C_6H_4\text{-}o\text{-}Me)_4(PMe_3)_2(\mu_3\text{-}OH)_2]$,[3] whose structure was determined by X-ray crystallography, suggest an analogous formulation as $[Ni_3(\eta^1\text{-}CH_2C_6H_5)_4(PMe_3)_2(\mu_3\text{-}OH)_2]$. No satisfactory analytical data can however be obtained for this complex which, as with the related *o*-methylbenzyl derivative, decomposes upon attempted recrystallization, even under an inert atmosphere. For these reasons its investigation has not been pursued any further.

Compounds **1a** and **2** are best prepared by the oxidative addition of $C_6H_5CH_2Cl$ to $[Ni(cod)_2]$ in the presence of the required amount of PMe_3, as shown in eqs (1) and (2).

$$[Ni(cod)_2]+C_6H_5CH_2Cl+2PMe_3 \longrightarrow [Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]+2cod \quad (1)$$

$$[Ni(cod)_2]+C_6H_5CH_2Cl+PMe_3 \longrightarrow [Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]+2cod. \quad (2)$$

They have been found to be related by an intermolecular process which involves PMe_3 association and dissociation [eq. (3)], and indeed, on a macroscopic scale, compound **2** can be obtained by addition of 1 equiv of PMe_3 to solutions of **2**, while the latter is formed by PMe_3 abstraction from **1a** using $[Ni(cod)_2]$.

$$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2] \underset{+PMe_3}{\overset{-PMe_3}{\rightleftharpoons}} [Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]. \quad (3)$$

Both compounds have been characterized by IR and ^1H, ^{13}C and ^{31}P NMR spectroscopy. The ^1H NMR spectrum of **1a** shows two singlets at δ 0.98 (18H) and 1.71 (2H) ppm corresponding to the PMe_3 and the methylene benzylic protons, respectively. The lack of observation of coupling is clearly due to an exchange process involving PMe_3 dissociation. A similar situation has been found in other nickel alkyl complexes of related composition, and has been explained in terms of a fast exchange between traces of free PMe_3 and complexed PMe_3, possibly through the intermediacy of a five-coordinate species.[4] Such a process, however, could not be operative in the present system, since addition of free PMe_3 to solutions of **1a** does not increase the rate of PMe_3 exchange, but it rather induces decomposition, with formation of $[NiCl_2(PMe_3)_3]$, $[Ni(PMe_3)_4]$ and $C_{14}H_{14}$ (1,2-diphenylethane) as shown in eq. (4).

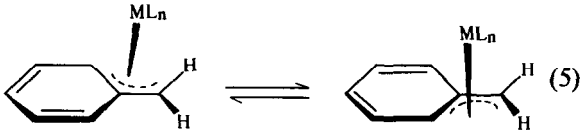
$$2[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]+3PMe_3 \longrightarrow [NiCl_2(PMe_3)_3]+[Ni(PMe_3)_4]+C_{14}H_{14}. \quad (4)$$

Hence, it seems more likely that the process responsible for the observed NMR features implies phosphine dissociation and re-association through the intermediacy of the pseudoallylic complex **2**, and this is not only in accord with the above comments regarding the reversible transformation **1a** $\rightleftharpoons$ **2** but also with the observation of only one set of proton resonances for mixtures of **1a** and **2**, with chemical shifts being an average of those corresponding to compounds **1a** and **2** (see below). As expected, **1a** exhibits a single $^{31}P\{^1H\}$ NMR signal, while in the $^{13}C\{^1H\}$ NMR spectrum a singlet is observed for each of the carbon atoms of the benzyl ligand as well as for those of the PMe_3 groups (Table 1).

A related situation is found in the η^3-benzyl complex, **2**. The fluxionality of this species is clearly indicated by the appearance of broad, unresolved signals in the NMR spectra. Thus, the $^{31}P\{^1H\}$ NMR exhibits a broad singlet at -7.9 ppm, while the ^1H NMR spectrum displays a broad singlet at 1.0 ppm for the methylene benzylic protons. In the room temperature $^{13}C\{^1H\}$ NMR spectrum, a doublet is observed at δ 15.0 ppm for the PMe_3 ($^1J_{CP}$ = 30.2 Hz), a broad singlet at 22.0 ppm for the methylene carbon atom and three resonances (intensity ratio *ca* 2 : 2 : 1) between 117–134 ppm for the *ortho*, *meta* and *para* benzyl carbon atoms. No signal can be found for the *ipso* carbon atom of the benzyl ligand. In order to gain further information on the fluxionality of these species and on their interconversion process, variable temperature NMR studies have been carried out with complex **2** and with approximately equimolar mixtures of **1a** and **2**.

Upon cooling a toluene-d_8 solution of **2** at $-60°C$, a doublet at 0.9 ppm is observed for the PMe_3 protons ($^2J_{HP}$ = 9.8 Hz) and a second doublet at 1.1 ppm ($^3J_{HP}$ = 21.3 Hz) for the two benzyl protons, which remain equivalent under these conditions. Only broad, partially resolved signals are found for the aromatic protons. These features are maintained at temperatures down to $-90°C$, the spectrum becoming less resolved due possibly to viscosity effects. Similarly, the methylene carbon atom gives rise to a doublet at 23.7 ppm ($^2J_{CP}$ = 11.3 Hz) due to coupling to the phosphorus nucleus, while four resonances at 133.5 (2C), 128.2 (1C) and 117.7 (2C) are observed in the aromatic region, along with a singlet at 114.6 ppm which is due to the quaternary carbon atom. The equivalence of the two benzyl methylene protons and that of the two *ortho* and the two *meta* carbon atoms can be

explained in terms of a fast suprafacial rearrangement,[5] as shown in eq. (5).



(5)

This process, however, would not account for the loss of coupling, observed at temperatures above $-10°C$, between the methylene carbon or hydrogen atoms and the ^{31}P nucleus of the phosphine ligand. A second fluxional process, which is very slow in the NMR time scale at temperatures of $-10°C$ and below, must therefore operate at temperatures above $-10°C$, and this is proposed to be the intermolecular process depicted in eq. (3), that, as already indicated, interrelates complexes **1a** and **2** through a PMe_3 dissociation and association process. Its occurrence can be conclusively demonstrated by variable temperature NMR studies. Thus, the $^{31}P\{^1H\}$ NMR of a *ca* 1 : 1 mixture of **1a** and **2** exhibits, at room temperature, a very broad signal, which splits into two singlets at -7.9 (**1a**) and -16.4 (**2**) on cooling at $-40°C$. Similarly, the room temperature $^{13}C\{^1H\}$ NMR spectrum displays three broad resonances for the *ortho*, *meta* and *para* carbon atoms of species **1a** and **2**, present in the frozen equilibrium of eq. (3). This temperature-dependent behaviour clearly demonstrates the existence of the equilibrium between the η^1-benzyl complexes **1a** and the pseudoallylic species **2**.

In conclusion, two different types of fluxional processes are observed for complex **2**. A suprafacial jump, similar to that observed in other benzyl complexes,[5,6] which is very fast even at $-90°C$, and an intermolecular phosphine exchange with traces of PMe_3 present in solution. From the above data and by similarity with the structure found for the *o*-methylbenzyl analogue by X-ray studies,[3] structure **C** can be proposed for this compound.

C

Aryl derivatives of composition $[NiAr(X)(PMe_3)_2]$ *and* $[(\eta^5\text{-}C_5H_5)Ni(Ar)(PMe_3)]$. *Preparation and spectral properties*

The addition of *ca* 1 equiv of the Grignard reagent $Mg(C_6H_5)Br$ to a suspension of $[NiCl_2(PMe_3)_2]$ in diethyl ether, produces extensive decomposition and formation of the desired aryl derivative only in very low yields. The chloride complex $[Ni(C_6H_5)Cl(PMe_3)_2]$ (**3a**), and its bromide analogue, $[Ni(C_6H_5)Br(PMe_3)_2]$ (**4a**), can be obtained in good yields by the oxidative addition of C_6H_5X (X = Cl, Br), to $[Ni(cod)_2]$, in the presence of 2 equiv of PMe_3. While the reaction with bromobenzene takes place readily under ambient conditions, that of chlorobenzene requires heating at 60°C, for 24 h, for completion.

NMR studies for the complexes $[Ni(C_6H_5)X(PMe_3)_2]$ indicate a square-planar structure with *trans* phosphine ligands. Thus, the ^1H NMR spectrum for complex **4a** shows a virtually coupled triplet at 0.9 ppm, characteristic of bisphosphine compounds with strong coupling between the phosphorus nuclei ($^2J_{HP_{app}} = 3.6$ Hz). In addition, the phosphine ligands give rise to a singlet in the $^{31}P\{^1H\}$ NMR spectrum and to a triplet at 13.6 ppm in the $^{13}C\{^1H\}$ NMR. Other pertinent NMR data for these aryl derivatives are included in Table 1 and require no further comment.

Upon addition of 1 equiv of the Grignard reagent derived from the mesityl ligand, $Mg(2,4,6\text{-}C_6H_2Me_3)Br$, to a suspension of $[NiCl_2(PMe_3)_2]$, a fairly clean and fast reaction takes place which provides good yields (*ca* 60%) of the mesityl derivative $[Ni(2,4,6\text{-}C_6H_2Me_3)Br(PMe_3)_2]$ (**6**). Formation of this bromo derivative is obviously due to a metathetical replacement of the chloride ligand in complex $[Ni(2,4,6\text{-}C_6H_2Me_3)Cl(PMe_3)_2]$ (**5**) by the bromide present in solution. Similar M—X to M—X′ exchanges (X′ = heavier halogen) are frequently observed during alkylation reactions.[7,8] For instance, alkylation of $[M(\eta^5\text{-}C_5H_5)_2Cl_2]$ (M = Ti, Zr, Hf) with $Mg(CH_2SiMe_3)Br$, gives the bromoalkyl product $[M(\eta^5\text{-}C_5H_5)_2Br(CH_2SiMe_3)]$, without contamination of the chloro complex, and the driving force for this exchange has been associated with the "hard" nature of the Mg^{2+} ion. The chloride derivative $[Ni(2,4,6\text{-}C_6H_2Me_3)Cl(PMe_3)_2]$ (**5**) can be obtained by reaction of the dichloride, $[NiCl_2(PMe_3)_2]$, with 1 equiv of the diaryl magnesium reagent, $Mg(2,4,6\text{-}C_6H_2Me_3)_2$. Compounds **5** and **6** are highly crystalline materials, soluble in common organic solvents and fairly air stable, even in solution. Spectroscopic data for these compounds (Table 1) are also in accord with their formulation as *trans*-$[Ni(2,4,6\text{-}C_6H_2Me_3)X(PMe_3)_2]$.

Interaction of **5** or **6** with an excess of NaCp (1.5 equiv), produces the cyclopentadienyl derivative $[Ni(\eta^5\text{-}C_5H_5)(2,4,6\text{-}C_6H_2Me_3)(PMe_3)]$ (**7**) in high yields [eq. (6)].

$$[Ni(2,4,6\text{-}C_6H_2Me_3)X(PMe_3)_2] + NaCp \longrightarrow [CpNi(2,4,6\text{-}C_6H_2Me_3)(PMe_3)] + NaX + PMe_3 \quad (6)$$

Table 1. Selected NMR data for the new complexes

As expected, the Cp protons give rise to a singlet at 5.17 ppm, indicating pentahapto coordination to the nickel atom. ^{13}C and ^{31}P NMR studies are also in agreement with the proposed formulation. Compound **7** is very thermally stable and can be sublimed under vacuum (0.1 mm), at 100°C, without decomposition.

Carbonylation reactions

Interaction of carbon monoxide (20°C, 1 atm) with compounds **1a**, **3a** and **4a**, produces the corresponding insertion products, **1b**, **3b** and **4b**, as exemplified in eq. (7) for the benzyl derivative **1b**.

$$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2] + CO \longrightarrow [Ni(\eta^1\text{-}COCH_2C_6H_5)Cl(PMe_3)_2] \quad (7)$$

All these carbonyl species are orange crystalline solids, which show no tendency towards CO dissociation under ambient conditions. The presence of an acyl ligand is indicated by the appearance of a medium intensity IR band in the region 1600–1630 cm^{-1}, due to the CO stretching of the coordinated acyl group. The similarity of their NMR spectra with those of the parent compounds **1a**, **3a** and **4a**, clearly suggests conservation of the *trans* geometry. At variance with the behaviour found for these compounds, carbonylation of the mesityl derivatives **6** and **7**, cannot be achieved even under rather forcing conditions (4–5 atm of CO, 50–60°C). This is likely due to steric hindrance of the *o*-methyl groups of the mesityl ligand,[9] which may prevent association of CO to yield the aryl–carbonyl intermediate species proposed for the carbonylation reaction.

EXPERIMENTAL

Microanalyses were by Pascher Microanalytical Laboratory, Bonn and the Microanalytical Service of the University of Sevilla. The spectroscopic instruments used were Perkin–Elmer models 577 and 684 for IR spectra and Varian XL-200 for ^1H, ^{13}C and ^{31}P NMR spectra. All preparations and other operations were carried out under oxygen-free nitrogen, following conventional Schlenk techniques. Solvents were dried and degassed before use. The light petroleum used had b.p. 40–60°C. PMe_3,[10] $NiCl_2(PMe_3)_2$[11] and $Ni(cod)_2$[12] were prepared according to literature methods.

$[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) *and* $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ (**2**)

Since the conventional Grignard route does not provide reproducible and efficient procedures for the independent preparation of compounds **1a** and **2** (see Results and Discussion), only the oxidative addition of $C_6H_5CH_2Cl$ to $[Ni(cod)_2]$ procedure is reported.

To a stirred suspension of $[Ni(cod)_2]$ (0.274 g, *ca* 1 mmol) in 30 cm^3 of diethyl ether, cooled to −70°C, an excess of $C_6H_5CH_2Cl$ (0.15 cm^3, 1.3 mmol) and 0.2 cm^3 of PMe_3 (2 mmol) were added. The reaction mixture was warmed and stirred at room temperature for 20 h, when a yellow–brown solution was obtained. The solvent was removed under vacuum, the residue extracted with 20 cm^3 of diethyl ether and filtered to give a clear solution from which yellow–brown crystals of the desired product were collected after partial removal of the solvent and cooling overnight. Yield 0.2 g, *ca* 60%.

A similar reaction, using 1 equiv of PMe_3, provided the pseudoallyl complex **2** in *ca* 50% yield. Complex **2** is obtained as red crystals from diethyl ether. Found: C, 45.9; H, 6.2. Calc. for $C_{10}H_{16}PClNi$: C, 45.9; H, 6.1%.

Interconversion reactions of **1a** *and* **2**

(a) To a suspension of $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PMe_3)]$ (**2**) (0.26 g, *ca* 1 mmol) in Et_2O (20 cm^3), PMe_3 was added (0.1 cm^3, 1 mmol). The mixture was stirred for 30 min, during which time the red starting material dissolved forming a brown solution. The solvent was evaporated to dryness and the residue crystallized from Et_2O to afford yellow crystals of **1a** in 60% yield.

(b) To a mixture of $[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) (0.1 g, *ca* 0.3 mmol) and $[Ni(cod)_2]$ (0.05 g, *ca* 0.15 mmol), Et_2O (10 ml) was added. The solution, initially brown–yellow, darkened to red. After stirring for 10 min, the solution was cooled to produce compound **2** in 20% yield.

Reaction of $[Ni(\eta^1\text{-}CH_2C_6H_5)Cl(PMe_3)_2]$ (**1a**) *with an excess of* PMe_3

A solution of **1a** (0.33 g, *ca* 1 mmol) in Et_2O (20 cm^3) was treated with 0.5 cm^3 of PMe_3. The mixture was stirred at room temperature for 3 h and cooled at −30°C. Crystalline dark blue $[NiCl_2(PMe_3)_3]$ (0.15 g, 0.4 mmol) was filtered off and the remaining pale solution was evaporated to dryness. ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ studies, carried out with a C_6D_6 solution of the residue, reveal the presence of $[Ni(PMe_3)_4]$ and $C_{14}H_{14}$ (1,2-diphenylethane, identified by comparison of its IR, ^1H and ^{13}C NMR spectra with those of an authentic sample) as the major species in solution.

$[Ni(C_6H_5)X(PMe_3)_2]$ [X = Cl (**3a**); Br (**3b**)]

These compounds are prepared as described above for the benzyl derivative **1a**, using C_6H_5X (X = Cl, Br). The reaction of $[Ni(cod)_2]$ with C_6H_5Br was complete within about 4 h, while that with C_6H_5Cl required stirring in tetrahydrofuran, at 50–60°C for 20–24 h. Yields were about 50–65%, and the compounds could be crystallized from diethyl ether. $[Ni(C_6H_5)Cl(PMe_3)_2]$. Found: C, 44.8; H, 7.2. Calc. for $C_{12}H_{23}P_2ClNi$: C, 44.6; H, 7.1%. $[Ni(C_6H_5)Br(PMe_3)_2]$. Found: C, 39.1; H, 6.3. Calc. for $C_{12}H_{23}P_2BrNi$: C, 39.2; H, 6.3%.

$[Ni(2,4,6\text{-}C_6H_2Me_3)X(PMe_3)_2]$, [X = Cl (**5**); Br (**6**)] *and* $[Ni(2,4,6\text{-}C_6H_2Me_3)(C_5H_5)PMe_3]$ (**7**)

2.7 cm^3 of a 0.55 N solution of $Mg(2,4,6\text{-}Me_3C_6H_2)_2$ in tetrahydrofuran (*ca* 1.5 eq) were added to a cold (−60°C) suspension of $[NiCl_2(PMe_3)_2]$ (0.42 g, 1.5 mmol) in Et_2O (30 cm^3). The solution was allowed to reach room temperature and stirred for 5 h. The solvent was then stripped off under reduced pressure and the residue extracted with 25 cm^3 of Et_2O and centrifuged. Upon cooling at −30°C overnight the product was obtained as brown–yellow crystals (0.33 g, 60% yield).

The bromide derivative, **6**, was prepared similarly, but using $Mg(2,4,6\text{-}C_6H_2Me_3)Br$ as the alkylating reagent. The reaction mixture, composed of 2 mmol of $[NiCl_2(PMe_3)_2]$ and 2 mmol of the Grignard reagent was stirred at −60°C for 30 min and at room temperature for an additional 20 min (Yield 0.51 g, 62%). Found: C, 44.0; H, 7.2. Calc. for $C_{15}H_{29}P_2BrNi$: C, 43.9; H, 7.1%.

The reaction of **5** or **6** with an excess of NaCp (1.5 equiv) at 20°C for 12 h, produces complex **7** in 80% yield as red–brown needles. Found: C, 64.0; H, 8.6. Calc. for $C_{17}H_{25}PNi$: C, 64.0; H, 7.8%.

$[Ni(COR)X(PMe_3)_2]$, [R = $C_6H_5CH_2$, X = Cl (**1b**); R = C_6H_5, X = Cl (**3b**); X = Br (**4b**)]

Carbon monoxide was bubbled at room temperature through a solution of the alkyl or aryl precursors, **1a**, **3a** or **4a**, in diethyl ether (*ca* 0.5 mmol; 25 cm^3) for about 5 min, after which time an orange crystalline precipitate of the carbonylation product was obtained. The solvent was removed under reduced pressure and the resulting solid recrystallized from diethyl ether at 0°C, to provide orange crystals of the desired products in *ca* 90% yield. $[Ni(COCH_2C_6H_5)Cl(PMe_3)_2]$. IR (Nujol mull) 1600 cm^{-1} (CO). $[Ni(COC_6H_5)Cl(PMe_3)_2]$. Found: C, 44.7; H, 6.8. Calc. for $C_{13}H_{23}P_2ClONi$: C, 44.4; H, 6.6%. IR (Nujol mull) 1610 cm^{-1} (CO). $[Ni(COC_6H_5)Br(PMe_3)_2]$. Found: C, 39.8; H, 5.9. Calc. for $C_{13}H_{23}P_2BrONi$: C, 39.4; H, 5.8%. IR (Nujol mull) 1625 cm^{-1} (CO).

(*Received* 13 *June* 1988; *accepted* 11 *July* 1988)

Abstract—Difluorophosphine-substituted ureas have been prepared by the reaction of PF_2Cl with N,N′-bis(trimethylsilyl)ureas. Three of these PF_2-substituted ureas have been employed to synthesize chelate complexes from $Ni(CO)_4$ and $Mo(CO)_6$. The ^1H, ^{13}C, ^{19}F and ^{31}P NMR characterization of both the PF_2-substituted ligands and their $Ni(CO)_2$- and Mo^0-chelate complexes is described. A complete set of coupling constants was determined from the iterative analysis of the low temperature ^{19}F and ^{31}P spectra of N,N′-bis(difluorophosphino)-N,N′-dimethylurea.

Phosphorus-containing derivatives of urea have attracted industrial interest since the 1970's.[1] Some compounds were shown to be potential flame retardants while others were found to display biological activity. Their use as herbicides has been described.[1] Urea derivatives containing difluorophosphine groups have not, however, been described previously.

Through the modification of a synthetic principle mentioned in the literature[2] we have been able to synthesize the compound PF_2Cl efficiently and in appreciable quantity,[3,4] enabling the use of this compound as a precursor to PF_2-substituted ureas.[3] The synthesis of some N—PF_2 substituted ureas, and some of their complexes with Ni^0 and Mo^0, and the characterization of these by NMR spectroscopy are the subject of this paper.

Synthesis of difluorophosphine-substituted derivatives of urea

The synthesis method employed throughout was the reaction of N,N′-bis(trimethylsilyl)ureas with PF_2Cl, which was found to proceed smoothly at −30 to −25°C, in accord with eq. (1),

$$\underset{\textbf{1a–d}}{(R^1)(Me_3Si)NC(:O)N(SiMe_3)(R^2)} + \underset{\textbf{2}}{2PF_2Cl} \rightarrow \underset{\textbf{3a–d}}{(R^1)(F_2P)NC(:O)N(PF_2)(R^2)} + 2Me_3SiCl \quad (1)$$

1a, 3a: $R^1 = R^2 = H$
1b, 3b: $R^1 = R^2 = Me$
1c, 3c: $R^1 = Me$; $R^2 = Et$
1d, 3d: $R^1 = Me$; $R^2 = c\text{-}C_6H_{11}$.

*Author to whom correspondence should be addressed.

Dedicated to Sir Geoffrey Wilkinson, on the occasion of his retirement from Imperial College, London, in recognition of his seminal contributions to organometallic and coordination chemistry.

The reactions were conducted in heavy-walled glass tubes, in the absence of solvent. Product **3a** was obtained as an unstable solid, after volatile products had been pumped off, while products **3b–3d** were liquids which could be purified by vacuum distillation. The characterization of compounds **3a–3d** was by elemental analysis, mass spectrometry and NMR spectroscopy (*vide infra*).

The ligand properties of the novel PF_2-substituted ureas have been evaluated, in some cases. Derivatives involving $(H)(PF_2)NC(=O)N(PF_2)(H)$ (**3a**) and $(Me)(PF_2)NC(=O)N(PF_2)(Me)$ (**3b**) with Ni^0 and Mo^0, have been synthesized through displacement reactions with **3a** and **3b** of the carbonyls $Ni(CO)_4$ and $Mo(CO)_6$, in accord with eqs (2) and (3)

While the substitution reaction in $Ni(CO)_4$ was conducted in the temperature range $-20°C$ to room temperature, the reaction of $Mo(CO)_6$ was effected at room temperature, with UV irradiation. The complexes **4a**, **4b** and **5** were characterized by elemental analysis (with exceptions), mass spectrometry and NMR spectroscopy (*vide infra*). Two reports by Nixon and his co-workers have appeared, concerning the use of **3b** as a ligand in complexes with Rh and Ir,[5] and in a mixed-metal complex, involving Mo and Rh.[6]

Mass spectra of compounds **3a–3d**, **4a**, **4b** *and* **5**

Mass spectra have been recorded for all the PF_2-substituted ureas, **3a–3d**, and for their metal complexes **4a**, **4b** and **5**. Although of low relative abundance, a molecular ion peak has been observed in all cases, confirming the molecular weight and identity of the compounds. In the case of the uncoordinated compounds **3a–3d**, and for the tris-chelate of Mo^0, the fragment $m/z = 69$ $(PF_2)^7$ was characteristically observed as the most abundant degradation product. Other fragments, originating from the urea backbone were equally characteristic (see Table 1). In addition to their nominal masses the molecular ions of the metal complexes, **4a**, **4b** and **5**, are characterized by their specific isotopic patterns.

NMR spectroscopic investigations

The NMR data in Table 2 are all consistent with the proposed structures. The ^{19}F shifts are in the expected range and the formation of the nickel dicarbonyl complexes, **4a** and **4b**, from compounds **3a** and **3b** causes the anticipated decrease in nuclear screening. Thus the change of 28.7 and 29.4 ppm for **3a** on going to **4a**, and **3b** on going to **4b** is similar to data reported in the literature for Me_2NPF_2 (22.0 ppm) and $C_5H_{10}NPF_2$ (22.1 ppm).[8]

The poor solubility of **3a** and **4a** in most organic liquids prevented a variable temperature NMR investigation. This was possible, however, with **3b**, **3c** and **4b**. The ambient temperature ($\sim 30°C$) ^{19}F and ^{31}P NMR spectra of **3b** were analysed as the A and X parts, respectively, of an $(A_2X)_2$ spin system.[9] Even at this temperature, however, various lines in the spectrum have line widths different to the others (see Fig. 1) and the spectral parameters are solvent dependent (Table 3). Thus the exceptionally large value of $^4J_{PP}$ is particularly sensitive to the effect of the solvent and temperature (Table 4). The temperature behaviour of both the ^{19}F and ^{31}P NMR spectra are shown in Fig. 1. At the lowest temperature ($-112°C$) both spectra are consistent with the system being of the $(ABX)_2$ type. Iteration gave the parameters in Table 2. The equivalence of the phosphorus atoms in the analysis excludes hindered rotation about the C—N bond as the cause of the form of these spectra. The largest fluorine–fluorine coupling constant (21.05 Hz) is due to geminal

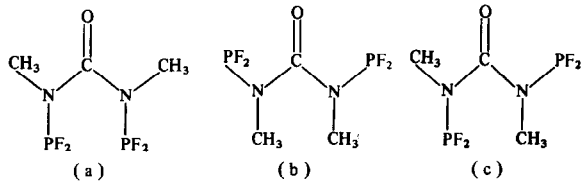
[b] Based on ^{98}Mo.

coupling and not to long range through-space coupling.

Although the temperature behaviour of this complex system has not been simulated using band-shape analysis[10] the coalescence temperature of approximately −82°C in the fluorine NMR spectrum suggests an energy barrier in the region 6–10 kcal mol^{-1}.* This value is characteristic of the barrier to internal rotation about the P—N bond.[11] Thus the molecule in its lowest energy conformation corresponds to either conformers a or b, or some rotationally averaged mixture of them; the unsymmetrical structure, c, may be ruled out.



* Although a simple two-site exchange gives a barrier of 8 kcal mol^{-1} such a simplification probably leads to considerable error in the calculated barrier.

The magnitude of the barrier to internal rotation about the C—N bond cannot be evaluated as a second coalescence phenomenon was not observed. The large $^4J_{PP}$ suggests a planar system with the coupling information being transmitted through the bonds, as a through-space transmission would also necessitate long-range fluorine–fluorine interactions[12] of which there appears to be very little evidence ($^6J_{FF}$ are all ~ 0 Hz).

The ^{13}C NMR spectra of **3c** and **3d** unambiguously confirm the proposed structures. The ^{19}F and ^{31}P NMR spectra of **3a** were broad at ambient temperature. Cooling to −30°C gave a sharpening of the lines but no apparent coalescence phenomenon. At this temperature the non-symmetrical spectra were indicative of hindered rotation about the N—P bond. Although the spectra could not be simulated, attempts at simulation showed that the form of the spectrum could only be produced by assuming an ABCDXY spin system with non-equivalence of all the fluorine and phosphorus nuclei. Similarly an analysis of the complex ^{19}F spectrum of **3d** was not attempted.

Table 2. NMR spectral parameters for compounds **3a–3d**, **4a**, **4b** andf **5** at ambient temperature (~ 30°C)

[a] Not sufficiently soluble to obtain spectrum.
[b] Centre of spectrum.
[c] Not recorded.

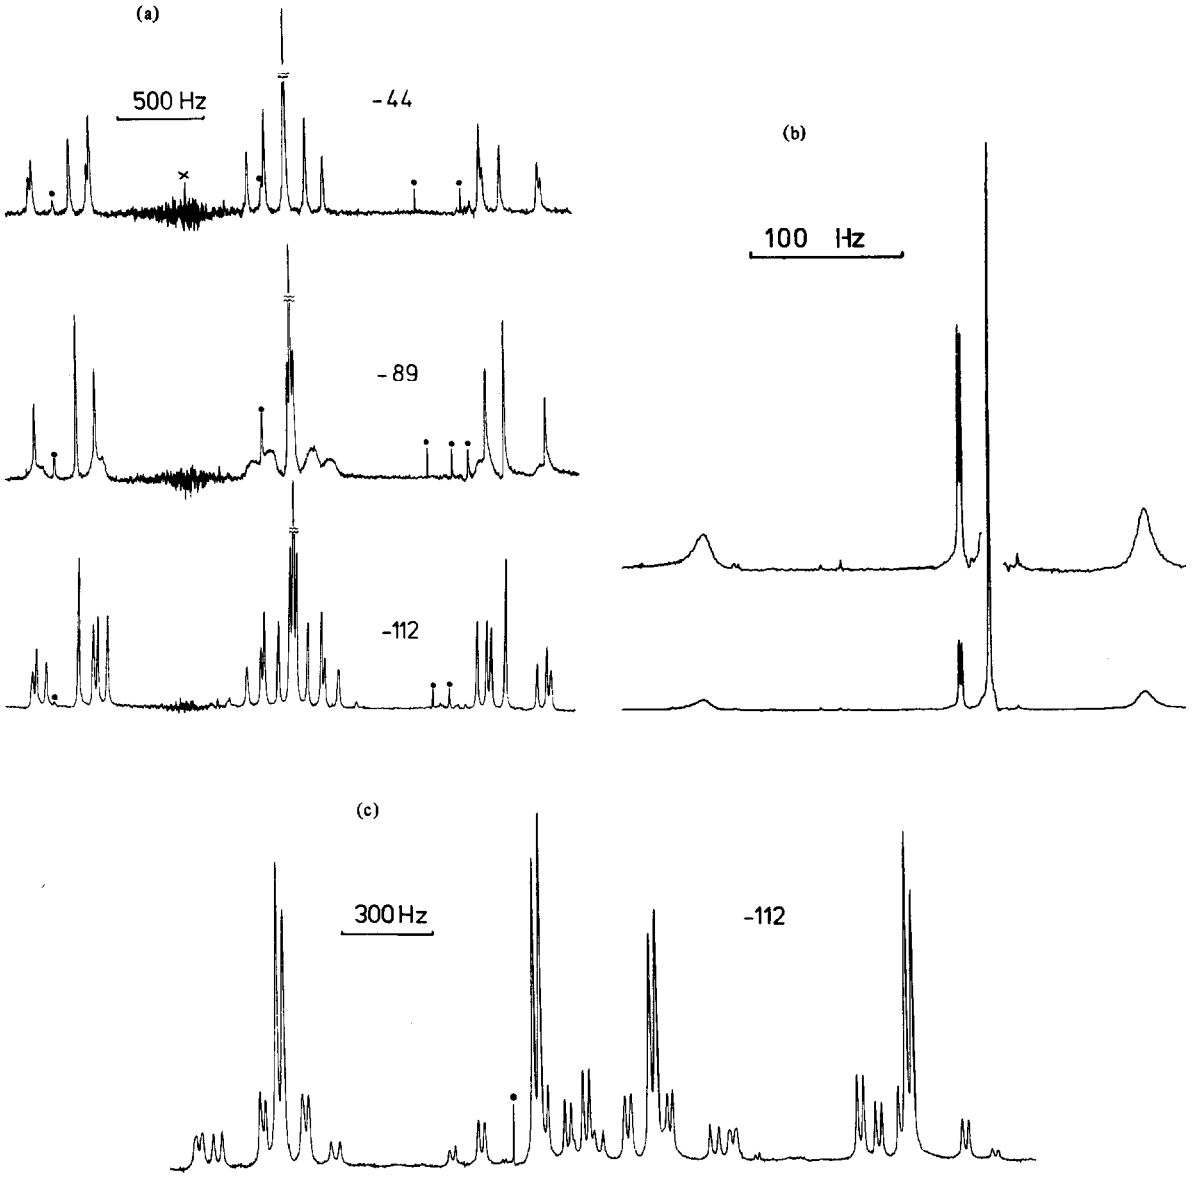

Fig. 1. Variable temperature NMR spectra of (Me)(F_2P)NC(:O)N(PF_2)(Me) (**3b**) (· denotes impurities; × instrumental artifacts). (a) Full ^{31}P NMR spectra at −44, −89 and −112°C; (b) low frequency half of symmetrical ^{19}F {^{1}H} NMR spectrum at 30°C; (c) full ^{19}F NMR spectrum at −112°C.

As expected, the ^{19}F and ^{31}P NMR spectra of **4b** were temperature independent over a limited temperature range. Analysis of the spectra was straightforward. The equivalence of the phosphorus shifts and the presence of two $^4J_{FF}$ values indicate the presence of the ring system. For **4a** only the intense lines of the fluorine spectrum were observed. However, the value $|^1J_{PF}+{}^3J_{PF}|$ of 1152.6 Hz is indicative of ring formation, being similar to that for **4b** (1148.8 Hz) but quite different from that of the non-complexed analogues (**3a**, 1241.4 and **3b**, 1244.8 Hz).

EXPERIMENTAL

All experiments were conducted with careful exclusion of air and moisture. Solvents were dried by standard procedures.[13]

NMR spectra. The NMR data were recorded on JEOL C-60 HL (^{1}H, ^{19}F, ^{31}P), Varian XL-100 (^{19}F, ^{31}P, ^{13}C) and Varian CFT-20 (^{13}C) NMR spectrometers. The variable temperature spectra used in the spectral analyses of **3b**, **3c** and **4b** were recorded in the FT-mode on the Varian XL-100 spectrometer, which was controlled with a Varian

620-L computer equipped with a moving head disc together with complementary software. The spectra were analysed with the aid of a program based upon LAOCOON III and all computations were carried out in single precision on a PDP-10 computer.

Chemical shifts were measured relative to internal tetramethylsilane for ^1H and ^{13}C, fluorotrichloromethane for ^{19}F and external 85% *ortho*-phosphoric acid for ^{31}P. All shifts follow the IUPAC convention and are given on the δ scale with positive values being used to denote a shift to high frequency of the reference.

IR spectra. These were recorded on a Beckman IR-20 instrument (capillary films between KBr discs).

Mass spectra. These were recorded on either an AEI MS 30 or a Varian-MAT CH4 instrument (direct inlet system, 70 eV).

Starting materials. The following compounds were prepared by the procedures indicated: PF_2Cl (**2**),[7] $[(H)(Me_3Si)NC(:O)N(SiMe_3)(H)]$ (**1a**),[14] $[(Me)(Me_3Si)NC(:O)N(SiMe_3)(Me)]$ (**1b**),[15] $[(Me)(Me_3Si)NC(:O)N(SiMe_3)(Et)]$ (**1c**).[16] $[(Me)(Me_3Si)NC(:O)N(SiMe_3)(c\text{-}C_6H_{11})]$ (**1d**) is a new compound which was synthesized from cyclohexylisocyanate and hexamethyldisilazane, following the method of Klebe *et al.*[15]

A mixture of hexamethyldisilazane (40 g, 0.228 M) and cyclohexylisocyanate (28.5 g, 0.228 mol) was stirred for 3 days at room temperature. Unreacted starting materials were pumped off at 30°C (0.01 mm). The higher-boiling residue was fractionally distilled at 83–87°C (0.01 mm). The yield of **1d** was 25 g (36%). $C_{14}H_{32}N_2OSi_2$ (300.58) Found: C, 56.1; H, 11.2; N, 10.3; Si, 18.42. Calc.: C, 55.9; H, 10.7; N, 9.3; Si, 18.7%. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker AM 400 spectrometer and were compatible with the proposed structure.

Reaction of N,N′-bis(trimethylsilyl)-N,N′-bis(hydrogen or organo)ureas with difluorophosphorus(III) chloride, PF_2Cl—general procedure

The experiments were conducted in 250 cm^3 heavy-walled glass tubes, fitted with a TEFLON® stopcock and a side arm, bearing an NS 14.5 ground joint. These tubes were heated to 130°C and allowed to cool slowly to room temperature while a stream of dry nitrogen was passed through them. Subsequently, the N,N′-bis(trimethylsilyl)urea was placed into the tube in a countercurrent of nitrogen. The stopcock was closed, and the tube was attached to a vacuum line, via the stopcock. The contents of the tube were cooled to −196°C, evacuated and the appropriate amount of PF_2Cl (**2**) (weighed separately in a trap) was condensed in. The reaction mixture was allowed to reach the reaction temperature which was maintained, using a cryostat. Subsequently, the reaction mixture was again cooled to liquid nitrogen temperature and the tube was evacuated via the vacuum line. The reaction mixtures were separated into their components by fractional condensation. If the desired compound did not exhibit a vapour pressure measurable at −63°C all volatile by-products could be removed by distillation from a chloroform–dry ice bath at −63°C. As a rule, $SiMe_3Cl$ and the product remained as a residue. If the latter was sufficiently stable it was fractionally distilled at reduced pressure.

In the case where the product had a vapour pressure at −63°C, fractional condensation was used. $SiMe_3Cl$ was collected in a −63°C trap, $SiMe_3F$ in a −96°C trap, PF_2Cl in a −160°C trap, and PF_3 in a −196°C trap. The cold baths employed are specified with the individual experiments.

N,N′-Bis(difluorophosphine)urea, $[H(F_2P)N]_2C(:O)$ (**3a**). N,N′-Bis(trimethylsilyl)urea (**1a**) (7.0 g, 34.2 mmol) and **2** (9.6 g, 91.9 mmol) were allowed to react for 4 h at −25°C. The product, **3a**, is readily decomposed in air. In solvents, e.g. CH_2Cl_2 and CD_3CN, decomposition with formation of PF_3 is apparent after *ca* 15 min. Yield: quantitative; m.p. 169–173°C (dec.). On account of its instability **3a** was not analysed.

N,N′-Bis(difluorophosphino)-N,N′-dimethylurea, $[Me(F_2P)N]_2C(:O)$ (**3b**). N,N′-Bis(trimethylsilyl)-N,N′-dimethylurea (**1b**) (8.0 g, 34.4 mmol) and **2** (10.4 g, 99.6 mmol) were allowed to react at −28°C for 3 h. Yield: 6.95 g (90%); b.p. 52°C (9.5 mm). $C_3H_6F_4N_2OP_2$ (224.03) Found: C, 16.3; H, 2.7; F, 33.6. Calc.: C, 16.1; H, 2.7; F, 33.9%.

N,N′-Bis(difluorophosphino)-N-methyl-N′-ethylurea, $[Me(F_2P)NC(:O)N(PF_2)Et$ (**3c**). **3c** was obtained from $Me(Me_3Si)NC(:O)N(SiMe_3)Et$ (**1c**)

(4.64 g, 18.69 mmol) and **2** (4.45 g, 46.63 mmol) as a colourless liquid. Yield: 2.28 g (51%); b.p. 29°C (1.8 mm). $C_4H_8F_4N_2OP_2$ (238.06) Found: C, 20.8; H, 3.5; F, 31.0. Calc.: C, 20.2; H, 3.4; F, 31.9%.

N,N'-Bis(difluorophosphino)-N-methyl-N'-cyclohexylurea, $Me(F_2P)NC(:O)N(PF_2)C_6H_{11}$ (**3d**). **3d** was obtained as a liquid from $Me(Me_3Si)NC(:O)N(SiMe_3)C_6H_{11}$ (7.8 g, 25.9 mmol) and **2** (8.1 g, 77.6 mmol) after reaction for 4 h at −28°C. Yield: 4.69 g (62%); b.p. 58°C (0.06 mm). $C_8H_{14}F_4N_2OP_2$ (292.15) Found: C, 33.4; H, 4.96; F, 25.2. Calc.: C, 32.9; H, 4.83; F, 26.0%.

[*N,N'* - *Bis(difluorophosphino)urea]dicarbonylnickel*(0), $[H(F_2P)NC(:O)N(PF_2)H]Ni(CO)_2$ (**4a**). The reaction was conducted in a r.b. flask charged, in a nitrogen atmosphere, with nickel carbonyl (1.0 g, 5.86 mmol, in 15 cm^3 of pentane). 30 cm^3 of a mixture of pentane–tetrahydrofuran was then added, followed by the dropwise addition of **3a** (1.0 g, 5.1 mmol, in 15 cm^3 of tetrahydrofuran). The reaction mixture was stirred magnetically for 7 h at room temperature. All volatile products were pumped off at *ca* 1 mm, and the product was left as an oil. Yield: 1.1 g (70%). The mass spectrum showed a molecular ion peak at *m/z* 310 based on ^{58}Ni ($C_3H_2F_4N_2NiO_3P_2$, mol. wt 309.883). IR absorptions in the carbonyl region (ether): 2077, 2042, 1750 cm^{-1}.

[*N,N'* - *Bis(difluorophosphino)* - *N,N'-dimethylurea*] *dicarbonylnickel*(0), $[Me(F_2P)NC(:O)N(PF_2)Me]Ni(CO)_2$ (**4b**). A mixture of $Ni(CO)_4$ (1.41 g, 8.26 mmol) in 10 cm^3 petroleum ether (40/60) and **3b** (1.97 g, 8.79 mmol) was prepared at −20°C. After the mixture had been stirred at room temperature for 24 h volatile products were removed by pumping at *ca* 1 mm. **4b** was left as an oil. Yield: 1.35 g (45%). The mass spectrum showed a molecular ion peak at *m/z* 338 based on ^{58}Ni ($C_5H_6F_4N_2NiO_3P_2$, mol. wt 337.914). IR absorptions in the carbonyl region (petroleum ether) 2085, 2043, 1695 cm^{-1}.

Tris[N,N'-bis(difluorophosphino)-N,N'-dimethylurea]molybdenum(0), $[Me(F_2P)NC(:O)N(PF_2)Me]_3Mo$ (**5**). A mixture of **3b** (2.28 g, 10.18 mmol) and $Mo(CO)_6$ (0.72 g, 2.73 mM) in 150 cm^3 ether was subjected for 30 h to UV irradiation. After the volatile materials had been removed **5** was left as a crystalline solid, which was readily soluble in ether and dichloromethane. Yield: 1.99 g (91%). The mass spectrum showed a molecular ion peak at *m/z* 770, based on ^{98}Mo ($C_9H_{18}F_{12}MoN_6O_3P_6$, mol. wt 769.873).

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF PYRIDINE-2-AMIDOXIME, $C_6H_7N_3O$, AND AQUA-BIS-(PYRIDINE-2-AMIDOXIME)COPPER(II) CHLORIDE, $[Cu(C_6H_7N_3O)(H_2O)]Cl_2$

GEORGE A. PEARSE,* PAUL R. RAITHBY and JACK LEWIS

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 22 *July* 1986; *accepted after revision* 25 *July* 1988)

Abstract—The crystals of pyridine-2-amidoxime, $C_6H_7N_3O$, are monoclinic, space group $C2/c$ with $a = 21.672(1)$, $b = 4.615(1)$, $c = 13.398(1)$ Å, $\beta = 106.58(1)°$ and $Z = 8$. The reaction of the ligand with copper(II) chloride dihydrate yields a dark green precipitate of formula $[Cu(C_6H_7N_3O)_2(H_2O)]Cl_2$ which crystallized in the monoclinic space group $C2/c$ with $a = 16.856(1)$, $b = 7.076(1)$, $c = 14.843(1)$ Å, $\beta = 106.40(1)°$ and $Z = 4$. The X-ray structure of the complex shows the five-coordinate nature of the metal atom which is bound through the heterocyclic and oxime nitrogen atoms of two *trans*-oriented bidentate ligands plus a water molecule to give a square-based pyramidal chelate.

Although the synthesis of pyridine-2-amidoxime (Py2AO) was reported about 30-years ago,[1] the literature contains no structural determination of either this bidentate ligand or its transition metal complexes. Py2AO (Fig. 1) possesses the α,α'-diimine moiety, —N=C—C=N—, similar to that present in 1,10-phenanthroline and 2,2′-bipyridyl, but without the steric rigidity of these two compounds, and forms solid complexes with transition metal ions.[2] Because of its unsymmetrical configuration, the possibility exists for *cis*- and *trans*-isomers in chelates having a 1:2 copper/ligand stoichiometry (Fig. 2). This investigation was carried out with the specific purpose of determining the structure of both the ligand and its copper(II) chloride complex. The results have been compared to a similar 1:2 compound of copper(II) with pyridine-2-aldoxime.[3]

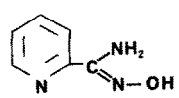

Fig. 1. Block diagram of the structure of pyridine-2-amidoxime.

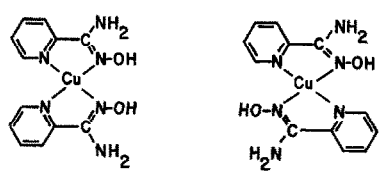

Fig. 2. Block diagram of the structure of *cis*- and *trans*-bis(Py2AO)Cu^{II}.

EXPERIMENTAL

2-Cyanopyridine was purchased from Aldrich Chemical Co. and used without further purification. All other chemicals were reagent grade. Density measurements were made by the floatation method using a mixture of diethyl ether and carbon tetrachloride for Py2AO and a mixture of benzene and 1,2-dibromoethane for the copper complex.

Pyridine-2-amidoxime, $C_6H_7N_3O$, was synthesized from 2-cyanopyridine as previously reported.[4] Recrystallization by slow evaporation of an aqueous solution gave large, well-formed, colourless crystals suitable for diffraction studies. Found: C, 52.4; H, 5.50; N, 30.5. Calc. for $[C_6H_7N_3O]$: C, 52.5; H, 5.1; N, 30.6%.

Aqua-bis-(pyridine-2-amidoxime)copper(II) chloride $[Cu(C_6H_7N_3O)_2(H_2O)]Cl_2$

To a solution of 1.70 g (10 mmol) of copper(II) chloride dihydrate in 40 cm^3 of distilled water was added 2.74 g (20 mmol) of pyridine-2-amidoxime in the minimum required amount of 95% ethanol. The solution turned dark green and crystals separated almost immediately (yield 82%, 3.50 g). Recrystallization by slow evaporation of a dilute aqueous solution gave large, well-formed, dark green crystals suitable for diffraction studies. Found: C, 33.9; H, 3.6; N, 19.6. Calc. for $[Cu(C_6H_7N_3O)_2(H_2O)]Cl_2$: C, 33.8; H, 3.8; N, 19.7%.

X-ray crystallography

General procedures have been described elsewhere.[5] Information about data collection for pyridine-2-amidoxime and aqua-bis-(pyridine-2-amidoxime)copper(II) chloride is given in Table 1. Atomic coordinates, thermal parameters and lists of F_o and F_c values have been deposited with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Figure 3 is a perspective view of pyridine-2-amidoxime showing the atom numbering. In the crystalline state the ligand exists as the *syn* isomer. Previous work,[4] using IR data, showed that the ligand is also in the *syn* configuration in solution. Because of the free rotation about the C(1)—C(6) bond, the ligand can assume the α,α'-diimine structure involving the N(1)—C(1)—C(6)—N(3) portion of the molecule. A comparison with pyridine-2-aldoxime leads to the conclusion that both ligands should react in a similar fashion utilizing the heterocyclic and oxime nitrogen atoms.

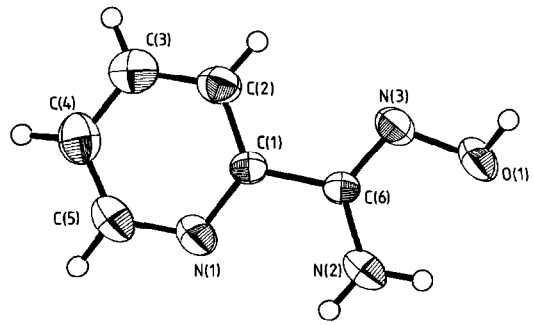

Fig. 3. Crystal structure of $C_6H_7N_3O$ showing the atomic numbering scheme.

The bis-(pyridine-2-amidoxime)copper(II) complex is shown in Fig. 4. The two ligands are arranged in a *trans* mode about the metal atom. An axially coordinated water molecule completes the pentadentate, square-based pyramidal structure.

Although the crystal structure of 1:2 copper(II) chloride/pyridine-2-aldoxime has not been reported, analytical and IR data strongly suggest that the ligands are in a *cis* arrangement.[3] Loss of one oxime hydrogen results in the solid coordination compound being *cis*-monohydrogen-bis-(pyridine-2-aldoxime)copper(II) chloride whereas this research resulted in the synthesis of *trans*-di-hydrogen-bis-(pyridine-2-amidoxime) copper(II) chloride. All attempts to prepare the *cis*-isomer with copper(II) chloride and pyridine-2-amidoxime were unsuccessful. Molecular models of the *cis*-pyridine-2-amidoxime/copper(II) chloride isomer do not preclude its formation based upon steric factors.

The bond lengths and angles for the ligand and the copper(II) complex are listed in Tables 2 and 3,

respectively. A comparison of these data shows that the ligand undergoes little distortion on complexation with copper(II), resulting in a very stable coordination compound. Selected bond lengths and angles for several other amidoxime ligands are listed in Table 4. The C=N and N—O bond lengths of the oxime group for the five listed compounds are quite compatible with those of pyridine-2-amidoxime. The bond angles for the C=N—O of the oxime group and the N=C—N of the oxime–amine group show little variation with the exception of those for 2-methyl-N,N-dimethylbenzamidoxime. This can be attributed to steric factors caused by the two methyl groups on the amine nitrogen which are not present in the other amidoximes.

From this work it has been ascertained that the amidoxime group in the free ligand exists in the amino–oxime form, —C:NOH(NH_2), rather than the tautomeric imino–hydroxylamine form, —C:NH(NHOH). The copper(II) complex utilizes the oxime nitrogen of the amidoxime group rather than the amine nitrogen to form a five-membered ring with the heterocyclic nitrogen.

Using atomic coordinates and isotropic thermal parameters, available as supplementary data, atomic deviations from various planes were calculated. When considering the C(1)—C(6)—N(2)—N(3) plane for the free ligand, there is little deviation from planarity with respect to the oxime and amine nitrogens. The same plane for the copper(II) complex exhibits an atomic deviation increase of approximately 0.11 Å between the oxime and amine nitrogens. This is to be expected from the square-pyramidal configuration of the complex which causes a slight rotation of the C(1)—C(6) bond upon complexation. Rotation of this bond causes the observed reduction in planarity of the N(2)—N(3) nitrogens. This research has shown that pyridine-2-amidoxime forms a *trans*-dihydrogen-bis-(pyridine-2-amidoxime) chelate with copper(II) chloride whereas pyridine-2-aldoxime forms a monohydrogen-*cis*-bis compound under the same preparative conditions.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF TWO COMPLEXES OF NICKEL(II) NITRATE WITH PYRIDINE-2-AMIDOXIME ($C_6H_7N_3O$): $[Ni(C_6H_7N_3O)_2(NO_3)_2]$ AND $[Ni(C_6H_7N_3O)_3](NO_3)_2 \cdot H_2O$

(*Received* 22 *July* 1986; *accepted after revision* 25 *July* 1988)

Abstract—The reaction between stoichiometric amounts of nickel(II) nitrate hexahydrate and pyridine-2-amidoxime in ethanol produces crystalline $[Ni(C_6H_7N_3O)_2(NO_3)_2]$, but in water yields $[Ni(C_6H_7N_3O)_3](NO_3)_2 \cdot H_2O$. Both complexes have been characterized by X-ray crystallography. The crystals of $[Ni(C_6H_7N_3O)_2(NO_3)_2]$ are triclinic, space group $P\bar{1}$ (no. 2), with $a = 8.544(1)$, $b = 9.300(1)$, $c = 12.790(1)$ Å, $\alpha = 85.14(1)$, $\beta = 77.81(1)$, $\gamma = 63.26(1)°$ and $Z = 2$. The crystals of $[Ni(C_6H_7N_3O)_3](NO_3)_2 \cdot H_2O$ are monoclinic, space group $P2_1/n$, with $a = 10.453(1)$, $b = 13.261(2)$, $c = 19.059(4)$ Å, $\beta = 98.19(1)°$ and $Z = 4$. Both complexes have a slightly distorted octahedral structure with the nitrate groups being coordinated ligands in the 1:2 complex and counter-ions in the 1:3 complex. The organic ligands coordinate through the heterocyclic and oxime nitrogens in both compounds.

As a bidentate ligand, pyridine-2-amidoxime incorporates the structural features of pyridine-2-aldoxime and 2-pyridylamine in a single molecule. The 1:2 and 1:3 nickel(II) nitrate complexes of the latter two ligands have been investigated.[1,2] In each case there can be no ambiguity with respect to the five-membered ring formed by the coordination of nickel(II) with the two available nitrogen atoms per ligand. Because pyridine-2-amidoxime contains both an oxime and an amine nitrogen on a carbon substituted at the pyridine ring α-position, coordination with nickel(II) could involve either of these two nitrogen atoms and the heterocyclic nitrogen. To determine the mode of chelation, both the bis- and tris-chelates of nickel(II) nitrate were prepared and the crystal structures were determined.

EXPERIMENTAL

2-Cyanopyridine was purchased from Aldrich Chemical Co. and used without further purification in the synthesis of pyridine-2-amidoxime as previously reported.[3] All other chemicals were reagent grade. Density measurements were made by the floatation method using a mixture of benzene and 1,2-dibromoethane.

Preparation of $[Ni(C_6H_7N_3O)_2(NO_3)_2]$

To a solution of 2.90 g (10 mmol) of nickel(II) nitrate hexahydrate in 75 cm^3 of absolute alcohol was added 2.74 g (20 mmol) of pyridine-2-amidoxime in the minimum required amount of the same solvent. The resulting mixture was heated to boiling, filtered and cooled to room temperature. Blue crystals formed which were separated by decantation, washed with cold ethanol and ether, and dried *in vacuo*. Found: C, 31.4; H, 3.1; N, 24.4. Calc. for $NiC_{12}H_{14}N_8O_8$: C, 31.5; H, 3.1; N, 24.5%.

Preparation of $[Ni(C_6H_7N_3O)_3](NO_3)_2 \cdot H_2O$

To a solution of 4.02 g (30 mmol) of pyridine-2-amidoxime in the minimum required amount of 95% ethanol was added 2.90 g (10 mmol) of nick-

*Author to whom correspondence should be addressed. Visiting Professor on leave from Le Moyne College, Syracuse, NY 13214, U.S.A., 1985–1986.

el(II) nitrate hexahydrate in 50 cm^3 of distilled water. The resulting mixture was heated to 80–90°C, filtered and allowed to evaporate to one third its original volume at room temperature, during which time red–brown crystals precipitated. The crystals were removed by filtration, washed with ethanol and ether, and air-dried. Found: C, 35.1; H, 3.7; N, 25.1. Calc. for $NiC_{18}H_{23}N_{11}O_{10}$: C, 35.3; H, 3.8; N, 25.2%.

X-ray crystallography

General procedures have been described elsewhere.[4] Information about data collection for the two nickel(II)–pyridine-2-amidoxime complexes is given in Table 1. Atomic coordinates, thermal parameters and lists of F_o and F_c values have been deposited with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

When an ethanolic solution of nickel(II) nitrate hexahydrate is treated with pyridine-2-amidoxime, a dark blue solution results if the ratio of ligand to nickel does not exceed 2 : 1. From this solution a blue complex of the formula $Ni(Py2AO)_2(NO_3)_2$ crystallizes in which Py2AO is the unionized ligand (Fig. 1). If three moles of ligand are added to one mole of nickel(II) in aqueous solution the initial colour is blue, which changes to wine-red and the tris-pyridine-2-amidoxime nickel(II) complex is obtained as red–brown crystals (Fig. 2).

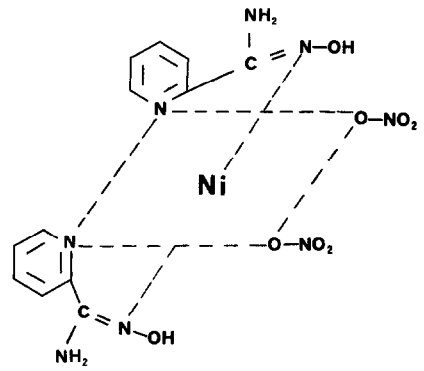

Fig. 1. Block diagram structure of the bis-nitrato-bis(Py2AO) Ni^{II}, $[Ni(C_6H_7N_3O)_2(NO)_3)_2]$.

Figure 3 is a perspective view of bis-nitrato-bis-(Py2AO)nickel(II). In the crystalline state this octahedral complex has two coordinated nitrate groups in the equatorial plane which are *cis* to each other.

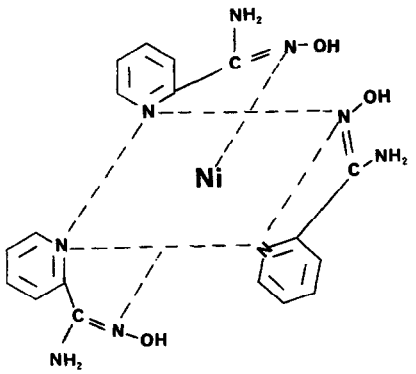

Fig. 2. Block diagram structure of the tris-(Py2AO)Ni^{II} nitrate, $[Ni(C_6H_7N_3O)_3](NO_3)_2$.

It is suggested that in the preparation of the 1 : 3 complex in aqueous solution, the initial blue colour is due to the $[Ni(Py2AO)_2(H_2O)_2]^{2+}$ ion as has been reported for the reaction of nickel(II) with 2,2-bipyridyl[5] and 1,10-phenanthroline.[6] As the ligand is added, the two *cis*-equatorial molecules are replaced by the third ligand, resulting in the structure shown in Fig. 4. Attempts to prepare $[Ni(Py2AO)_2(H_2O)_2](NO_3)_2$ were unsuccessful even though dissolution of $[Ni(Py2AO)_2(NO_3)_2]$ in water gives a unidivalent electrolyte. Addition of a third equivalent of the ligand to the 1 : 2 complex in aqueous solution results in the formation of the 1 : 3 complex. Therefore, it seems reasonable to assume that the aqueous blue solution of the 1 : 2 complex results from the replacement of the coordinated nitrate groups by water molecules.

The data in Tables 2 and 3 show that the Ni—N (pyridine) bond distances for both the 1 : 2 and 1 : 3 complexes are longer than the Ni—N(oxime) bonds. This is consistent with observations reported for the two isomeric nickel(II) complexes with 2,2′-iminodiacetamidoxime.[7,8] Studies in this laboratory show the bis-(Py2AO) copper(II) complex to exhibit this same bond length pattern.[9]

In the 1 : 2 nickel(II)–Py2AO complex, the two nitrate groups and the two heterocyclic nitrogens are approximately planar having a *cis–cis* arrangement. The axial positions are occupied by the oxime nitrogens. Figure 2 shows that the three organic ligands in the 1 : 3 complex have their heterocyclic nitrogens co-planar with one oxime nitrogen and the nickel(II) atom as determined by the X-ray study. This results in the two remaining oxime nitrogen atoms being *trans* to each other. All attempts to prepare additional isomers of the 1 : 2 and 1 : 3 complexes gave crystals of the structures shown in Figs 1 and 2.

This work has ascertained that pyridine-2-amidoxime utilizes the oxime nitrogen rather than the amine nitrogen of the amidoxime group to form five-membered chelate rings with the heterocyclic nitrogen and nickel(II). Preference for coordination in this manner results in an α,α′-diimine bidentate ligand similar to 2,2′-bipyridyl and 1,10-phenanthroline. Although the 1 : 2 complex could exist in a square-planar configuration, this research has shown both compounds to be octahedral in the solid state. It is interesting to note that in both of the compounds, the amine and oxime nitrogen

SYNTHESIS AND CHARACTERIZATION OF $[Cp_2Ti(CH_3CN)_3]^{2+}[AsF_6^-]_2$ — ^{19}F NMR SPECTROSCOPY OF TITANOCENE HEXAFLUOROARSENATES*

TH. KLAPÖTKE

(*Received* 5 *July* 1988; *accepted* 25 *July* 1988)

Abstract—$Cp_2Ti(AsF_6)_2$ (**1**) ($Cp = \eta^5$-C_5H_5) reacts with an excess of CH_3CN yielding quantitatively the new cationic titanocene complex $[Cp_2Ti(CH_3CN)_3]^{2+}[AsF_6^-]_2$ (**2**). **2** was characterized by elemental analysis, IR, ^1H NMR and ^{19}F NMR spectroscopy. Surprisingly, no reaction of **1** with CF_3CN could be observed. The ^{19}F NMR spectra of **1** at various temperatures are reported and discussed, too. The reaction behaviour of Cp_2TiCl_2 (**3**) towards ClF was investigated, and $CpTiCl_3$ (**4**) and traces of $CpTiCl_2F$ (**5**) were shown to be the products of this reaction. Surprisingly, no evidence for the formation of Cp_2TiClF could be found. These results are discussed and can be understood easily on the basis of simple thermodynamic estimations.

The reaction of **3** with nitriles in the presence of suitable Lewis acids MCl_n, yields ionic complexes with one or two nitrile ligands bonded to the Ti. The complexes $[Cp_2Ti(C_8H_4N_2)_2][SbCl_6]_2$ ($C_8H_4N_2$ = phthalonitrile), $[Cp_2Ti(Cl)(C_3H_2N_2)]_2[FeCl_4]$ ($C_3H_2N_2$ = malonitrile), and $[Cp_2Ti(Cl)(CH_3CN)][FeCl_4]$ have been isolated.[1–3] The N coordinated chelate complexes $[Cp_2Ti(bipy)][CF_3SO_3]_2$ and $[Cp_2Ti(phen)][CF_3SO_3]_2$ are also known.[4] Very recently we reported the synthesis of the first stable Lewis base free $Cp_2Ti(MF_6)_2$ (M = pnicogen) complexes where the MF_6 unit is directly coordinated to the Cp_2Ti fragment.[5,6] Whereas the mono-cyclopentadienyl species, $CpTi(MF_6)_3$, are unstable and till now were identified only at low temperature in solution,[7] $Cp_2Ti(MF_6)_2$ (M = As, Sb) are stable in the solid state and the structure of **1** was elucidated by single crystal X-ray diffraction.[6] The IR spectra and X-ray structure clearly show the covalent $Cp_2Ti(\cdots F\cdots AsF_5)_2$ bond interaction in **1** with a bridging fluorine and reduced MF_6 symmetry.

As the ^1H NMR spectroscopy was not sufficient to elucidate the Cp_2Ti—MF_6 bond situation in solution,[5,6] we investigated this particular problem by temperature-dependent ^{19}F NMR spectroscopy. In addition to this it seemed to be of interest to discover whether stable **1** would react with neutral nitrile ligands, yielding cationic titanocene derivatives according to eq. (1). Ternary adducts of $Ni(EF_6)_2$ (E = Sb, Bi) like $[Ni(CH_3CN)_6][EF_6]_2$ have been reported quite recently.[8]

$$\mathbf{1} + nR\text{—}CN \longrightarrow [Cp_2Ti(RCN)_n]^{2+}[AsF_6^-]_2. \quad (1)$$

As **1** can be prepared either by reaction of **3** with $AgAsF_6$ or by reaction of Cp_2TiF_2 with AsF_5,[6] we were interested to achieve a simple synthesis of Cp_2TiF_2. This is of interest because of the high price for the commercially available $AgAsF_6$, which usually is prepared by fluorination of a mixture of elemental Ag or AgF and an excess of As_2O_5 with BrF.[9] One possible way seemed to be the reaction of **3** with ClF according to eq. (2) which was estimated to be thermodynamically favoured (see below).

$$\mathbf{3} + 2ClF \longrightarrow Cp_2TiF_2 + 2Cl_2. \quad (2)$$

The results of our investigations according to the goals outlined above are described in this paper.

* Organotransition metal chemistry of highly fluorinated ligand systems (Organo-Übergangsmetall-Chemie hochfluorierter Ligand-Systeme): 4th communication (for 3rd communication see ref. 7).

EXPERIMENTAL

All techniques have been described in ref. 6. Cp_2TiCl_2 (**3**)[10] and $Cp_2Ti(AsF_6)_2$ (**1**)[6] were prepared as described in the works cited. Sulphur dioxide, ClF, AsF_5, CH_3CN and CF_3CN were purified by distillation. SO_2 and CH_3CN were dried over CaH_2. Silver fluoride (Alfa, 10125) was used without further purification. All reactions took place in an atmosphere due to the vapour pressure of SO_2, CH_3CN or CF_3CN, respectively.

Preparation of silver hexafluoroarsenate(V) [$AgAsF_6$]

In a 50 cm^3 thick-walled glass reaction vessel incorporating a "Young" valve (POR-10), 8 g of AsF (63.06 mmol) were suspended in 20 cm^3 of CO_2 (1). After cooling this mixture to −196°C, 13 g of AsF_5 (76.51 mmol) were condensed onto the frozen SO_2. The reaction mixture was allowed to warm to room temperature and was stirred at RT in the dark for 12 h. After the solvent had been evaporated, the remaining white residue was dried *in vacuo* at RT for 4 h. Yield: 18.69 g (99.87%). IR: ν (cm^{-1}) (Nujol mull) 700 vs (ν_3), 385 s (ν_4); (cf. ref. 11).

Preparation of bis(η^5-cyclopentadienyl)tris(acetonitrile)bis(hexafluoroarsenato)titanium(IV) [$Cp_2Ti(CH_3CN)_3][AsF_6]_2$ (*complex* **2**)

0.0691 g (0.1243 mmol) of **1** were dissolved in 5 cm^3 of CH_3CN and stirred at RT for 1 h. The solvent was condensed into a second vessel ($\Delta T \approx 10$°C, 5–10 h) and the remaining microcrystalline deep red residue was dried *in vacuo* at RT for 24 h. Yield: 0.0841 g, 0.1238 mmol (99.60%). Found: C, 27.9; H, 2.7; N, 6.1. Calc. for $C_{16}H_{19}As_2F_{12}N_3Ti$ (679.05) C, 28.3; H, 2.8; N, 6.2%. ^{1}H NMR (SO_2) δ (ppm) (int.) 7.28 (10.00) s, 2.69 (8.85) s, relative to TMS. ^{19}F NMR (CD_3CN) δ (ppm) (int.) −49.7 (1), −59.6 (1), −69.8 (1), −79.4 (1), relative to $CFCl_3$. $\Delta\nu = 929 \pm 25$ Hz. IR: ν (cm^{-1}) (Nujol mull) 3128 m (ν-CH, Cp), 2320 m ($\nu_3+\nu_4$, CH_3CN), 2293 s (ν-CN, ν_2-CH_3CN), 1128 w, 1028 sh and 1018 m (δ-CH, Cp), 957 w, 858 s (γ-CH, Cp), 698 vs (ν-AsF, ν_3-AsF_6), 398 s (δ-AsF, ν_4-AsF_6).

Attempted synthesis of $[Cp_2Ti(CF_3CN)_n]^{2+}[AsF_6^-]_2$ ($n = 2, 3$)

1.00 g (10.52 mmol) of CF_3CN (g) was condensed at −196°C onto 0.2561 g (0.4607 mmol) of **1** and this was allowed to warm up to room temperature. As **1** is insoluble in CF_3CN (under high pressure) a suspension was formed. After 2 h at RT the reaction mixture was recooled to −78°C and the volatiles were pumped off at this temperature *in vacuo*. The remaining solid (0.2558 g) was identical with **1** (^{1}H NMR and IR data).

Reaction of **3** *with* ClF

Onto a frozen solution of 0.270 g (1.08 mmol) of **3** in 5 cm^3 of SO_2, 0.118 g (2.17 mmol) of ClF were condensed at −196°C. After warming up and stirring for 12 h at RT, the solvent and the volatiles were pumped off *in vacuo* also at RT. Yield: 0.220 g (93%, calc. for $CpTiCl_3$). ^{1}H NMR ($CDCl_3$) δ (ppm) 7.07 s, relative to TMS. MS (50°C, 70 eV): *m/z* (int.), 218 (100) $CpTiCl_3^+$, 202 (11) $CpTiCl_2F^+$, 183 (76) $CpTiCl_2^+$, 148 (34) $CpTiCl^+$, 118 (36) $TiCl_2^+$, 109 (19) $CpTiCl_3^{2+}$, 83 (53) $TiCl^+$.

^{19}F *NMR of* **1**

^{19}F NMR (SO_2) δ (ppm) $T = 20$°C: −57.02 s, $b_{1/2} = 200$ Hz, $T = -70$°C: −61.53 s, $b_{1/2} = 350$ Hz; relative to $CFCl_3$.

RESULTS AND DISCUSSION

Preparative aspects

The reaction of **1** with an excess of CH_3CN (solvent) led in 100% yield to the preparations of **2** according to eq. (3).

$$\mathbf{1} + 3CH_3CN \xrightarrow{CH_3CN} \mathbf{2}. \qquad (3)$$

The identity of **2** was proved by elemental analysis, IR, ^{1}H and ^{19}F NMR spectroscopy (see Experimental and below).

Whereas some related cationic titanocene derivatives with one and two via N coordinated neutral ligands are known (see above and refs 1–4), **2** contains three CH_3CN molecules, thus realizing the coordination number five. The 12-electron fragment Cp_2Ti^{2+} obtains the noble gas configuration by coordinating three two-electron donor ligands. In the MO scheme of Cp_2Ti^{2+} two of the three unoccupied orbitals lowest in energy are bonding ($2a_1$ and b_2), while one is non-bonding ($1a_1$).[12] This is in agreement with the experimental result that one of the three CH_3CN ligands can be removed by pumping off **2** at a higher temperature for several days according to eq. (4).

$$\mathbf{2} \xrightarrow[40\text{–}50°C]{\text{dyn. vac.}} [Cp_2Ti(CH_3CN)_2]^{2+}[AsF_6^-]_2. \qquad (4)$$

The loss of one equivalent of CH_3CN was proved by weight change.

Surprisingly, **1** does not react with an excess of CF_3CN, yielding a cationic complex by analogy to the observed reaction with CH_3CN. **1** also crystallizes from SO_2 (l) as the covalent species and does not contain coordinated SO_2. Assuming that the crystal lattice energies of **2** and the CF_3CN analogue are more or less identical, the gaining of energy due to coordination of CF_3CN to Cp_2Ti^{2+} is less than the sum of the energy terms due to entropy and $Ti\cdots AsF_6$-bond interaction, which are working against the salt formation.

The preparation of Cp_2TiF_2 from **3** and ClF according to eq. (2) was not successful, surprisingly $CpTiCl_3$ was the reaction product [eq. (5)] and was identifed by ^1H NMR and mass spectroscopy.

$$3 + ClF \xrightarrow{SO_2} CpTiCl_3 + \text{"CpF"}. \quad (5)$$

According to eq. (6) the preparation of $AgAsF_6$ in 100% yield was shown to be very convenient. In this reaction all of the expensive AsF_5 is converted into $AgAsF_6$. Silver fluoride can be prepared from Ag_2O by using HF.[13] Equation (7) also describes a common method to prepare $AgAsF_6$.

$$AgF + AsF_5 \xrightarrow{SO_2} AgAsF_6 \quad (6)$$

$$2Ag + 3AsF_5 \longrightarrow 2AgAsF_6 + AsF_3. \quad (7)$$

Vibrational spectroscopy

In the IR spectrum (see Fig. 1) of **1** the strong, broad absorption at 530 cm^{-1} was assigned to the Ti—F symmetric and asymmetric stretching mode.[5,6] The disappearance of this band indicates that also in the solid state there is no direct bonding interaction between the $[Cp_2Ti(CH_3CN)_3]^{2+}$ cation and the $[AsF_6^-]$ anions.

Free acetonitrile (liquid) shows the C—N stretching mode (ν_2) at 2254 cm^{-1}.[14] In **2** this band is shifted to 2293 cm^{-1}. This result may indicate that **2** has strong σ-donor ($CH_3CN \rightarrow Ti$) but weak π-acceptor (back) bonding (cf. CN^-: 5σ, weakly antibonding; $2p\pi^*$ antibonding[15]).

NMR spectroscopy

The integration of the proton NMR spectrum of **2** in SO_2 solution clearly shows the composition of the complex as $[Cp_2Ti(CH_3CN)_3]^{2+}$ (see Fig. 2). The chemical shift in the ^1H NMR spectrum of **2** in SO_2 is similar to that observed for **1** in SO_2 solution.[6] However, CH_3CN in solution is also still coordinated as the only methyl singlet appears at 2.67 ppm, whereas free acetonitrile in SO_2 has a chemical shift of 2.05 ppm (own results).

The ^{19}F NMR spectra of **1** in SO_2 and **2** in SO_2 and CD_3CN show this effect, also. For instance, the

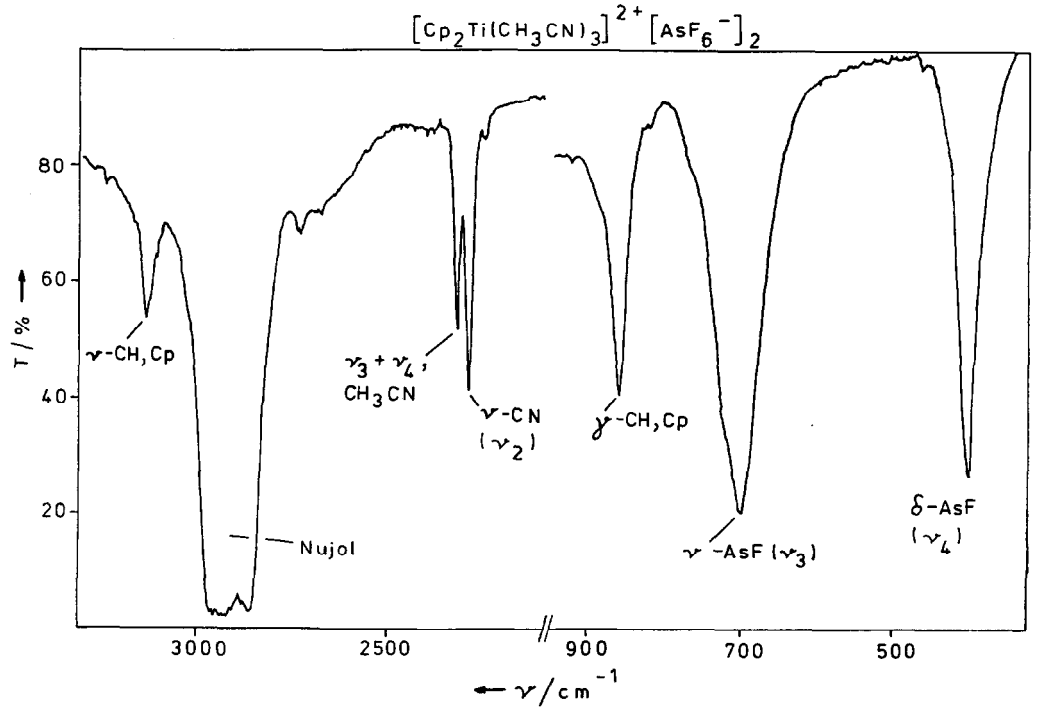

Fig. 1. IR spectrum of **2** in the regions 200–1000 cm^{-1} and 2000–3300 cm^{-1}.

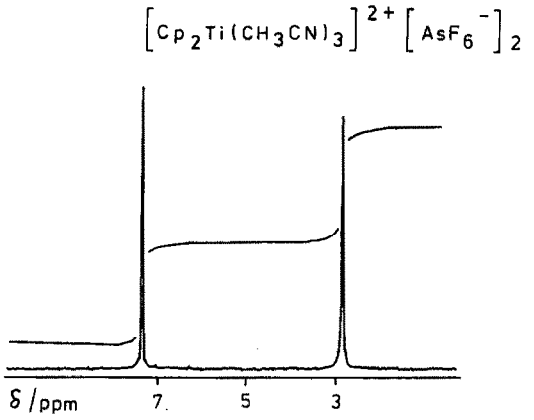

Fig. 2. ^{1}H NMR spectrum of **2** in SO_2, 20°C.

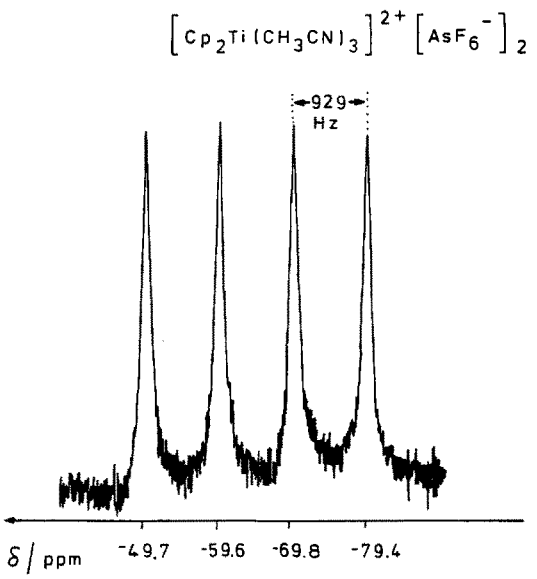

Fig. 3. ^{19}F NMR spectrum of **2** in CD_3CN, −40°C.

^{19}F NMR spectrum of **2** in CD_3CN, even at low temperatures (−40°C), consists of a nicely dissolved four-line pattern due to the As—F couplings (I, $^{75}_{33}As = 3/2$) in the octahedral AsF_6^- anion (see Fig. 3).

On the other hand, **1** dissolved in SO_2 shows at RT in the ^{19}F NMR spectrum only one peak which does not split into the expected pattern even at low temperatures (−70°C). This indicates free highly symmetric AsF_6^- ions in the first case (**2**), whereas this group is coordinated to the Ti centre in the second case (**1**), showing rapid exchange (pseudo-rotation) even at low temperatures (otherwise no singlet in the proton NMR spectrum could be expected).

Thermodynamic aspects

By the reaction of **3** with ClF neither Cp_2TiClF nor Cp_2TiF_2, but only $CpTiCl_3$ (with traces of $CpTiCl_2F$) was identified as the product. Nevertheless the reaction according to eq. (8) should be exothermic, $\Delta H_8 = -144$ kJ mol^{-1}, as was estimated in Scheme 1.

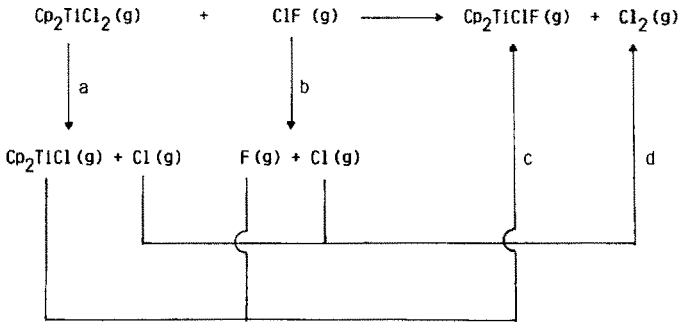
$$\mathbf{3} + ClF \longrightarrow Cp_2TiClF + Cl_2. \qquad (8)$$

However, a reaction according to eq. (9) was estimated to be even more thermodynamically favourable (see Scheme 2), $\Delta H_9 = -358$ kJ mol^{-1}.

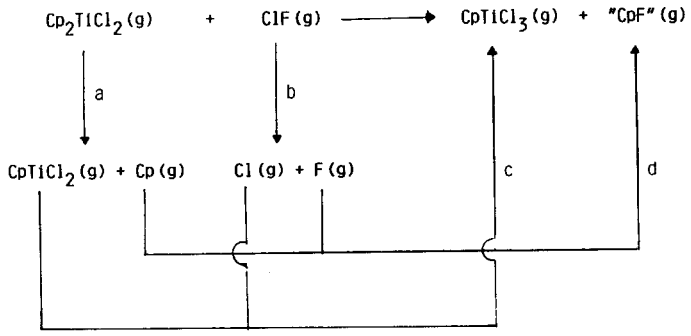
$$\mathbf{3} + ClF \longrightarrow CpTiCl_3 + \text{"CpF"}. \qquad (9)$$

Therefore one can easily understand why a process, shown by eq. (9) and not as indicated by eq. (8), occurs. Moreover, the sums of the bond energies of Ti—Cl (429 kJ mol^{-1})[16,17] and C—F (485 kJ mol^{-1})[19] on one side and Ti—F (585 kJ mol^{-1})[19] and C—Cl (327 kJ mol^{-1})[19] on the other side, explain that $CpTiCl_3$ is formed as the main product and only a small amount of $CpTiCl_2F$ was found.

It seems likely that some of the bond strength estimation data may either bear some experimental error or may be slightly inaccurate, as only ΔH but no ΔS values were estimated. However, this simple



Scheme 1. Thermodynamic cycle to estimate the heat of reaction 8. (a) Ti—Cl bond energy in **3**: 429 kJ mol^{-1};[17] (b) Cl—F bond energy in ClF: 255 kJ mol^{-1};[18] (c) Ti—F bond energy in TiF_4: 585 kJ mol^{-1};[19] (d) Cl—Cl bond energy in Cl_2: 243 kJ mol^{-1}.[18]



Scheme 2. Thermodynamic cycle to estimate the heat of reaction 9. (a) Ti—Cp bond energy in **3**: 301 kJ mol^{-1};[17] (b) Cl—F bond energy in ClF: 255 kJ mol^{-1};[18] (c) Ti—Cl bond energy in **3**: 429 kJ mol^{-1};[17] (d) C—F bond energy: 485 kJ mol^{-1}.[19]

thermodynamic analysis clearly shows that a synthesis of Cp_2TiF_2 from **3** and ClF according to eq. (2) seems to be very unlikely or even impossible.

CONCLUSIONS

Quite recently we described the first synthesis and characterization of stable titanocene derivatives containing MF_6^- groups (M = pnicogen) directly coordinated to the Cp_2Ti centre.[5,6] In the present work the preparation of the ionic $[Cp_2Ti(CH_3CN)_3]^{2+}[AsF_6^-]_2$ (**2**) is reported, in which three nitrile ligands are bonded to the Cp_2Ti^{2+} fragment. This also clearly shows the importance of the "covalent" hexafluoroarsenates mentioned above as useful reagents in the synthesis of cationic metallocene complexes. These compounds (neutral and cationic) are of interest not only on account of their structure in solution and in crystals, but also in respect of their transition metal fluorine bond situation and the rapid exchange processes of the coordinated hexafluoropnictogenate ligands. In addition, the highly hydrophilic (and water soluble) cationic species may well open up a new form of chemotherapeutics, as compounds containing the Cp_2Ti group often show antiproliferative activity, but their application is limited by their low solubility in polar solvents.[20]

Abstract—By reaction of 2,5-dimethyl 2,5-diisocyanohexane (TMB) and 1,2-diisocyanoethane (DHB) with CuX_2 ($X = CF_3SO_3^-$, ClO_4^-, BF_4^-), three types of complexes were isolated and characterized by magnetic susceptibility and EPR spectroscopy. In the violet CuL_2X_2 compounds, Cu^{II} atoms are in a square-planar environment and not magnetically interacting. For the mixed-valence green complexes $Cu_2L_3X_3$, the Cu^{II} and Cu^{I} metal centres both have a tetrahedral coordination, and the presence of independent Cu^{II} and Cu^{I} atoms in a 1:1 ratio was deduced from a magnetization experiment. Diamagnetic Cu^{I} complexes CuL_2X were also isolated. TMB complexes were prepared with Mn^{II} and Zn^{II}. In the former case, high-spin $Mn(TMB)(CF_3SO_3)_2 \cdot 2H_2O$ and low-spin $Mn(TMB)_3(PF_6)_2$ complexes were obtained, whereas Zn^{II} gave $Zn_2(TMB)_3(CF_3SO_3)_2 \cdot 2H_2O$. The ν(CN) frequency in the infrared spectra increases with the charge on the complex, and for complexes of the same charge, decreases when the diisocyanide-to-metal ratio increases. Although solubility was improved by using $CF_3SO_3^-$ as counter ion, it remained low and the complexes are likely to be polymeric, with the diisocyanide ligands in extended conformations playing a bridging role.

The metal complexes with diisocyanide ligands that most attracted attention were probably those of rhodium(I) and iridium(I), since these dinuclear molecules exhibit interesting properties for energy storage[1,2] or catalysis.[3] Dimeric palladium and platinum compounds,[4] and heterobimetallic Mn–Rh systems[5] have also been examined. Recently, a series of polymeric silver(I) complexes were described and structurally characterized.[6] With first-row transition metals, however, only a few complexes are known, because side reactions such as isocyanide polymerization, hydrolysis and decomposition, are catalysed by these metals.[7,8] The tetrameric nickel(II) compound $[Ni_4(OCH_3)_4(O_2CCH_3)_2(TMB)_4](BPh_4)_2$[9] appears to be the only one characterized by X-ray diffraction. Various $[\{Fe_2(Cp)_2(CO)_3\}_2(CN{-}(CH_2)_n{-}NC)]$ compounds[7] have been reported. Compounds of the types $[ML_3]PF_6$ and $M(CO)_nL$ with isocyanide-substituted diphenoxyethane ligands are also known.[10]

In the present study, TMB (**I**, "tetramethyl-bridge": 2,5-dimethyl 2,5-diisocyanohexane, $CNC(CH_3)_2CH_2CH_2C(CH_3)_2NC$) and DHB (**II**,

† Author to whom correspondence should be addressed.

"dihydrogen bridge": 1,2-diisocyanoethane $CNCH_2CH_2CN$) were reacted with first-row metal salts MX_2 ($M = Cu^{2+}$, Mn^{2+}, Zn^{2+}; $X = CF_3SO_3^-$, ClO_4^-, BF_4^- and PF_6^-). These three metals were selected because they adopt different coordination geometries and show different abilities to participate in redox processes. In order to minimize the formation of infinite polynuclear sequences via bridging by the counter ion, we used non-coordinating anions, mainly the $CF_3SO_3^-$ ion that commonly improves complex solubility.

EXPERIMENTAL

All reactions were carried out under N_2. The solvents were Puriss, Grade Fluka. The 2,5-dimethyl 2,5-diisocyanohexane (TMB) and 1,2-diisocyanoethane (DHB) ligands were prepared following literature methods.[11–13] Blue $Cu(CF_3SO_3)_2 \cdot 4H_2O$ was obtained by reaction of 2 equivalents of trifluoromethanesulphonic acid with basic copper carbonate ($CuCO_3 \cdot Cu(OH)_2$) in water. Very hygroscopic anhydrous $Cu(CF_3SO_3)_2$ was isolated when the reaction was conducted in methanol. $Zn(CF_3SO_3)_2 \cdot H_2O$ was obtained from a 2:1 ratio of CF_3SO_3H and basic carbonate ($2ZnCO_3 \cdot 3Zn(OH)_2$) in methanol. The same method was used to prepare $Mn(CF_3SO_3)_2 \cdot H_2O$ from methanol, starting with Mn^{II} carbonate. $Cu(BF_4)_2$ and $Cu(ClO_4)_2$ were generated *in situ* by reaction of $CuCl_2$ with the Ag^+ salt of the corresponding anion. $Mn(PF_6)_2$ was similarly obtained from $MnCl_2$ and $AgPF_6$.

Elemental analyses were performed by the Service Central de Microanalyse du CNRS, Lyon, France.

$Cu(TMB)_2(CF_3SO_3)_2$ (1)

TMB (4 mmol, 0.7 g) dissolved in methanol (20 cm^3) was quickly added to a stirred methanol solution (20 cm^3) of $Cu(CF_3SO_3)_2$ (2 mmol, 0.9 g), whereupon the solution turned blue. A violet precipitate was obtained at $-80°C$, which was collected by filtration, washed with cold ether, and dried *in vacuo*. Found: C, 38.1; H, 4.8; N, 7.9. Calc. for $C_{22}H_{32}F_6N_4O_6S_2Cu$: C, 38.3; H, 4.7; N, 8.1%.

$Cu(TMB)_2(ClO_4)_2$ (2)

Obtained from $Cu(ClO_4)_2$ by the same procedure. Found: C, 40.3; H, 5.3; N, 9.2. Calc. for $C_{20}H_{32}Cl_2N_4O_8Cu$: C, 40.6; H, 5.5; N, 9.5%.

$Cu(DHB)_2(CF_3SO_3)_2 \cdot H_2O$ (3)

By a similar procedure, 5.5 mmol (0.43 g) of DHB in ether (15 cm^3) were added at $-20°C$ to a stirred acetone solution (20 cm^3) of $Cu(CF_3SO_3)_2 \cdot 4H_2O$ (2.75 mmol, 1 g). Precipitation of a violet powder occurred immediately, which was filtered, washed with cold ether, and dried *in vacuo*. Found: C, 24.4; H, 2.2; N, 10.3; S, 10.8; F, 21.5; Cu, 12.5. Calc. for $C_{10}H_{10}F_6N_4O_7S_2Cu$: C, 22.2; H, 1.9; N, 10.4; S, 11.9; F, 21.1; Cu, 11.8%.

$Cu(DHB)_2(BF_4)_2$ (4)

Obtained from $Cu(BF_4)_2$ following the same procedure. Found: C, 24.1; H, 2.0; N, 14.0. Calc. for $C_8H_8N_4B_2F_8Cu$: C, 24.2; H, 2.0; N, 14.1%.

$Cu_2(TMB)_4(CF_3SO_3)_3 \cdot 5H_2O$ (5)

To 4.5 mmol (0.74 g) of TMB in ether (40 cm^3 were added 5 mmol (1.8 g) of $Cu(CF_3SO_3)_2 \cdot 4H_2O$ in ether (40 cm^3). A violet complex precipitated immediately. Ether was evaporated under vacuum and 30 cm^3 of acetone added. While the solution was refluxed for 30 min, it turned green. The volume was then reduced until a light green hygroscopic powder precipitated, which was filtered, washed with ether–dichloromethane and dried *in vacuo*. Found: C, 38.4; H, 5.7; N, 7.9. Calc. for $C_{43}H_{64}N_8F_9O_9S_3Cu_2$: C, 39.1; H, 5.6; N, 8.5%. We were unable to get completely satisfactory analytical results because **5** is very hygroscopic.

$Cu_2(DHB)_4(CF_3SO_3)_3 \cdot (CH_3)_2CO$ (6)

To 5 mmol (0.40 g) of DHB in 10 cm^3 of acetone were added 8 mmol (0.9 g) of $Cu(CF_3SO_3)_2 \cdot 4H_2O$ in 20 cm^3 of acetone. A blue-violet precipitate appeared immediately, which turned light green by heating the mixture at 50°C for 1 h. The green powder was filtered, washed with ether and dried *in vacuo*. Found: C, 27.5; H, 2.7; N, 11.4; F, 17.4; S, 9.2; Cu, 13.8. Calc. for $C_{22}H_{22}N_8F_9S_3O_{10}Cu_2$: C, 27.7; H, 2.3; N, 11.8; F, 17.9; S, 10.1; Cu, 13.3%.

$Cu_2(DHB)_4(BF_4)_3$ (7)

Obtained from $Cu(BF_4)_2$ following the same procedure. Found: C, 27.1; H, 2.1; N, 15.5. Calc. for $C_{16}H_{16}N_8F_{12}B_3Cu_2$: C, 27.1; H, 2.3; N, 15.8%.

$Cu(TMB)_2(CF_3SO_3)$ (8)

TMB (8 mmol, 1.4 g) in methanol (150 cm^3) was added slowly to 200 cm^3 of a 10^{-2} M solution of

$Cu(CF_3SO_3)_2$ in methanol at room temperature. The mixture was stirred for 2 h, then concentrated to 20 cm^3. At $-30°$, a white powder precipitated, which was filtered, washed with cold ether and dried *in vacuo*. Found: C, 46.9; H, 6.0; N, 10.1. Calc. for $C_{21}H_{32}N_4F_3SO_3Cu$: C, 46.6; H, 6.0; N, 10.3%.

$Cu(DHB)_2(CF_3SO_3)$ (9)

$Cu(DHB)_2(CF_3SO_3)_2 \cdot H_2O$ (**3**, 2 mmol, 1.1 g) suspended in methanol (200 cm^3) was stirred for 2 h under reflux. The solution became colourless and a white precipitate formed, which was filtered, washed with cold ether, and dried under reduced pressure. Found: C, 29.3; H, 2.4; N, 15.2. Calc. for $C_9H_8N_4F_3O_3SCu$: C, 29.0; H, 2.2; N, 15.0%.

$Mn(TMB)(CF_3SO_3)_2 \cdot 2H_2O$ (10)

To 5 mmol of $Mn(CF_3SO_3)_2 \cdot H_2O$ in acetone (20 cm^3) were added 5 mmol (0.82 g) of TMB in ether (50 cm^3). The solution was stirred for 2 h at room temperature. A white precipitate formed, which was filtered, washed with ether and dried *in vacuo*. Found: C, 26.1; H, 3.3; N, 5.5; F, 20.7; S, 12.6; Mn, 10.0. Calc. for $C_{12}H_{20}N_2F_6S_2O_8Mn$: C, 26.0; H, 3.6; N, 5.2; F, 20.6; S, 11.6; Mn, 9.9%.

$Mn(TMB)_3(PF_6)_2$ (11)

To 2.5 mmol of $Mn(PF_6)_2$ in methanol (50 cm^3) were added 7.5 mmol of TMB (1.23 g) in ether (50 cm^3). The solution was concentrated and at $-30°C$ a light yellow powder precipitated, which was filtered, washed with ether and dried *in vacuo*. Found: C, 41.8; H, 5.7; N, 9.7; F, 27.1; P, 7.3; Mn, 6.6. Calc. for $C_{30}H_{48}N_6P_2F_{12}Mn$: C, 43.0; H, 5.8; N, 10.0; F, 27.2; P, 7.4; Mn, 6.6%.

$Zn_2(TMB)_3(CF_3SO_3)_4 \cdot 2H_2O$ (12)

TMB (5 mmol, 0.82 g) dissolved in ether (60 cm^3) was added to 2.5 mmol of $Zn(CF_3SO_3)_2 \cdot H_2O$ in acetone (20 cm^3). The solution turned light yellow, and after concentration a light yellow powder precipitated, which was filtered, washed with ether and dried *in vacuo*. Found: C, 33.5; H, 4.0; N, 6.6; S, 10.3; F, 16.5; Zn, 10.4. Calc. for $C_{34}H_{52}N_6F_{12}S_4O_{14}Zn_2$: C, 32.5; H, 4.2; N, 6.7; S, 10.2; F, 18.1; Zn, 10.4%.

Physical measurements

IR spectra were recorded as Nujol mulls on a Perkin–Elmer 577 spectrophotometer. UV–vis. spectra were obtained on a Cary 14 spectrophotometer equipped with a diffuse reflectance attachment. EPR spectra were measured on a Bruker ER 200 TT spectrometer operating at X-band frequency between 100 and 300 K.

Magnetic susceptibilities were determined by the Faraday method, using a Cahn microbalance coupled with a Drusch electromagnet. Measurements were performed between 20 and 320 K. $HgCo(NCS)_4$ was used as standard ($X_g = 16.44 \times 10^{-6}$ cgs emu). The experimental values were corrected for the diamagnetism of the ligands.[14]

Magnetization was measured by translating the sample in a pick-up coil system. The induced voltage was first amplified by a high-performance amplifier and then integrated, a bipolar voltage-to-frequency converter and a reversible counter providing the true integral of the input voltage. Flux resolution was better than one maxwell, corresponding to a magnetization resolution of *ca* 10^{-5} emu. The measurements were commonly reproducible within 10^{-4} emu.

RESULTS AND DISCUSSION

Copper complexes

The reactions of DHB and TMB with CuX_2 salts containing the poorly coordinating X groups, $CF_3SO_3^-$, BF_4^- and ClO_4^-, were found to be solvent- and temperature-dependent. Three types of complexes were obtained in good yield (> 80%). The violet Cu^{II} complexes, $Cu(TMB)_2X_2$ (**1**, **2**) and $Cu(DHB)_2X_2$ (**3**, **4**), precipitated upon cooling, when two moles of diisocyanides were allowed to react with one mole of CuX_2. Heating dilute (10^{-2} M) solutions of $Cu(TMB)_2(CF_3SO_3)_2$ or $Cu(DHB)_2(CF_3SO_3)_2$ in methanol (2 h) led to the white Cu^I complexes, $Cu(TMB)_2(CF_3SO_3)$ (**8**) or $Cu(DHB)_2(CF_3SO_3)$ (**9**).

Mixed-valence Cu^I–Cu^{II} complexes $Cu_2(TMB)_4(CF_2SO_3)_3$ and $Cu_2(DHB)_4(CF_3SO_3)_3$ were reproducibly obtained as green powders when the corresponding $CuL_2(CF_3SO_3)_2$ compounds were heated at 50°C in acetone or in an acetone–ether mixture. The resulting compounds, which first crystallized as acetone solvates, were very hygroscopic, which explains the difficulties in getting reproducible microanalyses. However, reliable results were obtained for the corresponding $Cu_2(DHB)_4(BF_4)_3$ material, which gave the same EPR data as the $CF_3SO_3^-$ salt, and a similar IR spectrum, except for anion bands.

The Cu^{II} compounds are insoluble in all common organic solvents, whereas the Cu^I and the mixed-valence Cu^{II}–Cu^I species are sparingly soluble in methanol or acetonitrile.

Table 1. IR and magnetic data[a]

[a] 293 K.

[b] In the solid state, except for parenthesized values for Mn compounds, which were obtained from methanol solutions.

As already noted for metals in not very low oxidation states,[8,10,15] the ν(CN) frequency increases upon complexation (Table 1). As no bands are detected in the 1600–1700 cm^{-1} region, the isocyanide group cannot be present in a polymerized form or coordinated in a bridging bidentate way.[7,8] There are no residual absorptions for free isocyanide groups. The frequency decreases in the order Cu^{II} > mixed-valence Cu^{II}–Cu^{I} > Cu^{I}. Since the isocyanide-to-metal ratio is constant throughout the series, this trend can be related to the charge decreasing from Cu^{II} to Cu^{I}, which is also paralleled by increased back-bonding from filled copper *d* orbitals into the NC π^* system.[10]

Magnetic moments and EPR parameters of complexes **1–7** are reported in Table 1. Complexes **1–4** are paramagnetic Cu^{II} d^9 complexes without a Cu–Cu magnetic interaction. Their magnetic moments are within the normal range (1.7–2.2 BM)[16,17] for Cu^{II}. Square-planar coordination is indicated by the EPR parameters (A = 160–205 G) and consistent with the electronic spectra (band, *ca* 19100 cm^{-1} in the diffuse reflectance spectra).[18–20]

In contrast, complexes **5–7** have low magnetic moments, between 1.15 and 1.35 BM, at room temperature. They follow a Curie–Weiss law between 80 and 300 K (for **5**, $X(T-5.92) = 0.220$, and for **6**, $X(T-7.72) = 0.128$), showing that the copper centres are not magnetically coupled. The presence of Cu^{I} atoms must be assumed to explain the low magnetic moments. Thus, the compounds are presumably mixed-valence complexes of type I, that is, without magnetic interaction between the Cu atoms. This is confirmed by the magnetization curve measured for complex **5** at 1.05 K.†[21] The experimental data are represented in Fig. 1 together with the theoretical magnetization curves. If only Cu^{II} is assumed to be present, the magnetization value at saturation of 0.545 (b) gives rise to j and s values of 0.25. Obviously only about half of the copper is Cu^{II}, the remaining copper centre being diamagnetic Cu^{I}. Indeed, considering only Cu^{II} would give rise to the calculated magnetization curve (a) with M = 1.085 MB at saturation. This hypothesis is confirmed by the excellent fit between the experimental data and the theoretical curve calculated for a Cu^{II} population of 0.508 and a Cu^{I} population of 0.492 i.e. a 1 : 1 Cu^{II}/Cu^{I} ratio. The EPR data for compounds **3–5** are in agreement with this result

† The general equation for magnetization M in the case of an uncoupled $J = 1/2$ spin system reduces to $M = 0.5\,N\beta g \tan h(\beta gH/2kT)$, where g is the Lande factor and the remaining symbols have their usual meanings. At saturation, $M = g \cdot J$. The experimental EPR data give a g value of 2.175, allowing to calculate a J value of 0.25. For a magnetically dilute Cu^{II} species, $L = 0$, consequently, $J = S = 0.25$. The magnetic moment of the Cu^{II} species is related to J by the equation $\mu = g[J(J+1)]^{1/2}$. The experimental values of $g = 2.175$ and $J = 0.5$ give $\mu = 1.875$ BM, consistent with the expected values $1.7 < \mu < 2.2$ BM.

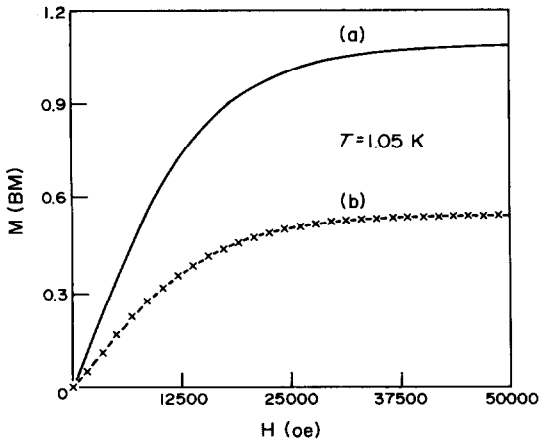

Fig. 1. Magnetization curves for $Cu_2(TMB)_4(CF_3SO_3)_3$ (**5**). (x = experimental points). Continuous curves calculated assuming (a) that all copper is present as Cu^{II}, and (b) that the complex is mixed-valence with Cu^{II} and Cu^{I} populations of 0.502 and 0.498, respectively.

since they correspond to magnetically dilute Cu^{II} atoms in tetrahedral environment (A = 130–140 G). This coordination geometry is also supported by the electronic spectra (band at 14,100 cm^{-1} for **5** and 12,000 cm^{-1} for **6**).[20,22,23]

Complexes **8** and **9** are diamagnetic copper(I) species. They are slightly soluble in polar solvents, but only microcrystalline powders were obtained. Copper(I) probably lies in a tetrahedral environment, since this geometry, common for d^{10} Cu^{I} complexes,[20] has been observed for the unidentate methylisocyanide complex $[Cu(CNMe)_4]BF_4$.[24]

The poor solubility of these complexes points to polymeric structures, and this must be achieved by bridging via the diisocyanide ligands. Indeed, besides the fact that the "non-coordinating" anions used here would not be efficient in bridging copper atoms into stable infinite chains, a simple count of the overall number of —NC groups per copper shows that they saturate the metal coordination sphere. In agreement with this conclusion are the spectroscopic data which show no evidence for free isocyanide groups. However, beyond the immediate metal surroundings, there is no basis to propose detailed polymerization patterns for these compounds.

Manganese complexes

Only TMB yielded well characterized compounds with MnX_2 salts. The colourless $Mn(TMB)(CF_3SO_3)_2 \cdot 2H_2O$ (**10**) precipitated from a 1 : 1 mixture of $Mn(CF_3SO_3)_2 \cdot H_2O$ and TMB, whereas the light yellow solid $Mn(TMB)_3(PF_6)_2$ (**11**) was obtained from a mixture of $Mn(PF_6)_2$ with excess ligand. Both materials are soluble in polar solvents, e.g. alcohols and acetonitrile.

The ν(CN) band occurs at 2210 cm^{-1} in **10** and at 2180 cm^{-1} in **11**. It is displaced to a higher frequency by coordination, as observed with $[Mn(CN)_6]^{2-}$ complexes,[25] and it decreases with increasing TMB/Mn molar ratio. The EPR data listed in Table 1 were determined on the solids and on methanol solutions. They are consistent with d^5 Mn^{II} species,[26] but interestingly, the compounds are in different spin states. Compound **10** is a high-spin Mn^{II} complex ($^6A_{1g}$ ground state) with a magnetic moment μ_{eff} of 5.95 BM at 298 K, nearly equal to the spin-only value.[16,17] Increasing the number of strong-field ligands around Mn results in a low-spin paramagnetic Mn^{II} species $Mn(TMB)_3(PF_6)_2$ ($^2T_{2g}$ ground state) with a magnetic moment μ_{eff} of 2.70 BM at 298 K. $[Mn(CN)_6]^{4-}$ and $[Mn(CNR)_6]^{2+}$ are also known to be low-spin systems.[25,27,28] No Mn^{II}–Mn^{II} magnetic interactions are detected from the EPR spectra, or the magnetic susceptibility data for **11**, which follows a Curie–Weiss law between 80 and 300 K ($X(T-6.39) = 0.869$).

In $Mn(TMB)_3(PF_6)_2$, the number of —NC groups per metal and the absence of uncoordinated —NC groups deduced from the IR spectra suggest a Mn^{II} centre surrounded by an octahedron of —NC ligands as in the $[Mn(CN)_6]^{4-}$ ion[29] and presumably in the various $[Mn(CNR)_6]^{2+}$ species.[25,28] Bridging by this large number of ligands probably defines a complex three-dimensional pattern in **11**. In complex **10**, the coordination sphere, including only two —NC groups per Mn, must be completed by water and/or $CF_3SO_3^-$ oxygens. Dissolution in methanol undoubtedly involves breaking of the polymeric structure into small units, but no details on this point are provided by the available data.

Zinc complex

The light yellow $Zn_2(TMB)_3(CF_3SO_3)_4 \cdot 2H_2O$ compound was obtained in good yield when TMB was added to $Zn(CF_3SO_3)_2 \cdot H_2O$ in a 2 : 1 ratio. Only one ν(CN) band is apparent at 2260 cm^{-1}, in the same range as for the Cu^{II} complexes. In Ag^{I} compounds of the same stoichiometry, the ν(CN) frequency was found to be 2180 cm^{-1}. The greater frequency observed here is consistent with the higher charge of Zn^{II}. The $[Ag_2(TMB)_3]X_2$ complexes ($X = ClO_4^-, PF_6^-$) form one-dimensional ladder-like polymers, with TMB molecules cross-linking infinite —Ag—TMB—Ag—TMB— chains.[6] With three soft —NC groups coordinated per metal, zinc is likely to retain a low coordination number and adopt the tetrahedral geometry common for this metal.[30] A structure similar to those

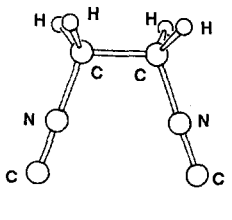
of silver salts in which the coordination sphere would be completed by water or anions can be proposed.

CONCLUSION

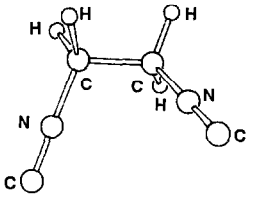
To achieve coordination with an —NC group, the metal normally defines a linear —N—C—M arrangement. Whether the two donor groups in a given diisocyanide can be suitably oriented to chelate a single atom, bridge a pair of adjacent metal atoms, or link distant metals along an infinite polymeric pattern is controlled to a large extent by the architecture of the carbon chain between the donor groups. There is evidence that at least a C_7 hydrocarbon chain is needed for a diisocyanide to form a chelate.[31]

We recently discussed in detail the conformations of TMB present in the various polymeric units observed for silver complexes.[6] Clearly, chelation would require severe distortions in the hydrocarbon chain, and both low-energy conformations of TMB position the —N—C units in orientations favouring polymers.

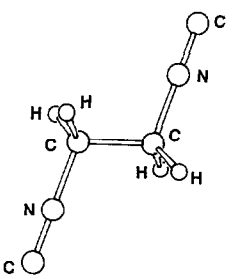
In the DHB molecule, the —N—C groups are so oriented that even in the eclipsed cisoid conformation I, the terminal sections are divergent and make chelation virtually impossible. Any rotation about the CH_2—CH_2 bond would make chelation still less favourable. Thus, the ligand lower-energy conformations II and III clearly favour polymeric arrangements rather than small molecular units. Two metal atoms lying 2.0 Å away from C along the lone pair direction in I would be 4.6 Å apart, and further apart in II and III. Therefore, as observed, no magnetic interactions can take place between the metal centres.



I



II



III

Despite the fact that the resulting polymers could not be completely defined in terms of uni, di- or tridimensional arrangements, the present work shows that under suitable conditions, side reactions can be avoided and diisocyanide complexes can be prepared with first-row metals.

(*Received* 8 *July* 1988; *accepted* 27 *July* 1988)

Abstract—Raman spectra of equimolar MCl–CuCl melts (M = Na, K, Rb and Cs) at 500°C consist of one single band with a frequency increasing from 255 to 268 cm^{-1} when going from Na to Cs. For KCl–CuCl melts no change in band position was observed either with changes in temperature (200–600°C) or with compositional changes ($0.250 < X_{CuCl} < 0.667$). CuCl–$AlCl_3$ melts ($0.33 < X_{CuCl} < 0.67$, $t = 300$ and 400°C) show a copper chlorine vibration at 220 cm^{-1}. The Al–Cl stretching and bending vibrations are shifted towards lower frequencies, relative to the vibrations of $AlCl_4^-$ in alkali chloride–aluminium chloride melts. Also the intensity ratio between 308 and 342 cm^{-1} bands (the strongest for $Al_2Cl_7^-$ and $AlCl_4^-$, respectively) is lower compared to MCl–$AlCl_3$ melts of similar $AlCl_3$ mole fraction. This suggests the formation of [$CuAlCl_4$] species with bent Cu—Cl—Al bridging and a distortion in the tetrahedral configuration of the chloride around aluminium. For CuCl dissolved in basic MCl–$AlCl_3$ (M = K, Cs) melts, both Raman spectra and freezing point depression data indicate formation of linear $CuCl_2^-$ complexes. Two liquid phases (essentially CuCl and $KAlCl_4$) were formed when CuCl was added to neutral KCl–$AlCl_3$ melts. In acidic MCl–$AlCl_3$–CuCl melts, a 220 cm^{-1} band was observed arising from a copper chloride vibration as in the CuCl–$AlCl_3$ melts. The density of the equimolar KCl–CuCl melt is 2.436 and 2.389 g cm^{-3} at 421 and 556°C, respectively.

Chloride melts containing copper have received considerable attention because of their application as catalysts, e.g. for the Deacon reaction and for the oxidative chlorination of hydrocarbons in connection with vinyl chloride production. Since the chemistry of such catalysts is rather poorly understood we decided to perform a Raman spectroscopic investigation on different copper(I) containing chloride melts in an attempt to better understand their properties.

The coordination chemistry of copper(I) has only been subject to a small number of investigations. According to the crystal structure studies performed, several types of coordination geometries are found: typically, copper(I) is tetrahedrally coordinated as in K_2CuCl_3, $CsCu_2Cl_3$, $CuAlCl_4$, and in the low and high temperature modifications of CuCl.[1–5] Two colinear bonds, i.e. $CuCl_2^-$, are known to exist in some copper(I) salts with large organic cations.[6–8]

This dichlorocuprate(I) ion is also present in organic solutions of copper(I) chloride with excess chloride added (as LiCl or HCl).[9,10] The Raman spectrum of this ion consists of one single band near 300 cm^{-1} assigned to the symmetrical stretching mode of the linear ion.[6,9,10] In melts at around 500°C, the Raman spectra[11] have bands at two

*Author to whom correspondence should be addressed.

different positions: at 275 cm^{-1} in CsCl–CuCl melts of 50–50 mol % composition and at 250 cm^{-1} in pure CuCl, basic CsCl–CuCl and LiCl–CuCl melts of all compositions. The bands have previously been explained[11] as being due to copper(I) chloride species with an average coordination number of two (275 cm^{-1}) and four (250 cm^{-1}).

Apart from Raman spectroscopy, several other methods have been applied to study MCl–CuCl melts.[12–17] The activities of CuCl determined by vapour pressure[12] and EMF measurements,[13,14] show large deviations from ideality for KCl–CuCl melts. Similar but smaller deviations are observed for the enthalpy of mixing for MCl–CuCl (M = Li, Na) and these increase markedly[15,16] for M = K, Rb and Cs. In the MCl–CuCl phase diagrams no evidence of compound formation is obvious in the case of M = Li, Na,[18,19] whereas compound formation is observed for M = K, Rb and Cs.[20–22] Finally, conductivity measurements[17] on KCl–CuCl melts in the temperature range 440–630°C show a minimum in equivalent conductivity at a copper(I) chloride mole fraction of nearly 0.33.

Few studies have been made on melts containing copper(I) chloride and aluminium chloride.[23,24] The phase diagram of the KCl–$AlCl_3$ system near equimolar composition has recently been studied with high precision.[25] The freezing point of a pure neutral $KAlCl_4$ melt was found to be 257.3 ± 0.1°C and the cryoscopic constant was 27 ± 2°C kg mol^{-1}. The phase diagram of the binary system CuCl–$AlCl_3$ showed that a congruently melting 1 : 1 compound is formed.[23] The NQR spectrum of this compound showed[26] only one ^{35}Cl-line and a recent investigation[3] of the crystal structure indicated the formation of a polymeric structure in which both Al^{III} and Cu^{I} atoms are surrounded by four chlorine atoms. $CuAlCl_4$ molecules exist in the vapour phase in the temperature range 189–390°C.[27] The results of an electrochemical study[24] on copper(I) chloride dissolved in NaCl–$AlCl_3$ melts at 175°C were explained in terms of the equilibrium $Cu^+ + 2Cl^- \rightleftharpoons CuCl_2^-$, with an equilibrium constant of 6.5×10^4 dm^6 mol^{-2}.

EXPERIMENTAL

Aluminium chloride, alkali chlorides and anhydrous copper(II) chloride were prepared by methods similar to the ones described in previous works.[28,29] Copper(I) chloride was synthesized directly in the melts by reaction between anhydrous copper(II) chloride[30] and excess copper metal (99.99% pure, obtained from N.K.T., Denmark). The reaction was carried out at 600°C in the case of the MCl–CuCl melts, and at 400°C for the melts which contained aluminium chloride. During reduction the colour of the melt changed from dark brown to yellow for the binary alkali chloride–copper(I) chloride melts and to faintly yellow for the aluminium chloride containing melts. The reaction was usually complete in two days, after which time no band due to copper(II) chloride complexes[31] could be observed in the visible spectra of the melts.

The apparatus and method for measuring the Raman spectra were almost identical to the ones previously described.[32] The optical cells were made of fused quartz tubing and sealed under vacuum. Most of them were equipped with a filter, which was used to remove excessive copper metal after the reduction was complete. The Raman spectra were recorded using a JEOL-JRS-400D spectrometer coupled to a cooled photomultiplier and a photon counting system. The 514.5 nm line of a CR argon ion laser with a typical intensity of 300 mW was used to excite the melts. The scan rates and spectral resolutions were 25–50 cm^{-1} min^{-1} and 2–5 cm^{-1}, respectively.

The densities were measured by a method developed in our laboratory.[33] For these experiments, in order to get reliable results, it was necessary to premix potassium chloride, copper(II) chloride and copper metal and filter off the excess metal. The cryoscopic measurements were performed using a technique similar to the one previously described.[34] The copper(I) was added as the $KCuCl_2$ mixed salt.

Other technical details and the nomenclature used in this work are the same as in previous publications.[31,32] The formality C' is defined as the initial molar amounts of the added salt dissolved in 1 dm^3 of the melt. The composition of the melts are given in mole fractions (X_{CuCl}, X_{KCl}, X_{AlCl_3}, etc.), but for the case in which two phases are present the notation $MCl/AlCl_3/CuCl$ is used indicating the molar ratios which were weighed. MCl–$AlCl_3$–CuCl melts are called acidic if $X_{AlCl_3} > X_{MCl}$ and basic if the opposite is the case.

The density necessary to calculate C'_{CuCl} in the MCl–$AlCl_3$–CuCl melts was obtained assuming ideal mixing of MCl–$AlCl_3$ with CuCl except for basic KCl–$AlCl_3$–CuCl melts for which ideal mixing between KCl–$AlCl_3$ and $KCuCl_2$ was supposed. The dependence of the density on composition and temperature is known for all of the binary MCl–$AlCl_3$ solvent mixtures: NaCl–$AlCl_3$,[35] KCl–$AlCl_3$[36] and CsCl–$AlCl_3$.[37] The data from the work of Klemm were used for the densities of CuCl.[38] Apparently no density work exists for the $KCuCl_2$ melt; therefore, we measured the density for this composition at two temperatures: 556 and 421°C. The densities were found to be 2.389 and 2.436 g

cm^{-3}, respectively. For values at other temperatures linear interpolation was assumed to give reasonably accurate results for the purpose of this work.

Raman spectra of MCl–CuCl *melts*

Figure 1 shows the spectra of MCl–CuCl melts (M = Na, K, Rb and Cs) with a mole fraction of 0.500, all recorded at 500°C. As can be seen from this figure all of the melts give rise to only a single band in the measured wavelength region. The position of each band is given in Fig. 1.

As it can be seen, the Raman frequency for the equimolar MCl–CuCl melts goes up steadily from 255 cm^{-1} for M = Na and to 268 cm^{-1} for M = Cs. For the latter band Gilbert *et al.*[11] obtained a value of 273 cm^{-1} at a lower temperature (450°C) and for M = Li a value of 250 cm^{-1} was found. Our spectra of KCl–CuCl melts with mole fractions of CuCl equal to 0.667, 0.333 and 0.250 were indistinguishable from the spectrum of the equimolar composition. To investigate whether the temperature had any effect, Raman spectra of KCl–CuCl melts with $X_{CuCl} = 0.667$ were measured between 200 and 600°C. In this temperature range the change in the Raman spectra were negligible.

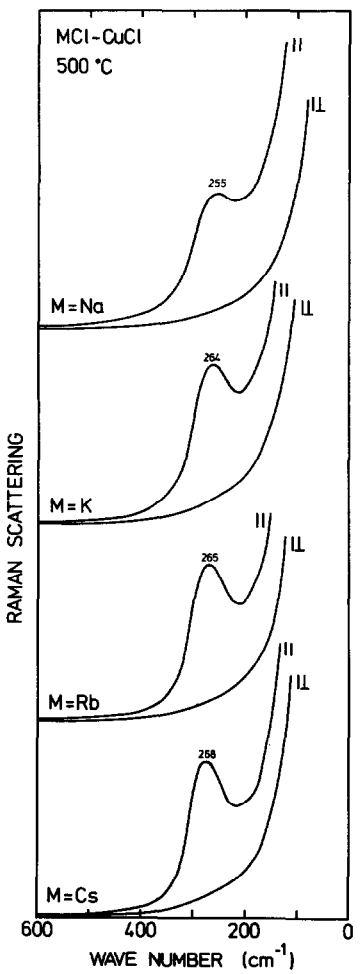

Fig. 1. Polarized (||) and depolarized (|⊥) Raman spectra of MCl–CuCl melts (M = Na, K, Rb, Cs) at 500°C, $X_{CuCl} = 0.500$. Slit width ~ 3 cm^{-1}.

From these results one can conclude that the coordination of chloride to copper(I) in the investigated range of KCl–CuCl melts does not change significantly neither with temperature nor with composition. In contrast to this, Gilbert *et al.*[11] have claimed that the KCl–CuCl melts behaved similarly to the CsCl–CuCl melts (i.e. gave two Raman bands at high alkali chloride contents). The band observed in the MCl–CuCl melts must be due to some kind of coordination between Cu and Cl, because the band is much more distinct than the usual broad Raman-wing bands characteristic of spectra from completely dissociated monatomic liquids like molten NaCl and KCl.[39] A possible explanation of the origin of Raman bands of equimolar MCl–CuCl melts is that copper(I) is tetrahedrally surrounded by chloride ions in LiCl–CuCl, as proposed by Gilbert *et al.*[11] and that a gradual change of the coordination from tetrahedral towards linear coordination of Cu^{I} occurs for increasing atomic number of the alkali metal counter cation. Support for this view can be found in the enthalpy of mixing data[15,16] in which only small interactions were observed in the cases of LiCl–CuCl and NaCl–CuCl melts, in contrast to KCl–CuCl, RbCl–CuCl and CsCl–CuCl melts where considerable deviations from ideality occurred. Furthermore, the large negative deviations in the vapour pressure[12] and EMF data[13,14] and the minimum in the equivalent conductivity of KCl–CuCl melts[17] also indicate structural changes in these melts compared to the pure CuCl melt.

Raman spectra of $CuCl–AlCl_3$ *melts*

Figure 2 shows Raman spectra of $CuCl–AlCl_3$ melts at various compositions; band positions are also indicated in this figure. The spectra of melts with a CuCl mole fraction of 0.33 and 0.50 were recorded at 300°C, whereas in the case of $X_{CuCl} = 0.667$, it was necessary to raise the temperature to 400°C because of the higher melting point at this composition.

It can be seen from Fig. 2 that all of the spectra have a strong polarized band at around 342 cm^{-1}. This band is assigned to the ν_1 (A_1) vibration of $AlCl_4^-$.

In addition to this band, a band appears at 308 cm^{-1} for $X_{CuCl} = 0.500$ and 0.333. The intensity of

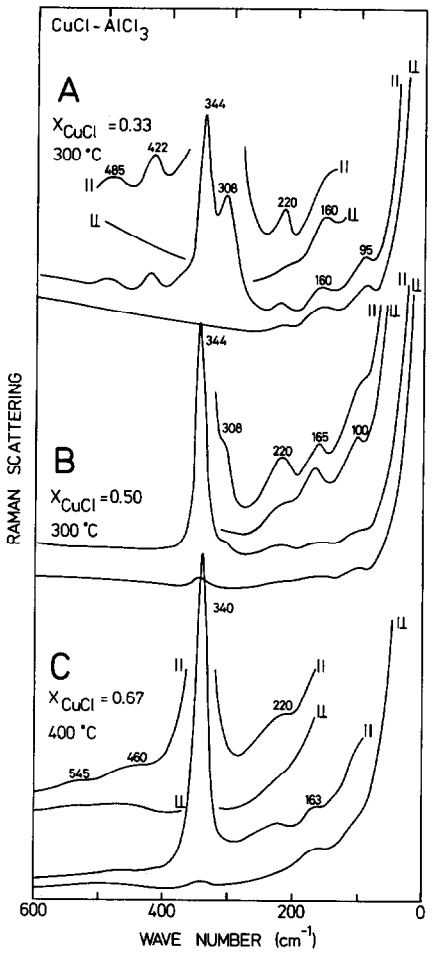

Fig. 2. Polarized (∥) and depolarized (∥⊥) Raman spectra of CuCl–$AlCl_3$ melts. Mole fractions and temperatures are indicated in the figure. For the amplified parts of the spectra the sensitivity was raised by a factor of 2.5 ($X_{CuCl} = 0.33$) and 5.0 ($X_{CuCl} = 0.50$ and 0.67).

this band relative to the 342 cm^{-1} band increases with the $AlCl_3$ contents of the melts. Also the frequency of 308 cm^{-1} is very near to that of the strongest band of the $Al_2Cl_7^-$ complex known from acidic MCl–$AlCl_3$ melts (M = alkali metal).[40,41] Therefore there is good reason to believe that $Al_2Cl_7^-$ is present in equimolar as well as in acidic CuCl–$AlCl_3$ melts. Other bands at around 100, 162, 422, 460, 485 and 545 cm^{-1} are also assigned to aluminium–chloro vibrations.

The band at 220 cm^{-1} observed in all of the melts is probably due to a copper chloride vibration, although Al_2Cl_6 also has a vibration near this frequency. It is, however, unlikely that this species should exist in the melts with a CuCl mole fraction of 0.50 or larger. This view can be justified since with increasing $AlCl_3$ contents $Al_2Cl_7^-$ should be formed prior to Al_2Cl_6, and from the intensity of the 308 cm^{-1} band observed in the Raman spectra with an $AlCl_3$ mole fraction of up to 0.500 one can see that $Al_2Cl_7^-$ is only present in small amounts in these melts. On the other hand, the presence of Al_2Cl_6 cannot be excluded in the melt with a CuCl mole fraction of 0.33.

In Table 1, the main Raman frequencies of the CuCl–$AlCl_3$ melts observed in our work are listed and compared to other binary chloro–aluminate melts. From this table it can be seen that the position of the ν_1 vibration for $AlCl_4^-$ in the CuCl–$AlCl_3$ melts at 344 cm^{-1} is lower than for the equimolar MCl–$AlCl_3$ melts (M = Na, K), in which it is well known that $AlCl_4^-$ forms a regular tetrahedron.[40,41] The bands at 100 and 165 cm^{-1} also occur at lower frequencies than the ν_2 and ν_4 vibrations of $AlCl_4^-$ in MCl–$AlCl_3$ melts. It is remarkable that these frequencies are close to those observed for the $Al_2Cl_7^-$ complex in the alkali tetrachloroaluminate melts.[40,41]

These band displacements indicate a distortion of the $AlCl_4^-$ tetrahedron in the CuCl–$AlCl_3$ melts. It should be further noticed that similar displacements are observed in the $SnCl_2$–$AlCl_3$ system.[42]

The intensity ratio of the 308 cm^{-1} band relative to the 342 cm^{-1} band for $X_{AlCl_3} = 0.67$ is much lower than the ratio of the corresponding bands (311 cm^{-1}/350 cm^{-1}) observed in MCl–$AlCl_3$ melts

Table 1. Main Raman frequencies ($\Delta\nu$ in cm^{-1}) of MCl_x–$AlCl_3$ melts of various compositions[a]

MCl_x	X_{MCl_x}	T (°C)	$AlCl_4^-(\nu_1)$	$AlCl_4^-(\nu_2)$	$AlCl_4^-(\nu_3)$	$AlCl_4^-(\nu_4)$	$Al_2Cl_7^-$	M---Cl	Reference

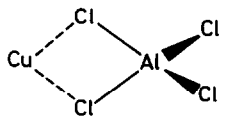
[a] $x = 1$ or 2 depending on the valency of metal (M).

(M = Li, Na, K and Cs) at the same $AlCl_3$ mole fraction and temperature.[40,41,43] This is probably an indication of bonding between Cu^I and $AlCl_4$ tetrahedra resulting in a displacement of the equilibrium

$$2AlCl_4^- \rightleftharpoons Al_2Cl_7^- + Cl^- \qquad (1)$$

to the left.

The rather low position (220 cm^{-1}) of the copper(I) chloride vibration in the CuCl–$AlCl_3$ melt suggests that copper is not linearly coordinated by chloride. A possible explanation is that the copper atom is connected to aluminium by bent chloride bridges forming a [$CuAlCl_4$] complex as shown in Structure 1. This is supported by the position of



Structure 1.

the previously mentioned displaced ν_1, ν_2 and ν_4 vibrations and by the splitting of the ν_3 vibration (at around 487 cm^{-1}) of $AlCl_4^-$ (Table 1). A similar model has recently been proposed by Gilbert *et al.*[42] for the coordination of Sn^{II} in $SnCl_2$–$AlCl_3$ for $X_{AlCl_3} > 0.66$. Also in this case, a low frequency band appears at ~ 220 cm^{-1} superimposed on the bands arising from aluminium–chloro vibrations. It is of course possible that $CuAlCl_4$ complexes are not monomeric, but form $(CuAlCl_4)_n$.

CuCl–MCl–$AlCl_3$ *melts* (M = K, Cs)

General. Figure 3 shows Raman spectra of 3.7 F CuCl (i.e. formal concentration = 3.7) dissolved in KCl–$AlCl_3$ melts with varying acidity. The bands around 120, 180, 350 and 490 cm^{-1} are the well known[40,41,43] vibrations of $AlCl_4^-$. For CuCl dissolved in acidic solvents [Fig. 3(A)], additional bands are observed at 222 cm^{-1} (polarized) and at ~310 cm^{-1}. The ~ 310 cm^{-1} band is probably due to the strongest vibration of $Al_2Cl_7^-$ whilst the 222 cm^{-1} band must arise from a copper chloride vibration (Al_2Cl_6 cannot be present at this composition). Spectra B and B′ arise from the bottom and top phase of the same sample. Only one band at 250 cm^{-1} is observed in spectrum B, whereas spectrum B′ shows the four bands characteristic of $AlCl_4^-$ and the ~ 310 cm^{-1} band from $Al_2Cl_7^-$. Spectra C and D are very similar to each other. In addition to the $AlCl_4^-$ bands, only one band in the 270–290 cm^{-1} region is observed.

Raman spectra of CuCl dissolved in CsCl–$AlCl_3$

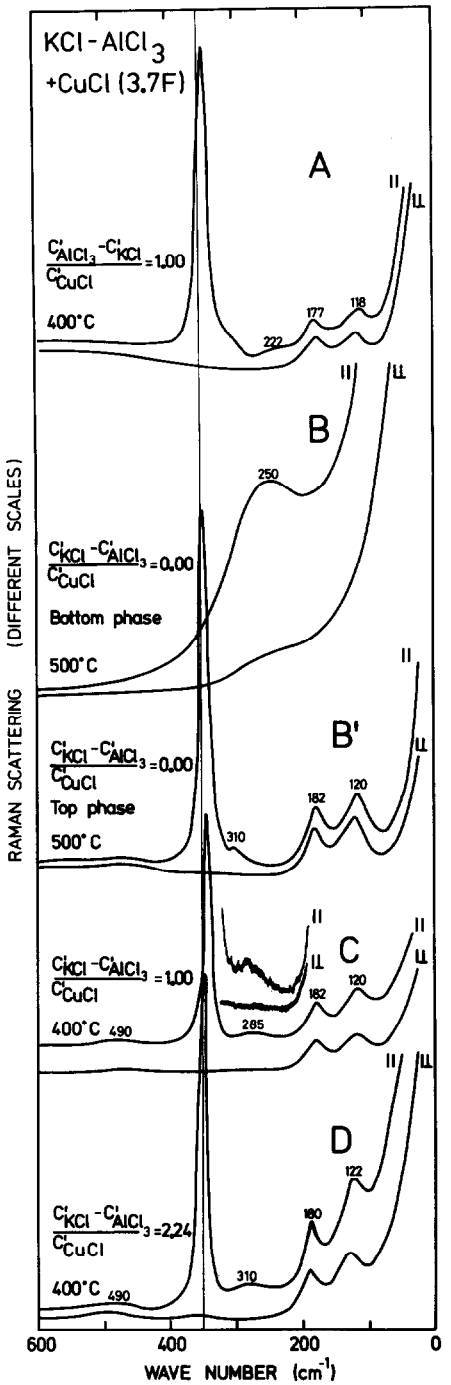


Fig. 3. Polarized (‖) and depolarized (‖⊥) Raman spectra of CuCl–KCl–$AlCl_3$ melts. The formal concentration of CuCl was 3.7 for all samples and the mole fractions of KCl and $AlCl_3$ were: (A) 0.2383_1, 0.3819_7; (B′) (bottom and top phase of the same sample), 0.3855_9, 0.3855_9; (C) 0.5000_0, 0.2880_4; (D) 0.6171_3, 0.1941_7. The temperatures are given on the figure together with the ratio of the excess formality of $AlCl_3$ or KCl to the formality of CuCl.

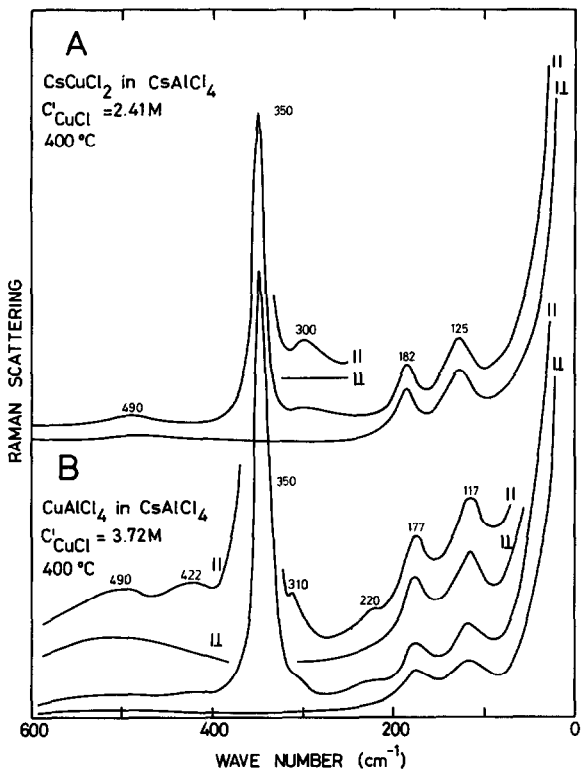

Fig. 4. Polarized (‖) and depolarized (‖⊥) Raman spectra of CuCl–CsCl–$AlCl_3$ melts. The formality of CuCl and the temperatures are given in the figure. The mole fractions of CsCl and $AlCl_3$ were: (A) 0.5004, 0.3436; (B) 0.2501, 0.4999. For the amplified parts of the spectra the sensitivity was raised by a factor of 2.5 for spectrum (A) and for spectrum (B) by a factor of 2.0 ($\nu < 350\ cm^{-1}$) and 5.0 ($\nu > 350\ cm^{-1}$).

melts of different compositions were recorded at 400°C (Fig. 4). The CsCl–$AlCl_3$ solvent in Fig. 4(A) is basic, allowing for the possible formation of $CsCuCl_2$. In this spectrum, a band at 300 cm^{-1} is observed together with the usual bands from $AlCl_4^-$. In Fig. 4(B), the solvent is acidic. Four bands are still observed due to $AlCl_4^-$, although two bands are slightly shifted towards lower frequencies (125 → 117 cm^{-1} and 182 → 177 cm^{-1}). In addition to the 310 cm^{-1} band of $Al_2Cl_7^-$, two bands at 220 and 422 cm^{-1} are also seen.

CuCl *in basic solvent.* A series of Raman spectra of $KAlCl_4$ solvent melts with $KCuCl_2$ added at formal concentrations between 1.91 and 3.72 showed the same bands as in Fig. 3(C). With increasing additions of $KCuCl_2$ the 285 cm^{-1} band increased relative to the 350 cm^{-1} band. This indicates that the 285 cm^{-1} band is due to a copper chloride vibration.

For the CuCl–CsCl–$AlCl_3$ melts, the 300 cm^{-1} band [in Fig. 4(A)] has the typical Raman position of linear $CuCl_2^-$ ions (known from organic solutions and solid compounds).

Cryoscopy: The formation of copper chloride complexes was further studied by cryoscopy. Figure 5 shows freezing point depression data for a neutral melt of $KAlCl_4$ during the addition of increasing amounts of $KCuCl_2$. Measured temperatures, compositions of the melts and the number of particles formed are listed in Table 2. These cryoscopic data unequivocally show that one particle, foreign to the solvent consisting of K^+ and $AlCl_4^-$, is formed per one added virgin $KCuCl_2$ particle.

The interpretation of this result is that the hypothetical reactions

$$KCuCl_2 \rightarrow K^+ + Cu^+ + 2Cl^- \quad (2)$$

$$KCuCl_2 \rightarrow K^+ + Cl^- + CuCl \quad (3)$$

can be excluded, since they produce three and two particles per $KCuCl_2$ (K^+ is common to the solvent). On the other hand, the reaction

$$KCuCl_2 \rightarrow K^+ + CuCl_2^- \quad (4)$$

is in accordance with the cryoscopic data, as are the series of homologuous reactions

$$\eta KCuCl_2 \rightarrow \eta K^+ + (\eta - 1)Cl^- + Cu_\eta Cl_{\eta+1}^- \quad (5)$$

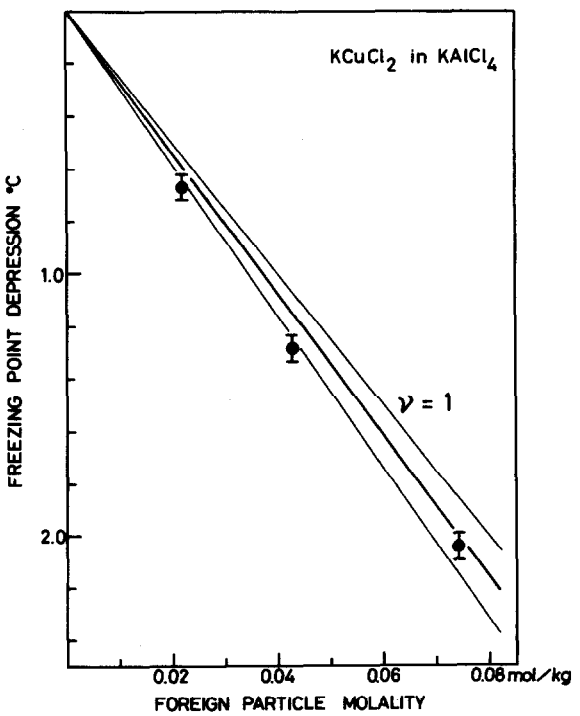

Fig. 5. Freezing point depression of $KCuCl_2$ in molten $KAlCl_4$. The lines show what one particle gives in theory, based on $\lambda = 27 \pm 2$°C kg mol^{-1}.

Table 2. Determination of the cryoscopic effect of $KCuCl_2$ on $KAlCl_4$[a]

Added sum of $KCuCl_2$ (mmol)	Molality, m_{KCuCl_2} (mol kg^{-1})	Observed freezing point, T_f (°C)	Depression, θ (°C)	Particle number, ν[b]
0	0	256.18	0	—
0.6097	0.02194	255.51	0.67	1.13
1.1893	0.04279	254.90	1.28	1.11
2.0571	0.07401	254.14	2.04	1.02

[a] The initial sample consisted of 27.7945 g of $KAlCl_4$, having an $AlCl_3$ mole fraction of 0.4990, calculated from weights.

[b] The particle number ν is defined as $\nu = \theta/\lambda m$, where λ is the cryoscopic constant of the solvent (here 27 ± 2°C kg mol^{-1}) and m is the molality in moles per kg of the solvent.

involving hypothetical ions like $Cu_2Cl_3^-$, $Cu_3Cl_4^-$, ..., $Cu_\eta Cl_{\eta+1}^-$. Such ions are not likely in melts (compare the crystal structure of KCu_2Cl_3).[1]

The common conclusion from the Raman spectra and the cryoscopic data is that copper(I) forms $CuCl_2^-$ in basic to neutral KCl–$AlCl_3$ and CsCl–$AlCl_3$ melts.

CuCl *in neutral solvents.* As mentioned previously, two liquid phases are observed when CuCl is added to neutral KCl–$AlCl_3$ melts (3.7 F CuCl in a melt of the composition $KCl/AlCl_3 = 1:1$) at 500°C. The top phase is colourless and the bottom phase is orange. On cooling the samples, the latter solidifies as the first one (at approximately 420°C). The Raman spectra of the two phases [Fig. 3(B) and (B′)] can be interpreted in the following way: the one band at 250 cm^{-1} observed in the bottom phase [Fig. 3(b)] corresponds in frequency and shape to the band observed by Gilbert *et al.*[11] for pure molten CuCl. Since the melting point and colour are also close to that of CuCl, it seems safe to conclude that the bottom phase mainly consists of CuCl. The Raman spectrum of the top phase [Fig. 3(B′)] only shows bands that can be assigned to $AlCl_4^-$ and $Al_2Cl_7^-$.

CuCl *in acidic solvents.* The Raman spectra of CuCl–KCl–$AlCl_3$ [Fig. 3(A)] and CuCl–CsCl–$AlCl_3$ [Fig. 4(B)] melts both show a polarized band at approximately 220 cm^{-1} in addition to the bands from the aluminum chloride vibrations. The band at 220 cm^{-1} is probably similar to the copper(I) chloride vibration observed in the CuCl–$AlCl_3$ melts, suggesting a non-linear coordination of Cu^I to chloride. In the case of CuCl–CsCl–$AlCl_3$, a band is observed at $\sim$ 422 cm^{-1}. This band can either be due to the $Al_2Cl_7^-$ vibration at 431 cm^{-1} in CsCl–$AlCl_3$ melts or to a splitting of the 493 cm^{-1} ν_3 vibration of $AlCl_4^-$. The latter explanation implies an association between Cu^+ and $AlCl_4^-$ as found for the CuCl–$AlCl_3$ melts.

(*Received* 18 *July* 1988; *accepted* 15 *August* 1988)

Abstract—A potentiometric study showed that aldoses of the *lyxo*-series: D-lyxose, D-mannose and L-rhamnose, form dinuclear anionic complexes with tungstate or molybdate ions in acidic solutions. ^{95}Mo NMR confirmed this result by revealing the presence of two non-equivalent metal atoms in the molybdate complexes. The corresponding formation constants were determined. The D-lyxose complexes had the higher stabilities, and the W^{VI} complexes were more stable than their Mo^{VI} homologues. The ^{13}C NMR spectra were reassigned by means of a 2-D experiment and showed that all three carbohydrates were complexed in pyranose form. The chelating hydroxyl groups were strongly deshielded and displayed increased direct coupling constants $^1J_{CH}$. It can be concluded that the prevailing species in aqueous acidic solution cannot be furanose complexes similar to that characterized in solid state from molybdate–D-lyxose mixtures.

Bilik's discovery[1] of an aldose epimerization reaction catalysed by Mo^{VI} in aqueous acidic solution has renewed the interest in the chemistry of molybdate complexes of sugars, which were not as well known as the related polyol complexes.[2] Although several studies by Weigel *et al.*[3–5] had established the formation of homologous molybdate or tungstate complexes of sugars in the 2:1 ratio, two polarimetric studies[6,7] concluded the existence of 1:1 molybdate–sugar species. However, a subsequent determination[8] of the structure of a crystalline molybdate–lyxose complex revealed a 2:1 stoichiometry, the ligand being complexed in furanose form. In solution, the structures of Mo^{VI}–sugar complexes have been investigated[9,10] by ^1H and ^{13}C NMR. It was suggested that the sugars were in pyranose form and that three hydroxyl groups chelated a metal atom. The ^{13}C spectra of W^{VI}–alditol complexes have been recently reported.[11]

Mechanistic studies[12–14] of the epimerization reaction have considered the above complexes as possible models for the reactive intermediate species. In this respect, further discussion would require the knowledge of the relative stabilities of such compounds. However, literature only afforded data[2,15] for the Mo^{VI} or W^{VI} complexes of two alditols, D-mannitol and D-glucitol. "Pseudo-stability constants" of tungstate carbohydrate complexes have been defined[16] from an electrophoretic study.

We have shown in a preliminary communication[17] that the affinities of polyhydroxy ligands towards tungstate and borate ions could be partially correlated. This paper presents a full report of the first determination of the thermodynamical stabilities of Mo^{VI} and W^{VI} complexes of aldoses. The ^{13}C NMR spectra of the most stable

Scheme 1.

complexes, formed with sugars of the *lyxo*-series (Scheme 1), were reinvestigated in order to precise their structures in aqueous solution. The ^{95}Mo spectra of Mo^{VI}–carbohydrate complexes were also obtained for the first time.

Potentiometric determination of formation constants

Since dinuclear complexes of Mo^{VI} and W^{VI} are generally formed with ligands of the carbohydrate family, the definition of "classical" stability constants appears impossible. As a matter of fact, uncomplexed dinuclear species of these elements do not exist in aqueous solution. Molybdate MoO_4^{2-} and tungstate WO_4^{2-} ions condensate in acidic medium to give heptameric isopolyanions $M_7O_{24}^{6-}$ (M stands for either Mo or W) and numerous other species. Detailed accounts on the composition of acidic solutions of molybdate[18,19] or tungstate[20] have been recently published. Therefore, it has become common practice to define the *formation constant* of a complex represented by (x, y, z) as the equilibrium constant of reaction (1):

$$xMO_4^{2-} + yL + zH^+ \rightleftharpoons (x, y, z)^{(2x-z)-} + nH_2O. \quad (1)$$

Souchay realized first[21] that since equilibrium (1) involved protons, pH measurements could be used to determine the stoichiometric coefficients x, y and z. This method was later developed for the determination of formation constants. Petterson[2] has reviewed and rationalized the large number of investigations on the D-mannitol–molybdate system, and Mikesova and Bartusek[15] have described an application to polyol complexes of Mo^{VI} and W^{VI}. The same principle was used to study the stabilities of carbohydrate complexes, but the procedure was adapted in order to obtain simultaneously their stoichiometries, which had been debated in the literature.

Principle

Let us admit that a unique complex of unknown composition (x, y, z) is formed by reaction (1). The charge of the complex is omitted for clarity. Its formation constant K_{xyz} is defined by relation (2):

$$K_{xyz} = (x, y, z)/(MO_4^{2-})^x(L)^y(H^+)^z. \quad (2)$$

Assuming K_{xyz} value is high, and using an excess of ligand, the addition of protons to a MO_4^{2-}–L mixture will form the complex in an almost quantitative amount. Hence, as observed earlier,[4,22,23] the titrations by a strong acid of molybdate and tungstate in the presence of various polyols and sugars define an equivalence point when exactly one proton per metal ion has been consumed, indicating that $x = z$.

From such titrations, a $pH_{1/2}$ value can be determined at the half-equivalence point. The equilibrium concentrations at this point are easily calculated from mass–balance relations:

$$(MO_4^{2-}) = c_M/2; \quad (x, y, z) = c_M/2x;$$
$$(L) = c_L - y(x, y, z),$$

in which c_M and c_L are the initial concentrations of MO_4^{2-} and L. Since ligand is in excess, generally $(L) \approx c_L$ and relation (2) becomes (3):

$$K_{xyz} = 2^{x-1}/x \cdot c_M^{x-1} \cdot c_L^y \cdot (H^+)_{1/2}^z, \quad (3)$$

which can be written in logarithmic form,

$$\log K_{xyz} = \log(2^{x-1}/x) - (x-1)\log c_M - y \log c_L + z\, pH_{1/2}. \quad (4)$$

EXPERIMENTAL

Materials

Mo^{VI} and W^{VI} stock solutions (0.1 mol l^{-1}) were prepared from disodium salts (Prolabo) and kept in polyethylene bottles. The carbohydrates of the purest analytical grade (Fluka or Aldrich) were used as obtained. The ionic strength of the solutions was kept constant ($I = 0.1$ mol l^{-1}) by the addition of KCl of analytical grade, and the titrations were made with standard HCl solutions (Prolabo Normadose).

Determination of formation constants

pH measurements were made using a Metrohm E 632 pH meter fitted with a combined Metrohm glass electrode. The temperature was maintained at 25°C by means of a water-jacketed cell and a thermostat.

In a typical experiment, a sodium molybdate or tungstate solution ($c_M = 5 \times 10^{-3}$ mol l^{-1}, $v = 100$ cm^3, KCl 0.1 mol l^{-1}) was first half-titrated with 2.50 cm^3 of HCl 0.1 mol l^{-1}. The sugar was then immediately added in solid form (0.5–1 g) to minimize dilution, and the pH was monitored for 15 min until stabilization. The operation was repeated four or five times to give the variations of $pH_{1/2}$ vs $\log c_L$. Then the titration was continued until the overall addition of 10 cm^3 of acid. A first equivalence point was observed at 5.00 ± 0.05 cm^3. In some cases, a second equivalence was found for 7.50 cm^3 of acid. The corresponding pK_a was determined at the half-equivalence point, corresponding to 6.25 cm^3 of acid and did not depend on c_M or c_L.

Some experiments were made using different c_M concentrations, typically 10^{-3} or 5×10^{-2} mol l^{-1}, in order to determine the variations of $pH_{1/2}$ vs $\log c_M$.

Attention was paid to the following points:

(a) The tungstate ions were not allowed to stay in acidic medium in the absence of ligand, because slow and irreversible condensation to inert dodecatungstates would occur.[24a]

(b) The glass electrodes were left in the solutions for the shortest possible time, in order to avoid their degradation by the molybdate or tungstate ions.[24b] Their quality was frequently checked with standard buffer solutions.

(c) We also verified that the use of large amounts of carbohydrates (> 0.1 mol l^{-1}) did not modify the values of the formation constants, as could have been expected from changing the aqueous solvent to water–sugar mixtures. This supposed effect could never be observed and was assumed to be smaller than the experimental errors.

NMR experiments

All 1-D and 2-D NMR spectra were recorded on a Bruker AM 400 spectrometer equipped with a 5 mm multinuclear probe.

Solution samples were prepared by dissolving weighted amounts of the reagents in 0.5 cm^3 of D_2O. The sugar concentration c_L was 1 mol l^{-1} and the metal/ligand ratio was 2.5. The solution was made acidic with concentrated aq. HCl (0.02 cm^3).

The ^{95}Mo spectra were measured at 26.076 MHz using sweep widths of 15,000 Hz and acquisition times of 30 ms. The chemical shifts were determined by the substitution method[25] using a 2 M Na_2MoO_4 solution in D_2O as reference. To reduce the effects of probe ringing on the baseline, left shifts were applied on the free induction decay prior to Fourier transform.

The following parameters were used for the ^{13}C spectra at 100.13 MHz: a sweep width of 8500 Hz, an acquisition time of 1 s and a digital resolution of 0.5 Hz/pt. The relaxation delay was 1 s and the pulse width corresponded to a 90° tip angle. The proton coupled spectra were obtained with nuclear overhauser enhancement by gating off the decoupler during data acquisition. The chemical shifts were referenced to TMS using an external C_6D_6 signal at 128 ppm.

RESULTS

Formation of (2,1,2) *complexes*

As the titration curves show that $x = z$, the x and y values can be obtained from the variations of $pH_{1/2}$ with $\log c_M$ and $\log c_L$, using another expression of relation (4), in which A is a constant term:

$$pH_{1/2} = A + (x - 1/x) \log c_M + (y/x) \log c_L.$$

In all the studied systems, plotting $pH_{1/2}$ vs $\log c_M$ or $\log c_L$ gave straight lines of slope = 0.50 within experimental error. We could conclude then that the stoichiometric coefficients were $x = 2$, $y = 1$ and $z = 2$, defining $(2,1,2)^{2-}$ formulae for the complexes.

The formation constants K_{212} were calculated using relation (5), obtained from relation (4) and the above stoichiometric coefficients:

$$\log K_{212} = 2pH_{1/2} - \log c_M - \log c_L. \qquad (5)$$

Examples of calculations for the three ligands, showing the variations of $pH_{1/2}$ vs $\log c_L$ at fixed c_M, are given in Table 1.

Formation of (2,1,3) *complexes*

A second protonation step occurred in the titrations of all molybdate complexes and was revealed by a second equivalence point when 3/2 protons had been consumed per metal atom. In agreement with other authors,[2,15] it was attributed to the formation of $(2,1,3)^-$ species:

$$(2,1,2)^{2-} + H^+ \rightleftharpoons (2,1,3)^-.$$

In the case of tungstate complexes, such a reaction was also observed in the case of L-rhamnose.

[a] m: Mass of D-lyxose, M = 150.15 g mol^{-1}, in 102.5 cm^3; mass of D-mannose, M = 180.16 g mol^{-1}, in 102.5 cm^3; mass of L-rhamnose hydrate, M = 182.18 g mol^{-1}, in 102.5 cm^3.

[b] Calculated using eq. (5); c_{Mo} or $c_w = 4.88 \times 10^{-3}$ mol l^{-1}.

On the other hand, no further protonation could be observed with D-lyxose and D-mannose.

The corresponding pK_a were determined as usual:

$$K_a = [(2,1,2)^{2-}](H^+)/[(2,1,3)^-].$$

The formation equilibrium of these species were written:

$$2MO_4^{2-} + L + 3H^+ \rightleftharpoons (2,1,3)^- + nH_2O.$$

Their formation constants K_{213} could be calculated as a combination of K_a and of K_{212}: $\log K_{213} = \log K_{212} + pK_a$.

The different formation constants are presented in Table 2.

NMR spectroscopy

The uncomplexed sugars in aqueous solution exist as a mixture of the α- and β-pyranose anomers.

Table 2. Formation constants ($t = 25°C$; $I(KCl) = 0.1$ mol l^{-1}) of molybdate and tungstate complexes of sugars of the *lyxo*-series. $\log K_{xyz}$ refers to the formation of the (x, y, z) species from xMO_4^{2-}, yL and zH^+. K_a is the acidity constant of the (2,1,3) complex

Accuracy: $\log K_{212} \pm 0.06$; $\log K_{213} \pm 0.11$.

Their complexes were formed by adding MoO_4^{2-} or WO_4^{2-} ions and acidifying by HCl. To increase complex formation, a small excess of metal was used (metal/ligand ratio = 2.5).

^{13}C NMR allowed the identification of the complexes in the presence of unbound ligand. Only one complex of D-lyxose was revealed (five new signals) with either Mo or W, and the chemical shifts did not depend on the nature of the metal. On the contrary, D-mannose formed several complexes in unequal ratio (from the comparison of signal intensities). The prevailing one showed a spectrum very similar to those of D-lyxose. The other species are currently under study.

In the case of L-rhamnose, only one tungstate complex could be observed, with the same pattern as those of the homologues described above. In contrast, molybdate formed two complexes in equal ratio, one of them was similar to the unique tungstate species.

The ^1H NMR spectra were determined and agreed closely with those reported[9] by Alfoldi *et al.*, who found that the $^3J_{HH}$ coupling constants had values characteristic of a pyranoid ring. It allowed us to perform a 2-D heteronuclear ^{13}C–^1H correlation experiment which gave the complete assignment of the ^{13}C spectrum of the D-lyxose complex. A comparison with Alfoldi *et al.*'s earlier assignments[10] showed that the C-2 and C-3 signals had been incorrectly attributed. Using the remarkable analogies between the ^{13}C spectra of these three sugars which belong to the same configurational series, the spectra of the complexes of D-mannose and L-rhamnose were readily assigned (Tables 3 and 4).

A ^{95}Mo NMR spectrum was determined for each sugar (Fig. 1) and displayed two characteristic signals for the complexed Mo^{VI} at $\delta = 30 \pm 4$ ppm and $\delta = 42 \pm 1$ ppm by reference to external MoO_4^{2-}. The presence of other complexes in low proportion broadened both signals for the complexes of D-mannose and L-rhamnose and could even give a supplementary signal in the case of L-rhamnose. The treatment of the signals by a Gaussian function before Fourier Transform improved the resolution and permitted us to determine the linewidths: < 90 Hz for D-lyxose, and between 150–180 Hz for D-mannose and L-rhamnose. Such differences between the sugars agree with the expected increase of the linewidths with the molecular radii. The sharpness of the signals nevertheless indicated that Mo^{VI} was situated in a relatively symmetrical environment. Moreover, both signals were always of identical intensities, showing that they must be assigned to two non-equivalent Mo atoms present in the dinuclear complexes.

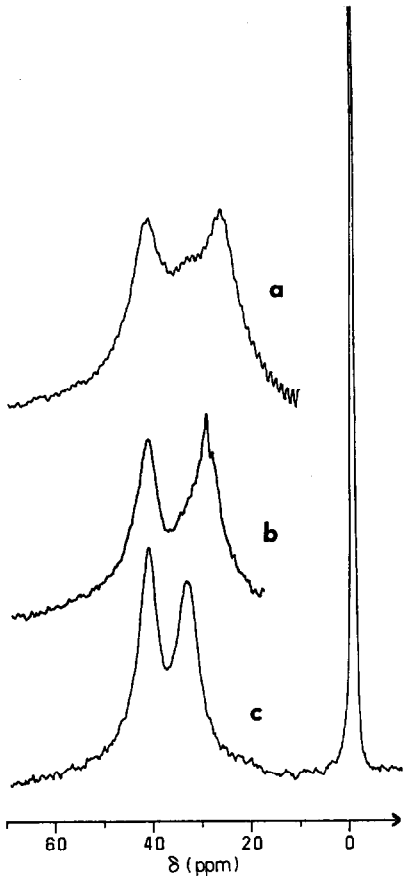

Fig. 1. 26.076 MHz ^{95}Mo NMR spectra of solutions of sodium molybdate (2.5 mol l^{-1}) and aldoses (1 mol l^{-1}) of the *lyxo*-series at pH ≈ 5. t = 20°C. (a) L-rhamnose; (b) D-mannose; (c) D-lyxose. The signal at $\delta = 0$ ppm is due to uncomplexed MoO_4^{2-} ions.

DISCUSSION

Structures of the complexes

The results of the potentiometric study prove without doubt that the complexes involve dinuclear species of Mo^{VI} and W^{VI} combined with one molecule of sugar. Although the measurements were made using a large excess of ligand, we did not detect the presence of 1 : 1 complexes, as had been claimed[6,7] in earlier reports. It is confirmed by the ^{95}Mo NMR study which clearly revealed the presence of two non-equivalent Mo atoms in the complexes of the three studied ligands.

The striking similarity of all the ^{13}C NMR spectra indicates that the three ligands have closely related structures in their Mo and W complexes. This method allows the identification of the carbons bearing the bonding hydroxyls, which appear strongly deshielded[10,11] and show increased values of their direct coupling constant $^1J_{CH}$.

Acyclic structures of the ligands were excluded, since no ^{13}C signals for terminal CHO groups were observed in the 150–200 ppm region.

α- or β-furanoses α-pyranose β-pyranose

Fig. 2. Haworth's formulae of the cyclic forms of D-lyxose.

In the case of D-lyxose, the pyranose or furanose nature of the cyclic form adopted by the ligand was deduced by remarking that the signal of the C-5 methylene carbon was little affected by complexation (Table 3). It contrasted with the behaviour of all other methine carbons, which were deshielded and displayed increased direct coupling constants. Thus the metal ion was bound to the four vicinal hydroxyls borne by C-1 to C-4, and not to the C-5 one. Since the carbon which bears no hydroxyl is C-5 in pyranose form and C-4 in furanose form (Fig. 2), it is obvious that D-lyxose is not complexed in furanose form.

It is difficult to decide whether the α- or β-pyranose form is involved in the complexes because the spectra of both uncomplexed pyranoses are very similar, which leads to almost equal chemical shift variations in both hypotheses. We favour the β-form on the basis of structural considerations, since the C-1 and C-2 hydroxyls are in *trans*-orientation in the α-form (Fig. 2). In this hypothesis, complexation has a deshielding effect of ≈ 10–15 ppm on the carbons C-2 to C-4 which bear bound hydroxyl groups. A larger effect, 17–18 ppm, is observed on C-1 which bear the anomeric OH group. The difference observed between C-1 and C-2, compared to the almost equal effect on C-3 and C-4 (which are in *trans*-orientation) suggests that C-1 and C-2 are orientated *cis*. This is another argument in favour of a β-pyranose structure of the ligands.

A final conclusion is that the dinuclear metallic core is chelated in an assymetric fashion by four OH groups of the ligand. This result disagrees with earlier interpretations[9,10] in which the ligand was assumed to be tridentate. A tentative assignment of the ^{95}Mo NMR signals was made by remarking that the 42 ppm signal did not depend on the sugar nature. Since the three sugars have identical configurations at C-1 to C-4, but differ at C-5, this signal was likely due to an Mo atom coordinated to C-1 and neighbouring hydroxyl groups. The more shielded signal at ≈ 30 ppm shifted by changing the sugar and should then be attributed to the Mo atom bound to C-4 and neighbouring hydroxyl groups.

Stabilities of the complexes

It was surprising to find that the tungstate complexes were nearly three orders of magnitude more stable than their molybdate homologues (Table 2), whereas both elements generally form complexes of similar stabilities.[28,29] The same finding was nevertheless reported[15] in the case of alditol complexes, indicating that the phenomenon could be specific for polyhydroxy ligands. However, we think that it does not necessarily implicate a particular affinity of tungstate towards this type of ligand, but can be a consequence of the dinuclear nature of the complexes. It is well known[20] that tungstate forms polyanions more easily then molybdate, and since the formation constants include a term due to the dimerization of the MO_4^{2-} ions, it is likely that the values calculated for W^{VI} might be higher than those relative to Mo^{VI}.

Accordingly, the differences between the $\log K_{212}$ values determined for W^{VI} and Mo^{VI} appear to be almost independent of the nature of the sugar, which is a strong indication that they may be due to intrinsic properties of the inorganic elements.

Considering now the ligands, the fact that D-lyxose and D-mannose form complexes of higher stabilities than those of all other known aldoses[17] and that they possess similar pyranose structures must be related to their belonging to the same configurational series, if carbons C-1 to C-4 are considered. It is another proof that complexation does not involve the CH_2OH groups of the ligands.

Since the stability order of tungstate complexes of pentoses has been shown[17] to be: D-lyxose > D-ribose > D-arabinose > D-xylose, and that the same order seems to hold for molybdate[9] complexes, it appears that a C-2, C-3 diol group of *erythro*-configuration is a much more favourable site for complexation than a *threo*-diol group. A related observation was made[17] in the alditol series, in which erythritol formed more stable W^{VI} complexes than DL-threitol.

On the other hand, the presence of the supplementary C-6 hydroxyl group in D-mannose does not seem to be favourable to complexation, since the D-lyxose complexes are the most stable. Yet, the even lower stabilities of the L-rhamnose complexes suggest that two opposite effects operate: an unfavourable steric hindrance of the C-5 substituent and a favourable influence of a hydroxyl group borne by C-6.

In conclusion, our results support dinuclear structures like those proposed long ago[5] by Angus, Bourne and Weigel for alditol complexes, which were recently confirmed.[11] Nevertheless, since the pyranose cycles are more rigid than the acyclic alditols, an adequate configuration of the four chelating hydroxyls (*lyxo* or *ribo*) is compulsory to accommodate the metallic core. Another possible model is given by the well-characterized bis(oxalate)–

dimolybdate complex[30] which can be written:

$[(C_2O_4)(H_2O)MoO_2—O—MoO_2(C_2O_4)(H_2O)]^{2-}$.

Because each Mo atom is chelated by a separate oxalate ligand, there is no steric strain in the compound and the Mo—O—Mo bridge was found[30] to be linear. However, in the carbohydrate complexes, the four chelating OH groups must be borne by the same molecule. Thus, in order to shorten the Mo—Mo distance, the metal ion may adopt a bent Mo—O—Mo bridged structure, and also form additional oxygen bridges. As a matter of fact, the dimolybdate–lyxose complex[8] characterized in the solid state was found to possess three Mo—O—Mo bridges, and a similar structure was later reported[31] for (bis)*ortho*quinone–dimolybdate complexes. It is clear however that since the aldoses studied in this paper were demonstrated to adopt the pyranose form in their complexes, furanose compounds analogous to that described by Taylor and Waters[8] could not be the prevailing species in aqueous acidic solution.

Abstract—The migratory insertion of organic isocyanides into the metal–carbon bonds of a series of tri-alkyls, $Ta(OAr)_2R_3$ (OAr = 2,6-dimethylphenoxide; R = CH_3, CH_2Ph), has been examined. Addition of 2,6-dimethylphenyl- or 2,6-di-isopropylphenylisocyanide (Ar′NC $\geqslant$ 2 equivalents) results in the essentially quantitative formation of the bis-insertion products, $Ta(OAr)_2(\eta^2\text{-}Ar'NCR)_2R$ (**1**). Spectroscopic as well as structural data are consistent with both iminoacyls being η^2-bound to the metal centre. In contrast, addition of *tert*-butylisocyanide to the tris-aryl $Ta(OAr)_2Ph_3$ proceeds to produce a mixed η^2-imine, η^2-iminoacyl compound $Ta(OAr)_2(\eta^2\text{-}Bu^tNCPh_2)(\eta^2\text{-}Bu^tNCPh)$ (**2**). This compound is presumably formed by a second phenyl group migration taking place in an intermediate of type (**1**). All of these compounds exhibit thermal instability to varying degrees. The methyl compound $Ta(OAr)_2(\eta^2\text{-}Ar'NCMe)_2(Me)$ rearranges over days at 25°C to produce a mixed amido, imido complex $Ta(OAr)_2(Ar'NCMe{=}CMe_2)(NAr')$ (**3a**). This is believed to be formed by intramolecular coupling and fragmentation in an intermediate, $Ta(OAr)_2(\eta^2\text{-}Ar'NCMe_2)(\eta^2\text{-}Ar'NCMe)$ of type (**2**). Support for this hypothesis comes from thermolysis of (**2**) to produce $Ta(OAr)_2(Bu^tNCPh{=}CPh_2)(NBu^t)$ (**3b**) which has been structurally characterized. The benzyl derivatives $Ta(OAr)_2(\eta^2\text{-}Ar'NCCH_2Ph)_2(CH_2Ph)$ also thermally produce mixed imido, amido compounds, only this time more dramatic fragmentation occurs to produce $Ta(OAr)_2(Ar'NCH_2CH_2Ph)(NAr')$ (**4**) and an organic fragment, $PhCH_2C{\equiv}CPh$. Structural studies confirmed this formulation. Mechanistic aspects of the reactivity of these η^2-iminoacyl and η^2-imine functionalities are discussed. Crystal data for $TaC_{48}H_{61}N_2O_2$ (**3b**) at −158°C are $a = 21.806(5)$, $b = 19.568(6)$, $c = 10.078(2)$ Å, $\beta = 90.63(1)°$, $Z = 4$, $d_{calc} = 1.358$ g cm^{-3}, in space group $P2_1/n$. Of the 5642 unique intensities collected with Mo-K_α, the 4790 with $F > 2.33\sigma(F)$ were used in the least-squares refinement to yield $R = 0.0419$, $R_w = 0.0439$. Crystal data for $TaC_{44}H_{51}N_2O_2$ (**4**) at −155°C are $a = 12.423(5)$, $b = 20.772(10)$, $c = 14.840(6)$ Å, $\beta = 93.27(2)°$, $Z = 4$, $d_{calc} = 1.426$ g cm^{-3} in space group $P2_1/n$. Of the 5004 unique intensities collected with Mo-K_α, the 3209 with $F_o > 3.00\ \sigma(F)$ were used in the least-squares refinement to yield $R = 0.0574$, $R_w = 0.0498$.

The migratory insertion of carbon monoxide into transition metal alkyl bonds is an important reaction which has deservedly received considerable resarch interest.[1–3] In the case of the high valent early *d*-block, lanthanide and actinide metals, the resulting acyl group is found exclusively to adopt an η^2-bound mode and exhibit a diverse range of reactivity.[4–8] A particularly characteristic reaction involves either the inter- or intramolecular coupling of these groups to produce *cis* and *trans* ene–diolate

*Author to whom correspondence should be addressed.

linkages.[7,8] The intramolecular version of this carbon–carbon double bond forming reaction has received mechanistic/theoretical treatment.[9] In the case of the isoelectronic η^2-iminoacyl group formed by the migratory insertion of organic isocyanides into metal–alkyl bonds,[10] we have demonstrated related reactivity.[10–12] Hence, intramolecular coupling to produce ene–diamide ligands has been observed, as well as the cross-coupling of acyls and iminoacyls to produce enamidolates.[11,12] Reactivity studies have indicated that acyl groups undergo these carbon–carbon bond forming reactions much faster than their nitrogen analogues.[13]

However, another important carbon–carbon bond forming reaction of η^2-acyls involves their further reduction by metal–alkyl bonds. Hence, there are numerous reports of ketone formation (either liberated or metal-bound) during carbonylation of early metal alkyls.[14,15] This pathway is a crucial step in the metal mediated reduction of CO, and in the case of metal–hydrides this type of reactivity (both inter- and intramolecular) has been extensively studied.[4–6,16] In the case of η^2-iminoacyls, the formation of imines has recently been documented[17] as well as further reduction to produce amido ligands.[18] During our studies of the reactivity of aryloxide supported metal–η^2-iminoacyl groups we have also observed facile η^2-imine formation under certain conditions.[17] In this paper we wish to report the formation and characterization of a series of tantalum η^2-imine complexes and their ensuing reactivity.

RESULTS AND DISCUSSION

Synthesis of η^2-imine and η^2-iminoacyl compounds

The reaction of the tris-alkyl compounds $Ta(OAr)_2R_3$ (OAr = 2,6-dimethylphenoxide, R = CH_3, CH_2Ph, Ph) with two or more equivalents of 2,6-dimethyl- or 2,6-di-isopropylphenylisocyanide results in the formation of the corresponding bis(η^2-iminoacyl) compounds (**1**) (Scheme 1). Attempts to insert a further equivalent of isocyanide proved fruitless. The solid state structure of (**1a**) has been reported previously.[10] The iminoacyl groups are seen to be both η^2-bound to the tantalum atom, and arranged so as to occupy four equatorial sites in a pentagonal bipyramidal coordination sphere. The carbon atoms of the iminoacyls are mutually *cis* with a C—Ta—C angle of 111.8(2)°. The spectroscopic data for all of the bis(η^2-iminoacyl) compounds (**1**) is entirely consistent with their adopting the same geometry in solution.[10] Especially characteristic is the chemical shift for the iminoacyl carbons at δ 245–260 ppm in the ^{13}C NMR spectrum. The observed arrangements of the two iminoacyl groups in compounds of type (**1**) is exactly the conformation one might initially expect prior to intramolecular coupling to produce an ene–diamido ligand. However, although all of these bis(η^2-iminoacyls) exhibit thermal reactivity to various degrees (*vide infra*) we have as yet to detect any ene–diamide derivative formed by their thermolysis. This contrasts with the clean (albeit high temperature) intramolecular coupling observed for $Ta(OAr)_3(\eta^2\text{-}ArNCCH_2Ph)_2$ to produce $Ta(OAr)_3[ArNC(CH_2Ph){=}C(CH_2Ph)NAr]$.[11,12] Theoretical studies of this coupling reaction at Group 4 metals as well as on the related intramolecular coupling of η^2-acyl groups at Cp^*_2M (M = Th, U) centres indicate that a concerted, in-plane formation of the carbon–carbon double bond is a symmetry disallowed, high energy pathway.[9,13,19] In the case of the bis(η^2-iminoacyl) compounds that contain only aryloxide ligation, it appears that there are no alternate reaction pathways besides ene-diamide formation. However, for mixed alkyl, η^2-iminoacyls, thermal reactivity proceeds via a more facile reaction sequence (*vide infra*).

Ar′ = 2,6-di-isopropylphenyl

Scheme 1.

The addition of *tert*-butylisocyanide to the triphenyl compound $Ta(OAr)_2Ph_3$ results in the rapid formation of a different type of derivative (**2**) (Scheme 2) in high yield. Spectroscopic data for (**2**) are consistent with it containing both an η^2-iminoacyl group as well as an η^2-imine function. This latter function results from a double alkyl migration to an organic isocyanide molecule, presumably via an intermediate η^2-iminoacyl of type (**1**).[17] However, attempts to spectroscopically (^1H NMR) detect an intermediate of type (**1**) in this reaction failed. The mild, pyridine induced formation of an η^2-imine compound from a mixed alkyl, η^2-iminoacyl compound has previously been demonstrated at Ti^{IV} aryloxide metal centres.[17] The two different types of metal-bound tertiary carbon atoms are clearly evident in the ^{13}C NMR spectrum of (**2**), appearing at δ 247.8 (η^2-Bu^t*N*CPh) and δ 78.8 ppm (η^2-Bu^{t}B*N*CPh_2). This latter value is in close proximity to those reported for other η^2-imine ligands

attached to Ta^{V}[20] and related d^0-metal centres.[21] A significant separation of the two types of N*Bu*^{t} groups is also observed in the ^{1}H NMR spectra, δ 0.78 and 1.50 ppm.

Thermal reactivity

Both types of compounds (**1**) and (**2**) exhibit thermal instability to varying degrees. In the case of the methyl derivative (**1a**), the compound will convert over days at 25°C in hydrocarbon solvents into a new tantalum compound (**3a**). The reaction can be readily monitored by ^{1}H NMR and spectra indicate that the conversion of (**1a**) to (**3a**) is essentially quantitative with no detectable intermediates. The spectroscopic data on (**3a**) is consistent with its formulation as a mixed imido, amido compound $Ta(OAr)_2(=NAr)(ArNCMe{=}CMe_2)$ as shown (Scheme 3). Specifically the ^{1}H NMR spectrum clearly shows the three non-equivalent methyl groups of the vinyl–amido function ($ArNCMe{=}CMe_2$) as well as the non-equivalent N-xylyl methyl resonances. We believe that (**3a**) is formed via initial formation of a very reactive η^2-imine, η^2-iminoacyl intermediate of type (**2**). This idea has excellent support by the product obtained on thermolysis of the isolated η^2-imine derivative (**2**). Mild thermolysis in toluene or benzene solution leads to an analogous product (**3b**), containing a triphenyl substituted vinyl linkage (Scheme 4). A plausible pathway for the reaction involves initial coupling of the η^2-imine and η^2-iminoacyl groups followed by fragmentation as shown (Scheme 5). The formulation of (**3b**) was confirmed by a single crystal X-ray diffraction study (Fig. 1). Table 1 contains some selected bond distances and angles for (**3b**). The molecular structure of (**3b**) (Fig. 1) can be seen to consist of an approximately tetrahedral arrangement of two oxygen and two nitrogen atoms around the tantalum metal centre. The aryloxide coordination, with relatively short Ta—O distances and large Ta—O—Ar angles, is unexceptional for this group bound to d^0-metal centres.[2] The Ta—NBu^t distance of 1.766(13) Å is comparable to those found for other tantalum(V) organoimido compounds as is the expected, almost linear, Ta—N—Bu^t angle of 170°.[23–25] The coordination properties of the vinyl, alkyl amido group,

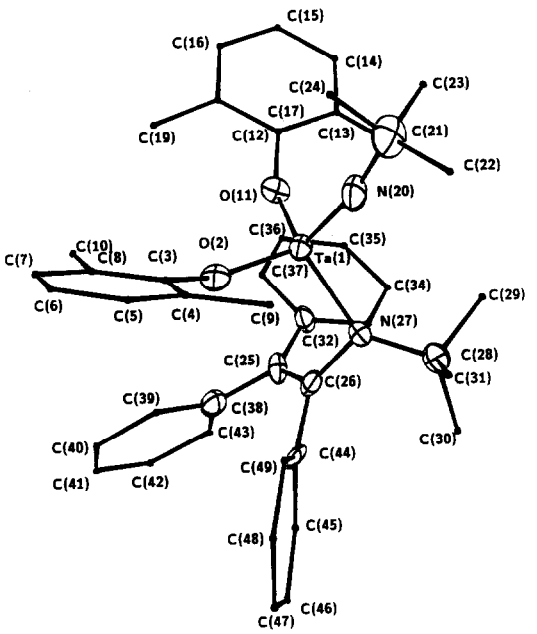

Fig. 1. ORTEP view of $Ta(OAr)_2(=NBu^t)(Bu^tNCPh{=}CPh_2)$ (**3b**) emphasizing the central coordination sphere.

$Bu^tNCPh{=}CPh_2$ is worthy of some comment. The Ta—N(27) distance of 1.996(11) Å is longer than the distance to the imido group by ~0.23 Å. This difference correlates well with the contraction of (0.2–0.3 Å) typically found on going from tantalum(V) bound alkyl to alkylidene functional groups.[26] The amido group coordination is distorted slightly as evidenced by the asymmetric Ta—N—C angles of 104.2(8) and 133.1(9)°. The opening up of the angle to the Bu^t group probably reflects the influence of steric pressures. A similar distortion is seen in another asymmetric amido ligand below. The C—C distance in the vinyl substituent attached to nitrogen is consistent with the presence of a double bond. However, the olefinic environment is twisted leading to a torsion angle of ≃20° between the NC(26)Ph and PhC(25)Ph planes. This twisting is presumably due to the steric pressure of the three phenyl substituents.

In contrast to this behaviour of the methyl and phenyl compounds, the benzyl derivatives (**1b**) and (**1e**) appear to be thermally more robust. However, on extended thermolysis in hydrocarbon solvents, they undergo conversion to a mixture of products, one organic, the other a new type of tantalum compound (**4a**) and (**4b**). Analysis of the organic product by ^1H NMR, GC–MS and IR spectroscopy identified the material as benzyl, phenyl acetylene, $PhCH_2C{\equiv}CPh$. The organometallic products (**4**) were identified as mixed imido, amido derivatives (Scheme 6), only this time the amido group contains a phenethyl (NCH_2CH_2Ph) side chain. This linkage is clearly visible in the ^1H NMR, appearing as a distinctive pair of multiplets separated by over 1 ppm (Experimental). A solid state structural study of (**4b**) confirmed this formulation (Fig. 2) and Table 2 contains some selected bond distances and angles. The molecular structure of (**4b**) can be seen

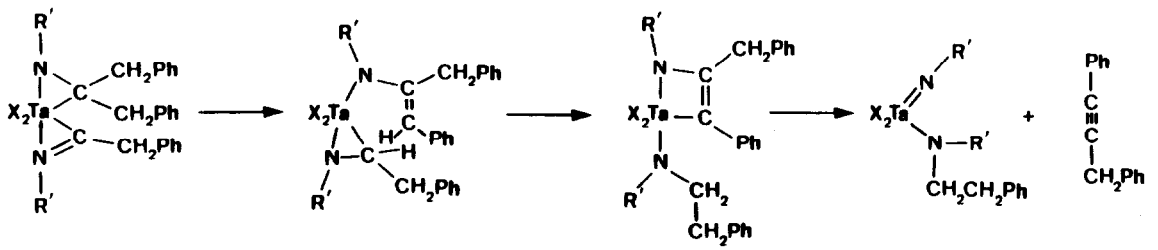
to be closely related to that of (**3b**) discussed above. The Ta—O and Ta—N distances are essentially identical between the two structures. Again a distortion of the amido ligand takes place, increasing the Ta—N-xylyl angle to 135.3(5)° compared to 110.5(5)° for the less bulky Ta—N—CH_2CH_2Ph side. The formation of (**4**) and benzyl, phenyl acetylene from (**1b**) could be rationalized using a number of different, equally contorted pathways. However, we feel that the initial step of the reaction involves thermal formation of a mixed η^2-imine, η^2-iminoacyl intermediate of type (**2**). Why this does not then undergo intramolecular coupling and fragmentation to produce vinyl amido compounds similar to those formed with methyl and phenyl derivatives is unclear. A steric rationalization seems unjustified in view of the fact that benzyl groups lie sterically between CH_3 and C_6H_5. A pathway which we favour is a sequential metallation of the α-benzyl carbon of the η^2-imine linkage, with the transfer of the hydrogen atoms to the η^2-iminoacyl to generate the $ArNCH_2CH_2Ph$ group (Scheme 7). The η^2-imine group is converted by this process to an azametallocyclobutene ring, which on elimination of the observed acetylene leaves behind the Ta=NAr, imido linkage.

These reactions, involving overall cleavage of organic isocyanides to form organoimido functions, have precedence in the reaction of WMe_6 with Bu′NC reported by Wilkinson *et al.*[21] as well as in a number of reactions involving the carbonylation of early transition metal poly-alkyl compounds.[27,28] In the latter cases, overall cleavage of CO is observed to generate oxo ligands at Ta^V and Zr^{IV} as well as trialkylvinyloxy groups. It, therefore, seems reasonable that similar pathways are operational for the reaction of both RNC and CO with these alkyl substrates. However, as with the formation of enediolates and enediamides, the organic isocyanide reactions proceed considerably slower than for their oxygen counterparts.

EXPERIMENTAL

All operations were carried out under a dry nitrogen atmosphere either in a Vacuum Atmospheres dri-lab, or by standard Schlenck techniques. Hydrocarbon solvents were dried by distillation from



Scheme 7.

sodium benzophenone under a nitrogen atmosphere. The preparation and spectroscopic properties of the compounds $Ta(OAr)_3Cl_2$,[29] $Ta(OAr)_2R_3$ (R = CH_3, CH_2Ph),[30] and $Ta(OAr)_2(\eta^2\text{-}R'NCR)_2R$ (R′ = 2,6-dimethylphenyl; 2,6-diisopropylphenyl; R = CH_3, CH_2Ph) have been previously reported.[10] ^1H and ^{13}C NMR spectra were obtained using a Varian Associates XL-200 spectrometer, while microanalytical data were obtained either at Purdue or from Galbraith.

Preparation of $Ta(OAr)_2Ph_3$

To an orange solution of $Ta(OAr)_3Cl_2$ (1.0 g, 1.63 mmol) in benzene (50 cm^3) was added slowly LiC_6H_5 (0.55 g, 6.5 mmol) with constant vigorous stirring at room temperature. The colour of the mixture lightened during the addition, progressing through pale yellow to almost colourless. After being allowed to stir for 3 h the suspension was filtered to remove LiCl and a little insoluble dark material. The clear filtrate was evaporated *in vacuo* to give the crude product as a grey–white solid which was washed with hexane. Recrystallization from toluene–hexane gave the pure product as pale yellow blocks. Yield = 40%. Found: C, 68.1; H, 5.6. $TaC_{44}H_{33}O_2$ requires: C, 68.2; H, 4.3%. ^1H NMR (C_6D_6, 30°C): δ 1.85 (s, OAr—2,6Me_2); 8.03 (m, *ortho* Ta—C_6H_5); 6.8–7.5 (m, other aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 18.6 (OAr—2,6Me_2), 200.2 (Ta—C_6H_5, *ipso* carbon).

$Ta(OAr_2)(\eta^2\text{-}Ar'NCPh)_2(Ph)$ (**1c**)

To a solution of $Ta(OAr)_2Ph_3$ (0.44 g, 0.67 mmol) in benzene (25 cm^3) xylylisocyanide (0.18 g, 1.4 mmol) was added slowly. The resulting clear solution was stirred for 1 h before the solvent was removed *in vacuo*. The resulting slightly tacky solid was washed with hexane and then taken up in the minimum amount of toluene. Slow cooling gave the product as colourless crystals. Yield = 70%. Found: C, 68.3; H, 6.1; N, 3.2. $TaC_{52}H_{51}N_2O_2$ requires: C, 68.1; H, 5.6; N, 3.1%. ^1H NMR (C_6D_6, 30°C): δ 2.06 (s, NAr—2,6Me_2), 2.42 (s, OAr—2,6Me_2); 8.35 (d, NCC_6H_5); 9.00 (d, Ta—C_6H_5), 6.9–7.4 (m, other aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 182.9 (Ta—C_6H_5, *ipso* carbon), 231.5 (η^2-N*C*).

$Ta(OAr)_2(\eta^2\text{-}Bu^tNCPh_2)(\eta^2\text{-}Bu^tNCPh)$ (**2**)

To a solution of $Ta(OAr)_2(Ph)_3$ (1.0 g, 1.53 mmol) in benzene (25 cm^3) was added Bu^tNC (0.28 g, 3.30 mmol). The mixture was allowed to stand for 1 h before the solvent was removed *in vacuo* to yield a red solid. The product proved difficult to purify, being very soluble in all hydrocarbon solvents. Yield = 78%. Found: C, 63.9; H, 6.7; N, 2.9. $TaC_{42}H_{51}N_2O_2$ requires: C, 63.1; H, 6.4; N, 3.5%. ^1H NMR (C_6D_6, 30°C): δ 2.21 (s, OAr—2,6Me_2), 0.78 (s), 1.50 (s, NBu^t), 6.9–7.9 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 247.8 (η^2-Bu^tNCPh), 78.8 (η^2-Bu^tNCPh_2), 18.2 (OAr—2,6Me_2), 29.9, 33.3 (NCMe_3).

$Ta(OAr)_2(=NAr)(ArNCMe{=}CMe_2)$ (**3a**)

A toluene solution of $Ta(OAr)_2(\eta^2\text{-}Ar'NCMe)_2(Me)$ (**1a**) was allowed to stand at room temperature for 10 days. The initially pale yellow solution slowly turned purple. Monitoring the reaction by ^1H NMR showed the smooth conversion of (**1a**) to (**3a**). The resulting solution was concentrated and hexane added to yield the product as dark crystals. The purple colour associated with this product is a mystery. On heating for a short time at $\approx$100°C in toluene the solution turned to a clear yellow with no changes whatsoever in the ^1H NMR spectrum. The purple colour is believed by us to be due to trace amounts of a highly coloured impurity possibly formed by polymerization of trace amounts of ArNC. Yield = (typically) 70–80%. Found: C, 60.9; H, 6.5; N, 3.8. $TaC_{37}H_{45}O_2N_2$ requires: C, 60.8; H, 6.2; N, 3.8%. ^1H NMR (C_6D_6, 30°C): δ 3.45 (s, NCMe=CMe_2), 1.46, 1.61 (s, NCMe=CMe_2), 2.14, 2.21 (s, NAr—2,6Me_2), 2.30 (s, OAr—2,6Me_2), 6.8–7.2 (m, aromatics).

$Ta(OAr)_2(=NBu^t)(Bu^tNCPh{=}CPh_2)$ (**3b**)

A solution of the mixed imine, iminoacyl (**2**) in toluene was heated at 105°C in a sealed tube for 30 min. The initially red–orange solution turned yellow during this time. Removal of solvent and recrystallization form toluene–hexane gave pale crystals of the product. Yield = 45%. Found: C, 64.4; H, 6.3; N, 3.4. $TaC_{42}H_{51}N_2O_2$ requires: C, 63.3; H, 6.4; N, 3.5%. ^1H NMR (C_6D_6, 30°C): δ 1.08 (s), 1.58 (s, NBu^t), 2.32 (s, OAr—2,6Me_2), 6.8–7.8 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 18.1 (OAr—2,6Me_2), 33.2, 34.0 (NCMe_3), 60.2, 67.4 (N*C*Me$_3$).

$Ta(OAr)_2(=NAr)(ArNCH_2CH_2Ph)$ (**4a**)

A solution of $Ta(OAr)_2(\eta^2\text{-}ArNCH_2Ph)_2(CH_2Ph)$ in toluene was heated at 110°C for 1 h. Removal of solvent gave a yellow oil whose ^1H NMR showed a mixture of (**4a**) and PhC≡CCH_2Ph (^1H NMR in C_6D_6, δ 3.15, singlet due to CCH_2Ph).

Taking the mixture up in hexane and cooling gave the organometallic product (**4a**) as pale yellow crystals on cooling. Yield = 38%. Found: C, 62.1; H, 5.8; N, 3.6. $TaC_{40}H_{45}N_2O_2$ requires: C, 62.7; H, 5.9; N, 3.6%. ^1H NMR (C_6D_6, 30°C): δ 2.43 (s, OAr—2,6Me_2), 2.40 (s), 2.62 (s, NAr—2,6Me_2), 4.71 (m, N$CH_2$$CH_2$Ph), 3.37 (m, NCH$_2$$CH_2$Ph), 6.5–7.5 (m, aromatics).

$Ta(OAr)_2(=NAr')(Ar'NCH_2CH_2Ph)$ (**4b**)

Prepared essentially in an identical fashion to (**4a**) only using $Ta(OAr)_2(\eta^2$-Ar—$NCH_2Ph)_2(CH_2Ph)$ (**1e**) as the thermolysis substrate. Yield = 28%. Found: C, 66.0; H, 6.8; N, 2.9. $TaC_{48}H_{61}N_2O_2$ requires: C, 65.6; H, 7.0; N, 3.2%. ^1H NMR (C_6D_6, 30°C): δ 2.33 (s, OAr—2,6Me_2), 0.99 (d), 1.13 (d, NAr'—2,6CHMe_2), 4.47 (m, NCH_2 CH_2Ph), 3.23 (m, NCH$_2$$CH_2$Ph), 6.8–7.3 (m, aromatics).

CRYSTALLOGRAPHIC STUDIES

Data pertinent to the crystallographic studies are contained in Table 3.

$Ta(OAr)_2(=NBu')(Bu'NCPh=CPh_2)$ (**3b**)

A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the Indiana University Molecular Structure Center[31] and cooled to −155°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$. Subsequent solution and refinement of the structure confirmed this choice.

Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. Data

[a] Crystal dimensions were: Face = 1 0 −1 d = 0.0450 mm. Face = −1 0 1 d = 0.0450 mm. Face = 0 1 0 d = 0.0260 mm. Face = 0 −1 0 d = 0.0260 mm. Face = −2 1 −2 d = 0.0400 mm. Face = 2 −1 2 d = 0.0400 mm.

were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of Patterson and Fourier techniques. The positions of all hydrogen atoms were clearly visible in a difference Fourier phased on the non-hydrogen atoms, and the coordinates and isotropic thermal parameters for hydrogens were varied in the final cycles of refinement.

Data were corrected for absorption for the final cycles of least squares. A final difference Fourier was essentially featureless, with the largest peak being 0.63e A^{-3}.

$Ta(OAr)_2(=NAr')(Ar'NCH_2CH_2Ph)$ (**4b**)

A suitable crystal was located and transferred to the goniostat and cooled to $-158°C$ for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with monoclinic symmetry and systematic absences corresponding to the unique space group $P2_1/n$ (alternate setting of $P2_1/c$). Subsequent solution and refinement of the structure confirmed this choice. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques, and refined by full-matrix least-squares. Hydrogen atoms were visible in a Fourier phased on the non-hydrogen parameters and were included in the final cycles. Non-hydrogen atoms were assigned anisotropic thermal parameters while hydrogens were allowed to vary isotropically.

A final difference Fourier was essentially featureless, with the largest peak being 0.50e A^{-3}. No absorption correction was performed, with psi scans for two peaks near chi = 90^0 being nearly flat.

TUNGSTEN(II) ALKYNE COMPLEXES CONTAINING MONODENTATE NEUTRAL OXYGEN AND SULPHUR DONOR LIGANDS

PAUL K. BAKER* and ELAINE M. ARMSTRONG

Department of Chemistry, University College of North Wales, Bangor, Gwynedd LL57 2UW, Wales, U.K.

(*Received* 11 *August* 1988; *accepted* 25 *August* 1988)

Abstract—The compounds $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) react with one equivalent of L (L = $OC(NH_2)_2$ or $SC(NH_2)Me$) at room temperature (for R = Me, L = $OC(NH_2)_2$ in acetone–methanol; R = Me, L = $SC(NH_2)Me$ in methanol; R = Ph, L = $OC(NH_2)_2$, $SC(NH_2)Me$ in acetone) to give good yields of the acetonitrile substituted products $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$. ^{13}C NMR spectroscopy indicates that the alkyne ligands in these complexes are donating a total of six electrons to the metal. Reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with one equivalent of L [L = $SC(NH_2)_2$ (tu) and $SC(NMe_2)_2$ (tmtu)] in acetone at various temperatures gave a mixture of products. However, reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with two equivalents of L (L = tu or tmtu) in acetone at room temperature gave the monobut-2-yne products $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$, whereas reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with two equivalents of tu in dichloromethane–methanol gave the non-carbonyl containing bisdiphenylacetylene complex $[WI_2(tu)_2(\eta^2\text{-}PhC_2Ph)_2]$. Reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with two equivalents of tmtu in acetone eventually gave the unusual iodide-bridged dimer $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2 \cdot$ tmtu. ^{13}C NMR spectroscopy suggests that the alkyne ligands in $[WI_2(tu)_2(\eta^2\text{-}PhC_2Ph)_2]$ are donating six electrons to the metal and each alkyne in the dimer $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2$ is donating four electrons to the tungsten.

Although there are a wide variety of alkyne complexes known containing anionic sulphur donor ligands of molybdenum(II) and tungsten(II), in particular complexes of the type $[M(CO)(\eta^2\text{-}RC_2R')(S_2CNR_2'')_2]$ and $[M(\eta^2\text{-}RC_2R')_2(S_2CNR_2'')_2]$ (M = Mo or W; R, R' = H, alkyl, aryl etc.; R'' = Me, Et, ^{i}Pr etc.),[1] to date there have been no alkyne complexes of molybdenum(II) and tungsten(II) containing monodentate neutral oxygen or sulphur donor ligands.

Since the discovery of $[WI_2(CO)_2L(\eta^2\text{-}PhC_2H)]$ (L = PMe_3 or $AsMe_3$) by Umland and Vahrenkamp[2] and $[WBr_2(CO)(\eta^2\text{-}CF_3C_2CF_3)_2]$ by Davidson *et al.*[3] in 1982 there has been considerable interest in haloalkyne complexes of molybdenum(II) and tungsten(II).[4] In recent years we have been investigating the chemistry of the highly versatile bisalkyne complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph).[5] In this paper we wish to describe the reactions of these complexes with some monodentate neutral oxygen and sulphur donor ligands.

EXPERIMENTAL

The complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) were prepared according to the published method.[5] All chemicals were purchased from commercial sources. ^1H and ^{13}C NMR spectra were recorded either on a Jeol FX60 or a Bruker WH-400MHz NMR spectrometer (all spectra were calibrated against tetramethylsilane). IR spectra were recorded on a Perkin–Elmer 197 IR spectrophotometer as $CHCl_3$ films between NaCl plates unless otherwise stated. The molecular weight of $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2 \cdot$ tmtu was determined using Rast's method,[6] using camphor as the solvent. Elemental analyses for carbon, hydrogen and nitrogen were recorded on a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas).

$[WI_2(CO)\{OC(NH_2)_2\}(\eta^2\text{-}MeC_2Me)_2]$ (1)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.500 g, 0.813 mmol) dissolved in a 40:60 (v/v) acetone–methanol mixture (20 cm^3), with continuous stirring under a stream of dry nitrogen, was added $OC(NH_2)_2$ (0.049 g, 0.816 mmol). After 17 h, filtration and removal of solvent *in vacuo* afforded the pale green complex, $[WI_2(CO)\{OC(NH_2)_2\}(\eta^2\text{-}MeC_2Me)_2]$, which was recrystallized from dichloromethane–acetone (Yield: 0.30 g, 58%).

In a similar reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 1 equivalent of $OC(NH_2)_2$ in acetone at room temperature gave $[WI_2(CO)\{OC(NH_2)_2\}(\eta^2\text{-}PhC_2Ph)_2]$ (2) (see Table 1 for yield and analytical data).

$[WI_2(CO)\{SC(NH_2)Me\}(\eta^2\text{-}MeC_2Me)_2]$ (3)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.500 g, 0.813 mmol) dissolved in methanol (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added $SC(NH_2)Me$ (0.061 g, 0.812 mmol). After 15 h, filtration and removal of solvent afforded the yellow crystalline complex, $[WI_2(CO)\{SC(NH_2)Me\}(\eta^2\text{-}MeC_2Me)_2]$, which was recrystallized from dichloromethane (Yield: 0.46 g, 87%).

In a similar reaction, $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 1 equivalent of $SC(NH_2)Me$ in acetone at room temperature gave $[WI_2(CO)\{SC(NH_2)Me\}(\eta^2\text{-}PhC_2Ph)_2]$ (4) (see Table 1 for yield and analytical data).

$[WI_2(CO)\{SC(NH_2)_2\}_2(\eta^2\text{-}MeC_2Me)]$ (5)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.500 g, 0.813 mmol) dissolved in acetone (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added $SC(NH_2)_2$ (0.186 g, 2.445 mmol). After 15 h, filtration and removal of solvent *in vacuo* afforded a purple crystalline complex, $[WI_2(CO)\{SC(NH_2)_2\}_2(\eta^2\text{-}MeC_2Me)]$, which was columned on silica at 0°C in 2-butanone, and recrystallized twice from acetone (Yield: 0.29 g, 53%).

$[WI_2\{SC(NH_2)_2\}_2(\eta^2\text{-}PhC_2Ph)_2]$ (6)

To a solution of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (0.300 g, 0.348 mmol) dissolved in a mixture of dichloromethane (15 cm^3) and methanol (3 cm^3), with continuous stirring under a stream of dry nitrogen, was added $SC(NH_2)_2$ (0.053 g, 0.693 mmol). After stirring at 30°C for 24 h, filtration and removal of solvent *in vacuo* afforded a pale yellow powder, $[WI_2\{SC(NH_2)_2\}_2(\eta^2\text{-}PhC_2Ph)_2]$, which was recrystallized from dichloromethane (Yield: 0.23 g, 69%).

$[WI_2(CO)\{SC(NMe_2)_2\}_2(\eta^2\text{-}MeC_2Me)]$ (7)

To a solution of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.500 g, 0.813 mmol) dissolved in acetone (15 cm^3) with continuous stirring under a stream of dry nitrogen was added $SC(NMe_2)_2$ (0.322 g, 2.435 mmol). After 15 h, filtration and removal of solvent *in vacuo* left purple $[WI_2(CO)$

Table 1. Physical and analytical[a] data for the complexes $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$, $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$, $[WI_2\{SC(NH_2)_2\}_2(\eta^2\text{-}PhC_2Ph)_2]$ and $[W(\mu\text{-}I)I(CO)\{SC(NMe_2)_2\}(\eta^2\text{-}PhC_2Ph)]_2 \cdot \{SC(NMe_2)_2\}$

[a] Calculated values in parentheses.

$\{SC(NMe_2)_2\}_2(\eta^2\text{-}MeC_2Me)]$ which was columned on silica at 0°C in 2-butanone. Removal of the solvent *in vacuo* and recrystallization from acetone afforded (**7**) (Yield: 0.36 g, 57%).

$[W(\mu\text{-}I)I(CO)\{SC(NMe_2)_2\}(\eta^2\text{-}PhC_2Ph)]_2\{SC(NMe_2)_2\}$ (**8**)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (0.500 g, 0.579 mmol) dissolved in acetone (15 cm^3), with continuous stirring under a stream of dry nitrogen, was added $SC(NMe_2)_2$ (0.153 g, 1.157 mmol). After stirring for 15 h the deep green precipitate was allowed to settle and the solvent decanted off. The product was washed with 4×10 cm^3 portions of acetone followed by 3×5 cm^3 portions of CH_2Cl_2. The complex was dried *in vacuo* (Yield: 0.40 g, 82%). Molecular weight for $C_{45}H_{56}N_6I_4O_2S_3W_2$: Found: 1637. Calc: 1684.

RESULTS AND DISCUSSION

The complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) react with one equivalent of L (L = $OC(NH_2)_2$ or $SC(NH_2)Me$) at room temperature (for R = Me, L = $OC(NH_2)_2$ in acetone–methanol; R = Me, L = $SC(NH_2)Me$ in methanol, R = Ph, L = $OC(NH_2)_2$, $SC(NH_2)Me$ in acetone) to give good yields of the new substituted products $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**). Reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with an excess of L [L = $SC(NH_2)_2$ (tu) or $SC(NMe_2)_2$ (tmtu)] in acetone at room temperature afford the monoalkyne complexes $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$ (**5** and **7**). However, the bisdiphenylacetylene complex $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ reacts with 2 equivalents of tu at 30°C in dichloromethane–methanol to give the non-carbonyl containing bisalkyne complex $[WI_2(tu)_2(\eta^2\text{-}PhC_2Ph)_2]$ (**6**). By contrast, reaction of the compound $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 2 equivalents of tmtu in acetone at room temperature eventually gives the novel iodide-bridged dimer $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2(tmtu)$ (**8**). All the new complexes have been fully characterized by elemental analysis (C, H and N) (Table 1), IR (Table 2), ^1H and in some cases ^{13}C NMR spectroscopy (Tables 3 and 4). The tmtu solvate $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2 \cdot tmtu$ (**8**) was confirmed by repeated elemental analyses, ^1H and ^{13}C NMR spectroscopy. The dimeric nature of (**8**) was confirmed by molecular weight measurements using Rast's method[6] (see Experimental). The new complexes (**1–8**) described in this paper are extremely air-sensitive and thermally unstable. They can be stored at 0°C under nitrogen for several hours.

Table 2. IR data[a] for the complexes $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$, $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$, $[WI_2\{SC(NH_2)_2\}_2(\eta^2\text{-}PhC_2Ph)_2]$ and $[W(\mu\text{-}I)I(CO)\{SC(NMe_2)_2\}(\eta^2\text{-}PhC_2Ph)]_2 \cdot \{SC(NMe_2)_2\}$

The reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with 1 equivalent of L (L = $OC(NH_2)_2$ or $SC(NH_2)Me$) probably proceed via an associative mechanism, since the alkyne ligands can rearrange their mode of bonding from supplying a total of six electrons to the tungsten in $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ to both alkynes donating two electrons each in the intermediate $[WI_2(CO)(NCMe)L(\eta^2\text{-}RC_2R)_2]$. Loss of acetonitrile from this intermediate would give the observed products.

The complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ have very similar spectral properties and colours to

$[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**). The X-ray crystal structures of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) have been determined,[5] hence the proposed structure of the complexes (**1–4**) is shown in Fig. 1.

The ^1H NMR spectra of (**1–4**) agreed with static structures shown in Fig. 1. The ^{13}C NMR spectra of (**2**) and (**3**) have alkyne (C≡C) contact carbon resonances at δ = 171.34 and 160.06 ppm for (**2**) and δ = 169.99 and 149.19 ppm for (**3**). Templeton and Ward[7] have correlated the values of ^{13}C alkyne contact carbon chemical shifts with the average number of electrons donated to the metal. The values given above for (**2**) and (**3**) indicate that the alkynes are donating three electrons each to the tungsten in these complexes. It is likely, however that one alkyne is donating four electrons and the other two electrons in these complexes with rapid exchange between these resonance hybrids (faster than the NMR time scale).

It is interesting to note that reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with one equivalent of L [L = $SC(NH_2)_2$ (tu) or $SC(NMe_2)_2$ (tmtu)] in acetone at various temperatures always gives a mixture of products. Several unsuccessful attempts were made to separate these mixtures by column chromatography.

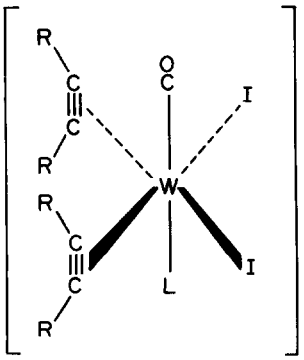

Fig. 1. Proposed structure for $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$.

Reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with an excess of L (L = tu or tmtu) in acetone at room temperature gave the monoalkyne complexes $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$. These complexes are analogous to the complexes $[MX_2(CO)L_2(\eta^2\text{-}RC_2R')]$ (M = Mo or W; X = Cl or Br; L = PEt_3, PPh_3 or py; $L_2 = Ph_2P(CH_2)_2PPh_2$) reported by Templeton and co-workers[4a,d] and $[WBr_2(CO)L_2(\eta^2\text{-}RC_2R')]$ (L = $CNBu^t$, $P(OMe)_3$ or PPh_3) by Davidson and Vasapollo[4b,c]. In order for these complexes to obey the effective atomic number rule, the but-2-yne ligands must donate four electrons to the metal which is suggested by the highly coloured nature of these compounds. However, due to the instability of these complexes in solution for long periods, no ^{13}C NMR spectra were obtained which should have confirmed this. However, it was found that the single resonance at δ = 3.02 ppm for the but-2-yne for (**5**) did not coalesce even down to −80°C in CD_2Cl_2.

By contrast reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 2 equivalents of tu in dichloromethane–methanol at 30°C affords the non-carbonyl containing product, $[WI_2(tu)_2(\eta^2\text{-}PhC_2Ph)_2]$ (**6**). This can be explained since diphenylacetylene is a poorer σ-donor and better π-acceptor ligand than but-2-yne and hence, substituting the acetonitrile by tu (which is a better π-acceptor ligand than acetonitrile) facilitates the loss of carbon monoxide rather than the alkyne ligand in this complex. The ^{13}C NMR spectrum indicated that both alkyne ligands in (**6**) are donating a total of six electrons to the tungsten (see Table 4).

Two equivalents of the more electron rich tmtu ligand react with $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ to eventually give the novel iodide-bridged dimer $[W(\mu\text{-}I)I(CO)(tmtu)(\eta^2\text{-}PhC_2Ph)]_2 \cdot tmtu$ (**8**). Following this reaction by IR spectroscopy indicated an initial green solution is formed after 3 min which has a carbonyl band at ν(CO) = 1908 cm^{-1} which is likely to be due to the monoalkyne complex $[WI_2(CO)(tmtu)_2(\eta^2\text{-}PhC_2Ph)]$. The disappearance of the band at 1908 cm^{-1} is concomitant with the formation of two new bands at ν(CO) = 1913 and 1905 cm^{-1} which are due to the dimer (**8**). Complex (**8**) is analogous to some of the other dimeric complexes we have previously reported $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$ (M = Mo or W; R = R′ = Ph; R = Ph; R′ = Me)[8] formed from reaction of $[MI_2(CO)_3(NCMe)_2]$ with 1 equivalent of RC_2R'. As expected the ^{13}C NMR spectrum of

(**8**) shows a resonance at $\delta = 209.88$ ppm due to the alkyne contact carbons, which suggests[7] the alkyne ligands are donating four electrons each to the tungsten atoms in this complex.

Finally, it should be noted that 2 equivalents of $OC(NH_2)_2$ and $SC(NH_2)Me$ react in acetone with $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ to give a mixture of products. Hence, subtle differences in the electronic and steric effects of the four ligands $OC(NH_2)_2$, $SC(NH_2)Me$, $SC(NH_2)_2$ and $SC(NMe_2)_2$ give a variety of different products when reacted with $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$.

Acknowledgements—We wish to thank Dr O. W. Howarth for obtaining several ^1H and ^{13}C NMR spectra at the University of Warwick and we thank the SERC for support.

SYNTHESIS AND PROPERTIES OF BERYLLIUM IODATES—III. SYNTHESIS, IR SPECTRA AND X-RAY DIFFRACTION ANALYSIS OF $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$

M. MANEVA* and M. GEORGIEV

Department of Inorganic Chemistry, Higher Institute of Chemical Technology, 1156 Sofia, Bulgaria

(*Received* 17 *March* 1988; *accepted after revision* 25 *August* 1988)

Abstract—The compound $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$ has been synthesized and identified by quantitative analysis, IR spectra and X-ray diffraction analysis. On the basis of the absorption bands in the IR spectra of the compound and its partially deuterated analogue the basic structural units making up the compound were shown to be $Be(H_2O)_4(IO_3)_2 \cdot 2HIO_3 \cdot 2H_2O$, as well as the existence of two kinds of non-equivalent water molecules.

Information on beryllium iodates is rather scanty and consists mainly of data about the synthesis and some properties of $Be(IO_3)_2 4H_2O$,[1–3] of $[Be_3(OH)_3(H_2O)_6](IO_3)_3 2HIO_3$[4] and of $[Be_3(OH)_3(H_2O_6](IO_3)_3 \cdot H_2O$.[5] The aim of the present investigation was to synthesize a new beryllium iodate from strongly acid solutions of HIO_3, the compounds obtained being identified by the methods of quantitative analysis, IR spectroscopy and X-ray diffraction analysis.

EXPERIMENTAL

The initial compounds used were $BeCO_3$ and HIO_3 (p.a. grade). Synthesis was performed under the following conditions: 0.76 g $BeCO_3$ were added to 100 cm^3 0.5 M solution of HIO_3 with continuous stirring, at constant temperature 343 K. The transparent solution obtained was concentrated to one-fourth of its initial volume, followed by cooling and by the addition of 75 cm^3 absolute C_2H_5OH to it. A colourless gel-like mass was obtained, which was treated several times with C_2H_5OH in the course of 48 hours. The crystalline precipitate obtained was filtered off, air-dried, and kept under ordinary conditions.

A compound of the same composition was also obtained upon dissolution of $Be(IO_3)_2 \cdot 4H_2O$ in concentrated solution of HIO_3 in 1:2 molar ratio followed by isothermal evaporation of the solution at 298 K.

The deuterated sample was prepared by two-fold dissolution of the compound in heavy water and precipitation with C_2H_5OH, with due observance of the conditions determined in the synthesis.

The compound synthesized in the described manner was subjected to quantitative gravimetric analysis for Be^{2+},[6] iodometrically for IO_3^- and I_2,[7] for OH^- by the Chernov[8] method and for hydrate water by Fisher's method. The analysis for OH^- was carried out in order to determine whether the beryllium aqua-complex contained in it had been hydrolysed. The quantitative measurements were carried out on samples obtained during different syntheses and upon different periods of storage. The data revealed complete reproducibility.

The IR spectra of the investigated compound and of its deuterated analogue were taken in the region of 4000–2800 cm^{-1} in a suspension of Hostaflon and of 2800–400 cm^{-1} in KBr tablets on a UR-10 Zeiss apparatus. The data from the X-ray diffraction analysis were obtained on a HZG 4C Zeiss apparatus and by Cu-K_α radiation.

RESULTS AND DISCUSSION

The data from the quantitative analysis of the composition of the compound are the following: Be = 1.10%; I = 61.96%; H_2O = 13.6%; OH^- = 0%. These data coincide most satisfactorily when compared with the theoretical ones for a compound with the composition $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$, namely: Be = 1.09%; I = 62.06%; H_2O = 13.8%; OH^- = 0%.

The IR spectra of the compound and of its partially deuterated analogue are presented in Table 1 and Fig. 1. The interplanar distances recorded from the diffractograms of $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$, compared to those of $Be(IO_3)_2 \cdot 4H_2O$, HIO_3, are presented in Fig. 2.

640 w			ν(I—O(H))
575 w	575 m		γ(I—OH)
545 sw	405 w	1.34	$\nu_\omega(H_2O)$

The presence of the $[Be(H_2O)_4]^{2+}$ complex in the structure of the investigated compound is to be anticipated, because the conditions of the synthesis do not allow for its hydrolysis. This complex is identified by its characteristic absorptions (Table 1, Fig. 1), the one at 860 cm^{-1} being due to the ν_3-valency vibration of the BeO_4 tetrahedron,[9-11] while the absorption at 980 cm^{-1} is due to the bending vibration δ(Be—OH_2). In the spectrum of the partially deuterated analogue the latter is observed at 950 cm^{-1} ($\nu_H/\nu_D = 1.03$). The existence of hydrate water coordinated around the beryllium is proved also by the presence of a weak librational vibration observed at 670 cm^{-1}. Its identification is confirmed by the observed weak absorption at 2360 cm^{-1}, which corresponds to the composite vibration $\delta(H_2O)+\nu_L$.[12]

A proof of the presence of entire redissociated molecules of iodic acid in the structure of the compound is absorption at 575 cm^{-1}, corresponding to the non-planar bending vibration γ(I—OH) (Table 1). The latter is to be observed also in the spectrum of iodic acid. The latter accounts also for the absorption at 640 cm^{-1} of ν(I—O(H)) and for that of the planar bending vibration δ(IOH) at 1240 cm^{-1}. This value is, however, considerably higher than that in the spectrum of the free iodic acid—1165 cm^{-1} (Fig. 1a)—which can be explained by the increased IOH angle in the structure of $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$.

The pattern in the region of the stretching vibrations IO_3^- is more complex than in the case of

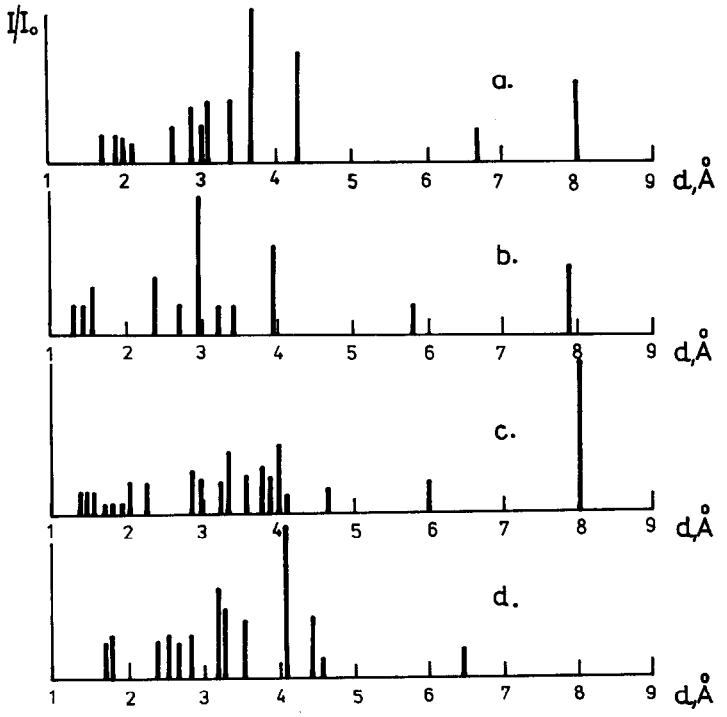

Fig. 2. Interplanar distance of: (a) $Al(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$; (b) $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$; (c) $Be(IO_3)_2 \cdot 4H_2O$; (d) HIO_3.

HIO_3 (Fig. 1c). A three-fold splitting of the stretching vibration ν_3 is to be observed, with maxima at 785, 750 and 685 cm^{-1}. This is to be expected, having in mind the complex pattern of interaction of the other IO_3^- groups—on the one hand linked directly with the aqua-complex, while on the other hand associated with the HIO_3 molecules on the basis of very strong hydrogen bonds. The latter may be accountable for the strongly shifted absorption band of one of the ν(OH) vibrations at 2920 cm^{-1}. Parallel with that, the HIO_3 molecules participate also in the hydrogen bonds with the water molecules not coordinated around beryllium, namely $HIO_3^- \cdots H_2O$. The stretching vibrations of their OH groups are manifested in the region of 3420–3050 cm^{-1}. The maxima observed in this absorption band for the ordinary and for the deuterated compounds show isotopic shifting within the limits of 1.32–1.34 and are easy to record. Its position in the spectrum is shifted considerably toward the lower frequencies, this being an indication of considerable covalency of the coordinative bond and of the presence of strong hydrogen bonds in the structure of the compound.

The planar bending vibration of the water molecules ($\delta(H_2O)$) is split, with $\Delta\delta = 30$ cm^{-1}. This fact is a proof of the presence of two kinds of crystallochemically inequivalent water molecules in the structure, and confirms the assumption about the presence of coordinated water molecules and of such as are participating only in hydrogen bonds with proton-acceptor groups.

It follows from the information obtained about the compound that its molecule is made up of tetrahedral beryllium aqua-complexes and of highly deformed iodate groups associated by means of very strong hydrogen bonds with the entire HIO_3 molecules. The latter, on the other hand, are also in a state of interaction with the water molecules not coordinated around beryllium, likewise on the basis of hydrogen bonds.

Consequently, the following molecular formula may be assumed for the compound:

$$\begin{bmatrix} H_2O & & H_2O \\ & \searrow\ \swarrow & \\ & Be & \\ & \nearrow\ \nwarrow & \\ H_2O & & H_2O \end{bmatrix} IO_3 \cdots HIO_3 \cdots H_2O$$

$$IO_3 \cdots HIO_3 \cdots H_2O.$$

The investigated compound has been characterized by its X-ray diffractogram (Fig. 2). The data obtained show that the interplanar distances recorded differ from those of the initial components.

Abstract—The surface enhanced Raman scattering (SERS) of the nitroprusside anion adsorbed on a silver electrode were obtained and compared with the normal Raman spectra of the chemically reduced species $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_4NO]^{2-}$. The results are in agreement with the reversibility of the system at the two first waves coupled with the equilibrium

$$[Fe(CN)_5NO]^{3-} \rightleftharpoons [Fe(CN)_4NO]^{2-} + CN^-,$$

as indicated by the characteristic vibrational bands of surface complexes $[Ag(CN)_{x+1}]^{x-}$ generated from this equilibrium. The attempts to obtain the spectra at the third reduction wave were not successful.

SERS effect has been a useful technique to study complexes adsorbed on silver and copper electrodes[1–3] and oxidation–reduction reactions.[4–7] The electroreduction of the nitroprusside ion had been studied in both aqueous solution[8,9] and non-aqueous aprotic media.[10–12] Voorst and Hemmerich[8] have shown that upon the reduction of nitroprusside in the pH range 7–10, the brown complex $[Fe(CN)_5NO]^{3-}$ is obtained, and at pH 4 the reduction yields the blue $[Fe(CN)_5NOH]^{2-}$ complex. Schmidt *et al.*[11–13] and Cheney *et al.*[9] have shown, respectively for aprotic and aqueous media, that the one-electron reduction of the nitroprusside produces mainly $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_4NO]^{2-}$, which are O_2 sensitive, generating the $[Fe(CN)_5NO]^{2-}$, $[Fe(CN)_4NO(OH)]^{2-}$ and polymeric species. Nast and Schmidt[12] have characterized the compounds obtained by the reduction of nitroprusside with alkaline metals in liquid ammonia and assigned their most important IR bands. Masek *et al.*[14,15] have studied the reactions involving the nitroprusside reduction products obtained during the three polarographic waves, in acidic and basic media.

In the present work the electroreduction of the nitroprusside ion adsorbed on a silver electrode was investigated by SER spectroscopy in the CN stretching and skeletal vibration regions. The results were compared with the normal Raman spectra of the products of one- and two-electron reduction of the nitroprusside, with the IR spectra reported in the literature[12] and with the studies of electroreduction on mercury electrode.[14,15]

EXPERIMENTAL

The $Na_2[Fe(CN)_5NO]\cdot 2H_2O$ was kindly donated by Dr H. E. Toma. Electrolyte solutions, 0.1 M KCl or KBr and 0.003 M nitroprusside ion, were prepared with double-distilled water and dissolved air, removed by N_2 bubbling. The working electrode, a 0.1 cm^2 silver rod supported by acrylic resin, was polished with 600 mesh wet sandpaper prior to use. The auxiliary and reference electrodes were platinum and saturated calomel (SCE), respectively. The spectrometer, potentiostat and experimental set-up were described elsewhere.[16,17]

The procedure to obtain the SERS was as follows: (i) after several oxidation–reduction cycles to activate the electrode surface, the sample was added to the cell at a potential close to the electrode oxidation potential (−0.1 V, KCl 0.1 M); (ii) a new cycle was performed at a rate of 20 mV s^{-1} and the spectra recorded at steps of 0.1 V, from −0.5 to

−1.2 V and also in the reverse way, from −1.2 to −0.5 V.

The spectral resolution was 7 cm^{-1} and the laser power (514.5 and 647.1 nm) adjusted to *ca* 20 mW.

The chemically reduced species used to obtain the normal Raman spectra, for comparison, were obtained from reduction of nitroprusside with $NaBH_4$.[8,9]

RESULTS AND DISCUSSION

In Fig. 1a, b the SERS of nitroprusside adsorbed on a silver electrode are shown at several electrode potentials, respectively for the skeletal and CN stretching vibration regions. The vibrational frequencies (cm^{-1}) for these regions are listed in Table 1. The spectra in Fig. 1 were obtained from −1.2 to −0.5 V; identical results were obtained changing the potential from −0.5 to −1.2 V.

According to Masek *et al.*[14,15] at potentials more negative than −0.4 V, reduced species are expected to be present in the bulk solution. Since the SERS differ from the spectra of the nitroprusside, both in solution and solid state (particularly in the CN stretching region), it is reasonable to suppose they are due to that reduced species.

Masek and Máslová[15] have shown that the reduction of nitroprusside on mercury electrode occurs in three steps: the two first reduction waves are represented as follows,

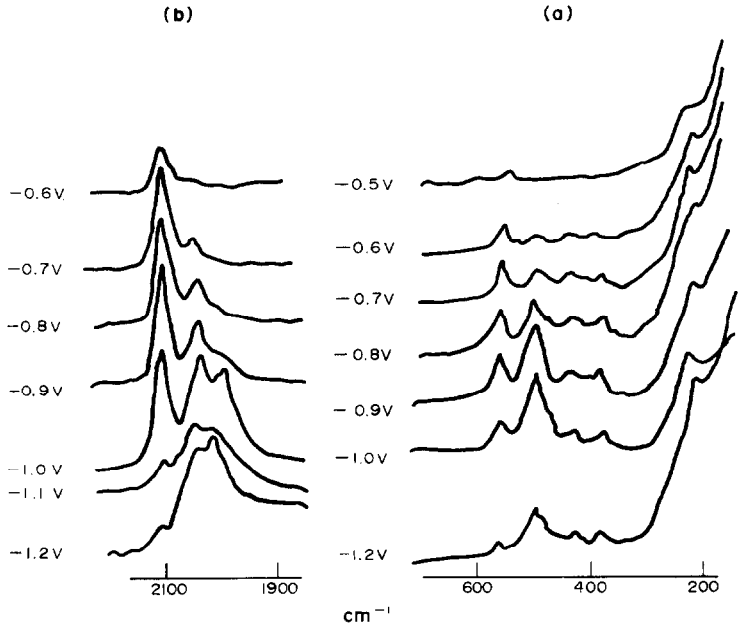

Fig. 1. SERS spectra of the electroreduced species on a silver electrode at the indicated potentials in 0.1 M KCl, $\lambda_{exc.}$ = 514.5 nm. (a) skeletal region and (b) CN region.

$$[Fe(CN)_5NO]^{2-} \overset{(i)}{\rightleftharpoons} [Fe(CN)_5NO]^{3-}$$
$$\downarrow\uparrow$$
$$[Fe(CN)_4NO]^{3-} \overset{(ii)}{\rightleftharpoons} [Fe(CN)_4NO]^{2-} + CN^-,$$

(i) the one-electron reduction at $E_{1/2} = -0.36$ V, yielding a primary product $[Fe(CN)_5NO]^{3-}$ in equilibrium with $[Fe(CN)_4NO]^{2-}$ and CN^-; (ii) the reduction, at $E_{1/2} = -0.56$ V, from $[Fe(CN)_4NO]^{2-}$ to $[Fe(CN)_4NO]^{3-}$ that reacts with $[Fe(CN)_5NO]^{2-}$ giving back the first electroreduction equilibrium. The third reduction wave, $E_{1/2} = -1.32$ V, yields $[Fe(CN)_5NH_2OH]^{3-}$. These authors mention the possibility, at pH > 6.5, of the formation of the two linkage isomers of nitroprusside, i.e. $[Fe(CN)_4(NC)(NO)]^{3-}$ and $[Fe(CN)_4(NC)(NO)]^{4-}$, after the second one-electron reduction. In acidic medium,[18] the first electroreduction gives the same products obtained in basic medium. However, the second reduction wave involving the protonated species $[Fe(CN)_5NOH]^{2-}$, gives the $[Fe(CN)_5NOH]^{3-}$ which, by a third reduction yields $[Fe(CN)_5NH_2OH]^{3-}$ at *ca* −1.3 V. Since the electroreduction of the nitroprusside has been studied on mercury electrodes, in order to be compared with our results on silver electrodes, the voltammograms using this electrode and a mercury electrode were obtained, giving the values −0.6 V, −0.9 V and *ca* −1.3 V on silver and −0.4 V, −0.6 V and −1.3 V on mercury, for such species.

It is worthwhile to discuss the behaviour of the bands at 500 and 560 cm^{-1}, in the skeletal region, and 2010 and 2060 cm^{-1}, in the CN stretching region. Figure 2 represents the intensity ratios I_{500}/I_{560} and I_{2010}/I_{2060} as functions of the applied potential. From Figs 1 and 2 it can be seen that the intensity of the bands at 500 and 2010 cm^{-1} increases when the potential is more negative than the second reduction wave (−0.9 V). The intensity of the bands at 560 and 2060 cm^{-1} shows only small dependence on the potential, in the range −0.6 to −1.2 V.

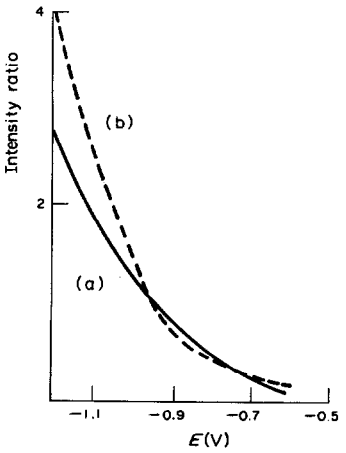

Fig. 2. Raman Intensity ratio vs potential: (a) I_{2010}/I_{2060} and (b) I_{500}/I_{560}, in 0.1 M KCl and $\lambda_{exc.} = 514.5$ nm.

In order to characterize the electroreduced species, the spectra of nitroprusside chemically reduced with one or two equivalents of $NaBH_4$, at pH 7.1, were obtained. In Fig. 3 the spectra of nitroprusside, normal Raman and SERS (−0.8 V), and that of the reduced species are compared. The spectra for the species reduced by one or two equivalents of $NaBH_4$ are practically identical. In the skeletal region, the SER spectrum shows more similarity with the spectrum of the reduced species, except for the absence of the band at 660 cm^{-1}, which has a contribution of the NO moiety.[19] In the CN stretching region, the band at 2157 cm^{-1} of the nitroprusside originates the bands at 2060, 2090 and 2115 cm^{-1} in the reduced species and at 2010, 2060, 2095(sh) and 2105 cm^{-1} in the SERS. There is a correspondence between the bands at *ca* 2060 and 2090 cm^{-1}. The band at 2105 cm^{-1} may correspond to the 2115 cm^{-1} or to a surface complex $[Ag(CN)_{x+1}]^{x-}$, which will be discussed later.

The bands at 500 and 2010 cm^{-1}, as previously mentioned, are enhanced at potentials more negative than the second one-electron reduction (−0.9 V) and can be assigned to the reduced species $[Fe(CN)_4NO]^{3-}$, at pH > 7. The assignment of the 2010 cm^{-1} is in agreement with Nast and Schmidt,[12] who observed bands at *ca* 2040 cm^{-1} in the IR spectra of this reduced species. According to these authors, when the Fe^{n+} ion is in an oxidation state lower than II the CN stretching shifts to lower frequencies. They assume that $[Fe(CN)_4NO]^{3-}$ has a configuration Fe^0–NO^+, obtained from the reduction of $[Fe(CN)_4NO]^{2-}$ (configuration $Fe^{I-}NO^+$). The Raman spectrum of nitroprusside, chemically reduced at pH 4, shows a band at 2115 cm^{-1}, also observed in the IR spectrum of $[Fe(CN)_4NO]^{2-}$.[12] The assignment of the band at 500 cm^{-1} is more difficult. However, due to its similar behaviour with the band at 2010 cm^{-1}, it can be assigned to the species $[Fe(CN)_4NO]^{3-}$. Nevertheless, the possibility of assigning it to $[Fe(CN)_5NO]^{3-}$ can not be discarded.

Efforts to observe the NO stretching vibration in the SERS were not successful, the same occurring with the attempts to obtain the SERS at pH 4 in buffered medium. The spectra in pH 7.0 buffered solution are identical to those at pH > 7. In non-buffered solutions an increase in the pH was observed after the electroreduction, probably due to the formation of CN^- ions.

In Fig. 1, strong bands at 220 and 2105 cm^{-1} are

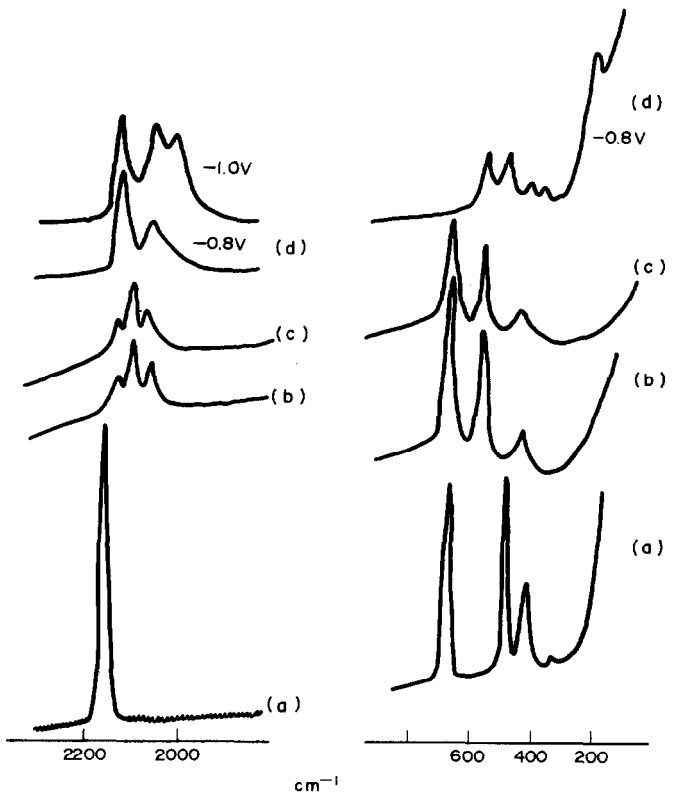

Fig. 3. Raman spectra : (a) nitroprusside, aqueous solution ; (b) product of the one-electron reduction of nitroprusside, $[Fe(CN)_5NO]^{3-}$; (c) product of the two-electron reduction of nitroprusside, $[Fe(CN)_4NO]^{3-}$, and (d) SERS at the indicated potentials, 0.1 M KCl, $\lambda_{exc.} = 514.5$ nm.

observed. The band at 220 cm^{-1} is not observed either in the nitroprusside or in the $[Fe(CN)_5NO]^{3-}$ normal Raman spectra. Since after the first reduction there is the equilibrium $[Fe(CN)_5NO]^{3-} \rightleftharpoons [Fe(CN)_4NO]^{2-} + CN^-$, those bands may be assigned to surface complexes $[Ag(CN)_{x+1}]^{x-}$ as described by several authors[20-23] for SERS of CN^- adsorbed on a silver electrode. This assignment is confirmed by the presence of the 220 cm^{-1} band in the SERS spectra in a 0.1 M KBr support electrolyte. In addition, the potential behaviour of the band at 2105 cm^{-1} corroborates this hypothesis.

At potentials more positive than -0.2 V the spectra in the presence of CN^- show a shift from 2110 to 2146 cm^{-1}, consistent with the decrease in the proportion of the surface complexes $[Ag(CN)_4]^{3-}$ and $[Ag(CN)_3]^{2-}$ relative to $[Ag(CN)_2]^-$.[20,21] In this work, we could not observe this behaviour since for potentials more positive than -0.4 V, the $[Fe(CN)_5NO]^{3-}$ is oxidized to $[Fe(CN)_5NO]^{2-}$, displacing the equilibria set up after the two electroreductions towards the nitroprusside. This embodying of the CN^- ions into the complexes $[Fe(CN)_4NO]^{3-}$ and $[Fe(CN)_4NO]^{2-}$ explains the absence of the surface complexes $[Ag(CN)_{x+1}]^{x-}$ spectra.

Summarizing, the SERS of the nitroprusside complex is consistent with the reversibility of the two reduction waves of the nitroprusside suggested by Masek and Maslova.[15] The spectra were assigned to the species $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_4NO]^{3-}$, by comparison with the normal Raman of the chemically reduced species and also by the behaviour of the Raman intensity vs applied potential. The bands at 220 and 2105 cm^{-1} are assigned to the surface complex $[Ag(CN)_{x+1}]^{x-}$ originated from the release of the CN^- ions. The non-observation of SERS spectra at potentials more negative than -1.3 V (third reduction wave) is probably due to the lability of the complex $[Fe(CN)_5NH_2OH]^{3-}$.

THE X-RAY CRYSTAL STRUCTURE OF TRIS (2,2′-BIPYRIDINE)OSMIUM(II) HEXAFLUOROPHOSPHATE

EDWIN C. CONSTABLE,* PAUL R. RAITHBY and DIANA N. SMIT

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 28 *July* 1988; *accepted* 8 *September* 1988)

Abstract—The X-ray crystal structure of the complex (bipy = 2,2′-bipyridine) is reported. The complex is isostructural with the corresponding ruthenium(II) complex $[Ru(bipy)_3][PF_6]_2$ with Os—N, 2.056(8) Å.

Complexes of the d^6 platinum group metal ions with diimine ligands (2,2′-bipyridine, 1,10-phenanthroline and 2,2′:6′,2″-terpyridine) have been known for many years, and have been of considerable recent interest because of their attractive photochemical and photophysical properties.[1] In particular, these complexes have been intensively investigated as components of both homogeneous and heterogeneous systems for photoconversion.[1] Furthermore, the solution properties of the ions indicate specific interactions between solvent molecules and the cations, which may be of relevance to their rôles as photocatalysts.[2] In order to understand the ground and excited state electronic properties of the complexes, and to probe possible solvent–solute interactions, it is necessary to have a good knowledge of their structures. In this paper, we report the crystal and molecular structure of the complex $[Os(bipy)_3][PF_6]_2$.

EXPERIMENTAL

2,2′-Bipyridine (Aldrich) and "osmium trichloride" (Johnson Matthey) were used as supplied; $[Os(bipy)_2Cl_2]Cl$ was prepared by the literature method.[3] Electronic spectra were recorded using a Pye-Unicam 8800 spectrophotometer; IR spectra were recorded using Perkin–Elmer 1710 FT or 983 spectrometers with the compound in compressed KBr pellets or in suspension in Nujol. NMR spectra were recorded on Brüker WM250 or AM400 spectrometers.

*Author to whom correspondence should be addressed.

Preparation of $[Os(bipy)_3][PF_6]_2$

2,2′-Bipyridine (0.312 g, 2 mmol) and $[Os(bipy)_2Cl_2]Cl$ (0.608 g, 1 mmol) were heated to reflux in $MeOCH_2CH_2OH$ (25 cm^3) for 24 h, after which period the dark coloured solution was filtered and diluted with MeOH (25 cm^3). A solution of $[NH_4][PF_6]$ (2.0 g) in MeOH (10 cm^3) was added, and the resultant dark green precipitate collected by filtration to yield $[Os(bipy)_3][PF_6]_2$ (0.600 g, 63%) (Found: C, 37.7; H, 2.6; N, 8.7. Calc. for $C_{30}H_{24}N_6OsP_2F_{12}$: C, 38.0; H, 2.5; N, 8.9%).

Crystal structural determination of $[Os(bipy)_3][PF_6]_2$

Dark green blocks of the complex were obtained by the recrystallization of $[Os(bipy)_3][PF_6]_2$ from hot methanol. A suitable dark green crystal was mounted on a glass fibre with epoxy resin.

Crystal data. $C_{30}H_{24}N_6OsP_2F_{12}$, dark green blocks, $M = 948.6$, trigonal, $a = 10.772(1)$, $c = 16.342(1)$ Å, $U = 2962$ Å^3 (by least-squares refinement of diffractometer angles for 54 automatically centred reflections, $20 < 2\theta < 25°$, $\lambda = 0.71609$ Å), space group $P3c1$ (No. 165), $Z = 2$, $D_c = 2.49$ g cm^{-3}, $F(000) = 926$. Crystal dimensions $0.076 \times 0.106 \times 0.513$ mm, Mo-K_α radiation ($\lambda = 0.7107$ Å), μ(Mo-K_α) = 128.76 cm^{-1}.

Data collection and processing. Stoe–Siemens four-circle diffractometer, 24-step ω-θ mode with scan width 0.04° per step, scan time 0.5–2.0 s per step, graphite monochromated Mo-K_α radiation; 6333 profile fitted intensities measured ($5.0 \leqslant 2\theta \leqslant 45.0°$), 969 unique [merging $R = 0.0104$

after empirical absorption correction based on an ellipsoidal fit of 256 azimuthal data (maximum, minimum transmission factors, 0.252, 0.207)] giving 814 with $F > 4\sigma(F)$. Three standard reflections showed no decrease in intensity during data collection.

Structure analysis and refinement. The structure was solved by direct methods followed by Fourier difference techniques. The Os and P atoms occupy special positions. Blocked full-matrix least-squares refinement with Os, P, N and C atoms anisotropic. Hydrogen atoms were not located directly, but were placed in idealized positions and allowed to ride on the relevant carbon with C—H fixed at 0.96 Å, and refined with a common isotropic temperature factor, $U = 0.078(19)$ Å^2. The PF_6^- counter ion was disordered, two sets of positions being located for the F atoms; these were refined with partial occupancies and a common isotropic factor, $U = 0.099(3)$ Å^2. The weighting scheme $w = 0.8179/[\sigma^2(F)+0.002|F|^2]$ gave satisfactory agreement analyses. Final converged R and R_w values were $R = 0.057$ and $R_w = 0.058$. A final electron density map showed no significant regions of electron density. Complex neutral atom scattering factors were taken from ref. 4. Calculations were performed using SHELX 76 on the IBM 370/165 computer at the University of Cambridge.[5]

RESULTS AND DISCUSSION

The green complex salt $[Os(bipy)_3][PF_6]_2$ is readily prepared by the reaction of $[Os(bipy)_2Cl_2]Cl$ with an excess of 2,2′-bipyridine in 2-methoxyethanol. In this reaction, the 2-methoxyethanol acts as both a solvent and a reductant. Recrystallization of the complex from methanol yields X-ray quality crystals. Microanalysis and ^{1}H NMR studies indicated that the complex contained no lattice solvent. The ^{1}H NMR and electronic spectra of solutions in methanol, and in 0.05 and 0.1 M methanolic CH_3ONa were identical, suggesting that significant nucleophilic attack by methoxide was not occurring.

The structure of the $[Os(bipy)_3]^{2+}$ cation, together with the numbering scheme adopted, is shown in Fig. 1. Selected bond lengths and bond angles are presented in Table 1. The cation exists as a discrete $[Os(bipy)_3]^{2+}$ ion, with crystallographically imposed trigonal symmetry. All the Os—N distances are equivalent, with Os—N, 2.056(8) Å. The bite angle of each 2,2′-bipyri-

dine ligand at the osmium is 77.8(4)°. There are no significant intermolecular contacts between the $[Os(bipy)_3]^{2+}$ cations and the $[PF_6]^-$ anions, and there is no evidence for the presence of lattice solvent molecules. All bond angles and bond lengths within the 2,2′-bipyridine ligands are unremarkable, and closely resemble those observed in other 2,2′-bipyridine complexes.[6]

The most remarkable feature of this structure is its similarity to those of $[Ru(bipy)_3][PF_6]_2$, with which it is isostructural, and other structurally characterized d^6 $[M(bipy)_3]^{n+}$ complexes. The M—N distances in $[Ru(bipy)_3]^{2+}$ (2.055 Å),[7,8] $[Ir(bipy)_3]^{3+}$ (1.999–2.033 Å),[9] and $[Rh(bipy)_3]^{3+}$ (2.031–2.039 Å)[10] do not differ significantly (within 3 ESDs) from those determined here for $[Os(bipy)_3]^{2+}$. Similarly, the bite angles in $[Ru(bipy)_3]^{2+}$ (78.7°),[7,8] $[Ir(bipy)_3]^{3+}$ (78.4–79.1°),[9] and $[Rh(bipy)_3]^{3+}$ (80.1–80.6°)[10] closely resemble those observed in $[Os(bipy)_3][PF_6]_2$.

The similarity of the structures of $[Os(bipy)_3][PF_6]_2$ and $[Ru(bipy)_3][PF_6]_2$ confirm that the differences in photophysical behaviour may be attributed solely to electronic differences in the metal–ligand interactions rather than to any steric or structural differences.

THIOCYANATE AND AZIDE COMPLEXES CONTAINING A MOLYBDENUM(II) MONONITROSYL CENTRE

NAJAT ALOBAIDI,* CHRISTOPHER J. JONES† and JON A. McCLEVERTY

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 15 *June* 1988; *accepted* 28 *September* 1988)

Abstract—The formally 16 electron complexes $[Mo(NO)LX_2]$ (L = $\{HB(3,5\text{-}Me_2C_3N_2H)_3\}$ and X = N_3 or NCS) have been synthesized. Both undergo one electron reduction (at −0.13 V (SCE) when X = N_3 and at −1.64 V when X = NCS).

The sterically demanding tripodal ligand hydrotris(3,5-dimethylpyrazolyl)borate (L) may be used to restrict both molybdenum(II), in the form of $\{Mo(NO)\}^{3+}$, and molybdenum(V), in the form of $\{MoO\}^{3+}$ to octahedral six-coordination. Enemark has exploited this principal in preparing models of the molybdenum cofactor in enzymes such as *sulphite oxidase*. Thus a range of derivatives [Mo(O)LXY] (X and Y are halide, alkoxide, phenoxide thiophenoxide) were prepared and their electrochemical properties determined.[1] All the complexes were found to undergo reversible or quasi-reversible one-electron reduction processes at potentials which varied depending upon the nature of X and Y. The azide and thiocyanate complexes, $[Mo(O)L(N_3)_2]$ and $[Mo(O)L(NCS)_2]$, were also prepared and the latter was found to undergo particularly facile reduction. Thus while bis-alkoxide complexes were reduced at *ca* −1.1 V (Ag/AgCl) and the bis-thiophenoxide at −0.28 V, the bis-azide was reduced at −0.31 V and the bis-thiocyanate at +0.12 V.

A related series of molybdenum(II) mononitrosyl derivatives, [Mo(NO)LXY] (X and Y are halide, alkoxide, phenoxide, thiophenoxide) has been prepared in our laboratories.[2] Electrochemical studies have shown that these too undergo reversible or quasi-reversible one-electron reduction processes at potentials which depend upon the nature of X and Y.[3,4] In view of the parallels between the syntheses of [Mo(O)LXY] and [Mo(NO)LXY], we were interested in extending the series of known nitrosyl complexes to include [Mo(NO)LXY] (X = Y = N_3 or NCS).

EXPERIMENTAL

All reagents were used as supplied, $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I_2]$ was prepared according to a previously described method.[5] Silica gel 60 (70–230 mesh) was used as the stationary phase for column chromatography unless otherwise stated. All reactions were carried out under nitrogen but purification procedures were carried out in air. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

IR spectra were recorded using a PE 297 spectrometer, ^1H NMR spectra were obtained using a Jeol GX 270 (270 MHz) instrument. Cyclic voltammetric and other electrochemical measurements were made using a Hitek PPR 1 waveform generator and DT 2101 potentiostat or a PAR 174A polarograph. Solutions were *ca* 10^{-3} mol dm^{-3} in the complex and 0.2 mol dm^{-3} in $[Bu^n_4N]BF_4$ as the base electrolyte. A platinum bead test electrode was used with an SCE reference electrode and ferrocene as internal standard. Under these conditions the formal electrode potential, E_f, for the Fc/Fc^+ couple was found to be at 0.43 V, with the cathodic and anodic peak potential separation, $\Delta E_p = 60$ mV. The number of electrons associated with electrode processes was estimated by comparison with $[Mo(NO)LCl_2]$.

$[Mo(NO)L(NCS)_2]$

A mixture of $[Mo(NO)LI_2]$ (0.5 g, 0.75 mmol), NaNCS (0.158 g, 2 mmol) and dibenzo-18-crown-6

* New address: Department of Physics, College of Education, AlMustansiriyah University, Baghdad, Iraq.
† Author to whom correspondence should be addressed.

(0.266 g, 0.74 mmol) was stirred in CH_2Cl_2 (50 cm^3) for 18 h, during which time the solution became red–brown in colour. The reaction mixture was filtered and the solvent removed from the filtrate by evaporation under reduced pressure. The residue was purified by column chromatography using CH_2Cl_2–hexane (70/30 v/v) as the eluent. The major red fraction to elute was collected, the solvent removed under reduced pressure and the residue recrystallized from a CH_2Cl_2–hexane mixture to give a dark red microcrystalline product (70 mg, 18%). Found: C, 37.9; H, 4.4; N, 23.2. Calc. for $C_{15}H_{22}N_{13}BMoO$: C, 37.9; H, 4.1; N, 23.4%.

[Mo(NO)L(N_3)$_2$]

A mixture of [Mo(NO)LI_2] (2.0 g, 3 mmol), NaN_3 (0.424 g, 6.5 mmol) and dibenzo-18-crown-6 (1.064 g, 3 mmol) was stirred in CH_2Cl_2 (150 cm^3) for 16 h, during which time the solution became green in colour. The reaction mixture was filtered and the solvent removed from the filtrate by evaporation under reduced pressure at room temperature. The residue was then immediately subjected to column chromatography using CH_2Cl_2 as the initial eluent but with a gradually increasing concentration of THF added to elute a major light green fraction. This was collected, the solvent removed under reduced pressure at room temperature and the residue recrystallized from a CH_2Cl_2–hexane mixture to give a green microcrystalline product (0.288 g, 19%). This material was found to be unstable and decomposed on warming or on standing in solution for prolonged periods. The thermal instability of this compound has precluded satisfactory elemental analyses, low values for N always being obtained. This may be attributed to the loss of N_2 from the compound by decomposition reactions occurring before combustion commenced.

RESULTS AND DISCUSSION

The complex [Mo(NO)L(NCS)$_2$] was formed in the direct reaction between [Mo(NO)LI_2] and sodium thiocyanate in dichloromethane, although only in low yield. Dibenzo-18-crown-6 was added as a phase transfer catalyst to promote dissolution of the sodium salt, and the components of the reaction mixture were separated by column chromatography to give the bis-thiocyanate complex as a dark red solid. The reaction between [Mo(NO)LI_2] and sodium azide in dichloromethane in the presence of dibenzo-18-crown-6 similarly afforded the bis-azide complex. However, in this case purification proved more difficult. Careful chromatography was necessary to separate the light green product from a mixture of paramagnetic brown and dark green materials which were also formed during the reaction. The purification of the bis-azide derivative was further complicated by its thermal instability and subsequent recrystallizations were performed at room temperature without warming, to avoid the decomposition reactions which occurred on heating this material. Attempts to prepare the monosubstituted derivatives, [Mo(NO)LIX] (X = N_3, NCS), using 1:1 reactant stoichiometries have thus far failed and only the bis derivatives have been isolated. Attempts to prepare [Mo(NO)L(NCO)$_2$] were also unsuccessful. Although a reaction between [Mo(NO)LI_2] and sodium cyanate occurred, the product proved too unstable to be isolated in a pure form.

The new compounds were characterized by spectroscopic methods and, in the case of [Mo(NO)L(NCS)$_2$], by elemental analysis. The IR spectrum of [Mo(NO)L(NCS)$_2$] contained ν_{NO} at 1675 cm^{-1}, ν_{BH} at 2550 cm^{-1} and $\nu_{NC(S)}$ at 2030 and 1965 cm^{-1}. The low values found for $\nu_{NC(S)}$ are indicative of N-bound thiocyanate, S-bound thiocyanate usually giving rise to $\nu_{(S)CN}$ in the region of 2100 cm^{-1}.[6] The appearance of a band attributable to $\nu_{(N)CS}$ at 805 cm^{-1} is also in accord with the presence of N-bound thiocyanate since S-bound thiocyanate gives rise to $\nu_{(N)CS}$ in the region 780–690 cm^{-1}.[6] The ^1H NMR spectrum of this complex contained signals in the area ratios 3:3:6:6 at δ_{TMS} = 2.30, 2.32, 2.43 and 2.49 ppm, attributable to the pyrazolyl methyl protons in L. The pyrazolyl 4-H protons appeared as signals of area ratio 1:2 at δ_{TMS} = 5.70 and 6.07 ppm. This spectrum is consistent with the presence of a plane of symmetry in the molecule as required by its formulation as a bis-thiocyanate derivative. The mass spectrum contained a molecular ion envelope based at m/z = 541 (^{98}Mo, ^{11}B) along with an ion at m/z = 511 attributable to $[M—(NO)]^+$.

The IR spectrum of [Mo(NO)L(N_3)$_2$] contained ν_{NO} at 1675 cm^{-1}, ν_{BH} at 2550 cm^{-1}, and ν_{N_3} at 2065 and 2040 cm^{-1}. These latter values maybe compared with that of 2068 cm^{-1} reported[1] for [Mo(O)L(N_3)$_2$]. The ^1H NMR spectrum of this complex contained signals in the area ratios 3:3:6:6 at δ_{TMS} = 2.32, 2.35, 2.37 and 2.51 ppm attributable to the pyrazolyl methyl protons in L. The pyrazolyl 4-H protons appeared as signals of area ratio 1:2 at δ_{TMS} = 5.80 and 5.94 ppm. Again this spectrum is consistent with the presence of a plane of symmetry in the molecule as required by its formulation as a bis-azide derivative.

The electrochemical properties of the new complexes were examined in MeCN solution by cyclic

[b] Platinum bead electrode, MeCN, 0.2 mol dm^{-3} Bu_4NBF_4, Ag/AgCl.[1]

voltammetry. Both showed only poorly defined oxidation processes and a single one-electron reduction process. In the case of [Mo(NO)L(NCS)$_2$] this occurred at $E_f = -1.68$ V with $\Delta E_p = 90$ mV and was subject to some kinetic control. However, the function $i_p^c v^{-1/2}$ (i_p^c = cathodic peak current) was independent of the scan rate, v. In the case of [Mo(NO)L(N$_3$)$_2$] a reversible reduction occurred at $E_f = -0.13$ V with $\Delta E_p = 60$ mV and again $i_p^c v^{-1/2}$ was independent of the scan rate.

The syntheses of [Mo(NO)L(NCS)$_2$] and [Mo(NO)L(N$_3$)$_2$] further extend the known range of related pairs of complexes [Mo(O)LXY] and [Mo(NO)LXY]. Thus a parallel between the chemistries of the $\{Mo(=O)L\}^{2+}$ and $\{Mo(NO)L\}^{2+}$ moieties may be seen in terms of the type of co-ligands X and Y which can form isolable complexes with these molybdenum centres. However, this parallel does not extend to the electrochemical properties of the two series of complexes. There appears to be no general correlation between the variations in the reduction potentials of [Mo(NO)LXY] and of [Mo(O)LXY] as a function of X and Y as shown in Table 1. In particular, the complex [Mo(NO)L(N$_3$)$_2$] has an anodic reduction potential comparable with that of [Mo(NO)LCl$_2$], while the reduction potential for [Mo(NO)L(NCS)$_2$] is more comparable with those found for bis-amide complexes [Mo(NO)L(NHR)$_2$].[3] The molybdenum(V) azide complex, [Mo(O)L(N$_3$)$_2$], also has a reduction potential similar to that of its dichloro analogue, but the potential for the reduction of [Mo(O)L(NCS)$_2$] is surprisingly anodic whereas that for [Mo(NO)L(NCS)$_2$] is very cathodic. There is no consistent difference between the reduction potentials of the two series of complexes as shown by the ΔE_f values. Furthermore, a linear regression analysis of the relationship between E_{fN} and E_{fO} gave a correlation coefficient of 0.2099, indicating that there is no significant correlation between the reduction potentials for the two series of complexes. There is, of course, no particular reason to expect a good correlation since the oxo-complexes are formally d^1 systems containing a π-donor oxo ligand, whereas the nitrosyl derivatives are formally d^4 and contain a π-acceptor ligand. In this context it is noteworthy that the replacement of OPh by SPh produces a more pronounced anodic shift in the reduction potentials of the oxo complexes than of the nitrosyl complexes.

PREPARATION AND CRYSTAL STRUCTURE OF $[(1,5\text{-}C_8H_{12})Rh(\mu\text{-}\eta^2\text{-}ReO_4)]_n$

JOHN R. SHAPLEY,* BRUCE R. WHITTLESEY and SCOTT R. WILSON

School of Chemical Sciences and Materials Research Laboratory, University of Illinois, Urbana, IL 61801, U.S.A.

(*Received* 10 *August* 1988; *accepted* 30 *September* 1988)

Abstract—The reaction of $[(COD)Rh(\mu\text{-}Cl)]_2$ (COD = $1,5\text{-}C_8H_{12}$) with 2 equivalents of $AgReO_4$ in dry tetrahydrofuran (THF) at room temperature leads to orange, crystalline $[(COD)Rh(\mu\text{-}\eta^2\text{-}ReO_4)]_n$. The structure consists of infinite chains in which square-planar rhodium and tetrahedral rhenium centres are linked by oxygen bridges to form a $(—ReO_2—O—Rh(COD)—O—)_n$ polymer. The two unique Rh—O—Re angles are 176(1) and 157(1)°.

The organometallic chemistry of metal centres coordinated to oxyanion ligands is receiving much current attention.[1] There has also been strong interest in studying platinum metal complexes on oxide supports in order to examine the nature of the metal–oxygen interaction and its possible affect on heterogeneously catalysed reactions.[2] In the course of our studies of low-valent platinum metal complexes in oxide environments,[3] we have synthesized the compound $[(COD)Rh(\mu\text{-}\eta^2\text{-}ReO_4)]_n$ **(1)** (COD = $1,5\text{-}C_8H_{12}$). To our knowledge, compound **1** is the first structurally characterized example of a complex in which the perrhenate group acts as a bidentate bridging ligand.

The reaction of $[(COD)Rh(\mu\text{-}Cl)]_2$ with 2 equivalents of $AgReO_4$ in dry THF under nitrogen at room temperature produces $[(COD)Rh(\mu\text{-}\eta^2\text{-}ReO_4)]_n$, which, after filtering and concentrating the solution, is isolated as orange crystals. Complex **1** is soluble only in coordinating organic solvents. In the solid state it reacts readily with traces of moisture in the air, as shown by the loss of resolution for the IR bands attributed to coordinated ReO_4^- at 943(vs), 935(sh), 909(sh) and 899(vs) cm^{-1}.[4] The polymeric nature of **1** is suggested by its field desorption mass spectrum, which exhibits peaks corresponding to the formula units $[(COD)Rh]_3[ReO_4]_2$, $[(COD)Rh]_2[ReO_4]_2$ and $[(COD)Rh]_2[ReO_4]$, as well as $[(COD)Rh][ReO_4]$.

The solid state structure of **1** consists of infinite chains in which the metal atoms are connected by oxygen bridges to form a $(—ReO_2—O—Rh(COD)—O—)_n$ polymer. The basic structural unit is shown in Fig. 1 and the molecular dimensions are collected in Table 1.† Each polymer chain is propagated as a spiral along a crystallographic two-fold screw axis and consequently is chiral; this metal–oxygen chain structure is similar to that found in pyroxene silicates.[5] Each of the rhodium atoms is coordinated to two bridging oxygens and the midpoints of the two olefinic bonds of the cyclooctadiene ligand in a square-planar fashion. The rhenium atoms are tetrahedrally coordinated to two bridging and two terminal oxygens. One of the two unique Re—O—Rh angles in the complex is nearly linear, and the other is significantly bent. This is consistent with a largely σ-bonding interaction of one oxygen atom with the Rh(1) centre and a largely

π-bonding interaction from the other. However, the two Rh—O distances are virtually equal, and the Re—O_{bridge} and Re—$O_{terminal}$ distances are likewise only marginally different. The 1,5-cyclooctadiene ligand does not exhibit any unusual features.

A variety of transition metal complexes containing the ReO_4^- moiety are known.[6–12] In nearly all of the complexes that have previously been characterized structurally by X-ray diffraction, the perrhenate group coordinates as a unidentate ligand to one metal. However, in the compound $[(^tBuN)_2(Me_3SiO)Re]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}\eta^1\text{-}OReO_3)$,[6] one of the perrhenate oxygen atoms bridges two other rhenium atoms in a manner similar to an alkoxide group. The structure of compound **1** is related to the mode of coordination found in $[\{(NBD)Rh\}_5\{Nb_2W_4O_{19}\}_2]^{3-}$,[13] in which each diene–rhodium unit is connected to two different metal centres via separate oxygen bridges, one of which is nearly linear (167°) and the other strongly bent (121°). It is not completely clear why this is the preferred structure for **1**, although it may be significant that this geometry is the most suitable for forming "linear" Rh—O—Re bridges while maintaining favourable O—M—O angles at the rhodium and rhenium centres. Further studies are necessary to determine if this is a general tendency.

Abstract—$(CF_3)_2NON{=}PH$, synthesized by a novel method involving the reactions of $(CF_3)_2NONO$ and PH_3, underwent cleavage of the NO—NP bond by HI to give $IN{=}PH$ and substitution reactions with the $(CF_3)_2NO$ radical to afford $RN{=}PR$, where $R = ON(CF_3)_2$. While $IN{=}PH$ gave the relatively stable addition product, INHPHI, with HI, the addition product RNHPRI, derived from $RN{=}PR$, proved to be unstable even at low temperatures.

In recent years, growing research interest has emerged on the chemistry of unsaturated compounds of the main-group elements with low coordination numbers.[1] Among them are the two-coordinate phosphorus(III) compounds of the type $RN{=}PR'$.[2] However until now, relatively few such compounds have been synthesized: $Bu^tN{=}PBu^t$ and $Me_3SiN{=}PN(SiMe_3)_2$.[3,4] Their stability has been attributed to the presence of bulky substituents.[5] We now report a novel method of preparing a new fluorine-containing iminophosphine, namely N - bis(trifluoromethyl)nitroxy - iminophosphine, $(CF_3)_2NON{=}PH$. Investigations of its properties have led to the discovery of a few other similar iminophosphine derivatives.

The reactions of *o*-nitrosobis(trifluoromethyl) hydroxylamine and phosphine in a 1:1 molar ratio, at room temperature in an evacuated glass ampoule, afforded N-bis(trifluoromethyl)nitroxy-iminophosphine, $(CF_3)_2NON{=}PH$, in 60% yield:

$$(CF_3)_2NONO + PH_3 \rightarrow (CF_3)_2NON{=}PH + H_2O. \quad \textbf{(A)}$$

An orange solid which is hygroscopic was also formed in the reaction ampoule. The iminophosphine (A) was isolated at −96°C in a trap as a white solid by trap-to-trap fractionation under high vacuum. Its IR spectrum gave the following peaks: 2272 cm^{-1}, ν(P—H); 821 cm^{-1}, δ(P—H); 1324, 1244, 1050 cm^{-1}, ν(C—F); 721 cm^{-1}, δ(C—F). The peak at 1662 cm^{-1} can be attributed to the P=N stretching vibration. The EI MS (70 eV) of (A) did not exhibit the parent ion but gave characteristic fragmentation ions at m/e 195 $[C_2F_5NON{=}PH]^{+\cdot}$, 176 $[C_2F_4NON{=}PH]^{+\cdot}$, 168 $[C_2F_6NO]^{+\cdot}$, 149 $[C_2F_5NO]^{+\cdot}$, 83 $[CF_3N]^{+\cdot}$ and 69 $[CF_3]^{+\cdot}$. Molecular weight determination by Regnault's method gave 215 g mol^{-1} ($C_2F_6ON_2P$ requires 214 g mol^{-1}).

Anhydrous hydrogen iodide did not undergo addition reactions with (A). Instead, it preferentially cleaved the NO—NP bond to give N-iodoiminophosphine, $IN{=}PH$ in 54% yield, together with a quantitative amount of bis(trifluoromethyl)hydroxylamine, as shown by the following equation:

$$(CF_3)_2NON{=}PH + HI \rightarrow (CF_3)_2NOH + IN{=}PH. \quad \textbf{(B)}$$

In addition, an intractable hygroscopic yellow solid was also formed in the reaction ampoule.

N-Iodoiminophosphine was trapped at −126°C as a white solid on vacuum fractionation. Its IR spectrum showed the P—H stretching vibration at

2245 cm^{-1} and P—H deformation at 846 cm^{-1}. The N=P stretching vibration was located at 1646 cm^{-1}. Its EI MS gave the parent ion at *m/e* 173 and a fragmentation ion at 142 $[INH]^{+\cdot}$. Molecular weight determination by Regnault's method gave 172 g mol^{-1} (INPH requires 172 g mol^{-1}). Analysis of iodine gave 72.98% (INPH requires 73.41%).

To date, N-iodoiminophosphine is the smallest stable four-atom iminophosphine that has been discovered. The presence of the N=P double bond was chemically confirmed by the addition product (**C**) which was formed with anhydrous hydrogen iodide at room temperature, according to the following equation:

$$IN{=}PH + HI \rightarrow INHPHI,$$
(**C**)

whereby the hydrogen migrated to the nitrogen atom and the iodine to the more electropositive phosphorus atom. Compound (**C**), trapped at −96°C as a pale yellow solid on vacuum fractionation, is a colourless gas at room temperature. Its IR spectrum gave peaks due to the NH group at 3220 cm^{-1} and the PH group at 2209 and 807 cm^{-1}. The peak at 1646 cm^{-1} due to the N=P stretching vibration disappeared. It is unstable on standing at room temperature, decomposing to give iodine, non-condensable gases and a pale yellow intractable solid which contains iodine and phosphorus. The EI MS of (**C**) gave the parent ion at *m/e* 301, and fragmentation ion at 299 $[INPI]^{+\cdot}$. Analysis of iodine gave 83.49% (H_2I_2NP requires 84.38%).

The presence of the P—H bond in (**A**) was demonstrated by the reaction with bis(trifluoromethyl)nitroxyl, which is a powerful hydrogen abstractor and a radical scavenger. The reactions afforded bis(trifluoromethyl)nitroxy-substituted iminophosphine (**D**) in 80% yield, together with a quantitative amount of bis(trifluoromethyl) hydroxylamine;

$$(CF_3)_2NON{=}PH + 2(CF_3)_2NO \rightarrow (CF_3)_2NON{=}PON(CF_3)_2 + (CF_3)_2NOH.$$
(**D**)

The iminophosphine (**D**) was isolated at −60°C in a trap as a colourless liquid on vacuum fractionation. Its IR spectrum gave peaks due to the $(CF_3)_2NO$ group at 1324, 1300, 1243, 1270, 1001 and 723 cm^{-1}, and the N=P stretching vibration at 1663 cm^{-1}. The EI MS of (**D**) did not give the parent ion but gave characteristic fragmentation ions at *m/e* 343 $[C_2F_6NON{=}PONC_2F_4]^{+\cdot}$, 199 $[PONC_2F_6]^{+\cdot}$, 168 $[(CF_3)_2NO]^{+\cdot}$ and 69 $[CF_3]^{+\cdot}$. Molecular weight determination by Regnault's method gave 382 g mol^{-1} (compound (**D**) requires 381 g mol^{-1}). The reactions between the bis (trifluoromethyl)nitroxyl radical and (**B**) did not follow the same course as those with (**A**). Instead, an intractable hygroscopic brown, polymeric solid and some bis(trifluoromethyl)hydroxylamine were produced. The brown solid contained iodine, phosphorus and the $(CF_3)_2NO$ group. The reactions most probably underwent concomitant polymerization and attack of the PH hydrogen by the nitroxyl radical.

Reactions of (**D**) with hydrogen iodide at −90°C gave 1 mole of bis(trifluoromethyl)nitroxyl, iodine, an intractable orange solid and non-condensable gases which were most probably nitrogen and hydrogen. Hydrogen abstraction did not occur as no bis(trifluoromethyl)hydroxylamine was detected. The orange solid contained the $(CF_3)_2NO$ group, as indicated by its IR spectrum, and phosphorus. The products from these reactions can be rationalized in terms of the formation of the addition product (**E**), which then underwent decomposition via the radical intermediates (**F**) and (**G**), as illustrated by the following reaction scheme:

$$(CF_3)_2NON{=}PON(CF_3)_2 + HI \rightarrow$$

$$(CF_3)_2NON(H)-PON(CF_3)_2(I)$$
(**E**)
$$\downarrow$$
$$(CF_3)_2NONH + (CF_3)_2NOPI$$
(**F**) (**G**)

$$2(CF_3)_2NONH \rightarrow 2(CF_3)_2NO + H_2 + N_2$$

$$(CF_3)_2NOPI \rightarrow 1/2I_2 + 1/n[(CF_3)_2NOP]_n.$$

APPENDIX 405

1. INTRODUCTION

Primary deuterium kinetic isotope effects have been used by organic chemists for many years to elucidate the rate-determining steps and the nature of the transition states in a wide range of organic reactions. However, the mechanistic interpretation of the magnitude of observed kH/kD ratios has always been somewhat problematic. The "maximum" primary isotope effect can be estimated from the observed differences in zero point energies (i.e. differences in the X—D versus X—H stretching frequencies) using the Bigeleisen equation [eq. (1)]

$$k\mathrm{H}/k\mathrm{D} \sim \exp\left[\frac{hc}{2kT}(\nu_{\mathrm{H}}-\nu_{\mathrm{D}})\right] \tag{1}$$

for a reaction which is thought to have a linear symmetrical transition state and in which substitution of deuterium for hydrogen has no effect on the energy of the transition state. These constraints are rarely realized. Non-linear transition states are thought to attenuate the size of the isotope effect. Reactions with late transition states (i.e. the rate of bond breaking exceeds the rate of bond making for the hydrogen transfer) would be expected to lower the energy of the transition state and also attenuate the size of the isotope effect. Recently it has been proposed that reactions with linear transition states should show temperature dependent kH/kD ratios while those with non-linear transition states should show temperature independent kH/kD ratios.[1]

In addition, there is a separate class of isotope effects in which the observed kH/kD ratio is larger than that predicted from eq. (1).[1,2] These large kH/kD values are thought to be associated with 'barrier tunnelling'. Reactions in which the ground state geometry of the reactant resembles that of the product very closely would be expected to have a very narrow barrier. If the barrier width approaches the wavelength of the hydrogen atom, proton or hydride involved in the reaction, the particle can tunnel through the barrier rather than go over it. Substitution of deuterium for hydrogen would effectively turn off the tunnelling component of the reaction leading to unexpectedly high kH/kD ratios. The observation of a high kH/kD ratio is not, however, a sufficient criterion for ascribing barrier tunnelling to a reaction. The observed difference in activation energy on going from the protium to the deuterium system must be greater than that calculated from differences in zero point energy (i.e. $\Delta E_{a_H^D} \gg \Delta E_{o_H^D}$).[1] In order to meet this criterion, details of the differences in zero point energy must be available and it must be possible to obtain kH/kD values over a range of temperatures. These requirements are not often met by many kinetic studies and thus there are few well documented examples of barrier tunnelling for different reaction types. The best documented cases of barrier tunnelling exist for reactions involving proton transfer.[1-3]

In the organometallic chemistry of mononuclear and dinuclear species, kinetic deuterium isotope effects have been used extensively to elucidate the mechanisms of H—H and C—H activation processes and in processes involving M—H bond cleavage. No attempt will be made here to be comprehensive, but rather to present examples which illustrate the range of systems studied with regard to reaction type, metal centre and the magnitude of observed isotope effects.

Perhaps the most straightforward example of a kinetic deuterium isotope effect in transition metal chemistry comes from the work of Norton *et al.* who studied the proton self-exchange between cyclopentadienyl metallates [eq. (2)].[4]

$$(\eta\text{-}C_5H_5)M(CO)_3H + (\eta\text{-}C_5H_5)M'(CO)_3^- \rightleftharpoons (\eta\text{-}C_5H_5)M(CO)_3^- + (\eta\text{-}C_5H_5)M'(CO)_3H \qquad (2)$$

$$M = M' = Cr, Mo, W.$$

The observed kH/kD ratios of 3.7 for eq. (2) are in excellent agreement with the value of 3.39 calculated from eq. (1).[4] These results clearly suggest a linear symmetrical transition state taking place directly between metal atoms and demonstrate that there is nothing intrinsically anomalous about the magnitude of kinetic deuterium isotope effects involving the M—H bond.

The largest kinetic deuterium isotope effects involving transition metal centres appear to be associated with C—H activation processes at electrophilic metal centres. For example, Bercaw and co-workers have noted a kH/kD = 9.7 at 34°C for the formation of an azametallocyclopropane [eq. (3)].[5]

$$Cp^*Ta\{N(CH_3)_2\}(CH_3)_3 \longrightarrow Cp^*\overline{Ta\{N(CH_3)CH_2\}}(CH_3)_2 + CH_4 \qquad (3)$$

$$Cp^* = \eta\text{-}C_5(CH_3)_5.$$

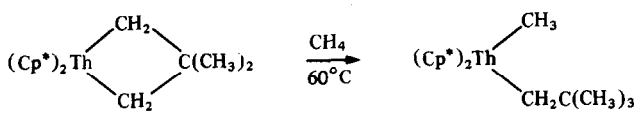
Given that the kH/kD calculated from eq. (1) for cleavage of an aliphatic C—H bond is 7 at room temperature, this value implies a significant tunnelling component for this intramolecular hydrogen transfer. Similarly kH/kD values of 4.8 (114°C) and 5.2 (180°C) have been reported for the elimination of toluene from a zirconium centre [eqs (4) and (5)][6]

$$Zr(OAr')_2(CH_2C_6H_5)_2 \xrightarrow[\Delta]{} \overline{Zr(OAr')(OC_6H_3Bu^tC(CH_3)_2CH_2)}(CH_2C_6H_5) + CH_3C_6H_5 \qquad (4)$$

$$Ta(OAr')_2(CH_3)_3 \xrightarrow[\Delta]{} \overline{Ta(OAr')(OC_6H_3Bu^tC(CH_3)_2CH_2)}(CH_3)_2 + CH_4 \qquad (5)$$

$$(OAr') = 2,6\text{-di-}t\text{-butylphenoxide.}$$

The reverse reaction (i.e. cleavage of a metallocycle by a hydrocarbon at an electrophilic metal centre) also shows a relatively large isotope effect. Thus cleavage of a metallocyclobutane at a thorium(IV) centre by methane [eq. (6)] gives kH/kD = 6 ± 2.[7]



(6)

Activation of the aromatic C—H bond in benzene by an electrophilic metal centre gives a $kH/kD = 5.5$ [eq. (7)][8]

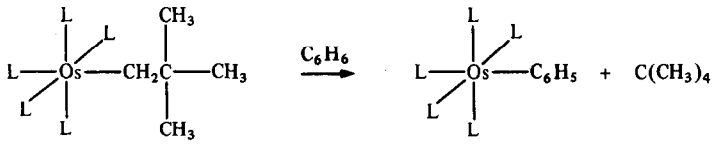
$$(Cp^*)_2LuCH_3 + C_6H_6 \longrightarrow (Cp^*)_2LuC_6H_5 + CH_4. \tag{7}$$

This isotope effect is operative for the bimolecular term of a two-term rate law (i.e. rate $= [k_1 + k_2(C_6H_6)][\text{complex}]$). The first-order term shows no isotope effect with C_6D_6 and is thought to arise from the reversible formation of a ring metallated intermediate.[8]

Much smaller isotope effects are observed for C—H activation at low valent late transition metal centres. Thus the photochemically generated intermediate $(Cp^*)IrP(CH_3)_3$, shows a $kH/kD = 1.38$ for the activation of cyclohexane [eq. (8)].[9]

$$(Cp^*)IrP(CH_3)_3H_2 \xrightarrow[-H_2]{h\nu} (Cp^*)IrP(CH_3)_3 \xrightarrow{C_6H_{12}} (Cp^*)Ir(PCH_3)_3(C_6H_{11})H. \tag{8}$$

Activation of the C—H bond in benzene at an electron rich osmium centre gave a $kH/kD = 2.2$ [eq. (9)].[10]

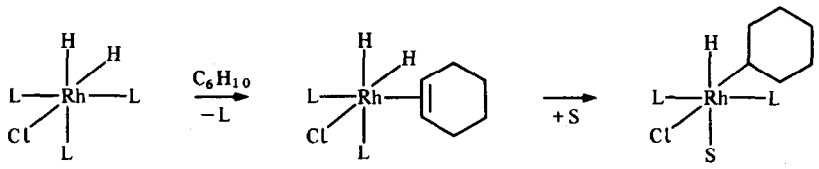


(9)

L = $P(CH_3)_3$

The large differences between kH/kD ratios at electrophilic metal centres and at electron rich metal centres delineated here, can be rationalized on the basis of early (for electrophilic metal centres) versus late (for electron rich metal centres) transition states for cleavage of the C—H bond. On the other hand, all the examples presented here for electrophilic metal centres involve direct transfer of hydrogen between carbon atoms, a reaction which could involve a large tunnelling component. The electron rich metal centres generally proceed via hydride intermediates which necessarily involve significant changes in geometry at the metal centre and might be expected to have little or no tunnelling component. These ideas need to be investigated further by carrying out variable temperature studies on the kH/kD ratios.

Reductive eliminations of C—H bonds from late electron rich transition metal centres also give relatively small kH/kD values. Thus, reductive elimination from a dihydride-alkene rhodium complex gives a $kH/kD = 1.15$ for the formation of a rhodium alkyl in the rate-determining step for olefin reductions [eq. (10)].[11]



(10)

L = PR_3 S = Solvent

Also, the binuclear reductive elimination mechanism elucidated by Norton *et al.* for osmium(II) hydrido alkyls shows a $kH/kD = 1.5$ [eq. (11)].[12]

$$2Os(CO)_4(H)CH_3 \xrightarrow[\Delta]{} CH_4 + H(CO)_4OsOs(CO)_4(CH_3). \tag{11}$$

It can be concluded from these examples that both C—H oxidative addition to and reductive elimination from mono- and binuclear electron rich metal centres will involve relatively small deuterium kinetic isotope effects (i.e. $kH/kD = 1$–2).

The oxidative addition of H_2 to electron rich metal centres also shows relatively small isotope effects ($kH/kD = 1$–2). Oxidative addition of $H_2(D_2)$ to the photochemically generated intermediate $Rh(Cl)\{P(C_6H_5)_3\}_2$ shows a $kH/kD = 1.4$ [eq. (12)].[13]

$$RhCl(CO)\{P(C_6H_5)_3\}_2 \xrightarrow[-CO]{h\nu} RhCl\{P(C_6H_5)_3\}_2 + H_2 \longrightarrow H_2RhCl\{P(C_6H_5)_3\}_2. \quad (12)$$

This value is in excellent agreement with the calculated value of 1.48 based on a theoretical model of the transition metal–dihydrogen bond involving donation from the H_2 σ-bond to empty orbitals on the metal (i.e. side-on coordination) and back donation from filled metal orbitals to the H_2 σ^*-orbital. The value of 1.4 is consistent with an early three-centred transition state involving little H—H bond breaking.[14]

Reductive elimination of H_2 from $H_2Os(CO)_4$ which has also been shown to proceed by a binuclear mechanism [as for eq. (11)] exhibits a kHH/kHD = 1.4 and a kHH/kDD = 2.9 [eq. (13)].[15]

$$2H_2Os(CO)_4 \longrightarrow H_2 + H_2Os_2(CO)_8. \quad (13)$$

Although these isotope effects are small they do indicate that reductive elimination of H_2 is one of two rate-determining steps in the reaction, the other being CO loss which preceeds formation of a proposed binuclear intermediate.

The reversible activation of H_2 has been observed by ^{1}H NMR techniques in the mononuclear dihydrogen complex $Os(\eta^2\text{-}H_2)H(CH_3CH_2)_2PCH_2CH_2P(CH_2CH_3)_2]^+$.[16] Here the terminal hydride exchanges with the side-on bound H_2 molecule and variable temperature studies on the $Os(\eta^2\text{-}HD)D$ system reveal kH/kD = 1.4, also in excellent agreement with the theoretical model for H_2 activation at transition metal centres.

Thermodynamic or 'inverse' isotope effects are quite common in organometallic chemistry and are observed in reactions where there is a reversible hydrogen transfer from a heavy metal atom to a light atom (O, N, C). They arise from the fact that ν(M—H) − ν(M—D) ≪ ν(C—H) − ν(C—D). The effect is generally manifested as a more rapid approach to equilibrium by the deuterated metal species. For example, in the addition of $HFe_2(CO)_8^-$ to α,β-unsaturated ketones a rapid pre-equilibrium between a diiron–alkene complex and the resulting diiron alkyl is established before the rate-determining step.[17] When $DFe_2(CO)_8^-$ is employed this equilibrium shifts towards the diiron alkyl since it has a C—D bond as opposed to an Fe—D bond. This gives a kD/kH = 3.5 which is in good agreement the value is 3.3, calculated from the expected differences in zero point energy using typical values for the Fe—H(D) and C—H(D) stretching frequencies.[17]

There are several examples in the literature of thermodynamic isotope effects in metal cluster chemistry.[18,19] In the equilibrium between the isomeric $(\mu\text{-}H)_2(\mu\text{-}CH_2)Os_3(CO)_{10}$ and $(\mu\text{-}H)(\mu\text{-}CH_3)Os_3(CO)_{10}$, site selection of deuterium for carbon over metal sites was observed for the dideuterated analogues of both isomers and was found to be ~ 1.5 : 1 by ^{1}H NMR methods and ~ 2.0 from neutron diffraction data at 35°C.[18] Calculated values based on differences in zero point energy gave a value of 2.2.[18] The observation of a significant thermodynamic isotope promises to be a valuable tool for identifying reversible M—H to C—H hydrogen transfers in multi-step reactions in mono- and polynuclear organometallic systems.

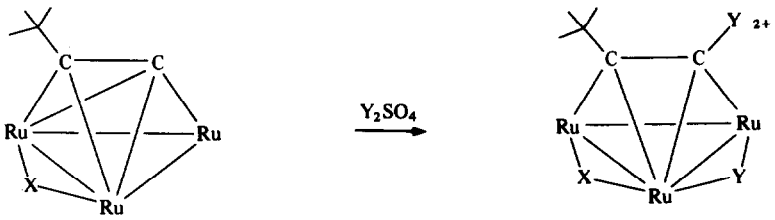
In the course of our studies on the mechanisms of reactions of small organic molecules with trinuclear transition metal clusters we have uncovered what appear to be two distinct categories of primary deuterium kinetic isotope effects, each of which is associated with a separate cluster process. We have observed a small isotope effect (kH/kD = 1.4–2.0) in cases where bridge opening or edge-to-edge migration of a μ-hydride is a rate-determining step in a ligand migration or in a cluster ligand reaction. A second category of large isotope effects (kH/kD = 28–50) seems to be associated with reactions involving transfer of hydrogen from a coordinated ligand to the metal core, or the reverse process. This categorization promises to provide an additional tool for finding the rate-determining step(s) in complex multi-step cluster reactions. We report here a summary of our experimental results to date including both published data and some preliminary results, along with results of other workers in the field who have documented similar observations.

2. THE SMALL PRIMARY ISOTOPE EFFECT (kH/kD = 1.4–2.0)

2.1 *Direct exchange of two μ-hydrides*

It was first pointed out by Johnson and co-workers[20] that when $(\mu\text{-}H)_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C{=}CH_2)$ (**1**) is deuterated by exchange with CF_3COOD to give $(H)(D)Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C{=}CH_2)$ (**1**-d_1) the rate of exchange of the inequivalent hydrides appeared to be slower in the deuterated species **1**-d_1.

Later, we measured the size of this kinetic isotope effect on hydride exchange by line-shape analyses of the ^{1}H NMR averaging of the two inequivalent hydrides in the complexes $(\mu\text{-H})_2(\mu_3\text{-}\eta^2\text{-HC}{=}\text{C}^t\text{Bu})\text{Ru}_3(\text{CO})_9^{2+}$ (**2**) and $(\mu\text{-H})(\mu\text{-D})(\mu_3\text{-}\eta^2\text{-DC}{=}\text{C}^t\text{Bu})\text{Ru}_3(\text{CO})_9^{2+}$ [(**2**-d_2) eq. (14), Fig. 1].[21]



(14)

(**2**) X = H Y = H
(**2**-d_2) X = H Y = D
(**2**-d_3) X = D Y = D

A value of kHH/kHD = 1.4±0.1 was obtained at 55°C. We also measured the rate of deuteride exchange in $(\mu\text{-D})_2(\mu_3\text{-}\eta^2\text{-DC}{=}\text{C}^t\text{Bu})\text{Ru}_3(\text{CO})_9^{2+}$ (**2**-d_3) (obtained according to eq. (1) using $(\mu\text{-D}(\mu_3\text{-}\eta^2\text{-C}^t_2\text{Bu})\text{Ru}_3(\text{CO})_9)$ by ^{2}H NMR and obtained a value of kHH/kDD = 1.8 (Fig. 1). This value must be taken as approximate since it was obtained from simulations which did not include quadrupolar effects in the line-shape analysis. However, the fact that kHH/kDD > kHH/kHD does exclude the possibility that the rate constant for migration of one hydride in $(\mu\text{-H})_2\text{Ru}_3(\text{CO})_9(\mu_3\text{-}$

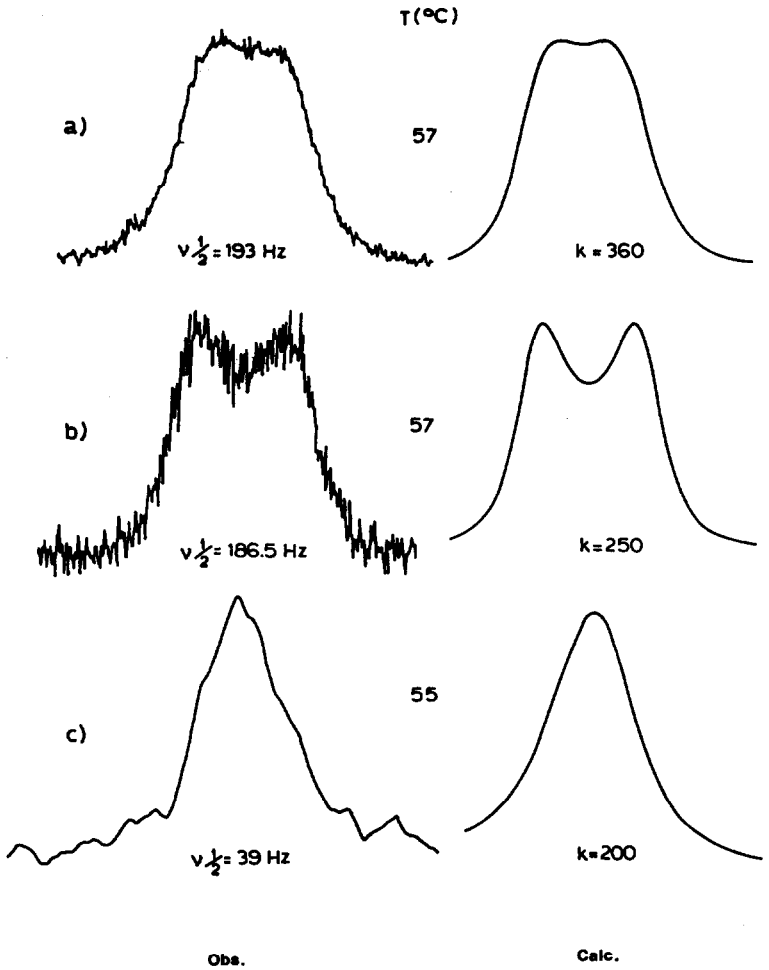


Fig. 1. (a) ^{1}H NMR of the hydride region of **2** in H_2SO_4 at 200 MHz; (b) ^{1}H NMR of **2**-d_2 in D_2SO_4 at 200 MHz; (c) ^{2}H NMR of **2**-d_3 in D_2SO_4 at 75 MHz.

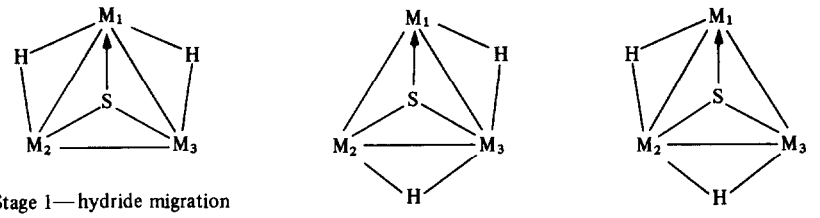
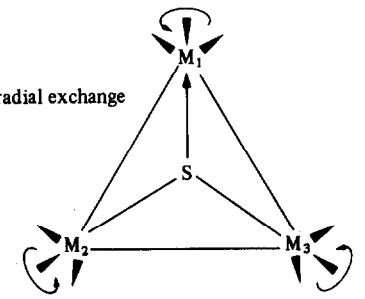


Stage 1—hydride migration

Stage 2—axial radial exchange



Scheme 1.

η^2-HC=C^{t}Bu)$^{2+}$ is much faster than the rate for the other unless the observed isotope effects are secondary, which they are not (*vide infra*). From the results obtained so far it does not seem likely that the isotope effect ratios obtained from direct hydride exchange in polyhydride species will be useful in distinguishing between consecutive and concerted hydride exchange because of their small size. More dynamic studies need to be carried out using ^{2}H NMR on polydeuterated clusters and mononuclear species before the full range of the isotope effect and its mechanistic implications can be appreciated.

In cases such as $(\mu\text{-H})_2M_3(CO)_9(\mu_3\text{-S})$ [M = Ru(**3**), Os(**4**)] where the two hydrides are magnetically equivalent, it is not possible to follow hydride exchange by ^{1}H NMR. These complexes exhibit a two stage carbonyl exchange process. The first stage of the exchange involves averaging of the three equatorial environments and the two axial environments, while the second stage of the exchange involves averaging of the axial with the radial carbonyls.[22] These results can be explained by invoking hydrogen migrations for the first stage of the exchange and localized axial–radial exchange for the second stage of the process (Scheme 1). In the case of **4**, actual motion of hydrogens has been demonstrated by the observed collapse of two sets of *trans*-^{1}H—^{183}Os two-bond coupling satellites to one in the same temperature range observed for the first stage of the exchange.[23] Studies of the VT–^{13}C NMR of phosphine derivatives of **4** show there is no intermetallic scrambling.[23] We have studied the VT–^{13}C NMR of $(\mu\text{-D})_2M_3(CO)_9(\mu_3\text{-S})$ [M = Ru (**3**-d_2), Os (**4**-d_2)] and found kH/kD ~ 1.5–1.7 for the first stage of the exchange from line-shape analysis of the VT–^{13}C NMR spectra, thus showing that the mechanism of exchange is the same for the osmium and ruthenium analogues (Fig. 2).[24] These results indicate that hydrogen migration is indeed responsible for the observed averaging of the three metal atom environments in the first stage of the exchange. It is also important to note here that the size of the isotope effect is insensitive to the mass of metal atom since kH/kD is almost identical for both the ruthenium and osmium analogues, as expected from the reduced masses ($\mu = (m_M \times m_H/m_M + m_H) \sim 1$). We are currently investigating the isotope effect on the higher energy exchange process in this class of molecules. So far, these studies illustrate the usefulness of kinetic deuterium isotope effects on hydride migrations in uncovering 'hidden processes' in the ligand dynamics of transition metal clusters.

2.2 *Axial–radial exchange of carbonyl groups*

The most useful application of the small primary isotope has been in establishing the connectivity of hydride migrations to other ligands on trinuclear clusters. Perhaps the clearest demonstration of

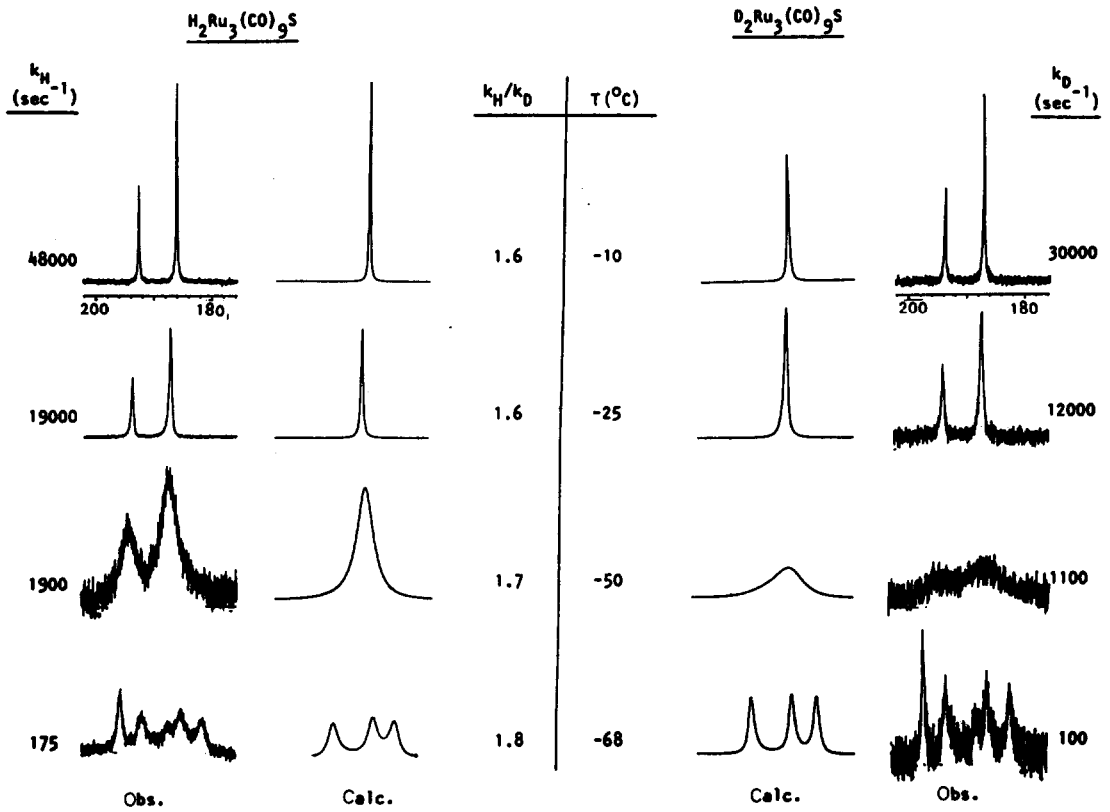


Fig. 2. VT–^{13}C NMR of (μ-H)$_2$Ru$_3$(CO)$_9$(μ_3-S) (**3**) and (μ-D)$_2$Ru$_3$(CO)$_9$(μ_3-S) (**3**-d$_2$) showing observed and calculated spectra for the first stage of exchange at 68 MHz.

this effect comes from VT–^{13}C NMR studies of (μ-H)HOs$_3$(CO)$_{10}$P(C$_6$H$_5$)$_3$ (**5**).[21,25] The bridge and terminal hydrogens in this series of complexes exchange according to Fig. 3. The turnstile motion of the two hydrides and CO(A) and CO(B) requires that CO(A) and CO(B) exchange sites. This process shows a temperature independent deuterium kinetic isotope effect for **5** of kHH/kDD = 1.5 (Fig. 3). This effect is also seen with (μ-H)(H)Os$_3$(CO)$_{10}$CN^{t}Bu (**6**) where the

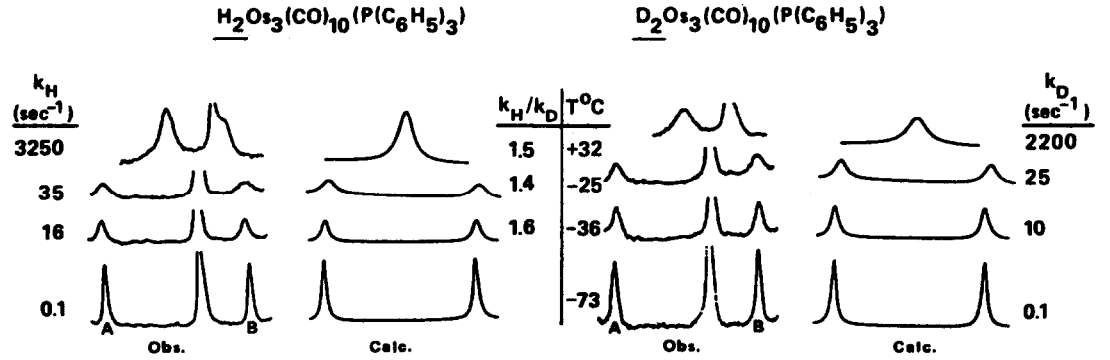

Fig. 3. Observed and calculated VT–^{13}C NMR in the carbonyl region of H(μ-H)Os$_3$(CO)$_{10}$P(C$_6$H$_5$)$_3$ (**5**) and D(μ-D)Os$_3$(CO)$_{10}$P(C$_6$H$_5$)$_3$ (**5**-d$_2$) at 20.1 MHz.

isocyanide occupies an axial position. Here the bridge–terminal interchange of the hydrides can be followed by ^{1}H NMR since these isocyanide complexes exist as mixtures of *cis* and *trans* isomers (with respect to the axial–terminal hydride and the isocyanide) which are interconverted by bridge–terminal exchange.[21]

Significantly, the higher energy localized exchange of the two carbonyl environments at the hydride bridge of the Os_3 triangle in $(\mu\text{-H})_2Os_3(CO)_{10}$ (**7**) shows no deuterium kinetic isotope effect (kHH/kDD = 1.0).[21,25] The hydrides have been shown to be rigid in $H_2Os_3(CO)_{10}$ at room temperature[25] and the absence of an isotope effect at least suggests that they are rigid near the fast exchange limit of the carbonyl environments at the hydride bridged edge of **7**. Taken together with the results for the $(\mu\text{-H})HOs_3(CO)_{10}L$ complexes, these results definitely show that the small isotope effect observed on axial–radial exchange of carbonyl groups cannot be secondary in nature.

With the above results in hand it is now possible to detect whether the motion of a hydride is connected with motion of other ligands even when it is not possible to directly observe hydride site exchange. For example, in the complex $(\mu\text{-H})Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2^tBu)$ (**8**) axial–radial exchange of the carbonyl groups at the hydride bridged edge of the triangle takes place at a significantly slower rate ($\Delta G^\ddagger = 62.7 \pm 1$ kJ mol^{-1}) than axial–radial exchange at the unique ruthenium atom ($\Delta G^\ddagger = 46 \pm 1$ kJ mol^{-1}).[26] The axial–radial exchange at the hydride bridged edge of the triangle shows an isotope effect (kH/kD $\sim$ 2) when the VT–^{13}C NMR spectra of the deuterated analogue $(\mu\text{-D})Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2^tBu)$ (**8**-d_1) was examined.[21] The value of this isotope effect must be taken as approximate since overlap of resonances precluded an accurate line-shape analysis. However, motion of the hydride is indicated or no kinetic deuterium isotope effect would be observed. The type of hydride motion however, is not indicated by these results. Alternate opening of the hydride bridge to a terminal hydride at each bridged ruthenium atom and movement of the hydride to a face bridging mode are the two likely possibilities. The hydride in this molecule has been located by neutron diffraction and is observed below the plane of the Ru_3 triangle on the opposite face to which the acetylido moiety is bound.[26] This position suggests that the hydride would have to move somehow in order to allow the pinwheeling motion by which axial–radial exchange occurs in this face capped cluster.[27] This conclusion is born out by the fact that the barrier to axial–radial exchange at the formerly bridged edge in the corresponding anion, $Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2^tBu)^-$, is considerably lower ($\Delta G^\ddagger = 41.8 \pm 2$ kJ mol^{-1}) than in **8**.[28]

2.3 *Face migrations of hydrocarbon ligands*

In the case of **8**, discussed in the previous section, and also in the case of the $\mu^3\text{-}\eta^3$-allyl clusters, $(\mu\text{-H})Ru_3(CO)_9(\mu_3\text{-}\eta^3\text{-}RC{=}{=}{=}C(R'){=}{=}{=}CR)$, our VT–^{13}C NMR studies indicate that the organic ligand is rigid relative to the carbonyl ligands which undergo localized axial–radial exchange and intermetallic carbonyl exchange.[26,28] In other structural configurations such as $(\mu\text{-H})_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}RC{\equiv}CR)$ and $(\mu\text{-H})M_3(CO)_9(\mu_3\text{-}\eta^2\text{-}RC{=}C{=}CR_2)$ (M = Ru, Os) both hydrogen and hydrocarbon ligand motions are indicated from VT–NMR studies, but the relationship between these two processes could not be clearly delineated.[29,30]

The class of molecules $(\mu\text{-H})_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}RC{\equiv}CR)$ exhibits a three stage exchange process for the carbonyl ligands. The first stage of the exchange involves collapse of the nine resonances observed at the low temperature (-100°C) limit to five resonances (at -70°C) and is readily explained by edge hopping of one hydride but not site exchange of the two hydrides (Fig. 4).[30] The second stage of the exchange collapses the five resonances to two in 1 : 2 relative intensity (at -20°C) and is thought to arise from localized scrambling of the carbonyl groups. The third stage of the exchange (above -20°C) averages all carbonyl environments and exchanges the two hydrides. This last stage of the exchange could involve alkyne motion and/or intermetallic carbonyl exchange.

Taking advantage of the diastereotopic methylene protons in $(\mu\text{-H})_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}CH_3CH_2C{\equiv}CCH_2CH_3)$ (**9**) we have shown that the alkyne is rigid in the temperature range of -100 to -20°C since the diastereotopic methylene resonances remain as a sharp AB pattern up to -20°C.[31] Above this temperature, alkyne motion and exchange of the two hydrides begin which averages all carbonyl environments. The calculated activation energy for hydride exchange ($\Delta G^\ddagger$ (300 K) $= 54 \pm 1$ kJ mol^{-1}) is slightly lower than that calculated for alkyne migration ($\Delta G^\ddagger = 60.0 \pm 1$ kJ mol^{-1}). An examination of the VT–^{1}H NMR of $(\mu\text{-D})_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}CH_3CH_2C{\equiv}CCH_2CH_3)$ (**9**-d_2) revealed an isotope effect of kHH/kDD = 1.50–1.75, in the temperature range -20 to $+34$°C,

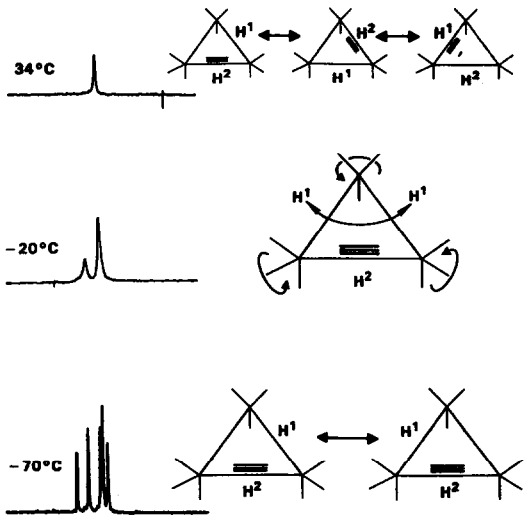

Fig. 4. VT–^{13}C NMR of the carbonyl region of $(\mu\text{-H})_2Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-RC}{\equiv}\text{CR})$ [R = CH_2CH_3 (**9**)] with the proposed exchange process for each stage of the exchange.

on the rate of migration of the alkyne group (Fig. 5).[31] The observed variation in the kHH/kDD ratio with temperature is approximately within the experimental error in the line-shape analysis ($\pm$10%). The average value of kHH/kDD = 1.65 is very close to a value of 1.5 observed for the axial–radial exchange of carbonyl groups, although formally different motions of the hydride are involved. In the $(\mu\text{-H})HOs_3(CO)_9L$ systems, opening of one hydride (or closing of the terminal

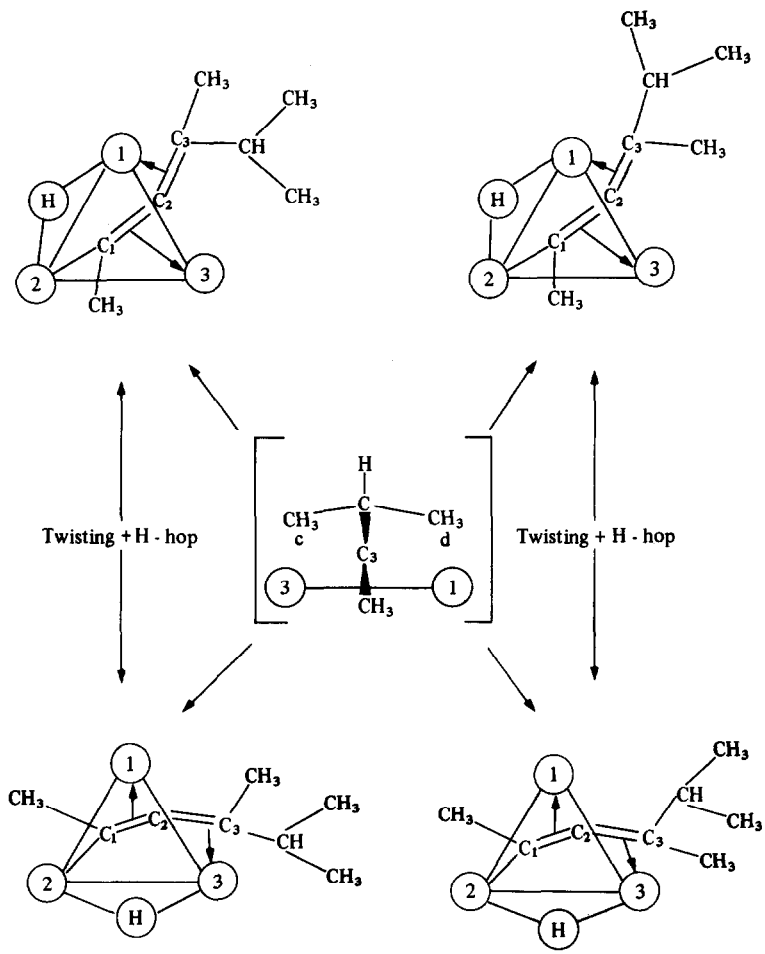
M = Ru, Os

Scheme 2.

hydride to a doubly bridged species) is the motion required, while in **9** edge hopping of the hydride is the required motion. Our results so far suggest that any type of motion of the hydride which is required for site exchange of another ligand (i.e. carbonyl or alkyne) will show an isotope effect where kH/kD ~ 1.5. It should also be noted here that the low temperature edge-to-edge migration of one hydride in **9** which results in the five line spectra seen at −70°C (Fig. 4) also shows an observable isotope effect, but it was not possible to evaluate kHH/kDD for this process due to severe overlap of resonances in the intermediate exchange regime.[31]

In the allenic complexes (μ-H)M_3(CO)$_9$(μ_3-η^3-RC═C═C(R)R) (M = Ru, Os; R = CH_3) we have observed an oscillating motion of the organic ligand which is apparently coupled with edge-to-edge migration of the hydride (Scheme 2). However, it was not possible to say whether the activation energy for the two processes is actually the same since the proton is in equivalent magnetic environments in both chemical configurations. We have addressed this point by synthesizing the unsymmetrical derivative (μ-H)Os_3(CO)$_9$(μ_3-η^3-CH_3C═C═C(CH_3)CH(CH_3)$_2$) (**10**) which exists as two isomers in solution (Scheme 3). Line-shape analysis of the VT-^{1}H NMR of the hydride and the



Scheme 3.

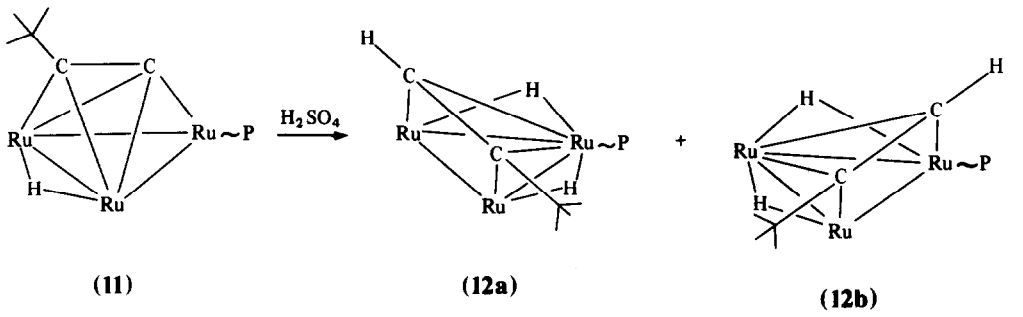
hydrocarbon regions gave identical activation energies ($\Delta G^{\ddagger}$ (300 K) = 70.8 ± 1 kJ mol^{-1}) for the averaging of the hydride and the methyl group environments in each isomer. A sample of **10** deuterated in the hydride position showed an isotope effect of kH/kD = 1.5 on the rate of averaging of the methyl groups in each isomer.[31]

Both of the examples discussed above show that when a hydrocarbon ligand migration requires hydride motion to exchange two equivalent geometries the motion of the hydride is the rate-determining step. This appears to be true even when the activation energy is slightly lower for hydrogen migration than for hydrocarbon motion.

2.4 *Chemical reactions involving hydride migrations*

It has been recognized for some time that the time scale of polytopal rearrangements in polynuclear clusters merges with the reaction time scale. However, examples where the rate of a specific dynamic process influences the rate of a cluster reaction have not been forthcoming. Recognizing the small isotope effect on hydride migrations discussed in the previous sections, we[32,33] and others [34] have recently uncovered several examples where substituting deuterium for hydrogen on a μ-hydride cluster changes the rate and/or the product distribution in a cluster reaction. In the three cases reported so far the kH/kD values reported are in the range 1.5–1.7. In light of the results discussed in sections 2.1–2.3 these kH/kD values suggest that opening or migration of μ-hydride is involved in the rate-determining step of these reactions.

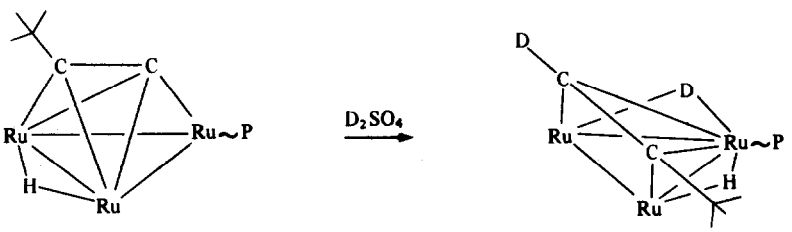
The first observation of a kinetic deuterium isotope effect in μ-hydride cluster chemistry was made in a study of the protonation of (μ-H)Ru$_3$(CO)$_8$(μ_3-η^2-C$'_2$Bu)(P(C$_6$H$_5$)$_5$) (**11**).[32] This complex undergoes a two step protonation in H_2SO_4 to give two kinetic products **12a** and **12b** [eq. (15)] in a 1.5 : 1 ratio.



(15)

(11) **(12a)** **(12b)**

Isomer **12b** slowly isomerizes to **12a** which can be isolated from the reaction mixture as its hexafluorophosphate salt. When D_2SO_4 is reacted with **11** only **12a** is detected by ^{1}H NMR [i.e. < 8% isomer b, eq. (16)].

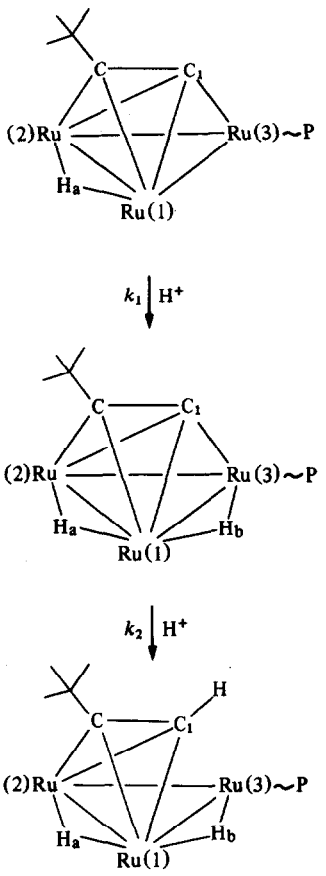


(16)

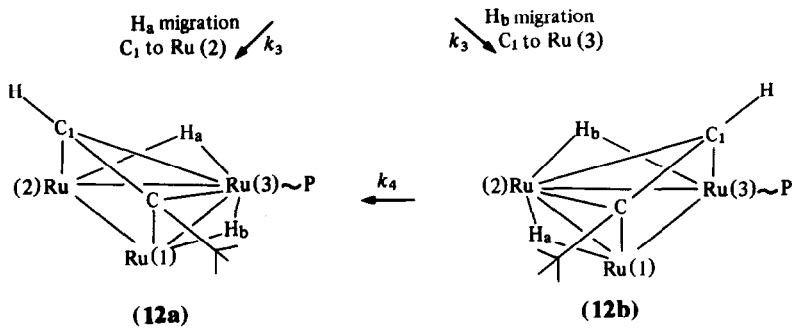
(11) **(12a)**

A sample of **11**, 65% deuterated in the hydride position, gave a 3 : 4 ratio of **12a**/**12b** when it was reacted with H_2SO_4, thus inverting the kinetic product distribution. Isomer **12b** slowly converts to isomer **12a** at the same rate as in the fully protic case.

These results can be understood in terms of the mechanism shown in Scheme 4. Initial protonation of **11** occurs on the metal core in H_2SO_4 as well as in acid solutions of CD_2Cl_2 and in neat



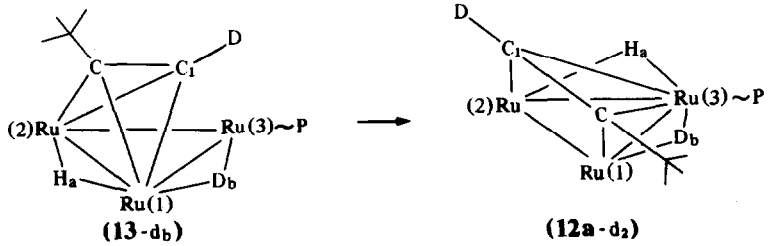
(13)



(12a) **(12b)**

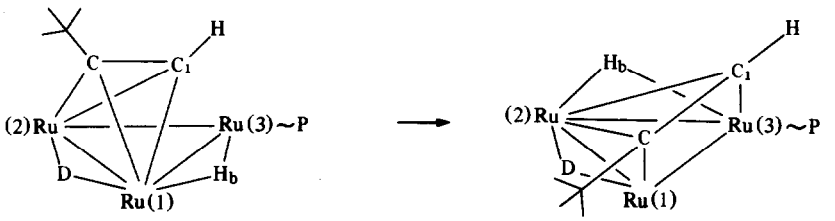
Scheme 4.

CF_3COOH (Scheme 4). If the second protonation takes place at the carbon atom, and is faster than hydride migration, intermediate **13** is produced. We propose that rearrangement of the organic ligand from a $5e^-$ to a $4e^-$ ligand requires a twisting motion of the ligand and migration of either H_a or H_b to give isomers **12a** or **12b**. In D_2SO_4 intermediate **13**-d_b is formed from which H_a migration and σ-bond formation to Ru(1) and Ru(2) is favoured [eq. (17)].



(13-d_b) **(12a-d_2)** (17)

σ-bond formation of Ru(2) and Ru(3) with *no* H_a or D migration is ruled out since this would yield some of the **b** isomer as a kinetic product and this is not observed. The use of 65% deuterated **11** gives **13**-d_a from which H_b migration and σ-bond formation to Ru(1) and Ru(3) is favoured [eq. (18)].



(13-d_a) (12b) (18)

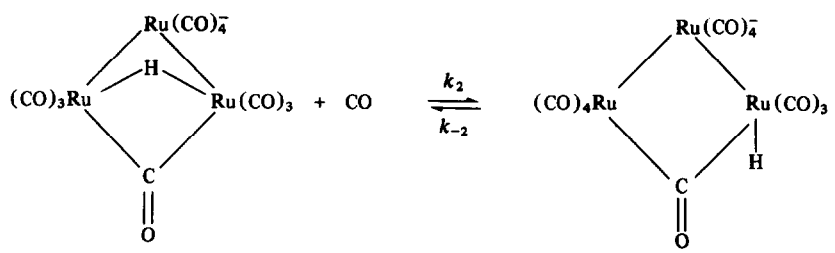
This interpretation of the observed deuterium isotope effect only requires that isomers **12a** and **12b** [eq. (15)] differ in their disposition of the hydride ligand with respect to the phosphine ligand, as they clearly do. An accompanying twisting motion of the organic ligand is also required to give **12a**, a structure which is symmetrical with respect to the phosphine ligand and unsymmetrical with respect to the organic ligand. We cannot rigorously exclude the possibility of intramolecular phosphine ligand migration but there is no precedent for this process in the literature, while there is precedent for migrations of organic ligands being associated with hydride migrations on trimetallic clusters, of the general type proposed here.[30,31]

It is not possible to extract an exact number for the deuterium isotope effect from these experiments since we do not know absolute rates of formation of **12a** or **12b**. The observed rate of rearrangement of **12a** to **12b** does not show a deuterium isotope effect after correction for the initial differences in isomer ratio. This is reasonable in that intramolecular hydride exchange randomizes deuterium on the metal core in the formation of **12a** when D_2SO_4 in reacted with **11**. The deuterium isotope effect is only observed for the more rapid hydride plus organic ligand migration. Since we have calculated the rate constant for hydride migration to be 10^2 s^{-1},[21] the second protonation step must have a rate constant larger than this value. We feel this is not unreasonable in the strong acid medium of H_2SO_4. The mechanism discussed above now has a basis in the observed isotope effects on hydride migrations and their direct connection to the motion of a μ_3-η^2-alkyne over the face of a trinuclear cluster (sections 2.1 and 2.3).

A recent study by Shore and co-workers[34] on intermolecular carbonyl exchange in $(\mu\text{-X})Ru_3(CO)_{11}^-$ [X = H(**14**) or D(**14**-d)] showed that the rate of ^{13}CO–^{12}CO exchange was 1.5 faster in the protic case for the associative part of the overall rate law:

$$\text{rate of } {}^{13}CO\text{–}{}^{12}CO \text{ exchange} = k_1[\text{cluster}] + k_2[\text{cluster}][CO].$$

This result was rationalized by invoking an opening of the μ-H-hydride bridge to a terminal hydride upon CO association [eq. (19)].

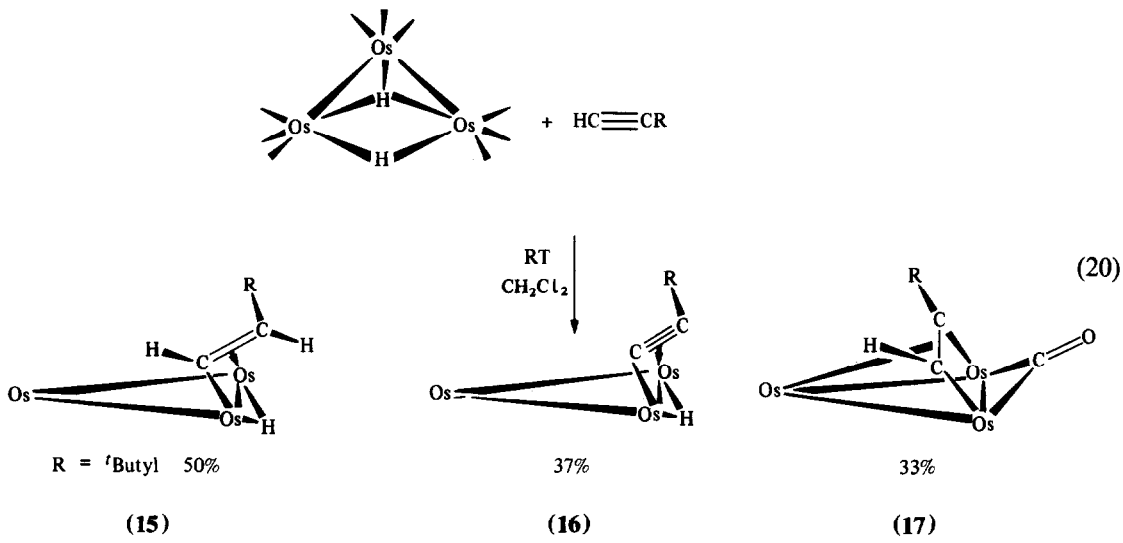


(14) (19)

The value of $k_2H/k_2D = 1.5$ fits very well with the observed isotope effect on hydride bridge opening in $H(\mu\text{-H})Os_3(CO)_{10}L$ systems (section 2.2). At very low CO pressures dissociative carbonyl exchange, for which hydride bridge opening is not required, is the dominant process for which a

kH/kD ~ 1 is observed. Similar results and the same kH/kD ratio were observed for the osmium analogue of **14**.

A second example where substitution of deuterium for hydrogen on a cluster results in a change in the kinetic product distribution is the reaction of $(\mu\text{-H})_2Os_3(CO)_{10}$ with terminal alkynes.[33] This reaction yields three major triosmium decacarbonyl products [eq. (20)]:



(20)

a μ-σ-π-vinyl complex (**15**), μ-σ-π-acetylido product (**16**) and a μ_3-η^2-alkyne complex (**17**). The product distribution in this reaction is highly sensitive to the steric bulk of the alkyl group of the terminal alkyne.[34] Thus, the relative amounts of **16** and **17** increase at the expense of **15** with increasing size of the alkyl group. In the case of acetylene, **15** is the only product, while for *t*-butyl acetylene the relative amounts shown in eq. (20) are obtained.

We have conducted a series of crossover experiments using deuterated cluster and alkyne (Table 1).[33] The experiments revealed a significant deuterium isotope effect on the product distribution. The

Table 1. Results of crossover experiments[a,b] for the reaction of $X_2Os_3(CO)_{10}+XC_2^tBu$ (X = H or D)

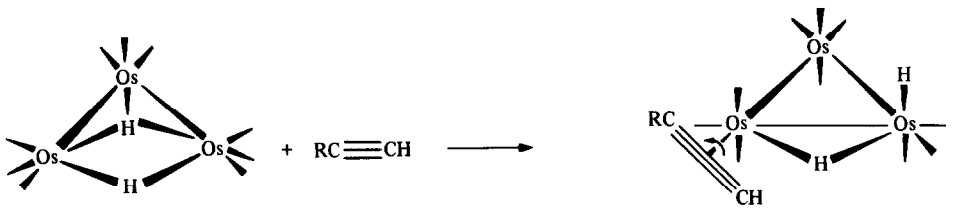
Case	Reactants, H vs D site: X in $X_2Os_3(CO)_{10}$	X in XC_2^tBu	Product percentages: **15**	**16**	**17**
1	H	H	50	37	13
2	H	D	45 (33% D in hydride)	39 (100% D in hydride)	16 (100% D)
3	D	H	32 (67% D in hydride)	51 (100% H in hydride)	17 (100% H)
4	D	D	23	56	21

[a] Reaction conditions: CH_2Cl_2, 25°C, 24 h, 3:1 mole ratio of alkyne to trinuclear cluster.

[b] Per cent conversion to **15**, **16** and **17** was 90% in all cases.

overall effect is the same as that obtained by increasing the steric bulk of the alkyl group on the alkyne, with **16** and **17** increasing in relative amounts at the expense of **15**. In addition, there is statistical scrambling of deuterium into the hydride position of **15** while there is no deuterium scrambling into the hydride position of **16** and the terminal alkyne hydrogen in **17** (Table 1).

The first step in this reaction is undoubtedly the coordination of the alkyne to the cluster. Because of the steric bulk of the alkyne, coordination is almost certainly in a radial position [eq. (21)].

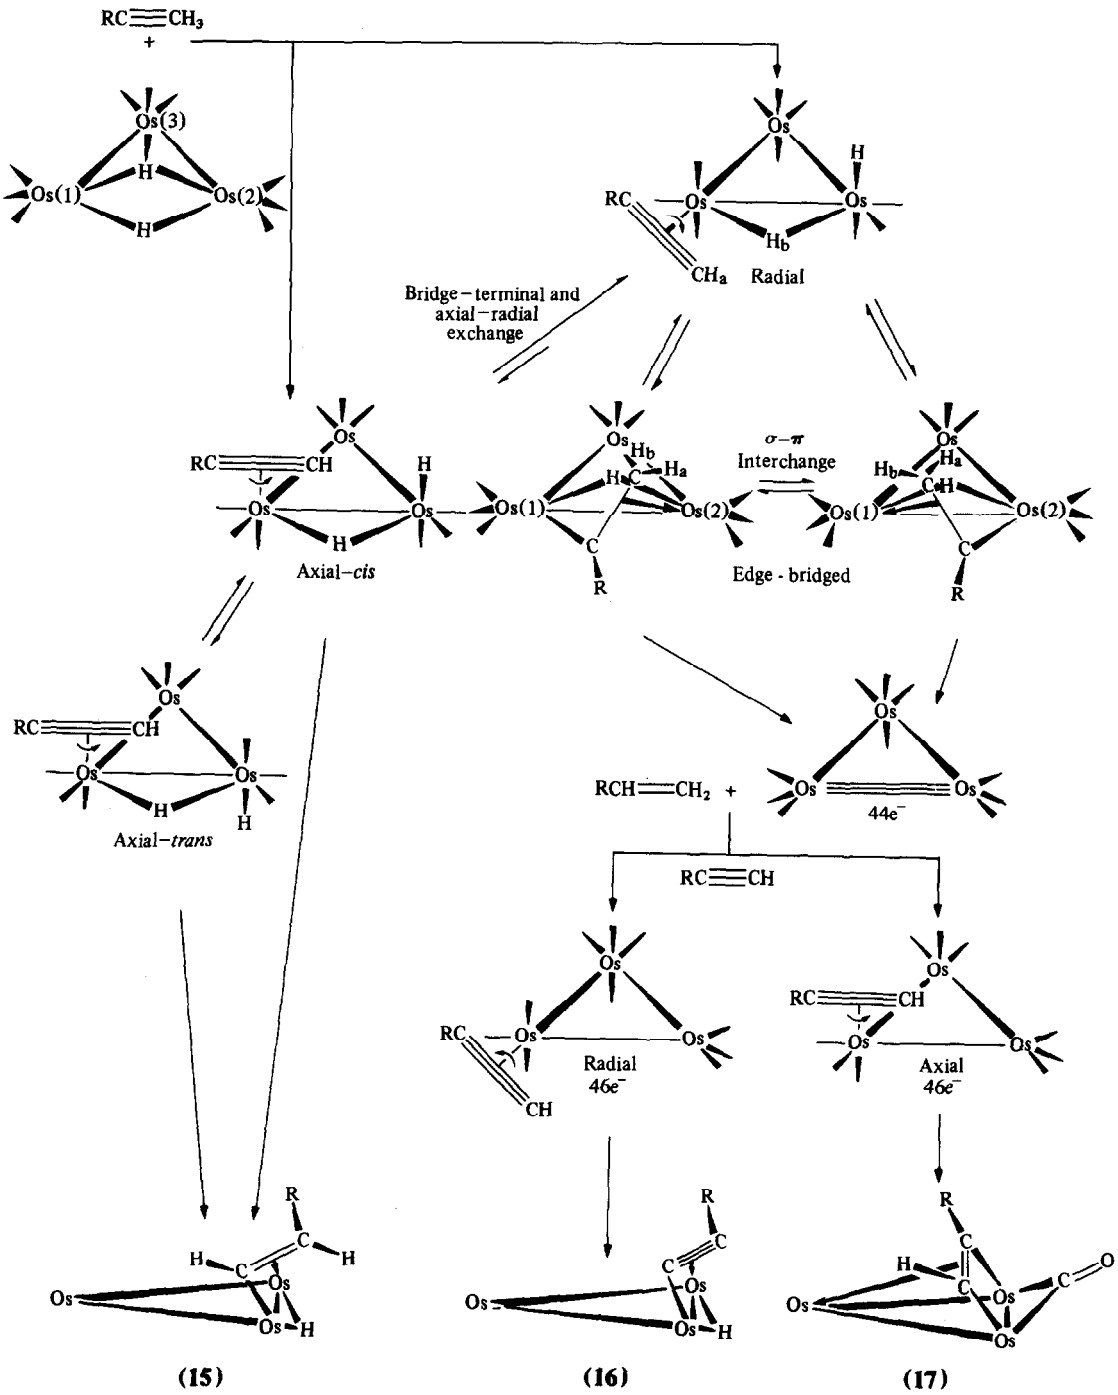


(21)

From this intermediate (which forms in undetectable amounts[33]), addition of an Os—H bond to the alkyne can occur with the hydrogen adding to either the terminal or internal carbon of the alkyne. Addition of the hydrogen to the terminal carbon could give an intermediate which undergoes reductive elimination of alkene and reaction with a second alkyne molecule to give **16** and **17**, while addition to the internal carbon would give **15** directly. Thus, the steric effect on the reaction can be understood in terms of the orientation of addition to the alkyne bond. However, it is more difficult to rationalize the observed isotope effects in terms of the orientation of addition to the alkyne bond alone. If the reductive elimination of alkene is a reversible process and the back reaction (alkene + cluster) is competitive with reaction of an unsaturated cluster intermediate with free alkyne, an inverse or thoermodynamic isotope effect could be operative. The observed shift in product distribution to **16** and **17** results from a shift in the equilibrium involving the alkyne adduct towards the unsaturated cluster intermediate and free alkene where more carbon–deuterium bonds are present. This explanation of the observed isotope effect on product distribution hinges on the reversibility of the reductive elimination of alkene for which there is no direct precedent in triosmium chemistry. We also feel that reaction with free alkyne would be much faster than the back reaction with alkene.

An alternative explanation for the observed kinetic isotope effect on product distribution, which also explains the observed steric effect, centres on the rate at which radial to axial migration of the coordinated alkyne occurs. Since **15** has the organic ligand coordinated on the face of the cluster, edge-to-face migration must take place during its formation from the radially coordinated alkyne adduct [eq. (21)]. Both the steric bulk of the alkyne and the presence of deuterium in the μ-hydride position (section 2.2) would slow down axial–radial interchange. Longer residence times in the radial position could allow a reversible hydride addition at the terminal end of the alkyne to occur to give an unstable edge bridged σ–π vinyl complex which could undergo reductive elimination of alkene or revert to the radially coordinated alkyne adduct (Scheme 5). A σ–π interchange of the edge bridging vinyl group which accomplishes a *cis–trans* interconversion would account for the observed scrambling of deuterium in compound **15** which is ultimately formed. The reversible formation of other edge bridged intermediates such as the μ-vinylidene complexes, $H(\mu\text{-}H)Os(CO)_{10}(\mu C{=}C(H)R)$ could also account for the observed scrambling. Irrespective of the nature of the edge bridged intermediate this interpretation of the deuterium isotope effect on the product distribution in eq. (20) has precedent in the known isotope effect for the axial–radial exchange and simultaneously explains the observed deuterium scrambling in **15** (Table 1) and the steric effect on the reaction.

The isotope effect ratio for this reaction is 1.6 (Table 1), which is very close to the value observed for axial–radial exchange in $H_2Os_3(CO)_{10}L$ (section 2.2). It is difficult to predict the size of a thermodynamic isotope effect for eq. (20), but a range of 2.0–3.5 would be predicted based on previous observations of this effect[18] and the calculated differences in zero point energies between $H_2Os_3CO_{10}L$ and $D_2Os_3(CO)_{10}L$ systems as calculated from the bridging and terminal hydride IR stretching frequencies.[35] The two alternative interpretations of the isotope effect observed for this



Scheme 5.

reaction [eq. (20)] illustrate the difficulties that can be encountered in interpreting small isotope effects in multi-step cluster reactions.

3. THE LARGE PRIMARY ISOTOPE EFFECT ($kH/kD = 7$–50)

3.1 *Ligand to metal hydrogen transfers in protonations of clusters*

Mays *et al.* have previously observed very large isotope effects in the protonation of neutral and anionic clusters with mineral acids (see Table 2).[36] In organic chemistry large isotope effects (i.e.

Table 2. Kinetic isotope effects in the protonation of transition metal clusters[a]

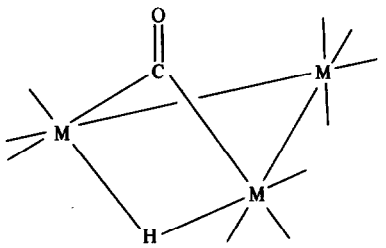
$OsCo_3(CO)_{12}^-$	16.2±1.0
$Os_3(CO)_{12}$	11±2
$[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$	7±1

[a] Taken from J. Knight and M. J. Mays, *J. Chem. Soc. A* 1970, 711.

isotope effects larger than calculated values based on differences in zero point energy) are thought to arise from reactions in which the barrier width is small and where the wavelength of the proton is similar to the width of the barrier. These types of barriers are usually associated with reactions in which there is very little distortion of the reactant ground state geometry on going from reactant to product.[1,3] The most common example of this type of reaction in organic chemistry is intramolecular proton transfer. The presence or absence of large kH/kD ratios has been used to characterize the transition states of these proton transfers.[3] In considering the large protonation isotope effects observed by Mays *et al.* we thought that their origin might be due to an initial protonation of oxygen followed by an intramolecular proton transfer down to the metal core [eq. (22)].

$$M_n(CO)_m^{n-} + H^+ \longrightarrow M_n(CO)_{m-1}(COH)^{(n-1)-} \longrightarrow HM_n(CO)_m^{(n-1)-} \quad (n = 0, 1). \qquad (22)$$

This seemed to us a very likely possibility in light of the recent work of Shriver[37] and Kiester[38] on the protonation of $(\mu\text{-H})M_3(CO)_{11}^-$ (M = Fe, Ru) (see structure **18**).



18 M = Fe, Ru, Os

In both the iron and ruthenium cases, initial protonation is at oxygen. In the ruthenium case, however, subsequent rearrangement to the dihydrido species $(\mu\text{-H})(H)Ru_3(CO)_{11}$ (**19**) can be observed [eq. (23)]. We have made a further investigation on the low temperature protonation of the $(\mu\text{-H})M_3(CO)_{11}^-$ (M = Fe, Ru) anions as well as the first investigation of the low temperature protonation of $(\mu\text{-H})Os_3(CO)_{11}^-$.[39] Indeed, we observed very large deuterium kinetic isotope effects on the transformation presented in eq. (22) for the low temperature protonation of the ruthenium and osmium anions.

$$\underset{\textbf{14}}{(\mu\text{-H})Ru_3(\mu\text{-CO})(CO)_{10}^-} + H^+ \xrightarrow{-80°C} \underset{\textbf{19}}{(\mu\text{-H})Ru_3(\mu\text{-COH})(CO)_{10}} \xrightarrow{-80°C} \underset{\textbf{20}}{(\mu\text{-H})(H)Ru_3(CO)_{11}} \qquad (23)$$

The protonation of $(\mu\text{-H})Fe_3(CO)_{11}^-$ with HSO_3F at −80°C gives only $(\mu\text{-H})(\mu\text{-COH})Fe_3(CO)_{10}$. This O-protonated species shows no tendency to rearrange to a dihydrido species at low temperature but decomposes with the evolution of H_2 as the temperature is increased to ambient.[37] The overall rate of protonation is the same when DSO_3F is used at −80°C, and no scrambling is observed

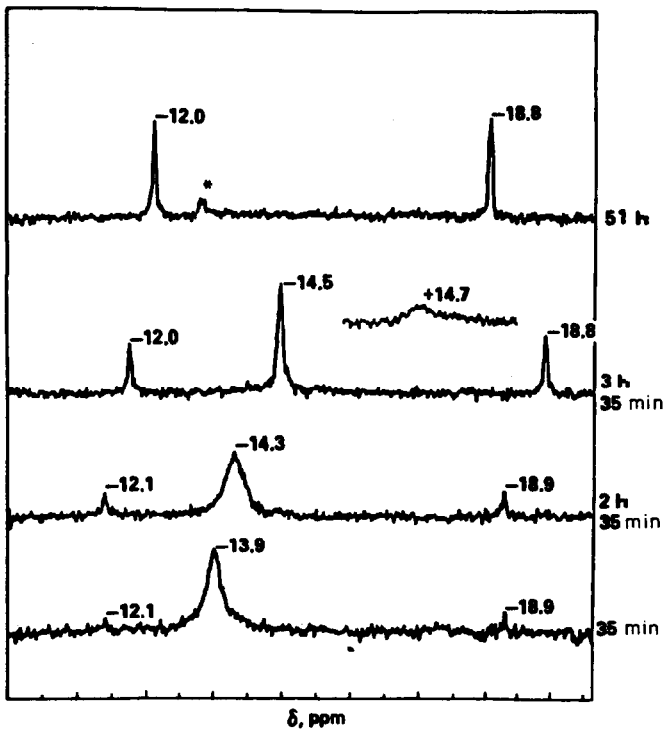


Fig. 6. Time dependent ^1H NMR spectra after addition of one equivalent of HSO_3F to a CD_2Cl_2 solution of **14** at −80°C. (*) Original **14** hydride signal observed at −13.0 ppm indicating a slight deficiency of the acid.

between the deuterium on the oxygen and the bridging hydride in the $(\mu\text{-H})(\mu\text{-COD})Fe_3(CO)_{10}$ produced.[39] These results clearly showed that there is no deuterium kinetic isotope effect in the proton transfer step from the acid to the oxygen of the bridging carbonyl [eq. (23)] and that there is no exchange between the hydride and the hydrogen on the oxygen.

In the case of **14** we found conditions (−80°C, 1 equiv HSO_3F in CD_2Cl_2) where only the O-protonated species $(\mu\text{-H})(\mu\text{-COH})Ru_3(CO)_{10}$ (**19**) is initially formed and where gradual conversion to the dihydrido species **20** is complete in approximately 50 h (Fig. 6). Under identical conditions, on protonation of **14** with DSO_3F, no conversion of **19** to **20** is observed (Fig. 7). At −40°C with HSO_3F, conversion of **19** to **20** is complete in about 1 h. When **14** is deuterated with DSO_3F at −80°C then warmed to −40°C, conversion to $(HD)Ru_3(CO)_{11}$ is only partially complete after 47 h. Clean conversion of $(\mu\text{-H})(\mu\text{-COD})Ru_3(CO)_{10}$ to $(HD)Ru_3(CO)_{11}$ is complicated by the formation of another unidentified hydride containing species at −40 to −60°C. It is therefore not possible to accurately access the magnitude of kH/kD for this ligand to metal hydrogen transfer, except to set a lower limit for the effect of ~ 50 at −40°C. Based on differences in zero point energy the maximum value for kH/kD (i.e. for a symmetrical–linear transition state) for cleavage of an O—H versus an O—D bond is ~ 50 at −80°C and ~ 25 at −40°C.* Given that it is highly unlikely that the transition state for this ligand to metal hydrogen transfer is either symmetrical or linear it is reasonable to propose that there is a significant tunnelling component for transfer of a hydrogen from a protonated carbonyl group to the metal core. In order to prove this one must show that $\Delta E_{a_D^H} \gg \Delta E_{0_D^H}$ (where E_a is the activation energy and E_0 is the zero point energy), which is not possible in the case of the conversion of **19** to **20**. These results do strongly suggest that the large isotope effects observed by Mays (Table 2) at room temperature arise from the initial protonation at the oxygens of the metal carbonyls followed by proton transfer to the metal core. That this type of transformation should involve a large tunnelling component seems reasonable since only minor

* Using a value of 3600 cm^{-1} for the O—H^- bond and 2525 cm^{-1} for the O—D bond.

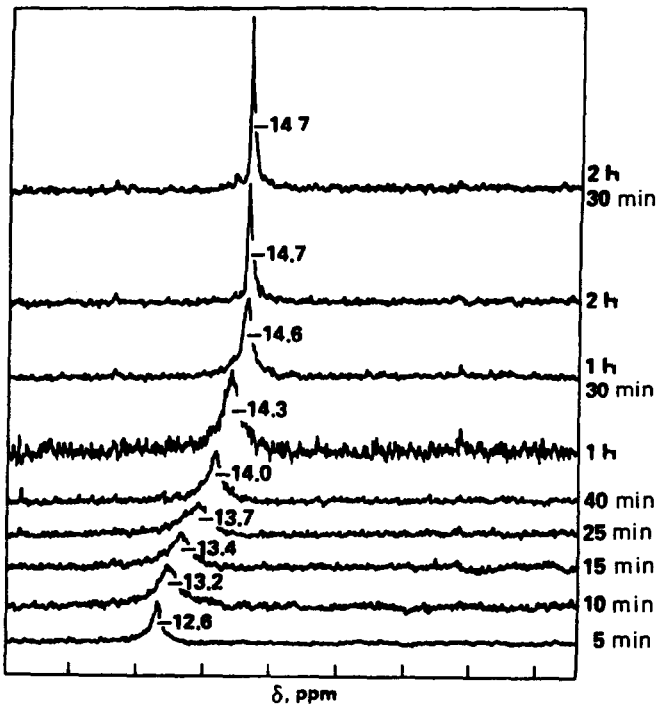

Fig. 7. Time dependent ^1H NMR spectra after addition of one equivalent of DSO_3F to a CD_2Cl_2 solution of **14** at −80°C. Original **14** hydride signal was observed at −13.0 ppm.

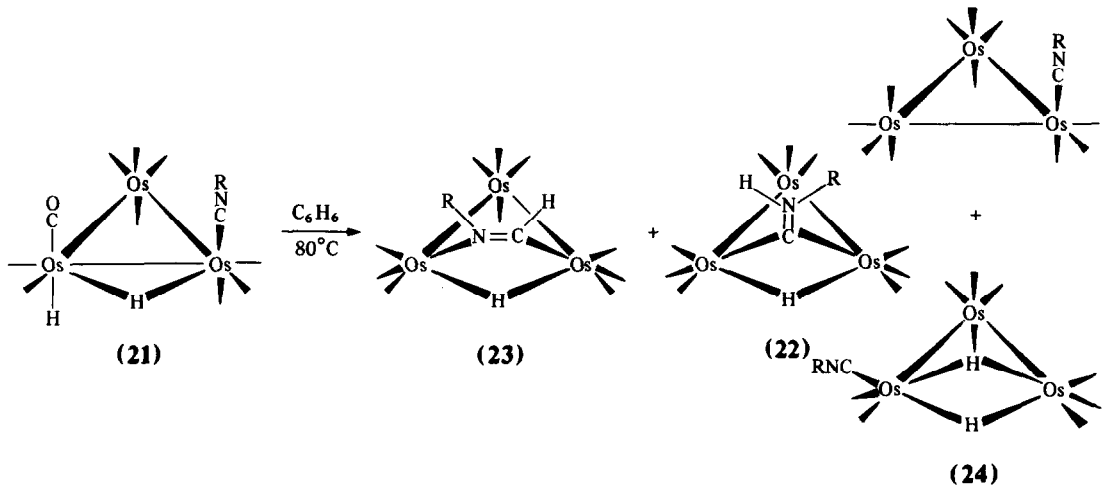
changes in cluster geometry are required on going from an O-protonated to M or M—M-protonated species. We are currently examining the low temperature protonations of the complexes investigated by Mays and co-workers at room temperature.[36]

Regardless of the actual magnitude of this large isotope effect or whether or not barrier tunnelling is actually involved, its sheer size will make it useful for identifying the kinetic site of protonation in polynuclear carbonyl clusters. For example, low temperature protonation of $(\mu\text{-H})Os_3(CO)_{11}^-$ with HSO_3F gives $H(\mu\text{-H})Os_3(CO)_{11}$ directly as the only detectable product.[39] Under the same conditions protonation with DSO_3F gives only $(\mu\text{-H})(\mu\text{-COD})Os_3(CO)_{10}$ up to 4 h after neutralization.[39] This species has never been observed before and was identified in solution on the basis of its low temperature ^{13}C NMR spectrum, for which the pattern of carbonyl resonances observed is identical with that of its iron analogue.[37] These studies reveal that the kinetic site of protonation in all three $(\mu\text{-H})M_3(CO)_{11}^-$ (M = Fe, Ru, Os) anions is the oxygen of the bridging carbonyl, despite the large increase in the stability of the metal–hydrogen bond of $H(\mu\text{-H})M_3(CO)_{11}$ as one goes down the iron triad.[36]

3.2 *Metal to ligand hydrogen transfers*

The large deuterium kinetic isotope effects for ligand to metal hydrogen transfers discussed in the previous section suggest that a similar effect should be observed in reactions where the reverse process (i.e. hydrogen transfer from metal to ligand) is the rate-determining step. This is particularly true for reactions with a large tunnelling component where proton barrier tunnelling would be quenched by deuterium substitution at the metal or the ligand atom.

The thermal reactivity of the series of complexes $H(\mu\text{-H})Os_3(CO)_{10}(CNR)$ (**21**) (R = CH_3, C_6H_5, $C(CH_3)_3$) has been studied by Adams and Golembeski.[40] Varying amounts of the two metal to ligand hydrogen transfer products, $(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-}\eta^1\text{-C=N(H)R})$ (**22**) and $(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-}\eta^2\text{-HC=NR})$ (**23**) are obtained in addition to smaller amounts of the two isomers of $(\mu\text{-H})_2Os_3(CO)_9(CNR)$ (**24**) and $Os_3(CO)_{11}(CNR)$ [eq. (24)].

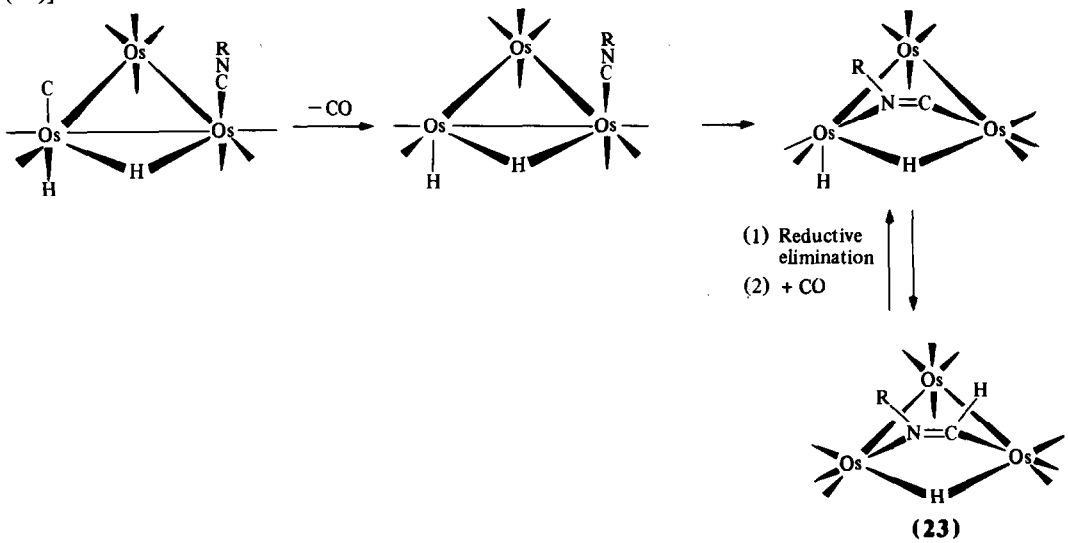


(24)

Transfer of hydrogen to nitrogen to give **22** is favoured in coordinating solvents, and is catalysed by base. Transfer of hydrogen to carbon to give **23** requires a carbonyl dissociation–association and can be formed from **24** in the presence of CO.[40,41] The amounts of **22** and **23** obtained are also dependent on R and these two products do not interconvert.[40]

We have found that for **21** ($R = CH_3$) clean conversion to **22** takes place at room temperature even in dry benzene-d_6 with a first-order rate constant, $k_H = 8.5 \pm 0.3 \times 10^{-4}$ min^{-1} at 30°C.[41] The same conversion using (D)(μ-D)$Os_3(CO)_{10}(CNCH_3)$ (**21**-d_2) gives a rate constant $kD = 3.1 \pm 0.3 \times 10^{-5}$ min^{-1} ($kH/kD = 26.9$). The calculated "maximum" isotope effect for this reaction is 3.5 based on the observed difference in stretching frequencies between the terminal M—H and M—D bond (2.7 based on the difference between the bridging M—H versus M—D bond).[35] These results strongly suggest a significant tunnelling component for this apparently polar osmium to nitrogen hydrogen transfer. Variable temperature studies to verify this point are underway. It is important to point out here that addition of base to benzene solutions of **21**-d_2 quenches the observed isotope effect as well as accelerating the rate of the metal to nitrogen hydrogen transfer (Table 3). Thus intermolecular proton transfer is a separate reaction pathway.

Thermolysis of **21** ($R = C_6H_5$) in benzene-d_6 gives only **23** ($kH = 1.23 \pm 0.2 \times 10^{-2}$ min^{-1} at 60°C). Thermolysis of the deuterated analogues under identical conditions showed a small inverse effect ($kD = 2.01 \pm 0.2 \times 10^{-2}$ min^{-1}, $kH/kD = 0.5$). This indicates that the metal to carbon hydrogen transfer is a reversible process.[40] Taken together with the fact that formation of **23** is repressed by a carbon monoxide atmosphere these results suggest that the metal to carbon hydrogen transfer is a reversible reductive elimination which takes place via an $H_2Os_3(CO)_9(RCN)$ intermediate [eq. (25)].



(25)

Under CO			

These conclusions are further corroborated by our recent investigation of the thermolysis of **21** (R = *p*-$CH_3C_6H_5$) where **22**, **23** and **24** are all obtained in detectable amounts (Table 4).[41] As can be seen from the data in Table 4 deuterium substitution on the cluster increases the amount of **23** while decreasing the amount of **22**. In fact, by performing the reaction under a carbon monoxide atmosphere **22** is the only product, while with deuterium under vacuum **23** is almost the exclusive product. These results illustrate the usefulness of deuterium kinetic isotope effects in evaluating the rate-determining step in multi-product reactions involving metal to ligand hydrogen transfers in transition metal hydride clusters. Furthermore, they show that metal to ligand hydrogen transfers can take place by very different mechanisms.

4. CONCLUSIONS AND FUTURE WORK

The two types of kinetic deuterium isotope effects presented here illustrate two ways in which cluster reaction pathways can involve a hydride ligand in a rate-determining step. The small primary isotope effect can be operative where edge-to-edge migration or bridge opening of a μ-hydride is a requirement for or a connected process with: (1) migration of a μ_3-capping ligand over the face of a cluster; (2) axial–radial (edge-to-face) interconversion; (3) opening of a coordination site on one metal atom of a cluster. Saturated clusters appear to behave like cog and wheel mechanisms and it is not surprising to find these connections in their intramolecular rearrangements. It is surprising, however, that the small primary isotope is so similar in magnitude for different dynamical processes. Theoretical studies which try to model the energies of μ-hydride bridge opening and the associated changes in metal–metal bond length are needed to gauge the expected magnitude of this effect. Unfortunately accurate potential surfaces for second and third row clusters like those presented here are difficult to come by. At this time it is not known whether this small isotope effect is strictly confined to μ-hydrides. It may well be that terminal hydride migration between two stereochemically distinct environments in a mononuclear species would also show this type of isotope effect. In fact, we recently observed an isotope effect (kH/kD = 1.6) on the *cis–trans* interconversion in $[(\eta\text{-}C_6H_5)Cr(CO)_2(P(CH_3)_2C_6H_5)H]^+$.[42] The small size of this effect is consistent with an early transition state in which there is little M—H bond breaking.[14] For the intramolecular hydrogen migrations

studied herein this seems quite reasonable since the hydride never completely dissociates from the metal cluster.

The examples of the large primary deuterium kinetic isotope effects presented here all appear to be associated with intramolecular proton transfers from metal to ligand or the reverse process. However, there is no reason to assume that deuterium kinetic isotope effects of similar magnitude could not be observed in reactions where a hydrogen atom or hydride transfer are involved in the rate-determining step. The primary criteria for a reaction to have a large tunnelling component are that the ground state geometry of the reactant and product are very similar and that the reaction should be close to thermoneutral.[1-3] The results obtained so far suggest that isotope effects in metal clusters are considerably larger than those observed for similar reactions in mononuclear species. However, the examples discussed here all involve transformations which occur at one edge of a trinuclear cluster and should therefore be observed in similar transformations in binuclear systems. It is more difficult, but not impossible, to imagine cases where proton transfer to or from a ligand in a mononuclear system would not involve considerable distortion of the ground state reactant geometry on going to the product. We are currently examining a series of mononuclear and binuclear systems where hydrogen transfer takes place from a metal atom to a coordinated ligand in order to elucidate these points further.

1. INTRODUCTION

The advantages of homogeneous catalysts with respect to reactivity and selectivity are well documented.[1] However, the sensitivity of the catalyst or its precursor to air or moisture, and the problems associated with the separation of the products from the catalyst have frequently presented a major economic barrier to commercial applications. Although research is still very active in the field of "heterogenized" homogeneous catalysis, with the aim of producing supported systems possessing the selectivity and reactivity advantages of homogeneous catalysts, coupled with the ease of separating products offered by heterogeneous systems, there has been little or no commercial success.

An alternative solution to the separation problem was proposed in the early 1970s,[2–4] when it was realized that a liquid–liquid bi-phasic system could be used and that the catalyst and its substrate need not necessarily be in the same liquid phase. Parshall[2] demonstrated the concept using molten $[R_4N][SnCl_3]$ or $[R_4N][GeCl_3]$, in combination with platinum chloride, as catalyst precursors for the hydrogenation of olefins. However, it was not until the exploitation of water soluble transition metal complexes based on sodium diphenylphosphinobenzene-*m*-sulphonate (**1**, DPPS)[5–11] that bi-phasic catalysis really became practical. The uses of bi-phasic hydrogenation have been reviewed by Joo and Toth,[11] and more recently, Sinou[12] has reviewed both the synthesis of water-soluble phosphines and their applications in catalysis. The industrial interest in the use of bi-phasic systems for hydroformylation and related processes can be seen from the patent literature.[13–18]

A second and related technique is that of transition metal phase transfer catalysis. This technique

* Present address: Johnson Matthey Technology Centre, Blount's Court, Sonning Common, Reading RG4 9NH, U.K.

based on an aqueous–organic system, containing both a phase transfer agent and a transition metal complex, has already been reviewed by Alper.[19–21] Possible applications of this technique for several processes related to heavy oil upgrading have already been demonstrated.

The industrial uses of this process are expanding rapidly. In North America alone it is estimated[22] that between 50,000,000 and 100,000,000 lb of chemicals are produced annually by phase transfer processes and that the demand for phase transfer agents has increased from an estimated 40,000 lb in 1980 to over 1,000,000 lb in 1985. This review is particularly concerned with the use of phase transfer and bi-phasic systems for the upgrading of crude hydrocarbon fractions.

2. DEFINITION OF TERMS

The term bi-phasic catalysis has been used to describe both two phase liquid–liquid as well as liquid–solid, gas–liquid and gas–solid reactions. In this review the term is used uniquely to describe a catalytic process using a mixture of two immiscible liquids but which does NOT require the presence of a phase transfer agent.

In general, but not necessarily, the catalyst has a high solubility in one phase, but only very limited solubility in the second phase in which the products (and substrates) are very soluble. The separation of products becomes, in such cases, a matter of separating the two immiscible phases.

Phase transfer catalysis normally refers to an aqueous–organic system in which a phase transfer agent possessing both hydrophobic and hydrophilic functions is necessary in order for the catalytic process to take place.

In the majority of phase transfer processes reported to date, the transition metal complex and the organic substrate are located in the organic phase. Therefore, although this technique involves a two phase liquid–liquid system, it does not necessarily overcome the problems associated with the separation of products and reactants from the soluble catalyst. Throughout this review a number of ligand and counter-ion systems will be encountered.

3. CATALYTIC PROCESSES

3.1 *Hydrogenation*

(a) *Bi-phasic hydrogenation.* Although some work has been reported on bi-phasic catalytic hydrogenation of water soluble unsaturated substrates using an organic soluble transition metal complex,[5,79,80] it was very soon realized that for the system to be of widespread practical use, the catalyst would have to be water soluble and the substrate should remain in the organic phase. It is therefore not surprising that the major developments in bi-phasic catalysis have paralleled developments in the preparation and chemistry of organophosphine ligands which would render their metal complexes soluble in highly polar solvents yet retain catalytic properties similar to those of organic soluble complexes. The first such phosphine synthesized was reported in 1958[23] but it was not until the mid 1970s[5–11] that bi-phasic catalytic applications of this ligand were reported. In the intervening period, the preparation and reactivity towards transition metals of other functionalized phosphine compounds were reported.[24] The catalytic activity of the resulting complexes was significantly lower than the complexes of the corresponding unfunctionalized phosphine.

The bi-phasic catalytic hydrogenation of a number of unsaturated species has been reported for both rhodium[5,6,13–18,25,26] or ruthenium[6–11,26] derivatives of sodium diphenylphosphinobenzene-*m*-sulphonate (**1**) and for rhodium derivatives of amphos ($[(Ph_2P)_2CH_2CH_2NMe_3]^+$).[27–31]

2

Several attempts are being made to apply bi-phasic catalytic hydrogenation to optically active systems using chiral diphosphine derivatives.[32–45] Although the objectives differ, the results obtained and the catalytic activity of the complexes studied is worthy of note. The use of the trisodium salt of tris(*m*-sulphonatophenyl)phosphine (**2**) as a ligand in various group VIII metal complexes has been reported[46] and the catalytic activity of the resulting complexes is being investigated. The use of solutions containing this ligand and $RhCl_3 \cdot 3H_2O$ as hydrogenation catalysts has been reported by Patin and co-workers.[47,48]

Other than the work carried out by Beck and co-workers[10] on the mechanism for the bi-phasic catalytic hydrogenation of various unsaturated substrates using $[RuCl_2(DPPS)_2]$ or $[HRuCl(DPPS)_3]$ and the kinetics for the hydrogenation of various unsaturated carboxylic acids[25] using $[RhCl(DPPS)_3]$, very little information concerning the mechanistic aspects of these reactions has been reported, Wilkinson[6] suggests that the mechanisms for $[RhCl(DPPS)_3]$ resemble those reported for $[RhCl(PPh_3)_3]$.[49] In their paper on the hydrogenation of cyclohexene at 1 atm using $[RhCl(DPPS)_3]$, Dror and Manassen[5] report that a co-solvent is necessary, and that the reaction occurs in the bulk of the aqueous phase. In contrast Wilkinson, using the same complex and substrate at 3 atm H_2 pressure, reports[6] that no co-solvent is necessary and that the reaction apparently occurs at the interface between the two phases.

For the catalytic hydrogenation of cyclohexene using $[RhCl(DPPS)_3]$[5,6] the co-solvent plays a major role. The rate is very solvent dependent, and this can be attributed, to an increase in both the hydrogen and the substrate solubility in the co-solvent aqueous phase.

For these bi-phasic systems, the recovery and re-use of the catalyst is of major economic importance. Wilkinson[6] remarks that, for $[RhCl(DPPS)_3]$ systems, the organic phase is colourless after a catalytic run. Dror and Manassen[5] report that the aqueous solutions of this complex do retain their catalytic activity and can be re-used. The rhodium content of the organic phase for the system based on amphos ($[(Ph_2P)CH_2CH_2NMe_3]^+$) as the ligand have been determined and less than 0.1% of the rhodium remains in the organic phase.[27–31]

Baird and Wilkinson[6,27–31] have reported on the stability of the various complexes with respect to air. The species based on DPPS have been reported to be very air-sensitive when the group VIII metal is rhodium and the system has been exposed to H_2. In contrast, the complexes based on the amphos ($[(Ph_2P)CH_2CH_2NMe_3]^+$) system are much more stable to oxidation by air and can even be used in a partial air atmosphere.[27–31] The lack of stability of the diphenylphosphinobenzene-*m*-sulphonate systems in the presence of various ketonic co-solvents has been reported by Dror and Manassen.[5] Recent work by Patin and co-workers[47,48] using tris(phenylsulphonato)phosphine as ligands for a rhodium complex, formed *in situ* from $RhCl_3$ hydrate, have indicated that the phosphine is oxidized during the catalytic reaction, and that the active species in this system may be colloidal rhodium.[81]

Preliminary studies[50] of the tolerance of $[RhCl(DPPS)_3]$ to sulphur compounds are very encouraging, with no loss of reactivity towards the substrate (1-hexene or cyclohexene) being detected. Further work examining the tolerance of this and other water soluble systems, to the sulphur species likely to be found in heavy oils, are being examined.

(b) *Phase transfer hydrogenation.* A number of articles have described the use of water soluble $K_3[Co(CN)_5H]$ for the catalytic hydrogenation of various unsaturated compounds[51–55] under both bi-phasic and phase transfer conditions. This system and the related diamine substituted system[56] cleanly hydrogenate dienes to alkenes. Although these systems are catalytically active in the absence of the phase transfer agent, their activity is very limited. The presence of the phase transfer agent greatly improves the stability of the catalyst to both base attack and to poisoning by the substrate, and also increases the reaction rate. Alper and Heverling[57] have shown that cobalt carbonyl under acidic phase transfer conditions and in the presence of molecular hydrogen can hydrogenate various alkenes. This system, however, was apparently unreactive towards the hydrogenation of anthracene but is stable in the presence of sulphur compounds.[58,59]

The complex $[\{(hxd)Rh(\mu\text{-}Cl)\}_2]$ is an active catalyst precursor for the hydrogenation of arenes under phase transfer conditions and of α,β-unsaturated carbonyl compounds under bi-phasic conditions. In each of the reports on the use of this rhodium species,[60,61] it is not clear whether or not the catalyst is in solution, and, at least for the bi-phasic system, there is evidence to suggest that the catalyst may be a very active form of colloidal rhodium.

Blum and co-workers have demonstrated the reactivity of rhodium chloride in the presence of

Aliquat 336 (tricaprylmethylammonium chloride), under phase transfer conditions, for the hydrogenation of a variety of alkynes, alkenes and arenes[62] as well as α,β-unsaturated species.[63] When a $RhCl_3$–Aliquat solution is exposed to H_2 in the absence of substrate, an unreactive precipitate of rhodium metal is formed. However, if the organic substrate is added before exposing the system to H_2, then both the aqueous and organic phases remain free from solid or colloidal material. This result has been interpreted in terms of the formation of a rhodium hydride intermediate which is stabilized by the unsaturated organic substrate. Although the rhodium is in the organic phase it can be recovered in the aqueous phase by the use of sodium chlorate,[64] the organic phase does, however, retain its catalytic activity and can be re-used providing it is not exposed to oxygen. This system is apparently active in the presence of mercaptans. These rhodium based phase transfer systems use an organic soluble transition metal species which must be recycled if these routes are to be of significant use.

3.2 *Sulphur removal*

(a) *Bi-phasic.* Cobalt carbonyl has been shown to be an effective catalyst precursor for the desulphurization of mercaptans under bi-phasic conditions.[58,59,65] In 1985, Alper *et al.*[66] reported their work on the desulphurization of mercaptans under both bi-phasic and phase transfer conditions. The reaction is reported to be non-catalytic with respect to the metal carbonyl, although catalytic amounts converted the mercaptans into thioethers in reasonable yields. In each of these systems the metal complex is added in the organic phase, in which it will presumably remain. If these systems are to be exploited some method of catalyst recovery must be developed (or such small amounts of metals used that recovery becomes unnecessary).

(b) *Phase transfer systems.* (i) Basic phase transfer conditions: The first reported catalytic applications of phase transfer techniques to the treatment of organosulphur compounds were by Blum[62] and Alper.[66] Stoichiometric elimination of sulphur from aryl mercaptans occurred at 60°C, in 5 M sodium hydroxide using $[Fe_3(CO)_{12}]$ and tetrabutyl ammonium hydrogen sulphate. This work, and the related work using $[Mn(CO)_5Br]$ and elemental sulphur[67] have formed the basis for a study, for AOSTRA, on the use of a catalytic phase transfer systems for the desulphurization of crude oil and bitumens. Of a wide range of catalyst precursors tested, the most effective in basic media is $[Mn(CO)_5Br]$. More recent work[69,70] suggests that this system is complex and that the results obtained are very dependent on the particular hydrocarbon feed used. There are some limitations to the use of $[Mn(CO)_5Br]$; PhSH and Ph_2S react with the $[BzEt_3N]^+$ cation to yield BzSPh and other compounds. No H_2S was evolved on acidification of the aqueous phase.

These results suggest that the primary attack is not at sulphur, and that various redistribution reactions occur. Further evidence to support this hypothesis comes from the differences between the size exclusion chromatograms of products and feed on a sample of Athabasca bitumen. These preliminary results suggest a loss in the middle molecular weights to form both higher and lower molecular weight fractions.

(ii) Acidic phase transfer conditions: The use of both bi-phasic and phase transfer conditions with aqueous tetrafluoroboric acid for the stoichiometric sulphur removal from mercaptans by $[Fe_3(CO)_{12}]$ was reported by Alper and Sibtain.[71] This reaction was not catalytic under either CO or N_2 atmospheres. More recently this work has been extended to the catalytic elimination of sulphur from an Athabasca bitumen. The most effective catalyst appears to be $[Mo(CO)_6]$, although these reactions are considerably slower than those with $[Mn(CO)_5Br]$ under basic conditions. These systems are extremely active for the polymerization of *n*-alkanes, and such polymerization reactions would be very detrimental to any heavy oil upgrading process where the cleavage of high molecular weight fragments into lower molecular weight species is necessary.

3.3 *Nitrogen removal*

To date there have been no reports of the reduction of nitrogen containing hetero-atom species to the corresponding hydrocarbon and ammonia. Alper has, however, reported the conversion of nitro compounds to amines under phase transfer conditions using $[RuCl_2(PPh_3)_3]$[72] in the presence of synthesis gas. Similar results were obtained using bimetallic rhodium–cobalt[73] or rhodium carbonyls[74] in the presence of carbon monoxide. A detailed study of the processes in the bimetallic

system, revealed that the role of the cobalt species is to re-activate the rhodium species, which is poisoned by the quarternary ammonium salt.

The formation of Et_2NPh, EtNHPh and PhMe from solutions containing $[Mn(CO)_5Br]$ and $[BzEt_3N]^+$ has been noted.[70] This reaction appears to be catalytic with the initial major product being Et_2NPh, which undergoes further reactions.

3.4 *Oxygen removal*

References to oxygen removal using either phase transfer or bi-phasic systems have not been reported, although Zahalka and Alper[75] reported the use of $[\{(hxd)Rh(\mu\text{-}Cl)\}_2]$ in the presence of β-cyclodextrin and H_2 to reduce aromatic carbonyl compounds to the corresponding hydrocarbons at room temperature and atmospheric pressure. The primary reaction under these conditions is carbonyl reduction, but some ring hydrogenation is also observed. Aliphatic carbonyl compounds are unreactive under these conditions.

3.5 *Isomerization*

(a) *Bi-phasic.* Although the use of bi-phasic catalytic systems for the hydrogenation of hydrocarbons has not been studied specifically, several authors have commented on side reaction in which terminal alkenes are isomerized to internal alkenes. Both Baird[30] and Wilkinson[6] report that up to 25% of their products from the intended hydrogenation of 1-hexene, using rhodium complexes of either amphos ($[(Ph_2P)CH_2CH_2NMe_3]^+$) or sodium diphenylphosphinobenzene-*m*-sulphonate as ligands, was 2-hexene. Similarly the use of water soluble rhodium complexes[18] or ruthenium complexes for the hydroformylation of terminal alkenes can also lead to the formation of relatively large amounts of internal olefins.

(b) *Phase transfer processes.* The use of rhodium or ruthenium based phase transfer systems for the isomerization of various allyl alcohol derivatives has been reported.[64,76–78] Blum[64] has demonstrated that terminal alkene substituted aromatics can be isomerized using rhodium chloride in the presence of Aliquat 336 (tricaprylmethylammonium chloride) with reasonable rates. These authors report that although the catalyst is in the organic phase it can be extracted back into the aqueous phase by the use of sodium chlorate.

4. CONCLUSIONS

There is ample evidence to demonstrate the potential utility of either bi-phasic or phase transfer processes for hydrogenation, sulphur (and to a more limited extent, nitrogen) removal. If, however, these systems are to be used towards the upgrading of heavy oil or bitumen, more experimental work is necessary to determine the fate of the transition metal species in the presence of the heteroatom compounds, especially the sulphur species.

The results obtained so far support the idea that it is feasible to undertake the upgrading of heavy oils or bitumens under extremely mild conditions.*

KINETICS OF SOLVOLYSIS OF DIHALO-(3,3′,3″-TRIAMINOTRIPROPYLAMINE)COBALT(III) PERCHLORATE

SALAH S. MASSOUD* and RONALD M. MILBURN

Department of Chemistry, Boston University, Boston, MA 02215, U.S.A.

(*Received* 11 *May* 1988; *accepted* 21 *June* 1988)

Abstract—The kinetics of the primary solvolysis reaction of $[Co(trpn)X_2]^+$ ions (trpn = 3,3′,3″-triaminotripropylamine = $N(CH_2CH_2CH_2NH_2)_3$; X = F, Cl, Br) in acetonitrile were studied. At 25°C, the rate constants for the release of one halide are 7.8×10^{-4}, 1.66×10^{-3} and 1.87×10^{-2} s^{-1} for X = F, Cl and Br, respectively. The corresponding activation parameters $\Delta H^{\ddagger}$ (kcal mol^{-1}) and $\Delta S^{\ddagger}$ (cal K^{-1} mol^{-1}) are as follows: 24.7(±0.6), 10.8(±1.8); 13.6(±0.6), −25.8(±1.8); 5.05(±0.8), −49.5(±2.4) for the same series. The rate constants were found to be independent of the initial complex concentration. The solvolysis product $[Co(trpn)(CH_3CN)Br]BrClO_4$, of the reaction of the complex $[Co(trpn)Br_2]ClO_4$ with acetonitrile, was isolated and characterized. No evidence was found for the second solvolysis step. The results are discussed in terms of the dissociative I_d mechanism.

The acid hydrolysis kinetics of octahedral $[Co(trpn)X_2]^+$ (trpn = 3,3′,3″-triaminotripropylamine = $N(CH_2CH_2CH_2NH_2)_3$; X = F, Cl, Br) and $[Co(trpn)(CH_3CN)_2]^{3+}$ ions have been studied and compared with those of the other tetraamine cobalt(III) complexes.[1] The kinetic data showed that the rates of acid hydrolysis for $[CoN_4X_2]^+$ species (N_4 = non-replacable monodentate– or polydentate–amine) decreases in the order trpn > tn_2 > tren > en_2 [en = $NH_2(CH_2)_2NH_2$; tn = $NH_2(CH_2)_3NH_2$; tren = $N(CH_2CH_2NH_2)_3$]. We have also pointed out that Co(III)–trpn represents a compromise between a system of fixed geometry, due to the tripodal nature of the ligand the fifth and the sixth coordination sites are forced to be *cis*, and a fully labile species.[1] These properties might be of great importance in some biological processes, particularly in the dephosphorylation reactions of ATP^{2-4} (ATP = adenosine 5′-triphosphate).

The extreme lability of $[Co(trpn)X_2]^+$ complexes was attributed to the flexibility of the six-membered ring systems in the Co^{III}–trpn moiety, such flexibility is likely to contribute to the ease of forming the transition state in a mechanism which is primarily dissociative in nature.[1,5]

In this paper we have expanded our study on $[Co(trpn)X_2]^+$ complexes to the non-aqueous medium, which might expose light, and should be useful in understanding the behaviour of these complexes in substitution reactions. Many studies of solvolysis reactions of cobalt(III)– and chromium(III)–tetraamine have been undertaken, but most of these reactions were complicated by *cis*/*trans* isomerization.[6–11] However, the solvolysis reactions of $[M(tren)Cl_2]^+$ ($M = Cr^{III}$ or Co^{III}) have been examined in different aprotic solvents and were not complicated by *cis*/*trans* equilibria.[12] Therefore, it is anticipated that the trpn ligand would be of similar stereochemical interest as tren, and this paper reports the results of the investigation of the rate of solvolysis of the complex ions $[Co(trpn)X_2]^+$ (X = F, Cl, Br) in acetonitrile.

EXPERIMENTAL

The complexes $[Co(trpn)F_2]ClO_4 \cdot 3/2$, $[Co(trpn)Cl_2]ClO_4$ and $[Co(trpn)Br_2]ClO_4$ were synthesized as described in our recent report.[13] The kinetic measurements were made spectrophotometrically (Cary 210 UV–vis. spectrophotometer) at an appropriate wavelength,

*Author to whom correspondence should be addressed. Present address: Department of Chemistry, Faculty of Science, Alexandria University, Alexandria, Egypt.

where a substantial absorption difference occurs between the reactants and products. This wavelength was 430 nm for the difluoro, 450 nm for the dichloro and 500 nm for the dibromo species. A weighed sample of the complex, held in a 5 cm^3 volumetric flask was rapidly treated with dry acetonitrile (acetonitrile was dried over 4 Å Linde molecular sieves and then distilled), which has been equilibrated at the same temperature. The flask was swirled vigorously (2–3 min), the volume was completed to the mark by adding acetonitrile to give a solution of 3–6 mM of the complex, and a part of the contents was then transferred to the thermostatted spectrophotometric 1 cm cell. The temperature was controlled to within ± 0.1°C by circulating water through the compartment surrounding the cells.

The rate constants were calculated by linear least-squares of the first-order plots $\ln(A_t - A_\infty)$ vs time, where A_∞ is the final absorbance and was taken when no further changes were detected and A_t is the absorbance at time t. These plots were linear for at least three half-lives. Duplicate runs agreed to within 5%.

RESULTS AND DISCUSSION

The crystallization of $[Co(trpn)(H_2O)_2](ClO_4)_3 \cdot 2H_2O$ in acetonitrile afforded the well characterized diacetonitrile complex.[13] The reaction of $[Co(trpn)Br_2]ClO_4$ with acetonitrile led to the isolation of $[Co(trpn)(CH_3CN)Br]BrClO_4$. The IR spectra of the acetonitrile complexes showed $\bar{\nu}_{CN}$ at 2300 cm^{-1} suggesting the coordination of CH_3CN to the central cobalt.[13] However, when the bromoacetonitrile complex was refluxed for a long time in dry CH_3CN, the diacetonitrile complex was not isolated. Also, when the solvolysis of the $[Co(trpn)X_2]^+$ species (X = F, Cl or Br) was carried out in dry acetonitrile, the product solution gave constant spectra, even when it was heated in the stoppered spectrophotometric cell at 40–50°C for 30 min. No changes in the spectrum were observed either after heating or after standing for a prolonged period of time. Such observations clearly indicate the absence of occurrence of any further slower reaction in these systems after the completion of the primary solvolysis step. Thus, the kinetics of the primary solvolysis step of the complex ions $[Co(trpn)X_2]^+$ (X = F, Cl or Br) in CH_3CN were not complicated either by further reactions or by isomerization,[13] and the species formed is $[Co(trpn)(CH_3CN)X]^{2+}$, where the halide must be *cis* to the coordinated CH_3CN molecule. The absorption spectral data of the halo-acetonitrile and the diacetonitrile complexes are given in Table 1. The visible spectra of these species in acetonitrile is consistent with the octahedral *cis* geometry[13] and clearly show that the lower energy *d–d* band maxima is shifted to longer wavelengths with decreasing ligand field strength, i.e. in the order $CH_3CN > F > Cl > Br$.

Theoretically, two possible isomers are possible for the solvolysis product; $[Co(trpn)(CH_3CN)X]^{2+}$ depending on whether the coordinated halide is *cis* or *trans* to the tertiary nitrogen in the Co–trpn moiety. These two positions are chemically non-equivalent;[14] replacement of the *trans*-halide in the $[Co(trpn)X_2]^+$ ion would produce the α-haloacetonitrile isomer, while replacement of the *cis*-halide would lead to the β-isomer. The possible isomers of the $[Co(trpn)(CH_3CN)X]^{2+}$ ion are shown in Fig. 1.

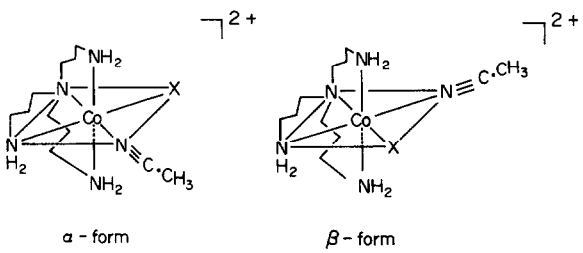

Fig. 1. Possible isomers of the $[Co(trpn)(CH_3CN)X]^{2+}$ cation.

Complex ion	$\lambda_{max}(\varepsilon)^a$	$\lambda_{min}(\varepsilon)$	$\lambda_{max}(\varepsilon)$	$\lambda_{min}(\varepsilon)$
$[Co(trpn)(CH_3CN)F]^{2+}$	529(69.6)	446(52.5)	362(95.9)	345(92.7)
$[Co(trpn)(CH_3CN)Cl]^{2+}$	575(57.6)	484(21.3)		
$[Co(trpn)(CH_3CN)Br]^{2+}$ [b,c]	~ 580			
$[Co(trpn)(CH_3CN)_2]^{3+}$ [c]	498(97.6)	418(27.6)		

[a] λ in nm and ε in $M^{-1}\,cm^{-1}$.
[b] Saturated solution.
[c] Data taken from ref. 1.

Of the two possible halo ligands that can be lost in the first solvolysis step, the one *trans* to the tertiary amine group in the trpn is thought to be the most labile. The assignment was made based on the X-ray study of the *mer*-[Co(dien)$(NO_2)_2$Cl] complex [dien = $NH(CH_2CH_2NH_2)_2$], where the *trans* position to the NH group in the polyamine was found to be the most labile.[15]

Thus, the solvolysis of the $[Co(trpn)X_2]^+$ ions in acetonitrile proceeds according to the stoichiometric equation (1).

$$[Co(trpn)X_2]^+ + CH_3CN \xrightarrow{k_1} [Co(trpn)(CH_3CN)X]^{2+} + X^- \quad (1)$$

The rate law for the reaction is given by

$$-\frac{d[Co(trpn)X_2]^+}{dt} = k_1[Co(trpn)X_2]^+$$

The rate constants k_1, calculated from the linear plots of $\ln(A_\infty - A_t)$ vs t are summarized in Table 2. It should also be noted that the rate is essentially unaffected by the initial complex concentration. Inspection of the data in Table 2 reveals that, at a given temperature, the rate of solvolysis decreases in the order Br > Cl > F. The same pattern of reactivity was also observed for substitution reactions in alkyl halides for an S_N1 mechanism.[16] Therefore, it seems that the solvolysis reactions of $[Co(trpn)X_2]^+$ complexes proceeded via a dissociative I_d mechanism. The same mechanism has also been suggested for the solvolysis reactions of *cis*-$[Coen_2X_2]^+$ (X = Cl or Br) in DMF,[7,8] and for $[M(tren)Cl_2]^+$ [M = Co^{III} or Cr^{III}] in different aprotic solvents.[12]

The activation parameters ($\Delta H_1^\ddagger$ and $\Delta S_1^\ddagger$) were evaluated from the linear Eyring plots of $\ln k_1/T$ vs $1/T$, and are collected in Table 3. The relationship between $\Delta H_1^\ddagger$ and $\Delta S_1^\ddagger$ for the series studied is illustrated in Fig. 2. The parallel changes in $\Delta H_1^\ddagger$ and $\Delta S_1^\ddagger$ lead only to small changes in $\Delta G^\ddagger$, and for such a closely related series a common mechanism is implied.[17] The slope of the linear plot of $\Delta H_1^\ddagger$ vs $\Delta S_1^\ddagger$ gives the isokinetic temperature, which is equal to 315 K. Below this temperature the reactions are

[a] Data taken from ref. 1.

controlled by $\Delta H_1^{\ddagger}$ values and above this temperature by $\Delta S_1^{\ddagger}$ values.[17]

Inspection of the data in Table 3 reveals that $\Delta S_1^{\ddagger}$ values are both positive and negative, probably due to the variable nature of the complex–solvent interactions. For the complex ions $[Co(trpn)X_2]^+$, the rate of halide substitution by CH_3CN decreases in the order Br > Cl > F and $\Delta H_1^{\ddagger}$ decreases in the opposite direction. This correlation reflects the ease of Co—X bond breaking in the transition state for a dissociative type of reaction. Further, the rate of fluoride substitution in water is greater than in acetonitrile (Table 3). Since it is now accepted that a solvent with a larger dielectric constant should be better in facilitating the separation of charges in the transition state for a dissociative type reaction.[18]

In conclusion, it should be repeated that the results of substitution reactions of $[Co(trpn)X_2]^+$ can be explained on the basis of a dissociative I_d mechanism.

Abstract—Hydrazine is oxidized by dissolved oxygen in aqueous solutions containing $[Fe(CN)_5]^{3-}$, in slightly acidic or alkaline conditions. The reaction involves the oxidation of $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ to $[Fe^{III}(CN)_5(N_2H_4)]^{2-}$ as the first step, and kinetic features suggest that this is followed by dimerization to $[(NC)_5Fe^{III}—(N_2H_4)—Fe^{II}(CN)_5]^{5-}$; $Fe^{III}—Fe^{III}$ and $Fe^{II}—Fe^{II}$ dimers are then originated by fast electron-transfer. The first of these evolves to $[(NC)_5Fe^{II}—(N_2H_2)—Fe^{II}(CN)_5]^{6-}$; this diimide complex shows a strong MLCT band at 515 nm and is very stable in alkaline solutions (pH 8) free of O_2 or H_2O_2. In the presence of these, or in more acidic media it evolves further to $[Fe(CN)_5(H_2O)]^{3-} + N_2$.

The mechanism of hydrazine oxidation in aqueous solution depends on the nature of the oxidizing agent, particularly on its ability to act as a one- or two-electron reagent. Much work has been carried out to unravel the nature of the hydronitrogen species formed in the course of evolution from N_2H_4 to N_2. The intimate features of the reactions with the different transition metal complexes used as oxidants are however, to a large extent, still an open question: the prevalence of inner- vs outer-sphere routes, the nature and reactivity of radical intermediates, decomposition products, etc.[1]

The autoxidation of hydrazine is a slow process in aqueous solution, due to kinetic barriers; however, it has been known for a long time that traces of metal ions (Cu, Fe) catalyse the oxidation of hydrazine by dissolved oxygen. Similar questions, as mentioned above, can be posed about the mechanism of these important processes.[2] It is likely that coordination of hydrazine to the metallic centre occurs previous to the electron-transfer step, but the identification of coordinated reactants, intermediates or products is not easy in labile species such as the aquo-ions of the first transition series.

A more favourable situation is set up with the $[Fe(CN)_5(N_2H_4)]^{3-}$ complex; the rates of dissociation and the stability constants of this ion, and of the related ion $[Fe^{III}(CN)_5(N_2H_5)]^{2-}$, have been determined in aqueous deoxygenated solutions. When air is present, however, orange–red colours develop and decomposition of the complex ensues, with the evolution of gaseous products. Oxidative dehydrogenation of amines coordinated to transition metal ions has been reported.[4–6] As shown in this paper, hydrazine is autoxidized in the presence of the $[Fe(CN)_5]^{3-}$ moiety.

EXPERIMENTAL

Reagents

$Na_2[Fe(CN)_5(N_2H_5)]\cdot 2H_2O$ was prepared as described before,[7] and characterized by its UV–vis. and IR spectra.

$[Fe^{III}(CN)_5(H_2O)]^{2-}$ was prepared in solution following, in general, the procedure of James *et al.*[8]

*Authors to whom correspondence should be addressed.

0.46 g of $Na_3[Fe^{II}(CN)_5(NH_3)]\cdot 3H_2O$, was oxidized with aqueous Br_2 (4 cm^3). Excess Br_2 was removed by streaming N_2 for 10 min; 16 cm^3 of NaOH (0.125 N) was added and the solution was left standing in the dark for 1 h to complete the formation of $[Fe^{III}(CN)_5(OH)]^{3-}$. This species was purified by gel permeation chromatography; the eluted fraction containing the desired species was identified spectrophotometrically. Addition of adequate buffers (acetic acid/acetate for pH 4; phosphate for pH 6.26) yields $[Fe^{III}(CN)_5(H_2O)]^{2-}$, as shown by its spectrum.

All other reagents were analytical grade and were used without any further purification. Solutions were prepared with doubly distilled water.

Spectral measurements

Visible and UV spectra and absorbance–time profiles were recorded on a Shimadzu UV 210 A spectrophotometer fitted with a thermostated cell holder. When needed, the cells were tightly stoppered and sealed with paraffin wax to avoid air entering. Near-IR measurements were performed in a Cary 2300 spectrophotometer. Raman spectra were recorded in a Spex spectrophotometer, provided with a 1403 double monochromator; the 514.5 nm line of a Spectra-Physics 165 argon ion laser was used for excitation (power: 50–100 mW). The solution flowed through a capillary to avoid decomposition.

Kinetic measurements

These were performed spectrophotometrically at adequate wavelengths (400, 440 and 515 nm). For slow reactions successive spectra were recorded in the whole visible range.

Experiments were carried out under very diverse conditions of complex, hydrazine, oxygen and H^+ concentrations. Typical experimental conditions are listed in Table 1. The pH was adjusted with acetic acid/acetate (pH ~ 4), phosphate (pH 6–8) and borax (pH ~ 9). In the case of a large hydrazine excess (*ca* 10^{-2} mol dm^{-3}) the time evolution of this reagent in aerated solutions was followed by titrating periodically, samples with KIO_3.[9]

In the experiments performed to study the early stages of reaction, a small amount of complex was dissolved directly in the appropriate solution and placed in the spectrophotometric cell. The experiments designed to study the following reactions were carried out with weighed amounts of solid and involved isolation of the cell from the atmosphere.

Gel permeation chromatography experiments

Solutions of $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ were partially oxidized by reaction with restricted amounts of oxygen in a closed vessel to yield red solutions, and subsequently treated with ascorbic acid to reduce the Fe^{III} species; the red complex formed during the first stage does not fade on addition of ascorbic acid. The mixture was seeded in a Shephadex G-25 column and the spectra of the eluted fractions were recorded.

RESULTS

Catalytic autoxidation of hydrazine in the presence of $[Fe^{II}(CN)_5L]^{n-}$ *ions*

Labile $[Fe^{II}(CN)_5L]^{n-}$ ions (L = H_2O, NH_3, N_2H_4) enhance the rate of hydrazine autoxidation, in a process that is highly pH-dependent. At pH 4 there is no enhancement of the rate of hydrazine consumption compared to blank solutions, whilst at pH 6.2 and 9.3, the effect of $[Fe^{II}(CN)_5L]^{n-}$ ions is great. Thus, at 25°C the concentration of a hydrazine solution which was originally 0.01 mol dm^{-3}, decreases after 20 h to 9.6×10^{-3} in the absence of metal complexes, and to 9.3×10^{-3}, 5.2×10^{-3} and 7.2×10^{-3} in the presence of $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ (2×10^{-4} mol dm^{-3}) at pH 4.10, 6.24 and 9.29, respectively.

These observations clearly indicate that hydrazine autoxidation proceeds via $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ ions; the $[Fe^{II}(CN)_5]^{3-}$ moiety is able to process hydrazine in large amounts compared to the stoichiometric ratio of the complex, suggesting the involvement of Fe^{II}–Fe^{III}–Fe^{II} cycles:

$$[Fe^{II}(CN)_5(H_2O)]^{3-} + N_2H_4 \longrightarrow [Fe^{II}(CN)_5(N_2H_4)]^{3-} + H_2O$$

$$[Fe^{II}(CN)_5(N_2H_4)]^{3-} \xrightarrow{+O_2,\ -N_2} [Fe^{III}(CN)_5(N_2H_4)]^{2-} \xrightarrow{+O_2} \quad (1)$$

At pH ~ 4 blue-greenish colloidal precipitates begin to form after 30 min. From approximately 22 to 50 h, the spectra of the supernatant solutions show only a weak band at 440 nm, which decreases in intensity with time. The precipitates are known to be of the Prussian Blue type, arising as products of the thermal and/or photochemical decomposition of Fe^{II} and Fe^{III} species through cyanide release.[10] At pH 6, precipitates are observed after several hours; these are however white.

The subsequent discussion will refer to experiments containing no excess free hydrazine, i.e. the mechanism of the reaction of $[Fe(CN)_5(N_2H_4)]^{3-}$ with oxygen shall be explored, with solid $Na_2[Fe(CN)_5(N_2H_5)]\cdot2H_2O$ being used as the source of the complex anion.

The reaction of $[Fe(CN)_5(N_2H_4)]^{3-}$ *with oxygen*

(1) Fe^{II} *oxidation to* Fe^{III} *without decomposition of hydrazine.* At pH 4, the spectra of the products in the early stages indicate that $[Fe^{III}(CN)_5(H_2O)]^{2-}$ is present (390, 340 nm);[8] this fact, together with the previously stated results on the lack of consumption of hydrazine, suggest that the reaction is similar to that observed in the aquation–autoxidation reactions of the $[Fe(CN)_5(NH_3)]^{3-}$ ion;[11] the evolution of our system appears to be even faster, due to the lower half-life for the aquation of $[Fe(CN)_5(N_2H_5)]^{2-}$, *ca* 10 s.[3]

$$[Fe^{II}(CN)_5(N_2H_5)]^{2-} + H_2O \longrightarrow [Fe^{II}(CN)_5(H_2O)]^{3-} + N_2H_5^+ \quad (2)$$

$$[Fe^{II}(CN)_5(H_2O)]^{3-} + 0.5O_2 + H^+ \longrightarrow [Fe^{III}(CN)_5(H_2O)]^{2-} + 0.5H_2O_2. \quad (3)$$

The mechanism is not simple, however. Step (3) has been shown to be catalysed by aqueous ferrous species;[11] furthermore, in our system a peak at *ca* 1300 nm develops together with the build-up of the 390–340 nm absorptions, strongly suggesting the presence of mixed-valence $Fe^{II,III}$ species,[12] most probably $[(CN)_5Fe^{II}—NC—Fe^{III}(CN)_4(OH)_2]^{5-}$. As stated earlier, the system rapidly evolves with the formation of precipitates of the Prussian Blue type.*

(2) *Oxidation of hydrazine through* Fe^{II}—Fe^{III}—Fe^{II} *cycles*

(2.1) *UV–vis. spectral evidence*: at pH 6–7, observed spectral changes include the following sequential processes, see Fig. 1.

(a) A fast shift from 400 to 440 nm, accompanied by a substantial increase in absorbance. This process is complete in a few minutes not only at pH 6–7, but also at the higher studied pH values; the resulting species is characterized by λ_m = 440 nm, $\varepsilon = 2\times10^3$ dm^3 mol^{-1} cm^{-1}. Evidence points to the formation of a species containing Fe^{III}: thus, the initial spectrum and further evolution is similar to that observed in mixtures of N_2H_4 and $[Fe^{III}(CN)_5(H_2O)]^{2-}$; both the energy and intensity of the band are reasonable for a LMCT transition in a $[Fe^{III}(CN)_5]^{2-}$ moiety.[13]

In view of the evidence to be discussed below, we postulate this species to be a dimer, $[(CN)_5Fe^{III}(N_2H_4)Fe^{III}(CN)_5]^{4-}$, [**1**, III–III].† Quantitative

* The time scale, as well as the spectral data, are also compatible with the operation of a mechanism involving firstly an outer sphere oxidation of the original ion, and secondly a rapid electron scrambling with aquated ferrous complexes.

† In what follows, hydronitrogen bridged dimers are identified as complexes [**i**, *m*–*n*], **i** characterizing the bridging ligand (**i** = **1**, N_2H_4; **i** = **2**, N_2H_2) and *m* and *n* being Roman numerals that indicate the oxidation state of each Fe centre.

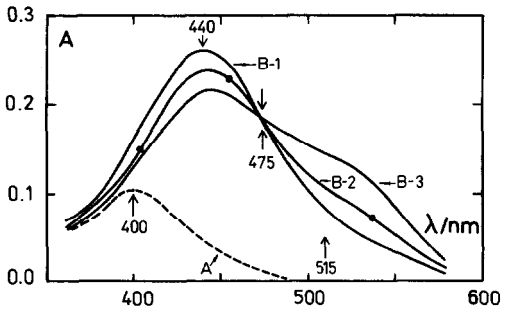

Fig. 1. (A) Spectrum of a solution containing 2×10^{-4} mol dm^{-3} $[Fe(CN)_5N_2H_4]^{3-}$, 0.1 mol dm^{-3} hydrazine and 10^{-3} mol dm^{-3} ascorbic acid (pH 6.10). (B) Sequential spectra of 2.3×10^{-4} mol dm^{-3} $[Fe(CN)_5N_2H_4]^{3-}$: (1) 4 min, (2) 7 min and (3) 12 min (pH 6.00). O_2 initial concentration = 2.3×10^{-4} mol dm^{-3}.

transformation of $[Fe(CN)_5(N_2H_4)]^{3-}$ to [**1**, III–III], resolved from further reactions, is achieved only for a low initial $[Fe(CN)_5(N_2H_4)]^{3-}$ concentration and in excess oxygen. Under other conditions, the expected maximum absorbance is not attained, indicating a consumption of either $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ or [**1**, III–III] (or both) through other processes during the same time scale.

At pH > 8, the fast process is better resolved in time and shows complex features, such as an initial increase in the absorbance at 440 nm followed by a decrease and a second increase, probably reflecting the complexities of the evolution from the monomeric iron(II) complex to the dimeric iron(III) complex [**1**, III–III].

(b) The second stage corresponds to the decay of the 440 nm band and the formation of a red species, band maximum at 515 nm. At pH 6.1, this process is reasonably well resolved in time from subsequent events, although the kinetics indicate some overlapping (see below). Simple first-order behaviour is observed in solutions where the ratio $[Fe^{II}]/[O_2]_0$ is high, indicating that the simplest situation can be envisaged as a transformation of the Fe^{III} species absorbing at 440 nm into the red species, without participation of oxygen; if this is present however, its influence is two-fold: both the rates of appearance and fading of the 515 nm band increase; the maximum absorbance attained is also very sensitive to excess oxygen, and decreases substantially in oxygen-rich solutions. From the data in oxygen-defective solutions, the molar absorptivity of the red species is $\sim 3 \times 10^3$ dm^3 mol^{-1} cm^{-1}. Spectral characteristics indicate a diimide complex featuring N_2H_2 bound to an Fe^{II} centre(s), the electronic transition being of the MLCT type, from Fe^{II} to ligand antibonding orbitals.[14] A similar transition has been reported for the $[Fe(CN)_4(NH{=}CH{-}CH{=}NH)]^{2-}$ ion formed by oxidation of $[Fe(CN)_4(en)]^{2-}$[15] and for $[Fe(CN)_5N(C_6H_4)C(H){=}NH]^{3-}$ formed from $[Fe(CN)_5N(C_6H_4)CH_2NH_2]^{3-}$.[4] Intense red colours have also been found in $[Ru(NH_3)_6]^{2+}$–N_2H_4–O_2 systems and attributed to the $[Ru(NH_3)_5(NH{=}NH)]^{2+}$ ion.[16]

The rate of formation and the stability of the red species is very sensitive to pH, see Fig. 2, and to the presence of excess Fe^{II} complexes or oxygen.

(c) The last stage is the decay of the 515 nm band. As stated, this process is very sensitive to other species in solution. At high pH and large Fe^{II} excess, the fading process becomes vanishingly slow (see Fig. 2, curve D).

The above observations suggest that Scheme 1 applies at pH 6–8.

(2.2) *Resonance Raman evidence*: direct evidence on the nature of the red species, confirming its identification as a diimide complex is given by the appearance of a peak at 1440 cm^{-1} in the resonance Raman spectrum of the red solution; this is shifted to lower wave numbers compared to the N=N stretching in solid transdiimide (ν_3 = 1529 cm^{-1}),[17] as expected from the back-bonding influence of Fe^{II}.[3] Furthermore, a peak at a similar wave number has been reported for diimide Cu^{I} complexes.[18]

(2.3) *Near IR evidence*: in the solutions obtained in the early stages of the reaction at pH 6.1, there is no absorption in the 1300 nm region; the situation contrasts with the spectral behaviour of oxygenated solutions of aquated $[Fe(CN)_5(NH_3)]^{3-}$ in the same concentration range (*ca* 10^{-3} mol dm^{-3}).[19] Thus, hydrazine hinders the formation of cyanide bridged dimers; it should be noted that the negative IR

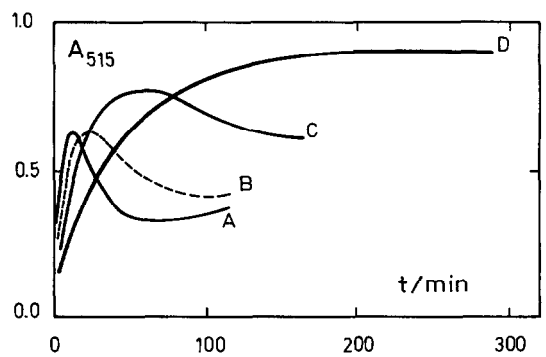

Fig. 2. Absorbance at 515 nm as a function of time; $[Fe(CN)_5N_2H_4]^{3-} = 5 \times 10^{-3}$ mol dm^{-3}; pH: (A) 6.06, (B) 6.33, (C) 6.74 and (D) 7.22. The rather fast decay observed at pH 6.1–6.3 is due to an excess of the reactant ion. At lower concentrations the decay is much slower (if due precaution is taken to avoid air entering).

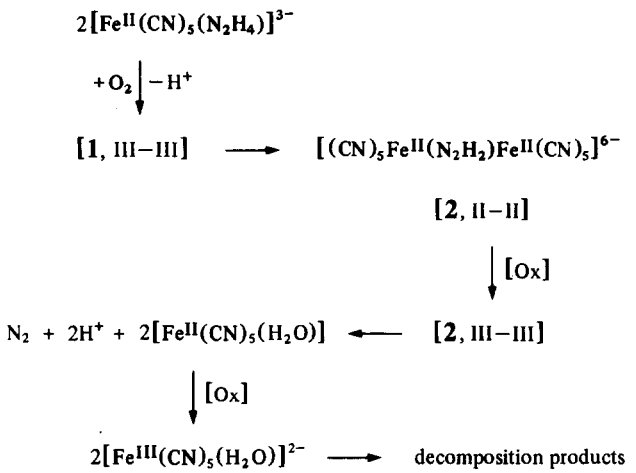

Scheme 1.

evidence does not rule out the occurrence of [1, II–III] dimers formed through reaction (4), because of the saturated nature of hydrazine.

$$[Fe^{III}(CN)_5(N_2H_4)]^{2-} + [Fe^{II}(CN)_5(H_2O)]^{3-} \rightleftharpoons [1, II\text{–}III] + H_2O. \quad (4)$$

(2.4) *Gel permeation chromatographic behaviour.* Gel permeation chromatographic separation of the parent complex and the red species was carried out in mixtures formed through partial oxidation followed by quenching with ascorbic acid. Such mixtures are indefinitely stable in the absence of light. Upon passage through the Sephadex column, the red species is eluted approximately 10 min earlier than $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$. This behaviour demonstrates that the red species is of larger size, substantiating its identification as a dimer.

Cyanide-bridged dimers formed in the absence of hydrazine behave in a similar fashion.[20]*

DISCUSSION

Kinetic evidence

In most cases, quantitative kinetic data cannot be obtained because of the complexity of many concurring parallel and sequential steps. Some features are however of interest.

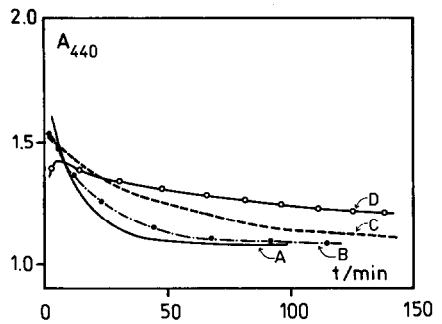

Fig. 3. Absorbance at 440 nm as a function of time, of a solution containing 5×10^{-3} mol dm^{-3} $[Fe(CN)_5N_2H_4]^{3-}$ and 2.3×10^{-4} mol dm^{-3} $[O_2]$ at various pH values: (A) 6.06, (B) 6.33, (C) 6.74 and (D) 7.22.

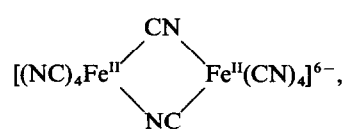
(a) The rate of the initial process (400 → 440 nm) decreases with pH (range 6–9); in all cases the reaction is complete within 1 min. The process at pH ⩾ 6, provides a sigmoidal A/t profile that suggests some type of autocatalysis, e.g. the involvement of labile Fe^{II} species.

(b) The decay of the 440 nm band cannot be fitted in general to first-order kinetics (see Fig. 3) except at pH 6 and high enough iron concentration (5×10^{-3} mol dm^{-3}) (Fig. 4). Under these conditions $k = 1.3 \times 10^{-3}$ s^{-1}. Figure 3 shows that a change in pH from 6.06 to 7.22 slows the apparent decay at 440 nm; the behaviour is no longer first-order, probably because of overlapping with the following stages. Even at pH 6, for $[Fe]_{total} < 5 \times 10^{-3}$ mol dm^{-3}, absorbance decay departs from first-order behaviour.

The rate of transformation of the N_2H_4 complex into the corresponding N_2H_2 complex increases as the pH decreases. This pH effect can be explained as a consequence of shifts in the dimerization equilibrium:

* Even though Emschwiller suggests that the dimers obtained in ref. 20 are of the type



mixed valence cyanide single-bridged species are more likely in aerated media (see refs 12 and 19).

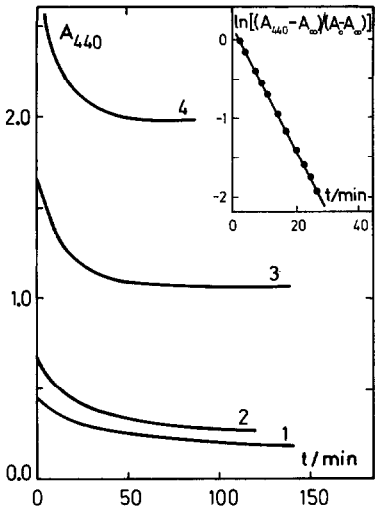


Fig. 4. Absorbance at 440 nm as a function of time at pH 6.06, $[O_2]_0 = 2.3 \times 10^{-4}$ mol dm^{-3}, and various initial $[Fe(CN)_5N_2H_4]^{3-}$ concentrations: (1) 5×10^{-4}, (2) 10^{-3}, (3) 5×10^{-3} and (4) 10^{-2} mol dm^{-3}. Inset: first-order plot corresponding to plot (3).

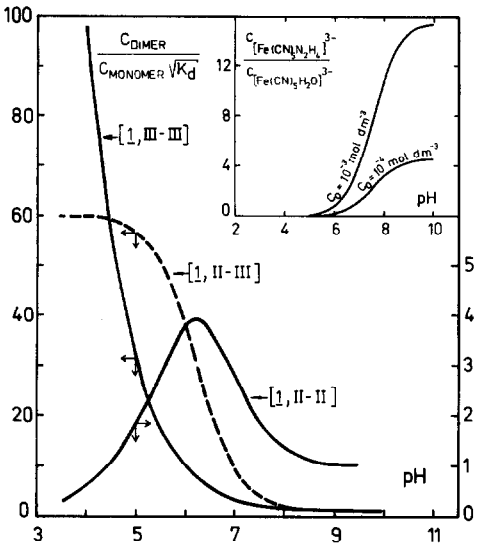

Fig. 5. pH influence on the ([Dimer]/[Monomer]) $\times (K_d)^{-1/2}$ relation for [Dimer] = [(1, II–II)], [(1, III–III)], or [(1, II–III)]. K_d is the corresponding dimerization equilibrium constant, i.e. eq. (4) for (1, III–III) and analogous equilibria for the other two cases. Inset: dependency of $([Fe(CN)_5N_2H_4]^{3-}/[Fe(CN)_5H_2O]^{3-})$ concentration relation with pH for total complex concentration (C_0) 10^{-4} and 10^{-3} mol dm^{-3}.

$$[\mathbf{1}, \text{III–III}] + N_2H_4 \rightleftharpoons 2[Fe^{III}(CN)_5(N_2H_4)]^{2-} \quad (5)$$

coupled with:

$$N_2H_4 + H^+ \rightleftharpoons N_2H_5^+ \quad (6)$$

which is important in the pH range 6–9. Thus, higher pH values would be conducive to dimer destruction through eq. (5); on the other hand, at lower pH, aquation of Fe^{II}—$(N_2H_5)^+$ hinders hydrazine oxidation (note also that hydrazine, either free or complexed, is monopronated in this pH range, deprotonation being therefore a prerequisite for dimer formation). Even though the ratio [(1, III–III)]/[Fe^{III}—(N_2H_4)] continues to increase, [(1, III–III)] and [Fe^{III}—(N_2H_4)] both become very low. The pH dependency of the ratio [(1, III–III)]/[Monomer] is shown in Fig. 5; combined with the aquation equilibrium depicted in the inset of Fig. 5, this equilibrium suffices to rationalize the pH influence.

(c) The rate of decay of the red diimide complex is sensitive to several species: oxygen, Fe^{III} complexes, excess $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ and pyridine; it is also very sensitive to pH, see Fig. 5. Thus, not only oxidants [O_2, Fe^{III}], may destroy coordinated diimide. The influence of excess pyridine can be explained through substitution equilibria of N_2H_2 in the dimer [2, II–II]:

$$[\mathbf{2}, \text{II–II}] + H_2O \underset{k_{-7}}{\overset{k_7}{\rightleftharpoons}} [(NC)_5Fe^{II}(N_2H_2)]^{3-} + [Fe^{II}(CN)_5(H_2O)]^{3-} \quad (7)$$

$$[(NC)_5Fe^{II}(N_2H_2)]^{3-} + H_2O \xrightarrow{k_8} \begin{cases} [Fe^{II}(CN)_5(H_2O)]^{3-} + N_2H_2 \\ \xrightarrow{\text{fast}} N_2 \end{cases} \quad (8)$$

Free diimide decomposes rapidly in aqueous solution, and the overall rate should then be controlled by the ratio $k_8/k_{-7}[Fe^{II}(CN)_5(H_2O)]^{3-}$. In the absence of scavengers, very small amounts of $[Fe^{II}(CN)_5(H_2O)]^{3-}$ suffice to prevent the destruction of the red species [at least through pathways (7) and (8)]. At pH 6, when the red solutions are treated with excess pyridine, this scavenges the $[Fe^{II}(CN)_5(H_2O)]^{3-}$ produced in eq. (7), and the resulting observation is a decay of the red colour. This suggests that the $[Fe^{II}(CN)_5(N_2H_2)]^{3-}$ monomer, in the absence of $[Fe^{II}(CN)_5(H_2O)]^{3-}$ to restore the dimer, decomposes rapidly through eq. (8).

The instability of the diimide complex in less alkaline media can be accounted for by the prevalence of different further reactions of H_2O_2;[6] in acidic media Fe^{II} centres are oxidized to Fe^{III}:[21]

$$\{Fe^{II}(CN)_5\}^{3-} + H_2O_2 \overset{H^+}{\rightleftharpoons} \{Fe^{III}(CN)_5\}^{2-}. \quad (9)$$

In eq. (9), $\{Fe^{III}(CN)_5\}^{2-}$ represent metal moieties featuring various possible sixth ligands (H_2O, N_2H_4). The $\{Fe^{III}(CN)_5\}^{2-}$ moieties created in eq. (9) later oxidize bound diimide, most probably through outer sphere electron exchange to yield Fe^{III}—(N_2H_2)—Fe^{III} complexes that further decompose, thus the red colour fades in acidic media. This interpretation is supported by the following observation: if an alkaline solution containing the fairly stable diimide complex is acidified with a solution containing ascorbic acid as an antioxidant, the red colour remains unchanged for large periods indicating that H^+ *per se* does not attack the diimide complex. Pathway (9) becomes more important when excess complex is present.

In alkaline media, reaction (9) becomes very slow and only a direct oxidation[3] of N_2H_4 is possible (during longer time spans):

$$[\mathbf{1}, \text{II–II}] + H_2O_2 \xrightarrow{OH^-} [\mathbf{2}, \text{II–II}]. \quad (10)$$

Evidence from related systems

The mechanistic conclusions outlined above are in line with known facts from related systems. In our case, in more alkaline media, $[Fe(CN)_5(N_2H_4)]^{3-}$ becomes more stable towards aquation,[3] and eq. (11) alone should represent the initial stages of reaction.

$$2[Fe^{II}(CN)_5(N_2H_4)]^{3-} + O_2 + H^+ \longrightarrow 2[Fe^{III}(CN)_5(N_2H_4)]^{2-} + HO_2^-. \quad (11)$$

Although it is not possible to learn much about the mechanism of reaction (11) from our data, the time scale is comparable with that of outer sphere autoxidation reactions of $[Ru(NH_3)_5L]^{n+}$ complexes.[22] The sigmoidal character of the plot of absorbance at 440 nm vs time suggests a possible catalytic path involving labile Fe^{II} centres.[11]

Next, evidence useful to assess the likelihood of dimerization shall be considered: the rate constant for the substitution of water in $[Fe^{II}(CN)_5(H_2O)]^{3-}$ by a double negatively charged ligand [dimerization reaction (4)] is of the order of 3 $dm^3\ mol^{-1}\ s^{-1}$ (I = 1 mol dm^{-3}, $NaClO_4$);[23] thus, under our conditions reaction (4) could occur readily, in a time scale governed by the rate of formation of $[Fe^{II}(CN)_5(H_2O)]^{3-}$. At pH 6, this is formed essentially according to eq. (2) with a pseudo-first-order rate constant $k = 2.0 \times 10^{-2}\ s^{-1}$;[3] aquation should proceed until an equilibrium ratio $[Fe^{II}(CN)_5(H_2O)]^{3-}/([Fe^{II}(CN)_5(N_2H_4)]^{3-} + [Fe^{II}(CN)_5(N_2H_5)]^{2-})$ in the range 0.40–1.76 is achieved (for total complex concentration in the range 10^{-4}–10^{-3} mol dm^{-3}).

Dimerization of two labile Fe^{II} complexes is also possible by a process similar to (4), eq. (12), although the higher negative charge on the incoming $[Fe^{II}(CN)_5N_2H_4]^{3-}$ substituent would make the process slower.[24]

$$[Fe^{II}(CN)_5(N_2H_4)]^{3-} + [Fe^{II}(CN)_5(H_2O)]^{3-} \rightleftharpoons [\mathbf{1}, \text{II–II}] + H_2O. \quad (12)$$

Fast electron exchange between monomers and dimers should give rise to the dimers [**1**, II–II] and [**1**, III–III] from [**1**, II–III].[24] These three dimers and the related Fe^{II} and Fe^{III} monomers may be considered as equilibrated for any process taking place in longer time spans.

From dimerization equilibrium data for related systems,[24] it is possible to estimate $K_d \cong 7 \times 10^{-4}$ for reaction (13). This amounts to 5% of the iron being present as dimer [**1**, II–II] in our experiments at pH > 10 (no N_2H_4 protonation).

$$2[Fe^{II}(CN)_5(N_2H_4)]^{3-} \overset{K_d}{\rightleftharpoons} [\mathbf{1}, \text{II–II}] + N_2H_4. \quad (13)$$

Substantially higher values are calculated for Fe^{III}—Fe^{II} dimers. A higher stability of the hydrazine bridged dimer as compared to [Fe^{II}—(NC)—Fe^{III}] dimers is also suggested as a possible explanation for the absence of IV bands at 1300 nm.

A high affinity of Fe—(NH=NH) for $[Fe(CN)_5(H_2O)]^{3-}$ is expected: pyrazine bridged dimers are well known;[25] the stability constant K'_D:

$$[(NC)_5Fe^{II}\text{—}(NH{=}NH)]^{3-} + [Fe^{II}(CN)_5(H_2O)]^{3-} \overset{K'_D}{\rightleftharpoons} [\mathbf{2}, \text{II–II}] + H_2O \quad (14)$$

is expected to be 10^4–10^6 mol dm^{-3}, depending on the ionic strength. Whence, the ratio [**2**, II–II]/$[(NC)_5Fe^{II}\text{—}(NH{=}NH)]^{3-}$ in solutions containing

excess $[Fe^{II}(CN)_5(N_2H_4)]^{3-}$ is calculated to be always high.

When compared with the mechanism of dehydrogenation of diamines bis-coordinated to the $[Fe^{III}(CN)_4]^-$ moiety,[6] the different influence of pH on the rate of formation and stability of the red species is related to the possibility of coordinating two Fe^{III} centres to the bridging ligand in the present system, and the need of two (as opposed to four in ref. 4) oxidant equivalents per mole of ligand.

Dimerization equilibria, being labile, largely change the reactivity pattern of the system. The formation of a red species with —C=N— bonds in the ligand has also been observed with $[Fe(CN)_5(picolilamine)]^{3-}$; in this case oxidation by persulphate leads to coordinated  , yielding red complexes;[5] dimers are also involved in this system.

SYNTHESIS AND STUDY OF SOME NOVEL Co^{II}, Ni^{II} AND Cu^{II} COMPLEXES WITH SILICON ISOTHIOCYANATES AS LIGANDS

A. S. SYNGOLLITOU-KOURAKOU,* I. A. TOSSIDIS and A. CHRISTOFIDES

Department of General and Inorganic Chemistry, Aristotelian University of Thessaloniki, Thessaloniki, Greece

(*Received* 23 *February* 1988; *accepted* 6 *July* 1988)

Abstract—New complexes of Co^{II}, Ni^{II} and Cu^{II} with silicon isothiocyanates of the type $R_xSi(NCS)_{4-x}$ (where $x = 0, 1, 2, 3$) have been synthesized and characterized using elemental analyses, magnetic susceptibility measurements and spectral (electronic and infrared) data. The Co^{II} and Ni^{II} complexes have a polymeric tetrahedral structure, whereas a tetragonal structure has been assigned to the Cu^{II} complexes. Various ligand field and nephelauxetic parameters have been evaluated and thermoanalytical data for the complexes of $CH_3Si(NCS)_3$ are also reported.

So far, little has been reported concerning the nucleophilic reactivity of silicon isothiocyanates.[1–5] In the course of this work it was found that a- and b-unsaturated organosilanes are useful reagents as mild and stable nucleophiles, acting formally as the corresponding organometallics.[6,7] In fact, the trimethylsilicon isothiocyanate showed nucleophilic behaviour at the nitrogen and sulphur ends, respectively.[5] The same compound has been also reported[8] as an HNCS-donor in several heterocyclic syntheses. Moreover, the structure and the donor activity of the silicon isothiocyanate products have been described.[9] More recently, $(CH_3)_2Si(NCS)_2$ and $(CH_3)_3SiNCS$ have been employed as ligands for preparing complexes with either soft or hard acids.[10]

In an effort to understand the coordination ability of $Si(NCS)_4$, $CH_3Si(NCS)_3$, $(CH_3)_2Si(NCS)_2$ and $(CH_3)_3SiNCS$ ligands, we have prepared some complexes with transition metal ions such as Co^{II}, Ni^{II} and Cu^{II}.

The results concerning the synthesis and characterization of twelve novel complexes are reported in this paper. The thermal properties of the $CH_3Si(NCS)_3$ complexes with Co^{II}, Ni^{II} and Cu^{II} are also reported and discussed.

EXPERIMENTAL

(a) *Physical measurements*

IR spectra were recorded in the region 4000–250 cm^{-1} on a Perkin–Elmer 467 spectrophotometer using KBr discs. Electronic absorption spectra were obtained on a Perkin–Elmer Hitachi 200 spectrophotometer in the solid state with Nujol mulls. The carbon, hydrogen and nitrogen analyses were performed on a Perkin–Elmer 240 elemental Analyser. The metal determinations were carried out by published methods.[11] Magnetic susceptibility measurements in the solid state were carried out by the Faraday technique using $Hg[Co(SCN)_4]$ as the calibrant, at room temperature. The thermoanalytical curves were obtained on a Mettler TA 2000 system in a dynamic atmosphere of nitrogen; sample sizes of 20–40 mg were used at a heating rate of a 6° min^{-1}. The chart speed was maintained at 5 mm min^{-1}.

(b) *Preparation of the complexes*

The ligands were prepared by procedures outlined elsewhere.[12,13] All the complexes were synthesized in a similar way and the following example is representative.

The ligand $Si(NCS)_4$ (0.22 mmol) dissolved in

B (free ion) Co = 967 cm^{-1}. *B* (free ion) Ni = 1030 cm^{-1}.

CCl_4 (20 cm^3) was added slowly under continuous stirring and cooling, to a solution of the metal chloride (0.2 mmol) in CCl_4 (50 cm^3). The mixture was then refluxed for 3 h affording a coloured precipitate, which was filtered off, washed with dry ethanol and ether and dried *in vacuo*.

RESULTS AND DISCUSSION

The reaction of $Si(NCS)_4$, $CH_3Si(NCS)_3$, $(CH_3)_2Si(NCS)_2$ and $(CH_3)_3SiNCS$ with chlorides of Co^{II}, Ni^{II} and Cu^{II} gave solid coloured compounds of the following types: $[Si(NCS)_4 \cdot 4MX_2]$, $[CH_3Si(NCS)_3 \cdot 3MX_2]$, $[(CH_3)_2Si(NCS)_2 \cdot 2MX_2]$ and $[(CH_3)_3Si(NCS) \cdot MX_2]$ regardless of the amount of ligand.

The complexes are insoluble in water and in most common organic solvents, the latter suggesting polymeric structures. The majority of the compounds, which were obtained in 50–70% yields, are not air stable. The characterization of the novel compounds was established by elemental analysis, spectroscopic methods (IR, UV–vis.) and magnetic measurements. The thermoanalytical analysis data for complexes **IV**, **V**, **VI** are also discussed. The analytical results with the IR data and their assignments are presented in Table 1.

All the studied compounds show [14–19] the three diagnostic regions, C—N stretching, C—S stretching and NCS bending modes of the —NCS group at 2150–2050 cm^{-1}, 720–690 cm^{-1} and 470–420 cm^{-1}, respectively. The position of the ν(C—N) band is shifted to higher frequencies in comparison to those of the free ligand.[12,13] However, the ν(C—S) band is shifted to lower wavenumbers compared to those of the free ligands, whereas the band due to δ(NCS) lies at 470–420 cm^{-1} and is shifted to higher wave numbers than those of the free ligands. The sharp peak obtained above 2000 cm^{-1} is assigned to ν(C—N) and the frequencies of the bands (C—S) and (NCS) which are considered as criteria for establishing[15,16,18] that the ligands are S-bonded. However, a weaker coordination through the nitrogen atom in the case of polymeric structures is not excluded.

The electronic spectral data and the solid state magnetic moments of the studied complexes are given in Table 2. All the electronic spectra show a maximum of medium intensity at 45.0–46.0 kK and an intensive band at 38.4–40.0 attributable[20] to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions located on the ligand. The spectra of the Co^{II} complexes exhibit bands in 5.7–6.0 and 15.7–16.1 kK regions which can be assigned to $^4T_1(F) \leftarrow {}^4A_2(F)$ and $^4T_1(P) \leftarrow {}^4A_2(F)$ transitions, respectively. The Ni^{II} complexes show bands at 6.0–6.2 and 14.7–15.0 kK attributable to $^3A_2(F) \leftarrow {}^3T_1(F)$ and $^3T_1(P) \leftarrow {}^3T_1(F)$ transitions, respectively. The electronic spectra, the Dq, B and β values,[21] the colours and the magnetic moments at room temperature, for the Co^{II} and Ni^{II} complexes suggest that they have an essentially tetrahedral structure and the NCS groups are S-bonded since the N-bonded thiocyanate lies above Cl^- in the spectrochemical series.[22]

In the Cu^{II} complexes the absence of a magnetic moment is rather indicative of the presence of dinuclear Cu^{II} species with a diamagnetic ground state.

The thermogravimetric study for the **IV**, **V** and **VI** complexes shows that these compounds have two decomposition stages. The TG thermogram of the complex **IV** displays two steps at 160 and 280°C, both endothermic, which correspond to the loss of $\{CH_3Si(NC)_3Cl\}$ first (Found: 25.8. Calc.: 26.6%) and then $\{CoS_3Cl_6\}$ (Found: 54.7. Calc.: 53.4%), leaving a residue of 2Co (Found: 19.4. Calc.: 20.0%).

The DTA thermogram of complex **V** has endothermic peaks at 170 and 360°C, and the mass losses correspond to the loss of $\{CH_3Si(NC)_3Cl_4\}$ (Found: 43.4. Calc.: 43.2%) and $\{Ni_2S_3Cl_2\}$ (Found: 46.9. Calc.: 46.7%), leaving a residue of Ni (Found: 9.6. Calc.: 10.1%). The DTA thermogram of compound **VI** shows endothermic peaks at 160 and 330°C which correspond to the loss of $\{CH_3Si(NC)_3Cl_3\}$ (Found: 36.6. Calc.: 37.6%), $\{Cu_2S_3Cl_3\}$ (Found: 53.0. Calc.: 52.6%) and a residue of Cu (Found: 10.2. Calc.: 9.8%).

Generally, the TG and DTA curves of the studied complexes show that first a mixture of organosilicon species is removed, which contains no sulphur and may be considered as a decomposition product of the ligand involved. In the same step the metal also forms a compound with sulphur and chlorine which in the second one decomposes leaving the metal as a residue above 450°C. The presence of decomposition products containing sulphur and metal may imply that the M—S bond is more thermally stable than the C—S bond.

SYNTHESIS AND SPECTROSCOPIC CHARACTERISTICS OF BIS(ETHENYLDIMETHYLSILYLMETHYL)PLATINUM(II) COMPLEXES CONTAINING TERTIARY PHOSPHINE LIGANDS

ROBERT D. KELLY and G. BRENT YOUNG*

Inorganic Chemistry Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 26 *May* 1988; *accepted* 6 *July* 1988)

Abstract—Various complexes $L_2Pt(CH_2SiMe_2CH:CH_2)_2$ have been synthesized by diene displacement from $(cod)Pt(CH_2SiMe_2CH:CH_2)_2$ [$L = PMe_3$, PEt_3, $PMePh_2$, PPh_3; L_2 = dppm, dppe, dppp, dppb, dppf].† With monodentate phosphines, monophosphine complexes $LPt(CH_2SiMe_2CH:CH_2)(CH_2SiMe_2CH:CH_2)$ may be formed, in which tetracoordination of platinum is completed by η^2-binding of one ethenylsilyl ligand. With tricyclohexylphosphine, this is isolated as the sole product, while with less bulky phosphines inseparable mixtures develop of monophosphine, bis-phosphine and diene complexes. All of these species have been characterized by ^1H, ^{13}C and ^{31}P NMR and IR techniques.

Thermolytic rearrangements of organotransition metals frequently involve hydrogen migrations from alkyl and sometimes aryl or alkenyl ligands. Hydrogen transfer from β- and α-carbons were established fairly early as important reaction paths.[1] More recently, migrations from more remote carbon atoms have emerged[2] in addition to a variety of cyclometallations on ligands with ligating atoms other than carbon.[3] It is recognized that study of these relatively controllable, intramolecular C—H bond activations may yield an important understanding of the phenomenon as a whole and may lead to the evolution of metal systems which mediate the direct functionalization of inert hydrocarbons. Concurrently, a few organometallic species have been discovered which activate C—H bonds in an intermolecular fashion in homogeneous solution.[4]

In prevous studies we have examined δ-hydrogen migrations from both aromatic and aliphatic sites which generate five-membered rings.[5,6] Our interest in comparing the reactivity of corresponding olefinic C—H bonds has led us to synthesize complexes of types $L_2Pt(CH_2SiMe_2CH:CH_2)_2$ and $[LPt(R)(CH_2SiMe_2CH:CH_2)$, which have, in principle, a five-membered cyclometallation potential. Here, we report on their preparations and some notable spectroscopic characteristics. These ligands are more correctly termed "ethenyldimethylsilylmethyl" but for the sake of brevity we shall refer instead to "sila-neohexenyl" groups.

EXPERIMENTAL

General and instrumental

Elemental analyses were carried out by Imperial College Microanalytical Laboratories. NMR spectra were recorded on Bruker WM250 (^1H, 250.13 MHz; ^{13}C, 62.9 MHz), Bruker WM400 (^1H, 400.13 MHz) and JEOL FX90Q (^1H, 89.55 MHz; ^{13}C, 22.51 MHz; ^{31}P, 36.21 MHz) spectrometers. The instruments were temperature-calibrated for kinetic measurements using a methanol reference standard.[7] IR data were collected as 4% KBr dispersions on a Perkin–Elmer 683 or 1720 Fourier Transform instrument.

All reactions were carried out under nitrogen or argon unless otherwise noted, using standard anaerobic techniques.[8] Solvents were distilled under

nitrogen prior to use; diethyl ether and hexane from sodium/benzophenone, toluene from sodium.

Chloromethyldimethyl(vinyl)silane was used as supplied by Lancaster Synthesis. Trimethylphosphine, triethylphosphine, diphenylmethylphosphine, tricyclohexylphosphine, dppm, dppe, dppp and dppb were used as supplied by Strem Chemicals. Triphenylphosphine, cod, dppf, d_8-toluene and d_6-benzene were used as supplied by Aldrich Chemical Company.

(1) *Preparations of* cis-L_2PtR_2 [R = $CH_2SiMe_2CH:CH_2$]

Bis-sila-neohexenyl(cycloocta-1,4-diene)platinum(II). $Mg(CH_2SiMe_2CH:CH_2)Cl$ was prepared by addition of $ClCH_2SiMe_2CH:CH_2$ (8.0 g, 59.2 mmol) in diethyl ether (30 cm^3) to a stirred suspension of Mg shot (6.1 g, 0.25 mol) in diethyl ether (30 cm^3) at room temperature. After 12 h stirring at ambient temperature, the solution was filtered off and analysed (0.9 mol dm^{-3}, 91% yield). A portion of the Grignard solution (8.2 cm^3, 11.46 mmol) was added dropwise to a stirred suspension of (cod)$PtCl_2$[9] (1.42 g, 3.82 mmol) in diethyl ether (60 cm^3) at −20°C. The mixture was allowed to reach room temperature and stirred for a further 4 h. The resulting stirred suspension was cooled to −15°C and hydrolysed by dropwise addition of degassed, saturated ammonium chloride solution (40 cm^3). The ethereal layer was separated and the aqueous phase washed with diethyl ether (20 cm^3) and the combined ether extracts dried over anhydrous magnesium sulphate and decolourized with activated charcoal. Removal of the solvent *in vacuo* gave a white oil (1.2 g, 71%) with a satisfactory analysis (Table 1). (IR: 3050m, 3005m, 2960–2850s, 1590w, 1520w, 1480w, 1435m, 1400s, 1340m, 1315w, 1245vs, 1185w, 1165w, 1015s, 945vs, 835vs, 815vs, 765vs, 725s, 680s, 605w, 520m, 460w.)

cis - *bis*(*sila - neohexenyl*) - *bis* - (*trimethylphosphine*) *platinum*(II). To a solution of (cod)$Pt(CH_2SiMe_2CH:CH_2)_2$ (0.20 g, 0.40 mmol) in benzene (3 cm^3) at room temperature was added by microsyringe PMe_3 (81.4×10^{-3} cm^3, 0.80 mmol). The flask was left overnight at ambient temperature. Solvent removal *in vacuo* gave the analytically pure white oil. Yield: 100%. (IR: 3035m, 2945s, 2905s, 1585w, 1420m, 1400m, 1300m, 1285m, 1235s, 1010m, 960s, 890s, 830s, 810s, 760m, 720s, 675m, 520w.)

Prepared according to the same method were:

cis - *bis*(*sila - neohexenyl*) - *bis* - (*triethylphosphine*) *platinum*(II). Product: colourless oil. Yield: 100%. (IR: 3045m, 2980–2890vs, 1590w, 1455s, 1400s, 1380m, 1240s, 1035vs, 1010s, 940s, 830vs, 810vs, 760vs, 715vs, 680s, 630w, 520w.)

cis - *bis*(*sila - neohexenyl*) - *bis* - (*diphenylmethylphosphine*)*platinum*(II). Product: colourless crystals from hexane. Yield: 54%. (IR: 3045s, 2980s, 2930vs, 2880vs, 1595m, 1580w, 1480m, 1430vs, 1415s, 1395s, 1305m, 1235vs, 1085vs, 1010s, 1000s, 950s, 935s, 895s, 880vs, 815vs, 765s, 745vs, 725vs, 690vs, 525s, 510vs, 485s, 435s, 420s, 360w.)

cis - *bis*(*sila - neohexenyl*) - *bis* - (*triphenylphosphine*) *platinum*(II). Product: colourless crystals from hexane. Yield: 55%. (IR: 3050m, 2960m, 2935m, 2875m, 1590w, 1575w, 1485m, 1435s, 1400m, 1260s, 1240s, 1185m, 1095vs, 1030s, 1015s, 960m, 940m, 815vs, 760–725s, 690vs, 540vs, 520vs, 515vs, 490s, 435m, 420m.)

cis - *bis*(*sila - neohexenyl*)[*bis*(*diphenylphosphino*) *methane*]*platinum*(II). Product: white crystals from hexane. Yield: 56%. (IR: 3052m, 2966s, 2895m, 2849s, 1590m, 1579w, 1489m, 1442vs, 1399m, 1367m, 1309w, 1269w, 1242vs, 1187m, 1105vs, 1089s, 1003s, 980m, 940vs, 831vs, 815vs,

772vs, 756–678vs, 549vs, 506vs, 486vs, 443s, 441s, 361m.)

cis - *bis*(*sila - neohexenyl*)[*bis*(1,2 - *diphenylphosphino*) *ethane*]*platinum*(II). Product: white crystals from hexane. Yield: 49%. (IR: 3052m, 2959s, 2903m, 2872s, 1590w, 1575w, 1489m, 1438vs, 1406s, 1312w, 1238s, 1105vs, 1074m, 1003s, 941vs, 831vs, 815vs, 760–670vs, 537vs, 490vs, 447s, 357m.)

cis - *bis*(*sila - neohexenyl*)[*bis*(1,3 - *diphenylphosphino*) *propane*]*platinum*(II). Product: white crystals from hexane. Yield: 60%. (IR: 3051m, 2939s, 2881m, 2864m, 1587w, 1572w, 1484m, 1449s, 1400m, 1235s, 1155m, 1099s, 1009m, 969m, 944s, 816(d)vs, 750s, 741s, 725s, 696vs, 654s, 512vs, 494s, 486s, 445w.)

cis-*bis*(*sila-neohexenyl*)[*bis*(1,4-*diphenylphosphino*) *butane*]*platinum*(II). Product: white crystals from hexane. Yield: 66%. (IR: 3052m, 2951s, 2888s, 1590m, 1575w, 1489m, 1442vs, 1403s, 1312m, 1242s, 1183m, 1101s, 1003s, 952s, 913s, 835vs, 819vs, 768vs, 745vs, 702vs, 529vs, 502vs, 443s, 361m.)

cis - *bis*(*sila - neohexenyl*)[*bis*(1,1 - *diphenylphosphino*) *ferrocene*]*platinum*(II). Product: yellow needles from hexane. Yield: 44%. (IR: 3052w, 2950m, 2904m, 1590w, 1579w, 1481m, 1438s, 1406m, 1312w, 1265m, 1242s, 1168s, 1101vs, 1034s, 1019s, 941m, 819vs, 768s, 749vs, 729s, 702vs, 647m, 553s, 522s, 498vs, 475s, 443s, 353w.)

(2) *Preparations of* $L\overline{Pt(CH_2SiMe_2CH:CH_2)}R$

cis-(*sila-neohexenyl*)(η^2-*cycloplatinasila-neohexenyl*) (*tricyclohexylphosphine*)*platinum*(II). Both (cod) $Pt(CH_2SiMe_2CH:CH_2)_2$ (0.20 g, 0.40 mmol) and Cy_3P (0.12 g, 0.40 mmol) were dissolved in benzene (4 cm^3) and left at ambient temperature for 17 days. Removal of the solvent *in vacuo* gave a white solid which was analytically pure (0.13 g, 47%). (IR: 3052m, 2943vs, 2857vs, 1590w, 1563w, 1508m, 1450s, 1403m, 1367w, 1344m, 1301m, 1265s, 1238s, 1203m, 1179s, 1104s, 1031s, 937s, 882s, 850s, 819vs, 768s, 745s, 686m, 674m, 608m, 525s, 498m, 455w, 396m, 369w.)

cis - (*sila - neohexenyl*)(η^2 - *cycloplatinasila - neohexenyl*)(*trimethylphosphine*)*platinum*(II). (cod)Pt $(CH_2SiMe_2CH:CH_2)_2$ (0.20 g, 0.40 mmol) was dissolved in toluene (3 cm^3) and PMe_3 (40.7×10^{-3} cm^3, 0.40 mmol) added by microsyringe. The solution was left in the dark at ambient temperature for 33 days. Removal of the solvent *in vacuo* gave a pale yellow oil which contained the product (25%, Table 2), but could not be purified further.

Similar observations applied to:

syringe. After 6 days at room temperature the starting materials were unchanged.

cis-(*sila-neohexenyl*)(η^2-*cycloplatinasila-neohexenyl*)(*tri-o-tolylphosphine*)*platinum*(II). Both (cod)Pt($CH_2SiMe_2CH{:}CH_2$)$_2$ (0.20 g, 0.40 mmol) and P(4-C_6H_4Me)$_3$ (0.12 g, 0.40 mmol) were dissolved in benzene (2 cm^3) and left at ambient temperature for 30 days. Removal of the solvent *in vacuo* gave the unreacted starting materials.

RESULTS AND DISCUSSION

(a) *Synthesis*

(1) cis-L_2PtR_2. These complexes have been isolated using methods similar to those previously reported.[5] Treatment of (cod)$PtCl_2$ in ether with three equivalents of RMgCl produces the diolefin complex (cod)PtR_2. Displacement of the diene by stoichiometric amounts of tertiary phosphines produces *cis*-L_2PtR_2 (L = PMe_3, PEt_3, PPh_2Me, PPh_3; L_2 = dppm, dppe, dppp, dppb, dppf) in good yields. These substitutions are generally complete in 1–14 days at ambient temperature.

The compounds are mostly air-inert, white, crystalline solids except for those with cod, PMe_3 and PEt_3, which are colourless liquids. All have been characterized by elemental analysis (Table 1). Their NMR (^1H, ^{13}C and ^{31}P) and IR spectroscopic characteristics are discussed later.

(2) $L\overline{Pt(R)(CH_2SiMe_2CH{:}CH_2)}$. There is clear potential for the unsaturated function of the sila-neohexenyl ligand to coordinate to platinum.[10] This feature is likely to influence their reactivity relative to, say, their sila-neophenyl* analogues. We were interested to characterize isolable examples of η^2-ene derivatives.

The tricyclohexylphosphine complex of this type has been isolated as an air-stable, white solid by reaction of one equivalent of phosphine with (cod)PtR_2 at ambient temperature for 17 days. The identity and structure of this species has been established by elemental analysis, and by ^1H, ^{13}C and ^{31}P NMR studies.

Attempts to produce analogues with a range of monodentate phosphines have, in all other cases, produced inseparable mixtures of (cod)PtR_2, L_2PtR_2 and $L\overline{Pt(R)(R)}$ (L = PMe_3, PEt_3, PPh_2Me, PPh_3), even with reaction times of up to 33 days (Table 2). The thermal lability of (cod)PtR_2 (at 60°C) and of $L\overline{Pt(R)(R)}$ (L = PMe_3, PEt_3) (at 45°C) precluded heating the mixtures. ^{31}P NMR spectroscopy on freshly mixed reaction solutions showed that the added phosphine first forms L_2PtR_2 by displacement of diene. This is followed by an intramolecular displacement of one phosphine by alkene to form $L\overline{Pt(R)(R)}$.

A major influence on these equilibria is evidently the steric bulk of the phosphine (Table 2). For PCy_3 ($\theta = 170°$)[11] the bis-phosphine complex cannot be prepared. Reactions of (cod)PtR_2 with P(2-C_6H_4Me)$_3$ ($\theta = 194°$)[10] and $P(Bu^t)_3$ ($\theta = 182°$)[11] afforded no phosphine complexes. These ligands are apparently too bulky to allow even mono-coordination.

Although we have been unable as yet to isolate many of these compounds, their NMR characteristics (^1H, ^{13}C, ^{31}P) have been collected (*vide infra*). At temperatures up to thermal decomposition onset, there is no evidence for intramolecular fluxionality in which the coordinated and uncoordinated alkenes exchange roles.

(b) *Spectroscopic studies*

(1) *cis*-L_2PtR_2. (i) ^1H NMR (*Table* 3): a notable feature of these spectra is the multiplet observed for the hydrogens on the ligating carbon, an apparent quartet with platinum "satellites". The second-order resonance is most correctly attributed, in the PMe_3 complex, for example, to an $A_2A'_2RR'X_9X'_9$ spin system [A = ^1H (Pt–methylene), R = ^{31}P, X = ^1H (P–methyl)].[12] The satellite set correspondingly comprise an $A_2A'_2MRR'X_9X'_9$ system (M = ^{195}Pt, 34% abundant).

The general pattern is similar to that observed in related $L_2Pt(neophyl)_2$† complexes (L = PEt_3, dppe),[5] although the ^2J(H—Pt) values are 5–15 Hz larger for sila-neohexenyl derivatives.

The vinylic hydrogens produce the expected pattern of three doubled doublets; in each case $J_{trans} > J_{cis} > J_{gem}$ (Table 3).

The hydrogens on coordinated phosphine show typical, characteristic absorption patterns,[5] except for (dppf)PtR_2. Here, H_1 of the phenyl group generates a very broad singlet at ambient temperature, and H_y and H_z of the cyclopentadienyl rings display slightly broadened but otherwise unresolved signals (Fig. 1). As the temperature is reduced, however, each of these peaks broadens further, and subsequently resolves into multiplets (Fig. 1). From the line widths at half-height ($\Delta\nu = b_{1/2}$), the rates (k_c) and free energies of activation ($\Delta G_c^{\ddagger}$) for the process responsible for each of these coalescence points can be calculated (Table 4 and Fig. 1).[13]

Unless the diphosphine adopts the *syn*-eclipsed

* Sila-neophyl = phenyldimethylsilylmethyl.

† Neophyl = 2-methyl-2-phenylpropyl.

conformation for chelation,[14] the complex lacks a plane of symmetry. Its conformers (Fig. 2) are enantiomeric, and magnetically non-equivalent hydrogens H_y and H_y' generate distinct resonances (as do H_z and H_z'). Slow exchange between these conformers accounts for the observed low temperature spectrum (Fig. 1) representing, ideally, an $A_2B_2C_2D_2$ system (assuming that coupling between hydrogens on different rings is negligible). At higher temperatures, rapid exchange gives rise to a time-averaged spectrum ($A_2A_2'B_2B_2'$) in which single resonances represent H_y and H_z. Similarly the two phenyl substituents on each phosphorus are magnetically non-equivalent [Fig. 2(b)]. This is most prominently reflected in the behaviour of the H_1 resonances at 8.1 and 7.6 ppm (Fig. 1) which collapse to a broadened triplet at higher temperatures.[15] Assuming, reasonably, that the values of $\Delta G_c^{\ddagger}$ (Table 4) derive from the same process, then we estimate that $\Delta H^{\ddagger} \sim 46.4$ (±0.5) kJ mol^{-1} and $\Delta S^{\ddagger} \sim -27.0$ (±0.8) J mol^{-1} K^{-1}.

The *syn*-eclipsed diphosphino–ferrocene conformation would also produce the same spectroscopic patterns.[14] We favour the enantiomeric *gauche*-staggered forms as the resting conformations for dialkylplatinum(II) derivatives on the basis of established structures for related complexes with comparable metal size and coordination geometry.[15]

(ii) ^{31}P NMR (*Table* 5): the characteristically low value of ^1J(Pt—P) for (dppm)PtR_2 stems from the angular constraints around P and Pt imposed by the four-membered ring. Similar observations have

appeared elsewhere. For example, for R = Me, J = 1434 Hz;[16] for R = Ph, J = 1392 Hz;[17] for R = 1-adamantylmethyl, J = 1236 Hz.[18]

Phosphorus nuclei incorporated in chelate rings display a ring contribution, Δ_R, to their coordination chemical shifts whose magnitude and direction depends on ring substitution and size, often useful in structural assignments. Table 6 shows the effect of ring size on coodination chemical shifts. These values agree well with those reported for L_2PtMe_2 (L_2 = dppm, dppe, dppp, dppb)[19] and confirm that these complexes have mononuclear structures rather than, for example, phosphine-bridged dimetallic configurations.

The value of ^1J(Pt—P) is *ca* 300 Hz greater in sila-neohexenyl complexes than in the neophyl analogues[5] (Fig. 3). This clearly represents some modification in Pt—P bonding and broadly indicates that sila-neohexenyl induces a notably weaker *trans*-influence than neophyl (and most other alkyl) groups as measured by this technique.[21] Discussion of the underlying reasons requires consideration of corresponding modifications in ^{13}C NMR parameters (*vide infra*).

(iii) ^{13}C NMR (*Table* 7): the doubled doublets which arise from the ligating carbons form a characteristic A_2XX' spin pattern.[5] A superimposed A_2MXX' system gives rise to ^{195}Pt satellites (A = ^{13}C, X = ^{31}P, M = ^{195}Pt, 34% abundant). Here, ^1J(Pt—C) is some 150 Hz smaller for sila-neohexenyl than for neophyl.[5] This is a general feature on comparisons of silylmethyl and alkylmethylplatinum analogues.[20,22] Indeed, for L_2 = dppe, the decrease in ^1J(Pt—C) (23.4%) almost exactly matches the increase (23.5%) in ^1J(Pt—P) (Fig. 3). It is widely accepted that these interactions are dominated by Fermi-contact con-

tributions.[23–25] Consequently, any differences derive from changes in the *s*-orbital components of the respective bonds.

Compared with sila-neohexenyl, neophyl shows an enhanced ability to concentrate Pt(6*s*) character in the Pt—C bond, presumably in response to more effective overlap with the C(2*s*) component of its own donor orbital. There is also a marked increase in *trans*-^2J(P—C) in the neophyl case, further evidence of an increase in overall *s*-orbital bond order in the P—Pt—C framework.

These phenomena can most plausibly be explained in terms of a greater carbon 2*s* contribution to Pt—C bonding for the neophyl ligand. According to the propositions of isovalent hybridization, carbon will tend to direct 2*s*-character away from its most electronegative substituents.[26] Comparing neophyl and sila-neohexenyl ligands, carbon is more electronegative than silicon, while platinum remains the most electropositive of the groups bound to the methylenic carbon. The Pt—C bond is thus likely to benefit most from enhanced

carbon 2*s*-availability in the neophyl case. Significantly, for (dppe)Pt$(CH_3)_2$, both ^1J(Pt—C) at 610 Hz and ^1J(Pt—P) at 1783 Hz[27] have values intermediate between neophyl and sila-neohexenyl, consistent with the electronegativity of H, intermediate between C and Si (Fig. 3).

(iv) *IR spectroscopy*: IR data for this series of compounds are listed in the Experimental. A weak band at *ca* 1590 cm^{-1} in all these complexes is characteristic of an alkene C=C vibration.[28] When a phenyl group is present, a second, stronger band appears at *ca* 1600 cm^{-1} due to aryl C···C vibrations. The very strong doublet centred at *ca* 850 cm^{-1} is assigned to Si—C stretching. In the phenyl-substituted complexes, the two strong peaks at *ca* 750 and 700 cm^{-1} are out-of-plane C—H bending modes typical of five adjacent phenyl hydrogens.

(2) L$\overline{Pt(CH_2SiMe_2CH:CH_2)}$R. (i) ^{1}H *NMR* (*Table* 8): the most indicative features of this coordination mode are the patterns originating from the Pt-bound alkene function, comprising one doubled doublet and two eight-line patterns (all of which

display ^{195}Pt-satellites). By selective ^1H-decoupling, the eight-line multiplets have been assigned to H'_A and H'_B (Fig. 4) which display spin–spin coupling with ^{31}P. The four-line spectrum derives from H'_C. A shift-correlated 2D plot (Fig. 5) confirms these assignments for $L = PCy_3$. Figure 6 shows a simulation of the spectrum expected for an ABCX spin system (A,B,C = ^1H; X = ^{31}P) based on our assigned values for coupling constants in this same complex. There is close agreement between prediction and observation.

In each case the hydrogens of the η^2-alkene show

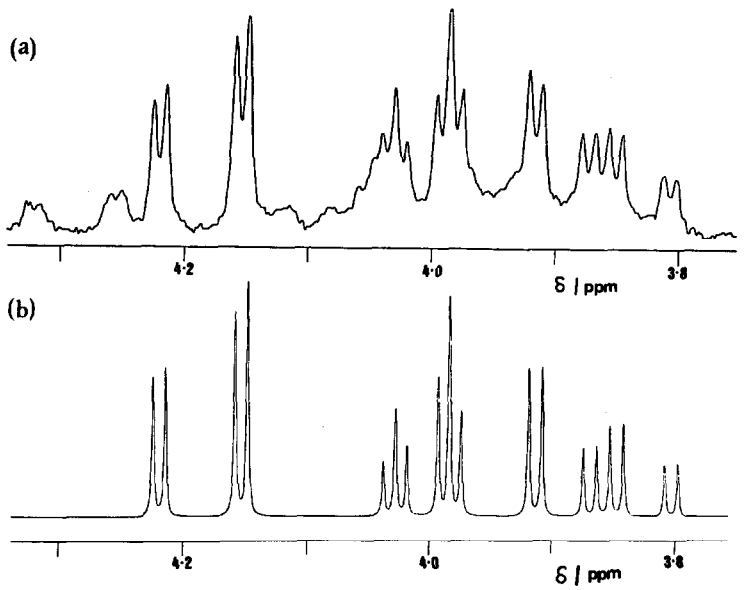

Fig. 6. (a) Observed and (b) simulated [in absence of J(Pt—H)] ^1H NMR spectra for $[(C_6H_{11})_3Pt]\overline{Pt(CH_2SiMe_2CH:CH_2)}(CH_2SiMe_2CH:CH_2)$.

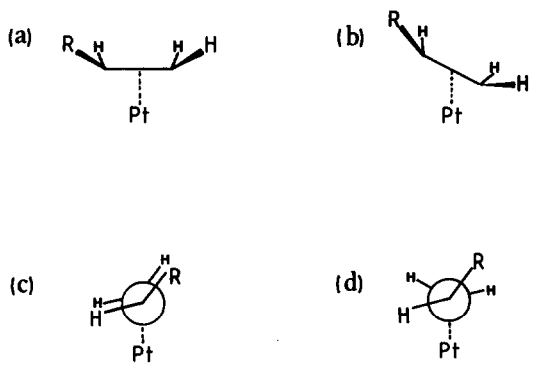

Fig. 7. Deviations from ideal η^2-alkene–Pt coordination.

the usual significant upfield coordination shift ascribed to partial rehybridization at carbon towards sp^3.[29,30] This also explains the general decrease in J(H—H) within the η^2-alkene, most marked for the geminal coupling $J(H_B—H_C)$.

There are three possible deviations from ideal, symmetrical alkene coordination (Fig. 7). The size of J(Pt—H) proposedly reflects the distance between the two nuclei.[29,31] Here, the notably larger value of $J(Pt—H'_C)$ suggests that H'_C (and Si) approach Pt more closely [cf. Fig. 7(b)], hardly surprising in view of the connection between Si and Pt via the ligating aliphatic carbon.

Irrespective of local modifications, a face-bound η^2-alkene will generate a metallacyclic ring which deprives the molecule of any axis or plane of symmetry. This might be expected to give rise to non-equivalence between several magnetic environments including the two ^{1}H nuclei of each metal-bound methylene group and between the two methyl groups on either silicon atom. In the tricyclohexylphosphine derivative the methylene signals are obscured but there is no indication of non-equivalence within distinct silicon methyl groups, each of which generates a slightly broadened single resonance (Table 8). No unequivocal conclusions can yet be drawn from other phosphine complexes, whose spectra are complicated in the regions of interest due to the presence of *cis*-$(R_3P)_2PtR_2$.

(ii) ^{31}P *NMR* (*Table* 2): all these complexes display values for ^1J(Pt—P) in the range 2014–2040 Hz, characteristic of phosphorus *trans* to alkyl ligands and in accord with the *cis*-oid structure (Fig. 4) proposed.[5] These values are consistently *ca* 20 Hz greater than for the corresponding L_2PtR_2. Steric constraints imposed by chelation may decrease the σ-donor efficiency of the ligating aliphatic carbon, resulting in a slight reduction in effective *trans*-influence.[21] The effect, however, is not spectacular.

The ^{31}P chemical shifts are generally to lower field than for L_2PtR_2, with the exception of $L = PPh_3$, which displays an upfield shift of 1.7 ppm.

(iii) ^{13}C *NMR* (*Table* 9): there are two doublet resonances with flanking satellites ascribable to ligating aliphatic carbons, at *ca* −1 and 9 ppm. The first has ^1J(Pt—C) = *ca* 410 Hz and ^2J(P—C) = *ca* 82 Hz, while the other has ^1J(Pt—C) = *ca* 720 Hz and ^2J(P—C) = *ca* 3 Hz. By comparison with corresponding data for *cis*-L_2PtR_2, the former is clearly *trans* to PR_3 and the latter is assigned *trans* to the η^2-alkene function.

The carbons of the coordinated alkene resonate 40–60 ppm to higher field than those in the free ligand. A conventional modulated spin–echo experiment has established that the lower field "triplet" [J(Pt—C) = *ca* 70 Hz] arises from the terminal carbon C'_B.

The characteristic upfield coordination shifts proposedly reflect the extent of depopulation of olefin π- with concomitant population of alkene π^*-orbitals.[32] Unequal shifts have been associated with asymmetric alkene coordination in which one carbon is nearer to platinum [Fig. 7(b)].[33] This might suggest that C'_A makes the closer approach (its coordination shift is −66.2 ppm compared with −41.8 ppm for C'_B). The apparent zero coupling between C'_A and Pt can only be attributed to self-cancellation of opposed-sign multipath coupling, also evident for the silicon-bound methyl carbons[34] (Fig. 8).

Proximity to ^{195}Pt has also been linked with larger values for ^1J(Pt—C).[33,35] Here, C'_B unequivocally displays the larger coupling constant. It seems more likely that the alkene will be tilted in this sense due to connection to the metal via the sila-alkyl chain and as suggested by the ^{1}H NMR data (*vide supra*).

Again, the inherent asymmetry of the complex might be expected to impose magnetic non-equivalence on the two methyl carbons attached to each silicon atom. No such distinction emerges.

We have been unable so far to obtain suitable crystals of any of the complexes to allow resolution of these stereochemical questions by X-ray diffractometry. Attempts to produce crystalline samples

with other bulky ligands—viz. PBu^t_3 and P(2-tolyl)$_3$—have been fruitless; these phosphines did not react with $(cod)PtR_2$.

(iv) *IR spectroscopy*: the IR data for the tricyclohexylphosphine complex are listed in the Experimental. The weak band at *ca* 1590 cm^{-1} is characteristic of an alkene C=C vibration and corresponds with the L_2PtR_2 complexes. A stronger band at *ca* 1508 cm^{-1} is due to the platinum-coordinated C=C vibration; the band-lowering of *ca* 80 cm^{-1} is consistent with those reported in the literature.[28] The very strong bands at *ca* 850 and 819 cm^{-1} are Si—C stretching vibrations, as seen in the L_2PtR_2 complexes.

Acknowledgements—We thank Sue Johnson and Dick Sheppard of this Department, and Dr Geoff Hawkes and his staff at Queen Mary College, London, for NMR measurements (ULIRS); and also Dr Henry Rzepa here for most helpful discussions. We are indebted to the SERC for the award of a studentship (to R.D.K.) and are additionally grateful to Johnson Matthey plc, for their generous loan of platinum salts.

ELECTRONIC STATES OF HOT IONS AND THE REACTIVITY OF $[MoOCl_3(PPh_3)_2]$ TOWARDS e_s^- IN TRI-*n*-BUTYLPHOSPHATE

J. O. DZIĘGIELEWSKI* and K. FILIPEK

Department of Inorganic and Radiation Chemistry, Institute of Chemistry, Silesian University, 9 Szkolna Street, 40006 Katowice, Poland

(*Received* 1 *July* 1988; *accepted* 27 *July* 1988)

Abstract—The reactivity of Mo^V ions towards e_s^- was studied by spectroscopic analysis. The crystal field parameters $Dq = 2200\ cm^{-1}$, $Ds = -4310\ cm^{-1}$ and $Dt = 152\ cm^{-1}$ were determined and the energy terms were calculated. The electronic structure of the hot ion was determined as $(d_{xy})^1\ (d_{x^2-y^2})^1$. The decay of the hot ion leads to the excited state $(d_{xy})^1\ (d_{xz}, d_{yz})^1$ and then to the diamagnetic complex with the $(d_{xy})^2$ configuration. The rate constant of the reaction of e_s^- with $[MoOCl_3(PPh_3)_2]$ was calculated as $1.3 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$. The influence of the structural parameters on the radiation–chemical processes was examined.

The radiation chemistry of transition metal complexes has been extensively explored for many years.[1–6] Attention is focused, however, on the oxidation[3–15] or the reduction[1–6,16–25] of the central ions. The rate constants of redox reactions are the only results of such experiments. The central ions of complex compounds can be either reduced e.g. by e_s^-, H atoms, radicals, or oxidized e.g. by OH radicals, Cl_2^- and O^- ions. These processes lead to electronic configurations of the ions which are not stabilized by the ligand field.[26–27] The electronic states, obtained in this way, are called "hot" ones. The properties of the hot ions depend on electronic and molecular features of the irradiated complexes.[19–22] It is still difficult to make *a priori* comparison between a structural characteristic of a complex compound and its reactivity towards e_s^-, and a mechanism of its reduction. Electronic states of the hot ions and mechanisms of its decay are influenced by the structural parameters of the complex. By testing the reactivity of the complexes and the mechanisms of their radiolysis it is possible to determine energy levels of the substances acting as acceptors of electrons. In radiation chemistry this problem has been neglected so far, but it is very important in the calculation of the potential barrier between an electron trap and the e_t^- scavenger. On the other hand, it is possible to generate some new electronic states by irradiation. In this case the exact determination of the ligand field parameters and a calculation of the energy terms is comparatively easy. The sequence of the electronic configuration determined by spectroscopic methods can be supported by the analysis of the radiation yields of decomposition, i.e. the bond cleavage.[21] Other examples of the usefulness of these considerations are some possibilities of synthesis of the high purity compounds[18] as well as the formation of new complex compounds which are not stabilized by the ligand field.[19] Furthermore, it is also possible, using the radiation methods, to evaluate catalytic abilities of some complexes in the radiation processes as e.g. reduction of molecular nitrogen.[28] In this paper we try to explain the influence of some structural features on the electronic states and some properties of the hot ions. A Mo^V complex with triphenylphosphine was used as an acceptor for electrons in tri-*n*-butylphosphate (TBP) solution.

EXPERIMENTAL

$[MoOCl_3(PPh_3)_2]$ was prepared according to the literature.[29] TBP (puriss p.a., Fluka) was extracted with 10% KOH, then washed with distilled water and distilled *in vacuo*.

$[MoOCl_3(PPh_3)_2]$ solutions in TBP were saturated with Argon or N_2O for 15 min, frozen in a cryostat at 77 K then irradiated in a cobalt source

Issledovatel (USSR) using a dose rate of 0.6×10^{16} eV cm^{-3} s^{-1} (determined with a Fricke's dosimeter and converted into the electron density of TBP).

In frozen solutions the appearance and decay of the absorption bands as a function of temperature were recorded. In irradiations (at room temperature) of solutions of the Mo^V complex in TBP the changes of the bands intensities at 230, 260, 315, 450 and 730 nm were measured.

These spectral measurements were made using a Beckman 5240 spectrophotometer. The changes in the paramagnetic susceptibility due to irradiation of the Mo^V complex in solution were determined by the ^1H NMR method described by Evans[30,31] using a Varian FT-80 A multinuclear spectrometer.

RESULTS AND DISCUSSION

Absorption bands of *t*-$[MoOCl_3(PPh_3)_2]$ in TBP are shown in Fig. 1. The characteristics of the bands are presented in Table 1. The presented spectrum is similar to those of the complexes $[MoOCl_3L_2]$ (L = phosphine) (e.g. ref. 32). The lowest energy band was attributed to a $b_2 \rightarrow e$ transition.[32-34]

Table 1. Band positions, molar extinction coefficients (ε) and assignments

Band (nm)	ε	Assignment
235	15,800	$\pi_O \rightarrow d_{xz}, d_{yz}$
260	12,000	$\pi_{phen} \rightarrow 3d_P$
315	2410	$\pi_{Cl} \rightarrow d_{xy}$
450	350	$^2B_2 \rightarrow {}^2B_1$
730	35	$^2B_2 \rightarrow {}^2E$

Assuming C_{4v} or C_{2v} symmetry of the Mo^V complex, the ligand field parameters *Dq*, *Ds* and *Dt* were determined and the energies of the terms were calculated as it is shown in Fig. 2.

On the basis of these calculations (see Fig. 2) the absorption bands appearing as a result of irradiation of the frozen solution of $[MoOCl_3(PPh_3)_2]$, in TBP saturated with argon, were quantitatively interpreted (Fig. 3). The band at 600 nm (17000 cm^{-1}) is attributed to the $^3B_1 \rightarrow {}^3A_1$ transition, whilst that at 400 nm (25000 cm^{-1}) is the $^3E \rightarrow {}^3A_1$ transition. Since these two bands

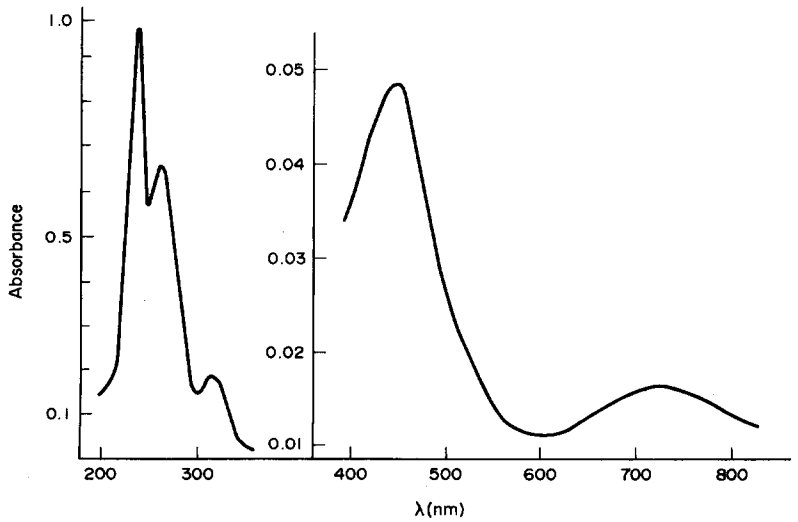

Fig. 1. Absorption bands of *t*-$[MoOCl_3(PPh_3)_2]$ in TBP.

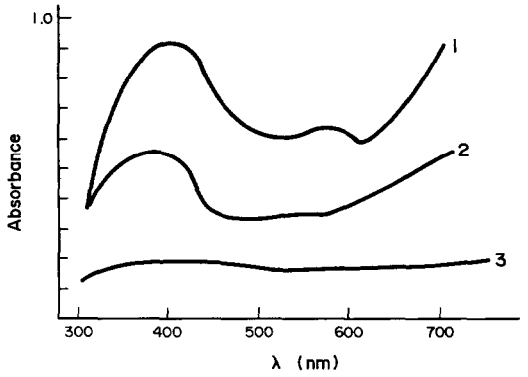

Fig. 3. Absorption bands arising after irradiation of the frozen solution of the Mo^V complex in TBP (conc = 10^{-4} mol dm^{-3}, dose = 5×10^{18} eV cm^{-3}). (1) 110 K, (2) 150 K, (3) 190 K.

appear after irradiation they are assumed to be due to the Mo^{IV} hot ion. This is regarded to be a product of the reaction of $[MoOCl_3(PPh_3)_2]$ with e_t^-, and has the $(d_{xy})^1$ $(d_{x^2-y^2})^1$ configuration. The lower intensity band (at 600 nm) disappears at 150 K, while the band at 400 nm disappears at 190 K. The lower intensity of the former band is due to the lower probability of the acceptance of e_t^- by the higher energy orbital $(d_{x^2-y^2})$ in comparison with the (d_{xz}, d_{yz}) orbitals. Moreover, the lower intensity of the band at 600 nm can be connected with the decay of the hot ion. The mechanism of this decay involves the formation of the excited state: $(d_{xy})^1$ $(d_{xz}, d_{yz})^1$ and then a transition to the ground state having the configuration $(d_{xy})^2$. The electron configuration of the excited state of Mo^{IV} is also a result of the direct acceptance of e_t^- by the (d_{xz}, d_{yz}) orbitals of Mo^V.

Knowing the electron configuration of the hot, the excited and the ground levels of the Mo^{IV} ion we can now discuss the problems of reactivity and transformations of the Mo^V complex under the influence of electrons. Hence, the cleavage of the π-bond between the Mo and Cl atoms can be attributed to the filling of the (d_{xy}) orbital. Because of the weak σ-bond, Mo—Cl, and a decrease of the oxidation number, the Cl^- ions are assumed to be released from the coordination sphere of Mo^{IV}. Simultaneously, the π-bond $Mo \overset{\pi}{\underset{\sigma}{\rightleftarrows}} PPh_3$ can be formed. It is responsible for the increasing covalency of the Mo—P bond, therefore PPh_3 should remain in the coordination sphere. The electron-transfer from the d_{xz} and d_{yz} orbitals to the d_{xy} orbital may be responsible for the Mo=O group in the Mo^{IV} complex remaining, since an electron on the (d_{xz}, d_{yz}) orbitals may weaken the π-bond between the Mo and O atoms. All these expectations have been experimentally confirmed in this work.

The magnetic susceptibility of the irradiated solution of $[MoOCl_3(PPh_3)_2]$ in TBP (conc = 6×10^{-2} mol dm^{-3}) was measured by Evans' method.[30,31] The ^1H signal of acetone was shifted from 156.5 to 166.9 Hz, while the effective magnetic moment was reduced from 1.79 to 0 BM, which is the appropriate value for a diamagnetic substance.

After irradiation we found no changes in the intensity of the bands at 235 nm or 940 cm^{-1} ($\nu_{Mo=O}$). These facts seem to confirm the presence of the Mo=O group in the reduced Mo^{IV} complex whose symmetry (C_{4v} or C_{2v}) has not been changed. The band at 260 nm is decreased slightly owing to irradiation, e.g. doses higher than 2×10^{18} eV cm^{-3} do not have any influence on the intensity, in solution of Mo^V in TBP (conc = 5.9×10^{-4} mol dm^{-3}). This fact is connected with the formation of the π-bond between the Mo^{IV} ion and the acceptor $3d$ orbitals of the P atom. Therefore, it is less likely that the π-electrons of the phenyl delocalize to the $3d$ orbitals of P atom. The removal of Cl^- ions from the coordination sphere of Mo^{IV} is supported by the intensity decrease of the band at 315 nm. The number of liberated Cl^- ions vs dose and concentration of the Mo^V complex are presented in Fig. 4.

The bands at 450 and 730 nm decreased due to irradiation. Thus, it can be concluded that the Mo^V ion is reduced. The yields of Mo^V reduction were calculated on the basis of the intensity decrease of the intensive crystal field band at 450 nm. The number of reduced molecules of the Mo^{IV} complex vs dose and concentration of the Mo^V complex are shown in Figs 5 and 6. The yields of the Mo^V reduction and the cleaved Mo—Cl bonds were

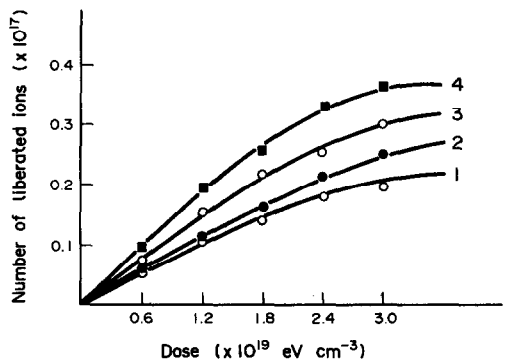

Fig. 4. Number of liberated Cl^- ions in irradiated Mo^V solution vs dose according to the following Mo^V concentrations in TBP: (1) 2.90×10^{-4}, (2) 3.25×10^{-4}, (3) 4.45×10^{-4}, (4) 5.90×10^{-4} mol dm^{-3}.

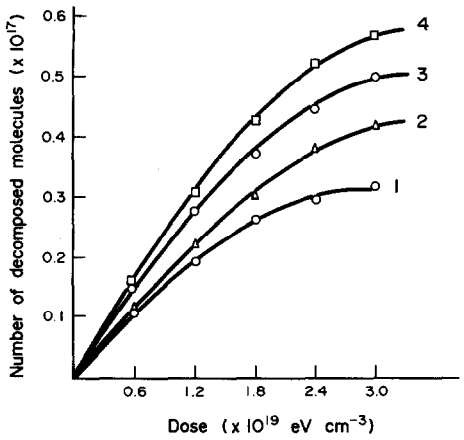

Fig. 5. Number of decomposed Mo^{V} molecules in TBP solutions saturated with Argon vs dose: (1) conc = 2.95×10^{-4}, (2) conc = 3.45×10^{-4}, (3) conc = 4.15×10^{-4}, (4) conc = 4.50×10^{-4} mol dm^{-3}.

obtained from Figs 4–6 and are presented in Table 2.

It can be noticed that Mo^{V} is reduced by e_s^-, since the yields of reduction (G) are higher in solutions saturated with argon (G_{Ar}) than in those saturated with N_2O (G_{N_2O}). The value of $\Delta G = G_{Ar} - G_{N_2O}$ corresponds to the yields of Cl^- ions liberated from the coordination sphere of the complex, which is in agreement with our predictions.

In the case of the oxalate complex of Mo^{V}, the hot ion with the $(d_{xy})^1$ $(d_{xz}, d_{yz})^1$ configuration is formed.[20] The π-bond $M\ddot{o}\underset{\sigma}{\overset{\pi}{\rightleftharpoons}}C_2O_4$ is inefficient and the σ-bond is also very weak. Therefore, the low spin state of the central ion is not stabilized by the ligand field and this fact is responsible for the change of the ground state term from $^1A_1$ to ^3E. Thus, the Mo^{IV} ion has the $(d_{xz}, d_{yz})^2$ configuration, the π-bond, $C_2\ddot{O}_4\underset{\sigma}{\overset{\pi}{\rightleftharpoons}}Mo$, is formed and $C_2O_4^{2-}$ ions

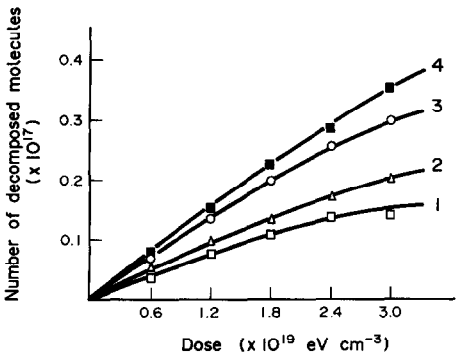

Fig. 6. Number of decomposed Mo^{V} molecules in TBP solutions saturated with N_2O vs dose: (1) conc = 2.95×10^{-4}, (2) conc = 3.45×10^{-4}, (3) conc = 4.15×10^{-4}, (4) conc = 4.50×10^{-4} mol dm^{-3}.

are stabilized in the coordination sphere of the Mo^{IV} ion. The electrons of d_{xz} and d_{yz} orbitals bring about the cleavage of the π-bond in the MoO group.[20] We can draw the conclusion that the type of π-bond, as well as the position in the spectrochemical series, exert an influence on the formation and the decay of the hot ions and, as a consequence, on the mechanisms of the complex compounds radiolysis.

In the light of the presented results the following mechanism of $[MoOCl_3(PPh_3)_2]$ radiolysis in TBP is proposed:

$$TBP \longrightarrow e_s^-, TBP^+, R, \ldots \quad (1)$$

$$e_s^- [MoOCl_3(PPh_3)_2] \longrightarrow [MoOCl_3(PPh_3)_2]^- \quad (2)$$

$$e_s^- + TBP \longrightarrow \text{radiolysis products} \quad (3)$$

$$e_s^- + N_2O \longrightarrow N_2 + O^- \quad (4)$$

$$[MoOCl_3(PPh_3)_2]^- + TBP \longrightarrow [MoOCl_2(PPh_3)_2TBP] + Cl^- \quad (5)$$

$$O^- + (C_4H_9O)P(OH)_2^+ \longrightarrow (C_4H_9O)_2P(OH) + OH \quad (6)$$

$$OH + TBP \longrightarrow H_2O + R{-}P(=O)(C_4H_9). \quad (7)$$

The formation of e_s^- in tri-*n*-alkylphosphates solutions has been known for many years.[35] The formation of the $(C_4H_9O)_2P(OH)_2^+$ cation from TBP^+ together with the simultaneous C_4H_7 group abstraction was shown previously.[36] The O^- anion-radicals and OH radicals [see reactions (4) and (6)], due to their high reactivity towards TBP,[4] do not react with the molybdenum complex but they do react with the solvent. By applying the steady state approximation to reactions (1)–(3), the following relationship was derived:

$$\frac{1}{\Delta G} = \frac{1}{G_{e_s^-}} + \frac{k_1[TBP]}{k_2 G_{e_s^-}[MoOCl_3(PPh_3)_2]}.$$

Figure 7 shows ΔG^{-1} as a function of the reciprocal of Mo^{V} concentration.

From Fig. 7 the values $G_{e_s^-} = 0.63$ and $k_1[TBP]/k_2 G_{e_s^-} = 2.3\times10^{-3}$ were found. Thus, $k_1/k_2 = 4\times10^{-4}$ and assuming $k_1 = 5\times10^6$ dm^3 mol^{-1} s^{-1} [37] we found $k_2 = 1.3\times10^{10}$ dm^3 mol^{-1} s^{-1}. On the basis of the results from Table 2, i.e. the yields of the Mo—Cl bond cleavage, the values $G'_{e_s^-} = 0.63$ and $k'_2 = 1.1\times10^{10}$ dm^3 mol^{-1} s^{-1} were calculated in a similar manner. The values of $G_{e_s^-}$

and $G'_{e_s^-}$, and k_2 and k'_2 are nearly the same, so the expectations concerning the liberation of Cl^- ions from the coordination sphere of Mo^{IV} as a result of Mo^V reduction are confirmed. The value of k_2 is about five times higher than the rate constant of the reaction between e_s^- and the oxalate complex of Mo^V,[20] despite the fact that the acceptor orbitals of $[MoOCl_3(PPh_3)_2]$ have higher energy than those in the case of the oxalate complex. This fact seems to confirm the influence of the structural parameters of the complex on its reactivity. On the other hand, the activation energy is lower for a Mo—Cl bond cleavage (triphenylphosphine complex—more active) than for a Mo=O bond cleavage (oxalate complex—less active). The latter energy is connected with the symmetry change.

The different energetic requirements for the reactions discussed are due to the different structural parameters of the electron scavengers.

SPECTRAL AND MAGNETIC MOMENT STUDIES ON SOME METAL COMPLEXES WITH DIETHYLENETRIAMINE-N,N,N′,N″,N″-PENTA(METHYLENEPHOSPHONIC ACID)

B. VENKATESWARA RAO* and D. M. PURI

Department of Chemistry, Kurukshetra University, Kurukshetra, India

(*Received* 11 *September* 1986; *accepted after revision* 15 *August* 1988)

Abstract—Diethylenetriamine-N,N,N′,N″,N″-penta(methylenephosphonic acid) forms polynuclear complexes of the type $M_5L \cdot xH_2O$ (where M^{II} = Fe, Co, Ni, Cu and Cd) and $Cr_4L(OH)_2 \cdot H_2O$. Six-coordinated metal complexes are formed as inferred from their IR and electronic spectral data. Characterization has also been accompanied by an EPR study of the copper(II) complex. Antiferromagnetism in the complexes, inferred from their subnormal magnetic moments at room temperature, was confirmed by cryomagnetic data which obeyed the Curie–Weiss law. Thermoanalytical studies show the end-product to be metal oxide and phosphorous pentoxide.

Oakes *et al.*[1,2] made a comparative study of the metal complexes of diethylenetriamine pentaacetic acid (DTPA) and ethylenediamine tetraacetic acid (EDTA) with metal complexes of diethylenetriamine-N,N,N′,N″,N″ pentamethylenephosphonic acid) (DTPMP) and ethylenediamine tetrakis(methylenephosphonic acid), respectively. They studied the soluble ionic complexes in aqueous solution using a ligand-to-metal ratio of 1 : 1. However, no attempt to isolate the products and study their structures seemed to have been made by the authors.[1,2] In view of the above, we report here the isolation and structural study of some bi- and trivalent metal complexes with diethylenetriamine - N,N,N′,N″,N″ - penta(methylenephosphonic acid).

EXPERIMENTAL

Diethylenetriamine - N,N,N′,N″,N″ - penta (methylenephosphonic acid) (DTPMP) as the hexahydrate was synthesized by the method of Peck and Hudson.[3] After purification and removal of water, the ligand was obtained as a colourless highly viscous product. Found: C, 15.3; H, 5.8; N, 6.2; P, 23.1. Calc. for $C_9H_{28}O_{15}N_3P_5 \cdot 6H_2O$: C, 15.9; H, 5.9; N, 6.2; P, 22.8%.

Bivalent metal acetates (BDH AnalaR), chromium nitrate (Thomas and Thomas, India), diethylenetriamine (Sisco Chemicals, Bombay) were used as received after ascertaining their purity. 40% aqueous formaldehyde solution was used.

Preparation of the metal complexes

An aqueous solution of the ligand (0.001 mol) was added slowly with constant stirring to the metal salt solution (0.005 mol), followed by the addition of 0.0025 mol of aq. Na_2CO_3 solution, which resulted in the formation of a precipitate. A small amount of acetone was added for easy filtration. The precipitate was first washed with hot water then 50% aqueous acetone and finally with 98% acetone. It was then dried at 60–70°C. Elemental analyses are given in Table 1.

Physical measurements

PMR spectra were taken on a R-32 Perkin–Elmer (90 MHz) instrument. Magnetic susceptibility measurements at room temperature as well as at different temperatures were carried out using a Princeton applied research model 155 Vibrating Sample Magnetometer incorporating a digital read-out. The instrument and methods used for the

remainder of the analyses were the same as described earlier.[4,5]

RESULTS AND DISCUSSION

Reactions of the bi- and trivalent metal ions and DTPMP can be represented by the following two equations.

$$5M^{2+}(aq)+H_{10}L(aq)\rightarrow M_5L\cdot xH_2O(s)+10H^+$$

$$[M^{II}=Fe, Co, Ni, Cu \text{ and } Cd]$$

$$4Cr^{3+}(aq)+H_{10}L(aq)+3H_2O \rightarrow Cr_4L(OH)_2\cdot H_2O+12H^+.$$

The complexes are insoluble in all the common organic solvents as well as water and do not melt even up to 270°C, suggesting these to be polynuclear–polymeric in nature.

The structure of the free ligand was confirmed from IR and PMR spectral studies. In the IR spectrum, a band at 1240 cm^{-1}, due to the presence of the phosphoryl group[6] was observed. The presence of other bands at 2950, 1620, 1570, 1140, 1070, 1020 and 965 cm^{-1} suggested that the ligand has a Zwitter ionic structure. The proton magnetic resonance spectrum of DTPMP in D_2O showed that methylene protons resonated at δ 2.35 indicating the presence of 18 methylene protons. Similar observations have also been made by Oakes *et al.* Another signal at δ 10.5 may either be due to some impurity but more likely due to OH (intramolecularly hydrogen bonded).

In the IR spectra of the metal complexes, the band for phosphoryl groups seemed to be absent at 1240 cm^{-1} probably due to the formation of coordination linkages. Bands were observed in the ranges 1070–1050 cm^{-1} and 1010–950 cm^{-1} which could be due to a deprotonated phosphonic acid group. New bands were observed at 410, 370, 340 and 310 cm^{-1}. The first two bands were assigned to ν(M—O) linkages as also observed by others[7] and the fourth band may be due to the coordination linkage between the metal and the nitrogen atom.[8]

Electronic absorption spectra of the complexes show that the metal ions have octahedral environments[9,10] and the results are comparable with those reported by Oakes and van Kralingen.[1,2]

Room temperature magnetic moment values of the complexes were found to be lower than those expected for free ions, suggesting the possibility of antiferromagnetism in these complexes.[11,12] Values of θ obtained from plotting $1/\chi_M$ against temperature K further comfirmed this nature, since it was observed from the graph that the complexes obeyed the Curie–Weiss law.

The EPR spectrum of a powdered sample of Cu^{II}–DTPMP complex could provide only a value of g_{av} (2.052) and no hint about individual g_x, g_y, g_z or $g_\parallel$ and $g_\perp$ values. This value favours the presence of tetragonal distortion.[13] However, this value cannot be compared with those obtained by Oakes *et al.* for their Cu^{II}–DTPMP complex because in their case, there does not seem to be much metal–metal interaction or antiferromagnetism.

Thermal analyses of $Ni_5(DTPMP)\cdot 20H_2O$ and $Cd_5(DTPMP)\cdot 16H_2O$ have been studied. They were heated in air at the rate of 10°C min^{-1} in the range 20–1000°C. It was inferred that the complexes first lost their water molecules up to 370°C and finally at higher temperatures they were found to give the final products of metal oxide and phosphorous pentoxide.[14]

(*Received* 29 *June* 1987; *accepted after revision* 15 *August* 1988)

Abstract—White crystalline $KCuF_3$ has been synthesized from the reaction of $Cu(OH)_2$ with KHF_2 and a small amount of 40% HF at pH $\leqslant$ 4, while the synthesis of blue fluoro(sulphato)cuprates(II), $Na[CuF(SO_4)]\cdot 2H_2O$, $K[CuF(SO_4)]\cdot 3H_2O$ and $NH_4[CuF(SO_4)]\cdot 3H_2O$, has been accomplished by reacting $Cu(OH)_2$ with AF and A_2SO_4 (A = Na, K or NH_4), in the ratio of 1 : 1 : 1, in the presence of a small amount of 40% HF. Alternative synthesis of the latter involving reactions among $Cu(OH)_2$, F^-, and SCN^-, and H_2O_2 or SO_2(g) and H_2O_2 gave CuSCN and $Cu^{II}[Cu^{I}SO_3]_2\cdot 2H_2O$, respectively, instead of the desired product. The compounds have been characterized by elemental analyses, chemical determination of the oxidation state of copper, magnetic susceptibility and ESR measurements, IR, laser Raman (LR), and electronic spectroscopic studies. The complex $[CuF(SO_4)]^-$ species has a distorted octahedral polymeric structure containing both F^- and SO_4^{2-} as bridging ligands.

There has been a general interest in fluorometallates, particularly the perovskites[1–3] mainly owing to their unusual properties.[4–6] Fluorocuprates(II) form a distinct class among perovskites as regards the nature of coordination, structure and the observed colour anomaly.[7] Thus, whereas the AMF_3 (A = univalent cation; M = bivalent transition metal) complexes generally have a cubic perovskite structure, the $ACuF_3$ compounds display a lower symmetry, distorted tetragonal geometry with the Jahn–Teller effect.[8–10] Access to pure fluorometallates has been a general problem,[7] and consequently there have been instances which involve information based on impure products.[11] Moreover, information on mixed-ligand fluorocuprates(II) are restricted to a few papers.[12,13] Such complexes of transition metals enable a comparison of their properties with those of the corresponding binary fluoro complexes. In addition, mixed-fluoro complexes display some interesting properties,[14–19] some of which also have biochemical significance.[13,20]

As a part of our programme on studies of the fluoro and mixed-fluoro complexes of transition metals,[15–18,20,21] as well as the current interest in the copper(II)–fluoro chemistry,[13] we extended our investigations to fluoro and mixed fluorocuprates(II). Reported in this paper are a direct synthesis of $KCuF_3$, and synthesis, characterization and the assessment of the structure of novel mixed-ligand fluorocuprates(II): $Na[CuF(SO_4)]\cdot 2H_2O$, $K[CuF(SO_4)]\cdot 3H_2O$ and $NH_4[CuF(SO_4)]\cdot 3H_2O$. An effort has also been made to rationalize the changes in magnetic properties in going from $[CuF_3]^-$ to $[CuF(CO_4)]^-$ complexes.

EXPERIMENTAL

The chemicals used were all of reagent grade quality. IR spectra were recorded on a Perkin–Elmer model 983 spectrophotometer in KBr as well as in Nujol mull media. Laser Raman (LR) spectra were recorded on a SPEX Ramalog model 1403 spectrometer. The 5145 Å laser line from the Spectra-Physics model 165 Argon laser was used as the excitation source. The scattered light at 90° was

*Author to whom correspondence should be addressed.

detected with the aid of a cooled RCA 31034 photomultiplier tube followed by a photon count processing system. The spectra were recorded at ambient temperatures using pressed pellets of the compounds. Magnetic susceptibility measurements were made by using the Guoy method with $Hg[Co(NCS)_4]$ as the calibrant. Electronic spectra were recorded on a Cary model 2300 spectrophotometer. The pH of the reaction solutions was measured with a Systronics type 335 digital pH meter and also with pH indicator (BDH) papers. ESR spectra were recorded using a Varian E 109-ESR spectrometer (X-band) with 100 kHz field modulation.

Synthesis of potassium triflurocuprate(II), $KCuF_3$

Copper(II) hydroxide was prepared from an aqueous solution of $CuCl_2 \cdot 2H_2O$ by precipitating it with a 5% solution of NaOH. The precipitate was centrifuged and washed free from alkali and chloride.

In a typical reaction, an aqueous suspension of a freshly prepared copper(II) hydroxide, as obtained above (from 2.0 g, 11.74 mmol of $CuCl_2 \cdot 2H_2O$), was dissolved in *ca* 1 cm^3 of 40% HF. The solution was filtered to remove any traces of undissolved material. A concentrated solution of KHF_2, maintaining the molar ratio of Cu/KHF_2 at 1 : 2, was added to the above filtrate with vigorous stirring (the pH of the solution was found to be below 4). Stirring was continued until white microcrystalline $KCuF_3$ precipitated out. The product was separated by centrifugation, washed twice with ethanol and finally dried *in vacuo* over P_4O_{10}. The yield of $KCuF_3$ was 1.5 g (80%).

Synthesis of alkali-metal and ammonium monofluoro(sulphato)cuprates(II) *hydrates*, $Na[CuF(SO_4)] \cdot 2H_2O$, $K[CuF(SO_4)] \cdot 3H_2O$ *and* $NH_4[CuF(SO_4)] \cdot 3H_2O$

Freshly prepared copper(II) hydroxide was dissolved in a minimum volume of 40% HF (in a similar way to that described above). This was then treated with a concentrated solution of alkali metal or ammonium fluoride and the corresponding sulphate, with maintenance of the $Cu/AF/A_2SO_4$ molar ratio of 1 : 1 : 1. The mixture was warmed on a steambath for *ca* 15 min with occasional stirring. The light blue solution thus obtained was cooled to room temperature and filtered. The filtrate was stirred magnetically for *ca* 15 min followed by the addition of ice-cold ethanol until a precipitate just began to appear. The solution was then kept in a freezer for about 1/2 h for complete precipitation of the light blue microcrystalline $Na[CuF(SO_4)] \cdot 2H_2O$, $K[CuF(SO_4)] \cdot 3H_2O$ or $NH_4[CuF(SO_4)] \cdot 3H_2O$ compounds. The products were isolated, purified and dried in manners analogous to those described for $KCuF_3$.

Starting from 2.0 g (11.74 mmol) of $CuCl_2 \cdot 2H_2O$ in each case, the yields of $Na[CuF(SO_4)] \cdot 2H_2O$, $K[CuF(SO_4)] \cdot 3H_2O$ and $NH_4[CuF(SO_4)] \cdot 3H_2O$ were 2.1 g (75%), 2.6 g (82%) and 2.3 g (78%), respectively.

Elemental analysis

Copper was estimated iodometrically.[22a] The fluoride content of $KCuF_3$ was determined gravimetrically[22b] as lead chloride fluoride. However, for the mixed-ligand fluoro(sulphato) complexes, fluoride was first precipitated as PbClF and then the chloride was estimated by Volhard's method from which the fluoride content was calculated.[22b] Sulphate was estimated gravimetrically as $BaSO_4$.[22c] Sodium, potassium and nitrogen were determined by the methods described in our earlier papers.[23]

The analytical data and room temperature magnetic moments are reported in Table 1, while the important IR and electronic spectral bands with their assignments are summarized in Table 2.

RESULTS AND DISCUSSION

The difficulties associated with the preparation and definitive characterization of $KCuF_3$ are well known. A wide variety of colours for $KCuF_3$, from white to blue, was reported in the literature[6-9] and a correlation between the colour and composition of the compound established.[7,24] The bluest of the potassium complexes was shown to be the extreme case of $KCu(OH)F_2$. Consequently, a preparation of pure $KCuF_3$ has long been looked for since the available methods proved impractical to produce an uncontaminated product. The results of our investigations[16-18,21,25] of the fluoro chemistry of metals suggest that freshly prepared hydrated metal oxides or hydroxides are very suitable starting materials for the synthesis of fluoro and mixed-ligand fluoro complexes of the corresponding metals. Further, it was expected that use of potassium bifluoride, KHF_2, would help, not only in maintaining acidity, but also in providing a high fluoride ion concentration to facilitate formation of the pure product. Accordingly, the reaction of freshly prepared $Cu(OH)_2$ with KHF_2 in the presence of 40% HF at pH $\leqslant$ 4 led to the synthesis of a pure white microcrystalline compound, $KCuF_3$. Similar reactions at pH > 4 yielded contaminated

products. It may therefore be emphasized that high concentrations of both H^+ and F^- are necessary for the synthesis of pure potassium trifluorocuprate(II), $KCuF_3$.

In our endeavour to get access to the hitherto unknown mixed-ligand fluoro(sulphato) complexes of copper(II), the reaction of $Cu(OH)_2$ with 40% HF, alkali metal or ammonium fluoride, and the corresponding sulphate was carried out. This led to the synthesis of $Na[CuF(SO_4)]\cdot 2H_2O$, $K[CuF(SO_4)]\cdot 3H_2O$ or $NH_4[CuF(SO_4)]\cdot 3H_2O$ at $pH \leqslant 4$. The products isolated by conducting similar reactions at $pH > 4$ were found to be impure with inconsistent composition and colour suggesting therefore that a $pH \leqslant 4$ is conducive to the successful synthesis of the desired complexes. The role of ethanol was to precipitate the compounds.

In view of the sequence of reactions and the products obtained, it is believed that the fluorocuprate(II), CuF_3^-, ion is first formed, in the reaction of $Cu(OH)_2$ with AF and 40% HF, which subsequently undergoes a partial replacement of fluoride by SO_4^{2-} to afford the complex $[CuF(SO_4)]^-$. This certainly indicates that sulphate can compete with F^-, under the present experimental conditions, to coordinate with Cu^{II}. It is pertinent to mention that, while the mixed-ligand fluoro(sulphato)cuprates(II) can be synthesized easily, our attempted synthesis of the corresponding fluoro(oxalato)cuprates(II) has not been successful. The product was found to be a binary oxalatocuprate(II) containing chelated oxalate. It is notable that while the mixed fluoro(sulphato) complexes of Mn^{III},[16] Co^{II}[18] and Cu^{II} (present report) can be synthesized directly from the reaction of the corresponding hydroxides with alkali sulphate and hydrofluoric acid, fluoro(sulphato)ferrates(III) could not be synthesized[26] by a similar procedure. The success could be achieved[26] for the latter, only by conducting the chemical oxidation of SCN^- to SO_4^{2-} by H_2O_2 in the presence of F^- ions and Fe^{III}. In an attempt to synthesize fluoro(sulphato) cuprates(II) from the reactions of $Cu(OH)_2$ with F^-, SCN^- and SO_2(g), respectively, in the presence of H_2O_2, such reactions were carried out. Unfortunately the formation of CuSCN in the former and that of the red $Cu^{II}[Cu^{I}SO_3]_2\cdot 2H_2O$[27] in the latter precluded synthesis of the compounds looked for.

Characterization and assessment of structures

White potassium trifluorocuprate(II), $KCuF_3$ and light blue $Na[CuF(SO_4)]\cdot 2H_2O$, $K[CuF(SO_4)]\cdot 3H_2O$ or $NH_4[CuF(SO_4)]\cdot 3H_2O$ are all microcrystalline products, insoluble in common organic solvents. They decompose in water, precluding molar conductance measurements, and they result on the etching of glass slides in the presence of moisture. The compounds are stable in the dry and can be stored in polyethylene ampoules. Their stability can be ascertained by estimation of copper contents and recording of IR spectra periodically. The importance of chemical determination of oxidation states of metals capable of displaying variable oxidation states, has been emphasized in our earlier papers.[15-18,21] The results of the iodometric determination of the oxidation state of copper showed that the metal occurs in its +2 state in each of the compounds presented in this report.

The effective magnetic moment of $KCuF_3$ at 298 K was found to be 1.35 BM, in conformity with that reported by Machin *et al.*,[4] indicating a considerable antiferromagnetic interaction being operative between contiguous Cu^{2+} ions in the crystal lattice. The electronic spectrum of $KCuF_3$, recorded immediately after making its solution, showed a broad, weak and assymmetric band at 12050 cm^{-1} owing to the transition $B_{1g} \rightarrow E_g$, arising from an appreciable splitting of the ^2E_g ground state of Cu^{II} as a consequence of the Jahn–Teller effect.[28] This

in turn shows that the CuF_3^- ion has a distorted octahedral structure. The IR spectrum of $KCuF_3$ is straightforward and shows an absorption at 485 cm^{-1} assigned to the ν(Cu—F) mode.[29] A relatively lower ν(Cu—F) value points to a rather elongated Cu—F bond or enhanced ionic character. The position and broadening of the band point to the possibility of a —F—Cu—F—Cu—F— interaction in the crystal lattice leading to a polymeric structure. This agrees very well with the observed magnetic moment of the complex. The most significant aspect of the IR spectrum of the newly synthesized $KCuF_3$ is the complete absence of any absorption around 3400 cm^{-1} supporting our contention that the compound is free from OH^-.

Unlike $KCuF_3$, the fluoro(sulphato)cuprate(II) complexes are light blue in colour and contain water of crystallization. The principal features of their IR spectra are the absorptions due to coordinated sulphate and fluoride. The IR signatures for the S—O modes of sulphate, at 1160(s), *ca* 1115(s) and 1050(s) cm^{-1} assigned to ν_3, at *ca* 980m cm^{-1} due to ν_1, at *ca* 655(s), 615(s) and 570(s) cm^{-1} owing to ν_4, and at *ca* 455(m, br) cm^{-1} attributed to ν_2, attest the presence of coordinated SO_4^{2-}. The appearance of ν_1 and ν_2, as well as splitting of the ν_3 and ν_4 modes into three bands each clearly point to the bidentate nature of the sulphato ligand.[30] Further, a comparison of the IR results with those of the other sulphato complexes indicates that the ν_3 modes of the sulphato ligand of the present complexes fall in a comparatively lower region, suggesting in turn that the SO_4^{2-} is coordinated in a bridging bidentate manner.[30,31] The IR spectra of the complexes also support this view by exhibiting signals at *ca* 1150, 1110, and 1050 cm^{-1} due to ν_3, at *ca* 975 cm^{-1} due to ν_1, at *ca* 650, 610 and 570 cm^{-1} owing to ν_4, and *ca* 450 cm^{-1} due to the ν_2 mode of the coordinated sulphato ligand. Another common feature of the IR spectra of these complexes is a band at *ca* 485 cm^{-1} which has been assigned to a ν(Cu—F) mode. The broad nature of the band and its position imply the occurrence of a bridging fluoride rather than a terminal one. These observations thus suggest a double bridge arrangement involving both F^- and SO_4^{2-} leading to a situation presumably parallel to that encountered for fluoro(sulphato)manganate(III).[32] The additional bands at *ca* 3440 and 1640 cm^{-1}, observed in each of the spectra, resemble in shape and position, those of ν(O—H) and δ(H—O—H) modes of uncoordinated water.[15] Pyrolysis of $Na[CuF(SO_4)]\cdot 2H_2O$, $K[CuF(SO_4)]\cdot 3H_2O$ and $NH_4[CuF(SO_4)]\cdot 3H_2O$ at 125–130°C for 3 h led to the weight losses of 15.05%, 19.75% and 21.4%, respectively. The observed weight loss in each case corresponds to the loss of water molecules, lending further support to the presence of lattice water. The IR spectra of the compounds recorded before and after pyrolysis were similar except for the complete absence of water modes in the spectra of the pyrolysed samples. This causes us to infer that the complex ion does not undergo any apparent change on heating at 125–130°C.

The effective magnetic moments of the fluoro(sulphato)cuprate(II) hydrate at 298 K were found to lie between 1.60 and 1.65 BM. Although these values are lower than one normally expects for a Cu^{II} (d^9) system,[4] they are higher than that of $KCuF_3$. An internal comparison of observed magnetic moments of the two types of complex suggests that strong antiferromagnatism, operative in the case of $KCuF_3$, is largely controlled in the mixed-fluoro complexes in going from $[CuF_3]^-$ to $[CuF(SO_4)]^-$. Similar observations were also made in the case of some other metals.[16–18,25] Electronic spectra of the fluoro(sulphato)cuprate(II) complexes, recorded immediately after preparing their aqueous solutions, exhibited a band for each at *ca* 12400 cm^{-1} due to the transition $B_{1g} \rightarrow E_g$. This conforms with the occurrence of Cu^{II} in a distorted octahedral environment.[28] The ESR spectrum of solid $K[CuF(SO_4)]$, taken as a representative, at 298 K showed signals corresponding to three g values of 2.42, 2.20 and 2.13 with an average of 2.25. These compare very well with the literature data on Cu^{II} systems.[33] Further, the rhomic g values provide evidence for a fairly large component of low symmetry in the ligand field around the Cu^{II} centre leading to a distorted octahedral structure[33] of the complex species. Thus, it is evident from the results of physical studies that the complex $[CuF(SO_4)]^-$ has a distorted octahedral polymeric structure involving both fluoride and sulphate as bridging ligands between the contiguous Cu^{II} centres in the crystal lattice.

CONCLUSION

Pure $KCuF_3$ has been synthesized from the reaction of $Cu(OH)_2$ with KHF_2 and dilute hydrofluoric acid at pH $\leqslant$ 4. The appropriate acidity and a high concentration of F^- ions are of crucial importance. Mixed-ligand fluoro(sulphato)cuprate(II) complexes may be synthesized by reacting $Cu(OH)_2$ with 40% HF, alkali sulphate and the corresponding fluoride. Alternative routes involving oxidation of SCN^- or SO_2(g) by H_2O_2 in the presence of Cu^{II} and F^- ions have not been successful. A strong antiferromagnetism operative in the binary complex, $[CuF_3]^-$, is controlled to a large extent in the mixed-ligand $[CuF(SO_4)]^-$ complex. The results

of physical studies provide evidence for a distorted octahedral polymeric structure of the complex species with both fluoride and sulphate acting as bridging ligands in the crystal lattice.

A KINETIC STUDY OF THE REACTION BETWEEN THIOUREA AND ETHYLENEDIAMINETETRAACETATO RUTHENATE(III) COMPLEX BY THE STOPPED FLOW TECHNIQUE

M. M. TAQUI KHAN* and R. M. NAIK

Discipline of Coordination Chemistry and Homogeneous Catalysis, Central Salt and Marine Chemicals Research Institute, Bhavnagar 364 002, India

(*Received* 19 *April* 1988; *accepted after revision* 15 *August* 1988)

Abstract—The kinetics of reaction between thiourea and $[Ru^{III}(H\text{-}EDTA)(H_2O)]$ (**1**) were investigated in aqueous solution as a function of pH, temperature and metal ion concentration at 0.1 M ionic strength using the stopped flow technique. It was established that the monoanionic species of complex **1**, $[Ru^{III}(EDTA)(H_2O)]^-$ (**2**) is the major reacting species over the pH range 1.5–8.5. The substitution reaction follows first-order kinetics in $[Ru(EDTA)(H_2O)]^-$ as well as in thiourea concentrations over a wide concentration range of the two reactants. The rate constant (k_1) was found to be $(2.04\pm0.17)\times10^3$ M^{-1} s^{-1} at 25°C and $\mu = 0.1$ M (KCl). From the activation parameters of the reaction it was concluded that the substitution reaction of $[Ru(EDTA)H_2O]^-$ follows an associative mechanism. The reactivities of different species of the thiourea complexes formed, have also been discussed.

The potentially hexadentate chelating agent EDTA forms complexes with many metal ions. The EDTA complexes of Ru^{III} have been known for more than a decade.[1–5] We have recently investigated the equilibrium and electrochemical and kinetic studies on the interaction of $[Ru(H\text{-}EDTA)H_2O]$ (**1**) with H_2O_2 and O_2.[6,7] The potentiometric data on **1** shows the EDTA ligand to be pentadentate in aqueous solution at low pH values.[6] The complex has a pK_a of 7.86 ± 0.02 at 30° ($\mu = 0.1$ M KCl) corresponding to the dissociation of a proton from the coordinated H-EDTA moiety. Furthermore, the single titrable proton corresponding to the above pK_a value is consistent with the presence of a water molecule bound to the metal ion. Thus, all the available experimental observations reveal that the dominant form of complex **1** contains pentadentate EDTA in aqueous solution with the sixth coordination site of the metal centre occupied by a water molecule (or by a hydroxide ion at higher pH values).

In this paper, we report the kinetics of the reaction between thiourea and complex **1** at $\mu = 0.1$ M KCl and temperature (T) = 25°C in the pH range 1.5–8.5. The equilibrium constant and the stoichiometry of the complex formed, have also been determined by the mole ratio method.[8] The activation parameters for the reaction have been evaluated and discussed. The rate constants due to different reactive species were calculated.

EXPERIMENTAL

The complex[9] $K_2[RuCl_5\cdot H_2O]$ was used as the starting material for the synthesis[10] of the complex $K[Ru(H\text{-}EDTA)H_2O]$ (**1**). A. R. grade thiourea was used as such without any purification. The ionic strength of the reactants was maintained at 0.1 M using KCl. The temperature of the reactants was maintained at the desired value by a thermostat before mixing the reactants inside the reaction chamber of a stopped flow spectrophotometer Hi-Tech coupled with an Apple data processor. The reaction was followed under pseudo-first-order conditions taking a large excess of thiourea by monitoring the peak at 468 nm which is the λ_{max} of $[Ru(EDTA)(thiourea)]^-$ complex formed.[11] The pseudo-first-order rate constants were calculated from plots of log $(A_\infty - A_t)$ vs time.

*Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

1. *Stoichiometry of the reaction of thiourea with complex* **1**

The mole ratio method was used to determine the stoichiometry of the complex formed by the displacement of water by thiourea in complex **1**. The absorbance at 468 (λ_{max} of [Ru(EDTA-H)(thiourea)]) was measured as a function of mole ratio of [Ru(H-EDTA)H_2O] to [thiourea]. The plot of absorbance vs mole ration in Fig. 1 clearly indicates that a 1:1 complex is formed immediately after mixing of the reactants. The equilibrium constant for reaction (1) was determined from the ratio of intercept to slope of the plot of

$$\frac{1}{\Delta A} \text{ vs } \frac{1}{[\text{Thiourea}]}$$

(Fig. 2). The value of equilibrium constant K determined is 9.04×10^3.

5.0	9.70	1.94

$k_1^{av} = (2.04 \pm 0.17) \times 10^3\ M^{-1}\ s^{-1}$.

2. *Kinetics of the substitution reaction*

The reaction between **1** and thiourea follows first-order dependence in **1** as well as in thiourea concentration over a wide range of concentrations. The pseudo-first-order plots of log ($A_\infty - A_t$) vs time were linear for at least three half lives of the reaction. The results in Table 1 show that the reaction is first-order in both the reactants over a wide range of concentration and pH. The values of pseudo-first-order rate constants (k_{obs}) obtained from the plot of log ($A_\infty - A_t$) vs time are plotted against thiourea concentration (Fig. 3).

3. *Dependence of rate on pH*

The kinetic measurements over a wide pH range of 1.5–8.5 (Fig. 4) (Table 2) show the pH dependence of the reaction. The rate constant of the reaction was found to increase in the pH range 1.5–4.5, remain constant in the pH range 4.5–6.5 and decrease in the higher pH range (6.5–8.5) (Fig. 4).

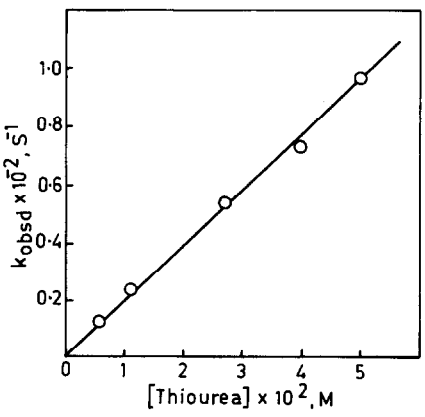

Fig. 3. Thiourea dependence of observed pseudo-first-order rate constant for the reaction of thiourea with [Ru(EDTA)H_2O]. Reaction conditions as in Table 1.

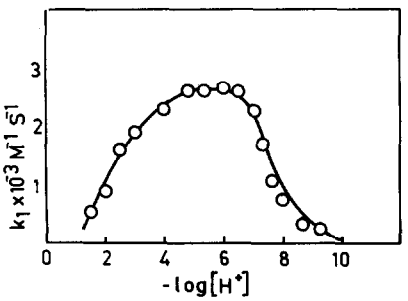

Fig. 4. pH Dependence of the reaction of thiourea with [Ru(H-EDTA)H_2O]. [Ru(H-EDTA)H_2O]$_T = 5 \times 10^{-4}$ M, [Thiourea] $= 5 \times 10^{-2}$ M, $\mu = 0.1$ M (KCl) and $T = 25°C$.

This interesting behaviour of the reaction over the entire pH range can be explained in terms of different reactivities of species **1** towards the nucleophile $SC(NH_2)_2$. Complex **1** can exist in three forms viz. protonated [Ru(H-EDTA)H_2O] **1a**, neutral [Ru(EDTA)H_2O]$^-$ **1b** and hydroxo form [Ru(EDTA)OH]$^{2-}$ **1c**. The species **1b** was found to be the most reactive species over the whole pH region. The rate constants due to these species can be calculated by an algebraic assignment of the specific rate constants outlined below. The rate of reaction (1) may be expressed by eq. (2).

$$[Ru(H\text{-}EDTA)H_2O] + [thiourea] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Ru(H\text{-}EDTA)(thiourea)] + H_2O. \quad (1)$$

$$\text{Rate} = k_1 [Ru(H\text{-}EDTA)H_2O]_T [thiourea]. \quad (2)$$

8.62	0.35
9.30	0.30

The total concentration of Ru^{III} complex [Ru(EDTA)(H_2O)]$_T$ can be expressed by a sum of the concentration of the three species **1a**, **1b** and **1c**.

$$[Ru(H\text{-}EDTA)H_2O]_T = \underset{\mathbf{1a}}{[Ru(H\text{-}EDTA)H_2O]} + \underset{\mathbf{1b}}{[Ru(EDTA)H_2O]^-} + \underset{\mathbf{1c}}{[Ru(EDTA)OH]^{2-}}. \quad (3)$$

Substituting the pK_{a_1} and pK_{a_2} values[6] of [Ru(EDTA)H_2O]$^-$ and [Ru(EDTA)OH]$^{2-}$, eq. (3) can be finally expressed in the form of eq. (4):

$$\frac{[Ru(H\text{-}EDTA)H_2O]_T}{[Ru(H\text{-}EDTA)H_2O]} = 1 + \frac{K_{a_1}}{[H^+]} + \frac{K_{a_1} \times K_{a_2}}{[H^+]^2}, \quad (4)$$

where K_{a_1} and K_{a_2} are expressed as follows,

$$K_{a_1} = \frac{[Ru(EDTA)H_2O][H^+]}{[Ru(H\text{-}EDTA)H_2O]} = 4.27 \times 10^{-3}\,M, \quad \text{(ref. 12)}$$

$$K_{a_2} = \frac{[Ru(EDTA)(OH)]^{2-}[H^+]}{[Ru(EDTA)H_2O]} = 2.34 \times 10^{-8}\,M. \quad \text{(ref. 12)}$$

The pH dependence of the rate constant for reaction (1) can be analysed in terms of the following reaction pathways:

$$[Ru(H\text{-}EDTA)H_2O] + L \xrightarrow{k_a} [Ru(H\text{-}EDTA)L] + H_2O, \quad (5)$$

$$[Ru(EDTA)H_2O]^- + L \xrightarrow{k_b} [Ru(EDTA)L]^- + H_2O, \quad (6)$$

$$[Ru(EDTA)(OH)]^{2-} + L \xrightarrow{k_c} [Ru(EDTA)L]^- + OH^-, \quad (7)$$

where L = thiourea.

The rate constant (k_1) given by eq. (2) can be expressed in terms of the specific rate constants k_a, k_b and k_c of the three species in the form:

$$k_1 \left(\frac{[Ru(H\text{-}EDTA)H_2O]_T}{[Ru(H\text{-}EDTA)H_2O]} \right) = k_a + k_b \left(\frac{K_{a_1}}{[H^+]} \right) + k_c \left(\frac{K_{a_1} \times K_{a_2}}{[H^+]^2} \right). \quad (8)$$

In order to simplify the evaluation of the rate parameters of eq. (8), one can consider the sections of the pH rate profile of Fig. 4.

In the pH range 1.5–4.5, it is assumed that $k_b \gg k_a$

or k_c. Thus, it is reasonable to neglect the contribution from path k_c (eq. 8) in the above pH range. Similarly, in the pH range (4.5–8.5), the contributions from path k_a (eq. 5) can be ignored.

Applying the above approximations to eq. (8), the rate expression finally reduces to eqs (9) and (10), respectively:

$$k_1\left(1+\frac{K_{a_1}}{[H^+]}\right)=k_a+k_b\left(\frac{K_{a_1}}{[H^+]}\right),$$

(at pH $\leqslant$ 4.5) (9)

$$k_1\left(1+\frac{[H^+]}{K_{a_1}}\right)=k_c+k_b\left(\frac{[H^+]}{K_{a_2}}\right).$$

(at pH $\geqslant$ 4.5) (10)

The plot of the left hand side of eq. (9) vs $1/[H^+]$, yields a straight line (Fig. 5) which gives the values of the rate constants ($k_a = 5\times10^2\,M^{-1}s^{-1}$) and ($k_b = 2.34\times10^3\,M^{-1}s^{-1}$) from the intercept and slope of the above plot, respectively. Similarly, a plot of the left hand side of eq. (10) vs $[H^+]$ gives a straight line where the values of the constants ($k_c \approx 0\,M^{-1}s^{-1}$) and ($k_b = 2.6\times10^3\,M^{-1}s^{-1}$) were calculated from the intercept and slope of the plot, respectively (Fig. 6). The intercept of Fig. 6 is almost zero within experimental error. This clearly shows that the species $[Ru(EDTA)(OH)]^{2-}$ is the least reactive of the three species. The reactivities of different species of **1** over the entire pH range, thus follow the order $[Ru(EDTA)(OH)]^{2-}$ < $[Ru(H\text{-}EDTA)H_2O]$ < $[Ru(EDTA)H_2O]^-$. The substitution of the aqua group by thiourea, thus proceeds through the major path k_b in the entire pH range studied. Similar rate vs pH profiles were observed in several other systems.[11,12]

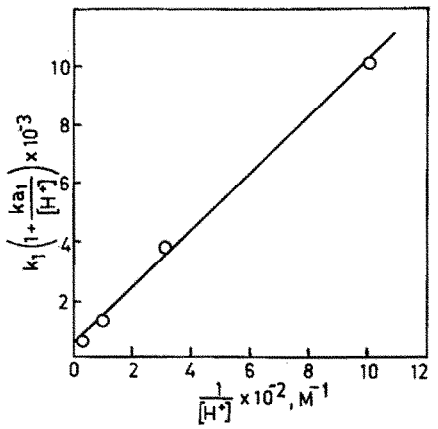

Fig. 5. Resolution of rate constants due to the reaction of $[Ru(H\text{-}EDTA)H_2O]$ and $[Ru(EDTA)H_2O]^-$ with thiourea. Plot of

$$k_1\left(1+\frac{K_{a_1}}{[H^+]}\right) \text{ vs } \frac{1}{[H^+]},$$

at $\mu = 0.1$ M and $T = 25$°C.

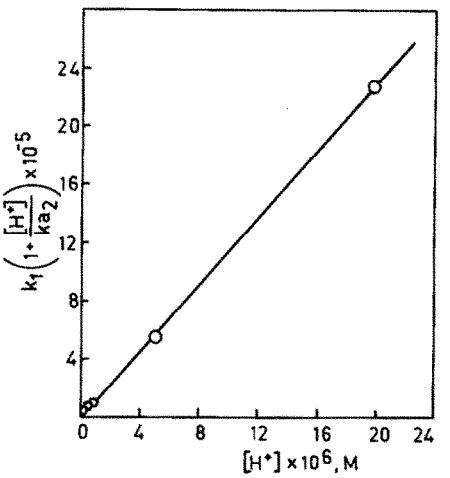

Fig. 6. Resolution of rate constant due to the reaction of $[Ru(EDTA)H_2O]^-$ and $[Ru(EDTA)(OH)]^{2-}$ with thiourea. Plot of

$$k_1\left(1+\frac{[H^+]}{K_{a_2}}\right) \text{ vs } [H^+],$$

at $\mu = 0.1$ M KCl and $T = 25$°C.

4. *Effect of temperature on reaction rate*

The reaction was studied over a wide temperature range. The activation energy E_a was calculated from the plot of log (k_1) vs $1/T$ (Fig. 7; Table 3). The enthalpy of activation, $\Delta H^{\ddagger}$ and entropy of activation, $\Delta S^{\ddagger}$ were also calculated. The values of the

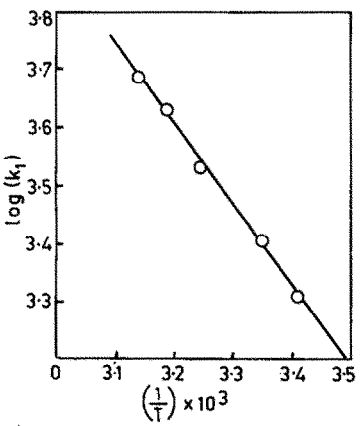

Fig. 7. Plot of log (k_1) vs $1/T$ for the determination of activation parameters E_a, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. $[Ru(H\text{-}EDTA)H_2O] = 5\times10^{-4}$ M, [Thiourea] $= 5\times10^{-3}$ M, $\mu = 0.1$ M KCl, pH $= 3.0\pm0.02$.

Table 3. Temperature dependence of the rate constant (k_1) for the reaction of thiourea with [Ru(H-EDTA)H_2O], [Ru(H-EDTA)H_2O]$_T = 5\times10^{-4}$ M, [Thiourea] $= 5\times10^{-3}$ M, pH $= 3.0\pm0.02$ and $\mu = 0.1$ M (KCl)

$10^{-3}\times k_1$ ($M^{-1}s^{-1}$)	Temperature (K)
2.06	293
2.56	293
3.45	308
4.30	313
4.90	318

parameters, E_a, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were found to be 26.7 kJ mol^{-1}, 24.4 kJ mol^{-1} and -97.2 JK^{-1} mol^{-1}, respectively.

The high negative value of $\Delta S^{\ddagger}$ favours an associative S_N^2 mechanism for the displacement of water by thiourea in complex **1**. The values of enthalpies of activation for substitution reactions of Ru^{III}—OH_2 species with other ligands were found to be in the range 80–100 kJ mol^{-1}.[13,14] These data clearly indicate a high energy barrier for cleavage of the M—OH_2 bond and a dissociative nature of these reactions.

In the displacement reaction of water by thiourea in complex **1**, however, the enthalpy barrier is lowered to an appreciable extent possibly due to an associative mechanism. It is to be emphasized here that the associative mechanism is only indicative from the second-order mechanism which is always obtained by the I_d replacement of water. The reactivity of complex **1** towards substitution reaction through an associative activation is possible because of the presence of free carboxylate group in complex **1** and availability of labile coordination sites on the complex. Recently, the single crystal X-ray analysis has confirmed that EDTA is five coordinate in complex **1** and in [Ru(EDTA-H)Cl_2], EDTA is four coordinate.[15] This flexibility of coordinated EDTA in complex **1** thus allows the simultaneous coordination of thiourea and the H_2O molecule in the transition state and supports a low energy associative pathway. The space filling model of complex **1** indicates that hydrogen bonding between the free carboxylate group, the coordinated water molecule and thiourea appears favourable. The highly negative value of $\Delta S^{\ddagger}$ again supports steric crowding in the transition state and distortion in the EDTA ligand in complex **1**. Other structurally similar complexes[16,17] viz. [Fe(EDTA)H_2O]$^-$ and [Cr(EDTA)H_2O]$^-$ also follow an associative mechanism like complex **1** in their reaction with nucleophiles.

HOMOGENEOUS CATALYTIC HYDROGEN FORMATION USING A DITUNGSTEN CLUSTER AND LOW VALENCY METAL IONS IN AQUEOUS ACIDIC SOLUTIONS

CONSTANTINOS MERTIS* and NIKOS PSAROUDAKIS

University of Athens, Inorganic Chemistry Laboratory, Navarinou 13A 10680 Athens, Greece

(*Received* 20 *June* 1988; *accepted* 15 *August* 1988)

Abstract—The formally triply-bonded nonachlorodimetallates $[W_2(\mu\text{-}Cl)_3Cl_6]^{3-}$ (**6**) and $[Re_2(\mu\text{-}Cl)_3Cl_6]^{-}$ (**8**) undergo a two-electron homogeneous reduction by the chromous or vanadous ions to give the quadruply-bonded species $[W_2Cl_8]^{4-}$ (**4**) and $[Re_2Cl_8]^{2-}$ (**7**). In aq. HCl solutions complex **6** is an effective catalyst for the anaerobic oxidation of Cr^{II} and V^{II} to Cr^{III} and V^{III} with simultaneous dihydrogen formation.

Direct commercial production of hydrogen from water by electrolysis is uneconomic and considerable research into the possibility of splitting water using light[1] or thermal[2] energy is being carried out.

Industrially, hydrogen is produced heterogeneously from synthesis gas ($CO—H_2$) by the water–gas shift reaction. Homogeneous catalysts for this reaction are known and effective on a laboratory scale but require drastic conditions and much effort has been devoted to obtain hydride complexes[3a] operating at lower temperatures. There exist neutral, basic, and also acidic [$Rh(CO)_2I_2^-$, KI, CH_3CO_2H, HCl, H_2O or K_4PtCl_4, $SnCl_4 \cdot 5H_2O$, CH_3CO_2H, HCl, H_2O at 100°C] systems.[3b]

Although not strictly related to the above processes, relevant homogeneous hydrogen-producing acidic systems ($K_3Mo_2HCl_8$, $CrCl_2$, H_2O, HCl at 25°) have been recently reported[4] based on the ability of the dimolybdenum species to form hydrides which then react with the low-valency metal ion, equation (1):

$$[Mo_2HCl_8]^{3-} + 2Cr^{2+} + H^+ \xrightarrow{H^+} [Mo_2Cl_8]^{4-} + 2Cr^{3+} + \tfrac{1}{2}H_2. \quad (1)$$

Proton oxidative addition to the quadruply-bonded octachlorodimetallate anions $[M_2Cl_8]^{4-}$ (M = Mo, **1**; M = W, **4**) yielding the formally triply-bonded hydrides $[M_2(\mu\text{-}H)(\mu\text{-}Cl)_2Cl_6]^{3-}$ (M = Mo, **2**; M = W, **5**) coupled with diprotonation and loss of hydrogen to produce the analogous nonachloro derivatives $[M_2(\mu\text{-}Cl)_3Cl_6]^{3-}$ (M = W, **6**) are well established reactions, eqs (2) and (3):

$$[M_2Cl_8]^{4-} \xrightarrow{HCl} [M_2HCl_8]^{3-} \xrightarrow[-H_2]{HCl} [M_2Cl_9]^{3-}.$$
(2) (3)

The structures both of the reactants **1**, **4** and of the products **2**, **3**, **6** are known.[5]

However, reaction (1) requires strenuous conditions in the case of molybdenum (60°C in 12 M HCl), whereas the rhenium derivative $[Re_2Cl_8]^{2-}$ (**7**) resists protonation even after refluxing for several hours. Accordingly, $[Mo_2(\mu\text{-}Cl)_3Cl_6]^{3-}$ (**3**) and $[Re_2(\mu\text{-}Cl)_3Cl_6]^{-}$ (**8**) are best prepared by electrochemical oxidation[6] of **2** or chlorine oxidation[7] of **7**, respectively. In contrast, the isoelectronic and isostructural tungsten compound **4**, reacts[8] at −78°C giving **6**, presumably via the reactive[9] unstable hydride **5**.

Reactions (2) and (3) are easily reversible for molybdenum[4,10] and also the reduction of **8** to **7** for rhenium[7] whereas for tungsten they are not.[8,11,12] This enhanced susceptibility of W—W bonds to protons or other oxidants and the irreversibility of these reactions has been the reason for:

(a) the slow development in the chemistry of the W_2^{4+} unit and the long and numerous efforts for the isolation of **4** achieved eventually by the Na/Hg reduction[8,13] of $(WCl_4)_n$ or

*Author to whom correspondence should be addressed.

$W_2Cl_6(THF)_4$ in tetrahydrofuran, eq. (4):

$$W_2Cl_6(THF)_4 + 2Na/Hg \xrightarrow[-30°C]{THF} \tfrac{1}{2}Na_4(THF)_xW_2Cl_8 + \text{“}WCl_2\text{”}. \quad (4)$$

The product is thermally unstable at room temperature, in any solvent it dissolves,[8] eq. (5):

$$Na_4(THF)_xW_2Cl_8 \xrightarrow[\theta > 0°C]{THF} 4NaCl + 2\text{“}WCl_2\text{”}; \quad (5)$$

and

(b) the belief that these allegedly important catalytic species are in fact kinetic and thermodynamic sinks and therefore relatively uninteresting in terms of their catalytic properties.

We now describe the facile homogeneous two-electron reduction of the diamagnetic **6** and **8** to give **4** and **7**, respectively by the paramagnetic $Cr^{2+}_{(aq)}$ or $V^{2+}_{(aq)}$ ions and the low-temperature catalytic anaerobic oxidation of Cr^{II} and V^{II} to Cr^{III} and V^{III} by **6** with simultaneous hydrogen evolution in aq. HCl solutions.

EXPERIMENTAL

The potassium salts of $[Mo_2Cl_9]^{3-}$, $[W_2Cl_9]^{3-}$ and the tetra-*n*-butyl ammonium salts of $[Re_2Cl_8]^{2-}$ and $[Re_2Cl_9]^{-}$ were prepared by literature methods.[7,11,14,15] $CrCl_2$ was supplied by Ventron and $VCl_2 \cdot 4H_2O$ was prepared electrochemically.[16] All reagents were of analytical grade and thoroughly purified. Demineralized by ion exchange and doubly-distilled water was used. Solvents were very carefully deoxygenated by freeze pumping and all reactions were carried out under strictly anaerobic conditions (atmosphere of argon). Microanalyses were performed in this Laboratory and at the Research Center "Democritos". Tungsten was determined by neutron activation and chloride ions, photometrically. Electronic spectra were recorded with a Hitachi and a Carry 17; Dihydrogen was detected by gas chromatography (GC; Varian 90-P).

Reaction of tripotassium-1,1,1-*trichloro*-2,2,2-*trichloro-tris-μ-chloro-ditungsten*(III) *with* $CrCl_2$ *or* VCl_2

To a solution of $K_3W_2Cl_9$ (0.240 g, 0.298 mmol) and KCl (0.023 g, 0.309 mmol) in aq. 6 M HCl (100 cm^3), $CrCl_2$ (0.327 g, 3.02 mmol) or $VCl_2 \cdot 4H_2O$ (0.596 g, 3.07 mmol) was added at room temperature and under stirring. After *ca* 2.5 h the mixture was filtered, the solvent was removed *in vacuo* and the residues were extracted with tetrahydrofuran. The solution was removed by filtering and the residue was washed with small portions of tetrahydrofuran, dried *in vacuo*, and identified by elemental analysis and spectroscopy to be $K_3W_2Cl_9$; yield 80%.

Reaction of tripotassium 1,1,1-*trichloro*-2,2,2-*trichloro-tris-μ-chloro-dimolybdenum*(III) *with* $CrCl_2$ *or* VCl_2

The same procedure as described for $K_3W_2Cl_9$ or the corresponding $[(n\text{-}C_4H_9)_4N]_3Mo_2Cl_9$[4] was employed for the reduction of **3** to **1** (6 M HCl, $t = 2.5$ h); yield 87%.

The reaction was monitored by visible spectroscopy in 8–10 M HCl, and mixtures of **1** and **2** depending on the reaction time, were isolated following the same work-up procedure.

Reaction of tetra-n-*butylammonium*-1,1,1-*trichloro*-2,2,2-*trichloro-tris-μ-chloro-dirhenium*(IV) *with* $CrCl_2$ *or* VCl_2

To a solution of $[Bu^n_4\text{—}N]Re_2Cl_9$ (0.502 g, 0.538 mmol) and $(Bu^n_4\text{—}N)Cl$ (0.150 g, 0.541 mmol) in tetrahydrofuran (20 cm^3) was added at room temperature a solution of $CrCl_2$ (0.399 g, 3.25 mmol) or $VCl_2 \cdot 2CH_3OH$ (0.61 g, 3.28 mmol) dissolved in 6 M HCl (5 cm^3).

The mixture was left to react under stirring *ca* 2 h and a blue precipitate was formed. This was filtered, washed with methanol dried *in vacuo*, and identified by elemental analysis and spectroscopy to be $(Bu^n_4\text{—}N)_2Re_2Cl_8$; yield, 92%.

RESULTS AND DISCUSSION

When carefully deoxygenated aqueous solutions of one equivalent of $K_3W_2Cl_9$/KCl and an excess of $CrCl_2$, **9**, were mixed at room temperature or at −5°C, the colour quickly changes and a precipitate is formed. The mixture was filtered, washed with water and tetrahydrofuran leaving behind a grey–black powder insoluble in most common organic solvents.

The light green filtrate contains a mixture of $Cr^{2+}_{(aq)}$ (broad peak at 650–700 nm) and $Cr^{3+}_{(aq)}$ (peaks at 412 and 590 nm).[17] Similar results are obtained when an aq. 0.125 M HCl solution of VCl_2 (**10**) was employed. The composition of the precipitate depends on the reaction conditions (acid con-

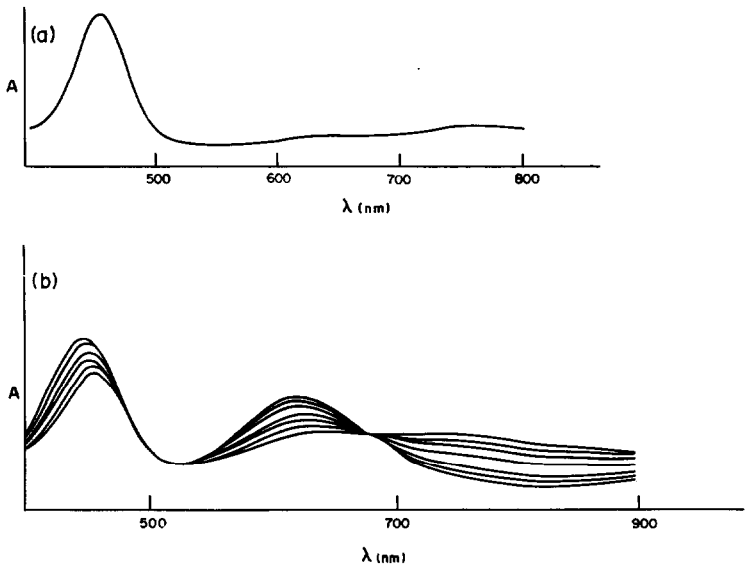

Fig. 1. (a) Spectrum of $K_3W_2Cl_9$ (6.5×10^{-4} M) in 6 M HCl at 25°C. (b) Spectral changes of a mixture of $K_3W_2Cl_9$ (6.9×10^{-4} M) and $CrCl_2$ (1.6×10^{-2} M) in 6 M HCl at 25°C recorded at 15-min intervals.

centration) and approximately analyses as "$WCl_{2-x}(OH)_x$", $x = 0 \ldots 1$.

The insolubility of various salts of **6** [K^+, $(Ph_4As)^+$, $(Bu^n_4—N)^+$] in tetrahydrofuran precluded the reaction at low temperature in this medium where the intensely blue-coloured **4** is more stable[8] (598 nm, 0°C) and attempts to detect or to isolate it as its TMEDA adduct.[13]

In mixture(s) of tetrahydrofuran–water, in which all the reactants are soluble, a transient formation of a bluish colour at −20°C is observed but it is followed by fast decomposition as described above.

However, the same reaction when carried out in aq. HCl solutions (from 6 to 12 M) produced only small amounts of the insoluble precipitate and hydrogen evolution was observed (identified by GC).

The reaction can be followed spectroscopically (Fig. 1).

The intensity of the peak at 452 nm attributed to **6** increases whereas a peak at 615 nm due to $Cr^{3+}_{(aq)}$, probably as a mixture of $[Cr(H_2O)_5Cl]^{2+}$ (peaks at 430, 605 nm) and $[Cr(H_2O)_4Cl_2]^{2+}$ (peaks at 450, 635 nm),[17] appears. Also, the peak due to $V^{2+}_{(aq)}$ (860, 560 nm) at 860 nm disappears and a shoulder at 400 nm characteristic of the $V^{3+}_{(aq)}$ ion (peaks at 588, 400, 263)[18] appears next to the peak of **6** at 452 nm.[19]

After removing the solvent *in vacuo*, the residues were extracted with tetrahydrofuran leaving behind a deep green solid identified as **6**; the filtrates contain Cr^{III} in the form of the dichloro complex $[Cr(THF)_4Cl_2]^+$ (peaks at 445 and 640 nm) or V^{III} (peaks at 502, 751 nm).[18] If a large excess of the reducing metal ion was used (from 4 to 200 mol) under identical conditions, the reaction proceeds exothermically and cooling is necessary. Again hydrogen is evolved, **6** was recovered unchanged and **9** or **10** were oxidized quantitatively to their trivalent states.

In view of the instability of **4**, expected to be even greater in water than in organic solvents, we propose that in aqueous media a two-electron reduction occurs to give **4** [eq. (6)] followed by its fast decomposition and/or hydrolysis:

$$\underset{\mathbf{6}}{[W_2Cl_9]^{3-}} + 2Cr^{2+} \xrightarrow{H_2O} \underset{\mathbf{4}}{[W_2Cl_8]^{4-}} + 2Cr^{3+} + Cl^- \quad (6)$$

In acid, decomposition is prevented because reactions (2) and (3) intercept reproducing **6**, thus the W_2^{6+}/W_2^{4+} couple participates in the catalytic cycle (Fig. 2).

The hydrogen evolved comes from reactions (2) and (3). The electrons required are provided by the low-valency metal ions which are consumed (oxidized), respectively. Parallel formation of hydrogen from the reduction of the tungsten hydride (**5**), similarly as for molybdenum [eq. (1)] is possible, and may occur to a small extent at low acid concentrations in which reaction (3) is slower.

With the potassium salt of **3** analogous results are obtained but because the rate of reaction (2) is slow, and (3) does not practically proceed under the reaction conditions, the hydrogen evolved derives from reaction (2). The Mo_2^{4+}/Mo_2^{6+} couple essen-

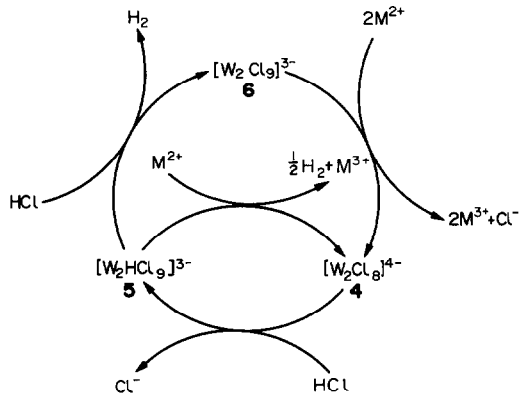

Fig. 2. The binuclear tungsten complex **6** catalyses the evolution of H_2 in HCl solutions in the presence of excess $M^{2+}_{(aq)}$, M = Cr, V.

tially catalyses reaction (7)[20] which is usually very slow even at HCl concentrations as high as 12 M,

$$M^{2+} + H^+ \longrightarrow M^{3+} + \tfrac{1}{2}H_2 \qquad (7)$$

M = Cr, V.

This cycle can be monitored by electronic spectroscopy (**3** with **10**), the interconversions $\mathbf{3} \xrightarrow{+2e^-} \mathbf{1} \underset{+2e^-}{\overset{-2e^-}{\rightleftharpoons}} \mathbf{2}$ and $V^{2+}_{(aq)} \longrightarrow V^{3+}_{(aq)}$ are discernible, and the intermediate products could be isolated by controlling the acid concentration (**3** with **9**).

Also, the rhenium complex **8** was easily converted to **7** from the room temperature interaction of one equivalent of $Re_2Cl_9(Bu^n_4—N)/(Bu^n_4—N)Cl$ in tetrahydrofuran with two equivalent of **9** or **10** in aq. HCl (6 M). The solution instantly from green turns blue and after a while blue crystals precipitate which were characterized to be the tetra-*n*-butyl ammonium salt of **7**. The Cr^{II} and V^{II} were oxidized to Cr^{III} and V^{III}, respectively, eq. (8):

$$\underset{\mathbf{8}}{[Re_2Cl_9]^-} + 2M^{2+} \xrightarrow{HCl} \underset{\mathbf{7}}{[Re_2Cl_8]^{2-}} + 2M^{3+} + Cl^- \qquad (8)$$

M = Cr, V.

The inability of the $(Re^{4}—Re)^{6+}$ core to undergo reaction (2) renders the reaction stoichiometric instead of catalytic. The mechanistic aspects of these homogeneous electron transfer reactions and the implications to chemical or biochemical catalysis are further examined.

ACID DISSOCIATION AND NICKEL-COMPLEX FORMATION CONSTANTS OF SOME NITROSONAPHTHOLSULPHONATE LIGANDS

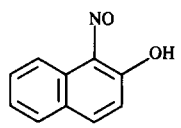
S. BAJUE, P. DASGUPTA, G. C. LALOR* and H. ROBOTHAM

Department of Chemistry, University of the West Indies, Mona, Kingston 7, Jamaica

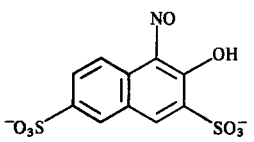
(*Received* 2 *August* 1988; *accepted* 15 *August* 1988)

Abstract—The acid dissociation constants of several 1-nitroso- and 2-nitroso-naphtholsulphonate ligands, and the formation constants of their Ni^{2+} mono-complexes are reported. The measurements were performed in the temperature range 20.0–30.0°C and ionic strength 0.1 mol dm^{-3}.

Ortho-nitrosonaphthols, like 1-nitroso-2-naphthol (**1**) and 1-nitroso-2-naphthol-3, 6-disulphonate (**2**), form complexes with many metal ions.



1



2

The formation and dissociation reactions of the cobalt and nickel complexes of these ligands have been of particular interest in our laboratories.[1-5] It has become clear that data on the various equilibria can contribute to the understanding of these reactions since the mechanism includes a number of pre-equilibria such as acid–base dissociation, ion-pair formation, and nitrosonaphthol–quinone oxime tautomerism.

Unlike keto–enol equilibria,[6] the nitrosonaphthol–quinone oxime equilibria are not amenable to measurement under the present experimental conditions. A stopped-flow spectrophotometric study on acidification of the ligands over a range of wavelengths and acid concentrations showed a single rapid change (< 2 ms) consistent with protonation and no subsequent relaxation, confirming that all equilibria are rapid. The various rate constants must be extracted by computer fittings of the data.

Although there may be significant amounts of the oxime tautomer present, the ligands are, as usual, referred to as nitrosonaphthols and abbreviated as ON-NAS-OH. The pK_a and K_f values then relate to eqs (1) and (2) respectively:

$$\text{ON-NAS-OH} \overset{K_a}{\rightleftharpoons} \text{ON-NAS-O}^- + \text{H}^+, \quad (1)$$

$$\text{ON-NAS-O}^- + \text{Ni}^{2+} \overset{K_f}{\rightleftharpoons} \text{ON-NAS-ONi}^+. \quad (2)$$

EXPERIMENTAL

Reagents

Preparation of 1-nitroso-2-naphthol-3-sulphonic acid. A published method[7] for the preparation of this compound gave very poor yields. A modified procedure using the following reaction sequence gave good yields: 2-hydroxy-3-naphthoic acid → 2-methoxy-3-naphthoic acid → 2-methoxy-3-naphthalene isocyanate → 2-methoxy-3-naphthaleneamine → 2-methoxy-3-naphthalene sulphinic acid → 2-naphthol-3-sulphonic acid → 1-nitroso-2-naphthol-3-sulphonic acid.

2-Methoxy-3-naphthoic acid. To a solution of 48 g (0.26 mol) of 2-hydroxy-3-naphthoic acid in 500 cm^3 of acetone, was added 96 g (0.7 mol) of potassium carbonate followed by 60 cm^3 (0.6 mol) of dimethyl sulphate. The flask was closed by a calcium chloride drying tube and the reaction mixture was stirred for 24 h after which time the contents were poured into 1 dm^3 of ice-cold water. About 10 g of KOH was then added and the mixture concentrated on a rotavap. After cooling the reaction mixture was adjusted to pH 4 with 50% aq. HCl at which stage 2-methoxy-3-naphthoic acid precipitated out. The product was collected, washed

*Author to whom correspondence should be addressed.

thoroughly with water and dried in a vacuum desiccator. Yield, 35 g; m.p. 131°C.

2-Methoxy-3-naphthalene isocyanate. 32 g (0.16 mol) of 2-methoxy-3-naphthoic acid was dissolved in 100 cm^3 of a 1 : 1 mixture of trifluoroacetic acid and trifluoroacetic anhydride. The flask was stoppered with a cotton wool plug, cooled to about 0°C and 15 g (0.22 mol) of sodium azide was added in portions while stirring. The reaction proceeded rapidly and after gas evolution had ceased the mixture was allowed to stand at 0–5°C while stirring for a further 15 min. The reaction mixture was then concentrated on a rotavap and on cooling the product crystallized out but it was not collected. The next step was carried out in the same flask.

3-Methoxy-2-naphthaleneamine. 260 cm^3 of 70% aq. ethanol was added to the flask containing the isocyanate. KOH pellets were added until the solution was alkaline. The mixture was then refluxed for 5 h and then poured into crushed ice whereupon the product formed as a white solid. It was filtered off, washed thoroughly with water and dried over KOH pellets in a vacuum oven at 50°C. It was recrystallized from benzene. Yield 25 g; m.p. 109°C.

2-Methoxy-3-naphthalene sulphinic acid. The above methoxyamine was diazotized and converted to the sulphinic acid derivative using chemically prepared copper powder and sulphur dioxide according to a published method.[7] It was recrystallized by dissolving it in the minimum amount of 10% aq. sodium carbonate solution, cooling in ice and then slowly adding cold dilute HCl to give the sulphinic acid as a pale pink powder. The yield was about 60%. The product is unstable and was used immediately after preparation.

2-Methoxy-3-naphthalene sulphonic acid. Finely powdered potassium permanganate (2 g) was dusted into a well-stirred solution of 2.5 g of the sulphinic acid in 100 cm^3 of acetone over a period of 30 min. The mixture was boiled for 5 min, cooled and filtered. The solid cake was extracted with 100 cm^3 of hot water in portions and the extract was evaporated to dryness to give the potassium salt of the sulphonic acid as an off-white solid. Yield 2.4 g. It was recrystallized from aq. ethanol.

2-Naphthol-3-sulphonic acid. This compound was prepared from the methoxy naphthalene sulphonic acid by refluxing it with 50% HCl for 1 h. The product was washed with ice-cold concentrated HCl and dried over NaOH in a vacuum desiccator. The compound is a very hygroscopic off-white solid.

1-Nitroso-2-naphthol-3-sulphonic acid, sodium salt. This was prepared from the 2-naphthol-3-sulphonic acid by nitrosation with $NaHO_2$ and HCl at 0°C. The resulting solution was saturated with $NaClO_4$ and on cooling the sodium salt separated as the trihydrate. It was recrystallized from an ethanol–water mixture. Recrystallization from dilute acids yielded the free sulphonic acid.

The other ligands were prepared by published methods.[8,9] The ligands were characterized by C, H and N analyses, by IR and proton NMR spectroscopy, and by equivalent weight determinations.

Stock solutions of nickel(II) perchlorate were analysed gravimetrically using dimethylglyoxime. Lithium perchlorate solutions used to maintain the ionic strength at 0.1 mol dm^{-3} were standardized by an ion exchange method. Solutions of sodium cacodylate were used for pH control.

Equilibrium measurements

The hydrogen-ion concentration was calculated from the pH of the solution. The pH and absorbances were measured with an Orion 801A pH meter and a Zeiss PMQII spectrophotometer, respectively. Temperature control was better than ± 0.1°C.

The acid dissociation constants were measured spectrophotometrically and evaluated by means of the equation

$$pK_a = pH + \log (D_L - D)/(D - D_{HL}), \qquad (3)$$

where D_{HL}, D_L and D are the absorbances of the acidic and basic forms of the ligands, and a mixture of both respectively.

The equilibrium constants were also measured spectrophotometrically using wavelengths at which there was a maximum difference in the absorbances between the ligands (HL), and the nickel complexes (NiL). To ensure that only the monochelate complex was formed the $[Ni^{2+}]$ exceeded the ligand concentration by a factor of at least 50.

The equilibrium constant according to eq. (4),

$$Ni^{2+} + HL^{n-} \underset{}{\overset{K}{\rightleftharpoons}} NiL^{(2-n)+} + H^+, \quad (n = 1 \text{ or } 2) \qquad (4)$$

was evaluated from the expression

$$K = [NiL] \times C_{H+}/\{[Ni]_0([NH]_0 - [NiL])\}, \qquad (5)$$

where C_{H+}, $[Ni]_0$, and $[HL]_0$ are the measured hydrogen ion, the initial nickel and ligand concentrations, respectively. The [NiL] was evaluated from

$$[NiL] = A - \varepsilon_{HL}[HL]/(\varepsilon_{NiL} - \varepsilon_{HL}), \qquad (6)$$

where A is absorbance measured against a Ni blank, and ε_{HL} and ε_{NiL} are the molar absorbances of HL and NiL. For any set of measurements, the $[Ni^{2+}]$

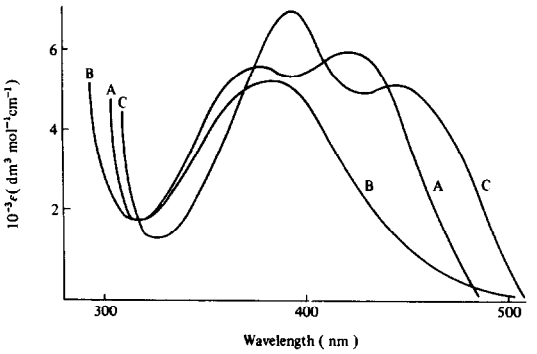


Fig. 1. UV–vis spectra of 1-nitroso-2-naphthol-3-sulphonate in pH 12 buffer (A), pH 2 buffer (B), and of Ni(1-nitroso-2-naphthol-3-sulphonate) in aqueous solution (C).

and [HL] were held constant and the $[H^+]$ varied by addition of a standard $HClO_4$ solution.

RESULTS AND DISCUSSION

Typical spectra of the 1-nitroso ligands in the acidic and basic forms, and of the NiL complex, are shown in Fig. 1. Figure 2 shows the corresponding spectra for a 2-nitroso ligand. The spectra of the base form of the ligands are similar to those of the NiL complexes, but there is a shift to lower energies of the absorption bands on coordination of the nickel.

The pK_a values measured at 20.0, 25.0 and 30.0°C are in Table 1. Table 2 shows pK_a values for several naphthols and nitrosonaphthols; in general there is good agreement between values obtained in this study and those obtained by other workers.[8] The only marked difference is with 1-nitroso-2-

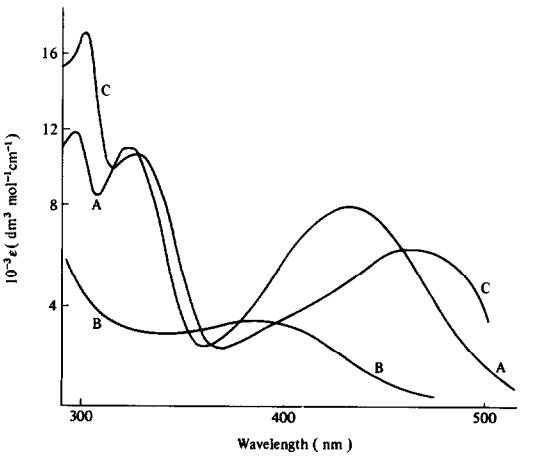

Fig. 2. UV–vis spectra of 2-nitroso-1-naphthol-5-sulphonate in pH 12 buffer (A), pH 2 (B), and of Ni(2-nitroso-1-naphthol-5-sulphonate in aqueous solution (C).

naphthol-8-sulphonate whose pK_a was reported[8] as 7.74 compared with the 8.10 obtained in this study.

In general, nitrosonaphthols are weak acids, with pK_a values ranging from 5.90 for 2-nitroso-1-naphthol-4, 6-disulphonate to 8.10 for 2-nitroso-1-naphthol-8-sulphonate. The rather high pK_a for the latter compound is unusual since the 2-nitroso-1-naphthols are otherwise stronger acids than the 1-nitroso compounds. Enhanced hydrogen bonding in the 8-sulphonate would account for its high pK_a value.

Of the 1-nitroso compounds the 3-sulphonate (pK_a = 7.57) is the least acidic, while the most acidic is the 3,6-disulphonate. The comparison of pK_a values of naphthols and corresponding nitrosonaphthols shown in Table 2 indicate that introduction of a SO_3 group in the 3-position of the naphthalene ring increases the pK_a, relative to that of the 6-SO_3 derivative, only for the 2-naphthol system. For the 1-nitroso system the pK_a decreases. This difference is probably due to reduced intramolecular hydrogen bonding with the 3-sulphonate nitrosonaphthol due to competition with the $—NO\cdots HO^-$ system or to less destabilization of the base because the O^- negative charge can be delocalized over the $(O—N—C—C—O)^-$ system.

A similar comparison can be made with the 1-naphthol derivatives. In this case the 8-SO_3 substituent causes the pK_a to increase in both the 1-naphthol and 2-nitroso-1-naphthol systems, relative to the 5-SO_3 derivative. These observations may indicate that the 2-nitroso-1-naphthols are more similar to the naphthol, and may exist more as the nitroso tautomer, than the 1-nitroso-2-naphthols in aqueous solutions. This to some extent supports the NMR results of Shono *et al.*[9] in Me_2SO–dioxane and Me_2SO–acetic acid solvents. The variation of the pK_a values (Table 1) with temperature is rather small; the change is about 0.1 pK_a units for a 10°C change in the temperature.

Values of the equilibrium constant K are shown in Table 3, together with complex formation constants, K_f, which refer to the reaction

$$Ni^{2+} + L^{n-} \rightleftharpoons NiL^{(2-n)+}, \qquad (7)$$

K and K_f are related to $K = K_a K_f$, where K_a is the acid dissociation constant of the ligand. Table 4 shows the K_f values for the nickel mono-complexes of various nitrosonapthtol ligands and it can be noted that the values obtained in this work are, again with the exception of Ni(2-nitroso-1-naphthol-8-sulphonate), in good agreement with those obtained by Saarinen *et al.*[8]

In general the K_f values are smaller for the 2-nitroso-1-naphthol derivatives when ligands of similar basicity are compared. This difference in K_f may reflect some interest, but no obvious preference in the 1-nitroso-2-naphthol system or could be ascribed to a difference in the position of the tautomeric equilibrium. If the latter is the case, then the results imply that complexing is more favourable with the oxime tautomer, which appears to be dominant for the 1-nitroso-2-naphthol ligands.

The rate expression[5] for the complexation reactions is complicated as exemplified by a possible

mechanism shown in Scheme 1. This explicitly involves K_a, K_aK_f, $K_{a'}$ and $K_{a''}$. We have now measured K_a and K_aK_f but there is no direct experimental evidence for $K_{a'}$ and $K_{a''}$. Computer fitting of the data appears to be the only way to obtain the numerical values of the kinetic parameters.[5] Work is now underway to complete these fits for all the NiL complexes listed in Table 3.

ELECTROCHEMICAL REACTIONS OF TRICARBONYL(CYCLOHEXADIENYLIUM)IRON SALT: REGIOCHEMISTRY DURING THE CROSS COUPLING REACTION AND TRAPPING OF THE 19-ELECTRON TRANSIENT TRICARBONYL(CYCLOHEXADIENYL RADICAL)IRON SPECIES

WEN-SHU HWANG,* RONG-LI LIAO, YI-LING HORNG and CHI WI ONG*

Department of Chemistry, National Sun Yat-Sen University, Kaohsiung, Taiwan 80424

(*Received* 18 *July* 1988; *accepted* 18 *August* 1988)

Abstract—Electrochemical reduction of the 18-electron tricarbonyl(4-methoxyl-1-methylcyclohexadienylium)iron hexafluorophosphate was found to generate a 19-electron transient species which could dimerize by cross coupling between both the C-1 and C-5 termini, or could be trapped with chloroform or benzyl bromide. The regiochemistry of reaction for the 19-electron tricarbonyl(cyclohexadienyl radical)iron complex is compared with the usual 18-electron tricarbonyl(cyclohexadienylium)iron complex during nucleophilic addition and the differences in observations are discussed.

Attention to tricarbonyl(cyclohexadienylium)iron salts has been focused mainly on the chemo-, regio- and stereo-specific nucleophilic additions, and its applications in the synthesis of a number of interesting and important natural products.[1] There have been few studies on its electrochemical properties. Pearson[2] has recently reported the electrochemical dimerization of tricarbonyl(1-methoxylcarbonylcyclohexadienyl)iron hexafluorophosphate which proceeds in a regioselective manner.

We have investigated the electrochemical behaviour of tricarbonyl(4-methoxy-1-methyl-cyclohexadienylium)iron hexafluorophosphate (**1**) and found that a one-electron reductive process takes place to generate a reactive transient 19-electron species. The titled compound **1** was chosen because nucleophilic addition occurred almost exclusively at the C-1 terminus. Any changes in regioselectivity in the reactions of the 19-electron tricarbonyl (4-methoxy-1-methylcyclohexadienyl radical)iron complex (**2**) can be readily observed. This paper will contrast the regioselection of compound **1** to that of **2**. The involvement of a free radical species in **2** was further proved by trapping experiments. Finally, the results of this study offer a possible correlation between the dienyl MO and the metal d^2sp^3 orbital.

RESULTS AND DISCUSSION

The single sweep cyclic voltammogram (CV) of the complex **1** was recorded with a stationary platinum microelectrode at 25°C in acetonitrile solution containing 0.1 M tetraethylammonium perchlorate (TEAP). The complex exhibited a well-defined cathodic wave, but no anodic process was detected on the reverse scan, even at sweep rates as high as 10 V s^{-1}, indicative of the existence of a fast and irreversible follow-up chemical process. Further evidence of the rapidity of the follow-up chemical process can be gained by the analysis of the sweep dependence of the cathodic wave.[3,4] Thus Fig. 1 reveals that the current in the foot of the wave is singularly independent of the sweep rate. This behaviour, originally noted by Reinmuth,[5] could indicate that the forward electron-transfer step is totally irreversible. No deterioration of the electrode response was also observed upon repeated CV scans, indicative of a cathodic reduction which cleanly leads to products without fouling the electrode surface.

Bulk electrolysis at a platinum gauze electrode of a 1.22 mM acetonitrile solution of the complex **1** at the CV peak potential (0.48 V) resulted in the passage of 1.04+0.05 faraday of charge per complex. In addition, the carbonyl IR stretching frequencies for **1** at 2070 and 2040 cm^{-1} disappeared upon

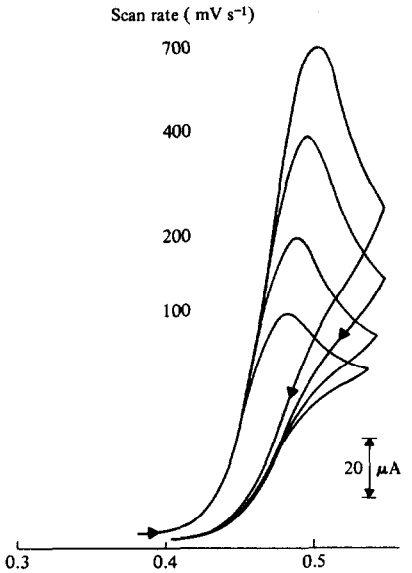

Fig. 1. First-scan cyclic voltammograms of 1.22×10^{-3} M Tricarbonyl(4 - methoxy - 1 - methylcyclohexadienylium) iron hexafluorophosphate in acetonitrile solution containing 0.1 M TEAP at a platinum microelectrode using various sweep rates. Electrode potentials in volts vs saturated Ag/AgCl.

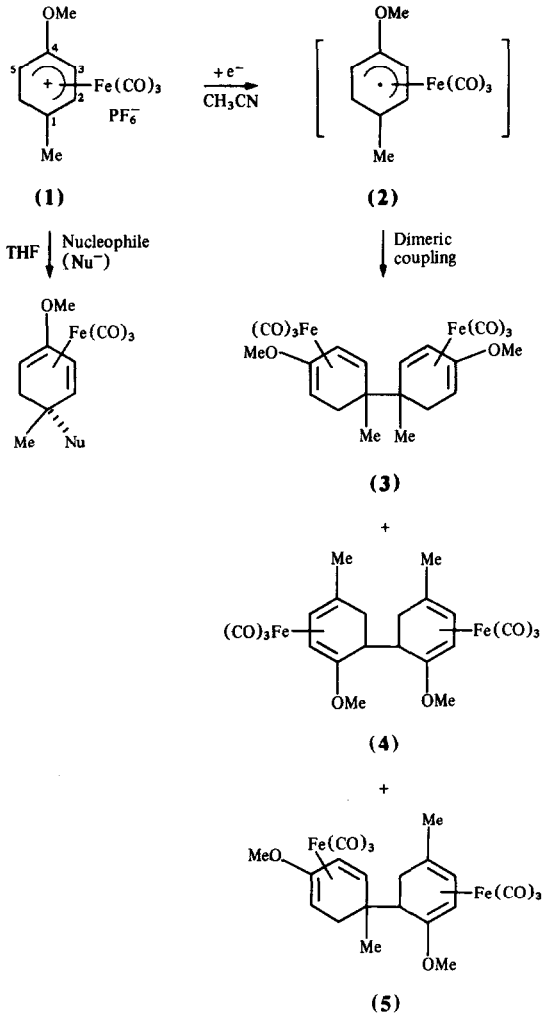

Scheme 1.

exhaustive one-electron reduction, and new bands appeared at 2010 and 1960 cm^{-1}.

When the electrochemical reduction of **1** was carried out till coulometry showed exhaustive transfer of one-electron, isolation and characterization of the product showed a mixture of complexes **3**, **4** and **5**. This result indicates that the electrochemically-generated 19-electron complex **2** undergoes reductive dimerization in a non-regioselective manner. The involvement of a free radical intermediate (**2**) was further revealed by successful trapping experiments. Trapping experiments with chloroform lead to the isolation of a new complex (**6**), together with **3**, **4** and **5**. A benzyl bromide trapping agent also gave a mixture of complexes which showed the trapping of benzyl groups and bromide.

The dimerization of electrochemical-generated radical complex **2** would be expected to be kinetically second-order. The theory applicable to EC mechanisms, predicts that the quantity $d(E_p)/d(\log v)$ will be 29.1 mV if the subsequent chemical reaction is first-order with respect to the species produced in the electrode reaction, and 19 mV if this reaction is kinetically second-order.[6] Theoretical analysis of the cyclic voltammogram, $d(E_p)/(\log v)$ in Fig. 1 gave a value of 20.8 mV which is fairly close to that predicted for the second-order mechanism.

H^1 NMR analysis of the product obtained by electroreduction of **1** revealed that **3**, **4** and **5** are formed in nearly equal amounts. This observation strongly contrasts with the results obtained from regioselective nucleophilic addition of **1** under similar conditions.[7] A plausible explanation may be arrived at if we assume that the SOMO of the 19-electron complex (**2**) is mainly the non-bonding orbital of the dienyl ψ_3 (Fig. 2) with little involvement of the iron hybrid orbitals, then we see that the methoxy substituent contribution to the orbital coefficient at the C-5 terminus is nullified to favour reductive dimerization equally well at both C-1 and C-5 termini in **2**. Electron-rich systems repel each other, thus the transfer of one electron to the dienyl of **1**, to generate **2**, will diminish the back bonding by d^2sp^3 metal orbitals. In the previous finding of the usual nucleophilic addition to **1**, the frontier orbital involved (LUMO) in the reaction is the anti-bonding orbital ψ_4.[8] In this case the methoxy substituent will deactivate nucleophilic addition to the C-5 terminus under charge control and conversely activate C-5 during orbital control.

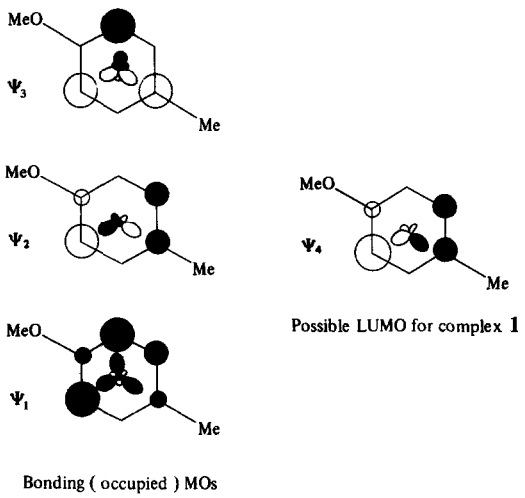

Fig. 2. Dienyl bonding to $Fe(CO)_3$ fragment. (See ref. 1 for explanation of orbital diagrams.)

In conclusion, the 19-electron dienyl–$Fe(CO)_3$ complex can be generated by a single electron reduction, electrochemically. This investigation establishes that a different overall reaction pathway takes place during electrochemical reductive dimerization as compared with nucleophilic addition to dienylium–$Fe(CO)_3$ such as **1**. The results of this study showed the importance of the relative amount of interaction between dienyl ψ_2 and the metal d^2sp^3 orbital and regioselection.

EXPERIMENTAL

General

All manipulations of air sensitive compounds were conducted under nitrogen in a drybox or *in vacuo*. Acetonitrile was refluxed over CaH_2 for several hours and then directly distilled, and redistilled twice from a 3:2 mixture of $KMnO_4$/anhydrous K_2CO_3. Finally it was distilled from P_4O_{10} before use. ^1H NMR spectra were obtained on a Bruker FT-100 or XL-400 superconducting NMR spectrometer with Me_4Si as reference. IR spectra were recorded on a Perkin–Elmer 1300 spectrophotometer, and mass spectra with AES MS 12 with GC–MS capability. Compound **1** was prepared according to the procedure described in the literature.[8]

Electrochemistry

Cyclic voltammetry was performed at ambient temperature in CH_3CN solution containing 0.1 M tetraethylammonium perchlorate (TEAP) as supporting electrolyte. A Princeton Applied Research (PAR) model 173 potentiostat equipped with a PAR 179 digital coulometer, which was provided with a feedback compensation for ohmic drop between the working and reference electrodes was used. The voltage follower amplifier (PAR 178) was mounted externally to the potentiostat with a minimum length of high impedance connection to the reference electrode for low noise pick up. CV were recorded on a PAR RE-0089 X-Y recorder and the scan rate controlled by a universal programmer (PAR 175). The electrochemical cell was constructed according to the design of Van Duyne and Reilly.[9] The distance between the platinum working electrodes and the tip of the salt bridge was 1 mm to insure a minimum ohmic drop. The platinum electrode was routinely cleaned by soaking in concentrated nitric acid for 15 min, followed by repeated rinsing with distilled water, and drying at 120°C prior to use.

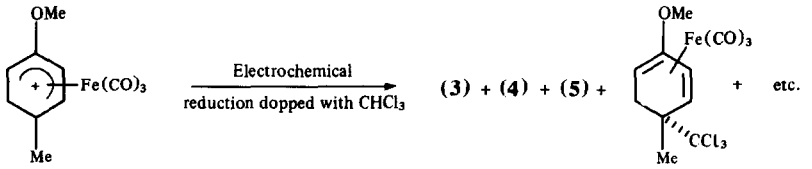
The peak potential E_p of the complex **1** was independent of the concentration in the range between 10^{-4}–10^{-2} M and were always reproducible to within ± 50 mV. The repeated CV scan did not affect the appearance of the voltammogram.

Bulk electrolysis of complex **1** (500 mg, 1.22 mM) in CH_3CN with 0.1 M TEAP was conducted at 0.48 V vs a saturated Ag/AgCl reference electrode in a three compartment cell, *ca* 20 cm^3 capacity for 3 h under oxygen-free nitrogen. After exhaustive electrolysis, 122 C was consumed which amounts to the transfer of 1.04 electron per complex. The IR spectrum of an aliquot of the solution showed complete disappearance of the carbonyl stretching frequencies at 2070 and 2040 cm^{-1} with the appearance of peaks at 2010 and1960 cm^{-1}. The solvent was removed *in vacuo* and the resulting solid residue washed with water and extracted with ether, which after drying over anhydrous Na_2SO_4 and removal of solvent afforded the product (195 mg, 39%). After preparative TLC (benzene/hexane, 1:2) pure regioisomers **3**, **4** and **5** were obtained.

Trapping experiments

Experiments were carried out as above with the addition of trapping agent to the CH_3CN solution during the electrolysis and working up in the same manner. When chloroform was added as the trapping agent, a new product (**6**) was isolated together with **3**, **4** and **5** after preparative TLC separation. In the case of benzyl bromide as the trapping agent, a complex mixture was obtained with separation difficulties and was submitted directly for GC–MS analysis which showed compounds containing the incorporation of benzyl and bromine groups.

Determination of the product ratio: these were carried out on the initial mixture obtained after the electrochemical reduction of complex **1** using



(1) (6)

Scheme 2.

expanded spectra and integral studies from the ^1H 400 MHz spectrum. They were found to be approximately in a 1:1:1 ratio. The regioisomers were separated by preparative TLC; their individual spectra are recorded as below.

All compounds were obtained as a diastereomeric mixture.

Complex **3**: $\nu_{max}(CHCL_3)$ 2045, 1975 cm^{-1}; $\delta(CDCl_3)$ 4.98 (2H, m), 3.62 (3H, s), 3.59 (3H, s), 3.18 (2H, br. m), 2.85 (2H, complex m), 2.48 (2H, dd), 1.65 (2H, dd), 1.00 (6H, 2 × s). *m/e* 528 (M^+), 356 (M^+–Fe(CO)$_3$–CO–4), 263 (M^+/2–1), 253 (M^+/2–CO–1), 122 (M^+/2–Fe(CO)$_3$–2).

(*Received* 5 *July* 1988; *accepted* 25 *August* 1988)

Abstract—We report the structure of $Bi[(C_2H_5O)_2PS_2]_3$; the compound crystallizes as yellow prisms in the monoclinic space group $p2_1$ with $a = 8.618(6)$ Å, $b = 9.698(2)$ Å, $c = 17.569(9)$ Å; β, 92.95(7)°. $D_{calc} = 1.37$ g cm^{-3} for $Z = 2$ molecules/unit cell. The structure was resolved by Patterson and Fourier methods and refined by full matrix least-squares method to a final discrepancy index based on I, of 0.085 for the 2072 independent reflections above 3σ (I). The bismuth atom is surrounded by six sulphur atoms from the three chelating phosphoro dithioate groups in a pseudo trigonally distorted octahedron (C_3 symmetry), with a lone pair positioned in one of the triangular octahedral faces. Bi—S bond lengths of the capped face (cf) are 2.799 Å (av.) longer than the Bi—S uncapped face (uf) (av. 2.758 Å). The mean S_{cf}—Bi—S_{cf} angle is 98.6° compared with 94.9° for S_{uf}—Bi—S_{uf}. Intraligand angles S—Bi—S average 72.0° and the ligand bite is 3.27 Å.

The title compound is isostructural with its analogue $Sb[(C_2H_5O)_2PS_2]_3$, and consists of discrete molecules and does not present any intermolecular contacts.

We have prepared a series of complexes of Sb^{III} and Bi^{III} with bidentate S-donor ligands, of general formula :M(S—S)$_3$, for M = Sb, Bi, and S—S = dialkyl phosphoro dithioate, dialkyl xantate, dialkyl dithiocarbamate, to be used as "passivating agents" in catalytic cracking of petroleum.[1]

The contamination of the catalysts by metals such as nickel, vanadium and iron, in the process of cracking, can be reduced by adding some compounds known as "passivating agents" with very efficient results but by a process the nature of which is still obscure. These decontaminants, are in general, compounds of non-transition elements with molecular stereochemistry governed by the valence-shell electron pair repulsion model (VSEPR).[2] These compounds are not expected to possess a regular octahedral structure with a MS_6 core, but rather one based on a 7-coordination polyhedron[3] with a lone pair of electrons occupying the seventh position. Gradually the structures of various of these decontaminants have been elucidated. There are different geometries found for these molecules: capped octahedron (CO), pentagonal bipyramid (PB) and trigonal prism (TP); the presence of the lone pair is evident from the arrangement of the nearest neighbours.

In compounds :M(S—S)$_3$ with CO structure the lone pair occupies the capping position; they present pseudo C_{3v} symmetry with three short and three long bonds, together with an avoided region ascribable to a lone pair of electrons. The long bonds are in the capped face (cf). The site of the lone pair does not appear to be equidistant from the three sulphurs of the capped face.

At present, we are studying the behaviour of the compounds mentioned above in the cracking pro-

*Author to whom correspondence should be addressed.

sesses in conjunction with the study of its thermogravimetric and thermodifferential decomposition, in order to be able to clarify the nature of the passivation process. In this paper, we present the molecular structure of $Bi[(C_2H_5O)_2PS_2]_3$.

EXPERIMENTAL

Crystalline $Bi[(C_2H_5O)_2PS_2]_3$ was prepared by treating a solution of ammonium *O,O'*-diethylphosphoro dithioate (0.97 g, 5 mM) in acetone (30 cm^3) with an acetonic solution of $BiCl_3$ (0.5 g, 16 mM, 20 cm^3 acetone). Immediately a white precipitate of NH_4Cl appeared. After 1 h of reaction (at room temperature with stirring), the solution was filtered off, concentrated and precipitated with pentane. A yellow solid was separated and washed with ethyl ether. Recrystallization from *n*-pentane gave yellow prisms suitable for X-ray study.

Crystal data

Details of the processing procedure are given in Table 1. The bismuth atom was readily found from a Patterson map and all remaining non-hydrogen atoms were located by Fourier and difference Fourier syntheses. Isotropic refinement was made by full matrix least squares. Due to thermal agitation, positions and isotropic thermal factors for atoms C_{61} and C_{62} were fixed in the last refinement. At this point an absorption correction was made by Walker and Stuart's method[5] and the structure was refined

by full matrix least-squares with anisotropic thermal parameters for Bi, P and S and isotropic for O, C. The H-atoms, fixed at calculated positions, were included in the refinement with isotropic thermal parameters of the atoms to which they are attached, $R = 0.085$, $R_w = 0.084$.

RESULTS AND DISCUSSION

Description of the structure. The molecular geometry and the packing in the unit cell are depicted in Figs 1 and 2. Bond lengths and angles around the bismuth are given in Table 2.

As illustrated in Fig. 1 the coordination polyhedron of the bismuth atom can be described as a distorted capped octahedron with a stereochemically active lone pair in the capping position and approximately on a molecular pseudo-triad axis, which passes through the bismuth atom. Six sulphurs from the three anisobidentate phosphoro dithioate ligands are in the vertices of the distorted octahedron.

Lone pair–bond pair repulsions in the bismuth coordination sphere result in longer bond lengths for those bonds adjacent to the lone pair and shorter lengths for those more remote, the former averaging 2.808 Å and the latter averaging 2.749 Å; in accordance with these results, the capped face is formed by $S_1S_4S_6$. S—Sb—S angles involving long Sb—S bonds (av. 98.6°) are greater than those involving the shorter bonds (av. 95.5°). Interligand S—Sb—S angles are: 72.0° (av.) and the ligand "bite", 3.268 (av.) Å.

This type of distorted CO structure has been found in a series of As^{III}, Sb^{III} and Bi^{III} compounds. In Table 3, we have collected some data from the literature, to see in more detail the stereochemistry of these 7-coordinate compounds. Among them we have included our results. To diminish interligand repulsions, compounds :M(S—S)$_3$, with different S-donor chelating ligands have been chosen: xanthates[9] and dithiocarbamates,[10] where the groups S_2CO, S_2CN are planar, or phosphoro dithioates[12–14] with tetrahedral P surrounded by two sulphur and two oxygen atoms. In all these compounds with a MS_6 core, there are three long and three short M—S distances. The asymmetry of the M—S bond lengths is believed to arise as a result of a stereochemically active lone pair of electrons protruding from the three-fold axis, through the triangular array formed by the sulphur atoms involved in the long M—S bonds. We have chosen these ligands because the size of the ligand bite (2.97–3.28 Å) is markedly shorter than the van der

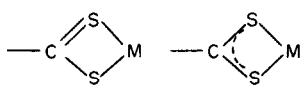
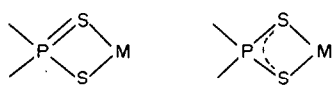
Waals radius sum, so that there is enough interligand room to allow the stereochemical activity of the lone pair make itself felt.

In Table 3 the stretching deformation is given by D_S = M—S_{uf}/M—S_{cf} and the bending deformation, D_b = S_{uf}—M—S_{uf}/S_{cf}—M—S_{cf}. Certain trends are discernible if one compares the results; thus one can see that the lone pair becomes less decisive as the atomic weight of the central atom (As > Sb > Bi) increases. We also see that when ligands have the isopropyl group the stereochemistry is dominated by interligand repulsions and the lone pair is inhibited from achieving its full stereochemical activity. Apparently the absence of strong repulsive interactions between ethyl groups of neighbouring ligands allows perturbations of :M(S—S)$_3$ groups by the stereochemically active lone pair to proceed with relative ease.

It may be that the stereochemical activity of the lone pair is not necessary for the rationalization of these structures, as a trigonally distorted octahedron would be highly probable as a direct consequence of the anisobidentate character of these ligands. In fact there is a disparity in the C—S distances in xanthates and dithiocarbamates, such that the C—S distances associated with the short M—S bond are lengthened appreciably while those associated with the long M—S bond are shortened.



(a) (b)



(a) (b)

In the same way, with phosphorodithioate ligands, P—S bond distances also fall into two classes: the short distances are associated with S-atoms forming long M—S interactions while the longer P—S bonds are associated with S-atoms forming short bonds to M. This situation is quite noticeable for antimony compounds but with bismuth ones as the differences in Bi—S bond lengths are smaller, the accuracy of the P—S bond distances is too low to distinguish between (a) anisobidentate or (b) isobidentate ligands, although (a) coordination is suggested.

From all the foregoing we can see that the interpretation is unclear, because of competing factors, to control the overall geometry of :M(S—S)$_3$ molecules; nuclear repulsion energies, steric requirements of the ligands and bite size, are all important factors.

The title compound is isostructural with Sb $[(C_2H_5O)_2PS_2]_3$.

At this moment we are studying the passivation power of the complexes, :M$(S_2COEt_2)_3$, :M$(S_2CNEt_2)_3$, :M$[(OEt)_2PS_2]_3$, :M$[(OC_{10}H_{21})_2S_2P]_3$, M = Sb, Bi, in the catalytic process of petroleum cracking. The accumulation of Ni, V, Fe, etc., diminishes the percentage of petrol and increases the production of hydrogen and coke. By tracing the production process of hydrogen we have been able to deduce the activity of the said passivating agents. At the same time we have prepared mixtures of nickel naphthenate with the different "passivating agents" and have gone on to study their thermo-differential and thermo-gravimetric decomposition.

The results obtained will be the subject of a separate publication.

THE SYNTHESIS OF IRON(III) AND COBALT(III) COMPLEXES OF FACULTATIVE HEXADENTATE LIGANDS. THE X-RAY CRYSTAL STRUCTURE OF $[Fe\{(NC_4H_3\text{-}2\text{-}CH{=}NCH_2CH_2NHCH_2)_2\}]PF_6$

(*Received* 28 *March* 1988; *accepted* 31 *August* 1988)

Abstract—A series of hexadentate ligands have been prepared from the condensation of 1,8-diamino-3,6-diazaoctane or 1,8-diamino-3,6-dithiaoctane with 1-hydroxy-3-methoxybenzophenone, 2-hydroxypropiophenone, 2-hydroxybenzophenone or pyrrole-2-aldehyde, and from 3-methoxysalicylaldehyde with tris(2-aminoethyl)amine. Their ability to encapsulate cobalt(III) and iron(III) in complexes of 1 : 1 ligand–metal stoichiometry is reduced by the incorporation of sulphur donor atoms, or by the replacement of the terminal six-membered chelate rings of the salicylaldehyde derivatives by a five-membered ring in the pyrrole–aldehyde derivatives. Mössbauer spectral data are reported for the iron complexes and the molecular structure of $[Fe\{(NC_4H_3\text{-}2\text{-}CH{=}NCH_2CH_2NHCH_2)_2\}]PF_6$ has been determined by single crystal X-ray diffraction techniques.

Facultative hexadentate ligands capable of octahedral coordination to a transition metal ion may encapsulate it in a 1 : 1 complex whose exterior exhibits the properties of an organic material. Such species are of interest in a variety of contexts; particularly in the production of metal containing pharmaceuticals and the formulation of selective metal ion extractants. Three basic structural types are possible for such ligands. The first is a simple linear hexadentate ligand exemplified by $HOC_6H_4CH{=}N(CH_2)_2E(CH_2)_2E(CH_2)_2N{=}CHC_6H_4OH$, in which E = NH (**1a**) or S (**1b**). The second type may be singly branched having three "arms" as in $N(CH_2CH_2N{=}CHC_6H_4OH)_3$ (**3a**) or may be derived from 1,3,5-triaminocyclohexane. The third structural type is doubly branched as, for example, in EDTA. The work described here is concerned with dinegative ligands of the first structural type. The effects of varying E, or the nature of the terminal binding sites, on the formation and properties of monocationic complexes with metal(III) ions have been assessed in a series of 11 compounds containing Fe^{III} or Co^{III} as representative metals.

*Author to whom correspondence should be addressed.

The preparation of a linear hexadentate ligand of the first type was described by Dwyer and Lions in 1950.[1] This involved the condensation of salicylaldehyde with 1,8-diamino-3,6-dithiaoctane to give **1b**. Complexes of this ligand with Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Co^{III} were described. Subsequently, complexes of other ligands including **1a** were described.[2–11] The molecular structure of the Ni^{II} complex of **1a** has been determined[12] and confirms the ligand's ability to reach all octahedral sites on the nickel ion. Hexadentate ligands derived from the reactions of amines with 2-formylpyridine,[7,8,13,14] substituted salicylaldehydes[3,15] and pentane-2,4-dione[9,16–18] have also been reported.

More recently, complexes of Fe^{II} and Fe^{III} with certain hexadentate ligands have aroused interest because of their anomalous magnetic behaviour. The equilibria between high and low spin states in the solid state and in solution have been investigated by variable temperature, magnetic moment and Mössbauer spectroscopic measurements.[13,16–18] As part of an investigation into complexes of lipophilic ligands capable of encapsulating metal ions, we have prepared a variety of hexadentate ligands (**1c–h**; **2a**, **2b**; **3a**, **3b**; **4a**, **4b**) from the condensation

of 1,8-diamino-3,6-diazaoctane (trien) or 1,8-diamino-3,6-dithiaoctane (thiatrien) with 1-hydroxy-3-methoxybenzophenone, 2-hydroxypropiophenone, 2-hydroxybenzophenone, 2-hydroxy-4-methoxybenzophenone, pyrrole-2-aldehyde or pentane-2,5-dione. The trianionic ligand (**3b**) derived from 3-methoxysalicylaldehyde with tris(2-aminoethyl) amine (tren) has also been prepared and characterized.

EXPERIMENTAL

Synthetic studies

Technical grade 1,8-diamino-3,6-diazaoctane from Aldrich and 97% tris(2-aminoethyl)amine from Fluka were used as received. Salicylaldehyde (98%) from Aldrich was distilled from calcium carbonate before use. 3-Methoxysalicylaldehyde (*o*-vanillin, Aldrich, 98%), 2-hydroxypropiophenone

(Aldrich, 97%), 2-hydroxyacetophenone (Aldrich, 97%), pyrrole-2-carboxaldehyde (Aldrich, 99%) and 2-hydroxy-4-methoxybenzophenone (Lancaster Synthesis) were used as supplied. 2,4-Pentanedione (Fisons SLR grade) was distilled before use.

1,8-Diamino-3,6-dithiaoctane,[1] bis(salicylideneimino)-3,6-dithiaoctane,[1] bis(acetylacetonimine) 3,6-dithiaoctane,[9] $(Hsal)_2$trien,[10] $(Hsal)_3$tren,[13] [Fe{$(sal)_3$tren}],[13] [Fe{$(sal)_2$trien}]PF_6[15] and [Co{$(sal)_2$trien}]$Cl \cdot 2.5H_2O$[11b] were prepared by the methods described in the literature.

Methanol was dried over magnesium methoxide before use. All other solvents were reagent grade and used without further purification.

Physical measurements

IR spectra were recorded, as KBr discs, on a Perkin–Elmer 297 spectrophotometer. ^1H NMR spectra were obtained at 100 MHz using a Varian HA 100 instrument, or at 270 MHz (for Co^{III} complexes) using a Jeol GX 270 instrument. Me_4Si was used as the internal standard. UV–vis spectra were recorded using a Perkin–Elmer 330. Mass spectra were recorded on a Kratos MS 80 instrument by positive ion fast atom bombardment using a glycerol matrix. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, University of Birmingham.

Magnetic susceptibilities in the solid state were measured by the Gouy method using Hg $[Co(NCS)_4]$[19] as a calibrant. Pascal constants (from the table given by Figgis and Lewis[20]) were used to correct for ligand and anion diamagnetism as follows: (in 10^{-9} m^3 mol^{-1}) $[(sal)_2trien]^{2-}$ 2.458; $[(aceph)_2trien]^{2-}$ 2.756; $[(proph)_2trien]^{2-}$ 3.09; $[(sal)_2thiatrien]^{2-}$ 2.62; $[(pyrrol)_2trien]^{2-}$ 1.84; $[(benph)_2trien]^{2-}$ 4.035; $[(sal)_3tren]^{3-}$ 2.99; $[(van)_3tren]^{3-}$ 3.61; $[HB(pz)_3]^-$ (pz = pyrazol-1-yl) 1.066; PF_6^- 0.8055. ^{57}Iron Mössbauer spectra were recorded with a Cryophysics MS-102 microprocessor-controlled Mössbauer spectrometer at 298 K using a $^{57}Co/Rh$ source and absorbers containing *ca* 10 mg iron cm^{-2}. The drive velocity was calibrated with a $^{57}Co/Rh$ source and a natural iron foil absorber. All the spectra were computer fitted and the ^{57}Fe chemical isomer shift data were calculated relative to the metallic iron.

Tris(3 - *methoxysalicylideneimino*)*triethylamine*, $(Hvan)_3$tren

Tris-(2-aminoethyl)amine (0.50 g, 3.4 mmol) and sodium acetate trihydrate (0.67 g, 4.9 mmol) were dissolved in a mixture of hot ethanol (4 cm^3) and water (1 cm^3). A solution of 3-methoxysalicylaldehyde (1.56 g, 10.25 mmol) in ethanol (2 cm^3) was added and the yellow solution heated for 5 min. The solution was cooled and evaporated to dryness under reduced pressure. The resulting yellow oil was triturated with diethyl ether to give the product as a yellow powder which was collected by filtration and dried *in vacuo*. Yield, 0.52 g (28%); m.p. 119–120°C.

1,8 - *Bis*(2 - *hydroxyacetophenonimine*) - 3,6 - *dithiaoctane*, $(Haceph)_2$thiatrien

1,8-Diamino-3,6-dithiaoctane (1 g, 5.5 mmol), 2-hydroxyacetophenone (1.51 g, 11.1 mmol) and 1 drop of concentrated HCl were heated together at 100°C for 90 min. The resulting yellow oil was cooled to give a yellow solid which was triturated with diethyl ether and recovered by filtration. It was dried *in vacuo*. Yield, 1.46 g (63%); m.p. 145–147°C.

1,8 - *Bis*(2 - *hydroxypropiophenonimine*) - 3,6 - *dithiaoctane*, $(Hproph)_2$thiatrien

This ligand was prepared by the previous method using 2-hydroxypropiophenone. In this case a yellow–orange oil was obtained on cooling. This was triturated with diethyl ether to give a pale yellow solid. The crude solid was recrystallized from ethanol to give the product as bright yellow crystals. Yield, 1.27 g (52%); m.p. 62–64°C.

Bis - 1,8 - (*pyrrole* - 2 - *carboxaldimino*) - 3,6 - *dithiaoctane*, $(Hpyrrol)_2$thiatrien

A solution of 1,8-diamino-3,6-dithiaoctane (0.50 g, 2.8 mmol) in warm ethanol (10 cm^3) was added to a solution of pyrrole-2-carboxaldehyde (0.53 g, 5.57 mmol) in ethanol (15 cm^3). The solution was stirred overnight at room temperature. The product precipitated as a cream solid and was recovered by filtration. It was washed with diethylether and dried *in vacuo*. Yield, 0.83 g (89%); m.p. 116–118°C.

[Fe{$(van)_3$tren}]

Tris(3 - methoxysalicylidenimino)triethylamine (0.20 g, 0.36 mmol) was dissolved in hot methanol (20 cm^3) and a solution of anhydrous iron(III) chloride (0.06 g, 0.37 mmol) in methanol (5 cm^3) added. An immediate colour change to black–purple occurred. A solution of sodium acetate trihydrate (0.19 g, 1.4 mmol) in water (20 cm^3) was next added and the mixture stirred and heated for 10 min. The volume of the resulting solution was then reduced to *ca* 5 cm^3 before cooling to 0°C to induce

precipitation of the product. The solid obtained was collected by filtration, washed with water, acetone and diethyl ether and then dried *in vacuo*. The product was obtained as a black–purple powder. Yield 0.15 g (68%); m.p. > 200°C.

$[Fe\{(pyrrol)_2trien\}]PF_6$

1,8-Diamino-3,6-diazaoctane (0.45 g, 3.08 mmol) was dissolved in dry methanol (30 cm^3) and sodium methoxide (0.33 g, 6.2 mmol) was added. Pyrrole-2-carboxaldehydc (0.59 g, 6.2 mmol) was then added and the solution refluxed for 20 min. After this time, iron(III) chloride hexahydrate (0.84 g, 3.1 mmol) was added to the hot solution and the resulting purple solution refluxed for a further 15 min, before being cooled to room temperature. The solvent was then removed under reduced pressure and the residue extracted with water. The resulting solution was filtered and NH_4PF_6 (0.60 g, 3.7 mmol) in water (5 cm^3) was added to the filtrate. The resulting purple precipitate was collected by filtration and dried. It was recrystallized twice from acetone–diethyl ether to give the product as black–purple microcrystals. Yield, 0.87 g (54%); m.p. > 200°C.

$[Fe\{(aceph)_2trien\}]PF_6$

2-Hydroxyacetophenone (0.95 g, 6.98 mmol) was added to a solution of 1,8-diamino-3,6-diazaoctane (0.50 g, 3.42 mmol) in methanol (25 cm^3). The resulting yellow solution was stirred at room temperature for 1 h. Sodium acetate trihydrate (1.3 g, 9.55 mmol) and anhydrous iron(III) chloride (0.55 g, 3.39 mmol) were then added and the red–brown solution was refluxed for 30 min. The solution was cooled, filtered and the solvent removed under reduced pressure. The residue was extracted with water, filtered and an aqueous solution of NH_4PF_6 (1 g) was added to the filtrate. The red–brown precipitate which formed was collected by filtration and recrystallized twice from acetone–diethyl ether (using $MgSO_4$ to dry the acetone solution before adding the diethyl ether). The product was obtained as red–brown microcrystals. Yield 0.58 g (30%); m.p. 155–156°C (dec).

$[Fe\{(proph)_2trien\}]PF_6$

This compound was prepared according to the previous method using 2-hydroxypropiophenone (2.57 g, 17.1 mmol), 1,8-diamino-3,6-diazaoctane (1 g, 6.8 mmol) and iron(III) chloride hexahydrate (1.85 g, 6.84 mmol). The *complex* was obtained as red–brown microcrystals. Yield, 1.32 g (32%); m.p. > 200°C.

$[Fe\{(Mbenph)_2trien\}]PF_6$

This was prepared according to the method described above for $[Fe\{(aceph)_2trien\}]PF_6$ using 2-hydroxy 4-methoxybenzophenone (0.98 g, 4.3 mmol), 1,8-diamino-3,6-diazaoctane (0.25 g, 1.71 mmol) and iron(III) chloride (0.27 g, 1.68 mmol). The *complex* was obtained as a red–brown powder. Yield, 0.57 g (44%); m.p. 155–156°C (dec).

$[Fe\{(sal)_2thiatrien\}]$

1,8-Bis(salicylideneimino)-3,6-dithiaoctane (0.20 g, 0.51 mmol) and sodium acetate trihydrate (0.05 g, 0.37 mmol) were dissolved in warm methanol (30 cm^3). NH_4PF_6 (0.16 g, 0.98 mmol) was then added, followed immediately by a solution of iron(III) chloride hexahydrate (0.14 g, 0.52 mmol) in methanol (10 cm^3). The colour immediately changed to dark purple. The solution was refluxed for 10 min, then cooled and filtered. The blue–black microcrystalline solid residue was washed with diethyl ether and air dried. The product could be recrystallized from acetone–diethyl ether. Yield, 0.16 g (53%); m.p. > 200°C.

$[Fe\{HB(pz)_3\}_2]PF_6$

A solution of anhydrous iron(III) chloride (0.18 g, 1.12 mmol) in water (5 cm^3) was added to a solution of potassium hydrotris(pyrazole-1-yl) borate (0.54 g, 2.16 mmol) in water (5 cm^3). A bright orange solid was produced. Further water was added to dissolve the solid and the solution filtered. NH_4PF_6 (0.25 g, 1.5 mmol) in water (2 cm^3) was added to the filtrate. A bright orange solid was precipitated, which was recovered by filtration and dried *in vacuo*. It was recrystallized from acetone–diethyl ether to give the product as bright red microcrystals. Yield, 0.33 g (49%); m.p. > 250°C.

$[Co\{(sal)_2thiatrien\}]PF_6$

Cobalt(II) acetate tetrahydrate (0.20 g, 0.80 mmol) in hot methanol (10 cm^3) was added to a solution of 1,8-bis(salicylideneimino)-3,6-dithiaoctane (0.26 g, 0.67 mmol) in hot methanol (15 cm^3) and the mixture was refluxed for 10 min. Air was then drawn through the solution for 30 min. Water (25 cm^3) was next added and air drawn through the solution for a further 2.5 h. NH_4PF_6 (0.14 g) in water (2 cm^3) was then added to precipitate the product as a green–brown solid. This was recovered

by filtration, washed with water, ethanol and diethyl ether and dried *in vacuo*. Yield, 0.29 g (73%); m.p. > 250°C.

$[Co\{(aceph)_2thiatrien\}]PF_6$

This compound was prepared by the previous method using cobalt(II) acetate tetrahydrate (0.2 g, 0.8 mmol) and the ligand (0.30 g, 0.72 mmol). The crude product was recrystallized from acetone–diethyl ether to give dark green microcrystals. Yield, 0.31 g (70%); m.p. 256°C (dec).

$[Co\{(proph)_2thiatrien\}]$

This was prepared according to the method described for $[Co\{(aceph)_2thiatrien\}]PF_6$ using cobalt(II) acetate tetrahydrate (0.2 g, 0.8 mmol) and the ligand (0.31 g, 0.7 mmol). The crude product was recrystallized from acetone–diethyl ether to give dark green microcrystals. Yield, 0.26 g (45%); m.p. 253°C (dec).

$[Co\{(acac)_2thiatrien\}]PF_6$

Cobalt(II) acetate tetrahydrate (0.25 g, 1 mmol) in hot methanol (10 cm^3) was added to a solution of the ligand (0.25 g, 0.73 mmol) in ethanol (5 cm^3). Immediately after this, H_2O_2 (0.6 cm^3 of 2.75%) was added and the dark green solution was refluxed for 15 min. The volume was then reduced under vacuum and NH_4PF_6 (0.35 g) in water (5 cm^3) was added. On shaking, a dark green solid precipitated; this was recovered by filtration, washed with water, ethanol and diethyl ether and air dried. It was recrystallized from acetone–diethyl ether to give dark green microcrystals which were dried *in vacuo*. Yield, 0.12 g (30%); m.p. > 250°C.

$[Co\{(aceph)_2trien\}]PF_6$

2-Hydroxyacetophenone (0.31 g, 2.28 mmol) in ethanol (15 cm^3) was added to a solution of 1,8-diamino-3,6-diazaoctane (0.15 g, 1.0 mmol) in ethanol (20 cm^3). The solution was stirred at room temperature for 4 h and then evaporated to dryness *in vacuo*. The resulting oil was dried overnight in a vacuum desiccator over silica gel.

The ligand was dissolved in acetone (20 cm^3) and the solution added to cobalt(II) chloride hexahydrate (0.24 g, 1 mmol) in water (10 cm^3). A little activated carbon was then added and air drawn through the solution for 5 h. 2 M NaOH solution (1 cm^3) was added and air drawn through the solution for a further 2 h. The mixture was then cooled in ice and filtered. The residual solid was washed with hot water (30 cm^3) and NH_4PF_6 (0.15 g) added to the filtrate. The precipitated solid was filtered off and recrystallized from acetone–diethyl ether to give the product as dark brown plates which were dried *in vacuo*. Yield, 0.16 g (25%); m.p. 192–194°C (dec).

$[Co\{(proph)_2trien\}]PF_6$

This was prepared by the previous method using 2-hydroxypropiophenone (0.59 g, 3.9 mmol), 1,8-diamino-3,6-diazaoctane (0.26 cm^3, 1.75 mmol) and cobalt(II) chloride hexahydrate (0.87 g, 3.66 mmol).

The product was obtained as red–brown crystals. Yield, 0.25 g (22%); m.p. 154–155°C (dec).

Structural studies

A crystal of $[FeC_{16}H_{22}N_6]PF_6$ (0.8 × 0.3 × 0.5 mm) was mounted on an Enraf–Nonius CAD-4 diffractometer; cell dimensions and intensities were measured by ω–2θ scans with graphite-monochromated Mo-K_α radiation.

Three standard reflections measured every 2 h showed no significant variation over the period of data collection. 5466 reflections were scanned within $2 < \theta < 25°$ covering the index ranges: h, 0–12; k, −6–16; l, −16–16. Of these, 3515 are unique (merging R_{int} 0.024), and after application of Lorentz and polarization corrections, 2714 structure amplitudes with $F > 5\sigma(F)$ were considered observed and used in the analysis.

Crystal data. $[FeC_{16}H_{22}N_6][PF_6]$, $M = 499.2$, monoclinic, space group $P2_1/c$, $a = 10.644(7)$, $b = 13.829(2)$, $c = 13.665(4)$ Å, $\beta = 91.75(2)°$, $U = 2010.5$ $Å^3$, $Z = 4$, $D_c = 1.649$ g cm^{-3}, $F(000) = 1020$, μ(Mo-K_α) = 0.927 mm^{-1}, $\lambda = 0.71069$ Å.

The structure was determined by Patterson and Fourier methods, and refined by least-squares, using anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions, riding on their respective bonded atom. The weighting scheme used was $w = 1/[\sigma^2(F) + 0.0015F^2]$, and the refinement converged to $R = 0.0855$, $R' = 0.0915$ (maximum shift/error ratio in final cycle 0.244). The residual electron density in a final difference map was within the range −0.66–1.75 e $Å^{-3}$ with all main peaks close to the Fe atom.

In view of the low merging R_{int}, the rather high R values and rather large residual electron density are difficult to explain. An attempt to improve the situation by applying an empirical absorption correction[21] was not successful.

Table 1. Elemental analyses[a] and imine stretching frequencies[b]

Compound	Carbon	Hydrogen	Nitrogen	$\nu_{C=M}$ (cm^{-1})

[a] Found % (Calc. %).
[b] Recorded as KBr discs.
[c] Crystallizes as a 1 : 1 solvate with acetone.

Complex neutral atom scattering factors were employed. Computations were carried out on the University of Birmingham Honeywell computer, and on the CDC 7600 at the University of Manchester Regional Computer Centre with the SHELX,[22] PLUTO[23] and DIFABS[21] programs. Final atomic coordinates, displacement factors, coefficients, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor from whom copies can be obtained.*

RESULTS AND DISCUSSION

Synthetic studies

The synthesis of the hexadentate ligands follows well established precedents involving a condensation reaction of the appropriate amine, 1,8-diamino-3,6-diazaoctane, tris-(2-aminoethyl)amine or 1,8-diamino-3,6-dithiaoctane with the appropriate aldehyde or ketone to produce a Schiff base ligand. The ligands $(Hsal)_2trien$ (**1a**), $(Haceph)_2$ thiatrien (**1b**), $(Hpyrrol)_2thiatrien$ (**2b**), $(Hsal)_3$ tren (**3a**), $(Hvan)_3tren$ (**3b**) and $(Hacac)_2thiatrien$ (**4b**) were isolated as solids which were readily characterized. The other ligands were prepared *in situ* before reaction with metal ions, since they could only be isolated as oils. Although most of the hexadentate ligands reacted readily with Fe^{III} and Co^{II} (which was then oxidized to Co^{III} to form 1 : 1 complexes) attempts to prepare Fe^{III} and Co^{III} complexes of $(Hpyrrol)_2thiatrien$ and a Co^{III} complex of $(Hpyrrol)_2trien$ were not successful. Complexes of the 1,8-diamino-3,6-dithiaoctane based ligands with Fe^{III} were also difficult to prepare. Although these ligands gave colour changes with Fe^{III}, attempts to isolate and purify the complexes were only successful in the case of $[Fe\{(sal)_2thiatrien\}]PF_6$. This complex proved to be unstable in solution, as indicated by a colour change from deep red–brown to pale orange after several hours. However, it appeared to be stable in the solid state for prolonged periods. Elemental analyses for the new compounds are presented in Table 1.

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

The IR spectra of the complexes and the free ligands all contained a strong band in the region 1590–1642 cm^{-1} (Table 1) which may be assigned to the C=N stretching vibration.[24] Complexation was accompanied by a bathochromic shift in the ligand core frequency. In the IR spectra of the ligands derived from salicylaldehyde 2-hydroxyacetophenone, 2-hydroxypropiophenone and 4-methoxybenzophenone, strong bands were observed in the region 1270–1285 cm^{-1}. These may be assigned to the C—O (phenolic) stretching vibration.[11b] Upon coordination of the ligands to metal ions these bands are shifted to high frequencies (1315–1340 cm^{-1}). One exception to this is found with [(Hsal)$_2$thiatrien] and its Fe^{III} complex, where the ν_{C-O} band is observed at the same frequency in both the ligand and the complex. In addition to these bands the ligands derived from trien or tren, and their complexes, exhibit a series of bands in the region 1130–1250 cm^{-1} which may be assigned to H_2C–N stretching vibrations. The position of these bands remains largely unchanged upon coordination of the ligands to the metal ions.

The complexes of the ligand derived from trien exhibit several bands in the 3000–3700 cm^{-1} region which may be assigned to N—H stretching vibrations.[15] An explanation for the appearance of these multiple peaks, some of which are sharp, was offered by Das Sarma and Bailar[11b] who suggested that the coordination of secondary amines to the metal results in an effect similar to that observed in amine salts, where the N—H stretching frequency is split into a number of bands.

Bands characteristic of C—H deformation for two-substituted benzene rings are observed in the range 740–780 cm^{-1} for the salicylaldehyde and substituted salicylaldehyde based ligands. The C—C stretching bands are observed in the regions 1500–1600 cm^{-1} and 1460 cm^{-1}, while C—H stretches (aliphatic) are observed in the range 2850–3000 cm^{-1}. In addition, all the complexes isolated as PF_6^- salts exhibited a strong band at *ca* 840 cm^{-1} due to the P—F stretching vibration.

The ^1H NMR spectra of the ligands and Co^{III} complexes are presented in Table 2 and are in accordance with their formulations. In the spectra of the ligands derived from salicylaldehyde, 2-hydroxyacetophenone and 2-hydroxypropiophenone, the signals at δ_{TMS} = 13–13.5 ppm are removed by shaking with D_2O and may be assigned to —OH protons. The ligands (Hsal)$_2$thiatren, (Hvan)$_3$tren, (Hsal)$_2$thiatrien, (Hsal)$_2$trien and (Hpyrrol)$_2$thiatrien exhibit a resonance of relative area two in the region δ_{TMS} 7.76–8.32 ppm which does not exchange with D_2O and may be assigned to the azamethine protons, —CH=N.[24a] In (Hacac)$_2$thiatrien, a CH resonance is observed at δ_{TMS} 5.00 ppm. For (Hpyrrol)$_2$thiatrien, the NH proton resonance is observed as a broad singlet at δ_{TMS} 11.2 ppm and is removed on shaking with D_2O.

The ^1H NMR spectra of the Co^{III} complexes are presented in Table 3. [Co{(sal)$_2$thiatrien}]PF_6 and [Co{(sal)$_2$trien}]$Cl \cdot 2.5H_2O$ exhibit two resonances at δ_{TMS} = 8.36 and 8.5 ppm, respectively, which again may be assigned to the azamethine proton. In general, little shift is observed in the positions of the NMR signals upon coordination of the ligands to the metals.

The mass spectra (Table 3) of [Fe{(sal)$_3$tren}] and [Fe{(van)$_3$tren}] were recorded by the electron impact method and exhibit molecular ions at m/z = 511[13] and 601 ^{55}Fe, respectively. All other mass spectra were recorded by fast atom bombardment using a glycerol matrix. The spectra all contain ions at an m/z value one unit higher than the molecular mass (M) corresponding with $[M+H]^+$. Such behaviour is typical of results obtained using glycerol matrices and is in accord with the formulation of the complexes as cationic 1 : 1 ligand–metal complexes.

Electronic spectral data for the complexes are summarized in Table 4. As observed by Tweedle and Wilson[15] the electronic spectrum of [Fe{(sal)$_2$trien}]PF_6 exhibits a low energy charge-transfer band centred at 610 nm (ε_{max} 1400) and a higher energy band at 490 nm (ε_{max} 3000). The lower energy band may be assigned to the low spin form and the higher energy band to the high spin form, the latter predominating at room temperature. In the complexes [Fe{(proph)$_2$trien}]PF_6, [Fe{(aceph)$_2$trien}]PF_6 and [Fe{(Mbenph)$_2$trien}]PF_6 only the higher energy bands in the range 475–490 nm are observed corresponding to the high spin form. Similarly, [Fe{(sal)$_2$thiatrien}]PF_6 exhibits an absorption band at 562 nm (ε_{max} 4100) which can be assigned to the high spin form. The complex [Fe{(pyrrol)$_2$trien}]PF_6 shows two absorption bands at 715 (ε_{max} 500) and 550 nm (ε_{max} 1820). Given that the magnetic data and ^{57}Fe Mössbauer spectra (*vide infra*) for this complex (Table 4) indicate that it exists in the low spin iron(III) state at room temperature, in the solid state the intense band at 550 nm may be due to the low spin form.

The absorption spectrum obtained of [Fe{(sal)$_3$tren}] in acetonitrile corresponds with that reported in the literature[13] and is similar to the spectrum of the new complex [Fe{(van)$_3$tren}]. All these absorption bands may be assigned to metal–ligand charge-transfer processes and no low intensity bands of purely *d–d* character were observed.

All the Co^{III} salts except [Co{(sal)$_2$trien}]$Cl \cdot 2.5H_2O$ and [Co{(aceph)$_2$trien}]PF_6 have simi-

[c] Signal removed on shaking with D_2O.

lar absorption spectra. Each exhibited an absorption in the region 635–670 nm (ε_{max} 500–1200) in addition to a strong absorption at 345–395 nm (ε_{max} 4000–7000) with a shoulder at *ca* 450 nm. The spectra of $[Co\{(sal)_2trien\}]Cl \cdot 2.5H_2O$, $[Co\{(aceph)_2trien\}]PF_6$ and $[Co\{(proph)_2trien\}]PF_6$ are similar, containing absorption maxima in the range 590–570 nm ($\varepsilon_{max} \sim 230$) and at 385 nm ($\varepsilon_{max}$ 6750).

The magnetic moments and ^{57}Fe Mössbauer parameters recorded in the solid state from the Fe^{III} complexes are presented in Table 4. All the complexes except $[Fe\{(pyrrol)_2trien\}]PF_6$ and $[Fe\{HB(pz)_3\}_2]PF_6$ (which was prepared for comparative purposes) have magnetic moments in the range 5.7–6.1 BM at 29 K, typical of high spin (^{6}A) Fe^{III} complexes.[25] The ^{57}Fe Mössbauer spectra recorded from the compounds $[Fe(sal)_2thiatren]PF_6$,

[a] μ_{eff} (BM) determined by the Gouy method using $Hg[Co(NCS)_4]$ as calibrant. δ (mm s^{-1}) maximum standard deviation 0.04 mm s^{-1} (hs = high spin, ls = low spin) with iron foil as reference. ΔE_Q (mm s^{-1}) maximum standard deviation 0.08 mm s^{-1}.

[b] Recorded in acetonitrile.

[c] Recorded in acetone.

[d] Recorded in 1 : 1 (v/v) methanol–water solution approximately 10^{-4} mol dm^{-3} in complex.

$Fe(sal)_3tren$ and $Fe(van)_3tren$ are characteristic of high spin iron(III) in near octahedral coordination and are therefore consistent with this interpretation. The larger quadrupole splitting of the $[Fe\{(sal)_2$ thiatrien$\}]PF_6$ may reflect a greater distortion of the electronic environment about iron(III) as a result of coordination to a $N_2O_2S_2$ donor set as compared to the N_3O_3 ligand.

The magnetic moments of 2.17 and 2.15 BM which were recorded from the compounds $[Fe\{(pyrrol)_2trien\}]PF_6$ and $[Fe\{HB(pz)_3\}_2]PF_6$ are characteristic of low spin (^2T) iron(III) species. All six of the donor atoms in both of these complexes, as well as in low spin $[Fe\{(pyrrol)_3tren\}]$,[25] are nitrogen atoms and their behaviour therefore contrasts with the high spin properties of other complexes reported here which contain O_2N_4, O_3N_3 or $O_2N_2S_2$ donor atom sets. The ^{57}Fe Mössbauer spectra recorded from $[Fe\{(pyrrol)_2trien\}]PF_6$ and $[Fe\{HB(pz)_3\}_2]PF_6$ are also characteristic of low spin iron(III), although the quadrupole splitting for $[Fe\{(pyrrol)_2trien\}]PF_6$ is larger than normally expected and that for $[Fe\{HB(pz)_3\}_2]PF_6$ is somewhat smaller. The crystal structure of $[Fe\{(pyrrol)_2trien\}]PF_6$ (*vide infra*) shows the iron(III) to be accommodated in a significantly distorted octahedral array of donor atoms. In contrast, iron(III) in $[Fe\{HB(pz)_3\}_2]PF_6$ is coordinated to six nitrogen atoms from two tripodal ligands and thereby enjoys a less distorted octahedral environment.

The ^{57}Fe Mössbauer spectra recorded from $[Fe\{(aceph)_2trien\}]PF_6$ and $[Fe\{(proph)_2trien\}]PF_6$ were characterized by rather broad lines and were not dissimilar from those previously recorded[16] at 298 K from $[Fe\{(acac)_2trien\}]PF_6$. The data are consistent with the magnetic measurements and show the compounds to be $S = 5/2$ high spin iron(III) species.

Structural studies

Selected bond lengths and angles from the single-crystal X-ray diffraction study on $[Fe\{(pyrrol)_2$ trien$\}]PF_6$, are listed in Table 5. The structure of the complex is illustrated in Fig. 1, which also shows the atomic numbering. The coordination about the iron atom is distorted octahedral, similar to that observed in related complexes.[12,16,26]

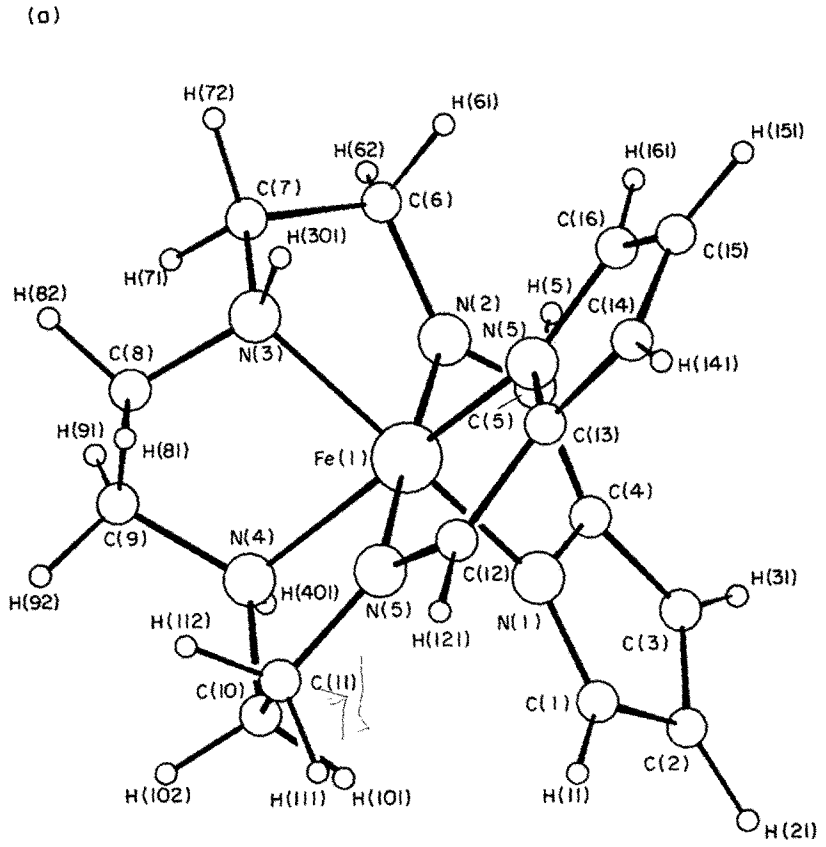

Fig. 1. (a) The structure of $[Fe\{(pyrrol)_2trien\}]^+$ showing the atom labelling. (b) A stereoview of the cation.

However, this complex cation, with a donor set of six nitrogen atoms, exhibits a greater distortion from octahedral geometry than the related cations in $[Fe\{(sal)_2trien\}]NO_3 \cdot H_2O$ and $[Fe\{(sal)_2trien\}]Cl \cdot H_2O$,[16] which have O_2N_4 donor atom sets. The angles N(1)—Fe—N(3), N(6)—Fe—N(4) and N(2)—Fe—N(5) deviate considerably from 180° (161.5, 161.8, 176.9°), whilst the 12 angles subtended at the iron atom by adjacent donor atoms range from 80.4 to 102.4°. This range may be compared to those of 83.9–95.3°, 83.9–95.2° and 83.5–96.0° for the Cl^-, Br^- and NO_3^- salts of $[Fe\{(sal)_2trien\}]^+$, respectively.[16,25]

Inspection of the Fe—N bond lengths reveals that two distinct groups are present:

(1) those between iron and a saturated, i.e. sp^3 hybridized nitrogen, 2.014 and 2.067 Å;
(2) those between iron and a pyrrolic nitrogen, or an unsaturated, i.e. sp^2 hybridized nitrogen, which are slightly shorter, range 1.915–1.943 Å.

These bond lengths are similar to the Fe—N lengths found[16] in the $[Fe\{(sal)_2trien\}]^+$ structures, wherein the iron is in the low spin ($s = \frac{1}{2}$) state. In the high spin ($s = 5/2$) $[Fe\{(acac)_2trien\}]^+$ and $[Fe\{(acac\ Cl)_2trien\}]^+$ complexes, in contrast, the Fe—N lengths are *ca* 0.17 Å longer.[16] Our structural results are, therefore, in agreement with the magnetic susceptibility and Mössbauer spectral data, indicating low spin iron in $[Fe\{(pyrrol)_2trien\}][PF_6]$ (Table 4).

The greater distortion from octahedral geometry of this complex may be a consequence of the stereochemical limitations imposed by the presence of five five-membered chelate rings, as opposed to three five-membered and two six-membered chelate rings in the $[Fe\{(sal)_2trien\}]^+$ cations. The two chelate rings adjacent to pyrrole rings are planar to within 0.01 Å. Bond lengths indicate electron delocalization over these moieties. The other three five-membered chelate rings deviate from planarity, with maximum atom displacements of −0.198, 0.298 and −0.305 Å. Thus the pyrrole ring confers considerable rigidity on the adjoining chelate ring, producing planarity at the two extremities of the ligand, and contributing to the distortion from octahedral geometry.

The PF_6^- counter ion approximates closely to octahedral geometry, maximum angular distortion, 3.1°. The P—F bond lengths are in the range 1.570(8)–1.594(7) Å in agreement with previous results.[27]

The results obtained from the structural studies show that the conversion of the six-membered terminal chelate rings in $[Fe\{(sal)_2trien\}]^+$ to five-membered rings in $[Fe\{(pyrrol)_2trien\}]^+$ is accompanied by significant additional distortions from an ideal octahedral geometry. When the Co^{III} ion is used in place of Fe^{III} the 1 : 1 complex either does not form or is of such limited stability that it cannot be isolated under similar conditions to those used to obtain the iron complex. This may reflect the inability of the ligand $(sal)_2trien$ to accommodate sufficiently the coordination requirements of the smaller Co^{III} ion. In solution at least, the incorporation of —S— donor atoms in place of —NH— in going from $[Fe\{(sal)_2trien\}]^+$ to $[Fe\{(sal)_2thiatrien\}]^+$ also results in a reduction in the stability of the complex. When both of these structural changes are combined in the ligand $(pyrrol)_2thiatrien$, the result is that 1 : 1 metal–ligand complexes with Fe^{III} or Co^{III} cannot be isolated under the conditions we have used.

COMPLEXES OF MOLYBDENUM(0),(II) AND TUNGSTEN(0),(II) WITH SOME MACROCYCLIC POLYTHIAETHERS

D. SEVDIĆ,* M. ĆURIĆ and Lj. TUŠEK-BOŽIĆ

Rudjer Bošković Institute, Department of Chemistry, 41000 Zagreb, P.O. Box 1016, Croatia, Yugoslavia

(*Received* 16 *June* 1988; *accepted* 1 *September* 1988)

Abstract—Reactions of potentially tetradentate and hexadentate macrocyclic polythiaethers 1,4,8,11-tetrathiacyclotetradecane (TTP) and 1,4,7,10,13,16-hexathiacyclooctadecane (HTO) with $Mo(CO)_6$ and $W(CO)_6$ have been studied. The new complexes of molybdenum(0) and tungsten(0): $[Mo(CO)_3]_2[TTP]$, $[Mo(CO)_3][HTO]$, $[Mo(CO)_3]_2[HTO]$, $[W(CO)_3][TTP]$ and $[W(CO)_4]_2[HTO]$, were isolated. The interaction of these compounds with iodine afforded the seven-coordinate complexes of molybdenum(II) and tungsten(II): $[Mo(CO)_3I_2][TTP]\cdot CH_2Cl_2$, $[Mo(CO)_3I_2]_2[HTO]$ and $[W(CO)_3I_2][TTP]\cdot CH_2Cl_2$. The complexes obtained were characterized on the basis of elemental analyses, magnetic measurements and IR, ^1H NMR, ^{13}C NMR and mass spectra.

A great deal of interest has been directed to obtaining information on derivatives of molybdenum and tungsten hexacarbonyl complexes in which one or several carbonyl ligands were replaced by various ligands containing sulphur donor atoms.[1–11] Among them, macrocyclic polythiaethers have drawn less attention, and only a few complexes of molybdenum(0) and tungsten(0) with these ligands have been reported.[12–14]

Our previous studies have concentrated on complex formation of molybdenum(VI), (V), (IV) and (III) with macrocyclic polythiaethers TTP and HTO, respectively.[15,16] As an extension of these investigations, in the present report we wish to describe the synthesis and spectral properties of some carbonyl complexes of molybdenum(0), (II) and tungsten(0), (II) with these ligands (Fig. 1).

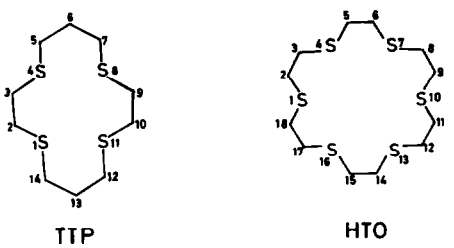

Fig. 1. Investigated ligands.

EXPERIMENTAL

Starting materials

Macrocyclic polythiaethers 1,4,8,11-tetrathiacyclotetradecane (TTP) and 1,4,7,10,13,16-hexathiacyclooctadecane (HTO) were prepared as described earlier.[17,18] The compounds $Mo(CO)_6$ and $W(CO)_6$ (Merck) were used without further purification. All solvents were purified by standard methods, dried and saturated with dry argon before use.

Preparation of complexes

All reactions were carried out under a stream of dry argon.

μ - 1,4,8,11 - *Tetrathiacyclotetradecane* - *bis[tricarbonylmolybdenum*(0)] (I). A mixture of 1.320 g (5 mmol) of $Mo(CO)_6$ and 0.268 g (1 mmol) of TTP in absolute ethanol (60 cm^3) was refluxed for 2 h with vigorous stirring. The yellow crystalline product was isolated by filtration in air of the hot solution, purified by means of repeated washings with hot ethanol and dried *in vacuo* at ambient temperature. Found: Mo, 30.2; C, 31.0; H, 3.6; S, 19.9. Calc. for $Mo_2C_{16}H_{20}S_4O_6$: Mo, 30.5; C, 30.6; H, 3.2; S, 20.4%.

*Author to whom correspondence should be addressed.

Tricarbonyl(1,4,7,10,13,16 - *hexathiacyclooctadecane*)*molybdenum*(0) (**II**). An equimolar amount of $Mo(CO)_6$ (0.264 g, 1 mmol) and HTO (0.360 g, 1 mmol) in absolute ethanol (30 cm^3) was heated under reflux for 2 h. The light yellow precipitate formed was separated by filtration of the hot solution, washed with the reaction solvent and dried. Found: Mo, 17.7; C, 33.7; H, 5.2; S, 35.8. Calc. for $MoC_{15}H_{24}S_6O_3$: Mo, 17.8; C, 33.3; H, 4.5; S, 35.5%.

μ - 1,4,7,10,13,16 - *Hexathiacyclooctadecane* - *bis*[*tricarbonylmolybdenum*(0)] (**III**). This complex was prepared similarly to **II** by using 1.056 g (0.4 mmol) of $Mo(CO)_6$ and 0.360 g (1 mmol) of HTO in 70 cm^3 of absolute ethanol and refluxing the reaction mixture for about 3 h. Found: Mo, 26.4; C, 29.7; H, 3.6; S, 26.5. Calc. for $Mo_2C_{18}H_{24}S_6O_6$: Mo, 26.6; C, 30.0; H, 3.4; S, 26.7%.

Tricarbonyl(1,4,8,11 - *tetrathiacyclotetradecane*) *tungsten*(0) (**IV**). A mixture of 0.705 g (2 mmol) of $W(CO)_6$ and 0.268 g (1 mmol) of TTP in absolute ethanol (30 cm^3) was refluxed with continuous stirring under the constant irradiation from a Camag TL-900 UV lamp for 10 h. The yellow crystals which precipitated were collected by filtration of the hot solution in air, washed with hot ethanol and dried *in vacuo* at ambient temperature. Found: W, 33.8; C, 28.9; H, 3.6; S, 24.0. Calc. for $WC_{13}H_{20}S_4O_3$: W, 34.3; C, 29.1; H, 3.7; S, 23.9%.

μ - 1,4,7,10,13,16 - *Hexathiacyclooctadecane* - *bis*[*tetracarbonyltungsten*(0)] (**V**). According to the procedure given above for **IV**, a mixture of 1.412 g (4 mmol) of $W(CO)_6$ and 0.360 g (1 mmol) of HTO in absolute ethanol (70 cm^3) was refluxed under constant irradiation from a Camag TL-900 UV lamp for 12 h. The yellow crystalline precipitate was filtered off, washed and dried. Found: W, 38.0; C, 25.8; H, 2.8; S, 20.7. Calc. for $W_2C_{20}H_{24}S_6O_8$: W, 38.6; C, 25.2; H, 2.5; S, 20.1%.

Di - iodotricarbonyl(1,4,8,11 - *tetrathiacyclotetradecane*)*molybdenum*(II)*dichloromethane*(1/1) (**VI**). The complex $[Mo(CO)_3][TTP]$ (0.78 g, 1.73 mmol) was dissolved in dichloromethane (20 cm^3) and cooled to $-10°C$. A solution of 0.50 g (1.92 mmol) of I_2 in dichloromethane (10 cm^3) was added dropwise with stirring. The mixture was vigorously stirred further for 2 h at $-10°C$. The orange crystals formed were filtered off under a stream of dry argon, washed with cool dichloromethane and dried *in vacuo*. The same product was obtained starting from complex **I**. Found: Mo, 12.5; C, 21.2; H, 3.0; S, 16.9; I, 32.3. Calc. for $MoC_{14}H_{22}S_4I_2Cl_2O_3$: Mo, 12.2; C, 21.3; H, 2.8; S, 16.3; I, 32.2%.

μ - 1,4,7,10,13,16 - *Hexathiacyclooctadecane* - *bis*[*di - iodotricarbonyl molybdenum*(II)] (**VII**). A suspension of 0.95 g (1.76 mmol) of the complex $[Mo(CO)_3][HTO]$ in dichloromethane (25 cm^3) was cooled at $-10°C$ and a solution of 0.50 g (1.92 mmol) of I_2 in dichloromethane (10 cm^3) was added slowly. The mixture was stirred for a further 2 h. The orange precipitate formed was filtered off, rinsed with the cool dichloromethane and dried. The same compound was obtained starting from complex **III**. Found: Mo, 15.4; C, 17.2; H, 2.2; S, 16.2; I, 41.1. Calc. for $Mo_2C_{18}H_{24}S_6I_4O_6$: Mo, 15.6; C, 17.6; H, 1.9; S, 15.6; I, 41.3%.

Di - iodotricarbonyl(1,4,8,11 - *tetrathiacyclotetradecane*)*tungsten*(II) *dichloromethane*(1/1) (**VIII**). This compound was prepared in an analogous manner to **VI**, starting with 0.86 g (1.59 mmol) of complex **IV** and 0.45 g (1.80 mmol) of I_2 dissolved in dichloromethane. Found: W, 21.2; C, 18.7; H, 2.4; S, 15.2; I, 29.4. Calc. for $WC_{14}H_{22}S_4I_2Cl_2O_3$: W, 21.0; C, 19.2; H, 2.5; S, 14.6; I, 29.0%.

Physical measurements

IR spectra of the complexes were recorded as KBr pellets on a Perkin–Elmer 580 B (4000–180 cm^{-1}) spectrophotometer. ^1H and ^{13}C NMR spectra were obtained in CD_2Cl_2 solutions on a JEOL FX 90Q spectrometer (90 MHz for ^1H and 22.5 MHz for ^{13}C) and on a Brucker spectrometer (300 and 360 MHz for ^1H, 70.5 and 90 MHz for ^{13}C). Tetramethylsilane was used as an internal standard. Mass spectra were obtained on a Varian CH-7 mass spectrometer, using an ionization current of 100 μA, an electron energy of 70 eV and an ion accelerating voltage of 3 kV. Magnetic susceptibilities were determined by the standard Gouy method at 295 K using $CuSO_4 \cdot 5H_2O$ as calibrant. X-ray powder patterns were obtained using an X-ray diffractometer (Philips) with a proportional counter using Cu-K_α radiation.

RESULTS AND DISCUSSION

Reactions of $Mo(CO)_6$ and $W(CO)_6$ with macrocyclic polythiaethers TTP and HTO give some tricarbonyl and tetracarbonyl complexes of molybdenum(0) and tungsten(0). These novel compounds are yellow, microcrystalline and diamagnetic solids which decompose very slowly in air, while their solutions are much less stable. By oxidation with iodine in dichloromethane they are converted to the new seven-coordinate complexes of molybdenum(II) and tungsten(II). These complexes are microcrystalline or powder-like, coloured orange, diamagnetic and less air-stable than the complexes of the zero-valent metals. They can be stored under argon only for several days.

Table 1. Conditions for preparation of the complexes

	Complex	Starting compound	Metal/ligand ratio	Solvent	Colour
I	$[Mo(CO)_3]_2[TTP]$	$Mo(CO)_6$	5:1	Ethanol	Yellow
II	$[Mo(CO)_3][HTO]$	$Mo(CO)_6$	1:1	Ethanol	Yellow
III	$[Mo(CO)_3]_2[HTO]$	$Mo(CO)_6$	4:1	Ethanol	Yellow
IV	$[W(CO)_3][TTP]$	$W(CO)_6$	1:1 2:1	Ethanol	Yellow
V	$[W(CO)_4]_2[HTO]$	$W(CO)_6$	1:1 2:1 4:1	Ethanol	Yellow
VI	$[Mo(CO)_3I_2][TTP]\cdot CH_2Cl_2$	$[Mo(CO)_3][TTP]$ $[Mo(CO)_3]_2[TTP]$	1:2	Dichloromethane	Orange
VII	$[Mo(CO)_3I_2]_2[HTO]$	$[Mo(CO)_3][HTO]$ $[Mo(CO)_3]_2[HTO]$	1:2	Dichloromethane	Orange
VIII	$[W(CO)_3I_2][TTP]\cdot CH_2Cl_2$	$[W(CO)_3][TTP]$	1:2	Dichloromethane	Orange

Conditions of preparation with some physical properties of the complexes are given in Table 1, the most important IR data are listed in Table 2, while the NMR spectra are shown in Table 3. The complexes were formulated mainly on the basis of chemical and spectral analysis. The low solubility and stability of most of the complexes in common solvents, limited their further characterization. Generally, binuclear complexes are less soluble than the mononuclear complexes, as well as are molybdenum complexes compared to those of tungsten.

Complexes of molybdenum(0) *and tungsten*(0)

Investigations of the interactions of $Mo(CO)_6$ and $W(CO)_6$ with TTP and HTO, respectively, have shown that either the mononuclear or the binuclear complexes could be formed depending on the concentration of the reactants used in the reactions. The binuclear complexes of molybdenum were obtained only when the concentration of the metal was in large excess in relation to the concentration of the ligand. So the complex $[Mo(CO)_3]_2[HTO]$ was formed with the metal–ligand ratio 4:1, and the complex $[Mo(CO)_3]_2[TTP]$ with the molar ratio 5:1. On the other hand, an equimolar metal–ligand ratio afforded the mononuclear complexes $[Mo(CO)_3][HTO]$ and $[Mo(CO)_3][TTP]$,[13] respectively.

It was observed that in the reaction of $W(CO)_6$ with HTO only the binuclear complex $[W(CO)_4]_2$ [HTO] was formed regardless of the concentration of the reactants. With the ligand TTP the mononuclear complex $[W(CO)_3][TTP]$ and the binuclear complex $[W(CO)_4]_2[TTP]$[13] could be formed depending on the metal–ligand ratio used.

The IR frequencies associated with the characteristic functional groups of the free macrocyclic polythiaethers and their metal complexes are presented in Table 2. Only for the complex $[W(CO)_3]$ [TTP] could the IR spectrum be obtained both in the solid state and in a dichloroethane solution. Its spectrum in solution has two intense bands in the carbonyl stretching region, indicating a C_{3v} local symmetry with a facial tricarbonyl configuration. In the solid state the basic two line spectrum is dominant, but almost every peak shows a shoulder due to the greater distortions of the complex molecule in the solid state packing. We can assign two carbonyl absorptions to A_1 and E vibration modes. This carbonyl IR pattern also closely resembles those obtained for some molybdenum and tungsten complexes, *fac*-$M(CO)_3L_3$[19] and *fac*-$M(CO)_3L$,[2,11,13,20] containing sulphur donor ligands. Furthermore, it is clearly apparent that the positions of the carbonyl absorptions as well as their relative intensities are very similar for all other tricarbonyl complexes of TTP and HTO (**I, II** and **III**), suggesting the same facial tricarbonyl configuration. This configuration is preferable in the metal tricarbonyl complexes with a ligand of lower π-bonding ability than the carbonyl groups.

All investigated complexes give a series of strong to medium bands between 650 and 510 cm^{-1}, characteristic of M—CO bending, and a weak band in the 490–470 cm^{-1} region due to the M—S stretching vibrations. Significant differences between the spectra of macrocyclic polythiaethers and their complexes may be noticed in the region 1220–660 cm^{-1} where

bands arising from various modes of vibrations of the thiaether and methylene groups are present. Two strong bands in the IR spectra of the free ligands, TTP (692 and 675 cm^{-1}) and HTO (683 and 660 cm^{-1}), are assigned to the C—S stretching vibrations. Coordination of the sulphur atoms from the ligand to the metal atom causes both a decrease in the frequency and a lowering of the intensity of the C—S—C stretching mode. In complexes **I** and **III** the ν(C—S) bands disappeared completely indicating that all sulphur atoms are engaged in the complex. In the complex $[Mo(CO)_3]_2[HTO]$ the ligand HTO probably acts in a double tridentate bridging manner between two molybdenum units, and it can be thus presumed that molybdenum atoms have an octahedral configuration. For complex **I** where the tetradentate ligand TTP can act only in a double bidentate bridging manner between two molybdenum units, the formally five-coordinate molybdenum(0) in the complex $[Mo(CO)_3]_2$ [TTP] can be postulated. The same coordination has been found for some tricarbonylmolybdenum(0) complexes with phosphine ligands.[21,22]

IR spectra of tungsten tetracarbonyl complexes with TTP (**V**) differ substantially to those obtained for the tricarbonyl complexes. Although the optimum resolution of the carbonyl absorptions is not possible in the solid state spectrum, the four-line pattern may be recognized, suggesting the C_{2v} local symmetry with the *cis*-tetracarbonyl configuration. This pattern strongly resembles that expected for *cis*-C_{2v} disubstituted octahedral carbonyls.[4,20] Due to the disparate carbonyl ligand configuration, the great differences may also be noticed in the M—CO stretching and bending vibrations. While the former is found only in this complex as the medium band at 390 cm^{-1}, the latter gives two bands at lower frequencies (615 and 580 cm^{-1}). Furthermore, the *trans*-rocking and twisting methylene vibrations have completely disappeared, indicating a greater change in conformation of the macrocyclic ligand. In order to retain the six coordination, the HTO ligand in this complex acts as a bridge between two tungsten units in a double bidentate manner.

Unfortunately, most of the complexes are too insoluble for observing the NMR spectra. Only for the $[W(CO)_3][TTP]$ and $[Mo(CO)_3][HTO]$ complexes have the satisfactory ^1H and ^{13}C NMR spectra been obtained in dichloromethane solution. The results obtained are given in Table 3 and Fig. 2. Significant differences were observed when comparing the NMR spectra of the complexes with the spectra of the free macrocyclic polythiaethers. On the basis of spectral data it is evident that the considerable changes in conformation of the polythiaether ring occur upon complex formation. The bidentate or tridentate coordination of the macrocyclic ligands is proposed in the metal complexes.

The free TTP ligand has three sets of resonant signals for methylene protons of the polythiaether ring, a quintet at δ 1.98 ppm for the β-propanomethylene protons and overlapping triplet and

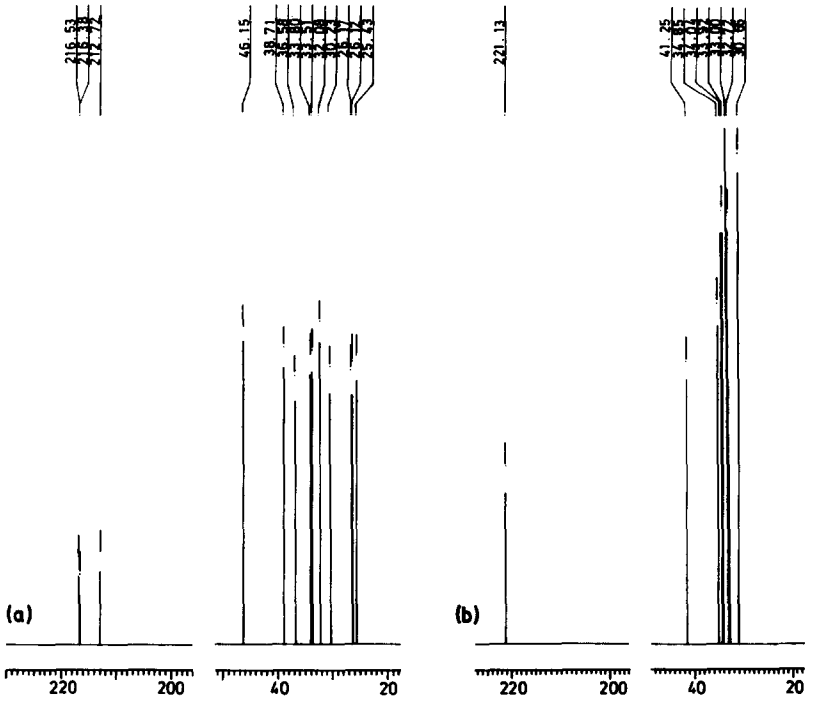

Fig. 2. ^{13}C NMR spectra of the complexes (a) $[W(CO)_3][TTP]$ and (b) $[Mo(CO)_3][HTO]$.

singlet patterns at δ 2.67 and 2.77 ppm, respectively, for the protons of α-propanomethylene and ethylene groups.[23] The ^{13}C NMR spectrum consequently shows three absorptions at δ 30.02, 30.24 and 31.49 ppm for β-, α-propano and ethano carbon atoms, respectively.

The NMR spectra of the $[W(CO)_3][TTP]$ complex are much more complex and are in agreement with the proposed unsymmetrical tridentate coordination of the ligand through the S(1), S(4) and S(11) sulphur atoms (Fig. 3). The ^1H NMR spectrum shows a well defined quintet at δ 2.11 ppm and a very complex multiplet at δ 2.30–3.38 ppm. The quintet is assigned to the protons of one β-propanomethylene group depicted as H(6). The relatively small downfield shift of these protons indicates an essentially free ligand character of the corresponding methylene group. On the other hand, the protons of the other β-propanomethylene group H(13), which is near to the S(1) and S(11) coordination sites, are shifted strongly to lower field and

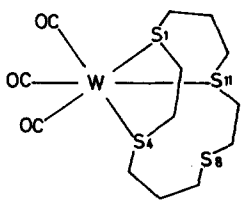

Fig. 3. Proposed structure of $[W(CO)_3][TTP]$.

overlap with the resonances of the other methylene protons. This part of the spectrum is too complex to allow precise assignments. A similar spectrum was obtained for the corresponding Mo complex of TTP, where an analogue structure of the complex was postulated.[13] Furthermore, the ^{13}C NMR spectrum of complex **IV** gives 10 resonances due to the 10 non-equivalent methylene groups (Fig. 2), confirming the unsymmetrical locked ligand coordination. The resonances corresponding to the carbonyl groups appear as three single absorptions, and no internuclear spin coupling with tungsten is observed. The chemical shift differences between the two lower field resonances is extremely small ($\Delta\delta$ = 0.17 ppm). These small deformation changes between the carbonyl groups are not visible in the spectra of the Mo complex, nor in the IR spectra of both complexes. The results obtained confirm the assumption that the ^{13}C chemical shift of the coordinated carbonyl groups is very sensitive to changes in stereochemistry and electronic environment.[24–28]

The HTO ligand having all methylene groups in identical environments, gives very simple NMR spectra. A singlet at δ 2.83 ppm is assigned to the methylene polythiaether protons, and a singlet at δ 32.56 ppm to the 12 equivalent methylene carbon atoms. The spectra of the $[Mo(CO)_3][HTO]$ complex are more complicated due to a greater number of non-equivalent thiaether fragments, as a result

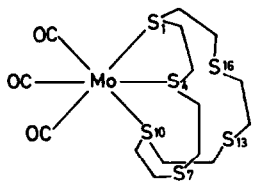

Fig. 4. Proposed structure of $[Mo(CO)_3][HTO]$.

of the non-symmetrical tridentate coordination of the ligand (Fig. 4). The ^1H NMR spectrum of complex **II** exhibits an unresolved multiplet in the δ 2.71–3.10 ppm range. More detailed information about the coordination of the polythiaether ring was provided by ^{13}C NMR spectra (Fig. 2). Seven absorptions, with one of double intensity, assigned to eight non-equivalent methylene groups, dictate the binding of the HTO ligand through the S(1), S(4) and S(10) donor sulphur atoms. Because of the close proximity to the coordinated sulphur atoms S(1) and S(4), the methylene carbons C(2) and C(3) give the resonance with the strongest downfield shift with respect to the free ligand carbon absorption. On the other hand, it may be presumed that the resonance at δ 30.66 ppm with the slight upfield shift, is derived from the methylene carbons C(14) and C(15) which are the furthest from the coordination sites. The other methylene carbon resonances could not be assigned with certainty. The presence of only one carbonyl ligand resonance indicates the fluctuation of the tricarbonyl ligand set. The same behaviour has also been observed in some carbonyl complexes of molybdenum with various macrocyclic and phosphine ligands.[13,29]

Complexes of molybdenum(II) *and tungsten*(II)

Although a wide variety of phosphine and arsine substituted halocarbonyl complexes of the type $[MX_2(CO)_3L]$ and $[MX_2(CO)_3L_2]$ (X = Cl, Br or I; M = Mo or W) have been described,[30,31] very few seven-coordinate complexes of molybdenum(II) and tungsten(II) containing sulphur donor ligands have been reported.[2,3] Iodine oxidation of molybdenum and tungsten zero-valent complexes of the macrocyclic polythiaethers TTP and HTO has been investigated. It was shown that oxidation of both molybdenum complexes of TTP, $[Mo(CO)_3][TTP]$ and $[Mo(CO)_3]_2[TTP]$, as well as of its tungsten complex $[W(CO)_3][TTP]$, with a controlled amount of iodine always leads to the formation of the 1:1 complex. Further, it is of interest that both TTP compounds obtained, $[Mo(CO)_3I_2][TTP]$ and $[W(CO)_3I_2][TTP]$, contain one molecule of dichloromethane, which is supported by elemental analyses and mass spectra. HTO complexes, $[Mo(CO)_3][HTO]$ and $[Mo(CO)_3]_2[HTO]$, react with iodine giving the 2:1 complex $[Mo(CO)_3I_2]_2$ [HTO]. It seems that with regard to the number of sulphur atoms in the ligand, as well as to the size of the macrocyclic ring, the formation of the 1:1 complex for TTP and the 2:1 complex for HTO, respectively, is sterically preferable.

Comparing the IR spectra of di-iodo metal carbonyl complexes with those obtained for the macrocyclic polythiaether complexes of zero-valent metals, it is evident that considerable changes may be noticed only in the regions which contain bands attributed to ν(CO) and δ(M—CO) vibrations. Upon oxidation with iodine the metal becomes more electropositive by forming an M—I bond, and consequently while the carbonyl stretching bands are shifted to higher frequencies, the bands associated with the M—CO bending are shifted to lower frequencies. For all other characteristic absorption bands no significant changes are observed.

The IR spectra of complexes **VI** and **VIII** show three strong bands in the carbonyl stretching region, and are very similar to those obtained earlier for seven-coordinate complexes.[2,31] As the reported X-ray crystal structures of the seven-coordinate complexes with bidentate phosphine and arsine ligands[32] reveal capped octahedral geometry with one carbonyl ligand in the unique capping position, it is highly likely that our di-iodo complexes have a similar capped octahedral structure with a C_s local symmetry. The ^1H NMR spectrum of **VIII** confirms the bidentate coordination of the macrocyclic ligand TTP in its metal complexes. On the other hand, the binuclear HTO complex **VII** exhibits only two bands associated with the carbonyl stretching absorption. Unfortunately, the extremely low solubility and stability of this complex prevent any investigation in solution, and therefore it is difficult to presume its structure with certainty.

The ^1H NMR spectrum of the complex $[W(CO)_3I_2]$ [TTP] shows five sets of resonant signals for the methylene protons of the polythiaether ring, suggesting the symmetrical bidentate ligand coordination through the S(1) and S(4) sulphur atoms (Fig. 5). One quintet is assigned to the protons of the β-propanomethylene groups, two triplets to the protons of the α-propanomethylene groups and two singlets to the ethylene protons. While the chemical shifts of both the β_1-, and one set of α-propanomethylene protons, H(7) and H(12), as well as one set of ethylene protons, H(9) and H(10), are essentially unchanged upon complex formation, the other set of α-propanomethylene protons, H(5) and H(14), and ethylene protons, H(2) and H(3), which are near to the sites of coordination, are shifted downfield by 0.63 and 0.31 ppm, respectively, due

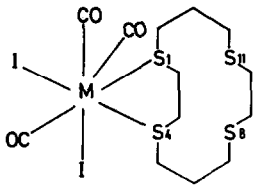

Fig. 5. Proposed structure of $[M(CO)_3I_2][TTP]$, (M = Mo or W).

to the deshielding influence of the binding sulphur atoms. As the NMR spectra were performed in CD_2Cl_2, it is impossible to assign the absorption arising from the dichloromethane molecule present in the complex. Although for the molybdenum complex with TTP, the satisfactory ^1H NMR spectrum was not obtained, an adequate structure could be proposed (Fig. 5) on the basis of IR and X-ray data. Molybdenum and tungsten complexes show the same pattern in the IR spectra and in the X-ray powder photographs, indicating that these two compounds are isomorphous.

The results obtained led us to presume that the ligand coordination modes are controlled by a combination of factors, including the metal size in relation to the size of the macrocyclic polythiaether hole, the presence of competing ligands, and the electronic nature of the metals.

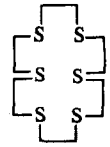
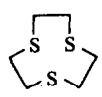
(*Received* 19 *July* 1988; *accepted* 8 *September* 1988)

Abstract—Reaction of $AgNO_3$ with 1 molar equivalent of $[18]aneS_6$ ($[18]aneS_6$ = 1,4,7,10,13,16-hexathiacyclooctadecane) in water–MeOH (1 : 1 v/v) affords the complex cation $[Ag([18]aneS_6)]^+$. $[Ag([18]aneS_6)]PF_6$ crystallizes in the monoclinic space group $I2/m$ with a = 5.295(4), b = 13.959(10), c = 13.951(9) Å, β = 95.15(10)°, V = 1027 Å^3, D_c = 1.983 g cm^{-3}, Z = 2. The complex cation has $C_{2h}(2/m)$ symmetry with Ag^I bound to all six thia donors of $[18]aneS_6$ with two short [Ag—S(1) = 2.6665(12) Å] and four significantly longer (Ag—S(4) = 2.7813(10) Å) Ag—S distances. This 2+4 coordination of $[18]aneS_6$ reflects the tendency of the d^{10} Ag^+ ion to increase its coordination number with soft donor ligands. Chemical oxidation of $[Ag([18]aneS_6)]^+$ and $[Ag([9]aneS_3)_2]^+$ at 293 K in highly acidic media affords the corresponding stable Ag^{II} species, which have been identified by ESR and UV–vis spectroscopy. These Ag^{II} species can only be generated electrochemically in MeCN at 293 K as transient intermediates. The enhanced stabilization of $[M([9]aneS_3)_2]^{2+}$ (M = Ag^{II}) and $[M([9]aneS_3)_2]^{3+}$ (M = Fe^{III}, Ni^{III}, Pd^{III}) under acidic conditions is discussed.

The chemistry of macrocyclic thioether complexes is of intense current interest.[1,2] This stems from the observation that, whereas non-cyclic thioether ligands are generally poor donors to metal centres,[3] a wide range of stable complexes of cyclic thioethers can be prepared. At the forefront of these studies have been complexes of the ligands 1,4,7,10,13,16-hexathiacyclooctadecane ($[18]aneS_6$)[4–6] and 1,4,7-trithiacyclononane ($[9]aneS_3$).[7–10] These ligands form a series of complexes with transition metal ions showing highly unusual stereochemical and redox characteristics.[1,4,7] As a continuation of our studies on macrocyclic thioether complexes of second and third row transition metal ions,[1] we report the synthesis, structure and redox chemistry of the Ag^I complex of $[18]aneS_6$.



[18]ane S_6



[9]ane S_3

Wieghardt and co-workers[11] and Cooper and co-workers[12] have reported recently the synthesis and structure of the complex cation $[Ag([9]aneS_3)_2]^+$. This species shows octahedral Ag^I with the two trithia ligands bound facially to the metal centre [Ag—S = 2.697(5), 2.753(4) Å]. In addition, Wieghardt and co-workers have characterized[9] a highly interesting trimeric Ag^I cation, $[Ag_3([9]aneS_3)_3]^{3+}$, incorporating bridging thioether ligands. Parallel to these works, we have been investigating the stereochemical and redox properties of the complementary $[Ag([18]aneS_6)]^+$ cation, and we describe our results herein.

RESULTS AND DISCUSSION

Reaction of $AgNO_3$ with 1 molar equivalent of $[18]aneS_6$ in refluxing water–MeOH (1 : 1 v/v) affords a colourless solution. Addition of NH_4PF_6 to the filtered solution yields $[Ag([18]aneS_6)]PF_6$

*Author to whom correspondence should be addressed.

as a colourless product. The fast atom bombardment mass spectrum of the complex shows peaks at $M^+ = 469$ and 467 corresponding to $[^{109}Ag([18]aneS_6)]^+$ and $[^{107}Ag([18]aneS_6)]^+$, respectively. IR spectral and analytical data were consistent with the formulation $[Ag([18]aneS_6)]PF_6$. A single crystal X-ray structural determination was undertaken to confirm the stereochemistry of the complex, and the connectivity of the potentially hexadentate thioether macrocycle.

Crystals of $[Ag([18]aneS_6)]PF_6$ were obtained from MeCN–Et_2O. Two views of the complex cation are shown in Fig. 1(a) and (b). The crystal structure shows the complex to have $C_{2h}(2/m)$ symmetry with a distorted octahedral stereochemistry around the Ag^I ion. All six thia donors of $[18]aneS_6$ are bound to the metal centre with two short axial bonds [Ag—S(1) = 2.6665(12) Å] and four significantly longer equatorial bond lengths [Ag—S(4) = 2.7813(10) Å, ∠S(1)AgS(4) = 80.35(3), ∠S(4)AgS(4′) = 77.43(3)°]. The structure can thus be described as 2+4 coordinate, and reflects the tendency of the d^{10} Ag^+ ion to increase its coordination number with soft donor ligands.[13] The Ag—S bond lengths in $[Ag([18]aneS_6)]^+$ are particularly long for complexes of $[18]aneS_6$, and are similar to those reported previously for $[Ag([9]aneS_3)_2]^+$ (Ag—S = 2.753(4), 2.697(5) Å).[11] It is interesting to compare the structure of $[Ag([18]aneS_6)]^+$ with that of $[Pd([18]aneS_6)]^{2+}$.[4] For the latter complex, the stereochemistry at Pd^{II} is octahedrally distorted with four short equatorial [Pd—S = 2.3114(14), 2.3067(15) Å] and two long range apical interactions (Pd···S = 3.2730(17) Å, $\angle S_{ax}PdS_{eq} = 75.06(5)°$), i.e. 4+2 coordinate.[4] Thus, on going from d^8 Pd^{II} to d^{10} Ag^I, we see a change in binding of $[18]aneS_6$ from formally tetragonally elongated to formally tetragonally compressed octahedral stereochemistry. Increases in the equatorial M—S bond lengths reflect the increase in the ionic radius of the metal centre [0.78 Å for Pd^{II}. 1.29 Å for Ag^I[14]]. The ability of $[18]aneS_6$ to encapsulate such a large metal ion as Ag^I is remarkable, and suggested to us that this system was set up for redox activity at the Ag centre; the metal free $[18]aneS_6$ is redox inactive between −2.0 and +2.0 V in MeCN.

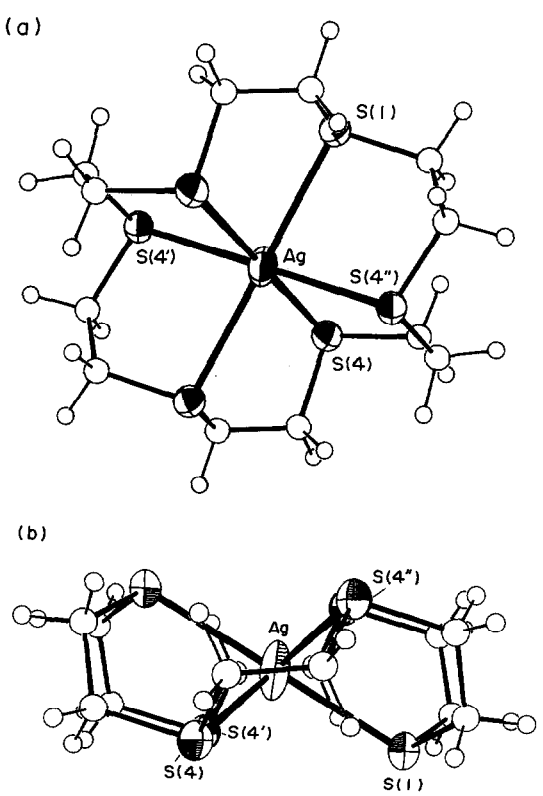


Fig. 1. Two views of the X-ray crystal structure of $[Ag([18]aneS_6)]^+$ with numbering scheme adopted.

Cyclic voltammetry of $[Ag([18]aneS_6)]^+$ in MeCN (0.1 M $^nBu_4NPF_6$) at platinum electrodes shows a sluggish oxidation near $E_{pa} = +1.00$ V vs Fc/Fc^+ which is essentially irreversible; only a small return wave is observed even at fast scan rates indicating that the oxidized product is unstable in MeCN. Importantly, a quasi-reversible reduction observed at $E_{1/2} = -0.42$ V vs Fc/Fc^+, is assigned tentatively to an $Ag^{I/0}$ couple. However, attempts to generate the reduced species by controlled potential electrolysis at 298 K were unsucessful with deposition of Ag metal occurring at the working electrode. Repeated reductive cyclic voltammetric scans of $[Ag([18]aneS_6)]^+$ in MeCN at 298 K also led to deposition of Ag metal at the electrode surface. The binding of Ag^0 to the hexathia ligand is intriguing, and occurs presumably via Ag—S bond breaking in the Ag^I precursor.

It was important to compare these results on $[Ag([18]aneS_6)]^+$ with those of the corresponding nine-membered ring system $[9]aneS_3$. The related $[Ag([9]aneS_3)_2]^+$ cation has been reported to undergo a reversible oxidation at +1.30 V vs NHE in $MeNO_2$ to afford a transient Ag^{II} species. This deep blue product could be generated as a stable species only at −70°C by chemical oxidation with Ce^{IV} in MeOH.[12] In our hands, the oxidation of $[Ag([9]aneS_3)_2]^+$ is only quasi-reversible at high scan rates at 298 K ($E_{pa} = +0.79$ V, $E_{1/2} \simeq +0.75$ V vs Fc/Fc^+), consistent with the transient nature of the oxidized product in MeCN at ambient temperatures. Electrochemically, therefore, the oxidative chemistry of $[Ag([18]aneS_6)]^+$ and $[Ag([9]aneS_3)_2]^+$ appears to be similar with the oxidized product being unstable in organic media. We also observed a reduction for $[Ag([9]aneS_3)_2]^+$

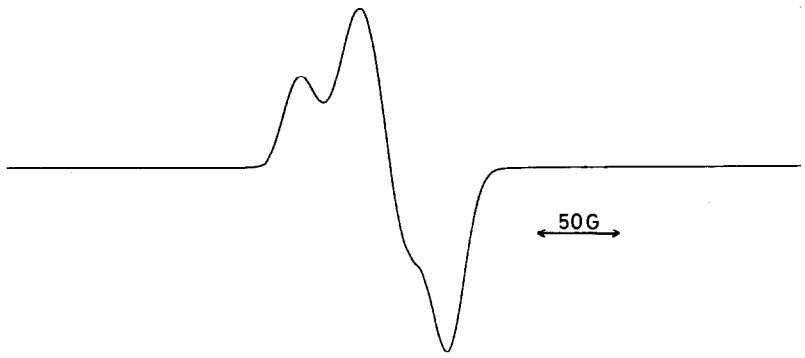

Fig. 2. *X*-Band ESR spectrum (77 K) of the Ag^{II} oxidation product of $[Ag([18]aneS_6)]^+$ in H_2SO_4 glass.

at $E_{pc} = -0.57$ V vs Fc/Fc^+ which was less reversible than for $[Ag([18]aneS_6)]^+$ suggesting that dissociation of $[9]aneS_3$ from the reduced metal centre occurs more rapidly than dissociation of $[18]aneS_6$. This is consistent with the greater denticity of the hexathia over the trithia ligand, and with the expected lability of a formally Ag^0 metal centre. Current work is aimed at trying to stabilize these reduction products.

Paramagnetic Ag^{II} complexes have been reported with a variety of donor ligands.[15] More interestingly, the stabilization of such species has been shown to be enhanced in strongly acidic, non-reducing aqueous solutions.[16] Related to this, Fabbrizzi and co-workers have noted[17] the increased stability of Cu^{III} macrocyclic complexes in acidic media, while we have found similar effects on the stability of oxidized products such as $[Pd([9]aneS_3)_2]^{3+}$.[1,7] We therefore reasoned that highly acidic, aqueous conditions might be effective in stabilizing the Ag^{II} products of $[18]aneS_6$ and $[9]aneS_3$.

Addition of concentrated (98%) H_2SO_4 solution to $[Ag([18]aneS_6)]^+$ at 298 K affords a blue solution ($\lambda_{max} = 564$ nm, $\varepsilon_{max} \simeq 5000$ M^{-1} cm^{-1}), the ESR spectrum of which, as a frozen glass at 77 K, shows a strong anisotropic signal with $g_1 = 2.063$, $g_2 = 2.028$, $g_3 = 2.007$ assigned to the formation of a Ag^{II} species (Fig. 2).[15,16] The blue solution decays to a colourless solution over a period of 2 h at 298 K. Addition of 70% $HClO_4$ solution to $[Ag([18]aneS_6)]^+$ affords the same oxidized product, although in this case the product tends to precipitate out of solution over a period of minutes. The absorption at 564 nm is assigned tentatively to a $S(p\pi) \rightarrow Ag(d)$ charge-transfer transition. Addition of these concentrated acids to $[Ag([9]aneS_3)_2]^+$ likewise affords a blue solution ($\lambda_{max} = 570$ nm, $\varepsilon_{max} = \simeq 8000$ M^{-1} cm^{-1}), the ESR spectrum of which, as a frozen glass at 77 K, shows a strong anisotropic signal with $g_1 = 2.066$, $g_2 = 2.034$, $g_3 = 2.012$ (Fig. 3). This blue Ag^{II} species is stable in solution at room temperature for several days; this contrasts with the transient nature of the

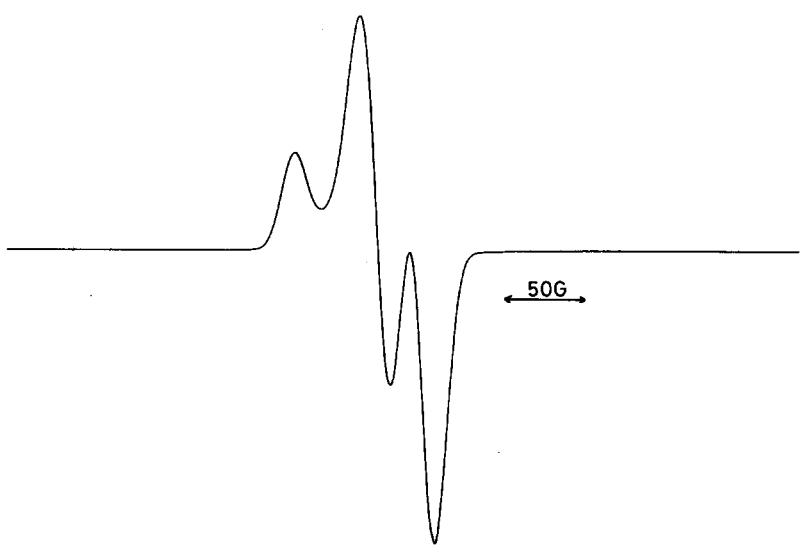

Fig. 3. *X*-Band ESR spectrum (77 K) of the Ag^{II} oxidation product of $[Ag([9]aneS_3)_2]^+$ in $HClO_4$ glass.

complex in organic solvents under ambient conditions.[12] We are currently simulating the above ESR data to identify possible ^{107}Ag and ^{109}Ag components.

We have found that the stability of other high valent metal complexes of [9]aneS$_3$ is enhanced in acidic aqueous media. Thus, the complexes $[M([9]aneS_3)_2]^{3+}$ (M = Fe^{III},[9,10] Ni^{III},[10] Pd^{III}[1,7]) are stable indefinitely in 70% $HClO_4$ solutions, and can be crystallized from them. This observation is particularly important for the complex cation $[Fe([9]aneS_3)_2]^{3+}$ which decomposes very readily in organic solvents.[9] The role of $HClO_4$ in these reactions should be commented upon. The perchlorate anion is well known to be kinetically a very poor oxidant[18] and, indeed, dilute solutions of $HClO_4$ or concentrated solutions of $NaClO_4$ do not generate the above cations from their 2+ analogues. Highly concentrated $HClO_4$ solutions ($\geqslant$ 70%) are, however, very active oxidizing agents.[19] We have not investigated the kinetics of these oxidation reactions; however, the ability of highly concentrated $HClO_4$ solutions (in vast excess to the metal complex substrate) to oxidize these species may also be due to trace oxy-chloro impurities present in solution.

EXPERIMENTAL

IR spectra were recorded as KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department microanalytical service. ESR spectra were recorded as solids or as frozen glasses down to 77 K using a Bruker ER200D X-band spectrometer. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three electrode potentiostatic system in acetonitrile containing 0.1 M ^{n}Bu$_4$NPF$_6$ or ^{n}Bu$_4$BF$_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag/AgCl reference electrode. All potentials are quoted vs ferrocene/ferrocinium, Fc/Fc$^+$. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer.

Synthesis of [Ag([18]aneS$_6$)]PF$_6$

To a refluxing solution of [18]aneS$_6$ (0.1 g, 2.77×10^{-4} mol) in water–MeOH (20 cm^3, 1 : 1 v/v) was added $AgNO_3$ (0.045 g, 2.64×10^{-4} mol) in water (5 cm^3). The reaction solution was refluxed for 5 min and the hot solution filtered into a solution of excess NH_4PF_6 (0.2 g, 1.23×10^{-3} mol) in water (30 cm^3). The colourless precipitate was collected and recrystallized from MeCN–Et$_2$O to give [Ag([18]aneS$_6$)]PF$_6$ (0.08 g, 49% yield). Found: C, 23.1; H, 3.68. Calc. for [Ag([18]aneS$_6$)]PF$_6$: C, 23.5; H, 3.94%. Fast atom bombardment mass spectrum: Found M$^+$ = 469, 467. Calc. for [^{109}Ag([18]aneS$_6$)]$^+$ M$^+$ = 469. Calc. for [^{107}Ag([18]aneS$_6$)]$^+$ M$^+$ = 467. IR spectrum (KBr disc): 2956, 2917, 2896, 1425, 1416, 1285, 1260, 1202, 1192, 1154, 924, 840vs,br, 733, 705, 684, 614, 555, 407 cm^{-1}.

X-Ray structure determination of [Ag([18]aneS$_6$)]PF$_6$

A colourless crystal (0.09 × 0.16 × 0.52 mm) suitable for X-ray analysis was obtained by isothermal distillation of Et$_2$O into a solution of the complex in MeCN. The crystal was mounted with its *a* axis parallel to the spindle of a STADI-2 two-circle diffractometer.

Crystal data. $C_{12}H_{24}S_6Ag^+PF_6^-$, $M = 613.46$, monoclinic, space group *I*2/*m* (an alternative setting of *C*2/*m*) with $a = 5.295(4)$, $b = 13.959(10)$, $c = 13.951(9)$ Å, $\beta = 95.15(10)°$, $V = 1027$ Å^3 [from 2θ, ω and μ values of 36 reflections; $\bar{\lambda}$(Mo-K_α) = 0.71069 Å], $D_c = 1.983$ g cm^{-3}, $Z = 2$; $F(000) = 616$, $\mu = 16.84$ cm^{-1}

Data collection and processing. STADI-2 diffractometer, graphite-monochromated Mo-K_α *X*-radiation, ω scans with scan width $(1.0+0.5\sin\mu/\tan\theta)°$, 1050 reflections measured ($2\theta_{max} = 50°$, h 0 → 5, k 0 → 16, l −16 → 16), 919 unique ($R_{int} = 0.029$), giving 829 with $F \geqslant 6\sigma(F)$. No significant crystal decay, no absorption correction.

Structure analysis and refinement. The Ag atom was fixed at the origin, and the S and P atoms located by inputting its position to DIRDIF.[20] Iterative rounds of least-squares refinement and difference Fourier synthesis[21] located all other non-H

atoms. Some disorder in the PF_6^- ion was modelled by placing an F atom with a site occupancy of 0.17 in a general position. Anisotropic thermal parameters were refined for all non-H atoms. Hydrogen atoms were included in fixed, calculated positions.[21] A secondary extinction parameter refined to $0.0034(5) \times 10^{-4}$; the weighting scheme, $w^{-1} = \sigma^2(F) + 0.000109F^2$ gave satisfactory analyses. At convergence, R and $R_w = 0.0411$ and 0.0564, respectively, for 73 parameters and $S = 1.407$. The maximum and minimum residues in the final ΔF syntheses were +0.61 and −1.14 eÅ^{-3}, respectively. Illustrations were prepared using ORTEP,[22] molecular geometry calculated utilized CALC,[23] and scattering factor data were taken from ref. 24. Bond lengths, angles and torsion angles are given in Tables 1–3.

Full structural parameters are available from the Director of the Cambridge Crystallographic Data Centre.

COMPLEXES OF NAPHTHALENE-2,3-DIOL (H_2ND) WITH GROUP VI AND GROUP VIII METALS, AND THE X-RAY CRYSTAL STRUCTURE OF *CIS*-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$

(*Received* 28 *July* 1988; *accepted* 8 *September* 1988)

Abstract—The new naphthalene-2,3-diolato (2−) (ND) complexes *cis*-$[M_2O_5(ND)_2]^{2-}$, *cis*-$[MO_2(ND)_2]^{2-}$ (M = Mo, W), *trans*-$UO_2(ND)\cdot 3H_2O$, *trans*-$[OsO_2(ND)_2]^{2-}$ and *cis*-$M'(PPh_3)_2(ND)$ (M′ = Pd, Pt) have been isolated. The X-ray crystal structure of *cis*-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$ has been determined. The crystals are orthorhombic, space group *Pbca*, $a = 9.084(4)$, $b = 13.625(4)$, $c = 39.512(18)$ Å, $Z = 8$, $R = 0.041$ from 2554 observed reflections. The naphthalene-2,3-diolato ligands function as bidentate bridges, one oxygen atom of each spanning two *cis*-MoO_2 units while the other lies *trans* to a symmetric Mo—O—Mo bridge. The two naphthalene units are splayed by *ca* 18° and sheared by *ca* 24° with respect to each other. Raman, IR, ^1H and ^{13}C NMR spectra of the complexes have been recorded.

We have recently studied complexes with Group VI and VIII metals of chelating O,O′ "non-innocent" ligands such as catechol (H_2cat),[1–4] catecholamines,[5] tropolone (H trop),[6] and maltol (H malt);[7] such complexes often display unusual stereochemical or electrochemical features. We report here new complexes of molybdenum, tungsten, osmium, uranium, palladium and platinum with the ligand naphthalene-2,3-diol (H_2ND; Fig. 1) and the X-ray crystal structure of one such complex, *cis*-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$.

Surprisingly few complexes are known of this readily available ligand. There are solution studies on its complexation with molybdenum,[8–12] tungsten,[10–12] uranium,[13] iron, vanadium[8] and titanium,[8] niobium,[14] beryllium and aluminium.[15] The isolated complexes are *cis*-$[Ru(NH_3)_4(ND)]Cl$,[16] $Sn(ND)_2$ and $(Bu^n_4N)_2[Sn(ND)_3]$,[17] $(Et_3N)[Ph_3Sb(ND)Cl]$,[18] and $(pyH)[PhSi(ND)_2]$.[19] X-ray crystallographic studies were described for the latter two complexes.

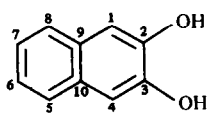

Fig. 1. Naphthalene-2,3-diol (H_2ND), with atom numbering scheme.

RESULTS AND DISCUSSION

All the complexes were prepared by the reaction of an ethanolic solution of H_2ND with the appropriate metal salt {$[MoO_4]^{2-}$, $[WO_4]^{2-}$, *trans*-$K_2[OsO_2(OH)_4]^{2-}$, *trans*-$M(PPh_3)_2Cl_2$ (M = Pd, Pt)}; the uranyl complex was made from uranyl acetate and the ligand in ethanol.

We were unable, despite many attempts, to obtain complexes with other platinum group metals with the ligand.

X-ray crystal structure of cis-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$

anion and gives the atom numbering. The molecule has approximate non-crystallographic C_2 symmetry.

The ligand is not simply bidentate as it is in $(Et_3NH)[Ph_3Sb(ND)Cl]$[18] and in (pyH)[PhSi $(ND)_2]$[19] but adopts a rôle similar to that of the catecholato ligand in *cis*-$(NH_4)_2[Mo_2O_5(cat)_2]\cdot 2H_2O$ and $Ba[Mo_2O_5(cat)_2]\cdot 5H_2O(H_2cat)$,[20] and of the 3,5-ditertbutylcatecholato ligand (H_2DBcat) in $(Bu^n_4N)_2[Mo_2O_5(DBcat)_2]$.[21] One oxygen atom [O(4) and O(18)] of each naphthalene-2,3-diolato ligand forms a single bond to each molybdenum atom [Mo(1)—O(4) 1.970(5) Å, Mo(2)—O(18) 1.994(4) Å] while the other forms an asymmetric bridge between two molybdenum atoms [Mo(1)—O(5), Mo(2)—O(5), Mo(2)—O(17), Mo(1)—O(17): 2.170(4), 2.447(5), 2.155(4) and 2.405(4) Å, respectively]. The angles subtended by the two molybdenum atoms at O(5) and O(17) are 85.8(1) and 87.2(1)°, respectively. There is also a symmetrical oxo bridge between the two molybdenum atoms [Mo(1)—O(1) 1.931(4), Mo(2)—O(1) 1.936(4) Å; Mo(1)O(1)Mo(2) angle 109.0(2)°]. These bridge distances and angles are quite close to those observed in $(NH_4)_2[Mo_2O_5(cat)_2]\cdot 2H_2O$ and in $Ba[Mo_2O_5(cat)_2]\cdot 5H_2O$ (H_2cat).[20] Thus the triangular plane O(1), O(5), O(17) forms a common face for two substantially distorted MoO_6 octahedra, and the Mo(1)—Mo(2) distance of 3.149(1) Å does not indicate any substantial metal–metal interaction.

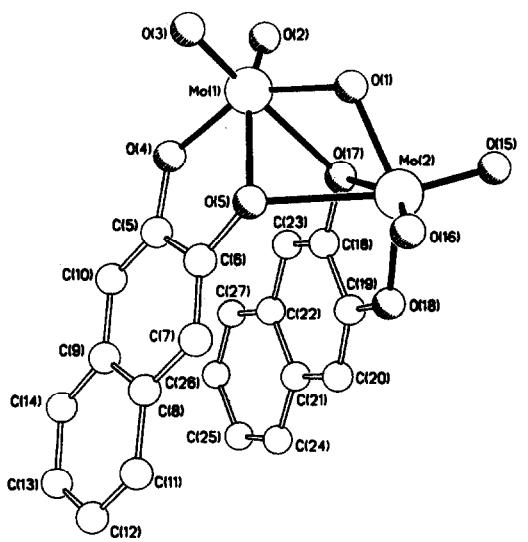

Fig. 2. Perspective view of $[Mo_2O_5(ND)_2]^{2-}$ giving atom numbering.

In addition, each Mo atom has two terminal oxo ligands *cis* to each other (mean Mo=O 1.71 Å, mean OMoO angle 105.3°) very similar to the

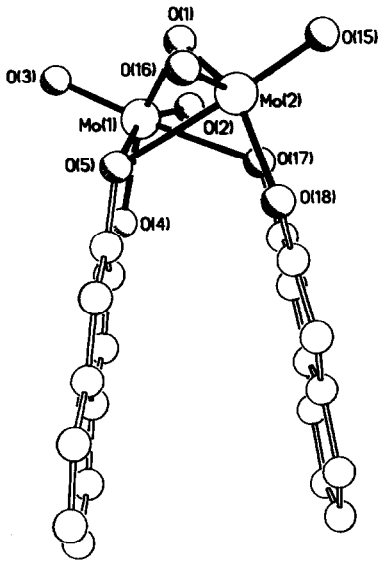

Fig. 3. View of the $[Mo_2O_5(ND)_2]^{2-}$ anion approximately in the plane of the two naphthalene units showing their splaying.

corresponding parameters in *cis*-$(NH_4)_2[Mo_2O_5(cat)_2]\cdot 2H_2O$,[20] *cis*-$K_2[MoO_2(cat)_2]\cdot H_2O$[22,23] and *cis*-$[MoO_2(trop)_2]$.[6] The *trans* effect of O(5) and O(17) gives rise to a significant lengthening (*ca* 0.2 Å) of the Mo(1)—O(5) and Mo(2)—O(17) bonds compared with Mo(1)—O(4) and Mo(2)—O(18). Analogous effects have been noted for *cis*-$[MoO_2(trop)_2]$.[6] In our complex the ligand "bite" is 76°; in $(Et_3NH)[Ph_3Sb(ND)Cl]$ it is 79.6°.[18]

The naphthalene rings are essentially planar; the splay angle between them (see Figs 3 and 4) is 18° compared with the splay angle of 20° between ligand planes in the 9,10-phenanthrenesemiquinonate (1−) (9,10-PSQ) complex $Mo_2O_5(9,10\text{-PSQ})_2$.[21]

The dianions pack "head-to-head" and "tail-to-tail" in the crystal. The ammonium cations and the water molecules create an infinite network of hydrogen bonds (Table 2) that stitch together the oxygen atoms of both adjacent and "head-to-head" molecules in the structure.

Vibrational spectra

In Table 3 we report Raman and IR spectra of the complexes. As expected, the O—H stretch [ν(O—H)] found in the free ligand at 3200–3500 cm^{-1} is not observed in the complexes, and the IR band found at 1375 cm^{-1} in the free ligand, which by analogy with catechol, we assign to an OH deformation [δ(OH)] was also not observed in the complexes. Bands near 1485 and 1270 cm^{-1} are strong in both the ligands and the complexes; the 1270 cm^{-1} mode has been assigned to ν(C=O) in $Sn(ND)_2$ and Sn(ND),[17] and that at 1485 cm^{-1} we suggest, by analogy with catecholato ligands, may arise from ν(C—C).

The molybdenum and tungsten complexes show, in addition to bands attributable to the ligand, strong Raman bands near 900 cm^{-1}, polarized in the case of aqueous solutions of $[MoO_2(ND)_2]^{2-}$ (M = Mo, W) which are weak in the IR. These we assign to $\nu_s(MO_2)$, the symmetric M=O stretch of a *cis*-MO_2 moiety. Those near 860 cm^{-1}, weak in the Raman (and depolarized in aqueous solutions of $[MO_2(ND)_2]^{2-}$) but strong in the IR we assign to $\nu_{as}(MO_2)$, the asymmetric M=O stretch of a *cis*-MO_2 moiety. Similar assignments were made for the analogous *cis*-dioxo complexes containing cat-

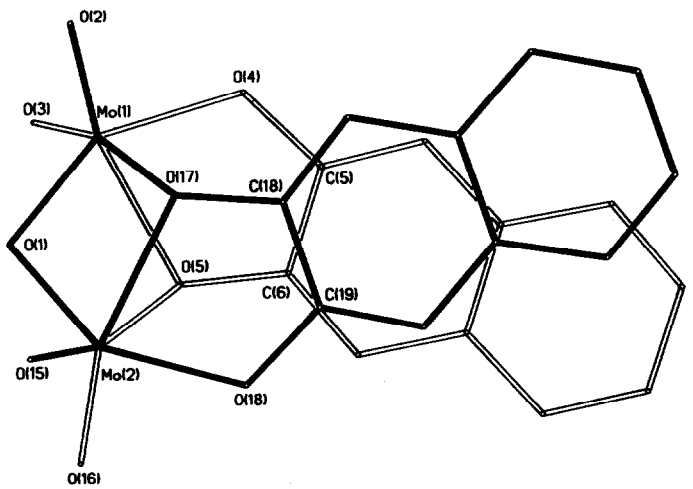

Fig. 4. Skeletal representation of the anion viewed normal to that shown in Fig. 3, showing the shearing of the naphthalene units.

Table 2. Hydrogen-bonding geometries

Atoms X—H···O	Distance (Å) X···O	H···O	Angle (°) X—H···O
N(1)—H_a···O(1)	3.14	2.21	169
N(1)—H_b···O(5)	2.99	2.07	168
N(1)—H_c···O(28)	2.91	1.98	174
N(1)—H_d···O(3)	2.98	2.24	136
N(2)—H_a···O(1)	3.04	2.12	166
N(2)—H_b···O(29)	2.83	1.92	164

N(2)—H_d···O(3)	2.98	2.08	161
O(28)—H_a···O(18)	3.02	2.20	139
O(28)—H_b···O(4)	2.85	1.97	149
O(29)—H_a···O(18)	2.85	1.93	155

echol,[1,2] catecholamine,[5] tropolone[6] and maltol[7] complexes. In $UO_2(ND)\cdot 3H_2O$ and $K_2[OsO_2(ND)_2]$, strong Raman bands at 843 and 868 cm^{-1}, respectively, have no IR counterparts, while there are strong IR bands at 930 and 830 cm^{-1}, respectively, with no Raman counterparts; these we assign, as in analogous cases[1,2,5-7] to $\nu_s(MO_2)$ and $\nu_{as}(MO_2)$ of *trans*-O=U=O ("uranyl") and *trans*-O=Os=O ("osmyl") moieties. For *cis*-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$, bands near 500 cm^{-1} are very tentatively assigned to modes arising from the symmetric stretch $\nu_s(M_2O)$ of the M^OM oxo bridge. Bands in all the complexes near 650 cm^{-1}, not found in the ligand, may arise from metal–oxygen stretches [ν(MO)] of the ligands; similar bands were also assigned for $Sn(ND)_2$ and $[Sn(ND)_3]^{2-}$.[17]

^1H *and* ^{13}C *NMR spectra*

The ^1H spectra of the ligand in $(C^2H_3)_2SO$ have recently been reported and assigned,[17] as has that of $[Sn(ND)_3]^{2-}$. In Table 3 we list our assignments for the ligand (see Fig. 1 for atom numbering scheme). The $H_{1,4}$ protons appear as a singlet while $H_{6,7}$ and $H_{5,8}$ are each composed of two indistinguishable doublets; protons of the hydroxy groups appear as broad singlets at δ 9.50 and 8.47 in $(C^2H_3)_2SO$ but are not observed in the complexes. For the complexes there is relatively little difference in the spectral pattern, but a shift to higher field is observed, consistent with electron withdrawal by the metal causing decreased electron density in the aromatic rings (similar effects are observed in catecholato complexes).[1]

The ^{13}C NMR spectrum of the ligand has been measured and assigned.[24] We were able to measure the ^{13}C spectra of *cis*-$K_2[MoO_2(ND)_2]\cdot 3H_2O$ and *cis*-$Na_2[W_2O_5(ND)_2]\cdot 6H_2O$ only, since they were the only complexes sufficiently soluble in ^2H_2O. The only two resonances to undergo major shifts are C_2 and C_3, those nuclei adjacent to the oxygen donor atoms; as in catecholato, catecholamine, tropolone and maltol complexes they are shifted to a lower field on coordination, and there is a similar but smaller consequential shift for C_9 and C_{10} (see Table 4).

EXPERIMENTAL

Preparations

cis-$(NH_4)_2[Mo_2O_5(ND)_2]\cdot 2H_2O$. Ammonium molybdate $(NH_4)_2[MoO_4]$ (0.4 g, 2 mmol) was dissolved in water (5 cm^3) and a solution of naphthalene-2,3-diol (0.32 g, 2 mmol) in ethanol (5 cm^3) was added. A brown–red solution was immediately formed which was left to cool for several hours. The orange–red crystals were filtered off, washed with a little water and diethyl ether, and finally dried *in vacuo*. Recrystallization was carried out from aqueous solution. Found: C, 36.2; H, 3.6; N, 4.1. $C_{20}H_{24}N_2O_{11}Mo_2$ requires: C, 36.4; H, 3.6; N, 4.2%).

cis-$M^I_2[MoO_2(ND)_2]\cdot nH_2O$ (M^I = K, n = 3; M^I = Ph_4P or Bu^n_4N, n = 0). Potassium molybdate, $K_2[MoO_4]$ (0.48 g, 2 mmol), was dissolved in water (5 cm^3) and a solution of naphthalene-2,3-diol (0.64 g, 4 mmol) in ethanol (5 cm^3) was added. The solution became brown–red on mixing. It was cooled and then evaporated until a solid was first seen to form. The orange–red precipitate was filtered off, washed with ethanol and diethyl ether, and dried in a desiccator. Found: C, 41.9; H, 2.8. $K_2[MoO_2(ND)_2]\cdot 3H_2O$ requires: C, 41.7; H, 3.2%.

The tetraphenylphosphonium or *n*-tetrabutylammonium salts of $[MoO_2(ND)_2]^{2-}$ were also made by addition of aqueous solutions of Ph_4PCl

[a] Shifts in ppm relative to $(CH_3)_4Si$.
[b] In 2:1 ^2H_2O–$(C^2H_3)_2SO$.

or Bu^n_4NCl such that the molar ratio of cation–metal was 2:1. Found: C, 73.0; H, 4.7. $(Ph_4P)_2[MoO_2(ND)_2]$ requires: C, 72.7; H, 4.7%. Found: C, 67.1; H, 8.6; N, 2.8. Calc. for $(Bu^n_4N)_2[MoO_2(ND)_2]$: C, 67.2; H, 9.1; N, 3.0%.

cis-$Na_2[W_2O_5(ND)_2]\cdot 6H_2O$. To sodium tungstate, $Na_2[WO_4]\cdot 2H_2O$ (0.66 g, 2 mmol) dissolved in water (5 cm^3) was added naphthalene-2,3-diol (0.32 g, 2 mmol) in ethanol (5 cm^3). A bright yellow solution was obtained which was left to stand until a yellow precipitate separated out. This was filtered off, washed with ethanol and diethyl ether, and then dried *in vacuo*. Found: C, 25.1; H, 2.6. $Na_2[W_2O_5(ND)_2]\cdot 6H_2O$ requires: C, 26.1; H, 2.6%.

The n-*tetrabutylammonium salt* $(Bu^n_4N)_2[WO_2(ND)_2]$. This was prepared by the addition of an equivalent aqueous solution of $(Bu^n_4N)Cl$ to the yellow aqueous solution of the tungsten complex. Found: C, 61.6; H, 8.1; N, 2.6. $(Bu^n_4N)_2[WO_2(ND)_2]$ requires: C, 61.4; H, 8.3; N, 2.8%.

trans-$K_2[OsO_2(ND)_2]$. Potassium osmate, *trans*-$K_2[OsO_2(OH)_4]$, was prepared by the literature method.[25]

To a solution of *trans*-$K_2[OsO_2(OH)_4]$ (0.2 g, 0.5 mmol) in water (5 cm^3), naphthalene-2,3-diol (0.16 g, 1 mmol) in ethanol (5 cm^3) was added dropwise with stirring. A dark brown colour was observed and the solution was left to cool. A fine dark precipitate separated out, and this was filtered off and treated as above. Found: C, 39.6; H, 2.2. $K_2[OsO_2(ND)_2]$ requires: C, 38.9; H, 2.0%.

trans-$UO_2(ND)\cdot 3H_2O$. To a hot solution of uranyl acetate $UO_2(CH_3COO)_2\cdot 2H_2O$ (0.84 g, 2 mmol) in ethanol (20 cm^3) was added naphthalene-2,3-diol (0.32 g, 2 mmol) in ethanol (10 cm^3). The mixture was refluxed for 2 h on a steam bath when a brown precipitate separated out, which was washed with hot ethanol and ether, and dried *in vacuo*. Found: C, 23.9; H, 2.4. $UO_2(ND)\cdot 3H_2O$ requires: C, 24.9; H, 2.5%.

$M(PPh_3)_2(ND)$ (M = Pd, Pt). Both *cis*-$Pd(PPh_3)_2Cl_2$[26] and *cis*-$Pt(PPh_3)_2Cl_2$[27] were prepared according to the literature methods. The Gandolfi[28] method was used with some modifications for the preparation of the complexes as follows: to naphthalene-2,3-diol (0.32 g, 2 mmol) in benzene (6 cm^3) and methanol (12 cm^3) was added KOH (0.22 g, 4 mmol) in methanol (12 cm^3) with stirring. To this solution *cis*-$Pd(PPh_3)_2Cl_2$ (0.85 g, 1.2 mmol) or *cis*-$Pt(PPh_3)_2Cl_2$ (0.9 g, 1.1 mmol) was added with continuous stirring at room temperature for 3.5 h, after which pink (Pd) or yellow (Pt) precipitates were isolated, washed with methanol, then water and finally with methanol followed by ether. The precipitate was dried *in vacuo*. Found: C, 69.2; H, 4.5. $Pd(PPh_3)_2(ND)$ requires: C, 70.0; H, 4.6%. Found: C, 63.1; H, 4.1. Calc. for $Pt(PPh_3)_2(ND)$: C, 62.9; H, 4.1%.

Crystal data

$C_{20}H_{24}Mo_2N_2O_{11}$, $M = 660.3$, orthorhombic, $a = 9.084(4)$, $b = 13.625(4)$, $c = 39.512(18)$ Å, $U = 4890$ Å^3, space group *Pbca*, $Z = 8$, $D_c = 1.79$ g cm^{-3}, Cu radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 91 cm^{-1}, $F(000) = 2639$.

Measurements

Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.23 \times 0.16 \times 0.03$ mm was used. 3029 independent reflections were measured ($2\theta \leqslant 110°$), of which 2554 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors; an empirical absorption correction based on 324 azimuthal measurements was applied.

Structure analysis

The structure was solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically. The ammonium and water pro-

tons were located from a ΔF map and refined isotropically subject to an N—H and O—H distance constraint. The positions of the remaining hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2\ U_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinement was by block-cascade, full-matrix least-squares to $R = 0.41$, $R_w = 0.039$ $[w^{-1} = \sigma^2(F) + 0.00024F^2]$. The maximum and minimum residual electron densities in the final ΔF map were 0.74 and -0.87 Å^{-3}, respectively. The mean and maximum shift/error in the final refinement were 0.029 and 0.295, respectively.

Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[29] Scattering factors were taken from the *International Tables for X-ray Crystallography*.*[30]

Raman spectra were measured on a Spex Ramalog 5 instrument with a Coherent Radiation Innova 90 krypton-ion laser with excitation at 6471 (red) or 5682 Å (yellow), as spinning discs with a KBr base for solids or in sealed capillaries for solutions. IR spectra were measured in liquid paraffin films between caesium iodide plates on a Perkin–Elmer 683 instrument. NMR spectra were measured on a Bruker WM-250 spectrometer.

THERMODYNAMICS OF IONIZATION OF HYPOPHOSPHOROUS AND PHOSPHOROUS ACIDS. SUBSTITUENT EFFECTS ON SECOND ROW OXY ACIDS

JOHN W. LARSON* and MARGARET PIPPIN

Department of Chemistry, Marshall University, Huntington, WV 25755-2520, U.S.A.

(*Received* 10 *June* 1988; *accepted* 28 *September* 1988)

Abstract—An NMR method has been used to determine the pK_a values for H_3PO_2 and H_3PO_3 at 5, 25, 45, 65, and 85°C. The standard enthalpies and entropies of ionization of these acids are: for H_3PO_2 −12.69 kJ and −66.3 J K^{-1}, for H_3PO_3 −14.86 kJ and −73.8 J K^{-1}, and for H_3PO_4 −7.74 kJ and −67.1 J K^{-1}. Because of its ability to participate in backbonding, substitution of OH for H leads to decreased acidity in the phosphorous oxy acid series.

Early interest in the phosphorous oxy acids H_3PO_2, H_3PO_3 and H_3PO_4 centred on the surprisingly strong acidity of lower oxidation state acids of the series. Recognition that the phosphorous acid existed in the H—$PO(OH)_2$ tautomer and hypophosphorous acid in the $H_2PO(OH)$ tautomer is a classic case of the exception proving the rule; in this case the Ricci–Pauling rules[1] of the strengths of inorganic oxy acids.

This acid series remains interesting for two reasons. First, the only interpretation of the unexpected stability of the P—H tautomers is the empirical observation[2] that "it is a general feature of phosphorous chemistry that three-valent phosphorous is never found bound to OH, but rather changes to five-valent phosphorous bound to H and =O". A more fundamental explanation grounded in bonding theory would be useful. Second, in this series the substitution of O—H for H leads to a weaker acid. This trend is opposite the inductive effect observed in other acids.

Previous studies of the acidities of hypophosphorous acid[3–7] and phosphorous acid[5–9] have resulted in widely differing values depending on the ionic strength of the solution and the temperature of the measurement. The present study was undertaken to provide pK_a values of these acids at infinite dilution and 25°C, to compare with the accurately determined value of phosphoric acid.[10] The pK_as were also determined at 5, 45, 65 and 85°C which allows calculation of the ΔH^0 and ΔS^0 of ionization of the acids. No previous experimental measurements of these quantities have been made. This additional information may help in understanding the structural dependence of the acidity of these acids.

The method used in this study is based on the work by Moedritzer[11] and Haas and Gillman[6] who observed that the NMR PH coupling constant varies with the degree of ionization of the acid.

EXPERIMENTAL

Analysis of sodium phosphite pentahydrate from BDH Chemicals and sodium hypophospite monohydrate from Fisher Scientific after heating *in vacuo* to 200°C, indicated the true formulas of $Na_2HPO_3 \cdot 4.86H_2O$ and $NaH_2PO_2 \cdot 0.79H_2O$. Stock solutions of H_3PO_2 (made by ion exchange from NaH_2PO_2), H_3PO_3 (from Aldrich) and H_3PO_4 (from Fisher Scientific) were analysed by standard acidometric titration methods. ^{31}P NMR of all pure solutions showed no oxidation of the lower valence phosphorous compounds. All solutions were made up by weight.

Proton and phosphorous magnetic resonance spectra were obtained on a Varian XL-200 spectrometer. Coupling constants were obtained for several solutions by both H and P NMR. These coupling constants were reproducible to 0.2 Hz. Temperature calibrations carried out with both a mercury in glass thermometer and using an internal

*Author to whom correspondence should be addressed.

standard of ethylene glycol indicated control to ±0.3°C.

RESULTS

Phosphorous acid

The ^{31}P NMR of phosphoric acid consists of a doublet with hydrogen–phosphorous coupling constants of 566.5 Hz for HPO_3^{-2} and 629.5 Hz for HPO_2OH^{-1} based on the direct measurements on solutions containing these species. These values are in good agreement with the values obtained by Haas and Gillman.[6] The coupling constant of 686 Hz for $HPO(OH)_2$ is based on the measured values of J_{PH} of H_3PO_3 in concentrated solutions and in 1.5 m HCl. In both cases reiterative calculations were made to correct for the degree of ionization and protonation. It is considerably higher than the value of 669 obtained previously.[6]

Determination of pK_{a_1} was made from measurements on two different series of solutions. The first series consisted of seven dilutions of a 5.294 m stock solution of pure H_3PO_3 that covered the concentration range from 4.1 to 0.09 m. The equilibrium constant for the first ionization of this acid may be calculated from the following equations

$$pK_a = -\log(m_H m_A/m_{HA}) - \log(\gamma_H\gamma_A/\gamma_{HA}) \quad (1)$$

$$m_A/m_{HA} = (686-J)/(J-629.5) \quad (2)$$

$$m_H = m_0(686-J)/56.5 \quad (3)$$

and

$$\log(\gamma_H\gamma_A/\gamma_{HA}) = 2f^\gamma + BI, \quad (4)$$

where f^γ is a function containing the Debye–Huckel limiting law and given by

$$f^\gamma = -A\{I^{1/2}/(1+1.2I^{1/2}) + (2/1.2)\ln(1+1.2I^{1/2})\} \quad (5)$$

and B is an empirical parameter. Equation (4) gives the activity coefficient to the first power in ionic strength.[10,12] Substituting these into eq. (1), gives eq. (6).

$$\log\{(686-J)^2/[56.5(J-629.5)]\} - 2f^\gamma = pK_a - BI. \quad (6)$$

Graphs of the left hand side of eq. (6) vs I yield a straight line with an intercept of pK_a at $I = 0$. A typical plot is shown in Fig. 1 for the data at 25°C.

A second series of measurements was done on a mixture of H_3PO_4, H_3PO_3 and Na_2HPO_3 in the ratio of about 1:1.75:0.5. For the proton switching reaction, eq. (7), the pK_a can be expressed by eq. (8).

$$HPO(OH)_2 + O_2P(OH)_2^{-1} = HPO_2(OH)^{-1} + OP(OH)_3 \quad (7)$$

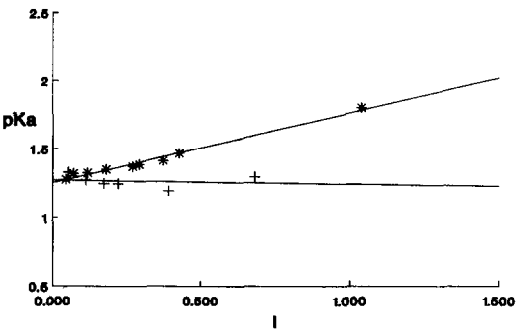

Fig. 1. Graphical determinations of the pK_a of phosphoric acid at 25°C. Values from pure H_3PO_3 (+) and from mixtures of H_3PO_3, NaH_2PO_3 and H_3PO_4 (*).

$$pK_a(HA) = pK_a(HA') - \log(m_{HA}m_{A'}/m_{HA'}m_A) - (B—B')I. \quad (8)$$

Values m_{HA}/m_A are as given in eq. (2) along with accurate temperature dependent pK_a values for phosphoric acid reported in the literature,[13] and values $m_{A'}/m_{HA'}$ calculated re-iteratively from the stoichiometry of the mixture and either acid dissociation equilibrium constant are combined to obtain values of all of the terms on the right except the last. The graphical determination of pK_a at 25°C is completed by plotting the first and second terms of this equation vs ionic strength as is shown in Fig. 1. The advantages of this second method are that no first-order correction for activity coefficients is needed for the isoelectric reaction, eq. (7), and the results are directly referenced relative to the acid to which it is most closely related.

The large slope in the plot of the second series was initially surprising. It is apparently related to the strong tendency of $H_2PO_4^-$ to H-bond with strong acids. Pitzer and Silvester[10] have discussed this characteristic in analysis of concentrated H_3PO_4 solutions. Our results indicate that the equilibrium constant is about two for reaction (9) compared to

$$HPO(OH)_2 + O_2P(OH)_2^- = HPO(OH)_2 - O_2P(OH)_2^- \quad (9)$$

the value of about 0.2 when the acid is the weaker phosphoric acid.

The agreement of the results from these two methods was excellent; always well within the uncertainty of either method. The standard deviations in pK_a values of phosphorous acid were ±0.03 by method 1 and ±0.01 by method 2. A weighted average of the two values is reported in Table 1 at 5, 25, 45, 65 and 85°C.

The most accurate previous value of pK_a is 1.29[5,7] at 18°C. This can be compared with a value of 1.19 at 18°C interpolated from the results reported here.

Table 1. pK_a values for the dissociation of H_3PO_4, H_3PO_3 and H_3PO_2 as a function of temperature

Temperature (°C)	pK_a H_3PO_4[13]	H_3PO_3	H_3PO_2
5	2.066	1.075	1.070
25	2.146	1.257	1.244
45	2.246	1.441	1.405
65	2.358	1.616	1.554
85	2.480	1.783	1.689

To obtain the most accurate relative enthalpy of ionization, a van't Hoff plot of $pK_a(H_3PO_4) - pK_a(H_3PO_3)$ vs $1/T$ led to ΔH_7^0 of -7.12 kJ mol^{-1}. This combined with the thermodynamics of ionization[13] of the reference acid, H_3PO_4, leads to the values reported in Table 2.

Hypophosphorous acid

The proton NMR of $H_2PO_2^-$ consists of a doublet with a coupling constant of 518.4 Hz that changes to a value of 575.9 Hz when protonated. Coupling constants were measured on a total of 26 different solutions between 0.5 and 1.5 in ionic strength. Six of these solutions were dilute solutions of pure H_3PO_2, 16 were buffer solutions made from either H_3PO_2 and NaH_2PO_2 or NaH_2PO_2 and HCl, and four were mixtures of H_3PO_2, NaH_2PO_2 and H_3PO_4. The results of these experiments were calculated similarly to those described in detail for phosphorous acid. As with phosphorous acid, the second virial coefficients, B, for the solutions were small except for the mixtures with phosphoric acid present, again indicating H-bonded species forming between H_3PO_2 and $H_2PO_4^-$. This data led to the pK_a values of H_3PO_2 reported in Table 1. The total uncertainty in these values is ± 0.02 and includes estimates of the uncertainties due to determination of the coupling constant for the acid and temperature calibration, as well as the 0.01 standard deviation. Our interpolated value for pK_a of 1.183 at 18°C may be compared with the literature values[5,7] of 1.10 and a value[4] of 0.99 determined at 25°C compared to our value of 1.244.

Calculation of the relative enthalpy of ionization leads to a value of 4.95 kJ more exothermic than phosphoric acid. A summary of resulting thermodynamics of ionization of all three acids is reported in Table 2. No previous enthalpy and entropy of ionization data have been reported for phosphorous and hypophosphorous acids. The uncertainties in these values are 0.9 kJ and 3 J K^{-1}, respectively.

Table 2. Thermodynamics of ionization of H_3PO_2, H_3PO_3 and H_3PO_4 at 25°C

Acid	ΔG^0 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J K^{-1}) (J K^{-1} mol^{-1})
H_3PO_4	12.25	−7.74	−67.1
H_3PO_3	7.15	−14.86	−73.8
H_3PO_2	7.10	−12.69	−66.3

DISCUSSION

The thermodynamic data in Table 2 reveal that the acidity trend of this series is due primarily to the change in enthalpy of ionization, while the entropy of ionization varies little within the series. The magnitudes of the entropies of ionization for all three acids are consistent with values for other acids where the first ionization results in anions with the negative charge delocalized primarily on two oxygen atoms, such as acetic acid (-92 J K^{-1}), H_3AsO_4 (-67 J K^{-1}) and $HClO_2$ (-87 J K^{-1}).

The enthalpy driven increase in the acidity of phosphorous acid compared to phosphoric acid is opposite to the direction expected based on the inductive effect of the OH group compared to H. Thus, in the series of acids of the form RCO_2H, RCH_2CO_2H, RNH_3^+, ROH and *meta*-substituted benzoic acids, the order of acidity is $CH_3O > HO > H > CH_3$. For the series of acids $RP(O)(OH)_2$, the order of acidity[5,14] is $H > CH_3O > HO > CH_3$, similar to the order found in *para*-substituted benzoic acids.[15] This pronounced acid-weakening effect of the RO and HO groups can be interpreted in terms of the conjugate electron donation, **II**, which stabilizes the acid. Comparable electron donation in the conjugate base is less important because the oxygen atoms already bear a partial negative charge.

I **II**

The importance of backbonding is also reflected in the dramatically increased basicity of the lone pair of electrons on phosphorous in the bases of phosphine and hypophosphorous acid. The equilibrium constants for eq. (10) may be compared to eq. (11)

$$PH_3 + H^+ = PH_4^+ \qquad K \sim 10^{-14} \qquad (10)$$

$$HOPH_2 + H^+ = HOPH_3^+ \qquad K \sim 10^{+9} \qquad (11)$$

calculated from the measured K_b^6 (10^{-2}) and the tautomer equilibrium constant[5,14] (10^{10}–10^{12}) for hypophosphorous acid.

THE TELLURIUM ANALOGUE OF THE HYDROXIDE ION: SYNTHESES AND STRUCTURE OF $(PPh_4)TeH$

JOHN C. HUFFMAN

Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

and

ROBERT C. HAUSHALTER*

Exxon Research and Engineering Company, Annandale, NJ 08801, U.S.A.

(*Received* 24 *August* 1988; *accepted* 28 *September* 1988)

Abstract—Treatment of the ethylenediamine (en) extracts from solids of nominal composition K_2SiTe_3 and K_2GeTe_3 with $(PPh_4)Br$, gives the tetraphenylphosphonium salt of the hydrogen tellurium (1−) anion, $(PPh_4)TeH$ (**1**). Telluride (**1**) was identified by elemental analysis, IR spectroscopy and a single crystal X-ray structure determination. Crystals of **1** were isomorphous with tetragonal $(PPh_4)Br$, space group $I\bar{4}$, with cell constants at −160°C of $a = 11.945(7)$, $c = 6.867(3)$ Å, $Z = 2$ and $V = 979.8$ Å^3.

While the lighter members of the chalcogenide dianions, X^{2-}, and hydrogen chalcogenide anions, XH^-, such as the oxide and hydroxide ions, have been among the most studied species in chemistry, the corresponding heavier chalcogenide anions, particularly those of tellurium, have received very little attention. Recently, the first members of the Te_x^{2-} series with $x = 3$–5 have been structurally characterized in $Te_3^{2-}\cdot en$,[1] $Te_4^{2-}\cdot 2CH_3OH$[2] and Te_5^{2-},[3] which are very intensely coloured red–purple solids. Some confusion apparently exists concerning the simplest telluride, Te^{2-}, as it has been reported to be both red[4] and colourless.[5] The protonated telluride ion, TeH^-, has not been well characterized either, even though its preparation was first reported in 1838.[6] Since Bineau's original paper[6] there have been sketchy reports in the literature on the preparation of TeH^-, which was usually prepared by the reaction of H_2Te with ammonia. In 1939, Teichert and Klemm[7] reported the preparation and characterization of M(XH) (M = Na, K, Rb, Cs; X = S, Se) but were unable to prepare TeH^- using similar procedures. An approximate equilibrium constant for the reaction $H_2Te + NH_3 \rightarrow (NH_4)TeH$ was reported in 1950[8] but was complicated by the rapid decomposition of H_2Te near 25°C. Colourless $(NH_4)_2Te$, however, can be prepared cleanly from elemental tellurium and aluminium powder in aqueous NH_3.[9] We would like to report the synthesis and characterization of $(PPh_4)TeH$ (**1**), which to our knowledge is the first example of a well characterized solid containing the hydrogen telluride (1−) anion.

EXPERIMENTAL

All operations were performed under a high purity (< 1 ppm O_2) argon atmosphere. The metals were obtained from Cerac Inc., Milwaukee, Wisconsin. Ethylenediamine (en) was purified by stirring for 2 days with CaH_2, distillation onto K_4Sn_9 and finally vacuum transfer of the en from the red solution of K_4Sn_9. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, New York.

K_2SiTe_3 *and* K_2GeTe_3

These alloys were prepared by heating stoichiometric amounts of K and Ge or Si powder (−325 mesh) to 400°C for 2 min in a quartz vessel under argon. After cooling to 25°C, a stoichiometric amount of −30 mesh Te powder was added and

*Author to whom correspondence should be addressed.

the mixture carefully melted and agitated for 5 min. The black, glassy alloys were then ground to a fine powder.

$(PPh_4)TeH$ (1)

Finely powdered K_2SiTe_3 or K_2GeTe_3 were extracted with en for 8 h with vigorous stirring using ~ 5 cm^3 en/g alloy. Filtration, followed by treatment of the filtrate with an equal volume of saturated $(PPh_4)Br$ in en, gave a 10–30% yield (based on equivalents of K_2MTe_3 used) of orange crystals of **1** after standing for 48 h. In some experiments with K_2GeTe_3 the formation of Ge/Te polyanions was also observed.[10]

Table 1

Empirical formula	$TeH^-P(C_6H_5)_4^+$
Colour of crystal	Yellow–orange
Crystal dimensions	$0.08 \times 0.09 \times 0.09$ mm
Space group	$I\bar{4}$-bar
Cell dimensions (at -160°C; 32 reflections	$a = 11.945(7)$ Å $b = 11.945(7)$ Å $c = 6.867(3)$ Å
Z (molecules/cell)	2
Volume	979.80 Å^3
Calculated density	1.586 g cm^{-3}
Wavelength	0.71069 Å
Molecular weight	468.00 g mol^{-1}
Linear absorption coefficient	16.046 cm^{-1}

RESULTS AND DISCUSSION

Extraction of the low melting, black, glassy alloys of nominal composition K_2GeTe_3 and K_2SiTe_3 with ethylenediamine (en) under H_2O/O_2 free conditions, gives solutions from which $(PPh_4)TeH$ can be isolated by treatment with saturated solutions of $(PPh_4)Br$. Since en is the only proton source in the system, the TeH^- probably forms by aminolysis of Si—Te bonds or by a reaction at the alloy surface.

Crystals of **1**, which are extremely air-sensitive and instantly turn black on exposure to air, are isomorphous with $(PPh_4)I$, space group $I\bar{4}$, with $a = 11.945(7)$ and $c = 6.867(3)$ Å (at -160°C) and $Z = 2$. The crystals were identified as **1** by elemental analysis. Found: C, 61.7; H, 4.8; P, 6.6; Te, 27.5. Calc. for $C_{24}H_{21}PTe$: C, 61.5; H, 4.5; P, 6.6; Te, 27.3%. The IR absorption spectrum shows a broad absorbance centred near 1975 cm^{-1} which we assign to the Te—H stretching modes.

The single crystal X-ray data* for **1** were collected at -160°C and solved using the coordinates for the isomorphous $(PPh_4)Br$ and refined to residuals $R = 0.0312$ and $R_w = 0.0328$. The crystal data for **1** is shown in Table 1. The structure consists of isolated TeH^- and PPh_4^+ ions. The hydrogen atom in TeH^- was not located but there were several peaks with density 0.3–0.5 e Å^{-3} near the tellurium atom. No attempt was made to refine these positions.

We have consistently found crystals of $(PPh_4)TeH$ to be orange. Since pure preparations of several Te^{2-} salts have been reported to be colourless, and electrochemically generated TeH^- is reported to be colourless,[11] it is not clear that the orange colour of crystals of **1** is necessarily due to TeH^-. The orange colour may be due to the inclusion of small amounts of hydrogen ditelluride, Te_2H^-, or decomposition of the TeH^- itself. Dihydrogen telluride, H_2Te, is thermally unstable and decomposes rapidly even at 0°C, thus one might expect limited stability for the monohydrogen derivative as well. Crystals of **1** darken upon storage over several weeks while a dilute solution of **1** in en became very dark within hours at 25°C.

In summary, the TeH^- anion is stable enough to be isolated at room temperature and has been characterized as its PPh_4^+ salt. Crystals of $(PPh_4)TeH$ slowly decompose at 25°C while solutions of TeH^- have only limited stability at 25°C.

*Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Data Centre.

CHARGE-TRANSFER COMPLEXES OF DIOXYGEN, LEWIS ACID HALIDES AND AROMATIC HYDROCARBONS*

SYDNEY BROWNSTEIN† and NAM FONG HAN

Division of Chemistry, National Research Council of Canada, Ottawa, Canada, K1A 0R9

(*Received* 22 *April* 1988; *accepted after revision* 5 *September* 1988)

Abstract—Ternary complexes of dioxygen with one of the following halides: BF_3, BCl_3, GeF_4, PF_5, $AlCl_3$, $SiCl_4$, $SnCl_4$ and $TiCl_4$, and one of hexamethylbenzene, mesitylene, anthracene and 9,10-dimethylanthracene have been identified by UV spectroscopy.

Since ternary charge-transfer complexes have been observed with nitric oxide, some aromatic hydrocarbons and some Lewis acid halides, it seemed worthwhile to investigate whether similar interactions would occur with dioxygen as the electron acceptor.[1] No interaction has been reported between dioxygen and the Lewis acid halides of this study under the very mild conditions which we employed. There is an extensive description of the interaction of dioxygen and aromatic compounds in solution. It can be summarized by saying that the interactions are so weak that they are only observable during chance collisions between the two species.[2] Interactions have been reported between aromatic hydrocarbons and BF_3,[3] $SnCl_4$ and $TiCl_4$.[4] All of these interactions are readily distinguishable from those which we have observed in the ternary systems of this study.

EXPERIMENTAL

Magnetic resonance spectra were obtained on a Bruker AM-400 spectrometer operating at 400 MHz for protons. Optical spectra were obtained on a Cary 210 spectrometer in CH_2Cl_2 as solvent, with concentrations expressed as moles per kg of solvent. Equilibrium constants have also been calculated using the same unit. ESR spectra were obtained at 77 K on a Varian E4 spectrometer. Microanalyses were performed by Canadian Microanalytical Service Ltd, Vancouver.

Chemicals

Boron, phosphorus and germanium fluorides, boron, silicon, tin and titanium chlorides, hexamethylbenzene, anthracene and 9,10-dimethylanthracene were used without further purification. Mesitylene, methylene chloride and aluminum chloride were purified and used as previously described.[5] Dioxygen was used directly from the supplier's cylinder. Sample preparation was always done using vacuum-line and dry box techniques.[5]

RESULTS AND DISCUSSION

A freshly prepared solution of hexamethylbenzene, boron trichloride and dioxygen darkens in colour during a few days at room temperature to a reddish-brown shade similar to that found with NO and BCl_3,[5] or $NOBCl_4$.[6] The most pronounced absorption bands, and where possible, the approximate concentrations and equilibrium constants are listed in Table 1. The concentrations of the complexes are obtained by assuming an extinction coefficient of 6800 for the long wavelength absorption since this was the value found in the analogous NO^+ and NO systems.[1,6] The absorbance is the net absorbance extrapolated to infinite time as listed in Table 2. With BF_3, PF_5 and GeF_4, absorptions corresponding to two distinct complexes are observed. One complex, which forms slowly, gradually decays and is replaced by the second. The results are listed in Tables 1 and 2. Representative spectra are presented in Fig. 1. In each case, the eventual complexes have rather similar optical spec-

tra. The equilibrium constants calculated in Table 1 assume complete solution of the halide and dioxygen. A more reasonable assumption is that both the halide and dioxygen are distributed between the vapour and liquid phases according to their relative volumes. From the known cell constants, corrected equilibrium constants of 45, 200 and 140 are calculated for BCl_3, BF_3 and PF_5, respectively. The absorptions due to the GeF_4 complexes were still growing at too rapid a rate after 28 days for a reasonable extrapolation to equilibrium values. In each of the preceding cases removal of all volatile materials by pumping under vacuum gave a residue of hexamethylbenzene alone, which shows that complex formation is reversible. Similar but non-quantitative results were obtained with $AlCl_3$, $SiCl_4$, $SnCl_4$ and $TiCl_4$ as Lewis acid halides. A very broad, weak and featureless absorption extending into the visible gives these complexes their characteristic colour. In every case, proton and carbon magnetic resonance spectra had signals characteristic of hexamethylbenzene alone. This is consistent with rapid exchange of hexamethylbenzene and a low concentration of its complex. If the exchange were to occur by a dissociation mechanism, it would have to be slow, since the rate of formation is slow. Therefore, one can conclude that the exchange must occur by a displacement mechanism in which a complexed hexamethylbenzene leaves as an uncomplexed aromatic molecule approaches. The rapid exchange suggests that a species with two complexed aromatic molecules may have a limited stability.

								12	0.753	0.712
								16	1.090	0.994
								23	1.558	1.101
								28	1.857	1.164

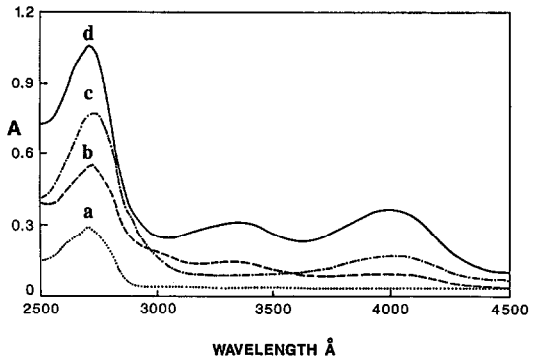

Fig. 1. UV spectra of hexamethylbenzene, dioxygen, halide systems. (a) Hexamethylbenzene alone; (b) with dioxygen and BF_3 after 10 days; (c) with dioxygen and PF_5 after 1 day; (d) with dioxygen and PF_5 after 7 days.

PF_5 form ternary charge-transfer complexes with absorption bands at 2650 and 2720 Å. The BF_3 and GeF_4 complexes also have an absorption maximum at 2920 Å while the BCl_3 complex has additional maxima at 3180 and 5140 Å, and the PF_5 complex at 3080 and 5100 Å. None of the bands were sufficiently well separated to justify equilibrium constant calculations.

Anthracene, dioxygen and BF_3 or BCl_3, but not PF_5, GeF_4 nor $SnCl_4$ react to give a dark green solid, insoluble in all the common solvents. With 9,10-dimethylanthracene as the aromatic hydrocarbon, a similar solid was obtained with BF_3, BCl_3, GeF_4 and PF_5 as Lewis acid halides. The crude product from 9,10-dimethylanthracene, BCl_3 and oxygen has: C, 64.4; H, 4.2; Cl, 11.9; O, 4.4%. The 2:1:1 complex would have: C, 68.4; H, 5.0; Cl, 19.0; O, 5.7%, which suggests that it is the primary product. These solids have a single ESR signal with a g value of 2.003. For the materials produced with BF_3 and BCl_3 there is approximately one unpaired electron for each 100 aromatic molecules.

We may conclude that in the absence of side reactions, aromatic hydrocarbons may react with dioxygen and Lewis acid halides to give charge-transfer compounds, which are weaker than the corresponding ones with NO,[1] which are weaker than those with NS^+,[7] which are weaker than those with NO^+.[5]

SYNTHESIS AND STRUCTURAL CHARACTERIZATION OF A MIXED VALENCE OCTANUCLEAR POLYOXOMOLYBDATE, $[(C_4H_9)_4N]_4[Mo_8O_{24}(OCH_3)_2]\cdot CH_3OH\cdot H_2O$

SHUNCHENG LIU and JON ZUBIETA*

Department of Chemistry, State University of New York at Albany, Albany, NY 12222, U.S.A.

(*Received* 27 *June* 1988; *accepted* 27 *September* 1988)

Abstract—Reaction of $[(C_4H_9)_4N]_2Mo_2O_7$ with hydrazones, $R_2C{=}NNH_2$, yields the novel Mo^V/Mo^{VI} mixed valence octanuclear polyoxomolybdate, $[(C_4H_9)_4N]_4[Mo_8O_{24}(OCH_3)_2]\cdot CH_3OH\cdot H_2O$. The structure of the anionic cluster consists of a tetranuclear core $[Mo_4O_8(OR)_2]^{4+}$ of edge-sharing Mo octahedra, coordinated to two bridging dipodal $[MoO_4]^{2-}$ units and two corner sharing $[MoO_4]^{2-}$ units. Crystal data: $P2_1/n$ space group, with $a = 17.166(2)$, $b = 15.719(2)$, $c = 18.933(3)$ Å, $\beta = 95.08(1)°$, $V = 5088.9(8)$ Å^3, $Z = 2$, $D_{calc} = 1.46$ g cm^{-3}. Structure solution and refinement based on 3626 reflections, $R = 0.068$.

Recent advances in the coordination chemistry of polyoxometalate anions are largely consequences of the availability of reactive polyoxoanions which are soluble in non-aqueous, organic solvents.[1] Stimulated by the pioneering work of Klemperer and co-workers,[2] the reaction chemistry of polyoxometalate anions in non-aqueous solvents has been developed to include replacement of peripheral oxo groups by organometallic units,[3–10] by a variety of simple organic ligands with oxygen,[2,11–16] nitrogen,[17–25] and sulphur donors,[26] and by inorganic ligands such as halide and sulphido donors.[27–29] Furthermore, reactions involving redox processes, as well as simple ligand substitution, have been observed under appropriate conditions to yield mixed valence Mo^V/Mo^{VI} clusters.[26,30] Exploitation of the appropriate organic reducing agents in reactions with polyoxometalates in organic solvents should permit the development of a novel class of polymetalate clusters, a tactic we have employed in the synthesis of the title complex, $[(C_4H_9)_4N]_4[Mo_8O_{24}(OCH_3)_2]\cdot CH_3OH\cdot H_2O$.

Reaction of 4 equivalents of $[(C_4H_9)_4N]_2[Mo_2O_7]$ with 1 equivalent of a hydrazone, $R_2C{=}NNH_2$, in methanol, followed by addition of ether, yields deep red crystals of the diamagnetic complex $[(C_4H_9)_4N]_4[Mo_8O_{24}(OCH_3)_2]\cdot CH_3OH\cdot H_2O$.† The IR spectrum displays a complex pattern of features between 725 and 960 cm^{-1} associated with the presence of chemically distinct terminal Mo–oxo groups and bridging Mo–oxo groups. The single strong absorption at 957 cm^{-1} is characteristic of ν(Mo=O) for Mo^V–oxo sites, while the 729 cm^{-1} feature is assigned to triply bridging oxo groups (Mo_3O). Other absorptions in this region were not assigned. The electronic spectrum displays intense charge-transfer transitions (O → Mo) at 225 and 318 nm. The complex crystallizes in the monoclinic space group $P2_1/n$ with $a = 17.166(2)$, $b = 15.719(2)$, $c = 18.933(3)$ Å, $\beta = 95.08(1)°$, $V = 5088.9(8)$ Å^3, $Z = 2$ (based upon the octanuclear formulation), $D_{calc} = 1.46$ g cm^{-3}. A total of 5734 reflections were collected within the limits $2° \geqslant 2\theta \geqslant 45°$. Structure solution and refinement based upon 3626 reflections

with $F_o > 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å) converged at $R = 0.068$.*

The structure of the complex anion $[Mo_8O_{24}(OCH_3)_2]^{4-}$ is shown in Fig. 1, with selected bond lengths and angles listed in the caption. The structure consists of discrete octanuclear anions, constructed from edge- and corner-sharing Mo octahedra and tetrahedra. The central core of the structure is provided by four edge-sharing Mo octahedra associated with Mo(1), Mo(2), Mo(1a) and Mo(2a). The Mo(1) centres of this tetranuclear core exhibit coordination to two triply bridging oxo groups, two doubly bridging oxo groups, a terminal oxo group and a bridging methoxy group; while the Mo(2) centres are bonded to a single triply bridging oxo unit, three doubly bridging oxo groups, a terminal oxo group and a bridging methoxy group. The short Mo(1)—Mo(2) distance of 2.599(2) Å is characteristic of Mo^V/Mo^{VI} mixed valence complexes and consistent with direct metal–metal bonding, providing a mechanism for magnetic coupling of two Mo^V d^1 sites localized in the tetranuclear unit.[31] A most unusual feature of the structure is the presence of structurally distinct tetrahedral $[MoO_4]^{2-}$ units. While the Mo(3) groupings adopt bridging, dipodal geometry spanning opposite edges of the tetranuclear core, the tetrahedral units associated with the Mo(4) centres assume a corner-sharing linkage mode to the Mo(2) centres of the core. Although both the dipodal bridging tetrahedral groups[18,21] and the corner-sharing monodentate $[MoO_4]$ unit[32] have precedents in polyoxomolybdate chemistry, the title complex provides a unique instance of a structure displaying both coordination types.

As illustrated in Fig. 2, the tetranuclear core of $[Mo_8O_{24}(OCH_3)_2]^{4-}$ is identical to that previously reported for $[Mo_4O_8(OR)_4Cl_4]^{2-}$.[22,23] The structures are related by substitution of the terminal alkoxy and chloride ligands of $[Mo_4O_8(OR)_4Cl_4]^{2-}$ by the bridging and terminal $[MoO_4]^{2-}$ groups of $[Mo_8O_{24}(OCH_3)_2]^{4-}$, retaining the common $[Mo_4O_8(OR)_2]^{4+}$ core. This structural analysis emphasizes the ability of the $[MoO_4]^{2-}$ unit to function as a ligand, the linkage flexibility of the $[MoO_4]^{2-}$ ligand, and the ease of substitution of peripheral ligand groups associated with polymolybdate structures, while maintaining the integrity of the structural core.

*Final atomic positional and thermal parameters, bond lengths and angles, and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have been submitted to the Cambridge Crystallographic Data Centre.

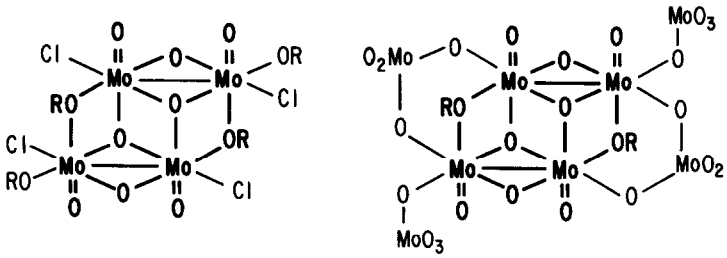

Fig. 2. Schematic representations of the structures of $[Mo_4O_8(OR)_4Cl_4]^{2-}$ and $[Mo_8O_{24}(OMe)_2]^{4-}$, showing the common tetranuclear core, $[Mo_4O_8(OR)_2]^{4+}$.

The presence of reduced Mo^V centres in the structure establishes the role of the hydrazone reagent as a reducing agent, functioning in a Wolff–Kishner type of reduction reaction.[33] The use of organic reducing agents appears to provide a facile methodology for the introduction of Mo^V sites into polymolybdate clusters,[26,33,34] which, when combined with the exploitation of the propensity toward aggregation of organic soluble $[MoO_4]^{2-}$ units, allows the synthesis of novel cluster species with unusual electronic and redox properties. Investigations of the chemical and electrochemical reduction of polyoxomolybdate species in organic solvents are currently under investigation.

Abstract—Crystalline peroxo molybdate(VI) complexes with imidazole are reported: $(C_3H_5N_2)_2[O\{MoO(O_2)_2H_2O\}_2]$ (**1**), $MoO_2(O_2)(C_3H_4N_2)2H_2O$ (**2**) and $K_2MoO_2(O_2)_2(C_3H_4N_2)4H_2O$ (**3**). They represent the first peroxo metal compounds containing imidazole. IR spectra display characteristic ν(Mo═O) between 967 and 955 cm^{-1}, and ν(O—O) between 892 and 853 cm^{-1}. The X-ray crystal structure of (**1**) shows the presence of a μ-oxo group bridging two pentagonal bipyramidal $\{MoO(O_2)_2H_2O\}$ moieties, each hydrogen bonded to an essentially planar imidazolium cation via one of the oxygens of a coordinated peroxo group.

Peroxo molybdenum compounds are selective oxidation catalysts[1,2] and molybdenum is important in biochemistry. We report here the first peroxo complexes containing imidazole to be isolated from aqueous solutions, which are also the first molybdenum compounds with imidazole. This work demonstrates that imidazole remains unchanged in the aqueous peroxo Mo^{VI} solutions, where catalytic conversion of malic, malonic and aspartic acid to oxalates, and nicotinic acid to N-oxide has been observed.[3,4] The imidazole group of histidine side chains participates in the binding of metal atoms in many metalloproteins, and has been found to coordinate to Mo^{V} in a histidine complex.[5] In view of the presence of molybdenum at active centres of enzymes and catalysts which catalyse hydrogenation and selective oxidation,[6] it is important to discover the reactivity of imidazole in the presence of molybdenum peroxides.

Three crystalline yellow solids containing imidazole, peroxides and molybdenum were separated from aqueous solutions: the prismatic title complex (**1**), the thin needle crystals corresponding to an empirical composition $MoO_2(O_2)(C_3H_4N_2)2H_2O$ (**2**) and the microcrystalline potassium salt of composition $K_2MoO_2(O_2)_2(C_3H_4N_2)4H_2O$ (**3**). Found: C, 12.7; H, 2.1; N, 9.7; O_2^{2-}, 13.0. Calc. for (**2**), $MoC_3H_8N_2O_6$: C, 13.6; H, 3.0; N, 10.6; O_2^{2-}, 12.2%. Found: C, 7.8; H, 2.1; N, 6.0; O_2^{2-}, 16.5. Calc. for (**3**), $K_2MoC_3H_{12}N_2O_{10}$: C, 8.8; H, 2.9; N, 6.8; O_2^{2-}, 15.6%. Complexes (**1**) and (**2**) were prepared by dissolving MoO_3 (1.44 g, 10 mmol) in 30% hydrogen peroxide (10 cm^3), and adding imidazole (0.68 g, 10 mmol) dropwise and slowly, to a clear, yellow solution under stirring while maintaining the temperature between 45 and 50°C. The resulting brown–red reaction mixture was then

*Author to whom correspondence should be addressed.

stirred for 1 h, until the yellow colour returned. Prismatic crystals separated from this solution on standing at room temperature for about 24 h, at pH 4.0–4.5. They decomposed explosively at about 125°C. Rapid imidazole addition lead to overheating, and a mixture of crystals from complexes (**1**) and (**2**) was generally obtained from such preparations. Pure needle crystals of (**2**) were prepared essentially in the same manner as (**1**), but successful preparations were sparse. Faster imidazole addition, higher temperature and omission of stirring of the reaction mixture at the end, seemed to help. Although appearing over a wide pH range of 4–6, complex (**2**) precipitated best between pH 5 and 6. Complex (**3**) was synthesized by adding KOH to the reaction mixture described above, and raising the pH to about 6. The separation of a pure complex was difficult again, because of coprecipitation of various potassium oxoperoxo molybdates, having similar lattice energy and solubility, formed in solution at higher pH.

Yellow prismatic crystals of the title complex (**1**) are so far the only ones large enough for X-ray structure analysis. Crystal data: $(C_3H_5N_2)_2[O\{MoO(O_2)_2H_2O\}_2]$, monoclinic, $a = 14.516(3)$, $b = 6.802(2)$, $c = 15.187(4)$ Å, $\beta = 91.99°$, $U = 1561.7$ Å, space group $I2/a$, $Z = 4$. X-ray diffraction data were collected by standard methods on an Enraf–Nonius four-circle CAD-4 diffractometer, using Mo radiation ($\lambda = 0.71073$ Å). Of 7055 independent reflections, 3939 were used [$F_o^2 \geq 3\sigma(F_o^2)$] in the final refinement of the structural parameters; $R = 0.042$, $R_w = 0.050$. A three-dimensional Patterson synthesis was used to determine the heavy atom positions, which phased the data sufficiently well to permit location of the remaining non-hydrogen atoms from Fourier synthesis. Full-matrix least-squares refinement was carried out.

The structure of the complex is shown in Fig. 1. The coordination about each molybdenum atom is essentially that of a pentagonal bipyramid, found previously in a number of complex peroxo molybdates[VI].[1–4,7–11] The axial positions are occupied by the terminal oxo group, Mo=O, 1.682(2) Å, and the oxygen of a weakly coordinated water molecule, Mo—O, 2.441(2) Å, resembling the structures of dimeric $K_2[O\{MoO(O_2)_2H_2O\}_2]$[7] and $(pyH)_2[O\{MoO(O_2)_2H_2O\}_2]$,[8] and monomeric $MoO(O_2)_2(\alpha\text{-AA})H_2O$ (α-AA = gly, pro).[11] The equatorial plane in (**1**) is formed by four peroxo oxygens and the central bridging oxygen, with none of the atoms deviating more than 0.04 Å from the mean plane, and the molybdenum atom placed 0.37 Å above this plane. The equatorial plane is essentially orthogonal to the plane containing the symmetrically bridging oxygen (Mo—O, 1.914(2) Å; Mo—O—Mo angle, 149°), the Mo=O bond, and the water oxygen. The imidazolium ring is hydrogen bonded to an oxygen of a peroxo group, (N···O) 2.794(2) Å. The Mo—O(peroxo) and the O—O bond lengths fall in the expected range[3,4,7–11] and are 1.953(7) and 1.466(4) Å, respectively. The imidazolium cation is essentially planar, with no atom more than 0.07 Å out of the least-squares plane. A significant shortening of the C(4)—C(5), 1.298(8) Å and N(1)—C(5), 1.321(5) Å, bonds has occurred when compared with the non-protonated free or coordinated imidazole.[12–14]

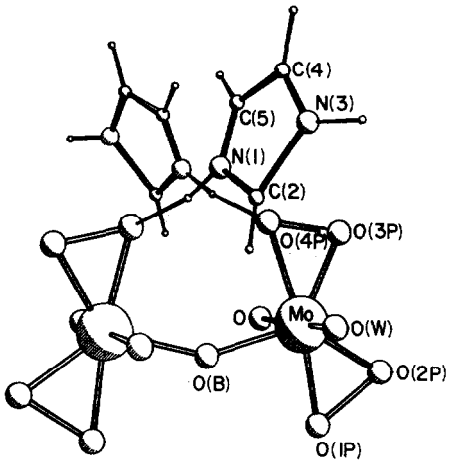

Fig. 1. The structure of $(C_3H_5N_2)_2[O\{MoO(O_2)_2H_2O\}_2]$.

IR spectra of complexes (**1**), (**2**) and (**3**) differ in a significant way. In addition to imidazole bands,[15,16] they all show strong bands assigned to ν(Mo=O) and ν(O—O),[1–4,9–11] which are distinct for each complex. Complex (**1**) only displays a strong band at 3279 cm^{-1}, assigned to ν(NH) of the imidazolium cation,[15] with ν(Mo=O) and ν(O—O) occurring at 964 and 853 cm^{-1}, respectively. In the spectrum of complex (**2**), ν(Mo=O) and ν(O—O) appear as broad and poorly resolved bands at 955 and 892 cm^{-1}, indicating the presence of a polymeric, probably very complex structure.[17] A well resolved spectrum of complex (**3**) shows ν(Mo=O) and ν(O—O) bands at 967 and 858 cm^{-1}, respectively. Additional bands appear in the spectra of complexes (**2**) and (**3**) between 350 and 300 cm^{-1}, most likely due to the ν(Mo—N) from the imidazole coordinated to molybdenum. Cyclic voltammograms of the complexes in aqueous solutions show three irreversible pH dependent cathodic (−900 to −1350 mV) and anodic (1100–1300 mV) peaks. A cathodic shift of about 75 mV was observed for complex (**1**), implying that species generated at the electrode interphase differ, and that it is more difficult to reduce molybdenum in complex (**1**).

These studies indicate that in molybdenum–peroxide–imidazole aqueous systems, complex equilibria exist among several oxoperoxo metal species involving imidazole. These equilibria depend upon the concentration of the components, the pH and the temperature. At the lowest pH (4–5) the imidazolium complex (**1**) was separated, and at only slightly higher pH (5–6) the coordination of imidazole to molybdenum induced the precipitation of complexes (**2**) and (**3**). Lattice energy and solubility of the crystals are responsible for the selection of a particular complex species to be isolated, and coprecipitation of several compounds is common because of their similar solubility. In spite of such difficulties, separation of the equilibrium species into the solid phase remains one of the best ways to understand the reactivity of such systems in the solution. Experiments to obtain crystals of (**2**) and (**3**) large enough for X-ray structure analysis are currently in progress.

SYNTHESIS, STRUCTURE AND PROPERTIES OF MONONUCLEAR AND DINUCLEAR MOLYBDENUM(III) BROMIDE COMPOUNDS. LIGAND-INDUCED, REVERSIBLE BREAKAGE OF A METAL–METAL BOND IN $Mo_2Br_6(dppe)_2$

BETH E. OWENS and RINALDO POLI†

Department of Chemistry and Biochemistry, University of Maryland, College Park, MD 20742, U.S.A.

(*Received* 29 *July* 1988; *accepted* 7 *October* 1988)

Abstract—$MoBr_3(THF)_3$ reacts with 1 equivalent of bis(diphenylphosphino)ethane (dppe) in THF to yield $MoBr_3(dppe)(THF)$ (**1**). The THF ligand in the latter molecule can be easily replaced by MeCN to afford $MoBr_3(dppe)(MeCN)$ (**2**). When treated in a non-donor solvent, **1** loses THF and dimerizes to one of two isomeric $Mo_2Br_6(dppe)_2$ molecules (green, **3**, kinetic product; purple, **4**, thermodynamic product) depending on experimental conditions. An X-ray analysis of **4** shows an edge-sharing bioctahedral structure and the presence of a Mo—Mo bond. Both **3** and **4** can be reconverted to the parent compound **1** by warming in the presence of excess THF. Compound **2** can also be transformed into the dinuclear compound **4**.

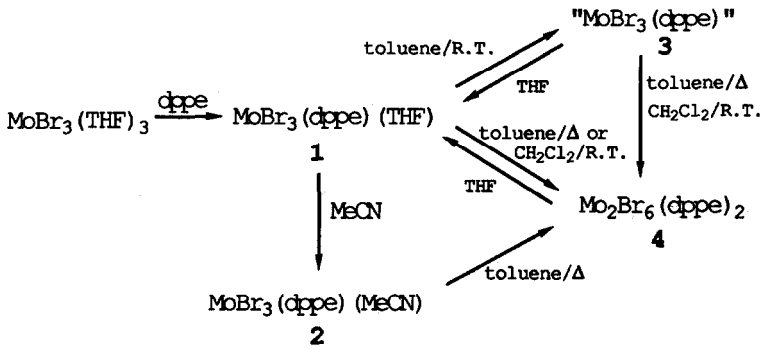
The chemistry of molybdenum compounds in oxidation state III is extremely vast and offers many possible applications, ranging from catalysis to materials science to biochemistry. The chemistry of molybdenum(III) is also among the richest in the field of metal–metal bonding.[1] The simple mononuclear, octahedral compounds of stoichiometry MoX_3L_3 (X = anionic ligand, L = neutral ligand) have been prepared with a variety of different neutral ligands, but most of the studies have been restricted to the trichloride system.[2] This fact can be attributed to the lack of simple preparative procedures for useful starting materials such as $MoX_3(THF)_3$ (X = Br, I; THF = tetrahydrofuran), similar to the widely used $MoCl_3(THF)_3$ where the THF ligands are easily replaced by other ligands. This is unfortunate for several reasons: a comparative study of different molybdenum(III) halide derivatives can be helpful for assessing the importance of electronic and steric factors on chemical reactivity; the bromide and iodide compounds may provide alternative and possibly better starting materials for the generation of other molybdenum(III) compounds as well as compounds of molybdenum in different oxidation states; finally, new types of reactivity and/or structural features may be found.

Cotton and Poli recently reported the synthesis, structure and THF replacement chemistry of $MoI_3(THF)_3$.[3] We successfully applied the same strategy to the large-scale preparation of the already known[4] $MoBr_3(THF)_3$.‡ We report here preliminary studies on THF substitution chemistry on $MoBr_3(THF)_3$ which led to the observation, to our knowledge unprecedented, of a ligand-induced and reversible interconversion between a mononuclear and a metal–metal bonded dinuclear compound.

A suspension of $MoBr_3(THF)_3$ in THF reacts smoothly at room temperature with an equimolar amount of bis(diphenylphosphino)ethane (dppe) to afford a clear orange solution containing $MoBr_3(dppe)(THF)$ (**1**), which can be isolated as a yellow, slightly air-sensitive microcrystalline solid in good yields by addition of diethyl ether to con-

† Author to whom correspondence should be addressed.

‡ $Mo_2Br_4(CO)_8$ and Br_2 in equimolar amounts were stirred together in THF for a few hours at 0°C, then overnight at room temperature. A 90% yield of analytically pure material was obtained.



Scheme 1.

centrated solutions.† We believe **1** is a mononuclear, octahedral complex, with a *mer* arrangement of the three bromo ligands, on the basis of an X-ray crystal structure determination on the corresponding triiodide molecule[5] and the similarity of the IR spectra of the two compounds. Also, octahedral trihalide complexes of molybdenum, as well as of other metals, are known to prefer the *mer* arrangement with only a few documented exceptions.[6]

The THF molecule in **1** can be easily replaced by other ligands (see Scheme 1). Compound **2**, $MoBr_3$(dppe)(MeCN), can be obtained by adding an excess of acetonitrile to THF solutions of **1**, although better yields can be obtained by reacting the isolated **1** with pure MeCN.‡

When compound **1** is dissolved in a solvent other than THF and no other ligand is present, it slowly loses the coordinated THF molecule and converts into a different product, the nature of which depends upon the experimental conditions employed. In toluene at room temperature a green–brown compound, **3**, precipitates. In CH_2Cl_2 or in refluxing toluene a purple compound, **4**, is obtained. **3** can be converted into **4** under the same conditions where the latter is obtained directly from **1**. Both compounds **3** and **4** analyse correctly for $MoBr_3$(dppe).§ The recrystallization of **3** and **4** is rather problematic. Any attempt to recrystallize **3** results in its partial conversion to **4**. Compound **4** easily incorporates the crystallization solvent§ to afford very poorly soluble forms of the compound that are then impossible to separate from other insoluble impurities. Compound **4** is slightly soluble in polar chlorinated hydrocarbons but an attempt to recrystallize it from hot 1,1,2-trichloroethane resulted in decomposition. The change of colour from purple to orange–red and the shift of a visible absorption band, λ_{max}, from 558 to 495 nm suggest that at least partial halide exchange with the solvent may have taken place. $Mo_2Cl_6(dppe)_2$ has $\lambda_{max} = 507$ in CH_2Cl_2.[7]

Single crystals of **4** that were suitable for an X-ray analysis were obtained from $CHCl_3$.‖ The compound is dinuclear with an edge-sharing bioctahedral configuration, the six bromo ligands occupy-

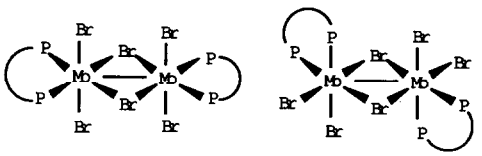
§ Compound **3**. Found: C, 42.5; H, 3.5; Br, 30.7. Calc. for $C_{26}H_{24}Br_3MoP_2$: C, 42.5; H, 3.3; Br, 32.7%. Compound **4** typically gave analyses consistent with the incorporation of variable amounts of the crystallization solvent. An X-ray analysis confirmed the presence of interstitial solvent (see text). A sample of compound **4** obtained in **1** in refluxing toluene analysed correctly. Found: C, 42.8; H, 3.2; Br, 32.2. IR (Nujol mull/cm^{-1}): 3050 w, 1590 w, 1580 w, 1490 m, 1415 w, 1440 s, 1195 w, 1160 w, 1100 m, 1075 w, 1030 w, 1005 w, 870 w, 830 w, 815 w, 745 m, 705 m, 695 s, 675 w, 650 vw, 620 vw, 525 m, 520 m, 500 w, 475 w. UV–vis [CH_2Cl_2, R.T., λ_{max}/nm (ε)]: 345(25810), 555(2040).

‖ Crystal data for compound **4**·$4CHCl_3$: monoclinic; space group $I2/m$; $a = 15.653(2)$; $b = 19.180(4)$; $c = 13.723(2)$ Å; $\beta = 108.52(1)°$; $V = 3907(2)$ Å^3; $d_c = 1.65$ g cm^{-3}; μ(Mo-K_α) = 40.85 cm^{-1}. At the end of the structure refinement for $Mo_2Br_6(dppe)_2$, a few clusters of peaks appeared in the difference Fourier map in the proximity of the crystallographic mirror planes, but it was not possible to assign a reasonable model to any of them. The number of interstitial chloroform molecules (four per dimer) is inferred by comparison with the published isostructural $Mo_2Cl_6(dppe)_2 \cdot 4CH_2Cl_2$,[7] considering that CH_2Cl_2 and $CHCl_3$ occupy roughly the same volume. The final agreement factor reached ($R = 0.13$) is for the model not including any disordered solvent molecules.



I II

ing the four axial and the two bridging positions, as illustrated in I. Because of disorder in the interstitial solvent molecules we have not been able to refine the structure to a perfectly acceptable *R* factor† and we wish to report here these crystallographic data insofar as they establish the geometry of the complex and to indicate the presence of a metal–metal interaction [Mo—Mo′ = 2.799(7) Å].

Other edge-sharing bioctahedral compounds of molybdenum(III) with bridging chloro, hydroxo and alkylsulphido ligands have been structurally characterized. They exhibit a Mo—Mo distance in the range 2.47–2.79 Å.[8] $Mo_2Cl_6(dppe)_2$ has also been recently reported,[7] having a Mo—Mo distance of 2.762(1) Å. The metal–metal interaction in this type of compound has been described in terms of either a $\sigma^2\pi^2\delta^2$ or a $\sigma^2\pi^2\delta^{*2}$ electronic configuration.[7,9]

Even at the level of structure refinement which was achieved, it seems that compound **4** has a slightly larger metal–metal distance than any of the molybdenum(III) edge-sharing bioctahedral dimers reported to date.[8] This is consistent with the higher bulk of the bridging ligand and should reflect on the strength of the metal–metal interaction and ultimately on the chemical reactivity of the compound.

Compound **4** is converted back to the parent compound **1** when warmed in neat THF or in 1,1,2-trichloroethane containing a large excess of THF, as shown by UV–vis spectroscopic monitoring of the reaction. The attainable temperature in refluxing CH_2Cl_2 is insufficient to cause the same transformation.

There are several examples in the literature of dinuclear, halide-bridged compounds that are reversibly converted to mononuclear complexes by addition/removal of donor solvent molecules[10] but, to the best of our knowledge, none of these contain a direct metal–metal interaction. $MoCl_3(PMe_3)_3$ is reported to lose one PMe_3 ligand in refluxing toluene to afford a product described as the edge-sharing bioctahedral $Mo_2Cl_6(PMe_3)_4$, but no structural data are reported for the product and the "back-reaction" has not been described.[11]

Compound **2** is stable at room temperature towards loss of the monodentate neutral ligand and dimerization to compounds **3** and/or **4**. Heating in toluene at the reflux temperature smoothly converts compound **2** into compound **4**. This observation suggests a Mo^{III}–ligand bond strength in the order THF < MeCN.

Concerning the nature of compound **3**, if we exclude the unlikely possibility of a five-coordinate monomer, the most reasonable guess is that we have a dinuclear structure as represented in II. Although most of the edge-sharing bioctahedral compounds with bis-chelating diphosphines that have been structurally characterized show an arrangement of type I,[8a] there is at least one precedent for a structure of type II, $Mo_2Cl_6(EtSCH_2CH_2SEt)_2$.[8b] Consistent with our structural assignment, compound **3** is also converted into compound **1** when heated in THF. We are planning to undertake kinetic and equilibrium studies on this system and on others containing diphosphine ligands with different steric/electronic properties.

No chemical reactivity has been reported for the chloride analogue of compound **4**, $Mo_2Cl_6(dppe)_2$,[7] but on the basis of its reported metal–metal bond distance, its conversion to the mononuclear compound $MoCl_3(dppe)(THF)$ should be harder. Conversely, the transformation of the hypothetical monomer into the dimer should be easier. With the triiodide system, however, the opposite behaviour is expected because of the higher bulk of the iodo ligands. Work is in progress in our laboratory to test these hypotheses.

THE USE OF HEXAMETHYLDISILTHIANE IN THE SYNTHESIS OF TRANSITION METAL THIOHALIDES

VERNON C. GIBSON,* ALAN SHAW and DAVID N. WILLIAMS

Department of Chemistry, University Science Laboratories, South Road, Durham DH1 3LE, U.K.

(*Received* 19 *September* 1988; *accepted* 11 *October* 1988)

Abstract—The thiohalide compounds $W(S)Cl_4$, $W(S)_2Cl_2$, $Mo(S)Cl_3$, $Nb(S)Cl_3$, $Ta(S)Cl_3$, $Nb(S)Cl_3(CH_3CN)_2$, $Ta(S)Cl_3(CH_3CN)_2$, $Mo(O)(S)Cl_2$ and $W(O)(S)Cl_2$ may be obtained in high yield by low temperature treatment of the appropriate metal halide with hexamethyldisilthiane.

Transition metal thiohalides have proved accessible by a variety of methods.[1–6] However, most routes involve high temperature sealed tube/furnace procedures. The only report of a generally applicable room temperature procedure concerns the reaction of transition metal halides with Sb_2S_3 in CS_2 solvent over 1–3 days.[7]

In recent studies, we have shown that hexamethyldisiloxane is a particularly useful reagent for the mild synthesis of oxyhalide materials[8,9] according to eq. (1).

$$MCl_x + (Me_3Si)_2O \longrightarrow M(O)Cl_{x-2} + 2Me_3SiCl. \quad (1)$$

Therefore, we envisaged that the analogous sulphur reagent, $(Me_3Si)_2S$, would be suitable for the controlled, mild synthesis of related thiohalide compounds [eq. (2)] which are not conveniently accessible by other methods.

$$MCl_x + (Me_3Si)_2S \longrightarrow M(S)Cl_{x-2} + 2Me_3SiCl. \quad (2)$$

Indeed, we have found that reactions of transition metal halides with $(Me_3Si)_2S$ proceed with such exothermicity that cooling is generally required. Thus, dropwise addition of a cooled (−30°C) dichloromethane solution of $(Me_3Si)_2S$ to a suspension of the appropriate metal halide in dichloromethane at −78°C, followed by warming of the mixture to room temperature with stirring allows the high yield preparation of the known thiohalide compounds $Mo(S)Cl_3$, $W(S)Cl_4$, $W(S)_2Cl_2$, $Nb(S)Cl_3$ and $Ta(S)Cl_3$. This procedure also allows the synthesis of the mixed oxythiohalide derivatives $W(O)(S)Cl_2$ and $Mo(O)(S)Cl_2$. The tungsten compound may be obtained from WCl_6 by sequential treatment with equimolar amounts of $(Me_3Si)_2O$ and $(Me_3Si)_2S$ in either order of addition. $Mo(O)(S)Cl_2$ is obtained from the reaction of $Mo(O)Cl_4$ with $(Me_3Si)_2S$ and, to our knowledge, has not been reported previously.

If the reaction is carried out in a coordinating solvent such as acetonitrile, then solvent adducts such as $Nb(S)Cl_3(CH_3CN)_2$ and $Ta(S)Cl_3(CH_3CN)_2$ may be obtained in excellent yield [eq. (3)].

$$MCl_5 + (Me_3Si)_2S \xrightarrow{CH_3CN(s)} M(S)Cl_3(CH_3CN)_2 \quad M = Nb, Ta. \quad (3)$$

Here, we give details of the preparations of base-free $W(S)Cl_4$ and the solvent adduct $Nb(S)Cl_3(CH_3CN)_2$. Commercially available reagents can be tolerated since the solubility of the products allows their ready purification. The other less soluble thiohalide materials may be prepared by essentially analogous procedures, but it is advisable to use pure reagents e.g. locally prepared $(Me_3Si)_2S$[10] rather than commercially available material [commonly contaminated with $(Me_3Si)_2O$] since subsequent separation of oxide contaminants is less easy.

EXPERIMENTAL

All reactions and product manipulations were performed on a conventional vacuum line using standard Schlenk techniques, or in a dry-box under an atmosphere of argon. Solvents were dried, distilled and degassed prior to use. Metal, sulphur and halide analyses were provided by the microanalytical service at Durham. IR spectra (Nujol mulls between KBr and/or CsI plates) were recorded using Perkin–Elmer 577 and 457 spectrophotometers. $MoCl_5$, WCl_6, $NbCl_5$, $TaCl_5$ (Aldrich) and $Mo(O)Cl_4$ (Alfa) were either used as received or purified, where necessary, by sublimation. $W(O)Cl_4$ was prepared by a literature procedure.[8] $(Me_3Si)_2S$ is commercially available (Fluka) or may be prepared by a literature procedure.[10]

Synthesis of $W(S)Cl_4$

A dichloromethane solution of $(Me_3Si)_2S$ (2.25 g, 12.6 mmol in 15 cm^3 CH_2Cl_2) was added dropwise with stirring to a suspension of WCl_6 (5.0 g, 12.6 mmol) in dichloromethane (20 cm^3) at $-78°C$, over a period of 15 min. An immediate reaction ensued leading to a red solution and precipitation of a brown, amorphous solid. The mixture was allowed to warm to room temperature and stirred for a further 30 min. Filtration of the supernatant solution, followed by concentration and cooling to $-78°C$ afforded red moisture sensitive crystals of $W(S)Cl_4$ (2.95 g, 65%). A second extraction of the residue with CH_2Cl_2 (20 cm^3) followed by crystallization resulted in a combined yield of 75% of analytically pure $W(S)Cl_4$. Found: W, 51.5; Cl, 39.5; S, 9.0. Calc. for Cl_4SW: W, 51.4; Cl, 39.6; S, 9.0%. IR: ν(W=S) 560 cm^{-1} (sharp, strong).

Synthesis of $[Nb(S)Cl_3(CH_3CN)_2]$

An acetonitrile solution of $(Me_3Si)_2S$ (1.97 g, 11.1 mmol in 10 cm^3 CH_3CN) was added dropwise to a suspension of $NbCl_5$ (3.0 g, 11.1 mmol) in acetonitrile (20 cm^3) at $-30°C$. The mixture was warmed to room temperature with stirring to give a green solution which gradually turned yellow with stirring overnight. The volatile components were then removed under reduced pressure and the residue was dried *in vacuo* to give a 95% yield of crude $Nb(S)Cl_3(CH_3CN)_2$. An analytically pure sample was obtained by re-extraction with CH_3CN (30 cm^3), followed by filtration, concentration to half volume and cooling to $-30°C$ to afford yellow crystals. Yield 2.26 g (65%). Found: Nb, 29.9; Cl, 32.9; S, 10.1; C, 15.1; H, 2.0; N, 8.1. Calc. for $C_4H_6N_2Cl_3NbS$: Nb, 29.7; Cl, 33.9; S, 10.2; C, 15.3; H, 1.9; N, 8.9%. IR: ν(C≡N) 2310(s), 2280(s); ν(Nb=S) 532(s) cm^{-1}.

NEW PRECURSORS FOR CHEMICAL VAPOUR DEPOSITION OF PLATINUM AND THE HYDROGEN EFFECT ON CVD

R. KUMAR, S. ROY, M. RASHIDI and R. J. PUDDEPHATT*

Department of Chemistry, University of Western Ontario, London, Canada N6A 5B7

(*Received* 14 *August* 1988; *accepted* 24 *October* 1988)

Abstract—Volatile organoplatinum(II) complexes have been studied as precursors for low temperature chemical vapour deposition (CVD) of platinum films. The temperature of CVD and the carbon contamination of the films can both be decreased by conducting the CVD process in the presence of hydrogen. Good adherence of the films to a silicon semiconductor is obtained.

The noble metals, particularly gold, palladium and platinum, are used extensively in semiconductor device processing and are usually deposited by sputtering or electron-beam evaporation. Platinum is particularly difficult to filament-evaporate because it rapidly forms an alloy with tungsten and because its vapour pressure is low, yet it is valuable in forming platinum silicide ohmic and Schottky diode contacts to silicon and also to gallium arsenide.[1] The evaporation methods can lead to degradation of the semiconductor devices and there would therefore be advantages in using a milder deposition method, such as CVD.[2,4] This technique, operating at low temperature and pressure, has recently been the subject of intense research with special emphasis on CVD of gold films,[5–12] but with some renewed interest in platinum.[1–3,13–15]

For the noble metals, a major problem has been to find organometallic precursors for CVD which have sufficient volatility and which decompose to the pure metal under mild thermal or photochemical conditions.[1–15] Platinum precursors have been $[PtCl_2(CO)_2]$,[2,3] bis(diketonato)platinum(II) complexes,[1–3,13,15] trimethyl(β-diketonato)platinum(IV)[3] and trimethyl(η-cyclopentadienyl)platinum(IV).[3,14] The platinum films usually contain much carbon, chlorine or other impurities.[1–3] This paper describes new alkylplatinum(II) precursors and shows that CVD, in the presence of hydrogen, reduces both the pyrolysis temperature and the amount of carbon contamination.

Some results for CVD of platinum are shown in Table 1. The major new class of organoplatinum precursors comprises the alkylplatinum(II) complexes, such as *cis*-$[PtMe_2(MeNC)_2]$ and $[PtMe_2(COD)]$ (COD = 1,5-cyclooctadiene) and some known precursors are included for comparison. In all cases, when CVD was carried out at 250°C, with the precursor warmed to 40–120°C so as to give reasonably rapid deposition, the platinum films which were formed contained carbon impurities, as found in previous studies.[1–3] Analysis of platinum films deposited on silicon wafers was carried out by XPS; films were cleaned before analysis by argon sputtering since much of the surface carbon impurity was formed after CVD by adsorption of atmospheric carbon.

Now, since platinum is an excellent hydrogenation catalyst, CVD experiments in the presence of hydrogen (10^{-3} torr) were carried out (Table 1). In nearly all cases, the carbon impurities were reduced in the presence of hydrogen and in some cases the effect was dramatic. We presume that organic carbon is hydrogenated and hence the surface is continuously cleaned. Another useful effect of H_2 is to decrease the temperature required for CVD. For example, with $[PtMe_2(COD)]$, $[PtMe(\eta^1\text{-}C_5H_5)(COD)]$ and $[PtMe(\eta^5\text{-}C_5H_5)(CO)]$, CVD was observed at 135°C and was efficient at 180°C in the presence of hydrogen, but the onset of CVD occurred at 235°C in the absence of hydrogen.

$[Pt(\eta^3\text{-}C_3H_5)(\eta^5\text{-}C_5H_5)]$[e]	No	60	38	2
$[PtMe_3(acac)]_2$	No	66	30	4

[a] CVD carried out in a vertical reactor. Adherence tested by the scratch test.

[b] Known complexes were prepared according to ref. 16.

[c] After argon sputtering for 30 s.

[d] Sample purified by sublimation.

[e] ^{13}C NMR ($CDCl_3$): δ = 26.8 [^1J(PtC) = 383, CH_2]; 70.2 [^1J(PtC) = 75, CH]; 90.7 [^1J(PtC) = 32, C_5H_5].

It is likely that greater effects on both the purity of the films and the temperature of CVD could be obtained at higher hydrogen pressures, but decreased volatility of the precursors is a problem under these conditions. Low temperature CVD is particularly important for metallization of the thermally sensitive III–V semiconductors.

In summary, this work has shown that alkylplatinum(II) complexes are useful precursors for CVD of platinum, and that lower temperature CVD and a reduction in the carbon impurities in the platinum films can be accomplished by carrying out the CVD in the presence of hydrogen. Such CVD processes may have applications not only in the metallization of electronic devices but also in the preparation of heterogeneous platinum catalysts. Studies of the mechanistic basis for the CVD are in progress.

Acknowledgements—We thank NSERC (Canada) and the province of Ontario for funding through the strategic grant programme and centres of excellence (OCMR) programme, respectively. XPS analyses were carried out by Surface Science Western.

HETEROLEPTIC POLYPYRAZOLYLBORATE COMPLEXES OF THE LANTHANIDE IONS. THE SYNTHESIS OF CARBOXYLATE COMPLEXES AND THE MOLECULAR STRUCTURE OF $[Yb\{HB(C_3N_2H_3)_3\}_2\{O_2CPh\}]$

MICHAEL A. J. MOSS and CHRISTOPHER J. JONES*

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 19 *August* 1988; *accepted* 31 *October* 1988)

Abstract—The heteroleptic lanthanide ion complexes $[LnL_2X]$ ($L = HB\{C_3N_2H_3\}_3$, Ln = Y, Sm, Eu, Yb, Lu and $X = O_2CPh$; Ln = Y, Yb, Lu and $X = O_2CMe$) have been prepared and characterized. They are monomeric and a single crystal X-ray diffraction study of $[YbL_2(O_2CPh)]$ shows that the molecule has a distorted square antiprismatic (SAP) coordination geometry which lies on the geometric pathway from SAP to dodecahedral. The average Yb—O distance is 2.33(2) Å and the average Yb—N distance is 2.43(4) Å. The complexes $[LnL_2(X—X)LnL_2]$ (Ln = Y, Yb, Lu and $X—X = O_2CCO_2$) have also been prepared.

In a study of the ability of uninegative bidentate co-ligands (X^-) to complete the steric saturation of the lanthanide (Ln) coordination sphere in $[LnL_2X]$ (L = hydrotrispyrazol-1-ylborate), we have shown that when X = pent-2-ene-2,4-diolate ($acac^-$) stable monomeric complexes are formed for the whole of the series of lanthanide elements from La to Lu.[1,2] However, if the size of the chelate ring formed by X is reduced from six to five by having X^- = cyclohepta-1,3,5-triene-1,7-diolate ($trop^-$), insoluble, presumably oligomeric, compounds are formed with La, Ce and Pr.[3] In order to assess the effect of further reducing the size of the chelate ring formed by X we have now prepared a series of carboxylate complexes in which four-membered chelate rings are formed.

An aqueous solution containing $MeCO_2^-$, L^- and Ln^{3+} ions in a 1:2:1 ratio rapidly produces a precipitate formulated as $[LnL_2(O_2CMe)]$ (Ln = Y, Yb, Lu) on the basis of spectroscopic data and elemental analyses. Similar complexes may be formed when Ln = Eu or Gd but in these cases substantial amounts of $[LnL_3]$ are also found in the reaction mixture. When Ln = Sm, $[SmL_2(O_2CMe)]$ may be identified in the initial precipitate but when this material is dissolved in polar organic solvents disproportionation occurs to give $[SmL_3]$ as the only isolable product. The complexes $[LnL_2(O_2CMe)]$ (Ln = Y, Yb) can also be prepared under non-aqueous conditions by reacting AgO_2CMe, KL and anhydrous $LnCl_3$ in dry THF under nitrogen. A cerium complex could also be prepared by this anhydrous route and had spectroscopic properties consistent with the formulation $[CeL_2(O_2CMe)]$. However, this material was unstable in solution and could not be isolated in a pure form.

The soluble heteroleptic benzoate complexes $[LnL_2(O_2CPh)]$ (Ln = Y, Sm, Eu, Yb, Lu) are formed readily in aqueous solution but reactions involving the larger lanthanides (Ln = La–Nd) afford only insoluble materials. A similar reaction involving 4-tertiarybutylbenzoic acid and yttrium afforded the unexpected heteroleptic complex $[YL(O_2CC_6H_4\text{-}4\text{-}CMe_3)_2]$. The interaction of oxalate, L^-, and the lanthanide ions in aqueous solution leads to the formation of insoluble products for the larger lanthanides (La–Nd). However, for the smaller lanthanides (Ln = Y, Sm–Lu) the products are soluble in polar organic solvents and, on the basis of spectroscopic and elemental analysis data may be formulated as $[(LnL_2)_2(C_2O_4)]$. All of

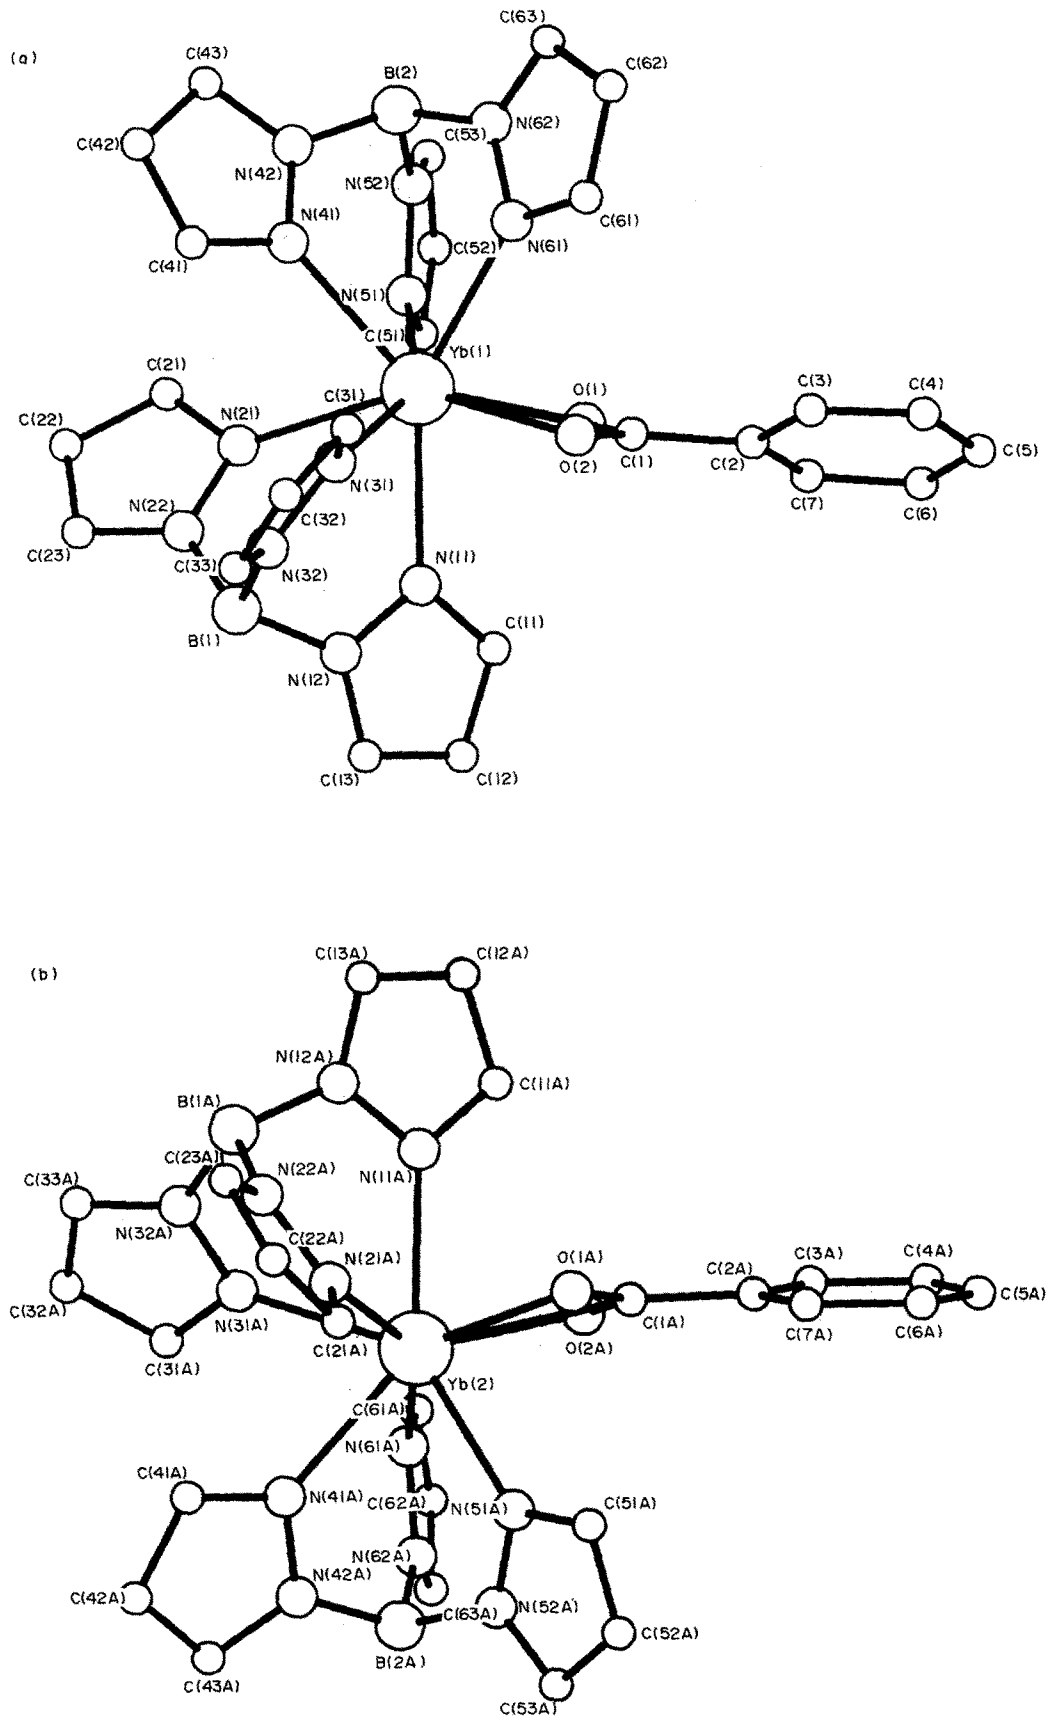

Fig. 1. The structures and atom numbering of (a) molecule (1) and (b) molecule (2).

the soluble carboxylate complexes obtained were found to exhibit dynamic ^{1}H NMR spectra as found for the related β-diketonate and tropolonate complexes,[2–4] but unlike the rigid behaviour found for $[YbL_3]$.[5]

In order to obtain more detailed structural information on an example of these carboxylate complexes, a single crystal X-ray diffraction study was carried out on $[YbL_2(O_2CPh)]$.* The crystal structure consists of discrete molecular units, there being two independent molecules in the asymmetric unit and four molecules in the unit cell. The structures and atom numbering of molecules (1) and (2) are shown in Fig. 1. Both molecules contain eight-coordinate ytterbium centres bound to one bidentate benzoate ligand and two tridentate L ligands. The coordination geometry of ytterbium in $[YbL_2(O_2CPh)]$ is best described as square antiprismatic (SAP) with the distortion of both "squares", so that it is on the geometric pathway from SAP to dodecahedral. This is in contrast to $[YbL_2(trop)]$ which had only one "square" distorted so that it is on the geometric pathway from SAP to bicapped trigonal prismatic (BCTP). At first sight the structure appears to be similar to those of $[YbL_2(acac)]$[2] and $[YbL_2(trop)]$.[3] However, there is one important difference between these structures and that of the benzoate complex. In the latter structure the coordinating nitrogen atoms of the ligands, L, are closer to the ytterbium ion, and to compensate for this the coordinating oxygen atoms of the benzoate ligand are further away. Thus the mean Yb—N bond distance is 2.43 Å (ranges: molecule (1), 2.369(6)–2.462(7) Å; molecule (2), 2.363(6)–2.481(6) Å) for this structure compared with 2.49 Å (range: 2.401(7)–2.601(6) Å for $[YbL_3]$,[6] 2.49 Å (ranges: molecule (1), 2.444(10)–2.576(11) Å; molecule (2), 2.432(14)–2.526(13) Å) for $[YbL_2(acac)]$[2] and 2.48 Å (range: 2.425(12)–2.548(10) Å) for $[YbL_2(trop)]$.[3] The mean Yb—O(benzoate) distance is 2.33 Å (ranges: molecule (1), 2.310(5)–2.360(6) Å; molecule (2), 2.319(5)–2.336(5) Å), compared with Yb—O(diketonate) distances of 2.22 Å (ranges: molecule (1), 2.199(11)–2.258(9) Å; molecule (2), 2.200(9)–2.238(9) Å) in $[YbL_2(acac)]$[2] and 2.24 Å (range: 2.222(9)–2.267(8) Å) in $[YbL_2(trop)]$.[3] Due to the shorter Yb—N bonds in $[YbL_2(O_2CPh)]$ the steric angle factor (SAF)[7] for L in $[YbL_2(O_2CPh)]$ is anomalously high. The mean SAF for L calculated from data for $[YbL_3]$, $[YbL_2(acac)]$ and $[YbL_2(trop)]$ is 0.305(3) compared to a value of 0.320 in $[YbL_2(O_2CPh)]$. The SAF value for the benzoate ligand is calculated to be 0.174. The SAS value for the complex $[YbL_2(O_2CPh)]$ is therefore 0.814, which is only slightly smaller than the values of 0.833 and 0.819 for $[YbL_2(acac)]$ and $[YbL_2(trop)]$, respectively.[8]

To our knowledge $[YbL_2(O_2CPh)]$ is the first structurally characterized lanthanide complex which has been found to contain a non-bridging, chelating bidentate benzoate ligand. The related bis(cyclopentadienyl) lanthanide acetates, benzoates and formates were first reported in 1963.[9] These were found to be dimeric containing bridging carboxylate ligands, as were $[(\eta^5\text{-}C_5H_5)_2Yb(O_2CR)]_2$ (R = Me, C_6F_5 and C_5H_4N).[10] The pentafluorobenzoate complex $[(\eta^5\text{-}C_5H_5)_2Yb(O_2CC_6F_5)]_2$ has been structurally characterized, and is a doubly carboxylate-bridged dimer.[10] The limited structural data available[11] for $[(\eta^5\text{-}C_5H_5)_2Yb(O_2CPh)]_2$ indicate that this molecule is also a doubly carboxylate-bridged dimer. In the case of pentamethylcyclopentadienyl complexes, $[(\eta^5\text{-}C_5Me_5)_2Yb(O_2CR)]_n$ is reported to be monomeric ($n = 1$) when R = CF_3, but dimeric ($n = 2$) when R = Bu^t, but no molecular structure data were obtained.[12] The only structurally characterized, simple, lanthanide benzoate complex of which we are aware is $[Dy(\mu\text{-}O_2CPh)(k'\text{-}O_2CPh)_2(H_2O)_4]\cdot H_2O$ which consists of infinite chains containing eight-coordinate Dy^{3+} ions bound to monodentate and bridging bidentate benzoate ligands.[13]

In conclusion it may be noted that, as the size of the chelate ring formed between Ln and the co-ligand X in $[LnL_2X]$ (X = acac, trop or carboxylate) is reduced from six to four, complexes containing the larger lanthanide ions become unstable with respect to disproportionation. However, the complexes in which Ln is Y, Yb or Lu remain stable as monomeric molecular species. This behaviour contrasts with that of the related cyclo-

* Crystal data. $C_{25}H_{25}B_2N_{12}O_2Yb$, $M = 720.2$, Triclinic, $a = 9.148(1)$, $b = 15.796(8)$, $c = 20.089(10)$ Å, $\alpha = 81.57(5)$, $\beta = 88.65(2)$, $\gamma = 88.15(3)°$, $U = 2870$ Å^3, $Z = 4$, $D_c = 1.67$ g cm^{-3}, space group $P\bar{1}$ (No. 2), Mo-K_α radiation ($\lambda = 0.7107$ Å, $\mu = 31$ cm^{-1}), $T = 293$ K. Data were collected on a CAD4 diffractometer at the Crystallography Unit, Universities of Aston and Birmingham. 10020 unique reflections were measured ($2 < 2\theta < 55°$) with $I > 2.5\sigma I$. The structure was solved using conventional heavy-atom methods. It was necessary to locate the atoms for the two independent molecules in the asymmetric unit. The final model with 697 parameters varied, refined to $R = 0.0504$ and $R_w\{= [\Sigma w(|F_o| - |F_c|)^2]^{1/2}\} = 0.0519$. Final Atomic coordinates, bond lengths and angles, thermal parameters and $F_o - F_c$ values have been deposited as supplementary material with the Editor, from whom copies may be obtained. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

pentadienide complexes which tend to dimerize or oligomerize and may be attributed to the greater steric demands of the trispyrazolylborate ligand.

THE SYNTHESES AND X-RAY CRYSTAL STRUCTURES OF RHENIUM(V) COMPLEXES CONTAINING FACULTATIVE PENTADENTATE LIGANDS

HILARY J. BANBERY, FERIDA McQUILLAN, THOMAS A. HAMOR,* CHRISTOPHER J. JONES* and JON A. McCLEVERTY

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 17 *October* 1988; *accepted* 3 *November* 1988)

Abstract—The reaction between $[ReOCl_4]^-$ and the Schiff base ligand $\{HOC_6H_4$—2-$CH{=}N(CH_2)_2\}_2S$ in ethanol, affords the monomeric complex $[ReO(OEt)\{OC_6H_4$—2-$CH{=}N(CH_2)_2\}_2S]$. However, a similar reaction using the amine ligand $\{HOC_6H_4$—2-$CH_2NH(CH_2)_2\}_2S$, obtained by reduction of the Schiff base, affords a binuclear complex $[ReO\{2\text{-}(OC_6H_4$—2-$CH_2N(CH_2)_2S(CH_2)_2NHCH_2)C_6H_4O\}_2ReO]$. The molecular structures of these complexes have been determined and show that, in the former complex, the thioether sulphur remains uncoordinated giving rise to an eight-membered chelate ring. In the latter complex each pentadentate ligand binds to both metal ions forming an amide complex with one and an amine complex with the other. The two rhenium atoms are components of a 10-membered dimetallocyclic $\{$—$ReSCH_2CH_2N$—$\}_2$ ring.

As part of a study of the complexation of rhenium by polydentate facultative ligands containing both "hard" and "soft" donor atoms, we have investigated the reactions between $[ReOCl_4]^-$ and two pentadentate ligands, each containing one sulphur, two oxygen and two nitrogen donor atoms. The first of these ligands is the Schiff base $\{HOC_6H_4$—2-$CH{=}N(CH_2)_2\}_2S$ (sal_2thimH_2), obtained from the condensation of salicylaldehyde and 1,5-diamino-3-thiapentane. The second ligand is $\{HOC_6H_4$—2-$CH_2NH(CH_2)_2\}_2S$ (sal_2thamH_4), obtained by reduction of the Schiff base with borohydride to give amine rather than imine nitrogen donor sites. The saturation of the chain linking the phenoxide moieties also results in increased ligand flexibility and we were particularly interested in the effect this change might have on the way in which the donor atom set coordinated to rhenium.

The new ligands have been fully characterized by spectroscopic methods and by elemental analyses. Both were reacted with $[ReOCl_4]^-$ in dry ethanol in the absence of air. The reaction with sal_2thimH_2 afforded a green complex which exhibited $\nu_{Re=O}$ at 944 cm^{-1} in its IR spectrum, in addition to bands attributable to the presence of the ligand sal_2thim. The ^1H NMR spectrum confirmed the presence of the ligand, and the elemental analysis data and X-ray diffraction study described below have established that the compound is the neutral complex, $[ReO(OEt)(sal_2thim)]$.

The reaction involving sal_2thamH_4 also afforded a green complex, the IR spectrum of which contained bands attributable to $\nu_{Re=O}$ at 900 and 880 cm^{-1}. Bands attributable to the pentadentate ligand were also observed. The presence of the ligand was confirmed by ^1H NMR spectroscopy, and the elemental analyses and X-ray diffraction study described below have established that the complex is $[ReO\{2\text{-}(OC_6H_4$—2-$CH_2N(CH_2)_2S(CH_2)_2NH$ $CH_2)C_6H_4O\}_2ReO]\cdot 2CH_2Cl_2$.

Crystals of $[ReO(OEt)(sal_2thim)]$ are monoclinic, $P2_1/n$, $a = 13.709(2)$, $b = 9.656(9)$, $c = 15.835(3)$ Å, $\beta = 103.55(2)°$, $Z = 4$. 3624 reflections in the range $\theta = 2$–$25°$, measured with an Enraf–Nonius CAD-4 diffractometer, 2803 having $[I > 2.5\sigma(I)]$

*Authors to whom correspondence should be addressed.

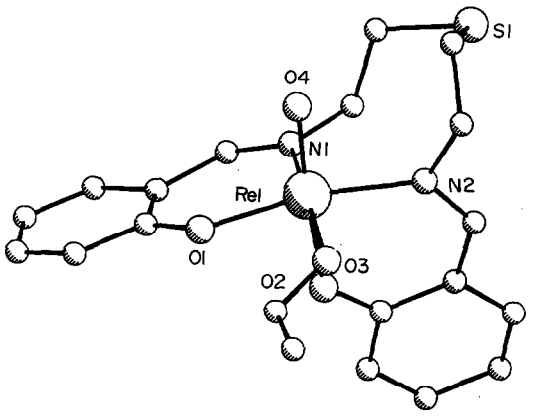

Fig. 1. The molecular structure of [ReO(OEt)(sal$_2$thim)] showing the atom labelling. Hydrogen atoms have been omitted for clarity.

were used in the analysis. The structure was solved[1] by Patterson and Fourier methods and refined[2] by least-squares using anisotropic temperature factors for the heavier atoms. Hydrogen atoms were included in calculated positions, but their parameters were not refined. The final R is 0.030; unit weights which gave a satisfactory weighting analysis were used. An empirical absorption correction was applied to the data using DIFABS.[3] The molecular structure* is shown in Fig. 1. The rhenium atom is in an approximately octahedral coordination environment, the maximum angular deviation from ideal values being 14.1°. One phenolic oxygen, O(2), of the ligand lies *trans* to the rhenyl oxo group, angle O(2)—Re—O(4) 165.9(2)°. The second phenolic oxygen, O(1), binds *cis* to the rhenyl oxo group and to the ethoxy group, which is in turn *trans* to an imine nitrogen, angle O(3)—Re—N(1) 168.3(3)°. The thioether sulphur atom does not bind to the rhenium but becomes part of an eight-membered {—ReNCH$_2$CH$_2$SCH$_2$CH$_2$N—} chelate ring. This behaviour contrasts with that found for [TcON {(CH$_2$)$_2$N=CHC$_6$H$_4$—2-O}] in which all five ligand donor atoms bind to the [TcO]$^{3+}$ moiety.[4]

Crystals of [ReO(sal$_2$thamH)]$_2$·2CH$_2$Cl$_2$ are monoclinic $P2_1/n$, $a = 11.733(3)$, $b = 9.655(3)$, $c = 18.496(2)$ Å, $\beta = 91.11(2)°$, $Z = 2$. Data collection and structure determination were as for [ReO(OEt)(sal$_2$thim)]. The final R is 0.036 for 2739 reflections. The molecular structure is shown in Fig. 2. Again, the rhenium atom is in a distorted octahedral coordination environment, maximum angular deviation from ideal values is 19.3°, in which one phenolic oxygen of the ligand lies *trans* to the rhenyl oxo group, angle O(2)—Re—O(3) 160.7(3)°. In combination with the amine nitrogen associated with the same phenyl ring, this oxygen forms part of a bidentate chelate with one rhenium atom. The

*Atomic coordinates, bond lengths and angles and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre.

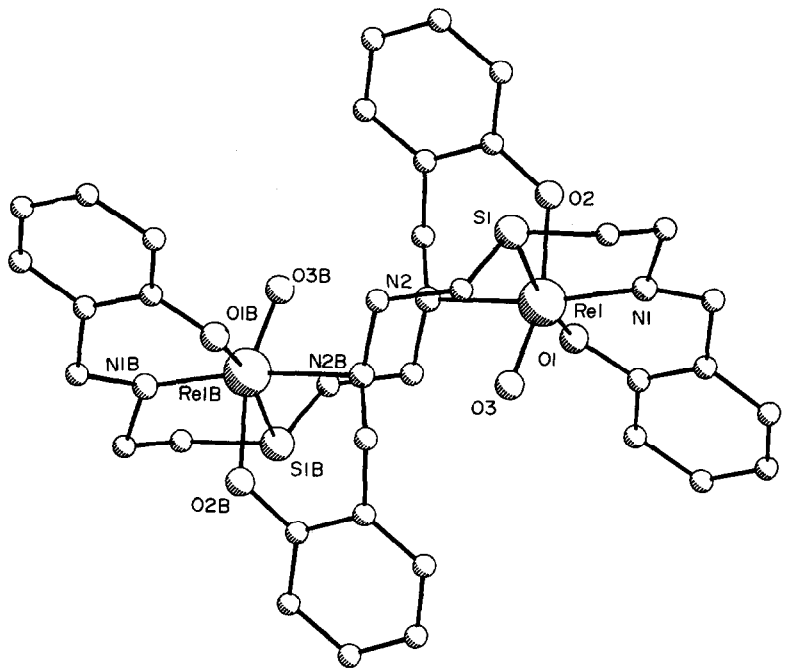

Fig. 2. The molecular structure of [ReO(sal$_2$thamH)]$_2$·2CH$_2$Cl$_2$ showing the atom labelling. Hydrogen atoms and the CH$_2$Cl$_2$ molecules have been omitted for clarity.

thioether sulphur and the remaining amide nitrogen and phenolate oxygen of the ligand, bind to *mer* sites on the other rhenium. The second ligand is bound in a complementary way to complete the dinuclear structure which contains a 10-atom bimetallocyclic ring, —Re—S—$(CH_2)_2$—NH—Re—S—$(CH_2)_2$—NH—. Although the hydrogen atoms were not located, the amido and amine nitrogen atoms, N(1) and N(2), respectively, could be clearly distinguished from their bonding geometries. Thus the angles at N(2) are close to tetrahedral, in the range 107.7–112.5°, whilst those at N(1) show a near planar geometry (sum of angles 353.3°). The Re—N distances, Re—N(1), 1.925(10) Å and Re—N(2), 2.288(9) Å, are also consistent with this, the former distance being indicative of $p\pi$–$d\pi$ electron donation from ligand to metal.

In conclusion it may be noted that, although the strategy of saturating the azomethine groups to increase ligand flexibility did lead to coordination of the thioether sulphur, the encapsulation of a single rhenium by a single ligand was still not achieved. The interplay between ligand flexibility and the preference for neutral complex formation leads to a highly complex situation in the formation of these rhenium(V) complexes. It would appear that the presence of the larger sulphur atom in the facultative ligand structure places limitations on the ability of the ligand to fully coordinate to a single metal ion. Similar effects have been noted[5] in attempts to prepare iron(III) and cobalt(III) complexes of hexadentate ligands. In these cases, stable complexes could be isolated only when oxygen or nitrogen donor atoms were present in the facultative ligand, but the incorporation of sulphur in the ligand precluded the isolation of stable 1 : 1 complexes.

THE CHEMICAL MECHANISM FOR ELECTRON TRANSFER AND BRIDGE REDUCIBILITY

WILLIAM L. PURCELL

Department of Chemistry, University of Miami, Coral Gables, FL 33124, U.S.A.

(*Received* 13 *June* 1988; *accepted* 2 *November* 1988)

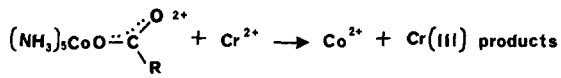
Abstract—One limiting mechanism proposed for bridged inner-sphere, electron transfer reactions, the chemical mechanism, involves rate-limiting reduction of the bridge to a radical by the reducing centre followed by rapid reduction of the oxidizing centre by the radical bridge. One predicted kinetic trait of such reactions is a correlation between the electron transfer rate constant and the "reducibility" of the bridge. This predicted trend is quantified here for the first time, with bridge reducibility expressed in terms of adiabatic gas-phase electron affinities. Also, a new kinetic test to distinguish outer-sphere electron transfers from those proceeding the chemical mechanism is shown to develop from the dependence of the rate constant on electron affinity.

Two limiting mechanisms are believed to occur for electron transfer reactions that proceed by an inner-sphere route, resonance transfer and the chemical (or radical) mechanism.[1] Of the two, the latter has proven much more amenable to chemical testing, and is now firmly established. The pulse radiolysis studies of Hoffman and co-workers have clearly demonstrated the viability of a mechanism in which a ligand is reduced prior to final metal cation reduction.[2–5] In a few cases, an intermediate radical species has been detected.[6–9] Finally, Gould has demonstrated for several systems that both bound and unbound ligands are reduced at similar rates.[10] Nevertheless, in the vast majority of inner-sphere electron transfer reactions, direct evidence for or against a chemical mechanism is lacking. Sadly, in many cases the mere assignment of an inner- or outer-sphere route proves impossible. Such is the case with the majority of photoredox processes.

In this paper we report on a test for the chemical mechanism based upon a predicted, but previously unobserved, relationship between bridging ligand "reducibility" and the rate constant for electron transfer. Outer-sphere reactions do not show the same trend and, thus, may be distinguished from the inner-sphere chemical mechanism reactions.

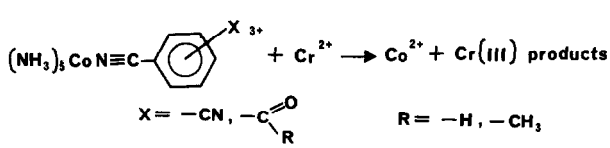
A fundamental kinetic trait predicted for inner-sphere electron transfer by the chemical mechanism is the dependence of the rate constant on the "reducibility" of the bridging ligand, since the bridge is the electron acceptor in the rate-limiting step.[11] Unfortunately, this predicted trend has not been observed except in the most qualitative terms. Cannon has compiled the most extensive set of literature data in an attempt to correlate various measures of reducibility to the experimental rate constants for electron transfer.[12] However, neither polarographic half-wave potentials, charge-transfer band maxima, nor rates of uncomplexed bridging ligand reduction reactions, have served as suitable reducibility parameters in the attempted correlations (plots (a), (b) and (c), respectively, on pp. 252–253 of ref. 12). A rough estimate of the correlation coefficients of the three plots presented by Cannon are 0.67, 0.62 and 0.31 for (a), (b) and (c), respectively. Before concluding that the predicted correlation is not followed, one should realize that the particular reactions considered by Cannon, namely chromium(II) reductions of carboxylatopentaamminecobalt(III) complexes, are known to be quite sensitive to steric effects from the carboxylate R groups (see reaction (1) below).[13] Also, inexact values for many of the reducibility parameters undoubtedly contributed to poor correlations in some of the data points. For

example, many of the carboxylate ligand parameters were estimated from methyl or ethyl esters of the acids, and in some cases the physical constants were obtained in a variety of solvents.[12] Also, as pointed out by a reviewer, some of the reactions undoubtedly do not follow a chemical mechanism.



(1)

Based upon the above analysis concerning Cannon's attempt to achieve the predicted correlation for the chemical mechanism, the following minimum criteria are necessary if the expected correlation is to be observed: the electron transfer reactions should either be free of, or be subject to constant, steric factors across the series of reactant complexes, the physical constants used to express bridge reducibility should be free of variable medium (e.g. solvent) effects, and the functional groups utilized as the binding sites for the reductant and the oxidant should be invariant. This functional group requirement seems reasonable, since a significant change in the functional group attached to a cobalt(III) oxidizing centre would be expected to change the redox potential of the complex, and, thus, inject another variable into the rate constant equation. The same requirement for the reductant attack site also seems proper since experimental rate constants for electron transfer are products of two, usually inseparable, constants for the overall reaction. These are an equilibrium constant for precursor complex formation (Q_p) and the rate of internal electron transfer within this precursor (k_{et}).[14] Data now exist in the literature for a limited number of reactions which meet all the above criteria. The reactions involved are represented by eq. (2) below.[15–18] The measures of bridge reducibility are Kebarle's recently reported adiabatic gas-phase electron affinities of the organonitriles indicated in eq. (2).[19]



(2)

Figure 1 shows the correlation between $\ln(k_{expt})$ for reaction (2) and the electron affinities (EAs) of the six organonitrile bridging ligands whose structures are presented in Fig. 1. Also presented in Fig. 1 are points for reduction of the dicyanobenzene complexes of pentaamminecobalt(III) by both vanadium(II) and hexaammineruthenium(II).[18] Reductions by the latter reagent are necessarily outer-sphere, while the vanadium(II) reduction data will require some discussion.

The data presented in Fig. 1 deserve special comment. Clearly, the prediction of a correlation between bridging ligand reducibility and electron transfer rate constants for a chemical mechanism has been realized, at least for the six ligands in Fig. 1 and eq. (2). The displacement for the two sets of ligands (remote cyano functions vs remote carbonyl functions) was to be expected since, as mentiond above, the observed rate constants contain an equilibrium constant for precursor complex formation, which would certainly differ for chromium(II) attack at two such different functional groups. Bridged inner-sphere mechanisms were unambiguously assigned in the original kinetic studies for only three of the six chromium(II) reductions represented in Fig. 1.[15,16] Inner-sphere mechanisms were inferred for the remaining three reactions based upon the magnitudes of the rate constants[15,16] and/or rate ratio comparisons.[18]

Vanadium(II) reductions of the 1,2- and 1,3-dicyanobenzene complexes were assigned outer-sphere mechanisms by Gould[18] based upon vanadium(II) to hexaammineruthenium(II) rate ratios. However, the 1,4-dicyanobenzene complex reduction by vanadium(II) was assigned a significant inner-sphere term (45%) based upon the same rate ratio comparison. However, the rate ratio in the latter case is 0.16 which is comparable to those of the other two complexes (0.23 and 0.14). Furthermore, the rate ratio is almost identical to the 0.17 ratio obtained with the benzonitrile complex which *must* be outer-sphere with vanadium(II). Therefore, this Author believes that the assignment of a significant inner-sphere pathway for the 1,4-dicyanobenzene complex with vanadium(II) is not justified by the rate ratios. Certainly, all three vanadium(II) points in Fig. 1 mirror the behaviour of the three hexaammineruthenium(II) outer-sphere points and support an outer-sphere mechanism assignment.

The results of Fig. 1 suggest that in the absence of the chromium(III) product criterion for mechanistic assignment, a correlation (or lack thereof)

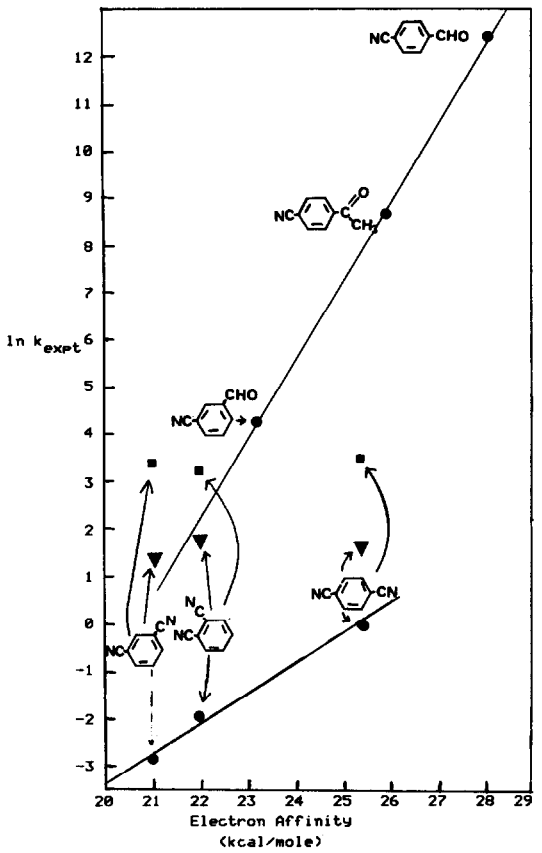


Fig. 1. Plot of $\ln(k_{expt})$ for the reduction of pentaamminecobalt(III) complexes of the organonitrile ligands indicated by various reducing agents: ●, chromium(II) reductions; ■, hexaammineruthenium(II) reductions; ▲, vanadium(II) reductions.

with potential bridging ligand electron affinities can serve to distinguish inner-sphere from outer-sphere electron transfers. The unreliable nature of the rate ratio method for such a mechanistic distinction has been discussed by Gould.[20]

The correlations noted herein do not, however, either provide for, or suggest the existence of, a distinction between the chemical and resonance transfer mechanisms from electron affinity considerations. Taube has noted that bridge reducibility should also be a factor in resonance transfer mechanisms.[11b,c,21] Still, other factors such as the donor characteristics (ionization potentials) of the bridging ligands could also be of importance in resonance transfer reactions, and, thus negate a simple, one parameter fit to the rate constants. Also, the different slopes for the two lines in Fig. 1 were unexpected and remain to be explained. Experiments are underway to clarify these points.

ANNOUNCEMENTS

XXVII INTERNATIONAL CONFERENCE ON COORDINATION CHEMISTRY

2–7 JULY 1989

BROADBEACH, QUEENSLAND, AUSTRALIA

Further information and copies of the Registration Brochure can be obtained from the Conference Secretariat: XXVII ICCC, UniQuest Ltd, University of Queensland, St Lucia, QLD 4067, Australia.

The following associated meetings will be held in the week preceding and the week following the ICCC meeting. Please contact the appropriate Convenor for further information and the Registration Circular.

XIV INTERNATIONAL SYMPOSIUM ON MACROCYCLIC CHEMISTRY

25–28 June 1989
Townsville, North Queensland

Convenor: Dr L. F. Lindoy
James Cook University
Department of Chemistry
and Biochemistry
Townsville, QLD 4811.

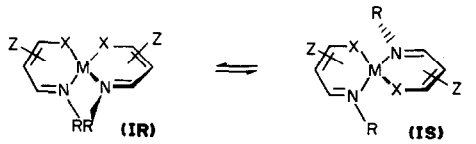
(*Received* 16 *June* 1988; *accepted* 25 *August* 1988)

Abstract—Novel bis-chelate Hg^{II} complexes with a series of 1-isopropyl-3-methyl-4-N-aryl(alkyl)aminomethylene-5-thion(seleno)pyrazole derivatives $(pyr(NR)X)_2Hg$ of type (**I**) have been prepared. For the first time intramolecular reactions of tetrahedral inversion at the metal centre and degenerate ligand exchange reactions proceeding on the NMR time-scale have been observed. The activation barrier of the inversion for the complex of type (**I**) with R = C_6H_{11}-cyclo, X = S has been found by use of dynamic ^1H NMR spectroscopy (500 MHz) to be 54.3 kJ mol^{-1}. For a series of complexes (**I**) the activation barriers against intermolecular ligand exchange processes lie in the range of 65–69 kJ mol^{-1}. An X-ray study of (**I**) (R = C_6H_{11}-cyclo, X = S) revealed a pseudo-tetrahedral bond configuration of mercury, while the sulphur atoms demonstrate a tendency toward linear alignment with the angle SHgS′ of 141.0° (1).

Fifteen years ago, Eaton and Holm[1] pioneered an investigation of the stereochemical non-rigidity of the d^0,d^{10}-metal bis-chelate complexes of general type (**I**). Since then, extensive studies of the dynamic behavior of a series of related Zn^{II},[2–6] Cd^{II},[4,7–9] Be^{II},[5,10,11] and B^{III}[12–14] complexes have been undertaken.



(1)

R = aryl, alkyl; X = O, S, Se;
Z = aryl, alkyl, benzo-, hetero-

The following rearrangement mechanisms are conceivable to lead to overall inversion at a metal centre (**IR**) ⇌ (**IS**):

(1) intramolecular digonal twist rearrangement proceeding without metal–ligand (M–L) bond scission;

(2) intramolecular M–L bond rupture–formation process through a tricoordinate achiral intermediate state;

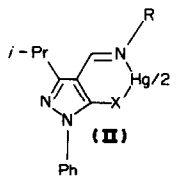
(3) intermolecular ligand exchange reaction of type (2)

$$ML_2 + M^*L_2^* \rightleftharpoons ML_2^* + M^*L_2. \qquad (2)$$

The preference of one of these mechanisms, i.e. there relative rates depends mostly on the nature of the metal centre. So far Hg^{II} chelates of type (**I**) have not

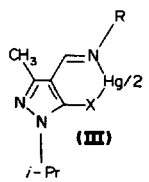
*Author to whom correspondence should be addressed.

been investigated in detail, though a fairly high frequency for the type (1) process had been assumed for the complexes of type (II) on the grounds of averaging the methyl resonances of their diastereotopic isopropyl groups at low temperature (−80°C).[4] This evidence seems to be supported by the data covering organomercury compounds containing the —CSHgR unit. The rates of phenylmercury migrations are several orders of magnitude larger than those for similar lead and tin derivatives.[15,16]



(II)

R = aryl, alkyl; X = S, Se



(III)

R = aryl, alkyl; X = S, Se

In the present work the novel Hg^{II} bis-chelate complexes of type (III) have been prepared and their fluctional behaviour studied in more detail thanks to the better solubility of these complexes in such solvents as CD_2Cl_2 and $CDCl_3$ which facilitated the NMR application. The X-ray structural investigation of one of the complexes (III) (R = C_6H_{11}-cyclo, X = S) has been performed.

EXPERIMENTAL

Synthesis

The ligands, 1-isopropyl-3-methyl-4-N-alkyl(aryl) aminomethylene-5-thion(seleno)pyrazoles were synthesized according to the literature.[4] The complexes of type (III) were obtained by 5 min reflux of an ethanol solution of mercury acetate and the corresponding ligand (1 : 2). Colourless crystals or powders were filtered off and purified by further crystallization from a toluene–octane (1 : 1) mixture. The yields of purified substances amount to 70–80%. Melting points and analyses are given in Table 1.

NMR spectroscopy

^1H NMR spectra were recorded using TESLA BS-567A and BRUKER AM-500 spectrometers operating at 100 and 500 MHz, ^{199}Hg spectra using JEOL FX-100 spectrometer at 17.84 MHz. ^1H and ^{199}Hg chemical shifts were measured with respect to HMDS as internal standard and $(CH_3)_2{}^{199}Hg$ as external standard. The temperature was kept within $\pm 1.5°$ accuracy, monitored by means of a thermocouple mounted in the probe and calibrated with methanol and ethylene glycol.

Computer simulated spectra were calculated according to literature methods.[7,17] Values of τ were obtained from visual comparison of computed and experimental spectra. Activation parameters were obtained from the least squares Eyring plots ($\ln(k/T)$ vs $1/T$).

For kinetic studies, commercially available solvents CD_2Cl_2, $CDCl_3$, $C_6D_5CD_3$ exposed for 24 h over 4 Å molecular sieves were used.

forming hexagon-based prisms were obtained by slow evaporation of the toluene–octane solution.

The crystal data: $C_{28}H_{44}HgN_6S_2$, $M_r = 729.4$; $a = 26.083(8)$; $b = 10.741(5)$; $c = 11.155(6)$ Å; $\gamma = 90.96(4)°$; $V = 3125(4)$ Å^3; $Z = 4$; $d_{calc} = 1.56$ g cm^{-3}; space group $B2/b$ (second setting). The unit-cell dimensions were refined on a DRON-1 diffractometer with a monocrystal attachment. Intensity data from 1843 independent non-zero ($I \geqslant 2\sigma(I)$) reflections of the $hk0$–$hk11$ type, crystal dimensions $0.14 \times 0.23 \times 0.14$ mm^3, were collected using a layer line registration method on a DARUM diffractometer, $0.038 \leqslant \sin\theta/\lambda \leqslant 0.600$ Å^{-1}, Cu-K_α radiation with graphite monochromator. The ESDs were introduced by Gauss integration[18] using Udelnov's program.[19] The structure was determined by direct methods and refined by least-squares on 1657 reflections with full-matrix anisotropic approximation using the Cruickshank weighting scheme to $R = 0.056$. Bond distances and valence angles are listed in Table 2. Calculations were carried out on a BESM-6 computer using the RENTGEN-75 program package.[20] The diagram of the molecular structure (Fig. 1) was obtained by use of the ELLIDS program.[21]

No shortened van der Waals contacts, with the exception of the S···C(2) distance of 3.474 Å, were found in the crystal lattice, typical of molecular crystals.

RESULTS AND DISCUSSION

X-ray data

According to the X-ray results, the mercury atom in the HgN_2S_2 moiety possesses the strongly distorted tetrahedral configuration with an angle of 95.6° between the SHgN(1) and S′HgN(1′) planes. The six-membered metallocycle is not planar, but has an envelope conformation with a 6.8° folding along the S—N axis. The mercury atom is displaced from the SC(1)C(2)C(3)N(1) plane by up to 0.188 Å. Mercury valence angles deviate considerably from the typical tetrahedral value of 109.5° and range from 97.4(2)° to 141.0(1)°. The largest SHgS′ angle exhibits a strong tendency of the mercury towards linear coordination of sulphur atoms. Another peculiarity of the molecular structure is the similarity of the Hg—S 2.391(2) Å and Hg—N 2.397(8) Å bond lengths in spite of a considerable difference between the covalent radii of sulphur (1.04 Å) and nitrogen (0.71 Å) atoms. Levelling of Hg—S and Hg—N bond distances along with the unusual valence angles at mercury are characteristic of some other mercury complexes. A comprehensive analysis of the data available[22] reveals that Hg—L bonds do not obey an additivity rule and may broadly vary even within a uniform set of ligands. For strongly electronegative donor centres such as S or Cl in tetracoordinated mercury complexes, an approxi-

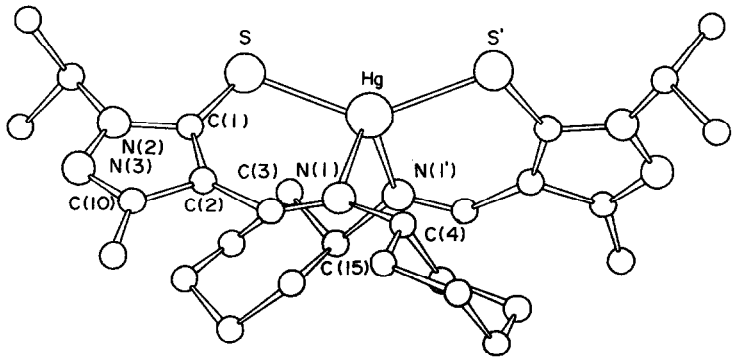

Fig. 1. Molecule of bis(1-isopropyl-3-methyl-4-cyclohexylaldimino-5-pyrazolethionato) Hg^{II}. C_6H_{11}-cyclo substituents are shown occupying one of two alternative positions.

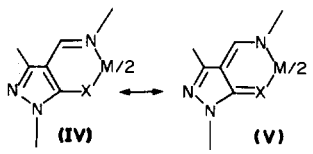
mately linear alignment of one pair of bonds has been found accompanied by shortening of the corresponding bond lengths achieving 2.36–2.49 Å for Hg—S bonds and lengthening bond distances for another pair of bonds.[23]

In general, bond distances and valence angles at the metal centre for (III) were found to be close to those in similar mercury complexes: Hg—S 2.324; 2.327; Hg—N 2.48; 2.47 Å; SHgS′ 164°; NHgN′ 91° in bis(8-mercaptoquinolino) Hg^{II},[24] Hg—S 2.43; 2.46 Å; Hg—N 2.38; 2.32 Å; SHgS′ 122°; NHgN′ 78° in $Hg(Me_2en)SCN_2$.[25]

The electronic structure of the coordinated ligand in (III) may be approximately described in terms of the resonance hybrid (3) of iminothiolate (IV) and



aminothionate (V) forms. As seen from the data of Table 3 for M = Zn, Cd, Ni, the first one is dominant while the last one makes the major contribution in the case of the free ligand (M/2 = H). Because of the softness of mercury in complexes (III), which favours the stronger Hg—S coordination as compared to the Hg—N one, an increasing contribution of the thiolate form should be expected. This might be viewed as shortening formally double and lengthening formally single bonds in (IV) (M = Hg) relative to (V) (M/2 = H). Nevertheless, the mercury atom in (III) causes no drastic changes in the electronic structure of the coordinated ligand, only slightly affecting the corresponding bond lengths.

NMR investigation

Even at temperatures as low as −80°C in CD_2Cl_2 solution all the complexes (III) show in their ^1H NMR spectra (100 MHz) an averaged doublet signal of diastereotopic methyls of isopropyl groups. In general, this may be accounted for by two reasons. The first one is the fast exchange process (IR) ⇌ (IS) averaging methyl resonances, while the second one, frequently ignored,[29,30] concerns rather low differences (occasional equivalence) in methyl resonance shifts $\Delta\nu$. In the latter case the use of a spectrometer operating at the higher frequency may be diagnostic. Indeed, when applying 500 MHz facilities, we succeeded in detecting the separated spectra as two spin doublets at −80°C. The value of $\Delta\nu$ is only 5 Hz (0.01 ppm) which corresponds to only 1 Hz for the 100 MHz spectrometer and this explains our previous unsuccessful attempts to freeze the inversion of Hg^{II} chelates.[4] Experimental and calculated spectra are shown in Fig. 2. The values of kinetic and activation parameters are given in Table 4.

Since the rate of inversion is not affected by varying the concentration of solution (0.03–0.006 M) and by the type of solvent, the rearrangement might be considered to occur via an intramolecular pathway. The most plausible mechanism of the process appears to be digonal twisting with inclusion of a planar transition or intermediate structure. The rate of inversion for the Hg^{II} complex is the biggest in comparison with those of analogous Zn^{II} and Cd^{II} complexes.[4] The following order of R ⇌ S interconversion rates is observed: Hg > Cd > Zn. The values of dihedral angles O formed by two SMN planes in a series of isoligand complexes (III) Zn^{II}, Ni^{II}, Cd^{II}, Hg^{II} (Table 3) might be considered as an

indication of a degree of the static digonal twist distortion from the pseudo-tetrahedral ($\theta = 90°$) configuration at the metal centre. However, no correlation exists between these distortions and the energy barriers (kJ mol^{-1}) against tetrahedral interconversion: Ni (40–75); Hg (54.3) < Cd (50–65) < Zn (80–95).[4,31] Interestingly, the Hg^{II} complex is the only one in this series showing the S···S *trans*-distortion.

An intramolecular bond rupture–bond closure mechanism can be invoked to explain the observed enantiomerization of Hg^{II} chelate complexes (III). This mechanism was found to operate in the case of analogous B^{III}[12–14] and Be^{II}[5] complexes with the similar chelate rings. If it occurs, it may be in principle identified by a temperature dependence of the ^{199}Hg–^{15}N spin-coupling constant as it was in the case of the isoligand $^{111}Cd^{II}$ complex.[8]

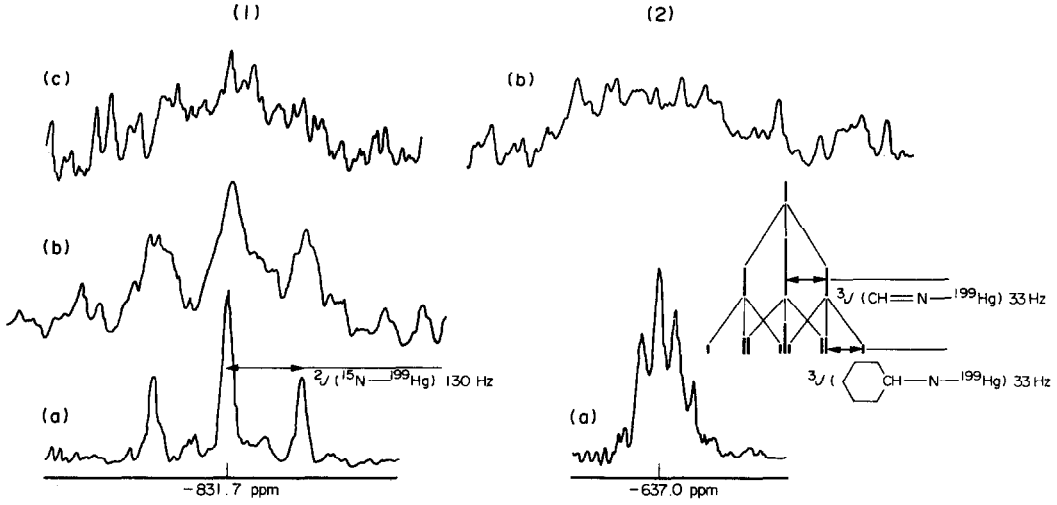

Fig. 3. ^{199}Hg NMR spectra. (1) ^{199}Hg—^{1}H spectra of (II) (R = CH_2Ph, X = Se) enriched (93%) with ^{15}N isotopes (solvent $CDCl_3$–CD_2Cl_2 (4 : 1), c = 0.03 mol dm^{-3}): (a) −61; (b) −50; (c) −36°C. (2) ^{199}Hg spectra of (III) (R = C_6H_{11}-cyclo, X = S) (solvent $C_6D_5CD_3$, c = 0.03 mol dm^{-3}): (a) 30; (b) 100°C.

The spin-coupling constant ^1J (^{199}Hg—^{15}N) in complex (II) (R = $C_6H_5CH_2$, X = Se) (for synthesis see literature[4]) was found to be equal to 130 Hz. The ^{199}Hg—{^{1}H} NMR temperature-dependent spectra are shown in Fig. 3. At elevated temperatures the triplet signal broadened and coalesced, which indicates a dissociative process due to the Hg—N bond rupture stage. Unfortunately, at the middle-exchange conditions the spectra of appropriate quality for full line shape analysis could not be recorded even though *ca* 80 000 transients were provided. The same problem occured in the case of the ^{199}Hg NMR study of (III) (R = C_6H_{11}-cyclo, X = S). At 30°C under slow-

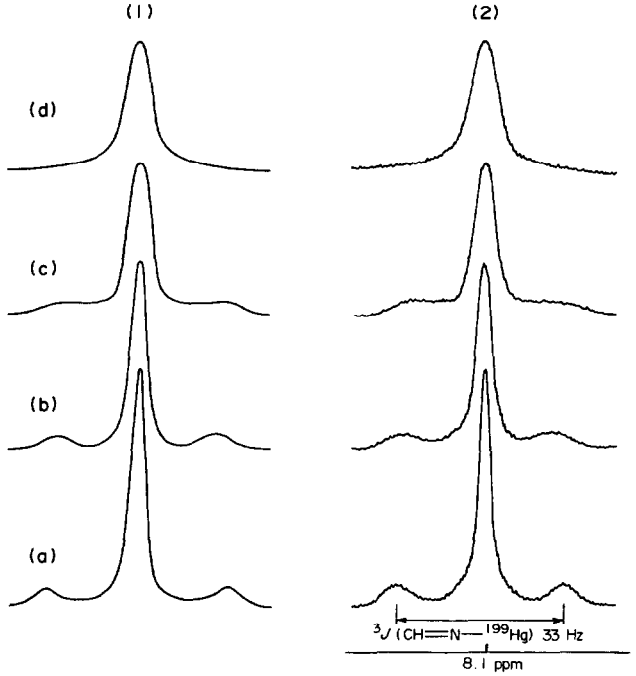

Fig. 4. Calculated (1) and experimental (2) 100 MHz ^{1}H NMR spectra of CH=N group protons of (III) (R = C_6H_{11}-cyclo, X = S): (a) T = 40°C, k = 11 s^{-1}; (b) 60°C, 22 s^{-1}; (c) 80°C, 44 s^{-1}; (d) 90°C, 65 s^{-1}.

exchange conditions, the multiplicity of the spectrum is due to the accidentally coincident couplings ^3J (CH=N—^{199}Hg) and ^3J (C_5H_{10}CH—N—^{199}Hg) of 33 Hz.

Sufficient spectral pattern was accomplished by studying the ^{1}H NMR temperature dependence of the ^{199}Hg—^{1}H coupling of the protons of the CH=N group at natural (16.9%) ^{199}Hg abundance. The typical spectra for the complex (**III**) (R = C_6H_{11}-cyclo, X = S) are given in Fig. 4. When the temperature of solution was above 30°C both the satellite signals and the central signal related to CH=N protons in isotopomers which do not contain ^{199}Hg nuclei broaden and coalesce.

The kinetic and activation parameters (Table 4) were obtained from a comparison of the experimental spectra at various temperatures with theoretically simulated ones on the grounds of the proportion of the exchange rates to the concentrations of isotopomeric molecules. The process observed may be attributed to intermolecular degenerate ligand exchange reactions of type (2) previously reported for Cd^{II}[8] and Pb^{II}[32] complexes.

As seen from Table 4, the rate of inversion at the mercury centre, found from the averaging of diastereotopic group signals, is *ca* three orders of magnitude larger than that for ligand exchange. This appears to be a general trend for the type (**I**) metal chelates. There is no significant influence of the substituents R at the nitrogen atom on the rates of ligand exchange reactions. In selenium containing complexes (**III**) (X = Se) the slow-exchange spectral pattern was not obtained as indicated by a singlet CH=N signal when the temperature of solution was as low as −80°C. This evidences faster ligand exchange reactions in these complexes as compared to that of their sulphur analogues (X = S).

Abstract—The kinetics of the reaction of $Ti(HEDTA)(H_2O)$ with $Ru_2(CH_3COO)_4^+$ and with $Ru(NH_3)_5py^{3+}$ (py = pyridine) have been studied in LiCl media of 1.0 M ionic strength. Both reactions follow second-order kinetics with the rate constant dependent on acidity according to the rate law: $k_2 = kK/([H^+]+K)$, where K is close to 0.1 M [the acid-dissociation constant of $Ti(HEDTA)(H_2O)$], and k is 1.6×10^4 M^{-1} s^{-1} for $Ru_2(CH_3COO)_4^+$ at 25°C and k is 2.0×10^5 M^{-1} s^{-1} for $Ru(NH_3)_5py^{3+}$ at 4.5°C. The rate constant for reaction of $Ti(HEDTA)(OH)^-$ and $Ru_2(CH_3COO)_4^+$ is about one order of magnitude higher than the rate constant for reduction of $Ru_2(CH_3COO)_4^+$ by $Ti(OH)^{2+}$, as would be expected on the basis of the shift in Ti^{III} redox potential that is caused by ligation of HEDTA and the known influence of change in driving force on rates of outer-sphere Ru^{III}–Ti^{III} redox reactions. The rate of reduction of $Ru(NH_3)_5py^{3+}$ by $Ti(HEDTA)(OH)^-$ at 4.5°C is more than two orders of magnitude higher than the reduction rate of the same oxidant by $Ti(OH)^{2+}$ at 25°C. This non-bridging ligand effect is at least 100 times larger than can be understood on the basis of change of redox potential, and is best ascribed to a large increase in the stability constant of the precursor complex.

Ru^{III}–Ti^{III} redox reactions involve a variety of mechanisms.[1] If the Ru^{III} oxidant contains only ligands that are not good bridging groups, then outer-sphere ET occurs, with $Ti(OH)^{2+}$ acting as a reductant; if an electron-delocalized ligand is present in the coordination sphere of the oxidant, then outer-sphere ET also involves Ti^{3+} as reductant. For instance, in reactions[2] of Ti^{III} and $Ru_2(CH_3COO)_4^+$, both Ti^{3+} and its conjugate base are effective reductants, but in the case of reaction[3] of $Ru(NH_3)_5py^{3+}$ with Ti^{III}, only $Ti(OH)^{2+}$ (and not Ti^{3+}) is effective as reductant. There is a clear difference in rate law for the two reactions (two terms in the first case as against one in the second). In both cases, all observed rate constants lie along the linear free energy relationship (log second-order rate constant vs reaction driving force) that applies to outer-sphere Ru^{III}–Ti^{III} redox reactions.

If the Ru^{III} oxidant contains an effective lead-in group an inner-sphere mechanism dominates. The

[a] 1.0 M LiCl.

presence of HEDTA as a non-bridging ligand on Ti^{III}, increases rates of inner-sphere Ru^{III}–Ti^{III} reactions, by increasing lability of Ti^{III}[4] and also by altering the stability of the precursor complex.[5] We now report kinetic studies of the influence of HEDTA as a non-bridging ligand on the rates of reductions by Ti^{III} of both the mixed valence ($Ru^{II,III}$) compound $Ru_2(CH_3COO)_4^+$ and $Ru(NH_3)_5py^{3+}$.

EXPERIMENTAL

Tetrakis(μ - acetato)diruthenium(III)chloride (hereafter, the cation of this salt will be designated $Ru_2(CH_3COO)_4^+$) was synthesized as described.[6] Elemental analysis and the extinction coefficient at 425 nM in H_2O ($\varepsilon = 695\ M^{-1}\ cm^{-1}$) agree with literature values. Pyridinepentaammineruthenium(III) perchlorate (hereafter, the cation of this salt will be designated $Ru(NH_3)_5py^{3+}$) was prepared as described by Gaunder and Taube.[7] The wavelengths of maximum absorbance (nm)/extinction coefficient ($M^{-1}\ cm^{-1}$) are $248/4.67 \times 10^3$, $256/4.71 \times 10^3$, $262/4.63 \times 10^3$, in good agreement with literature values.[8]

Titanium(III) solutions were prepared under nitrogen as described.[1] N-(2-hydroxyethyl)-ethylenediaminetriacetatoaquotitanium(III) (hereafter, Ti(HEDTA)H_2O) was prepared at least 5 min before a kinetic experiment, by mixing Ti^{3+} solution with a solution of N-(2-hydroxyethyl)-ethylenediaminetriacetic acid (hereafter, HEDTA), in 10% excess. Rates were unchanged by the presence of a 10-fold excess of HEDTA.

When Ti(HEDTA)(H_2O) was added to a solution of $Ru_2(CH_3COO)_4^+$, the colour changed from deep brown to yellow, corresponding to the decrease of an absorption peak at 425 nm. The colour of $Ru(NH_3)_5py^{3+}$ solution changed from light green to deep yellow after mixing with Ti(HEDTA)(H_2O) solutions. For both reactions, spectrophotometric titration showed that 1 mol of Ru^{III} was consumed for each mole of Ti^{III} added.

Reactions were studied in LiCl media at 1.0 M ionic strength. Kinetic experiments were carried out with Ti^{III} in at least 10-fold excess. Rates of reaction were measured using a computer-linked Durrum stopped-flow spectrophotometer. Decrease in absorbance at 425 nm, the wavelength of maximum absorbance, was monitored when Ti(HEDTA)(H_2O) was added to $Ru_2(CH_3COO)_4^+$ at $25.0 \pm 1.0°$. Reduction of $Ru(NH_3)_5py^{3+}$ by Ti(HEDTA)(H_2O) was followed by monitoring absorbance-increase at 408 nm, a wavelength close to the absorbance maximum. Since the latter reaction was too fast to follow at room temperature, the reaction cell was maintained at $4.5 \pm 2°C$. For both systems, pseudo-first-order rate plots were linear for at least three half-times. Values of the pseudo-first-order rate constant, k_{obs}, (obtained by

a linear least-squares procedure) were generally reproducible within 5% (Table 1).

Kinetic experiments in the absence of added HEDTA gave results that agreed with previously reported results[2,3] within experimental error. The presence of HEDTA increases the rate of the redox reaction for both oxidants, but the effect is much smaller for $Ru_2(CH_3COO)_4^+$ than for $Ru(NH_3)_5py^{3+}$. At constant acidity, rate constants (k_{obs}) for reduction by Ti(HEDTA)(H_2O) of both $Ru_2(CH_3COO)_4^+$ and $Ru(NH_3)_5py^{3+}$ increase linearly with Ti(HEDTA)(H_2O) concentration. Values of the second-order rate constant k_2 (k_{obs}/[Ti(HEDTA)(H_2O)]) decrease with increasing acidity. In the case of the reduction of $Ru_2(CH_3COO)_4^+$ the data are consistent with the rate law:

$$k_2 = kK/([H^+]+K).$$

For the $Ru_2(CH_3COO)_4^+$ reaction, plots of k_2 $[H^+]$ vs $[H^+]$ yielded values of second-order rate constant $k = 1.6 \times 10^4$ M^{-1} s^{-1} and $K = 0.10$ M. The value of K is the same as has been reported[4] for the acid-dissociation constant of Ti(HEDTA)(H_2O). Absence of a high-acid intercept indicates that the primary reductant is the conjugate base, Ti(HEDTA)$(OH)^-$, and suggests that the rate constant for reaction of Ti(HEDTA)(H_2O) with $Ru_2(CH_3COO)_4^+$ is not much greater than that of Ti^{3+}. The difference of rate constant between $Ti(OH)^{2+}$ and Ti(HEDTA)$(OH)^-$ is just what would be expected in view of the shift in redox potential[4] caused by the non-bridging ligand and the known dependence[1,3] of rate constant for Ru^{III}–Ti^{III} outer-sphere electron transfer reactions on reaction driving force.

In the case of the reaction of $Ru(NH_3)_5py^{3+}$, the data also can be fitted in the same way, yielding values of $k = 2.0 \times 10^5$ M^{-1} s^{-1} and $K = 0.08$ M, but the fit is less good, and it is not as clear that there is a high-acid intercept. In this case, the difference of rate constant (either k_2 or k) between $Ti(OH)^{2+}$ (measured at 25°C) and Ti(HEDTA)$(OH)^-$ (at 4.5°C) is much greater than for the other system, and it is also substantially larger than can be accounted for on the basis of shift in redox potential. It is possible that the coordinated pyridine plays a different role in the reaction that involves the organic ligand, than it does in the reaction of the simple aquo ion. A more likely rationalization of the unusually large non-bridging ligand effect is that formation constant for the precursor complex formed in the system involving the more highly-charged oxidant is more sensitive to the decreased charge of the reductant than is the system involving the oxidant with lower charge.

The presence of HEDTA on the reductant eliminates the gross rate-law difference that obtains when these two oxidants are reduced by Ti^{III} in the absence of that ligand. This in turn shows that HEDTA has a larger effect on the rate of outer-sphere electron transfer that is mediated by OH^- than on the rate of electron transfer between $Ru_2(CH_3COO)_4^+$ and $Ti(H_2O)_6^{3+}$ which is mediated[2] by the carboxylate–diruthenium molecular orbitals. Non-bridging ligand effects can give information on subtle differences in effectiveness of interactions of electron-donor and electron-acceptor orbitals.

Abstract—Some new three coordinated diaryl antimony(III) amides of the type Ar_2SbL (Ar = phenyl, pentafluorophenyl and L = $—NR_2$ = —$\overline{NCOCH_2CH_2CO}$, —$\overline{NCOC_6H_4CO}$, —$\overline{NCOCOC_6H_4}$, —$\overline{NNNC_6H_4}$, —$\overline{NC(CH_3)NCH\cdot CH}$, $\overline{NC(S)SC_6H_4}$, —$\overline{NC(CH_2Cl)NC_6H_4}$, —$\overline{NC_6H_4C_6H_4}$) have been isolated and characterized by elemental analysis, solid state IR spectra, conductivity and molecular weight measurements. The amides are unaffected by water, methanol and CS_2. However, PhNCO was found to add across the Sb—N bond and Br_2 and CH_3COOH cleave the Sb—N bond in preference to the Sb—Ar bond(s).

In sharp contrast to the well documented phenylantimony(III) compounds, Ph_nSbX_{3-n} (n = 1 or 2, X = halide,[1] alkoxides,[2] carboxylate,[3] thiol,[4] dithiophosphate,[5] xanthate,[6] etc.), those containing Sb(III)—N bonds are largely limited to aminostibines, $Ph_nSb(NEt_2)_{3-n}$ (n = 1 or 2) both prepared by the reaction of lithium diethylamide with halo or dihalo stibine at low temperatures (−80°C).[7] On the other hand organoantimony(V) nitrogen derivatives have been studied extensively in recent years.[8–10]

As a part of our research programme on organoantimony(V)[9–11] and antimony(III)[12] compounds, we have now isolated a series of diarylantimony(III) amides and studied some of their reactions.

EXPERIMENTAL

The diarylantimony(III) chlorides R_2SbCl (R=C_6H_5;[1] C_6F_5[12]) wer prepared by the redistribution reaction of R_3Sb and $SbCl_3$. The organic amides, imides and heterocyclic moieties were prepared by standard techniques and were purified by crystallization.

Molecular weights were determined cryoscopically in benzene. Conductivity data were obtained in acetonitrile with the aid of a Philips "magic eye" type PR conductivity bridge using a dip type conductivity cell. The IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer in the range of 4000–200 cm^{-1} using KBr discs. ^1H NMR spectra of the compounds in $CDCl_3$ solution were determined on a Varian EM 360 L spectrophotometer using TMS as an internal standard. Special precautions were taken to exclude moisture.

Two typical examples of antimony amides preparation are described below in detail and the conditions for the other reactions are summarized in Table 1.

Reaction of Ph_2SbCl *with succinimide*

In an oxygen-free atmosphere, a solution of diphenylantimony(III) chloride (0.3112 g, 1 mmol) in benzene (30 cm^3) and succinimide (0.099 g, 1 mmol) in the same solvent (30 cm^3) were stirred together in the presence of triethylamine at room temperature for 3 h. $Et_3N\cdot HCl$ (m.p. = 248°C) was filtered off. The filtrate on concentration *in vacuo* yielded a white crystalline solid and was recrystallized from petroleum ether (40–60°C) to afford diphenylantimony(III) succinimide.

Reaction of diphenylantimony(III) *chloride with the sodium salt of phthalimide*

A solution of diphenylantimony(III) chloride (0.3112 g, 1 mmol) in benzene (25 cm^3) and a sodium salt of phthalimide (0.169 g, 1 mmol) in the same solvent were stirred together at room temperature for 3 h under nitrogen, and NaCl was filtered off.

[a] Hygroscopic.

The filtrate on concentration *in vacuo* afforded a white crystalline solid and was recrystallized from petroleum ether (40–60°C) to give diphenylantimony(III) phthalimide.

Reaction of $Ph_2SbNCOC_6H_4CO$ *with* Br_2

To a solution of amide (1 mmol) in $CHCl_3$ (20 cm^3), bromine (2 mmol) in the same solvent (5 cm^3) was slowly added at 0°C over 30 min. The mixture was allowed to come to room temperature and was then freed from volatiles *in vacuo*. The IR spectrum of the residue and TLC in benzene showed the presence of both diphenylantimony(III) bromide and bromophthalimide. No attempts were made to separate the products.

Reaction of $Ph_2SbNNNC_6H_4$ *with* PhNCO

A mixture containing equimolar amounts of diphenylantimony(III) 1,2,3-benzotriazole (0.3937 g, 1 mmol) and phenylisocyanate (0.119 g, 1 mmol) was heated for 4 h. The resulting brown liquid was treated with diethyl ether (40–60°C) to afford light brown crystals of the PhNCO adduct. Yield = 0.34 g (65%); m.p. = 131°C. Found: C, 58.0; H, 3.1; N, 11.2. Calc: C, 58.6; H, 3.7; N, 10.9%.

RESULTS AND DISCUSSION

Diarylantimony(III) amides can conveniently be prepared by the interaction of diarylantimony(III) chloride with an amide (succinimide, phthalimide, isatin, 2-methylimidazole, 2-chloromethylbenzimidazole, 1,2,3-benzotriazole, carbazole and benzothiazoline-2-thione) in the presence of triethylamine as hydrogen chloride acceptor [eq. (1)] or by the interaction of diarylantimony(III) chloride with the sodium salt of the corresponding ligand [eq. (2)].

$$Ar_2SbCl + HL \xrightarrow[\text{Benzene}]{Et_3N} Ar_2SbL + Et_3N \cdot HCl \quad (1)$$

$$Ar_2SbCl + NaL \xrightarrow[\text{Benzene}]{} Ar_2SbL + NaCl \quad (2)$$

Ar = C_6H_5 or C_6F_5;
L = $—NR_2$ = $—NCO(CH_2)_2CO$,
$—NCOC_6H_4CO$, $—NCOCOC_6H_4$, $—NNNC_6H_4$,
$—NC(CH_3)NCHCH$, $—NC(S)SC_6H_4$,
$—NC(CH_2Cl)NC_6H_4$, $—NC_6H_4C_6H_4$.

All the reactions were found to proceed under mild conditions and were generally quantitative. Unlike the phenyl amino stibines, $Ph_nSb(NEt_2)_{3-n}$ which are obtained as liquids,[7] are colourless solids, with sharp melting points and are monomeric in freezing benzene. They are stable towards air and moisture; the melting point of sample (III) did not change even after stirring (1 h) with water at room temperature. The molar conductance of a 10^{-3} M solution in acetonitrile ranges between 15–25 ohm^{-1} cm^2 mol^{-1} at 25°C which shows the absence of ionic species in solution.

Reactions of amides

The Sb—N bond in Ar_2SbNR_2 is cleaved in preference to Sb—Ar bonds by Br_2 to give the corresponding halide, as in eq. (3).

$$Ar_2Sb(NCOC_6H_4CO) + Br_2 \longrightarrow Ar_2SbBr + COC_6H_4CONBr. \quad (3)$$

$Sb(NMe_2)_3$ is known to react with CS_2 to give $Sb(SCSNMe_2)_3$.[13] However, Ar_2SbNR_2 failed to react with an excess of CS_2 even after prolonged refluxing. On the other hand PhNCO added to the Sb—N bond in the manner of equation below [eq. (4)].

$$Ar_2SbNR_2 + PhNCO \longrightarrow Ar_2Sb—\underset{\displaystyle Ph}{\overset{}{N}}—\overset{\displaystyle O}{\overset{\|}{C}}—NR_2. \quad (4)$$

The formation of the PhNCO adduct was confirmed by the absence of ν(NCO) at 2200 cm^{-1} and the appearance of a new medium intensity band at 1700 cm^{-1} due to ν(C=O). A medium band at 1600 cm^{-1} may be assigned to ν(C—N). The failure of the reaction of CS_2 with Ar_2SbNR_2 may partly be attributed to the weak dipole nature of the former coupled with the presence of the electron withdrawing group bonded to antimony amide. Similar reactions of CS_2, RNCS and RNCO with organometal–nitrogen bonded compounds have previously been reported.[14]

IR spectra of amides

The IR spectra of all the compounds show almost identical absorption bands due to phenyl or pentafluorophenyl groups and these bands do not differ significantly from those reported earlier for diarylantimony(III) derivatives.

Absorption frequencies having diagnostic value are given in Table 1. Absorption frequencies due to carbonyl groups, symmetric as well as asymmetric, in the amido derivatives have been assigned. The ureido derivatives show the presence of a strong band in the region 1710–1750 cm^{-1} indicating the "ester type" CO group(s).

The Sb—C vibrations in the case of phenyl and

pentafluorophenyl derivatives corresponding to the y mode consistently appear in the range 448–460 cm^{-1}.[10-11] The assignment of the Sb—N band is uncertain due to the presence of phenyl absorptions in the region. However, on the basis of previous observations it is tentatively assigned at 510–520 cm^{-1}.[7]

^1H *NMR spectra*

The ^1H NMR spectra of $Ph_2SbN(COCH_2CH_2CO)$ in $CDCl_3$ at room temperature showed a singlet at δ 2.68 ppm (due to $—CH_2CH_2$ group) and a multiplet centred at δ 7.50 ppm [due to an aromatic proton (10 H, C_6H_5)]. Similarly, the compound $Ph_2SbNC(CH_3)NCH \cdot CH$ showed a complex multiplet centred at δ 7.35 [due to an aromatic proton (10 H, C_6H_5)], a singlet at δ 2.25 (due to a CH proton) and a singlet at δ 2.4 ppm (due to Me protons). The integration of the peaks is consistent with the proposed stoichiometry.

Thus on the basis of IR, NMR spectra, molecular weight and conductance data, the newly synthesized amido derivatives may be assigned a pyramidal structure. Similar structures have previously been assigned in the case of R_2MX (R = Me, Ph; M = As, Sb and Bi; X = halide).[15]

SYNTHESIS AND SPECTROSCOPIC CHARACTERISTICS OF 2-METHYL-2-PHENYLPROPYL- AND DIMETHYL(PHENYL)SILYLMETHYLNICKEL(II) COMPLEXES

STEPHEN I. BLACK and G. BRENT YOUNG*

Inorganic Chemistry Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 2 *September* 1988; *accepted* 8 *September* 1988)

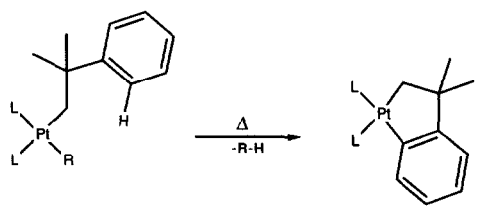
Abstract—Three types of organonickel derivatives, NiR_nL_m (R = CH_2CMe_2Ph, CH_2SiMe_2Ph) have been characterized. (1) $NiCp(R)L$ [L = PPh_3, P(cyclo-$C_6H_{11})_3$]; (2) *trans*-$Ni(R)(X)L_2$ (X = Cl, L = PMe_3, PEt_3, PBu^n_3, PMe_2Ph); (3) NiR_2L_2 (L_2 = bipy, Me_2bipy, Bu^t_2bipy, Me_4phen, R = CH_2CMe_2Ph and CH_2SiMe_2Ph; L_2 = Ph_2phen, bipym, dppe and L = PMe_3, R = CH_2SiMe_2Ph only). Synthetic strategies and spectroscopic characteristics for these complexes are discussed. In general contrast to their silylmethyl analogues, neophylnickel complexes are labile. $NiCp(CH_2CMe_2Ph)(L)$ readily undergoes H-transfer isomerization to give the 2-*tert*-butylphenyl complex $NiCp(2\text{-}C_6H_4CMe_3)(L)$. NiR_2L_2 (R = CH_2CMe_2Ph, L_2 = R^t_2bipy) undergo thermolytic rearrangement also by intramolecular aromatic C—H activation to give metallacycles which react further under the prevailing conditions.

Dialkylplatinum(II) derivatives L_2PtR_2 generally favour rearrangement via H-transfer reactions.[1] Analogous nickel(II) and palladium(II) species are, however, often thermolytically more versatile and may, for example, undergo reductive elimination via C—C bond formation.[2] In parallel with our studies on a variety of neophyl-† and sila-neophylplatinum† complexes,[3d] whose preferred reaction mode is aromatic δ-C—H activation and transfer (Scheme 1), we have undertaken an investigation of corresponding organonickel and organopalladium systems in an effort to understand more fully the controls on the reactivity of this group of metals towards organic fragments. Here we report on the synthesis and characterization of three types of organonickel complex where R is neophyl or sila-neophyl: CpNiR(L) (L = P-donor); *trans*-L_2NiRX (L = monodentate P-donor, X = halide); L_2NiR_2 (L = N-donor or bidentate P-donor). Several neophylnickel complexes have been reported recently.[4] In cases of overlap, we detail new or modified synthetic routes and additional spectroscopic information. During the course of our work a brief report has appeared of metallacycle formation proposedly from a dineophylnickel(II) precursor.[4d]

EXPERIMENTAL

General

Ether, hexane and THF were distilled before use from sodium–benzophenone. Toluene was distilled from sodium. Deuterated solvents were used as received from Aldrich Chemical Company, but stored under argon in grease-free vessels. Phos-



R= Me or neophyl

L_2= 2Py, COD, bipy, bipym, phen, Et_3P

Scheme 1.

* Author to whom correspondence should be addressed.

† Neophyl = 2-methyl-2-phenylpropyl; sila-neophyl = dimethyl(phenyl)silylmethyl.

phines were also stored under argon but otherwise used as received from Strem Chemicals. Pyridines (Aldrich Chemical Company) were stored over activated Linde 4 Å molecular sieves. Unless otherwise noted, all reactions were carried out under argon using standard techniques. NMR spectra were obtained using JEOL FX90Q and Bruker WM 250 instruments. Satisfactory elemental analyses were obtained for new compounds (Table 1).

Precursors

Bis(phosphine)nickel complexes were prepared by modified literature procedures,[5] by mixing solutions of $NiCl_2 \cdot 6H_2O$ in ethanol with the phosphine. This method for the triphenylphosphine and the tricyclohexylphosphine complexes, rather than those reported,[5] requires overnight reflux of the solutions, giving blue–violet and red solids, respectively.

Ni(Cp)(Cl)L (L = PCy_3, PPh_3)

These compounds were prepared via established routes, by mixing equimolar acetone solutions of the dichlorobis(phosphine)nickel(II) with nickelocene. This route is only successful for relatively bulky phosphines.[6] Attempts to prepare other compounds resulted in mixtures.

Preparation of η^5-cyclopentadienylbis(triethylphosphine)nickel(II) *chloride*

$NiCl_2(Et_3P)_2$ (1.19 g, 0.9 mmol) was reacted with CpTl (0.88 g, 0.9 mmol) in 40 cm^3 dry acetone at room temperature for 30 min. The mixture became brown then green and a pale precipitate formed. The mixture was filtered and 30 cm^3 ether added and filtration repeated. On cooling, well-formed green plates of the product separated. The product is very soluble in polar solvents, such as water, to give green solutions, but gives brown or red solutions in less polar solvents in which it is only slightly soluble. (Yield, 80%.)

Preparation of 4,4′-*bis*-tert-*butyl*-2,2′-*bipyridyl*

This was produced in *ca* 10% yield by refluxing 4-*tert*-butylpyridine (25 cm^3) and cyclohexene (10 cm^3) over degassed 5% Pd/C (1 g) for 7 days. The volatile liquids were distilled off (for recycling) and the product was extracted and recrystallized using hot toluene or ethanol. The dried product was analytically pure. Another method, using Raney nickel, has recently appeared.[7] The product is not as readily purified, however. If the reaction is conducted in the absence of cyclohexene, the yield of product approaches 80%[8] but the product is heavily contaminated with the corresponding terpyridyl from which it is difficult to separate.

Preparations of neophyl- and sila-neophenylmagnesium reagents

$Mg(CH_2SiMe_2Ph)Cl$ was prepared in the standard way from the chloroalkylsilane and magnesium in THF at ambient temperature, usually in concentrations of *ca* 1.0 mol dm^{-3}. Reaction of $PhMe_2CCH_2Cl$ with magnesium in THF is slower and the reaction requires overnight reflux to give 95% yield (also in solutions of approximately 1.0 mol dm^{-3}).

Preparation of η^5-cyclopentadienyl(neophyl)(triphenylphosphine)nickel(II)

$NiCp(PPh_3)Cl$ (0.5 g, 1.2 mmol) was dissolved in toluene (30 cm^3) at −15°C. $Mg(CH_2CMe_2Ph)Cl$ (1.3 mmol) was added rapidly, as a solution in THF and the mixture became successively green, then brown. After stirring for 1 h the solvents were removed and the residues extracted with hexane (60 cm^3) to give a green–brown solution. Crystals obtained from this solution contain two compounds (total yield up to 80%) which can be separated by chromatography on silica, eluting with hexane, into a slightly air-sensitive green compound (R = CH_2CMe_2Ph) and a brown–green compound (R = 2-$C_6H_4Bu^t$).

Preparation of η^5-cyclopentadienyl(4-tert-*butylphenyl*)(*triphenylphosphine*)*nickel*(II)

Powdered $NiCp(PPh_3)Cl$ (0.73 g, 1.7 mmol) was suspended in ether (40 cm^3) at −15°C. Mg(2-$C_6H_4Bu^t$)Br in diethyl ether (2 mmol) was added rapidly. The solution immediately became greenish-brown. The solution was stirred at ambient temperature for 4 h, depositing a pale precipitate. The ether was removed and the residue extracted with petrol to give a red–brown solution. This was passed through a short alumina column (prepared under argon) to give a brown–green solution which on removal of the solvent gave the pure product. (Yield, 50%.)

Preparation of Ni(Cp)(CH_2SiMe_2Ph)L (L = PCy_3, PPh_3)

These compounds were prepared as for the triphenylphosphine analogue. Extraction and crystallization using 40–60°C petroleum ether gave pure, air-stable green crystals. (Yield, 55% for the

PPh_3 compound and 65% for the Cy_3P compounds.)

Preparation of trans-*chloro(neophyl)bis(dimethylphenylphosphine)nickel*(II)

$NiCl_2(PMe_2Ph)_2$ (1.35 g, 3.32 mmol) was suspended in ether (20 cm^3) at −20°C. $Mg(CH_2CMe_2Ph)Cl$ (3.4 mmol) in THF, was added rapidly via syringe. The solution slowly became more orange. It was stirred as it warmed to ambient temperature (*ca* 3 h). The ether was reduced to *ca* 5 cm^3 *in vacuo*, hexane (40 cm^3) added and the solution filtered. Small, pure, air-sensitive orange needles of the product formed on cooling. (Yield, 55–65%.)

Preparations of trans-*chloro(neophyl)bis(trimethylphosphine)nickel*(II) *and* trans-*chloro(neophyl)bis(triethylphosphine)nickel*(II)

These were executed as above except that the reactions were faster and the triethylphosphine compound was isolated as an orange oil which could not be induced to crystallize. (Yields, *ca* 70%.)

Preparation of trans-*chloro(sila-neophyl)bis(trimethylphosphine)nickel*(II)

$NiCl_2(PMe_3)_2$ (0.48 g, 1.74 mmol) was suspended in ether (30 cm^3) at −20°C. $Mg(CH_2SiMe_2Ph)Cl$ (1.8 mmol in THF) was added via syringe and the mixture instantly became orange and rapidly deposited a fine, pale precipitate. This was stirred for 20 min at ambient temperture and the ether was removed under reduced pressure. The residues were extracted with 2×30 cm^3 hexane. On vacuum removal of *ca* 10–20 cm^3 of hexane and cooling, well-formed orange crystals of the analytically pure product were isolated. (Yield, 60%.)

Preparations of trans-*chloro(sila-neophyl)bis(triethylphosphine)nickel*(II) *and* trans-*chloro(sila-neophyl)bis(dimethylphenylphosphine)nickel*(II)

These were executed as above. The triethylphosphine compound could only be isolated as an orange oil, which was, however, spectroscopically pure. (Yields, 80 and 70%, respectively.)

Preparation of trans-*chloro*(4-tert-*butylphenyl)bis(dimethylphenylphosphine)nickel*(II)

$NiCl_2(PMe_2Ph)_2$ (0.70 g, 1.72 mmol) was suspended in ether (25 cm^3) at −10°C. Mg(2-$C_6H_4Bu^t$)Br (1.8 mmol in diethyl ether) was added in one portion via syringe. The mixture became orange and, on stirring and warming to ambient temperature, gave a brown solution and a pale precipitate. The ether was removed under reduced pressure and the mixture extracted with toluene (30 cm^3) to give a deep red–brown solution, which, when reduced to *ca* 5 cm^3, deposited well-formed orange–brown plates on cooling. The product did not appear to be air-sensitive as a solid, in contrast to

Table 1. Elemental analyses

the neophyl and sila-neophyl compounds. (Yield, 65%.)

Preparation of 4,4′-tert-*butyl*-2,2′-*bipyridylbis* (*neophyl*)*nickel*(II)

$NiCl_2Bu^tpy_4$ (1.23 g, 1.8 mmol) and Bu^t_2bipy (0.45 g, 1.7 mmol) were suspended in THF (40 cm^3) at −60°C, and *ca* 0.5 cm^3 Bu^tpy added. This mixture gives a pale violet colour characteristic of the parent complex in solution. $Mg(CH_2CMe_2Ph)Cl$ (3.8 mmol in THF) was added slowly with rapid stirring. This quickly produced a brown solution. This was stirred vigorously and allowed to warm to room temperature over 3 h to give a deep green solution. The solvent was removed under vacuum and the residues extracted with hexane (3 × 25 cm^3). The extracts were reduced to *ca* 40 cm^3, when crystal deposition was evident. Cooling produced a mass of well-formed square plates. (Yield, 60–70%.) The compound can be recrystallized from hexane or toluene as analytically pure crystals, however it appears to decompose (or isomerize) if left standing in solution or in the solid state for long periods of time even under argon.

Preparation of bis(*sila-neophyl*)*bis*(4-tert-*butylbipyridine*)*nickel*(II)

$NiCl_2Bu^tpy_4$ (1.0 g, 1.5 mmol) was suspended in ether (50 cm^3) at −70°C. Bu^tpy (1.0 cm^3) and $Mg(CH_2SiMe_2Ph)Cl$ (3.2 mmol in THF) were added rapidly with stirring. The cooling bath was removed and the solution allowed to warm to ambient temperature with vigorous stirring. After *ca* 2 h the solution was orange–brown and no precursor could be seen. The ether was then removed *in vacuo* and the residues extracted with hexane (3 × 50 cm^3). The hexane was then similarly reduced to about 50 cm^3 and cooled to give a good yield of slightly sticky but well-formed brown square plates. The compound is unstable in solution, depositing nickel metal on standing at ambient temperatures. It may also be unstable under vacuum—explaining a slightly aberrant analysis. Normally it need not be isolated and can be used directly as a hexane solution in the synthesis of further compounds. (Yield, 80%.)

Preparation of bis(*sila-neophyl*)(3,4,7,8-*tetramethylphenanthroline*)*nickel*(II)

A hexane solution of $Ni(CH_2SiMe_2Ph)_2(Bu^tpy)_2$ (1.13 mmol/40 cm^3 hexane) was added rapidly to a strongly stirred suspension of Me_4phen (0.27 g, 1.14 mmol) in ether (20 cm^3). The mixture rapidly became deep violet. It was stirred for 1 h, by which time all the starting materials had gone into solution. The solution was filtered and *ca* half the solvent removed *in vacuo*. A mass of fine violet needles separated on cooling to −20°C overnight. (Yield, 85%.)

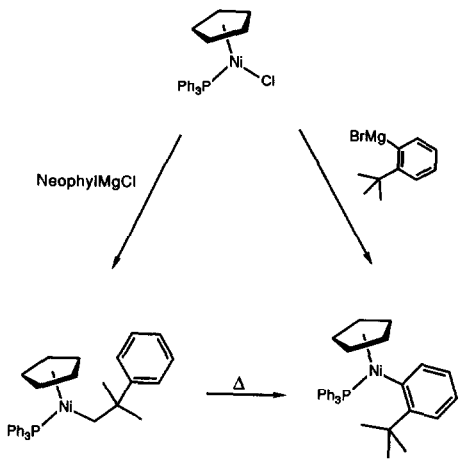
Preparation of (2,2′-*bipyrimidyl*)*bis*(*sila-neophyl*) *nickel*(II)

Considerable difficulty was experienced in attempted preparations of this compound, apparently caused by the potential of the monometallic product to dimerize with the elimination of bipym. The reaction conditions were crucial in determining whether any of the "monomer" was isolated. Optimum conditions required that an excess of dissolved bipym was always present in the reaction mixture. A solution of $Ni(CH_2SiMe_2Ph)_2Bu^tpy_2$ (2.1 mmol) in hexane (100 cm^3) and ether (20 cm^3) was slowly (*ca* 1 h) added to a rapidly stirred solution of bipym (0.44 g, 2.8 mmol) in toluene (75 cm^3). The mixture rapidly became brown–green. The solvent was removed and the solid residue extracted with ether (50 cm^3) to give a green solution and a dark red residue (this step should remove excess insoluble bipym or dimer which appears to be only sparingly soluble in non-polar solvents). The ether was removed *in vacuo* to give a green oil. The oil was washed with hexane to give a brown solution and a green solid that analysed as $Ni(CH_2SiMe_2Ph)_2$ (bipym) · 1/2bipym. (Yield, 40%.)

RESULTS AND DISCUSSION

(1) Ni(Cp)(R)L

Synthesis. Several complexes of this type with L = Ph_3P and a variety of R groups have been reported.[9] The neophyl analogue, however, was originally reported to be labile and was not isolated.[10] Its decomposition produced mainly neophylcyclopentadiene, 2,5-dimethyl-2,5-diphenylhexane (bineophyl), *tert*-butylbenzene and traces of 1-*tert*-butyl-2-neophylbenzene. The isolation of the compound has, however, been reported more recently.[4] We have found that reaction of $NiCp(PPh_3)Cl$ with $Mg(CH_2CMe_2Ph)Cl$ in diethyl ether at −10–0°C followed by solvent evaporation and extraction into petroleum ether gives an approximately equimolar *mixture* of $NiCp(PPh_3)(CH_2CMe_2Ph)$ and its isomer $NiCp(PPh_3)(2\text{-}C_6H_4CMe_3)$, which could be separated by chromatography (previous reports appear to have neglected the isomeric product). The identity of the latter was confirmed by its indepen-



Scheme 2.

dent synthesis from $NiCp(PPh_3)Cl$ and $Mg(2\text{-}C_6H_4CMe_3)Br$. Once isolated, the neophyl complex does isomerize to the *tert*-butylphenyl species (Scheme 2), but much more slowly than would account for the amount of the aryl metal in the initial product mixture; so we conclude that the rearrangement is accelerated under the conditions that prevail in the Grignard transmetallation. These observations lend support to previous contentions on the rearrangement of neophyl metals although, oddly, this nickel system was not one of those displaying such a capacity.[10] Only rarely have the 2-*tert*-butylphenyl metal products been isolated.[1f] We are currently engaged in a mechanistic study of the H-transfer isomerization. The corresponding sila-neophyl complex, $NiCp(PPh_3)(CH_2SiMe_2Ph)$, shows no parallel reactivity in solution up to *ca* 60°C when it begins to decompose, apparently by a different route, giving paramagnetic products.

To broaden our understanding of this isomerization, we have attempted to prepare analogues with trialkylphosphines, but with little success. Mostly, the corresponding halide precursors do not behave analogously. For example two different approaches to $NiCp(Cl)(PEt_3)$—by admixture of $NiCp_2$ and $NiCl_2(PEt_3)_2$ and reaction of $NiCl_2(PEt_3)_2$ and CpTl—led ultimately to the green ionic species $[NiCp(PEt_3)_2]Cl$.[11] With the latter route the reaction was quantitative. The compound is air-stable, water-soluble and slightly soluble in acetone, in which its solutions are brown at 25°C but green at −20°C. In less polar organic solvents it is only sparingly soluble to give pale pink solutions. Presumably these media favour equilibration by phosphine dissociation to produce the neutral species $NiCp(PEt_3)Cl$. We have not been able to alkylate this compound with either $Mg(CH_2CMe_2Ph)Cl$ or $LiCH_2CMe_2Ph$. We have, however, been able to produce the analogue $NiCp(Cl)(PCy_3)$ via a similar route to the triphenylphosphine complex, but with a longer reaction period and a higher reaction temperature. This compound reacts cleanly with $Mg(CH_2SiMe_2Ph)Cl$ to give the green $NiCp(CH_2SiMe_2Ph)(PCy_3)$.

Spectroscopy. Important NMR characteristics appear in Tables 2 and 3. In their ^1H NMR spectra, the Ni—CH_2 groups show couplings to phosphorus of about 10 Hz. The Cp—H resonances occur between 5 and 6 ppm, the aryl compound showing the greatest downfield shift, as expected. This enables the compounds to be distinguished readily. The ^{31}P resonances also distinguish between the aryl and alkyl compounds; the resonances are typical of those observed in other similar compounds. In ^{13}C NMR spectra, under ideal conditions, a coupling between the phosphorus and the Cp carbons of *ca* 2 Hz can be seen. Usually, though, it is very difficult to eradicate small traces of paramagnetic and/or often insoluble impurities which prevent resolution of small couplings. (This, in addition, had hindered considerably our mechanistic studies of this group of compounds.) The resonances for the aromatic hydrogens on the sila-neophyl and neophyl groups are shifted from their position in the chloroalkanes by a marked amount depending on their proximity to nickel—the *ortho*-hydrogens show greatest shifts. They appear as a discrete doublet at lowest field in the aromatic proton range. The equivalent protons in the sila-neophyl compounds appear as a complex multiplet also at low field (*vide infra*). This effect is probably due to paramagnetic anisotropy in the metal *d*-orbitals and has been analysed in detail for nickel and palladium.[12] It is also evident in the spectra of platinum analogues.[1e,3h] IR spectra show mixtures of bands associated with the component parts of the molecules. Sila-neophyl and neophyl are easily distinguished by the distinctive bands associated with the CMe_2 and $SiMe_2$ groups at *ca* 800 and 1400 cm^{-1}, among others.

(2) *trans*-$Ni(R)(X)L_2$

Compounds of this type are among the most common for divalent nickel[13] and two such neophyl derivatives have been reported ($L = PMe_3$, $L = PMe_2Ph$).[4a] We have extended the range of phosphine ligands and of spectroscopic characteristics and have also developed the analogous sila-neophyl chemistry.

Synthesis. Optimum conditions require addition of the requisite organomagnesium halide to an ether suspension of NiX_2L_2 at −10–0°C. Less soluble halonickel precursors require 1–2 h reaction time at

ambient temperatures (L = PMe_2Ph, PMe_3), while the more soluble derivatives (L = PEt_3, PBu^n_3) react almost instantly. The new compounds are highly moisture- and air-sensitive and are crystalline with the exception of $Ni(CH_2CMe_2Ph)Cl(PEt_3)_2$ which is an orange oil at ambient temperature, unlike its PMe_3 analogue.

$Mg(CH_2SiMe_2Ph)Cl$ reacted with dihalonickel precursors appreciably faster than the neophylmagnesium derivative. The sila-neophyl products were generally more soluble and easier to crystallize than their neophyl counterparts and, when pure, are notably more inert to air and moisture (though they are still very air-sensitive). $Ni(CH_2SiMe_2Ph)Cl(PEt_3)_2$ is, like its neophyl analogue, an orange oil at ambient temperature.

Spectroscopy. NMR characteristics are summarized in Tables 2 and 3. Neophyl compounds are different from their sila-neophyl counterparts in several respects. NMR indicates that the former are fluxional at room temperature; P—C and P—H couplings are not resolved for the methylene groups of the alkyl ligand. Both the ^{13}C and ^1H signals emerge as triplets at about $-10°C$ in all three complexes (in toluene-d_8), however. The sila-neophyl complexes do not show any fluxional behaviour up to moderate temperatures. It is difficult to imagine a simple, sterically promoted phosphine dissociation (of the type that has been suggested[4]) that would explain the difference between the two groups of complexes. Anyway, such systems have been observed to be less fluxional with larger halides. At reduced temperatures, the complexes also exhibit the virtual coupling typical of strongly coupled, mutually *trans*-^{31}P nuclei. This disappears along with the P—H coupling as the temperature increases. The alkyl ligands show spectroscopic characteristics similar to those in the other two groups of nickel compounds.

(3) NiR_2L_2

This is also a widely studied area of organonickel chemistry and several bis-neophyl compounds have been partially characterized (L_2 = phen, bipy).[4b] We now report modified and alternative syntheses, a broader range of ancillary ligands, additional spectroscopic information and the parallel development of a range of sila-neophyl compounds.

Synthesis (a) R = *neophyl.* Bis-neophylnickel complexes with L = bipy and phen have been synthesized previously by metathetical displacement of the diamine in the highly labile intermediate (Ni(neophyl)$_2$(tmed), obtained from alkylation of $NiCl_2(py)_4$ in the presence of tmed.[4] We have been investigating the same precursors but were seeking to proceed directly to the desired product by displacement of pyridine from NiR_2py_2, formed *in situ* but not isolated. Under conditions similar to those reported by Carmona *et al.*, only poor yields of NiR_2L_2, where L_2 = bipy, phen, could be produced. The major impediment is the thermal lability of NiR_2py_2. The insolubility of its precursor, $NiCl_2py_4$ and also of the ancillary ligands (L_2) at the requisite low temperatures, guarantees that the concentration of reactant species remains low, with a consequent high probability that thermolysis of NiR_2py_2 will occur before substitution of the pyridine by L_2. One partially successful solution to this problem was the introduction of (soluble) tmed to trap the dialkylnickel as the less labile NiR_2(tmed).[4b] We adopted an alternative strategy. First, we reasoned that perhaps higher concentrations of, ideally, a more inert dialkylnickel precursor could be introduced into solution via related, but more soluble, $NiCl_2L'_4$ complexes. These precursors were readily prepared (from a range of readily available starting materials) by addition of an excess of the ligand L′ to solutions of $NiCl_2 \cdot 6H_2O$ or $NiBr_2 \cdot 3H_2O$ in ethanol. We explored derivatives where L′ was 4-phenylpyridine, 4-*tert*-butylpyridine (Bu^{t}py), 2,6-dimethylpyridine (2,6-lutidine), 2,5-lutidine, 2,4-lutidine, 2,3-lutidine, 3,4-lutidine and 3,5-lutidine. Only Bu^{t}py had a pronounced effect on the solubility of the halide derivative and hence the rate of transalkylation. It may also improve the thermolytic inertness of the intermediate.

$Mg(CH_2CMe_2Ph)Cl$ reacts readily with $NiCl_2(Bu^tpy)_4$ above $-30°C$; little alkylation is apparent below this temperature and decomposition of the dialkyl is appreciable above 0°C. The reaction is unsatisfactory if conducted in ether with ethereal MgRX but is faster in THF or in THF–ether mixtures. The ancillary ligands can be present initially or can be added after transalkylation at $-30°C$ (yields are poor if the mixture is allowed to warm too much). In the absence of L_2, the blue colour (the parent complex is only slightly soluble in THF giving a pale blue–violet solution) of $NiCl_2(Bu^tpy)_4$ rapidly becomes green on addition of MgRCl, and the solution then slowly becomes brown as the concentration of NiR_2L_2 increases. In the presence of L_2 the only colour observed is that of the product—substitution of L′ appears to be as rapid as the formation of the intermediate dialkyl. Substitution is, however, slow in the absence of Grignard.

The best success with this route has been obtained by using ligands, L_2, which have sufficient solubility under the prevalent conditions to ensure a rate of displacement of Bu^{t}py faster than the decay of the dialkyl. Bipy and phen have very limited solubility,

although green, crystalline $Ni(CH_2CMe_2Ph)_2(bipy)$ can be obtained in this way in poor yield (*ca* 25%). More amenable are the various substituted homologues of bipy and phen. Good yields of $Ni(CH_2CMe_2Ph)_2L_2$ where $L_2 = Me_2bipy$ (60%) and Bu^t_2bipy (75%) were recovered. These green, crystalline compounds are extremely air- and moisture-sensitive as solids and in solution.

These ligands endow appreciably greater solubility on their complexes than bipy and this suits them better for spectroscopic and mechanistic studies. Bu^t_2bipy is especially notable in this respect, and we have developed an efficient synthesis of the ligand which does not suffer from the drawback of extensive terpyridyl formation (which is common in this type of reaction).[8]

By the same route, $Ni(CH_2CMe_2Ph)_2(Ph_2phen)$ is recovered in low yield as an intensely blue oil (the phen compound is known to be blue) which we have been unable to crystallize or purify further, although ^1H NMR suggests it is essentially pure.

$Ni(CH_2CMe_2Ph)_2(dppe)$, on the other hand, is labile at or below ambient temperature, and we were unable to isolate it. The yellow compound can, however, be observed at temperatures below 0°C but it becomes red on warming to ambient temperature and we have failed to isolate any products from the resulting mixture. Derivatives with monodentate phosphines appear to be equally reactive.

Some of these compounds are also accessible by direct *trans*-alkylation of $NiCl_2L_2$ by $Li(CH_2CMe_2Ph)$. For example, $Ni(CH_2CMe_2Ph)_2(bipy)$ can be isolated in high yield (>80%) via treatment of $NiBr_2(bipy)$ with $Li(CH_2CMe_2Ph)$ in ether at low temperatures. Although a rarely used procedure for $NiR_2(bipy)$ complexes,[14] this can be a more reliable route since it avoids the problem of the poor solubility of bipy or the possible instability of any intermediate. The main drawbacks are the less convenient synthesis of $NiBr_2bipy$ and, in this instance, neophyl lithium. The latter is produced in *ca* 30% yield by interaction of 2% Na/Li alloy and neophyl chloride at −70°C. Little rearranged by-product $LiCMe_2CH_2Ph$ is observed (<5% by GC).

$NiBr_2(dppe)$ also reacts with neophyl lithium to give an orange solution, but the mixture decomposes on warming to a red solution from which none of the desired product could be isolated.

Synthesis (b) $R = CH_2SiMe_2Ph$. Reaction of $NiCl_2L_4$ (L = py, Bu^{t}py) with $Mg(CH_2SiMe_2Ph)Cl$ occurs much more readily than with the neophylmagnesium reagent. Like the previously reported $Ni(CH_2CMe_3)_2py_2$, both sila-neophyl derivatives are essentially inert at ambient temperature when pure, but both are unstable in a vacuum and in solution at room temperature. Both are extremely air- and moisture-sensitive, although the Bu^{t}py compound is much more convenient to handle as it is highly crystalline, forming large square plates. Usually, though, the compound was not isolated but was reacted with other ligands, L_2, *in situ*.

By this route $Ni(CH_2SiMe_2Ph)_2L_2$ complexes were prepared, where L_2 = bipy, Me_2bipy, Bu^t_2bipy, dppe, tmed and dppm. The dppm complex could only be isolated as a dark orange oil, however, and was characterized by NMR alone. All the bipyridyl complexes give green crystals, the tmed complex is a brown, semi-crystalline solid and the dppe complex forms well shaped yellow cubes. Complexes with phenanthroline ligands are not so readily formed because of the insolubility of the ligands under the reaction conditions. A simple modification, though, gives some of them in high yields: the pyridine intermediate is extracted into toluene or petrol and is added to a toluene solution of the ligand; the complexes form immediately. Me_4phen produces violet needles and Ph_2phen produces a blue–violet solid.

Due to its versatility as a ligand, an increasing number of metallo-derivatives of 2,2′-bipyrimidyl are emerging,[15] although none has so far featured nickel. Tractable products are only obtained by slow addition of a solution of $NiR_2(Bu^tpy)_2$ in petrol to an excess of bipym fully dissolved in toluene. Otherwise, inseparable mixtures result. The ultimate product is a green, highly air- and moisture-sensitive solid whose analytical and spectroscopic characteristics indicate $Ni(CH_2SiMe_2Ph)_2(bipym)\cdot 1/2bipym$. This formulation is apparently stable in acetone solution at ambient temperature, but in toluene, further bipym is released with the formation of a brown complex which we believe contains $R_2Ni(\mu\text{-bipym})NiR_2$, on the basis of comparisons with platinum-analogues.[15]

During the course of our work Carmona *et al.* have reported the formation of a nickelaindan from the reaction of $Mg(CH_2CMe_2Ph)Cl$ and $NiCl_2(PM_3)_2$ in the presence of iodide.[4d] This was proposedly formed by ready elimination of Me_3CPh from dineophylnickel(II). Other studies have suggested that silicon-containing compounds of the form of Si-neophyl are much less susceptible to these cyclization reactions. We attempted a similar procedure with $Mg(CH_2SiMe_2Ph)Cl$ and $NiCl_2(PMe_3)_2$. On NMR evidence, a dialkyl complex is produced which does not crystallize readily. The indications are, though, that the previous contention is correct.[4d]

Spectroscopy. NMR measurements on these complexes have been hindered previously by the insoluble nature of many of this class of compound. We have been able to overcome these difficulties to

some extent because both the alkyl ligands and the bidentate nitrogen donors chosen have better solubilizing properties than those previously studied. Our observations are summarized in Tables 2 and 3. The ^{13}C resonances can be difficult to assign unambiguously and the spectra are broadly similar to those observed previously for analogous platinum compounds. The alkyl groups appear with the same distinctive patterns as they have in the other two organonickel series. When the aromatic protons are all visible, the neophyls show an apparent A_2M_2X pattern with a doublet at low field and two triplets in a 2:2:1 ratio. The sila-neophyls show only two complex multiplets; the *ortho*-protons are nevertheless, always shifted significantly downfield. These differences in fine structure arise from the actual complexity of the AA'MM'X system which can produce greatly differing line shapes for only slightly different couplings or shifts. It is not clear whether these differences are caused by differing electronic influences on the aromatic rings of carbon and silicon or by steric effects (resulting in different distances from nickel and hence different shifts due to the paramagnetic anisotropy of the metal orbitals). The position of the Ni—CH_2 resonances are similar to those observed for a range of neopentyl and trimethylsilylmethyl compounds before, as are the positions of the CH_3 resonances.

CONCLUSIONS

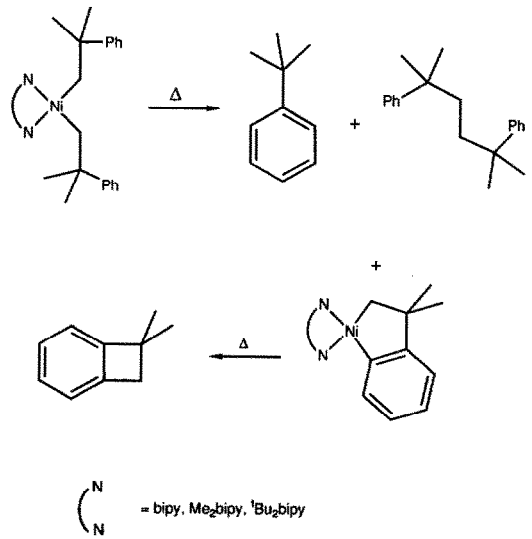
We have extended the synthetic range of three major types of organonickel(II) compounds using the neophyl and Si-neophyl ligands. The reactions leading to sila-neophyl species tend to be cleaner, and the products significantly more air- and moisture-stable and thermolytically inert than their neophyl counterparts.

In the NiCp(R)L series, the neophyl compounds are, contrary to some previous reports,[10] isolable, but are susceptible to H-transfer isomerization, while the sila-neophyl compounds are not.

In the series, *trans*-$Ni(R)XL_2$, the neophyl complexes are again more sensitive to temperature and to the atmosphere, although we have not yet identified the primary decomposition products. Similar δ-H-transfer isomerization has, however, been excluded, as requisite *ortho-tert*-butylphenyl compounds have been synthesized directly. These are very inert and readily identifiable by NMR, and are not observed in sealed tube thermolyses of the neophyl compounds.

For the dialkylnickel complexes, once more it is the neophyl ligand that imparts much greater lability in all reactivity which we have observed. The compounds decay rapidly in the presence of O_2, ROH and chlorocarbons (CCl_4, $CHCl_3$ or CH_2Cl_2), to generate mixtures of *tert*-butylbenzene and the coupling product 2,5-dimethyl-2,5-diphenylhexane (bineophyl) in varying proportions. There is evidence, supported by previous work on other complexes,[16] that some of the reactions may occur via one-electron steps. For example, the reaction with CCl_4 gives considerable amounts of Cl_3CCCl_3, which is rapidly formed as the coupling product of $^{\bullet}CCl_3$ radicals. The organic product distribution, though, is *not* indicative of a radical reaction as neophyl radicals are known to give rearrangement products. This suggests a possible first step in the reaction of, possibly halide transfer from CCl_4 to nickel accompanied by electron transfer from nickel to give the $Cl_3C^{\bullet}$ radical and a nickel(II) intermediate which then has a choice of further reactions. Some neophyl chloride is detected as a product of these reactions, so one of the options may be reductive elimination of RCl; the other major path might be reductive elimination of RR. The complexes are not as chemically inert as some earlier reports have supposed,[10] and the previously reported thermolytic product distributions should be interpreted with some caution in the light of the compounds' reactivity with oxygen, water and solvents.

Our preliminary results suggest that Ni(neophyl)$_2$L$_2$ (L$_2$ = bipy, Me$_2$bipy, Bu$^t_2$bipy) undergo thermal metallacyclization via δ-H activation yielding Ni(2-$C_6H_4CMe_2CH_2$)L$_2$ (Scheme 3) and Bu^{t}Ph, similar to the platinum compounds. Either, because the mechanism is more complex in the nickel case or because further, secondary reactions take place under the prevailing conditions, an insoluble residue and a hydrocarbon product identified



Scheme 3.

by GC–MS as 2,2-dimethyl-1,4-benzocyclobutane, are produced in addition to the expected products (Scheme 3). The mechanistics of these reactions are being explored currently in greater depth. We have also observed the metallacyclization of the PMe_3 compound reported recently by Carmona *et al.*[4] The $Ni(CH_2SiMe_2Ph)_2$ skeleton is clearly more robust and the range of accessible compounds is, consequently, greater, including the unusual bipym derivative. The reactivities of this series of compounds under more vigorous conditions has still to be investigated fully, but no metallacyclizations have been observed in preliminary studies. The inertness of silylmethyl compounds relative to alkylmethyl analogues has been observed elsewhere.[17] An unequivocal explanation has yet to be found.[18] Steric differences may play a part, but there are clealry also electronic differences as demonstrated by the spectroscopic characteristics of these compounds and their relatives.[3] Current mechanistic work on complexes containing these ligands will clarify the issues.

(*Received* 3 *August* 1988; *accepted* 28 *September* 1988)

Abstract—Insertion of CO into the Os—OMe bonds in $[Os(O)_2(OMe)_4]^{2-}$ leads to the formation of methoxide bridged dimers, $[Os(O)_2(COOMe)_2(\mu\text{-}OMe)]_2^{2-}$, as their K^+, Me_4N^+ and $^nBu_4N^+$ salts. The X-ray structure of the $^nBu_4N^+$ derivative is reported. Reduction of RuO_4^- in acetic acid by CO gives the anion $[fac\text{-}Ru(O_2CMe)_3(CO)_3]^-$, which has been structurally characterized as the $^nPr_4N^+$ salt. IR, NMR and conductivity data are also reported.

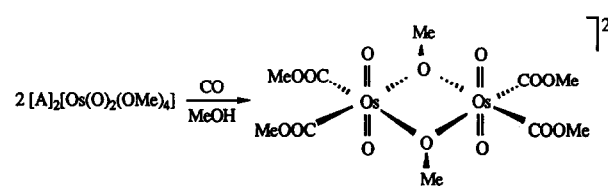
There has been considerable study of high oxidation state complexes of ruthenium and osmium.[1a,b,2] We now report carbonylation reactions of the anion $[Os(O)_2(OMe)_4]^{2-}$ and of the anion $[RuO_4]^-$ in acetic acid solution.

RESULTS AND DISCUSSION

Osmium

The complex $K_2[Os(O)_2(OMe)_4]$ (**1**) is a useful synthetic reagent.[1b,3] Since this salt has very limited solubility properties, we sought a more soluble derivative. Unfortunately, metathesis reactions with alkylammonium halides were unsuccessful, but substitution of alkylammonium hydroxides for KOH in the synthesis of the anion gave the same bright blue–green methanol solutions characteristic of **1**, which we propose contain $[NR_4]_2[Os(O)_2(OMe)_4]$ (**2**, R = Me; **3**, R = ^{n}Bu). Attempts to isolate these materials as solids failed due to the decomposition to brown oils on evaporation or precipitation—their reaction chemistry was, therefore, examined *in situ*.

Carbonylation of methanolic solutions of **1–3** gradually results in a colour change from blue to yellow. Crystalline complexes were subsequently isolated by either cooling (**1** and **2**) or evaporation followed by recrystallization from THF (**3**). These reactions proceed as in eq. (1).



4, A = K; 5, A = Me_4N; 6, A = $^nBu_4N$ (1)

Complexes **4–6** result from insertion of CO into two Os—OMe bonds, followed by methoxide elimination and dimerization. Each pseudo-octahedral osmium(VI) centre thereby attains an 18-electron configuration.

*Authors to whom correspondence should be addressed.

These hygroscopic, diamagnetic salts have been characterized by elemental analysis, IR and NMR spectroscopy and, in the case of **5**, by X-ray crystallography.

The carbomethoxy ligands display two strong IR stretches at 1660 and 1640 cm^{-1} (for **4**) and the intense $Os(O)_2$ band has moved from 825 cm^{-1} (in **1**) to 870 cm^{-1} (in **4**). Conductivity data for **6** in MeCN accord for a 2 : 1 electrolyte. NMR spectra serve to differentiate between the two different types of —OMe groups: the ^1H NMR spectrum of **6** in $CDCl_3$ shows two singlets at δ 4.70 and 4.30 (relative intensities 1 : 2). Corresponding peaks in the ^{13}C NMR spectrum are found at δ 50.27 and 58.87, respectively. In addition, a single ^{13}C resonance at δ 181.0 is assigned to the osmium-bound carbonyl carbon of the —COOMe group. NMR data for **4** and **5** were inaccessible due to their limited solubilities.

Attempts to extend this chemistry to other alkoxides have met with little success. Repeating the synthesis of **1–3** in alcohols other than MeOH (or in mixtures with MeOH) resulted in decomposition to oily brown mixtures. Interestingly, no reaction was observed on attempted carbonylation of the chelating alkoxide complex $K_2[Os(O)_2(C_2H_4O_2)_2]$.[4] Reaction of the hydroxo species $K_2[Os(O)_2(OH)_4]$[5] with CO in water resulted in decomposition to a black insoluble powder. Finally, treatment of OsO_4 with CO in acetic acid at 100°C gave a black precipitate. The IR spectrum of this material showed bands assignable to $—O_2CMe$ and Os—CO groups, but further characterization was impossible due to the complete insolubility of the compound in common solvents; repeating the reaction in the presence of $^nBu_4NO_2CMe$ failed to yield tractable complexes.

The structure of the dimeric anion in **5**, which lies on a centre of symmetry, is shown in Fig. 1; selected bond lengths and angles are given in Table 1. The bridging methoxides are pyramidal at the oxygen and the presence of the centre of symmetry results in a *trans* arrangement of the C—O bonds. The Os—O bridge bonds are equal within experimental error. The dioxo-osmium unit is essentially linear, and the Os=O bonds are slightly longer than those in the tetrahedral osmium(VI) oxo-aryl, $Os(O)_2(mesityl)_2$.[6] The Os—C(acyl) bonds, which lie *trans* to the Os—O bonds of the methoxy bridge, are slightly shorter than that to the formyl carbon in $Os(CO)(CHO)(dppe)_2$.[7]

Ruthenium

Heating an acetic acid solution of $[^nPr_4N][RuO_4]$[8] under a CO atmosphere results in a colour change from green, through black, to clear yellow. Work-up of this solution gave a mixture of products as judged by IR and NMR spectroscopy. However, one complex was isolated in crystalline form and has been identified by elemental analysis, IR and NMR spectroscopy and, unequivocally, by X-ray crystallography. Yellow crystals of $[^nPr_4N][fac\text{-}Ru(O_2CMe)_3(CO)_3]$ (**7**) were isolated in 13% yield after crystallization from THF.

In the IR spectrum, **7** exhibits strong bands at 2104, 2035 and 2019 cm^{-1} for the Ru—CO ligands, and absorptions due to the unidentate acetate groups at 1612 and 1596 cm^{-1} (ν_{asym}) and 1363 and 1314 cm^{-1} (ν_{sym}). The methyl groups in these ligands show a singlet at δ 2.02 in the ^1H NMR spectrum in $CDCl_3$. This complex would appear to be the only example of a monomeric ruthenium carbonyl acetate, however, $Ru(O_2CCF_3)_2(CO)_3(THF)$,[9] $[Ru(O_2CMe)(CO)_3]_2$,[10] $[Ru(O_2CMe)(CO)_2]_n$,[10] and various $[Ru(O_2CMe)(CO)_2L]_2$[10] and $Ru(O_2CMe)_2(CO)_2(L)_2$[11] complexes (L = tertiary phosphine or arsine, C_5H_5N or MeCN) have been reported.

The crystal structure of **7** contains two symmetry independent units which are, however, chemically equivalent. A diagram of one of the anions is given

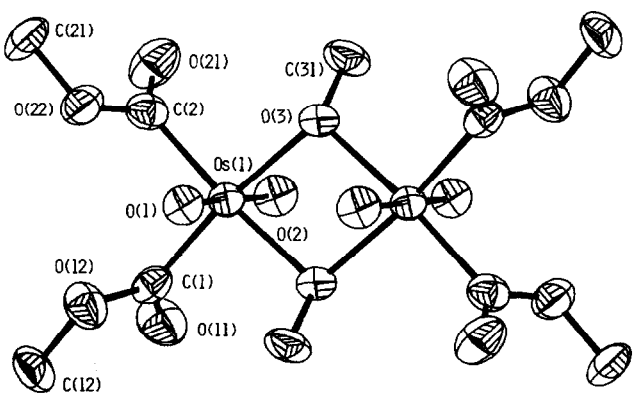


Fig. 1. The structure of the anion in $[Me_4N]_2[Os(O)_2(COOMe)_2(\mu\text{-}OMe)]_2$ (**5**).

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z): (a) $-x, -y, -z$.

in Fig. 2, selected bond lengths and angles for both in Table 2. The anions have a *fac* octahedral structure and within the limits of experimental error equivalent bond lengths are equal. The accuracy of the structure is not high, due to a large degree of thermal motion and/or disorder in all components. Accordingly, it is not possible to discuss in detail any special features of the structure. However, it is perhaps worth noting that the Ru—O—C angles to the monodentate acetates are all very similar and close to 120°.

EXPERIMENTAL

Microanalyses were carried out by Imperial College or Pascher Laboratories. Melting points were

determined in sealed capillaries and are uncorrected. Spectrometers. IR: Perkin–Elmer 683 (values in cm^{-1}); NMR: Jeol FX 90Q (in $CDCl_3$, 20°C, referenced to $SiMe_4$ at δ 0.00). All operations were carried out under argon using dry, degassed solvents. Conductivities were determined on a Data Scientific PTI-18 instrument.

$[Me_4N][Os(O)_2(OMe)_4]$ (2)

A solution of NMe_4OH in MeOH (2.3 cm^3 of a 20% solution) was added to OsO_4 (0.25 g, 1.0 mmol) in MeOH (10 cm^3) at −78°C. The orange solution was warmed to 20°C to give a bright blue solution of **2**.

$[^nBu_4N]_2[Os(O)_2(OMe)_4]$ (3)

Prepared as for **2** but using a 1M solution of $^nBu_4NOH$.

$K_2[Os(O)_2(COOMe)_2(\mu\text{-}OMe)]_2 \cdot (MeOH)$ (4)

Complex **1** (0.27 g, 0.55 mmol) in MeOH (20 cm^3) was pressured with CO (20 psi). After 20 h, the golden-yellow solution was cooled to −15°C for 8 h to afford **4** (0.20 g, 88%) as yellow needles (m.p. > 340°C). Found: C, 14.5. Calc. for $C_{11}H_{22}K_2O_{15}Os_2$: C, 15.5%. Due to the compound's insolubility in common solvents, our attempts at recrystallization (in order to obtain a better analysis) were unsuccessful. IR: 3500br, 1660s, 1640s, 1420m, 1180m, 1100br, 1060s, 942m, 868s, 477m.

$[Me_4N]_2[Os(O)_2(COOMe)_2(\mu\text{-}OMe)]_2$ (5)

Carbon monoxide was bubbled through the MeOH solution of **2** described above. Cooling to −78°C for 6 h gave yellow plates (m.p. 165–170°C) in 60% yield. Yellow prisms suitable for X-ray crystallography were obtained by recrystallization from MeCN at −15°C. Found: C, 24.8; N, 3.12. Calc. for $C_{19}H_{46}N_2O_{14}Os_2$: C, 25.1; N, 3.09%. IR: 1645s, 1630s, 1490m, 1420m, 1175m, 1094s, 1065s, 1032s, 944m, 863s, 785w, 689w, 468s.

$[^nBu_4N]_2[Os(O)_2(COOMe)_2(\mu\text{-}OMe)]_2$ (6)

After carbonylation of the MeOH solution of **3** above, the yellow solution was evaporated under reduced pressure and the residue recrystallized from THF. Yield *ca* 70%, yellow needles (m.p. 118–122°C). Found: C, 41.4, N, 2.32. Calc. for $C_{41}H_{90}N_2O_{14}Os_2$: C, 41.4; N, 2.28%. IR: 1673s, 1642m, 1415w, 1072s, 1050s, 953w, 879s, 477m. ^1H NMR: 1.51 (br, 12H), 2.08 (br, 16H), 3.78 (br, 8H),

4.30 (s, 6H), 4.70 (s, 3H). $^{13}C\{^1H\}$ NMR: 13.65(s), 19.63(s), 24.15(s), 50.27(s), 58.87(s), 181.0(s). Conductivity: $\Lambda_M = 94$ ohm^{-1} cm^2 mol^{-1} (in MeCN, 0.01M).

[^{n}Pr$_4$N][*fac*-Ru(O$_2$CMe)$_3$(CO)$_3$] (7)

A solution of [^{n}Pr$_4$N][RuO$_4$] (0.50 g, 1.4 mmol) in acetic acid (10 cm^3) was heated to 100°C under CO (50 psi) for 10 h. The yellow solution was evaporated *in vacuo* and the sticky residue extracted into THF (50 cm^3). After filtration through Celite, the volume of solvent was reduced to *ca* 10 cm^3 and the solution was cooled to −15°C overnight. Pale yellow prisms (m.p. 162–163°C, decomp.) were obtained after filtration (0.10 g, 13%). Found: 44.4; H, 6.65; N, 2.87. Calc. for $C_{21}H_{37}NO_9Ru$: C, 46.0; H, 6.80; N, 2.55%. IR: 2104s, 2035s, 2019s, 1974w, 1612s, 1596s, 1490s, 1363s, 1315s, 1005w, 754m, 677m, 626m, 575w. ^{1}H NMR: 1.00 (t, 12H), 2.73 (m, 8H), 2.02 (s, 9H), 3.17 (t, 8H).

X-ray crystallography

Crystals of both compounds were sealed in thin-walled glass capillaries under argon. Following preliminary photography, unit cell and intensity data were obtained using a CAD4 diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), according to previously detailed procedures.[12] The structures were solved via standard heavy atom methods and refined by full-matrix least-squares. For **5**, non-hydrogen atoms were refined anisotropically, hydrogens isotropically. For **7**, the structure was refined in two blocks, one containing parameters for the anions, the other for the cations. Non-hydrogen atoms were refined anisotropically, and hydrogens inserted in idealized positions and refined as components of rigid groups with group U_{iso} values. The refinement was not very satisfactory due almost certainly to high thermal motion (or disorder) in both cations and anions. Experimental data and details of the analyses are given in Table 3.

Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles, and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

INTERACTION OF IRON CARBONYLS WITH LEWIS BASES

YU. A. BELOUSOV,* T. A. KOLOSOVA and V. N. BABIN

A. N. Nesmeyanov Institute of Organoelement Compounds, USSR Academy of Sciences, 28 Vavilov Str., 117813 Moscow, U.S.S.R.

(*Received* 16 *February* 1988; *accepted* 28 *September* 1988)

Abstract—The interaction of $Fe_n(CO)_m$ ($n = 1$, $m = 5$; $n = 2$, $m = 9$; $n = 3$, $m = 12$) with Lewis bases taken in the anionic form (as NaL salts, where L = azolide, OR, SR, NR_2, NO_2; $R_2C = NO_2$, where R = H or alkyl) and in the neutral form (dimethyl sulphoxide, dimethyl formamide, pyridine, *o*-phenanthroline) was studied. The first stage of the reaction is the formation of an iron carbonyl–Lewis base complex. In the second stage one-electron transfer from this activated complex to the free iron carbonyl gives rise to both the Fe^I complexes and the anion radicals $Fe_2(CO)_8^-$, $Fe_3(CO)_{11}^-$, $Fe_4(CO)_{13}^-$ and $Fe_3(CO)_{12}^-$. The latter species are active particles prone to interconversions and are capable of participating in cluster-formation processes. A Water Gas Shift Reaction (WGSR) mechanism involving iron carbonyl radical anions is proposed.

The iron carbonyl–Lewis base (L) system is responsible for a variety of both catalytic and non-catalytic conversions involving carbon monoxide. Interest in the CO-based syntheses and metal carbonyls used as catalysts is attributed to the recent development of C_1-chemistry permitting the use of resources alternative to petroleum.

Owing mainly to the studies of Hieber and coworkers[1] it is known that the predominant route of the iron carbonyl–Lewis base reaction is a two-electron redox disproportionation to give carbonyl ferrates, eq. (1)

$$Fe_{n'}(CO)_{m'} + kL \rightarrow [FeL_k]^{2+} + [Fe_n(CO)_{m-1}]^{2-} \quad (1)$$

or hydridocarbonyl ferrates $[FeL_k]^{2+}[HFe_n(CO)_{m-1}]_2^-$, where $n = 1$, $m = 5$; $n = 2$, $m = 9$; $n = 3$, $m = 12$; $n = 4$, $m = 14$, and $n' = 1$, $m' = 5$; $n' = 2$, $m' = 9$; $n' = 3$, $m' = 12$, and $2 \leqslant k \leqslant 6$.

The interpretation of redox disproportionation as a two-electron process underlies various mechanisms of reactions involving the iron carbonyl–Lewis base system and, in particular, catalytic cycles.[2,3]

All these mechanisms are based on a common idea of a preliminary formation of complexes where the Lewis base is bonded to the CO ligand. Then it is assumed that there occurs either elimination of the carbonylated product to give a 16-electron species "$Fe(CO)_4$"[2] or a two-electron reduction to give a carbonyl (hydridocarbonyl) ferrate anion with a subsequent (at the stage of hydrogen evolution) backward two-electron oxidation to generate the same $Fe(CO)_4$. Both types of the anions are stable enough to be isolated in the form of salts, and the adducts with a

bond can sometimes be detected in the course of the reaction.[4,5] However, formation of the coordinatively unsaturated and electron-deficient species $Fe(CO)_4$ was hypothesized from the fact that it was detected by IR spectroscopy in the inert gas matrix at temperatures around 20 K.[6] It is quite clear that this postulate is a weak point in the traditional approach to the mechanism of catalytic conversions. The formation of such ideas seems to be influenced by the Tolman rule[7] for determining the predominant routes of the reaction of the homogeneous catalysis via 16- and 18-electron complexes.

On the other hand, there exists an independent branch of carbonyl chemistry dealing with the odd-electron Fe^{-1} derivatives, i.e. iron carbonyl rad-

*Author to whom correspondence should be addressed.

ical anions[8–11] which can be generated either electrochemically or with the use of strong reducing agents such as a sodium mirror and sodium benzophenone ketyl.[10,12]

By studying iron carbonyl reactions with various anionic Lewis bases such as azolides,[13] nitronates,[14,15] sodium thiolates[16] and other N- and O-bases[17] directly in the ESR spectrometer cavity, we have found that the common feature of all these reactions is the formation of iron carbonyl radical anions at the initial stages, with small conversions. Their concentration was found to be fairly high (as great as 10^{-5}–10^{-2} M). The existence of such radical species in high concentrations is indicative of the presence of one-electron stages as the iron carbonyls react with the Lewis bases. Therefore, the main purpose of this study is to establish the role of one-electron processes and radical anions in iron carbonyl–Lewis base reactions.

EXPERIMENTAL

IR spectra were taken with a UR-10 instrument, and ESR spectra with an ERS-221 instrument (ZWG–DDR), in the *X*-band range with a high frequency of 100 kHz modulation. The parameters of the spectra are given for a temperature of −80°C. The reactions were conducted directly in an ampoule placed in the ESR spectrometer cavity at the equimolar reagents ratio and *ca* 0.1 M concentrations in THF. The samples were conditioned in a vacuum of 10^{-4} torr, and the THF was bulb-to-bulb distilled into the ampoule containing the reagents. The THF was dehydrated over sodium benzophenone ketyl and the iron pentacarbonyl was purified by distillation. The dimethylformamide, dimethylsulphoxide and pyridine, were purified by the known methods[18] and degassed *in vacuo* by multiple freeze–pump–thaw cycles. The compounds $^{57}Fe(CO)_5$,[19] $Na_2Fe(CO)_4 \cdot 1.5$ diox[20] $(PPN)_2[Fe_2(CO)_8]$,[21,22] $(PPN)_2[Fe_3(CO)_{11}]$,[23] $(PPN)_2[Fe_4(CO)_{13}]$,[24] $[(C_2H_5)_4N]_2[Fe_5C(CO)_{14}]$,[25] $Fe_5C(CO)_{15}$,[25] $[(C_2H_5)_4N]_2[Fe_6C(CO)_{16}]$,[25] $PPN[Fe(CO)_4COOCH_3]$,[4] $PPN[Fe(CO)_3NO]$[26] and $Fc^+PF_6^-$, where Fc^+ is ferricenium,[27] were synthesized by the known methods. The sodium salts of nitroparaffines, thiols and alcohols were synthesized from the corresponding compounds and sodium hydride in THF.

RESULTS AND DISCUSSION

(1) *Reactions of iron carbonyls with Lewis bases*

(1.1) *Anionic Lewis bases.* Iron carbonyls were found to react faster with the anionic Lewis bases than with the neutral ones. Therefore a variety of N-, O- and S-containing compounds were used as the bases in the form of sodium salts such as azolides (AzNa), amides ($NaNR_2$), alcoholates (NaOR), thiolates (NaSR), nitronates [$Na(R_2CNO_2)$] and nitrite ($NaNO_2$), where R = H or alkyl. When the reaction takes place in THF solution at −80°C, one can observe the appearance of signals from the radical species. Comparison with the data reported by Krusic *et al*[9] suggests that these signals correspond to the iron carbonyl radical anions $Fe_2(CO)_8^-$ **(I)** ($g = 2.0385$), $Fe_3(CO)_{11}^-$ **(II)** ($g = 2.0498$), $Fe_4(CO)_{13}^-$ **(III)** ($g = 2.0135$) and $Fe_3(CO)_{12}^-$ **(IV)** ($g = 2.0013$).

It was only natural to interpret these data as indicating a one-electron reduction of the starting carbonyl species, occurring in these systems. There is a vivid analogy with the iron carbonyl reduction processes taking place in the electrochemical conditions or under the effect of strong reducing agents such as sodium mirror or benzophenone ketyl.[11,12]

However, we are inclined to think that the Lewis bases used by us, especially, for example, nitrite and nitronate ions, can hardly be regarded as reducing agents. On the one hand, it follows from the reduction potentials of the anionic Lewis bases (if they are known), and on the other hand, a small probability of the one-electron reduction by eq. (2) is suggested by the absence of L˙ radicals:

$$Fe_n(CO)_m + L^- \not\rightarrow Fe_n(CO)_m^- + L^\cdot. \qquad (2)$$

We believe that the stage of the one-electron transfer is preceded by that of complexing to bring about the activation of the base and carbonyl species:

$$Fe_n(CO)_m + L^- \xrightarrow[-xCO]{} \underset{\mathbf{A}}{[Fe_n(CO)_{m-x} \cdot L]^-} \qquad (3)$$

$x = 0, 1, 2.$

The one-electron transfer then directly occurs from the anionic complex **A** to the next iron carbonyl molecule. Thus in Fe^I and Fe^{-I} complexes the degrees of oxidation are formal and appear as:*

$$[Fe_n(CO)_{m-x} \cdot L]^- + Fe_n(CO)_m \rightarrow [Fe_n(CO)_{m-x} \cdot L]^\cdot + Fe_n(CO)_m^- \xrightarrow{-CO} Fe_n(CO)_{m-1}^- \qquad (4)$$

$x = 0, 1, 2.$

* Strictly speaking, the degrees of oxidation should be designated as $1/n$ and $-1/n$, i.e. by the number of atoms in the corresponding complex. The designation used by us should be considered with this reservation.

Table 1. IR data for the complexes $Na[Fe(CO)_4C(O)L]$

L	ν(CO), THF (cm^{-1})					References
C_2H_5S	2031	1959	1913	1900	1661	This work

The value of x is governed by the order in which the elimination of the first CO group and electron-transfer take place. This depends on the structure of complex **A** and electron-transfer conditions.

Adduct **A** appearing at the first stage of the process may represent firstly, the charge-transfer complex $[Fe_n(CO)_m \ldots L]^-$, second, a product resulting from the addition of a base at the carbonyl group, $[Fe_n(CO)_{m-1}C(O)—L]^-$ and third, substitution of one or more carbonyl ligands to give a direct Fe—L bond. The formation of such complexes in solution has been described earlier,[5] and some of them can be isolated in a pure form.[4]

Moreover, IR studies of the reactions of iron pentacarbonyl with sodium thiolates in THF show that with excess thiolate in these systems there appears an absorption band in the region between 1620 and 1670 cm^{-1}, typical of the "acyl"-type carbonyl group (Table 1).

It is thought that, depending on the specific conditions, all the above forms are realizable. The question is, which of them can act as a reducing agent. In particular, in our case, the role of the direct reducing agent seems to be played by the type **A** complexes.

Such complexes were synthesized in the form of salts with the bis(triphenylphosphine)iminium cation, $(PPN)[Fe(CO)_4COOCH_3]$[4] and $(PPN)[Fe(CO)_3NO]$.[26] ESR studies of the reactions of methoxycarbonyl tetracarbonyl ferrate and tricarbonyl nitrosyl ferrate with iron pentacarbonyl indicate that in this case, a fast reduction of $Fe(CO)_5$ readily occurs to give rise to the iron carbonyl radical anions **I–IV** even at temperatures below −80°C. Moreover, the entire set of the radical species detected in the reaction with $Fe(CO)_4COOCH_3^-$ was identical to that obtained in the reaction of $Fe(CO)_5$ with sodium methylate.

Thus the reaction systems involving the iron carbonyl–anionic Lewis base, at their initial stages, and small conversions, give rise to two groups of radicals, one of which is represented by the Fe^{-I} derivatives, i.e. iron carbonyl radical anions, and the other by the Fe^{I} carbonyl derivatives containing a base fragment. The second group will be discussed in more detail in sub-clause 2. The redox stage where these radicals are formed is preceded by the activated complexing of the anionic base with the iron carbonyl molecule.

(1.2) *Neutral Lewis bases.* Redox disproportionation can also occur in the case when a Lewis base had a neutral form (L′). We believe that the general scheme of the process is, in principle, similar to that discussed in the preceding section [eqs (3) and (4)]. However, in this case [eqs (5) and (6)] the process, at the same reagent concentrations, occurs far slower, probably due to the lower rates of the activating complex-formation process which may represent a limiting stage. The lower reaction rate can also be caused by charge generation [eq. (6)]. In particular, the reactions of iron pentacarbonyl with the neutral bases (ROH, RSH, R_2NH) yielding a set of radicals practically identical to that resulting from the reactions involving the anionic forms, occur far slower and at elevated temperatures only.

The ESR method was used by us to study the reactions of iron carbonyls with traditional solvents exhibiting donor properties and representing Lewis bases in the neutral form. Consideration was given to reactions with pyridine, dimethylformamide, dimethylsulphoxide and *o*-phenanthroline:

$$Fe_n(CO)_m + L' \rightleftharpoons \underset{\mathbf{A}}{[Fe_n(CO)_m \cdot L']} \qquad (5)$$

$$[Fe_n(CO)_m \cdot L'] + Fe_n(CO)_m \rightarrow \underset{\mathbf{B}}{[Fe_n(CO)_{m-x} \cdot L']^+} + Fe_n(CO)_m^-$$

$$[Fe_n(CO)_m \cdot L'] \xrightarrow[-CO]{L',\ -e^-} [Fe(L')_k]^{2+}$$

$$Fe_n(CO)_m^- \xrightarrow{-CO} Fe_n(CO)_{m-1}^-$$

$$[Fe(L')_k]^{2+} + Fe_n(CO)_{m-1}^- \xrightarrow{+e^-} [Fe(L')_k]^{2+}[Fe_n(CO)_{m-1}]^{2-}$$

L′ = Py, DMF, DMSO; $k = 6$
L′ = *o*-Phen; $k = 3$. (6)

It was shown that in all cases, at fairly small conversions, one can observe the generation of the iron carbonyl radical anions **I–IV**. Further, these radical anions give rise to carbonyl ferrate dianions with the subsequent appearance of the salts, $[Fe(L')_k][Fe_n(CO)_{m-1}]$.

Comparison of the reaction rates in the series $Fe(CO)_5$–$Fe_2CO)_9$–$Fe_3(CO)_{12}$ indicates that the easiest reaction is observed for $Fe_3(CO)_{12}$ and the most difficult one for $Fe(CO)_5$. This can be attributed to the fact that the reductive potential of $Fe_3(CO)_{12}$, $E_{1/2\,red} = -0.32$ to -0.44 V[8,11] and that of $Fe(CO)_5$, $E_{1/2\,red} = -1.64$ to -1.77 V.[11] Therefore, the electron-transfer stage [eq. (6)] is most readily realizable in the first case.

Thus, the mechanism involving the stage of activating complex-formation and the subsequent stage of a one-electron transfer from the donor-activated carbonyl complex to the carbonyl, can be regarded as a fairly general mechanism in iron carbonyl disproportionation reactions under the effect of Lewis bases.

To explain the one-electron processes occurring with participation of iron carbonyls, the conception of the activating complex-formation has been used by us for the first time. However, this approach is based on the ideas put forward by Abakumov[28] as applied to the reactions of quinones and their complexes. He was the first to express the idea of the applicability of such considerations to organometallic systems.

(2) *Radical* Fe^I *carbonyl complexes and their conversion paths*

While iron carbonyl radical anions **I–IV**, being essentially stable radicals, are detected readily, the same procedure for type **B** radicals resulting from eq. (4) is much more complicated. The Fe^I complexes (d^7 iron atom configuration) are usually very unstable and, on losing carbonyl ligands, they rapidly convert to inorganic Fe^{II} derivatives. Therefore, they can only be detected in separate cases, e.g. in reactions of $Fe(CO)_5$ with NO_2^- and $R_2CNO_2^-$.[15]

Sometimes such species can be detected in the form of spin adducts with 2-methyl-2-nitrosopropane (in reactions of iron carbonyls with $L^- = R_2CNO_2^-$).[15] An additional reason for the problem associated with the detection of mononuclear carbonyl Fe^I complexes lies in the fact that the corresponding signals including the reported ones[29–31] are located in the g region between 2.035 and 2.050, with the result that they overlap the most intense signals from **I** and **II**.

A more favourable situation is observed with the reactions of $Fe(CO)_5$ with thiolates and sodium hydrosulphide. From the outset of these reactions one can detect the broad signals from the **B** type radicals: $g = 2.0463$ (L = S—n-C_4H_9), $g = 2.0465$ (L = S—t-C_5H_{11}) and $g = 2.0459$ (L = SH).

The set of Fe^I complexes also includes two more groups of radical species with the signals within $2.020 \leqslant g \leqslant 2.022$ and $2.017 \leqslant g \leqslant 2.019$. These species always appear at the outset of the $Fe(CO)_5$—L reactions. The representatives of the latter group also appear in the reaction of $Fe_3(CO)_{12}$, but the intensities of the corresponding signals are far smaller than those in the reactions of iron pentacarbonyl.

The radicals that show up in the region $g = 2.020$–2.022 are unstable and are rapidly consumed at the initial process stages. The corresponding signals are small in intensity. This group includes, *inter alia*, a radical resulting from the $Fe(CO)_5$—NaL reaction, where $L^- = NO_2^-$ and $CH_2NO_2^-$ and giving a signal with $g = 2.0217$, and a quintet splitting on two nitrogen nuclei, $a_N = 1.6$ G (1:2:3:2:1).[15]

The radicals with $g = 2.017$–2.019 are more stable. Irrespective of the type of Lewis base, the corresponding signals have a singlet form in reactions with $Fe(CO)_5$ and are split into a quartet (1:3:3:1), $a_{^{57}Fe} = 1.8$–1.9 G, in those with $^{57}Fe(CO)_5$. The latter fact suggests the presence of three irons in each of the radicals of these groups. The higher stability of such radicals is likely due to a greater delocalization of an unpaired electron on the metallocycle.

In some cases the spectra show the presence of signals from an additional, fourth, group ($g = 2.033$–2.034), e.g. $g = 2.0338$ (L = SH); $g = 2.0337$ (L = SC_2H_5); $g = 2.0336$ (L = S—n-C_4H_9), and $g = 2.0333$ (L = S—n-C_8H_{17}). These radicals are characterized by us by the formula $Fe_2(CO)_6L_2^-$ since similar species, i.e. $Fe_2(CO)_6(N—t\text{-}Bu)_2^-$ ($g = 2.0335$, $a_N = 2.9$ G, 1:2:3:2:1)[15] and $Fe_2(CO)_6(SR)_2^-$,[16] were obtained by us from the corresponding neutral complexes by reduction on a sodium mirror in a THF solution. The signals with $g = 2.033$–2.034 are always present in reactions of iron pentacarbonyl with S-bases, sometimes in those with N-bases and never in the case of alkalis and alcoholates. This trend, defined by the stability of the radical anions $Fe_2(CO)_6L_2^-$, correlates well with the dependence of the $Fe_2(CO)_6L_2$ yields in various iron carbonyl reactions on the nature of a heteroatom in a Lewis base. The latter fact is known from the literature. Thus, for example, in the reactions of $Fe_2(CO)_9$ with thiols, alkyl sulphides and dialkyl disulphides, the $[Fe_2(CO)_6L_2]$ yields are at least 50%,[32] and in those

with N-bases, a few per cent.[33] The existence of such complexes in the case of $L = OR^-$, OH^- is unknown. It has led us to believe that the radical Fe^I carbonyl-containing complexes of the above types are intermediates resulting from the conversion of the initially formed **B** species [at the stage of one-electron transfer, eqs (4) and (6)] to the final diamagnetic compounds.

We believe that the conversion scheme can be represented as follows: the initially formed radical complex **B** reacts either with the parent iron carbonyl or the next molecule of the base. For example, in the case of $Fe(CO)_5$ and the anionic base, the following reactions are possible:

$$[Fe(CO)_4C(O)L]^- + Fe(CO)_5 \xrightarrow[-CO]{} [Fe_2(CO)_7L]^- \quad (7)$$

$$[Fe(CO)_4C(O)L]^- + L^- \xrightarrow[-CO]{} [Fe(CO)_3L_2]^{\cdot-}. \quad (8)$$

As stated above, the signal with $g = 2.0217$ in the reaction with the N-base has a quintet splitting, which corresponds to the presence of two nitrogens in this radical. The remaining radicals of this group ($g = 2.020$-2.022) also seem to contain two fragments of the base L and can have a structure of the type $[Fe(CO)_3L_2]^{\cdot-}$.

If L is a hard base (N- or O-type), it destabilizes the coordination sphere of the carbonyl complex so that the iron is readily oxidized to Fe^{2+}, to give rise to either the coordination complexes of the type $[FeL_2]_x$ (if L = anion) or a cation $[FeL'_k]^{2+}$ salts (if L′ is in the neutral form).

If L^- is a mild base (thiols and their sodium salts), one can observe stabilization of the coordination sphere within the iron carbonyl fragment:

$$[Fe(CO)_3L_2]^{\cdot-} + Fe(CO)_5 \xrightarrow[-CO]{} [Fe_2(CO)_6L_2]^{\cdot-} \quad (9)$$

$$[Fe_2(CO)_7L]^- + L^- \xrightarrow[-CO]{} [Fe_2(CO)_6L_2]^{\cdot-}. \quad (10)$$

Further clusterization can take place at this stage:

$$[Fe_2(CO)_6L_2]^{\cdot-} + Fe(CO)_5 \xrightarrow[-CO]{} [Fe_3(CO)_9L_2]^{\cdot-} \rightarrow \text{etc.} \quad (11)$$

The radicals $[Fe_2(CO)_6L_2]^{\cdot-}$ and $[Fe_3(CO)_9L_2]^{\cdot-}$ are oxidized to the neutral complexes and are thus stabilized, retaining their d^7-electron configuration. The radical-based approach to the conversion mechanism for the Fe^I complexes allows the explanation for the formation and stabilization of the various compounds of the type $[Fe_2(CO)_6L]$ and $[Fe_3(CO)_9L]$ incorporating reduced[34] or rearranged[35,36] ligands or unusually coordinated ones, e.g., via a carbon skeleton.[36]

However, in conclusion of this sub-clause we must stress that much work has to be done in the future for elucidating the composition and structure of the radicals described above.

(3) *Iron carbonyl radical anions and ways for their conversion*

As stated in sub-clause 1, in reactions of iron carbonyls with Lewis bases we detect the iron carbonyl radical anions **I**–**IV**. As a rule, they are observed in reactions with all iron carbonyls, but the sequence of the appearance of these anions, the rate of their accumulation and consumption are dependent on the parent iron carbonyl nuclearity.

Starting with $Fe_3(CO)_{12}$, the first signals to appear are those from the trinuclear radical anions, $Fe_3(CO)^{\cdot-}_{12}$ (**IV**) and $Fe_3(CO)^{\cdot-}_{11}$ (**II**), and then from $Fe_4(CO)^{\cdot-}_{13}$ (**III**) and $Fe_2(CO)^{\cdot-}_8$ (**I**). In the case of precursors in the form of the mono- and binuclear iron carbonyls $Fe(CO)_5$ and $Fe_2(CO)_9$, there first appear signals from the binuclear radical anion **I**, then from **II** and **IV**, and finally from the tetranuclear species **III**. Usually, the intensity of the latter species is low. A similar order in which the iron carbonyl radical anions are generated has been reported for the reduction of the iron carbonyls on a sodium mirror.[9]

Although in reactions involving $Fe(CO)_5$ the first usually detectable radical anions are $Fe_2(CO)^{\cdot-}_8$, it is known from the literature[37] that low-temperature matrices may contain the mononuclear $Fe(CO)^{\cdot-}_5$ and $Fe(CO)^{\cdot-}_4$ species, too. In our case, in reactions involving $Fe(CO)_5$, they also seem to appear first, being precursors of $Fe_2(CO)^{\cdot-}_8$. Therefore, the redox disproportionation eqs (3) and (4) for $Fe(CO)_5$ are expected to have the following form:

$$Fe(CO)_5 + L^- \rightarrow [Fe(CO)_4C(O)L]^- \quad (12)$$

$$[Fe(CO)_4C(O)L]^- + Fe(CO)_5 \rightarrow [Fe(CO)_4C(O)L]^{\cdot} + Fe(CO)^{\cdot-}_5 \quad (13)$$

$$Fe(CO)^{\cdot-}_5 \rightarrow Fe(CO)^{\cdot-}_4 + CO \quad (14)$$

$$Fe(CO)^{\cdot-}_4 + Fe(CO)_5 \rightarrow Fe_2(CO)^{\cdot-}_8 + CO. \quad (15)$$

When the process takes place in a closed system, as for instance, in our case, in sealed ampoules, some of the stages are distinguished by an equilibrium which is shifted towards "the heavier" iron carbonyl radical anions (a nuclearity growth phenomenon):

$$Fe_2(CO)^{\cdot-}_8 + Fe(CO)_5 \rightarrow Fe_3(CO)^{\cdot-}_{12} + CO \quad (16)$$

$$Fe_3(CO)^{\cdot-}_{12} \rightarrow Fe_3(CO)^{\cdot-}_{11} + CO \quad (17)$$

$$Fe_3(CO)^{\cdot-}_{11} + Fe(CO)_5 \rightarrow Fe_4(CO)^{\cdot-}_{13} + 3CO, \quad (18)$$

It is likely that in this case we are confronted with a kind of "oligocondensation" of iron pentacarbonyl.

Iron carbonyl radical anions **I–III** have an open electronic shell with 33, 47 and 59 cluster valence electrons, respectively. Radical metallo complex species are known to frequently possess a stereochemical non-rigidity. The coordination sphere of the radical anions **I–IV** also seems to be fairly labile and capable of skeleton rearrangement, as well as a fast ligand and electron exchange. All this favours a rapid growth of the radical ion clusters.

Similar processes in the gaseous phase have already been described.[38] However, as applied to solutions, there is a widely spread method by which the growth of the number of nuclei in iron carbonyl clusters takes place by a nucleophile substitution mechanism involving diamagnetic carbonyl ferrate dianions,[39] for example:

$$Na_2Fe(CO)_4 + Fe(CO)_5 \xrightarrow[-CO]{} Na_2Fe_2(CO)_8. \quad (19)$$

Therefore, such reactions have been also studied by an ESR method.

In fact, the interaction of $Na_2Fe(CO)_4 \cdot 1.5$diox and $(PPN)_2[Fe_2(CO)_8]$ with $Fe(CO)_5$ and $Fe_3(CO)_{12}$ appeared to occur readily, the usual set of iron carbonyl radical anions **I–IV** being formed at the outset of the process. In reactions involving salts of tri- and tetranuclear anions, such as $(PPN)_2[Fe_3(CO)_{11}]$ and $(PPN)_2[Fe_4(CO)_{13}]$, with the trinuclear carbonyl $Fe_3(CO)_{12}$, the binuclear radical anion **I** is formed in trace amounts only, the predominant products being the heavier radical anions **II–IV**. These data indicate that at small conversions the carbonyl ferrate–iron carbonyl reactions involve a one-electron transfer with the participation of these species. Such a process can be regarded as a direct one-electron reduction:

$$Fe_n(CO)_{m-1}^{2-} + Fe_{n'}(CO)_{m'} \rightarrow Fe_n(CO)_{m-1}^{-} + Fe_{n'}(CO)_{m'-1}^{-} + CO. \quad (20)$$

Generally speaking, the situation can be discussed alternatively within the frameworks of the above proposed eqs (3) and (4), if $L^- = Fe_n(CO)_{m-1}^{2-}$. Then:

$$Fe_n(CO)_{m-1}^{2-} + Fe_{n'}(CO)_{m'} \rightarrow [Fe_{n'}(CO)_{m'}Fe_n(CO)_{m-1}]^{2-} \quad (21)$$

$$[Fe_{n'}(CO)_{m'}Fe_n(CO)_{m-1}]^{2-} + Fe_{n'}(CO)_{m'} \xrightarrow[-CO]{} [Fe_{n'}(CO)_{m'}Fe_n(CO)_{m-1}]^{-} + Fe_{n'}(CO)_{m'-1}^{-}. \quad (22)$$

It should be noted, however, that the salts of the carbonyl ferrate anions, i.e. $[Fe_3(CO)_{11}]^{2-}$ and $[Fe_4(CO)_{13}]^{2-}$ do not react with $Fe(CO)_5$ at $-80°C$. The traces of iron carbonyl radical anions in this case can only be detected at room temperature in a few tens of minutes,* which is inconsistent with the stages of the activating complex formation process [eqs (21) and (22)]. Therefore, we believe, the most suitable process will be that described by eq. (20) for the direct reduction of the iron carbonyls.†

Thus one of the major properties of iron carbonyl radical anions is their ability to react with neutral iron carbonyl molecules to give rise to such radical anions with large nuclearity. There then arises a problem concerning the limits of the cluster growth process.

The literature contains data on the large iron carbonyl clusters also incorporating a carbide carbon, such as $[Fe_4C(CO)_{11}]^{2-}$, $Fe_5C(CO)_{15}$, $[Fe_5C(CO)_{14}]^{2-}$ and $[Fe_6C(CO)_{16}]^{2-}$.[25,40] Therefore it is natural to pose a question about the feasibility of carbide clustering in the reactions of iron carbonyls with Lewis bases and the associated problem concerning the assignment of the signals of the paramagnetic particles in the ESR spectra.

To solve this problem, we have studied the oxidation reactions of the salts $(PPN)_2[Fe_5C(CO)_{14}]$ and $(PPN)_2[Fe_6C(CO)_{16}]$ with ferricenium hexafluorophosphate, as well as the reduction of $Fe_5C(CO)_{15}$ on a sodium mirror in THF solution at $-80°C$. The first stages of these reactions give signals which were assigned to the carbide radical anions:

$Fe_5C(CO)_{14}^{-}$ $g = 2.0780$ $\Delta H \approx 11$ G

$Fe_5C(CO)_{15}^{-}$ $g = 2.0274$ $\Delta H \approx 3$ g

$Fe_6C(CO)_{16}^{-}$ $g = 2.0091$ or $g = 2.0017$ $\Delta H \approx 20$ G.

(Probably, the signal with $g = 2.0017$ can be assigned to $Fe_6C(CO)_{17}^{-}$.)

At larger conversions the spectra show the presence of signals from the iron carbonyl radical anions **I–IV**. Thus the carbide radical anion clusters are divided into smaller units. This suggests the existence of a common (in terms of mechanism) principle governing the formation of iron carbonyl clusters with and without the carbon ligand. As this takes place, the temperature factor produces a significant effect on the mutual conversions of ordinary and carbide radical anions.

In the reactions of iron carbonyls with Lewis bases

*In the case of $Fe_2(CO)_9$, poor solubility of both reagents in THF makes it difficult to quantitatively interpret the low-temperature spectra.

†Equation (20) can be regarded as an alternative of the redox disproportionation eq. (4), if "an extra" electron pair in the dianion is identified with the donor ligand. The same considerations can be applied to the analysis of the iron carbonyl–hydrocarbonyl anion $[HFe_n(CO)_{m-1}]^-$ formally taking $L^- = H^-$.

in the temperature region between −90 and +20°C we have not discovered any signals belonging to the carbonyl carbide clusters containing five and six irons. The process of their formation is essentially a catalytic variation of the Bell–Boudouard reaction, $2CO \rightarrow C + CO_2$, occurring at higher temperatures. This problem will be discussed in a separate communication.

Iron carbonyl radical anions **I–III**, being electron-deficient species, show a trend towards completion of the electronic shell; therefore their future in the reactions of iron carbonyls with Lewis bases is conversion to the corresponding 34-, 48- and 60-electron carbonyl ferrate anions. We believe that the role of the reducers of radical anions **I–IV** is played by unstable intermediate Fe^{I} complexes which were discussed in sub-clause 2 of this paper. The possibility of such a redox process is due to the accumulation of donor ligands in the coordination sphere of the Fe^{I} complexes, on the one hand, and formation of thermodynamically stable final products, on the other. For example, for the anionic base L^-:

$$Fe_n(CO)^{-}_{m-1} + [Fe(CO)_3L_2]^- \xrightarrow[-CO]{} Fe_n(CO)^{2-}_{m-1} + 1/x(FeL_2)_x \quad (23)$$

$$Fe_n(CO)^{-}_{m-1} + Fe_2(CO)_6L_2^- \longrightarrow Fe_n(CO)^{2-}_{m-1} + Fe_2(CO)_6L_2 \quad (24)$$

$$Fe_n(CO)^{-}_{m-1} + Fe_3(CO)_9L_2^- \longrightarrow Fe_n(CO)^{2-}_{m-1} + Fe_3(CO)_9L_2 \quad (25)$$

and for the neutral L′:

$$Fe_n(CO)^{-}_{m-1} + [Fe(CO)_3L'_2]^+ \xrightarrow[-CO]{L'} Fe_n(CO)^{2-}_{m-1} + [Fe(L')_k]^{2+}. \quad (26)$$

Thus, the final result will be the occurrence of a two-electron disproportionation scheme. The products resulting from reactions (23)–(26) are stable and usually terminate the reactions under discussion. They can be isolated preparatively, in high yields, in the form of the salts of the carbonyl ferrate anions of the type $Na_2[Fe_n(CO)_{m-1}]$ or $[Fe(L')_k][Fe_n(CO)_{m-1}]$,[1] the coordination complexes $(FeL_2)_x$,[41] as well as the diamagnetic bi- or trinuclear complexes $Fe_2(CO)_6L_2$ and $Fe_3(CO)_9L_2$.[32,33]

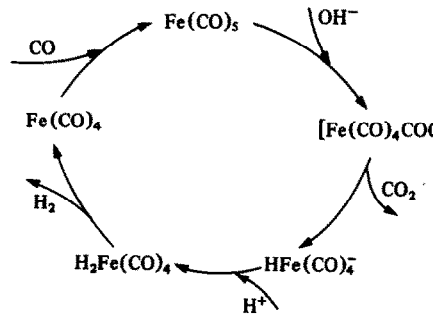
CONCLUSIONS

Thus the one-electron processes and radical ion complexes play an important role in the stoichiometric reactions of iron carbonyls with various Lewis bases. Moreover, these complexes are universal in that there exists practically no systems such as iron carbonyl–Lewis bases, in which they would not be formed at the early stages in fairly high steady-state concentrations.

The incompleteness of the electronic shell of the iron carbonyl radical anions and Fe^{I} radical derivatives facilitates the occurrence of the reactions of electron exchange, ligand substitution,[12] deoxygenation[15] and clusterization [for the latter case see eqs (15)–(18)]. In proton media the iron carbonyl radical anions are capable of converting to iron carbonyl hydride radicals.[11] Taking into account their universal nature and ability to undergo ready conversions at a relative stability, only these radical anions, iron carbonyl hydride radicals and Fe^{I} derivatives were assumed to be catalytically active species in a host of iron carbonyl-catalysed reactions. As far as various even-electron complexes, for example, carbonyl ferrate anions, are concerned, they represent either precursors or products of radical conversions, frequently being outside the catalytic cycles.

It would be interesting to discuss, in terms of the radical mechanism, such an important and typical kind of conversion as a WGSR mechanism: $CO + H_2O \rightleftharpoons CO_2 + H_2$.

The majority of researchers dealing with the WGSR mechanism[3] advocate either eq. (27) or a more sophisticated eq. (4) relying on a two-electron redox disproportionation process which is not always suitable for the interpretation of the experimental data.



(27)

The one-electron transfer processes disclosed by us in the system "base activated carbonyl–free carbonyl" [eqs (3) and (4)] warrant another approach to the interpretation of the WGSR mechanism.

For example, for a reaction involving $Fe(CO)_5$ the first two stages coincide with the known eq. (27):

$$H_2O \rightleftharpoons H^+ + OH^- \quad (28)$$

$$OH^- + Fe(CO)_5 \rightleftharpoons [Fe(CO)_4COOH]^-. \quad (29)$$

However, a one-electron transfer stage then occurs to give rise to the iron carbonyl radical anions:

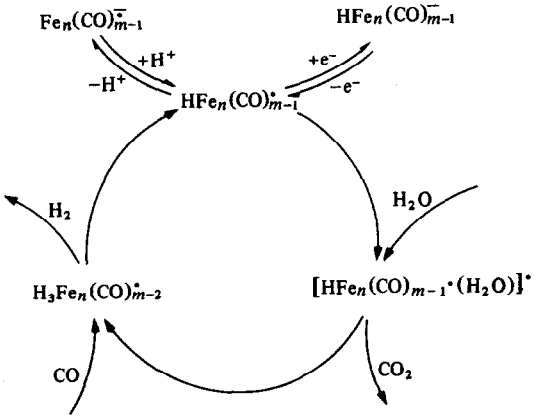
$$[Fe(CO)_4COOH]^- + Fe(CO)_5 \rightarrow$$
$$[Fe(CO)_4COOH]^{\cdot} + Fe(CO)_5^{\cdot-}$$
$$\downarrow -CO$$
$$Fe(CO)_4^{\cdot-}$$
$$\downarrow Fe(CO)_5$$
$$Fe_2(CO)_8^{\cdot-},\ Fe_3(CO)_{11}^{\cdot-},$$
$$Fe_4(CO)_{13}^{\cdot-},\ Fe_3(CO)_{12}^{\cdot-}. \quad (30)$$

In a proton media, these radical anions give iron carbonyl hydride radicals such as $HFe(CO)_4^{\cdot}$, $HFe_2(CO)_8^{\cdot}$ and $HFe_3(CO)_{11}^{\cdot}$.[42]

$$Fe_n(CO)_{m-1}^{\cdot-} + H^+ \rightleftharpoons HFe_n(CO)_{m-1}^{\cdot}. \quad (31)$$

They, like iron carbonyl radical anions,[15] can deoxygenate water in their coordination sphere to give radicals of the type $H_3Fe_n(CO)_{m-2}^{\cdot}$ such as $H_3Fe(CO)_3^{\cdot}$ and $H_3Fe_2(CO)_7^{\cdot}$.[42] The hydrogen molecule is then replaced by CO.

Thus the catalytic cycle includes reactions involving various carbonyl hydride radicals and can be presented as shown in eq. (32)



(32)

This equation makes it possible to explain the many facts which cannot be interpreted very well with the use of the traditional mechanism.[3,4] The WGSR process can be subdivided into three groups of elementary stages. The first group consists of four stages and plays a preparatory role:

—activating complex-formation of iron carbonyls and the Lewis base (H_2O, OH^-);

—one-electron transfer with the formation of coordinatively unsaturated iron carbonyl radical anions, i.e. derivatives;

—rearrangement of the radical ion species to give a set of iron carbonyl radical anions of various nuclearity;

—proton transfer between the water and the iron carbonyl radical anions to give iron carbonyl hydride radicals.

The second group of three elementary stages, according to eq. (32), represents the catalytic cycle including the reduction of water in the coordination sphere of the Fe^{-I} carbonyl radical anions at the expense of the CO ligands of the complex.

The third group consists of the carbonyl hydride radicals leaving the catalytic cycle as a result of their reduction to hydrydocarbonyl ferrate anions.

Thus, the key role in the reactions of the iron carbonyls with the Lewis bases is played by the activating complex-formation process and a subsequent one-electron transfer from the iron carbonyl–donor complex to the iron carbonyl. This gives rise to Fe^{I} and Fe^{-I} compounds which then undergo further conversions: the iron carbonyl radical anions are clusterized and the Fe^{-I} complexes are stabilized due both to the growing number of donor ligands and iron nuclei. At the later stages, the disproportionation process becomes more profound to give rise to the final products, i.e. Fe^{II} salts, the counterions of which are represented by carbonyl ferrate anions or hydridocarbonyl ferrate anions.

The specificity of the metal is frequently displayed by the behaviour of organometallic compounds. However such one-electron disproportionation reactions proceeding under the effect of Lewis bases, can be expected to take place for other metal carbonyls, including those of Ru,[43] Os[44] (iron subgroup) as well as nickel tetracarbonyl.[45]

(*Received* 31 *May* 1988; *accepted* 28 *September* 1988)

Abstract—Oxidative additions of the neutral sulphur ligands (tetra-*t*-butyl)-2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane (= "$^{bu}S_4$"—H_2), 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane (= "S_4"—H_2) and *o*-methylthiobenzenethiol (= "MeS_2"—H) to $[RhCl(PPh_3)_3]$, lead to S-coordinated Rh^{III}–hydride complexes with only one or two PPh_3 co-ligands. Reaction with "$^{bu}S_4$"—H_2 gives $[\mu$-"$^{bu}S_4$"$\{Rh(H)Cl(PPh_3)_2\}_2]$ (**1**) and $[Rh(H)(PPh_3)("^{bu}S_4")]$ (**2**); $[Rh(H)(PPh_3)("S_4")]$ (**3**) is obtained with "S_4"—H_2 and $[Rh(H)(PPh_3)_2("S_4")]$ (**5**) can be detected as intermediate. $[Rh(H)(PPh_3)("MeS_2")_2]$ (**6**) and $[Rh(H)Cl(PPh_3)_2("MeS_2")]$ (**8**) form with "MeS_2"—H; in solution, **8** transforms into $[Rh(H)Cl(PPh_3)(MeS_2)]_2$ (**9b**) and $[RhCl(PPh_3)("MeS_2")]_2$ (**10**). **3** and **6** react with $CHCl_3$ and HCl to give $[RhCl(PPh_3)("S_4")]$ (**5**) and $[RhCl(PPh_3)("MeS_2")_2]$ (7), respectively. **6** and **10** were characterized by X-ray structure analyses.

The interaction between hydrogen and transition metals in order to form metal hydrogen bonds is the basis of many catalytic reactions. The formation of metal hydrogen bonds is taken for granted in technical process,[2] in the photolysis of water, in the presence of transition metal compounds[3] and as well in the H/D exchange between water and H_2 which is catalysed by hydrogenases.[4]

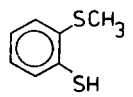
The prevailing co-ligands of isolable hydride complexes are phosphines;[5] in contrast, hydride complexes with sulphur co-ligands (and this holds even for thioethers which are isoelectronic to phosphines), have been much less investigated. The few hydride complexes with sulphur ligands usually also contain phosphine as well as other ligands, as it is found in, for example, $[Rh(H)Cl(PPh_3)_2(SC_6H_4CH_3)]$, $[Rh(H)Cl(PPh_3)_2(SH)]$,[6] $[(triphos)(H)Rh(\mu\text{-}SH)_2Rh(H)(triphos)](BPh_4)_2$,[7] $[Ir(H)X(CO)(PPh_3)(SR)]$ (X = halide, R = alkyl or aryl),[8] $[Ir(H)(CO)(Ph_2PCH_2CH_2SH)]^+$,[9] $[Ru(H)(PPh_3)_2(SR)]$[10] or $[Mo(H)_2(S_2C_6H_3R)(PMePh_2)_3]$ (R = H, Me).[11] In fact, hydride complexes with exclusively sulphur co-ligands seem to be very rare species and to our knowledge the only described examples are the crownthioether complex $[Rh(H)(TTP)](BF_4)_2$ (TTP = 1,4,8,11-tetrathiacyclotetradecane)[12] and the thiolate complex $[Li(THF)_4]_3[Mo(H)(S_2C_6H_4)_3]$.[13] It is difficult to assess the reason for the rarity of such complexes, although in some cases the easy elimination of thiols is thought to be responsible for the instability of thiolate metal hydrides.[14]

* For part XL, see ref. 1.

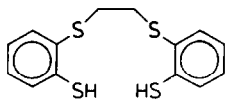
†Author to whom correspondence should be addressed.

The rarity of transition metal sulphur hydride complexes is particularly surprising with respect to hydrogenases[15] and nitrogenase, which also shows hydrogenase activity.[16] Here, the activation of hydrogen is assumed to take place at transition metal sulphur centres, implying that transition metal hydride complexes are particularly potent hydrogen catalysts.

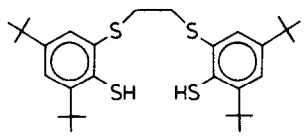
In order to assess the influence of sulphur ligands on transition metal hydrogen bonds we have tried to synthesize transition metal hydride complexes with a high degree of sulphur coordination and included it in our investigations of complexes of rhodium. By oxidative additions of the bi- and tetradentate thioether–thiols "MeS_2"—H =



"MeS_2"—H



"S_4"—H_2



"$^{bu}S_4$"—H_2

o-methylthiobenzenethiol, "S_4"—H_2 = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane and "$^{bu}S_4$"—H_2 = (tetra-*t*-butyl)-2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane to rhodium(I) centres we have obtained rhodium(III) hydride complexes with two and more sulphur donor atoms whose syntheses and properties will be reported here.

EXPERIMENTAL

All operations were carried out under gaseous nitrogen at room temperature unless otherwise noted; solvents were dried and distilled before use. Spectra were run on the following instruments: IR, Zeiss IMR 16 IR spectrometer (solids in KBr tablets, solutions in CaF_2 cuvettes with compensation of solvent bands); NMR, Jeol JNM PMX 60 and FT JNM-GX 270 spectrometer; mass spectra, Varian MAT 212 mass spectrometer (EI and FD mode). Starting materials were prepared as described in the literature: "MeS_2"—H,[17] "S_4"—H_2,[18] "$^{bu}S_4$"—H_2[19] and $[RhCl(PPh_3)_3]$.[20] $RhCl_3 \cdot 3H_2O$ was purchased from Ventron, Karlsruhe.

Syntheses

$[\mu$-"$^{bu}S_4$" $\{Rh(H)Cl(PPh_3)_2\}_2]$ (**1**). "$^{bu}S_4$"—H_2 (170 mg, 0.31 mmol) in 10 cm^3 of THF was added to the red solution of $[RhCl(PPh_3)_3]$ (290 mg, 0.31 mmol) in 25 cm^3 of THF. After 12 h the precipitating orange–yellow solid was filtered off, washed with THF and dried for 2 h *in vacuo*. Yield: 150 mg, 52%. Found: C, 66.2; H, 6.0; S, 6.4. Calc. for $C_{102}H_{106}Cl_2P_4Rh_2S_4$ (1860.45): C, 65.9; H, 5.7; S, 6.9%.

$[Rh(H)(PPh_3($"$^{bu}S_4$"$)]$ (**2**). The orange filtrate of **1** was evaporated, and the oily residue extracted with petrol ether until a yellow solid formed; it was separated, washed with petrol ether and dried for 4 h *in vacuo*. Yield: 120 mg, 43%. Found: C, 64.5; H, 7.1%. Calc. for $C_{48}H_{60}PRhS_4$ (899.15): C, 64.1; H, 6.7%.

$[Rh(H)(PPh_3)($"S_4"$)]$ (**3**). A solution of "S_4"—H_2 (310 mg, 1 mmol) in 10 cm^3 of THF was added to the red solution of $[RhCl(PPh_3)_3]$ (925 mg, 1 mmol) in 50 cm^3 of THF and refluxed for *ca* 2 h. The resulting yellow–brown solution was evaporated to dryness, and the yellow residue washed with petrol ether and dried for 4 h *in vacuo*. Yield: 590 mg, 87%. Found: C, 56.7; H, 3.9. Calc. for $C_{32}H_{28}PRhS_4$ (674.71): C, 57.0; H, 4.2%.

Recrystallization from THF–petrol ether (1:2) at 20°C gave red crystals of the solvate $[Rh(H)(PPh_3)($"S_4"$)] \cdot$THF (**3a**). Found: C, 57.8; H, 4.2. Calc. for $C_{36}H_{36}OPRhS_4$ (746.82): C, 57.9; H, 4.9%.

$[RhCl(PPh_3)($"S_4"$)]$ (**4**). Recrystallization of **3** from $CDCl_3$ at 20°C gave red crystals of **4** $\cdot CDCl_3$. Found: C, 48.0; H, 3.3. Calc. for $C_{33}H_{27}Cl_4DPRhS_4$ (829.55): C, 47.8; H, 3.3%.

$[Rh(H)(PPh_3)_2($"S_4"$)]$ (**5**). A solution of "S_4"—H_2 (150 mg, 0.48 mmol) in 10 cm^3 of THF was added to the red solution of $[RhCl(PPh_3)_3]$ (450 mg, 0.48 mmol) in 30 cm^3 of THF. After stirring for 2 h the resulting orange–brown solution was evaporated to dryness, the orange residue being washed with petrol ether and dried for 2 h *in vacuo*. Yield: 340 mg, 76%. Found: C, 64.0; H, 4.7. Calc. for $C_{50}H_{43}P_2RhS_4$ (937.01): C, 64.1; H, 4.6%.

$[Rh(H)(PPh_3)($"MeS_2"$)_2]$ (**6**). (a) A solution of "MeS_2"—H (585 mg, 3.78 mmol) and $[RhCl(PPh_3)_3]$ (875 mg, 0.94 mmol) in 60 cm^3 of THF was stirred for 2 h. Evaporation of the solvent gave an oily residue, which was extracted with MeOH–petrol ether (1:1). The resulting orange product was filtered off, washed with petrol ether and dried for 2 h *in vacuo*. Yield: 585 mg, 92%.

Found: C, 56.8; H, 4.4. Calc. for $C_{32}H_{30}PRhS_4$ (676.73): C, 56.8; H, 4.5%.

(b) A solution of $[Rh(PPh_3)_2(\text{"}MeS_2\text{"})]$ (**11**) (135 mg, 0.17 mmol) and "MeS_2"—H (30 mg, 0.2 mmol) in 30 cm^3 of THF was stirred for 16 h. Evaporation of the solvent gave an oily brown residue, which was extracted with MeOH. The resulting solution was filtered and evaporated to dryness again. The orange residue was washed with acetone and petrol ether and dried for 3 h *in vacuo*. Yield: 60 mg, 52%. Found: C, 56.8; H, 4.4. Calc. for $C_{32}H_{30}PRhS_4$ (676.73): C, 56.8; H, 4.5%.

$[RhCl(PPh_3)(\text{"}MeS_2\text{"})_2]$ (**7**). (a) "MeS_2"—H (310 mg, 2 mmol) was added to the red solution of $[RhCl(PPh_3)_3]$ (925 mg, 1 mmol) in 70 cm^3 of acetone and stirred for 2 h under air. The resulting orange suspension was filtered; after *ca* 4 days red crystals precipitate from the filtrate, which are separated and dried for 2 h *in vacuo*. Yield: 575 mg, 81%. Found: C, 54.1; H, 4.0. Calc. for $C_{32}H_{29}ClPRhS_4$ (711.18): C, 54.0; H, 4.1%.

(b) Concentrated HCl (1.2 cm^3) was added to a suspension of $[Rh(H)(PPh_3)(\text{"}MeS_2\text{"})_2]$ (**6**) (135 mg, 0.2 mmol) in 30 cm^3 of acetone. After stirring for 12 h the red solution was filtered and evaporated to dryness. The residue was washed with MeOH and petrol ether, and recrystallized from $CHCl_3$. Yield: 105 mg, 75%. Found: C, 54.4; H, 3.9. Calc. for $C_{32}H_{29}ClPRhS_4$ (711.18): C, 54.0; H, 4.1%.

$[Rh(H)Cl(PPh_3)_2(\text{"}MeS_2\text{"})]$ (**8**). "MeS_2"—H (140 mg, 0.8 mmol) in 20 cm^3 of acetone was added to a red suspension of $[RhCl(PPh_3)_3]$ (740 mg, 0.8 mmol) in 80 cm^3 of acetone. After stirring for 2 h the yellow precipitate which forms was filtered off, washed with petrol ether and dried for 4 h *in vacuo*. Yield: 440 mg, 67%. Found: C, 63.0; H, 4.6; S, 7.8. Calc. for $C_{43}H_{38}ClP_2RhS_2$ (819.22): C, 63.0; H, 4.7; S, 7.8%.

$[Rh(H)Cl(PPh_3)(\text{"}MeS_2\text{"})]_2$ (**9b**). (a) Gaseous HCl (4.5 cm^3) was added to a red solution of $[Rh(PPh_3)_2(\text{"}MeS_2\text{"})]$ (**11**) (155 mg, 0.2 mmol) in 30 cm^3 of THF. After stirring for 12 h a yellow precipitate formed, which was separated by filtration, washed with THF and dried for 4 h *in vacuo*. Yield: 45 mg, 38%.

(b) "MeS_2"—H (475 mg, 3.07 mmol) was added to a red solution of $[RhCl(PPh_3)_3]$ (2.84 g, 3.07 mmol) in 100 cm^3 of THF. After refluxing for 3 h a yellow precipitate formed which was separated by filtration from the hot solution, washed with THF and dried for 2 h *in vacuo*. Yield: 700 mg, 41%. Found: C, 53.6; H, 4.0; S, 12.0. Calc. for $C_{50}H_{46}Cl_2P_2Rh_2S_4$ (1113.84): C, 53.9; H, 4.2; S. 11.5%.

$[RhCl(PPh_3)(\text{"}MeS_2\text{"})]_2 \cdot CH_2Cl_2$ (**10**). The green filtrate of **9** was evaporated to dryness and the green residue dissolved in 50 cm^3 of CH_2Cl_2, which was covered by a layer of petrol ether. After 6 weeks the resulting black crystals were filtered off and dried for 4 h *in vacuo*. Yield: 385 mg, 21%. Found: C, 52.0; H, 3.7; S, 11.0. Calc. for $C_{52}H_{46}Cl_4P_2Rh_2S_4$ (1196.76): C, 51.2; H, 3.9; S, 10.7%.

X-ray data collection and structure determinations

Single crystals of **6** were obtained by a two-fold recrystallization from THF solutions which were covered by a layer of petrol ether; those of **10** were obtained in the same way from CH_2Cl_2 solutions. The single crystals were sealed under nitrogen in glass capillaries; the structures were solved by direct methods. The non-hydrogen atoms were refined anisotropically and the aromatic hydrogen atoms were placed at calculated positions and refined as rigid groups. The hydrogen atoms of the methyl groups were placed in ideal tetrahedral positions and rotated around their central carbon atoms during refinement; the hydride hydrogen atom of **6** was found by difference Fourier synthesis and refined as a rigid group. Table 1 summarizes the data and information relating to data collection and structure refinement.

RESULTS AND DISCUSSION

The reaction of the sterically demanding tetradentate thioether thiol "$^{bu}S_4$"—H_2 with $[RhCl(PPh_3)_3]$ yields two hydride complexes according to eq. (1).

Oxidative addition of SH groups to the rhodium(I) centre gives the binuclear [μ-"^{tbu}S$_4$"{Rh(H)Cl(PPh$_3$)$_2$}$_2$] (**1**) as well as the mononuclear [Rh(H)(PPh$_3$)("^{tbu}S$_4$")] (**2**). The yellow compound **2** becomes the major product if the [RhCl(PPh$_3$)$_3$] solution is slowly added to the solution of the ligand; vice versa, the orange **1** preferably forms if the ligand is added to the Rh-complex in the ratio 1 : 2.

In contrast to all other "^{tbu}S$_4$" complexes known at present, **1** is insoluble in most organic solvents and hence it could be identified only by elemental analyses and by its IR spectrum, which shows a characteristic ν(Rh—H) band at 2140 cm^{-1}. Mononuclear **2** is very soluble in organic solvents, e.g. CH_2Cl_2, $CHCl_3$ or THF. In the KBr IR spectrum, the ν(Rh—H) band is observed at 1990 cm^{-1}, and in the ^{1}H NMR spectrum the hydride signal appears at -10.25 ppm, being split into a pseudo-triplet by coupling to the rhodium and phosphorus atoms (Fig. 1).

The *t*-butyl groups yield four sharp singlets; this indicates the *cis* position of the hydride and PPh$_3$ ligands, and the structure of **2** shown in eq. (1), which has only C_1 symmetry.

The analogous reaction of [RhCl(PPh$_3$)$_3$] with the unsubstituted parent ligand "S$_4$"—H$_2$ likewise yields the hydride complex [Rh(H)(PPh$_3$)("S$_4$")] (**3**), but heating in refluxing THF is notably needed to achieve the complete coordination of the sulphur ligand, see eq. (2).

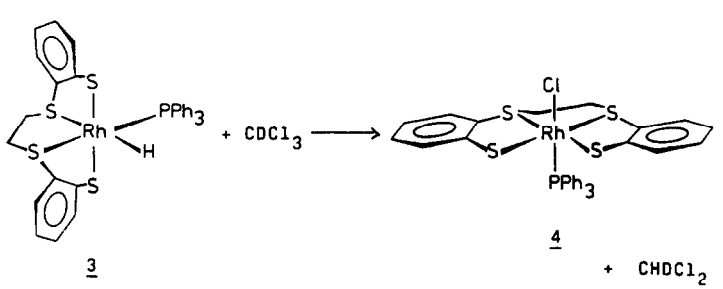
m = multiplet; d = doublet; s = singlet.
[a] Relative intensities in parentheses.
[b] See text.
[c] No M^+ ion observed.
[d] In d_8-THF.
[e] Overlapping doublets of doublets giving a pseudo-triplet.
[f] In $CDCl_3$.
[g] Overlapping doublet of triplets giving a pseudo-quartet.

3 is obtained after recrystallization from THF–petrol ether as **3**·THF; its characteristic ν(Rh—H) band appears at a slightly higher frequency, at 2020 cm^{-1} (in KBr). In the ^{1}H NMR spectrum (in d_8-THF) a pseudo-triplet is again observed for the hydride ligand at −10.98 ppm (Table 2).

The Rh—H bond of **3** is relatively stable towards acids, for example HCl/H_2O or HBF_4/Et_2O, but it is highly reactive towards chlorinated alkanes. This was noticed when **3** was dissolved in $CDCl_3$ in order to run a ^{1}H NMR spectrum; no hydride signal was observed at −10.98 ppm, but instead a multiplet appeared at 5.25 ppm due to the formation of $CHDCl_2$. From this solution, the chloro complex [Rh(Cl)(PPh_3)("S_4")] (**4**) was isolated, which had formed according to eq. (3).



3 4 (3)

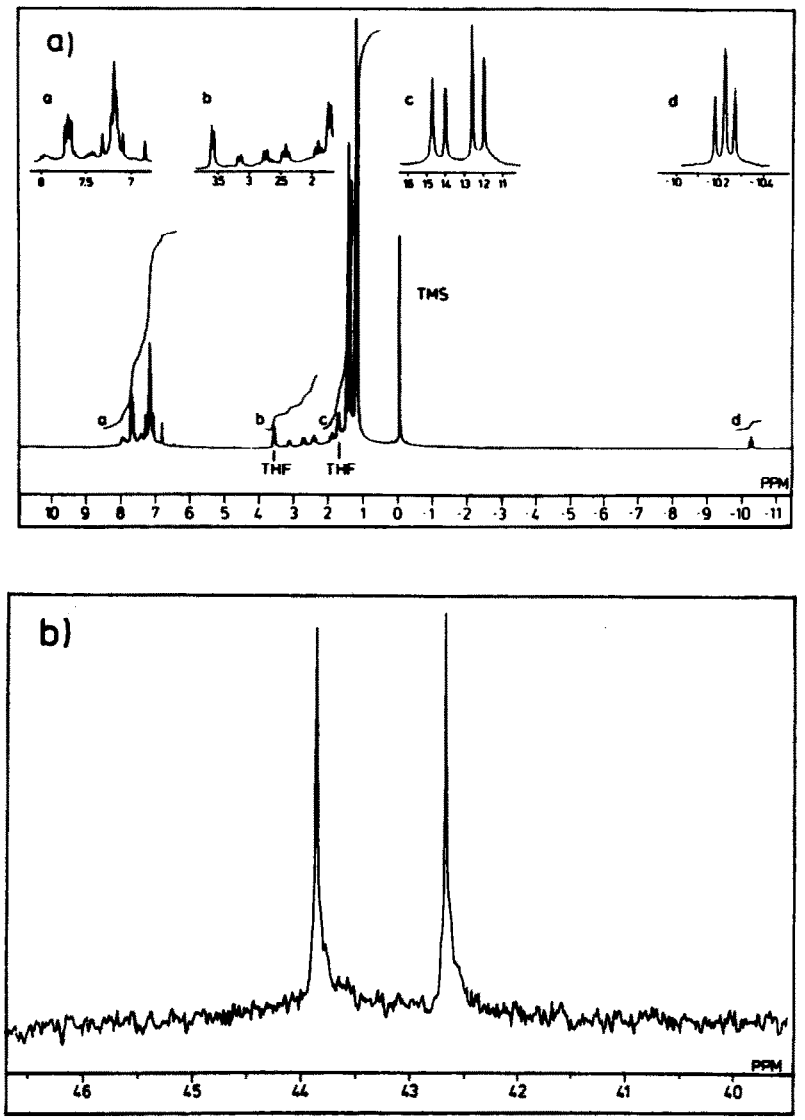


Fig. 1. NMR spectra of [Rh(H)(PPh$_3$)("^{bu}S$_4$")]: (a) ^{1}H NMR spectrum in d_8-THF (270 MHz), (b) ^{31}P NMR spectrum.

The ^{1}H NMR spectra of **3** and **4** differ remarkably. **3** shows an asymmetric multiplet for the C_2H_4 bridge between 3.3 and 2.0 ppm which is typical of six-coordinate "S_4" complexes with C_1 symmetry. **4**, however, gives only a slightly broadened singlet for the C_2H_4 bridge in $CDCl_3$. This might indicate that the chloro-complex **4** has a higher symmetry (C_2) than the hydride **3**, as illustrated by the figures of eq. (3); the necessary rearrangement may take place via the five-coordinated intermediate [Rh(PPh$_3$)("S_4")]. Evidence for the facile formation of such a fragment is seen in the FD mass spectrum of **4** which shows an intensive peak at $m/e = 674$ in addition to the M^+ ion at $m/e = 709$.

Halogenation of hydride complexes by halogen alkanes is a common reaction[21] and reaction (3) shows that in this respect hydride complexes with a coordination sphere dominated by sulphur do not behave differently; for example, the reactions between [CpMo(H)(CO)$_3$] and CCl_4,[22] [Rh(H)(PPh$_3$)$_4$] and CH_3I[23] or [Pt(H)Cl{P(OEt)$_3$}$_2$] and CCl_4[24] lead also to a H/X exchange, and in the latter case even a concomitant *trans* → *cis* rearrangement takes place.

As expected, the coordination of "S_4"—H_2 to the rhodium centre of [RhCl(PPh$_3$)$_3$] takes place stepwise. The reaction was carried out at room temperature according to eq. (4)

$$[RhCl(PPh_3)_3] + \text{"}S_4\text{"}—H_2 \xrightarrow[-HCl,\,-PPh_3]{THF/RT/2\,h} [Rh(H)(PPh_3)_2(\text{"}S_4\text{"})] \quad (4)$$

(5)

After 2 h of reaction the intermediate [Rh(H)$(PPh_3)_2$("S_4")] (**5**) can be isolated as an orange–yellow solid. It contains two PPh_3 ligands and the "S_4"$^{2-}$ ligand might act tridentately only; **5** was characterized by elemental analyses, its ν(Rh—H) band at 1980 cm^{-1} and a hydride signal at −10.98 ppm in the ^{1}H NMR spectrum. The ^{31}P NMR spectrum shows the signals of **3**, of the free PPh_3 ligand as well as of other PPh_3—Rh complexes, indicating that in solution the reaction slowly continues, finally yielding **3**.

The chelate effect and generation of three chelate rings certainly favours the coordination and oxidative addition, respectively, of the tetradentate "S_4"—H_2 to the rhodium(I) centre of [$RhCl(PPh_3)_3$]. Although these effects are expected to be less pronounced with bidentate ligands, two "MeS_2"—H can also be coordinated, yielding complexes of the type [Rh(H)(PPh_3)("MeS_2")$_2$] (**6**). In this case, however, a much larger number of stereoisomers is possible and unambiguous structure assignment on the basis of spectroscopic data becomes difficult. Scheme 1 shows a selection of these isomers, which differ with respect to the position of the hydride and PPh_3 ligands as well as that of the thioether and thiolate donors.

In order to obtain **6** according to eq. (5)

$$[RhCl(PPh_3)_3] + 4\,\text{"}MeS_2\text{"}\text{—}H \xrightarrow[-2PPh_3,\,-HCl]{THF/RT/2h} [Rh(H)(PPh_3)(\text{"}MeS_2\text{"})_2] + 2\,\text{"}MeS_2\text{"}\text{—}H \quad (5)$$

(**6**)

an excess of "MeS_2"—H is needed, even if the stoichiometry does not demand it; as will be described below, the reaction takes a different course, if only stoichiometric amounts of "MeS_2"—H or less are used.

The large number of CH_3 and ^{31}P signals in the ^{1}H and ^{31}P NMR spectra, respectively, of the raw product indeed indicates the formation of several isomers, but after recrystallization, **6** yields yellow crystals which obviously contain mainly one isomer. It shows a characteristic ν(Rh—H) band at 2060 cm^{-1} in the KBr IR spectrum and the hydride signal at −12.60 ppm in the ^{1}H NMR spectrum,

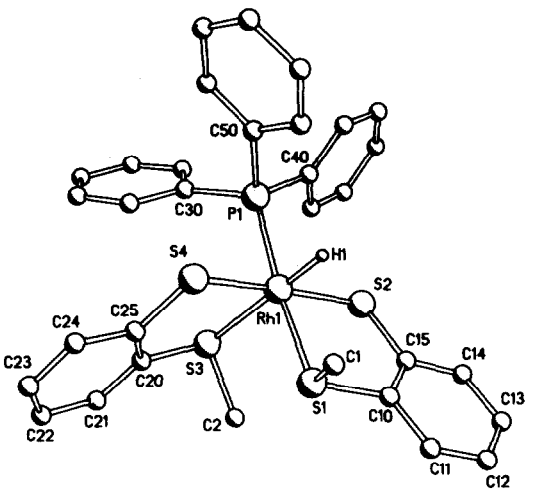

Fig. 2. Molecular structure of **6** (H atoms omitted).

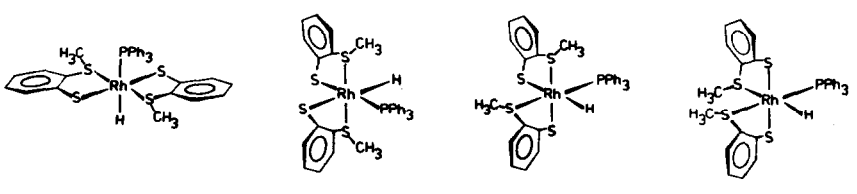
which is split again into a pseudo-triplet due to rhodium and phosphorus coupling. The two methyl groups give rise to two equally intensive signals at 2.15 and 3.00 ppm; the former one appears as a singlet and the latter one is slightly split. These data are compatible e.g. with the isomers c or d of Scheme 1. This structure assignment is corroborated by the ^{31}P{^{1}H} NMR spectrum: it shows as the major signal, only one doublet ($^1J_{(Rh-P)}$ = 129.4 Hz).

The X-ray structure analysis of **6** allowed the unequivocal structure assignment. Figure 2 shows the molecular structure, and Table 3 lists selected bond distances and angles. The rhodium atom is pseudo-octahedrally surrounded by four S, one P and one H atom. The thiolato sulphur atoms occupy *trans* positions and the Rh—S(thioether) distance *trans* to the hydride ligand is a remarkable 10 pm longer than the other Rh—S distances; this is certainly due to the large well-known *trans* influence of hydride ligands. The Rh—P distance of 228.6(2) pm lies in the range of other complexes where the PPh_3 is *trans* to a thioether sulphur atom, e.g. [Rh(CO)(PPh_3)("MeS_2")] (Rh—P: 227.6 pm).[1]

As was mentioned above, **3** with the tetradentate "S_4"$^{2-}$ ligand, showed no observable reaction with acids such as hydrochloric acid or HBF_4–Et_2O at normal conditions. **6** is much more reactive and



Scheme 1. Selection of stereoisomers of [Rh(H)(PPh_3)("MeS_2")$_2$] (**6**).

yields the chlorocomplex **7** under smooth conditions according to eq. (6):

$$[Rh(H)PPh_3)(\text{“}MeS_2\text{”})_2] + HCl \xrightarrow[-H_2]{\text{acetone/RT/24 h}} [RhCl(PPh_3)(\text{“}MeS_2\text{”})_2]. \quad (6)$$

(7)

7 also forms directly, if $[RhCl(PPh_3)_3]$ is reacted under aerobic conditions according to eq. (7):

$$[RhCl(PPh_3)_3] + 2\,\text{“}MeS_2\text{”}—H \xrightarrow[-\text{other products}]{\text{acetone/air/RT/2 h}} [RhCl(PPh_3)(\text{“}MeS_2\text{”})_2]. \quad (7)$$

(7)

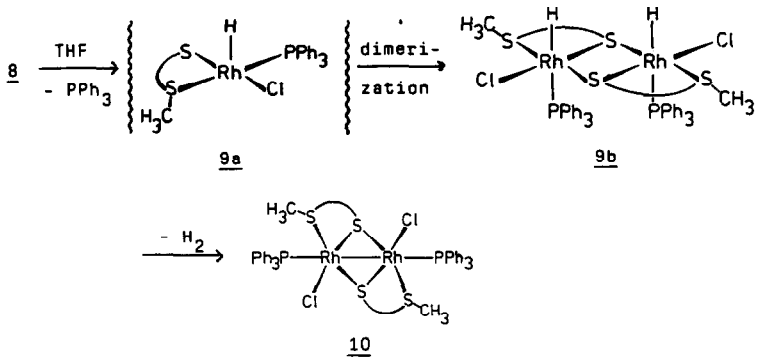
Although **7** crystallizes as small red cubes, the ^1H NMR spectrum again shows several methyl signals. A singlet at 2.70 ppm and a multiplet at 2.55 ppm prove that **7** is formed as stereoisomers and accordingly in the $^{31}P\{^1H\}$ NMR spectrum, two doublets with an intensity ratio of 4 : 1 with $^1J_{(Rh—P)} = 114.7$ and 113.6 Hz are observed.

In order to obtain **6** according to eq. (5) an excess of "MeS_2"—H is necessary. This became understandable when we investigated the reaction between $[RhCl(PPh_3)_3]$ and only 1 equivalent of "MeS_2"—H, in order to synthesize $[Rh(H)Cl(PPh_3)_2(\text{“}MeS_2\text{”})]$ (**8**).

$$[RhCl(PPh_3)_3] + \text{“}MeS_2\text{”}—H \xrightarrow[-PPh_3]{\text{acetone/RT/2 h}} [Rh(H)Cl(PPh_3)_2(\text{“}MeS_2\text{”})]. \quad (8)$$

(8)

The isolation of **8** in pure form is only possible if the synthesis is carried out in solvents in which **8** is insoluble, e.g. acetone. Here, the suspended $[RhCl(PPh_3)_3]$ slowly dissolves upon addition of "MeS_2"—H and **8** precipitates simultaneously. **8** is unstable in any solvent in which is dissolves, e.g. THF, because it then immediately undergoes further reactions leading to the intermediates **9a** and **9b**, resulting ultimately in the binuclear rhodium(II) complex **10** according to eq. (9).



(9)

The structure of **10** could be determined by X-ray structure analysis (see below); **10** seems to be the most stable complex in this system.

The lability of **8** was detected when we tried to obtain the NMR spectra in $CDCl_3$. In the ^1H NMR spectrum, a hydride signal was observed at -15.35 ppm, which is split into a pseudo-quartet by coupling to the rhodium and two phosphorus atoms. The methyl region shows several signals between 2.0 and 3.1 ppm indicating the presence of at least two complexes. By integration and taking the hydride signal as reference, the singlet at 2.20 ppm can be assigned to **8**, whereas the singlet at 3.10 ppm stems from the rhodium(II) complex **10**. In the ^{31}P NMR spectrum, two doublets of doublets resulting from the two non-equivalent phosphorus atoms of **8** show that at least a few minutes after dissolution, **8** is still the major species in solution. Several smaller phosphorus signals, including the signal of free PPh_3 at -6.50 ppm, however, indicate the formation of new species. The lability of **8** might also be responsible for the fact that in the FD mass spectrum no molecular ion, but only two signals at $m/e = 555$ ($[M—PPh_3]^+$) and $m/e = 782$ ($[M—HCl]^+$) can be observed.

The loss of PPh_3 leads from **8** to [Rh(H)Cl(PPh_3)("MeS_2")] (**9a**), whereas the loss of HCl yields formally [Rh(PPh_3)$_2$("MeS_2")] (**11**); these two compounds seem to play key roles when [RhCl(PPh_3)$_3$] is reacted with either the neutral "MeS_2"—H or the anion "MeS_2"$^-$, and subsequently with different reagents, giving rise to a large number of reactions and complexes, which are summarized in Scheme 2.

[Rh(PPh_3)$_2$("MeS_2")] (**11**) had been characterized before,[1] all other compounds were found here and, except complex **9a**, they were all isolated and characterized; the [Rh(PPh_3)("MeS_2")]-fragment is common to all reactions and complexes.

Thus, by heating **8** in THF, according to eq. (10), the coordinatively unsaturated and 16 e$^-$-configurated **9a** forms. It is, however, unstable and dimerizes in order to give binuclear **9b**, which precipitates in yellow microcrystals from the green solution.

$$[Rh(H)Cl(PPh_3)_2(\text{“}MeS_2\text{”})] \xrightarrow{THF/65°C/4\,h} \mathbf{9b} + \mathbf{10} + \text{other products.} \quad (10)$$

The same complex **9b** forms directly if [RhCl(PPh_3)$_3$] and "MeS_2"—H are heated in boiling THF:

$$[RhCl(PPh_3)_3] + \text{“}MeS_2\text{”}—H \xrightarrow{THF/65°C/4\,h} \mathbf{9b} + \mathbf{10} + \text{other products.} \quad (11)$$

It is again obtained, if HCl adds oxidatively to [Rh(PPh_3)$_2$("MeS_2")] (**11**) at room temperature:

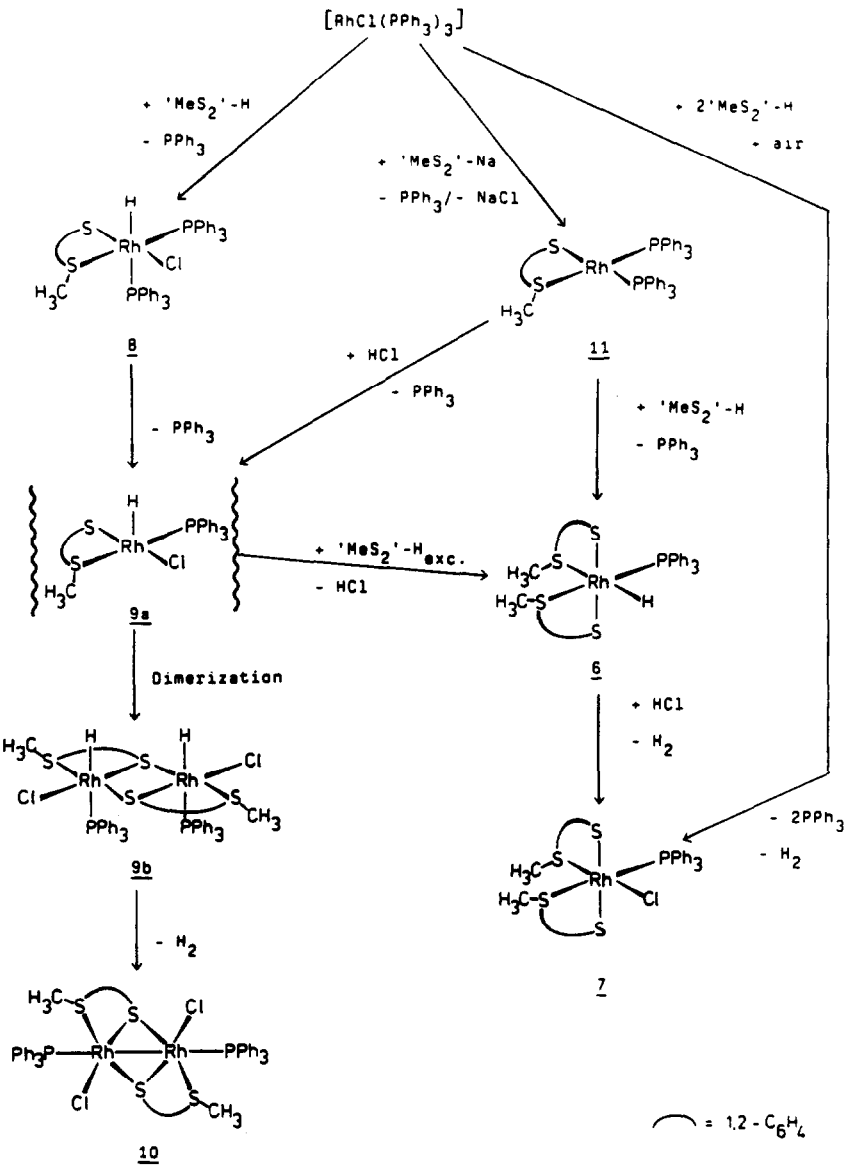
$$[Rh(PPh_3)_2(\text{“}MeS_2\text{”})] + HCl \xrightarrow[\mathbf{(11)}]{THF/RT/12\,h} \mathbf{9b}. \quad (12)$$

In all three cases a green solution forms, from which **9b** precipitates as yellow crystals. **9b** is insoluble in all common organic solvents and it could thus be characterized only by elemental analyses, its IR spectrum showing a sharp ν(Rh—H) band of medium intensity at 2040 cm^{-1}.

The intermediate formation of coordinatively unsaturated **9a** explains why it is necessary to apply an excess of "MeS_2"—H in reaction (5) in order to obtain **6**. Only in the presence of sufficient "MeS_2"—H is the dimerization of **9a** prevented, and **6** forms by the addition of a second "MeS_2"—H and the loss of HCl. Finally, Scheme 2 explains also, the ultimate formation of the binuclear rhodium(II) complex **10** from **9b** by a bicentric reductive elimination of H_2 and concomitant Rh—Rh bond formation. This species is observed only if the unsaturated species **9a** can form, but it is no longer detected as soon as two "MeS_2" ligands have coordinated to the Rh centre.

X-ray structure determination of [RhCl(PPh_3)("MeS_2")]$_2 \cdot CH_2Cl_2$ (**10**)

The elucidation of the molecular structure of **10** was possible by X-ray structure determination. The



Scheme 2. Reactions and complexes in the system $[RhCl(PPh_3)_3]$/"MeS_2"—H.

asymmetric unit of the cell contains two independent molecules of **10**, the bond distances and angles of which differ only marginally. Figure 3 shows a view of one of the molecules, and Table 4 lists selected bond distances and angles of the two molecules. In the binuclear complex, each Rh atom is pseudo-octahedrally coordinated by three sulphur, one phosphorus, and one chlorine in addition to the neighbouring rhodium atom. The two thiolato sulphur atoms function as bridges connecting the two $[RhCl(PPh_3)(\text{"}MeS_2\text{"})]$ fragments in such a manner that the Rh_2S_2 unit has a dihedral angle of 71.4° along the S—S edge. The Rh—Rh distance of 268.9 pm suggests a single bond between the two rhodium centres;[25] Rh—Rh double bonds are usually assumed to be in the range of 250 pm.[26]

Taking the Rh—Rh bond into account, the structure of **10** may also be described as two facially connected octahedral $[RhCl(PPh_3)(\text{"}MeS_2\text{"})]$ fragments; this suggests, eventually, a bent Rh—Rh bond as has been postulated for $Co_2(CO)_8$.[27]

CONCLUSIONS

The oxidative addition of bi- and tetradentate thioether thiol ligands to rhodium(I) centres leads to sulphur-coordinated rhodium hydride complexes. The chelate effect of these ligands prevents the elimination of thiols and is responsible for the stability of the rhodium(III) hydride complexes.

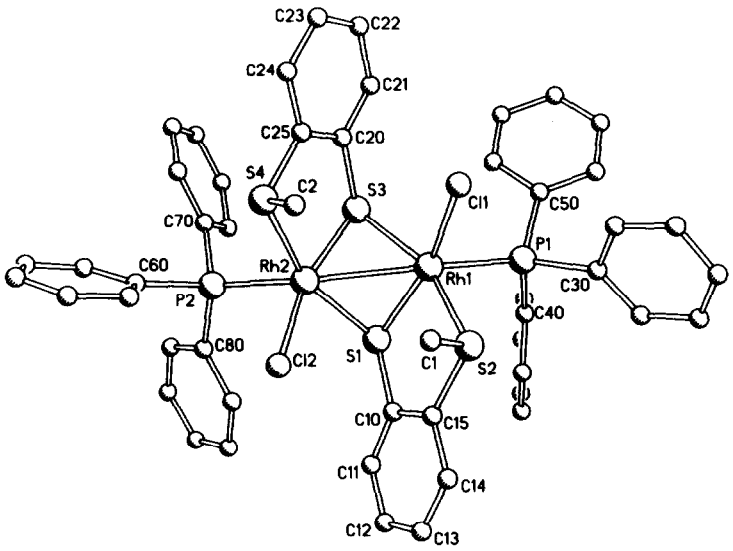

Fig. 3. Molecular structure of **10** (H atoms omitted).

In the system $[RhCl(PPh_3)_3]$/"MeS_2"—H, the coordinatively unsaturated $[Rh(PPh_3)$("MeS_2")] fragment plays a key role and the binuclear rhodium(II) complex $[RhCl(PPh_3)$("MeS_2")$]_2$ (**10**) is the ultimate product. In some cases, the hydride ligands may be easily substituted by chloride: $[Rh(H)(PPh_3)$("S_4")] (**3**) reacts with $CDCl_3$ to give $[RhCl(PPh_3)$("S_4")] (**4**), and $[Rh(H)(PPh_3)$("MeS_2")$_2$] (**6**) reacts with HCl to give $[RhCl(PPh_3)$("MeS_2")$_2$] (**7**).

Supplementary material

The atomic positional and thermal vibration parameters, plus complete distance, angle and structure factor tables have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

SYNTHESIS AND CHARACTERIZATION OF MOLYBDENUM(0) AND TUNGSTEN(0) CARBONYL DERIVATIVES OF METHYLENEBIS[DIPHENYLPHOSPHINE OXIDE] AND BIS[(DIPHENYLPHOSPHINYL)METHYL]PHENYLPHOSPHINE OXIDE

P. PLANINIĆ* and H. MEIDER

Rudjer Bošković Institute, Department of Physical Chemistry, Zagreb, Croatia, Yugoslavia

(*Received* 3 *May* 1988; *accepted after revision* 29 *September* 1988)

Abstract—The reaction of molybdenum and tungsten hexacarbonyls with the ligands $[(C_6H_5)_2P(O)]_2CH_2$ (MDPO) and $[(C_6H_5)_2P(O)CH_2]_2P(O)C_6H_5$ (RPPh) has been investigated. The new compounds *cis*-$M(CO)_4$MDPO, *cis*-$M(CO)_4$RPPh, *fac*-$M_2(CO)_6(MDPO)_3$ and *fac*-$M(CO)_3$RPPh, where M = Mo^0 or W^0, have been prepared. All complexes isolated are diamagnetic with an octahedral geometry. Results of IR, Raman and NMR spectra have been discussed.
