Substituted carbonyl complexes of the group VI metals have been the subject of interest for many years.[1] The most examined ligands in the metal carbonyl chemistry have been various types of substituted phosphines which rather easily displace carbon monoxide from $M(CO)_6$.[2–5] Considerably less attention has been paid to phosphine oxides as ligands toward chromium, molybdenum and tungsten carbonyls. Tricarbonyl and tetracarbonyl complexes of molybdenum(0) and tungsten(0) with different monodentate phosphine oxides, as well as complexes of the $M_2(CO)_6L_3$ type, where M = Mo or W, and L = bidentate ligand, i.e. ethylenebis[diphenylphosphine oxide], were reported and characterized by IR spectroscopy a couple of decades ago.[6–8] From that time little work has been carried out on molybdenum and tungsten carbonyl complexes with phosphine oxide ligands.

Our interest has been focused on the synthesis and investigation of the complexing ability of some phosphine oxide derivatives which are potentially tridentate ligands since they contain three PO groups bridged by two CH_2 groups. These compounds proved to be good complexing agents for a number of transition metals.[9–11] The present work describes the isolation and characterization of some carbonyl complexes of molybdenum(0) and tungsten(0) with methylenebis[diphenylphosphine oxide] (MDPO) and bis[(diphenylphosphinyl) methyl]phenylphosphine oxide (RPPh). The bidentate ligand MDPO has been widely used as a complexing agent for a great number of transition metals,[12] but its carbonyl complexes have not been reported until now. The obtained RPPh compounds represent the first carbonyl complexes with a trisphosphine oxide ligand.

RESULTS AND DISCUSSION

Thermal reaction of the appropriate metal hexacarbonyl with MDPO and RPPh ligands in benzene, toluene or xylene yielded the corresponding molybdenum(0) and tungsten(0) complexes of the general type: $M(CO)_4L$ (L = RPPh, MDPO), $M(CO)_3$RPPh and $M_2(CO)_6(MDPO)_3$, where M = Mo^0, W^0. Analytical data are given in Table 1.

MDPO and RPPh ligands form tetracarbonyl complexes with molybdenum and tungsten of the same stoichiometry. It was noticed that MDPO as a bidentate ligand formed this type of complex more readily than the RPPh ligand. The tungsten tetracarbonyl complex with MDPO was obtained from xylene after 1 h of refluxing the components in the molar ratio of 1 : 1. The replacement of tungsten with molybdenum under the same reaction conditions yielded a precipitation of a mixture of

different carbonyl species. In order to isolate the corresponding molybdenum complex we had to take an excess of metal hexacarbonyl (2 : 1 ratio) and use lower temperatures (120°C) and a shorter reaction time (30 min). Tetracarbonyl complexes with RPPh could be obtained only if the metal–ligand ratio was at least 3 : 1 for molybdenum and 2 : 1 for tungsten, along with a rather short reaction time.

The first step in the course of preparation of tricarbonyl complexes was tetracarbonyl again, as evidenced by IR spectra. Continued heating, however, caused a decrease of the IR absorptions due to tetracarbonyl species and an increase of absorption of the tricarbonyls. The reaction was readily accomplished in 2 h for molybdenum and in about 4 h for tungsten. In general, the yield was very good for the tricarbonyl species (80–90%) and rather low for the tetracarbonyl complexes (10–17%).

The isolated compounds are diamagnetic, yellow or yellow–brown, air-sensitive solids. They are crystalline as evidenced by X-ray diffraction. The molybdenum complexes are more stable than the tungsten ones, but they can all be kept in a dry argon atmosphere for several months. The complexes are insoluble in most of the usual organic solvents, although they dissolve in DMF and DMSO with decomposition. The insolubility of the obtained complexes makes their isolation from the reaction mixture rather simple, but prevents their investigation by certain physical and spectroscopic techniques.

IR spectra

The IR spectral data of the examined complexes are presented in Table 2. Tricarbonyl and tetracarbonyl complexes show a marked difference in both the ν(CO) and ν(PO) region of the spectra. Figure 1 shows IR spectra of $W(CO)_4RPPh$ and $W(CO)_3RPPh$ complexes in the range 2100–900 cm^{-1}.

For the complexes $M(CO)_4L$ (L = RPPh or MDPO ligands), four absorption bands appear in the CO stretching region of the spectra [2000–1800 cm^{-1}, Fig. 1(a)] indicating that these species possess a C_{2v} symmetry of ligands around the central metal.[13] The absorption bands belong to four IR active carbonyl stretching modes ($2A_1+B_1+B_2$). The bands were assigned and used for calculations

of the force constants according to the Cotton–Kraihanzel secular equations.[14] Since intermolecular interactions in the solid state can have appreciable effects upon the frequencies, the obtained values must be interpreted with caution, but they may be of interest as there are no complete data for other phosphine oxide derivatives of the group VI metal carbonyls in the literature. The calculated force constants of M(CO)$_4$MDPO and M(CO)$_4$RPPh complexes are presented in Table 3. They can be compared to those obtained for the corresponding complexes with some N-donor ligands which like phosphine oxides, are considerably poorer π-acceptors than the phosphines.[14b,c,15]

In addition to the carbonyl region, the section of the IR spectra from 1250–1100 cm^{-1} where bands due to PO stretching vibrations occur, is characteristic. These absorption bands are, in the spectra of the complexes, shifted to lower wavenumbers with regard to the free ligands (Table 2), thus indicating coordination of the phosphoryl oxygen.[16] Instead of three bands being present in the spectra of both ligands (at 1211, 1194 and 1175 cm^{-1} for MDPO, and at 1215, 1192 and 1163 cm^{-1} for RPPh), only one band at $\sim$1160 cm^{-1} appears in the spectra of all tetracarbonyl species (Table 2). Spectra of RPPh complexes show an additional shoulder on the higher energy side of the ν(PO) band. Since IR spectra of M(CO)$_4$MDPO and M(CO)$_4$RPPh complexes are nearly identical, especially in the CO stretching region, the RPPh ligand probably acts as bidentate in these complexes. The third phosphoryl oxygen from the ligand must be free, or involved in some kind of hydrogen bond.[11]

IR spectra of M(CO)$_3$RPPh and M$_2$(CO)$_6$(MDPO)$_3$ complexes show very close similarity in both shape and position of the characteristic bands. The spectra of tungsten(0) complexes exhibit the usual slight lowering of the ν(CO) absorption bands ($\sim$10 cm^{-1}) with regard to the spectra of the corresponding molybdenum(0) complexes. In all these spectra, two main strong bands, corresponding to the CO stretching vibrations, are present: a sharper band at around 1900 cm^{-1}, and a broader, split one at 1730–1740 cm^{-1}, Fig. 1(b). A spectrum with nearly identical CO stretching vibrations was reported for the trisubstituted molybdenum carbonyl complex with triphenylphosphine oxide.[7] These results are compatible with the formation of facial tricarbonyl complexes (C_{3v} local symmetry, A_1+E modes).[13] Splitting of the lower energy band into two components may arise from the lowering of the C_{3v} to C_s symmetry,[17] with regard to the polydentate structure of the ligands or in some instances, from the crystal effects in the solid state.[17]

The interesting feature of these spectra is that the ν(CO) frequency of the lower energy band appears in what is usually considered to be the bridging carbonyl region. The CO stretching vibrations in phosphine oxide complexes in general, appear at

Table 3. Carbonyl stretching frequencies and force constants for *cis*-M(CO)$_4$MDPO and *cis*-M(CO)$_4$RPPh complexes

Complex	ν(CO) (cm^{-1})				Force constants (mdyn Å^{-1})		
	A_1	A_1	B_1	B_2	k_1	k_2	k_i
Mo(CO)$_4$MDPO	2015	1890	1852	1808	14.25	15.22	0.40
Mo(CO)$_4$RPPh	2012	1895	1850	1805	14.20	15.26	0.38
W(CO)$_4$MDPO	1998	1870	1845	1800	14.14	14.92	0.40
W(CO)$_4$RPPh	2000	1868	1845	1802	14.16	14.91	0.41

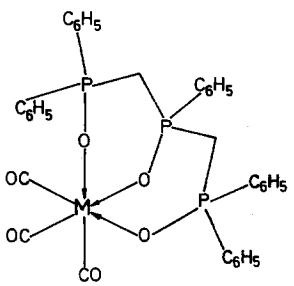
lower wavenumbers than in the analogous derivatives having tertiary phosphines as ligands. This is a consequence of the lower π-accepting ability of the oxygen compared to phosphorus. A decrease of ν(CO) values in facial tricarbonyl complexes may also be enhanced by the *trans* effect of the oxygen donor ligands,[18,19] since in these species all three CO groups are in a *trans* position to the oxygen.

At the same time as ν(CO) decreases with subsequent substitution of the CO groups, ν(PO) increases as a consequence of the redistribution of the negative charge on the metal atom. Thus, in the tricarbonyl complexes ν(PO) absorption bands are shifted to higher wavenumbers with regard to the tetracarbonyls (Table 2, Fig. 1).

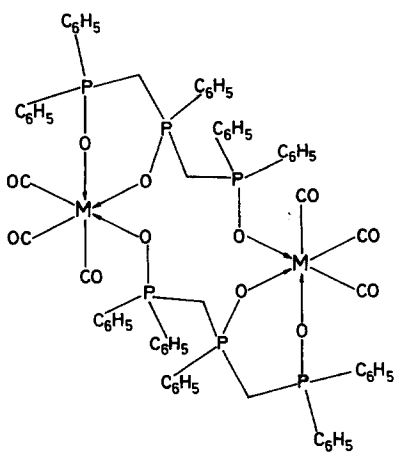
The similarity of the spectra of $M(CO)_3RPPh$ and $M_2(CO)_6(MDPO)_3$ suggests the same local symmetry of three facial carbonyls and three phosphoryl oxygens around the metal atoms in both types of complexes (Structures **1**, **2** and **3**).

Raman spectra

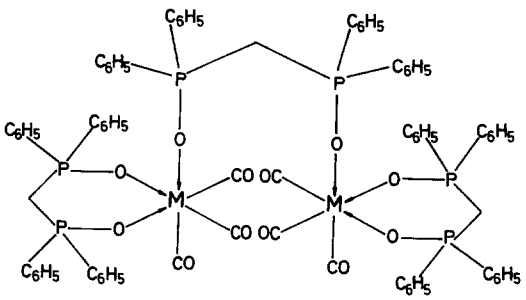
Raman spectra of facial tricarbonyl complexes are similar in shape to the corresponding IR spectra. Inspection of Table 2 shows in addition some IR–Raman coincidences. In particular, for the RPPh



Structure 1. *fac*-$M(CO)_3RPPh$; M = Mo, W.



Structure 2. *fac*-$[M(CO)_3RPPh]_2$; M = Mo, W.



Structure 3. *fac*-$M_2(CO)_6(MDPO)_3$; M = Mo, W.

complexes the strong IR line at ~ 1900 cm^{-1} matches within experimental error the medium Raman band at approximately the same position. Splitting of the lower energy bands is considerably greater in Raman (~ 75 cm^{-1}) than in IR spectra (~ 20 cm^{-1}) of these complexes. For tricarbonyl MDPO complexes coincidences have been observed for the absorption bands at ~ 1720 cm^{-1}. According to the exclusion rule, a centre of symmetry in the crystal units of these complexes has to be excluded.[20,21] Tetracarbonyl complexes decompose under laser beams, and therefore, Raman spectra could not be recorded.

NMR spectra

^{13}C and ^{31}P NMR data for the RPPh ligand and $Mo(CO)_3RPPh$ complex are given in Table 4.

The CP MAS ^{13}C NMR spectrum of the $Mo(CO)_3RPPh$ complex exhibits several peaks from 126 to 135 ppm assigned to carbons from the phenyl rings.[22] In addition, the spectrum shows two signals, at 38.89 and 29.07 ppm, corresponding to the CH_2 groups of the ligand.[22] The difference between the two CH_2 absorptions suggests that these two CH_2 groups of the ligand are not equivalent in the complex. The absence of CO signals in the ^{13}C NMR spectrum of the complex is probably due to the long relaxation time of carbonyls.

In the CP MAS ^{31}P NMR spectrum of the RPPh ligand, we observed three absorption peaks in the approximate ratio of 1 : 1 : 1. Chemical shifts are consistent with those obtained for similar phosphine oxide ligands.[23–25] The resonance at 29.70 ppm is assigned to the central phosphorus atom. The higher field signals corresponding to the terminal PO groups appear at 27.69 and 26.57 ppm. Slight differences in the C—P—C bond angles or the presence of some kind of hydrogen bond may cause this inequivalence of the two terminal PO groups of the ligand in the solid state NMR.

The CP MAS ^{31}P NMR spectrum of the Mo $(CO)_3RPPh$ complex exhibits three well-resolved

Table 4. ^{13}C and ^{31}P NMR data of the RPPh ligand and *fac*-$Mo(CO)_3$ RPPh complex

Compound	$\delta(C)^a$ (CH_2)	$\delta(P)^a$
RPPh	Not measured	29.70, 27.69, 26.57
$Mo(CO)_3$RPPh	38.89, 29.07	35.13, 31.75, 26.91

[a] Chemical shift values [δ(C) and δ(P)] in ppm relative to tetramethylsilane and trimethylphosphate, respectively, with positive values downfield from references.

resonances at: 35.13, 31.75 and 26.91 ppm in a ratio of 1:1:1. On the other hand, in a monomeric facial complex with two PO groups occupying chemically equivalent sites, one would expect two absorption peaks in the ^{31}P NMR spectrum in a ratio of 2:1. The inequivalence of the terminal PO groups can arise from a rigid conformation of the bicyclic metal–chelate system. However, the NMR signals and the insolubility of the complexes suggest that a dimer structure with the bridging RPPh ligand is more likely (Structures **1** and **2**).

EXPERIMENTAL

Materials

The ligands, methylenebis[diphenylphosphine oxide] (MDPO) and bis[diphenylphosphinyl)-methyl]phenylphosphine oxide (RPPh) were prepared according to the data in the literature.[12,26] Metal hexacarbonyls were used directly as obtained commercially (p.a. Merck). The solvents were purified, dried over the appropriate drying agents and freshly distilled under argon prior to use. All manipulations were performed under a dry argon atmosphere.

Physical measurements

IR spectra were recorded on KBr pellets using a Perkin–Elmer Model 580B spectrophotometer.

Raman spectra were taken on solid samples in sealed capillaries, with a Coherent Radiation Model Innova 100-15 spectrometer with 20 mW power, with the sample in the 514.5 nm line of an argon ion laser as the exciting radiation. Spectra were recorded using a Dilor Z-24 triple monochromator.

Magnetic susceptibilities were measured by the Gouy method at 22°C using $CuSO_4 \cdot 5H_2O$ as calibrant.

Magnetic resonance CP MAS spectra were recorded by the Bruker, Analitische Messtechnik, GMBH, Karlsruhe, on a Bruker MSL 400 spectrometer operating at 100.63 MHz for ^{13}C and 161.98 MHz for ^{31}P. Chemical shifts were measured at 22°C with tetramethylsilane as internal standard (^{13}C) and trimethylphosphate as external standard (^{31}P). Because some of the complexes are unstable, the NMR data (^{13}C and ^{31}P) were measured only for the RPPh ligand and the $Mo(CO)_3$RPPh complex.

Preparation of complexes

$Mo(CO)_3$RPPh was obtained by mixing 0.264 g (1 mmol) of $Mo(CO)_6$, 0.554 g (1 mmol) of RPPh and 25 cm^3 of benzene, which were boiled under reflux for 3 h, in a two-neck flask, on an oil bath, with stirring. A light yellow precipitate separated out. The solution was cooled to room temperature, and the microcrystalline solid filtered off, washed with a few cm^3 of benzene and dried in the vacuum of a water suction-pipe. The yield was 0.670 g (90%). The complex is stable in air for several days.

$W(CO)_3$RPPh was prepared by refluxing a mixture of 0.352 g (1 mmol) of $W(CO)_6$ and 0.665 g (1.2 mmol) of RPPh in 30 cm^3 of toluene for 5 h. A yellow product (0.658 g 80%) was filtered off, washed with toluene and dried as above. The complex is much less stable than the corresponding molybdenum compound.

$Mo_2(CO)_6(MDPO)_3$ was obtained by mixing 0.264 g (1 mmol) of $Mo(CO)_6$, 0.624 g (1.5 mmol) of MDPO and 30 cm^3 of xylene. These were heated at 120°C with stirring for 2 h. A yellow product separated out. The complex was isolated as outlined above. The yield was 0.725 g (90%).

$W_2(CO)_6(MDPO)_3$. A mixture of 0.176 g (0.5 mmol) of $W(CO)_6$ and 0.312 g (0.75 mmol) of MDPO in 12 cm^3 of toluene was boiled under reflux for 3 h. The orange–yellow, highly air-sensitive precipitate separated out in a yield of 0.350 g (80%).

$Mo(CO)_4$RPPh was obtained after the mixture of 3 mmol of $Mo(CO)_6$ (0.792 g) and 1 mmol of RPPh (0.554 g) was refluxed in 40 cm^3 of benzene for 20 min. The yellow–brown product, which separated on the sides of the flask, was collected by filtration, washed with a few cm^3 of benzene and dried. The yield was 0.075 g (9.8%).

$W(CO)_4RPPh$ was obtained by mixing 0.704 g (2 mmol) of $W(CO)_6$ and 0.554 g (1 mmol) of RPPh. These were boiled under reflux in 40 cm^3 of xylene for 40 min. A yellow–brown compound (0.102 g) (12%) was obtained, which was filtered off, washed with xylene and dried as above.

$Mo(CO)_4MDPO$ was obtained by mixing an amount of 0.528 g (2 mmol) of $Mo(CO)_6$ with 0.416 g (1 mmol) of MDPO. These were heated in 35 cm^3 of xylene at 120°C for 30 min. A yellow–brown solid separated out in a yield of 0.090 g (14%).

$W(CO)_4MDPO$ was obtained by refluxing equimolar amounts of $W(CO)_6$ (0.352 g, 1 mmol) and MDPO (0.416 g, 1 mmol) in 35 cm^3 of xylene for 2 h. The precipitate was filtered off, washed with xylene and dried. The yield was 0.121 g (17%).

SYNTHESIS, CHARACTERIZATION AND STRUCTURAL ELUCIDATION OF INDIUM(III) COMPLEXES OF 2-ALKYLAMINOCYCLOPENTENE-1-CARBODITHIOIC ACID AND OF ITS ESTERS

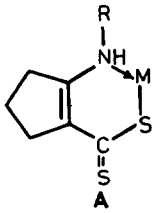
SHAILENDRA K. SINGH, YASHPAL SINGH, AUDHESH K. RAI and RAM C. MEHROTRA*

Chemical Laboratories, University of Rajasthan, Jaipur-302004, India

(*Received* 13 *June* 1988; *accepted* 29 *September* 1988)

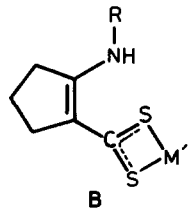
Abstract—Reactions of $InCl_3$ and the sodium salts of 2-alkylaminocyclopentene-1-carbodithioic acids, R(H)NC$^{\frown(CH_2)_3\frown}$CC(S)SH (where R = H, Me, Et and *n*-Bu) and esters of the parent acid, H_2NC$^{\frown(CH_2)_3\frown}$CC(S)SR^1 (where R^1 = Me and CH_2NEt_2) in 1:3 molar ratios, yield derivatives with the general formulae, In[S(S)C$^{\frown(CH_2)_3\frown}$CN(H)R]$_3$ and In[N(H)C$^{\frown(CH_2)_3\frown}$CC(S)SR^1]$_3$, respectively. These complexes have been characterized by elemental analyses, molecular weight determinations and conductometric measurements, as well as on the basis of their IR and NMR (^{1}H, ^{13}C and ^{14}N) spectral data. The bonding of indium with the acids is through SS$^-$, whereas with esters bonding occurs from the N—S sites.

Complexes of N- and S-bonded, N-alkyl and ester derivatives of 2-aminocyclopentene-1-carbodithioic acid with different transition metals exhibit[1–6] a remarkable diversity in coordination patterns, some of which may be illustrated by the formulae below (**A–C**).



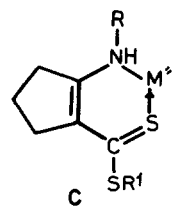
A

M = Ni^{II}, Pd^{II}, Pt^{II}, Fe^{II}, Rh^{I}, Cu^{I}, Hg^{I}; R = H, Et.



B

M^1 = Co^{II}, Co^{III}, Cr^{III}.



C

M^{11} = Ni^{II}, Pd^{II}; R^1 = Me, CH_2NEt_2.

A survey of the literature reveals that no attempt has been made to synthesize metal complexes of these ligands with non-transition elements, except for some organotin derivatives[7] of the ACDA esters. In view of the interesting results reported for transition metal complexes, it has been considered worthwhile to synthesize a few substituted ACDA ligands and investigate the nature of their complexation reactions and of bonding with indium.

EXPERIMENTAL

Chemicals

All the chemicals used were of reagent grade. Cyclopentanone (Sisco) was distilled (b.p., 130°C) before use and indium trichloride (Fluka) was used

*Author to whom correspondence should be addressed.

as such. All the solvents used were dried by standard methods. The ligand ACDA and its substituted derivatives have been synthesized by the literature methods[8,9] and have been characterized by melting point determination, elemental analysis, IR, ^{1}H and ^{13}C NMR spectral analyses.

General method of preparation of the complexes

All the complexes have been synthesized by the reactions of indium trichloride and the sodium salts of ligands in 1 : 3 molar ratios in hot benzene solution. The sodium salts of the ligands were obtained by their reactions with calculated amounts of sodium methoxide in hot benzene solution after constant stirring for 1 h. Since, a similar method has been followed for the synthesis of all indium derivatives, the preparation of only one compound is described here for the sake of brevity.

The benzene solution of the freshly prepared sodium salt of BuACDA (1.38 g, 5.83 mmol) was added dropwise to a stirred suspension of indium trichloride (0.43 g, 1.93 mmol) and stirring was continued for about 2 h. During the course of the reaction, the temperature was maintained below 60°C. Sodium chloride thus obtained was filtered off and removal of the solvent under reduced pressure, yielded a yellow coloured solid compound which was recrystallized from benzene–hexane, yield 93%.

Some indium complexes were found to be sparingly soluble in benzene. In these cases the solvent was distilled off and the sodium chloride was removed by washing with aqueous ethanol, leaving the insoluble compound which was finally washed with *n*-hexane and dried *in vacuo*.

Analyses

Indium was estimated gravimetrically as indium oxide. Nitrogen and sulphur were estimated by Kjeldahl's[10] and Messenger's method,[10] respectively.

Physical measurements

Molecular weights were determined on a Knauer vapour pressure osmometer in dimethylsulphoxide solution at 45°C, and conductivity measurements were carried out using a Systronics conductivity meter, type 302 SR No. 475, in nitrobenzene solution.

The IR spectra as Nujol mulls or KBr pellets were recorded with Perkin–Elmer 577 and Philips Pye–Unicam, SP 3-300, spectrophotometers. The ^{1}H and ^{13}C NMR spectra of the ligands were recorded on a 270 MHz Bruker spectrometer, at ambient temperatures, and the ^{1}H, ^{14}N and ^{13}C NMR spectra of the complexes were recorded in $CDCl_3$ or DMSO-d_6 solution, on a JEOL FX 90 Q spectrometer using TMS as an internal reference. For ^{14}N spectra, ammonium nitrate was used as an external reference.

[a] LH ligands.
[b] Sparingly soluble.
[c] Insoluble.
[d] Highly soluble in common organic solvents.

RESULTS AND DISCUSSION

The metal complexes were obtained by the reactions of indium trichloride with the sodium salts of the ligands in 1 : 3 molar ratio in benzene solution:

$$InCl_3 + 3R(H)NC(=CH_2)_3=CC(S)SNa \longrightarrow In[S(S)CC(=CH_2)_3=CN(H)R]_3 + 3NaCl$$

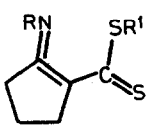
(where R = H, —CH_3, —C_2H_5, *n*-C_4H_9)

$$InCl_3 + 3Na(H)NC(=CH_2)_3=CC(S)SR^1 \longrightarrow In[(H)NC(=CH_2)_3=CC(S)SR^1]_3 + 3NaCl$$

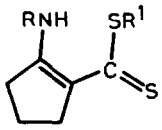
(where R^1 = —CH_3, —$CH_2N(C_2H_5)_2$).

The stoichiometry of the compounds has been confirmed by their analytical data (Table 1). Some of these complexes are fairly soluble in common organic solvents like chloroform, benzene and THF, whereas others are found to be insoluble. The soluble metal complexes are found to be non-electrolytic in nitrobenzene solution and monomeric in dimethylsulphoxide solution at 45°C.

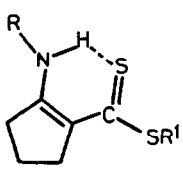
Following earlier suggestions,[3,9] the ligands may be assumed to exist in the following six tautomeric forms (I–VI).



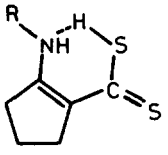
(I)



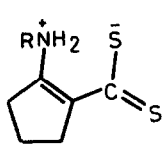
(II)



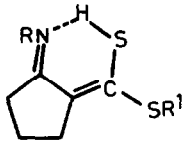
(III)



(IV)



(V)



(VI)

(where R = H; R^1 = —CH_3, —$CH_2N(C_2H_5)_2$.
R = —CH_3, —C_2H_5, *n*-C_4H_9; R^1 = H).

On the basis of IR and ^{1}H NMR spectral data, Takeshima *et al.*[8] proposed structure **I**, whereas Bordas *et al.*[9] suggested structure **III** for these ligands. However, Nag and Joardar[3] reported the existence of structure **III** exclusively in DMSO-d_6 solution, while in $CDCl_3$ solution a partial contribution of structure **VI** was also proposed. The assignments for SH/NH proton signals are also inconsistent in the existing literature.[3,8,9]

In order to establish the position of NH and SH signals, low temperature ^{1}H NMR spectra of two representative derivatives, 2-butylaminocyclopentene-1-carbodithioic acid (BuACDA) and the methyl ester ($ACDE_1$) of ACDA have been recorded. The room temperature spectrum of BuACDA, in $CDCl_3$ solution, exhibits a broad signal at δ 12.8 ppm which splits into a multiplet at −50°C due to the coupling of the proton attached to the nitrogen atom with CH_2 protons of the butyl group attached to the nitrogen atom, confirming that the signal appearing at δ 12.8 ppm is due to the —NH proton of the ligand BuACDA. However, in the ^{1}H NMR spectrum of $ACDE_1$ in which the SH proton of ACDA is replaced by a methyl group and where the two protons are bound to the nitrogen atom, two broad signals at δ 11.2 and 6.2 ppm have been observed. The SCH_3 protons appear at δ 2.6 ppm as a sharp singlet. In the low temperature (−70°C) ^{1}H NMR spectrum, both the broad signals at δ 11.2 and 6.2 ppm split into multiplets. The above low temperature ^{1}H NMR spectral data confirm the existence of tautomeric form **III** exclusively for ACDA and its alkyl and ester derivatives.

IR spectral study of the ligands and the indium complexes

Following earlier observations,[3,5,8,9] broad bands observed at ≈2550 and ≈3400 cm^{-1} in the IR spectra of ACDA and its N-alkyl derivatives can

be assigned to SH and NH/NH_2, respectively. The disappearance of the former and the unaltered position of the latter in the indium complexes confirm that the bonding occurs only through S in these derivatives. The strong bands observed at 1605–1590 cm^{-1}, 1490–1480 cm^{-1}, 1360–1310 cm^{-1} and1280–1270 cm^{-1} in the ligands and their metal complexes may be assigned to the combination of $\nu_{NH+C=C}$, $\nu_{CH_2+C=C}$, $\nu_{C=N+C=S}$, and mixing of $\nu_{C=S+C=N}$ modes, respectively.

The occurrence of an asymmetric CSS stretching frequency around 1000 cm^{-1} has been reported in the case of metal dithiocarbamate[11] and dithiocarbazate[12] complexes for disulphur chelation, whereas for the involvement of only one sulphur atom, this band splits[11] into two. The appearance of only a single band in the range 1010–910 cm^{-1} in the indium complexes of ACDA and its N-alkyl substituted derivatives, therefore, indicates involvement of both sulphur atoms in these complexes. The band at $\approx$610 cm^{-1} in the ligands and the corresponding metal complexes has been assigned to either a symmetrical CSS or C—S. A new band appearing at 350–335 cm^{-1} may be assigned to ν_{In-S}.

In the IR spectrum of the free ligand $ACDE_1$, an absorption band has been observed at $\approx$3250 cm^{-1} which can be assigned[5,7] to a ν_{NH_2} vibration. A downward shift of $\approx$50 cm^{-1} of this band in the spectrum of $In(ACDE_1)_3$ indicates the deprotonation of one of the NH_2 protons on complexation. This is confirmed by a smaller ($\approx$15 cm^{-1}) downward shift of the absorptions observed in the ranges 1270 ± 5 and 1150 ± 5 cm^{-1} which have been ascribed to $\nu_{C=N+C=S}$ and $\nu_{C=S+C=N}$ modes, respectively.

The appearance of two bands for asymmetric CSS at 940 and 910 cm^{-1} clearly indicates the involvement of the sulphur atom during chelation. Further, the appearance of both M—N and M—S absorption frequencies at 550 and 350–325 cm^{-1}, respectively, indicate the participation of both the nitrogen and sulphur atoms of the ligand in bonding.

^1H *NMR spectral studies of the ligands and their complexes*

A sharp singlet observed for the —SH proton in the spectra of the ligands (Table 2) is found to be absent in the corresponding metal derivatives, indicating the removal of a —SH proton and the formation of In—S bonds.

In the ^1H NMR spectrum of ACDA, two broad signals assigned to the $—NH_2$ protons have been observed at δ 6.1 and 11.2 ppm, showing the non-equivalence of the protons of the amino groups. This may be attributed to the involvement of one of the $—NH_2$ protons in hydrogen bonding through the sulphur atom (C=S, structure **III**) of the ligand. In the spectrum of the indium complex, $In(ACDA)_3$, one of the two signals (δ 6.1 ppm) appears almost in the same region while the second signal, observed at δ 11.2 ppm in the free ligand, shifts upfield to δ 7.8 ppm. This may be due to the breaking of the hydrogen bond (N—H $\cdots$ S=) during complexation. However, the existence of two signals for the $—NH_2$ protons, instead of one signal even on complexation, indicate the probability of some weak interaction between one of the NH_2 protons and the sulphur atom (—C=S) of the dithiocarboxylate group. A similar phenomenon has been observed in the ^1H NMR spectra of the free BuACDA and its indium complex.

In the ^1H NMR spectra of indium complexes of S-alkyl or ester derivatives of ACDA (Table 2), the signal observed at δ 11.2 ppm in the ligand and assigned to hydrogen bonded (—N—H $\cdots$ S=), disappears and the —NH signal observed at δ 6.1 ppm is shifted downfield to δ 8.4 ppm, indicating the removal of one of the protons of the amino group on complexation. The signals at δ 11.2 ppm observed by us in these ligands (ester derivatives) have not been reported by earlier workers.[5–7]

A perusal of the ^1H NMR spectral data of the ligand (methyl ester) reveals that the signal at δ 2.61 ppm due to $S—CH_3$ shifts downfield (by 0.6 ppm) on complexation, which supports the participation of the C=S group on bonding with indium.

^{13}C *NMR spectral studies of the ligands and their complexes*

The signals in the ^{13}C NMR spectra of the ligand and their corresponding complexes are summarized in Table 3.

In the spectrum of BuACDA, the signal for the C(6) atom attached to the thiol group appears at δ 191.5 ppm, which shifts downfield and is observed at δ 199.9 ppm. Such a large shift of 8.4 ppm [for C(6)] may be due to the deshielding of the carbon atom because of the deprotonation of one thiol group and coordination through the other sulphur atom.

However, in the spectrum of $ACDE_1$, signals observed at δ 165.3, 201.5 and 13.8 ppm ascribed to the carbon atoms, C(2), C(6) and C(α), respectively, shift downfield and appear at δ 166.5, 203.9 and 16.9 ppm, respectively, in the corresponding indium complexes. These data further confirm the presence

^{14}N *NMR spectral studies*

In order to confirm the mode of bonding proposed on the basis of IR, ^1H and ^{13}C NMR spectral evidence, ^{14}N NMR spectra of BuACDA and its indium complex have been recorded in chloroform solution, using ammonium nitrate as external reference. The spectrum of BuACDA exhibits two signals for the nitrogen at δ −65.3 and −64.4 ppm (J = 7.3 Hz) due to the coupling of the attached proton. The unaltered position of these signals even in the corresponding indium complex, further confirm our assumption that the nitrogen is not

Attempts to record the ^{14}N NMR spectra of N-bonded complexes of esters were not successful, which may be due to the quadrupole moment of ^{14}N and the coupling of nitrogen (I = 1) and indium (I = 9/2) resulting in a very broad signal which may escape detection.

Acknowledgements—Thanks are due to Mr Suman K. Gupta for taking a keen interest in recording all the NMR spectra. One of us (S.K.S.) is grateful to the State Government of Rajasthan and U.G.C., New Delhi, for financial support under the Special Assistance Programme.

THE STEPWISE COMPLEX FORMATION IN THE COBALT(III)–AZIDE SYSTEM

NINA COICHEV and EDUARDO ALMEIDA NEVES*

Instituto de Química, Universidade de São Paulo, Cx. Postal 20780, CEP 01498, São Paulo, Brazil

(*Received* 27 *July* 1988; *accepted* 29 *September* 1988)

Abstract—Measurements of conditional potential of the Co^{III}/Co^{II} system in several sodium azide solutions (0.30–1.78 M) of ionic strength 2.0 M, held with sodium perchlorate, in aqueous medium at 25°C, lead to the following overall formation constants: $\beta_1 = 3\times10^8\ M^{-1}$, $\beta_2 = 1\times10^{15}\ M^{-2}$, $\beta_3 = 7\times10^{19}\ M^{-3}$, $\beta_4 = 1.5\times10^{23}\ M^{-4}$, $\beta_5 = 1.3\times10^{23}\ M^{-5}$ and $\beta_6 = 1.0\times10^{24}\ M^{-6}$. Calculations require introduction of the stepwise formation constants of the cobalt(II) complexes and $E^{0\prime}$ for Co^{III}/Co^{II} in non-complexing media, from literature data, in order to calculate the Leden's function, $F^0(L)$, referred to Co^{III} complexes. The first three formation constants were estimated from the linear plot of $(\log\beta_n)/n$ vs n (number of ligands) with β_4, β_5 and β_6 data.

The cobalt(III) stabilization in concentrated sodium azide solution was first mentioned by Senise[1] who observed a slow colour change of the cobalt(II) solutions, containing the blue $[Co(N_3)_4]^{2-}$ anion, due to oxidation, to the brown mixture of azide complexes of cobalt(III): the solid, explosive compound $Tl_3[Co(N_3)_6]$, was isolated from this medium. The induced oxidation of sulphur(IV), by dissolved oxygen, markedly accelerates this reaction and a spot test was developed for sulphite.[1,2]

Due to the high molar absorptivity of cobalt(III) in the azide medium, a method for determination of this element in trace levels in nickel salts was presented.[3]

This high spectrophotometric sensitivity led to the development of a method for the determination of sulphur(IV) in rain water,[4] based on the formerly described induced reaction.[2] It has been found that the best conditions for this quantitative method[4] is by performing in a 0.5 M sodium azide solution in a pH 5.5–6.5 range. In order to better understand mechanisms and to make thermodynamic considerations about this induced reaction, this paper deals with potentiometric measurements in $Co^{III}/Co^{II}/N_3^-$ solutions for obtaining equilibrium constants in the cobalt(III)/azide system.

EXPERIMENTAL

Reagents and standard solutions

All reagents were from AR or CP specification, from Merck or Mallincrodt brands.

Sodium azide was recrystallized from water, washed with ethanol to remove traces of hydroxide, vacuum dried and then placed in an oven at 110°C until constant weight. Under these conditions it can be used as a primary standard.

Cobalt(II) perchlorate was prepared from the direct reaction of excess carbonate with 2.0 M perchloric acid for 3 days, under stirring at room temperature. After filtering, free perchloric acid was added up to 0.010 M, in order to avoid hydrolysis. Standardization was carried out electrogravimetrically.

Sodium perchlorate (5 M) used for making up the ionic strength of working solutions, was standardized after dilution to a 0.1 M concentration level, by titrating the strong acid eluted from a cationic exchanger column.

Standard perchloric acid was used in the working solutions to displace hydrazoic acid, HN_3, from the azide ions. In order to keep such working solutions free from oxygen, without losing the volatile hydrazoic acid, all standard solutions were previously bubbled with purified nitrogen, before mixing.

Working solutions

The following working solution (**I**) was prepared in a 100 cm^3 volumetric flask: 0.02000 M $Co(ClO_4)_2$, 2.000 M NaN_3 and 0.1500 M $HClO_4$ (to form HN_3). Lead dioxide was added directly to this solution to form cobalt(III), according to the following stoichiometry:

$$PbO_2 + 2[Co(N_3)_4]^{2-} + 4HN_3 + 2N_3^- \longrightarrow Pb(N_3)_2 + 2H_2O + 2[Co(N_3)_6]^{3-}.$$

This final solution (**I**) contained 5.00 mM Co^{III} and 15.0 mM Co^{II}. The free azide concentration was estimated to be 1.90 M, after discounting its consumption to form hydrazoic acid and complexes. In this procedure, nitrogen evolution was not observed in the presence of cobalt(II), due to the oxidation of hydrazoic acid by lead dioxide.

A solution (**II**) was prepared without oxidation: $[Co^{II}] = 0.01500$ M, $[HN_3] = 0.2000$ M, $[N_3^-] = 0.1790$ M and 1.76 M $NaClO_4$.

A solution (**III**) contained: $[Co^{2+}] = 0.01500$ and 1.96 M $NaClO_4$.

Potentiometric measurements

The following cell was used, thermostated at 25.0 ± 0.1°C:

$$Hg \mid Hg_2Cl_2, \text{NaCl sat.} \vdots 0.015 \text{ M } Co(ClO_4)_2, 1.96 \text{ M } NaClO_4 \vdots \text{working solution} \mid Pt.$$

The reference electrode from Micronal has a small compartment for the salt bridge, which was filled immediately before use. Measurements were carried out with a potentiometer sensitive to 0.1 mV.

10.00 cm^3 of the working solution (**II**) was potentiometrically titrated with solution (**I**), up to 20.00 cm^3. The potential of the cell shifted with the change of the $[Co^{III}]/[Co^{II}]$ ratio and free azide concentration. Another series of measurements was taken by titrating 10.00 cm^3 of solution (**I**) with solution (**III**).

Three sets of measurements were taken by repetition of the two titrations. The average of three potentiometric measurements of each particular solution formed during the titrations, was used to calculate the conditional potential, $E_x^{0'}$, for each estimated free azide concentration.

RESULTS AND DISCUSSION

Equations and treatment of data

The measured potential of the Co^{III}/Co^{II} system in complexing media of constant ionic strength, E_x, leads to the following conditional potential, $E_x^{0'}$ for each free azide concentration at the experimental conditions described herein:

$$E_x^{0'} = E_x - 0.05916 \log([Co^{III}]/[Co^{II}]). \quad (1)$$

These $E_x^{0'}$ values are slightly lower than the measured value in the non-complexing medium, $E_s^{0'}$, due to the preferential complexation of cobalt(III) cations by azide with regard to the cobalt(II) cations. The potential shift due to complexation in this system, with the element in two oxidation states, leads to the calculation of the ratio of Leden's functions[5-7] for cobalt(III), F_{III}^0, and cobalt(II), F_{II}^0:

$$E_{xs}^{0'} = E_x^{0'} - E_s^{0'} = -0.05916 \log(F_{III}^0/F_{II}^0). \quad (2)$$

Rearranging:

$$F_{III}^0 = \{10 \exp[(E_s^{0'} - E_x^{0'})/0.05916]\} \times F_{II}^0. \quad (3)$$

The Leden's function for the mononuclear cobalt(II) complexes in azide media of ionic strength 2.0 M, from the literature,[8] can be calculated as:

$$F_{II}^0 = 1 + 5.7[N_3^-] + 19[N_3^-]^2 + 7[N_3^-]^3 + 16[N_3^-]^4 + 4.4[N_3^-]^5. \quad (4)$$

The calculated F_{II}^0 data for each azide concentration was used to calculate F_{III}^0 using eq. (3).

From a series of data available from Bard,[9] a Warnqvist's[10] datum is the most reliable to use as $E_s^{0'}$ in eq. (3). This conditional potential, +1.85 V vs the normal hydrogen electrode, was measured in acidic sodium perchlorate media of ionic strength 3.5 M, higher than that used in this paper (i.e. 2.0 M). However, the potential shift due to complexation with azide is so high (more than 1 V), that an uncertainty of a few hundreds of volts corresponds to a small relative error. Discounting 0.24 V for the reference electrode, the value of +1.61 V was actually used in eq. (3).

The average ligand number (Bjerrum's function)[6,7] for cobalt(III), can be calculated from the following equation where potentials refer to small increments in azide concentrations, from the titration curves:

$$\bar{n}_{III} = \{(E_{x1}^{0'} - E_{x2}^{0'})/0.05916(\log[N_3^-]_2 - \log[N_3^-]_1)\} + \bar{n}_{II}. \quad (5)$$

Derivation of the potentiometric curve from titrations leads to differences in the average ligand number for the two oxidation states. The values for cobalt(II), $\bar{n}_{II}$, can be calculated with the known formation constants[8] and introduced into eq. (5). The calculated $\bar{n}_{III}$ and $\bar{n}_{II}$ were useful to calculate the free azide concentration from the analytical

one, $C_{N_3^-}$, after corrections were made from the dilutions during the titrations. The following equation was used to iteratively find the free azide concentration:

$$[N_3^-] = C_{N_3^-} - [HN_3] - \bar{n}_{II}[Co^{II}] - \bar{n}_{III}[Co^{III}]. \quad (6)$$

Table 1 contains the experimental and calculated data used to obtain the equilibrium constants. A number of calculation steps were considered in the treatment of the potentiometric data, in order to obtain the equilibrium constants:

(1) The first estimate of free azide concentration

Standard deviation (potential), $S = 3.5 \times 10^{-3}$.

was made by considering in eq. (6), $\bar{n}_{III} = 6$ and $\bar{n}_{II}$[6,7] calculated from the formation constants from the literature[8] and with the azide concentration from which $[HN_3]$ was discounted.

(2) The use of eq. (5) has shown that $\bar{n}_{III}$ is not constant along the azide range and changes from 4.8 to 5.8, which suggests stepwise complex formation. On this basis, three iterative corrections in eq. (6) have been found sufficient to obtain the free azide.

(3) The use of eq. (3) leads to the F^0_{III} data in Table 1. Conventional treatment of the data[6,7] or solution of weighted simultaneous equations[11] has been found to be inadequate to obtain the equilibrium constants, due to the non-existence of potentiometric data at lower ligand concentrations. Instability of cobalt(III) solutions provides unreliable measurements with a free azide concentration of less than 0.22 M. F^0_{III} data is a polynomial with the sum of $\beta_n[N_3^-]^n$ terms.[5-7] Estimation of the last constant was taken from the limiting value of F^0_{III} towards the higher ligand concentration:

$$\beta_6 = (F^0_{III})/[N_3^-]^6. \quad (7)$$

This has been found to be a reasonable approach to show that β_6 is of the order 10^{24}. Discounting these preliminary data of the F^0_{III} values, in the range of 5–5.5 for $\bar{n}_{III}$, β_5 was first estimated as being of the order 10^{23} from:

$$\beta_5 = (F^0_{III} - \beta_6[N_3^-]^6)/[N_3^-]^5. \quad (8)$$

Similarly, estimation of β_4 in the 4.7–5 $\bar{n}_{III}$ range, also leads to the order 10^{23}, after discounting $\beta_5[N_3^-]^5$ and $\beta_6[N_3^-]^6$ in several F^0_{III} values.

(4) A linear plot of $(\log\beta_n)/n$ vs n (number of azide ligands)[12] leads to the estimation of β_1, β_2 and β_3, as 10^8, 10^{15} and 10^{19}, respectively. This estimation is based on values proportional to the average free energy involved in ligand attachment to the higher complexes.

(5) The whole process was repeated and the following final values for the overall formation constants were found: $\beta_1 = 3\times10^8\ M^{-1}$, $\beta_2 = 1\times10^{15}\ M^{-2}$, $\beta_3 = 7\times10^{19}\ M^{-3}$, $\beta_4 = 1.5\times10^{23}\ M^{-4}$, $\beta_5 = 1.3\times10^{23}\ M^{-5}$ and $\beta_6 = 1.0\times10^{24}\ M^{-6}$.

Combination of eqs (1) and (2) leads to the following equation which permits the calculation of the potential E_x at any free azide concentration, and the $C_{Co^{III}}/C_{Co^{II}}$ concentration ratio of the complexes, at 25°C:

$$E_x = E_s^{0'} + 0.05916\log(C_{Co^{III}}/C_{Co^{II}}) - 0.05916\log(F^0_{III}/F^0_{II}). \quad (9)$$

F^0_{II} is calculated by eq. (4) and F^0_{III} by a similar equation in which the first three exponential terms can be neglected for azide concentrations higher than 0.1 M.

Interpretation of results

The calculated $E_x^{0'}$ data values from eq. (2) gave an uncertainty of ±3.5 mV, as compared with the experimental data. This prevision is better than the expected uncertainty introduced by the $E_s^{0'}$ value, 1.85 V[11] (or 1.61 vs the calomel electrode) in eq. (3).

Figure 1 shows the distribution diagram of the complexes. Even at a free azide concentration of 10^{-4} M, the contributions of the $[CoN_3]^{2+}$ and $[Co(N_3)_2]^+$ species are fairly negligible. In the studied azide concentration range (0.2–1.8 M) the $[Co(N_3)_6]^{3-}$ species predominates but with significant contribution from the $[Co(N_3)_5]^{2-}$ and $[Co(N_3)_4]^-$ anions.

The magnitude of equilibrium constants in the Co^{III}/N_3^- system is considerably higher than that of the Co^{II}/N_3^- one [see eq. (4)] and shows a marked tendency of the azide ions to behave as a "hard type" base.[13] Destruction of these cobalt(III) complexes takes place easily by acidification of the medium or dilution, with a return to cobalt(II) levels; alkalinization causes $Co(OH)_3$ precipitation. This behaviour reveals a great lability which is not found in many cobalt(III) complexes, as with cyanide or ammonium complexes.

Charge transfer from ligand to metal is feasible, as occurs with the Cu^{II}/N_3^-[14] and Fe^{III}/N_3^-[15-16] systems. In fact, a broad band with high molar absorptivities is observed, with one peak at 365 nm (Fig. 2). This spectral characteristic shows virtually no change as a function of the azide concentration until 0.5 M.

The azide ion is thermodynamically unstable and is potentially a very powerful reducing agent, as

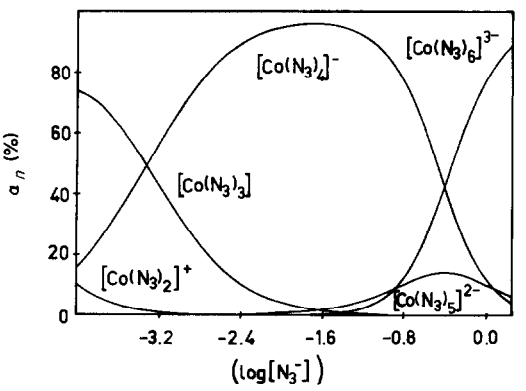

Fig. 1. The distribution diagram of the cobalt(III)–azide complexes calculated from the equilibrium constants.

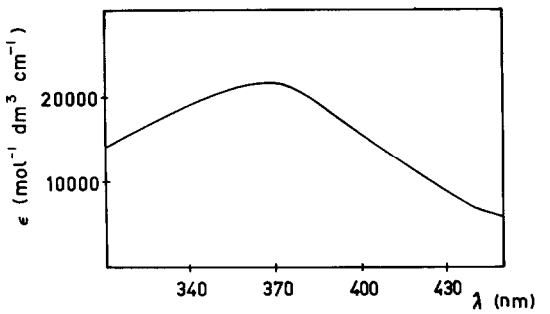

Fig. 2. UV–vis absorption spectrum of 1.00×10^{-5} M cobalt(III) in 1.90 M N_3^-, 0.10 M HN_3 and 0.050 M H_2O_2.

inferred from the standard reduction potential of the N_2/N_3^- system of -3.4 V.[17] In spite of that, the reactivity of the ligand toward oxidizing agents is fairly low under a variety of conditions and in the absence of a catalyst. The ligand is not oxidized by permanganate or hydrogen peroxide in alkaline media.[14] Hydrazoic acid is much more reactive and can be oxidized by strong oxidizing agents such as permanganate, cerium(IV) and dichromate. The stabilization of cobalt(III) is possible only due to the inertia of the azide ions towards oxidation, a behaviour quite different from that observed with thiocyanate.

The oxidation of cobalt(II) (1 mM) to cobalt(III) by the dissolved oxygen, catalysed by sulphur(IV), is convenient for analytical purposes at a 0.50 M free azide concentration, with 0.1–0.01 M free hydrazoic acid.[18] Calculations with present potential data using eq. (9) show that for a wide azide concentration range, the $O_2,H^+/H_2O_2$ system ($E^{0'} = +0.695$ V) seems thermodynamically unable to provide the cobalt(III) concentration levels experimentally found by the induced oxidation, at lower azide concentrations. The $O_2,H^+/H_2O$ system ($E^0 = +1.23$ V) is the only system really capable of performing such catalysed oxidations at 0.2–0.7 M azide concentrations. Interpretation of this induced reaction, with the participation of free radicals, will subsequently be reported with several conditional equilibrium constants, calculated for this redox process.

Abstract—A potentiometric and spectroscopic study has been carried out on the copper(II) complexes formed by 2,*x*-dihydroxybenzoic acids ($x = 4$, 5 or 6) in aqueous solution. It has been found that, in the low pH range, the ligands coordinate through the carboxylate group. At above pH 5 the major species are chelated complexes in which one or two ligands bind the metal ion through the carboxylate and adjacent phenolate groups. The results are compared to earlier literature data available for copper(II) dihydroxybenzoate and salicylate complexes.

The modelling of the interactions of metal ions with soil organic matter, as well as the study on the bioavailability to plants of metal ions, have started much interest in the elucidation of the behaviour of phenolic ligands.[1] Dihydroxybenzoic acids (DHB) and their analogues were found to be interesting low molecular weight models with very efficient binding ability, especially the ligands having two aromatic hydroxyls in *ortho* positions.[2–6] In the copper(II)-3,4-dihydroxybenzoic acid system, rather complicated coordination equilibria were observed.[6] In dilute aqueous solutions the bidentate catechol part of this ligand predominates as the binding site for the metal ion, although the carboxyl group may also participate in the metal ion binding. This leads to the formation of the polynuclear species.

Earlier solid-state studies have shown that at low pH, the carboxylic group could be the main donor in the formed complexes with several other diphenolic acids such as 2,4- 2,5- and 2,6-dihydroxybenzoic acids,[7–10] though the phenolate oxygen binding was also clearly indicated.[2,3,6] In this communication, we report the potentiometric and spectroscopic findings obtained for the systems containing copper(II) and 2,4-, 2,5-, and 2,6-dihydroxybenzoic acids in aqueous solutions.

EXPERIMENTAL

Potentiometric studies

Stability constants for complexes containing proton and copper(II) were determined by pH-metric titration of 25 cm^3 samples. The concentration of the ligand in the samples was 0.004 or 0.002 M. Metal-to-ligand molar ratios of 1:1, 1:2, 1:4, 1:6.6 and 1:10 were used in the titrations and the ionic strength was adjusted to 0.2 M with KCl. The titrations were performed in the pH range from 2.5 to 11, or until precipitate, depending on the molar ratio used, occurred. The pH was measured with a Radiometer pHM 64 instrument with G2040B glass

* Author to whom correspondence should be addressed.

and K4040 calomel electrodes. Since the ligands tend to undergo oxidation, all measurements were performed in a TTA 80 titration unit under an argon atmosphere. The electrode system was calibrated by the method of Irving *et al.*[11] so the pH-meter readings could be converted into hydrogen ion concentrations. In all cases, the temperature was 25°C. The calculations of the stability constants were made with PSEQUAD computer program.[12]

Spectroscopic studies

Absorption spectra were recorded on a Beckman Acta M IV spectrophotometer and EPR spectra were measured on a Varian E 9 spectrometer (X band) at 110 K. The measurements were performed under argon for the concentrations of samples similar to those used in the potentiometric studies.

RESULTS AND DISCUSSION

Proton complexes

All ligands studied have two measurable protonation constants (see Table 1). The acidity of the phenolic groups in position two is very weak, thus their dissociation was studied at high ligand concentration (0.08 M) up to high pH (~13.4). It was found that the ligand titration curves run together with the titration curve for the strong acid of the same concentration. Accordingly, the phenolic groups do not undergo dissociation in the measurable pH range; this is distinctly different from that reported earlier.[2] The high dissociation constants of these hydroxyl groups were proved also by spectrophotometric titration. The UV spectrum of the ligands remained unchanged over the pH range 11–13.2, showing the lack of deprotonation of phenolic hydroxyls. The very weak acidity of these OH groups in the *ortho* position to carboxylate, can be explained by the strong intramolecular hydrogen bond between COO^- and phenolic groups.

Copper(II) complexes

The calculated copper(II) complex formation constants, together with the earlier literature data, are given in Table 2. These three ligands behave as the hydroxy-salicylic acids (derived equilibrium constants for salicylic acid calculated from literature data[13] are also included in Table 2). The data for the 2,4- and 2,5-DHB are in fairly good agreement with those presented earlier.[2] The fitting of the experimental pH-metric data by the PSEQUAD program can be slightly improved by the introduction of the species in which the metal ion binds the DHB molecule only via the carboxylate oxygen, i.e. when the formation of the CuAH or $Cu(AH)_2$ species is assumed. The species distribution vs pH, see Figs 1–3, indicates that the total concentration of each of these species is rather low (10% or less), except in the case of the copper(II)–2,6-DHB system. In the latter case the concentrations of the CuAH and $Cu(AH)_2$ complexes approach 25 and 15%, respectively. It has to be mentioned, however, that the pH-metric determinability of these species is poor, since metal ion coordination and proton dissociation take place in the same pH range, hence the copper(II)–carboxylate coordination has only minor pH effects. The EPR spectra prove unambiguously, the formation of these minor species at a pH below 5 in all the cases studied (Table 3). The formation of the complexes with monodentate carboxylate coordination was also proposed earlier for the cupric complexes with salicylic acid.[14]

The major species formed at above pH 5 is the CuA chelated complex in which the metal ion is bound to the DHB ligand through COO and the phenolate oxygen (O^-) being in the *ortho* position to the carboxylate (2-OH). A further increase of pH leads to the formation of the other chelated species, the CuA_2 complex, in which two ligands are bound in the mode described above. The equilibrium constants characteristic to the part-processes of complex formation (see Table 2) clearly indicate the salicylate-type coordination in the complexes CuA and CuA_2. Thus, their stoichiometric compositions are more precisely $Cu(HAH_{-1})$ and $Cu(HAH_{-1})_2$.

In the more basic solutions, the deprotonation of the unbound hydroxyl at positions four, five or six takes place. The stepwise deprotonation constants (Table 2) obtained for the 2,4- and 2,5-DHB complexes are higher than the p*K* values of these groups obtained for the respective free ligands, probably due to the strong electron-releasing effect of the coordinated phenolate. This value for the copper(II)–2,6-DHB system was too high to be evaluated reliably. The differences between the two stepwise p*K*'s obtained for the CuA_2 complexes is equal to 0.6 log units, corresponding to the stat-

istical case of the dissociations of two protonated groups with the same acidity.

The spectroscopic data fit very well with the potentiometric results and the assignment of the respective complexes is presented in Table 3. The coordination of the phenolate oxygen is clearly seen, due to the charge transition between this donor and the cupric ion, which is observed in the 380–430 nm range.[15,16] The coordination of the phenolic hydroxyl groups is also clearly indicated by the distinct increase in energy of the *d–d* transitions observed for the respective complexes (see for example, ref. 6).

CONCLUSIONS

The binding ability of the dihydroxybenzoic acids strongly depends on the position of their donors. The most effective seems to be the set of two hydroxyls which are in *ortho* positions (catechol like) as was found in the case of 3,4-dihydroxybenzoic acid.[6] The ligands with carboxyl and hydroxyl groups placed on the adjacent aromatic ring carbons are also very effective chelating ligands which form complexes with the (COO^-, O^-) donor set. In all cases, the involvement of the carboxylic function seems to be basic at low pH range, but phenolic groups and their positions are of primary importance for the structures and the stability of the formed complexes.

REACTION OF THE HYDRIDO-BRIDGED, GROUP 6 METAL CARBONYL DIMERS WITH ORGANIC ALKOXIDES. AN APPARENT BETA-HYDRIDE ELIMINATION REACTION PERTINENT TO CATALYSIS

P. L. GAUS,* LISA M. JONES and LORETTA A. ZAMISKA

Department of Chemistry, The College of Wooster, Wooster, OH 44691, U.S.A.

(*Received* 31 *May* 1988; *accepted* 3 *October* 1988)

Abstract—IR spectroscopic and GC–MS studies have been made of the reaction between the Group 6 metal carbonyl dimers $[\mu\text{-}HM_2(CO)_{10}]^-$ (where M = Cr and W) and organic alkoxides, $R^1R^2CHO^-$, both as the PPN^+ salts. Where $R^1 = R^2$ = Ph or Me, the reactions result in the oxidation of the alkoxide to benzophenone and acetone, respectively, as determined by GC–MS. IR spectroscopic studies indicate that the reaction involves cleavage of the hydrido-bridged dimer reactants to give the hydride monomers, $[HM(CO)_5]^-$, and an intermediate alkoxo complex, $[R^1R^2CHO—M(CO)_5]^-$. The overall rate of oxidation of a given alkoxide is slower when M = W than when M = Cr. It is proposed that the alkoxo intermediate is responsible for the formation of the ketone products.

The organometallic chemistry of the alkoxide anion is especially well developed in systems where the alkoxide ligand is either bulky or stabilized against beta elimination.[1] The chemistry of simple, mononuclear organometallic alkoxides containing non-bulky alkoxide ligands that are capable of beta elimination reactions is less well developed. This is true for two reasons. Firstly, the organometallic complexes that contain non-bulky alkoxide ligands are prone to condensation reactions that produce clusters or solid state structures having bridging alkoxide groups.[1,2] Secondly, those alkoxide ligands having a hydrogen atom attached to the proper carbon atom, i.e. $R^1R^2CHO^-$, can undergo an apparently facile, simple, unimolecular beta-hydride elimination reaction[3] that is entirely analogous to the well known counterpart among the metal alkyls.[3a,4] Until very recently, it was held that such beta-hydride elimination reactions of the organometallic alkoxides were characteristically more facile than for the organometallic alkyls, because it was thought that the metal–oxygen bond was intrinsically weaker than the metal–carbon bond, which would destabilize a metal–alkoxide towards a unimolecular elimination process. However, the elegant studies of Bercaw and co-workers,[3b] in which beta-hydride elimination reactions of platinum alkoxo complexes have been compared in detail with the well known platinum alkyls of Whitesides and co-workers,[5] have made it clear that although the alkoxo complexes undergo beta-hydride elimination at a much lower temperature than do the corresponding alkyls, this is not likely due to an inherent difference in metal–oxygen vs metal–carbon bond strengths.

Because of the importance of beta-hydride elimination reactions of organometallic alkoxides in catalysis (in particular in catalytic hydrogenations,[6] catalytic formation of alkyl formates[7] and higher alcohol processes[8]), we have undertaken a study of the reaction of organic alkoxides with those organometallic compounds that should be capable of offering chances to study the beta-hydride elimination chemistry of organometallic alkoxides. We report here on the initial results of our study into the reactions of the hydrido-bridged, Group 6 metal carbonyl dimers, $[\mu\text{-}HM_2(CO)_{10}]^-$ (where M = Cr or W), with alkoxide anions containing a beta-hydrogen atom, viz. $R^1R^2CHO^-$ (where $R^1 = R^2$ = Ph or Me).

EXPERIMENTAL

All reactions were performed under an atmosphere of dry argon gas using standard Schlenk

*Author to whom correspondence should be addressed.

techniques. The THF solvent was freshly distilled from purple Na–benzophenone, and all transfers were made either via cannula or syringe.

IR spectra were recorded in 0.1 mm CaF_2 liquid cells on a Perkin–Elmer 1800 FTIR instrument. Identification of the volatile products was performed by GC–MS on a Hewlett Packard 5890 gas chromatograph equipped with an HP 5970 mass selective detector.

The dimeric reactants, $[\mu\text{-}HM_2(CO)_{10}]^-$, were prepared as the PPN^+ salts using the literature procedure.[9] The PPN^+ salts of the organic alkoxides were prepared from the sodium salts by room temperature metathesis with PPN^+Cl^-, using the THF–hexane mixtures. We did not observe attack on the PPN^+ cation, as has been reported for methoxide at high temperatures.[10]

Reactions were performed using various mole ratios of the two reactants, by transferring a solution of known concentration (typically 10^{-2}–10^{-3} M) of $PPN[\mu\text{-}HM_2(CO)_{10}]$ onto a dry, gravimetric sample of the organic alkoxide. The solutions were stirred gently at 25°C for up to 7 days, and IR spectra were recorded periodically by withdrawing a sample using syringe techniques. At the conclusion of the IR study, the solutions were exposed to the atmosphere, filtered through alumina, and analysed using GC–MS techniques. Acetone was separated at 20°C from THF on a methylsilicone column, whereas benzophenone was separated at 150°C. In some reactions, the acetone was lost due to entraining with the argon purge gas; its positive identification (significant, increasing absorbance in the IR spectrum at 1716 cm^{-1}) as a reaction product was most facilitated when the reactions were performed under a static argon pressure, rather than a continuous sweep.

RESULTS AND DISCUSSION

The reactions of the dimeric, hydrido-bridged reactants $[\mu\text{-}HCr_2(CO)_{10}]^-$ and $[\mu\text{-}HW_2(CO)_{10}]^-$ with either diphenyl methoxide, Ph_2CHO^-, or isopropoxide, $(CH_3)_2CHO^-$, have been studied using mole ratios of organometallic reactants to organic alkoxide reactants ranging from 1:1 to 1:10. Although the oxidized organic product (either acetone or benzophenone) was observed in most reactions, the greatest amounts were observed in reactions that employed an excess of the alkoxide reactant. We therefore present the following results in categories depending on the ratios of $[\mu\text{-}HM_2(CO)_{10}]^-$ to $R^1R^2CHO^-$ that were employed in the various experiments. Additionally, each reaction was accompanied by a slow, steady deposition of solid material, which caused the overall IR absorbances arising from the organometallic materials to decrease with time. Thus the IR spectra must be interpreted in light of these overall decreasing ν_{CO} IR absorbances. The spectra shown in the figures are labelled so that this general and steady loss of organometallic reactant to solids is apparent. The amount of solid that typically formed over the course of a given reaction was less when the proportions of the organic alkoxide reactant were high, i.e. in experiments employing 1:10 mole ratios of $[\mu\text{-}HM_2(CO)_{10}]^-$ to $R^1R^2CHO^-$. The rate of appearance of acetone or benzophenone became negligible in every case where the IR spectrum indicated that all of the hydrido-bridged dimer reactant had been consumed.

When a dry, anaeorbic THF solution of a 1:10 mole ratio of $PPN^+[\mu\text{-}HCr_2(CO)_{10}]^-$ and $PPN^+Ph_2CHO^-$ was stirred at 25°C under an argon atmosphere, there was no immediate change in the colour or appearance of the solution as first mixed, or in the IR spectrum of the solution. Over the next 7 days, however, there occurred a gradual and uniform change in the IR spectrum of the solution, as depicted in Fig. 1. The IR spectrum that was obtained soon after mixing is shown in Fig. 1(A). This is essentially the IR spectrum in the ν_{CO} region of the dimeric, hydrido-bridged, organometallic reactant, $[\mu\text{-}HCr_2(CO)_{10}]^-$. The values of the three characteristic frequencies[9,11] were found to be: ν_{CO} = 2030 (w), 1940 (s), 1878 (m) cm^{-1}. With the passage of time, the IR spectrum in the ν_{CO} region changed in the manner shown in Fig. 1. After 24 h [Fig. 1(B)], the ν_{CO} absorbances characteristic of $[\mu\text{-}HCr_2(CO)_{10}]^-$ were less intense, and a small peak appeared at 1664 cm^{-1}. This absorbance at 1664 cm^{-1} continued to increase in intensity over the next 6 days. An authentic sample of benzophenone was found to have the same ν_{CO} IR spectrum. The product was also determined to be benzophenone using GC–MS techniques after the IR experiments shown in Fig. 1 were completed. Thus the sole volatile organic product that was found in the reaction mixture after 7 days (other than unreacted Ph_2CHO^-, converted in work-up to Ph_2CHOH) was found to have a GC retention time and a mass spectrum that was identical to that of a known sample of $Ph_2C{=}O$. In addition, as shown in Fig. 1, there appeared only one other soluble organometallic material during the course of the reaction. This is the material having ν_{CO} IR absorbances at 1882 (s) and 1852 (m) cm^{-1}, and it was the only soluble carbonyl-containing organometallic product. This material obviously formed in conjunction with the disappearance of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and with the appearance of benzophenone. Thus the single, soluble, organometallic

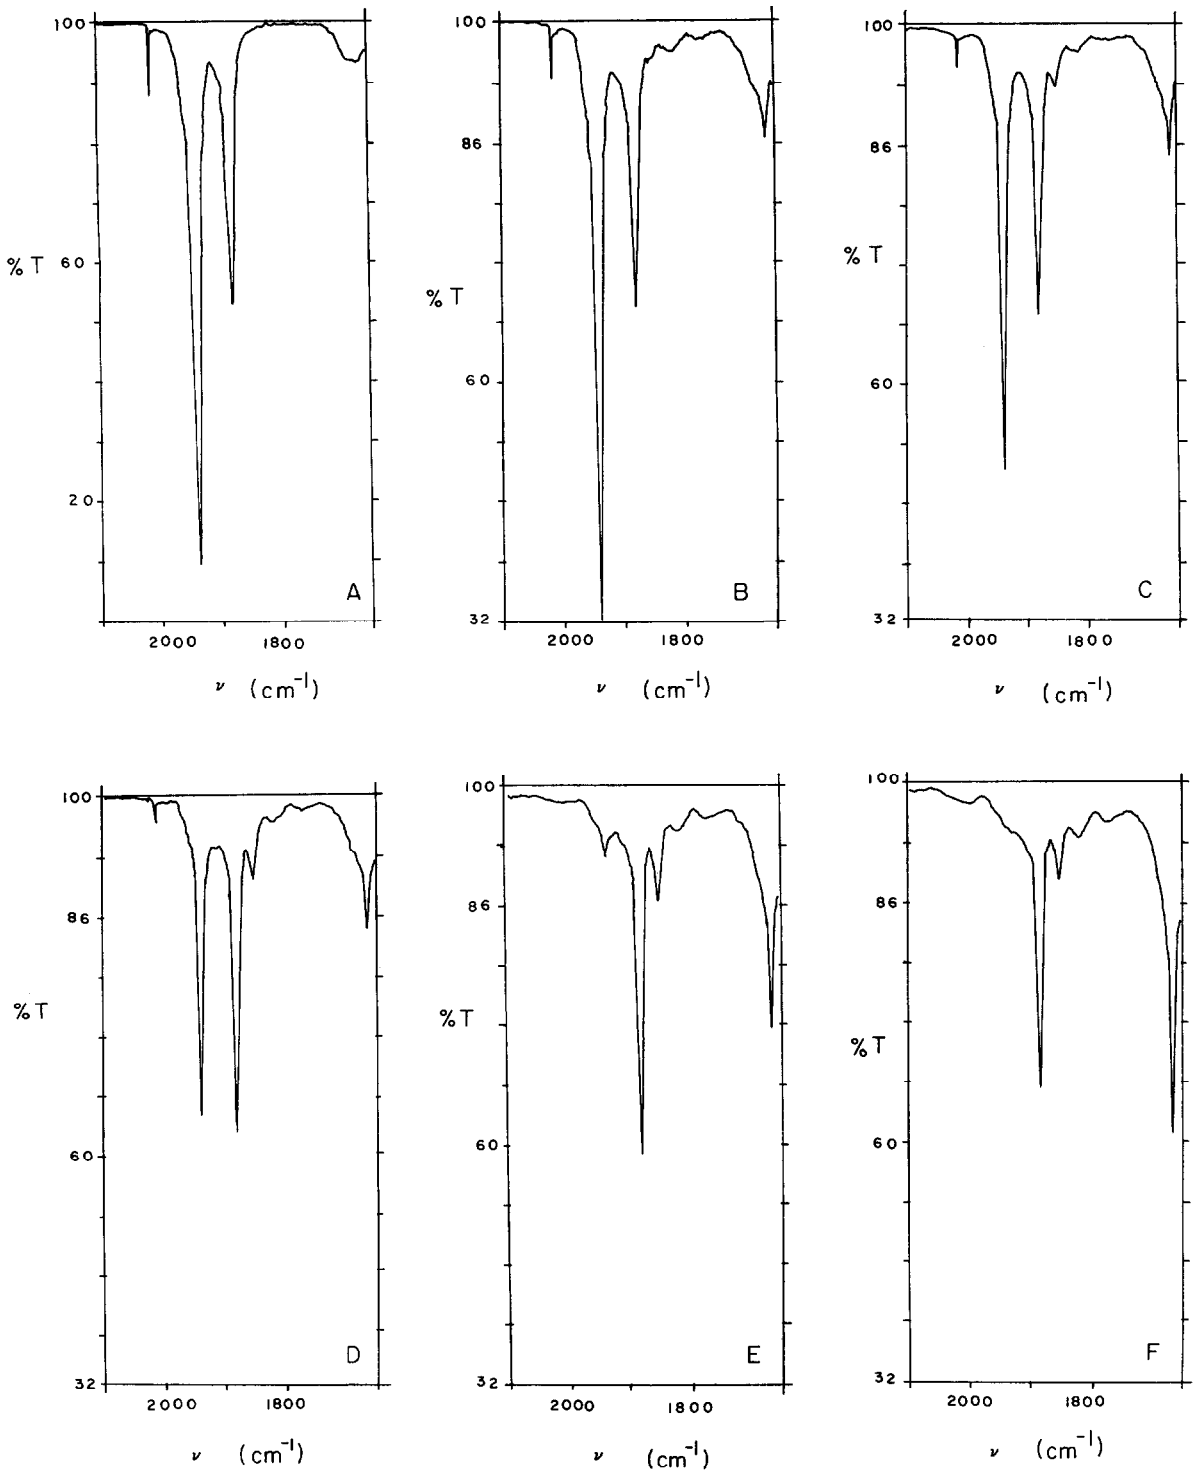

Fig. 1. IR spectra recorded at various times in the reaction of a 1:10 mole ratio of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and Ph_2CHO^- in THF at 25°C. (A) At the time of mixing; (B) after 24 h; (C) after 36 h; (D) after 64 h; (E) after 136 h; (F) after 160 h.

product of the reaction was the monomeric hydride, $[HCr(CO)_5]^-$, whose IR spectrum[11] is known and matches the ν_{co} frequencies that were observed here.

The above results differ in significant ways from those that were obtained with reactions that employed a 1:1 mole ratio of reactants. The reaction of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and Ph_2CHO^- in a 1:1 mole ratio did not result in complete disappearance of the ν_{co} absorbances of $[\mu\text{-}HCr_2(CO)_{10}]^-$, nor in the formation of as much benzophenone as did the

reaction described above. Additionally, although the reaction did give some monomeric hydride, $[HCr(CO)_5]^-$, there was another ν_{co} IR absorption observed at 1920 cm^{-1}. This frequency is typical of those given by monomeric alkoxo derivatives[12] of the type $[RO—Cr(CO)_5]^-$, and we conclude that this constitutes evidence for the intermediate $[Ph_2CHO—Cr(CO)_5]^-$. This is substantiated by the results obtained from the reaction of the chromium dimer with isopropoxide.

In a manner entirely analogous to the reaction of diphenyl methoxide as described above, the reaction of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and $(CH_3)_2CHO^-$ in a 1:10 mole ratio resulted in the formation of acetone (ν_{co} = 1716 cm^{-1}) over the course of several days. The concomitant disappearance of ν_{co} IR absorbances characteristic of the dimer reactant, and the formation of ν_{co} IR absorbances characteristic of $[HCr(CO)_5]^-$ also occurred. When the reaction was performed using a 1:1 mole ratio of reactants, the amount of acetone that was formed was less, the disappearance of the dimeric reactant was incomplete, and an intermediate was found to appear in conjunction with the disappearance of $[\mu\text{-}HCr_2(CO)_{10}]^-$. The most typical IR spectrum is shown in Fig. 2. Thus after 122 h of reaction at 25°C, some dimeric reactant remained (ν_{co} = 2030 (w), 1940 (s), 1880 (m) cm^{-1}). Also, both acetone

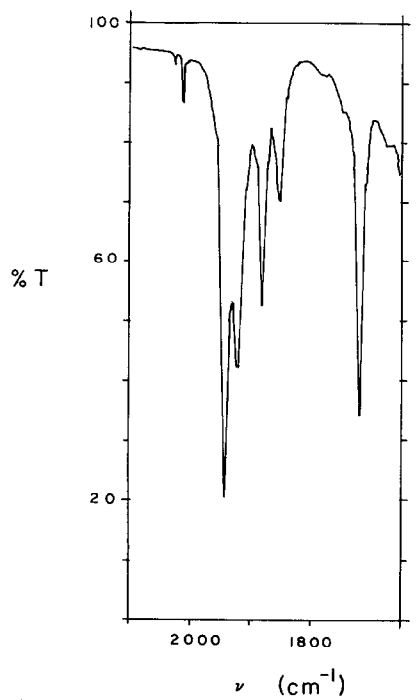

Fig. 2. The IR spectrum recorded after 122 h during the reaction of a 1:1 mole ratio of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and $(CH_3)_2CHO^-$ in THF at 25°C.

(ν_{co} = 1716 cm^{-1}) and $[HCr(CO)_5]^-$ (ν_{co} = 1880, 1850 cm^{-1}) had clearly formed. Most importantly, two of the three absorbances characteristic[7,10,12] of alkoxo pentacarbonyls of chromium, namely ν_{co} = 1920 (s) and 2055 (w) cm^{-1} are present, which we assign to the intermediate $[(CH_3)_2CHO—Cr(CO)_5]^-$.

Although a number of mechanistic possibilities exist, it seems reasonable that the above evidence should be taken to indicate that the reaction of $[\mu\text{-}HCr_2(CO)_{10}]^-$ with either diphenylmethoxide or isopropoxide results first in the rate-determining formation of both the monomeric hydride $[HCr(CO)_5]^-$ and an intermediate alkoxo pentacarbonyl, as shown in eq. (1):

$$[\mu\text{-}HCr_2(CO)_{10}]^- + R^1R^2CHO^- \rightleftarrows [HCr(CO)_5]^- + [R^1R^2CHO—Cr(CO)_5]^- \quad (1)$$

Since such alkoxo complexes are known to be substitution labile,[6a,7,10,12] this intermediate is capable of being responsible for the condensations that were found to give solids. In fact, such mononuclear chromium alkoxides are known[13] to give rise to clusterification, giving polynuclear alkoxides such as $[Cr_4(CO)_{12}(\mu_3\text{-}OR)_4]^{4-}$. Most importantly, the substitution lability of the intermediate, $[R^1R^2CHO—Cr(CO)_5]^-$, satisfies one important criterion for beta-hydride elimination, and we conclude that the second step of the process studied here constitutes simple, unimolecular beta-hydride elimination, as shown in eq. (2):

$$[R^1R^2CHO—Cr(CO)_5]^- \rightleftarrows [HCr(CO)_5]^- + R^1R^2C{=}O. \quad (2)$$

The ability of such alkoxo complexes to undergo beta-hydride elimination has been previously documented.[12a] Obviously there are a number of intriguing mechanistic subtleties that may develop, including cooperative effects arising from multimetal systems, as has been discussed by Norton.[14] We are presently examining the mechanism of the reaction in more detail.

It should also be reported that reactions of $[\mu\text{-}HCr_2(CO)_{10}]^-$ and *n*-butoxide gave results that were similar to those reported above, except that the oxidized organic products were apparently aldol condensation products of *n*-butoxide and butanal. An intermediate, presumably $(CH_3CH_2CH_2CH_2O\,Cr(CO)_5]^-$, was also observed, ν_{co} = 1919 cm^{-1}.

The corresponding reactions of the organic alkoxides with the hydrido-bridged tungsten dimer proceeded more slowly, and ultimately gave less oxidized organic products. Thus the reaction of $[\mu\text{-}HW_2(CO)_{10}]^-$ and Ph_2CHO^- in a 1:10 mole ratio gave a small amount of benzophenone. No

intermediates were detected, and attempts to perform the reaction at a higher temperature resulted in the formation of solids and significant amounts of $W(CO)_6$. Reactions employing a 1:1 mole ratio gave no products. Similarly, with isopropoxide, $[\mu\text{-}HW_2(CO)_{10}]^-$ was found to give small amounts of acetone, more slowly than with the chromium analogue.

Finally, it should be noted that these results are consistent with the reversible nature of the beta-hydride elimination process. The facile reversibility of beta-hydride elimination has been indicated by certain exchange experiments,[12a] and it is required if such a reaction is to function effectively in a catalytic cycle. The reversible nature of the reaction is indicated in the results reported here by the fact that the amount of oxidized organic product, and the presence of an alkoxo pentacarbonyl intermediate, depend on both the nature and the amount of organic alkoxide reactant that is employed.

(*Received* 17 *August* 1988; *accepted* 3 *October* 1988)

Abstract—The synthesis of a new tridentate ligand, bis[2-(1-methylimidazolyl)methyl] amine, [B-MIMA], is described. The compound has been characterized by ^1H and ^{13}C NMR spectroscopy and mass spectrometry, and forms complexes with various copper(II) salts. Crystallographic studies have been completed on the blue product from the reaction of B-MIMA with copper(II) acetate, $[Cu(B\text{-}MIMA)(CH_3COO)](ClO_4)$ (**6**). Crystal data for **6** are: triclinic, $P\bar{1}$, $a = 5.176(2)$, $b = 8.489(3)$, $c = 10.066(3)$ Å, $\alpha = 95.09(5)$, $\beta = 95.72(3)$, $\gamma = 102.37(4)$, $V = 427.1$ Å and $Z = 1$. The structure was solved using the Patterson method which revealed the position of the copper atom and successive difference Fourier syntheses which revealed the location of the remaining atoms. The atom positions were refined by least-squares methods producing a final agreement factor of $R = 0.021$ and $R_w = 0.029$ for 1897 observed reflections. The structure consists of a polymeric acetate bridged network of distorted square-pyramidal copper(II) ions. The five coordinate geometry around each metal ion is a result of the bonding of three nitrogen atoms from the B-MIMA ligand and two oxygen atoms from different acetate ions. The acetate ions act as bidentate ligands bridging different copper ions and the resulting extended bridging network extends out the crystallograhic *a* axis. Spectroscopic, magnetic and electrochemical properties of the complex are described and compared with related compounds. The solution spectroscopic properties of **6** suggest that the square-pyramidal geometry of the metal ion in the solid-state is not retained in solution.

Histidine is known to be present at the active site of numerous metalloproteins,[1] in particular, electronically coupled Type III binuclear copper proteins such as haemocyanin[2] and tyrosinase.[2] Haemocyanin[2,3,4] functions as an oxygen carrier in the haemolymph of arthropods and molluscs while tyrosinase[1,2,3,5] functions both as a monophenolase $\left(\text{phenol} \xrightarrow[Cu^+]{O_2} o\text{-diphenol}\right)$ and as a two-electron oxidase $\left(o\text{-diphenol} \xrightarrow{Cu^{2+}} o\text{-quinone}\right)$. The active sites of the oxy forms of the two proteins are thought to be very similar.[1c] A preliminary X-ray crystallographic structure of deoxyhaemocyanin (deoxy Hc)[6] isolated from *Panularis interruptus* shows that the Cu^I ions are coordinated to three imidazole residues of histidine. From various spectroscopic studies, the oxy form of haemocyanin (oxy Hc) is thought to have two[7,8] or three[8,9] imidazole residues from histidine bonded to each of the cupric ions.

There has been much effort recently to synthesize low molecular weight inorganic analogues of the active site of these copper proteins.[10–15] In several instances the spectroscopic, magnetic[10,12f] and chemical reactivity (O_2 bonding and mono-

*Author to whom correspondence should be addressed.

phenolase activity) properties[11] have been successfully duplicated. In general, the model studies have focused on preparing binucleating ligands containing pyridine,[1b,c,11,14] pyrazole,[1b,12] benzimidazole[1b,13,14] and cyclic polyaza macrocyclic ligands[16] that are capable of binding two metal ions in close proximity. Along similar lines we have begun a systematic study of the structural and magnetochemistry of the metal complexes of a new N_3 tridentate bis-imidazolyl ligand. It is our objective to use this compound to prepare new binucleating ligands containing biologically more relevant imidazole functionalities, in order to construct functional models of the binuclear centres in haemocyanin and tyrosinase.

In the present report, we describe the synthesis of the polyimidazole ligand, bis[2-(1-methylimidazolyl)methyl]amine [B-MIMA],[17] and the preparation and characterization of a polymeric copper(II) complex, [Cu(B-MIMA)(CH_3COO)](ClO_4). The results from an X-ray structural analysis on [Cu(B-MIMA)(CH_3COO)](ClO_4) and the spectroscopic, magnetic and electrochemical properties of the complex will be discussed.

EXPERIMENTAL

Materials and methods

Reagent grade chemicals were used in all experiments. Solvents were dried by standard procedures prior to use. The identity and purity of the ligand B-MIMA was determined by ^1H and ^{13}C NMR spectroscopies, and mass spectrometry. All elemental analyses were performed by either Galbraith Laboratories Inc., Knoxville, Tennessee or Desert Analytics Organic Microanalysis, Tuscon, Arizona. ^1H and ^{13}C NMR spectra were recorded on a Varian XL-300 spectrometer. Chemical shifts are reported as δ units in ppm relative to an internal standard of $(CH_3)_4Si$. Mass spectra were recorded on a VG-7035 GC-MS mass spectrometer in the EI mode at 20 eV. IR spectra were recorded as DRIFTS on a Nicolet 9000 FTIR spectrophotometer using KCl as a diluting matrix. Solid-state electronic spectra were recorded as mull transmission spectra with a Shimadzu 600 spectrophotometer. Visible absorption spectra were recorded also with a Shimadzu 600 spectrophotometer using quartz cells of 1 cm thickness. Spectroscopic grade DMF was used as a solvent for all measurements. Extinction coefficients are reported in units of M^{-1} cm^{-1}. Electrochemical measurements were made at room temperature using a PAR 173 potentiostat, a PAR 175 universal programmer, a PAR 179 digital coulometer and Houston Model 2000 X-Y recorder. Controlled-potential coulometry required the use of a platinum gauze working electrode. The three-electrode cell utilized a Ag/AgCl reference electrode, a coiled platinum wire auxillary electrode and a polished glassy-carbon working electrode.

The solid-state room temperature magnetic moment was determined with a PAR Model 155 vibrating sample magnetometer calibrated with $HgCo(NCS)_4$. Pascal constants were used to correct data for diamagnetism.[18] The EPR spectrum of a frozen solution of [Cu(B-MIMA)(CH_3COO)](ClO_4) in DMF was obtained using a Varian E-109 spectrometer equipped with an Oxford Instruments Inc. cryostat. All EPR spectra of the copper complexes were calibrated using diphenylpicrylhydrazyl (DPPH) as a standard.

Synthesis of the ligand and copper(II) complexes

1-Methyl-2-imidazolecarboxaldehyde (**1**). Compound **1** was prepared according to a procedure published previously by Iverson and Lund.[19] Under a nitrogen atmosphere, 1.6 M *n*-butyllithium (68 cm^3, 0.108 mol) was slowly added to a suspension of 1-methylimidazole (8.2 g, 0.1 mol) in 250 cm^3 of dry diethyl ether at $-45°C$. The resulting mixture was allowed to stir at $-50°C$ for 1 h, after which freshly distilled dimethylformamide (12.5 cm^3, 0.15 mol) in 20 cm^3 of diethyl ether was quickly added. The reaction mixture was stirred overnight and the temperature of the dry ice–acetone bath allowed to slowly rise to 0°C. Over a period of 15 min, 10 cm^3 of water was cautiously added to the solution, followed by 65 cm^3 of 4 N HCl. The layers were separated and the ether was washed with 5×15 cm^3 portions of 4 N HCl. The combined acid extracts were saturated with potassium carbonate and extracted with 4×30 cm^3 of chloroform. The combined chloroform extracts were dried over magnesium sulphate, filtered and evaporated. The resulting residue was distilled at reduced pressure to give 7 g (64%) of **1** as a colourless oil which crystallized on standing. Boiling point 65°C (1.0 torr), m.p. 38–39°C (Lit. b.p. 89–95 (12 torr), m.p. 38–39°C).[19] ^1H NMR ($CDCl_3$, δ): 4.01 (s, 3H), 7.16 (s, 1H), 7.27 (s, 1H), 9.79 (s, 1H).

1-Methyl-2-imidazolecarboxaldehyde oxime (**2**). Compound **2** was prepared according to the method of Gebert and von Kerékjártó.[20] A solution of **1** (2.20 g, 0.02 mol) in 10 cm^3 of ethanol was added to $NH_2OH \cdot HCl$ (1.40 g, 0.02 mol) and Na_2CO_3 (1.06 g, 0.01 mol) dissolved in 20 cm^3 of water cooled to 0°C. The resulting precipitate was filtered and washed with 30 cm^3 of cold 33% ethanol to give 2.2 g (88%) of **2**. Melting point

176°C (Lit. 176°C).[21] ^{1}H NMR ($CDCl_3$, δ): 3.8 (s, 3H), 6.95 (s, 1H), 7.2 (s, 1H), 8.0 (s, 1H), 10.1 (s, 1H).

1-Methyl-2-aminomethylimidazole dihydrochloride (**3**). A solution of **2** (1.0 g, 0.008 mol) in 50 cm^3 of methanolic hydrochloride was hydrogenated at atmospheric pressure and 65°C over 10% palladium–charcoal for 4 h. The catalyst was filtered, washed with 10 cm^3 of methanol and the filtrate cooled to −20°C for 3 h. The precipitate was filtered and washed with 2×10 cm^3 portions of methanol·HCl to give 1.20 g (82%) of **3**. Melting point 251°C. ^{1}H NMR (d_6-DMSO, δ): 4.0 (s, 3H), 4.43 (s, 2H), 7.75 (s, 1H), 7.77 (s, 1H), 8.25 (6s, 4H).

Bis(2-(1-methylimidazolyl)methyl)amine trihydrochloride (**4**). A solution of **3** (2.0 g, 0.011 mol) in 50 cm^3 of methanol containing KOH (0.6 g, 0.011 mol) was added to a solution of **1** (1.2 g, 0.011 mol) in 50 cm^3 of methanol and hydrogenated at atmospheric pressure over 10% palladium–charcoal for 4 h. The catalyst was filtered off and the solvent reduced to a volume of 25 cm^3. The KCl salt was then filtered off and 300 cm^3 of methanolic·HCl added. After cooling to −20°C for 4 h, the precipitate was filtered and washed with 2×10 cm^3 portions of methanolic·HCl to give 2.3 g (68%) of **4**. Melting point 214°C. ^{1}H NMR (d_6-DMSO, δ): 3.16 (2, 1H), 4.04 (s, 6H), 4.64 (s, 4H), 7.78 (s, 2H), 7.82 (s, 2H).

Bis(2-(1-methylimidazolyl)methyl)amine [B-MIMA] (**5**). The free base **5** was obtained by dissolving **4** (1.88 g, 0.006 mol) in a saturated aqueous K_2CO_3 solution and extracting with 5×50 cm^3 portions of chloroform. The extracts were combined, dried over magnesium sulphate, and the solvent removed to give 1.2 g (97%) of B-MIMA. Melting point 122°C. Found: C, 58.3; H, 7.2; N, 34.1. Calc. for $C_{10}H_{15}N_5$: C, 58.5; H, 7.4; N, 34.1%. Mass spectra (205.26 g mol^{-1}, M/Z): 206($M+H^+$, 7); 167(27); 139(30.7); 110(36); 95(77); 83(55); 73(15). IR (KCl; cm^{-1}): $\nu_{C=N}$ 1645 cm^{-1}, $\nu_{C=N=C=C}$ 1435 cm^{-1}, ν_{NH} 3207 cm^{-1}. ^{1}H NMR ($CDCl_3$, δ): 2.27 (s, 1H), 3.55 (s, 6H), 3.78 (s, 4H), 6.75 (s, 2H), 6.85 (s, 2H). ^{13}C NMR ($CDCl_3$, δ): 32.3 (CH_3); 44.4 (CH_2); 121.0 and 126.8 (ring CH); 145.8 (ring quart. C).

Acetato [bis(2-(1-methylimidazolyl)methyl)amino] copper(II) perchlorate, [Cu(B-MIMA)(CH_3COO)](ClO_4) (**6**). A solution of **5** (0.41 g, 0.002 mol) in 5 cm^3 of methanol was added to a solution of $Cu(CH_3CO_2)_2$ (0.4 g, 0.002 mol) and $NaClO_4$ (0.122 g, 0.001 mol) in 10 cm^3 of methanol. The resulting blue solution was filtered and allowed to stand. Large blue crystals formed and were filtered and washed with methanol to give 0.58 g (80%) of **6**. The compound was recrystallized from methanol. **Caution!** Even though the perchlorate complex isolated here was not found to be shock sensitive, care is recommended in its handling. Found: C, 33.7; H, 4.2; N, 16.3. Calc. for $C_{12}H_{18}N_5ClCuO_6$: C, 33.7; H, 4.2; N, 16.4. IR (KCl; cm^{-1}): $\nu_{C=N}$ 1625, $\nu_{C=N=C=C}$ 1445, $\nu_{CO_2(asym)}$ 1595, $\nu_{CO_2(sym)}$ 1410, ν_{NH} 3205 cm^{-1}. UV–vis [DMF; λ_{max}, nm (ε, M^{-1} cm^{-1})]: 301(1270), 682(70). (Mull; λ_{max}, cm^{-1}) 14800. EPR (DMF) $g_\parallel = 2.26$; $g_\perp = 2.05$, $A_\parallel = 0.0159$ cm^{-1} (powdered crystals); $g_\parallel = 2.24$, $g_\perp = 2.07$.

X-ray crystallography, data collection, reduction of X-ray diffraction data. The crystal chosen for data collection was an irregular plate cut from a cluster of crystals. Cell constants and orientation matrices were determined by least-squares refinement of the diffraction geometry of 25 accurately centred reflections ($8 < \theta < 14°$). The choice of space group ($P1$) was confirmed using the program TRACER[22] and by the successful solution and refinement of the structure. Data were collected at room temperature on an Enraf–Nonius CAD4 automated diffractometer using the ω–2θ scan technique. As a check on crystal and electronic stability, three representative reflections were measured every 60 min. The intensities of these reflections remained constant within experimental error throughout data collection, so no decay correction was applied. The data were corrected for Lorentz and polarization effects, and an empirical absorption correction based on a series on psi scans was applied. All data were processed and the crystal structure solved using the SDP package.[22] A summary of the crystal data, experimental details and refinement results for compound **6** are given in Table 1.

Structure solution and refinement of compound **6**

The structure was solved using the Patterson method which revealed the position of the copper atom. The remaining atoms were located in succeeding difference Fourier syntheses. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located (range 0.88–1.05 Å) and added to the structure factor calculation with isotropic thermal parameters set to $1.3 \times B_{iso}$ of the bonded atom. Hydrogen parameters were not refined. Refinement was carried out by full-matrix least-squares on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where the weight w is defined as $4F_o^2/[\sigma(F_o^2)]^2$. Scattering factors were taken from Cromer and Waber[23] and anomalous dispersion effects were included in F_c;[24] the values for $\Delta f'$ and $\Delta f''$ were those of Cromer.[25] At one stage in the refinement, the enantiomeric model was calculated and showed the initial choice to be the correct one ($R = 0.023$ vs $R = 0.033$). An isotropic extinc-

tion parameter could not be refined. The model converged with final agreement factors of $R = \Sigma(|F_o|-|F_c|)/\Sigma|F_o| = 0.021$ and $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.029$. The highest peak in the final difference Fourier had a height of 0.034(4) e Å^{-3}. Plots of $\Sigma(|F_o|-|F_c|)^2$ vs $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. Tables containing structure factors, atomic positional and anisotropic thermal parameters, hydrogen coordinates, bond angles and distances, and torsion angles have been deposited as supplementary material with the Editor, from whom copies are available upon request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis

There have been several examples of polyimidazole ligands and their metal complexes reported recently,[26–31] however, the ligands generally have a tripod shape and are not easily derivatized. We wish to report the results of our initial efforts to prepare and characterize new polyimidazole ligands. In particular, this study will focus on the preparation of the bis-imidazole ligand, B-MIMA. We have used this N_3 tridentate ligand to prepare binucleating polyimidazole ligands.[17] Similar synthetic approaches have been successfully exploited by Karlin[11] and Sorrell[12] and co-workers for the preparation of polypyridine and polypyrazole ligands, respectively.

The tridentate ligand, B-MIMA (**5**), has been prepared following the procedure outlined in Fig. 1. The procedure is a general one and has been used in the preparation of several derivatives of **5**.* The aldehyde (**1**) and corresponding oxime (**2**) intermediates, depicted in Fig. 1, have been prepared previously by others (see Experimental) and the ^{1}H, ^{13}C NMR spectra and melting points of recrystallized samples of these compounds agree with literature values. Catalytic hydrogenation of **2** affords the amine (**3**) in good yields (82%). The amine (**3**) reacts smoothly with **1** in methanol forming the Schiff base intermediate which is not isolated but rather hydrogenated *in situ* affording gram quantities of the off-white solid **4**, as the trihydrochloride. The ^{1}H and ^{13}C NMR spectra of the free base of **4** agree with the proposed structure and

*We have used this general method to prepare **2** and **4** substituted imidazole analogues of B-MIMA which contain either methylene or ethylene backbone linkages. The synthesis and properties of these compounds will be reported elsewhere.

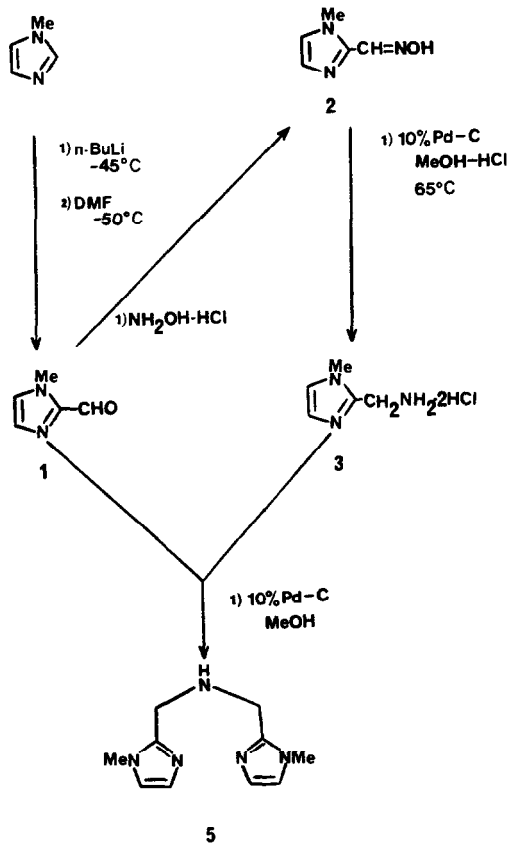

Fig. 1. Synthetic scheme for preparing the tridentate ligand, B-MIMA (**5**).

a molecular ion at 205.26 mass units has been detected by mass spectrometry. The IR spectrum of the free base **5** exhibits a ν_{NH} stretch at 3207 cm^{-1} characteristic of a secondary amine and strong stretches at 1645 and 1436 cm^{-1}, which are attributable to the C=N and —C=N—C=C— symmetric stretching modes of the imidazole ring, respectively.[32]

The blue copper(II) complex, [Cu(B-MIMA)(CH_3COO)](ClO_4) (**6**), was prepared by mixing stoichiometric amounts of copper(II) acetate and the free base of B-MIMA (**5**) in methanol, followed by precipitation of the complex with $NaClO_4$. The same complex can be isolated by reacting stoichiometric amounts of copper(II) perchlorate with **5** in methanol followed by precipitation of the metal complex with sodium acetate.

Description of the solid-state structure of [Cu(B-MIMA)(CH_3COO)](ClO_4) (**6**)

Compound **6** crystallizes from methanol in the triclinic space group $P\bar{1}$ with one molecule per unit cell. Crystal data for the complex are given in Table 1 and selected bond distances and angles are reported in Table 2.

The geometry around the copper(II) ion is best described as a distorted square-pyramid as illustrated in the packing diagram in Fig. 2. The basal plane of the square-pyramid is defined by atoms N(1), N(3), N(5) of the B-MIMA ligand and O(1) of the acetate ion. The mean displacement of the four atoms from the best least-squares plane defined by their positions is 0.012(2) Å. The axial coordination site is occupied by another oxygen atom [O(2)′] of an acetate group which is associated with an adjacent complex molecule. The copper atom is displaced from the equatorial plane towards the axial oxygen by 0.085 Å. The Cu—O(2)′ distance of 2.414(2) Å is longer than the equatorial Cu—O(1) distance of 1.928(2) Å, but is within the range of values reported for parallel stacked dimeric copper(II) complexes[33a-e] and [Cu(diethylenetriamine)X]$_2$Y$_2$ complexes.[33f-i] The intramolecular Cu—O(2) distance, on the other hand, is 3.017(2) Å which is too long to be considered as a bonding interaction.[34] The acetate group is, therefore, bridging two different metal ions and this bridging interaction extends out the crystallographic *a* axis resulting in a polymeric *syn–anti* step structure with a Cu—Cu separation of 5.176(2) Å.

In structurally similar copper(II) complexes, the second carbonylic oxygen atoms are generally greater than 2.70 Å from the metal ion and the Cu—O—C angles are approximately 50°. In **6** the carbonylic oxygen atom is 3.017(2) Å from the copper atom at an angle of 47.1°. In addition, the carbonylic oxygen atoms are usually hydrogen bonded to either solvate molecules[35-38] in the crystal lattice or coordinated imidazole N—H

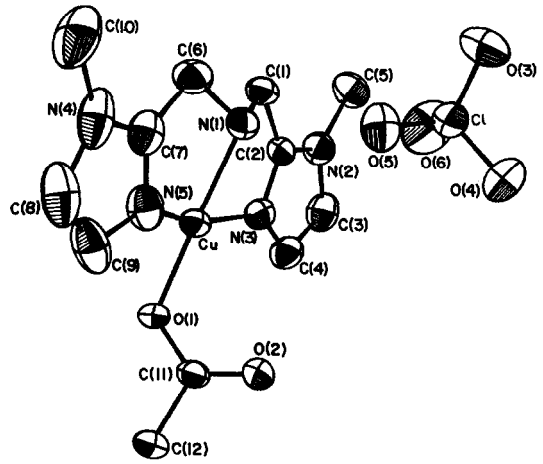

Fig. 2. Crystal packing diagram showing the *syn–anti* acetate bridging interaction in [Cu(B-MIMA)(CH_3COO)](ClO_4). Stacking interaction is along the 100-plane.

Numbers in parentheses are estimated standard deviations in the least significant digits.

protons[37,38] associated with adjacent complex molecules.

The polymeric *syn–anti* step structure observed for **6** (Fig. 3) resembles the structure reported for $[Cu_2(ClCH_2COO)_3EtSal(C_2H_5OH)]_\infty$[36] and $[Cu(dien)X]_2Y_2$[33f-i], and has been observed in the polymeric structure of bis(L-asparinato)Zn^{II}.[39] In this later complex the second carboxylic oxygen atom of neighbouring molecules complete the octahedral coordination geometry around the metal ion with

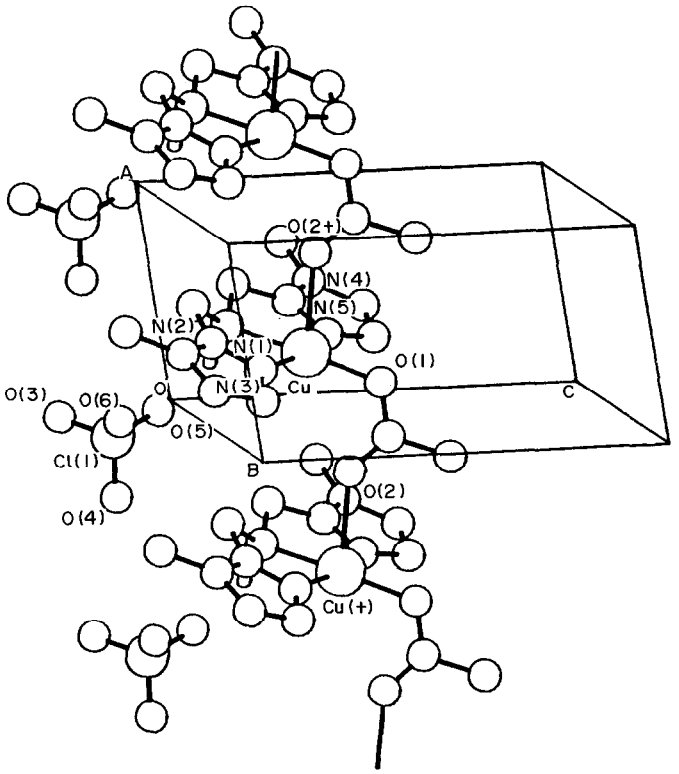

Fig. 3. ORTEP view of the complex molecule showing the atom numbering scheme and thermal motion ellipsoids (50%).

out-of-plane Zn—O distances of 2.278 and 2.481 Å.

The Cu—N bond lengths of **6** are typical of values reported previously for other copper–imidazole complexes[1b,16a,40–42] [N(1), 2.047(2), N(3), 1.947(2) and N(5), 1.967(3) Å]. The N—Cu—N angles of 81.3(1), 81.4(2) and 162.0(1)° reflect the strain imposed on the coordination environment by the five-membered chelate rings formed upon coordination of the *B-MIMA* ligand. The 1-methylimidazole rings are planar with no significant deviation from the least-squares planes through the five atoms and are nearly coplanar with a dihedral angle of 7.56°. The Cu—O bond angles are more obtuse, with the largest deviation from 90° being the O(1)—Cu—O(2') angle of 103.0(2)°. Angles closer to 90° are observed for a structurally related tridentate bis-imidazole ligand which forms eight-membered chelate rings with the copper(II) ion.[31]

The perchlorate counter ions also stack along the crystallographic *a* axis and are weakly hydrogen bonded to the N(1) proton of the complex. The HN(1)—O(5) distance is 2.030(3) Å and the N(1)—HN(1)—O(5) angle is 150.0°.

Properties

The IR spectrum of the B-MIMA changes slightly upon coordination to the copper(II) ion. Most noticeable changes are observed in the —C=N— (1645 cm^{-1}) and —C=N=C=C— (1435 cm^{-1}) symmetric stretching modes. The 1645 cm^{-1} band shifts to 1625 cm^{-1} and the 1440 cm^{-1} band shifts to 1445 cm^{-1}, implying direct coordination of imine nitrogen atoms of the ring. Carbonyl stretches for the bridging acetate ion are observed at 1595 and 1410 cm^{-1}, corresponding to the ν(COO—) asymmetric and symmetric stretches, respectively. Similar multiple bands in the region characteristic of carboxylate stretches have been reported for $\{Cu(L\text{-}Asp)(2\text{-}MeIm)\}\cdot H_2O$ and related complexes.[38]

The room temperature, solid electronic spectra of **6** exhibits a broad maximum at 14,800 cm^{-1} which is in agreement with data reported for other mixed oxygen and nitrogen ligand square-pyramidal complexes.[38] The polymeric solid-state structure of $\{Cu(B\text{-}MIMA)(CH_3COO)\}(ClO_4)$ is not retained in solution. The complex is readily soluble in polar solvents and its absorption spectrum in methanol shows a strong charge-transfer absorption at 301 nm (ε = 1270 M^{-1} cm^{-1}) and a *d–d* band at 682 nm (ε = 70 M^{-1} cm^{-1}), indicative of a square-planar geometry around the copper(II) ion.

Magnetism

At room temperature the magnetic moment of **6**

is 1.82 BM, a value that is typical of $S = 1/2$ Cu^{II}.[43] The X-band EPR spectrum recorded on a ground crystalline sample of **6** shows an axial spectrum with $g_{\|} = 2.24$ and $g_{\perp} = 2.07$ (Supplementary material). No $\Delta M_s =$ two transition has been detected in the solid-state EPR spectrum[43,44] of the complex at temperatures between 298 and 3.8 K. It appears that the acetate bridge does not promote spin–spin exchange coupling between copper(II) ions in the chain. The orthogonal nature of the acetate bridge most likely accounts for the apparent absence of exchange coupling. However, the recently reported μ-acetato bridged $[Cu(dien)(OAc)]_n(ClO_4)_n$ complex[33i] has been found to be a quasi one-dimensional complex in which the copper(II) ions are ferromagnetically coupled.

A frozen DMF solution of **6** at 77 K displays an axial EPR spectrum typical of square-planar copper(II) complexes with $g_{\|} = 2.26$, $g_{\perp} = 2.05$ and $A_{\|} = 0.0159$ cm^{-1}. Seven nitrogen superhyperfine lines have been resolved on the low field parallel component of the spectrum.

Electrochemistry

In acetonitrile and dimethylformamide, the copper(II) complex undergoes irreversible oxidation at a platinum electrode surface. Cyclic voltammetric studies indicate that the reduced species undergoes chemical decomposition, presumably due to the loss of the acetate ion at the working electrode, since no oxidation current is detected on the reverse scan. In DMF at a glassy-carbon electrode, however, the electrochemical behaviour is slightly better behaved. Cyclic voltammetry on **6** (Supplementary material) in DMF at a glassy-carbon electrode reveals a quasi-reversible one-electron reduction (relative to Fc/Fc^+) of the copper(II) ion at $E_{1/2} = -0.239$ V vs Ag/AgCl, with a peak-to-peak separation of 270 mV. The ratio of i_a/i_c is 0.89 suggesting that there is some degradation of the complex upon reduction.[45]

A similar copper(II) complex containing a N_3 bis-imidazolyl chelate has been studied by Karlin *et al.*[31] The reduction potential of their complex is approximately 0.50 V more positive than complex **6**. A possible explanation for the greater stabilization of the copper(I) species with Karlin's ligand may be that the larger (eight-membered) ring size more easily accommodates the tetrahedral geometry most likely formed upon reduction of the copper(II) ion. In addition, Karlin has reported that $Cu_2(py_2)Cl_3PF_6$[44] undergoes a quasi-reversible one-electron reduction at -0.045 V vs NHE (-0.242 V vs Ag/AgCl in DMF), which is closer to the reduction potential observed for compound **6**. Further studies correlating the effect of chelate ring size on the reduction potentials of copper(II) complexes containing tridentate N_3 bis-imidazolyl ligands are in progress.

Summary

A new N_3 tridentate bis-imidazolyl ligand (**5**) has been prepared and characterized. The ligand readily forms complexes with copper(II) and the corresponding acetate adduct is polymeric in the solid state. Solution spectroscopic properties are typical of a square-planar Cu(II) complex indicating the polymeric solid-state structure is not retained in solution. The complex ion displays quasi-reversible redox properties in DMF at glassy-carbon electrode surfaces, but irreversible electrochemistry at platinum.

Future directions

We are continuing our investigation of the chemistry of the N_3 tridentate ligand, B-MIMA (**5**), and its derivatives. In particular, we have prepared a variety of bridged binucleating derivatives[47] and are exploring their coordination and spectroscopic properties with metal ions such as: Cu, Mn, Fe and Co. Of particular interest is the copper(I) chemistry of a *m*-xylyl bridged bis(B-MIMA) analogue since a structurally similar pyridinyl[11d] compound mimics the phenolase activity observed for the redox active binuclear copper metalloprotein, tyrosinase.[1b,2] Reaction of the copper(I) complexes of polyimidazolyl ligands with biologically important molecules such as O_2, are under current investigation and will be the subject of future reports.

Supplementary material

Tables of positional parameters of non-hydrogen atoms, anisotropic thermal parameters, fractional coordinates for H atoms, bond distances and angles for H atoms, least-squares planes and torsion angles, as well as figures of the electronic spectrum, EPR spectra and cyclic voltammogram of the complex (13 pp.) are available upon request from the Editor or Author.

(*Received* 25 *July* 1988; *accepted after revision* 5 *October* 1988)

Abstract—Reaction of $[n\text{-}Bu_4N]_2[Mo_2O_7]$ with propane-1,3-dithiol in methanol yields the triply-bridged binuclear complex $[n\text{-}Bu_4N][Mo_2O_3(OCH_3)(SCH_2CH_2CH_2S)_3]$ (**1**). Complex **1** exhibits the confacial bioctahedral geometry characteristic of this class of complexes. In contrast, the reaction of $[n\text{-}Bu_4N]_4[Mo_8O_{26}]$ with 2-mercaptoacetic acid and triethylamine in methanol results in the isolation of a complex $[Et_3NH]_2[Mo_2O_2(SCH_2CO_2)_4]$ (**2**), representing the first example of a new class of binuclear molybdenum(V) species. The structure is characterized by a "*trans*-planar" $[Mo_2O_2S_2(\text{thiolate})]^{4+}$ core and an unusually long Mo···Mo distance of 3.078(1) Å. Crystal data. Complex **1**: triclinic space group $P\bar{1}$, $a = 9.310(2)$, $b = 11.328(2)$, $c = 19.954(3)$ Å, $\alpha = 74.93(1)$, $\beta = 78.19(1)$, $\gamma = 81.53(1)°$, $V = 1979.2(10)$ Å^3, $Z = 2$, $D_{calc} = 1.369$ g cm^{-3}; structure solution and refinement based on 5292 reflections, $R = 0.0570$. ‡ Examples of tungsten complexes with the $[W_2O_2YY'Z]^{3+}$ core are also known.[15]

ligand donor groups and not limited to thiolate coordination, structurally characterized examples of the triply-bridged $[Mo_2O_2YY'Z]^{3+}$ core (**IV**)[7–14]‡ display some degree of thiolate coordination. Type **IV** binuclear structures may be derived geo-

metrically from the common *syn* conformer of the type **III** species, illustrated below, by addition of a third, weakly interacting, bridge donor Z. Although type **IV** structures may be described as confacial bioctahedra, the structural relationship of the $[Mo_2O_2YY']$ bridge of type **IV** structures to the $[Mo_2O_4]$ bridge of the type **III** species is apparent in the Mo—Mo distance, the folding of the $[Mo_2YY']$ rhombus along the YY′ vector, and the disposition of the terminal oxo groups. Type **IV** complexes containing the 2-mercaptoethanolate ligand exhibit some structural diversity while retaining the $[Mo_2O_2(SCH_2CH_2O)Y']^{3+/2+}$ core, in which the $(SCH_2CH_2O)^{2-}$ ligand assumes a bidentate doubly-bridging mode, spanning the Y to Z bridge positions.[11,13] Reaction conditions, such as stoichiometry, solvent and counter ions, were found to have pronounced effects on the ligation modes adopted by the additional mercaptoethanolate groups required to complete the molybdenum coordination requirements in the type **IV** complexes.

As part of our continuing investigations of the chemistry of organic solvent soluble polyoxomolybdate anions with thiolate ligands,[16] we have studied the reactions of $[n\text{-}Bu_4N]_2[Mo_2O_7]$ with 1,3-dimercaptopropane and mercaptoacetic acid in an effort to evaluate donor group influences on the degree of complex aggregation and on the coordination geometry. In contrast to the class **IV** triply-bridged structure of the propane-1,3-dithiolate complex $[Mo_2O_2(OCH_3)(SCH_2CH_2CH_2S)_3]^-$, the 2-mercaptoacetate complex $[Mo_2O_2(SCH_2CO_2)_4]^{2-}$ was found to display a $[Mo_2O_2(SCH_2CO_2)_2]^{2+}$ core with the unique features of a planar $[Mo_2S_2]$ bridge, with an *anti* disposition of the terminal oxo groups and an unusually long Mo···Mo distance. Structure **V** illustrates the structural framework for this class of binuclear complexes.

RESULTS AND DISCUSSION

Synthesis and spectroscopic properties

Under the synthetic conditions of a large excess of thiolate and mononuclear oxomolybdate precursors,[1,17] reactions of thiols with molybdenum(VI) yield a class of dark blue–green mononuclear molybdenum(V) complexes of the general formulation $[MoO(SR)_4]^-$:

$$[MoO_2(CH_3CHOHCHOMe)_2] \cdot 2CH_3CHOHCHOHMe + 5HSR \rightarrow [MoO(SR)_4]^- + 1/2RSSR + 4CH_3CHOHCHOHMe + H_2O + R_3NH^+.$$

Similarly, reactions of polyoxomolybdates with an excess of thiolate ligand yield mononuclear or binuclear oxomolybdate(V) complexes of classes **I** and **III**, respectively.[17]

$$[Mo_8O_{26}]^{4-} + 40HSR \rightarrow 8[MoO(SR)_4]^- + 4RSSR + 18H_2O + 4R_3NH^+$$

$$[Mo_8O_{26}]^{4-} + 24HSR \rightarrow 4[Mo_2O_4(SR)_4]^{2-} + 4RSSR + 10H_2O + 4R_3NH^+.$$

However, modifications in the nature of the molybdate precursor, in counter ions and solvents have been shown to have profound consequences on the products isolated in reactions of molybdates with thiolate ligands. Thus, $[Mo_8O_{26}]^{4-}$ reacts with 2-mercaptoethanol as the limiting reagent to yield $[Mo_{10}O_{28}(SCH_2CH_2O)_2(HOCH_3)_2]^{4-}$,[16] rather than the class **IV** dimers which constitute the major products under conventional reaction conditions.

While reaction of $[MoO_2(acac)_2]$ with excess propane-1,3-dithiol yields $[MoO(SCH_2CH_2CH_2S)_2]^-$, complex **1**, $[Mo_2O_2(OCH_3)(SCH_2CH_2CH_2S)_3]^-$, may be synthesized directly from the reaction of $[Mo_2O_7]^{2-}$ with the dithiol in methanol solution. Under appropriate reaction conditions, class **I** mononuclear species have been demonstrated to be unstable with respect to class **IV** binuclear complexes,[13] such that treatment of $[MoO(SR)_4]^-$ with a source of methoxy, amido or azido ligands yields triply-bridged analogues of type **IV**. The reaction conditions employed in the preparation of **1** favour the incorporation of the methoxy group and hence the triply-bridged geometry.

The IR spectrum of **1** exhibits features at 2958 and 1062 cm^{-1} associated with ν(C—H) and ν(C—O) for the coordinated methoxy group. The intense band at 930 cm^{-1} is characteristic for ν(Mo—O_t), while the 460 and 370 cm^{-1} bands are presumably due to the [Mo(μ-S thiolate)$_2$(μ-OCH_3)Mo] bridge.[7]

Since modification of donor groups may dramatically affect the coordination geometry of oxomolybdenum thiolate complexes, the reaction of $[Mo_8O_{26}]^{4-}$ with 2-mercaptoacetic acid was investigated. The cherry-red diamagnetic product of the reaction analysed for $[(C_2H_5)_3NH][MoO(SCH_2CO_2)_2]$, and a subsequent X-ray structural

study confirmed the binuclear structure $[(C_2H_5)_3NH]_2[Mo_2O_2(SCH_2CO_2)_4]$ (**2**).

The IR spectrum of **2** displays two strong bands at 1670 and 1610 cm^{-1} assigned to ν(C=O) of the ligand and bands in the 920–950 cm^{-1} region characteristic of ν(Mo=O_t). No bands attributable to bridging oxo groups or to a triply-bridged geometry were observed, leading to the conclusion that the coordination geometry of **2** must be unusual.

The ^1H NMR spectrum of **2** revealed two AB four-line multiplets associated with the methylene groups of the 2-mercaptoacetate ligands, indicating the presence of two distinct ligand environments. Furthermore, within each methylene unit, the protons are inequivalent to give rise to the observed AB patterns.

Structural studies

As shown in Fig. 1, the structure of the anion of **1** consists of discrete binuclear species $[Mo_2O_2(OCH_3)(SCH_2CH_2CH_2S)_3]^-$ with two non-equivalent pseudooctahedral molybdenum atoms sharing a face defined by two bridging thiolate sulphur donors and the oxygen atom of the bridging methoxy group. The unusual asymmetry in the molybdenum geometries is imposed by the odd number of dithiolate ligands, Mo(1) being ligated by two dithiolates which also provide bridging sulphurs for Mo(2), which is additionally ligated by a chelating but non-bridging dithiolate. The structure is essentially identical to that of $[Mo_2O_2(N_3)(SCH_2CH_2CH_2S)_3]^-$ [17] with the azido bridge replaced by the methoxy group of **1**. The $[Mo_2O_2(SCH_2CH_2CH_2S)_3]^0$ core has an analogy in Tc chemistry, the neutral $[Tc_2O_2(SCH_2CH_2S)_3]$, which may be described as two Tc square pyramids sharing a common edge defined by sulphur donors from two ethanedithiolate ligands.[18] A significant structural difference is the long Tc···Tc distance of 3.654(1) Å, which is consistent with the absence of a direct metal–metal interaction. The presence of the bridging methoxy group in **1** leads to the description of the structure in terms of two confacial octahedra, with a short Mo···Mo distance common to molybdenum(V) binuclear complexes (Table 1). The structural parameters of the bridge are very similar to those of other class **IV** complexes, which have been discussed in detail in several recent publications.[6,7] A comparison of the bridge parameters of **1** to those of selected class **IV** complexes is presented in Table 2. The non-equivalence of the molybdenum geometries is reflected in the unsym-

metrical Mo—S bridge distances, 2.464(6) Å (av.) for Mo(1)—S_b and 2.515 Å (av.) for Mo(2)—S_b.

The structure of the molecular anion of **2** is shown in Fig. 2 and seen to consist of discrete binuclear units $[Mo_2O_2(SCH_2CO_2)_4]^{2-}$ with a crystallographic centre of symmetry at the midpoint of the Mo(1)—Mo(1a) vector, relating the unique halves of the binuclear complex. The overall geometry may be described as two molybdenum octahedra sharing an edge defined by the S(1)—S(1a) vector. As suggested by the ^1H NMR studies, the 2-mercaptoacetate ligands assume two distinct coordination modes: terminal chelating through S(2) and O(4), and bridge chelating with S(1) bridging the molybdenum centres and O(1) ligated to a single molybdenum site.

The *trans* influence of the oxo group is reflected in the long Mo—O(1) bond distance of 2.145(4) Å, compared to the more normal Mo—O(4) distance of 2.052(4) Å and in the displacement of the molybdenum atom from the S(1)—S(1a)—O(1)—S(2) plane by 0.24 Å in the direction of the terminal oxo group O(3). The terminally chelating 2-mercaptoacetate group S(2)—C(3)—C(4)[O(5)]—O(4) is planar, with unexceptional bonding parameters reflected in the short C(4)—O(5) distance, relative to C(4)—O(4), indicating localization of multiple bond character in the C(4)—O(5) unit. The ligand bite distance S(4)···O(4) of 2.902(4) Å is characteristic for five-membered rings of this type. In contrast, the bridging 2-mercaptoacetate ligand is distinctly non-planar, with S(1a) *ca* 0.44 Å out of the C(2a)—C(1)—O(2)—O(1) plane. Furthermore, the S(1a)···O(1) bite distance has expanded to 3.235(4) Å. The distortions of the chelate geometry are attributed to the geometric constraints imposed on the ligand, as a consequence of spanning bridge and

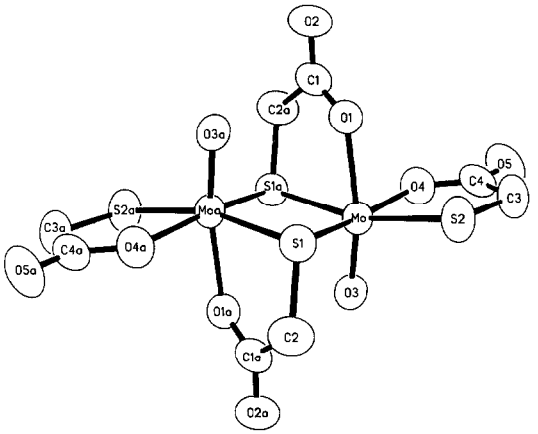

Fig. 2. Perspective view of the structure of $[Mo_2O_2(SCH_2CO_2)_4]^{2-}$, showing the atom-labelling scheme.

terminal coordination sites of the molybdenum centres.

The bridge geometry is characterized by crystallographically imposed planarity of the Mo_2S_2 rhombus and an *anti* orientation of the oxo groups. The Mo(1)—Mo(1a) distance of 3.078 Å is extremely unusual in view of the range of 2.65–2.95 Å generally observed for binuclear molybdenum(V) complexes of types **III** and **IV**. The long Mo—Mo distance implies the absence of a direct metal–metal interaction in **2**, suggesting that the observed diamagnetism of the complex is a consequence of effective antiferromagnetic coupling of the molybdenum(V) d^1 sites through the $[Mo_2S_2]$ bridge, in a fashion similar to that observed for class **II** $[Mo_2O_3]^{4+}$ bridged binuclear systems.

The "*trans* planar" geometry of the $[Mo_2O_2S_2]$ core is grossly analogous to the di-μ-sulphido bridged core of $[(\eta^5\text{-}C_5H_5)_2Mo_2O_2S_2]$[19] with certain significant differences. Whereas the structure of $[(\eta^5\text{-}C_5H_5)_2Mo_2O_2S_2]$ consists of edge-sharing tetragonal pyramids, the structure of **2** is characterized by edge-sharing octahedra. Furthermore, *anti* fusion of the basal edges of two tetragonal pyramids results in Mo–oxo vectors displaced away from the Mo_2S_2 rhombus, characterized by Mo—Mo—O angles greater than 90°.[20] In contrast, the Mo–oxo vectors of **2** are displaced towards the Mo_2S_2 rhombus, with an Mo—Mo—O angle of 78.1° and a O(1)···O(3a) distance of 2.77 Å which is well within the sum of van der Waals radii (Table 3).

Although, for binuclear complexes of type **III** and the related di-μ-sulphido bridged complexes, the *syn* conformer is predicted to be more stable[21] and is indeed most often observed,[22–26] we have no evidence for the existence of a *syn* conformer for **2**. To our knowledge, the geometry described for **2** is unique for binuclear molybdenum(V) complexes, representing a new class of bridged binuclear molybdenum(V) species.

EXPERIMENTAL

Materials and methods

All reactions were performed in freshly dried and distilled solvents. Dichloromethane was technical grade and was redistilled from $CaCl_2$ and P_4O_{10}. All other solvents were reagent grade, and were obtained from standard commercial sources without further purification. $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ was prepared according to the published method.[27]

The following instruments were used in this work: IR, Perkin–Elmer 283B IR spectrophotometer; ^{1}H NMR, Bruker T-90 spectrometer; UV–vis spectra, Varian DMS 90 UV-Visible spectrophotometer; X-ray crystallography, Nicolet R3m/V diffractometer.

Preparation of compounds

$[(n\text{-}C_4H_9)_4N][Mo_2O_2(OCH_3)(SCH_2CH_2CH_2S)_3]$ (**1**). $[(n\text{-}C_4H_9)_4N][Mo_2O_7]$ (3.10 g, 5.7 mmol) was dissolved in methanol (30 cm^3) and added to a stirred solution of $HSCH_2CH_2CH_2SH$ (2.2 g, 20.3 mmol) in methanol (20 cm^3). After refluxing for 24 h at 50–60°C, the resultant red solution was filtered and concentrated to 15 cm^3. Upon addition of 20 cm^3 of anhydrous ether and standing at room temperature for 7 days, dark red crystals of **1** appeared

Abstract—Reaction of α-$(Bu_4N)_4[Mo_8O_{26}]$ with diphenylcarbazone ($dpcH_2$) yields the red crystalline complex $(Bu_4N)[MoO_2(C_6H_5NNC(O)NNC_6H_5)(C_6H_5(H)NNC(O)NNC_6H_5)]$ (**I**), a complex displaying two distinct chelate ring types. Treatment of **I** with HCl yields $(Bu_4N)[MoOCl_3(C_6H_5NNC(O)NNC_6H_5)]$ (**III**), a pseudo-octahedral complex with the $[MoOCl_3]^+$ core. The reaction of α-$(Bu_4N)_4[Mo_8O_{26}]$ with diphenylcarbazone ($dptcH_2$) gave a complex analogous to **I**, $(Bu_4N)[MoO_2(C_6H_5NNC(S)NNC_6H_5)(C_6H_5(H)NNC(S)NNC_6H_5)]$ (**II**) and, surprisingly, 2,3-diphenyltetrazolium-5-thiolate, $C_6H_5NNC(S)NNC_6H_5$ (**IV**). Complex **I** displays a pseudo-octahedral geometry with MoO_4N_2 coordination and presents distinct geometries for the chemically inequivalent ligand types $(dpc)^{2-}$ and $(dpcH)^-$. The structure of **II** is analogous to that of **I** with $MoO_2N_2S_2$ coordination geometry but, more significantly, reveals the site of protonation of the $(dptcH)^-$ ligand as the terminal *exocyclic* nitrogen. Crystal data: **I**, monoclinic space group $P2_1/n$, $a = 11.026(3)$, $b = 21.600(5)$, $c = 18.851(4)$ Å, $\beta = 98.04(1)°$, $V = 4445.1(12)$ Å^3, 2804 reflections, $R = 0.065$; **II**, monoclinic space group $P2_1/c$, $a = 12.209(3)$, $b = 20.090(4)$, $c = 19.097(2)$ Å, $\beta = 96.45(1)°$, $V = 4654.4(9)$ Å^3, 3835 reflections, $R = 0.047$; **III**, $P2_1/n$, $a = 14.853(2)$, $b = 15.698(4)$, $c = 17.062(4)$ Å, $\beta = 90.10(1)°$, $V = 3978.2(10)$ Å^3, 3128 reflections, $R = 0.082$; **IV**, $C2/c$, $a = 14.755(2)$, $b = 12.193(2)$, $c = 6.958(2)$ Å, $\beta = 97.42(2)°$, $V = 1241.3(8)$, 1055 reflections, $R = 0.047$.

The current interest in the transition metal chemistry of organohydrazines derives in part from their potential relationship to intermediates in the reduction of coordinated dinitrogen[1] and has been stimulated by the variety of structural types identified for terminally bonded, edge-on bonded and chelating ligand modes, illustrated in Fig. 1.[2–13] In the specific case of the chemistry of organohydrazines with oxomolybdates, a variety of mononuclear[14,15] and polynuclear complexes[16] have been isolated depending upon reaction conditions.

In the course of our investigations of the chemistry of polyoxomolybdates with organonitrogen ligands in non-aqueous solvents, the reactions of α-$(NBu_4)_4[Mo_8O_{26}]$ with diphenylcarbazone and diphenylthiocarbazone have been explored. Although dithizone or diphenylcarbazone, $C_6H_5NNC(O)NHNHC_6H_5$, has long been employed in photometric determinations of molybdenum,[17] the intensely coloured organohydrazidomolybdate complexes which are formed have re-

* Author to whom correspondence should be addressed.

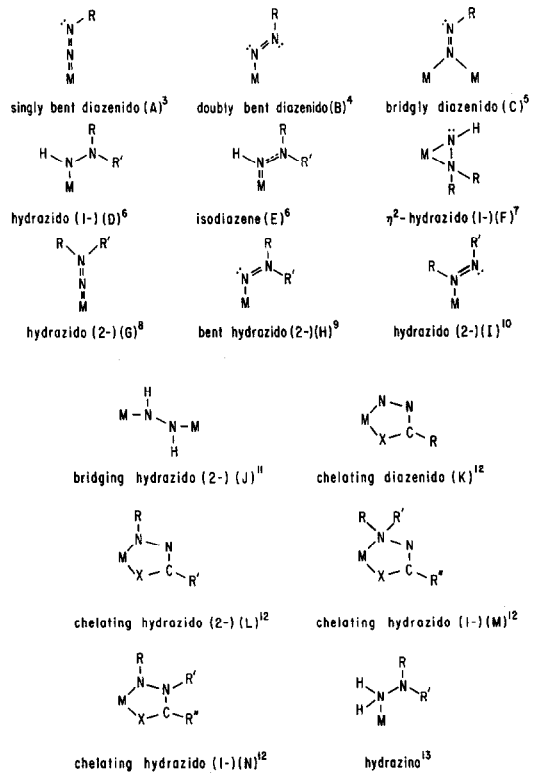

Fig. 1. Schematic representations of various structural types identified for metal–organohydrazine interactions. Superscripts refer to literature references.

mained uncharacterized. Furthermore, organocarbazone ligands represent a type of potentially multidentate and ambidentate ligand capable of a variety of bonding modes.

In this paper we report the structures of the products of the reactions of polyoxomolybdate anions with diphenylcarbazone and diphenylthiocarbazone, $[MoO_2(C_6H_5NNC(X)NNC_6H_5)(C_6H_5(H)NNC(X)NNC_6H_5)]^-$ [X = O (**I**) and X = S (**II**)]. The complexes **I** and **II** provide unique examples of species exhibiting chemically and structurally distinct dithizonate chelate ring types (L) as a consequence of protonation of an exocyclic substituent. Attempts to protonate the coordinated dithizonate ligands yielded a complex exhibiting the $[MoOCl_3]^+$ core, $[MoOCl_3(C_6H_5NNC(O)NNC_6H_5)]^-$ (**III**).

In the course of these investigations, several metal-mediated organic transformations were also observed. Reaction of **I** with organic bases yielded complexes incorporating the *o*-amidophenol ligand, while the unusual organic heterocycle $C_6H_5NNC(S)NNC_6H_5$ (**IV**) was isolated from preparations of **II** and structurally characterized.

RESULTS AND DISCUSSION

Preparations and properties of complexes

Reactions of polyoxomolybdates with simple organohydrazines and certain functionalized organohydrazines capable of chelation to the metal, yield a variety of polyoxomolybdate coordination complexes, displaying tetranuclear or octanuclear cores.[16] On the other hand, under similar reaction conditions benzoylhydrazine and thiobenzoylhydrazine react with polymolybdates to yield only tris-chelate species $[Mo(HNNCSPh)_3]$[12e] or polyoxomolybdate aggregates which do not incorporate the ligand unit. Appropriate modification of the $H_2NN(H)C(X)R$ unit (X = O or S) has been demonstrated to provide ligands capable of reaction with molybdate solutions to yield intensely coloured solutions suitable for spectroanalytical studies.[17] The diphenylcarbazone derivatives $C_6H_5NHNHC(X)NNC_6H_5$ (X = O $dpcH_2$; X = S $dptcH_2$) have been employed extensively in colorimetric studies of molybdenum.

Reaction of a suitable organic solvent soluble polymolybdate, such as $(Bu_4N)_2[Mo_2O_7]$[18] or $(Bu_4N)_4[Mo_8O_{26}]$, with $dpcH_2$ yields exclusively the mononuclear molybdenum(VI) complex $(Bu_4N)[MoO_2(dpcH(dpc)]$ (**I**). The dark purple, diamagnetic complex displays an IR band at 1595 cm^{-1} characteristic of ν(N=N), associated with the uncoordinated (N=NPh) unit of the ligand, and a second band at 1540 cm^{-1} which may be associated with ν(N=N) within the chelate ring. The strong bands at 903 and 872 cm^{-1} are assigned to ν_s and ν_{as} of the *cis*-dioxomolybdate(VI) group, respectively. The sharp medium intensity feature at 3296 cm^{-1}, associated with ν(N—H), confirms that one of the ligands is singly deprotonated $(dpcH)^-$. The appearance of a resonance at 9.82 ppm in the ^1H NMR spectrum of **I** confirms the presence of the protonated $(dpcH)^-$ ligand. Since complex **I** is formally described as a molybdenum(VI) species, the second dithizonate ligand must be present in the doubly deprotonated form $(dpc)^{2-}$, as the chelating hydrazido(2−) type (L). Although complexes **I** and **II** are unique examples of species presenting chemically and structurally distinct dithizonate chelating ligands, formally of type (L), there are a number of examples of complexes exhibiting mixed coordination to both terminally bound hydrazido(2−) and hydrazido(1−) groups of types (D) and (G)[6,8] or to mixed diazenido-hydrazido(2−) chelating ligands of the (K) and (L) structural prototypes.[12]

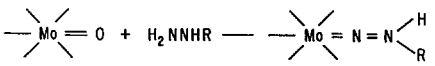
The electronic spectrum of **I** is characterized by intense ligand centred charge-transfer bands at

225 and 380 nm, and a less intense transition at 535 nm which appears to be associated with the [Mo—N—N] chromophore of molybdenum(VI)–hydrazido complexes.[16] Upon slow addition of HCl to an acetonitrile solution of **I**, the characteristic purple colour of the solution is discharged to yield a bright red solution, from which crystals of $(Bu_4N)[MoOCl_3(dpc)]$ (**III**) deposit upon standing for several days. The stoichiometry of the reaction and the isolation of free ligand as a major product of the reaction are consistent with the protonation of one ligand site and a single oxo group, resulting in displacement of the ligand and H_2O by three chloride donors [see eq. (1)].

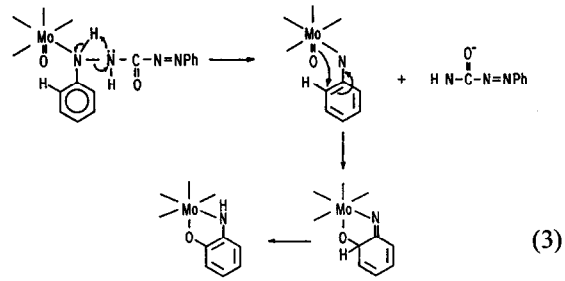
$$[MoO_2(dpc)(dpcH)]^{1-}\ (I) + 3HCl \longrightarrow [MoOCl_3(dpc)]^{1-}\ (III) + dpcH_2 + H_2O \quad (1)$$

The visible spectrum of **III** exhibits features similar to those of **I** at 235 and 278 nm, assigned to a ligand based change-transfer process, and at 533 nm assigned to a ligand-to-metal charge-transfer associated with the [Mo—N—N] chromophore. In addition, a new band at 449 nm may be associated with the $[MoOCl_3]^+$ unit; a similar feature appears in the electronic spectrum of $[MoOCl_3(PhNNC(O)Ph)]^-$.[19] The IR spectrum of **III** exhibits bands at 1620 and 965 cm^{-1} which are characteristic of $\nu(N{=}N)$ and $\nu(Mo{=}O)$, respectively.

The oxo groups of **I** are also substitution labile in the common condensation-type reactions, exploited in the synthesis of *cis*-diazenidomolybdenum complexes.[16] Reaction of **I** with a stoichiometric amount of phenylhydrazine in methanol [eq. (2)], yielded a dark purple solution, from which dark prismatic crystals of $(Bu_4N)_2[Mo_4O_6(OCH_3)_2(OC_6H_4NH)_2(NNC_6H_5)_4]$ were isolated in low yield. This tetranuclear complex displays the structural core characteristic of a class of *cis*-bisdiazenidomolybdenum species,[16] and will be discussed in detail in a subsequent article.[20] Although the mechanism of complex formation has not been elucidated, the reaction may proceed through coordination of the terminal hydrazido nitrogen of the diphenylcarbazone ligand to the molybdenum–oxo unit, followed by oxo group attack on the *ortho* position of the phenyl substituent and a 1,3-proton shift, in a manner reminiscent of quinone–methide chemistry [eq. (3)].

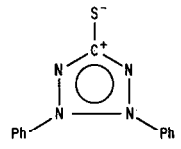


(2)

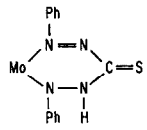


(3)

In contrast to the chemistry observed for $(dpcH_2)$, reaction of $[Mo_8O_{26}]^{4-}$ with diphenylthiocarbazone $(dptcH_2)$ yields a mixture of products, a complex anologous to **I**, $(Bu_4N)[MoO_2(dptc)(dptcH)]$ (**II**), and an organic species identified as 2,3-diphenyltetrazolium-5-thiolate, (Ph)NNC(S)NN(Ph) (**IV**).[21] The isolation of **IV** in high yield suggests that the process may exploit the ambidentate nature of the $(dptcH_2)$ ligand, which can potentially ligate through the nitrogen donors, as illustrated by structure (P) for the $(dptcH)^-$ form of the ligand.[22] Although the cyclization of this form of the ligand appears feasible, the fate of the hydrogen atoms is not obvious, nor are the details of the mechanism of formation.



(IV)



(P)

Complex **II** displays IR bands at 1600 and 1535 cm^{-1} associated with $\nu(N{=}N)$ of the $(dptc)^{2-}$ and $(dptcH)^-$ ligands. The bands assigned to ν_s and ν_{as} for Mo=O of the *cis*-dioxomolybdenum(VI) group are observed at 885 and 860 cm^{-1}, respectively, a shift of *ca* 15 cm^{-1} to lower energy than that observed for **I**. This observation is consistent with the greater π-accepting properties of the sulphur ligated dptc-chelates relative to the oxygen donor dpc groups, and the concomitant increased competition with the oxo groups for the metal t_{2g} type electrons, resulting in a relatively weaker Mo=O interaction. The electronic spectrum of **II** displays features at 259 and 476 nm, assigned to internal ligand charge-transfer and to the [Mo—N—N] chromophore, respectively. The additional band at 604 nm is characteristic of thiohydrazido type chelate complexes of molybdenum[12d,e] and is ten-

tatively assigned to the [Mo—S] chromophore. A broad feature at 9.95 ppm in the ^{1}H NMR spectrum of **II** is assigned to the proton associated with the singly deprotonated $(dptcH)^-$ ligand. The NMR spectrum of **II** is analogous to that of **I** indicating that the species are isostructural in solution.

Attempts to protonate the chelate ligands of **II** or to react **II** in the conventional condensation type reactions, yielded mixtures of intractable materials and uncomplexed molybdates, $[Mo_8O_{26}]^{4-}$ or $[Mo_6O_{19}]^{2-}$.

Description of the structures of (**I**), (**II**), (**III**) *and* (**IV**)

The structure of the complex anion of **I** is illustrated in Fig. 2, and selected bond lengths and angles are presented in Table 1. The structure of **I** consists of discrete mononuclear anions possessing pseudo-octahedral geometry with the oxo groups of the common *cis*-dioxomolybdenum $[MoO_2]^{2+}$ unit and the N and O donors of two chelating diphenylcarbazone derived ligands defining the MoO_4N_2 coordination. An unusual feature of the structure

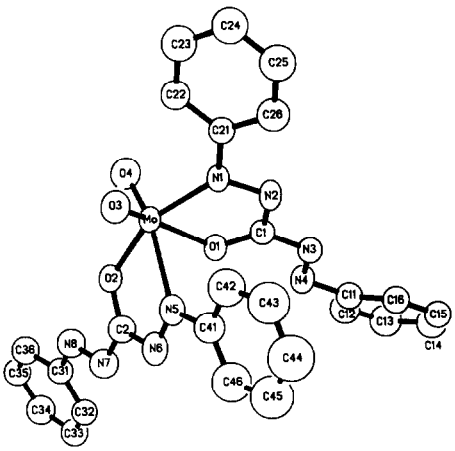


Fig. 2. ORTEP view of the structure of $[MoO_2(dpc)(dpcH)]^-$ (**I**), showing the atom labelling scheme.

is the presence of both $(dpc)^{2-}$ and $(dpcH)^-$ ligands, which necessarily display significantly different bond length and angle parameters, both for the endocyclic [Mo—NNCO] units and the exocyclic [CNNPh] moieties. As illustrated in Fig. 3(a), a comparison of the bonding parameters of the

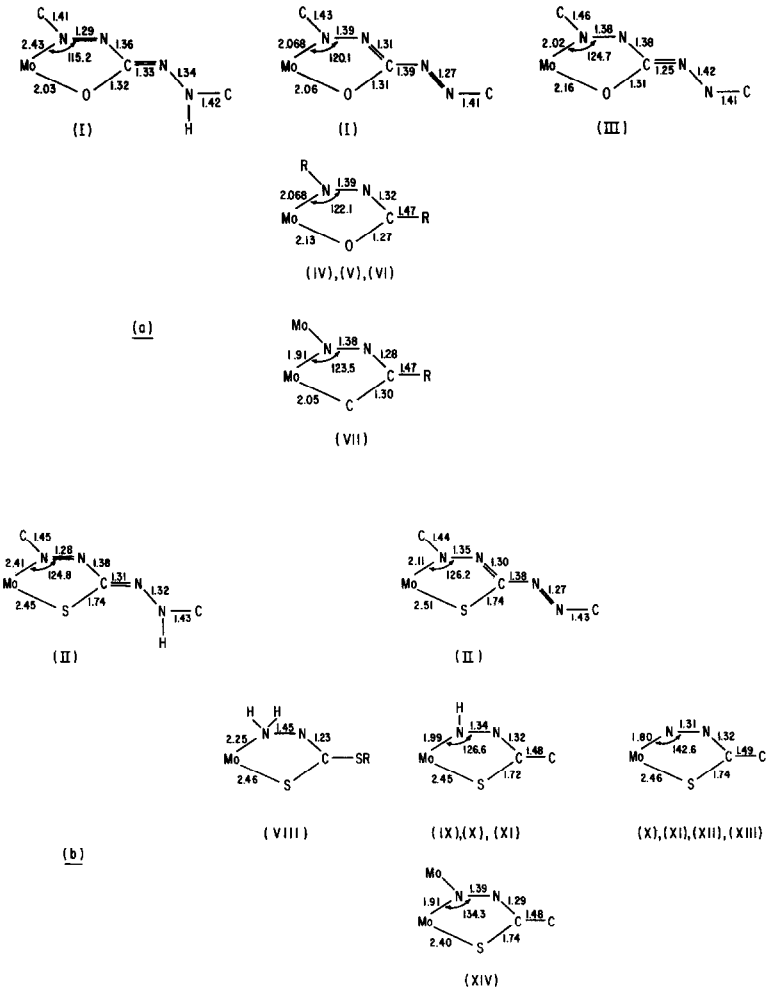

Fig. 3. (a) Schematic representation of the various [MoNNCO] chelate ring types observed for the structures of **I** and **III**, and a comparison with average structural parameters for similar chelates in previously reported structures. **IV**, $[MoCl_3O(ArNNCOPh)]^-$ (ref. 19); **V**, $[MoCl_2(NAr)(ArNNCOPh)]$ (ref. 23); **VI**, $[MoCl(NNCOPh)(HNNCOPh)(PR_3)_2]$ (ref. 24); **VII**, $[MoO(S_2CNEt_2)_2(NNCOPh)_2]$ (ref. 12d). (b) Schematic representation of the two [MoNNNCS] chelate ring types observed for **II** and a comparison with average structural parameters for similar chelate ring types. **VIII**, $[Mo(NNC(S)SEt)(H_2NNC(S)SEt)(S_2CNR_2)]$ (ref. 12e); **IX**, $[Mo(HNNNCSPh)_3]$ (ref. 12a); **X**, [Mo(NNCSAr)(HNNCSAr)(Me_2CNNCSAr)] and **XI**, [Mo(NNCSAr′)(HNNCSAr′)(Me_2CNNCSAr′)] (ref. 12c); **XII**, $[Mo(NNCSPh)(HNNCSPh)(ON(CH_3)CSPh)]$ (ref. 6a); **XIII**, [Mo(NNC(S)SR)(Me_2CNNC(S)SR)(MeSC(S)NNC(S)SMe)] (ref. 25); **XIV**, $[Mo_2O(S_2CNEt_2)_2(NNCSPh)_2]$ (ref. 12d).

[Mo—N(1)N(2)C(1)O(1)] ring with those of previously reported benzoylhydrazido(2−) molybdenum chelates[12] of type (L) establishes a geometry consistent with this assignment. The second chelate moiety [Mo—N(5)N(6)C(2)O(2)] must then be assigned as the singly deprotonated species $(dpcH)^-$, although the site of protonation cannot be assigned unambiguously. The unusually long Mo—N(5) bond distance of 2.432(8) Å results from the *trans* influence of the O(4) oxo group and the significant double bond character of the N(5)—N(6) bond drawing electron density from the Mo—N(5) interaction.

A comparison of the structure of **I** with that of the analogous diphenylthiocarbazone derivative $(Bu_4N)[MoO_2(dptc)]$ **(II)** reveals similar structural trends, illustrated in Fig. 4 and tabulated in Table 2. The bond lengths and angles for the chelated ligands once again confirm the inequivalence of ring geometries due to the presence of both $(dptc)^{2-}$ and $(dptcH)^-$ chelating ligands. The metrical parameters associated with the [Mo—S(2)C(2)N(6)

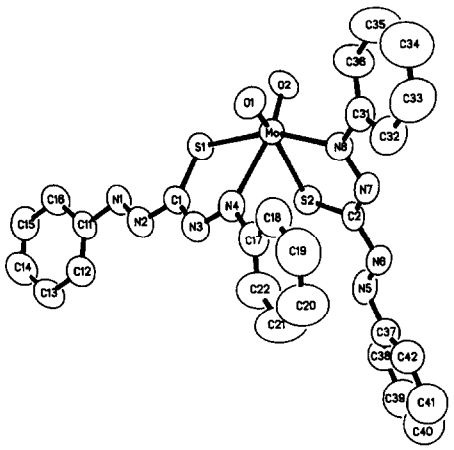

Fig. 4. A view of the structure of $[MoO_2(dptc)(dptcH)]^-$ (II), showing the atom labelling scheme.

N(5)] ring are similar to those observed for [Mo—O(1)C(1)N(2)N(1)] in **I** and conform to structural trends for previously cited examples of thiohydrazido(2−) molybdenum heterocycles,[16] as shown in Fig. 3(b). The second ring [Mo—S(1)C(1)N(2)N(1)] displays a pattern of ligand parameters identical to that observed for [Mo—O(2)C(2)N(6)N(5)] of **I** and associated with the protonated $(dptcH)^-$ ligand type. Furthermore, the low temperature data collected for **II** allowed identification of the protonation site as N(1). It is instructive that examples are available for molybdenum complexes incorporating thiohydrazido(1−), thiohydrazido(2−) and thiohydrazido(3−) chelating ligands, presented schematically in Fig. 3(b). It is clear that the chelate geometry of the [Mo—S(2)C(2)N(6)N(5)] ring of **II** is distinct from that observed for the thiohydrazido(1−) molybdenum chelate of $[Mo(N_2C(S)SC_2H_5)(H_2NNC(S)SC_2H_5)(S_2CNMe_2)]$[12a] which presents a hydrazido(1−) chelate of type (M). The ring parameters allow differentiation of the two chelate types without recourse to location of the protonation site in X-ray studies. It is also evident from the structural analysis of Fig. 3(b) that the chelating hydrazido(1−) and diazenido groups of [Mo(NNCSPh)(HNNCSPh)(ON(CH$_3$)CSPh)][6a] were incorrectly identified in ref. 6a and that the assignments should be exchanged as indicated in

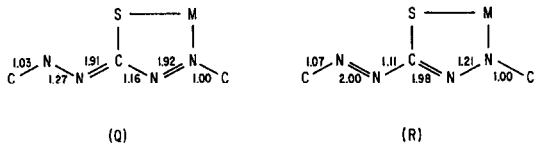
Fig. 3 to conform to the structural analysis presented herein.

The observation of the protonation site as the exocyclic nitrogen N(1), demonstrates that effects of protonation are transmitted through the ligand π-system to the chelate ring. Thus, the significant bond length differences between the chelate rings associated with $(dptc)^{2-}$ and $(dptcH)^{-}$ are not consequences of protonation of a *chelate* ring nitrogen site, as in (M) or (N) type hydrazido(1−) chelates, but of the exocyclic nitrogen.[26]* The $(dpcH)^{-}$ and $(dptcH)^{-}$ ligands may be considered as derived from the enol form of the singly deprotonated ligand (Q), coordinating through the sulphur and the imido nitrogen, while the doubly deprotonated ligands, $(dpc)^{2-}$ and $(dptc)^{2-}$, conform to structural trends established for hydrazido (2−) chelates. Although extensive delocalization throughout the Ph—N—N—C—N—N—Ph backbones and the chelate rings of both ligand forms is indicated by the bond length and angle data summarized in Fig. 3, valence structure (Q) makes a major contribution to the overall structure of the $(dptcH)^{-}$ ligand, while canonical form (R) is dominant in the structure of $(dptc)^{2-}$. Bond order calculations, based upon Pauling's method[27] and corrected for hybridization,[28] yield the approximate bond characters shown below. Although many factors influence bond lengths, making bond order–bond length relationships difficult to quantify, the general trends are apparent.



(Q) (R)

The structure of the molecular anion of $(Bu_4N)[MoOCl_3(dpc)]$ (**III**) is shown in Fig. 5 and selected bond lengths and angles are tabulated in Table 3. The pseudo-octahedral coordination geometry about the molybdenum atom is defined by the three chloride donors, the oxo group and the O, N donors of the chelating $(dpc)^{2-}$ ligand. The parameters associated with the hydrazido(2−) ligand are similar to those observed for $[MoOCl_3(ClC_6H_4CONNPh)]^{-}$ and consistent with the doubly deprotonated $(dpc)^{2-}$ form of the ligand. Further discussion of the ligand geometry is limited by the lack of precision in parameters.

The structure of the 2,3-diphenyltetrazolium-5-thiolate (**IV**) is shown in Fig. 6. The planarity of the S—C(7)—N(2)—N(1)[C(1)]—N(1a)[C(1a)]—N(2a) grouping is consistent with the aromaticity of the molecule. The short C—N and N—N bond distances within the heterocyclic ring are also indicative of extensive delocalization throughout the ring. The bond parameters tabulated in Table 4 are similar to those observed for analogous heterocyclic structures.[21]

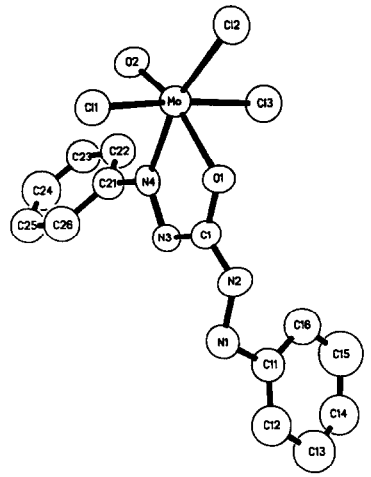


Fig. 5. ORTEP view of the structure of $[MoOCl_3(dpc)]^{-}$ (**III**), showing the atom labelling scheme.

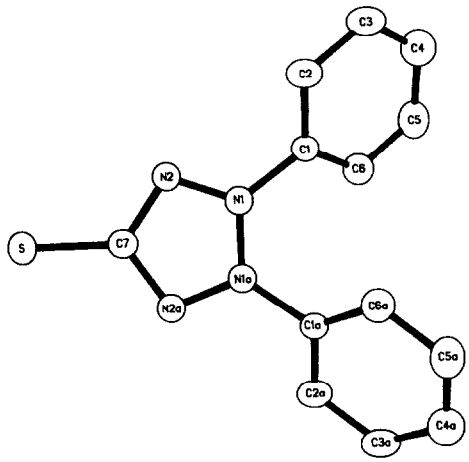

Fig. 6. The structure of $C_6H_5NNC(S)NNC_6H_5$ (**IV**), showing the atom labelling scheme.

CONCLUSIONS

The organohydrazine derivatives, diphenylcarbazone ($dpcH_2$) and diphenylthiocarbazone ($dptcH_2$), react with oxomolybdate(VI) anions in organic solvents to give mononuclear anionic complexes of the type $[MoO_2(PhNNC(X)NNPh)$

*The protonation site had also been established for organomercury(II) dithizonates in ref. 26.

$(Ph(H)NNC(X)NNPh)]^-$, X = O (**I**) or S (**II**). The intensely coloured complexes **I** and **II** are unusual in that each presents two structurally distinct dithizonate chelate rings, based on the chelating hydrazido (L) geometric prototype. Detailed structural studies and comparisons with previously reported examples of organohydrazidomolybdenum(VI) chelate structures reveal systematic geometric patterns associated with the various ligand types and establish that the site of protonation of the $(dpcH)^-$ or $(dptcH)^-$ ligands is the terminal exocyclic nitrogen rather than a ring nitrogen, N_α or N_β. Whereas the distinctive metrical parameters associated with chelating organohydrazine derived ligands of types (K) to (N) are direct consequences of protonation or alkyl substitution of chelate ring nitrogen atoms, N_α or N_β, the geometries associated with the inequivalent chelate types of this study result from transmission through the ligand π-backbone effects of protonation of a substituent group (exocyclic) nitrogen atom.

Whereas **I** undergoes protonation reactions in acid to yield $[MoOCl_3(dpc)]^-$ (**III**) and conventional condensation reactions to give polynuclear species, **II** yields only decomposition products and intractable materials under similar reaction conditions. The isolation of 2,3-diphenyltetrazolium-5-thiolate (**IV**) as a major by-product in the synthesis of **II** suggests that $(dptcH_2)$ may function as a ambidentate ligand coordinating through the terminal nitrogen donors to give (N,N′) hydrazido coordination. However, no examples of (N,N′) organocarbazone coordination were isolated.

EXPERIMENTAL

Materials and methods

All preparations were carried out in freshly distilled, dry solvents, and unless otherwise noted, no precautions to eliminate atmospheric oxygen were taken. Reagent grade solvents were used throughout. $(n\text{-}Bu_4N)_4[Mo_8O_{26}]$ was prepared by the literature method. All other reagents were obtained from standard commercial sources and used without further purification.

The following instruments were used in this

Preparation of compounds

$[(n\text{-}C_4H_9)_4N][MoO_2(C_6H_5NNC(O)NNC_6H_5)(C_6H_5(H)NNC(O)NNC_6H_5)]$ (**I**). α-$(Bu_4N)_4[Mo_8O_{26}]$ (2.15 g, 1.0 mmol) was dissolved in 80 cm^3 of warm CH_2Cl_2 and, after cooling to room temperature, diphenylcarbazone (3.8 g, 16.0 mmol) was added. After overnight stirring, followed by concentration to 30 cm^3, the deep red solution was layered with 30 cm^3 of anhydrous ether. After standing for 2 weeks, dark, prismatic crystals were obtained. Filtration followed by ether washing and air drying at room temperature yielded 0.96 g of product (Yield: 15%). Found: C, 59.3; H, 7.14; N, 14.5. Calc. for $C_{42}H_{57}N_9O_2Mo$: C, 59.5; H, 6.78; N, 14.8%. IR (KBr, cm^{-1}): 3296(m), 2960(m), 1595(m), 1502(s), 1485(s), 1382(m), 1228(s), 1192(s), 1020(s), 900(s), 872(s), 760(m). UV–vis [CH_3CN; λ max, nm (ε, cm^{-1} M^{-1})]: 535 (4.1×10^2), 380 (6.2×10^2); 225 (6.0×10^2). ^1H NMR (300 MHz, $CDCl_3$, δ in ppm): alkyl protons (C_4H_9—): 0.74, 1.21, 1.36, 3.05; phenyl protons: 7.34, 7.61; —NH: 9.82.

$[(n\text{-}C_4H_9)_4N][MoO_2(C_6H_5NNC(S)NNC_6H_5)(C_6H_5(H)NNC(S)NNC_6H_5)]$ (**II**). α-$(Bu_4N)_4[Mo_8O_{26}]$ (2.15 g, 1.0 mmol) was dissolved in 80 cm^3 of warm CH_2Cl_2. After cooling to room temperature, diphenylthiocarbazone (4.0 g, 16.0 mmol) was added. After overnight stirring and concentration to 30 cm^3, the deep purple solution was layered with 30 cm^3 of anhydrous ether. After 2 weeks, purple crystals of **II** were obtained in 20% yield. Found: C, 57.1; H, 6.49; N, 14.6. Calc. for $C_{42}H_{57}N_9O_2S_2Mo$: C, 57.3; H, 6.53; N, 14.3%. IR (KBr, cm^{-1}): 3300(w), 2960(m), 1600(m), 1530(m), 1485(s), 1365(s), 1320(s), 1180(s), 1160(s), 1100(s), 955(m), 880(m), 855(m), 760(s), 680(m). UV–vis [CH_3CN; λ max, nm (ε, cm^{-1} M^{-1})]: 604 (4.3×10^2), 476 (2.3×10^3); 366 (7.0×10^2), 259 (2×10^3), 222 (1.2×10^3). ^1H NMR (300 MHz, $CDCl_3$; δ in ppm): alkyl protons (C_4H_9—): 0.74, 1.22, 1.36, 3.05; phenyl protons: 7.40, 7.61; —NH, 9.95.

Dehydrotithiazone, $C_6H_5NNC(S)NNC_6H_5$ (**IV**). The filtrate from the preparation of **II** was allowed to stand for 2 weeks, whereupon bright orange crystals of **IV** deposited in 23% yield. Alternatively, the methanol solution from the preparation of **II** may be passed through a silica gel column, after concentration but prior to addition of ether, and eluted with methanol–CH_2Cl_2. Complex **II** is eluted initially as a dark purple solution, followed by an intense orange band of **IV** (Yield, 35%). Found: C, 61.0; H, 3.82; N, 21.9. Calc. for $C_{13}H_1N_4S$: C, 61.4; H, 3.97; N, 22.0%. IR (KBr, cm^{-1}): 3000(m), 1490(s), 1370(m), 1320(vs), 1250(m), 1220(m), 980(s), 760(s), 690(s). UV–vis [CH_3CN; λ max, nm (ε, cm^{-1} M^{-1})]: 260 (2.8×10^3).

$[(n\text{-}C_4H_9)_4N][MoOCl_3(C_6H_5NNC(O)NNC_6H_5)]\cdot CH_2Cl_2$ (**III**). Addition of concentrated HCl (1 cm^3) to a solution of α-$(Bu_4N)_4[Mo_8O_{26}]$ (2.15 g, 1.0 mmol) and diphenylcarbazone (3.8 g, 16 mmol) in 80 cm^3 of CH_3OH, results in a bright red solution. After stirring for 12 h, the solution was evaporated to dryness and the resultant red powder was dissolved in 30 cm^3 of CH_2Cl_2, layered with anhydrous ether, and allowed to stand for 8 days. A total of 1.4 g of purple crystals was collected (Yield, 22%). Alternatively, treatment of **I** with an excess of HCl in CH_2Cl_2 yields **III** in quantitative amounts. Found: C, 45.4; H, 6.24; N, 9.05. Calc. for $C_{30}H_{49}N_5O_2Cl_5Mo$: C, 45.9; H, 6.24; N, 8.92%. IR (KBr, cm^{-1}): 2960(m), 1610(s), 1480(m), 1420(m), 1240(s), 1020(w), 960(m), 690(m), 450(w). UV–vis [CH_3CN; λ max, nm (ε, cm^{-1} M^{-1})]: 448 (8.8×10^2), 389 (3.8×10^2), 275 (1.4×10^3), 233 (2.5×10^3). ^1H NMR (300 MHz, CD_3OD; δ in ppm): alkyl protons (C_4H_9—): 0.95, 1.33, 1.56, 3.20; phenyl protons: 6.80, 7.11.

X-ray crystallographic studies

The details of the crystal data, data collection methods and refinement procedures are given in Table 5. Atomic positional parameters for **I**, **II**, **III** and **IV** are given in Supplementary Tables A1, A2, A3 and A4, respectively. Tables of bond lengths and angles, anisotropic temperature factors and calculated and observed structure factors are available.*

The $[(n\text{-}C_4H_9)_4N]^+$ cations of structures **I**, **II** and **III** exhibited some degree of disorder. A model assigning carbon positions to the major peaks consistent with likely atomic positions was adequate as judged by final Fourier maps which exhibit residuals of electron density of 1.0–1.5 e $Å^{-3}$ in the region of the cations. These were the major

*Supplementary material available. Fractional coordinates have been deposited with the Director, Cambridge Crystallographic Centre. Complete listings of bond distances and angles are available from the Editor, Queen Mary College.

excursions of electron density on a scale of 0.8–1.3 e $Å^{-3}$ for hydrogen atoms.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURES OF 1:1 COMPLEXES OF NICKEL(II) NITRATE WITH 1,10-PHENANTHROLINE AND WITH 2,2′-BIPYRIDYL

FRANK WALMSLEY, A. ALAN PINKERTON and JUDITH A. WALMSLEY*

Department of Chemistry, University of Toledo, Toledo, OH 43606, U.S.A.

(*Received* 27 *August* 1988; *accepted* 5 *October* 1988)

Abstract—Blue crystals of $[Ni(phen)(H_2O)_4](NO_3)_2 \cdot H_2O$ (where phen = 1,10-phenanthroline) and of $[Ni(bipy)(H_2O)_3(NO_3)]NO_3$ (where bipy = 2,2′-bipyridyl) were prepared and their structures determined by single crystal X-ray crystallography. In the phenanthroline complex, the nitrates are not coordinated to the nickel but in the bipyridyl complex, one nitrate is coordinated to the nickel as a monodentate ligand. The IR spectra and magnetic susceptibilities are reported.

Transition metal complexes of 1,10-phenanthroline (phen) and 2,2′-bipyridyl (bipy) have been of interest for many years. Among other uses, these complexes have been part of an effective method for metal analysis. Additional knowledge about the structure of complexes that may exist in aqueous solution is of potential value in understanding intermediates in ligand exchange reactions in aqueous solution. Nickel(II) complexes have been of special interest including reports of spectral and magnetic properties[1] and of formation constants.[2] With three ligands per nickel, the complexes are usually red, with two per nickel they are usually pink or violet, and with one per nickel, blue; there are, of course, numerous exceptions to these generalities.[1] While structures of 1:1 complexes of nickel(II) sulphate with these ligands have been reported,[3,4] little is known about 1:1 nickel(II) nitrate complexes. We report the preparation and structure of two such complexes, including IR and magnetic susceptibility data.

EXPERIMENTAL

Synthesis

$[Ni(phen)(H_2O)_4](NO_3)_2 \cdot H_2O$. Reagent grade $Ni(NO_3)_2 \cdot 6H_2O$ (5.81 g, 20 mmol) was dissolved in 5 cm^3 of deionized distilled H_2O. 1,10-Phenanthroline monohydrate (0.80 g, 4 mmol) was added to the $Ni(NO_3)_2$ solution with stirring. The solid phenanthroline slowly dissolved. Initially, some pink solid formed which subsequently dissolved forming a blue solution. A small amount of unreacted phenanthroline was filtered off. The solution was allowed to evaporate slowly until blue crystals formed. Under a microscope it was possible to see two types of crystals. The major component was blue rods and these were the crystals used in this study. The minor component appeared as blue needles. A few purple crystals (probably bis or tris complexes) were observed and were removed prior to use for measurements requiring bulk samples.

$[Ni(bipy)(H_2O)_3(NO_3)]NO_3$. Reagent grade $Ni(NO_3)_2 \cdot 6H_2O$ (5.81 g, 20 mmol) was dissolved in 5 cm^3 of deionized distilled H_2O. 2,2′-Bipyridyl (0.63 g, 4 mmol) was added to the $Ni(NO_3)_2$ solution with stirring and slight warming. The solid bipyridyl slowly dissolved with some of the solid turning pink before dissolving to give a blue–green solution. The solution was allowed to evaporate slowly until blue plate-like crystals formed.

IR and magnetic susceptibility

IR spectral measurements were made as reflectance spectra, using KBr as diluent, on a Nicolet SX-60 FTIR instrument under standard operating conditions (4 cm^{-1} resolution). Magnetic susceptibility measurements were made by the Gouy method at 20°C as previously reported.[5]

Crystal structures

Preliminary examination and X-ray intensity data collections were performed on an Enraf–Nonius CAD4 automatic kappa axis diffractometer equipped with a graphite crystal, incident beam monochromator (Mo-K_α, $\lambda = 0.71073$ Å). Calculations were carried out on a VAX 11/750 computer using VLXSDP. Both structures were solved using conventional Patterson and Fourier techniques and refined by full-matrix least-squares. A summary of the crystallographic data is given in Table 1.*

RESULTS AND DISCUSSION

$[Ni(phen)(H_2O)_4](NO_3)_2 \cdot H_2O$

The X-ray crystal structure results as shown in Fig. 1 reveal an octahedral environment of ligands around the nickel composed of one bidentate 1,10-phenanthroline molecule and four water molecules. The nitrate ions are not coordinated to the nickel and are thus considered to be ionic. The bond lengths of the atoms bonded to the nickel are listed in Table 2, and the bond angles which include the nickel atom are listed in Table 3.

O(1)	Ni	O(3)	87.2(2)
O(1)	Ni	O(4)	84.4(2)
O(2)	Ni	O(4)	88.1(2)
O(2)	Ni	O(3)	88.8(2)
O(3)	Ni	O(4)	90.2(2)

Numbers in parentheses are estimated standard deviations in the least significant digits.

The bond lengths and angles are in agreement with those reported for other phenanthroline complexes of nickel.[6] It has been suggested that the bite of the phenanthroline molecule is inflexible; thus the N—M—N angle changes only as a result of a change in the M—N distance due to a change in the radius of the metal.[6] This inverse relationship between the M—N distance and N—M—N angle has been documented.[6] In comparison with the $Ni(phen)_3^{2+}$ ion, the average Ni—N distance in $Ni(phen)(H_2O)_4^{2+}$ is less (2.056 vs about 2.090 Å) and the average N—Ni—N angle is greater (81.3 vs about 79.4°). Thus the nickel atom with one phenanthroline attached appears to be smaller than a nickel atom with three phenanthrolines attached. This may be due to the bulk of three phenanthroline molecules causing steric repulsions, resulting in each phenthroline moving away from the nickel atom to reduce the repulsions. This may also be due to metal–ligand back bonding. With one phenanthroline molecule, the amount of back bonding to the phenanthroline will be greater. When there are three phenanthroline molecules, the electron density donated from the nickel must be distributed among the three ligands, resulting in a lesser amount of back bonding per phenanthroline. A greater amount of back bonding increases the metal–ligand bond order and reduces the bond length in the case with one phenthroline compared to the case with three phenanthrolines.

The magnetic moment of [Ni(phen)$(H_2O)_4$][$(NO_3)_2 \cdot H_2O$ is 3.11 BM at 20°C, which is typical for octahedral nickel(II).

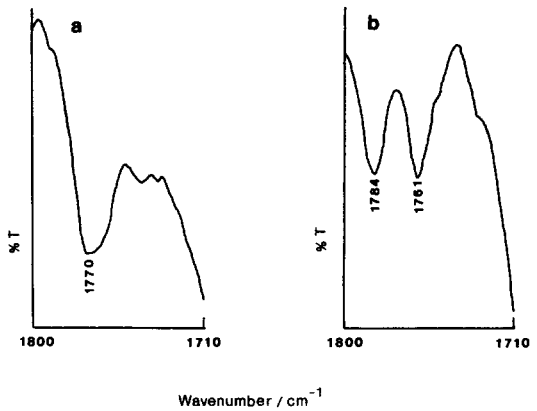

Fig. 2. IR absorptions in the 1700–1800 cm^{-1} region: (a) [Ni(phen)$(H_2O)_4$][$(NO_3)_2 \cdot H_2O$ and (b) [Ni(bipy)$(H_2O)_3(NO_3)$]NO_3.

Nitrate groups exhibit absorptions in the IR region of 1700–1800 cm^{-1} which are due to combinations of fundamental frequencies. The absorptions in this region have been used to distinguish among the various coordination modes of the nitrate group: ionic, monodentate, bidentate and bridging.[7] Ionic nitrates are expected to have a single absorption in the IR spectrum in this region.[7] As shown in Fig. 2(a), this compound has an expected single absorption at 1770 cm^{-1}. This single absorption indicates the presence of ionic nitrate which is in agreement with the X-ray crystal structure which shows no coordinated nitrates.

[Ni(bipy)$(H_2O)_3(NO_3)$]NO_3

The X-ray crystal structure results as shown in Fig. 3 reveal an octahedral environment of ligands

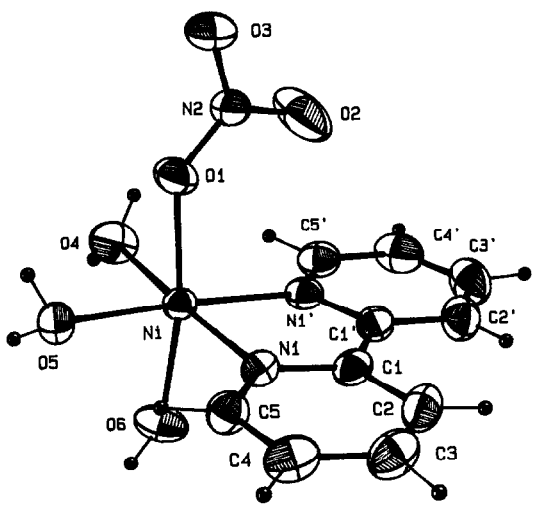

Fig. 3. ORTEP view of the nickel environment in [Ni(bipy)$(H_2O)_3(NO_3)$]NO_3. Atoms are represented by 50% probability ellipsoids.

Table 4. Selected bond distances (Å) for [Ni(bipy)$(H_2O)_3(NO_3)]NO_3$

Atom 1	Atom 2	Distance
Ni	N(1)	2.045(2)
Ni	N(1′)	2.061(3)
Ni	O(1)	2.103(2)
Ni	O(4)	2.038(2)
Ni	O(5)	2.072(2)
Ni	O(6)	2.056(3)

Numbers in parentheses are estimated standard deviations in the least significant digits.

around the nickel, composed of one bidentate 2,2′-bipyridyl molecule, three water molecules, and one monodentate nitrate ligand. The second nitrate is not coordinated to the nickel and is thus considered to be ionic. The bond lengths of atoms bonded to nickel are listed in Table 4 and the bond angles which include the nickel atom are listed in Table 5.

The bond lengths and angles are in agreement with those reported for other 2,2′-bipyridyl complexes of nickel.[3,4] It has been reported that coordinated metal–water distances are shorter when the water is trigonal rather than tetrahedral.[4] Of the three coordinated water molecules in this structure, one [O(4)] has a distinctly shorter bond distance than the other two and similar to the short bond distance in the compound of Healy.[4] Coordinated water molecules referred to as trigonal water are actually planar or nearly planar. By comparing deviations from planarity, it is possible to distinguish between trigonal and tetrahedral water

Table 5. Selected bond angles (Å) for [Ni(bipy)$(H_2O)_3(NO_3)]NO_3$

Atom 1	Atom 2	Atom 3	Angle
N(1)	Ni	N(1′)	79.5(1)
N(1)	Ni	O(1)	92.54(9)
N(1′)	Ni	O(1)	98.9(1)
N(1)	Ni	O(4)	176.2(1)
N(1)	Ni	O(5)	92.81(9)

O(1)	Ni	O(5)	80.86(9)
O(1)	Ni	O(6)	170.0(1)
O(4)	Ni	O(6)	91.0(1)

Numbers in parentheses are estimated standard deviations in the least significant digits.

Table 6. Deviations (Å) from the best plane for each Ni---OH_2 in [Ni(bipy)$(H_2O)_3(NO_3)]NO_3$

	O(4)	O(5)	O(6)
Ni	−0.013	−0.043	−0.020
O	0.084	0.248	0.115
H	−0.027	−0.102	−0.044
H	−0.044	−0.103	−0.051

molecules. The data in Table 6 indicate the deviations from the best plane for each of the three water molecules including the nickel atom in the plane. The water labelled O(4) has a small deviation from planarity and is presumably trigonal. This water molecule also has a short Ni—O distance (2.038 Å) in agreement with the previous report.[4] The other two water molecules have larger deviations from planarity with the water containing O(6) being more planar than the water containing O(5). The bond orders also increase in the same way that planarity decreases; that is, the Ni—O(6) distance is shorter than the Ni—O(5) distance. Another way to consider this is to compare the H—O—H angles, although this is less sensitive due to the greater uncertainty in locating the hydrogen atoms. The H—O—H angles decrease from 112° for H—O(4)—H, to 111° for H—O(6)—H, to 97° for H—O(5)—H, the same order as the changes in the Ni—O distances.

The X-ray crystal structure shows that one of the two nitrate groups is bonded to the nickel through one oxygen—a monodentate nitrate group. Monodentate nitrate ligands bonded to nickel are expected to have two absorptions in the IR region between 1700 and 1800 cm^{-1} with a separation of about 20–25 cm^{-1}.[7] As shown in Fig. 2(b), the IR spectrum in this region has absorptions at 1761 and 1784 cm^{-1}, a separation of 23 cm^{-1}. The X-ray crystal structure also shows that one of the nitrate groups is not coordinated to the nickel—an ionic nitrate. An ionic nitrate normally would be expected to have a single absorption in this region, just as in the phenanthroline complex. Thus, a monodentate nitrate plus an ionic nitrate would normally give three absorptions in this region. Only the two absorptions due to the monodentate nitrate are observed. Why is the ionic nitrate absorption missing? Some compounds with ionic nitrates that do not have any absorptions in this region have been reported.[7] These compounds are all hydrates, as opposed to anhydrous salts such as $NaNO_3$ and $Sr(NO_3)_2$, and it was suggested[7] that extensive hydrogen bonding may be responsible. The X-ray data show that all the oxygens of the ionic nitrate group receive hydrogen bonds in the bipyridyl complex, which is in agreement with the suggestion.

The magnetic moment of $[Ni(bipy)(H_2O)_3(NO_3)]NO_3$ is 3.51 BM at 20°C. This is slightly high for octahedral nickel(II), but deviations from a regular octahedron as exhibited by this complex tend to raise the magnetic moment.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF THE TUNGSTEN–RUTHENIUM COMPOUND $[WRu(\mu\text{-}\sigma,\eta^2\text{-}CH{=}CH_2)(CO)_4(cis\text{-}Ph_2PCH{=}CHPPh_2)(\eta\text{-}C_5H_5)]$

STEPHEN A. BREW, JOHN C. JEFFERY and F. GORDON A. STONE†

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, U.K.

(*Received* 23 *September* 1988; *accepted* 24 *October* 1988)

Abstract—The compounds $[W(\equiv CMe)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Ru(CO)_3(cdpe)]$ (cdpe = *cis*-$Ph_2PCH{=}CHPPh_2$) react in tetrahydrofuran at reflux temperatures to give in *ca* 70% yield the dimetal compound $[WRu(\mu\text{-}\sigma,\eta^2\text{-}CH{=}CH_2)(CO)_4(cdpe)(\eta\text{-}C_5H_5)]$. The structure of the latter has been established by X-ray diffraction. The W—Ru bond [2.973(1) Å] is spanned by the vinyl group which is σ-bonded to the ruthenium atom (Ru—C 2.095(5) Å) and η^2-coordinated to the tungsten (W—C 2.209(5) and 2.313(5) Å). The two metal atoms are each ligated by two carbonyl groups, but one CO attached to tungsten semi-bridges the metal–metal bond (W—C—O 169.2(5)°). The cyclopentadienyl group is η^5-bonded to the tungsten, and the *cis*-$Ph_2PCH{=}CHPPh_2$ ligand is coordinated to the ruthenium (Ru—P 2.300(1) and 2.396(1) Å).

The alkylidyne–tungsten compounds $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (R = alkyl or aryl), as well as related species in which the cyclopentadienyl ligand is replaced by the groups $\eta\text{-}C_5Me_5$, $HB(pz)_3$ (hydrotris(pyrazol-1-yl)borate), or $\eta^5\text{-}C_2B_9H_9Me_2$, are versatile reagents for preparing dimetal or polynuclear metal complexes containing bonds between tungsten and other transition elements.[1] The methodology involves a combination of a low-valent metal–ligand fragment with the C≡W moiety present in the alkylidyne–tungsten species. The metal–ligand fragment is derived from a complex containing a labile group (CO, NCMe, C_2H_4, or THF, etc.). Indeed, the scope of this synthetic procedure is so wide that there are very few transition metals which have not been attached to a tungsten atom via reactions of this type.

Recently we have shown[2] that depending on the stoichiometry employed, the reaction between the compounds $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Ru(CO)_4(\eta\text{-}C_2H_4)]$ affords, respectively, the complexes $[W_2Ru\{\mu_3\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_7(\eta\text{-}C_5H_5)_2]$ or $[WRu_3(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_{11}(\eta\text{-}C_5H_5)]$. Formation of these tri- and tetranuclear metal compounds, rather than a dimetal complex, prompted us to study the reaction between $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Ru(CO)_3(cdpe)]$ (cdpe = *cis*-$Ph_2PCH{=}CHPPh_2$). It was anticipated that this combination of reagents might yield $[WRu(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_4(cdpe)(\eta\text{-}C_5H_5)]$, since the presence of the cdpe group in the ruthenium precursor should deactivate the system, thereby inhibiting the formation of products containing more than two metal atoms. Unfortunately, no appreciable reaction occurred between $[Ru(CO)_3(cdpe)]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ in toluene, until the mixture had been refluxed for *ca* 24 h. Even under these vigorous conditions only insignificant quantities of product were obtained, consisting of a mixture of complexes each in an amount too small to be characterized. Accordingly, the more reactive ethylidyne species $[W(\equiv CMe)(CO)_2(\eta\text{-}C_5H_5)]$ was employed. The latter with $[Ru(CO)_3(cdpe)]$ in THF gave a dimetal compound in high yield, but the product was not the expected μ-ethylidyne complex $[WRu(\mu\text{-}CMe)(CO)_4(cdpe)(\eta\text{-}C_5H_5)]$.

RESULTS AND DISCUSSION

Mixtures of $[W(\equiv CMe)(CO)_2(\eta\text{-}C_5H_5)]$ and $[Ru(CO)_3(cdpe)]$ in THF at reflux temperatures gave an orange complex, **1**, which was isolated pure after column chromatography on alumina. It was not possible to identify **1** from the spectroscopic data. In particular, the $^{13}C\text{-}\{^1H\}$ NMR spectrum

† Author to whom correspondence should be addressed.

showed no signal in the region δ 300–400 ppm characteristic for a μ-*C*Me nucleus bridging a dimetal centre.[3] Moreover, in the ^{1}H NMR spectrum there was no resonance for a methyl group. Fortunately, suitable crystals of **1** could be grown, enabling an X-ray diffraction study to be carried out. The structure of the molecule is shown in Fig. 1, and selected bond distances and angles are listed in Table 1.

The compound was thus identified as the μ-vinyl complex, [WRu(μ-σ,η^2-CH=CH$_2$)(CO)$_4$(cdpe)(η-C$_5$H$_5$)] (**1**), in which the bridging ligand is σ-bonded to the ruthenium (C(5)—Ru 2.095(5) Å) and η^2-coordinated to the tungsten (C(5)—W 2.209(5), C(6)—W 2.313(5) Å). Numerous homodinuclear metal complexes are known in which a vinyl group adopts the μ-σ,η^2 bonding mode found in **1**. Indeed, the first compounds having this structural feature were discovered over 25 years ago.[4] We have recently determined the crystal structure of the trimetal complex [WRu$_2$\{μ-σ,η^2-*trans*-CH=C(H)C$_6$H$_4$Me-4\}(μ-CO)(CO)$_3$(η-C$_5$H$_5$)$_2$(η-C$_5$Me$_5$)] in which a substituted-vinyl group bridges a W—Ru bond. However, in contrast with **1**, the vinyl group in the trimetal species is σ-bonded to the tungsten and η^2-coordinated to the ruthenium.[5] Moreover, the W—Ru distance (2.771(1) Å) is appreciably shorter than that in **1** (2.973(1) Å). This is also true of the W—Ru separation (2.769(1) Å) in the

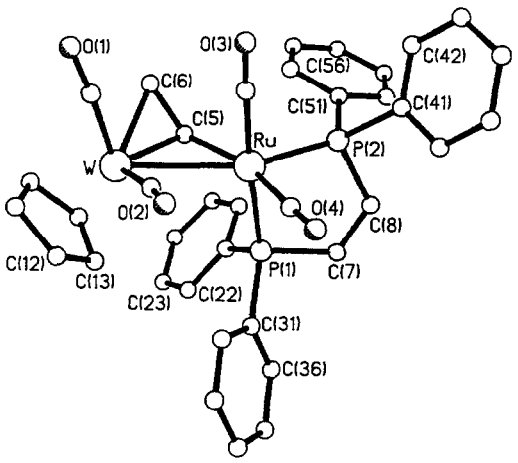

Fig. 1. The molecular structure of [WRu(μ-σ,η^2-CH=CH$_2$)(CO)$_4$(cdpe)(η-C$_5$H$_5$)].

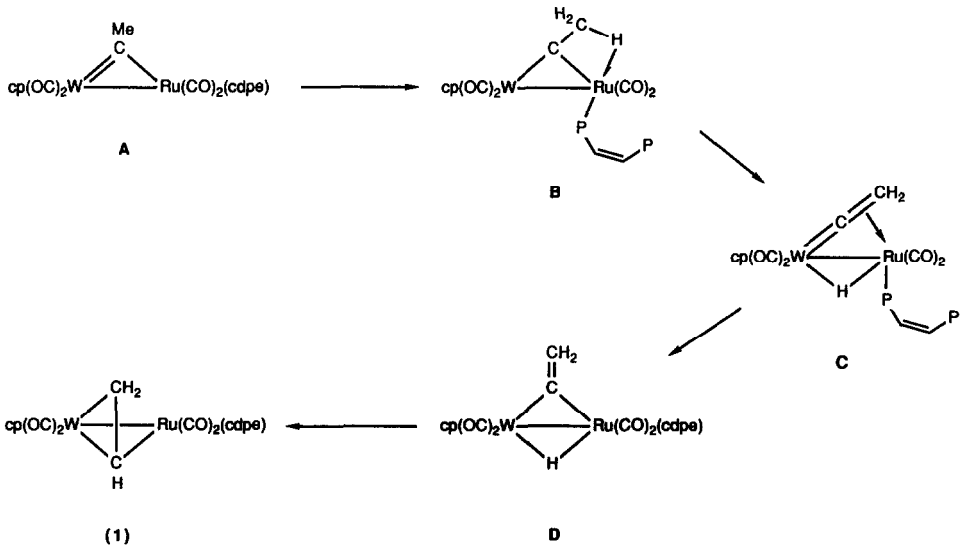
complex [WRu(μ-Cl)(μ-CMe)(Cl)(CO)₂(PPh₃)₂(η-C₅H₅)], in which the metal–metal bond is spanned by ethylidyne and chlorido groups.[6]

The ruthenium atom in **1** carries two terminal CO groups and the cdpe ligand (P(1)—Ru 2.396(1), P(2)—Ru 2.300(1) Å). As expected, the tungsten atom is bonded by the cyclopentadienyl ring and two CO ligands. However, one of the latter groups semi-bridges the W—Ru bond (W—C(2)—O(2) 169.2(5)°).

Compound **1** adds to the growing number of tungsten–ruthenium species which may be obtained by adding low-valent ruthenium fragments to the C≡W bonds in alkylidyne–tungsten complexes. However, the great majority of the products obtained by this method are not dimetal species but complexes containing the core fragments WRu_2,[5] W_2Ru,[2,6,7] W_3Ru[2,8] and WRu_3.[2] Apart from compound **1**, only two dimetal species have been prepared; the aforementioned complex [WRu(μ-Cl)(μ-CMe)(Cl)(CO)₂(PPh₃)₂(η-C₅H₅)] and the complex [WRu(μ-Cl)(μ-CMe)(Cl)(CO)₂(PPh₃)(η-C₂Me₂)(η-C₅H₅)], the structure of which is as yet unresolved.[6]

The origin of the μ-CH=CH₂ group in **1** is clearly the μ-CMe fragment present in the precursor [W(≡CMe)(CO)₂(η-C₅H₅)]. This rearrangement is of interest in the context of the reactivity of ethylidyne, vinyl and vinylidene fragments when bonded to di- or trimetal centres. There are several well documented examples of the conversion of μ-CMe groups into μ-C=CH₂ fragments when ligating metal atoms.[9,10] This transformation can be accomplished by deprotonation of the μ-CMe ligand with base,[11–13] or by a thermally induced hydrogen migration process in which the hydrogen atom transferred usually but not always ends up bridging two metal centres.[14,15] Almost certainly in the conversion of a μ-CMe fragment into the ligands μ-C=CH₂ and μ-H, intermediates are traversed containing a μ-CH=CH₂ group, and it is in this context that the formation of **1** is of interest. A possible pathway is indicated in Scheme 1. From previous work[1] it may reasonably be anticipated that the reaction between [W(≡CMe)(CO)₂(η-C₅H₅)] and [Ru(CO)₃(cdpe)] would initially form the intermediate **A**, which under the reaction conditions is evidently unstable. It is possible that the strong *trans* influence of the ethylidyne group leads to dissociation of a ligated group at the ruthenium centre. This might involve release of a CO molecule, or the cdpe ligand becoming monodentate, as indicated in Scheme 1. The presence of a vacant site coupled with the electronic unsaturation at the ruthenium atom, would then facilitate an agostic C—H→Ru interaction, thereby providing a mechanism for hydrido group transfer as shown. Hence the pathway B → C → D, and finally to **1**, could be readily traversed.

Prior to the results reported herein there appears to be no precedent for the synthesis of a μ-vinyl compound from a μ-ethylidyne complex via a thermal reaction of the type described. However, Casey *et al.*[13] have observed that at *ca* 90°C the cationic pentylidyne complex [Fe₂(μ-CBuⁿ)(μ-CO)(CO)₂(η-C₅H₅)₂]⁺ is converted in essentially quantitative yield into the bridging pentenyl species [Fe₂{μ-σ,η²-CH=C(H)C₃H₇}(μ-CO)(CO)₂(η-C₅H₅)₂]⁺. In contrast, the ethylidyne complex [Fe₂(μ-CMe)(μ-CO)(CO)₂(η-C₅H₅)₂]⁺ does not rearrange even at 120°C. Our results thus suggest that the μ-CMe



Scheme 1. cp = η-C₅H₅, *cis*-Ph₂PCH=CHPPh₂ = cdpe = P⌒P.

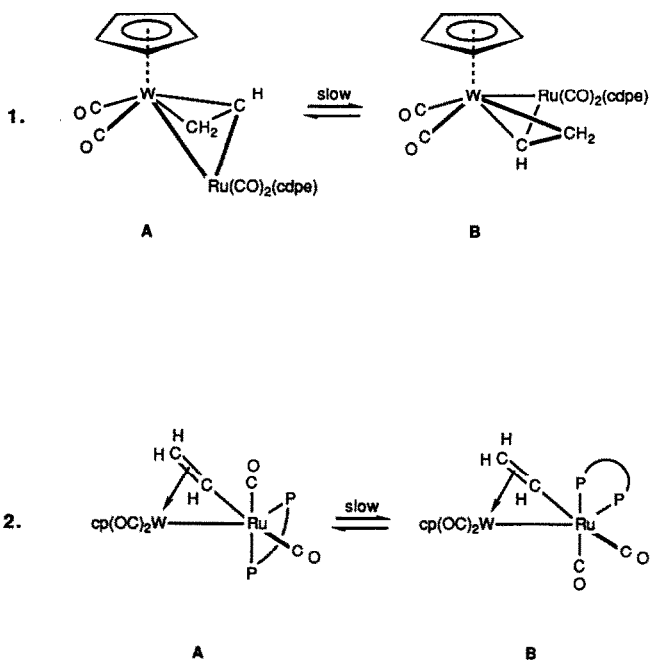
group is more readily activated for hydrogen migration when bridging a heteronuclear W—Ru bond than when bridging a homonuclear Fe—Fe linkage.

Once the structure of **1** was established by X-ray diffraction, it was possible to interpret the spectroscopic data for the complex (see Experimental). The IR spectrum in the carbonyl region showed four bands at 2015, 1956, 1862 and 1779 cm^{-1}. The latter peak may be assigned to the semi-bridging CO group. Examination of the NMR spectra at room temperature revealed the presence of two closely related isomers, and the slightly broadened peaks observed suggested that these might be interconverting slowly. The data given below were obtained from spectra measured at −80°C, at which temperature sharp peaks due to the major and the minor isomers (2:1) were observed. Only signals for the major isomer are discussed.

The ^1H NMR spectrum revealed three resonances at 2.44, 2.69 and 5.63 ppm, each corresponding to one proton, and these may be assigned to the μ-CH=CH_2 ligand in **1**.[16–19] The signal at δ 5.63 due to the CH group was a multiplet and coupling constants could not be determined. However, the resonances for the CH_2 group at δ 2.44 (J(HH) 11 Hz) and 2.69 (J(HH) 8 Hz) were doublets, the values of the coupling constants falling in the range expected for *trans*- and *cis*-CH=CH configurations, respectively.

In the ^{13}C-{^1H} NMR spectrum there are four CO resonances at δ 231.9, 228.5 (WCO), 201.4 (br, RuCO) and 197.9 ppm (d, RuCO, J(PC) 15 Hz). Peaks at δ 148.2 (d of d, J(PC) 37, 37 Hz) and 145.6 ppm (d of d, J(PC) 27, 39 Hz) may be assigned to the PCH=CHP moiety. The μ-CH=CH_2 group displays signals at δ 137.6 (d, J(PC) 49 Hz) and 43.0 ppm which may be tentatively assigned to the CH and CH_2 nuclei, respectively. In the spectrum of the compound [WPt(μ-σ,η^2-CH=CH_2)(CO)$_2$(PMe_3)$_2$(η-C_5H_5)] the corresponding signals are at δ 129.9 and 37.2 ppm.[19] The other peaks in the spectrum of **1** are as expected for the presence of the η-C_5H_5 and Ph groups. The ^{31}P-{^1H} NMR spectrum showed two singlet resonances at δ 71.7 and 65.1 ppm, as expected for the presence of two non-equivalent phosphorus nuclei.

The NMR properties of **1** in solution might be due to site-exchange of the ligands at the ruthenium centre, pivoting of the μ-CH=CH_2 group about the W—Ru bond with an exchange of the σ- and π-interactions between the two metal centres,[16–18,20] or a process similar to that invoked to explain the fluxionality of the π-allyl complex [W(CO)$_2$(η^3-CH_2CHCH_2)(η-C_5H_5)].[21] The latter complex is mapped with **1** since the Ru(CO)$_2$(cdpe) fragment is isolobal with a CH_2 group.[22] Hence it is attractive to consider that **1** undergoes the exchange process shown in Scheme 2(1) which is analogous to that proposed to account for the variable temperature NMR properties of [W(CO)$_2$(η^3-CH_2CHCH_2)(η-C_5H_5)]. Isomer **A** in Scheme 2(1) is the form established by the X-ray diffraction study and is assumed to be the major isomer. Alternatively, the NMR data do not exclude site-exchange at the ruthenium



Scheme 2.

centre, as depicted in Scheme 2(2). Intuitively we regard pivoting of the μ-CH=CH$_2$ group about the W—Ru bond to be less likely than the processes shown in Scheme 2.

EXPERIMENTAL

All experiments were carried out under nitrogen. Solvents were rigorously dried before use. Light petroleum refers to that fraction of b.p. 40–60°C. NMR spectra were recorded with JNM FX90Q, GX200 or GX400 instruments, and IR spectra were measured with Nicolet MX10 or MX5 spectrophotometers. For NMR data all chemical shifts are in ppm and coupling constants are in Hz. The ^{13}C-{^1H} NMR chemical shifts are positive to high frequency of $SiMe_4$, and the ^{31}P-{^1H} chemical shifts are positive to high frequency of 85% H_3PO_4 (external). The compounds [W(≡CMe)(CO)$_2$(η-C$_5$H$_5$)][23] and [Ru(CO)$_4$(η-C$_2$H$_4$)][2,24] were prepared by methods previously reported. The complex [Ru(CO)$_3$(cdpe)] was obtained as described below.

Synthesis of the complex [Ru(CO)$_3$(cdpe)]

A sample of [Ru$_3$(CO)$_{12}$] (0.30 g, 0.47 mmol) in light petroleum (*ca* 250 cm^3) contained in a water-cooled, round-bottom flask was irradiated with light from two 100 W light bulbs, while a slow stream of ethylene was continually passed through the mixture. After several hours the solution became colourless signifying complete conversion of the [Ru$_3$(CO)$_{12}$] into [Ru(CO)$_4$(η-C$_2$H$_4$)] (ν_{CO} (max) at 2104w, 2023s and 1998s cm^{-1}).[2] The light petroleum solution of [Ru(CO)$_4$(η-C$_2$H$_4$)] was then added slowly (*ca* 30 min) to a CH_2Cl_2 (15 cm^3) solution of cdpe (0.61 g, 1.53 mmol), the mixture being continuously stirred and purged with nitrogen. If the solution of [Ru(CO)$_4$(η-C$_2$H$_4$)] is added too rapidly to the cdpe the yield of desired product is reduced, due to the formation of side-products including [Ru$_2$(μ-cdpe)(CO)$_6$].[25] Stirring was continued for *ca* 9 h before solvent was removed *in vacuo*. The yellow residue was dissolved in CH_2Cl_2–light petroleum (8 cm^3, 1 : 3) and chromatographed on an alumina column (3 × 20 cm). Elution with the same solvent mixture afforded a yellow fraction. Removal of solvent *in vacuo* give pale yellow *microcrystals* of [Ru(CO)$_3$(cdpe)] (0.18 g, 65%) (Found: C, 59.9; H, 3.8. $C_{29}H_{22}O_3P_2Ru$ requires: C, 59.9; H, 3.8%). ν_{max}(CO) at 2007s, 1936m and 1910vs cm^{-1} (in CH_2Cl_2). NMR (in $(CD_3)_2CO$): ^1H, δ 7.36–7.56 (m, 22 H, CH and Ph); ^{13}C-{^1H}, δ 211.6 (t, CO, *J*(PC) 11), 147.3 (m, CH=CH), 137.4 [m, C^1(C$_6$H$_5$)], 132.6, 130.9 and 129.4 (m × 3, Ph); ^{31}P-{^1H}, δ 78.5s.

Chloroform solutions of [Ru(CO)$_3$(cdpe)] slowly decompose at room temperature affording quantitatively the ruthenium(II) species [RuCl$_2$(CO)$_2$(cdpe)] (Found: C, 53.7; H, 3.8. $C_{28}H_{22}Cl_2O_2P_2Ru$ requires: C, 53.8; H, 3.6%). ν_{max} (CO) at 2081m and 2014s cm^{-1}. ^{31}P-{^1H} NMR (in $CDCl_3$), δ 67.5 [d, *J*(PP) 7] and 47.7 [d, *J*(PP) 7], with weak signals due to minor isomers observed.

Synthesis of the complex [WRu(μ-σ,η²-CH=CH$_2$)(CO)$_4$(cdpe)(η-C$_5$H$_5$)]

A mixture of [Ru(CO)$_3$(cdpe)] (0.20 g, 0.34 mmol) and [W(≡CMe)(CO)$_2$(η-C$_5$H$_5$)] (0.11 g, 0.34 mmol) was refluxed for 48 h in THF (30 cm^3). The solvent was removed *in vacuo*, and the residue was dissolved in CH_2Cl_2–light petroleum (1 : 4), and chromatographed on an alumina column (3 × 15 cm). Elution with the same solvent mixture removed initially a trace of an unidentified product. Further elution gave an orange fraction which after removal of solvent *in vacuo* yielded orange *microcrystals* of [WRu(μ-σ,η²-CH=CH$_2$)(CO)$_4$(cdpe)(η-C$_5$H$_5$)] (**1**) (0.21 g, 70%) (Found: C, 49.4; H, 3.7. $C_{37}H_{30}O_4P_2RuW$ requires: C, 50.2; H, 3.4%). ν_{max} (CO) at 2015m, 1956vs, 1862s and 1779m cm^{-1} (in CH_2Cl_2). NMR (in CD_2Cl_2 at −80°C): ^1H (major isomer), δ 2.44 (d, 1 H, CH_2, *J*(HH) 11), 2.69 (d, 1 H, CH_2, *J*(HH) 8), 4.43 (s, 5 H, C_5H_5), 5.63 (m, 1 H, CH), and 6.64–8.16 (m br, 22 H, CH=CH and Ph); ^{13}C-{^1H} (peaks for minor isomer indicated by an asterisk), δ 231.9, *231.5, 228.5, *227.0 (WCO), 201.4 (m br), *199.6, *198.5 [d, *J*(PC) 8], 197.9 [d, RuCO, *J*(PC) 15], *150.2 [d of d, *J*(PC) 27, 39], 148.2 [d of d, *J*(PC) 37, 37], *147.2 [d of d, *J*(PC) 39, 42], 145.6 [d of d, PCH=CHP, *J*(PC) 27, 39], 137.6 [d, *J*(PC) 49], *136.8 [d, *C*H=CH$_2$, *J*(PC) 46], 134.9 – 123.9 (Ph), *89.0, 87.6 (η-C$_5$H$_5$), *45.4 and 43.0 (CH=*C*H$_2$). ^{31}P-{^1H} (peaks for minor isomer indicated by an asterisk), δ 71.7, 65.1, *60.0 [d, *J*(PP) 28] and *58.7 [d, *J*(PP) 28].

X-ray crystallographic data

Orange crystals of **1** were grown from CH_2Cl_2–light petroleum (1 : 4). Diffraction data were collected on a Nicolet R3m/μ diffractometer at 298 K using a crystal of dimensions *ca* 0.52 × 0.40 × 0.20 mm. Of the 4825 intensities measured (ω-scans, $2\theta \leqslant 45°$), 3881 unique intensities had $F \geqslant 5\sigma(F)$, and only these were used in the solution and refinement of the structure. Intensity data were corrected for Lorentz, polarization and X-ray absorption effects. The latter by a procedure based upon azimuthal scan data.

Crystal data. $C_{37}H_{30}O_4P_2RuW$, $M = 885.5$,

monoclinic, $a = 10.340(2)$, $b = 26.525(4)$, $c = 12.105(2)$ Å, $\beta = 95.44(2)°$, $U = 3305(1)$ Å^3, $Z = 4$, $D_c = 1.78$ g cm^{-3}, $F(000) = 1728$, space group $P2_1/n$, μ(Mo-K_α) = 41.01 cm^{-1}, Mo-K_α X-radiation ($\bar{\lambda} = 0.71073$ Å graphite monochromator).

The structure was solved and all non-hydrogen atoms were located by conventional heavy-atom and difference Fourier methods. The vinyl hydrogen atoms could not be located with certainty and were not included in the refinement. All remaining hydrogen atoms were included in calculated positions with common refined isotropic thermal parameters. Refinement by full-matrix least-squares converged at $R = 0.025$ ($R_w = 0.029$) with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.001|F|^2]$.† The final electron density difference synthesis showed no peaks greater than 0.68 or less than -0.94 e Å^{-3}. Scattering factors were from ref. 26. All calculations were carried out on a DEC Microvax computer using the *SHELXTL* system of programs.[27]

(*Received* 19 *September* 1988; *accepted* 4 *November* 1988)

Abstract—$PdCl_2$ reacts with K_2Te_4 in DMF to produce $Pd(Te_4)_2^{2-}$, which was isolated as a bis-PPh_4^+ salt. The X-ray structure of this compound revealed a square-planar palladium atom with two chelated Te_4^{2-} ligands. $Pt(PPh_3)_4$ reacts with $(Bu_4N)_4Hg_4Te_{12}$ in DMF to produce $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2$ which was also characterized by single-crystal X-ray diffraction.

There is a growing interest in the synthesis of new telluride and polytelluride complexes for use as IR sensory materials,[1] superconducting solids[2] and amorphous spin glasses with tunable conducting properties.[3,4] Several new pseudo-binary polytelluride complexes have recently been prepared that could serve as precursors to metastable materials, that are inaccessible by other synthetic methods.[4] These compounds include $Mo_4Te_{16}(en)_4^{2-}$,[5] $NbTe_{10}^{3-}$,[6] $Hg_4Te_{12}^{4-}$,[7] $^1_\infty[Hg_2Te_5^{2-}]$,[7] $Cr(\eta^2\text{-}Te_2)_2(CO)_2^{2-}$,[8] $Fe_2Te_3(CO)_6^{2-}$[9] and $Cr_3Te_{24}^{3-}$,[10] to name a few. We report here the synthesis and structures of two new telluride complexes, namely $Pd(Te_4)_2^{2-}$†[11] and $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2$.

The $Pd(Te_4)_2^{2-}$ ion, **1**, was prepared by reacting anhydrous $PdCl_2$ with a DMF extract of a melt of nominal composition K_2Te_4 (*ca* 2 equiv of K_2Te_4 per $PdCl_2$) followed by the addition of excess PPh_4Br in ethylenediamine (en) according to eq. (1)

$$PdCl_2 + 2K_2Te_4 \xrightarrow[DMF/en]{\text{excess } PPh_4Br} Pd(Te_4)_2(PPh_4)_2 + 2KCl + 2KBr. \quad (1)$$

The palladium–telluride complex was isolated as a crystalline bis-tetraphenylphosphonium salt of formula $Pd(Te_4)_2(PPh_4)_2$ in a *ca* 30% yield based on $PdCl_2$. The crystals were small opaque rectangles that would not redissolve in en at room temperature. The compound was characterized by microprobe analysis and single-crystal X-ray diffraction.‡

Two views of the $Pd(Te_4)_2^{2-}$ ion are given in Fig. 1. The top view shows the two chelating Te_4^{2-} chains that form the familiar square-planar coordination geometry about palladium. The ion has D_2 point symmetry with three, mutually orthogonal, two-fold rotation axes passing through the palladium

* Authors to whom correspondence should be addressed.

† Just prior to the submission of this manuscript, we discovered that Kanatzidis had apparently made the same compound.[11]

‡ Crystal data for $Pd(Te_4)_2(PPh_4)_2$: triclinic, space group $P\bar{1}$, $a = 11.035(2)$, $b = 23.394(5)$, $c = 10.529(4)$ Å; $\alpha = 102.73(2)$, $\beta = 100.46(3)$, $\gamma = 97.21(2)°$, $V = 2568(1)$ Å^3, $Z = 2$, Mo-K_α radiation ($\lambda = 0.71069$ Å) at 23°C. An empirical absorption correction was applied ($\mu = 49.19$ cm^{-1}). The structure was solved by a combination of direct methods and difference Fourier syntheses, and successfully refined by full-matrix least-squares with $R = 0.056$ and $R_w = 0.071$ for 4899 reflections with $(I) > 4\sigma(I)$.

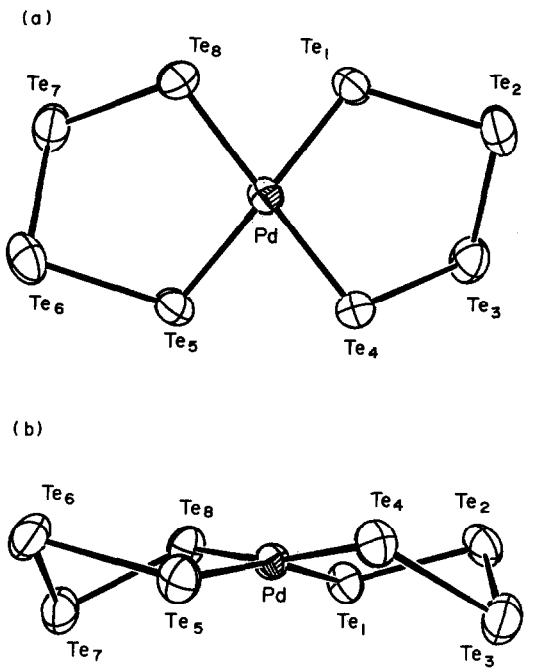

Fig. 1. Two views of the $Pd(Te_4)_2^{2-}$ anion. Pertinent bond distances (Å) and angles (°) are: Pd—Te(1), 2.600(2); Pd—Te(4), 2.585(2); Pd—Te(5), 2.603(2); Pd—Te(8), 2.586(2); Te(6)—Te(7), 2.714(3); Te(2)—Te(3), 2.716(3); other intrachain Te—Te distances, 2.76(2) (av); Te(1)—Te(8), 3.214(2); Te(4)—Te(5), 3.256(2). Te(4)—Pd—Te(1), 104.57(7); Te(4)—Pd—Te(5), 77.76(7); Te(5)—Pd—Te(8), 104.59(8); Te(8)—Pd—Te(1), 76.60(7).

atom. The side view [Fig. 1(b)] illustrates the puckered nature of the $PdTe_4$ rings which are quite similar to the MS_4 rings in the $M(S_4)_2^{2-}$ sulphur analogues (where M = Ni, Pd).[12] The Pd—Te distances average 2.59(2) Å and are indicative of single bonds based on expectations from the covalent radius of Pd^{2+} [13] and M—Te distances in other polytelluride complexes.[5,7,14] The Te—Te contacts within the Te_4 chains average 2.74(4) Å, which are typical single bond distances.[5,7,14] The Te—Pd—Te angles are distorted from 90°, with obtuse angles within the $PdTe_4$ rings [104.6(1)° (av)] and acute angles between rings [77(1)° (av)]. The Te(1)—Te(8) and Te(4)—Te(5) separations are non-bonding at 3.24(4) Å (av).

We have also been investigating the reactions between zero-valent, unsaturated transition-metal fragments (ML_n) with homo- and heteropolyatomic anions. These studies have produced the remarkable compounds $Sn_9Cr(CO)_3^{4-}$ [15] and $As_7Cr(CO)_3^{3-}$ [16] but we have been unsuccessful in isolating transition-metal complexes that contain intact heteropolyatomic anionic fragments such as $SnTe_4^{4-}$ [17] or $Au_4Te_4^{4-}$.[18] For example, the reaction between $Cr(CO)_3(\eta^6$-mesitylene) and an en extract of KAuTe (which presumably contains $K_2Au_4Te_4^{2-}$ anions in solution[18]) in the presence of excess 2,2,2-crypt yields $Cr(\eta^2\text{-}Te_2)_2(CO)_2^{2-}$ with two disordered K^+/Au^+ cations [$(K_xAu_{1-x}$-2,2,2-crypt) where $x < 1$].[8] Clearly, complex equilibria are

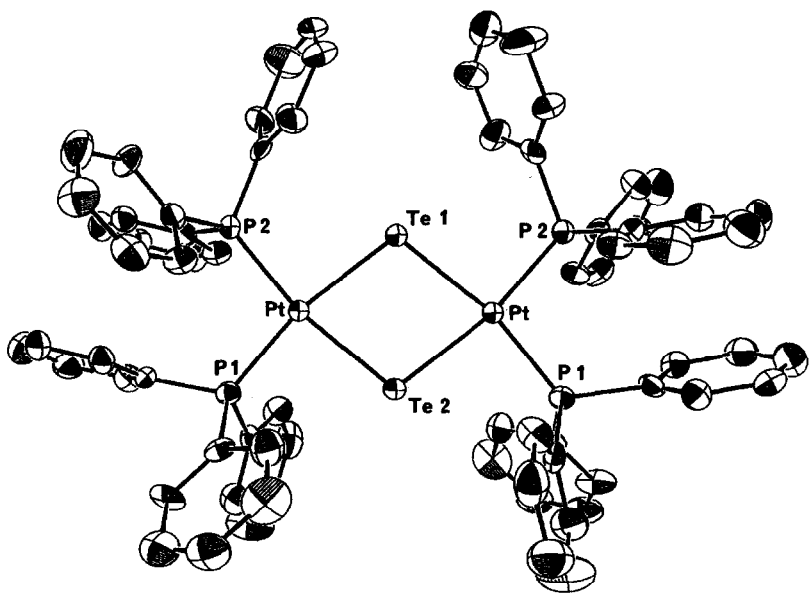

Fig. 2. A perspective of the $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2$ molecule as viewed perpendicular to the Pt_2Te_2 plane. Pertinent bond distances (Å) and angles (°) are: Pt—Te(1), 2.612(1); Pt—Te(2), 2.628(1); Pt—P(1), 2.308(4); Pt—P(2), 2.276(3); Te(1)—Te(2), 3.258(2). Te(1)—Pt—Te(2), 76.90(3); Te(2)—Pt—P(1), 90.78(9); P(1)—Pt—P(2), 100.4(1); Te(1)—Pt—P(2), 91.86(2); Pt—Te(2)—Pt, 102.66(5); Pt—Te(1)—Pt, 103.54(5).

established when these polyatomic anions are dissolved and subsequent reactions are not straightforward. Such is the case for the reaction between $(Bu_4N)_4Hg_4Te_{12}$[7] and $Pt(PPh_3)_4$.

A 1 : 1 (mol %) mixture of $(Bu_4N)_4Hg_4Te_{12}$[7] and $Pt(PPh_3)_4$ in DMF results in the formation of $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2 \cdot 3DMF$ (**2**). Compound **2** was isolated as brown parrallellogram-shaped crystals in *ca* 20% yield based on platinum. The fate of the mercury in this reaction is currently unknown. The molecular structure* of **2**, shown in Fig. 2, comprises two edge-shared square-planar platinum fragments bridged by two Te^{2-} ligands with a planar Pt_2Te_2 core. The Pt—Te distances are 2.62(2) Å (av), with a non-bonding Te—Te separation of 3.26(1) Å. The molecule sits on a crystallographic two-fold rotation axis defined by the Te—Te vector and is most likely isostructural with sulphur and selenium analogues.[19] Two of the solvate DMF molecules are crystallographically equivalent, whereas the third unique solvate molecule is disordered about the two-fold axis. The solvate molecules do not interact with the $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2$ complex in the solid state.

It is interesting to compare the structure of **2** with that of (triphos)Ni(μ-η^2-Te_2)Ni(triphos) [triphos = $MeC(CH_2PPh_2)_3$] which has a Te—Te separation of 2.802(1) Å.[20] The latter molecule appears to have a "neutral" Te_2 fragment that bridges two zero-valent nickel atoms, whereas compound **2** clearly has two non-interacting Te^{2-} ligands that bridge two Pt^{2+} centres.

* Crystal data for $(Ph_3P)_2Pt(\mu\text{-}Te)_2Pt(PPh_3)_2$; monoclinic, space group $C2/c$, $a = 18.150(8)$, $b = 17.587(6)$, $c = 29.916(5)$ Å; $\beta = 92.20(3)°$, $V = 7628.4$ Å^3, $Z = 4$, Mo-K_α radiation ($\lambda = 0.71073$ Å) at 23°C. An empirical absorption correction was applied ($\mu = 47.7$ cm^{-1}). The structure was solved by a combination of direct methods and full-matrix least-squares with $R = 0.049$ and $R_w = 0.065$ for 3452 reflections with $(I) > 3\sigma(I)$.

BOOK REVIEW

Advanced Inorganic Chemistry: A Comprehensive Text. 5th edn. F. Albert Cotton and Geoffrey Wilkinson. John Wiley, New York, 1988. xvii + 1455 pp, Figures and tables, 16 × 23.5 cm, $44.95.

Inasmuch as my reviews of the first four editions of this popular standard reference text have appeared in *J. Chem. Educ.* (1963, **40**, 230; 1967, **44**, A240; 1973, **50**, A347; 1981, **58**, A204), I shall concern myself here primarily with the differences between the 4th and 5th editions of a book which successfully accomplishes its purpose—" to provide the [senior-year or first-year graduate] student with the background necessary to comprehend current research literature in inorganic and certain aspects of organometallic chemistry". At first sight the new edition appears to conform to the unfortunate trend of texts to become longer and longer, being a full 2.1 cm (more than 3/4 in) thicker than the previous edition. In this case, however, appearance is deceptive, for the 5th edition is a mere 60 pages longer than the 4th edition. The increase in thickness is largely due to the use of heavier paper, which, together with larger and darker type, make this new edition more legible and attractive than the previous one. The book has been completely revised, updated (most of the references are from primary journals from mid-1979 to mid-1987), and expanded to emphasize the latest developments (1472 vs 1412 pp.) by the judicious rearrangement and careful rewriting of chapters and of material within sections, as well as by the meticulous insertion of new material.

The authors' trend toward decreasing the amount of theoretical material in previous editions has continued because "the continuing rapid growth of the chemistry... required the addition of important new facts to all of the descriptive material", "much of the theoretical background has found its way into textbooks used at a lower (American undergraduate) level" and "we have, over the years, become less persuaded of the value of certain types of theory" ("Theories come and go. Twenty-five years ago, when we began writing these books, there were widely accepted ideas about bonding that have by now fallen into disuse, and even disrepute").

Part 1, "Survey of Principles" (formerly titled "Introductory Topics") has been condensed from five chapters (209 pp.) to two chapters (83 pp.). Former Chapters 1, 2 and 4—"Monomolecular Solids" (25 pp.), "Symmetry and Structure" (33 pp.) and "Classification of Ligands by Donor Atoms" (88 pp.), respectively—have been eliminated, and some of their material has been placed elsewhere. Chapter 1, "Concepts in Stereochemistry and Bonding" (32 pp.) is an expanded version of the former Chapter 5, "Stereochemistry and Bonding in Main Group Compounds" (17 pp.). Chapter 2, "Introduction to Ligands and Complexes" (49 pp.) is an updated version of former Chapter 3 of the same title (46 pp.).

Part 2, "The Chemistry of the Main Group Elements", now the longest part of the book, has been expanded from 402 to 535 pages by the addition of new sections such as "Alkali Metal Salts of Complex Anions", "Compounds with Element–Element Double Bonds", "Ligands Formed by the Group VA (15) Elements" (The new IUPAC group numbering system as well as the familiar Mendeleev system is used throughout the book), "Oxygen and Oxygen Compounds as Ligands", "Sulfur and Sulfur Compounds as Ligands" and "Halide Ions and Halogen Compounds as Ligands". Expanded and updated sections include "Alkali Metal Complexes", "Carbon and Carbon Compounds as Ligands", "Dinitrogen and Nitrogen Compounds as Ligands", "Chemical Properties of Dioxygen", "Singlet Oxygen" and "Oxo Acids of Sulfur". Substantially expanded chapters include those on "Boron: Group IIIA (13)" (from 63 to 72 pp.), "Carbon . . ." (from 22 to 31 pp.), "Nitrogen . . ." (from 31 to 77 pp.), "The Group VA (15) Elements . . ." (from 45 to 62 pp.), "Oxygen . . ." (from 19 to 47 pp.), "The Group VIA (16) Elements . . ." (from 40 to 53 pp.) and "The Group VIIA (17) Elements . . ." (from 35 to 43 pp.). The chapter on "The Group IVA (14) Elements . . ." has been substantially condensed (from 55 to 40 pp.).

Part 3, "The Chemistry of the Transition Elements", formerly the longest part of the book, has been condensed from 428 to 393 pages. Former Chapter 20,"The Transition Elements and the Electronic Structures of Their Compounds" (70 pp.), has been severely compressed into Chapter 17, "Survey of the Transition Metals" (24 pp.), by deletion of the sections on "The Molecular Orbital Theory", "Electronic Absorption Spectra" and "Structural and Thermodynamic Consequences of Partly Filled *d* Shells". Chapter 19, "The Elements of the Second and Third Transition Series", has been expanded from 159 to 179 pages. New sections in Part 3 include "Spin-State Crossovers", "Mixed Oxidation States and Other Topics", "Niobium and Tantalum Cluster Complexes" and "Triple and Quadruple M—M Bonds", while the sections on "Magnetic Properties of Transition Metal Compounds", platinum metals and organometallic compounds have been expanded.

Part 4, "Survey of Selected Areas . . ." (formerly "Special Topics"), has been expanded from 297 to 356 pages. Former Chapter 25, "Metal Carbonyls and Other Complexes with π-Acceptor Ligands", retitled "Transition Metal Carbon Monoxide Compounds", has been rearranged and rewritten but not increased in length (31 pp.). Former Chapter 26, "Metal-to-Metal Bonds and Metal Atom Clusters", has been expanded from 33 to 45 pages by the addition of much new material. Former

Chapter 27, "Transition Metal Compounds with Bonds to Hydrogen and Carbon" (70 pp.), has been completely rewritten and expanded (89 pp.) into three separate chapters: "Transition Metal Compounds with Bonds to Hydrogen" (25 pp.), "Compounds with Transition Metal Single, Double, and Triple Bonds to Carbon" (30 pp.), and "Compounds of Transition Metals with Alkenes, Alkynes, and Delocalized Hydrocarbon Systems" (34 pp.). Former Chapter 28, "Reaction Mechanisms and Molecular Rearrangements in Complexes" (51 pp.), retitled "Reaction Mechanisms of Transition Metal Complexes" (52 pp.), has remained virtually unchanged in length. Former Chapter 29, "Transition Metal to Carbon Bonds in Synthesis" (31 pp.), has been rewritten and expanded to "Oxidative-addition and Migration (Insertion) Reactions" (38 pp.), while former Chapter 30, "Transition Metal to Carbon Bonds in Catalysis" (45 pp.), has been expanded to "Homogeneous Catalytic Synthesis of Organic Chemicals by Transition Metal Complexes" (59 pp.). Once again, the text ends with a chapter on "Bioinorganic Chemistry", now expanded from 36 to 42 pages.

The useful appendices have been expanded from 19 to 31 pages. Those on "Atomic Orbitals" (3 pp.), "The Quantum States Derived from Electronic Configurations" (5 pp.) and "Magnetic Properties of Chemical Compounds" (4 pp.) have been deleted, and new appendices on "Ionic Radii" (4 pp.), taken largely from former Chapter 1, and on "Basic Concepts of Molecular Symmetry; Character Tables" (21 pp.), taken largely from former Chapter 2, have been added. The detailed index has been expanded from 30 to 45 pages.

Although the introductory quotation is ascribed to Marcelin (rather than the correct Marcellin) Berthelot, the book is virtually free of errors, and the date of the discovery of Zeise's salt, the earliest known organotransition metal complex, has been corrected from 1845 (4th edn) to 1827 (p. 71). In short, in this 5th edition, Al Cotton and Geoff Wilkinson have continued their comprehensive and authoritative coverage of modern inorganic chemistry, while incorporating the latest developments and changes in areas of research activity, without allowing the size of their book to get out of hand. Considering the wide scope of this text, its price makes it a "best buy".

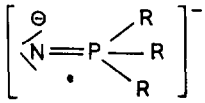
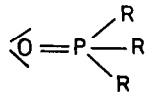
1. INTRODUCTION

Phosphorane iminato complexes of the transition metals are compounds with the ligand NPR_3^- (A), which is not known as a free ion. The group is isoelectronic with the corresponding, mostly very stable phosphorane oxide (B). Both types of compounds form stable complexes with Lewis acidic metal halides. Whereas in the case of the phosphorane oxide ligand (B) only compounds of the



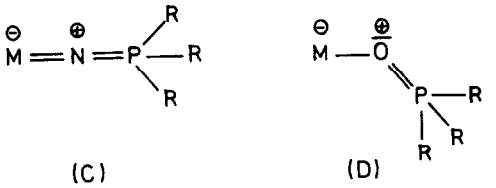
(A)



(B)

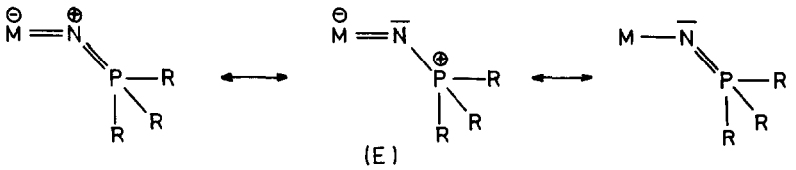
* Author to whom correspondence should be addressed.

donor–acceptor type (D) are known, the transition metal is connected by the nitrogen atom of the anion (A) via a short distance that can be interpreted as a double bond (C). The substituent R



(C) (D)

bound to the P atom, are usually organic residues, rarely halogen atoms for complexes of type (C). The sequence MNP is generally linear, though, compounds with smaller bond angles down to 130° are known as well. Independent of these bond angles, the observed bond distances always represent double bonds. For the case of a bent MNP group, the situation is best described by the resonance formulae (E). Among cyclic diphosphorane iminato complexes the bent arrangement is forced by



(E)

the geometry of the ring; the M—N—P bond angles are, however, in these cases also close to 139°. Less common are arsane iminato complexes. Nevertheless, spectroscopic findings allow the conclusion that a similar bonding situation is present.

2. SYNTHESES

2.1. *Syntheses from nitrido complexes*

Nitrido complexes of molybdenum, tungsten, rhenium, ruthenium and osmium in which the nitrido ligand acts as a terminal ligand of the type M≡N or as a bridging type $M{\equiv}\overset{\oplus}{N}{-}\overset{\ominus}{M}$, respectively,[1] are frequently able to react with suitable phosphanes to yield phosphorane iminato complexes.

The first examples of phosphorane iminato complexes of molybdenum and tungsten were prepared in 1970 by the reaction of triphenylphosphane with molybdenum or tungsten nitride chloride,[2] respectively, in boiling dichloromethane:[3]

$$\underset{M = Mo, W}{MNCl_3 + PPh_3} \longrightarrow \underset{\textbf{(I)}}{M(NPPh_3)Cl_3}. \qquad (1)$$

Compounds **I** are linked by chloro bridges. The constitution of these complexes however was not revealed until later. When reaction (1) is carried out with an excess of PPh_3 in CCl_4 at a higher temperature, the dimeric complex $[Mo(NPPh_3)Cl_3(PPh_3)]_2$ **(II)**[4] is obtained which has chlorine bridges. The additional molecule of PPh_3 is coordinated to the molybdenum atom. Reaction (1) is accompanied by a simultaneous redox reaction in which the transition metal is reduced from +VI to +IV and correspondingly the phosphorus is oxidized to the phosphorane imine ligand.

In 1973, Griffith and co-workers found productive syntheses for various phosphorane iminato complexes of ruthenium and osmium.[5] The reactions of the tetrachloro and tetrabromo nitrido osmates, $AsPh_4[OsNX_4]$, with PPh_3 in cold acetone, proceeded according to eq. (2):[5]

$$\underset{(X = Cl, Br)}{AsPh_4[OsNX_4] + 3PPh_3} \xrightarrow{OCMe_2} \underset{\textbf{(III)}}{[Os(NPPh_3)X_3(PPh_3)_2] \cdot Me_2CO} + AsPh_4X. \qquad (2)$$

Whereas the analogous reaction with $AsPh_4[RuNCl_4]$ only leads to the formation of $AsPh_4[RuCl_4(PPh_3)_2]$, complexes of type **III** with the general formula $[M(NPR_3)Cl_3(PR_3)_2]$ (M = Ru or Os; PR_3 = PPh_3, PPh_2Et, $PPhEt_2$ or PPh_2Me), could be obtained in high yields by the reaction of excess

PR_3 with $[MNCl_3(AsPh_3)_2]$ in cold acetone:[5]

$$[MNCl_3(AsPh_3)_2]+3PR_3 \longrightarrow [M(NPR_3)Cl_3(PR_3)_2]+2AsPh_3. \quad (3)$$

In the case of $PR_3 = PPhMe_2$, the intermediately formed complexes, $[M(NPPhMe_2)Cl_3(AsPh_3)_2]$, could be isolated.[5] Compounds **III** usually are orange–brown crystalline powders, the effective magnetic moments of which are ~ 1.8 BM for the osmium complexes and approximately 2.8 BM for the ruthenium complexes, corresponding to metal atoms in the oxidation state +IV.[5]

The mechanism of the synthesis of the phosphorane iminato complexes from nitrido compounds, can be interpreted as a nucleophilic attack of the phosphorus atom of the phosphane on the nitrido nitrogen atom.[5] Apparently, two factors are of importance: the ligands at the phosphorus atom of the phosphane as well as the electron density of the nitrogen atom which is influenced by the transition metal atom of the nitrido component. Finally, the capability of reducing the transition metal is also one condition for the synthesis of phosphorane iminato complexes. Examples in which the Lewis basic properties predominate are the nitrido complexes of rhenium(V) and rhenium(VI). This is obvious from the formation of donor–acceptor complexes with boron trihalides like $[Re(NBX_3)Cl_2(PR_3)_3]$,[6] $[Re(NBCl_3)Cl_2(PMe_2Ph)_3]$[7] and $AsPh_4[Re(NBBr_3)Br_4]$,[8] as well as with gold(I) chloride, $[Re(NAuCl)Cl_2(PMe_2Ph)_3]$.[7] The reaction of PPh_3 with $ReNCl_4$—a nitrido complex of rhenium(VII) that forms a columnar structure with alternating $Re^{\ominus}\equiv N^{\oplus}—Re^{\ominus}\equiv N^{\oplus}$ bonds[9]—however, occurs without problems at $-20°C$ in CH_2Cl_2 solution:[10]

$$ReNCl_4+2PPh_3 \longrightarrow [(PPh_3)Cl_4Re(NPPh_3)]. \quad (4)$$

On the other hand, $ReNCl_3$ or $[ReNCl_4]^-$ only react with PPh_3 on forming adducts,[10] presumably because the reduction potential of PPh_3 does not suffice to reduce rhenium(VI) to rhenium(IV). Dilworth *et al.*[11] reported a similar observation in the synthesis of $[Re(NPPh_3)(SPh)_4]$ from $ReNCl_2(PPh_3)_2$ and SPh^- in acetonitrile, which only proceeds upon exposure to oxygen and wherein the first formed $[ReN(SPh)_4]^{2-}$ is oxidized intermediately to the rhenium(VII) complex, which then reacts with PPh_3 yielding the phosphorane iminato complex:[11]

$$[ReNCl_2(PPh_3)_2] \xrightarrow{SPh^-} [ReN(SPh)_4]^{2-} \xrightarrow{O_2} [ReN(SPh)_4] \xrightarrow{PPh_3} [Re(NPPh_3)(SPh)_4]. \quad (5)$$

In the case of the reaction of the diimine complex $[MoNCl_4]_2$ with triphenyl phosphane, the synthesis of the phosphorane iminato complex proceeds because of the cleavage of the N=N bond without any change in the +V oxidation state of the molybdenum atom:[4]

$$Cl_4Mo^{\ominus}=N^{\oplus}=N^{\oplus}=Mo^{\ominus}Cl_4+4PPh_3 \longrightarrow 2[MoCl_4(NPPh_3)(PPh_3)]. \quad (6)$$

The same compound is also obtained by the reaction of PPh_3 with the chloro thionitrene complex $[MoCl_4(NSCl)]_2$,[4] whereby a reduction of molybdenum(VI) to molybdenum(V) occurs:[4]

$$[MoCl_4(NSCl)]_2+7PPh_3 \longrightarrow 2[MoCl_4(NPPh_3)(PPh_3)]+2SPPh_3+Cl_2PPh_3. \quad (7)$$

The course of reaction (8) also underlines the importance of the redox potential of the reactants for the formation of phosphorane iminato complexes from nitrido compounds. Whereas the treatment of $PPh_4[MoNCl_4]$ with PCl_5[12] does not yield a phosphorane iminato complex, the chlorine substituted product is easily formed by the presence of phosphorus trichloride:[4]

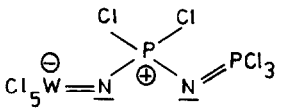
$$2PPh_4[MoNCl_4]+PCl_3+PCl_5 \longrightarrow 2PPh_4[MoCl_5(NPCl_3)]. \quad (8)$$

Reaction (9), however, proceeds with the preservation of the +VI oxidation state at the tungsten atom. The reaction of tungsten nitride chloride with bis(trichlorophosphorane)iminium chloride, primarily leads to the tetrachloro nitrido tungstate, which, however, already reacts further at room temperature in CH_2Cl_2 solution to yield the phosphorane iminato complex:[13]

$$WNCl_3+[Cl_3PNPCl_3]Cl \longrightarrow [Cl_3PNPCl_3][WNCl_4] \longrightarrow Cl_5WNP(Cl_2)NPCl_3. \quad (9)$$

The astonishing formation of the molecule $Cl_5WNP(Cl_2)NPCl_3$ from the ionic precursor complex can be explained by the continuously conjugated chain of the framework WNPNP, which is obvious from the almost planar arrangement and the only slightly different P—N bonds (see Section 4).

According to the NMR spectrum, the compound has to be understood as a zwitter-ion.[13]



2.2. *Syntheses from azido complexes of transition metals*

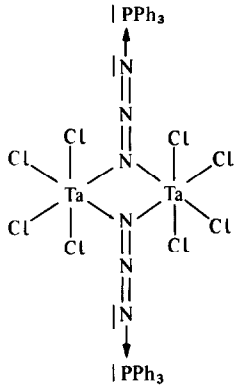
The first example of this type of synthesis was found by Strähle and co-workers by the reaction of niobium tetrachloride azide, $[NbCl_4N_3]_2$,[14] with triphenylphosphane in 1,2-dichloromethane:[15]

$$[NbCl_4N_3]_2 + 2PPh_3 \longrightarrow [Nb(NPPh_3)Cl_4]_2 + 2N_2. \quad (10)$$

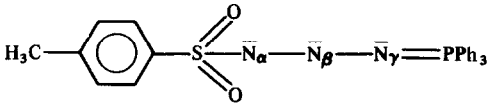
The reaction proceeds rapidly and nearly completely at room temperature. Later, it was also possible to apply this reaction to the corresponding tantalum compound $[TaCl_4N_3]_2$.[14] In this case, however, the reaction with triphenylphosphane takes a more complex course. Besides the formation of the phosphorane iminato complex $[Ta(NPPh_3)Cl_4]_2$,[16] the monomeric phosphorane iminato complex $[Ta(NPPh_3)Cl_4(HNPPh_3)]$,[16] solvated by the phosphorane imine $HNPPh_3$, is additionally obtained by the involvement of the solvent:

$$[TaCl_4N_3]_2 + 2PPh_3 + C_2H_4Cl_2 \longrightarrow [TaCl_4(NPPh_3)(HNPPh_3)] + TaCl_5 + C_2H_3Cl + 2N_2. \quad (11)$$

The reaction proceeds rapidly above 0°C. At lower temperatures, first the intensely yellow "phosphazide"[16] is formed, which in the case of the niobium compound [eq. (10)] is indicated by the transient red colour of the solution arising from a short lived intermediate only.[15]



For the mechanism of formation of phosphorane iminato complexes from transition metal azides, an analogous picture to the well investigated Staudinger reaction therefore arises. Primary attack of the triphenylphosphane at the γ-N atom has been proved for this reaction by the aid of ^{15}N labelled *p*-toluene sulphone acid azide.[17] Such an adduct was isolated in the form of the complex



$[CH_3—C_6H_4—N=N—N=PPh_3 \cdot WBr_2(CO)_3]$ and confirmed by a crystal structure determination.[18] The decomposition can be understood in terms of the elimination of the β-N and the γ-N atom as N_2 after an additional bond to the α-N atom was formed:[19]

$$R—\bar{N}=\underline{N}—\bar{N}=PPh_3 \longrightarrow R—\bar{N}(/\bar{N}=\bar{N}/)—PPh_3 \longrightarrow R—\bar{N}=PPh_3 + N_2. \quad (12)$$

Triphenylphosphane also reacts outright and with complete conversion with the pentachloro azido metallates of niobium and tantalum (in CH_2Cl_2 solution),[20] or with the corresponding pentabromo metallates (in CH_2Br_2 solution),[21] to yield the anionic phosphorane iminato complexes:

$$[MX_5N_3]^- + PPh_3 \longrightarrow [X_5M{=}N{=}PPh_3]^- + N_2. \quad (13)$$
$$(M = Nb, Ta;\ X = Cl, Br)$$

The counter ions, PPh_4^+ or $AsPh_4^+$, are used because their salts are readily soluble in CH_2X_2. In the case of the niobium compounds, spontaneous elimination of N_2 occurs. In the case of the tantalum compound the reaction needs photochemical activation. In refluxing CH_2Cl_2 under UV irradiation (several hours), the tetraphenylarsonium pentachloro azido niobate even reacts with triphenylarsane forming a triphenylarsane iminato complex,[21] which to our knowledge is the first compound of this type:

$$AsPh_4[NbCl_5N_3] + AsPh_3 \xrightarrow{h\nu} AsPh_4[Cl_5Nb{=}N{=}AsPh_3] + N_2. \quad (14)$$

The properties and the spectroscopic data for this arsane iminato complex correspond almost exactly with those of the analogous phoshorane iminato complexes.[21]

2.3. *Syntheses from nitrosyl complexes*

The reduction of nitrosyl complexes with phosphanes to form phosphorane iminato complexes has only occasionally been reported. The reactions proceed according to the stoichiometry:

$$\overset{\ominus}{M}{=}\overset{\oplus}{N}{=}\bar{O} + 2PR_3 \longrightarrow \overset{\ominus}{M}{=}\overset{\oplus}{N}{=}PR_3 + OPR_3. \quad (15)$$

They correspond formally to the uptake of six electrons for the nitrosyl nitrogen (from +III to −III). Four of the electrons come from the two phosphorus atoms of the two phosphane molecules—the residual two from the oxidation of the metal atom. Since the nitrosyl ligand NO^+ is isoelectronic with N_2, these reactions have model character for the understanding of the reduction of dinitrogen complexes, for which six electrons are also required.[22]

The reaction of $[MoCl_5(NO)]$ with dimethylphenylphosphane and with di(*n*-propyl)-phenylphosphane proceeds under very mild conditions:[23]

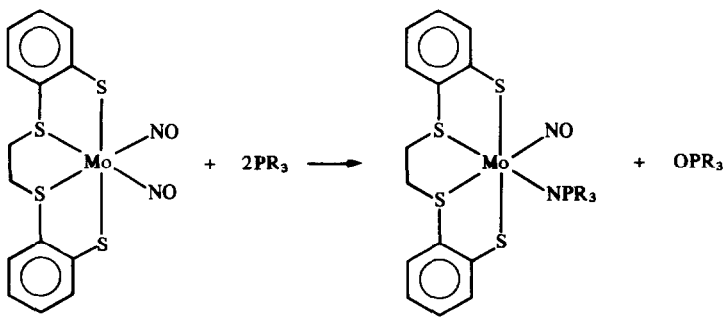
$$[MoCl_5(NO)] \xrightarrow{2R_3P} [MoCl_4(NPR_3)(OPR_3)]. \quad (16)$$

The reaction of triphenylphosphane with rhenium trichloride dinitrosyl[24] in dichloromethane even proceeds exothermically and spontaneously at room temperature:[25]

$$ReCl_3(NO)_2 + 2PPh_3 \longrightarrow [ReCl_3(NO)(NPPh_3)(OPPh_3)]. \quad (17)$$

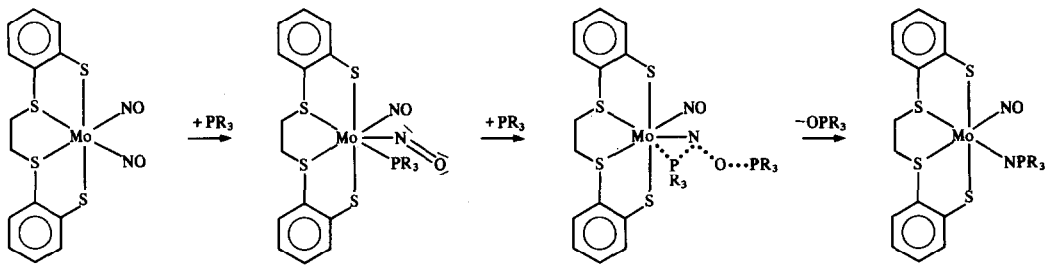
The complex dissolves easily to give a deep green colour in dichloromethane. The crystal structure determination (Section 4) makes a direct comparison of the two isoelectronic species $NPPh_3^-$ and $OPPh_3$ possible.

Sellmann and co-workers found that the dinitrosyl molybdenum complex $[Mo(NO)_2(dttd)]$ [$dttd^{2-}$ = 2,3,8,9-dibenzo-1,4,7,10-tetrathia decan(2−)] reacts with various phosphanes PR_3 (PR_3 = PMe_3, PEt_3, $PMePh_2$, $PEtPh_2$, PPh_3) in THF to form the corresponding phosphorane iminato complexes:[26]



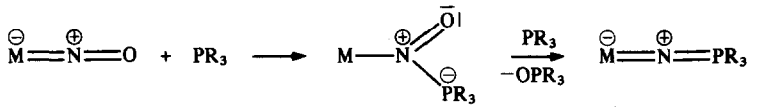
(18)

The reaction rates show a marked dependence on the phosphane substituent R. While reaction (18) with PMe_3,[26] as well as with $P(n\text{-But})_3$ and $P(Cy)_3$,[27] proceeds at room temperature within 5 min, the corresponding reactions with PPh_3[26] and with $Ph_2PC_2H_4PPh_2$[27] require 6 h in boiling THF. From this observation, Sellmann and co-workers infer a mechanism in which primary attack of the phosphorus atom occurs at the molybdenum atom, as it may be assumed that the different dimensions of the phosphane molecules are of greater influence with the already very sterically congested molybdenum atom than with the freely accessible nitrogen atom of the nitrosyl ligand. Due to the primary attack of the phosphane at the metal atom, the NO ligand could bend forming a one electron donor to maintain the 18 electron configuration at the molybdenum atom. Afterwards, deoxygenation of this NO ligand could be effected by a second phosphane molecule. Intramolecular P—N bond formation as well as isomerization eventually result in the final product:[26]



(19)

In other cases one should also discuss the possibility of a nucleophilic attack of the phosphane at the nitrosyl nitrogen atom and of a following deoxygenation by an additional phosphane molecule:



(20)

Generally predestined for a nucleophilic attack at the nitrosyl nitrogen atom are nitrosyl complexes with NO stretching vibrations in the region above $\sim 1870\ cm^{-1}$.[28] This condition is met for the nitrosyl complexes mentioned above, e.g. $[MoCl_5(NO)]$ ($2000\ cm^{-1}$)[23] and $ReCl_3(NO)_2$ (1910 and $1818\ cm^{-1}$),[24] but not, however, for the dinitrosyl complex $[Mo(NO)_2(dttd)]$ (1760 and $1665\ cm^{-1}$),[26] so that for this complex a mechanism according to reaction (19) is more likely.

Besides these two possibilities for a mechanistic course for the formation of phosphorane iminato complexes from nitrosyl complexes, the oxidation state of the central atom is also of importance. This follows for instance from the existence of the phosphane complex $[ReCl_2(NO)_2(PPh_3)_2]$ with rhenium(0), which does not show any tendency to form a phosphorane iminato complex.[29] From an analogy to the structurally investigated stibane complex $[ReCl_2(NO)_2(SbPh_3)_2]$,[30] one may conclude that the PPh_3 ligands are mutually *trans* to each other for the rhenium(0) phosphane complex. For $ReCl_3(NO)_2$ with rhenium(+I), however, spontaneous reaction with PPh_3 was observed [reaction (17)].

2.4. *Syntheses from metal halides and iminophosphoranes*

Preferred reagents for this route of synthesis are trimethylsilyl substituted iminophosphoranes, with their high tendency of forming the leaving group Me_3SiF or Me_3SiCl are used. The reactions take place according to the stoichiometry:

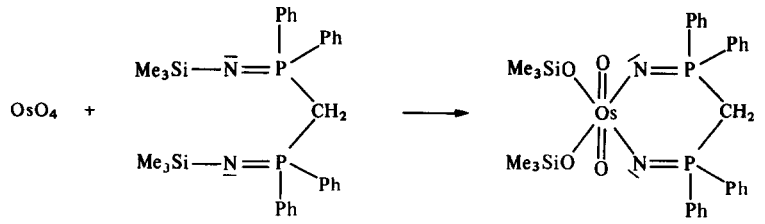
$$M\text{—}X + Me_3Si\text{—}N{=}PR_3 \longrightarrow M{=}N{=}PR_3 + X\text{—}SiMe_3 \qquad (21)$$
$$(X = F, Cl).$$

Occasionally hexamethyldisiloxane has also been used as a good leaving group. Thus the reaction of $VOCl_3$ with trimethylsilyltriphenyl iminophosphorane yields bis(triphenylphosphorane iminato)vanadium trichloride:[31]

$$VOCl_3 + 2Me_3SiN{=}PPh_3 \longrightarrow Cl_3V(NPPh_3)_2 + O(SiMe_3)_2. \qquad (22)$$

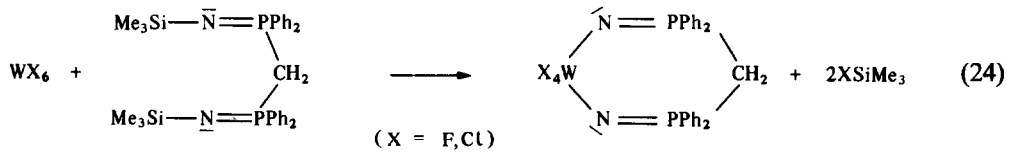
The reaction of osmium tetroxide with a bis(trimethylsilylated) disphosphorane, however, leads to

a trimethylsilyl group migration and to the formation of a chelate:[32]



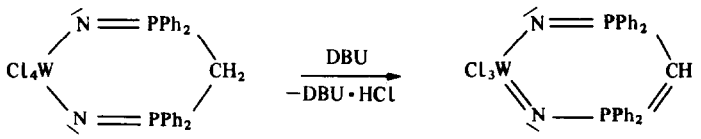
(23)

Determination of the molar mass proves the reaction product to be dimeric in solutions. Formation of a chelate is also observed with the reactions of the diphosphorane mentioned above with tungsten hexafluoride and -chloride:[33]



(24)

On treatment with the base DBU (1,8-diazabicyclo [5.4.0] undec-7-ene) HCl is split off from the chlorine derivative forming a conjugated heterocyclic system:[33]



(25)

The reaction product is isoelectronic with $Cl_3W[N_2P_2(Ph_2)N]$, which is obtained by a different route (see below). It can be assumed that the initial step in the formation of the phosphorane iminato complex, according to reaction type (21), is a donor–acceptor complex, although these initial adducts cannot be isolated in general. One exception is the complex $[TiCl_4(Me_3SiNPPh_3)]$, which, however, was not fully characterized.[34]

In the case of the reaction of copper(II) chloride with trimethylsilyl triphenylphosphorane, however, a stable adduct was formed, which could be fully characterized by crystal structure determination[35] (see Fig. 1).

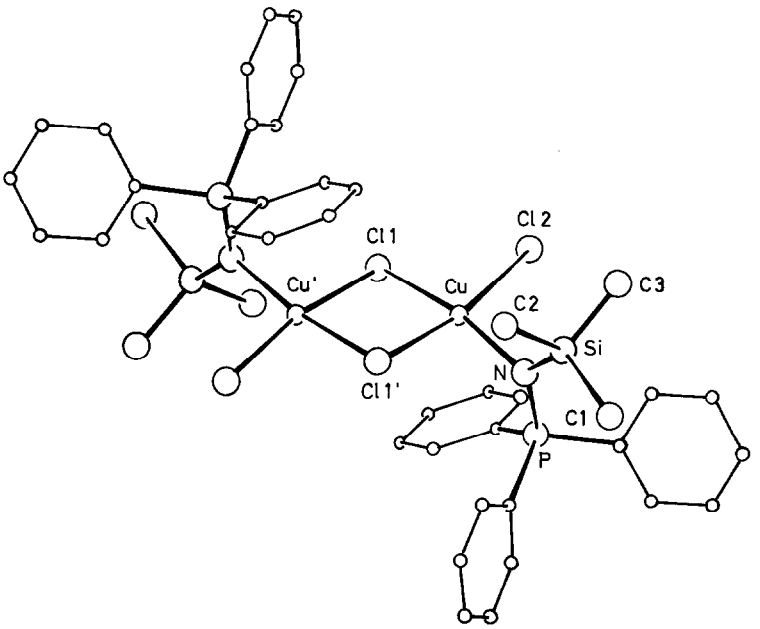


Fig. 1. Structure of the complex $[CuCl_2(Me_3SiNPPh_3)]_2$.

As expected, the nitrogen atom of the imino phosphorane is a donor atom, so that the subsequent formation of a phosphorane iminato complex is preformed. Preceding donor–acceptor complexes are also considered for the mechanism of the reactions (22) and (23), as bases like chinuclidine or chloride form complexes of the types $[VOCl_4]^-$,[36] $OsO_4 \cdot$ chinuclidine[37] and $PPh_4[OsO_4Cl]$[38] with $VOCl_3$ as well as OsO_4.

Many phosphorane iminato complexes have been synthesized according to the scheme of reaction (21). The first examples came from Dilworth and co-workers, in the reactions of cyclopentadienyl substituted titanium chloride:[34]

$$CpTiCl_3 + Me_3Si{-}N{=}PPh_3 \longrightarrow CpTiCl_2(NPPh_3) + ClSiMe_3. \quad (26)$$

Whereas $[Ti(\eta^5\text{-}C_5H_5)_2Cl_2]$ did not react and the reaction of $TiCl_4$ with $Me_3Si{-}N{=}PPh_3$ yielded the adduct mentioned above,[34] $TiCl(OR)_3$ ($R = C_3H_7$) could be converted to the bis(phosphorane iminato) complex on cleavage of the corresponding trimethylsilyl ether and simultaneous ligand exchange:[34]

$$2TiCl(OR)_3 + 2Me_3Si{-}N{=}PPh_3 \longrightarrow TiCl_2(NPPh_3)_2 + Ti(OR)_4 + 2Me_3SiOR. \quad (27)$$

Additional phosphorane iminato complexes obtaind according to the scheme of eq. (21) are:

$[TiCl(NPPh_3)(S_2CNEt_2)_2]$[34]
$[VOCl_2(NPPh_3)]$[34]
$[VOCl(NPPh_3)_2]$[34]
$[WF_4(NPPh_3)_2]$[39]
$[WF_4(NPMe_3)_2]$[40]
$[MoCl_4(NPPh_3)]_2$[41]
$[MoCl_3(NPPh_3)]_2$[42]
$[WCl_5(NPPh_3)]$[42]
$[WCl_4(NPPh_3)_2]$[42]
$[ReCl_3(NPPh_3)_2]_2$.[42]

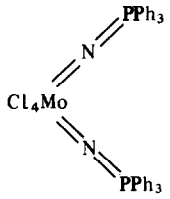
An unexpected reaction occurred on the attempt to convert $PPh_4[MoCl_6]$ with trimethylsilyl triphenylphosphoranimine to an anionic phosphorane iminato complex. The reaction proceeds in dichloromethane at room temperature on redox disproportionation of the molybdenum, in the course of which three different products could be isolated:[42]

$$3PPh_4[MoCl_6] + 3Me_3Si{-}N{=}PPh_3 \longrightarrow (PPh_4)_2[MoCl_6] + PPh_4[MoNCl_4] + Ph_3PNPPh_3[MoCl_5(NPPh_3)] + 3ClSiMe_3. \quad (28)$$

It can be assumed that the phosphorane iminato complex $[MoCl_5(NPPh_3)]^-$, is produced first, which can also be synthesized and isolated from $[MoCl_4(NPPh_3)]_2$ and PPh_4Cl.[41] In CH_2Cl_2, however, it disproportionates in a slow reaction, when the only slightly soluble $(PPh_4)_2[MoCl_6]$ favours the course of the reaction:

$$2[MoCl_5(NPPh_3)]^- \longrightarrow [MoCl_6]^{2-} + [MoCl_4(NPPh_3)_2]. \quad (29)$$

The two phosphorane iminato ligands in $[MoCl_4(NPPh_3)_2]$, as well as in other bis(triorganophosphorane iminato) complexes, should be in a *cis* arrangement because of the strong π-bond contribution to the metal nitrogen bonds, so that the formation of the hexaphenyldiphosphazenium ion is facilitated:[42]



$$\longrightarrow [Ph_3PNPPh_3]^{\oplus}\,[MoNCl_4]^{\ominus} \quad (30)$$

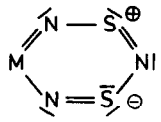
2.5. *Miscellaneous syntheses*

Chlorothionitrene complexes, in which the $M{=}\overset{\oplus}{N}{=}\underset{\ominus}{\overset{-}{S}}{-}Cl$ moiety with the two-fold negatively charged $NSCl^{2-}$ group[43] is present, have occasionally been used as starting materials for the synthesis of phosphorane iminato complexes. This also includes the already mentioned synthesis of $[MoCl_4(NPPh_3)(PPh_3)]$ from $[MoCl_4(NSCl)]_2$ and excess triphenylphosphane [eq. (7)].[4] The

rhenium(VI) chlorothionitren complex, $[ReCl_4(NSCl)\cdot OPCl_3]$, can also be transformed with excess phosphorus trichloride into a phosphorane iminato complex:[44]

$$2[ReCl_4(NSCl)\cdot POCl_3] + 5PCl_3 \longrightarrow [ReCl_4(NPCl_3)]_2 + 2PSCl_3 + 2POCl_3 + PCl_5. \quad (31)$$

The reaction is combined with a reduction of the rhenium atom to +V. Cyclothiazeno complexes of the type



with a planar six-membered ring (see review in ref. 45) can in some cases also be decomposed to phosphorane iminato complexes on treatment with triphenylphosphane. In this way the synthesis of a bis(triphenylphosphorane iminato) complex of tungsten succeeded in addition to the formation of other products starting from cyclothiazeno tungsten trichloride[46] with excess triphenylphosphane:[47]

$$WCl_3(N_3S_2) \xrightarrow{PPh_3} WCl_4(NPPh_3)_2 + \cdots. \quad (32)$$

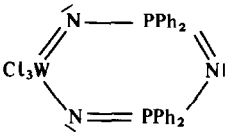
By analogy, the complex $[MoCl_4(NPPh_3)(Pyridine)]$ could also be prepared[48] from $[MoCl_3(N_3S_2)(Pyridine)]$[49] with triphenylphosphane and dichloromethane as solvent.

Using an analogous route, a phosphorane iminato complex of vanadium(IV)[50] is obtained by the reaction of triphenylphosphane with $[VCl_2(N_3S_2)(Pyridine)_2]$:[51]

$$[VCl_2(N_3S_2)(py)_2] + 2PPh_3 \xrightarrow{CH_2Cl_2} [VCl_3(NPPh_3)(py)_2] + \cdots. \quad (33)$$

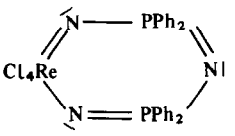
Of special interest are the reactions of the bifunctional linear phosphazenium salt, $[H_2NPPh_2NPPh_2NH_2]^+Cl^-$, with different metal halides such as tungsten hexachloride,[52] tungsten hexafluoride and bromide,[53] rhenium pentachloride,[53] vanadium tetrachloride,[53] niobium pentachloride and molybdenum nitride chloride,[54] which according to the scheme of eq. (34) lead to cyclic phosphorane iminato complexes:[52–54]

$$WCl_6 + [H_2NPPh_2NPPh_2NH_2]Cl \xrightarrow[-4HCl]{} \quad (34)$$



The reactions of VCl_4 and $ReCl_5$ require the oxidation by chlorine to transfer the metals into the highest possible oxidation state:[50]

$$ReCl_5 + Cl_2 + [H_2NPPh_2NPPh_2NH_2]Cl \xrightarrow[-4HCl]{} \quad (35)$$



By halogen exchange of the product of eq. (34) with silver fluoride, $[F_3W(N_3P_2Ph_4)]$ could also be obtained.[50]

3. REACTIONS

Only a little is known about the chemistry of phosphorane iminato complexes. On contact with water most complexes undergo complete hydrolytic decomposition; in alkaline solution ammonia is released and the corresponding phosphoranoxide is formed. The fluoro complexes $[WF_4(NPPh_3)_2]$[39] and $[NPPh_2CH_2Ph_2PNWF_4]$[33] are remarkably unreactive toward water, which could be a kinetic phenomenon. Sellmann and co-workers showed that the velocity of the hydrolytic cleavage of the Mo—N bond in the complexes $[Mo(NO)(NPR_3)(dttd)]$ strongly depends on the residue R. Whereas the complex with R = Me reacts in THF solution at room temperature with

water within a few minutes, the corresponding reaction with R = Ph requires the addition of conc. HCl:[26]

$$2Mo(NO)(NPR_3)(dttd) \xrightarrow{H_2O} [Mo(NO)(dttd)]_2 + \text{additional products.} \quad (36)$$

The reaction of the phosphorane iminato complexes with water is presumably initiated by a proton transfer at the nitrogen atom. Experiments by Griffith and co-workers showed an example of an osmium complex that underwent protonation with $[AsPh_4][H_5O_2]Cl_2$, as well as deprotonation of the imide complex with NEt_3/PPh_3:[5]

$$[Os(NPPh_3)Cl_3(PPh_3)_2] \cdot Me_2CO \underset{Et_3N}{\overset{[AsPh_4][H_5O_2]Cl_2}{\rightleftharpoons}} [Os(NHPPh_3)Cl_4(PPh_3)] \cdot Me_2CO + PPh_3. \quad (37)$$

Treatment of the imido complex with additional hydronium ions results in the irreversible cleavage of the Os—N bond:[5]

$$[Os(NHPPh_3)Cl_4(PPh_3)] + [AsPh_4][H_5O_2]Cl \longrightarrow [Ph_3PNH_2]Cl \cdot H_2O + AsPh_4[OsCl_5(PPh_3)] + H_2O. \quad (38)$$

Oxidative splitting of the P—N bond of a phosphorane iminato complex has been observed for $[Os(NPPhMe_2)Cl_3(AsPh_3)_2]$, which can be transformed with chlorine into the osmium(VI) nitrido complex, from which the phosphorane iminato complex can again be reproduced with $PPhMe_2$:[5]

$$[Os(NPPhMe_2)Cl_3(AsPh_3)_2] \underset{PPhMe_2}{\overset{Cl_2}{\rightleftharpoons}} [OsNCl_3(AsPh_3)_2]. \quad (39)$$

When the phosphorane iminato complexes are associated by halogen bridges, the bridging bonds can be opened by coordinating solvents forming definite donor–acceptor complexes. Examples are seen in reactions of the cyclophosphorane iminato complexes $[NPPh_2NPPh_2NMCl_3]_n$ (M = Mo,[54] W[52]) with acetonitrile, which lead to the solvated complexes $[NPPh_2NPPh_2NMCl_3 \cdot CH_3CN] \cdot CH_3CN$. The complex $[MoCl_4(NPPh_3)]_2$, dimerized by $MoCl_2Mo$ bridges, could be converted upon treatment with tetraphenylphosphonium chloride in dichloromethane to the pentachloro derivative:[41]

$$[MoCl_4(NPPh_3)]_2 + 2PPh_4Cl \longrightarrow 2PPh_4[MoCl_5(NPPh_3)]. \quad (40)$$

4. CRYSTAL STRUCTURES

Table 1 provides a survey of the results of crystal structure determinations of phosphorane iminato complexes. The P—N bond distances are largely independent of the M—N bond lengths and M—N—P bond angles and lie in the narrow range of 159–166 pm. This is significantly shorter than the expected value for a P—N single bond (178 pm[56]) but somewhat longer than the P—N distances in cyclophosphazenes which are approximately 155 pm,[56] e.g. $[PNCl_2]_3$, 156 pm.[57] In phosphoranimines, $Ph_3P{=}NR$, with isolated P=N double bonds, P—N distances of approximately 157–160 pm are observed, e.g. 157.5 pm for R = α-C_5H_4N[58] and 160 pm for R = C_6H_5.[59]

The metal–nitrogen bond lengths vary within the larger range of 171–190 pm. By comparison,[1] these values too, can be interpreted roughly as M=N double bonds. Despite the uncertainties which naturally arise by the determination of the coordinates of the nitrogen atom besides the strongly scattering transition metal, it can be inferred from the data in Table 1 that a relatively short M=N distance correlates with a correspondingly long P=N distance and *vice versa*. M—N—P bond angles span a large range between 177 and 130°. In this respect it is remarkable that no drastic changes of the bond lengths M—N and N—P can be recognized even with small bond angles. As shown in Section 6 this behaviour can be explained by a simple orbital consideration. The small M—N—P bond angles of the cyclic bis(phosphorane iminato) complexes are caused by the geometry of the ring. The number of *d*-electrons at the transition metal does not seem to influence the bonding properties of the phosphorane iminato groups. With the exception of $[Re(NPPh_3)(SPh)_4]$, in which the rhenium atom has the coordination number five, the metal atoms of all other complexes are six-fold coordinated.

Table 1. Structural data for phosphorane iminato complexes of transition metals

	Space group	Number of formula units per unit cell	M—N (pm)	N—P (pm)	M—N—P (°)	Number of *d*-electrons	Reference
$[NbCl_4(NPPh_3)]_2 \cdot C_2H_4Cl_2$ (**1**)	$C2/c$	8	177.6(8)	163.7(9)	171.1(6)	0	15
$[TaCl_4(NPPh_3)]_2$ (**2**)	$P2_1/c$	4	180.1(8)	159.3(9)	176.8(7)	0	16

Fig. 2. Structure of the complex $[MoCl_4(NPPh_3)]_2$.[41]

In the dimeric tetrachlorophosphorane iminato complexes of niobium(V), tantalum(V), and molybdenum(V), the metal atoms are linked by asymmetric chloro bridges to centrosymmetric dimers[15,16,41] (see Fig. 2). The M···M distances of the three examples differ only slightly (Nb···Nb = 409.0 pm,[15] Ta···Ta = 411.2 pm,[16] Mo···Mo = 408.8 pm[41]). Therefore, a bonding interaction in the molybdenum(V) compound can be excluded. The M—Cl bond distances in the bridges MCl_2M are very different in length; they are 244 and 278 pm in the molybdenum compound. The long Mo—Cl bond is subject to the *trans*-influence of the Mo=N bond of the phosphorane iminato ligand. In its extent it corresponds to the effect of dimeric organoimido complexes with metal–nitrogen triple bonds as in $[Cl_4W{\equiv}N{-}{}^tC_4H_9]_2$, in which the bond distances in the WCl_2W bridge are 241 and 275 pm.[60] The large electron density of the M=N bonds in the phosphorane iminato ligands also causes the ligands in the *cis* position to be pushed away so that in all cases the bond angles $L_4(cis)M{=}N$ are recognizably larger than 90° and the metal atoms are above the plane of the four *cis* arranged ligands.

The *trans*-influence of the phosphorane iminato ligand is also shown by the long bonds which are formed between the metal and donor atoms on solvation with donor molecules such as pyridine in complex **4**[48] (see Fig. 3) or with acetonitrile in the isotypic complexes **5**[54] and **9** (see Fig 4).[52]

The Mo—N(pyridine) distance in **4** is 236 pm, the M—N(acetonitrile) bond lengths in **5** and **9** are 239 and 237 pm, respectively. From these distances only weak donor–acceptor bonds can be inferred in all cases. The *trans*-influence of the $(NPPh_3^-)$ group in the ruthenium(IV) complex (**13**) on the *trans* chlorine atom is interestingly only marginal. This Ru—Cl bond length is 239.7 pm, whereas both *cis* chlorine atoms exhibit Ru—Cl distance of 238.8 pm.[55] In the tungsten(VI) complex (**10**), however, a recognizable *trans*-influence of the phosphorane iminato ligand $(NPCl_2NPCl_3^-)$ is again observed. In this case the difference between the W—Cl(*trans*)/W—Cl(*cis*) bond lengths is 12 pm on average[13] (see Fig. 5). The ligand group $(NPCl_2NPCl_3^-)$ is isoelectronic with the molecular phosphazene $(OPCl_2NPCl_3)$,[61] which also has a planar skeleton OPNP with comparable bonding parameters.

The complexes **7** and **8**, contain both phosphorane iminato ligands in the *cis* position.[39,40] In

this way good π-overlaps of both W—N bonds can be achieved, as is known from the *cis*-dioxo complexes of tungsten, as in the $[WO_2F_4]^{2-}$ ion,[62] for example. An indication of the high electron density of the *cis* positioned W=N bonds is also given by the large N—W—N bond angles, which are 98.5° for **7** and 99.6° for **8**.[39,40] A completely analogous situation is observed in complexes **12** and **6**, in which the phosphorane iminato ligand and the nitrosyl group are also in *cis* positions[25,27] (see Figs 7 and 8).

The N—M—N bond angles even attain values of 104.1° in complex **6** and 101.9° in complex **12**. The nitrosyl ligand is coordinated, in both examples, in a linear arrangement according to $\overset{\ominus}{M}{=}\overset{\oplus}{N}{=}\overline{O}$, so that a bond order of the M—N bond which corresponds to that of the phosphorane iminato ligand is realized.

5. SPECTROSCOPIC PROPERTIES

5.1. *IR spectra*

In the IR spectra of the phosphorane iminato complexes a characteristic strong absorption appears in the range of *ca* 1100 cm^{-1}, which is assigned as the antisymmetric stretching vibration of the MNP group (Table 2). The corresponding symmetrical stretching vibration has only been assigned for a few examples; it generally lies slightly below 600 cm^{-1}. Both vibrations are maximally coupled by a linear arrangement (A)[64] so that the difference in the wave numbers is the largest.

One example is $[MoCl_4(NPPh_3)(pyridine)] \cdot CH_2Cl_2$ which has a bond angle, Mo—N—P, of 177° and the two stretching vibrations at 1130 and 560 cm^{-1}, corresponding to a difference of 570 cm^{-1}. In the case of the rhenium complex, $[Re(NO)(NPPh_3)Cl_3(OPPh_3)]$, with a Re—N—P bond angle of 139°, corresponding to form (B), both stretching vibrations are at 1017 and 627 cm^{-1}. Thus, the difference decreases to a value of 390 cm^{-1} because they are not as strongly coupled due to the smaller bond angle.[64]

[a] ν_{as}, ν_s(NbNAs).
[b] Splitting by Fermi-resonance.
[c] $dttd^{2-}$ = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(2−).

The available structural and spectroscopic information is not sufficient to draw up a correlation diagram of these effects. The value of ν_{as}(MNP) alone, however, gives in many cases an indication of the M—N—P bond angle. In this way ν_{as} is observed for $[MoCl_4(NPPh_3)]_2$ (with a Mo—N—P bond angle of 166°) at 1128 cm^{-1}, but for [Mo(NO)(NPMePh$_2$)(dttd)] (with a Mo—N—P bond angle of 130°) at 1050 cm^{-1}. In the spectra of cyclic phosphorane iminato complexes, the conditions are more complicated because of the peculiarities of the ring vibrations.

The influence of the negative charge in the anionic complexes on the MNP stretching vibrations is small compared to the spectra of the corresponding uncharged complexes. Thus the ν_{as}(MoNP) of $[MoCl_4(NPPh_3)]_2$ hardly changes at all by the transition to the ion $[MoCl_5(NPPh_3)]^-$; in the case of the two examples $[NbCl_4(NPPh_3)]_2$ and $[NbCl_5(NPPh_3)]^-$, ν_{as}(NbNP) is shifted to smaller wave numbers i.e. from 1177 to 1138 cm^{-1}.

Some of the phosphorane iminato complexes are associated by halogen bridges. The complexes $[MCl_4(NPPh_3)]_2$ (M = Nb, Ta, Mo) for instance, form centrosymmetric dimers with the molecular symmetry C_{2h}. The MCl_2M rings are planar; the M—Cl bond distances differ in length with values of 244 and 278 pm, because of the *trans* influence of the $(NPPh_3)^-$ groups, whereas the lengths of the terminal M—Cl bonds are significantly shorter, being 235 pm. In the IR spectra, the stretching vibrations of the terminal M—Cl bonds (~ 350 cm^{-1}) and of the bridging type bond (~ 275 cm^{-1}) can be clearly distinguished. Two IR active vibrations of the B_u mode are expected according to the selection rules for MCl_2M rings of C_{2h} symmetry;[64] in many cases, however, these vibrations are accidentally degenerate so that only one band can be observed.

On the formation of halogeno complexes as the ion $[MoCl_5(NPPh_3)]^-$,[41] the negative charge causes a weakening of the M—Cl bonds, which is shown by the shift of the MCl stretching vibration to smaller wave numbers by approximately 30 cm^{-1}. The halogen *trans* to the phosphorane iminato ligand is subject to its *trans*-influence, which can be observed in the IR spectrum by the appearance of another M—Cl stretching vibration at lower wave numbers. This stretching vibration appears to be close to the range of the above mentioned stretching vibrations of the MClM bridge; for the ion $[MoCl_5(NPPh_3)]^-$, for instance, this band is observed at 282 cm^{-1}.[41] The extent of the *trans*-influence of the phosphorane iminato group is comparable with the effect of other π-bonded ligands and ligand groups such as $M{=}\underline{\bar{O}}$, $M{\equiv}N|$, $M{\equiv}\overset{\ominus}{\underline{N}}\overset{\oplus}{R}$, $M{=}\underline{\overset{\ominus}{N}}{=}\underline{\bar{S}}$, $M{=}\underline{\overset{\ominus}{N}}{=}\underline{\overset{\oplus}{O}}$ etc., for which extensive spectroscopic data for comparisons are available.[65]

5.2. *NMR spectra*

NMR spectroscopic investigations for phosphorane iminato complexes are relatively small at present. In addition to the ^{31}P NMR spectra, some ^{14}N NMR spectra have also been measured, as well as ^{95}Mo and ^{51}V NMR (Table 3). ^1H NMR spectra are of secondary importance for the present problem of the phosphorane iminato complexes, they will therefore not be discussed.

In complexes of the type $[Mo(NO)(NPR_3)(dttd)]$,[26] the chemical shifts in the ^{14}N NMR spectra verify the oxidation state (−III) for the nitrogen, and the chemical shifts of the ^{95}Mo NMR spectra verify the oxidation state (+III) for the molybdenum.[26] This corresponds to a transfer of five electrons to one of the nitrosyl nitrogen atoms in the course of reaction (18)—two originate from

the oxidation to the (NPR_3^-) ligand and two to the OPR_3 molecule, one follows from the oxidation of Mo(+II) to Mo(+III).[26] The chemical shifts of the ^{95}Mo NMR signal of [Cl$_3$MoNPh$_2$PNPh$_2$PN][54] and the ^{51}V NMR signal of [Cl$_2$VNPh$_2$PNPh$_2$PN][53] in contrast, prove the oxidation states of (+VI) and (+V), respectively.

The ^{31}P NMR spectra of the phosphorane iminato complexes exhibit a recognizable downfield shift in comparison with the non-metallated species like PhNPPh$_3$ (δ = 17.5 ppm[66]) or $N_3P_3Ph_6$ (δ = 14.3 ppm[67]). The deshielding of the phosphorus nuclei may be a consequence of the electron withdrawing influence of the metal centres, which is also expressed in the short metal–nitrogen bond distances.

In the case of compounds of the type [X$_n$MNPh$_2$PNPh$_2$PN] (X = halogen, n = 2, 3), which are associated by halogen bridges, it can be assumed that monomeric donor–acceptor complexes are formed by treatment with polar solvents like CH_3CN and dimethylformamide. The data of Table 3 for the mentioned types of compounds therefore refer to the corresponding donor–acceptor complexes.

6. BONDING IN THE M—N—P MOIETY

Table 1 shows that most phosphorane iminato complexes fall into two groups, one with an almost linear M—N—P arrangement and bond angles between 161 and 177°, and another with a bent M—N—P moiety and bond angles between 130 and 140°. Two different descriptions of the bonding in the M—N—P groups are therefore necessary. For the more common linear arrangement a possible bonding scheme was already suggested by Phillips and Skapski.[55] The bonding in the bent M—N—P group was briefly explained by Mronga *et al.*[25]

In the case of the almost linear M—N—P arrangement an *sp* hybridization must be assumed for the nitrogen atom, whereas the phosphorus atom is sp^3 hybridized, and the distorted octahedral coordinated metal atom has a d^2sp^3 hybridization using its d_{z^2} and $d_{x^2-y^2}$ orbitals. The M—N—P σ-bonds therefore result from an overlap of these hybrid orbitals leaving the metal d_{xz} and d_{yz} orbitals and the orbitals p_x and p_y of the N atom for the M—N π-bonding. For the P—N π-bonding in a linear arrangement only the d_{z^2} orbital of the P atom is available. The alternative orbital

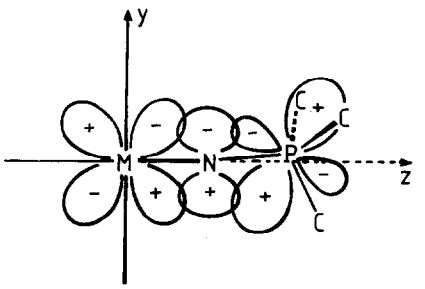

Fig. 9. Bonding situation in phosphorane iminato complexes with a nearly linear arrangement of the group M=N=P. The system of axes refers to the metal and nitrogen atoms only.[55]

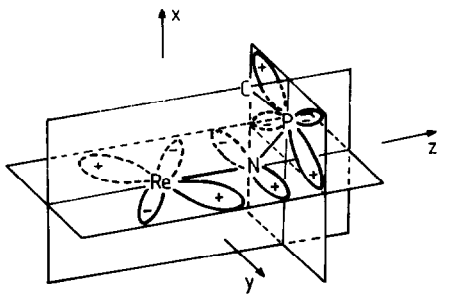

Fig. 10. Bonding scheme in a phosphorane iminato complex with a non-linear arrangement of the group M=N=P. The system of axes of the phosphorus atom is rotated by 45° around the z axis with respect to the system of axes of the metal and nitrogen atom.[25]

$d_{x^2-y^2}$, which could be involved in π-bonding in a tetrahedral coordination, is in this case not correctly disposed to interact with the nitrogen p_x or p_y orbitals.

In Figure 9, a schematic representation of the overlap in the M—N—P π-bonding is given. It results in a three-centre π-bond. In addition to that another perpendicular two-centre M—N π-bond can be formed by the d_{xz} orbital of the metal and the p_x orbital of the nitrogen atom.

A slight displacement of the phosphorus atom from the M—N axis leads to a better overlap of its d_{z^2} orbital with the p_y orbital of the nitrogen atom (Fig. 9). And in fact, such a displacement is always observed, resulting in a bond angle M—N—P between 161 and 177° (Table 1).

In the case of a bent M—N—P arrangement, an sp^2 hybridized N atom can be supposed using the s, p_x and p_z orbitals. An overlap of the p_y orbital of the nitrogen atom with the d_{z^2} orbital of the phosphorus atom to form a N—P π-bond is no longer possible in a bent M—N—P group. Therefore, only the $d_{x^2-y^2}$ orbital remains for π-overlap, as is schematically shown in Fig. 10. Together with the d_{yz} orbital of the metal a three-centre π-bonding again is formed.

However, for an additional two-centre M—N π-bond as in the case of the linear M—N—P group, no suitable orbital is available at the sp^2 hybridized nitrogen atom.

This difference between the bonding in the linear and in the bent M—N—P groups does not strongly influence the M—N and N—P bond lengths, which are in the same range in both arrangements. Therefore steric requirements may be responsible for the different geometries.

(*Received* 3 *November* 1987; *accepted after revision* 15 *August* 1988)

Abstract—From the reaction between *trans*-Ni^{II} bis-thiosemicarbazidate and acetone in basic medium, a brown compound has been shown to be *cis*-Ni^{II} bis-acetone-thiosemicarbazonate by single crystal X-ray determination. The complex consists of two acetonethiosemicarbazonate ligands bonded to the central Ni atom, through S atoms and hydrazinic N atoms, in a *cis*-distorted square structure.

Reactivity of coordinated thiosemicarbazones is thought to be closely related to its biological activity as a chelating agent for trace metals. For instance, Petering *et al.*[1] demonstrated that certain Cu^{II} complexes of thiosemicarbazones were the cytotoxic agents themselves and suggested that the metallic complex could promote the ligand activity. Therefore, studies of chemical reactivity of coordinated thiosemicarbazides (TSC) and thiosemicarbazones are of interest, as they can give information on the mechanism of cytotoxic action.

Several authors have studied the reactivity of coordinated TSC, either by increasing the complexity of the coordination compound,[2] by alkylating[3] or acylating[4] the S atom in Ni derivatives.

Here we report the reaction of [Ni(TSC-H)$_2$] with acetone in basic medium and the molecular and crystal structure determination of the product of the reaction. The obtained brown diamagnetic powder has an IR spectrum corresponding to the product obtained by direct reaction of acetone-thiosemicarbazone (ATSC) with Ni^{II} salts. This suggests that the coordinated TSC gave place to the corresponding thiosemicarbazone by Schiff base condensation of the acetone on the already coordinated hydrazinic nitrogen. Slow evaporation of the mother liquors of the reaction mixture of [Ni(TSC-H)$_2$] with acetone, afford the appropriate crystals for an X-ray diffraction study. The IR spectrum of the crystals is identical with that of the precipitated brown powder. Theoretical calculations using the CNINDO method were carried out, trying to explain the apparent *cis*-structure preference of the product.

EXPERIMENTAL

Compound preparation: TSC and nickel acetate (Aldrich) were used without purification. ATSC was prepared according to Jensen.[5] Ni^{II} bis-thiosemicarbazidate [Ni(TSC-H)$_2$] and Ni^{II} bis-acetonethiosemicarbazonate [Ni(ATSC-H)$_2$] were prepared according to Nardelli.[6] The latter compound was also obtained by the following procedure. A suspension of 1 mmol of [Ni(TSC-H)$_2$] in 50 cm^3 of acetone and 2 cm^3 of 1:5 NaOH in H_2O, was

* Part VI: J. Valdés-Martínez, A. Berruecos and R. A. Toscano to be published in *Afinidad*.

†Author to whom correspondence should be addressed.

refluxed with stirring. After the powder colour changed from brown-greenish to dark brown the reflux was maintained for one more hour. The product was collected by filtration, washed with acetone, ethanol and water and dried *in vacuo* overnight.

A Nicolet FT-SX instrument was used to record the IR spectra on KBr pellets.

The theoretical calculations were carried out with the CNINDO method,[7] using the reported X-ray data for TSC[8] and ATSC,[9] taking out the proton on N(2) and performing a 180° rotation on the N(2)—C bond in order to have the molecules in the chelating geometry.

Crystal data for *cis*-[Ni^{II}(acetonethiosemicarbazonate)$_2$] at 20°C; $a = 16.642(5)$, $b = 6.959(2)$, $c = 12.295(3)$ Å, $\beta = 107.28(2)°$, $V_c = 1359.6(9)$ Å^3, $D_{calc} = 1.56$ g cm^{-3}, $F(000) = 664$, μ(Mo-K_α) = 17.17 cm^{-1}, $Z = 4$, and space group C_c. Using a brown crystal, $0.12 \times 0.22 \times 0.30$ mm, lattice parameters were obtained from 25 machine-centred reflections with $5.1 < 2\theta < 22.0°$ λ(Mo-K_α) radiation, $\lambda = 0.7107$ Å). Reflections in two octants of reciprocal space were measured with an index range of h $0 \rightarrow 18$, k $0 \rightarrow 8$, 1 ± 14, on a Nicolet R3 four-circle diffractometer. Using the ω-scanning mode, variable scan speed and two standard reflections ($1\bar{1}3$; $11\bar{1}$) monitored every 50 measurements. The intensities were corrected for Lorentz and polarization effects and empirical absorption correction based on reflection intensity measurements at different azimuthal angles was carried out. Of the 1025 reflections within the two ranges of 3–45° collected, only 883 had values of $I > 2.5\sigma(I)$ and these were used in the final refinement of structural parameters. The structure was solved by the heavy atom method incorporated by G. N. Sheldrick into the SHELXTL system,[10] and refined by the least-squares technique with anisotropic temperature factors for the non-hydrogen atoms. The H atoms of CH_3 were allowed to ride on bonded C and assigned a fixed isotropic temperature factor, $U = 0.06$ Å^2, $\Sigma w(\Delta F)^2$ minimized, with a statistical weight of the form $w = [\sigma^2(F_o) + 0.0003(F_o)^2]^{-1}$. The final conventional R-factor was 0.028, $R = \Sigma (|F_o| - |F_c|)/\Sigma |F_o|$ and $R_w = 0.031$, $R_w = \{\Sigma [w^{1/2}(|F_o| - |F_c|]/\Sigma w^{1/2}|F_o|\}$ for the correct absolute configuration and $R = 0.038$ and $R_w = 0.045$ for its enantiomorph. Scattering factors and anomalous dispersion corrections for Ni, S, N, O and H were from ref. 11. In the last cycle $(\Delta/\sigma)_{max} = 0.20$; $\Delta\rho$ from -0.20 to 0.26 eÅ^{-3} and isotropic extinction parameter $X = 0.00009$. All computations were performed on a Nova 4S computer and plots drawn on a Tektronix plotter with the SHELXTL system of programs.

Crystal and molecular structure of [Ni(ATSC-H)$_2$]

An ORTEP drawing of the complex is shown in Fig. 1. Relevant bond distances and angles are shown in Table 1. The complex consists of two ATSC groups, each bound to the central Ni atom through the thiol S atoms and the hydrazinic N atoms, yielding two five-membered rings. The four atoms surrounding the Ni^{II} ion are significantly tetrahedrally distorted from the true square-planar configuration, S(1) and N(4) lie 0.287(4) and 0.306(4) Å, respectively above, whilst S(2) and N(1) lie 0.283(4) and 0.308(4) Å, respectively below the NiN_2S_2 mean plane. The Ni—S bond distances of 2.162(2) and 2.166(2) Å are in the range of 2.1–2.3 Å found in four coordinated Ni^{II} complexes, as has been pointed out by Lopez-Castro and Truter.[12] The Ni—N bond distances of 1.921(6) and 1.934(5)

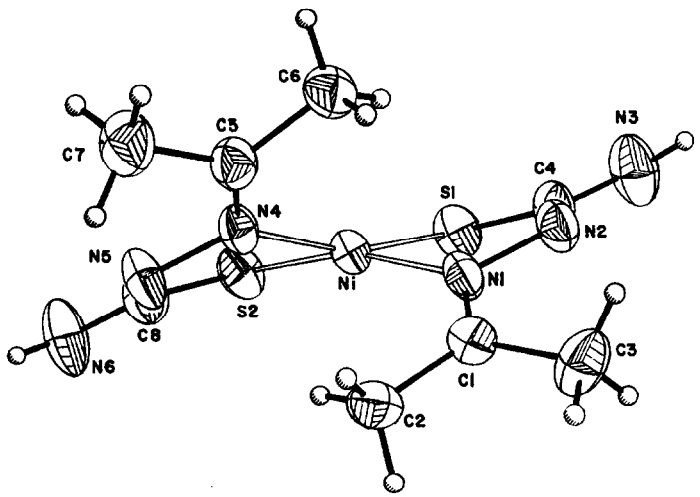

Fig. 1. ORTEP drawing of the [Ni(ATSC-H)$_2$] molecule giving the number scheme for the atoms.

Table 1. Bond lengths (Å) and angles (°) for [Ni(ATSC-H)$_2$]. The ESD's are given in parentheses

Bond lengths			
Ni—S(1)	2.166(2)	Ni—S(2)	2.162(2)

N(4)—C(5)—C(6)	128.7(5)	N(4)—C(5)—C(7)	121.9(6)
C(6)—C(5)—C(7)	117.4(5)	S(2)—C(8)—N(5)	124.1(5)
S(2)—C(8)—N(6)	119.5(6)	N(5)—C(8)—N(6)	116.4(6)

Å are comparable with the value of 1.844(7) Å found in ammine(salicylaldehyde-4-phenylthiosemicarbazonate)nickel(II).[13] The bond distances in the five-membered chelate rings are intermediate between the usual values for single and double bonds, however, both chelate rings deviate considerably from planarity, with the maximum deviations of 0.208(4) and 0.205(4) Å for N(1) and N(4) atoms. The [Ni(ATSC-H)$_2$] molecules are held together in the crystal by both van der Waals and crystal packing forces.

DISCUSSION

To our knowledge this is the first case of a molecular structure determination of a square-planar neutral bis-chelate with *cis*-structure for the ATSC ligand, although compounds with TSC and thiosemicarbazones have been studied since 1934.[14] For example, Jensen obtained "neutral" [Ni(TSC-H)$_2$] and "ionic" [Ni(TSC)$_2$]$^{2+}$ compounds; for the ionic compounds, *cis*- and *trans*-geometries have been assigned by X-ray and IR studies.

The neutral compound [Ni(TSC-H)$_2$], which was our starting material, has a *trans*-geometry according to a single crystal X-ray diffraction study.[15] Considering this fact and the steric hindrance of the isopropylidene groups, which prevents hexacoordination in Ni^{II} and Co^{II} derivatives,[16] one would not expect the resulting product, [Ni(ATSC-H)$_2$], to have *cis*-geometry, although a *trans*-to-*cis* isomerization would be possible. It is interesting to notice, that we were not able to obtain the *trans*-isomer, regardless of the synthetic method used. This may be a consequence of the *cis*-geometry being energetically favoured.

Trying to explain this apparent *cis*-preference we carried out the theoretical calculations of the electronic density on the atoms of both molecules TSC and ATSC using the CNINDO method.[7] The ligands were studied taking out the proton on N(2) and performing a 180° rotation on the N(2)—C bond in order to have the molecules in the chelating geometry. The electronic charges obtained are shown in Fig. 2.

The Ni—S distances in complexes with the TSC ligand, are shorter in the bis-chelate compounds with *cis*-geometry.[17] This might be a result of the stronger *trans*-effect of sulphur over nitrogen which would favour a *cis*-geometry.

In agreement with this, the calculated charge on the sulphur atom is higher than that on the hydrazine nitrogen atom N(1), with a difference of 0.635

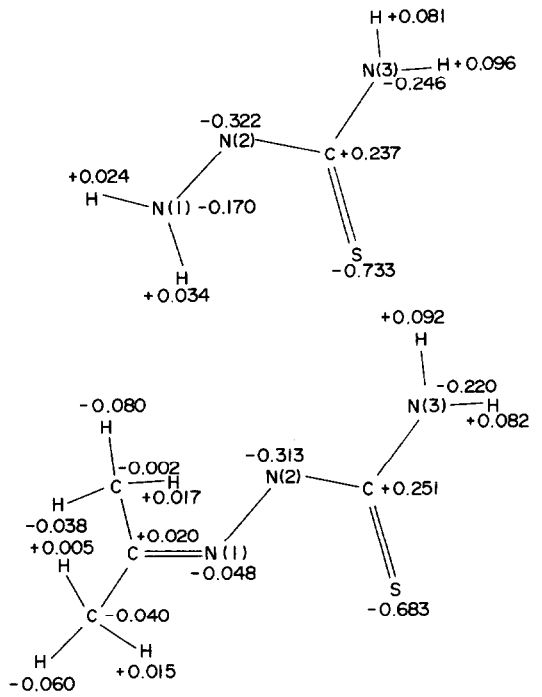

Fig. 2. Electronic charges for the TSC^- and $ATSC^-$ molecules, taking out the proton on N(2) and performing a 180° rotation on the N(2)—C bond.

between them in $ATSC^-$ and of 0.563 in TSC^-, therefore driving the sulphur atom in $ATSC^-$ more strongly than in TSC^-, to look for a geometry which would favour a stronger Ni—S bond.

Acknowledgement—We thank Mrs C. Vázquez for her technical assistance.

Abstract—The cyclic trifluorophosphoranes, $(CH_2)_nPF_3$ (n = 4, 5; **1c** and **1d**) were found to react with 8-trimethylsiloxyquinoline (**2**) with cleavage of the Si—O bond and formation of the mono-substituted derivatives, $(CH_2)_nPF_2(Ox)$, **4** and **5** (Ox = 8-oxyquinolyl). In the case of **4**, intramolecular coordination between the nitrogen atom of the quinolyl group and phosphorus rendering phosphorus hexa-coordinate (λ^6P) has been established by NMR spectroscopy (^{31}P, ^{19}F). By contrast, this type of interaction between N and P is not observed in the case of **5** which is, therefore, a normal substituted fluorophosphorane with λ^5P. Intramolecular coordination, involving λ^6P, is observed, however, in the case of the products originating from the reaction of the trimethylsilyl ester of N,N-dimethylglycine, $Me_2NCH_2C(:O)OSiMe_3$ (**6**) with both PF_5 and $PhPF_4$; it has been indicated for both **7** and **8** by NMR spectroscopy. In the case of **8**, a single crystal X-ray structure determination has confirmed the intramolecular coordination between P and N, with the formation of hexa-coordinate phosphorus.

Fluorophosphoranes, R_nPF_{5-n}, especially tetrafluorophosphoranes (n = 1), and some trifluorophosphoranes (n = 2), and also the parent compound, PF_5, are known to react with ionic nucleophiles, such as halide or pseudohalide[1–12] ions, with the formation of ionic species, involving hexa-coordinated phosphorus.

$$R_nPF_{5-n} + X^- \longrightarrow [R_nPF_{5-n}X]^- \quad (1)$$

n = (0) 1,2.

Similar adducts have also been prepared, involving neutral Lewis bases, e.g. phosphines,[13–15] ethers,[1,16,17] and amines.[16–22]

$$R_nPF_{5-n} + B \longrightarrow R_nPF_{5-n}B \quad (2)$$

n = (0) 1,2.

For the fluorophosphoranes a decrease in the acceptor strength, as the number of the hydrocarbon groups increases, is evident; i.e. the following order has been suggested:

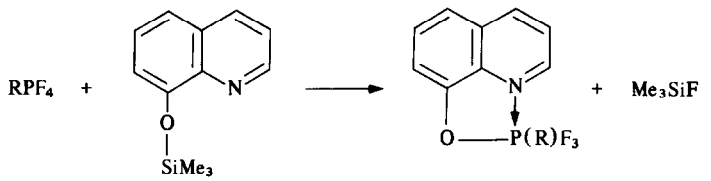
$(PF_5) > ArPF_4 > RPF_4 > Ar_2PF_3 > Ar(R)PF_3 > R_2PF_3$.

* Dedicated to Professor Sir Jack Lewis, FRS on the occasion of his 60th birthday.

** Author to whom correspondence should be addressed.

For the products of this Lewis acid–base interaction more or less strongly distorted octahedral geometry at phosphorus has been assumed, and has been established by NMR[1,3–12,14–16,18,20–22] and crystal structure analyses.[15,22–26]

In addition to these λ^6-fluorophosphates involving an intermolecular donor–acceptor bond some λ^6-fluorophosphates with an intramolecular N → P donor–acceptor bond have been studied. This type of interaction has been observed, e.g. for the products formed in the reaction of 8-trimethylsiloxyquinoline (**2**) (and its 2-methyl derivative) with fluorophosphoranes[27–29] [see eq. (3)]:



(3)

1 **2** **3**

1a R = F **3a** R = F

1b R = Me, Et, Ph **3b** R = Me, Et, Ph

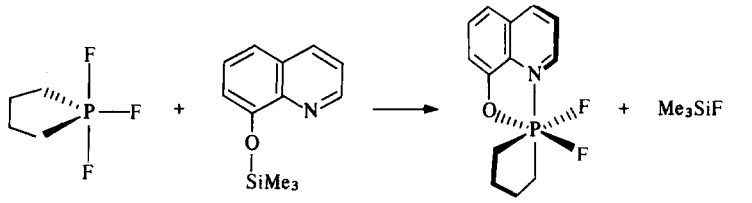
The products were characterized by NMR spectroscopy[27,29] and, in two cases, by single-crystal X-ray diffraction.[27,28] For the intramolecular complexes, obtained in the reaction between PF_5 and $PhPF_4$ with 2-methyl-8-trimethylsiloxyquinoline, distorted octahedral geometry at phosphorus has been established.

RESULTS AND DISCUSSION

Reaction of 8-*trimethylsiloxyquinoline* (**2**) *with the cyclic trifluorophosphoranes,* $(CH_2)_4PF_3$ (**1c**) *and* $(CH_2)_5PF_3$ (**1d**)

For the trifluorophosphoranes, **1c** and **1d**, trigonal–bipyramidal geometry with the $(CH_2)_4$ or $(CH_2)_5$ group attached diequatorially at λ^5P has been established by electron diffraction.[30] Their reaction with **2** was studied, in order to establish if merely substitution products with λ^5P would result, or whether the same type of intramolecular interaction as in **3** would occur.

The reaction of **1c** with **2** (equimolar ratio) was found to furnish **4** in nearly quantitative yield [see eq. (4)].



(4)

1c **2** **4**

In the ^{31}P NMR spectrum (24.3 MHz) of **4** a triplet (^1J(PF) 833) at $\delta_P = -68.3$ has been observed; a high field shift of nearly 100 ppm, compared to **1c** (δ_P 29.8).[31] High field shifts of this magnitude are considered indicative of hexa-coordination at phosphorus.[2,27] In the ^{19}F NMR spectrum of **4** two groups of signals, centred at $\delta_{F(A)} = -17.8$ and $\delta_{F(B)} = -55.2$, were observed. Since the δ_F values are different it is assumed that the two fluorine atoms are not located in *trans* positions at λ^6 phosphorus.

The lines in the ^{19}F NMR spectrum are broad and the P—F coupling constants for the two fluorine atoms are equal, of the order of 825 Hz.

^2J(FF) coupling (43 Hz) has been noted only for the low field resonance, F(A). Apparently ^3J(FH) coupling is observed only for F(B) (cf. Figs 1 and 2), coupling with protons of the CH_2 groups adjacent to phosphorus. F(B) is suggested to occupy a *cis* position, relative to the two CH_2 groups bonded to phosphorus. The smaller coupling between F(A) and the methylene protons suggests that F(A) is located *cis* to only one CH_2 group. ^3J(FH)(*trans*) coupling is not normally observed when ^{19}F and hydrocarbon groups are bonded to octahedral phosphorus.[3,16,24]

At least two possibilities must be considered, therefore, for the geometry of **4** (Figs 1 and 2).

In the X-ray structure investigations of $F_3(Ph)P(OxMe)$[28] and of $Me_2\overline{NCH_2C(:O)OP}(Ph)F_3$ (**8**) (*vide infra*), the phenyl groups were observed in the *trans* position, relative to the coordinatively bound nitrogen atoms. Assuming

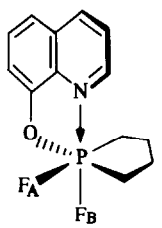


Fig. 1.

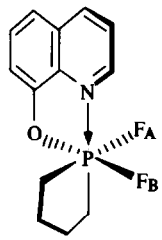

Fig. 2.

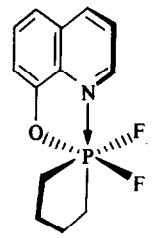

Fig. 3.

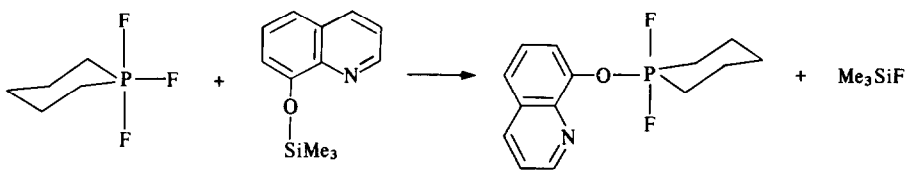
that the CH_2 groups in **4** are located *trans* to nitrogen, a geometry as shown in Fig. 3 is suggested.

Reaction of **1d** *with* **2**: *preparation of* $(CH_2)_5P(Ox)F_2$ **(5)**

In this reaction between equimolar amounts of **1d** and **2**, the formation of **5** in high yield was observed. Multiple substitution, as in the case of the reaction of aryltrimethylsilylethers with fluorophosphoranes,[32] did not occur [see eq. (5)].

Trigonal–bipyramidal geometry at phosphorus is expected for **5**, in contrast to **4**, by analogy to $Me_2P(Ox)F_2$.[27] The reason for this difference is probably the increase in Lewis acidity in **1c**, compared to **1d**, where λ^5P is part of a less strained ring system. Two structures for **5** may be considered (Figs 4 and 5); the arrangement with two axial fluorine atoms (Fig. 5) is expected to be the more stable one.



1d **2** **5** (5)

The δ_P value of **5** (−15.2), was found at only slightly higher field, compared to that of **1d** (δ_P 0.6).[33] It is assumed, therefore, at least for the solution state, that **5** is present as a fluorophosphorane, involving λ^5P, and not λ^6P (with basically octahedral geometry). N → P interactions cannot be excluded, though.

In the ^{19}F NMR spectrum of **5** only a doublet ($\delta_F = -22.4$) is seen, as expected for two equivalent fluorine atoms. The coupling constants, ^1J(PF), from the ^{31}P and ^{19}F NMR spectrum are 736 and 747 Hz, respectively.

Reaction of 2-(*N,N-dimethylamino*)*acetoxytrimethylsilane* **(6)** *with* **1a**: *preparation of* 2-(*N,N - dimethylamino*)*acetoxytetrafluorophosphate*, $Me_2\overline{NCH_2C(:O)OPF_4}$ **(7)**

The reaction occurred, in accordance with eq. (6), over 19 h at room temperature, in nearly quantitative yield,

$$\underset{\mathbf{6}}{Me_2NCH_2C(:O)OSiMe_3} + \underset{\mathbf{1a}}{PF_5} \longrightarrow \underset{\mathbf{7}}{Me_2\overline{NCH_2C(:O)OPF_4}} + Me_3SiF. \quad (6)$$

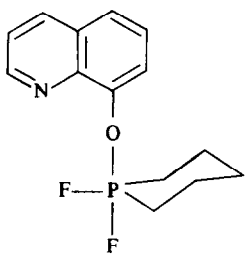


Fig. 4.

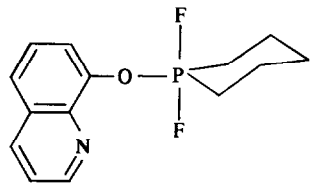

Fig. 5.

Table 1. ^{19}F NMR data of 7 and of $OxPF_4$ (3a)

	$Me_2\overline{NCH_2C(:O)OPF_4}$	$OxPF_4$
		$\delta_{F(A)}$	−65.8 ppm	−51.03 ppm
$\delta_{F(B)}$	−76.8 pm	−75.17 ppm
$\delta_{F(C)}$	−81.4 ppm	−80.52 ppm
$^1J(F_AP)$	851 Hz	787.5 Hz
$^1J(F_BP)$	840 Hz	755.8 Hz
$^1J(F_CP)$	751 Hz	747.9 Hz
$^2J(F_AF_B)$	69 Hz	54.6 Hz
$^2J(F_AF_C)$	47 Hz	50.4 Hz
$^2J(F_BF_C)$	65 Hz	64.1 Hz

In the ^1H NMR spectrum of **7** (recorded at 400 MHz) two groups of signals were observed for both the Me_2N and NCH_2 protons, suggesting octahedral geometry at phosphorus. The magnitude of the HP coupling constants (11.3 and 8.9 Hz) is too high for ^6J(HP) and ^4J(HP), and is taken as an indication of ^3J(HP) coupling, via nitrogen. The fine structure of these resonances is due to coupling, ^4J(HF) to the three fluorine atoms, *cis* to nitrogen. As in the case of $Me_3N \cdot PF_5$[16], $^4J(HF_{trans})$ was not observed. The signal of the NH_2 protons is split into a doublet of quartets. The values of ^4J(HF) are equal (1.8 Hz).

The resonance of the NMe_2 protons appears as two symmetrical groups of signals. Their fine structure is suggested to be caused by the superimposition of two triplets (dt), apparently due to two different coupling constants, ^4J(HF) between the NMe_2 protons and the three *cis* fluorine atoms, as required for octahedral geometry [2.4 Hz for $^4J(HF_A)$ (triplet) and 1.7 Hz for $^4J(HF_B)$ (doublet)]. Assuming octahedral geometry, the fluorine atoms, F_A (with $^4J(HF_A)$ 2.4) should be located *trans* to each other while F_B (with $^4J(HF_B)$ 1.7) is suggested to be located *trans* to oxygen.

The ^{19}F NMR spectrum of **7** was recorded at 56.4 and 94.2 MHz. The resonances in the 94.2 MHz spectrum were assigned as an A_2BCX system. The appearance of the ^{19}F NMR spectrum was similar to that observed for the product, formed in the reaction of phosphorus pentafluoride (**1a**) with 8-trimethylsiloxyquinoline (**2**)[29] (Table 1).

The signals due to F_A and F_B are much broader than the resonance for F_C. This is due, presumably, to coupling ^4J(FH) between F_A and F_B, and NMe_2 and NCH_2 protons.

For some anions with λ^6P, e.g. $[HPF_5]^-$[11], and in the adducts, $Me_3P \cdot PF_5$,[14] $H_3N \cdot PF_5$[23,24] and $Me_3N \cdot PF_5$,[16] the coupling constants, $^2J(HF_{trans})$, $^2J(PF_{trans})$, $^2J(^{14}NF_{trans})$, as well as $^4J(HF_{trans})$ are zero. It is assumed, therefore, that there is no coupling [^4J(FH)] between F_C and NMe_2 and NCH_2 groups. This suggests that F_C is located *trans* to nitrogen.

The δ_P value of **7** (−136.8) reveals a high field shift of 56.5 ppm, compared to PF_5 (**1a**) (−80.3).[34] Similar changes have been observed for the products of the reaction of fluorophosphoranes with **2** and with nitrogen donors, e.g. acetonitrile,[20] and ammonia.[23,24] The magnitude of δ_P is characteristic of λ^6P.

Coupling constants, ^1J(PF) of 844 and 749 Hz, respectively, were observed. In view of the difference between $^1J(F_AP)$ and $^1J(F_BP)$ (11 Hz) a doublet ($^1J(PF_C)$ 749) of quartets ($^1J(PF_{A,B})$ 844) is observed.

The suggested structure of **7** is shown in Fig. 6.

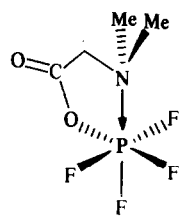

Fig. 6.

Reaction of **6** *with phenyltetrafluorophosphorane* (**1b**) (R = Ph): *preparation of* 2-(*N,N-dimethylamino*) *acetoxyphenyltrifluorophosphate*, $Me_2\overline{NCH_2C(:O)OP}(Ph)F_3$ (**8**)

The reaction was conducted under mild conditions (44 h; room temperature); **8** was obtained [eq. (7)], in nearly quantitative yield.

$$\underset{\mathbf{6}}{Me_2NCH_2C(:O)OSiMe_3} + \underset{\mathbf{1b}}{PhPF_4} \longrightarrow \underset{\mathbf{8}}{Me_2\overline{NCH_2C(:O)OP}(Ph)F_3} + Me_3SiF. \quad (7)$$

As discussed for **7** the HP coupling constants for the Me_2N and NCH_2 resonances are too large for ^6J(HP) and ^4J(HP) (8.7 and 11.1 Hz, respectively) and are caused, presumably, through coupling, ^3J(HP), via nitrogen. Besides this HP coupling, ^4J(HF) coupling (*ca* 1.8 Hz; presumably via nitrogen, too) has been observed in the ^1H NMR spectrum of **8**.

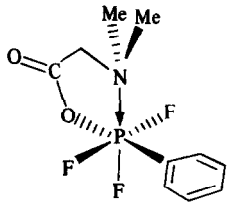

Fig. 7.

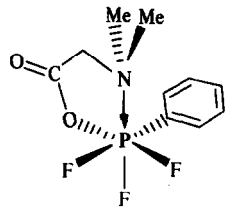

Fig. 8.

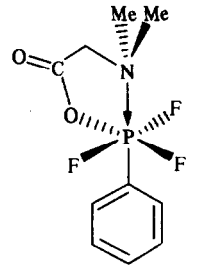

Fig. 9.

The resonances of the ^{19}F NMR spectrum have been assigned as an A_2BX system. The line assignment within the A_2B part was by comparison with published spectra:[35] $\delta_{F(A)}$ −56.1 ppm; $\delta_{F(B)}$ −59.0 ppm; $^1J(F_aP)$ 935 Hz; $^1J(F_BP)$ 935 Hz; $^2J(F_AF_B)$ 68 Hz.

The fact that the ^{19}F NMR spectrum of **8** is represented by an A_2BX spin system may be taken as an indication that the two fluorine atoms F(A), equivalent in the ^{19}F NMR spectrum, are *trans* to each other.

In the ^{31}P NMR spectrum of **8** a quartet at −119.6 ppm ($^1J(PF)$ 959 Hz) indicates a high field shift of 68 ppm, relative to $PhPF_4$ (−51.7),[2] suggesting λ^6P.

Assuming octahedral geometry at λ^6 phosphorus, the three isomers shown in Figs 7–9 are conceivable.

Since the NMR spectroscopic investigation does not allow an unequivocal decision for one of these structures, a single crystal X-ray diffraction study of **8** was conducted (Fig. 10).

The X-ray crystal structure analysis has confirmed the octahedral geometry at λ^6P in **8**, expected on the basis of the NMR investigations. Thus, the phenyl group is *trans* to nitrogen, as in the comparable compound $F_3(Ph)P(OxMe)$.[28] The coordinative P—N bond (201.3 pm) is significantly longer than in other species with λ^6P, e.g. $F_5P \cdot py$,[22] $F_5P \cdot NH_3$[24] and $F_4P(OxMe)$,[27] where bond lengths of 189.9, 184.2 and 191.1 pm, respectively, have been observed. It is suggested that the increase in the P—N bond length in **8** is due to the lower acceptor strength of the $F_3(Ph)PO$ grouping (compared to PF_5 and F_4PO). This becomes apparent upon comparing the P—N bond length in **8** and in $F_3(Ph)P(OxMe)$[28] where the acceptor groups are the same, and the observed bond length, 198.0 pm, is only marginally smaller than that in **8**. The P—F bond lengths in **8** (average 159.8 pm) are slightly increased, with respect to those in $PhPF_4$ (157.4 pm; gas-phase electron diffraction),[36] $[PF_6]^-$ (158 pm),[37] $F_5P \cdot py$,[22] $F_5P \cdot NH_3$[24] and $F_4P(OxMe)$[27] for which average values of 158.7, 159.5, and 158.8 pm, respectively, have been determined by X-ray diffraction. Average P—F bond lengths of 159.8 and 160.4 pm have been observed for the related species $F_3(Ph)P(OxMe)$.[28]

The largest deviation in the bond angles at phosphorus from those expected for ideal octahedral geometry (three 180° angles and 12 90° angles) is found for the angle O(1)—P—F(2) (9.1°).

The angles between the P—C(11) bond and P—F(1), P—F(2), P—F(3) and P—O(1) (93.5, 96.3, 94.2 and 92.7°) reveal a certain distortion of these

bonds towards N(4). A similar distortion has been observed for $F_3(Ph)P(OxMe)$[28] and, to a lesser degree, in other species with λ^6P;[22,24,27] it may be rationalized in terms of Gillespie's VSEPR model.[38,39] Apparently the electron density in the dative N(4)→P bond is more localized at the lighter atom than in the P—C(11) bond (see Table 2).

EXPERIMENTAL

The usual precautions in handling highly deliquescent substances were observed in the course of this work. Solvents were dried by standard procedures.[40]

IR spectra: Beckman instrument no. 4260 A.

The NMR spectra were recorded on the following instruments: Jeol JNMC 60 HL (^{1}H at 60 MHz, ^{19}F at 56.4 MHz, and ^{31}P at 24.3 MHz); Hitachi Perkin–Elmer R 24 B (^{1}H at 60 MHz); Varian CFT 20 (^{13}C at 20.1 MHz); Bruker HM 100 (^{19}F at 94.2 MHz); Bruker WM 400 (^{1}H at 400 MHz, ^{13}C at 100.6 MHz and ^{31}P at 162 MHz). (Internal TMS, internal $CFCl_3$ and external 85% H_3PO_4 references.) High-field shifts are listed with a negative sign, low field shifts with a positive sign. Conversion of shift values:[41] ^{1}H: $\delta_{(TMS)} = \delta_{(CHCl_3)} + 7.27 = \delta_{(CH_2Cl_2)} + 5.30$; ^{19}F: $\delta_{(CFCl_3)} = \delta_{(C_6F_6)} - 163$. The following abbreviations are used in reporting the NMR data: s = singlet; d = doublet; t = triplet; q = quartet; ddt = doublet of doublets of triplets; dq = doublet of quartets; m = multiplet.

Mass spectra: these were recorded on the Varian MAT CH-7 and Finnigan MAT 8430 (direct inlet system 70, eV) instruments.

The following starting materials were synthesized by the literature procedures indicated: 8-trimethylsiloxyquinoline;[42] cyclotetramethylenetrifluorophosphorane;[43,44] cyclopentamethylenetrifluorophosphorane.[43,45]

Reaction of N,N-dimethylglycine, $Me_2NCH_2C(:O)OH$ *with hexamethyldisilazane: preparation of 2-(N,N-dimethylamino)acetoxytrimethylsilane* (**6**)

A mixture, consisting of N,N-dimethylglycine (21.9 g, 0.21 mol), hexamethyldisilazane (22.35 g, 0.14 mol), trimethylchlorosilane (0.2 g, 0.002 mol) and toluene (50 cm^3) was refluxed for 20 h. Subsequently, the mixture was fractionally distilled through a 20 cm column; yield 32.1 g (0.18 mol; 86%); b.r. 51–54°C (9 mm).

$C_7H_{17}NO_2Si$ (175.31). Found: C, 49.1; H, 9.9.

Calc.: C, 48.0; H, 9.7%. ^{1}H NMR spectrum ($CHCl_3$): $\delta_{(CH_3)_3Si}$ 0.13 (s); $\delta_{[-N(CH_3)_2]}$ 2.19 (s); $\delta_{(CH_2)}$ 2.97 (s). ^{13}C NMR spectrum ($CDCl_3$): $\delta_{N(CH_3)_2}$ 2.7 (s); δ_{NCH_3} 46.9 (s); δ_{CH_2N} 63.1 (s); $\delta_{C(:O)}$ 172.8 (s).

Reaction of 8-*trimethylsiloxyquinoline* (**2**) *with* 1.1.1-*trifluoro*-1λ^5-*phospholane*, $(CH_2)_4PF_3$ (**1c**): *preparation of the intramolecularly coordinated adduct*, **4**

A mixture of **2** (7.85 g, 0.036 mol) and 5.29 g (0.037 mol) of **1c** was heated for 14 h at 50°C. After removal of the volatile trimethylfluorosilane (3.3 g, 0.036 mol; 99%) 9.8 g (100%) of a light green solid, very soluble in dichloromethane and acetonitrile, were left. Part of this product, prior to further characterization, was recrystallized from dichloromethane–petroleum ether (40:60); m.r. 137–142°C.

$C_{13}H_{14}F_2NOP$ (269.23). Found: C, 58.1; H, 5.6; P, 11.2. Calc.: C, 58.0; H, 5.2; P, 11.5%. MS: (*m/z*) 269 $[M]^+$ (52%); 125 $[(CH_2)_4PF_2]^+$ (100%). ^{1}H NMR spectrum ($CDCl_3$): $\delta_{(CH_2)_4}$ 0.92–2.30 (m); $\delta_{aryl\text{-}H}$ 6.8–9.2 (m). ^{19}F NMR spectrum ($CDCl_3$): $\delta_{F(A)}$ −17.8, *J*(FP) 825; $\delta_{F(B)}$ −55.2, *J*(FP) 825. ^{31}P NMR spectrum (CH_2Cl_2): δ_P −68.3(t), *J*(PF) 830.

Reaction of 8-*trimethylsiloxyquinoline* (**2**) *with* 1.1.1-*trifluoro*-1λ^5-*phosphorinane*, $(CH_2)_5PF_3$ (**1d**): *preparation of* **5**

As described in the preceding experiment, a mixture of **2** (4.89 g, 0.023 mol) and of **1d** (3.68 g, 0.023 mol) was heated at 50°C for 14 h. After removal of volatile trimethylfluorosilane (2.07 g, 0.023 mol; 100%), 6.4 g (100%) of a colourless solid, very soluble in dichloromethane and acetonitrile, was obtained, part of which was recrystallized from dichloromethane–petroleum ether (40:60); m.p. 97–100°C.

$C_{14}H_{16}F_2NOP$ (283.26). Found: C, 58.2; N, 5.8; P, 10.4. Calc.: C, 59.4; H, 5.7; P, 10.9%. MS: (*m/z*) 283 $[M]^+$ (4%); 139 $[(CH_2)_5PF_2]^+$ (100%). ^{1}H NMR spectrum ($CDCl_3$): $\delta_{(CH_2)_5}$ 1.15–2.20 (m); $\delta_{aryl\text{-}H}$ 7.26–9.10 (m). ^{19}F NMR spectrum ($CDCl_3$): δ_F −22.4 (d), *J*(FP) 734. ^{31}P NMR spectrum (CH_2Cl_2): δ_P −15.2 (t), *J*(PF) 748.

Reaction of phosphorus pentafluoride with 2-(*N,N-dimethylamino*)*acetoxytrimethylsilane* (**6**): *preparation of* 2-(*N,N-dimethylamino*)*acetoxytetrafluorophosphate* (**7**)

Phosphorus pentafluoride (2.05 g, 0.16 mol) was condensed at liquid nitrogen temperature with **6** (2.89 g, 0.16 mol). The reaction mixture was allowed to warm up to room temperature, and was left standing for 19 h. Formation of a light brown solid was observed. After removal of trimethylfluorosilane (1.51 g, 0.16 mol; 99%) 3.4 g (99%) of a light brown solid were left, part of which was recrystallized from dichloromethane–acetonitrile (1:2); m.r. 116–118°C.

$C_4H_8F_4NO_2P$ (209.08). Found: C, 23.0; H, 4.0. Calc.: C, 23.0; H, 3.9%. MS: (*m/z*) 208 $[M—H]^+$ (2%); 58 $[CH_2N(CH_3)_2]^+$ (100%). ^{1}H NMR spectrum (CD_3CN) at 400 MHz: $\delta_{[-N(CH_3)_2]}$ 2.98 (ddt), ^3J(HP) 8.9, $^4J(HF_A)$ 2.4, $^4J(HF_B)$ 1.7; $\delta_{(-NCH_2-)}$ 3.93 (dq), ^3J(HP) 11.3, ^4J(HF) 1.8. ^{13}C NMR spectrum (CD_3CN); (20.1 MHz): $\delta_{[-N(CH_3)_2]}$ 52.02 (d), ^2J(CP) 10; $\delta_{(-NCH_2-)}$ 63.16 (s); $\delta_{C(:O)}$ 167.36(2). ^{19}F NMR spectrum (CD_3CN) at 94.2 MHz: see Table 1. ^{31}P NMR spectrum (CD_3CN) at 162 MHz: δ_P −136.8 (dq), $^1J(PF_{A,B})$ 844, $^1J(PF_C)$ 749.

Reaction of phenyltetrafluorophosphorane with 2-(*N,N-dimethylamino*)*acetoxytrimethylsilane* (**6**): *preparation of* 2-(*N,N-dimethylamino*)*acetoxyphenyltrifluorophosphate* (**8**)

A mixture of phenyltetrafluorophosphorane (4.26 g, 0.23 mol) and 2-(N,N-dimethylamino) acetoxytrimethylsilane (**6**) (3.98 g, 0.23 mol) was allowed to stand at room temperature for 44 h. Formation of a light brown solid was noted. After removal of the volatile product, trimethylfluorosilane (2.10 g, 0.238 mol, 100%), 5.97 g of a light brown solid were left. The product was recrystallized from dichloromethane and was obtained as colourless crystals of m.r. 125–128°C.

$C_{10}H_{13}F_3NO_2P$ (267.19). Found: C, 45.0; H, 5.1. Calc.: C, 44.9; H, 4.9%. MS: (*m/z*) 267 $[M]^+$ (4%); 58 $[(CH_3)_2NCH_2]^+$ (100%). ^{1}H NMR spectrum ($CDCl_3$) at 400 MHz: $\delta_{[N(CH_3)_2]}$ 2.89 (dq), ^3J(HP) 8.7, ^4J(HF) 2.2; $\delta_{(-NCH_2-)}$ 3.62 (dq), ^3J(HP) 11.0, ^4J(HF) 1.8; $\delta_{(aryl\text{-}H)}$ 6.92–7.55 (m). ^{13}C NMR spectrum (CD_3CN) at 20.1 MHz: $\delta_{[N(CH_3)_2]}$ 51.3 (d), ^2J(CP) 4.6; $\delta_{(-NCH_2-)}$ 62.4 (s); $\delta_{o\text{-}aryl\text{-}C}$ 127.6 (d); ^2J(CP) 19.8; $\delta_{o\text{-}aryl\text{-}C}$ 129.3 (d), ^4J(CP) 2.4; $\delta_{m\text{-}aryl\text{-}C}$ 130.8 (d), ^3J(CP) 4.2; $\delta_{ipso\text{-}aryl\text{-}C}$ 142.3 (dq), ^1J(CP) 293, ^2J(CF) 34.4; $\delta_{C(:O)}$ 164.0 (s). ^{19}F NMR spectrum ($CDCl_3$): δ_F(A) −56.1, $^1J(F_AP)$ 935; δ_F(B) −59.0, $^1J(F_BP)$ 935, $^2J(F_AF_B)$ 68. ^{31}P NMR spectrum ($CDCl_3$) at 162 MHz: δ_P −119.6 (q), *J*(PF) 959 Hz.

X-ray analysis. Crystals of **8** obtained by recrystallization from dichloromethane have monoclinic symmetry, space group $P2_1$. The unit cell which has the parameters a = 630.61(6), b = 1044.81(12), c = 937.24(9) pm, β = 108.379(12)°, contains two molecules yielding a calculated density of 1.514 g cm^{-3}. The data were collected at 293 K on a Nicolet diffractometer using graphite-monochromated Cu-

K_α radiation ($\lambda = 154.18$ pm) in the θ–2θ mode in the range $3° \leqslant 2\theta \leqslant 135°$ at a scan speed between 2.93 and 29.30° min^{-1}, depending on the intensity of the reflection.

The data were corrected for Lorentz, polarization and absorption effects ($\mu = 2.269$ mm^{-1}). The structure was solved by direct methods and difference-Fourier syntheses. Hydrogen atoms were localized from difference Fourier maps and refined, together with isotropic temperature factors. The refinement, using 969 out of 1009 measured independent reflections, ($F \geqslant 2.5\sigma(F)$) converged at $R = 0.039$. A final difference map displayed no electron density higher than 0.27×10^6 e pm^{-3}. The program SHELX-76[46] and our own programs (D. Schomburg) were used. Complex atom scattering factors[47] were employed.

(*Received* 17 *March* 1988; *accepted after revision* 29 *September* 1988)

Abstract—From the interaction between N-tosyl-DL-asparagine (TsasnH), N-tosyl-L-glutamine (TsglnH) (tosyl = 4-toluenesulphonyl) and copper(II) ion in aqueous solution, compounds of formula $CuL_2 \cdot XH_2O \cdot YC_2H_5OH$ (L = tosyl-α-aminoacidate monoanion), $Cu(LH_{-1}) \cdot 2H_2O$ (LH_{-1} = tosyl-α-aminoacidate dianion) and $K_2[Cu(LH_{-1})_2]$ were isolated. By potentiometric and spectrophotometric measurements, the number and type of complex species and their cumulative formation constants were determined. The treatment of data confirmed, also in solution, the formation of the complexes separated in the solid state and defined the pH range in which they are stable. The coordination behaviour of these ligands is compared with that of parent amino acids and other N-tosyl-derivatives.

L-Asparagine and L-glutamine form, with Cu^{II} ion complexes of formulae CuL^+ and CuL_2 whose stability constants are slightly lower than those of simple amino acids like glycine, alanine etc.[1,2] and the measurements have also failed to detect stereoselectivity in the formation of bis-chelate complexes,[3,4] confirming the general trend observed for simple amino acids.[3,4] For the asparagine–Cu^{II} system, in the metal–ligand molar ratio of 1:2, above pH 10, deprotonation of the amide function occurs and the formation of a chromophore $CuN_2N_2^-O_2^-$ is supported by the shift of λ_{max} from 620 to 590 nm.[5]

This behaviour is not observed for glutamine as the chelation of the amide nitrogen requires an unfavoured hepta-atomic ring. As a result the solution coordination behaviour of N-acetyl-L-glutamine[6] closely resembles that of other N-acetyl, N-benzoyl and N-benzyloxycarbonyl amino acids and no stable solution species are formed before copper hydroxide precipitation.

On the contrary, the presence of tosyl and dansyl as N-protecting groups of amino acids leads to the formation of very stable mono- and bis(N,O-chelate) copper(II) complexes through the involvement of the carboxyl (primary ligating group) and the deprotonated sulphonamide nitrogen, at acidic or slightly alkaline pH, in aqueous and mixed-alcoholic media.[7]

Thus the introduction of the tosyl group on the amino nitrogen of asparagine and glutamine could affect their coordination properties by modifying the donor ability of the potentially active binding sites.

The results of the solid state and aqueous solution investigations on the Cu^{II}—N-tosyl-DL-asparagine and -L-glutamine are reported here and compared

Structure 1.

with the behaviour of parent ligands as well as other N-tosyl-derivatives (see Structure 1).

EXPERIMENTAL

Reagents

TsasnH and TsglnH were recrystallized from a 1:1 ethanol–water solution and the concentrations of the solution used throughout were tested potentiometrically. Sodium hydroxide carbonate-free 0.09861 mol dm^{-3} (C.Erba) standardized against phtalate (N.B.S.) was used as titrant. Copper(II) perchlorate hexahydrate was from Fluka and the concentration of the stock solution was determined with EDTA.

Potentiometry

Potentiometric measurements were performed under a nitrogen atmosphere ($I = 0.1$ mol dm^{-3}, $NaClO_4$) at 25 ± 0.1°C with the fully automatic Orion 960 Autochemistry system using a Ross 8102SC combined electrode and a Centronics GLPII printer for recording EMF and pH readings and titration curves.[8] The standard electrode potential, E° and the ionic product K_w were determined before and after each experiment by titration of a known amount of $HClO_4$ (0.1 mol dm^{-3}) with NaOH solution.

The overall stability constants ($\beta_{pqr} = [L_pM_qH_r]/[L]^p[M]^q[H]^r$) were refined by the computer program SUPERQUAD[9] with $\sigma_E = 0.3$ (mV error) and $\sigma_V = 0.005$ (volume error). All the calculations were performed on a IBM XT286 personal computer.

Spectrophotometric measurements

Absorption spectra were obtained on a Varian Cary 2300 spectrophotometer. The solutions were scanned by varying the NaOH amount at 25°C using 10 cm cells.

Preparation of complexes

The pale blue $CuL_2 \cdot XH_2O \cdot YC_2H_5OH$ compounds were prepared by mixing 0.015 dm^3 of a hot ethanolic solution (0.2 mol dm^{-3}) of the ligands and 0.02 dm^3 of aqueous copper acetate monohydrate (0.15 mol dm^{-3}) and slowly evaporating the blue solutions. (Found: C, 40.8; H, 5.5; N, 7.4; S, 8.3; solvents, 16.0. Calc. for $Cu(Tsasn)_2 \cdot 2H_2O \cdot 2C_2H_5OH$, $C_{26}H_{42}CuN_2O_{14}S_2$: C, 40.9; H, 5.6; N, 7.3; S, 8.4; solvents, 14.8%. Found: C, 36.9; H, 5.0; N, 7.4; S, 8.2; H_2O, 14.5. Calc. for $Cu(Tsgln)_2 \cdot 6H_2O$, $C_{24}H_{42}CuN_4O_{16}S_2$: C, 37.4; H, 5.5; N, 7.3; S, 8.3; H_2O, 14.0%.)

The compounds $K_2[Cu(LH_{-1})_2]$ were prepared by suspending 1 mmol of the corresponding binary compound in 0.03 dm^3 of a mixture of C_2H_5OH and H_2O (2:1) at 50°C and alcoholic (C_2H_5OH) KOH was added until pH $\simeq$ 11. By standing the deep blue solutions for 12 h at room temperature, blue (TsasnH) and blue-violet (TsglnH) crystals separated. (Found: C, 35.3; H, 3.5; N, 7.5; S, 8.7. Calc. for $K_2[Cu(TsasnH_{-1})_2]$, $C_{22}H_{24}CuK_2N_2O_{10}S_2$: C, 37.2; H, 3.4; N, 7.9; S, 9.0%. Found: C, 38.8; H, 3.7; N, 7.5; S, 8.4. Calc. for $K_2[Cu(TsglnH_{-1})_2]$, $C_{24}H_{28}CuK_2N_2O_{10}S_2$: C, 39.0; H, 3.8; N, 7.6; S, 8.7%.)

The compound $Cu(TsasnH_{-1}) \cdot 2H_2O$ was prepared by mixing 0.005 dm^3 of a methanolic solution (0.5 mol dm^{-3}) of TsasnH with 0.02 dm^3 of aqueous copper acetate monohydrate (0.125 mol dm^{-3}) and adding aqueous NaOH solution until pH = 5.3. On standing for 12 h pale green microcrystalline compounds separated. (Found: C, 34.5; H, 4.3; N, 7.3; S, 8.1. Calc. for $C_{11}H_{16}CuNO_7S$: C, 34.5; H, 4.2; N, 7.3; S, 8.3%.) The same kind of preparation, using TsglnH, did not separate any solid compound.

Physical measurements

The electronic spectra of the solid compounds were recorded as mull transmission spectra on a Varian Cary 2300 spectrophotometer. The IR spectra were recorded with a Perkin–Elmer 180 spectrophotometer on KBr pellets in the 4000–250 cm^{-1} spectral range. The EPR spectra were recorded with a Bruker ER 200-SRC spectrometer.

Analysis

Sulphur, nitrogen, carbon and hydrogen were analysed with a Carlo Erba elemental analyser Model 1106 by Mr G. Goldoni. The water and

solvent contents were determined gravimetrically with thermal analyses performed at a rate of 10°C min^{-1} with a Mettler TA 3000 instrument.

RESULTS AND DISCUSSION

Solid state

The pale blue $CuL_2 \cdot XH_2O \cdot YC_2H_5OH$ complexes show electronic and ESR data (Table 1) which are consistent with a CuO_n ($n = 5,6$) chromophore as found for other structurally known Cu^{II}—N-protected amino acidates.[10,11] In their IR spectra (supplementary material) no changes in band position, with respect to free ligands, are observed except for $\nu(COO)_{as}$ and $\nu(COO)_{sym}$, indicating a bonding mode through the carboxylate group; the presence of coordinated solvent molecules is derived from the strong bands found in the 3550–3470 cm^{-1} spectral range, attributed to ν(OH) absorption.

The pale green $Cu(TsasnH_{-1}) \cdot 2H_2O$ complex displays spectroscopic properties in agreement with a $CuNO_4$ chromophore because of their close similarity to those of the structurally known $[Cu(Ts\text{-}\alpha\text{-}alaH_{-1})(H_2O)_2] \cdot H_2O$, where the Ts-α-alaH$_{-1}$ dianion acts as bidentate chelate in the equatorial plane through deprotonated sulphonamide nitrogen and one carboxylate oxygen.[12] In its IR spectrum, the disappearance of ν(NH) and the shift to lower energy of $\nu(SO_2)$ bands are characteristic of the deprotonated sulphonamide group.

The same holds in IR spectra of bis-potassium salts which should possess two equatorial five-membered NO-chelate rings, as found in all those previously investigated $[Cu(Ts\text{-}\alpha\text{-}aminoacidatoH_{-1})_2]^{2-}$ species,[12] but the unambiguous assignment of a *trans* or *cis* configuration is prevented by the lack of structural data, because sulphonyl and terminal peptide groups both can play a role in determining crystal packing forces; nevertheless on the basis of literature data[13–15] and by comparison with other N-tosyl-α-aminoacidate copper(II) complexes[12,16] the *trans*-configuration is the most probable. For TsglnH complex the electronic and ESR results are consistent with an essentially square-planar geometry with chromophore CuN_2O_2.[12,13] The low energy *d–d* band (640 nm) of $K_2[Cu(TsasnH_{-1})_2]$ complex, close to the value observed for the same system in 1:2 metal–ligand molar ratio, in strongly alkaline solution, is indicative of a tetragonal geometry both in solid and solution states, as found in Cu^{II}–peptide systems.[17] In fact in the IR spectrum, the appearance of a splitting in all the bands assignable to the sulphonamide group (NH, SO_2, SN) suggests a direct involvement of SO_2 in metal coordination as in the homologous tosylglycinate complex.[18]

Solution behaviour

Protonation. Several titrations of the ligands were carried out over a pH range of about 2.8–11.3, with total initial concentrations of the ligands ranging from 4.434×10^{-3} to 8.642×10^{-3} mol dm^{-3} for TsglnH and 5.265×10^{-3} mol dm^{-3} for TsasnH. The dissociation equilibria are represented as follows and the protonation constants are reported in Table 2

$$CH_3C_6H_4SO_2\tilde{N}CHCOO^- + H^+ \overset{\beta_{101}}{\rightleftharpoons} CH_3C_6H_4SO_2NHCHCOO^- \quad (2)$$
$$\quad\quad\quad

Table 2. Proton and Cu^{II} complex stability constants at 25°C and $I = 0.10$ mol dm^{-3} ($NaClO_4$), with estimated standard deviations in parentheses[a]

Complex		TsasnH	TsglnH
L	$\log \beta_{101}$	11.38(2)	11.82(3)
LH	$\log \beta_{102}$	14.58(3)	15.10(3)
	$\log K_2^H$	3.20(2)	3.28(2)
$[CuLH_{-1}]$	$\log \beta_{110}$	9.71(5)	9.03(4)
$[Cu(LH_{-1})_2]^{2-}$	$\log \beta_{210}$	16.53(4)	15.89(2)
$[CuL_2]$	$\log \beta_{212}$	27.13(4)	28.00(10)

[a] The titrations were performed at 1:1, 1:2 and 1:4 metal–ligand ratios; for both ligands, in the 1:1 ratio, the data above pH 6.5 were excluded from calculations because of $Cu(OH)_2$ precipitation.

Complexation. For the Cu^{II}–TsglnH system, all the titrations are quite superimposable on that of the free ligand up to pH 4, suggesting that no complex formation takes place before carboxylate ionization is almost complete. Otherwise, the lowering in pH, clearly observed for 1:2 metal–ligand molar ratio in the Cu^{II}–TsasnH system, suggests that a carboxylate species is formed even at pH 3. For both ligands two pH-metric equivalent points are observed according to the reactions:

$$m_{NaOH} = m_{LH} + m_{Cu}$$

$$m_{NaOH} = m_{LH} + 2m_{Cu}$$

where m is the number of moles and the second equivalent point corresponds to the deprotonation of the bonded ligand. Thus the absence of a further equivalent point excludes the deprotonation reaction of terminal amide nitrogen as well as the formation of tris-chelate complexes.

The analysis of solution spectrophotometric measurements (Table 3) in the case of the Cu^{II}–TsasnH 1:2 system, shows after addition of 1.5 equivalents of base, a band maximum at 750 nm near to the value (745 nm) observed in the solid state in the spectrum of $Cu(TsasnH_{-1})\cdot 2H_2O$. After addition of two equivalents of base, the band maximum shifts to 660 nm, close to the value of 640 nm found for the solid $K_2[Cu(TsasnH_{-1})_2]$, and remains quite constant after addition of three and four equivalents of NaOH. The coordination behaviour of TsglnH is closely similar to that of TsasnH, and is confirmed also in the metal–ligand ratio of 1:4.

The overall stability constants for the solution species taken into account are reported in Table 2 and species distribution curves are shown in Figs 1 and 2 along with those of Cu^{II}–asparagine (asnH) and –glutamine (glnH) systems.[1,19,20]

The log β for mono- and bis-chelate complexes are significantly greater than those of unsubstituted ligands[1,2,19,20] ($\Delta \log \beta = 1.3$–2.2), as found for Cu^{II}–N-tosyl-L-leucinate system,[16] because of the corresponding greater donor ability of the deprotonated sulphonamide nitrogen as compared to amino nitrogen, confirming that, in general, the tosyl group enhances the ligand field strength with respect to unsubstituted amino acids.

The greater stability in the Cu^{II}–TsasnH system as compared to the TsglnH one, may be due to the position of the terminal amide group which, since in TsasnH it is nearer to the sulphonamide nitrogen, causes an enhancement in the inductive electrophilic effect of the sulphonyl group, thus favouring even more the metal-promoted sulphonamide deprotonation. In addition, a possible cooperative contribution from a stereoselective effect of the N-substitution of a bulky group cannot be excluded.[3a] Finally, the substitution of the tosyl group on nitrogen bonded to C^{α} atom, deactivates the terminal amide nitrogen preventing its reaction, contrary to what is found in the simple Cu^{II}–asparagine system. Indeed in the present case the complex anion formed by chelation through the deprotonated terminal amide and sulphonamide nitrogen, would be very unfavoured as the stability deriving from the CuN_4 chromophore is overcome by its unbalanced four negative charges.

Table 3. Position of absorption bands [λ_{max} (nm)] of the solution Cu^{II}–N-tosyl-DL-asparaginate and –N-tosyl-L-glutaminate complexes, $C_{Cu^{2+}} = 1.66 \times 10^{-3}$ mol dm^{-3}

ANIONIC 2,6-PYRIDINEDICARBOXYLATE COMPLEXES WITH SOME DIVALENT FIRST-ROW TRANSITION METALS

LAWRENCE C. NATHAN,* DONALD C. ZAPIEN, ANNE M. MOORING, CHRISTINE A. DOYLE and JULIE A. BROWN

Department of Chemistry, Santa Clara University, Santa Clara, CA 95053, U.S.A.

(*Received* 19 *July* 1988; *accepted* 3 *October* 1988)

Abstract—A series of $Na_2[M(pdc)_2]\cdot nH_2O$ complexes (M = Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, and Zn^{II}; pdc^{2-} = pyridine-2,6-dicarboxylate; n = 2 or 3) have been synthesized and characterized via molar conductance, magnetic susceptibility, IR and electronic spectral measurements, and thermogravimetry. The compounds are 2 : 1 electrolytes in aqueous solution and contain six-coordinate anionic complex ions. The loss of water and the decomposition of the anhydrous salts differ from compound to compound in this series; residues consist of Na_2CO_3 and metal oxide.

Pyridine-2,6-dicarboxylic acid (also known as dipicolinic acid and abbreviated herein as H_2pdc) has been studied extensively as a Lewis base. The interest in this ligand seems to centre on the versatile yet unpredictable manner in which it coordinates to a variety of metals. For example, X-ray studies have shown that complexes such as $Ag(Hpdc)_2\cdot H_2O$[1] and $Cu(Hpdc)_2\cdot 3H_2O$[2] actually contain one neutral H_2pdc and one pdc^{2-} ligand, while $Ni(Hpdc)_2\cdot 3H_2O$[3–5] has two $Hpdc^-$ ligands. In contrast to the tridentate coordination of the ligands in the above complexes, $Hpdc^-$ is bidentate in $V(Hpdc)_3\cdot 3H_2O$.[6] Other types of complexes which have been reported, include some polymeric $M(pdc)\cdot nH_2O$ species (M = Co^{II}, Ni^{II}, Cu^{II}; n = 0, 2, or 3),[7–9] some mixed-ligand complexes with acetylacetonate, 1,10-phenanthroline, 2,2′-bipyridyl, or 2,2′,2″-terpyridyl,[9] a series of $M_2(pdc)(Hpdc)_2\cdot nH_2O$ complexes (M = Co^{II}, Ni^{II}, Cu^{II}; n = 0 or 2),[9] and a series of lanthanide complexes of the types $M(Hpdc)_3\cdot H_2O$ and $M(pdc)(Hpdc)(H_2O)_n$ (n = 4 or 6).[10,11]

Based upon the coordination number of six, commonly adopted by many transition metals, and the ability of pdc^{2-} to function as a tridentate ligand, one expects to find anionic complexes of the type $[M(pdc)_2]^{x-}$ (x = 1 or 2). A number of such complexes has been reported for trivalent metal ions, examples being $Na[M(pdc)_2]\cdot 2H_2O$ (M = Ru^{III}, Ir^{III}),[12] $Na[Cr(pdc)_2]\cdot 1.5H_2O$,[13] $Rh[Cr(pdc)_2]$[14] and some Nd^{III} and Yb^{III} complexes of the type $Na_3[M(pdc)_3]\cdot nH_2O$.[15] Apparently similar anionic complexes with divalent metal ions have not been studied. This work focuses on the series $Na_2[M(pdc)_2]$ where M = Mn^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II}. Other anionic complexes previously reported included $(Ph_4As)_2[U(pdc)_3]\cdot 3H_2O$[16] and $(Ph_4As)_2[UO_2(pdc)_2]\cdot 6H_2O$.[17]

RESULTS AND DISCUSSION

Reaction of divalent metal carbonates and/or hydroxides with H_2pdc in aqueous solution in 1 : 1 or 1 : 2 mole ratios leads to $M(pdc)\cdot nH_2O$ and $M(Hpdc)_2\cdot nH_2O$, respectively,[2,7,8,18] with M = Co^{II}, Ni^{II} and Cu^{II}, and n = 0, 2, or 3. In this work, anionic complexes were prepared in aqueous solution by the reaction of divalent (hydrated) metal acetates, H_2pdc and NaOH in a 1 : 2 : 2 mole ratio. Elemental analyses and thermogravimetric data confirm the stoichiometry of the complexes as $Na_2[M(pdc)_2]\cdot nH_2O$ where M = Mn^{II} and Co^{II} with n = 2, and where M = Ni^{II}, Cu^{II} and Zn^{II} with n = 3. Conductance measurements on 0.001 M aqueous solutions (Table 1) indicate the presence of 2 : 1 electrolytes, for which Λ_M is expected to be in the 230–270 $cm^2\ ohm^{-1}\ mol^{-1}$ range.[19] While the reason for the slightly low values for the Ni^{II} and Cu^{II} complexes is unknown, the behaviour is similar to that observed for the Rh^{III} and Ir^{III}

$Na[M(pdc)_2]$ complexes, where Λ_M values in DMF fell essentially into the non-electrolyte range.[12]

IR data on the solid $Na_2[M(pdc)_2]\cdot nH_2O$ compounds are consistent with coordination of pdc^{2-}. The $\bar{\nu}_{sym}$(COO) band is shifted as expected from the free ligand value of 1290 cm^{-1} into the range 1376–1360 cm^{-1}. Similarly, the $\bar{\nu}_{asym}$(COO) band is shifted from the free ligand value of 1658 cm^{-1} into the range 1629–1613 cm^{-1}, and no bands appear near 1700 cm^{-1} as was the case when $Hpdc^-$ or H_2pdc was also present, such as in complexes of the type $M_2(pdc)(Hpdc)_2$.[9] The shift, $\Delta\bar{\nu}_{asym}$(COO), of about 40 cm^{-1} is consistent with the absence of an extended interaction in which the >C=O group of one ligand interacts with a second metal centre.[12] In addition, the extremely broad band in the 3200–2400 cm^{-1} range due to hydrogen-bonded —COOH groups in H_2pdc is absent in the complexes, further confirming complete deprotonation of H_2pdc. The typical upward shift of major pyridine ring bands is indicative of coordination of the ring nitrogen. A broad band centred at about 3390 cm^{-1} appears in the spectrum of the Ni^{II} and Cu^{II} complexes, due to the presence of the water of hydration. The Mn^{II}, Co^{II} and Zn^{II} complexes show a similar broad band centred around 3200 cm^{-1}, but each displays an additional sharp shoulder at 3534 cm^{-1}.

A coordination number of six suggests a pseudo-octahedral coordination sphere about the metal ions. Room temperature magnetic data (Table 1) are consistent with high-spin six-coordinate $M(pdc)_2^{2-}$ species. The observed magnetic moments are similar to those of $M(Hpdc)_2\cdot 3H_2O$, $M(pdc)\cdot 3H_2O$, M(pdc) and $M_2(pdc)(Hpdc)_2\cdot nH_2O$ ($n = 0$ or 2) species: 5.25–4.54 μ_B for Co^{II}; 3.45–2.85 μ_B for Ni^{II}, and 1.93 μ_B for the latter Cu^{II} complex.[7,9]

Electronic absorption spectra of the $Na_2[M(pdc)_2]\cdot nH_2O$ complexes are summarized in Table 1. The Cu^{II} complex has the single band expected for a six-coordinate d^9 species. Spectra of the Ni^{II} and Co^{II} complexes are also typical of six-coordinate species; most of the absorption peaks have clearly defined shoulders which suggest distortion from octahedral symmetry. The spectra of the latter two complexes are very similar to those reported for the corresponding Ni^{II} and Co^{II} $M(Hpdc)_2\cdot 3H_2O$ complexes.[7]

Several pdc^{2-} and $Hpdc^-$ complexes have been studied via thermogravimetric analysis. The thermogram of $(Ph_4As)_2[UO_2(pdc)_2]\cdot 6H_2O$ showed that water was lost up to about 120°C in three steps (first one, then three, then two moles). The anhydrous salt then decomposed between 250 and 450°C in several steps, proceeding via an intermediate proposed to be UO_2(pdc-Ph)$_2$ after the loss of two moles of $AsPh_3$.[16] Thermograms of the series $M(Hpdc)_2\cdot nH_2O$ (M = Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}; $n = 0$, 2, or 3) were reported by D'Ascenzo *et al.*[18] In air, the hydrates $Co(Hpdc)_2\cdot 3H_2O$, $Ni(Hpdc)_2\cdot 3H_2O$ and $Zn(Hpdc)_2\cdot 2H_2O$ lost all their moles of water in a single step, while $Fe(Hpdc)_2\cdot 2H_2O$ lost its water in two steps. All anhydrous compounds decomposed in two steps yielding the oxides Mn_3O_4, Fe_2O_3, Co_3O_4, NiO, CuO and ZnO. The order of stability was found to be Mn > Fe > Zn > Co > Ni > Cu, the reverse of the Irving–Williams sequence.

For the $Na_2[M(pdc)_2]\cdot nH_2O$ complexes studied here (Table 2 and Fig. 1), the three trihydrates (M = Zn^{II}, Ni^{II}, Cu^{II}) lose water in two steps (first two moles, then one mole). The dihydrates behave differently, with the Mn^{II} complex losing water in a single step and the Co^{II} complex losing it in two steps. There seems to be no correlation of the manner in which the water is lost and the appearance of the bands in the O—H stretching region of the aforementioned IR spectra. Decomposition of the anhydrous salts occurs in two distinct steps for Zn^{II}

and Ni^{II}, in perhaps two overlapping steps for Cu^{II}, and apparently in a single step for Co^{II} and Mn^{II}. The order of stability is Zn > Ni > Mn > Co > Cu, with Ni being out of the position predicted by the reverse Irving–Williams sequence. The residues were identified based on total weight loss (Table 2) and by standard qualitative analysis tests to be mixtures of Na_2CO_3 and the respective oxides ZnO, CuO, NiO, Co_3O_4 and Mn_3O_4.

EXPERIMENTAL

Synthesis of $Na_2[M(pdc)_2]$ *complexes*

The ligand pyridine-2,6-dicarboxylic acid, sodium hydroxide and the hydrated metal acetate salts were AR-grade chemicals and were used without further purification.

Solid NaOH (20 mmol) was dissolved in 75 cm^3 of water and heated to near boiling in a 250 cm^3 round-bottom flask. The ligand H_2pdc (20 mmol) was added with stirring until solution was complete. The appropriate hydrated metal acetate (10 mmol), dissolved in 50 cm^3 of hot water, was added to the basic ligand solution and the mixture was refluxed for 1–2 h. The resulting solution was reduced in volume to less than 50 cm^3 by heating on a steam bath or using a rotary evaporator. Cooling in an ice bath induced crystallization of the crude product. Products were filtered, washed with *n*-butyl alcohol and dried in vacuum over P_2O_5. It was necessary to recrystallize the Ni^{II}, Cu^{II} and Zn^{II} complexes; each compound was dissolved in cold water, filtered to remove unreacted ligand, then evaporated to near dryness to recover the product, which was then washed and dried as described above. Yields were 85–95% for the Co^{II} and Mn^{II} complexes and 50–75% for the others.

Physical and spectral measurements

Magnetic susceptibility measurements were carried out on solid samples by the Gouy method at 294 K and 5400 G. $HgCo(SCN)_4$ was used as calibrant. Diamagnetic corrections were made using Pascal's constants. The temperature-independent paramagnetism correction of 60×10^{-6} cgsu was used for the Cu^{II} complex.

Molar conductance measurements were made on 0.001 M aqueous solutions using a Markson Electromark analyser. Potassium chloride solutions were used as standards.

IR spectra were obtained as KBr pellets in the range 4000–650 cm^{-1} on a Beckman IR-8 spectrophotometer. Electronic absorption spectra were obtained as aqueous solutions (0.014–0.022 M) in the range 1300–340 nm on a Cary 14 spectrophotometer.

Thermogravimetric measurements were made in air on a home-constructed apparatus utilizing an iron-constantan thermocouple, ice-bath reference and a heating rate of 6° min^{-1}.

SPECTROPHOTOMETRIC STUDIES OF THE REACTIONS OF TERTIARY BISDIPHENYLPHOSPHINES $Ph_2P(CH_2)_nPPh_2$ WITH $n = 1$, 2 AND 3 ON DIBROMO-BIS(TRIPHENYLPHOSPHINE)COBALT(II), IN BENZENE SOLUTION. FORMATION OF PENTA-COORDINATED COMPLEXES

JEAN-CLAUDE PIERRARD, JEAN RIMBAULT and RENÉ P. HUGEL*

Laboratoire de Chimie Minérale, Université de Reims Champagne Ardenne, 51062 Reims, France

(*Received* 8 *April* 1988; *accepted* 4 *October* 1988)

Abstract—The reactions of $CoBr_2(PPh_3)_2$ at 25°C in benzene with $Ph_2P(CH_2)_nPPh_2$ with $n = 1$ (dpm), $n = 2$ (dpe) and $n = 3$ (dpp) have been followed spectrophotometrically and by conductivity measurements in CH_2Cl_2. The addition and substitution steps of the bidentate bisphosphines L—L on the initial cobalt complex have been identified and the equilibrium constants calculated at different wavelengths using least squares methods. With dpm, binuclear species are formed in three steps with bridging dpm molecules. With dpe and dpp, two steps are observed with the formation of the final red penta-coordinated complexes $[CoBr(L—L)_2]Br$; the intermediate complexes are different in each case. The overall constant for the equilibrium $CoBr_2(PPh_3)_2 + 2L—L \rightleftharpoons [CoBr(L—L)_2]Br + 2PPh_3$ is 1.06×10^5 for dpe and 1.20×10^3 for dpp, and depends on the size of the chelate rings.

Cobalt(II) halogenide complexes with tertiary phosphines and diphosphines are well known,[1,2] nevertheless, their solution behaviour has not been extensively investigated. After study of the substitution of triphenylphosphine ligands on $CoX_2(PPh_3)_2$ (X = Cl, Br, I and NCS) by triphenylphosphine oxide in benzene[3] or by triphenylphosphinesulphide,[4] we report here the interaction of three tertiary diphosphines $Ph_2P(CH_2)_nPPh_2$, with $n = 1$ (dpm), 2 (dpe) and 3 (dpp), on $CoBr_2(PPh_3)_2$, in benzene in order to establish the nature of the addition or substitution products, to estimate the corresponding equilibrium constants and to compare the chelating effect of the three diphosphines.

EXPERIMENTAL

Materials

$CoBr_2(PPh_3)_2$ was prepared as previously described.[5]

The $Ph_2P(CH_2)_nPPh_2$ ligands ($n = 1$, 2 and 3), purchased from Interchim, were purified by recrystallization in benzene followed by vacuum sublimation. Benzene was distilled over P_4O_{10} and deaerated with a stream of nitrogen. Handling and preparations of solutions were carried out in a glove-box.

Instrumentation

Electronic spectra were recorded on a Beckman 5240 spectrophotometer at 25 ± 0.2°C. The conductivity measurements in CH_2Cl_2 were made with a Tacussel CD 7 instrument at 1000 and 500 Hz.

General procedure

To a benzene solution of $CoBr_2(PPh_3)_2$, increasing amounts of dpm, dpe or dpp were added and the evolution of the electronic spectra followed. The initial benzene solution of $CoBr_2(PPh_3)_2$ always contains an excess of PPh_3 in order to minimize the perturbation due to traces of water, which may be present in the solvent for reasons previously explained.[3a]

*Author to whom correspondence should be addressed.

Moreover, for each equilibrium, the influence on the spectrum of dilution of a solution, with a given ratio R = diphosphine–cobalt, as well as the addition of PPh_3, respectively, gave indications on the variation of the number of involved species, and the possible interference of PPh_3 in the equilibrium.

Conductivity measurements have been made in CH_2Cl_2, (the dielectric constant of benzene being too low), in order to check the stoichiometry of the reactions, taking care in comparing the spectra in CH_2Cl_2 and benzene, to verify the presence or absence of the same species in both solvents.

Coleman, Varga and Mastin's graphical method[6] (further noted as the CVM method) was used to check the number of absorbing species involved in the equilibrium, and present in solution.

List of main symbols

C: analytical cobalt(II) concentration (mol l^{-1}).

R: ratio of analytical concentrations of diphosphine to cobalt.

B: analytical concentration of the excess of PPh_3 added in the initial solution (mol l^{-1}).

α, β, γ: proportion of cobalt engaged, respectively, in the first, second and third formed complex with exclusion of the initial $CoBr_2(PPh_3)_2$.

ε: molar absorptivity of the solution based on C, $\varepsilon = A/l \times C$.

A: absorbance.

l: optical path in cm.

ε_p, ε_1, ε_2, ε_3: molar absorptivities for $CoBr_2(PPh_3)_2$, for the first, second and third complex, respectively.

Calculations

The type of calculations carried out is illustrated in the following example of substitution equilibria between two absorbing complexes 1 and 2 with respective extinction coefficients ε_1 and ε_2. The ligands L and L′ are non-absorbing

$$\text{Complex } 1 + \text{L} \rightleftharpoons \text{Complex } 2 + \text{L}'$$

$$K = (\text{Complex } 2)(\text{L}')/(\text{Complex } 1)(\text{L}) = \frac{\alpha^2}{R(1-\alpha)^2}. \quad (1)$$

For each wavelength λ:

$$\varepsilon = A/C \times l = \varepsilon_1(1-\alpha) + \varepsilon_2\alpha,$$

ε is a linear function of α

$$\varepsilon = \varepsilon_1 + (\varepsilon_2 - \varepsilon_1)\alpha = a\alpha + b.$$

For a given solution ε, C and R are known.

K is calculated in order that the couples (ε, α) give the best straight line at a given value of λ. ε_1 and ε_2 are obtained by the extrapolation of the straight line to $\alpha = 0$ and $\alpha = 1$. Different arbitrary K values are used in relation (1) to yield, for a solution of analytical concentration C and ratio R, a value of α. We then have a series of couples (ε, α) for the n solutions.

By a least-squares method minimizing S, the best straight line going through the points (ε, α) is calculated with $S = \Sigma_1^n (1/\varepsilon^2)(\varepsilon - \varepsilon_{cal})^2$ where ε_{cal} is the calculated molar absorptivity at a given λ, from the straight line $\varepsilon_{cal} = a\alpha + b$. At the minimum of S, $\partial S/\partial a = 0$ and $\partial S/\partial b = 0$ yield a system of two relations with two unknowns, a and b:

$$\sum_1^n \frac{\alpha}{\varepsilon} = a\sum_1^n \frac{\alpha^2}{\varepsilon^2} + b\sum_1^n \frac{\alpha}{\varepsilon^2} \quad \text{and} \quad \sum_1^n \frac{1}{\varepsilon} = a\sum_1^n \frac{\alpha}{\varepsilon^2} + b\sum_1^n \frac{1}{\varepsilon^2}.$$

For each value of K the calculation of $S_{minimum}$ gives the standard deviation $\sigma = \sqrt{S/n-2}$.

The best K will be the one with the lowest σ value, so that the function $\varepsilon = f(\alpha)$ will be the best straight line. Supposing that σ, near its minimum, is at first approximation a second order function of K, the minimum of that function (pit mapping) yields the final best value of K. The K given in the text is this mean value at different wavelengths.

RESULTS AND DISCUSSION

Reaction of dpm *on* $CoBr_2(PPh_3)_2$

The conductivity variation in CH_2Cl_2 of a $CoBr_2(PPh_3)_2$ solution (1.016 mM) by addition of increasing amounts of dpm, shows an increase in conductivity with three breaks at R values of 0.5, 1.2 and 2.4, indicating the possible formation of three successive ionic species, with a dpm/Co stoichiometry of 0.5, 1 and 2, beginning with a dinuclear complex. The conductivity remains close to 20 μS cm^{-1} for $R = 1$. The spectra in CH_2Cl_2 are comparable to the spectra observed in benzene.

1st equilibrium. In benzene, the reaction is slow and the spectra are recorded 24 h after preparation of the solutions. The dilution of a $CoBr_2(PPh_3)_2$ solution ($C = 1.677 \times 10^{-4}$ mol l^{-1}, $B = 1.446 \times 10^{-3}$ mol l^{-1}) with dpm ($R = 0.255$) does not obey Beer's law and the addition of PPh_3 to the solution does not modify the spectra.

The spectra given in Fig. 1 correspond to solutions with a constant cobalt concentration and increasing quantities of dpm. The presence of several isosbestic points (610, 686 and 740 nm) and the application of the CVM method,[6] both indicate the presence of only two absorbing species in equilibrium. The spectrum of the complex formed suggests a C_{3v} symmetry about cobalt.

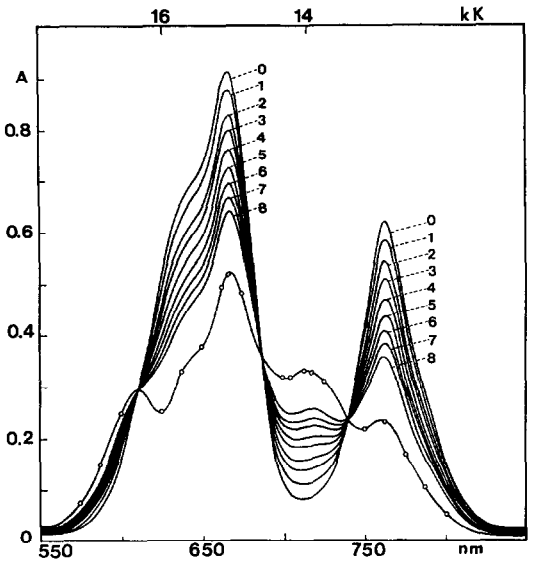

Fig. 1. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpm in benzene ($l = 5$ cm, $T = 25°C$), $C = 0.1677$ mM, $B = 1.446$ mM. Values of R for each solution given in parentheses 0 (0), 1 (0.051), 2 (0.102), 3 (0.153), 4 (0.204), 5 (0.255), 6 (0.306), 7 (0.375), 8 (0.408). ○ calculated spectrum of $Co_2Br_4(PPh_3)_2$(dpm).

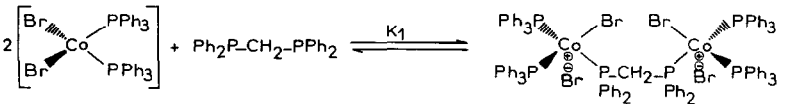
The following equilibrium yielding a dinuclear complex with a bridged dpm, agrees with the preceeding observations:



(2)

The formation of an ionic complex in benzene, undissociated in the form of an ionic pair, is likely in view of the low dielectric constant of the solvent (2.27). Hughes *et al.*[7] showed that at concentrations lower than 10^{-3} mol l^{-1}, the ionic pairs remain undissociated. In CH_2Cl_2 with a higher dielectric constant (9.08) these ionic compounds are slightly dissociated.

The conductivities of 26 different complexes, 1 : 1 electrolytes, in CH_2Cl_2 or $C_2H_4Cl_2$ are comparable (range 17–26 μS cm^{-1})[8] with those observed for our compounds calculated on the basis of one metal atom (22.5 μS cm^{-1}).

Further evidence in favour of the existence of the ionic pairs is the fact that even if the dinuclear complex can be obtained in benzene and remains soluble, it becomes insoluble after it has been crystallized as an ionic compound,.

The expression of the equilibrium constant K_1 is:

$$K_1 = \alpha/C^2(2R-\alpha)(1-\alpha)^2. \quad (3)$$

The molar absorptivities of the solutions are:

$$\varepsilon = A/l \times C = \varepsilon_p(1-\alpha)+\varepsilon_1(\alpha/2). \quad (4)$$

ε is a linear function of the ratio α of the dinuclear compounds formed

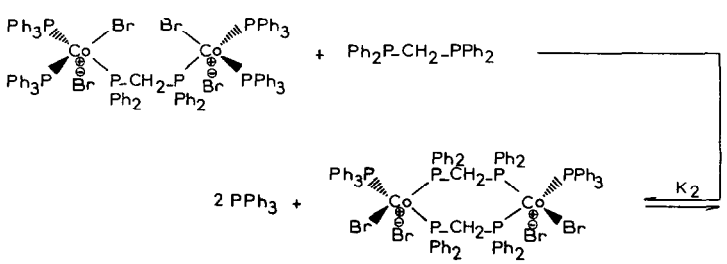
$$\varepsilon = (\varepsilon_1/2-\varepsilon_p)\alpha+\varepsilon_p. \quad (5)$$

A least-squares method gives the value of K_1 at several wavelengths (see Table 1). The mean value is $\bar{K}_1 = (1.73 \pm 0.14) \times 10^9$ mol^{-2} l^2.

From the value of $\bar{K}_1$, the concentrations of the absorbing species in solution are calculated as well as the spectrum of $Co_2Br_4(PPh_3)_2$(dpm) (Fig. 1).

2nd equilibrium. The recorded spectra of solutions with $C = 1.749 \times 10^{-4}$ mol l^{-1}, $B = 1.293 \times 10^{-3}$ mol l^{-1} and different values for $R = 0.766$, 0.958, 1.149 and 1.341, show an isosbestic point at 598 nm. The microsymmetry around cobalt is C_{3v} for the two absorbing species, but their molar absorptivities are close, so dilution of the solution with $0.7 < R < 1.4$ and the addition of PPh_3 are not conclusive. The calculation carried out for the 1st equilibrium is not possible here.

The proposed equilibrium is shown in eq. (6)



(6)

with

$$K_2 = \frac{2C\beta((B/C)+\beta)^2}{(1-\beta)(2R-1-\beta)}. \quad (7)$$

The molar absorptivities of the solutions are:

$$\varepsilon = A/l \times C = \varepsilon_1\left(\frac{1-\beta}{2}\right)+\varepsilon_2\frac{\beta}{2}. \quad (8)$$

ε_1 is known, and ε_2 will be calculated from the next equilibrium (*vide infra*). β is obtained from the experimental ε value, using (8) and K_2 is given by

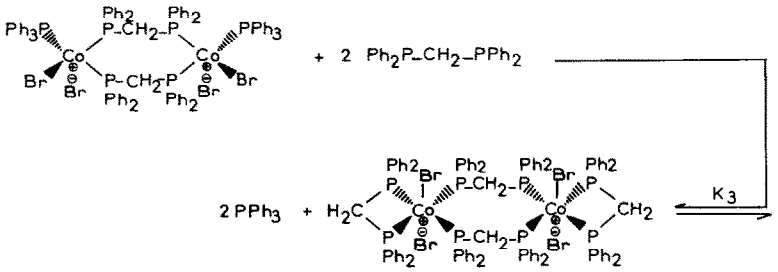
Table 1. Values of K_1 at various wavelengths

λ (nm)	637	650	665	703	715	762.5
K_1 (mol^{-2} l^2)	1.93×10^9	1.61×10^9	1.60×10^9	1.65×10^9	1.94×10^9	1.64×10^9

(7). For four solutions with $\beta = 0.388, 0.567, 0.708$ and 0.795, $\bar{K}_2 = (9.4\pm0.5)\times10^{-2}$ mol l^{-1}.

3rd equilibrium. The spectra of solutions with $5.6 < R < 30.6$ are given in Fig. 2. Application of the CVM method[6] indicates the presence of one equilibrium between two absorbing species. Dilution of solution 4 (Fig. 2) obeys Beer's law. The spectrum of the first species is characteristic for a C_{3v} symmetry, whereas the dark red second species is C_{4v} (square pyramid).

The equilibrium is shown in eq. (9)



(9)

with the following relations

$$K_3 = \frac{\gamma(1+\gamma)^2}{(1-\gamma)(R-1-\gamma)^2} \qquad (10)$$

$$\varepsilon = A/l\times C = \varepsilon_2\left(\frac{1-\gamma}{2}\right)+\varepsilon_3\frac{\gamma}{2} \qquad (11)$$

$$\varepsilon = \frac{(\varepsilon_3-\varepsilon_2)}{2}\gamma+\frac{\varepsilon_2}{2}. \qquad (12)$$

The calculation on eight solutions is similar to that carried out for the first equilibrium. The values at several wavelengths (given in parentheses and in nm) are: K_3: 1.02×10^{-2} (450); 1.01×10^{-2} (462.5); 1.03×10^{-2} (475); 1.05×10^{-2} (487.5); 1.01×10^{-2} (500); 1.03×10^{-2} (512.5); 1.09×10^{-2} (525); 9.84×10^{-3} (537.5); 9.24×10^{-3} (550); 1.02×10^{-2} (625); 1.22×10^{-2} (637.5); 1.20×10^{-2} (650); 1.02×10^{-2} (750) and therefore $\bar{K}_3 = (1.05\pm0.08)\times10^{-2}$.

The spectra of $Co_2Br_2(dpm)_4$ and $Co_2Br_4(PPh_3)_2(dpm)_2$ are then calculated (Fig. 2). ε_2 is used to estimate K_2 (*vide supra*).

Reactions of dpe *on* $CoBr_2(PPh_3)_2$

The conductivity in CH_2Cl_2 of $CoBr_2(PPh_3)_2$ solution (9.861×10^{-4} mol l^{-1}) increases rapidly with the addition of dpe: ionic complexes are

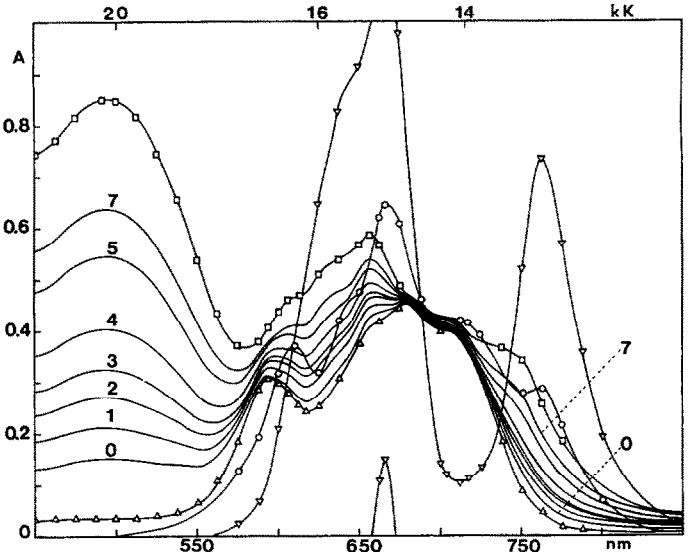


Fig. 2. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpm in benzene ($l = 5$ cm, $T = 25$°C), $C = 0.2119$ mM, $B = 0$. Values of R for each solution in parentheses 0 (5.627), 1 (7.411), 2 (9.196), 3 (10.980), 4 (14.549), 5 (21.687), 6 (25.256), 7 (30.609). ▽: observed spectrum of $CoBr_2(PPh_3)_2$; ○, △, □: calculated spectra for $Co_2Br_4(PPh_3)_2(dpm)$, $Co_2Br_4(PPh_3)_2(dpm)_2$ and $Co_2Br_4(dpm)_4$, respectively.

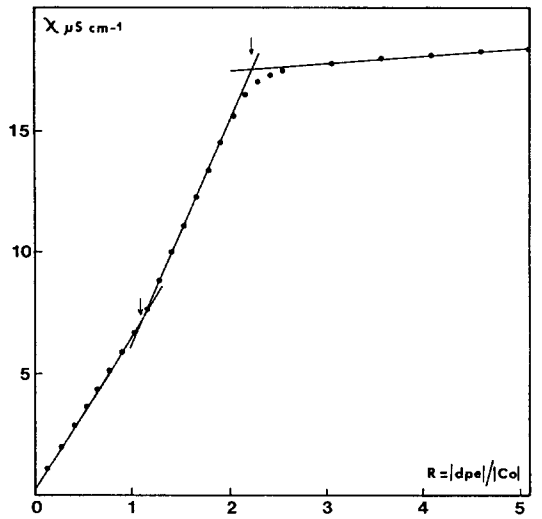

Fig. 3. Conductivity of a 0.9861 mM solution of $CoBr_2(PPh_3)_2$ vs R in CH_2Cl_2 (5000 Hz).

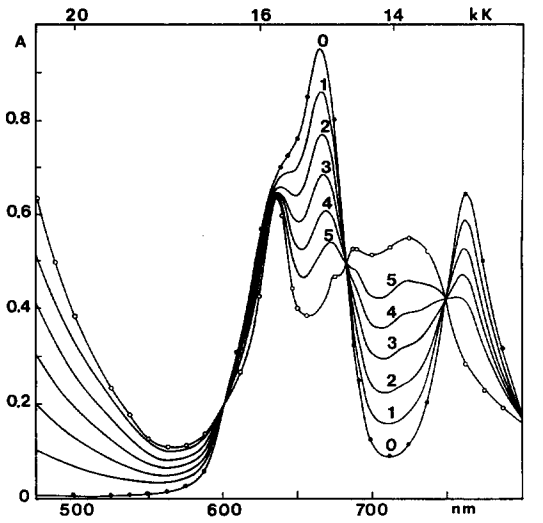

Fig. 4. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpe (l = 5 cm, T = 25°C), C = 0.1789 mM, B = 1.158 mM. Values of R in parentheses 0 (0), 1 (0.161), 2 (0.321), 3 (0.482), 4 (0.643), 5 (0.804), 6 (0.964), 7 (1.125), 8 (1.286). Spectra of solutions 6, 7 and 8 are omitted for clarity of the graph. ● experimental spectrum of $CoBr_2(PPh_3)_2$; ○ calculated spectrum of $CoBr_2(PPh_3)$ (dpe).

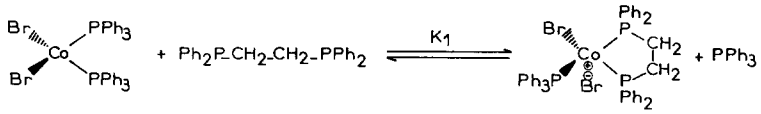
formed (Fig. 3). Breaks are observed at R values close to 1 and 2. The conductivity then remains practically constant for $R > 2.2$ (~ 18 μS cm^{-1}). This implies the formation of complexes with a stoichiometry of 1 and 2 dpe per cobalt. The spectrum in CH_2Cl_2 for the final green complex (R = 2.0) is similar to the one observed by Horrocks *et al.*,[9] with a trigonal bipyramidal coordination around the cobalt. The spectrum of the intermediate complex in CH_2Cl_2 is similar to the one observed in C_6H_6.

1st equilibrium. The spectra for solutions with $0 < R < 1.286$ are given in Fig. 4. Dilution of solution 5 obeys Beer's law; the addition of PPh_3 in this same solution moves the equilibrium towards the formation of the initial reagent $CoBr_2(PPh_3)_2$. The isosbestic points at 601, 683 and 700 nm and the CVM method[6] indicate a simple equilibrium between two absorbing complexes. The proposed equilibrium is:



(13)

with

$$K_1 = \frac{\alpha((B/C)+\alpha)}{(1-\alpha)(R-\alpha)} \qquad (14)$$

and

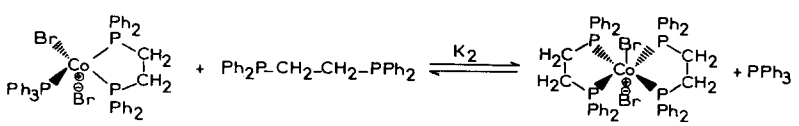
$$\varepsilon = A/l \times C = \varepsilon_p(1-\alpha)+\varepsilon_1\alpha. \qquad (15)$$

ε is a linear function of α

$$\varepsilon = (\varepsilon_1-\varepsilon_p)\alpha+\varepsilon_p. \qquad (16)$$

The values of K_1 obtained by linear regression on nine solutions are (wavelengths in parentheses and in nm) K: 886 (662.5); 897 (700); 899 (712.5); 890 (725) and 895 (762.5) and a mean value $\bar{K}_1 = 893 \pm 5$. $\bar{K}_1$ allows the calculation of the spectrum of $CoBr_2(PPh_3)$(dpe) (Fig. 4).

2nd equilibrium. The spectra of solutions with $1.344 < R < 4.703$ are given in Fig. 5. The final red complex is square-pyramidal. Again the isosbestic points at 622, 647, 685 and 757 nm and the CVM method[6] indicate a simple equilibrium. The equilibrium is concentration independent (solution 5 on Fig. 5 obeys Beer's law) whereas addition of PPh_3 regresses the equilibrium. It can be written as:



(17)

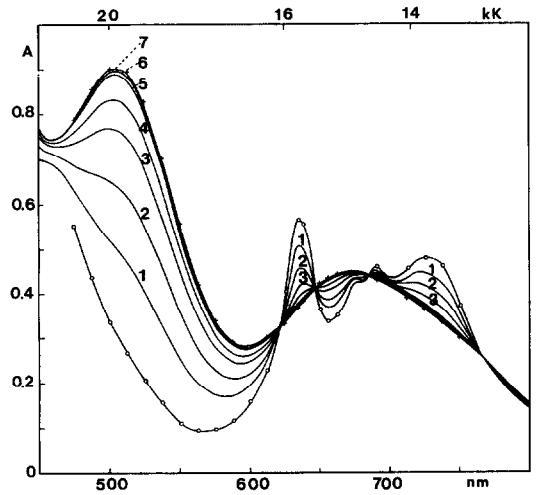


Fig. 5. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpe ($l = 5$ cm, $T = 25°C$), $C = 0.1565$ mM, $B = 1.125$ mM. Values of R given in parentheses 1 (1.344), 2 (1.680), 3 (2.015), 4 (2.351), 5 (3.359), 6 (4.031), 7 (4.703). ○ calculated spectrum of $CoBr_2(PPh_3)$(dpe); + calculated spectrum of $CoBr_2(dpe)_2$.

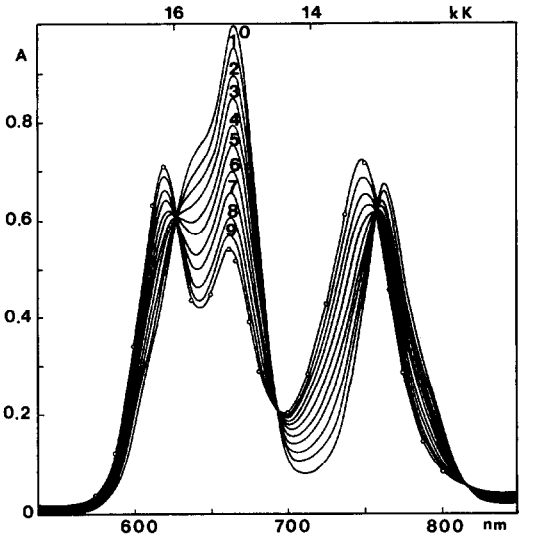

Fig. 6. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpp ($l = 5$ cm, $T = 25°C$), $C = 0.1875$ mM, $B = 1.209$ mM. Values of R given in parentheses 0 (0), 1 (0.106), 2 (0.212), 3 (0.318), 4 (0.425), 5 (0.531), 6 (0.637), 7 (0.743), 8 (0.849), 9 (0.955), 10 (1.062). Spectrum of solution 10 is omitted for clarity of the graph. ○ calculated spectrum of $CoBr_2$(dpp).

with

$$K_2 = \frac{\beta(1+\beta+(B/C))}{(1-\beta)(R-1-\beta)} \tag{18}$$

and

$$\varepsilon = A/l \times C = (\varepsilon_2 - \varepsilon_1)\beta + \varepsilon_1. \tag{19}$$

A linear regression on seven solutions gives the following K_2 values (with wavelengths in parentheses and in nm) K_2: 114 (500); 110 (512.5); 127 (525); 130 (635); 119 (725) and 114 (737.5) and a mean value $\bar{K}_2 = 119 \pm 8$.

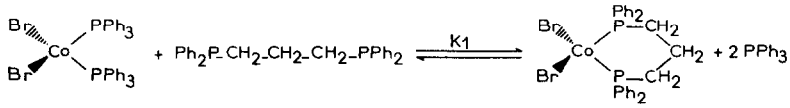
$\bar{K}_2$ allows the calculation of the spectra of the two complexes (Fig. 5). The spectrum of the intermediate $CoBr_2(PPh_3)$(dpe) is the same as the one calculated for the 1st equilibrium (Fig. 4).

complex corresponds to a green trigonal-bipyramidal complex, whereas the intermediate complex has a spectrum similar to the one observed in benzene solution.

1st equilibrium. The spectra for solutions with $0 < R < 1.062$ are shown in Fig. 6. Dilution of solution 7 shifts the equilibrium forward and the addition of PPh_3 shifts the equilibrium towards the starting product, $CoBr_2(PPh_3)_2$.

Again the presence of isosbestic points at 627.5, 694, 758 and 817.5 nm as well as the CVM method[6] indicate an equilibrium involving two absorbing species. The spectrum of the final product corresponds to the same C_{2v} microsymmetry as the starting material.

The equilibrium is:



(20)

Reaction of dpp *with* $CoBr_2(PPh_3)_2$

The conductivity measurements in CH_2Cl_2 show at the beginning, the formation of a non-ionic complex. Starting with $R = 1$, an ionic complex, only slightly dissociated, is formed and a break for $R = 2$ is observed. dpp/Co stoichiometries of 1 and 2 can be proposed. The spectrum in CH_2Cl_2 of the final

with a constant

$$K_1 = \frac{\alpha(2\alpha+(B/C))^2 C}{(R-\alpha)(1-\alpha)} \tag{21}$$

and

$$\varepsilon = A/l \times C = (\varepsilon_1 - \varepsilon_p)\alpha + \varepsilon_p. \tag{22}$$

A linear regression method gives α and K_1 on 10 solutions.

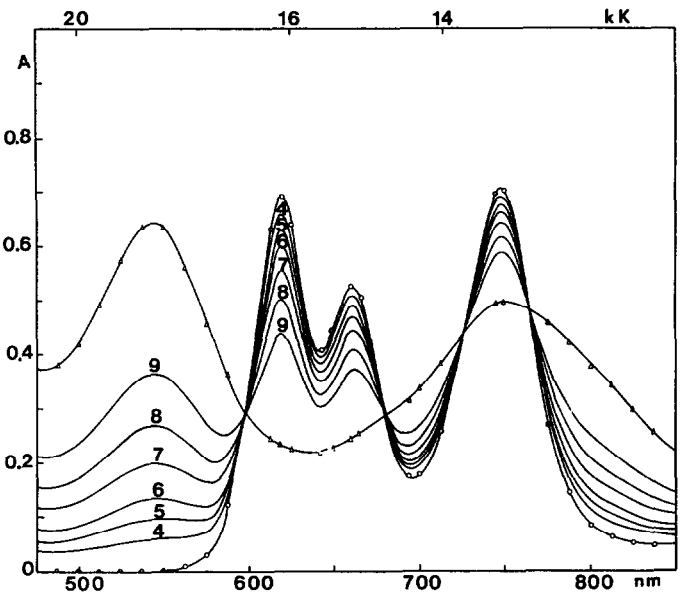


Fig. 7. Solution spectra of $CoBr_2(PPh_3)_2$ with increasing amounts of dpp ($l = 5$ cm, $T = 25°C$), $C = 0.1762$ mM. Values of R given in parentheses 1 (1.103), 2 (1.274), 3 (1.787), 4 (2.812), 5 (4.520), 6 (6.228), 7 (9.645), 8 (14.770), 9 (25.020). Spectra of solutions 1, 2 and 3 are omitted for reasons of clarity. ○ calculated spectrum of $CoBr_2(dpp)$; △ calculated spectrum of $CoBr_2(dpp)_2$.

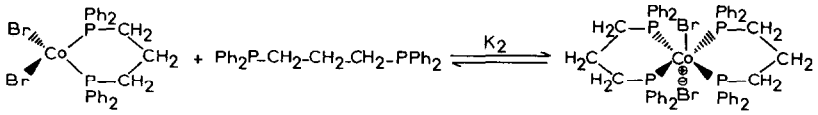
K_1: 3.75 (640 nm); 3.91 (650 nm); 3.62 (662.5 nm) and 4.02 (664 nm) with a mean value $\bar{K}_1 = 3.83 \pm 0.25$ mol l^{-1}.

The spectra calculated using $\bar{K}_1$ are given in Fig. 6.

2nd equilibrium. Spectra of solutions with $1.103 < R < 25.02$ are shown in Fig. 7. Dilution of solution 5 shifts the equilibrium toward the starting material whereas the addition of PPh_3 has no influence on the spectrum.

A new equilibrium between two absorbing species is observed by the presence of isosbestic points at 597.5, 680, 726 and 765 nm and the application of the CVM method.[6] The final spectrum corresponds to a square-pyramidal complex of C_{4v} microsymmetry.

The equilibrium inferred from the preceding observations is:



(23)

with

$$K_2 = \frac{\beta}{(1-\beta)(R-1-\beta)C}. \qquad (24)$$

ε is a linear function of β.

$$\varepsilon = A/l \times C = (\varepsilon_2 - \varepsilon_1)\beta + \varepsilon_1. \qquad (25)$$

The values of K_2 for seven solutions are shown in Table 2, with a mean value $\bar{K}_2 = 312 \pm 10$ mol^{-1} l.

This $\bar{K}_2$ value allows the calculation of the spectrum of the two complexes involved in equilibrium (23). The spectrum of $CoBr_2(dpp)$ is identical to the spectrum calculated for the 1st equilibrium.

CONCLUSIONS

The three bidentate ligands show a different behaviour when they react with $CoBr_2(PPh_3)_2$ in benzene. With a long hydrocarbonic chain, as in dpp ($n = 3$) or in dpe ($n = 2$), coordination around the metal with a six- or five-membered ring is favoured, whereas with a short one as in dpm ($n = 1$), a bridging mode of coordination on two metal atoms occurs, followed by the formation of a four-mem-

Table 2. Values of K_2 at various wavelengths

λ (nm)	525	537.5	550	619	640	662.5	664	748	750	812.5	825
K_2 (mol^{-1} l)	298	289	284	329	323	340	272	312	329	312	335

bered ring without breaking of the established bridges.

The steric hindrance of the diphosphines cannot explain the difference in reactivity. The Tolman cone angles[10] increase only slightly from dpm to dpp (dpm: 121°, dpe 125° and dpp 127°). Nevertheless, dpm is less favoured for chelation than dpe or dpp, because the four-membered ring produced on chelation is considerably strained.

The values of the equilibrium constants, $K_T = K_1 \times K_2$, corresponding to the formation of the final penta-coordinated complex starting with $CoBr_2(PPh_3)_2$ are, respectively, 1.06×10^5 for dpe and 1.20×10^3 for dpp. This order is that expected based on the size of the chelating rings.

In all cases, the final red complex is penta-coordinated with a square-pyramidal geometry containing the $CoBrP_4$ chromophore. These red compounds, obtained in benzene, are no longer soluble after they have been crystallized, owing to their ionic nature in $[CoBr(diphos)_2]^+Br^-$. The square-pyramidal structure allows a close approach of the halogen ion in benzene favouring ion-pair formation.

The interpretation of the electronic spectra will be given in a later publication.

Abstract—The syntheses of 1-amidino-O-alkylurea sulphates and their corresponding copper(II) and nickel(II) complexes are described. These compounds exhibit bi-univalent electrolyte conductances in aqueous solution. The electronic spectra and magnetic moments of the copper(II) and nickel(II) complexes are characteristic of square planar stereochemistry. Vibrational spectra provide useful information regarding ligand bonding sites.

Dicyandiamide (**1**) contains an active nitrile (C≡N) group. In the presence of dilute acid it combines with a molecule of water and is converted into guanylurea, which is also known as dicyandiamidine (**2**), while in the presence of ammonia and amines, biguanide (**3**), a strongly coordinating ligand, is formed.[1] If dicyandiamide is refluxed with alcohol in the presence of a copper(II), nickel(II), or palladium(II) salt, the addition of alcohols to dicyandiamide occurs with the formation of 1-amidino-O-alkylureas (**4**), which are also powerfully coordinating ligands.[2,3]

(R = alkyl group)

(**4**)

In this article we report a study of the preparation and properties of copper(II) and nickel(II) complexes of 1-amidino-O-alkylurea (**4**) (R = C_2H_5 $(CH_3)CH$, *n*-C_5H_{11}, and *n*-C_3H_7).

EXPERIMENTAL

1-*Amidino*-O-n-*propylurea sulphate*, $[AP^nUH]_2 \cdot H_2SO_4 \cdot 2.5H_2O$

The copper(II) complex, $[Cu(AP^nUH)_2](CH_3COO)_2$, was obtained by refluxing dicyandiamide (25 g), copper(II) acetate (25 g), and *n*-propanol (200 cm^3). The solution was cooled in a refrigerator, and the resulting complex acetate was separated by filtration. The rose-red precipitate was dissolved in ethanol, and the resulting solution was treated with an aqueous solution of ammonium sulphate, whereupon the dark red complex sulphate was precipitated. The precipitate was washed and suspended in water (150 cm^3). The copper was removed by precipitation with hydrogen sulphide, and the excess H_2S was removed by passing air through the

* Author to whom correspondence should be addressed.

suspension, which was then filtered. The filtrate was then concentrated to a volume of about 50 cm^3 on a steam bath and cooled in an ice bath. Excess acetone was then added with stirring, whereupon a white crystalline precipitate formed. The sulphate is very soluble in water, sparingly soluble in ethanol, and insoluble in acetone. The sample was dried over $CaCl_2$ at room temperature (yield, 23 g; 36%). Found: C, 28.0; H, 7.2; N, 26.0; SO_4, 22.4. Calc. for $[AA^nUH]_2 \cdot H_2SO_4 \cdot 2.5H_2O$: C, 28.2; H, 7.2; N, 26.2; SO_4, 22.5%.

1-*Amidino*-O-n-*amylurea sulphate* $[AA^nUH]_2 \cdot H_2SO_4 \cdot 3H_2O$

This compound was prepared by refluxing *n*-amyl alcohol (1-pentanol) (200 cm^3), copper(II) acetate (25 g), and dicyandiamide (25 g) as described above for the *n*-propyl derivative (yield, 16 g; 22%). Found: C, 33.9; H, 8.1; N, 22.6; SO_4, 19.2; H_2O, 10.6. Calc. for $[AA^nUH]_2 \cdot H_2SO_4 \cdot 3H_2O$: C, 33.8; H, 8.0; N, 22.5; SO_4, 19.3; H_2O, 10.8%.

1-*Amidino*-O-sec-*butylurea sulphate* $[AB^{sec}UH]_2 \cdot H_2SO_4 \cdot 2H_2O$

This compound was prepared by refluxing *sec*-butanol (150 cm^3), copper(II) acetate (25 g), and dicyandiamide (25 g) as described above for the *n*-propyl derivative (yield, 15 g; 22%). Found: C, 32.1; H, 7.3; N, 24.7; SO_4, 21.3; H_2O, 7.9. Calc. for $[AB^{sec}UH]_2 \cdot H_2SO_4 \cdot 2H_2O$: C, 32.0; H, 7.5; N, 24.6; SO_4, 21.3; H_2O, 8.0%.

Bis(1-*amidino*-O-n-*propylurea*)*copper*(II) *chloride*, $[Cu(AP^nUH)_2]Cl_2 \cdot 2H_2O$

Copper(II) chloride dihydrate (2 g), dicyandiamide (2 g), and *n*-propanol (20 cm^3) were refluxed for 6 h on a steam bath. The violet solution was filtered hot and allowed to stand in a refrigerator for 1 or 2 days, whereupon rose-violet crystals separated. These were collected by suction-filtration and recrystallized either from hot water or from hot ethanol and air-dried (yield, 2.5 g; 46%). Found: Cu, 13.8; Cl, 15.4; N, 24.5; C, 26.5; H, 6.6; H_2O, 7.8. Calc. for $[Cu(AP^nUH)_2]Cl_2 \cdot 2H_2O$: Cu, 13.9; Cl, 15.6; N, 24.6; C, 26.4; H, 6.6; H_2O, 7.9%.

Bis(1-*amidino*-O-n-*propylurea*)*copper*(II) *sulphate*, $[Cu(AP^nUH)_2]SO_4 \cdot 2H_2O$

To an aqueous solution of bis(1-amidino-O-*n*-propylurea)copper(II) chloride, an aqueous solution of potassium sulphate was added dropwise with constant stirring, followed by filtration. After the filtrate was concentrated by evaporation and cooled, reddish crystals separated, which were recrystallized from water and air-dried (yield, 2.5 g; 48%). Found: Cu, 13.2; C, 25.0; H, 6.2; N, 23.4; SO_4, 20.1; H_2O, 7.3. Calc. for $[Cu(AP^nUH)_2]SO_4 \cdot 2H_2O$: Cu, 13.1; C, 24.8; H, 5.8; N, 23.2; SO_4, 20.0; H_2O, 7.5%.

Bis(1-*amidino*-O-n-*propylurea*)*copper*(II) *nitrate*, $[Cu(AP^nUH)_2](NO_3)_2 \cdot 3H_2O$

This compound in the form of rose-violet crystals was prepared in the same way as the chloride compound, except that copper(II) nitrate was used instead of copper(II) chloride (yield, 2.3 g; 30%). Found: Cu, 12.0; C, 22.6; H, 5.6; N, 26.7; H_2O, 10.2. Calc. for $[Cu(AP^nUH)_2](NO_3)_2 \cdot 3H_2O$: Cu, 12.0; C, 22.8; H, 5.7; N, 26.6; H_2O, 10.2%.

Bis(1-*amidino*-O-sec-*butylurea*)*copper*(II) *chloride*, $[Cu(AB^{sec}UH)_2]Cl_2 \cdot 1.5H_2O$

This rose-red compound was prepared in the same way as $[Cu(AP^nUH)_2]Cl_2$ except that *sec*-butanol was used instead of *n*-propanol (yield, 2.4 g; 40%). Found: Cu, 13.2; C, 30.2; H, 6.6; N, 23.3; Cl, 14.9. Calc. for $[Cu(AB^{sec}UH)_2]Cl_2 \cdot 1.5H_2O$: Cu, 13.2; C, 30.1; H, 6.5; N, 23.4; Cl, 14.8%.

Bis(1-*amidino*-O-sec-*butylurea*)*copper*(II) *sulphate*, $[Cu(AB^{sec}UH)_2]SO_4$

This compound in the form of rose-red crystals was prepared like $[Cu(AB^{sec}UH)_2]Cl_2 \cdot 1.5H_2O$ with appropriate modification (yield, 2.6 g; 40%). Found: Cu, 13.3; C, 30.1; H, 6.5; N, 23.6; SO_4, 20.0. Calc. for $[Cu(AB^{sec}UH)_2]SO_4$: Cu, 13.3; C, 30.2; H, 6.5; N, 23.5; SO_4, 20.1%.

Bis(1-*amidino*-O-n-*amylurea*)*copper*(II) *chloride*, $[Cu(AA^nUH)_2]Cl_2 \cdot H_2O$

This compound in the form of rose-violet crystals was prepared in the same way as $[Cu(AP^nUH)_2]Cl_2 \cdot 2H_2O$ except that *n*-amyl alcohol (1-pentanol) was used instead of *n*-propanol (yield, 2.6 g; 46%). Found: Cu, 12.8; C, 33.9; H, 6.9; N, 22.4; Cl, 14.3. Calc. for $[Cu(AA^nUH)_2]Cl_2 \cdot H_2O$: Cu, 12.8; C, 33.8; H, 6.8; N, 22.5; Cl, 14.3%.

Bis(1-*amidino*-O-n-*propylurea*)*nickel*(II) *chloride*, $[Ni(AP^nUH)_2]Cl_2 \cdot 2H_2O$

An aqueous solution of 1-amidino-O-*n*-propylurea sulphate (2.5 g) and nickel(II) sulphate heptahydrate ($NiSO_4 \cdot 7H_2O$) (1.2 g) was made strongly

basic with sodium hydroxide solution, whereupon a yellow complex nickel base was precipitated. This precipitate was filtered and washed several times with water until free of base. The complex nickel base was then triturated with 2 N hydrochloric acid until neutral to litmus paper, and the product was recrystallized as bright yellow crystals from ethanol (yield, 2.3 g; 45%). Found: Ni, 12.8; C, 26.8; H, 6.3; N, 24.8; Cl, 15.8. Calc. for $[Ni(AP^{n}UH)_2]Cl_2 \cdot 2H_2O$: Ni, 13.0; C, 26.6; H, 6.2; N, 24.8; Cl, 15.7%.

Bis(1-*amidino*-O-sec-*butylurea*)*nickel*(II) *chloride*, $[Ni(AB^{sec}UH)_2]Cl_2 \cdot H_2O$

This compound in the form of yellow crystals was prepared like the previous compound with $[AB^{sec}UH]_2 \cdot H_2SO_4 \cdot 2H_2O$ substituted for $(AP^{n}UH]_2 \cdot H_2SO_4 \cdot 2.5H_2O$ (yield, 2.2 g; 40%). Found: Ni, 12.1; C, 25.0; H, 6.3; N, 23.1; Cl, 14.8. Calc. for $[Ni(AB^{sec}UH)_2]Cl_2 \cdot H_2O$: Ni, 12.1; C, 24.9; H, 6.2; N, 23.2; Cl, 14.7%.

Bis(1-*amidino*-O-sec-*butylurea*)*nickel*(II) *hydroxide*, $[Ni(AB^{sec}UH)_2](OH)_2 \cdot 2H_2O$

This yellow compound was prepared by digesting $[Ni(AB^{sec}UH)_2]Cl_2$ with sodium hydroxide solution (yield, 2 g; 80%). Found: Ni, 13.1; C, 32.4; H, 7.5; N, 25.1. Calc. for $[Ni(AB^{sec}UH)_2](OH)_2 \cdot 2H_2O$: Ni, 13.1; C, 32.1; H, 7.6; N, 25.1%.

Bis(1-*amidino*-O-n-*amylurea*)*nickel*(II) *chloride*, $[Ni(AA^{n}UH)_2]Cl_2 \cdot H_2O$

This yellow compound was prepared by triturating $[Ni(AB^{sec}UH)_2](OH)_2$ with dilute (2 N) hydrochloric acid until neutral to litmus and recrystallizing the product from ethanol (yield, 2.1 g; 50%). Found: Ni, 11.9; N, 22.7; C, 34.3; H, 4.5; Cl, 14.3. Calc. for $[Ni(AA^{n}UH)_2]Cl_2 \cdot H_2O$: Ni, 11.9; N, 22.7; C, 34.17; H, 4.4; Cl, 14.3%.

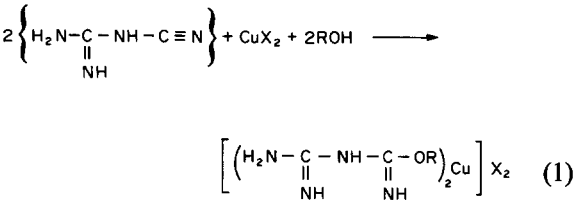
Analysis

The metals were analysed by standard analytical procedures: nitrogen, by the combustion method; carbon and hydrogen, by the Alfred Bernhardt Mikro-Analytische Laboratorium, West Germany; chlorine was determined as silver chloride. Electrical conductances were measured with a Philips PR 9500 conductivity bridge. IR spectra were recorded at the Central Drug Research Institute (Lucknow, India). Magnetic moments were obtained from corrected χ_M values determined by using a Gouy balance with $CuSO_4 \cdot 5H_2O$ as the calibrant. Solution spectra were obtained with a Hilger Uvispec spectrophotometer over the range of 350–1000 nm.

RESULTS AND DISCUSSION

Bis(ligand)copper(II) bases (hydroxides) are rose-red compounds which conform to the anhydro base formulation, indicating that the ligand can behave as a monoprotic acid. All these basic compounds liberate ammonia on treatment with ammonium chloride and can be neutralized with dilute HCl, H_2SO_4, or HNO_3 in alcohol to yield the corresponding salts, i.e. protonation of the free $—NH_2$ group of 1-amidino-O-alkylurea occurs even after complex formation.[1,2] Care was taken in the preparation of the salts with acids; otherwise, the compounds hydrolysed to give the corresponding aqua compound.[1,2]

It is now well established that the metal ion-promoted addition of alcohol to dicyandiamide leads to the formation of 1-amidino-O-alkylurea complexes.[2–6] All the copper(II) and nickel(II) complex bases (hydroxides) were insoluble in water, but the corresponding salts (chloride, bromide, nitrate and sulphate) are soluble in water as well as in methanol, ethanol, N,N-dimethylformamide, dimethyl sulphoxide, and pyridine. As the size of the alkyl group of the ligand increases, the solubility of the complexes in water decreases, while in organic solvents the solubility increases.



The present study shows that the copper(II) ion initiates alcohol (R = $C_2H_5(CH_3)CH$, *n*-C_3H_7, *n*-C_5H_{11}) addition, and the formation of complexes of the types $[CuL_2]X_2$ (X = Cl, NO_3, $0.5SO_4$, CH_3COO, etc.) is evident from the IR spectra of $[CuL_2]X_2$ and other related complexes. There are no typical nitrile bands (—C≡N) due to dicyandiamide at 2176 and 2222 cm^{-1}; instead, we observed a characteristic C—O—R (R = C_2H_5, $CH_3(CH)$, *n*-C_3H_7, and *n*-C_5H_{11}) stretch at about 1200 cm^{-1} and a C—H symmetrical deformation vibration at about 1400 cm^{-1}. There was no >C=O stretch at 1740 cm^{-1}, indicating that the products are not substituted guanylureas.[3]

IR bands appearing around ~ 540 cm^{-1} (s) assigned to ν(Ni—N) and ~ 530 cm^{-1} due to

ν(Cu—N) indicate the coordinate nature of guanidine nitrogen atoms.[7] The non-coordinating nature of the water molecules is confirmed by the absence of any recognized bands for rocking and wagging modes of vibration. Instead, a broad diffuse band around 3500 cm^{-1} indicates the lattice nature of the water molecules. The fact that the anhydrous compound, which shows no such band at about 3500 cm^{-1}, is obtained by heating at 100°C further substantiates this conclusion. In the IR spectra of all the nickel(II) and copper(II) complexes, the bands in the 3μ region arising due to ν_{asy}(N—H) (3300–3390 cm^{-1}) and ν_{sy}(N—H) (3100–3140 cm^{-1}) modes of vibration of the guanyl group[8] are observed almost in the same positions as those in the original ligand molecules, with a slight decrease in intensities, suggesting the participation of ligands in complex formation without deprotonation. The ν(C=N) stretching bands of the guanidine part of all the ligands appearing at 1650 cm^{-1} have been found to experience an average shift of (10±5) cm^{-1}, pointing to the probable participation of the imino nitrogen (=NH) of the guanyl moiety of the ligands in complex formation with the metal(II).[9–11] The IR spectral bands for these three ligands and their probable assignments are given in Table 1. No reaction occurs between dicyandiamide and an alcohol in the absence of copper(II), nickel(II), or palladium(II) ions. In fact, dicyandiamide can be recovered unchanged even after 50 h of refluxing in alcohols.[3,12–14]

Complexes of empirical formula $[CuL_2]X_2$ are biunivalent electrolytes since they exhibit conductance values of the order of 200 Ω^{-1} cm^2 mol^{-1} in aqueous solution at 25°C.[15] All copper(II) complexes show effective magnetic moment values of about 1.73 BM. The electronic spectra of bis(ligand)copper(II) salts show typical absorption bands characteristic of a square planar $[CuN_4]$ chromophore. The data show that the introduction of higher alkyl groups into the ligand has almost no effect on the spectra of either the copper(II) or nickel(II) complexes. For square planar geometry three transitions:

$$d_{xy} \rightarrow d_{x^2-y^2}; \quad d_{xz}, d_{yz} \rightarrow d_{x^2-y^2};$$
$$\text{and} \quad d_{z^2} \rightarrow d_{x^2-y^2},$$

are likely. In most copper(II) chelates these transitions are covered in a somewhat broad envelope. Other square planar $[CuN_4]$ chromophores appear in bis(biguanide)copper(II) (19.2 kK, $\varepsilon = 38.5$ in water),[1,16,17] bis(phenylbiguanide)copper(II) (18.2 kK, $\varepsilon = 65.5$ in water),[1,16] ethylenedibiguanidecopper(II) (19.2 kK, $\varepsilon = 50.5$ in water),[1,16,18] bis(ethylenediamine)copper(II) (18.2 kK, $\varepsilon = 63$

in water),[19] bis(1-amidino-O-alkylurea)copper(II) (18.5 kK, $\varepsilon = 43$ in water),[2,20] tetrakis(benzamidazole)copper(II) perchlorate (19.0 kK, solid state).[21] The absorption bands of bis(1-amidino-O-alkylurea)copper(II) (18.5 kK) indicate that these ligands exert similar crystal field effects on copper(II).[2,19–22] However, in the spectrum of the present bis(ligand)copper(II) chloride, a considerable shift of band positions occurs with change of solvents; the following tetragonality order was observed: water > ethanol > N,N-dimethylformamide (DMF) > dimethyl sulphoxide (DMSO) > pyridine (Py), in agreement with Dutta and De's results.[23]

The spectra of the bis(ligand)nickel(II) compounds in aqueous solution show absorption bands at 22.2 kK (Table 2).[2,18,24] The diamagnetism and band positions of these complexes indicate a square planar configuration.[25–27] In donor solvents such as DMSO, Py, etc., there is a shift of band position compared to that in water (Table 1), unlike that observed in square planar ethylenedibiguanidenickel(II) compounds.[4(a),28]

Since there are no changes in the band maxima of ethylenedibiguanidenickel(II) compounds, the d_{z^2} orbital, which must receive the donor solvents in the *trans* apical sites, is not the orbital immediately lower in energy than the $d_{x^2-y^2}$ orbital. The ordering proposed is $d_{x^2-y^2} > d_{xy} > d_{z^2} > d_{xz}, d_{yz}$. In the present series of complexes the band shift indicates a tetragonality of the complex, and a different *d* orbital order, which is $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xy}, d_{zx}$, with a 22.2 kK band representing a $d_{z^2} \rightarrow d_{x^2-y^2}$ transition.

PREPARATION AND CHARACTERIZATION OF *n*- AND *i*-BUTYLINDIUM THIOLATE*

RYOKI NOMURA,† SHIN'JI INAZAWA, KOUICHI KANAYA and HARUO MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Oka, Suita, Osaka 565, Japan

(*Received* 25 *May* 1988 : *accepted after revision* 11 *October* 1988)

Abstract—Butylindium thiolates $Bu^n_xIn(SR)_{3-x}$ ($x = 0$, R = Pr^n, Ph; $x = 1$, R = Pr^i, Hex^c, Ph; $x = 2$, R = Pr^n, Pr^i, Hex^c, Ph) and $Bu^i_xIn(SR)_{3-x}$ ($x = 1$, R = Ph; $x = 2$, R = Pr^n, Pr^i, Ph) are prepared in the reaction of Bu_3In and corresponding thiols in ether. Monothiolates can be obtained from all Bu_3In–alkanethiol combinations, but di- and trithiolates are isolated only from less hindered ones such as Bu^n_3In–Pr^nSH. While, more acidic benzenethiols can give mono-, di- and trithiolates. The mono- and dialkylthiolates, are distillable liquids and they are charactrized by means of NMR spectroscopy (^1H and ^{13}C). In contrast, the phenylthiolates are solids and have poor solubility in organic solvents. The molecular weight measurements show that the dithiolates are generally monomeric in solution.

Recent advances in the technique of OMCVD for fabricating III/V compound semiconductor materials have prompted work to investigate the nature of trialkyls of indium and their adducts with pnictogen compounds such as phosphines etc.[1–5] However, other fields of organoindium chemistry have remained insufficiently explored. Especially, only limited and non-systematic information is available for organoindium thiolates. Meanwhile, an intense interest has arisen in metal chalcogenides as photovoltaic or optoelectric device materials,[6–9] and we believe that the organometallic thiolates will be the most useful precursors for such chalcogenide materials.

Numerous research groups have reported the preparation of the organoindium thiolates since Coates and Whitecombe synthesized dimethylindium methylthiolate for the first time.[10–15] However, dithiolates were rarely obtained with the exception of dithiochelates.[16,17] In general, it has been found that the only product from the reaction of trialkyls of indium with even excess amounts of acids such as carboxylic acids, was the dialkylindium derivatives.[1] In some cases the elimination of three alkyl groups was possible under forcing conditions but monoalkylindium derivatives could not be obtained. However, the brief report from Kocheshkov *et al.*, where phenylindium derivatives were discussed, indicated that both dialkyl and monoalkylindium thiolates could be synthesized.[18] Also the organoindium thiolates already reported possessed high melting points and were sometimes insoluble in organic solvents. These properties may give rise to difficulties in purification. With the aim of obtaining soluble and/or volatile organoindium thiolates, we report the reactions of Bu^n_3In and Bu^i_3In with several thiols, carried out systematically, and analytical and spectrometric properties of the butylindium thiolates thus obtained.

EXPERIMENTAL

General

^1H and ^{13}C NMR spectra were recorded on a Hitachi R90H FT spectrometer, and the common acquisition conditions were described in the previous papers.[19,20] Coupling constants $^1J(^{13}C–^1H)$ were measured by means of the gated decoupling J-spin modulation mode of the instrument. Molecular weights were measured by cryoscopy in benzene solution. Analytical GLC was carried out with a

Shimadzu GC-8A connected with a glass column (2 mm × 3 m) packed with Porapack N. All the reactions were carried out under a dry N_2 atmosphere unless otherwise noted.

Trialkylindiums

Bu^n_3In and Bu^i_3In were synthesized by the Grignard method as reported previously.[21] Yields of Bu^n_3In and Bu^i_3In were 93 and 68%, respectively. Their boiling points and NMR data are indicated in Table 1.

Butylindium thiolates

Into a solution of the indium trialkyl (5 mmol) in 30 cm^3 absolute ether was added slowly, thiol (5 or 10 mmol) in ether (5 cm^3) at −78°C with stirring. The mixture was then allowed to warm up to room temperature and was stirred for another 6–24 h. If necessary, the solution was heated under reflux for an additional 2–6 h. Solvent and unreacted thiol were removed *in vacuo* and the crude thiolates were purified by vacuum distillation or by recrystallization from ether–hexane. The alkylthiolates were obtained as colourless, viscous oils, while indium tri(phenylthiolate) appeared to be a white powder insoluble in organic solvents. In contrast, Tuck *et al.* have reported that the reaction of indium trichloride with benzenethiol,[23] or of indium with diphenyl disulphide[24] gave soluble indium tri(phenylthiolate).

The prepared alkylindium thiolates are relatively stable in air, compared with the trialkylindiums and alkylindium alkoxides, but have some disagreeable odour. They became glassy in appearance along with a decrease of C and H contents after weeks under moist air.

RESULTS AND DISCUSSION

The reactions of Bu^n_3In and Bu^i_3In with several thiols were carried out as described above and the products and their yields are summarized in Table 2. Additionally, the spectral and analytical data of the isolated thiolates are also displayed in Tables 1 and 3, respectively.

$$R_3In + nR'SH \longrightarrow R_{3-n}In(SR')_n.$$

A dropwise addition of equimolar amounts of thiols into the ether solutions of the trialkyls of indium resulted in a gradual evolution of the corresponding butane isomer which was checked by GLC analysis and dialkylindium thiolates were

[b] Could not be isolated by distillation and NMR yields are presented here.

obtained in good yields. The monoalkylthiolates appeared as viscous liquids and were distillable under reduced pressures. On the other hand, the dialkylindium phenylthiolates were waxy or gummy solids at room temperature which melted as they decomposed. In contrast, more acidic diethyldithiocarbamic acid gave no butylindium derivatives, but a symmetrical indium(III) dithiocarbamate complex was formed as the sole product. It was reported that dialkylindium dithiocarbamates which were synthesized via the metathesis reaction between dialkylindium halides and sodium dithiocarbamate salts were spontaneously converted into the bis(dithiocarbamate) complex.[14] Therefore, in our case, the dialkylindium diethyldithiocarbamate is presumably formed initially and then the tris(dithiocarbamate) complex is obtained via subsequent disproportionation. However, tributylindium could not be detected as a final product as would be predicted by this scheme.

In the reactions where more than two molar equivalents of thiol were employed, the degree of substitution was found to be strongly dependent upon the isomer of the butyl group and/or those of the thiol moieties. Benzenthiol gave Bu^n_2InSPh, $Bu^nIn(SPh)_2$ and $In(SPh)_3$ in the reactions with Bu^n_3In in the molar ratios of 1 : 1, 2 : 1 and 3 : 1, respectively; and Bu^i_2InSPh, and $Bu^iIn(SPh)_2$ in the reactions with Bu^i_3In in 1 : 1 and 2 : 1 molar ratio, respectively. These phenylthiolates are solids at room temperature and poorly soluble in organic solvents.

In contrast, for some reactions with alkylthiols the product expected from reactant stoichiometry was not always obtained. For example, $Bu^n_2InSPr^n$ and $In(SPr^n)_3$ were formed in the reaction of Bu^n_3In with *n*-propanethiol in 1 : 1 and 2–3 : 1 molar ratio, respectively, but $Bu^nIn(SPr^n)_2$ could not be formed with any mole ratio of the starting materials. However, dibutylindium thiolates from the secondary alkanethiols seemed not to react with further thiol nucleophiles. Consequently, it was necessary to use more than the stoichiometric amounts of the thiols in order to prepare the dithiolates. Especially for the bulky triisobutylindium, the replacement of more than two butyl groups did not occur.

These phenomena could not be explained by the

[a] Hex^c means cyclohexyl.

reported bond energy ordering: e.g. $D_1 > D_3 > D_2$ observed for trimethylindium.[17] Perhaps such a disagreement may be related to steric crowding around the indium centre from both alkyl groups bound to the indium atom and the alkyl groups in the thiolate moieties. Therefore, the bulkiness of both alkyl groups and thiolates synergistically affects the degree of the substitution.

Generally the In—S bond is considered to have less dipolar effects than its oxygen analogue and its weak coordination ability has been reported.[1] Thus, several organoindium thio-derivatives are found to be monomeric in solutions. Therefore, we have observed the molecular weights of the following thiolates in benzene solution: $Bu^n_2InSPr^n$, $Bu^n_2InSPr^i$, $Bu^nIn(SPr^i)_2$, $Bu^n_2InSHex^c$, $Bu^nIn(SHex^c)_2$, $Bu^i_2InSPr^n$, and $Bu^i_2InSPr^i$. The observed molecularity is presented in Table 3. These data show that dithiolates are approximately monomeric in the concentration range 0.5–3.0 wt% in benzene but monothiolates of *n*-butylindium have some degree of association. In addition, it is very interesting that 1,2-ethanedithiol gave cyclic dithioindate as a sole product without the formation of the polymers consisting of a dithiol bridge. This cyclic compound was solid at room temperature and although only slightly soluble in most organic solvents, was found to be a dimer in benzene.

The degree of association seemed to depend upon the degree of branching in the indium alkyls and thiolate moieties. Therefore, among the monothiolates the molecularity decreased in the series for the following metal ligand–sulphur ligand combinations: Bu^n–Pr^n > Bu^n–Hex^c > Bu^n–Pr^i = Bu^i–Pr^n > Bu^i–Pr^i. Similarly, it has been reported that alkylzinc thiolates which have branches are liquid and almost monomeric in solution at room temperature, in comparison with the straight chain analogues

which were found to be dimeric to hexameric.[25] In the indium cases, this tendency was also dependent upon the alkyl groups bound to the indium centre.

NMR spectroscopy

^{1}H and ^{13}C NMR data of the compounds are summarized in Table 1. All the measurements were obtained in chloroform-*d* solution (10 wt%). For the solid samples, it was necessary to use more diluted solutions (0.1–1 wt%) because of their low solubilities. In the ^{1}H NMR spectra, the signals due to the α-protons in the butyl groups were generally superimposed on those of terminal methyl protons in the monothiolate compounds. However, those α-proton signals were down field of the terminal signals in dithiolates.

In ^{13}C NMR spectra, the signals due to the α-carbons in the *n*-butyl groups appeared at a slightly higher field than those in the starting Bu^n_3In. While the signals of α-carbons in the *i*-butyl groups appeared at lower fields by *ca* 10 ppm compared with Bu^i_3In. In contrast, an opposite tendency was found in the signals due to the β-carbons. Since isobutylindium thiolates are believed to be monomeric in solution from the molecularity measurements, it can be said that the chemical shifts in the isobutyl group may be affected only by the covalently-bonded sulphur ligands. However, since in the *n*-butyl cases some self-association was observed, the *n*-butyl chemical shifts have been further affected. The above mentioned effect was further supported by the spectrum of thiolate moieties. In this case the signal due to the δ Cl and C2 of the thiolate ligand resembled those of sulphides, not of thiolate anions.[26] These results also indicate the less polar and more covalent nature of In—S bonding in the compounds.

CONCLUSION

In conclusion, *n*- and *i*-butylindium thiolates were easily prepared from the corresponding trialkylindium and thiols. Benzenethiol was found to give mono-, di- and trithiolates. However, it was difficult to control the stoichiometry of the reactions with some alkanethiols and not all substitution products could be isolated.

(*Received* 5 *July* 1988; *accepted* 11 *October* 1988)

Abstract—The preparation and properties of copper(II) complexes of the title ligand (HL) are described and the X-ray crystal structures of $[Cu(HL)_2(NCS)_2]\cdot 2Me_2CO$ and $[Cu_2(HL)_2(L)_2(NO_3)_2]\cdot 4Me_2SO$ where L is the deprotonated form of HL. The crystal structure of $[Cu(HL)_2(NCS)_2]\cdot 2Me_2CO$ shows that HL chelates such that two nitrogen and two oxygen donors are mutually *trans* giving a centrosymmetric structure. The acetone molecules are strongly hydrogen bonded to the hydroxyl protons. In $[Cu_2(HL)_2(L)_2(NO_3)_2]\cdot 4Me_2SO$ the copper atoms are bridged by the O^- of two of the deprotonated ligands, each of which are also chelating. The two copper atoms and two bridging ligands define a plane with the other two ligands lying on the same side of this plane in such a way that the hydroxyl groups point towards each other. This dimeric cation is sited on a two-fold axis. One of the nitrate ions is positioned on the two-fold axis and bridges the hydroxyl groups, but in a disordered way. It is presumably this hydrogen bonding that holds the molecule in such an unusual conformation. The second nitrate ion occupies a cavity in the structure and is hydrogen bonded to an amino hydrogen of the deprotonated ligand.

Our original interest in 2-α-hydroxybenzylbenzimidazole (HL) was based on its reported antiviral activity and the suggestion that this might be related to chelation with trace metals.[1] We therefore synthesized a number of cobalt and nickel complexes with HL.[2] Several of these complexes adopted interesting structures and so it was decided to extend our study and investigate the coordination chemistry of HL with a variety of copper salts.

EXPERIMENTAL

HL was synthesized as described in the literature.[3] Analytical data for the complexes are given in Table 1. Yields of the complexes depended on the extent of solvent evaporation. In all cases the products were filtered off when approximately 2 g had crystallized.

$Cu(HL)_2Cl_2(EtOH)_2$

HL (4.5 g, 0.02 mol) was dissolved in ethanol (50 cm^3) and to this was added a solution of $CuCl_2\cdot 2H_2O$ (1.7 g, 0.01 mol) in ethanol (10 cm^3). On standing in an open flask, bright green crystals formed after several days. These were filtered off and air dried. After analysis a sample of this complex was desolvated by vacuum drying at 80°C to give a dark green solid.

X is Cl, Br or I.

$Cu(HL)_2Br_2(EtOH)_2$

Prepared as for the chloride but using $CuBr_2$ (2.2 g, 0.01 mol) to give green crystals. The desolvated form of this complex is very dark green.

$Cu(HL)_2I_2$

HL (4.5 g, 0.02 mol) and $Cu(ClO_4)_2\cdot 6H_2O$ (3.7 g, 0.01 mol) were dissolved in ethanol (50 cm^3). To this green solution was added KI (3.2 g, 0.02 mol) to give a deep yellow–green solution. This solution was filtered and the filtrate on standing overnight at 0°C produced dark green crystals which were filtered and crushed to give a dark red–brown powder. After analysis, this material was recrystallized from ethanol and the resulting dark brown crystals crushed and dried *in vacuo*.

$[Cu(HL)_2(NCS)_2]\cdot 2Me_2CO$

HL (4.5 g, 0.02 mol) and $Cu(ClO_4)_2\cdot 6H_2O$ (3.7 g, 0.01 mol) were dissolved in acetone (10 cm^3) and to the blue solution was added a solution of KSCN (2 g, 0.02 mol) in acetone (25 cm^3). After standing overnight at 0°C the precipitated $KClO_4$ was filtered off and the filtrate allowed to evaporate in an open petri dish. The green crystals that formed were filtered and recrystallized from acetone. One of these crystals was suitable for the X-ray study. A sample of this complex was vacuum dried at 100°C to give a greenish-brown, acetone-free solid.

$Cu(HL)_2(NO_3)_2$

$Cu(NO_3)_2\cdot 3H_2O$ (2.4 g, 0.01 mol) was dissolved in acetone (20 cm^3) and the solution shaken with 5 g of anhydrous Na_2SO_4. After standing for 1 h this solution was filtered onto HL (2.3 g, 0.01 mol). The resulting clear green solution on standing for several days produced a mass of needle-like green crystals which were filtered and dried *in vacuo* at 100°C. Any attempt to recrystallize this product resulted in the immediate precipitation of a blue solid.

$[Cu_2(HL)_2(L)_2(NO_3)_2]\cdot 4Me_2SO$

As for $CuHL_2(NO_3)_2$, but using only half the quantity of $Cu(NO_3)_2\cdot 3H_2O$ (1.2 g, 0.05 mol) and dissolving HL (2.3 g, 0.01 mol) in acetone (150 cm^3). The blue solid formed was recrystallized from dimethylsulphoxide and one of the crystals used for the X-ray study.

The diffuse reflectance spectra were recorded on a Beckman DK2 spectrophotometer and are given in Table 2. Magnetic measurements (Table 2) were carried out at room temperature on a Gouy balance of conventional design. IR spectra were recorded as Nujol mulls on a Grubb Parsons Mark I grating spectrometer (Table 3). Electrolytic conductances were measured with a Philips PR 9500 Bridge and standard cell (Table 3).

X-ray crystallography

Crystals of both compounds were sealed in thin-walled glass capillaries to guard against solvent loss. Following preliminary photography, unit cell and intensity data were obtained using a CAD4 diffractometer, graphite monochromated Mo-K_α radiation ($\lambda = 0.70169$ Å) according to previously detailed procedures.[4] The structures were solved via

standard Patterson and heavy atom methods and refined via full-matrix least-squares methods, using programs listed previously.[4]

Crystallograhic data

Compound **1**. $C_{36}H_{36}N_6O_4S_2Cu_2$, $M_r = 744.39$, monoclinic, $a = 8.696(9)$, $b = 11.052(4)$, $c = 19.105(7)$ Å, $\beta = 85.24(5)°$, $U = 1829.7$ Å^3, space group $P2_1/n$, $Z = 2$, $D_c = 1.35\,g\,cm^{-3}$, $\mu(Mo\text{-}K_\alpha) = 7.0\,cm^{-1}$. 3627 reflections measured ($1.5 \leqslant \theta \leqslant 25$), 3219 unique, 2123 observed [$I > 1.5\sigma(I)$]. Final R, R_w values were 0.047 and 0.045, for 237 parameters; non-hydrogen atoms were anisotropic, hydrogens in fixed positions with group U_{iso} values.

Compound **2**. $C_{64}H_{70}N_{10}O_{14}S_4Cu_2$, $M_r = 1442.62$, monoclinic, $a = 15.932(8)$, $b = 9.227(1)$, $c = 21.180(2)$ Å, $\beta = 98.51(3)°$, $U = 3079.2$ Å^3, space group $P2_1/n$, $Z = 2$, $D_c = 1.40$ g cm^{-3} $\mu(Mo\text{-}K_\alpha) = 7.9\,cm^{-1}$. 5340 reflections measured ($1.5 \leqslant \theta \leqslant 24$), 4813 unique, 2725 observed [$I > 1.5\sigma(I)$]. Final R, R_w values were 0.069 and 0.057, for 436 parameters. Non-hydrogen atoms were refined anisotropically, hydrogens inserted in ideal positions and refined with group U_{iso} values, riding on parent C or N atom. The nitrates are both disordered and component atoms were assigned relevant fractional occupancy (see Discussion). Sources of scattering factor data and computer programs used are as in ref. 4. Tables of atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure of $[Cu(HL)_2(NCS)_2]\cdot 2Me_2CO$ is shown in Fig. 1. The molecule lies on a centre of symmetry with the O, N chelate ligands thus arranged to give mutually *trans*-O, O and -N, N and with *trans*-N-bonded thiocyanates. Selected bond lengths and angles are given in Table 4. The Cu—N bond lengths to HL are slightly longer than those to the thiocyanates. The usual Jahn–Teller distortion for the octahedral copper(II) species results in considerable lengthening of the Cu—O bonds. It is possible that this lengthening in also aided by the

formation of hydrogen bonding interactions between the hydroxy hydrogens and the oxygens of acetone solvate molecules (see Fig. 1). The material obtained by desolvation of the acetonate has different electronic, spectral and magnetic properties (Table 2) and IR spectra (Table 3). These would seem to indicate a complex with a structure more radically different from Fig. 1 than just the absence of acetone, for example, a magnetic moment of 1.43 BM is indicative of some interaction between the copper ions. However, during the preparation of $[Cu(HL)_2(NCS)_2]\cdot 2Me_2CO$ it was observed that

decomposition took place if the solution was left standing for more than 2 or 3 days, and it could be that during desolvation at 100°C partial decomposition takes place to give a copper(I) species.

The structure of $[Cu_2(HL)_2(L)_2(NO_3)_2]\cdot 4Me_2SO$ is shown in Fig. 2. Selected bond lengths and angles are given in Table 5. The dimeric cation has a structure analogous to that found in the perchlorate complex.[5] On each copper atom, an anionic ligand is chelating through an imino nitrogen and the deprotonated hydroxy oxygen. This oxygen also bridges to the other copper atom, and two such interactions lead to the formation of a four-membered $[CuO]_2$ ring. The second ligand on each copper is then chelating such that one imino nitrogen lies in the dimer plane and completes a distorted square coordination, and the hydroxy oxygen coordinates through an axial site to give

[a] Atoms Cu(1a) and O(28a) are related to the parent atoms by the symmetry operation $2-x, -y, 1-x$.

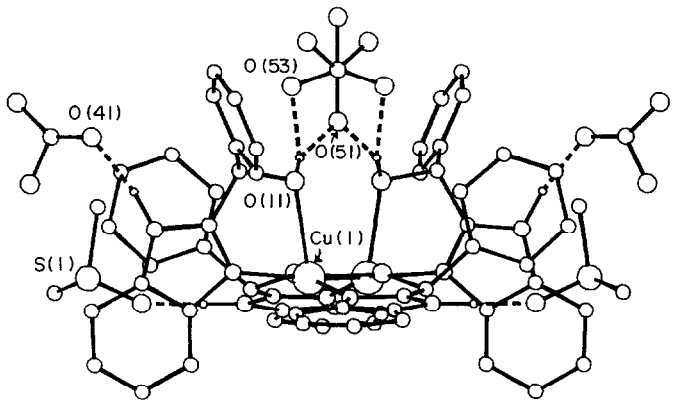

Fig. 3. A view of the dimer $[Cu_2(HL)_2(L)_2(NO_3)_2]\cdot 4Me_2SO$ perpendicular to the two-fold axis.

distorted square pyramidal geometry. The two axial CuO bonds lie on the same side of the dimer plane and the dimer has C_2 symmetry. One of the nitrate groups lies on the dimer (and crystallographic) two-fold axis and hydrogen bonds to the coordinating hydroxy groups' hydrogens, but in a disordered manner so that in half of the molecules the two OH hydrogens are bridged by one nitrate oxygen and in the other half by two nitrate oxygens. This is shown in Fig. 2. An analogous situation occurred with the perchlorate,[5] and it is quite possible that this is a structure-determining feature. The second nitrate is also disordered and is sited close to a further two-fold axis in the lattice. Oxygen atoms of this nitrate seem to be involved in H-bonding to the hydrogen of the amino nitrogen of the chelate/bridging ligand. Dimethyl sulphoxide molecules of solvation are also present in the lattice, but do not seem to be involved in any significant interactions. The mechanism of the rapid conversion of $Cu(HL)_2(NO_3)_2$ into $[Cu_2(HL)_2(L)_2(NO_3)_2]$ in solution is intriguing and a knowledge of the structure of $Cu(HL)_2(NO_3)_2$ would certainly help in elucidation of this mechanism. Unfortunately, apart from probably being monomeric, little else can be deduced about the structure of $Cu(HL)_2(NO_3)_2$ and attempts to grow crystals suitable for an X-ray study have not been successful.

The magnetic moments of $Cu(HL)_2X_2(EtOH)_2$ and $Cu(HL)_2X_2$ (where X is Cl^- or Br^-) show them to be magnetically dilute, and a reasonable structure to propose is one which is similar to that shown in Fig. 1 but with SCN^- replaced by Cl^- or Br^- and acetone replaced by ethanol. The molar conductance of these complexes is consistent with the coordinated halide ion (Table 3). However, a puzzling feature of the ethanolates is the spectral and magnetic changes on desolvation (Table 2). The spectral change is most readily observed since the solvates are bright green whereas the desolvated complexes are very much darker green. It is not possible to decide from the IR spectra where the ethanol is coordinated or hydrogen bonded.

The electronic spectrum, magnetic moment (Table 2) and ESR spectrum all indicate that the copper in $Cu(HL)_2I_2$ is present as copper(I). The molar conductance in nitrobenzene gives a value typical for uni–univalent electrolytes (Table 3). These observations can be rationalized on the basis of the formula $[Cu(C_{14}H_{11}N_2OI)(HL)]I$, in which one of the ligands has been iodinated. It is known, for example, that iodination of 2,4,5-trimethylimidazole gives 1-iodo-2,4,5-trimethylimidazole.[6,7]

SOLVOLYSES OF THIOCYANATES BY TRIFLUOROETHANOIC ACID

R. D. GILLARD,* NORDIN GARIF† and JULIO PEDROSA DE JESUS‡

Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL

(*Received* 19 *July* 1988; *accepted* 11 *October* 1988)

Abstract—The solvolyses by trifluoroethanoic ("trifluoroacetic" TFA) acid of several known and new thiocyanates have been studied using proton magnetic resonance. For the organic linkage isomers of RNCS (R = alkyl groups) isothiocyanates react (via N-alkyl monothiocarbamato trifluoroethanoates) to form alkylamines RNH_2, whereas the thiocyanates RSCN yield thiols, RSH and ammonia. The coordinated thiocyanates include isomers (some new) of dithiocyanatobisdiaminoethanerhodium(III) salts, characterized spectroscopically and through their reactions (additions of mercury(II) ions, reductions of iodate(V), isomerizations). Both linkage isomeric forms of coordinated thiocyanate with TFA formed ammonia (showing a sharp triplet at $\delta = 6.6$ ppm).

The thiocyanate group can bond to metal ions to form mononuclear complexes either through its nitrogen atom or through its sulphur atom. We synthesized[1] a series of complexes; *cis*- and *trans*-$[Rh(en)_2(NCS)_2]X$ (we have italicized the atom actually attached to the metal ion), where X is an anion which may be SCN^-.

Many methods comment upon the linkage isomers of thiocyanates. The application of NMR spectroscopy as a tool to elucidate the bonding mode of the thiocyanate ligand has gained widespread popularity. These experiments have utilized direct measurement for ^{13}C,[2] ^{14}N[3] and ^{15}N[4] of the ligand and the indirect measurement for ^1H,[5,6] ^1H with lanthanide induced shift,[7] $^1H\{^{195}Pt\}$ INDOR,[8] ^{31}P[9–13] and ^{195}Pt.[4] Following our success[14] (using a medium which slowed exchange) in analysing ^{14}N: ^{15}N ratios in ^{15}N-labelled ammine complexes $[Co(NH_3)_5X]Y_2$ by proton magnetic resonance, we sought a similar simple distinction (using proton resonance) between M—*N*CS and M—*S*CN moieties, where M represents a metal ion in a kinetically inert oxidation state.

We anticipated that the products of reaction (1)

$$R—NCS + HOOC\cdot CF_3 \rightleftharpoons R—NCSH^+ + \bar{O}OC\cdot CF_3 \quad (1)$$

should show no coupling to the ^{14}N of the proton of the coordinated isothiocyanic acid, whereas, in the products of reaction (2), such coupling

$$R—SCN + HOOC\cdot CF_3 \rightleftharpoons RSCNH^+ + \bar{O}OC\cdot CF_3 \quad (2)$$

in coordinated thiocyanic acid (kinetics permitting) should give a triplet ^1H signal. Solid complexes containing coordinated nitrous acid have been isolated,[15] such as $[Co(en)_2(ONOH)X]^{n+}$, and similarly, there is excellent evidence[16,17] for the persistence in solution during lengthy periods of coordinated thiocyanic acid, in protonated adducts of $[M(NH_3)_5(SCN)]^{2+}$ (M = Co, Rh), or $[Co(en)_2(SCN)_2]^+$. (The solid acid adducts of $[M(NCS)_6]^{3-}$ salts, e.g. $(NH_4)_3[(Mo(NCS)_6]CH_3CO_2H$[18] and $[Cr(NCS)_6]^{3-}$[19] are of a different type.)

We report here our findings on the compounds with R = alkyl and various kinetically inert inorganic moieties, like $[M(NH_3)_5]^{3+}$ (M = Co, Rh).

RESULTS AND DISCUSSION

Thiocyanate ions in TFA

Sodium and potassium thiocyanates dissolve readily in neat trifluoroacetic acid (TFA hereafter).

‡ Present address: University of Aveiro, 3800 Aveiro, Portugal.

The solution turns yellow and occasionally bubbles as the salt starts to dissolve. The ^1H NMR of the resulting solution shows a sharp triplet centred at $\delta = 6.67$ ppm [Fig. 1(a)]. The ^1H NMR spectrum of ammonium thiocyanate after dissolution in TFA also shows only this triplet, the signal[14] of the proton in quaternary ammonium ions. The identical ^1H NMR spectrum of NH_4Cl in TFA proves this finding [Fig. 1(b)]. Ogg and Ray reported[20] that anhydrous liquid ammonia furnished a triplet signal with $J_{^{14}NH} = 46$ Hz compared to $J_{^{14}NH} = 53$ Hz for NH_4^+ ions in TFA found in the present work.

The ^1H NMR spectrum of a proton attached to a nitrogen atom is always very broad and sometimes unobservable, for two reasons, intermolecular proton exchanges and quadrupolar relaxation. As in anhydrous ammonia,[20] the quadrupolar mechanism is dominant[21] in the acidic solution of NH_4^+ ions. The linewidth of NH_4^+ in TFA decreases with increasing temperature and *vice versa* [Fig. 1(c)], as expected for any quadrupolar mechanism. The behaviour is opposite to that expected for chemical exchange.[22]

The study of such reactions between thiocyanate ions and mineral acid was a matter of interest some years ago. The initial step is protonation, which, theoretically, can occur at the sulphur atom to produce thiocyanic acid H—*S*—C≡N, or at the nitrogen atom to produce isothiocyanic acid H—*N*=C=S, which predominates over its isomer in the vapour state,[23] or in solution.[24,25,*] ^1H NMR spectra of isothiocyanic acid in CCl_4 have been reported[26] (δ 4.95 ppm): cf. isocyanic acid H*N*CO (3.35, $J_{^{14}NH} = 64$ Hz) and hydrazoic acid HN_3 (4.10). Isothiocyanic acid H*N*CS is unstable[27] in *mineral* acid. The overall hydrolysis may be presented as in eq. (3); ammonium ions are a final product.

$$H^+ + HNCS + 2H_2O \longrightarrow H_2S + CO_2 + NH_4^+. \quad (3)$$

Thiocyanate salts in conc. H_2SO_4 (98%) (in the present work) show a sharp triplet centred at δ 5.45 ppm in comparison to the proton signals of NH_4^+ in TFA at δ 6.67 ppm.

A number of intermediates are involved in the hydrolysis. One is carbonyl sulphide OCS, which is reasonably stable in acid but slowly hydrolyses[27] to CO_2 and H_2S. Another (postulated by Klason[28]) is thiocarbamic acid $HSCONH_2$ [eq. (4)]:

$$NCS^- + H^+ + H_2O \longrightarrow H—S—\overset{\overset{O}{\|}}{C}—NH_2. \quad (4)$$

* The salt $[Ph_4As]H(NCS)_2$ was isolated by M. F. A. Dove from solutions of sulphur dioxide (see M. F. A. Dove, *Chem. Comm.* 1965, 23).

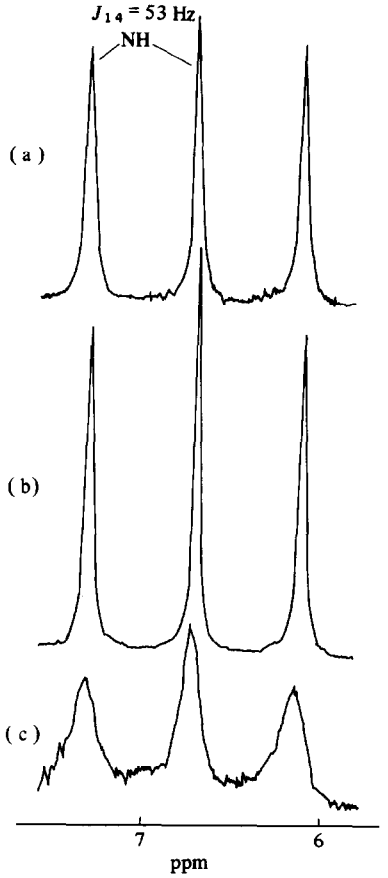

Fig. 1. Proton resonance spectra in TFA of (a) KSCN at 35°C; (b) NH_4Cl at 35°C; (c) KSCN at −5°C.

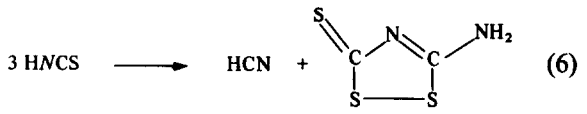
The free acid is unknown, but the ammonium salt decomposes[29] in acidic solution to produce CO_2 and H_2S via OCS. Stedman and his students have made detailed kinetic and spectroscopic studies[30,31] of the reaction of thiocyanate ions in various concentrations of H_2SO_4.

Drawing the analogy to such hydrolysis of thiocyanate ions in mineral acid solution, its solvolysis in TFA [pK_a (25°C) 0.25] is initiated by protonation to form isothiocyanic acid. The intermediate is probably monothiocarbamatotrifluoroacetate formed as in eq. (5)

$$SCN^- + HOOCCF_3 \rightleftharpoons SCNH \overset{H^+}{\rightleftharpoons} H_2N—\overset{\overset{S}{\|}}{C}—OOC \cdot CF_3. \quad (5)$$

However, reaction of SCN^- in TFA followed by ^1H NMR spectroscopy, failed to detect the proton signal of this thiocarbamato compound; only the triplet signal of NH_4^+ was obtained. This rapid solvolysis of thiocyanic acid has been briefly mentioned.[26] The isothiocyanic acid formed, polymerized and eventually produced the yellow iso-

perthiocyanic acid, as in eq. (6).



(6)

Organic isothiocyanates in TFA

The isothiocyanates R*N*CS (R = CH_3, C_2H_5, $C_6H_5CH_2$) were studied by ^1H NMR using TFA as the solvent. In a typical example, methyl isothiocyanate, H_3CNCS, the simplest, was dissolved in TFA. The solution immediately turned yellow. The course of the reaction was followed against time by means of ^1H NMR spectroscopy. Some of the spectra and δ values are given in Figs 2(a)–(g) and Table 1.

	Quartet	2.60[b]	$J_{HH} \sim 5$
292	Broad triplet	6.75	$J_{^{14}NH} \sim 53$
	Broad triplet	6.75	$J_{^{14}NH} \sim 53$
	Quartet	2.93[b]	$J_{HH} \sim 5$

[a] Measured in CCl_4.
[b] Measured at the centre of the quartet.

At the beginning, a doublet centred at δ 3.09 ppm emerged slowly, in addition to the singlet at δ 3.24 ppm from the parent methyl isothiocyanate. We interpret this doublet ($J_{HH} \sim 5$ Hz) as the signal of the methyl group split by a proton attached to the nitrogen atom of the N-methylmonothiocarbamatotrifluoroacetate, $CH_3NH—CS—OOCCF_3$, the suggested intermediate. This decomposes to

products. One has a quartet (1 : 3 : 3 : 1) centred at δ 2.90 ppm and a broad triplet centred at δ 6.75 ppm. This set is the ^1H NMR spectrum of the methylammonium ion, confirmed by comparison with the signal of the authentic methylamine (in alcohol) dissolved in TFA [see Figs 2(g,h)]. Under our experimental conditions (the concentration of H_3CNCS in TFA is 0.739 M at 35°C), the reaction goes to completion. The relative concentrations (reminiscent of a consecutive reaction) of various species during the course of the reaction were calculated from the proton integration and are plotted in Fig. 3.

The reaction of ethyl isothiocyanate CH_3CH_2NCS was also followed by ^1H NMR spectroscopy: examples of the spectra are shown in Figs 4(a)–(e). The intermediate (with a slightly more complicated splitting pattern) is believed to be

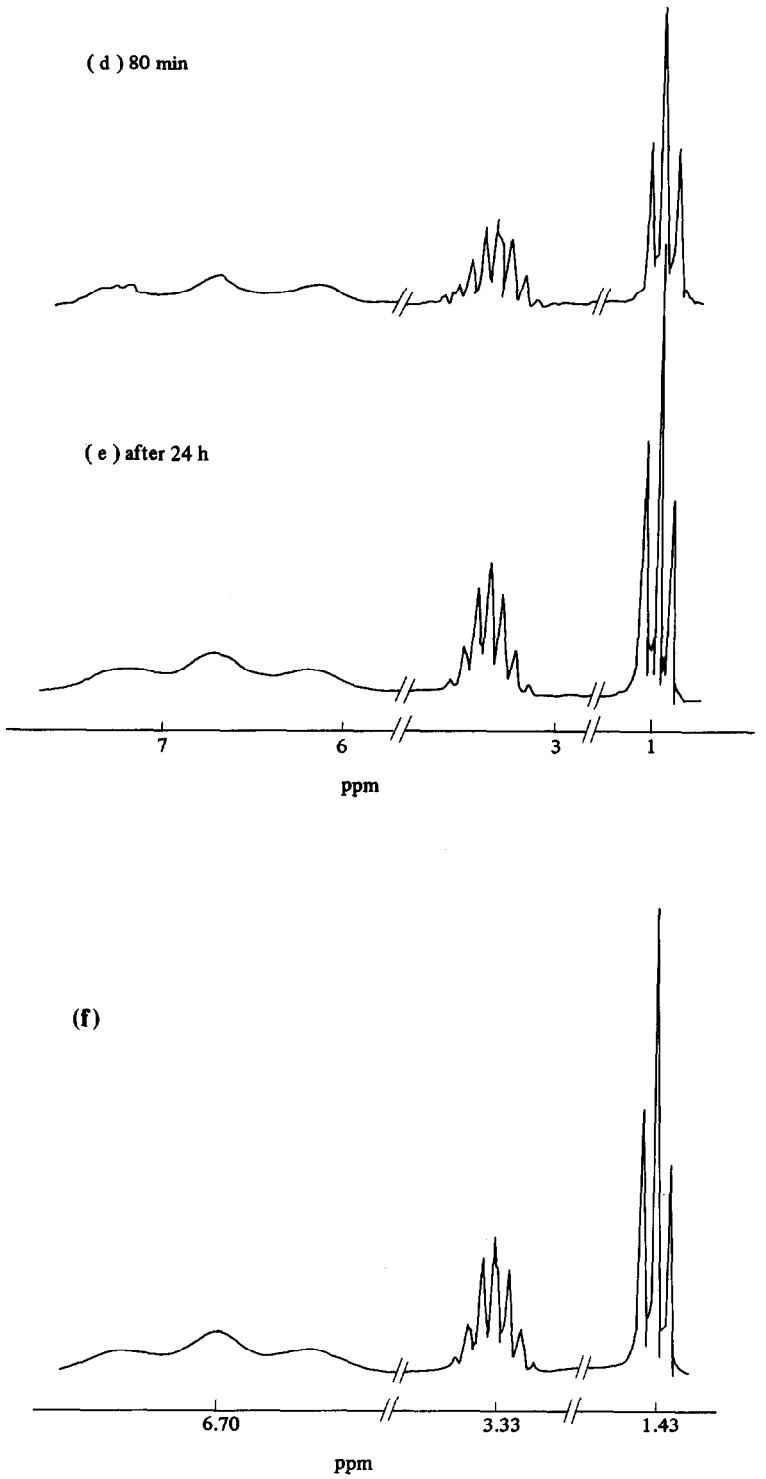

Fig. 4 (*continued*).

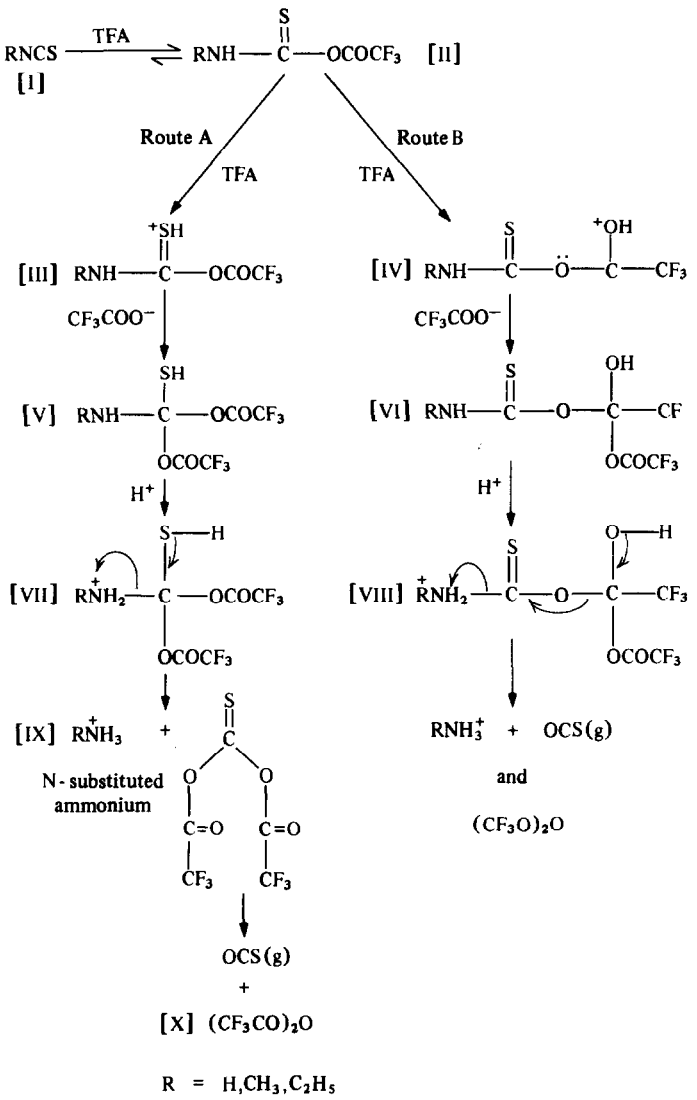
N-ethylmonothiocarbamatotrifluoroacetate. The intermediates then decomposed to the ethylammonium ion as one of the products [see Fig. 4(e)], again confirmed by comparing with authentic ethylamine in TFA [Fig. 4(f)].

Mechanism of the reactions between organic isothiocyanate and TFA. The rate and mechanism of hydrolysis of isothiocyanic acid by mineral acids has received adequate attention.[30,31] In contrast, the kinetics and mechanism of the hydrolysis of the

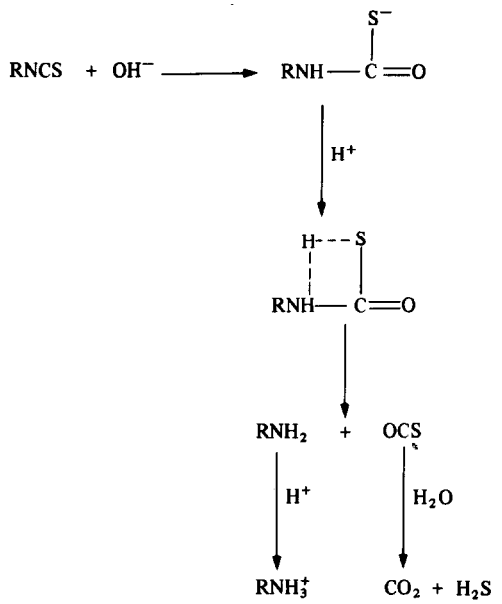


Scheme 1. Mechanisms for solvolysis of thiocyanates.

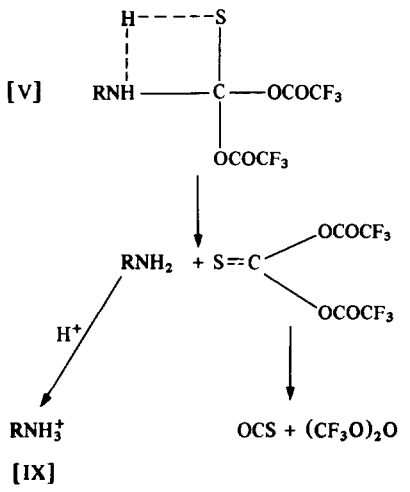
organic isothiocyanate derivatives has been little studied. However, simple organic isothiocyanates should[32] resemble isothiocyanic acid with respect to ready hydrolysis, giving an amine and carbonyl sulphide, which is in turn hydrolysed to CO_2 and H_2S. Mechanisms for solvolysis of organic isothiocyanates with TFA are shown in Scheme 1. From ^{1}H NMR spectra, the N-substituted monothiocarbamatotrifluoroacetate (**II**) is the common intermediate. This finding also indirectly confirms the proposed mechanism of solvolysis of isothiocyanic acid by TFA.

Subsequent decomposition (Scheme 1) of the intermediate is initiated either by further addition of TFA to C=S (route A) or to C=O (route B). The choice depends on (a) relative basicities, and (b) relative electrophilicities of the protonated form of intermediates (**III**) and (**IV**). Decomposition via either route A or B, will produce N-substituted ammonium ions (**IX**), carbonyl sulphide (OCS) and trifluoroacetic anhydride (**X**). The broad triplet signal of N-substituted ammonium ions is due to its lower symmetry compared to tetrahedral NH_4^+. The decomposition of simpler N-substituted monothiocarbamate formed from the reaction of RNCS with OH^- had been proposed[33] as in Scheme 2. So, it is possible that **V** of route A decomposes without further protonation on the nitrogen atom, as shown in Scheme 3.

Reaction of organic thiocyanate (RSCN) *with* TFA. Solutions of organic thiocyanates (RSCN) (R = CH_3, C_2H_5, ϕCH_2) do not exhibit a ^{1}H NMR signal other than that from the parent. Never-



Scheme 2. Possible intermediates of base hydrolysis.



Scheme 3. Possible alternative decomposition of intermediate (V) of Scheme 1.

theless, the protonation shown in eq. (2) probably occurs, but the NMR signal of the proton attached to the quadrupolar nitrogen atom is too broad to be observed.

Organic thiocyanates are hydrolysed by *mineral* acid, to give a thiol RSH, CO_2 and NH_3 as shown in reactions (7)–(10). The initial step (7) is the protonation of the thiocyanate group.

$$R—S—C\equiv N \overset{H^+}{\rightleftharpoons} R—S—C\equiv\overset{+}{N}H \qquad (7)$$

$$R—S—C\equiv\overset{+}{N}H + 2H_2O \longrightarrow RS—C(OH)NH + H_3O^+ \qquad (8)$$

$$RSC(OH)=NH \longrightarrow RSC(O)NH_2 \longrightarrow RSH + CO_2 + NH_3 \qquad (9)$$

$$NH_3 + H^+ \longrightarrow NH_4^+. \qquad (10)$$

A typical example of the reaction of ethyl thiocyanate with conc. H_2SO_4 is shown in Fig. 5. The sharp triplet is obviously due to the ammonium ion. The broad singlet at δ 7.9 ppm is most probably due to the proton attached to the nitrogen atom of the $RSC(O)NH_2$ molecule. The signals centred at δ 1.0 and 2.8 ppm are due to the ethyl group of the thiol compound.

Metal–thiocyanate complexes in TFA

To distinguish between reactivities of coordinated isothiocyanic acid and thiocyanic acid, a range of metal complexes containing linkage isomeric thiocyanates was needed. We used some well-known examples {such as[34] $[Pd(bipy)(NCS)_2]$ and $[Pd(bipy)(SCN)_2]$} and have also made[1] a number of isomers of $[Rh(en)_2(SCN)_2]^+$. We comment briefly on these compounds. Analytical results are given in Table 2 and some spectroscopic properties in Table 3 (supporting assignment of linkage isomers[39,40]) and Table 4 (confirming assignment of geometric isomerism, from the—chiefly hydrogenic—modes of the chelating ligands, at frequencies greater than 1000 cm^{-1}). A feature, which we re-

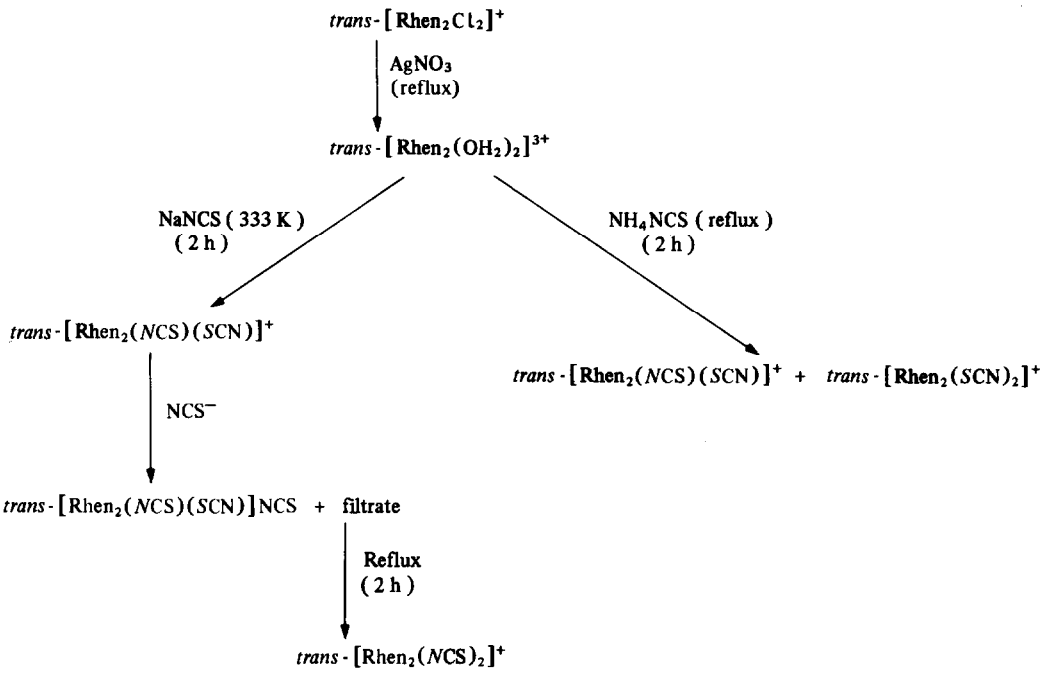

Scheme 4. Formation of linkage isomers of *trans*-$[Rh(en)_2(NCS)_2]^+$.

mark on separately,[35] is the Christiansen filter effect commonly found in these (and other) thiocyanato complexes. Because of this, care is needed to establish numbers and positions of vibrational bands in the ν_{CN} region.

Johnson and Basolo showed[36] that the reaction of *trans*-$[Rh(en)_2Cl_2](NO_3)$ with NaNCS gives *trans*-$[Rh(en)_2Cl(NCS)]^+$ and no disubstituted product. We therefore started here with silver-promoted aquation to *trans*-$[Rh(en)_2(OH_2)_2]^{3+}$: this, with an excess of NaNCS at 333 K, gives mainly *trans*-$[Rh(en)_2(NCS)(SCN)]^+$ (isolated as its thiocyanate). Further reaction of the mother liquor gives *trans*-$[Rh(en)_2(NCS)_2]^+$. Scheme 4 summarizes the *trans* isomers.

Among the *cis* isomers, we have made two, one being the known compound obtained by following the method[36] of Johnson and Basolo. Here, the major product was the thiocyanato–isothiocyanato thiocyanate.

$$cis\text{-}[Rh(en)_2Cl_2](NO_3) + KNCS \longrightarrow cis\text{-}[Rh(en)_2(NCS)(SCN)](NCS). \quad (11)$$

This analysed well (Volhard: cf. Table 2) for ionic thiocyanate. Using the chloride of the chloro factor, under reflux with an excess of KNCS, we obtained a new isomer:

$$cis\text{-}[Rh(en)_2Cl_2]Cl + KNCS \longrightarrow cis\text{-}[Rh(en)_2(NCS)_2](NCS). \quad (12)$$

In general, salts of our S-bonded isomers are more water soluble than the isomeric isothiocyanato complex salts. In the same way, the solid chlorides of the thiocyanato salts are hygroscopic, but their N-bonded isomers are not.

The IR spectra, 250–1000 cm^{-1}, recorded in Table 5, give further good evidence for the retention of *cis* or *trans* geometry in products and need no further discussion. (Diagrams are available.)[1(a)] Among other properties of these isomeric $[Rh(en)_2(NCS)_2]^+$ ions, we studied isomerizations (Scheme 4), addition of mercury(II), and oxidations by trioxoiodate(V) in acidic solution (i.e. iodic acid). These, being slow at room temperature, go to completion in a few hours at 333 K. Essentially (see Experimental) $[Rh^{III}—NCS]^{2+} \rightarrow [Rh^{III} \rightarrow NH_3]^{3+}$ + some $[Rh(CN)]^{2+}$; whereas $[Rh—SCN]^{2+}$ is unreactive.

Addition of aqueous mercury(II) chloride to aqueous *cis*-$[Rh(en)_2(NCS)_2]^+$ gave the clear-cut results of Fig. 6: similar findings for the *trans* species are given in Fig. 7. Additions of mercury(II) and silver(I) ions to pendant pseudo-halide (e.g. cyanides) or sulphur atoms of coordinated isothiocyanates, have been well studied.[41,42] Mercury ions also promote the solvolysis in water of halo–rhodium bonds, and the *cis*-$[M(en)_2Cl_2]^+$ ions (M = Co, Rh) show[43] a kinetic pattern arising from a long-lived stable chloride-bridged dinuclear intermediate, as in eq. (13).

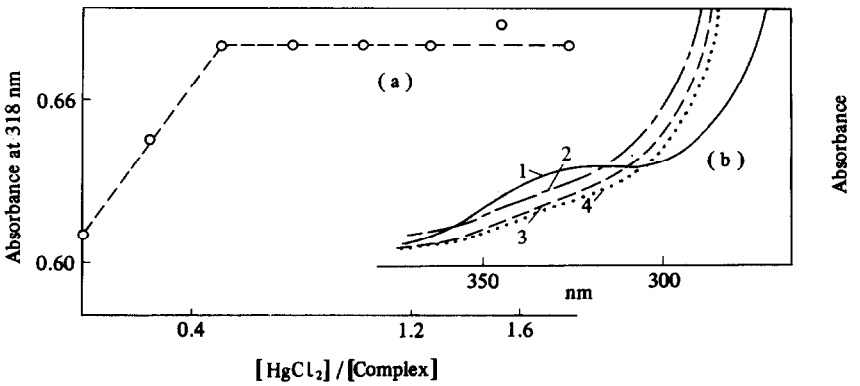

Fig. 6. Effect on the electronic absorption spectrum (———) of *cis*-$[Rh(en)_2(NCS)_2]^+$ of adding aqueous $HgCl_2$: (a) absorbance at 318 nm as f $[HgCl_2]$: [complex ion]; (b) addition in excess: 10 M (—·—·—), 20 M (— — — —), 30 M (·····).

$$cis\text{-}[Rh(en)_2Cl_2]^+ + Hg^{2+} \longrightarrow cis\text{-}[Rh(en)_2Cl_2Hg]^{3+} \longrightarrow \text{products.} \quad (13)$$

After periods ranging from several hours to several days, all the complexes studied, whether S-bonded (thiocyanate–metal complexes), or N-bonded (isothiocyanate–metal complexes), exhibit the same triplet signal in TFA centred at $\delta \sim 6.6$ ppm due to NH_4^+. In addition, the signals from other ligands appear (e.g. from bipy in the Pd compounds, and at δ 3.3 and 5 ppm from the ethylenediamine ligands of Rh^{III} complexes, Fig. 8). Clearly, in TFA, the complexes solvolyse; thiocyanate groups dissociated from the complexes eventually produce NH_4^+. This finding requires amplification (in a kinetic framework) to be useful in studies of linkage isomerism, but is directly useful in the analysis of N-isotopic abundance in thiocyanates, via the ^{14}N: ^{15}N coupling method.[14]

Larsson showed[16] that *cis*-$[Co(en)_2(NCS)_2]ClO_4$, dissolved in concentrated sulphuric acid, produces *cis*-$[Co(en)_2(NCSH)_2]^{4+}$, responsible for the colour change from red to bright yellow. Similar protonation is also observed[16] for $[Co(NH_3)_5NCS](ClO_4)_2$. The lifetime of the species are unknown, although Gillard and Maskill were able[17] to measure circular dichroism spectra for the resolved ion (+)-$[Co(en)_2(NCSH)_2]^{4+}$ in such solutions, so that racemization is slow and salts can indeed be crystallized.

^1H NMR spectra of these compounds in conc. H_2SO_4 were taken. Within 2 h of dissolution, hydrolysis had taken place and a triplet at δ 5.3 ppm was observed (see Fig. 9). The solvolysis of $[Co(NH_3)_5X]^{2+}$ (X = CN^-, ONO^-, NO_2^-, Cl^-, Br^-, F^-, NCS^-) by H_2SO_4 has been studied by ^1H NMR.[44-46] In every case, the anionic ligand is rapidly replaced by the $HOSO_3^-$ anion. However, the triplet signal for the particular case of the hydrolysis of $[Co(NH_3)_5NCS]^{2+}$ was not mentioned, and it may not have been observed because of quadrupolar relaxation.

The sharp triplet obtained here at 5.3 ppm and in TFA centred at $\delta = 6.6$ ppm, is due to the proton attached to the ^{14}N of NH_4^+, formed by solvolysis of N- or S-coordinated and free thiocyanate.

EXPERIMENTAL

Electronic spectra were recorded on a Pye-Unicam SP.8000 or on a Beckman DK-2A spectrophotometer. Values of pH were measured using

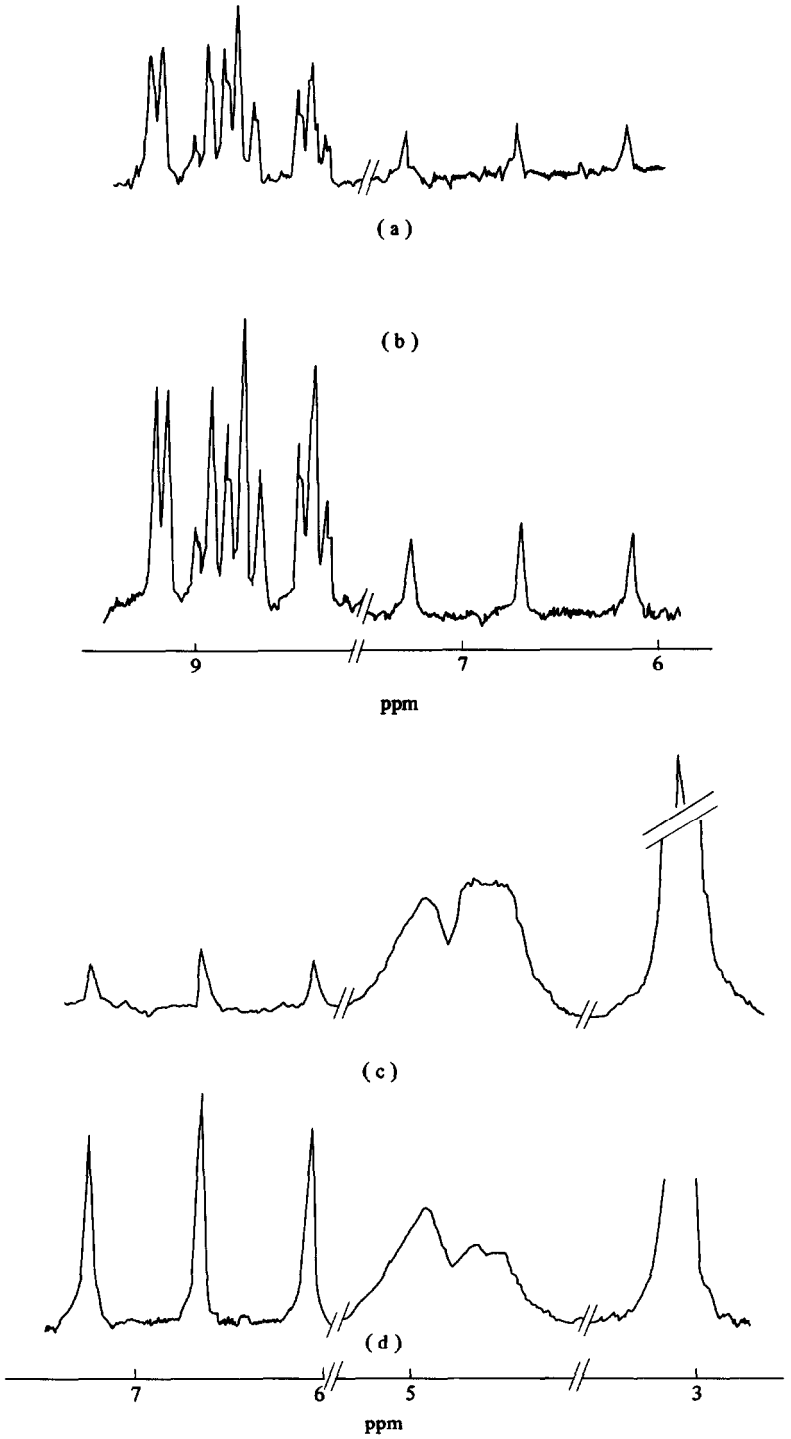

Fig. 8. Typical ^{1}H proton magnetic resonance spectra in TFA: (a) isothiocyanato species, Pd(bipy)(*N*CS)$_2$, after 1 day; (b) the same after 14 days; (c) thiocyanato species, *trans*-[Rh(en)$_2$(*S*CN)$_2$]X, X = Cl, after 1 day; (d) X = (NCS)$^-$, after 8 days.

a Corning digital pH-meter, model PT.15. IR spectra were recorded on a Perkin–Elmer 257 or Pye-Unicam SP200 spectrophotometer. Thermogravimetric analyses were performed using a Stanton–Redcroft TG-750 thermogravimetric balance. ^{1}H NMR spectra were obtained on a 90 MHz Perkin–Elmer R-32 spectrophotometer fitted with a digital signal analyser. Chemical shifts were measured relative to TSS [$NaMe_3Si(CH_2)_3SO_3$] or TMS ($SiMe_4$), as an internal standard. The temperature for ^{1}H NMR experiments was 35°C unless otherwise stated.

Purification of organic thiocyanates and isothiocyanates

Some minor impurities in phenyl isothiocyanate, C_6H_5NCS, and ethyl isothiocyanate, C_2H_5NCS, were observed by means of ^1H NMR spectroscopy in CCl_4. Purification was by distillation under reduced pressure (10–14 mm Hg). The purity was checked by ^1H NMR in CCl_4 and refractive indexes, at the sodium yellow lines, presented as: formula, literature[47] (20°C), observed (20.5°C): C_2H_5NCS: 1.5130, 1.5140; C_6H_5NCS: 1.6477, 1.6465; CH_3SCN: 1.4582, 1.4586; CH_3CH_2SCN: 1.4670, 1.4690; $C_6H_5CH_2SCN$: 1.5480, 1.5488.

^1H *NMR in* TFA

The ^1H NMR spectra of thiocyanate salts (Na^+, K^+, NH_4^+ etc.) were recorded on small amounts (15–20 mg) with about 0.5 cm^3 of TFA, and those of organic isothiocyanates were obtained by dissolving a small amount ($\sim$ 20 mg) of liquid in TFA; the spectra were recorded immediately and then at intervals. The concentrations in the reaction mixture of methyl isothiocyanate with TFA shown in Fig. 3 were deduced from the proton integration of the spectra.

TFA hardly dissolves most metal thiocyanate complexes. TFA was added to a capped sample bottle containing the metal complex, and the clear increasingly yellow solution was withdrawn from time to time to record spectra.

Rhodium^{III} complexes

trans-$[Rh(en)_2Cl_2]NO_3$. Following the method of Johnson and Basolo,[36] 2.0 g of $RhCl_3 \cdot 3H_2O$ gave 0.98 g of *trans*-$[Rh(en)_2Cl_2]NO_3$. Found: C, 13.1; H, 4.5; N, 19.2. Calc. for $[Rh(en)_2Cl_2]NO_3$: C, 13.5; H, 4.5; N, 19.7%. λ 406 nm ($\varepsilon = 763$ mol^{-1} dm^2) and 286 nm ($\varepsilon = 1280$ mol^{-1} dm^2) literature:[36] λ (406, 750) and λ (288, 1300). The present SI units for ε differ from those usually given.

The preparations of the thiocyanato complexes of the bis(1,2-diaminoethane)/rhodium(III) moiety are given here in some detail because they deviate from the original method[36] of Johnson and Basolo, who obtained a substance of composition $[Rh(en)_2(NCS)_2](NCS)$ by refluxing $[Rh(en)_2Cl_2]^+$ in sodium thiocyanate. However, they reported[36] that their product failed Gladstone's test (giving no coloration with aqueous ferric ions). Our products, containing ionic thiocyanate gegen-ions, give the blood-red colour instantly. In the present context of substitution at rhodium(III) centres by thiocyanate, it is worth recalling the fact[48] that, despite forcing conditions, only one of the two chloro ligands of *cis*-α-$[Rh(trien)Cl_2]^+$ could be substituted.

Electronic spectra are given in Table 6, chiefly as a further means of characterization: the intensities for these isotropic absorptions are high, like those of other thiocyanatorhodium(III) species, whether N- or S-bonded.

Titration of ionic thiocyanate. The Volhard method was used. Typically 10 cm^3 of a 3.2×10^{-3} M solution of the complex was titrated with 0.1 M $AgNO_3$ using an acidic Fe^{2+} solution as the indicator. Values from the direct and back titration were taken.

trans-$[Rh(en)_2(NCS)_2]X$ (X = NCS, Cl). 0.620 g (1.7 mmol) of *trans*-$[Rh(en)_2Cl_2]NO_3$ in 50 cm^3 of H_2O and 0.590 g of $AgNO_3$ was set to reflux for 2 h, and the silver chloride formed was carefully removed. To the filtrate, which contained *trans*-$[Rh(en)_2(OH_2)_2]^{3+}$ (checked by visible spectrum), 1.5 g of NaNCS was added. The solution was heated (in a steam bath) at 70°C for about 2 h, during which time a new absorption band grew at *ca* 350 nm. The volume was reduced to about 20 cm^3, and all was cooled in ice. The solid obtained was collected, washed with ice-cold water, ethanol and ether. This solid is *trans*-$[Rh(en)_2(NCS)(SCN)]$ (NCS); yield 0.11 g; λ 364 and 275 nm. IR spectroscopy shows strong sharp absorptions at 2140 and 2060 cm^{-1}.

The filtrate was again allowed to reflux for about 1 h, cooled and concentrated in vacuum to 10 cm^3 and finally kept overnight in the refrigerator. The resulting yellow precipitate was collected, washed with ice water, acetone and ether; yield 60 mg. Found: C, 19.6; H, 4.0; N, 22.8. Calc. for $[Rh(en)_2(NCS)_2](NCS) \cdot H_2O$: C, 20.2; H, 4.3; N, 23.6%. λ 340, 270 and 220 nm. IR: a strong sharp absorption at 2110 cm^{-1} was observed, characteristic of an N-bonded thiocyanate and at 2045 cm^{-1} due to ionic thiocyanate. *trans*-$[Rh(en)_2(NCS)_2]Cl$: *trans*-$[Rh(en)_2(NCS)_2](NCS)$ was suspended in water and moist anion-exchange resin (Amberlite IRA-400 in the chloride form) was added. The mixture was stirred (magnetically) until all dissolved. The solution was filtered several times and the yellow filtrate taken to dryness. IR shows only a single, broad, strong absorption at 2110 cm^{-1}.

trans-$[Rh(en)_2(SCN)_2]X$ (X = NCS, Cl). An aqueous solution (30 cm^3) of *trans*-$[Rh(en)_2Cl_2]NO_3$ (620 mg, 1.7 mmol) was refluxed with 590 mg (3.4 mmol) of $AgNO_3$ for 2 h and precipitated AgCl was removed by careful filtration. NH_4NCS (0.9 g) was added to the filtrate and the whole mixture was

Table 6. Electronic spectra in aqueous solution of some compounds of thiocyanate and rhodium(III), $[Rh(en)_2(NCS)_2]X$

[c] From ref. 36.

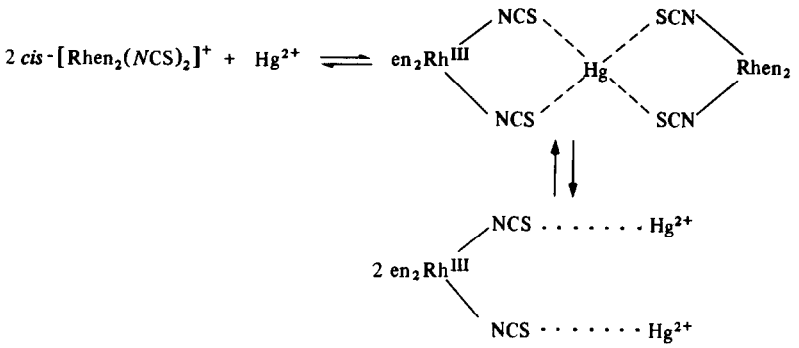
refluxed for about 1 h. The yellow solution was then reduced to about 10 cm^3 and left overnight in a refrigerator. The yellow–orange solid formed was collected, washed with ice-water, ethanol, ether and air-dried. This solid (140 mg) is again *trans*-$[Rh(en)_2(NCS)(SCN)](NCS)$, which was recrystallized from hot water. The volume of the filtrate F was reduced (*in vacuo*; 40°C) to about 5 cm^3 and it was left overnight in a refrigerator. The yellow solid obtained was collected, washed with ice–water, ethanol and ether; yield 70 mg. Found: C, 19.6; H, 4.2; N, 22.8. Calc. for *trans*-$[Rh(en)_2(SCN)_2](NCS)\cdot H_2O$: C, 20.2; H, 4.3; N, 23.3%. ν_{CN} at 2045(s, sp); 2110(s), 2130(s), 2140(sh). In an alternative treatment of F, it was taken to dryness, *in vacuo* at 40°C, and the product was redissolved in *ca* 3 cm^3 of hot water, allowed to cool to room temperature, and left at 2°C overnight. The yield was 95 mg.

The chloride salt was prepared by anion exchange as described previously. Its IR spectrum shows a single sharp strong absorption at 2110 cm^{-1} (ν_{CN}).

Isomerization of *trans*-$[Rh(en)_2(NCS)(SCN)]^+$ (*Scheme* 4). On refluxing a solution of *trans*-$[Rh(en)_2(NCS)(SCN)]^+$ in H_2O, the electronic spectrum changes to that of the *trans*-diisothiocyanate. The lower energy absorption band moves from 364 to around 340 nm, and two well defined shoulders are also observed at 270 and 220 nm. The product could not be isolated, although a few reactions have been studied.

Reactions with $HgCl_2$(aq): adding $HgCl_2$ (aq) to aqueous *cis*-$[Rh(en)_2(NCS)_2]^+$ changed the electronic spectrum (Fig. 6). Absorbance at 318 nm increases linearly from $[HgCl_2]/[Complex] = 0$–0.5 and then stays constant (up to $[HgCl_2]/[Complex] = 1.8$); Fig. 6(a). When a large excess of $HgCl_2$ is added, the changes shown in Fig. 6(b) are observed. The first absorption band moves to higher energy and the intensity at 320 nm decreases.

Reactions with IO_3^-: solid $NaIO_3\cdot H_2O$ (4.5 mg, 0.02 mmol) was added to 10 cm^3 of a solution of the complex (typically 2×10^{-3} M) previously acidified with $HClO_4$ (so that $[H^+] = 0.02$ M), at room temperature (when reaction was very slow) or at 333 K (reaction time *ca* 3 h) in a water bath. The I_2 formed was usually extracted with CCl_4. *cis*-$[Rh(en)_2(NCS)_2]^+$ with IO_3^- at room temperature gave a mixture of products, with, after anion exchange to the chloride, a new absorption at 2191 cm^{-1}, (CN^-) a broadening in the N—H stretching, bending and rocking regions (NH_3 ligand) and again the band at 2140 cm^{-1} (NCS^-). The lower energy absorption in the electronic spectrum moves to higher energies. Chromatography (cation ex-



Scheme 5. Adducts of mercury(II) with the *cis*-bis-isothiocyanate complex.

change resin, H^+ form) developed two main bands, one eluted with 0.1 M HCl {singly charged, *cis*-$[Rh(en)_2(NCS)(CN)]^+$} and the other with 0.5 M HCl {doubly charged, *cis*-$[Rh(en)_2(NH_3)(NCS)]^{2+}$, *cis*-$[Rh(en)_2(NH_3)(CN)]^{2+}$}.

The products from *cis*-$[Rh(en)_2(SCN)(NCS)]^+$ with IO_3^-, under the same conditions, were also analysed. On comparing the IR spectrum of the product (impure $[Rh(en)_2(SCN)(NH_3)]^{2+}$) with that of factor, there is no evidence for CN^- (absorption at 2191 cm^{-1}), but the changed NH_2 vibrations also occurred here. The absorption around 2120 cm^{-1} (associated with C—N stretching of the thiocyanate ligand) was observed. Two new, broad, strong bands are observed at ~ 2450 and ~ 840 cm^{-1}. In the electronic spectrum, the main feature is a new well defined band at around 245 nm.

The reaction of *trans*-$[Rh(en)_2(NCS)(SCN)]^+$ with IO_3^- at 333 K was followed: the products again involve coordinated NH_3, CN^- and NCS^- moieties. However, the reaction at room temperature produces no CN^-, although coordinated NCS^- and NH_3 are still present: the mixture of products is more complex than in the reactions of the other isomers.

Addition of an excess of $HgCl_2$(aq) to solutions of *trans*-$[Rh(en)_2(NCS(SCN)]^+$ and *trans*-$[Rh(en)_2(NCS)_2]^+$ was followed in a similar way.

The results of the titration of *cis*-$[Rh(en)_2(NCS)_2]^+$ with $HgCl_2$(aq), Fig. 6(a), suggest that the first association between the rhodium(III) complex and the mercuric ions, probably involves two moles of complex to one of Hg^{2+}(aq). When this ion is then added in excess, it associates in a 2:1 ratio (Hg–Complex), Scheme 5. This would explain the increase in intensity observed in the quantitative titration [Fig. 6(a)], as a new chelate ring is formed around the rhodium(III) centre. In addition, at this concentration of Hg^{2+}, and also when Hg^{2+} is present in excess, there is a shift of the bands to lower energies, both in this instance and with the *trans* compound.

Cobalt(III) *complexes*

cis-$[Co(en)_2(NCS)_2](ClO_4)$. This was prepared according to Gillard and Maskill.[17] Found: C, 17.0; H, 4.6; N, 19.9. Calc. for *cis*-$[Co(en)_2(NCS)_2](ClO_4)\cdot H_2O$: C, 17.5; H, 4.4; N, 20.4%. IR spectra contain a single broad ν_{CN} at 2105 cm^{-1}. λ 508 and 314 nm correspond to published values.

$[Co(NH_3)_5NCS](ClO_4)_2$. This was prepared as described in ref. 49 by reacting NaNCS with an aqueous solution of $[Co(NH_3)_5H_2O]^{3+}$ to form $[Co(NH_3)_5NCS](NCS)_2$. The perchlorate salt was prepared by dissolving the thiocyanate salt in water and a saturated solution of $NaClO_4$ was added. The resulting orange–red precipitate was collected, washed with water, ethanol, ether and sucked dry. Found: C, 3.0; H, 3.9; N, 19.3. Calc. for $[Co(NH_3)_5NCS](ClO_4)_2\cdot H_2O$: C, 2.9; H, 4.0; N, 20.1%. λ 496 and 306 nm correspond to known values.

Palladium(II) *complexes*

Pd(bipy)$(SCN)_2$. The compound (0.5 g) was prepared according to Basolo and Burmeister, from 0.84 g $K_2Pd(SCN)_4$. Found: C, 38.4; H, 2.3; N, 14.1. Calc. for Pd(bipy)$(SCN)_2$: C, 38.0; H, 2.1; N, 14.8%. IR spectra (Nujol) contain sharp, strong bands at 2114 and 2091 cm^{-1}.

Pd(bipy)$(NCS)_2$. The compound (0.21 g) was prepared from $K_2Pd(SCN)_4$ (0.84 g) with 0.32 g of 2,2′-bipyridyl. Found: C, 37.7; H, 2.4; N, 14.2. Calc. for Pd(bipy)$(NCS)_2$: C, 38.0; H, 2.1; N, 14.8%. IR spectra (Nujol) contain a single, broad, strong absorption at 2100 cm^{-1}.

Acknowledgements—This paper is based on the PhD theses of Nordin Garif (1983)[1(b)] and Julio Pedrosa de Jesus (1977),[1(a)] who respectively, thank the Universiti Teknologi Malaysia and the University of Aveiro for leave. We also thank Dr Neil Burford and Mr Gareth Phillips for some preliminary confirmatory work carried out by

them while undergraduates in Cardiff. We thank Prof. E. Whittle for advice on fluoro–organic chemistry and Dr D. A. Wilson for valued discussion of the resonance spectra.

(*Received* 16 *August* 1988; *accepted* 11 *October* 1988)

Abstract—Crystal structures of four univalent metal complexes with (phenylthio)acetic acid (PTAH), (2,4-dichloro-5-methylphenylthio)acetic acid (DCMPTAH), and 2-(phenylthio)propionic acid (PTPAH) have been determined using X-ray diffraction. The thallium complex, $[Tl(PTA)(PTAH)]_n$, (**1**) is orthorhombic, space group *Pccn*, $Z = 4$, $a = 10.466(6)$, $b = 26.75(1)$, $c = 6.013(2)$ Å. $[Cs(DCMPTA)(DCMPTAH)]_n$, (**2**) is triclinic, space group $P\bar{1}$, $Z = 1$, $a = 5.159(3)$, $b = 6.898(3)$, $c = 16.500(8)$ Å, $\alpha = 90.04(4)$, $\beta = 94.22(4)$ and $\gamma = 103.27(4)°$. PTAH forms an adduct $[Cs(PTA)(PTAH)]_n$, (**3**) which is monoclinic, space group *Cc* with $Z = 4$, $a = 35.88(1)$, $b = 7.201(2)$, $c = 6.907(1)$ Å, $\beta = 91.19(2)°$. PTPAH forms a conventional hydrated complex, $[Cs(PTPA)(H_2O)]_n$, (**4**), which is orthorhombic, *Pbca*, with $Z = 8$, $a = 8.849(4)$, $b = 9.500(3)$, $c = 29.78(1)$ Å. The structures (**1–4**) were refined to residuals of 0.078, 0.087, 0.030 and 0.036 for 1353, 1571, 2225, 1807 "observed" reflections, respectively. Both **1** and **2** are examples of acid salts of the type, MHX_2, where

* For Part IX, see ref. 1.

† Author to whom correspondence should be addressed.

X^- and HX are crystallographically equivalent. The molecules are polymeric and have bonded ligands as well as adducted acid species. **3** is an example of a type B ($M^+X^- \cdot HX$) salt with X^- and HX crystallographically different. **4** is an example of a normal Cs salt. The Tl compound (**1**) is disordered with only half the general position sites occupied by the metal atom. Each site is at the centre of a distorted MO_5S octahedron with very short bonds to both asymmetric bidentate and bridging carboxylate groups [Tl—O, 2.22, 2.44(1) Å] and to the thioether S [Tl—S, 2.517(4) Å]. In **2**, the Cs atom is at the centre of symmetry of a distorted MO_6 octahedron. It has a polymer structure with acetate bridges linking consecutive Cs atoms and carboxylate oxygen also bifurcated between two Cs atoms. The Cs—O distances are 3.123(10), 3.152(8) and 3.237(8) Å. Complex **3** has an irregular MO_8 polyhedron about Cs with bonds from both PTA and PTAH ligands [Cs—O range, 3.03–3.45(1) Å; mean, 3.23(1) Å], and extends into a 2-D polymer structure. Compound **4** is also polymeric but with distorted octahedral MO_6 coordination, bridging through both carboxylate and water oxygens [Cs—O range, 3.02–3.33(1) Å; mean, 3.20(1) Å].

As part of a general investigation into the metal-coordination chemistry of (phenylthio)alkanoic acids, a group of disordered compounds have been isolated in the solid state. These crystalline compounds have a general formula ($M^+X^- \cdot HX$). Speakman[2,3] classifies two fundamental types of acid–salt ($M^+X^- \cdot HX$) structures: type A, where the two X-units are crystallographically equivalent and type B, where the two X-units are crystallographically non-equivalent and occur as an anion and a neutral molecule. An aqueous solution of such an acid salt, MHX_2, is an optimum buffer with a pH very close to the pK_a of the acid HX. In all the type A cases quoted by Speakman, the intercarboxyl hydrogen bond occurs about either an inversion centre or a two-fold axis. This paper deals with both type A and B structures. These are $[Tl(PTA)(PTAH)]_n$ (**1**), $[Cs(DCMPTA)(DCMPTAH)]_n$ (**2**) (type A) and $[Cs(PTA)(PTAH)]_n$ (**3**) (type B), [PTA = (phenylthio)acetate; DCMPTA = (2,4-dichloro-5-methylphenylthio)acetate]. Also reported is the structure of a conventional caesium salt with the ligand 2-(phenylthio)propionic acid (PTPAH) which forms $[Cs(PTPA)(H_2O)]_n$ (**4**).

EXPERIMENTAL

Preparation

Complexes were made by reacting the appropriate acid in aqueous ethanol with an excess of metal carbonate.[4] After digesting for about 1 h, the excess carbonate was filtered off, and the solutions, on standing, yielded suitable crystals for diffraction.

Analysis: For **1**, found: C, 35.2; H, 3.29. Calc. for $C_{16}H_{15}O_4S_2Tl$: C, 35.6; H, 2.80% (anhydrous). $C_{16}H_{17}O_5S_2Tl$: C, 34.5; H, 3.07%, (monohydrate). For **2**, found: C, 34.0; H, 2.46; Cl, 22.0. Calc. for $C_{18}H_{15}Cl_4CsO_4S_2$: C, 34.1; H, 2.38; Cl, 22.4.

Crystal data, X-ray data collection and structure refinement

Table 1 lists details of cell parameters, data acquisition and structure solution. Data were processed using the profile fitting procedure of Diamond[5] and were corrected for absorption. Structures were solved by Patterson methods and refined using SHELX-76[6] on the University of Queensland's IBM 3083 computer (**1**, **3** and **4**) or SHELXTL[7] (**2**). For all structures, blocked-matrix anisotropic refinement (100 variable maximum) was used for all non-hydrogen atoms. Hydrogens were located from difference-Fourier syntheses and included at fixed positions with their isotropic U values set invariant at 0.05 $Å^2$. Residuals R and R_w are defined as: $R = [\Sigma ||F_o| - |F_c||/\Sigma |F_o|]$ and $R_w = [\Sigma w(||F_o| - |F_c||^2/\Sigma w|F_o|^2)^{0.5}]$. Neutral atom scattering factors were used.

Bond distances and angles are given in Table 2. Final atomic parameters, lists of anisotropic thermal parameters, intramolecular bond distances and angles, and observed and calculated structure factors are available from the Authors.

The Patterson-heavy atom method was used to solve the structure of **1**. The measured density (2.16 g cm^{-3}) indicates that there are four molecules of formula $C_{16}H_{15}O_4S_2Tl$ in the unit cell. For the space group *Pccn*, this implies that the Tl atoms lie at special positions, either at (0,0,0) (point symmetry $\bar{1}$) or (0,0,0.5) (point symmetry 2). The sharpened Patterson synthesis gave seven major vectors confirming the space group *Pccn* (D_{2h}^{10}, No. 56) ($0kl$, $l = 2n+1$ absent; $h0l$, $l = 2n+1$; $hk0$, $h+k = 2n+1$), with Tl at general positions (site occupancy = 0.5). This model refined successfully. To balance the charge of the univalent cation, the ligand must be disordered over two sites with half being present as the anion (PTA) and the other as the acid (PTAH).

Table 1. Experimental data for [Tl(PTA)(PTAH)]$_n$ (**1**), [Cs(DCMPTA)(DCMPTAH)]$_n$ (**2**), [Cs(PTA)(PTAH)]$_n$ (**3**) and [Cs(PTPA)(H_2O)]$_n$ (**4**)

DISCUSSION

$[Tl(PTA)(PTAH)]_n$ (1)

The Tl^I compound (**1**) is most unusual with the metal atom having half occupancy. If, on the other hand, Tl atoms were at all the eight equivalent positions, the Tl—Tl separations would be short [3.426 Å, $(0.5-x, y, 0.5+z, c$ glide about a at $x = 0.25)$ or 3.824 Å $(-x, -y, -z$, inversion centre)]. The shorter distance would disappear if water replaced the metal in half the Tl sites. This would make Tl seven coordinate with a long Tl—H_2O distance of 3.426(1) Å. As a result the water molecule would be likewise surrounded by the equivalent ligands. This is consistent with chemical analysis and density measurement. Somewhat analogous compounds have been reported[8] (although not of Tl), with water at a central site of an 18-crown-6 ether.

Another possibility could be the presence of Tl^{III}, in a structure such as $Tl^I_2(PTA)_2 \cdot Tl^{III}_2(PTA)_6$. This would explain the presence of identical PTA ligands but with half occupancy of four of the eight sites by Tl^I and two by Tl^{III}. This could also explain the short Tl–ligand distances, e.g. Tl—$O(11)^I$, 2.218(10) Å, which is comparable to typical Tl^{III}—O distances [$CsTl^{III}(SO_4)\cdot 2H_2O$,[9] Tl—O, 2.21–2.28 Å]. Tl^I—O distances are more typically 2.6–3.4 Å as found in Tl_2CO_3.[10] The Tl—S(7) distance in **1** [2.517(4) Å] is also short compared to the more typical values in diethyldithiophosphinatothallium(I)[11] of 3.06 Å.

Although the former possibility appears more tenable, the presence of water at this site cannot be confirmed crystallographically because of the magnitude of the electronic effect due to Tl.

In **1**, the metal is incompletely surrounded by its ligands. This is probably due to $6s^2$ electrons of Tl acting as a stereochemical lone pair occupying part of the coordination sphere and producing a distorted MO_5S octahedron with both very short asymmetric bonds to oxygens of bidentate and bridging carboxylate groups and to the thioether S. The linear polymer extends along the a axis at $x = 0$, 0.5. van der Waals' interactions appear to locate the rows of hydrophobic phenyl groups at $y = 0.25$, 0.75 (Figs 1 and 2).

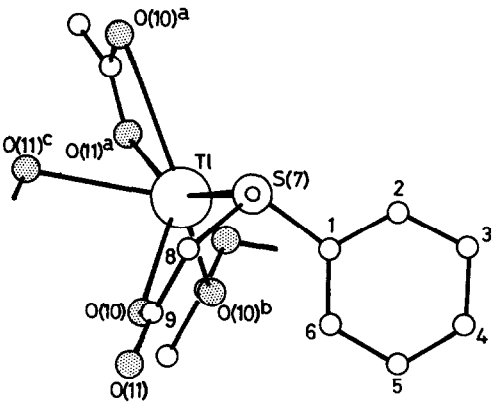

Fig. 1. $[Tl(PTA)(PTAH)]_n$, (**1**).

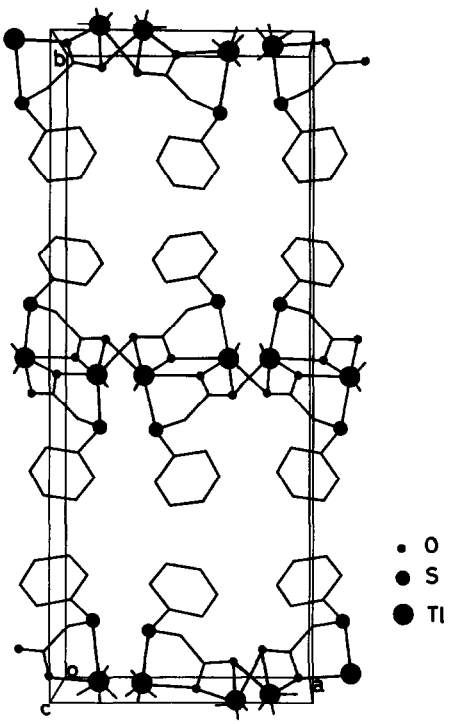

Fig. 2. The packing of **1** in the cell viewed perpendicular to ab. Alternate Tl sites are unoccupied.

$[Cs(DCMPTA)(DCMPTAH)]_n$ (2)

2 crystallizes in the space group $P\bar{1}$ with one molecule per unit cell. This indicates that the DCMPTA and DCMPTAH groups (the anion and the acid) are crystallographically identical giving a typical type A structure.[2] The Tl complex (**1**) also fits this category. Statistical tests indicate a centrosymmetric space group although these tests are not entirely definitive.[12,13]

2 has a distorted centrosymmetric MO_6 octahedral coordination around the Cs (Fig. 3). The metal is linked to alternate Cs atoms along the b axis through acetate bridges and down the a axis through another acetate bridge with O(10) bifurcated between consecutive Cs atoms (Fig. 4). There is no bonding between Cs and S. The results found for the ligand in complex **2** are comparable to that found in DCMPTA complexes of Cu^{II}.[14,15] The

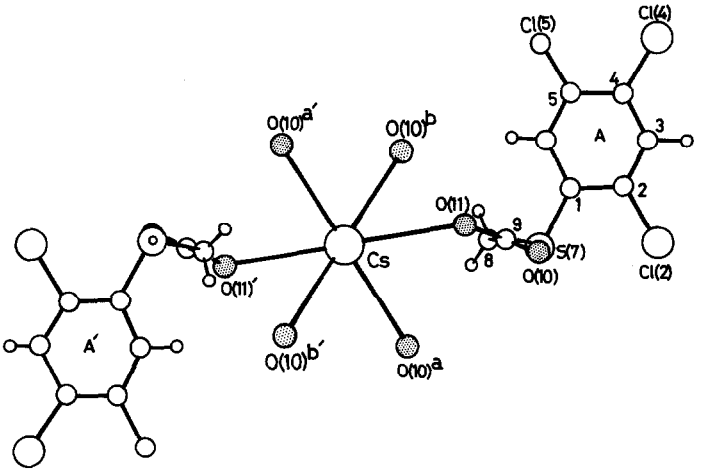

Fig. 3. [Cs(DCMPTA)(DCMPTAH)]$_n$, (2).

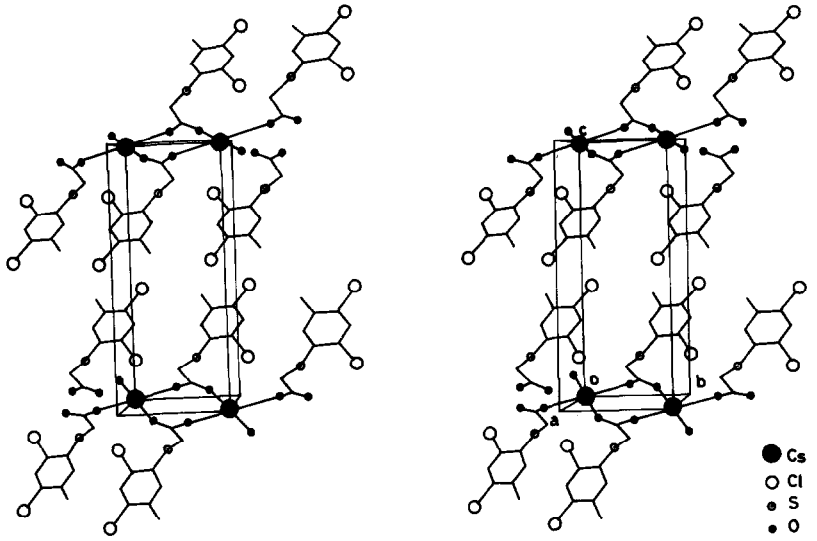

Fig. 4. Stereoview of the packing of **2** in the unit cell. The polymer chains extend down the *a* axis via carboxyl oxygens.

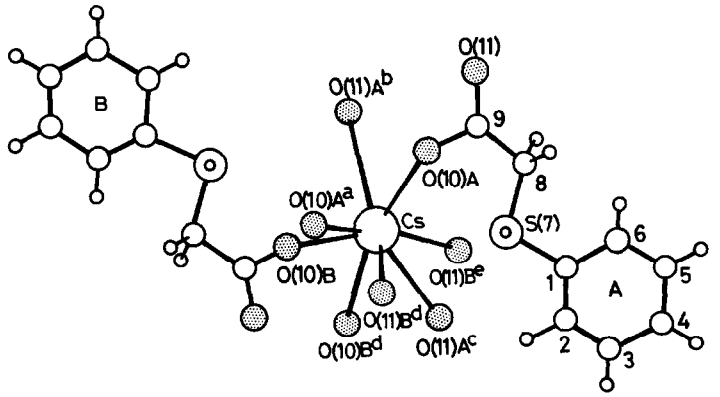

Fig. 5. [Cs(PTA)(PTAH)]$_n$, (3).

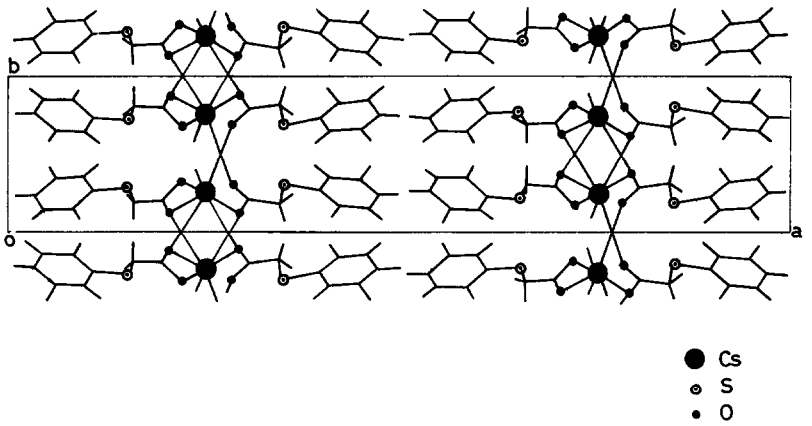

Fig. 6. The packing of **3** in the unit cell viewed down *c*.

Cs—O distances are quite typical of compounds considered to contain ionic Cs, e.g. 3.20(1) Å in $[Cs_2[Cu(H_2O)_6](SO_4)_2]$.[16]

[Cs(PTA)(PTAH)]$_n$ (3)

3 has irregular eight-coordination about Cs, comprising carboxylate oxygens from both PTA, (A) and PTAH, (B) ligands (Fig. 5). It is not possible to distinguish between these types, which are related by pseudo-two-fold symmetry. The packing of **3** in the unit cell (Fig. 6) shows a 2-D polymer which extends through the *b* direction in the cell. Hydrophilic centres involving the Cs—O network are located at $x = 0.25, 0.75$ in the cell while the hydrophobic phenyl rings of the PTA ligands are centred at $x = 0$, 0.5 with no significant intermolecular associations. The PTA and PTAH ligands are also similar and are essentially planar, the conformation of the parent acid.[4]

[Cs(PTPA)(H$_2$O)]$_n$ (4)

4 is also a polymer (Fig. 7) but unlike the type A and type B examples found for **1**, **2** and **3**, no acid molecules are found in the structure. Furthermore, the coordination involves a water ligand, completing a distorted octahedral polyhedron about Cs. The Cs—O range and mean are 3.02–3.33(1) and 3.20(1) Å, respectively. The water is involved in bridging Cs centres in the polymer structure, together with other carboxyl oxygens. The resulting polymer chains pack in the unit cell as a 2-D polymer (Fig. 8). The thiopropionate side chains of the PTPA ligands are convoluted, similar to the conformations of both 2-methyl-2-(phenylthio)propionate and 2-methyl-3-(phenylthio)propionate ligands in their metal complexes.[17]

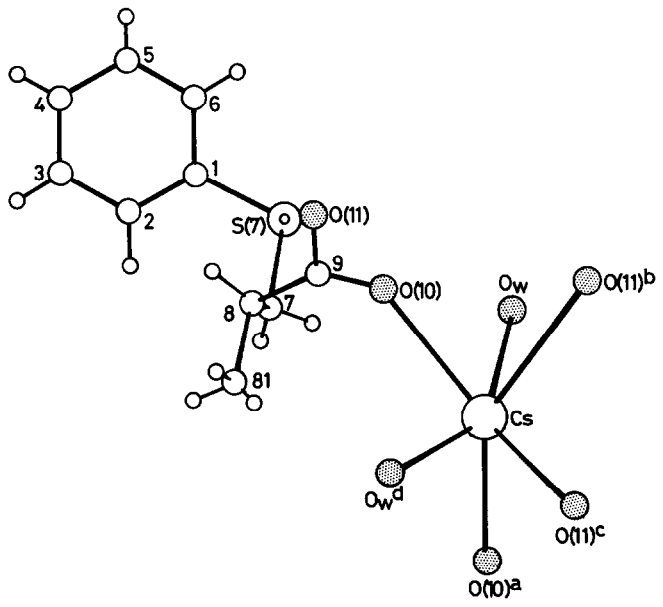

Fig. 7. [Cs(PTPA)(H$_2$O)]$_n$, (**4**).

A PRESSURE TUNING SPECTROSCOPIC STUDY OF THE SULPHIDO–METAL CLUSTERS, $M_6(\mu_3\text{-}S)_8(PEt_3)_6^{n+}$ (M = Fe, $n = 2$; M = Co, $n = 1$)

(*Received* 11 *August* 1988; *accepted after revision* 13 *October* 1988)

Abstract—The effect of pressure on the visible absorption spectra of the sulphido–metal clusters, $M_6(\mu_3\text{-}S)_8(PEt_3)_6^{n+}$ (M = Fe, $n = 2$; M = Co, $n = 1$) has been measured in both crystalline and polymethylmethacrylate environments up to 171 kbar. The broad absorption at *ca* 15.4 kK (650 nm) for each cluster has been deconvoluted into three separate peaks. In the case of the iron cluster, tentative assignments of the transitions are made on the basis of their shifts with pressure in conjunction with a previously-reported SCF-Xα calculation. The cobalt cluster shows a much weaker pressure dependence, which is attributed to weaker metal–metal interactions and more delocalized ligand character in the frontier orbitals.

Extensive interest in the chemistry of sulphido–metal clusters has developed in recent years, due mainly to their significance as models for heterogeneous metal–sulphide catalysts[1] or the active sites of certain redox proteins.[2] In particular, Ghilardi and co-workers have succeeded in the synthesis and structural characterization of octahedral, paramagnetic clusters of the type $M_6(\mu_3\text{-}S)_8(PEt_3)_6^{n+}$ (M = Fe, $n = 2$; M = Co, $n = 1, 0$).[3,4] These clusters are specifically noteworthy due to their structural similarity to clusters present in the bulk metal sulphides known as the Chevrel phases, some of which become superconducting upon the application of modest pressures.[5]

The electronic structure of these molecular clusters is an active issue. For $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$, magnetic susceptibility and EPR measurements suggest a ground state electron configuration with six unpaired electrons.[3] This is at odds with a SCF-Xα calculation that indicates only four unpaired spins, with the highest occupied level predominantly Fe—Fe bonding. The analogous cobalt cluster, with seven additional valence electrons, is also paramagnetic[4] but details of its magnetic properties or electronic structure are presently unknown.

In an effort to cast light on the nature of the bonding in these systems, a study of the effects of pressure on the visible electronic spectra of $M_6(\mu_3\text{-}S)_8(PEt)_6^{n+}$ (M = Fe, $n = 2$; M = Co, $n = 1$) was undertaken. Pressure tuning spectroscopy (PTS) has been demonstrated to be a powerful means of probing the electronic structure of various molecules, including metal clusters.[6] Changes in static pressure may effect dramatic changes in the electronic energy levels, with such changes highly dependent upon the nature of the orbital interactions in the molecule.

EXPERIMENTAL

$[M_6(\mu_3\text{-}S)_8(PEt_3)_6][B(C_6H_5)_4]_n$ (M = Fe, $n = 2$; M = Co, $n = 1$) were prepared by literature methods.[3,4] Crystalline samples of each were examined using Nujol as a pressure transmitting medium. Both compounds were also studied in a polymeric environment by dissolution in polymethylmethacrylate (PMMA). Each sample was loaded into a diamond anvil cell (DAC). All runs were reproduced at a minimum of two separate loads. The ruby fluorescence method was utilized for pressure calibration.[7] The light source employed was an Oriel tungsten halogen lamp, dispersed by a Kratos 1/4 m monochromator using either a 1000 or 450 blaze grating. Light in the visible region was detected by EMI 9558 or 9658 photomultiplier tubes, along with an Ortec photon counting system. Further details concerning the optical system may be found elsewhere.[8]

*Authors to whom correspondence should be addressed.

The resulting spectra were fit with a series of symmetric Gaussian peaks by means of a computer program that varied the values for each peak's height, location, and full width at half-maximum in order to achieve the minimum variance.

RESULTS AND DISCUSSION

The effect of increasing pressure on the visible spectrum of $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$ dissolved in PMMA is illustrated in Fig. 1. For each spectrum, the broad absorption at *ca* 15.4 kK (620 nm) is most accurately deconvoluted into three separate peaks. The effect of pressure on these three peaks is graphically represented in Fig. 2, both for molecules of the cluster dissolved in PMMA as well as for the crystalline material. Two points should be noted from these shifts. The first is that qualitatively the shifts are the same in both media. This implies that the effects of pressure are intramolecular in nature. The second point is that for each peak there is an initial dramatic blue shift of 10–15 cm^{-1}/kbar, up to approx. 100 kbar. At that point, the slopes of the shifts decrease by an order of magnitude.

Tentative assignments of the three peaks resolved for the Fe_6 cluster may be made by utilizing the above pressure shift data in conjunction with a previously reported SCF-Xα calculation. In Table 1, a comparison of the observed E_{max} values with possible symmetry-allowed one-electron transitions from the Xα calculation is given. From this comparison, it can be seen that the lowest energy peak most closely matches energetically the computed $6t_{2g} \rightarrow 10t_{1u}$ transition, an excitation originating from an MO of mostly Fe—P bonding character to a virtual level of delocalized P—Fe—S interactions. The next experimental absorption peak may be interpreted in terms of either $3t_{1g} \rightarrow 10t_{1u}$ or $4t_{2u} \rightarrow 6e_g$ transitions. The former transition both originates and terminates in MOs involving delocalized P—Fe—S bonding, while the latter originates from an MO primarily Fe—Fe bonding and ends in a delocalized P—Fe—S energy level. Finally, the highest energy band, closely matching the computed $4t_{2u} \rightarrow 7t_{2g}$ transition, involves a level of Fe—Fe interactions as its origin and terminates in a more delocalized Fe—S orbital.

Given the similar shifts of all peaks with increasing pressure, the above assignments are consistent with experimental observations. These assignments reflect pairs of transitions that either originate or terminate in molecular orbitals of identical symmetry (i.e. $4t_{2u}$ or $10t_{1u}$). In the case of the middle-energy peak, one cannot definitely distinguish

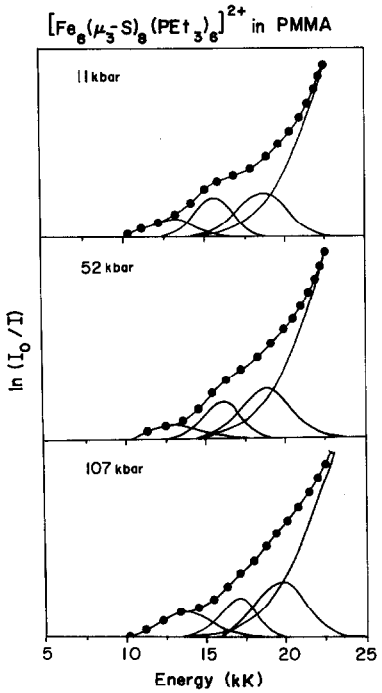

Fig. 1. The visible spectrum of $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$, dissolved in PMMA, at 11, 52 and 117 kbar.

Table 1. Observed and calculated E_{max} values of $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$ and the transition type

E_{max} (kK) Crystalline[a]	PMMA[a]	Calcd[b]	Transition type
12.1	13.0	13.7	$6t_{2g} \rightarrow 10t_{1u}$ (Fe—P → P—Fe—S)
14.9	15.5	15.7	$3t_{1g} \rightarrow 10t_{1u}$ (P—Fe—S → P—Fe—S)
		16.0	$4t_{2g} \rightarrow 6e_g$ (Fe—Fe → P—Fe—S)
18.0	18.5	17.5	$4t_{2u} \rightarrow 7t_{2g}$ (Fe—Fe → Fe—S)

[a] Experimental E_{max} values extrapolated to 1 atm.
[b] Ref. 3.

between the two possibilities given, although the $3t_{1g} \rightarrow 10t_{1u}$ assignment is somewhat closer energetically to the observed value. It should be emphasized also that these assignments concur with the ground state electronic configuration suggested by EPR and magnetic susceptibility data.[3]

The shifts with increasing pressure for the analogous peaks in the case of the cobalt cluster in both crystalline form and PMMA are illustrated in Fig. 3. While the scatter in the polymer data is substantial, it is apparent from consideration of the data from both media that there is an absence of a noteable blue shift for the two lowest energy bands in $Co_6(\mu_3\text{-}S)_8(PEt_3)_6^+$. This effect is most pronounced if one compares, for example, the shifts obtained for the crystalline Fe_6 cluster with the analogous Co_6 molecule (Fig. 4). While there is no detailed theoretical study available to assist in spectral assignments of this cobalt cluster, some qualitative explanations for the differences between the iron and cobalt analogues are possible. Consideration of structural data reveals that the average metal–metal bond lengths in the cobalt cluster are considerably

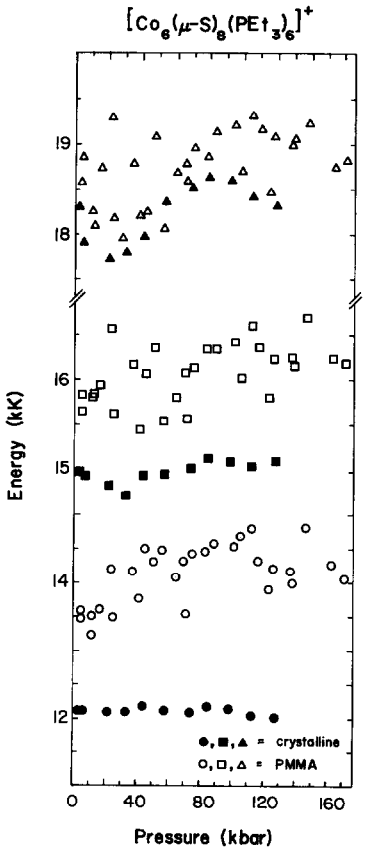

Fig. 3. The effect of pressure on the three visible absorption peaks of $Co_6(\mu_3\text{-}S)_8(PEt_3)_6^+$ in crystalline and PMMA environments.

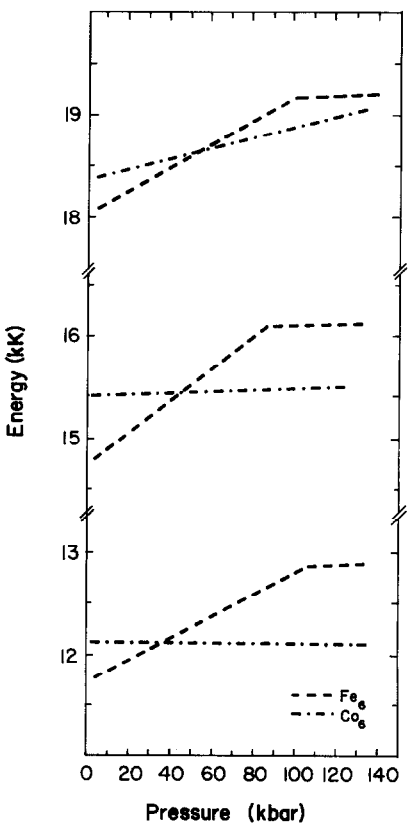

Fig. 4. Comparison of the shifts in crystalline $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$ and $Co_6(\mu_3\text{-}S)_8(PEt_3)_6^+$ (least-squares fit).

longer than in the Fe_6 analogue and also longer than those in other large cobalt clusters. These relatively long Co—Co bonds are presumably related to the high valence electron count (97) in this cluster, and reflect weaker metal–metal interactions as a consequence. It should also be noted that the metal–sulphur and metal–phosphorus distances are shorter in this cluster, and the balance between M—M and P—M—S energy levels will be affected as a result. Recall that in the case of the Fe_6 cluster, two of the assigned peaks are transitions from energy levels primarily of M—M character to more delocalized metal–ligand orbitals. Thus the absence of a substantial blue shift with increasing pressure for the visible absorption bands of this Co_6 cluster suggests that their transitions arise and terminate in electronic energy levels which are more delocalized throughout the entire cluster than the iron analogue.

Finally, it should be noted that the highest energy absorption of the Co_6 cluster in a crystalline environment does appear to mimic somewhat the analogous band in the Fe_6 cluster in terms of a blue shift. This result is taken albeit with some suspicion, since the intensity of this band is extremely close to an intense absorption in the UV (a band not accessible with our equipment). Thus it is doubtful if the measured shift is quantitatively meaningful.

In summary, the observations reported here provide a tentative assignment of the visible electronic spectrum of $Fe_6(\mu_3\text{-}S)_8(PEt_3)_6^{2+}$, an assignment which is consistent with previously reported experimental data. Distinct differences between the optical properties of the iron and cobalt analogues are present, due presumably to differences in their frontier electronic levels. Further experiments, in particular a rigorous theoretical study of $Co_6(\mu_3\text{-}S)_8(PEt_3)_6^{+}$, are needed to clarify these differences.

Abstract—The UV photoelectron (PE) investigation of dicarba-*closo*-dodecaboranes 1,12-$C_2B_{10}H_{12}$, 1-SH-1,12-$C_2B_{10}H_{11}$, 2-SH-1,12-$C_2B_{10}H_{11}$, 1-X-1,2-$C_2B_{10}H_{11}$ (X = SH, phenyl), 3-phenyl-1,2-$C_2B_{10}H_{11}$, 4-X-1,2-$C_2B_{10}H_{11}$, 8-X-1,2-$C_2B_{10}H_{11}$, 9-X-1,2-$C_2B_{10}H_{11}$, 9-X-1,7-$C_2B_{10}H_{11}$ (X = SH, CH_3S) and 1-SH-1,7-$C_2B_{10}H_{11}$ is reported. The first two band systems in the PE spectrum of 1,12-$C_2B_{10}H_{11}$ are assigned to cluster π-bonding orbitals and σB—H(C—H)-bonding orbitals, respectively. The interaction between exo-substituent and cluster π-orbitals is weak and the sulphur lone pair ionization energy depends simply on the mutual position of substituent and carbon atoms. The electron density at particular vertices in 1,2-$C_2B_{10}H_{12}$ decreases in the order $9 \gtrsim 8 > 4 > 3 > 1$.

Cluster compounds of boron have been the subject of extensive experimental and theoretical investigation.[1,2] The bonding in heteroboranes and perturbations of the electron densities brought about by heteroatoms or substituents are still not clearly understood. The rationalization of the electron structure and chemistry of polyhedral borane compounds contribute to the general understanding of electron deficient systems. The interest in these compounds is also stimulated by the analogy with the transition metal cluster species through the isolobal principle.[3,4] The separation of the skeletal bonding from the exo-skeletal bonding is useful for the rationalization of the cluster bonding and of Wade's electron counting rules,[5] but any endo–exo separation is not rigorous and thus the equatorial–apex approach and tensor surface harmonics (TSH) methods[6–11] are of limited use for the interpretation of the UV–PE spectra. Moreover, the carbon atoms substituting boron vertices in *closo* structures (deltahedral regular polyhedron) introduce a distortion of spherical symmetry inherent to the TSH approach. Within the Stone TSH approach, the molecular orbitals (MOs) of a cluster are built up from the orbitals of B—H groups. Three orbitals are available for the endo-cluster bonding, namely two *p* orbitals perpendicular to the B—H bond and an inward-pointing, radially oriented, *sp* hybrid. In the limit of spherical symmetry, the resulting MOs are labelled *S*, *P*, *D*, *F* etc. The MOs composed of the *sp* hybrid are labelled by the superscript σ, and the MOs composed of the *p* orbitals have the properties of vector surface harmonics and are labelled P^π, D^π etc. The correlation of some irreducible representations of the full rotation group with those of its I_h and D_{5d} subgroups is shown in Table 1.

Some carboranes were the subject of semi-empirical[12–19] and *ab initio*[20,21] calculations. The MNDO MO energies in a series of *closo*-boranes are in reasonable agreement with the results of TSH calculations involving the cage σ–π interaction[22] and with the *ab initio* results.[23] The MNDO calculated orbital energies were used for the interpretation of the HeI PE spectra of *closo*-carboranes, 1,2-

EXPERIMENTAL

The photoelectron spectrometer used was the VG Scientific UVG 3 instrument. The working resolution was 30–40 meV throughout the whole scanned range, since the analyser was operated in the constant passing energy mode. The HeI PE spectra were calibrated by an Ar–Xe mixture added to the measured sample. The temperature of evaporation varied in the 80–140°C range. The samples (**1–15**) (Fig. 1) were prepared by original methods[29–31] or according to already known procedures.[32–34] The MNDO program developed by W. Thiel[35] was used. The experimental coordinates of heavy atoms were fixed,[36] whereas the internal coordinates of the hydrogen atoms were allowed to relax. For the *closo*-$B_{12}H_{12}^{2-}$ species the I_h symmetry and B—B and B—H distances of 1.782 and 1.166 Å were adopted, respectively.

RESULTS AND DISCUSSION

1,12-*dicarbadodecaborane* (1) *and derivatives* (2, 3)

The PE spectrum of (**1**) is similar to the spectra of isomeric 1,2-$C_2B_{10}H_{12}$ and 1,7-$C_2B_{10}H_{12}$.[24] The higher symmetry of (**1**) (D_{5d} point group) brings about a smaller number and a better resolution of PE bands observed in the spectrum (Fig. 2). For the assignment of the photoelectron bands, the validity of the Koopmans' theorem,[37] i.e. equating of ionization energies to the negative of orbital energies, is assumed. In the PE spectrum, four overlapping bands are observed within the 10.5–12.1 eV interval (region A) and another three bands are found in the 13.5–14.3 eV interval (region B). The high energy region of the spectrum (region C) consists of two bands at 16.01 and 17.22 eV, and of a shoulder on the low energy side of the band peaking at 16.01 eV. The MNDO calculation provides a picture consistent with the PE spectrum: the five outermost occupied levels lie within the 1 eV interval (Fig. 3). These levels are the g_u and h_g symmetry species (in the I_h point group). The inspection of the composition of these levels shows that those belonging to the F species ($2e_{2u}$ and $3e_{1u}$ in D_{5d} point group) are composed purely of the boron and carbon p-orbitals which combine in lobes directed tangentially to the sphere circumscribing the cluster (Table 2). These levels which belong to the D representation, namely $2e_{2g}$, $2e_{1g}$ and $4a_{1g}$, have a considerable contribution from hydrogen s-orbitals. These levels are also of the π-type but the axes of the resulting surface orbitals are not perpendicular to the exo-bonds and thus they have a non-zero overlap with the hydrogen s-orbitals. The mixing of

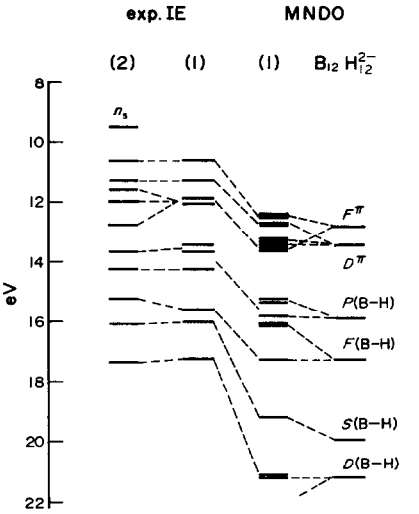

Fig. 3. Diagram of vertical IEs of 1,12-$C_2B_{10}H_{12}$ (**1**) and MNDO orbital energies for (**1**) and $B_{12}H_{12}^{2-}$. The scale is shifted by 10 eV to lower energy for $B_{12}H_{12}^{2-}$.

hydrogen *s*-orbitals with the *D* species is symmetrically allowed since the 12 hydrogen *s*-orbitals transform as a_g, t_{1u}, t_{2u} and h_g. Carborane (**1**) does not strictly have the I_h symmetry. Calculation of the regular icosahedral anion, $B_{12}H_{12}^{2-}$ (Table 3), shows that the deviation from the I_h symmetry does not affect to a significant extent the contribution of the hydrogen *s*-orbitals in the *D* surface levels.

[b] The sum of squares of atomic orbital coefficients over all hydrogen atoms.

Table 3. Calculated MO energies and composition of MOs for *closo*-$B_{12}H_{12}^{2-}$

I_h	R_3	$-\varepsilon$ (eV)	H^a (%)	Character
$1g_u$	F	2.8	0	π
$2h_g$	D	3.43	38	π
$2t_{1u}$	P	5.84	44	σ-BH
$1t_{2u}$	F	7.22	48	σ-BH
$2a_g$	S	9.92	40	σ-BH
$1h_g$	D	11.81	18	σ-BH
$1t_{1u}$	P	19.8	7	σ
$1a_g$	S	31.27	7	σ

[a] The sum of squares of atomic orbital coefficients over all hydrogen atoms.

The following five levels ($2e_{1u}$, $3a_{2u}$, $1e_{2u}$, $2a_{2u}$ and $3a_{1g}$) have a σ-exo bonding character. Within the Stone notation these levels belong to the P, F and S species. Thus on the basis of the MNDO calculated MO energies, the bands *a–d* in region A of the spectrum of (**1**) can be assigned to the F and D cluster π-levels and three observed bands *e–g* in region B to the F and P σ-BH orbitals. The band *i* and the shoulder *h* on its low energy side may be tentatively assigned to the a_{2u} component of the F σ-BH and to the S σ-BH level, respectively. The remaining band *j* may arise from the ionization of the highest component of the D σ-BH level but the agreement of the vertical IEs and the relative spacings of MO energies is rather poor in region C.

The substitution of the C(1) hydrogen by the SH-group lowers the symmetry of 1,12-$C_2B_{10}H_{12}$ to C_{5v} (if the non-linearity of the SH-group is neglected) and thus the number of the endo-bonding levels is conserved. The PE spectrum of the 1-SH-derivative (**2**) differs markedly in the band envelope within region A. Two bands (*b*, *c*) are observed instead of band *b* in (**1**) and the ionizations *c* and *d* of the parent compound seem to fall within band *d* and a new weak band *e* appears. The narrow peak *x* appearing at 9.50 eV is unambiguously due to the ionization of the sulphur lone pair (n_S). Since the π-conjugative interactions between skeletal π-orbitals and substituent *p*-orbitals were found to be weak,[24] the effect of the substituent is predominantly of the inductive nature. The n_S vertical IE is equal to that in methanethiol[38] and thus a similar electron density on the carbon atom may be anticipated.

The position of the first two π-ionizations is not affected by the substituent. This agrees with the calculated MO localizations. The two highest occupied π-levels have no contribution from the carbon orbitals and thus the SH substituent has only a slight effect on their IEs. On the other hand, the $2e_{1g}$, $4a_{1g}$ and $3e_{1u}$ π-levels have considerable contributions from the carbon orbitals. These levels may be more sensitive to the substitution and this may rationalize the changes of the band envelope within bands *c* and *d*, and the appearance of band *e* at 12.75 eV. The latter band may be assigned to the $4a_{1g}$ level for which the σ-overlap with sulphur orbitals is symmetry allowed and the calculation of parent (**1**) provides a high contribution of carbon bonded hydrogen *s*-orbitals. The same argument supports the assignment of band *h* to the $2a_{2u}$ exo-bonding level which seems significantly destabilized in (**2**).

The PE spectrum of 2-SH-1,12-$C_2B_{10}H_{11}$ (**3**) exhibits at least six transitions within region A. The higher number of bands observed is clearly due to the loss of the five-fold axis. The n_S ionization is shifted by 0.27 eV to lower IEs.

Phenyl derivatives (**11**, **12**)

The two sharp bands (*x*, *x'*) which appear before the onset of skeletal π-ionizations come from the ionization of the $e_{1g}(\pi)$-level of phenyl (Fig. 4). As is observed in the PE spectra of benzene derivatives, this level is split into the b_1 and a_2 orbitals (in C_{2v} point group). The splitting is a measure of the π–π interaction.[39] The observed splitting (0.29 eV) is lower than that found for methylbenzene[40] (0.52 eV) where only the hyperconjugative and the inductive effects work. It corroborates the conclusion that the π–π interaction between the cluster and exo-substituent is weak.

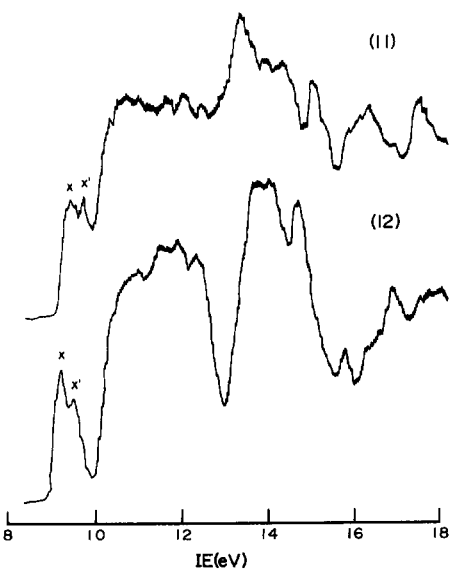

Fig. 4. HeI PE spectra of phenylcarboranes (**11**) and (**12**).

Mercapto and methylthio derivatives (**4–10, 13–15**)

Examples of PE spectra of the SH and CH_3 derivatives are shown in Fig. 5. The shape of the PE spectra of the parent 1,2-$C_2B_{10}H_{12}$ and 1,7-$C_2B_{10}H_{12}$ is conserved. A new band (x') emerges in the spectra of (**8**) and (**10**). It arises probably from the ionization of the sulphur angle determining orbital ($\tilde{n}_S$), rather than from the skeletal π-ionizations. The IEs of sulphur localized orbitals are summarized in Table 4. The n_S IE of CH_3S derivatives is 0.66–0.69 eV lower than that of corresponding SH derivatives.

The n_S IE decreases with an increase in the number of edges connecting the B—S(H, CH_3) vertex (denoted B_x) with the carbon vertices. When the number of edges between the carbon atoms and the B_x vertex are the same, then IEs are identical (within the experimental error) as follows from the comparison of pairs (**3**)–(**5**), (**7**)–(**14**) and (**8**)–(**15**) (see Table 4). The increase of one $C\cdots B_x$ distance in the 1,2-isomer from one to two edges (denoted $1 \rightarrow 2$) brings about a destabilization of 0.48 eV, as follows from the comparison of (**5**) and (**7**). A further increase in the $C\cdots B_x$ distance to three edges ($2 \rightarrow 3$) results in the destabilization by 0.04 eV in (**9**).

For the phenyl derivatives the destabilization of the phenyl $e_{1g}(\pi)$ level amounts to 0.26 eV on going

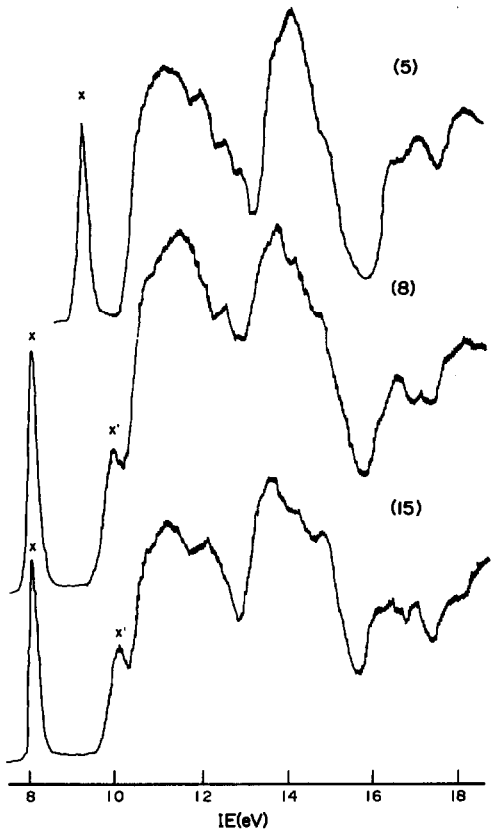

Fig. 5. HeI PE spectra of mercapto- and methylthiocarboranes (**5**), (**8**) and (**15**).

Table 4. n_S, $\tilde{n}_S$ and phenyl $e_{1g}(\pi)$ vertical IEs in substituted carboranes[a] (eV)

Distance (edges)[b]		HS—		CH_3S—		Phenyl $e_{1g}(\pi)$		
C(1)	C(x)	n_S	$\tilde{n}_S$	n_S	$\tilde{n}_S$	a_2	b_1	M[c]
				(eV)				
0	1	9.99 [4]				9.77	9.48	9.63 [11]
0	2	9.58 (9.51) [13]						
0	3	9.50 (9.47) [2]						
1	1	9.73[d]				9.51	9.22	9.37 [12]
1	2	9.25 (9.25) [5]		8.58 (8.56) [6]				
		9.24 (9.25) [3]						
2	2	8.77 (8.77) [7]		8.08 (8.09) [8]	10.01			
		8.77 (8.77) [14]	10.65	8.11 (8.09) [15]	10.14			
2	3	8.73 (8.73) [9]		8.03 (8.04) [10]	10.04			

[a] The values in parentheses are the calculated IEs if the destabilization of the substituent orbital is taken as 0.26, 0.48 and 0.04 eV for the increase in the number of edges separating the substituted skeletal atom from carbon atom from $0 \rightarrow 1$, $1 \rightarrow 2$ and $2 \rightarrow 3$, respectively. The compound's number is in brackets. The effect of both carbon atoms is assumed additive and [4] is taken as the reference point. In the MeS derivatives [6, 8, 10 and 15], the destabilization of the n_S orbital by 0.68 eV induced by the methyl group is assumed.

[b] The number of edges separating the substituted skeletal atom from carbon atoms C(1) and C(x); $x = 2, 7, 12$.

[c] The mean value of a_2 and b_1 IEs.

[d] Estimated value for 3-SH-1,2-$C_2B_{10}H_{11}$.

from the 1- to the 3-derivative, i.e. when the $C\cdots B_x$ distance increases by one C—B edge (denoted $0 \rightarrow 1$). We can assume the same destabilization of the SH derivative and thus the n_S IE of 9.73 eV can be estimated for 3-SH-1,2-$C_2B_{10}H_{11}$. This value is consistent with the n_S IE of (**5**) which can be formally derived from the 3-SH derivative by an increase of one $C\cdots B_x$ distance from one to two edges.

If the additivity of the effects of carbon atoms is assumed, the relative destabilization of the sulphur lone pair in the derivatives of 1,7-$C_2B_{10}H_{12}$ and 1,12-$C_2B_{10}H_{12}$ can be estimated. Derivative (**13**) is formally derived from (**4**) by the $(1 \rightarrow 2)$ shift. The estimated IE of 9.51 eV agrees well with the experimental one (9.58 eV). Compound (**14**) can be derived from (**4**) by the $2\times(1 \rightarrow 2)+(0 \rightarrow 1)$ shift which corresponds to the destabilization of 1.22 eV. The calculated IE agrees with the experimental value (8.77 eV). For derivatives (**2**) and (**3**), the destabilization can be calculated in the same way. It is equal to $(1 \rightarrow 2)+(2 \rightarrow 3) = 0.52$ eV for (**2**) and $(0 \rightarrow 1)+(1 \rightarrow 2) = 0.74$ eV for (**3**). These estimates, 9.47 and 9.25 eV, are consistent with the experimental values (9.50 and 9.25 eV, respectively).

The sulphur lone pair IE is influenced by the electron density at the point of substitution. The relative changes in n_S IE show that the electron density in 1,2-$C_2B_{10}H_{12}$ decreases in the order $9 \gtrsim 8 > 4 > 3 > 1$, and the electron density in the B(9) position in 1,7-$C_2B_{10}H_{12}$ is approximately equal to that in the B(8) position in 1,2-$C_2B_{10}H_{12}$, and position two in 1,12-$C_2B_{10}H_{12}$ is equivalent to the position four in 1,2-$C_2B_{10}H_{12}$. The observed decrease of the n_S IE correlates well with the site selectivity of the electrophillic attack,[41,42] electron densities inferred from the pK_a values of carborane thiols[43] and with the *ab initio* calculated charges.[21]

CONCLUSIONS

The exo-substitution proved to be a suitable probe for the experimental assessment of electron distribution in perturbed icosahedral cluster species. The electron densities seem to depend only on the number of edges separating the respective vertex from the skeletal heteroatoms. The effect of the two carbon atoms is additive. The MNDO calculated MO picture is consistent with the PE spectra and the observed substitution effect. Although the hydrogen *s*-orbitals' participation seems to differ from Stone's assumption of the complete exo–endo bonding separation, the proposed sequence of the highest occupied levels π-endo, σ-exo seems justified by the interpretation of PE spectra.

(*Received* 16 *August* 1988; *accepted* 20 *October* 1988)

Abstract—Complex formation between Fe^{3+} ions and malonic acid (H_2L), in acidic aqueous solutions containing 0.5 M $NaNO_3$ as inert ionic medium at 25°C, has been studied potentiometrically. The data were consistent with the following reactions and related stability constants:

$$Fe^{3+} + L^{2-} = FeL^{+} \quad \log \beta_{0,1,1} = 7.52$$
$$Fe^{3+} + 2L^{2-} = FeL_2^{-} \quad \log \beta_{0,1,2} = 13.29$$
$$Fe^{3+} + 3L^{2-} = FeL_3^{3-} \quad \log \beta_{0,1,3} = 16.93$$

which agree partially with previous models. No mixed complexes were detected, i.e. hydrolytic complex species. A suggestion of possible structures for the complex species formed is briefly discussed. In separate experiments and in the absence of Fe^{III}, protolytic reactions of malonic acid were studied under the same experimental conditions. A numerical comparison of these results with those already published was carried out by means of the Specific Interaction Theory (SIT).

The biological activity of metal ions depends to a great extent on the interactions with those metal complexing agents present in the environment[1] and the formation of strong soluble complexes between Fe^{III} and ligands bearing carboxylic groups which are present in nature, is widely known. A systematic study including chemical characterization of these agents is currently being carried out in our laboratories. Results on the complexation of Fe^{III} with tartrate have been published.[2] We have also investigated iron(III)–malonate complexes in acidic solutions. The presence of malonic acid retards to lower pH the precipitation of ferric hydroxide in aqueous solutions. These differences with respect to tartaric acid excited our curiosity to ascertain the role of side hydroxyl groups in similar ligands.

Iron(III)–malonate complexes have been studied by several authors using different techniques and thermodynamic conditions[3–9] (see Table 1). Thus, a kinetic study carried out by Cavasino[4] found

the species FeL. Gordienko,[5] using amperometric measurements, postulates the species FeL and FeHL. In a polarographic study, Schaap *et al.*[6] suggested the species FeL_3. Alternatively, Ramamoorthy and Manning,[8] from potentiometric data, give a model with the species FeL and FeL_2 to exlain the behaviour of the iron(III)–malonate system. Finally Dellien,[9] working in very acidic media and employing both potentiometric and calorimetric techniques, found the complex species FeL, FeL_2 and FeL_3. All these studies were performed at 25°C and different ionic media were employed. A careful and systematic study of the chemical interactions between Fe^{3+} and malonic acid in aqueous solutions has been carried out in the present work. Potentiometric data obtained in a wide concentration range of the reacting species were analysed to quantitatively characterize the complex species and related stability constants.

EXPERIMENTAL

Reagents, solutions and apparatus

Malonic acid (Scharlau, AR) was used with no further purification, its purity was verified by potentiometric titration. Ferric nitrate (Merck, AR) was used as supplied to prepare stock solutions in 0.5 M NO_3^-. The Fe^{III} content was determined as described in ref. 10. The free acidity, h, in iron solutions was obtained following ref. 11. $NaNO_3$ (Probus, AR), purified as described in ref. 12, was used as the ionic media. Solutions of carbonate-free NaOH were prepared and determined as described elsewhere.[12] Stock solutions of malonic acid, $Fe(NO_3)_3$, HNO_3 and NaOH were conditioned in $NaNO_3$ to achieve an ionic strength of 0.5 M.

A digital voltimeter (Crison Digilab 517) of 0.1 mV precision interfaced to an Epson HX 20 computer was used to control the potentiometric experiments. A glass electrode (Metrohm 1028) connected against a double junction reference electrode (Orion 9020) were employed to generate the EMF data.

Method of investigation

Continuous EMF measurements have been performed in order to analyse the equilibrium state of the system. The hydrogen ion concentration, h, has been experimentally determined in a number of solutions prepared from stock solutions of $Fe(NO_3)_3$, malonic acid, HNO_3 and $NaNO_3$.

Measurements of EMF were performed by titrations using the galvanic cell I formulated by:

$$RE//TS/GE, \qquad (I)$$

where GE indicates a glass electrode and RE represents a double junction reference electrode. Stability criteria of the EMF measurements considered the potential to be stable when the variation was less than 0.1 mV within 10 min.

For each experiment, the analytical concentrations of Fe^{III} (**B**) and malonate (**L**) were varied in the range 2.0–6.0 mM and 5.0–20.0 mM, respectively. Values of pH varied from 1.5 to 5.5, where precipitation of ferric hydroxide was observed.

The experimental data are collected in Fig. 1 in the form Z vs $-\log h$ at the different **B** and **L** levels. Z represents the number of H^+ bound to the total malonate and is defined by:

$$Z = (\mathbf{H} - h + Kw/h)/\mathbf{L} \qquad (1)$$

where **H** represents the analytical concentration of hydrogen ion.

In order to verify our equilibrium data, experimental points obtained in back titrations are plotted in Fig. 1 by means of full symbols. The good agreement between the forward and back titration data shows that only reversible processes take part in the

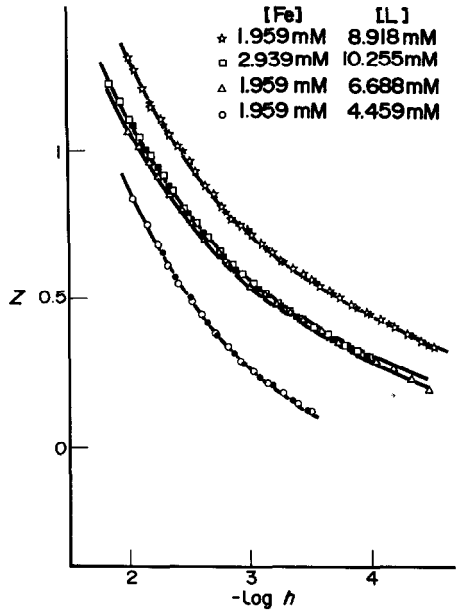

Fig. 1. Z plotted vs $-\log h$ for the different sets of experiments. Full points represent back titrations. Solid lines have been calculated by the model proposed in the present work.

complexation reactions. All the experiments were performed at 25 ± 0.2°C.

RESULTS

Analysis of the experimental information is based on the complex formation between ferric ions, Fe^{3+}, and malonic acid, expressed by the general equation:

$$pH + qFe + rL = H_pFe_qL_r; \quad \beta_{p,q,r} \qquad (2)$$

where $\beta_{p,q,r}$ represents the formation constants of the complex species with different p, q and r values. Charges are omitted for simplicity.

The stoichiometry of the complexes, and the constant $\beta_{p,q,r}$ have been determined by means of a numerical analysis of the experimental data. For this purpose, the computer programs LETAGROP[13] and SUPERQUAD[14] were used. In both cases, the treatment is based on the minimization of an error square sum U, defined by:

$$U = \sum_{N_p} (E_{calc} - E_{exp})^2 \qquad (3)$$

where E_{exp} represents the experimental EMF values, E_{calc} is a corresponding magnitude calculated by the program, assuming a determined model of species formed and related stability constants, and N_p is the number of experimental points.

As has been discussed previously,[2,15] a systematic analysis of such ternary systems (three reacting components) requires a well established knowledge of the binary interactions, i.e. the protolysis of malonic acid and hydrolysis of Fe^{III}. In our case, data for Fe^{III} hydrolysis has been taken from a previous work,[16] which was performed under the same experimental conditions. With respect to malonic acid, the following study was carried out.

Protolytic equilibria of malonic acid

Experiments in the absence of Fe^{III} were carried out in order to quantitatively characterize malonic acid protolysis in the desired thermodynamic conditions.

In this case, the EMF data have been treated both by the Rossotti's graphical method[17] and numerically by the programs LETAGROP and SUPERQUAD. Table 2 gives the results for these treatments, which are found to be in good agreement.

On the other hand and for the sake of comparison with other results reported in the literature,[4,5,18–20] the different values of stability constants have been correlated using the Specific Interaction Theory, SIT.[21,22] Such a treatment of the data can be summarized by the expression:

$$\beta_1^I = \beta_1^0 \gamma_H \gamma_L / \gamma_{HL} \qquad (4)$$

where β_1^I represents the protolytic constant at the ionic strength I, β_1^0 is the value of this constant at $I = 0$ and γ_H, γ_L, γ_{HL} the activity coefficients of H, L and HL species. The activity coefficients follow the expression:

$$\log \gamma_i = -z_i^2 D + \sum_k \varepsilon_{ik} m_k \qquad (5)$$

where D is the Debye–Huckel term, k represents the species with opposed charge to i in the ionic media, m_k represents their molality and ε_{ik} are the specific interaction coefficients between the corresponding species present in the aqueous solution. Applying SIT and rearranging eq. (4), the following expressions can be written for each one of the proto-

Table 2. Results obtained for the behaviour of malonic acid in aqueous 0.5 M $NaNO_3$, by different graphical and numerical methods. $K_{a1} = \beta_2 \beta_1^{-1}$, $\beta_1 = K_{a2}^{-1}$ where K_{a1} and K_{a2} are the corresponding acidic constants

lytic constants ($X = NO_3^-$):

$$Y_1 = \log \beta_1^I + 4D - \varepsilon_{H,X} m_X = \log \beta_1^0 + (\varepsilon_{L,M} - \varepsilon_{HL,M}) m_M \quad (6)$$

$$Y_2 = \log \beta_2^I + 6D - 2\varepsilon_{H,X} m_X = \log \beta_2^0 + \varepsilon_{L,M} m_M. \quad (7)$$

In Fig. 2, Y_1 and Y_2 vs I are represented for the different data considered. As seen, our results show a good fit in such a correlation.

Numerical treatment of the ternary system

With respect to the Fe^{III}–malonate system, a numerical analysis of data has been carried out, starting from previous results[3–9] to fit to our experimental data. The results of the calculation are collected in Table 3. As seen in this table, the best fit to the experimental data corresponds to the model where the species FeL, FeL_2 and FeL_3 are formed. This result is expressed by the following reaction equations, and the corresponding $\beta_{p,q,r}$ values are given:

$$Fe^{3+} + L^{2-} = FeL^+ \quad \log \beta_{0,1,1} = 7.52 \quad (8)$$

$$Fe^{3+} + 2L^{2-} = FeL_2^- \quad \log \beta_{0,1,2} = 13.29 \quad (9)$$

$$Fe^{3+} + 3L^{2-} = FeL_3^{3-} \quad \log \beta_{0,1,3} = 16.93 \quad (10)$$

Further analysis of the results, including polynuclear and mixed species (i.e. protolytic species) has shown that such species do not fit the experimental data.

Figure 3 shows the individual values of $(E_{calc} - E_{exp})$ mV in the acidic range studied. As seen, the proposed model shows no systematic deviations with respect to the experimental data.

Table 3. Results obtained on the numerical treatment of the experimental data for the system Fe^{III}–malonic acid

Model	(p, q, r)	U	σ (mV)	$\log \beta_{p,q,r}$

DISCUSSION

The results obtained in the present work correspond to the formation of a complex between Fe^{III} and malonic acid in aqueous solutions of 0.5 M $NaNO_3$ as the ionic medium.

The experimental data have verified the equilibrium state of the system as well as that no irreversible or sideways process is taking part in the reactions studied.

The complex species formed are represented by eqs (8)–(10). From the numerical treatment of the data, no polynuclear or protonated species were detected. This fact indicates a different behaviour of this system with respect to the Fe^{III}–tartrate system studied previously[2] in which the formation of polynuclear complexes has been postulated. On the other hand, the stability of the Fe^{III}–tartrate com-

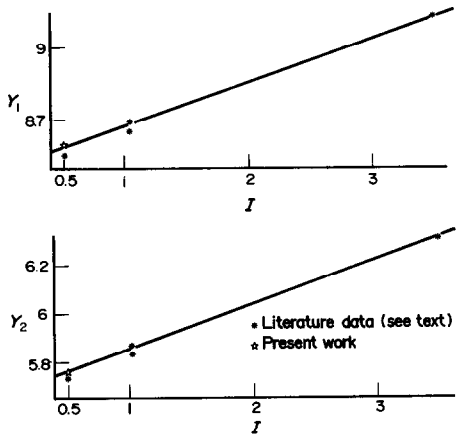

Fig. 2. Correlation of the protolytic constants of malonic acid by means of the Specific Interaction Theory (SIT).

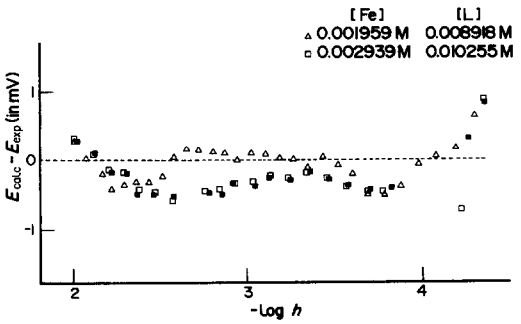

Fig. 3. $(E_{calc} - E_{exp})$ mV vs $-\log h$ for the different experimental values analysed. E_{calc} correspond to the EMF values calculated by the program on the basis of the proposed model.

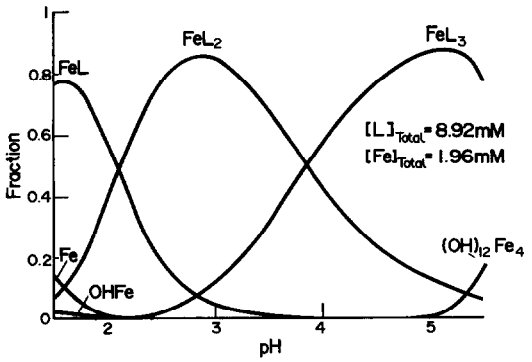

Fig. 4. Fraction diagram of the Fe^{III}–malonate complex species as a function of $-\log h$.

plexes is higher than the Fe^{III}–malonate, thus precipitation of ferric hydroxide is observed at a pH > 5.5, while in the presence of tartaric acid this does not occur. These differences may be explained by the contribution of the hydroxyl groups of the tartaric acid to form more stable complexes.

In Fig. 1 the solid lines represent calculated values of Z vs $-\log h$ using the model given by eqs (8)–(10). The agreement with experimental values shows a high confidence level on this model.

Figure 4 shows the distribution diagram of the species, calculated by the program HALTAFALL,[23] in the acidic range studied. As seen, a step-wise formation of complexes is observed.

The proposed model in the present work corresponds to species of stoichiometry 1 : 1, 1 : 2 and 1 : 3 respectively. For these stoichiometries, and taking into account that Fe^{III} complexes usually have an octahedral co-ordination geometry,[24] it is possible to speculate on probable structures of the proposed species. In Fig. 5, possible structures for the species FeL, FeL_2 and FeL_3 are suggested. These speculations are consistent with the absence of both polynuclear and protolytic complex species in the Fe^{III}–malonate system. At any rate, further experimental information would be needed to properly determine such structures, i.e. direct spectroscopic measurements of the related solutions.

Taking into account the information summarized in Table 1, a correlation between our results and those obtained by Dellien[9] is observed. It is found that the differences in the respective constant values are small in spite of the different media utilized (see Table 4). The work of Dellien shows, in the case of FeL_3 species, that the uncertainty in β_3 is rather large $[(4\pm2)\times10^{16}]$. This may be a consequence of the experimental information, which has been obtained in a very acidic range (the acid content, h, ranges from 30 to 150 mM). In this sense, it is interesting to observe the concentrations of the

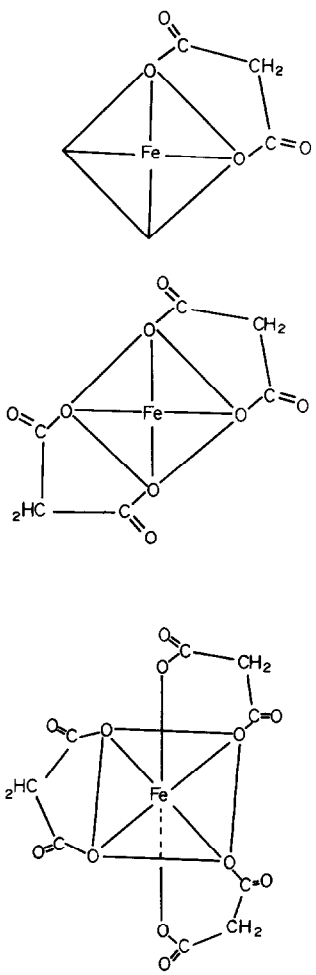

Fig. 5. Suggested structures for the Fe^{III}–malonate soluble complexes assuming an octahedral co-ordination of Fe^{III}.

complex species as a function of pH. Thus, in Fig. 4 it is observed that the presence of FeL_3 is less than 1% at pH < 1, while this species is the most abundant at pH 3.5. It is difficult to see how under such experimental conditions one can differentiate between species of such low concentration. In our case the work was extended up to pH ⩽ 5 where the different species, and especially FeL_3, can be easily distinguished.

Table 4. Differences between the values of stability constants for the Fe^{3+}–malonate equilibria obtained by Dellien[9] and the respective values proposed in this work

Species	$\log\beta$ (ref. 9)	$\log\beta$ (this work)
FeL	7.50	7.52
FeL_2	13.04	13.29
FeL_3	16.60	16.93

On the other hand, the slight differences observed between the constants derived in both investigations may explain that Fe^{3+}–NO_3^- interactions[25] are negligible under our experimental conditions.

PREPARATION AND CHARACTERIZATION OF MOLECULAR SIEVES BASED ON ALUMINIUM PHOSPHATE

YAN XU, PETER J. MADDOX and JOHN M. THOMAS*

Davy Faraday Research Laboratory, The Royal Institution, 21 Albemarle Street, London W1X 4BS, U.K.

(*Received* 27 *September* 1988; *accepted* 20 *October* 1988)

Abstract—An improved synthetic procedure for the preparation of MAPO-5 molecular sieves (M = Mg, Co, Mn, Ni, Cr) is reported. These compounds are shown to be monophasic by X-ray powder diffractometry and have surface areas between 250 and 270 $m^2\ g^{-1}$. Results of thermogravimetric analyses, scanning electron microscopy and *in situ* X-ray diffractometry are presented. Structural modification of the framework by the metal component is also discussed in the light of these data.

Of late, largely as a result of the work carried out by Flanigen, Lok, Wilson and co-workers,[1–6] many new types of open framework structures have been brought to light. Most of these have alternating trivalent aluminium and pentavalent phoshorus as the predominant occupants of the tetrahedral sites in their structures, with other elements such as lithium, beryllium, magnesium, boron, silicon and some transition elements[1] capable of being incorporated into the framework. These aluminium phosphates, metal aluminophosphates and metal–silicon–aluminophosphates (AlPO's, MAPO's and MSAPO's using the nomenclature of Flanigen *et al.*[1]) can also take up some of the structures previously identified among the zeolitic aluminosilicates (e.g. erionite, chabazite, faujasite). These materials are particularly promising as adsorbents especially for effecting difficult separations, but their catalytic properties have yet to be fully explored. As part of a larger investigation of novel catalytic reactions using these microporous aluminium phosphates, we focus in this paper on straightforward, improved methods of preparing some MAPO-5 molecular sieves, which contain *ca* 0.8 nm diameter, one-dimensional channels. We also report upon their characterization using a combination of X-ray diffractometry, thermogravimetry and other procedures, and comment on the extra-framework species which tend to occur in such microcrystalline samples.

EXPERIMENTAL

Synthesis

(i) *Materials.* Phosphoric acid (85%) was obtained from Aldrich Chemical Co. Ltd and aluminium hydroxide from Fluka Chemicals Ltd. Triethylamine (AR), hydrofluoric acid (40% AR), manganese(II) chloride tetrahydrate (AR), nickel(II) chloride hexahydrate (AR), cobalt(II) chloride hexahydrate and magnesium(II) chloride were obtained from BDH Chemical Co. Ltd. Chromium(III) nitrate nonohydrate was obtained from Alfa Products. Water was distilled and deionized before use.

(ii) *Preparation of aluminium phosphate solution.* Equimolar proportions of phosphoric acid and aluminium hydroxide were heated above 150°C for about 1 h, during which, small aliquots of water were continually added to maintain the reaction. Then extra water was added, and the mixture was filtered to remove unreacted aluminium hydroxide. The resulting filtrate is an aluminium phosphate solution with an Al–P molar ratio of 0.6, and this was employed for the synthesis of the MeAPO-5's.

(iii) *Preparation of* MAPO-5's (M = Mg, Co, Mn, Ni, Cr). The amount of each reactant used is based on the following molar ratios: 1.0 P_2O_5: 0.6 Al_2O_3: (0–0.3) $M^{2+/3+}$: (1.5–2.2) Et_3N: (40–100) H_2O: (0.2–1.0) F^-.

The metal chloride was dissolved in the aluminium phosphate solution in a plastic beaker.

Dropwise addition of triethylamine to this vigorously stirred solution, followed by addition of hydrofluoric acid resulted in a perfectly homogeneous solution of pH 5.5–7.0 after several hours. This reaction mixture was heated in a PTFE lined autoclave at 190°C for periods of up to 16 h. The product mixture was filtered, washed with copious amounts of water, dilute hydrochloric acid and water again. The resultant crystalline material was dried at 110°C for 2 h in air. ($AlPO_4$-5 was prepared if no metal salt was added to the reaction mixture.)

These samples contained the trapped triethylamine templating agent, and this could be removed by heating between 550 and 600°C for 3 h in air.

Characterization

XRD patterns were collected on a conventional Siemens D500 diffractometer using nickel filtered Cu-K_α radiation (0.02 step size, 2 s per point). *In situ* XRD experiments were performed using a specially designed cell from GTP Engineering Co. Ltd (Swindon, Wilts, U.K.) by heating the samples in a flow of dry air (50 cm^3 min^{-1}).

Surface area measurements were carried out using static BET conditions using nitrogen as adsorbent at 77 K. Chemical analyses were obtained from Butterworth Laboratories Ltd (Teddington, Middx, U.K.). Scanning electron microscopy/energy dispersive X-ray emission analysis data were collected at the JEOL Laboratories (London, U.K.). Simultaneous thermal gravimetric, differential thermogravimetry and differential thermal analyses were performed on a Stanton Redcroft STA780 machine (heating rate = 10° min^{-1} in nitrogen to 270°C, in air above 270°C). Diffuse reflectance spectra were collected on a Perkin–Elmer/Hitachi 200 spectrophotometer.

RESULTS AND DISCUSSION

(i) *Features of* MAPO-5 *synthesis*

The MAPO-5 molecular sieves were prepared by hydrothermal crystallization from a metal cation-doped, aluminophosphate gel containing an organic template. One of the important steps employed in our synthetic procedure is the preparation of an aluminium phosphate solution, which is free of unreacted aluminium hydroxide. $AlPO_4$-5 and MAPO-5's are, like all zeolites, metastable, and consequently their crystallization times are restricted. Previous syntheses[3–5] use aluminium hydroxide or alumina directly as the aluminium source, and since these reactants are thermodynamically stable, it takes a long time for aluminium to enter the zeolite phase, and as a result other non-zeolitic byproducts are formed in these syntheses. In our preparation, however, both the aluminium and the phosphorus exist mainly as active polymerized ions in solution prior to addition of the metal salt and templating agent. This modification results in highly shortened crystallization times and more crystalline samples.

The use of hydrofluoric acid is another feature in our syntheses. The advantages of fluoride anion involvement in the preparation of ZSM-5 have been demonstrated,[7] and it seems likely that it assists in the solubility of the aluminium and metal species. It probably also plays a minor role as a weak acid keeping the pH of the solution between 5.5 and 7.0. If too much hydrofluoric acid is added to the reaction mixture, however, the aluminium and metal species do not transfer completely to the zeolite phase, probably because of the stability of the soluble fluoride complexes (Table 1). Other fluoride sources, in particular, ammonium fluoride and potassium fluoride, were also used successfully in MAPO-5 synthesis.

Table 1. Syntheses conditions of $AlPO_4$-5 and MAPO-5 aluminium phosphates[a]

	$[Et_3N]/[P_2O_5]$	$[F^-]/[Al_2O_3+MeO_x]$[a]	Time at 190°C (h)	pH	Calcination temperature (°C)
$AlPO_4$-5	1.5–1.9	0.0–1.0	2–9	5.5–7.0	550
MgAPO-5	1.5–1.9	0.0–1.0	7–16	5.5–7.0	550–700
CoAPO-5	1.5–2.2	0.3–1.0	2–7	6.0–7.0	550–700
MnAPO-5	1.5–2.2	0.3–1.0	7–16	6.0–7.0	550–700
NiAPO-5	1.5–2.2	0.3–1.0	7–14	6.0–7.0	550–700
CrAPO-5	1.5–2.2	0.3–1.0	7–14	6.0–7.0	550

[a] MeO_x = substituted metal oxide equivalent.

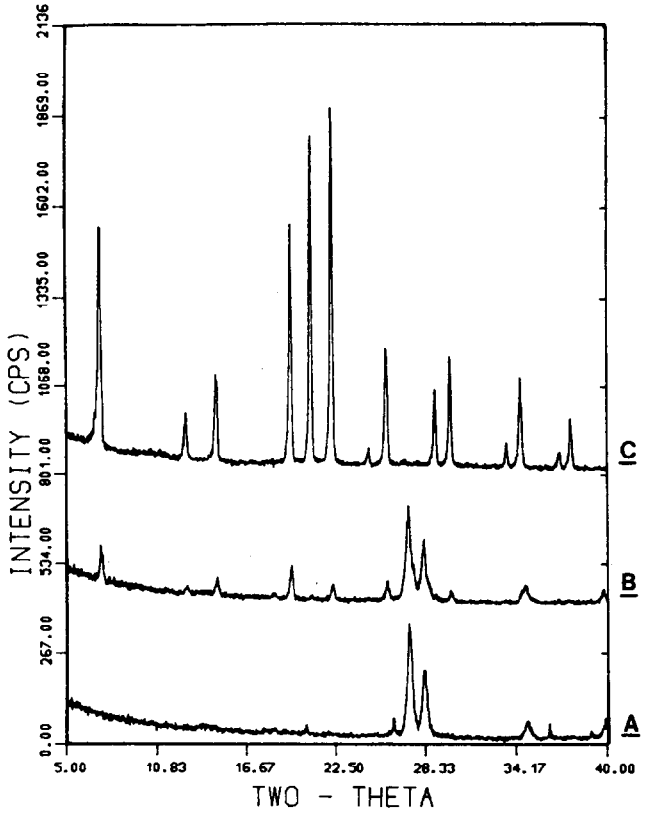

Fig. 1. Effect of the $[Et_3N]/[P_2O_5]$ ratio on crystalline products in CoAPO-5 synthesis: **A** $[Et_3N]/[P_2O_5] = 1.17$, **B** = 1.33, **C** = 1.60.

The organic template, triethylamine, plays a critical structure-directing role in the formation of the channels in the MAPO-5's. Tri-*n*-propylamine and tetra-*n*-propylammonium hydroxide are the templates usually employed for these particular molecular sieves, but we find triethylamine equally effective. The amount of triethylamine in the reaction mixture is crucial as shown in Table 1, and is further demonstrated by XRD patterns of the reaction products in the attempted synthesis of CoAPO-5 with different template/P_2O_5 molar ratios in Fig. 1.

Finally, the time of crystallization is an important variable because of the metastable nature of these compounds (Table 1); overlong crystallization times result in a major impurity. This has been identified by powder diffraction as an aluminium phosphate dense phase corresponding to one of the structural forms of silica, tridymite,[6] as illustrated in Fig. 2 for some NiAPO-5 syntheses.

(ii) *Structure and composition of* MAPO-5's

In metal substituted aluminium phosphate molecular sieves, the metal seems to substitute for the aluminium rather than the phosphorus atoms. This results in a negatively charged framework when the metal is divalent, and such materials have Brønsted acid sites and hence are potential cracking catalysts.[8-10]

The preparations of MgAPO-5, CoAPO-5, MnAPO-5 and NiAPO-5, in which the metal is formally divalent, are described above; only the magnesium, cobalt and manganese variants have previously been characterized and observed in high purity.[1,9] In addition, CrAPO-5 was synthesized, in which chromium is trivalent (Cr^{3+}ZSM-5 has been reported[11]); this material was expected to have a net neutral framework charge like $AlPO_4$-5 (assuming substitution of chromium for aluminium).

The subsequent discussion focuses on those synthesized samples with the highest metal substitution, which are monophasic by XRD; these are shown in Fig. 3 for the calcined samples in which the template has been removed from the channels. The XRD patterns indicate that they all have the structure of the aluminium phosphate molecular sieve number 5, reported by Bennett and coworkers.[7] The calculated unit cell parameters from these XRD patterns are given in Table 2. Smaller unit cell volumes are observed for $AlPO_4$-5 and

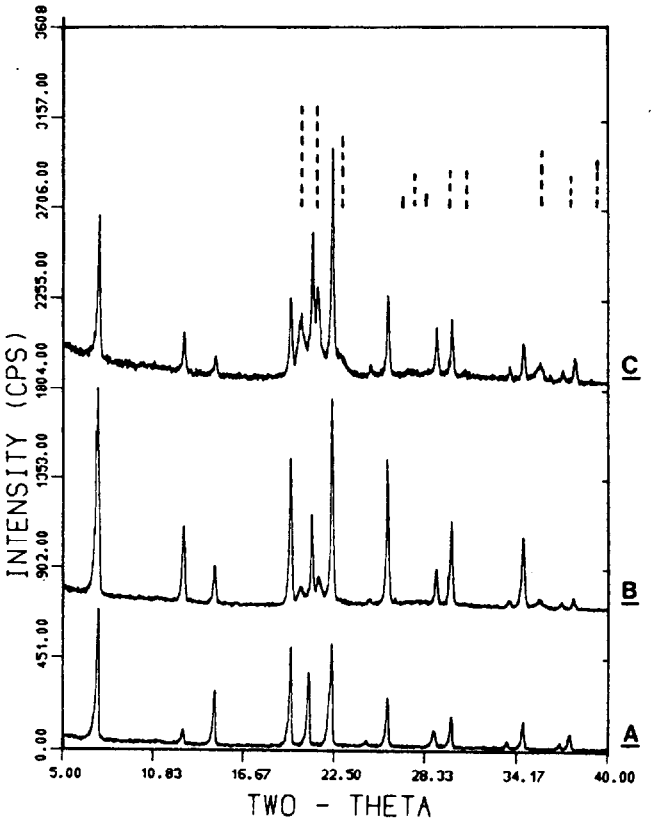

Fig. 2. Effect of reaction time on crystalline products in NiAPO-5 synthesis: **A** 12 h, **B** 16 h, **C** 20 h. Dotted lines show an aluminium phosphate dense phase reproduced from the JCPDS library.

CrAPO-5 than for divalent metal substituted variants, and this is related to the ionic radii of the metals (Table 2). Among the *transition* metal substituted MAPO-5's, the unit cell volume increases with increasing ionic radius. It is difficult, however, to fully explain all the subtle variations, and although the heteroatom content of each aluminophosphate is slightly different, these parameters are supporting evidence for isomorphic substitution of M^{n+} for Al^{3+}.

These molecular sieves contain one-dimensional channels of pore size 0.8 nm, along the *c* axis. Nitrogen adsorption isotherms were measured at 77 K, indicating that all the samples have surface areas between 250 and 270 $m^2\ g^{-1}$. This demonstrates that these molecular sieves contain open channels; furthermore, their metallic component cannot be blocking the pores of the structure, for instance, as an amorphous metal chloride, and is evidence for the substitution of the metal into the framework.

Chemical formulae based on elemental analyses of the aluminophosphates are given in Table 3. At first sight, these values are disconcerting because for MgAPO-5, NiAPO-5, CoAPO-5 and MnAPO-

5, the metal content is greater than the difference in phosphorus and aluminium content. These four molecular sieves, however, possess ion exchange properties as a result of the divalent metal substitution at the aluminium sites. An explanation for the observed analyses is that the metal occupies both framework (Al) sites and extra-framework positions. This was supported by ion exchange experiments on MnAPO-5 in which Mn^{2+} cations were displaced by Na^+ [12] by stirring in 0.2 M NaCl solution, with no resultant loss in crystallinity of the sample by XRD. MgAPO-5, CoAPO-5, MnAPO-5 and NiAPO-5 can be regarded as having both extra-framework metal cations and Brønsted acid sites, although in different proportions; this can be illustrated by idealized chemical formulae: $Mg^{2+}_{0.2}H^+_{0.7}$ $(Mg_{1.1}Al_{10.9}P_{12}O_{48})^{1.1-}$, $Co^{2+}_{0.1}H^+_{0.7}$ $(Co_{0.9}Al_{11.1}P_{12}O_{48})^{0.9-}$, $Mn^{2+}_{0.3}H^+_{0.1}$ $(Mn_{0.7}Al_{11.3}P_{12}O_{48})^{0.7-}$ and $Ni^{2+}_{0.1}H^+_{0.2}$ $(Ni_{0.4}Al_{11.6}P_{12}O_{48})^{0.4-}$ where the parentheses indicate the framework compositions. In contrast, this does not arise for CrAPO-5, because the chromium is trivalent and the net-framework charge is neutral. Hence, CrAPO-5 is unlike the other four MAPO-5's and more like $AlPO_4$-5, as other experiments will demonstrate.

It was mentioned above that the synthetic procedures used resulted in highly crystalline samples. Scanning electron micrographs of $AlPO_4$-5, MgAPO-5, NiAPO-5, MnAPO-5 and CoAPO-5 showed that they consist mainly of hexagonal prisms, with very few intergrowths and no aggregates. The MnAPO-5 prisms were about 300 μm long and 30 μm in diameter, whereas MgAPO-5, CoAPO-5 and NiAPO-5 prisms were shorter, between 50 and 100 μm in length. The CrAPO-5 sample, however, was made up of aggregates. Energy dispersive X-ray emission analysis on all

Table 4. Thermogravimetry results of $AlPO_4$-5 and MAPO-5 aluminium phosphates

	Template (I)		Template (II)		Structure
	Weight loss (%)	Temperature (°C)	Weight loss (%)	Temperature (°C)	collapse (°C)
$AlPO_4$-5	8.1	400	—	—	1200
MgAPO-5	4.6	385	3.7	570	750
CoAPO-5	2.3	370	4.6	550	770
MnAPO-5	3.8	377	3.2	580	—

CrAPO-5	7.7	390	—	—	—

the MAPO-5's showed that the metallic component is homogeneously distributed, and that there are no metal rich phases.

The structural differences between the MAPO-5's of different metal valency, mentioned above, was highlighted by careful thermogravimetric studies of the template-containing precursors. All samples released surface water below 100°C and a smaller amount of zeolitic water at about 250°C. For the magnesium, cobalt, manganese and nickel substituted aluminium phosphates, their templates are relased at two distinct temperatures; this has been noted previously in the case of cobalt,[9] and is a result of the template first evolving as free amine, and then by degradation of the proton or metal-complexed amine at a higher temperature (Table 4). CrAPO-5 and $AlPO_4$-5, however, have only one template weight loss, which is consistent with the neutral framework charge of these two structures. These differences are illustrated by differential thermal gravimetry and differential thermal analysis of $AlPO_4$-5, MgAPO-5 and NiAPO-5 in Fig. 4.

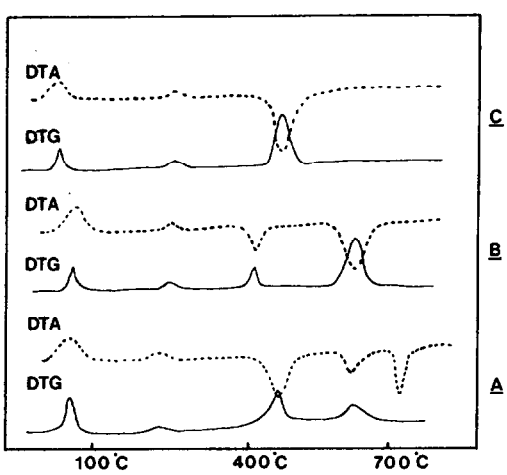

Fig. 4. Differential thermal analysis (DTA) and differential thermal gravimetric analysis (DTG) of some aluminium phosphates: **A** MgAPO-5, **B** NiAPO-5, **C** $AlPO_4$-5.

In situ X-ray diffraction was employed to observe the changes as the residual water and template were driven from the channels of $AlPO_4$-5 and NiAPO-5. Samples were heated in a flow of dry air and were allowed to equilibrate for 0.5 h at each particular temperature, before a diffraction pattern was collected. Figure 5 shows the result for the case of $AlPO_4$-5; heating to 100°C removes most of the water and causes an increase in crystallinity. Evolution of free triethylamine up to 300°C dramatically changes the relative intensities of the (110) and (200) reflections and slightly increases the unit cell size; further heating has little effect on the peak intensities. The identical experiment for NiAPO-5 has similar characteristics as water and free templates are removed from the channels as shown in Fig. 6. On heating to 550°C, however, these is another change corresponding to the loss of the complexed template (from thermogravimetric analysis). This is a unit cell contraction and a change in the relative intensities of the (210), (002) and (211) reflections.

Preliminary ^{27}Al and ^{31}P solid-state NMR of the aluminium phosphates were carried out, but the results are not discussed at length here, as they are somewhat puzzling. This may be related to the fact that the field strength at which the NMR is collected may affect the appearance of the spectra of these materials as reported recently.[13]

The results described above provide evidence for the incorporation of the metal component into the frameworks of the MAPO-5 aluminium phosphates. X-ray powder diffraction establishes the absence of non-MAPO-5 phases and the different lattice parameters suggest metal framework substitution. Adsorption measurements indicate that they contain unblocked channels and scanning electron microscopy shows a homogeneous heteroatom distribution. In the case of CoAPO-5, further evidence is the intense blue colour of the crystals, which is characteristic of divalent cobalt in

a tetrahedral environment; the diffuse reflectance spectrum of CoAPO-5 is shown in Fig. 7.[14] The new variants discussed in this paper, NiAPO-5 and CrAPO-5, still require further investigation to prove conclusively that framework incorporation has indeed taken place. Although trivalent chromium prefers an octahedral coordination, Cr^{3+}–ZSM-5 has been prepared and evidence for tetrahedral Cr^{3+} in the framework has been previously presented.[11] Recent work, based on magnetic susceptibility, has demonstrated that divalent nickel may have a tetrahedral coordination (though distorted) in a pollucite-like structure.[15]

Future work will focus on the precise nature of the metal substitution in MAPO-5 and some catalytic testing of these materials.

INFLUENCE OF OXIDATION STATE ON SUBSTITUTION BY ISOCYANIDE AND PHOSPHITE NUCLEOPHILES IN BIS(2,2′-BIPYRIDINE)DICARBONYLTUNGSTEN

JOSEPH A. CONNOR* and JOSEPHINE M. A. WALSHE

Chemical Laboratory, University of Kent, Canterbury, Kent CT2 7NH, U.K.

(*Received* 29 *September* 1988; *accepted* 20 *October* 1988)

Abstract—Purple crystals of *cis,trans*-$[W(CO)_2\{P(OMe)_3\}_2(bipy)]$ (bipy = 2,2′-bipyridine) are obtained in good yield by heating *cis*-$[W(CO)_2(bipy)_2]$ in trimethylphosphite. Substitution by isocyanides in *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$ produces purple–red six-coordinate tungsten(II) salts, *cis,cis*-$[W(CO)_2(CNR)_2(bipy)][BF_4]_2$ (R = C_6H_{11}, CH_2Ph, Ph) in moderate yields. Further substitution by isocyanide produces the known seven-coordinate complexes $[W(CNR)_5(bipy)][BF_4]_2$ and $[W(CNR)_7][BF_4]_2$. The new complexes have been characterized by microanalysis and spectroscopy (IR, ^1H, ^{13}C, ^{31}P NMR and electronic absorption). A comparison with the physical properties of isostructural analogues of tungsten(II) or tungsten(0), as appropriate, is made.

There are few examples of complex compounds containing more than two different types of ligand attached to a metal in a low formal oxidation state in which a two-electron oxidation or reduction does not result in either isomerization or a change in coordination number, or both. Recently we have observed that substitution in the six-coordinate *cis*-$[W(CO)_2(bipy)_2]^{2+}$ ion by neutral monodentate phosphine and phosphite ligands, L, results in the displacement of 2,2′-bipyridine and formation of six-coordinate *cis,trans*-$[W(CO)_2L_2(bipy)]^{2+}$ ions. These results stand in contrast to those obtained when the same ligands react with the seven-coordinated molybdenum(II) complex ion *cis*-$[Mo(CO)_2(bipy)_2(NCMe)]^{2+}$. Substitution by the same ligands in the six-coordinate metal(0) complexes, *cis*-$[M(CO)_2(bipy)_2]$ (M = Mo, W), may result in the displacement of either one or both bipy ligands depending on the conditions and the particular ligand used.[1] The stereochemistry of the product in which only one bipy ligand is substituted, is also dependent on the nucleophile. Taken together, these observations have indicated that we could learn more about the influence of oxidation state on the properties of isostructural metal complexes, than has been clear previously.

RESULTS AND DISCUSSION

Heating *cis*-$[W(CO)_2(bipy)_2]$ with pure trimethylphosphite at 100°C for 13 h produces a good (89%) yield of purple crystals of *cis,trans*-$[W(CO)_2\{P(OMe)_3\}_2(bipy)]$. The product is much more soluble in a range of solvents than the starting material. The product is characterized by two strong absorptions in the IR spectrum at 1825 and 1750 cm^{-1} (Nujol) assigned to *cis*-carbonyl ligands. Comparison of the $\nu(CO)$ values in $[W(CO)_2(bipy)L_2]$ indicates that the acceptor strength of L decreases in the order $P(OMe)_3 \geq EtNC > bipy$: the discrimination between phosphite and isocyanide is much less marked than in the analogous molybdenum(0) complexes.[1] The ^{31}P NMR spectrum shows one signal only at δ +58.55 ppm ($^1J(WP)$ 369 Hz) produced by *trans*-phosphite ligands. The lowest energy absorption of the complex at 530 nm (CH_3CN solution), which may have contributions from both metal-to-ligand charge-transfer and localized *d–d* (ligand field) transitions, exhibits solventochromism in a manner which is similar to $[W(CO)_4(bipy)]$; the value of the λ_{max} decreases by more than 100 nm as the polarity of the solvent increases from carbon tetrachloride to dimethylsulphoxide.

In acetonitrile solution the complex *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$ reacts at room temperature with 2

molar equivalents of isocyanide, RNC (R = C_6H_{11}, CH_2Ph, Ph), to form deep red solutions from which the six-coordinate salts *cis,cis*-$[W(CO)_2(CNR)_2(bipy)][BF_4]_2$ were isolated with some difficulty in a crystalline form and characterized by microanalysis. The addition of excess isocyanide to *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$ or, alternatively, to *cis, cis*-$[W(CO)_2(CNR)_2(bipy)][BF_4]_2$, in acetonitrile at room temperature produces the seven-coordinate salts $[W(CNR)_5(bipy)][BF_4]_2$. Previously, examples of these seven-coordinate complexes (R = *i*-Pr, *t*-Bu, C_6H_{11}, CH_2Ph) have been prepared[2] from the oxidative addition reaction of *cis*-$[W(CO)_4(bipy)]$ with $PhICl_2$ in the presence of the isocyanide. Reaction with a further excess of isocyanide in acetonitrile at reflux completed displacement of the original ligands from the metal and $[W(CNR)_7][BF_4]_2$ was obtained.

The IR spectra of $[W(CO)_2(CNR)_2(bipy)][BF_4]_2$ complexes show two pairs of absorptions in the 2200–1800 cm^{-1} range which are assigned to CO and CN stretching vibrations. These establish the *cis*-orientation of these ligands. Comparison of the values of ν(CO) in *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$, *cis,trans*-$[W(CO)_2\{P(OMe)_3\}_2(bipy)][BF_4]_2$,[3] and *cis,cis*-$[W(CO)_2(CNR)_2(bipy)][BF_4]_2$ indicates that, in a six-coordinate $[W(CO)_2(bipy)L_2]^{2+}$ ion, the ligands L (0.5(bipy), $P(OMe_3)$ and RNC), have similar donor–acceptor properties with reference to the tungsten(II) centre. This conclusion is reinforced by the observation that the positions of the bipy proton resonances in these compounds are also similar. The increasing pressure on the isocyanide ligands to accept electron density as a result of ($5d \rightarrow \pi^*$) π-bonding is indicated by the change in the chemical shift of the protons on the α-carbon atoms of the isocyanide ligand, as first CO and then bipy is replaced by isocyanide in the seven-coordinate fluxional dications $[W(CNR)_5(bipy)]^{2+}$ and $[W(CNR)_7]^{2+}$. The isocyanide ^{13}C resonances in the $[W(CNR)_5(bipy)][BF_4]_2$ complexes were observed as broad singlets without resolution of the ^{13}C–^{183}W coupling. In each case, the resonance is shifted to lower field ($\Delta\delta$ *ca* 2 ppm) from the free ligand value, which is evidence of significant (M → CNR) π-back-bonding in these complexes. This is in contrast to the usual shift to higher fields observed,[4] for example, in $[W(CO)_5(CNC_6H_{11})]$ ($\Delta\delta$ −16.2 ppm). All the other isocyanide ligand carbon resonances in the $[W(CNR)_5(bipy)]^{2+}$ complexes are shifted down field from those of the free ligand. The largest coordination shift, $\Delta\delta$, is experienced by the alkyl carbon adjacent to the isocyanide group when R = C_6H_{11} (5.44 ppm) or R = CH_2Ph (4.91 ppm).

The reactions described for $[W(CO)_2(bipy)_2]^{2+}$ are in contrast to the result obtained when isocyanides react with the analogous $[Mo(CO)_2(bipy)_2(NCMe)][BF_4]_2$. In the molybdenum system, substitution by isocyanide produces,[5] first, $[Mo(CNR)_3(bipy)_2][BF_4]_2$ (R = Et, *p*-tolyl) and subsequently, $[Mo(CNR)_5(bipy)][BF_4]_2$. Further substitution to give the known $[Mo(CNR)_7][BF_4]_2$ could not be achieved by heating with excess isocyanide at reflux, although $[Mo(CNC_6H_{11})_7]^{2+}$ reacts[6] with bipy to give $[Mo(CNC_6H_{11})_5(bipy)]^{2+}$. There is a delicate balance between different ligand environments in these analogous molybdenum(II) and tungsten(II) systems. Tungsten(II) preserves bonds to CO in preference to isocyanide: this order is reversed for molybdenum(II), consistent with the greater Lewis basicity of tungsten(II) towards the ligand of lower σ-donor/π-acceptor ratio. The change of coordination number at tungsten(II) which occurs between the six-coordinate *cis,cis*-$[W(CO)_2(CNR)_2(bipy)][BF_4]_2$ and seven-coordinate $[W(CNR)_5(bipy)][BF_4]_2$, is clearly an index of the steric properties of the isocyanide. There is evidence from IR spectra that the donor–acceptor (electronic) properties of alkyl isocyanide and trialkyl phosphite ligands are similar, but *cis,trans*-$[W(CO)_2\{P(OMe)_3\}_2(bipy)][BF_4]_2$ will not react[3] with excess phosphite to produce a seven-coordinate complex such as $[W\{P(OMe)_3\}_5(bipy)][BF_4]$ in the manner of an isocyanide. The cone angle[7] of trimethyl phosphite ($107 \pm 2°$) is significantly greater than that estimated (*ca* 78°) for cyclohexyl isocyanide. In contrast to the reactions with bidentate phosphine ligands,[3] it should be noted that seven-coordination at tungsten(II) is not achieved by fluoride abstraction in the presence of isocyanides.

The information obtained for the two pairs of tungsten complexes, *cis,cis*-$[W(CO)_2(CNCH_2R)_2(bipy)]^z$ ($z = 0$, R = Me; $z = 2^+$, R = Ph) and *cis,trans*-$[W(CO)_2\{P(OMe)_3\}(bipy)]^z$, shows a consistent pattern of the influence of oxidation state of the metal on spectroscopic properties. The frequency of absorption of both ν(CO) and, in the isocyanide complexes, of ν(CN) increases on oxidation; the frequency difference between these pairs of absorptions decreases in the higher oxidation state. Oxidation of the metal results in a shift of the bipy ligand proton resonances to lower field, particularly for H(4) and H(5) (*ca* 0.4 ppm). The methylene protons adjacent to the isocyanide group are also strongly (1.9 ppm) shifted to lower field. In the phosphite complexes, the ^{31}P resonance moves to lower field and the value of ^1J(WP) decreases as a result of oxidation, in a manner reminiscent of phosphine complexes of platinum.[8] The lowest energy absorption in the

visible region increases in energy with oxidation, consistent with the decrease in electron density at the metal atom involved in a MLCT process. Whereas this absorption in the tungsten(0) complexes displays very significant solvatochromism, this is not observed in the analogous tungsten(II) complex.

EXPERIMENTAL

Materials and methods were in general similar to those described in other papers from this laboratory.[3] All operations were carried out under dry, deoxygenated dinitrogen atmospheres. Solvents were dried, deaerated and distilled prior to use.

Preparation of cis,trans-2,2′-*bipyridinedicarbonylbis(trimethylphosphite)tungsten*

Trimethyl phosphite (30 cm^3, 0.25 mol) was added to *cis*-$[W(CO)_2(bipy)_2]$ (0.95 g, 1.72 mmol) and the mixture was heated at 373 K overnight (13 h). The dark green solution which formed was allowed to cool to room temperature, whereupon purple crystals precipitated. The solution was left at room temperature for 2 days. The crystalline product was isolated by filtration and washed with diethyl ether (0.99 g, 89% yield). Found: C, 33.5; H, 3.9; N, 4.1; P, 8.7; W, 29.5. Calc. for $C_{18}H_{26}N_2O_8P_2W$: C, 33.6; H, 4.1; N 4.4; P, 9.1; W, 28.5%. IR (Nujol) 1825s, 1750s, 1592m, 1300m, 1263w, 1050br, 767w, 725w, 705w, 519m cm^{-1}. ^1H NMR (CD_3CN): δ 9.24t (H6), 8.63d (H3), 8.05 (H4), 7.46t (H5) (bipy protons), 3.31m (OCH_3) ppm. λ_{max} 510 (DMSO); 540 (Me_2CO); 570 (THF); 590 (C_6H_6); 622 (CCl_4) nm.

Preparation of 2,2′-*bipyridinedicarbonylbis(cyclohexylisocyanide)tungsten*(II) *bis(tetrafluoroborate)*

Cyclohexyl isocyanide (0.36 cm^3, 3.44 mmol) was added to acetonitrile (10 cm^3) and the solution was added dropwise via a syringe to a vigorously stirred solution of *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$ (1.25 g, 1.72 mmol) in acetonitrile (50 cm^3). The colour of the reaction mixture became orange–red on addition of the isocyanide solution. The reaction mixture was stirred at room temperature for 11 h (overnight) to ensure completion of the reaction. The solvent was then removed under reduced pressure to yield a dark red oil. Attempts to precipitate this as a solid from acetone–diethyl ether, acetone–hexane, dichloromethane–hexane and THF–hexane solvent mixtures were unsuccessful. The oil was stirred with diethyl ether (100 cm^3) for a period of typically 4–5 days, the diethyl ether being replaced by fresh solvent two or three times. The product was isolated as a purple–red solid (0.95 g, 70% yield). Found: C, 40.5; H, 4.5; N, 7.1; W, 25.4. Calc. for $C_{26}H_{30}N_4B_2F_8O_2W$: C, 39.9; H, 3.8; N, 7.1; W, 23.3%. IR (Nujol) 2190s, 2130s, 1980m, 1910s, 1605m, 1315m, 1060br, 768m, 730m, 521w cm^{-1}. ^1H NMR (CD_3CN): δ 9.22d (H6), 8.66d (H3), 8.40t (H4), 7.86t (H5) (bipy protons), 4.50s, 1.72–1.36m ($C_6H_{11}NC$) ppm. The complex $[W(CO)_2(CNCH_2Ph)_2(bipy)][BF_4]_2$ was prepared in a similar manner. Found: C, 42.3; H, 2.6; N, 7.2; W, 22.4. Calc. for $C_{28}H_{22}N_4B_2F_8O_2W$: C, 41.8; H, 2.8; N, 7.0; W, 22.9%. IR (Nujol) 2175s, 2117s, 1973m, 1900s, 1607m, 1498m, 1060br, 818w, 770m, 730m, 698m, 603m, 523m, 493w cm^{-1}. ^1H NMR (CD_3CN): δ 9.10d (H6), 8.60d (H3), 8.34t (H4), 7.70t (H5) (bipy protons), 7.48–7.24m ($C_6H_5CH_2NC$), 5.36s ($C_6H_5CH_2NC$) ppm. The complex $[W(CO)_2(CNPh)_2(bipy)][BF_4]_2$ was also prepared. Found: C, 40.7; H, 2.8; N, 7.9; F, 18.4; W, 25.3. Calc. for $C_{26}H_{18}N_4B_2F_8O_2W$: C, 40.2; H, 2.3; N, 7.2; F, 19.6; W, 23.7%. IR (Nujol) 2130m, 2040s, 1940s, 1860s, 1597m, 1583m, 1310w, 1280w, 1050br, 865m, 810m, 750m, 725m, 679m, 650w, 632w, 535w, 515w cm^{-1}. IR (CH_3CN) ν(CO) 1965, 1867 cm^{-1}. ^1H NMR (CD_3CN): δ 9.54d (H6), 8.64d (H3), 8.34t (H4), 7.84t (H5) (bipy protons), 7.56–7.12m (C_6H_5NC) ppm.

Preparation of 2,2′-*bipyridinepentakis(benzylisocyanide)tungsten*(II) *bis(tetrafluoroborate)*

Excess benzyl isocyanide (1 cm^3, 8.28 mmol) was added dropwise via a syringe to a rapidly stirred solution of *cis*-$[W(CO)_2(bipy)_2][BF_4]_2$ (0.82 g, 1.49 mmol) in acetonitrile (40 cm^3). The solution turned red immediately. The reaction mixture was left stirring at room temperature for 48 h to ensure completion of the reaction. The solvent was then evaporated under reduced pressure to give a red oil. This was stirred in diethyl ether (100 cm^3) for a period of typically 4–5 days, with the diethyl ether being replaced with fresh solvent two or three times. The product was isolated as a free-flowing bright red powder (1.29 g, 79% yield). Found: C, 54.6; H, 4.0; N, 8.6; W, 12.0. Calc. for $C_{50}H_{43}N_7B_2F_8W$: C, 54.6; H, 3.9; N, 8.9; W, 16.7%. IR (Nujol) 2190m, 2120s, 1598m, 1495m, 1348m, 1151w, 1050br, 803w, 772m, 742m, 727m, 693m, 597m, 519w, 490 cm^{-1}. ^1H NMR (CD_3CN): δ 8.89d (H6), 8.42d (H3), 8.16t (H4), 7.54t (H5) (bipy protons), 7.35–7.16m ($C_6H_5CH_2NC$), 5.14s ($C_6H_5CH_2NC$) ppm. ^{13}C NMR (CD_3CN): δ 155.40 (C2), 153.99 (C6), 141.08 (C4), 128.53, 125.29 (C3,C5) (bipy carbons); 159.98 (NC) 135.89 (C1), 130.08 (C2,C6), 129.56, 127.98 (C3–C5), 50.21 (CH_2) (benzyl isocyanide carbons) ppm. λ_{max} (CH_3CN)

510 nm. The complexes $[W(CNPh)_5(bipy)][BF_4]_2$ and $[W(CNC_6H_{11})_5(bipy)][BF_4]_2$ were prepared as purple–red powders by a similar procedure. $[W(CNC_6H_{11})_7][BF_4]_2$ was obtained as yellow crystals (95% yield) from the reaction between cyclohexyl isocyanide (4.65 mmol) and $[W(CNC_6H_{11})_5(bipy)][BF_4]_2$ (0.33 mmol) in acetonitrile (reflux, 84 h). Found: C, 52.2; H, 6.9; N, 8.6. Calc. for $C_{49}H_{77}N_7B_2F_8W$: C, 52.5; H, 6.9; N, 8.7%. IR and ^1H NMR spectra were in agreement with published values.

ADDUCTS OF TRIMETHYLALUMINIUM WITH PHOSPHINE LIGANDS: X-RAY CRYSTAL STRUCTURES OF Me_3AlPPh_3 AND $Me_3AlP(o\text{-tolyl})_3$

DERK A. WIERDA and ANDREW R. BARRON*

Department of Chemistry, Harvard University, Cambridge, MA 02138, U.S.A.

(*Received* 31 *August* 1988; *accepted* 24 *October* 1988)

Abstract—The crystal and molecular structures of two phosphine adducts of trimethylaluminium are reported. Compound **1**, Me_3AlPPh_3, crystallizes in the rhombohedral space group R_3(obv), $a = b = 14.344(4)$, $c = 16.503(7)$ Å, $V = 2944(2)$ Å^3, $Z = 6$, $R = 0.0436$, $R_w = 0.0532$. Compound **2**, $Me_3AlP(o\text{-tolyl})_3$, crystallizes in the rhombohedral space group R_3C, $a = b = 14.978(1)$, $c = 34.195(5)$ Å, $V = 6643(1)$ Å^3, $Z = 4$, $R = 0.0574$, $R_w = 0.0601$. Structural features are discussed with reference to the ^{13}C and ^{31}P NMR spectroscopic data.

We have recently shown[1] that the dominant factor influencing the NMR chemical shifts in Me_3AlPR_3 complexes is steric repulsion between the aluminium methyl groups and the phosphine substituents. The ^{13}C chemical shifts of the Al—CH_3 groups may be used as an indication of the distortion from an idealized planar, monomeric $AlMe_3$, and the change in ^{31}P chemical shift (Δ)† of the phosphines on coordination to $AlMe_3$ correlates with the difference in R—P—R angles between free and coordinated phosphine.

The complex, $Me_3AlP(o\text{-tolyl})_3$, does not fit the trends found in ^{31}P Δ or Al—CH_3 ^{13}C chemical shifts. Based on a calculated cone angle for $P(o\text{-tolyl})_3$[2] of 194° a negative ^{31}P Δ is expected if the angle R—P—R decreases on coordination. The observed value, however, is positive (+7.7 ppm)[1] indicating that the C—P—C angle is opened on coordination. This observation suggests that the $P(o\text{-tolyl})_3$ ligand adopts a conformation so as to relieve steric strain between the *o*-tolyl and aluminium methyl groups.

In order to test the validity of the NMR data as a structural probe for Me_3AlPR_3 complexes we have undertaken an X-ray crystallographic study of Me_3AlPPh_3 and $Me_3AlP(o\text{-tolyl})_3$.

RESULTS AND DISCUSSION

Me_3AlPPh_3

The molecular structure of Me_3AlPPh_3 (**1**) is shown in Fig. 1 and selected bond lengths are given in Table 1. The complex contains a crystallographically-imposed C_3 axis coincident with the Al—P bond. The aromatic rings of the triphenylphosphine ligand adopt a propeller-like conformation, with the phenyl groups pitched 38.5° from the plane defined by Al, P and C(1). As a consequence of this the Al—C and P—C bonds are only partly staggered with a dihedral angle of 39.8°.

C(1)—C(2)—C(3)	120.1(2)	C(2)—C(3)—C(4)	120.8(2)
C(3)—C(4)—C(5)	119.8(2)	C(4)—C(5)—C(6)	120.2(2)
C(5)—C(6)—C(1)	120.1(2)		

The shortest non-bonding distances between the phenyl ring and aluminium methyl group are C(2)—C(10b) = 3.819(2) Å and C(2)—C(10A) = 3.993(2) Å. These contacts are emphasized by viewing the molecule along Al—P (Fig. 2). The Al—P distance, 2.535(1) Å, does not vary significantly from that found in Me_3AlPMe_3 (2.53(4) Å)[3] or $(Me_3Al)_2 \cdot (Ph_2PCH_2)_2$ (2.544(4) Å).[4]

A comparison of the structure of **1** and free monomeric $AlMe_3$[5] (see Table 2) shows that the lengths of the Al—C bonds increase, and that the C—Al—C angles decrease on coordination. Both changes are in the direction predicted by an increased aluminium *p*-character in the Al—C bonds on changing from a planar to tetrahedral geometry. From NMR results[1] the aluminium centre should be distorted further from planarity in Me_3AlPPh_3 than in Me_3AlPMe_3, this is indeed the case.

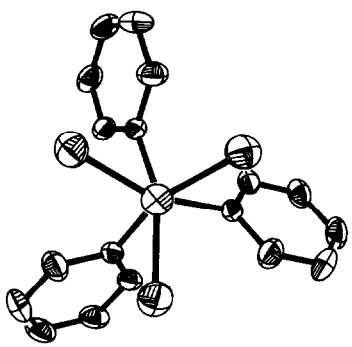

Fig. 2. The structure of Me_3AlPPh_3 (**1**) viewed down the Al—P vector.

The changes in PPh_3 geometry[6] on coordination are not so marked (see Table 2). The only appreciable change is an opening of the C—P—C angle by *ca* 1.6°. This is in contrast to the results from ^{31}P NMR spectroscopy[1] which predict that the C—P—C angle is reduced slightly on coordination. It is likely that this discrepancy between solid state and solution is a consequence of the distortions observed in the crystal structure of PPh_3.[6]

The unit cell of Me_3AlPPh_3 is comprised of six molecules with no unduly close intermolecular contacts.

$Me_3AlP(o\text{-tolyl})_3$

The molecular structure of $Me_3AlP(o\text{-tolyl})_3$ (**2**) is shown in Fig. 3; selected bond lengths and angles are given in Table 3. The complex contains a crys-

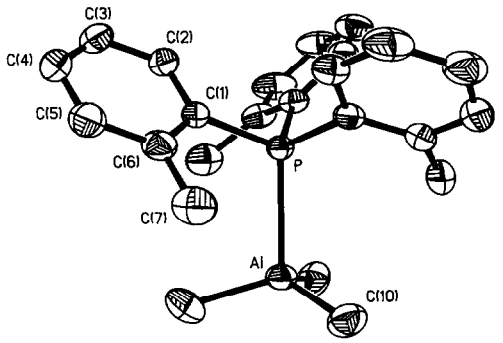

Fig. 3. X-ray crystal structure of $Me_3AlP(o\text{-tolyl})_3$ (**2**) showing the numbering scheme.

tallographically-imposed C_3 axis along the Al—P bond. The aromatic rings of the *o*-tolyl groups adopt a propeller-like arrangement, with a pitch of 50.2° from the plane defined by Al, P and C(1). As a consequence of this, the Al—C and P—C bonds are nearly eclipsed, with a dihedral angle of 10.5°. This conformation allows the *o*-tolyl methyl groups to be staggered with respect to the aluminium methyl groups (Fig. 4). The shortest non-bonding distances between the *o*-tolyl methyl and the aluminium methyl groups are C(7)—C(10) = 3.481(4) Å and C(7)—C(10) = 3.872(5) Å. The Al—P distance, 2.584(2) Å, is significantly longer than Al—P distances previously reported.[3,4]

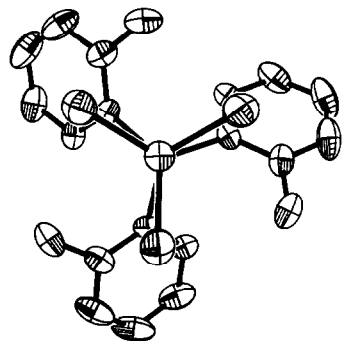

Fig. 4. The structure of $Me_3AlP(o\text{-tolyl})_3$ (**2**) viewed down the Al—P vector.

The changes in the Al—C bond distance and C—Al—C angle on coordination of $AlMe_3$ to $P(o\text{-tolyl})_3$ (see Table 2) are consistent with increased aluminium *p*-character in the Al—C bonds on changing from a planar to tetrahedral geometry. From ^{13}C NMR data it was predicted[1] that the C—Al—C angle for **2** should be smaller than that found for **1**; this is observed (Table 2). The ^{31}P Δ value for **2**[1] suggested a larger C—P—C angle on coordination than in free phosphine,[7] which is confirmed by the crystal structure (see Table 2).

It is of course possible that the conformation of the *o*-tolyl rings observed in the crystal structure is not retained in solution. It is clear, however, that changes in the geometry of **2** predicted by NMR are consistent with those observed in the solid state.

The unit cell of $Me_3AlP(o\text{-tolyl})_3$ is comprised of four molecules with no unduly close intermolecular contacts. All the intermolecular distances correspond to, or are greater than, normal van der Waals contacts.

CONCLUSIONS

The X-ray structural data reported here confirm that ^{13}C and ^{31}P NMR data can be used as an indication of changes in geometry around aluminium and phosphorus on coordination of phosphines to $AlMe_3$. There is no evidence, however, that NMR can be used to predict either the Al—P bond length, or the energy of dissociation of the complexes Me_3AlPR_3.

EXPERIMENTAL

Crystals were prepared as described in ref. 1 and sealed under nitrogen in Lindemann capillaries.

Unit-cell parameters and intensity data were obtained by following previously detailed procedures,[8] using a Nicolet R3m/v diffractometer operating in the θ–2θ scan mode with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Empirical absorption corrections were applied to the data using the program PSICOR. Further experimental data are giving in Table 3.

The structures were solved using the direct methods program XS,[9] which revealed the positions of the aluminium and phosphorus atoms. The remainder of the atoms were found using standard difference map techniques. Most, but not all of the hydrogens were visible in the final difference map. Hydrogens were included as fixed atom contributors in the final cycle (C—H = 0.96 Å).

Details of the refinements are given in Table 4. Bond lengths and angles are given in Tables 1 and 3. Atomic scattering factors and anomalous scattering parameters are as given in ref. 9.

PREPARATION AND LIGAND PROPERTIES OF BIS-THIONYLIMINO COMPLEXES OF THE TYPE $M(NSO)_2(PR_3)_2$. X-RAY STRUCTURE OF $Pt(NSO)_2(PMe_3)_2$

IVAN P. PARKIN, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science and Technology, South Kensington, London SW7 2AY, U.K.

(*Received* 21 *September* 1988; *accepted* 27 *October* 1988)

Abstract—Reaction of $S(NSO)_2$ with *cis*-$MCl_2(PR_3)_2$ (M = Pt, PR_3 = PMe_3, PEt_3, PPr^n_3, PBu^n_3, PPh_3, $PMePh_2$, PMe_2Ph and dppe; M = Pd, PR_3 = dppe) in liquid ammonia gives *cis*-$M(NSO)_2(PR_3)_2$ quantitatively by ^{31}P NMR and in 60% isolated yield. The new compounds have been characterized by microanalyses, IR, ^1H and ^{31}P NMR, mass spectrometry and in the case of $Pt(NSO)_2(PMe_3)_2$, X-ray crystallography. The molecule has *cis* square-planar geometry with approximate C_2 symmetry.

Compounds containing the NSO^- ligand have been the subject of recent work;[1,2] reaction of $Rh(CO)H(PPh_3)_3$ with $CsNSO_2$ gives $Rh(NSO)(CO)(PPh_3)_2$, whilst treatment of $Ti(Cp)_2Cl_2$ with KNSO yields the bis compound $Ti(Cp)_2(NSO)_2$.[3] The *cis* and *trans* isomers of $Pt(NSO)_2(PPh_3)_2$ have been made from $Pt(C_2H_4)(PPh_3)_2$; reaction with $Hg(NSO)_2$ gives the *trans* product[4] whilst with $PhAs(NSO)_2$ the *cis* isomer is obtained.[5] Reaction of $Hg(NSO)_2$ with *cis*-$PtCl_2(PR_3)_2$ has also been claimed[4] to give *cis*-$Pt(NSO)_2(PR_3)_2$ on the basis of ^{31}P NMR only, but there are discrepancies between the data reported in refs 4 and 5. In the light of these problems we have now developed a general synthetic route for the formation of $M(NSO)_2(PR_3)_2$.

We are currently investigating the synthetic potential of various sulphur–nitrogen reagents with metal complexes using liquid ammonia as solvent.[6,7] Here, we report the synthesis and spectroscopic characterization of the new complexes, $M(NSO)_2(PR_3)_2$ and $Ti(Cp)_2(NSO)_2$ from the reaction of $S(NSO)_2$ in liquid ammonia. The X-ray crystal structure of $Pt(NSO)_2(PMe_3)_2$ is also reported.

EXPERIMENTAL

All manipulations were performed under an inert atmosphere (argon or nitrogen). Solvents were dried before use: CH_2Cl_2 was distilled from CaH_2 and petroleum ether (60–80) distilled from sodium benzophenone. The ^{31}P NMR and some ^1H NMR were recorded using a JEOL FX90Q spectrometer operating at 36.21 and 89.55 MHz, and referenced to external 85% H_3PO_4 and internal $SiMe_4$, respectively. The other ^1H NMR were obtained on a Bruker WM 250 MHz operating at 250.13 MHz referenced to $CHCl_3$ at 7.24 ppm. IR spectra were obtained from KBr discs using a Perkin–Elmer 1720 spectrophotometer. Mass spectra were obtained both by EI and FAB (using thiodiethanol matrix) on a VG 2020 machine. Microanalyses were performed by the departmental service.

The compounds $PtCl_2(PR_3)_2$ (PR_3 = PMe_3, PEt_3, PPr^n_3, PBu^n_3, PMe_2Ph, $PMePh_2$, PPh_3 and dppe) and $PdCl_2$(dppe) were made as previously described.[8] $Ti(C_5H_5)_2Cl_2$ (Aldrich) and anhydrous ammonia (BOC) were used as supplied. $S(NSO)_2$ was prepared by the literature method.[9]

Preparation of $M(NSO)_2(PR_3)_2$

All these complexes (Table 1) were made by the same general method illustrated here for $Pt(NSO)_2(PPr^n_3)_2$ (**3**). *cis*-$PtCl_2(PPr^n_3)_2$ (0.080 g, 0.137 mmol) was added to a stirred red solution of $S(NSO)_2$ (0.021 g, 0.137 mmol) in liquid ammonia at −78°C. The resultant suspension was stirred for 30 min at −78°C and then the ammonia blown off by a stream of argon. The resultant yellow solid was

under the same experimental conditions as above except that the crystals were grown by slow diffusion of *n*-hexane (15 cm^3) into a CH_2Cl_2 (5 cm^3) solution at room temperature.

Crystal data. $C_6H_{18}N_2O_2P_2S_2Pt$, $M = 471.4$, monoclinic, $a = 9.963(2)$, $b = 13.903(2)$, $c = 11.406(2)$ Å, $\beta = 109.85(2)°$, $U = 1486$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 2.11$ g cm^{-3}. Yellow, air-stable prisms, dimensions $0.03 \times 0.20 \times 0.23$ mm, μ(Cu-K_α) = 225 cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 896$.

Data collection and processing. A Nicolet R3m diffractometer, ω-scan method, ($2\theta \leqslant 100°$), graphite-monochromated Cu-K_α radiation; 1523 independent measured reflections of which 1387 were observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction based on 362 azimuthal measurements (laminar correction (100) prominent). Minimum and maximum transmission factors were 0.018 and 0.097.

Structure analysis and refinement. The structure was solved by the heavy atom method and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent carbons. The methyl groups were refined as rigid bodies. Refinement was by block-cascade full-matrix least-squares to $R = 0.052$, ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.055$ ($w^{-1} = \sigma^2(F) + 0.00130F^2$). The maximum and minimum residual electron density in the final ΔF map were 1.47 and −1.46 eÅ^{-3}, respectively. The mean and maximum shifts/error in the final refinement cycle were 0.004 and 0.052, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system[10] and published scattering factors.

RESULTS AND DISCUSSION

Reaction between $PtCl_2(PR_3)_2$ and $S(NSO)_2$ gives $Pt(NSO)_2(PR_3)_2$ in good yield, *ca* 60% [eq. (1)]

$$Pt(PR_3)_2Cl_2 + S(NSO)_2 \longrightarrow Pt(NSO)_2(PR_3)_2 + SCl_2. \quad (1)$$

^{31}P NMR shows that the reaction proceeds almost quantitatively with the only other observable phosphorus-containing species being $PtS_2N_2(PR_3)_2$ (*ca* 5%). The observed disulphurdinitrido complex is probably formed from the products of the reaction between the eliminated SCl_2 and liquid ammonia [eq. (2)]

$$6SCl_2 + 18NH_3 \longrightarrow 3S_2N_2^{2-} + 12NH_4Cl + 6H^+$$

$$S_2N_2^{2-} + PtCl_2(PR_3)_2 \longrightarrow Pt(S_2N_2)(PR_3)_2 + 2Cl^-. \quad (2)$$

We have shown previously that reaction of an ammonia solution of SCl_2 with $PtCl_2(PR_3)_2$ gives exclusively $Pt(S_2N_2)(PR_3)_2$.[11] When a slight excess of $PtCl_2(PR_3)_2$ to $S(NSO)_2$ is used (1.2 : 1.0 molar ratio), *ca* 25% $Pt(S_2N_2)(PR_3)_2$ is observed by ^{31}P NMR. Further increasing the molar ratio to (2 : 1) gives $Pt(NSO)_2(PR_3)_2$ (25%), $Pt(NSO)Cl(PR_3)_2$ (50%) and $Pt(S_2N_2)(PR_3)_2$ (25%).

The ^{31}P NMR spectra of **1**–**7** (Table 2) consist of singlets with platinum satellites indicating that the

phoshines are equivalent. The magnitude of the ^{31}P–^{195}Pt coupling constant (*ca* 3100 Hz) is appropriate for platinum(II) and suggests nitrogen rather than oxygen bound NSO^- ligands. (2850 Hz for phosphorus *trans* to nitrogen in $Pt(S_2N_2)(PR_3)_2$, 3250 Hz in $Pt(S_2N_2H)(PR_3)_2^+X^-$.)[8,11] An oxygen bound ligand would be expected to have a greater coupling constant. Detailed analysis of the fragmentation pattern of the mass spectra shows peaks corresponding to $Pt(NSO)(NS)(PR_3)_2^+$ and $Pt(NS)_2(PR_3)_2^+$, both of which could not be readily accounted for if the complex was oxygen bound. Finally, nitrogen bound NSO^- ligands are more likely, as nitrogen is expected to formally carry the negative charge. The ^{31}P chemical shifts and ^1J couplings are dependant on the phosphine. The observed shifts in the complexes mirror the shifts in the uncoordinated phosphine. For example, on increasing the number of methyl groups from PPh_3 through to PMe_3 the chemical shift becomes more negative and the magnitude of ^1J is reduced. Methyl groups are better σ-donors than phenyl groups and poorer π-acceptors. Thus, increasing the number of methyl groups results in greater electron density on the phosphorus atoms, better shielding and more negative chemical shifts.

The ^{31}P NMR spectra of **11**–**13** are of the AX type with ^2J ^{31}P—^{31}P couplings of 20 Hz, typical for platinum(II).[8,11] The ^{195}Pt–^{31}P coupling constants of 3650 and 2850 Hz are typical of phosphorus *trans* to chlorine and nitrogen in platinum(II) complexes, leading us to postulate the existence of these $PtCl(NSO)(PR_3)_2$ complexes (N.B. no solid compounds of this formula have been isolated to date). Further evidence for our formulation comes from the position of the resonances in **11**. For example, phosphorus *trans* to nitrogen occurs at 0.2 ppm compared to 1.5 ppm in **2**, and phosphorus *trans* to chlorine occurs at 7.4 ppm compared to 9.1 ppm in $PtCl_2(PEt_3)_2$.

^1H NMR (Table 2) for **1**, **4** and **5** reveal methyl resonances split by both $^2J_{P—H}$ of 11 Hz and $^3J_{Pt—H}$ of *ca* 34 Hz. This again indicates identical phosphine groups in a symmetric environment. For the other complexes (**2**, **3**, **6**, **7**) the small differences in chemical shifts hide the couplings.

Compounds **1** and **9** exhibit characteristic NSO vibrations in the regions 1250–1200 cm^{-1} and 1090–1040 cm^{-1} corresponding to the asymmetric and symmetric stretching modes, respectively. Previous IR studies of RNSO compounds suggest that these two modes are not strongly coupled. Individual modes were assigned to ν(NS) or ν(SO) although the subject of disagreement in these compounds has been largely resolved with the higher frequency mode being assigned as the ν(NS). In this study compounds **1** and **2** both show two ν_{asym} and ν_{sym} vibrations and in the absence of coupled modes suggests two inequivalent NSO groups. This cannot be reconciled with the crystal structure which shows a symmetric environment and similarly with the ^{31}P NMR. For compounds **4**, **5**, **7** and **8** only one band for the ν_{asym} is observed although this is broadened relative to the ν_{asym} observed in **1** and **2**. However, the ν_{sym} shows two modes although these are partially covered by ligand modes.

The X-ray structure of **1** is shown in Fig. 1 with bond lengths and angles in Table 4. The molecule

(*Received* 21 *September* 1988; *accepted* 27 *October* 1988)

Abstract—Reaction of $Pt(COD)(S_2N_2)$ (**1**) with KCN gives $K_2[Pt(CN)_2(S_2N_2)]$ (**2**) which can be protonated using HCl. The X-ray structure of $[Et_4N][Pt(CN)_2(S_2N_2H)]$ (**3**) is reported. The anion has *cis* square-planar geometry with characteristic bond lengths and angles for the $S_2N_2H^-$ ligand.

As part of a continuing study into the chemistry of metal–sulphur–nitrogen systems we have recently reported on the preparation of the disulphur–dinitrido complex $Pt(COD)(S_2N_2)$ (**1**)[1] (COD = 1,5-cyclooctadiene), which we suggested had great promise as a starting material for the synthesis of previously unobtainable complexes of the type $PtL_2(S_2N_2)$. Here we report on the reaction of **1** with 2 equivalents of KCN which readily yields salts of $[Pt(CN)_2(S_2N_2)]^{2-}$ and, after protonation with HCl, $[Pt(CN)_2(S_2N_2H)]^-$. The structure of the latter anion, the nickel analogue of which has been known for some 30 years, has been confirmed by X-ray crystallography.

EXPERIMENTAL

General conditions and preparation of starting materials were as previously reported; a variation upon the preparation of $Pt(COD)(S_2N_2)$ is included below as it results in a product of higher purity than the earlier method.[1]

$Pt(COD)(S_2N_2)$ (1)

A mixture of $Pt(COD)Br_2$ (0.597 g, 1.3 mmol) and $[Me_2Sn(S_2N_2)]_2$ (0.31 g, 0.65 mmol) in CH_2Cl_2 (50 cm^3) was stirred for 4 h, after which time the volume of the solvent was reduced to 10 cm^3 *in vacuo* and the resulting solution treated with $[^nBu_4N]OH$ (1.3 cm^3 of a 1 M solution in MeOH, 1.3 mmol). After stirring for 1 min the solution was evaporated to dryness and the residue washed with water (50 cm^3), then dried and extracted into CH_2Cl_2 (20 cm^3). After filtration, the volume of the solution was reduced to 5 cm^3 and the product obtained as well-formed micro-crystals by slowly stirring hexane (50 cm^3) into the mixture. After further washings with hexane (30 cm^3) and Et_2O (50 cm^3) the solid was dried *in vacuo*. Micro-analysis. Found: C, 25.1; H, 3.2; N, 6.5. Calc. C, 24.3; H, 3.1; N, 7.1%. Typical yield ≈ 80%.

Crude $K_2[Pt(CN)_2(S_2N_2)]$

$Pt(COD)(S_2N_2)$ (0.2 g, 0.5 mmol) and KCN (66 mg, 1.0 mmol) were mixed as solids and, with the mixture cooled to 0°C using an ice bath, ethanol (15 cm^3) was added with stirring. After a few minutes just enough CH_2Cl_2 (*ca* 5–10 cm^3) was added to dissolve the remaining solid, while the temperature was maintained at 0°C. The resulting solution was stirred overnight with the ice bath allowed to slowly melt and the temperature to reach RT. The resulting mixture consisted of an orange solution with some unreacted KCN as precipitate; the solvent was evaporated *in vacuo* until enough CH_2Cl_2 had been removed to allow the unreacted $Pt(COD)(S_2N_2)$ to start to crystallize out. At this point more ethanol (*ca* 15 cm^3) was added and the suspension stirred for 10 min, followed by addition of CH_2Cl_2 (*ca* 1 cm^3) to dissolve any remaining precipitate. The resulting solution was stirred for a further 6 h then reduced in volume to *ca* 10 cm^3. Hexane (50 cm^3) was added giving crude

* Author to whom correspondence should be addressed.

$K_2[Pt(CN)_2(S_2N_2)]$ as a yellow precipitate, which was filtered and dried *in vacuo*. Yield 150 mg (72%).

$[Et_4N][Pt(CN)_2(S_2N_2H)]$

Crude $K_2[Pt(CN)_2(S_2N_2)]$ (84 mg, 0.2 mmol) was dissolved in degassed water (1 cm^3) and treated with dilute HCl (1 cm^3 of a 0.2 M solution) giving a green coloured solution with some precipitate. The water was removed *in vacuo* and the residue extracted into THF (20 cm^3). After filtration the volume of the THF was reduced and crude $K[Pt(CN)_2(S_2N_2H)]$ precipitated as a yellow–orange solid by addition of hexane (70 cm^3). Yield 50 mg.

This product was stirred with $[Et_4N]Br$ (30 mg, 0.14 mmol) in 1 : 1 EtOH–CH_2Cl_2 (20 cm^3) for 20 min, then the solvent was removed *in vacuo* and the residue extracted with CH_2Cl_2 (20 cm^3) followed by filtration through celite. The celite was washed with further amounts of CH_2Cl_2 ($\approx 5 \times 30$ ml) until the washings were colourless; the combined filtrate was reduced to 20 cm^3 and the product obtained as a green precipitate by addition of hexane.

Yield 53 mg (56% based upon $K_2[Pt(CN)_2(S_2N_2)]$ or 40% based upon **1**. Microanalysis. Found: C, 25.4; H, 4.4; N, 14.5. Calc. for $[(CH_3CH_2)_4N][Pt(CN)_2(S_2N_2H)]$: C, 25.5; H, 4.5; N, 14.9%.

Crystals suitable for X-ray crystallography were obtained by slow hexane diffusion into an EtOH solution.

Crystal data. $C_{10}H_{21}N_5PtS_2$, $M = 470.5$, orthorhombic, $a = 14.231(5)$, $b = 14.508(3)$, $c = 16.081(4)$ Å, $U = 3320$ $Å^3$, space group *Pcab*, $Z = 8$, $D_c = 1.88$ g cm^{-3}, Cu radiation, $\lambda = 1.54178$ Å, $\mu(Cu\text{-}K_\alpha) = 183$ cm^{-1}, $F(000) = 1807$.

Data collection and processing. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using the ω-scan method. A crystal of dimensions $0.13 \times 0.20 \times 0.33$ mm was used. 2235 independent reflections were measured ($2\theta \leqslant 116°$), of which 1921 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors; an empirical absorption correction (ellipsoidal) based on 376 azimuthal measurements was applied (maximum and minimum transmission factors were 0.070 and 0.008).

Structure analysis. The structure was solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically. The amine proton on N(1) was placed in a calculated trigonal position and then allowed to refine isotropically subject to a N—H distance constraint of 0.98 Å. The positions of the remaining hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2\ U_{eq}(C)$, and allowed to ride on their parent carbons. The methyl groups were refined as rigid bodies. Refinement was by block-cascade full-matrix least-squares to $R = 0.041$ ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.045$ ($w^{-1} = \sigma^2(F) + 0.00043F^2$). The maximum and minimum residual electron densities in the final ΔF map were 1.20 and -0.54 e $Å^{-3}$, respectively. The mean and maximum shifts/error in the final refinement were 0.019 and 0.214, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[2]

RESULTS AND DISCUSSION

The anion $[Ni(CN)_2(S_2N_2H)]^-$ was first prepared in 1957 by reaction of the dimeric nickel species $K_4[Ni_2(CN)_6]$ with S_4N_4,[3] and has subsequently been shown to be available from a similar reaction with $K_2[Ni(CN)_4]$[4] and from reaction of $Ni(S_2N_2H)_2$ with KCN.[5] However, despite the fact that the nickel species is so well known there have been no reports of salts of the platinum analogue, $[Pt(CN)_2(S_2N_2H)]^-$. This is primarily due to the fact that the platinum cyano complex $K_2[Pt(CN)_4]$ does not react with S_4N_4 in a similar manner to its nickel counterpart. Furthermore, while it is quite possible that $Pt(S_2N_2H)_2$ reacts with KCN to give the substituted species, no investigations into this reaction have been reported (possibly due to the difficulty of preparing bulk amounts of the starting material). Here we report on the preparation of $[Pt(CN)_2(S_2N_2H)]^-$ by a method which circumvents these problems, utilizing the recently discovered organometallic complex Pt(COD)(S_2N_2) (**1**).

Reaction of **1** with 2 equivalents of KCN in EtOH–CH_2Cl_2 results in the replacement of the labile COD group by two cyanides [eq. (1)]

$$\underset{(1)}{Pt(COD)(S_2N_2)} + 2KCN \longrightarrow \underset{(2)}{K_2[Pt(CN)_2(S_2N_2)]} + COD. \quad (1)$$

The solvent system in which the reaction is performed is crucial, for a number of reasons. One important consideration is the solubility of the reactants; KCN requiring EtOH, in which **1** is only poorly soluble. For this reason the reaction is performed in the presence of just enough CH_2Cl_2 to allow **1** to dissolve, although this often means that some KCN is precipitated during the course of the

reaction (see Experimental). Also, the reaction is performed at low temperature (at least initially), since heating mixtures of KCN and **1** much above room temperature results in the production of a highly coloured species, which is also apparent if the reaction is performed in MeOH instead of EtOH. It is possible that this coloured species may be a salt of the dimeric anion $[Pt(CN)(S_2N_2)]_2^{2-}$ although we have yet to confirm this.

Crude $K_2[Pt(CN)_2(S_2N_2)]$ (**2**), obtained in the above manner, is a yellow solid which appears to be air-stable and dissolves only in water and polar solvents. The IR of this product shows the expected S—N bands at 1055, 693 and 373 cm^{-1}, together with cyanide stretches at 2110 and 2124 cm^{-1} (cf. 2135 and 2124 cm^{-1} in $K_2[Pt(CN)_4]$). Also present are rather broad peaks in the region around 1100 cm^{-1}, typical of S=O stretches. Such impurities are common in complexes of the type $Pt(S_2N_2)(PR_3)_2$, which we have prepared by a variety of routes,[6] but can easily be washed out with water. In the case of **2**, which is water soluble, this is obviously not possible and it is for this reason that we have yet to prepare analytically pure samples; a typical microanalysis shows C, 6.5; N, 11.5%, compared to calculated values of 5.8 and 13.4%, respectively. However, the nature of the compound can be unequivocally deduced from the IR spectrum and, by inference, from the crystal structure of the protonated species.

Protonation of $[Pt(CN)_2(S_2N_2)]^{2-}$ is easily achieved and in some situations unavoidable. Thus attempts to prepare $[Et_4N]_2[Pt(CN)_2(S_2N_2)]$ by reaction of **2** with $[Et_4N]Br$ in CH_2Cl_2–EtOH lead to mixtures of an intractable oil together with green crystals of $[Et_4N][Pt(CN)_2(S_2N_2H)]$ (**3**). The latter is, however, best prepared by treatment of **2** with dil. HCl in H_2O, which gives crude samples of $K[Pt(CN)_2(S_2N_2H)]$ that can be converted to the tetraethylammonium salt by reaction with $[Et_4N]Br$ [eq. (2)]. Extraction of the product of this reaction into CH_2Cl_2, in which it is fairly soluble, yields samples of a high analytical purity. Typically, the overall yield of this final product, based upon the amount of $Pt(COD)Br_2$ initially used, is in the order of 30–35%. The IR spectrum of the compound includes bands at 2986 (ν[N—H]), 2139/2127 (ν[CN]) and 1048/689 cm^{-1} (ν[N—S]). It is noteworthy that, as we have previously observed for phosphine complexes, the relative intensities of the latter two bands is changed as a result of protonation. Thus, whereas in **2** the higher frequency band is the more intense of the two, in **3** the opposite is true.

$$\underset{(2)}{K_2[Pt(CN)_2(S_2N_2)]} + HCl \longrightarrow K[Pt(CN)_2(S_2N_2H)] + KCl$$
$$\Big\downarrow + [Et_4N]Br$$
$$[Et_4N][Pt(CN)_2(S_2N_2H)] + KBr. \qquad (2)$$
$$(3)$$

Attempts to prepare $K[Pt(CN)_2(S_2N_2H)]$ by reaction of $K_2[Pt(CN)_4]$ with S_4N_4 in MeOH seems to invariably fail. Thus, refluxing the platinum species with S_4N_4 (1 : 1) for 3 h, followed by evaporation of the solvent *in vacuo*, yields a pale yellow, hygroscopic residue. The IR of this residue shows bands due to unreacted $K_2[Pt(CN)_4]$ together with sulphur oxyanions such as thiosulphate, but none of the bands observed in the crude $K[Pt(CN)_2(S_2N_2H)]$ prepared as above. The absence of this product is also confirmed by the fact that the residue dissolves in H_2O to give a colourless solution. If the residue is extracted with CH_2Cl_2 this yields unreacted S_4N_4 (typically 70 mg from a reaction initially involving 120 mg).

Similarly, attempts to prepare salts of **2** by displacement of the phosphine groups in $Pt(S_2N_2)(PMe_2Ph)_2$ by cyanide (present as the $[^nBu_4N]^+$ salt) prove unsuccessful, although we have preliminary evidence to suggest that a monosubstituted species, in which one of the phosphines has been replaced, may be formed. On this point it is worth noting that cyanide deprotonates complexes of the type $[Pt(S_2N_2H)(PR_3)_2]X$; thus treatment of $[Pt(S_2N_2H)(PMe_2Ph)_2]BF_4$ with 1 equivalent of $[^nBu_4N]CN$ results in the formation of $Pt(S_2N_2)(PMe_2Ph)_2$, as observed by ^{31}P NMR.

Slow diffusion of hexane into an EtOH solution of **3** yields very well-formed crystals, suitable for X-ray crystallography. The anion has the expected square-planar geometry (Fig. 1, Table 1), with a maximum deviation from planarity of 0.03 Å [for N(3)]. It is noteworthy that, as in previously studied transition metal $S_2N_2H^-$ complexes,[7] the N—H proton lies significantly out of the plane of the metallocycle (0.25 Å). The bond lengths and angles in the PtS_2N_2 ring are consistent with previous results for protonated complexes, with characteristic angles at N(1), N(2) and S(1) in accord with the presence of a proton on N(1).[7] The bond lengths for the Pt—$(CN)_2$ unit are normal. There is an intermolecular N(1)—H···N(4) hydrogen bond (N(1)—N(4) 2.93 Å, H···N(4) 2.02 Å; N—H···N

Table 1. Bond distances (Å) and angles (°) in $[Et_4N][Pt(CN)_2(S_2N_2H)]$

angle 154°). Despite the planarity of the anions they do not display stacking properties in the crystal in this case, in contrast to previously studied phosphine complexes.[7] This is undoubtedly due to the very bulky nature of the cation and the absence of any potential hydrogen-bonding acceptor sites. Work on the preparation of crystalline samples containing smaller cations is underway.

Abstract—The air- and moisture-stable complexes $[Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}\{OC_6H_4Z\}_3]$ (Z = H, 3-NO_2, 4-NO_2, 2-F, 3-F, 4-F, 4-Bu^t), have been prepared by the reaction of the appropriate phenol with the known complex $[Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_3]$, in the presence of a base. The molecular structure of $[Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}(OC_6H_4\text{-}4\text{-}NO_2)_3]$ was determined by X-ray diffraction techniques. The complex has near C_{3v} point symmetry. The Zr—O(4-nitrophenoxide) distance is 1.978(1) Å and the Zr—O—C(4-nitrophenyl) angle is 161.4(1)°. The phenyl rings are oriented to lie in the clefts between the pyrazolyl rings.

The complex $[ZrLCl_3]$ (I) (L = $HB(3,5\text{-}Me_2C_3N_2H)_3$), is a precursor to a variety of complexes in which the projecting methyl groups of the $HB(3,5\text{-}Me_2C_3N_2H)_3$ ligand strongly favour an octahedral environment around the zirconium atom.[1] These include methoxide[1] and *t*-butoxide[2] derivatives as well as organometallic compounds,[3] but to our knowledge no reports of aryloxide complexes have appeared. In the course of our investigations[4–6] into the ability of sterically demanding tripodal ligands to regulate the chemistry at metal centres, we have prepared a series of trisphenoxide derivatives containing the $\{Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}\}^{3+}$ moiety.

The reaction of I with HOC_6H_4Z (Z = H, 3-NO_2, 4-NO_2, 2-F, 3-F, 4-F, 4-Bu^t) in dichloromethane containing triethylamine, afforded the air-stable tris-phenoxide complexes $[ZrL(OC_6H_4Z)_3]$, even when only a 2 : 1 stoichiometric ratio of HOC_6H_4Z to I was used. When 3 : 1 HOC_6H_4Z–I ratios were used yields of $[ZrL(OC_6H_4Z)_3]$ in the range 51–88% were obtained depending upon Z. These compounds were all soluble in dichloromethane and polar organic solvents but insoluble in water. They were characterized by ^{1}H NMR, IR and MS and all gave satisfactory elemental analyses for C, H and N. The ^{1}H NMR spectra of the complexes exhibited signals which were consistent with C_{3v} point symmetry for the molecules. In the case of $[ZrL(OC_6H_4\text{-}4\text{-}NO_2)_3]$, and the other four-substituted phenoxides, the NMR spectrum showed that both edges of the aryl ring were equivalent indicating that, at room temperature, rotation of the aryl ring about the C—O bond was rapid on the NMR timescale. An electrochemical investigation of $[ZrL(OC_6H_4\text{-}2\text{-}F)_3]$ by cyclic voltammetry at a platinum bead electrode in THF or acetonitrile revealed only highly irreversible reduction processes. No well defined product waves were apparent and it is likely that the reduction processes in these solvents lead to decomposition of the complex.

In order to obtain more detailed structural information about an example of these species a single crystal X-ray diffraction study was carried out on $[ZrL(OC_6H_4\text{-}4\text{-}NO_2)_3]$. Crystals of this complex are trigonal, $R\bar{3}$, a = 12.211(3) Å, α = 93.85(4)°, Z = 2.

* Authors to whom correspondence should be addressed.

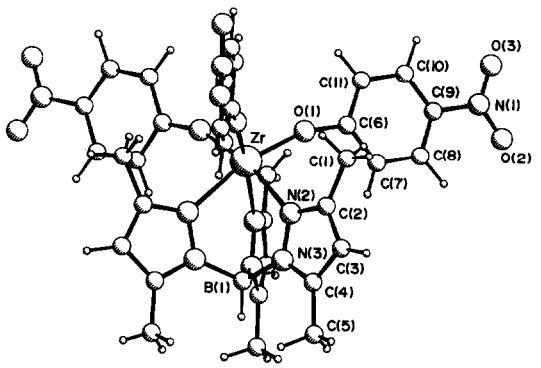

Fig. 1. A view of the complex showing the atom numbering.

Cell dimensions and intensities were measured with an Enraf–Nonius CAD-4 diffractometer using Mo-K_α radiation. 1767 reflections in the range $\theta = 2$–24° having $I > 2.5\sigma(I)$ were used in the analysis. The structure was solved by direct methods[7] and refined by least-squares using anisotropic temperature factors for the heavier atoms and isotropic temperature factors for the hydrogens. The calculations[8] were terminated when all shifts were $< 0.01\sigma$, and R and R_w were 0.027 and 0.038, respectively, $w = 1/\sigma^2(F)$.

A view of the complex* drawn with PLUTO[9] is shown in Fig. 1. The molecule exhibits C_3 symmetry with the zirconium, boron and the hydrogen atom bonded to the boron lying on a crystallographic three-fold axis. The approximation to C_{3v} symmetry is evident, the 4-nitrophenyl rings being twisted only slightly, by 4.3(2)°, out of the putative mirror plane. The basically octahedral coordination geometry at zirconium shows significant trigonal distortion. The three N—Zr—N angles are 79.4(1)° and the O—Zr—O angles, 98.6(1)°. The *cis*-N—Zr—O angles are close to 90° while the *trans* angles are 166.4(1)°. Noteworthy is the large (161.4(1)°) Zr—O—C(phenoxy) angle indicating a considerable degree of $p\pi \rightarrow d\pi$ donation from the ligand to the metal.

In the crystal structure of the analogous [ZrL(OBu^t)(η^2-C(Me)NCMe$_3$)Me][3] where zirconium is seven-coordinate, the Zr—N(pyrazolyl) bond distances are significantly greater, averaging 2.414 Å compared with our value of 2.301(2) Å. This difference may be attributed to the steric effect of the bulky *t*-butyliminoethyl group interacting with a methyl group of a pyrazolyl ring.[3] The Zr—O—C(butoxy) moiety has Zr—O = 1.924, O—C = 1.45 Å and an angle at oxygen of 174.4°. These compare with values of 1.978(1), 1.338(2) Å and 161.4(1)°, respectively, in the Zr—O—C(4-nitrophenoxy) moiety of our complex. In neither structure do intermolecular contacts appear to affect the geometry and these differences may be a manifestation of the additional electron delocalization involving the aromatic ring. The bonding geometry at such an oxygen atom, however, shows considerable flexibility. Thus in the crystal structure of [Zr(η^5-C$_5$H$_5$)$_2$(OC$_6$H$_4$-4-Cl)]$_2$O[10] the two chemically equivalent Zr—O—C(aryloxy) angles (153.1 and 177.3°) differ by 24°. In 13 Zr—O(aryloxy) residues whose geometries have been determined[10–14] by X-ray crystallography the Zr—O lengths range from 1.90 to 2.07 Å, mean 1.984 Å, the O—C lengths, from 1.305 to 1.40 Å, mean 1.361 Å, and the angles at oxygen from 148 to 177°, mean 165.5°, in reasonable agreement with our values. Interestingly there is a weak inverse correlation ($r = -0.60$) between the Zr—O length and Zr—O—C angle.

It is notable that in the structure described here the phenyl rings are oriented to lie between the 3-methyl groups of the ligand L. This behaviour contrasts with that found in mono- and bis-phenoxy, or arylamide, complexes containing the {Mo(NO)L} moiety in which the aryl rings are oriented away from the ligand L.[4] Thus, while L is highly sterically demanding in the region of the pyrazolyl rings, it is far less so in the region between the pyrazolyl rings, provided that relatively flat co-ligand substituents are involved.

COMMUNICATION

THE CLEAVAGE OF A PHOSPHA-ALKYNE AT A REDUCED TANTALUM CENTRE. POSSIBLE INTERMEDIACY OF A TANTALUM PHOSPHIDE

ALAN H. COWLEY* and STEPHEN W. HALL

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 27 *October* 1988; *accepted* 3 *November* 1988)

Abstract—The reaction of $Ta(OAr)_2Cl_3$ (Ar = 4-Me,2,6-*t*-$Bu_2C_6H_2$) with 3.0 equivalents of Na/Hg, followed by treatment with 3.0 equivalents of *t*-BuC≡P results in the formation of the 2,5-di-*t*-butyl-1,3,4-triphosphacyclopentadienyl (**1**) and 2,4,5-tri-*t*-butyl-1,3-diphosphacyclopentadienyl (**2**) anions. It is speculated that the formation of **1** involves the phosphide intermediate, $(ArO)_2Ta{\equiv}P$.

There have been recent reports of the cyclotrimerization of phospha-alkynes.[1] Arguing by analogy with the cyclotrimerization of alkynes it seemed reasonable to suggest the intermediacy of a metalladiphosphapentadiene. Given that metallacyclopentadienes have been isolated recently from the reaction of alkynes with reduced tantalum species,[2] we were prompted to undertake a comparable reaction using the phospha-alkyne, *t*-BuC≡P. However, the reaction took an unexpected course and resulted in the formation of di- and triphosphacyclopentadienide anions.

EXPERIMENTAL

The tantalum aryloxide, $Ta(OAr)_2Cl_3$ was prepared by treatment of $TaCl_5$ with 2.0 equivalents of LiOAr in C_6H_6 solution. The procedure was similar to that described for the synthesis of other tantalum(V) compounds of this type.[2] The $Ta(OAr)_2Cl_3$ was reduced with 3.0 equivalents of Na/Hg prior to the addition of 3.0 equivalents of *t*-BuC≡P.[3] After filtration of the reaction mixture, the solvent and volatiles were removed *in vacuo* and the resulting pale yellow solid was washed with *n*-hexane and toluene. Fractional crystallization from DME or THF afforded compounds **1** and **2** in isolated yields of 42 and 37%, respectively.

$^{31}P\{^1H\}$ NMR (121.5 MHz, 85% H_3PO_4 external THF) **1**: δ 245.5 (d, $^2J_{PP}$ = 47 Hz) 252.5 (t, $^2J_{PP}$ = 47 Hz); **2**: δ 187.6(s). ^1H NMR (300.0 MHz, Me_4Si, CD_3CN) **1**: δ 1.57(s); **2**: δ 1.46 (s, 9H), 1.62 (s, 18H). ^{13}C NMR (75.5 MHz, Me_4Si, THF-d_8), **1**: δ 37.4 (d of d of d, $^3J_{PC}$ = 10.6, $^3J_{PC}$ = 5.3 Hz); **2**: 36.7 (t, $^3J_{PC}$ = 9.8 Hz), 37.0 (d of d, $^3J_{PC}$ = 10.1; $^4J_{PC}$ = 8.3 Hz). Negative ion mass spectroscopy, **1**: *m/z* 231 (M^-); **2**: *m/z* 269 (M^-).

RESULTS AND DISCUSSION

The ^{31}P NMR data for **1** are in satisfactory agreement with those reported for the 2,5-di-*t*-butyl-1,3,4-triphosphacyclopentadienyl anion.[4] The 2,4,5-tri-*t*-butyl-1,3-diphosphacyclopentadienyl anion (**2**) has been suggested previously as a by-product in the preparation of **1**.[5] This structure assignment is confirmed by ^1H and $^{13}C\{^1H\}$ NMR, and negative ion mass spectroscopy.

Becker *et al.*[4] have demonstrated that **1** is formed via the reaction of *t*-BuC≡P with the phosphide

source, $LiP(SiMe_3)_2$. It therefore seems reasonable to imply a phosphide intermediate in the present case. One possibility is that *t*-Bu≡P is cleaved by the reduced tantalum species to afford the intermediates $(ArO)_2Ta{\equiv}P$ (**3**) and $(ArO)_2Ta{\equiv}C$-*t*-Bu (**4**). In turn, each of these species could react with 2 moles of *t*-BuC≡P to produce **1** and **2**, respectively. Consistent with this view is the observation that **1** and **2** are produced in an equimolar ratio. The source of the extra electrons for **1** and **2** is presumably the alkali metal. We note that the intermediate $(t\text{-}BuCH_2O)_3W{\equiv}P$, a very similar species to **3**, has been postulated recently by Chisholm *et al.*[6] Moreover, cleavage of *t*-BuC≡P by WCl_6 and $MoCl_5$ in the presence of $POCl_3$ has been reported by Becker and co-workers.[7] In both cases, a *t*-BuC≡CBu-*t* complex was formed but the phosphide-derived product(s) was not isolated.

Acknowledgements—Support by the National Science Foundation and the Robert A. Welch Foundation is greatly appreciated.

Note Added in Proof

A 1,4-diphospha-2-rhodacyclopentadiene complex has been isolated very recently. See P. Binger, B. Biedenbach, R. Mynott, C. Krüger, P. Betz and M. Regitz, *Angew. Chem. Int. Ed. Engl.* 1988, **27**, 1157.

AXIAL LIGAND SUBSTITUTION REACTIONS OF PHOSPHINE DERIVATIVES OF RUTHENIUM(II) AND RUTHENIUM(III) BENZOQUINONE DIOXIME COMPLEXES

MOHAMED A. KHALIFA*

Department of Chemistry, Faculty of Science Alexandria University, Alexandria, Egypt

(*Received* 12 *April* 1988; *accepted after revision* 6 *September* 1988)

Abstract—The synthetic, spectral and kinetic studies of ruthenium(II) macrocyclic complexes, $Ru(BQDH)_2L_2$ (where BQDH = benzoquinone dioximate), are reported. Axial ligands include nitrogen, phosphorus and sulphur donors. An oxidized species, $Ru(BQDH)(BQD)(PPh_3)_2$, formed via one-electron oxidation followed by loss of a bridging hydrogen, was characterized as a ruthenium(III) complex. Kinetic and thermodynamic data of axial ligand substitution showed that the reaction mechanism is dissociative (D) and that the five-coordinate intermediate possesses little or no ability to discriminate between nucleophiles. The ruthenium(II) complexes were found to be more labile than the corresponding ruthenium(III) complexes. *Trans*-group and leaving-group effects are discussed. The BQDH ruthenium complexes differ from the DMGH analogues in that the former are much more labile, owing to the high delocalization of the conjugated π-system of the BQDH. The ruthenium BQDH complexes were also found to be much more inert than the analogous iron complexes implying that the $M \rightarrow L$ π-back bonding is more important for ruthenium.

The chemistry of macrocyclic complexes and their closely related porphyrin and phthalocyanine-type complexes of ruthenium are relatively well known.[1–15] Kinetic studies of the ruthenium(II) complexes show different lability in the axial ligand substitution reactions. In carbonyl ruthenium(II) porphyrins, RuP(CO)(L), a remarkable lability of the nitrogen donors L *trans* to CO has been reported.[16,17] Similar labilization is observed for isocyanide derivatives of ruthenium porphyrins.[18] However, the corresponding $RuP(MeIm)_2$ and $RuP(Py)_2$ complexes are very inert.[19]

Sweigart[20,21] has reported the kinetic comparisons of axial ligand lability in the FePc and RuPc complexes of phosphines and phosphite. Recently, the kinetics of the reactions of a series of labile iron macrocyclic complexes have been reported[22] and the reaction mechanism was found to be dissociative (D). More recently, extensive kinetic studies of $Ru(DMGH)_2L_2$ bis-adducts have shown a substantially different lability in the axial ligation dynamics leading to a number of mechanistic considerations.[23] Dissociative (D), interchange dissociative "I_d" and associative "I_a" pathways were reported.

Furthermore, the electrochemistry of the ruthenium complexes of the BQDH has been studied[24] and reveals the isolation of two different products namely $Ru^{II}(BQDH)_2L_2$ and $Ru^{III}(BQDH)(BQD)L_2$. In the former the $(BQDH)_2$ acts as a dibasic macrocyclic ligand while in the latter (BQDH)(BQD) acts as a tribasic ligand. These findings prompted the interest to study the kinetic behaviour of these complexes towards axial ligation. This may demonstrate the effect of the structural differences of the in-plane ligand as well as the oxidation states of the central metal ion on the nucleophilic substitution reactions of axial ligands. Herein, the synthetic, spectral and kinetic data for the bis-adducts of ruthenium(II) and (III) complexes of BQDH are reported.†

* Present address: Department of Chemistry, Science and Mathematics Center, Makkah, P.O. Box 2064, Saudi Arabia.

† Ligand abbreviations: BQDH = benzoquinone dioximate (3,5-cyclohexadiene-1,2-dionedioximate); DMGH = dimethylglyoximate; P = porphyrin; Pc = phthalocyanine; MeIm = 1-methylimidazole; Py = pyridine; Pip = piperidine, PPh_3 = triphenylphosphine; $P(OBu)_3$ = tri-*n*-butylphosphite; DMSO = dimethylsulphoxide.

EXPERIMENTAL

Synthesis

Preparation of $Ru(BQDH)(BQD)(PPh_3)_2$. A solution of benzoquinone dioxime (0.58 g) and sodium hydroxide (0.174 g) in methanol (80 cm^3) was purged under a stream of Ar for 30 min in a Schlenk flask. Tris(triphenylphosphine)dichlororuthenium(II) (1.74 g) was then added and the reaction mixture was refluxed for 14 h. The intensely purple powder was collected, washed with deaerated water and methanol and dried *in vacuo* (yield 40%). Found: C, 64.2; H, 4.1; N, 5.8; P, 7.3. Calc. for $C_{48}H_{39}N_4O_4P_2Ru$: C, 64.1; H, 4.5; N, 6.2; P, 6.9%.

This complex can also be prepared by admitting oxygen to a solution of the $Ru(BQDH)_2(PPh_3)_2$ as previously reported.[24]

Other compounds. The complexes of $Ru(BQDH)_2(PPh_3)_2$ and $Ru(BQDH)_2(PPh_3)$(MeIm) were prepared according to the method of Bond and Khalifa.[24]

Tris(triphenylphosphine)dichlororuthenium(II), was prepared as reported previously by Hallman *et al.*[25] Benzoquinone dioxime was prepared by borohydride reduction of benzofurazan oxide.[26,27]

Ruthenium trichloride dihydrate (Matthey–Bishop, Inc.), tri-*n*-butylphosphite (Aldrich), triphenylphosphine (Aldrich), piperidine (Aldrich), dimethylsylphoxide (Aldrich) and N-methylimidazole (Aldrich) were used without further purification. Pyridine (Fisher) was distilled from KOH prior to use. Toluene (Aldrich) was freshly distilled from CaH_2 before use.

Kinetic measurements. Reactions were monitored spectrophotometrically using an Aminco DW-2a UV–vis spectrophotometer or a Perkin–Elmer Hitachi 340 recording spectrophotometer. Deaerated solutions in 1 cm quartz cells were thermostated in a close-fitting brass block. The temperature of the block was maintained by a constant flow of circulating water by means of a Lauda circulator (K-21 R). Solutions were thermostated for approximately 15 min prior to the reaction measurements. The slower reactions were followed by periodically scanning the spectrum between 350–800 nm. Chart speeds were adjusted to suit the rate of the reaction.

Concentrations of ruthenium complexes were typically about 1.0×10^{-4} M. Reactions were run under pseudo-first-order conditions with the added nucleophile in large excess. The nucleophile was injected into the serum-capped cell, containing the ruthenium complex, with a Hamilton gas tight syringe. All the reactions were followed until the absorbance at infinite time could be correctly read off or calculated. Final spectra were recorded. Plots of $\log(A - A_\infty)$ vs time were linear over 3 half-lives. Reproducibility of separate runs was typically $\pm 5\%$ or less. The observed rate constant $k_{obs} = 2.303 \times$ slope of the line. Plots of $\log k/T$ vs $1/T$ gave straight lines. The activation parameters, $\Delta H^\ddagger$ and $\Delta S^\ddagger$, were calculated from the slopes and the intercepts of the lines, respectively.

RESULTS AND DISCUSSION

Spectral data

The spectral data of $Ru(BQDH)_2(PPh_3)_2$ and its oxidized product are quite different (Table 1). The ruthenium(II) complex exhibits two well defined sharp bands at 457 and 402 nm. The oxidized species shows a broad band at 456 nm with a shoulder on the higher energy side at 415 nm. Similar behaviour has been reported by Canon and co-workers[28,29] for N,N′-ethylene bis(salicylideneaminato)bis(triphenylphosphine)ruthenium(II) complex. Under nitrogen, two bands with λ_{max} at 770 and 505 nm, were observed. However, on admitting oxygen, a well defined band appeared at 800 nm with a shoulder on the higher energy side at $\simeq$ 690 nm. Such behaviour was also observed by West *et al.*[30] and the oxidized complex was reported to be the corresponding ruthenium(III) species. Accordingly, the spectral behaviour for the $Ru(BQDH)_2(PPh_3)_2$ suggested that the oxidized species is a ruthenium(III) complex.

As mentioned in the Experimental, the oxidized species can be obtained either by admitting oxygen to the ruthenium(II) complex solution or by carrying out the synthesis in methanol. Even

Table 1. Electronic absorption spectra of ruthenium macrocyclic complexes in toluene

[a] Ref. 23.

under careful conditions of oxygen-free argon, the synthesis in methanol yields the ruthenium(III) complex. Such oxidizing power of methanol was previously reported by Cannon *et al.*[28,29] for closely related ruthenium complexes.

A summary of electronic spectral data for the macrocyclic complexes investigated in this study is given in Table 1. Data for $Ru(DMGH)_2(PPh_3)_2$ are also given for the purpose of comparison. The lower energy band for the BQDH ruthenium complexes as well as the band for the DMGH complexes were assigned as charge transfers from ruthenium to the in-plane macrocyclic ligand. Such assignment was also proposed by Taube *et al.*[2] for some ruthenium macrocyclic complexes.

An inspection of the spectral data reveals a systematic variation in properties according to the variation in the structure. Thus, λ_{max} depends on the ligand field exerted by the equatorial macrocyclic ligand and both σ- and π-effects of the axial ligands. The much lower energy of the M → L charge transfer transition in BQDH complexes relative to DMGH complexes is consistent with a lowering of the π^*-level of the dioxime moiety as a result of conjugation with the hexadiene group. On replacement of PPh_3, a good σ-donor and π-acceptor by either of MeIm, Py or Pip; which are only good σ-donors to give the mixed complexes, the long wavelength band shifts to lower energy. The shift is greater with the formation of the bis-MeIm, Py or Pip adducts. However, when DMSO is coordinated *trans* to PPh_3 in the ruthenium complex of BQDH, a shift to a higher energy relative to the bis-PPh_3 complex is observed. This is an indication that the DMSO is a better π-acid ligand than the PPh_3. Remarkably, when $P(OBu)_3$ was used to replace PPh_3, the long wavelength band shifts to a much higher energy. This indicates that $P(OBu)_3$ is a better π-acid ligand than both DMSO and PPh_3. Thus, being a good π-acceptor ligand, tributylphosphite accepts electron density from filled t_{2g} orbitals. Therefore reducing the ease of charge transfer from ruthenium to BQDH. On the other hand, MeIm, Py and Pip, would increase the ease of such transfer since they are good σ-donors. Thus, for the mixed phosphite phosphine complexes, more energy is required to perform such charge transfer; and hence gives lower wavelengths for absorption maxima. These results show that the energy of the $Ru(BQDH)_2L_2$ bis-adducts complexes decreases in the following order: $Ru(BQDH)_2(PPh_3)(P(OBu)_3)$ > $Ru(BQDH)_2(PPh_3)(DMSO)$ > $Ru(BQDH)_2(PPh_3)_2$ > $Ru(BQDH)_2(PPh_3)(MeIm)$. That the tributylphosphite is a strong π-acid and electron withdrawing ligand was also reported by Sweigart *et al.*[20]

Using the data in Table 1, it is now possible to arrange the axial ligands involved in this study according to their σ-donating or π-accepting ability. The σ-donor power of these ligands decrease in the following order: MeIm ~ Pip > Py > PPh_3. On the other hand, the π-accepting ability of the π-acid ligands decreases in the following sequence: $P(PBu)_3$ > DMSO > PPh_3. Hence, triphenylphosphine is known to be a σ-donor and π-acceptor ligand.[31]

Kinetic data

The reactions investigated in this study can be classified as follows:

$$Ru(BQDH)_2(PPh_3)_2 + MeIm \longrightarrow Ru(BQDH)_2(PPh_3)(MeIm) + PPh_3 \quad (1)$$

$$Ru(BQDH)_2(PPh_3)(MeIm) + PPh_3 \longrightarrow Ru(BQDH)_2(PPh_3)_2 + MeIm \quad (2)$$

$$Ru(BQDH)_2(MeIm)(PPh_3) + MeIm \longrightarrow Ru(BQDH)_2(MeIm)_2 + PPh_3 \quad (3)$$

$$Ru(BQDH)(BQD)(PPh_3)_2 + X \longrightarrow Ru(BQDH)(BQD)(PPh_3)(X) + PPh_3, \quad (4)$$

X = MeIm, Py, Pip, DMSO and $P(OBu)_3$.

Reactions (1), (2) and (4) were followed spectrophotometrically in toluene (Table 2). The successive spectra, for each system, pass through a sharp fixed isosbestic point(s), implying that these reactions proceed cleanly to completion. The spectra of the final products are almost identical to those of the prepared authentic samples in the appropriate solvents. Typical spectral changes with time on the addition of MeIm to $Ru(BQDH)_2(PPh_3)_2$ solution in toluene at 40°C are given in Fig. 1. As the reaction proceeds to completion, the absorbance of $Ru(BQDH)_2(PPh_3)_2$ at 457 and 402 nm decreases and the peaks at 496 and 406 nm due to the mixed complex $Ru(BQDH)_2(PPh_3)(MeIm)$ increase. Analysis of the absorbance at 457 and 496 nm gave consistent rate constants (Table 2).

As stated earlier, the spectra of the oxidized species of BQDH ruthenium complex changes drastically from that of the corresponding ruthenium(II) complex. Interestingly enough, the triphenylphosphine off rate for the oxidized species is also much slower compared with that for the corresponding ruthenium(II) complex under the same conditions (Table 2). Typical spectral changes with time on the addition of piperidine to a solution of the oxidized ruthenium complex in toluene at 70°C are shown in Fig. 2, reaction (4), X = Pip.

Table 2. Kinetic data for the reaction: (T)Ru(N_4)L + X → (T)Ru(N_4)X + L, in toluene

Macrocycle (N_4)	*Trans* group (T)	Leaving group (L)	Nucleophile (X)	Temperature (°C)	k_1[a] (s^{-1})

[a] The errors in the values of k are within ±5%. [b] Ref. 23.

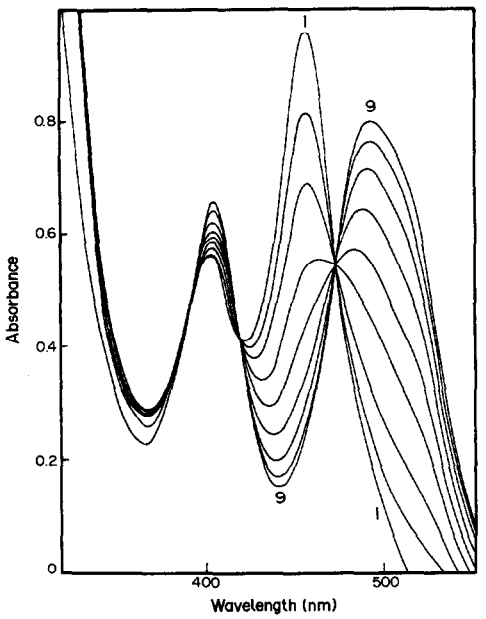

Fig. 1. Spectrophotometric changes with time for the reaction: $Ru(BQDH)_2(PPh_3)_2 + MeIm \rightarrow Ru(BQDH)_2(PPh_3)(MeIm) + PPh_3$, in toluene at 40°C. Spectra 1–9 were recorded at time 0, 5, 15, 35, 65, 115, 205, 320 and 505 min, respectively. Intervening spectra have been omitted for clarity.

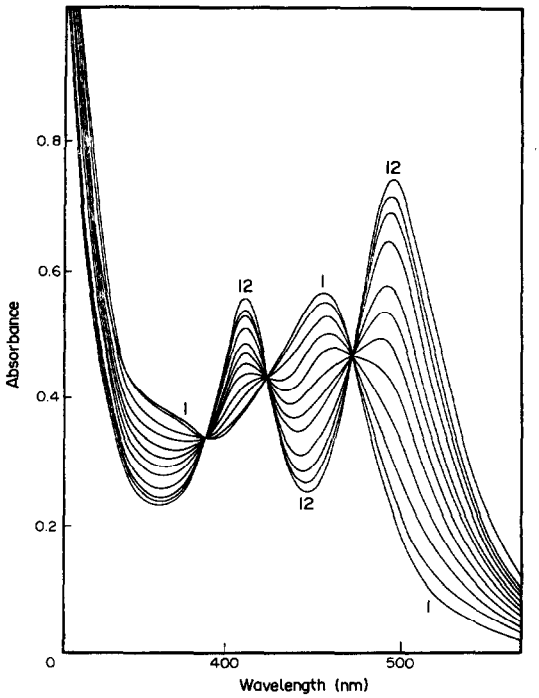

Fig. 2. Spectrophotometric changes with time for the reaction: $Ru(BQDH)(BQD)(PPh_3)_2 + Pip \rightarrow Ru(BQDH)(BQD)(PPh_3)(Pip) + PPh_3$, in toluene at 70°C. Spectra 1–12 were recorded at times 0, 5, 10, 15, 20, 25, 30, 35, 45, 60, 75 and 180 min, respectively.

The reaction proceeds cleanly to completion. The spectral changes are consistent with the formation of the mixed phosphine piperidine complex, λ_{max} 495 and 410 nm; and the disappearance of the bis-phosphine complex, λ_{max} 456 nm. The shift towards lower energy is consistent with Pip being a good σ-donor. Analyses of the spectral data at 495 or 456 nm gave excellent linear log plots and consistent rate constants (Table 2).

The reaction of the oxidized complex with good π-acid ligands such as tributylphosphite was also investigated. A shift of the absorption bands towards higher energy side was observed. Typical absorption changes are given in Fig. 3. The reaction proceeds smoothly to completion, showing two excellent isosbestic points. The formation of the mixed complex Ru(BQDH)(BQD)(PPh_3)–($P(OBu)_3$) was characterized by the increase of the absorbance at 434 and 390 nm. Analysis of the absorbance at 434 nm gave excellent linear log plots. The kinetic results and the activation parameters are listed in Tables 2 and 3, respectively.

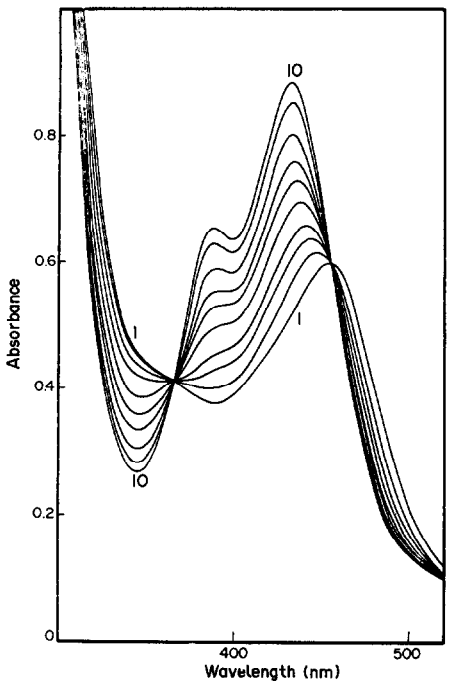

Fig. 3. Spectrophotometric changes with time for the reaction: Ru(BQDH)(BQD)(PPh_3)$_2$+$P(OBu)_3$ → Ru(BQDH)(BQD)(PPh_3)($P(OBu)_3$)+PPh_3, in toluene at 70°C. Spectra 1–10 were recorded at times 0, 4, 9, 14, 24, 34, 44, 64, 105 and 185 min, respectively.

The formation of the bis-amine complex, Ru(BQDH)$_2$(MeIm)$_2$, from the mixed phosphine methylimidazole complex, reaction (3), was found to be very slow. Such reactions were followed qualitatively by refluxing the reaction mixture in toluene. The rate constant was found to be several orders of magnitude slower than those listed in Table 2.

The general pattern of reactivity of the BQDH ruthenium complex parallel that of the DMGH ruthenium systems[23] and that of the TIM, Pc, DMGH and BQDH iron complexes[22] described previously. For the reaction

$$(T)Ru(N_4)L+X \longrightarrow (T)Ru(N_4)X+L, \quad (5)$$

where T is the *trans*-group; L the leaving group; X the nucleophile and N_4 represents the in-plane macrocyclic ligand, proceeding via a dissociative mechanism (D),

$$(T)Ru(N_4)L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (T)Ru(N_4)+L \quad (6)$$

$$(T)Ru(N_4)+X \xrightarrow{k_2} (T)Ru(N_4)X. \quad (7)$$

The pseudo-first-order rate constant neglecting the reverse reaction is given by

$$k_{obs} = \frac{k_1 k_2[X]}{k_{-1}[L]+k_2[X]}. \quad (8)$$

For [L] negligible and [X] large, expression (8) reduces to:

$$k_{obs} = k_1 \quad (9)$$

and the reaction proceeds with the formation of 100%

Table 3. Activation parameters for axial ligand substitution reactions of (T)Ru(N_4)L complexes in toluene[a]

Complex	Nucleophile (X)	$\Delta H^{\ddagger}$ (Kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal mol^{-1} deg^{-1})
(PPh_3)Ru(BQDH)(BQD)PPh_3	MeIm	19±2	10±3.5
	Py	21±2	5.0±2.5
	Pip	18±1	10±3
	$P(OBu)_3$	21±1	5.0±3
	DMSO	18.7±0.2	7.3±0.4
(PPh_3)Ru(BQDH)$_2$$PPh_3$	MeIm	21±1	5.0±3
(PPh_3)Ru(BQDH)$_2$MeIm	PPh_3	30±2	25±5

[a] L is the leaving group and T is the *trans*-ligand.

(T)Ru(N_4)X with a rate independent of the concentration or nature of the entering group X. These conditions are used to obtain "off rates" as previously described.[16-23]

The PPh_3 off rate for the BQDH ruthenium(II) bis-triphenylphosphine complex, $k_1 = 2.7 \times 10^{-3}$ s^{-1} at 60°C (Table 2). However, the PPh_3 off rate for the corresponding DMGH complex, $k_1 = 8.93 \times 10^{-5}$ s^{-1} at 70.5°C. This is clearly indicative that the BQDH complexes are much more labile toward PPh_3 loss than the DMGH complexes. This difference in lability can be rationalized on the basis that BQDH is a ligand with a delocalized π-system while DMGH is not. Thus, the higher the conjugation in the equatorial macrocyclic ligand, the more labile the system. The high delocalization of the conjugated π-system would produce a strong ligand field from the equatorial in-plane-macrocycle and thus results in weak long axial bonds. Thus, BQDH being a better π-acceptor than the DMGH ligand would result in more labile complexes for the former than the latter. Similar *cis*-effect was previously reported for analogous iron(II) macrocyclic complexes.[22]

From the experimental conditions it can be deduced that the equilibrium constants K_{eq} must be large. The reaction of $Ru(BQDH)_2(PPh_3)_2$ and MeIm was studied in both directions. For this case $k_f > k_r$, and for the conditions used the forward reaction went essentially to completion. Data in Table 2 allowed the equilibrium constant to be calculated. A value of $K_{eq} = 29$ for this reaction at 60°C implies that the reaction lies heavily to the right and greatly favours the formation of the mixed $Ru(BQDH)_2(PPh_3)$(MeIm) complex. This means that synergic π-bonding occurs in the mixed complex with the result that MeIm is extremely inert *trans* to PPh_3.

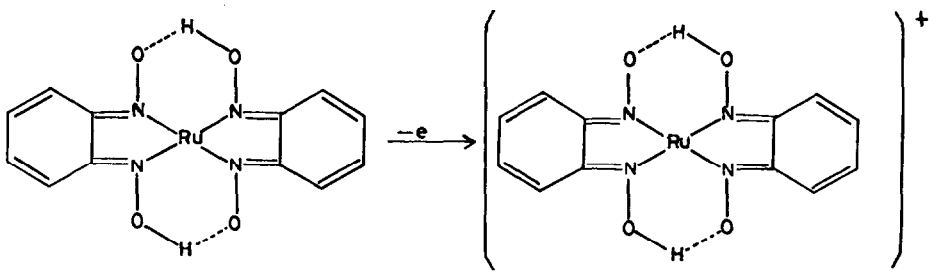
The kinetic behaviour of the oxidized ruthenium complex of the BQDH came as a surprise. Data in Table 2 showed that the oxidized species is $\simeq 10$ times slower towards the loss of PPh_3 than that for the ruthenium(II) complex. This kinetic inertness is a general feature of the ruthenium(III) amine complex and was previously reported.[32-34] If the oxidation is a ligand centred process to produce the cation radical, the kinetic results would have been the same for the oxidized species and the ruthenium(II) complex. Even more surprising are the results of the elemental analytical data. Analytical data for the ruthenium(II) complex of the BQDH were within experimental error, identical with those for the ruthenium(III) complex. Moreover, the data showed no evidence for coordinated chloride in the ruthenium(III) complex. These results indicate that the oxidation of the ruthenium(II) to ruthenium(III) complex takes place with loss of a proton.

The benzoquinoid structure is very stable and its protons are held strongly. On the other hand, a bridging hydrogen atom is weakly bonded and can easily be lost. Thus, the mechanism by which the ruthenium(II) complex of the BQDH is converted to ruthenium(III) species can be considered as follows: firstly, oxidation of the ruthenium(II) metal centre to ruthenium(III) proceeds to form an unstable cationic complex. Secondly, the high charge density at the new ruthenium(III) centre results in pulling the electron density from the nitrogen donor atoms. Thus producing a decrease of the electron density at the oxygens and increase in the acid–base properties of a bridging hydrogen atom. Such a process is strongly facilitated by the highly conjugated extended π-system of the BQDH.[35] This would lead to the loss of the bridging hydrogen atom producing the trinegative tetradentate macrocyclic ligand (BQDH)(BQD). Thus the final stable ruthenium(III) complex has zero charge. This mechanism can be represented by eqs (10) and (11). The two axial triphenylphosphine groups have been omitted for clarity.

Structure **(iii)** is the only structure which not only would fit the elemental analytical and spectral data, but also explains the electrochemical and kinetic behaviour that the oxidation site is a metal-centred rather than a ligand-centred process. Similar structure was previously suggested by Wilkinson and coworkers[36] for the $Ru(bdo_2en)(PPh_3)$ complex (where bdo = butan-2,3-dionemonooxime and en = ethylenediamine). Thus, the spectral, electrochemical, kinetic and elemental analytical results are conclusive evidence that the oxidized species is a ruthenium(III) complex of the BQDH and almost certainly does not contain the π-cation radical.

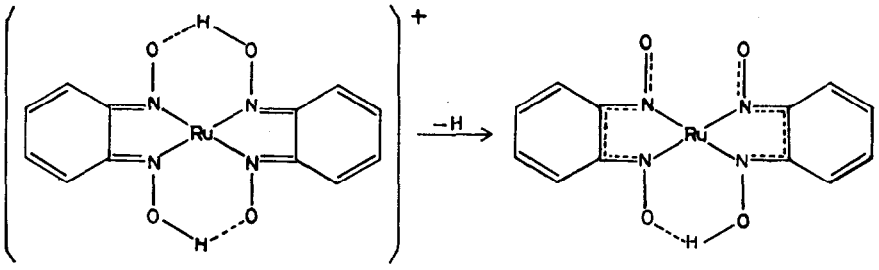
An alternative mechanism by which oxidation of $Ru(BQDH)_2(PPh_3)_2$ by molecular oxygen proceeds probably with an outer-sphere formation of the superoxide ion followed by its reaction with a second Ru^{II} ion to yield hydrogen peroxide and two molecules of $Ru(BQDH)(BQD)(PPh_3)_2$. A similar mechanism was proposed for the oxidation of $Ru(NH_3)_6^{2+}$ and $Ru(NH_3)_6^{3+}$ by molecular oxygen.[37]

Stabilization of unusual oxidation states is one of the most fascinating properties of the macrocyclic ligands. Electrochemical investigations suggest the formation of readily accessible thermodynamically stable ruthenium(IV) complexes of the BQDH and several other structurally related macrocyclic ligands.[24] Combination of the electrochemical and kinetic data reveals that the ruthenium(IV) complexes formed with a further oxidation step of the ruthenium(III) complexes, followed by



(10)

i ii



(11)

ii iii

a loss of the second bridging hydrogen to produce the tetranegative macrocyclic ligand. Thus the final ruthenium(IV) complex has zero charge. Similarly copper(0) complexes were previously reported for neutral macrocyclic ligands.[38]

Comparison of the axial ligand lability as measured by k_1 for the ruthenium macrocyclic complexes involved in this study with those previously reported for iron macrocyclic complexes[22] indicate that the ruthenium complexes are much more inert. This is probably due to the well-known superior π-backbonding ability of the ruthenium, leading to increased bond strength between the ruthenium and the axial ligands.

Remarkably, these results are in excellent agreement with the electrochemical data reported for a series of copper(II),[38] ruthenium(II) and (III),[24] and iron(II)[39] macrocyclic complexes. Polarographic studies showed stripping of the axial ligands from the copper(II) and iron(II) complexes. However, the axial ligands were strongly bound to the ruthenium ion of the ruthenium macrocyclic complexes. This is indicative that the copper(II) and iron(II) complexes are kinetically labile, while the ruthenium(II) and (III) complexes are kinetically inert. Thus the electrochemical data do not support the kinetic results.

COMPARISON OF COMPLEXIBILITY ON INORGANIC COBALT(II) COMPLEXES BETWEEN ION-EXCHANGER AND AQUEOUS SOLUTION MEDIA

HIROHIKO WAKI* and YOSHINOBU MIYAZAKI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka, Japan

(*Received* 1 *September* 1988; *accepted* 20 *October* 1988)

Abstract—The formation of cobalt(II) complexes with inorganic ligands in ion-exchanger solid phases has been investigated by direct spectrophotometric measurements. It was found that the stability constants of the one-to-one cobalt(II)–thiocyanate complex in the cation-exchanger phase are in all cases intrinsically higher than those in the solutions of the corresponding condition. This result can be ascribed to a low dielectric constant and high internal pressure as characteristic properties of the ion-exchanger phase, in comparison with the solution phase. This fact must be taken into consideration in using a conventional cation-exchange method for the determination of stability constants, in which the complex formation with anionic ligands in cation-exchangers has often been neglected for simplification in analysis.

Although a large number of studies on complex formation in solutions using an ion-exchange method have so far been reported,[1–4] little has been noted on complex formation within the ion-exchanger phase itself. It is known that the very high complexation of metal ions in the anion-exchanger phase is due to the high ligand anion concentration and that the very low complexation in the cation-exchanger phase is due to the exclusion of ligand anions. We considered that there should also be other factors such as dielectric constant and internal pressure etc. influencing complexation in the ion-exchanger phase, and attempted to find an intrinsic difference in complexation between the ion-exchanger phase and ordinary solution phase. We studied cobalt(II)–chloride and cobalt(II)–thiocyanate complex systems by applying absorption spectrophotometry to the solid phase.[5,6]

EXPERIMENTAL

Apparatus, reagents and ion-exchangers

A Hitachi Recording spectrophotometer EPS-3T was employed for absorbance measurements. All reagents used were of commercially available reagent grade. Cation-exchangers of different cross-linking degrees, Dowex 50W-X2, -X4 and -X8 (100–200 mesh) of the sodium form; and a cross-linked dextran gel-type cation-exchanger, SP-Sephadex C-25 of sodium form; were used in determining the stability constant of the one-to-one cobalt(II)–thiocyanate complex in each ion-exchanger phase.

Establishment of absorption spectra

A technique for the absorbance measurements of an ion-exchanger layer and its quantitative treatment have already been developed.[5,6] The ion-exchanger beads in which the complexes were sorbed were packed into a 2 mm quartz cell with a small amount of equilibrated solution, and the absorption spectrum was measured using a Hitachi Recording spectrophotometer EPS-3T. A net absorption spectrum on the sorbed chemical components was obtained by subtracting the absorbance of the interstitial solution from the observed overall absorbance of the sample layer. In order to make a correct spectral analysis, the net light path length of the ion-exchanger solid phase in the cell, as well as that of the interstitial solution, must be known. They were experimentally determined separately as follows.

* Author to whom correspondence should be addressed.

A potassium ferricyanide solution was used to determine the light path length of the interstitial solution. Since highly-charged anions such as $Fe(CN)_6^{3-}$ are almost entirely excluded from the cation-exchanger phase, the visible absorption spectrum of the cation-exchanger layer containing a potassium ferricyanide solution should be ascribed to that of the interstitial solution. The light path length of the interstitial solution in this cell can be obtained (in mm) by

$$l_i = 2\frac{A_i}{A_s} \quad (1)$$

where A_s and A_i are the absorbances of the equilibrated solution (using a 2 mm cell) and of the cation-exchanger layer (for a 2 mm cell), respectively.

In obtaining the light path length of the cation-exchanger phase in the same cell, a praseodymium chloride solution was used. The molar absorptivity of the praseodymium cation may be almost constant irrespective of its solution environment, that is, the molar absorptivity of the metal ion in the cation-exchanger phase is considered to be the same as that in the solution. Thus the light path length of the cation-exchanger phase (in mm) in the cell can be calculated by

$$l = \frac{\bar{A}^* - A_i}{\varepsilon_{Pr}\bar{C}_{Pr}} \quad (2)$$

where $\bar{A}^*$ is the overall absorbance of the ion-exchanger layer, A_i the absorbance of the interstitial equilibrium solution calculated using eq. (1), ε_{Pr} the molar absorptivity of the praseodymium ion and $\bar{C}_{Pr}$ the praseodymium ion concentration in the cation-exchanger phase expressed in mol dm^{-3}.

RESULTS AND DISCUSSION

Light path parameters for the ion-exchanger particle layer

The absorption spectrum for the cation-exchanger layer of Dowex 50W-X4 (100–200 mesh) equilibrated with a solution containing 0.004 M potassium ferricyanide and 0.5 M hydrochloric acid is shown in Fig. 1. The light path length of the interstitial solution was found to be 0.755 mm for a 2 mm cell using eq. (1), by comparison with the equilibrated solution spectrum.

The absorption spectrum for the cation-exchanger phase of the same resin, equilibrated with a 0.05 M praseodymium chloride–0.5 M perchloric acid solution using a 2 mm cell, is given in Fig. 2. The net light path length of the cation-exchanger phase was found to be 1.25 mm, using eq. (2).

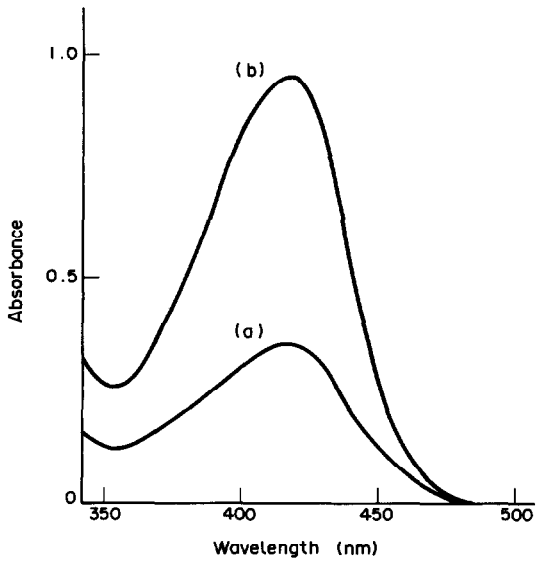

Fig. 1. Determination of the partial light path length for an interstitial solution in a 2 mm cell. (a) The absorption spectrum for a Dowex 50W-X4 layer equilibrated with a 0.004 M $K_3Fe(CN)_6$–0.5 M HCl solution. (b) The solution spectrum of the equilibrium solution.

In the same way, the light path parameters of a SP-Sephadex C-25 layer in a 2 mm cell were determined to be 1.02 mm for interstitial and 0.865 mm for solid phase.

These values were used in obtaining a correct

absorption spectrum of the sorbed chemical components within the ion-exchanger phase in further studies.

Absorption spectra of the ion-exchanger phase in the cobalt(II)–chloride system

The absorption spectrum of the cation-exchanger Dowex 50W-X4 phase equilibrated with a 0.476 M cobalt(II) chloride–5.4 M hydrochloric acid solution is shown in Fig. 3. The total chloride ion concentration in this cation-exchanger phase was calculated to be 2.64 M from the amount of chloride ions sorbed and the net volume of the ion-exchanger phase. For comparison, the absorption spectrum of a 0.290 M cobalt(II) chloride–2.06 M hydrochloric acid solution which has the same total chloride concentration is shown in the figure. Furthermore, the spectrum of the anion-exchanger AG 1-X4 phase equilibrated with a 0.290 M cobalt(II) chloride–1.84 M hydrochloric acid solution is also shown, the counter-chloride concentration in the solid phase is again 2.64 M.

Both cation- and anion-exchanger phase spectra had characteristic peaks at 520 nm (due to octahedral complexes) and 600–700 nm (due to tetrahedral higher complexes). On the other hand, the solution spectrum had a peak at 520 nm only. No peaks at longer wavelengths were observed.

Absorption spectra of the ion-exchanger phase in the cobalt(II) thiocyanate system

The absorption spectrum for the cation-exchanger Dowex 50W-X4 phase equilibrated with a 0.10 M cobalt(II) chloride–0.70 M sodium thiocyanate solution is shown in Fig. 4. The total thiocyanate ion concentration in this cation-exchanger phase was calculated to be 0.155 M from the amount of thiocyanate ion sorbed and the net volume of the ion-exchanger phase. For comparison, the absorption spectrum of a 0.10 M cobalt(II) chloride–0.155 M sodium thiocyanate solution which has the same total thiocyanate concentration is shown in the figure. The absorption spectrum for the ion-exchanger phase showed two characteristic peaks at wavelengths, 520 and 620 nm, although the solution again had a single peak at 520 nm, similar to the chloride system.

The comparison of these absorption spectra at the same ligand concentration, indicates that the complexibility in the ion-exchanger phase is intrinsically higher than that in the ordinary solution.

Determination of cation-exchanger corresponding solutions on complexation

In the foregoing sections, it was spectroscopically indicated that complexibility in the cation- or anion-

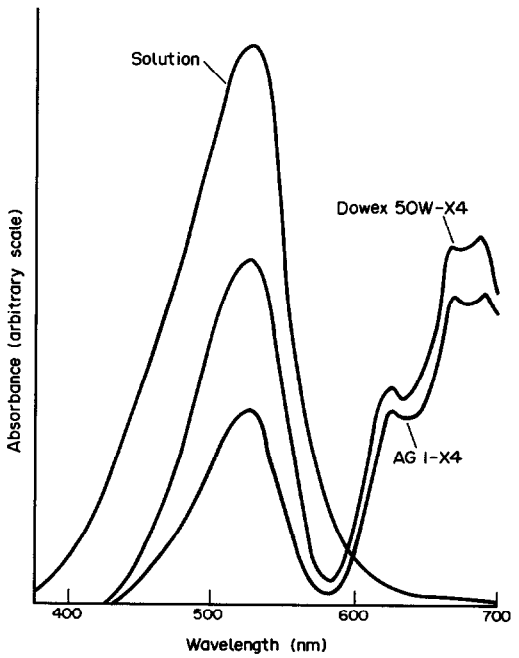

Fig. 3. Absorption spectra of the ion-exchanger phases and solution for the cobalt(II)–chloride system compared at the same ligand concentration (2.64 M).

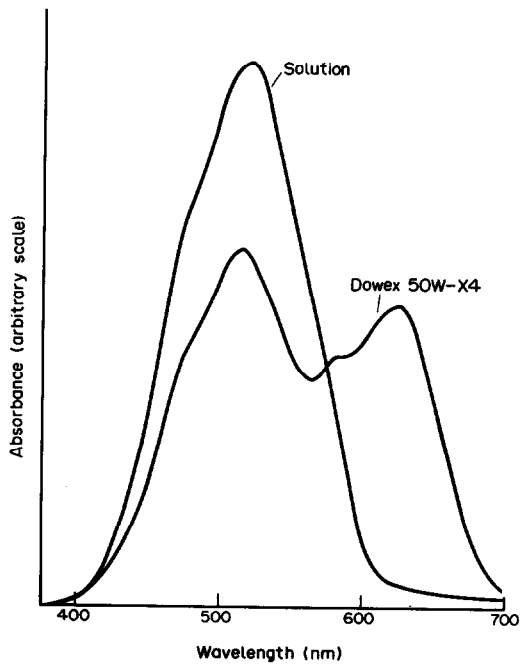

Fig. 4. Absorption spectra of the ion-exchanger phase and solution for the cobalt(II)–thiocyanate system compared at the same ligand concentration (0.155 M).

exchanger solid phase is much higher than in aqueous solutions of the same ligand concentration. We next tried to find which solution may correspond to the cation-exchanger phase in terms of complexation.

In comparing the complexation for different media, a spectral parameter A_r was conveniently introduced, which is defined as the ratio of absorbance at a wavelength for tetrahedral complexes (686 nm for the cobalt(II)–chloride system and 620 nm for the cobalt(II)–thiocyanate system) to that for octahedral complexes (520 nm for both systems), a higher A_r value indicating a higher complexation environment. The A_r for Dowex 50W-X4 of the chloride system was 1.06 (see Fig. 3) and that of the thiocyanate system was 0.89 (see Fig. 4).

Next, the A_r values for hydrochloric acid or sodium thiocyanate solutions of different concentrations containing cobalt(II) chloride were measured from their absorption spectra and plotted against each total ligand concentration (Figs 5 and 6). Interpolation has indicated that the Dowex 50W-X4 phase, equilibrated with a 0.476 M cobalt (II) chloride–5.4 M hydrochloric acid solution (internal chloride concentration is 2.64 M) has the same A_r value as that of the cobalt(II) solution with 5.81 M total chloride concentration. Furthermore, it was found that the resin phase, equilibrated with 0.10 M cobalt(II) chloride–0.70 M sodium thiocyanate solution (the internal thiocyanate concentration is 0.155 M) has the same A_r value as that of the cobalt(II) solution with 2.20 M total thiocyanate concentration. In all cases, the cation-exchange resin phase corresponded to a solution with a much higher ligand concentration in terms of complex formation.

Method for evaluating the stability constant of a complex in a cation-exchanger phase

When the reaction of M^{m+} and L^- forms only $ML^{(m-1)+}$, the apparent absorptivity in the ion-exchanger phase $\bar{\varepsilon}$ can be expressed as

$$\bar{\varepsilon} \equiv \frac{\bar{A}}{\bar{C}_M l} = \frac{\bar{\epsilon}_0[\overline{M^{m+}}]+\bar{\epsilon}_1[\overline{ML^{(m-1)+}}]}{[\overline{M^{m+}}]+[\overline{ML^{(m-1)+}}]} = \frac{\bar{\epsilon}_0+\bar{\epsilon}_1\bar{K}_1[\overline{L^-}]}{1+\bar{K}_1[\overline{L^-}]}, \quad (3)$$

where the upper bar refers to an ion-exchanger phase, $\bar{\epsilon}_0$ and $\bar{\epsilon}_1$ are the molar absorptivities of free M^{m+} and $ML^{(m-1)+}$, respectively, l is the light path length, $\bar{C}_M$ the total concentration of the sample metal and $\bar{K}_1$ the stability constant of $ML^{(m-1)+}$ in the ion-exchanger phase

$$\bar{K}_1 = \frac{[\overline{ML^{(m-1)+}}]}{[\overline{M^{m+}}][\overline{L^-}]}. \quad (4)$$

The following equation was derived from eqs (3) and (4) for the graphical analysis of the $\bar{K}_1$ value.

$$\bar{\phi} \equiv \frac{\bar{\varepsilon}-\bar{\epsilon}_0}{[\overline{L^-}]} = \bar{K}_1\bar{\epsilon}_1 - \bar{K}_1\bar{\varepsilon} \quad (5)$$

which is of the same form as the equation for the conventional solution analysis:

$$\phi \equiv \frac{\varepsilon - \epsilon_0}{[L^-]} = K_1\epsilon_1 - K_1\varepsilon. \quad (6)$$

Using a Donnan relation, $[\overline{L^-}]$ in eq. (5) is written in the form

$$[\overline{L^-}] = \frac{y_{B^+}y_{L^-}[B^+]}{\bar{y}_{B^+}\bar{y}_{L^-}[\overline{B^+}]}[L^-] = k[L^-], \quad (7)$$

where B^+ is a supporting cation in large excess. When the ionic strength and the concentration of B^+ in the equilibrating solution are constant, $\bar{y}_{B^+}$ or $\bar{y}_{L^-}$ may also be constant as well as y_{B^+} or y_{L^-}. Thus $[\overline{L^-}]$ can be evaluated by $[L^-]$ and a proportional constant k which had been determined using a known system. Accordingly, the stability constant of the one-to-one complex in the cation-exchanger phase can be determined from the slope of $\bar{\phi}$ vs $\bar{\varepsilon}$ plots of eq. (5), in analogy to the ϕ vs ε plot for the solution analysis.

Evaluation of stability constants of the cobalt(II)–thiocyanate complex in the cation-exchanger phase

In order to give more quantitative information about the above observation that the complexibility in an ion-exchanger phase is higher than that in an ordinary aqueous solution, we evaluated stability constants of the $CoSCN^+$ complex within cation-exchangers of different cross-linking degrees by a direct spectrophotometric technique.

Necessary data for evaluating the stability constants are listed in Table 1, where $[\overline{SCN^-}]$ was obtained using proportional constants in eq. (7), $k = 0.279$ (Dowex 50W-X2), 0.202 (-X4), 0.0837 (-X8) and 0.506 (SP-Sephadex C-25) which had been determined by a separate column equilibration experiment.

The graphical analysis for stability constants of the $CoSCN^+$ complex are shown in Fig. 7. For comparison, the stability constants of the same complex in aqueous solutions, prepared so that the ionic strengths were the same as those within the ion-exchanger phase, were also determined. An example of the solution analysis is also given in Fig. 7. The stability constant values obtained are shown in Table 2.

As can be seen from the table, the stability constants for the cation-exchanger phase were always larger than those for the aqueous solution of the same ionic strength. One of the reasons is undoubtedly a lower dielectric constant for the ion-exchanger phase due to the presence of organic components. Although the stability constant of

Equilibrating solutions are $NaSCN + NaClO_4$ ($I = 0.5$) containing 0.05 M $Co(ClO_4)_2$. The absorbance for the ion-exchanger phase is taken as $\bar{A} = \bar{A}^{514} - \bar{A}^{570}$, $\bar{C}_{Co}$ was obtained by dividing the total amount of cobalt(II) sorbed by the net volume of ion-exchanger phase, expressed in mol dm^{-3}.

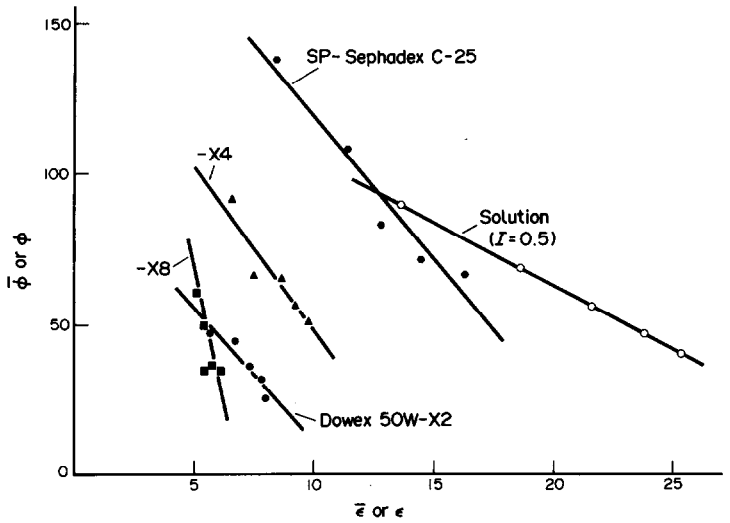

Fig. 7. Determination of stability constants of the one-to-one cobalt(II)–thiocyanate complex in cation-exchanger phases and aqueous solutions at 25 ± 1°C.

the aqueous solution was nearly constant, irrespective of ionic strength, that for the cation-exchange resin increased with an increase in the degree of cross-linking, that is, with an increase in ionic strength.

Another reason of higher complexibility for the ion-exchanger phase may be the presence of a high internal pressure produced by the resin network. When the following reaction occurs in the ion-exchange resin,

$$Co^{2+}(aqua) + SCN^{-}(aqua) \rightleftharpoons CoSCN^{+}(aqua) + nH_2O \quad (8)$$

some of the water molecules librated through the complexation reaction may be excluded from the resin phase. When water molecules are transferred to the solution phase from the highly-pressured ion-exchange resin phase, the energy $\pi\Delta V$ is released, π being the swelling pressure and ΔV the volume contraction of the resin phase through reaction. The higher the degree of cross-linking, the higher the internal pressure and the larger $\pi\Delta V$, thus the complexation increases.

In spite of the lower internal pressure and lower ionic strength of SP-Sephadex C-25 than the ion-exchange resins, the stability constant for SP-Sephadex C-25 is found to be somewhat larger than that for Dowex 50W-X2. This could probably be due to an attraction between the π-electrons of the thiocyanate ion and those of the benzene ring of the Dowex resins, which somewhat weakens the ligand activity of the thiocyanate ion.

In any case, these facts on the high complexation ability of the cation-exchanger phase should be sufficiently considered when using conventional cation-exchange methods for evaluating stability constants, where complexation with anionic ligands has frequently been neglected without any evidence for simplification.[7,8]

(*Received* 27 *September* 1988; *accepted* 27 *October* 1988)

Abstract—The bis-pyridine adduct of $In(SC_6H_5)_3$ has been prepared. A crystal structure determination shows that the molecule has two different conformations in the solid state, related to the orientations of the phenyl rings of the SC_6H_5 ligand. The crystalline form of $In(SeC_6H_5)_3$ is a homopolymer in which six-coordinate indium atoms are linked through bridging selenium atoms. The phenyl groups of the SeC_6H_5 ligand show an interesting disorder pattern. The structure of $In(SC_6H_5)_3$ is discussed in this context.

Recent papers[1–3] from this laboratory have described three different preparative routes to tris (benzenethiolato)indium(III). The compound is apparently a homopolymer, whose structure can be broken down by neutral or anionic donor ligands to give the appropriate mononuclear adducts; an X-ray crystallographic study of the tetraphenylphosphonium salt of $[InBr(SPh)_3]^-$ has also been reported.[1] The selenium analogue has similar properties, extending to its behaviour as a Lewis acid.[2]

We have now been able to obtain $In(SeC_6H_5)_3$ in crystalline form, and to show that this compound has a homopolymeric structure in the solid state. It has not been possible to carry out similar studies with $In(SC_6H_5)_3$, but the neutral adduct $In(SC_6H_5)_3py_2$ (py = pyridine) has been investigated, and the X-ray results confirm previous arguments based on spectroscopic studies.[1] The results are compared with those for other indium(III) compounds, and with certain other selenolato derivatives of d^{10} metal ions.

EXPERIMENTAL

Preparative

(i) *Tris(benzenethiolato)indium*(III)-*bis-pyridine.* Tris(benzenethiolato)indium(III) was prepared by the reaction of indium metal with diphenyldisulphide in refluxing toluene.[2] $In(SC_6H_5)_3$ (1 g) was dissolved in warm pyridine (5 cm^3), and the resultant solution allowed to evaporate slowly at room temperature. The crystals obtained after *ca* 2 months were collected and dried. The IR and ^1H NMR spectra confirmed the presence of both pyridine and SC_6H_5 ligand (Found: C, 55.7; H, 4.23. Calc. for $C_{28}H_{25}N_2S_3In$: C, 56.0; H, 4.20%).

(ii) *Tris(benzeneselenolato)indium*(III). $In(SeC_6H_5)_3$ was prepared by the reaction of indium metal with diphenyldiselenide in refluxing toluene.[2] Crystals suitable for X-ray crystallography were obtained by the slow evaporation of a dilute

solution in toluene (0.1 g in 100 cm^3) under a slow stream of nitrogen over a period of 10 days.

Structure determinations

Suitable crystals of either $In(SC_6H_5)_3py_2$ (**1**) or $In(SeC_6H_5)_3$ (**2**) were sealed in thin-walled glass capillaries and mounted and aligned on a Syntex $P2_1$ automated diffractometer. Data collection followed the procedures described previously.[4] The intensities of three monitor reflections were measured after every 100 reflections, and did not change significantly during data collection. The intensities were corrected for Lorentz and polarization effects. No absorption corrections were used in the refinement of **1**, because of the low absorption coefficient; in **2**, subsequent accidental loss of the crystal prevented the application of an absorption correction, but in the event this appears to have had little effect (see below). Details of cell constants and other relevant experimental data are given in Table 1.

For **1**, there were no systematic absences, and the space group $P\bar{1}$ was used in the refinement, and taken to be correct in view of the successful refinement. The position of the indium atoms was found by direct methods, and the structure was refined by block matrix methods, using the program SHELX.[6] At this point, two different forms of the molecule were identified, and both indium atoms [In(1), In(2)] were included in each block; in addition, block 1 contained six sulphur atoms, four nitrogen and 16 carbon atoms [C(11)—C(34)] and a scale factor (173 parameters), and block 2 contained In(1), In(2), 40 carbon atoms [C(35)—C(90)] and a scale factor (179 parameters). Indium, sulphur and nitrogen atoms were refined anisotropically, and carbon atoms isotropically. Hydrogen atoms were subsequently included in ideal positions [r(C—H) = 0.95 Å], and assigned U-values 1.10 × those of the carbon atoms attached to the hydrogen in question. The function minimized during the least-squares refinement was $(|F_o|-|F_c|)^2$, and a weighting scheme $1/[\sigma^2(F)+pF^2]$ was employed ($p = 0.00001$). The small residual electron density in the final difference map was not at any chemically significant position, and there was not secondary extinction.

For **2**, the systematic absences (hkl, $h+k = 2n+1$; $h0l$, $l = 2n+1$) indicated the space group $C2/c$ or Cc, but the systematic weakness suggested $C2/c$. Eventual structural solution and refinement in $C2/c$, together with a failure to obtain significantly improved results in Cc, confirmed the former as being the correct space group. The structure was solved by direct methods, using MULTAN 78. The indium atom was constrained to lie on an inversion centre, and Se(1) on a two-fold axis (see Fig. 1). When anisotropic refinement of In and Se atoms converged, the presence of large thermal ellipsoids for the carbon atoms, plus the fact that the asymmetric unit contains one and one half phenyl rings as indicated by the elemental analyses, suggested disorder in the phenyl rings. The phenyl group bonded to Se(1) requires two-fold symmetry within the ring, but is disordered about the two-fold axis

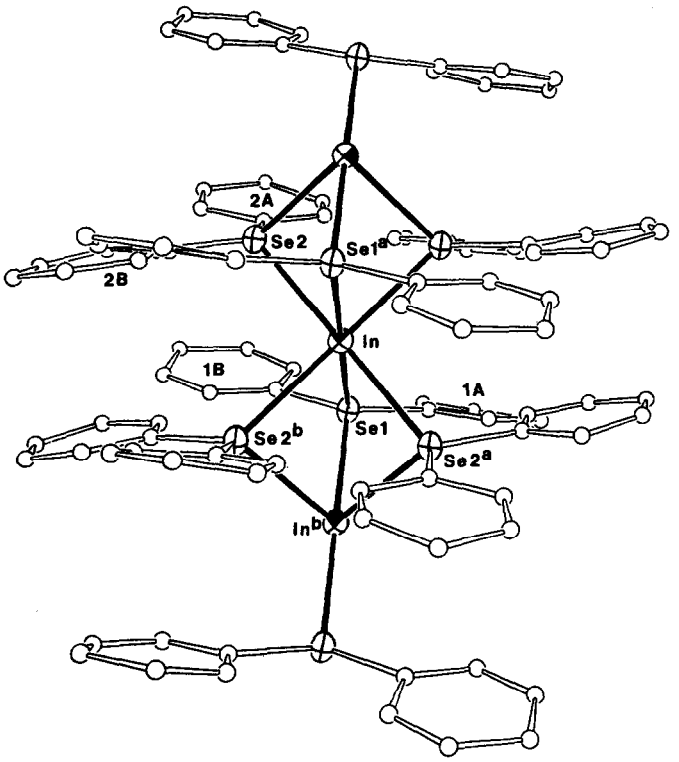

Fig. 1. ORTEP diagram showing a chain of $In(SeC_6H_5)_3$ parallel to the *a* axis. The Se and In atoms are drawn with 50% probability ellipsoids; and C atoms are arbitrarily small, and have 50% occupancy. Hydrogen atoms have been omitted for the sake of clarity. For symmetry related positions, see footnotes to Table 2.

passing through Se(1), and this axis generates the carbon atoms of ring 1B from those of 1A, with all of the carbon sites having 50% occupancy. The ring bonded to Se(2), which is the selenium atom on the general position, is also disordered, and was therefore divided into two sets "2A" and "2B", with each set having 50% occupancy. The carbon atoms were refined isotropically, and no attempt was made to include hydrogen atoms. The function minimized during full-matrix least-squares refinement was $w(|F_o|-|F_c|)^2$ and in the final cycles, a weighting scheme of the form $w = 1/[\sigma^2(F)+0.00001F^2]$ was employed. No evidence of secondary extinction was noticed. A final difference Fourier map contained a few peaks of the order of 1–1.5 $eÅ^{-3}$ in the vicinity of the indium and selenium atoms, which may be due to uncorrected absorption effects (see above).

Selected bond distances and angles for **1** and **2** are given in Tables 2 and 3, respectively, and Figs 1–3 show the molecular structures with the atomic numbering schemes. Tables of atomic coordinates, anisotropic thermal parameters, and observed and calculated structure factors for each compound are available as supplementary material from the Editor.

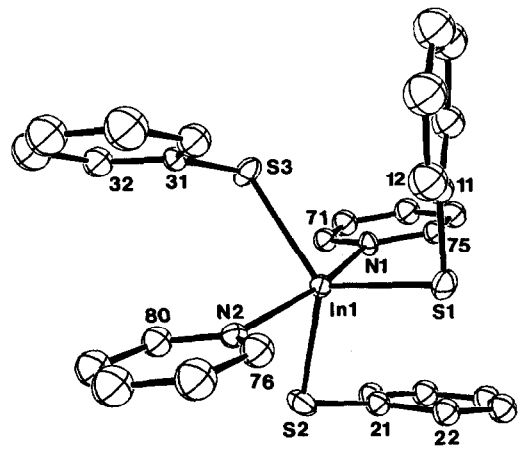

Fig. 2. ORTEP diagram of form A of $In(SC_6H_5)_3py_2$, showing the atomic numbering scheme. Atoms identified by numbers are carbons.

RESULTS AND DISCUSSION

The structure of $In(SC_6H_5)_3py_2$

[a] Esd's on average values are calculated with the use of the "scatter" formula:

$$\sigma = [\sum (d_i - \bar{d})^2/(N-1)]^{1/2},$$

where d_i is the ith, and $\bar{d}$ the mean, of N equal measurements.

1. The symmetry related positions are: a, $-x$, $-y$, $-z$; b, x, $-y$, $z-\frac{1}{2}$.
2. The carbon atoms of ring 1A are related to those of 1B by $-x$, y, $\frac{1}{2}-z$ and all the carbon atoms have 50% occupancy.
3. Esd's on average values have been calculated as in Table 2.

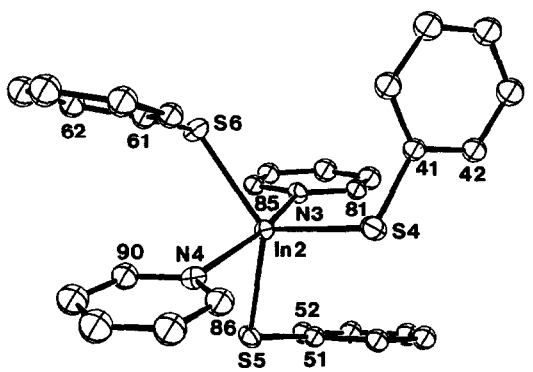

Fig. 3. ORTEP diagram of form B of $In(SC_6H_5)_3py_2$, showing the atomic numbering scheme. Atoms identified by numbers are carbons.

indeed a mononuclear species. The molecular structure is essentially based on a distorted trigonal bipyramidal InS_3N_2 kernel, with the sulphur atoms of the benzenethiolate ligands occupying the equatorial sites and the pyridine nitrogens in the axial positions. This compound then joins the increasingly large group of five-coordinate inorganic and organometallic compounds of indium(III), and this coordination state, which includes both trigonal bipyramidal and square-based pyramidal, must now be regarded as of equal importance with the longer established tetrahedral and octahedral stereochemistries.[6,7]

The structure consists of two independent molecules 1A and 1B which differ in the arrangement of the phenyl rings of the $-SC_6H_5$ ligands. In molecule 1A (Fig. 2), these three phenyl groups are in a cyclic arrangement, with ring C(11)—C(16) approximately normal to the other two. The dihedral angle between the plane of this ring and that of ring C(21)—C(26) is 90.3(2)°, and that between C(11)—C(16) and C(31)—C(36) is 84.4(2)°. The planes of C(21)—C(26) and C(31)—C(36) are then almost parallel, with a dihedral angle of 9.9(2)°. In 1B, the ring C(41)—C(46) is again almost normal to the other two phenyl rings, with dihedral angles of 98.9(2)° to C(51)—C(56), and 95.7(2)° to C(61)—C(66) and the latter two are at a dihedral angle of 8.2(2)°. Another way of describing the difference between 1A and 1B is in terms of the torsion angles involved at the In—S—C_6H_5 sites; in 1A, the angle In(1)—S(1)—C(11)—C(12) is 107.0(2)°, whereas in 1B the corresponding In(2)—S(4)—C(41)—C(46) angle is 67.2(2)°, and similarly, we find In(1)—S(1)—C(11)—C(16) at −75.0(2)°, and In(2)—S(4)—C(41)—C(42) at −117.8(2)°, a difference of about 40°.

Despite these significant differences in the orientation of the phenyl groups, the InS_3N_2 kernels of the two molecules are essentially identical, as are the $-SC_6H_5$ ligands in terms of their internal geometries. The N—In—N angle in 1A is 165.0(3)°, and in 1B, 162.6(3)°, both significantly less than the

180° required for trigonal bipyramidal stereochemistry. Although the S—In—S angles in 1A range from 111.5(1) to 128.3(1)°, the average is 120(3)°, while in 1B the average of 120(4)° arises from a range of 109.4(1)–131.6(1)°. Despite the two different orientations, the average In—S bond distance is the same in both structures, namely 2.458(8) Å, very close to the average value[1] of 2.450(4) Å in the anion $[BrIn(SC_6H_5)_3]^-$. A brief review of other In—S bond lengths has been given elsewhere,[1] with distances > 2.59 Å being reported, but differences in coordination number and ligand type between the various molecules studied prevent any detailed analysis at this point. The average S—C distance in the ligand is 1.77(1) Å, with all ligands being identical within experimental error in this respect, and this value is close to that of 1.75(2) Å in the structure previously reported.[1]

The average In—N bond distance is also identical in 1A and 1B, at 2.39(1) Å. In the molecule $Cl_2In(O_2CC_6H_5)py_2$, which also can be described as having a distorted trigonal bipyramidal structure with apical pyridine ligands,[8] the relevant In—N bond lengths are 2.250(5) and 2.300(6) Å, and a brief discussion of the results for other indium(III) complexes involving neutral aromatic nitrogen donors lead to an average value for In—N over a small group of compounds of 2.28 Å, with a range of 2.238(3)–2.514(19) Å. In general then, the present results are in keeping with previous work, but the significant difference between $In(SC_6H_5)_3py_2$ and $Cl_2In(O_2CC_6H_5)py_2$ is not easily understood.

We return below to the relationship between this compound and the parent $In(SC_6H_5)_3$.

The structure of $In(SeC_6H_5)_3$

Figure 3 confirms that $In(SeC_6H_5)_3$ is indeed a homopolymeric structure in the solid state, with linear chains formed by indium and selenium atoms running parallel to the *a* axis of the unit cell. Each indium is coordinated by six selenium atoms, and each selenium bridges two indium atoms. Crystallographically, each indium is on a centre of inversion; Se(1) lies on a two-fold axis and Se(2) on a general position, so that In and $Se(2^{a,b})$ form a planar chain, with Se(1) lying alternately above and below this plane. The four atoms In, In^b, Se(1) and $Se(1^a)$ also define a plane, perpendicular to the *b* axis, and this plane is at an angle of 89.7(1)° to a third plane involving In, Se(2), $Se(2^b)$, $Se(2^a)$ and $Se(2^c)$.

The geometry of the $InSe_6$ kernel is a highly distorted octahedral, with Se—In—Se angles which vary between 81.7(1)–98.3(1)°, with an average of 90° which is imposed by the symmetry relationships. The average In—Se bond length is 2.776(8) Å, and this appears to be the first such distance to be reported in a complex of this type. The In—Se distances in the adamantane-like $In_4Se_{10}^{8-}$ anion[9] are 2.543(2) for In—Se_t, and 2.565(2) Å for In—Se_{br}, but obviously the presence of the pendant phenyl groups must have some effect on the bond length in the present structure. The average In ··· In separation is 3.625 Å, much larger than the known In—In bonding distance[10] of 2.775(2) Å.

The geometry about each selenium atom is pyramidal, but the important feature of the ligand arrangement is that the phenyl rings are disorded, with each ring shown in Fig. 1 having an occupancy of 50%. The average Se—C distance is 1.92(3) Å, similar to that in $[Pb(SeC_6H_5)_3]^-$ [average value 1.91(1) Å],[11] $(C_6H_5)_2Se_2$ [1.93(5) Å][12] and $(C_6F_5)_2Se_2$ [1.910(15) Å].[12] Leaving aside the polymeric structure of **2**, the M—SeC_6H_5 geometry is quite similar to that in $[Pb(SeC_6H_5)_3]^-$.

Relationship between structure and properties

The most satisfying conclusion is that the structure of $In(SeC_6H_5)_3$ is indeed the homopolymer predicted from the chemical properties of the compound, although the details of the cross-linking could not be deduced from the general insolubility of the compound in non-donor solvents, or from its reaction with neutral or anionic donors.[2] Cross-linking by M ← S(Se) donation has frequently been proposed for the solid state structure of metal thiolates and selenolates, and the present work is in keeping with studies of $[Hg(SeCH_3)_2]_n$ and related compounds.[13]

Despite repeated attempts involving a variety of solution and vaporization techniques, we were unable to produce crystals of $In(SC_6H_5)_3$, and it is interesting to consider the possible reasons, given the relative ease with which the selenium analogue yielded good crystals. It seems certain that In—S bonds are thermodynamically stronger than In—Se bonds, which means that a homopolymeric $In(SC_6H_5)_3$ structure would be more stable to dissociation than $In(SeC_6H_5)_3$, and hence less soluble in organic solvents. In fact, the sulphur compound is soluble only in strong donors such as pyridine, or in refluxing benzene,[1] and complexation is clearly significant in the case of the donor solvents. A suitable solvent for crystallization is therefore lacking. Another factor acting against the formation of an ordered lattice may be the short In—S bonds, which as the present results show, are approx. 0.3 Å shorter than In—Se, so that a regular structure such as that in Fig. 1 may be difficult to replicate for $In(SC_6H_5)_3$, since the phenyl groups of one plane

may face considerable steric hindrance in packing with those of the next layer. Thus attempts to grow crystals of $In(SC_6H_5)_3$ from the vapour phase may be vitiated by irregular growth of the homopolymer, in contrast with the regular arrangement which is obviously possible for $In(SeC_6H_5)_3$.

A final conclusion to be drawn from the structure of $In(SeC_6H_5)_3$ is that the formation of adducts, such as $In(SeC_6H_5)_3L$ (L = 2,2′-bipyridine, 1,10-phenanthroline, or two triphenylphosphines) or $[InBr(SePh)_3]^-$, must involve a major rearrangement of the InSe kernel, assuming that these species are isostructural with the analogous SC_6H_5 compounds. The molecularity and stereochemistry of the species present in toluene, or in donor solvents, are clearly of importance in this context, and will be the subject of future investigations.

INFLUENCE OF 3-METHYL SUBSTITUTION ON THE ABILITY OF 2-PYRROLIDONE TO FORM HETEROMETALLIC POLYMERIC STRUCTURES; SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $[HgCu(C_5H_8NO)_2(CH_3O)(NO_3)]_2$, WHERE C_5H_8NO IS THE ANION OF 3-METHYL-2-PYRROLIDONE

DAVID M. L. GOODGAME,* DAVID J. WILLIAMS and RICHARD E. P. WINPENNY

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 28 *September* 1988; *accepted* 27 *October* 1988)

Abstract—Reaction of $Hg(C_5H_8NO)_2$ (where C_5H_8NO is the anion of 3-methyl-2-pyrrolidone) with copper(II) nitrate in methanol yields $[HgCu(C_5H_8NO)_2(CH_3O)(NO_3)]_2$ which has been characterized by X-ray diffraction. The crystals are triclinic, $P\bar{1}$, $a = 7.041(3)$, $b = 11.343(4)$, $c = 11.427(4)$ Å, $\alpha = 69.13(3)$, $\beta = 76.08(3)$, $\gamma = 84.17(3)°$, $V = 828$ Å^3, $Z = 1$. The structure was refined on 1338 reflections to $R = 0.074$. The compound has pairs of copper atoms bridged by two methoxide ions. Each copper atom has a square pyramidal coordination geometry formed by five oxygen atoms, two from methoxide ions, one from NO_3^-, and one from each of two different $Hg(C_5H_8NO)_2$ units. These last two provide additional bridges between the basal and apical coordination sites of the bridged copper atoms and, in so doing, form 10-membered macrocyclic rings. Adjacent dimers are linked by pairs of Hg···O(nitrate) interactions, forming a loosely bound polymeric structure.

We have recently shown that $Hg(C_4H_6NO)_2$, the product of the reaction between mercury(II) acetate and 2-pyrrolidone (C_4H_7NO) in methanol, forms an extensive series of heterometallic complexes with diverse and unusual polymeric structures. These polymers have been found to form chains, e.g. $\{[Hg_3Co(C_4H_6NO)_6](NO_3)_2\}_n$,[1] $[Hg_2Eu(C_4H_6NO)_4(NO_3)_3]_n$,[2] $[Hg_3Tb_2(C_4H_6NO)_6(NO_3)_6]_n$,[2] and $[Hg_2Th(C_4H_6NO)_4(NO_3)_4]_n$,[3] corrugated sheets, e.g. $[Hg_2Cu(C_4H_6NO)_4(NO_3)_2]_n$,[4] or three-dimensional networks, e.g. $[Hg_3Zn_2(C_4H_6NO)_6(NO_3)_{3.33}(CH_3O)_{0.67}]_n$.[5]

The adoption of a particular structural type appears to be influenced by two main factors: (a) the preferred coordination number and geometry of the heterometal binding to the oxygen atoms of the $Hg(C_4H_6NO)_2$ unit; and (b) the ability of that unit to adopt many different conformational modes by ligand rotation about the N—Hg—N bonds, without any significant departure from linearity at the mercury centre.

We have also been exploring the effects of the presence of alkyl groups adjacent to the donor atoms in the pyrrolidone ring, as the resulting increase in steric requirements would be expected to modify the structures of the corresponding heterometallic complexes in ways that are not easy to predict, because of the conformational possibilities of the HgL_2 units.

We report here the structure of a tetranuclear (Hg_2Cu_2) complex obtained with 3-methyl-2-pyrrolidone as the bridging ligand.

EXPERIMENTAL

Preparation

Bis(3-methyl-2-pyrrolidonato)mercury(II) (0.8 g, 2 mmol), prepared by an analogous method to that used[1] for the 2-pyrrolidone analogue, was dis-

* Author to whom correspondence should be addressed.

solved in methanol (40 cm^3) and a solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.24 g, 1 mmol) in methanol (5 cm^3) was added. The solution was filtered and allowed to evaporate at 3°C. After 3 weeks, small, blue, plate-like crystals had formed above the level of the solution. Found: C, 23.2; H, 3.2; N, 7.6. Calc. for $HgCu(C_5H_8NO)_2(CH_3O)(NO_3)$: C, 23.9; H, 3.5; N, 7.6%. In addition to these blue crystals a large quantity of colourless $Hg(C_5H_8NO)_2 \cdot H_2O$ separated from the bulk solution. Found: C; 28.4; H, 4.3; N, 6.8. Calc. for $Hg(C_5H_8NO)_2H_2O$: C, 29.0; H, 4.4; N, 6.8%. Evaporation at room temperature gave only this latter compound.

X-ray study

$[HgCu(C_5H_8NO)_2(CH_3O)(NO_3)]_2$ crystallizes as pale blue plates. The crystal data are: triclinic, $a = 7.041(3)$, $b = 11.343(4)$, $c = 11.427(4)$ Å, $\alpha = 69.13(3)$, $\beta = 76.08(3)$, $\gamma = 84.17(3)°$, $V = 828$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a centre of symmetry), $M_r = 1106$, $D_c = 2.14$ g cm^{-3}, μ(Cu-K_α) = 195 cm^{-1}. Refined unit cell parameters for a crystal of approximate dimensions $0.03 \times 0.06 \times 0.09$ mm were obtained by centring 18 reflections on a Nicolet R3m diffractometer. 1692 independent reflections ($\theta \leqslant 50°$) were measured with graphite monochromated Cu-K_α radiation using the omega-scan measuring routine. Of these, 1338 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. Lorentz, polarization and a numerical absorption correction (face indexed crystal, minimum and maximum transmission factors 0.25 and 0.58) were applied.

The structure was solved by the heavy-atom method which revealed the position of the mercury atom. The remaining non-hydrogen atoms were located from subsequent ΔF maps. Both 3-methyl-2-pyrrolidone ligands were severely disordered; for the first ligand it was possible to distinguish two geometries due to a conformational folding of the C(11) to C(14) portion of the ring; for the second, inversion of the methyl group [C(25)] occurs, giving two partial occupancy positions for this carbon, also high thermal motion for the remaining carbons of this ligand. For these reasons C(12a,b), C(13a,b), C(15a,b), C(21) and C(25a,b) were refined isotropically. The remaining atoms in the structure were refined anisotropically. No hydrogen atoms were included in the refinement. Refinement was by block-cascade full-matrix least-squares to $R = 0.074$, $R_w = 0.072$ [$w^{-1} = \sigma^2(F) + 0.001F^2$].

Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[6] Scattering factors were from ref. 7. Important bond lengths and angles are listed in Table 1.

Spectroscopy

The EPR spectrum was recorded on a polycrystalline sample at room temperature using a Q-band (*ca* 34 GHz) spectrometer comprising a Varian Q-band microwave bridge and a Newport 12-in type F magnet powered by a C905 rotary generator and post stabilizer.

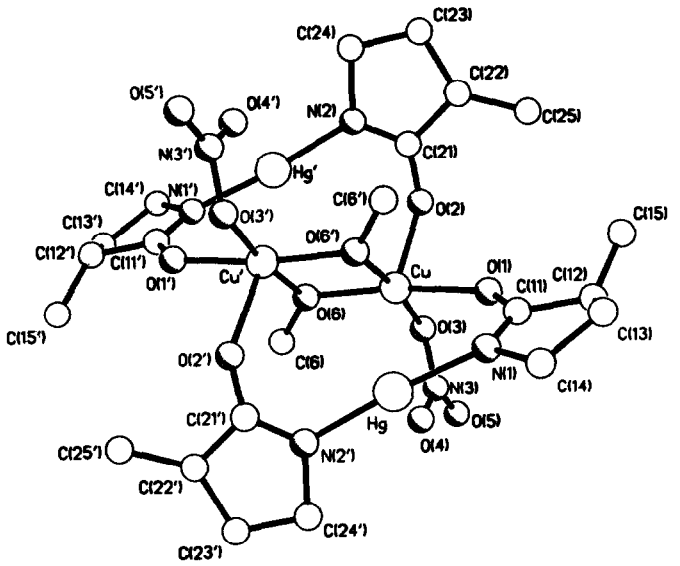

Fig. 1. Molecular structure of $[HgCu(C_5H_8NO)_2(CH_3O)(NO_3)]_2$ (where C_5H_8NO = the anion of 3-methyl-2-pyrrolidone) showing the crystallographic numbering scheme.

RESULTS AND DISCUSSION

The X-ray structural analysis on the blue crystals obtained from methanolic solutions of $Hg(C_5H_8NO)_2$ and copper(II) nitrate show that the compound has the stoichiometry $HgCu(C_5H_8NO)_2(CH_3O)(NO_3)$ (**A**), and that two such units are bridged by the methoxide ions to form the tetranuclear (Cu_2Hg_2) complex shown in Fig. 1.

The copper atoms are five-coordinate with distorted square pyramidal geometry. The atoms comprising the base are: one oxygen from 3-methyl-2-pyrrolidone, one from a nitrate ion, and two from the bridging methoxide ions. Deprotonation of methanol to form such methoxide bridges is well-known.[8-10] The apical oxygen comes from the second pyrrolidone ligand within the asymmetric unit.

The Cu—O bond lengths differ, the shortest being those involved in the formation of the Cu_2O_2 ring (*ca* 1.90 Å). The next shortest are the remaining basal Cu—O bonds (*ca* 1.99 Å) and, as expected, the longest bond is to the apical oxygen [2.25(2) Å]. A similar variation occurs in $Cu_2[o\text{-}Ph_2PC_6H_4C(O)CHC(O)C(CH_3)]_2(OCH_3)_2$ (**B**). There the bridging oxygens have Cu—O distances of *ca* 1.92 Å, the remaining basal oxygens *ca* 1.94 Å, and the apical Cu—O bond = 2.42(1) Å.

Symmetry requires that the Cu_2O_2 ring in **A** is planar; the Cu—O—Cu′ angle is 102°. The Cu—Cu′ distance (2.96 Å) is very similar to that in related compounds, e.g. in **B**, Cu—Cu = 2.98 Å, and in $Cu_2Cl_2(pyridine)_2(OCH_3)_2$[9] Cu—Cu = 3.04 Å. The Cu···Cu interactions in **A** are sufficient to remove any ^{63}Cu hyperfine splitting from the EPR spectrum of the compound, but they are not strong enough to produce an $S = 1$ type of spectrum. Instead, a normal $S = 1/2$ spectrum ($g_z = 2.34$, $g_{xy} = 2.08$) was observed at room temperature at Q-band frequency.

A sixth coordination position of each Cu^{II} ion is occupied by a mercury atom (Fig. 2). The Hg···Cu distance (3.18 Å), although fairly short, is probably too long to be considered as a formal Hg—Cu bond. The presence of the mercury atom prevents the approach of any other potential ligands. The Hg coordination is very similar to that seen in complexes of 2-pyrrolidone,[1-5] with Hg—N bonds of

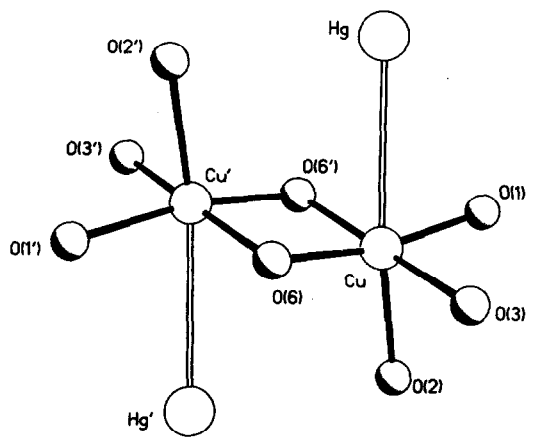

Fig. 2. The coordination environments of the two copper atoms in the dimeric unit.

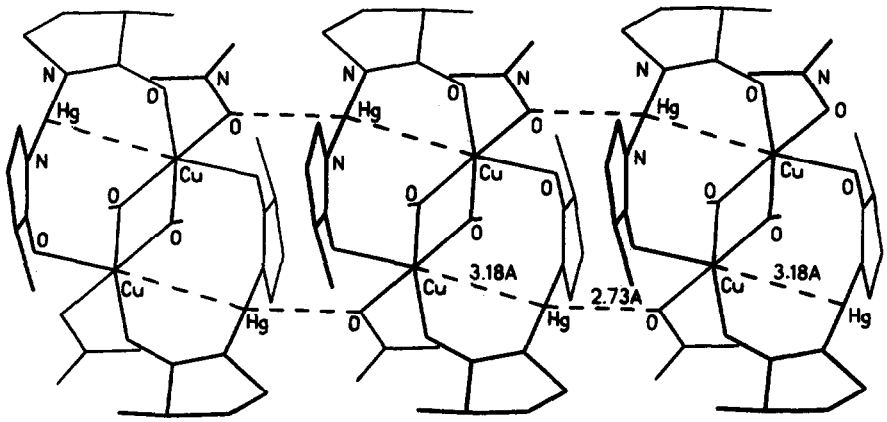

Fig. 3. Linking of adjacent dimers in the *a* direction *via* pairs of weak Hg···O(nitrate) interactions.

1.99 and 2.03 Å and an approximately linear N—Hg—N unit (175°). The slight departure from linearity is probably caused by inter-dimer interactions between a nitrate oxygen O(3) in one dimer and Hg′ in another [Hg′—O(3) = 2.73 Å]. Interestingly, the Hg′···O(3) vector makes a trigonal approach to the nitrate oxygen, with Cu, O(3), N(3), and Hg′ coplanar within 0.05 Å. Though these are the only inter-dimer links they do result in the formation of a loosely linked polymer (Fig. 3). A related, but more extensive, anion mediated network exists in $[HgAg(C_4H_6NO)_2(NO_3)]_2$, a dimeric complex involving 2-pyrrolidone.[11]

An important feature of the structures of the heterometallic complexes formed by 2-pyrrolidone is the presence of macrocyclic rings: 8-membered,[11] 16-membered,[1-3] or 32-membered.[4] In the present complex 10-membered rings are formed by each HgL_2 unit spanning the two copper centres, with basal coordination to one and apical coordination to the other. To achieve this there is a noticeable twist of the ligands about the mercury atom, with the angle between the mean planes of the two ligands being 74.2°.

The way in which dimerization is achieved in **A**, viz. methoxide bridges supplemented by the spanning action of the 3-methyl-2-pyrrolidone across the two copper centres, contrasts markedly with the situation in $[HgAg(C_4H_6NO)_2(NO_3)]_2$.[11] In that case, each HgL_2 unit binds to a silver atom in a chelating fashion, but with one of the oxygen atoms additionally serving as a bridging atom to the other silver atom of the dimer, forming an Ag_2O_2 ring.[11] It is tempting to ascribe the absence of this dimerization mode in **A** to the preferred geometry at copper which, for *cis*-binding at copper, requires a much smaller O_{bridge}—Cu—$O_{terminal}$ angle (*ca* 96° in **A**) than the corresponding O—Ag—O angles (*ca* 135 and 142°) in the Hg–Ag complex. This angle reduction would require bending of the HgL_2 unit.

However, this problem would not arise if the oxygens of HgL_2 were to occupy *trans*-positions about copper in forming an $O_{bridging}$—Cu—$O_{terminal}$ ring system. Therefore, it seems more likely that the dimerization mode adopted in **A** reflects the ease of methoxide bridge formation by Cu^{II} ions. Indeed, it might be more fruitful to regard these HgL_2 "ligands" as being able to span appropriate dinuclear metal units in uncommon ways, as well as forming extended polymers.

The drastic structural change from the sheet polymer formed[4] by the reaction of Hg(2-pyrrolidone)$_2$ and copper(II) nitrate, to the tetranuclear structure of **A** by the use of 3-methyl-2-pyrrolidone, suggests that these substituted analogues merit further attention, particularly in view of the diversity of structural types found so far for the unsubstituted ligand upon metal variation.

(*Received* 3 *October* 1988; *accepted* 31 *October* 1988)

Abstract—The condensation of 1,1′-bis(chlorocarbonyl)ferrocene and 1,1′-bis(chlorocarbonyl)ruthenocene with 4-aminobenzo-15-crown-5 gives the metallocene bis(crown ether) ligands 1,1′-bis[(2,3,5,6,8,9,11,12-octahydro-1,4,7,10,13-benzopentaoxacyclopentadecin-15-yl)amino]carbonylferrocene (**4**) and the ruthenocene analogue (**5**). ^{13}C NMR titrations of **4** and **5** with Na^+, K^+ and Cs^+ alkali metal salts lead to titration curves interpreted as suggesting 1 : 1 stoichiometry. The single-crystal X-ray structure of [**4**K]$PF_6 \cdot$ 4MeOH reveals an intramolecular sandwich complex with the potassium guest cation in the solid state. Competition fast atom bombardment (FAB) mass spectrometry selectivity experiments show **4** and **5** to exhibit exclusive K^+ selective complexation over either Na^+ or Cs^+.

Responsive macrocyclic receptor molecules whose binding strength and/or selectivity towards guest species can be influenced by physical and chemical means, have been the subject of many recent reports in the chemical literature.[1–5] Examples include pH-responsive crown ethers,[2,3,6,7] which change their cation binding ability in response to medium pH and photoresponsive crown ethers,[1,8] azoarene-capped oxygen macrocycles which undergo photo-induced reversible interconversion between the *trans* and *cis* azo linkages resulting in substantial changes in their cation binding properties.

Particular attention has been focused on the synthesis of redox-responsive macrocycles that contain redox-active functions such as quinone,[9–14] nitrobenzene[15] and metallocene moieties[16–23] in close proximity to a cation binding site. We are currently interested in preparing metallocene redox-active macropolycyclic host molecules designed to be *selective* as well as being redox-responsive to the host binding of inorganic and organic guest species.[19–22] One application of such receptors lies in their potential development as components of new chemical sensory devices.

We report here the synthesis, coordination and electrochemical studies of two new metallocene bis-benzo-crown ethers, **4** and **5**, and the single-crystal X-ray structure of [**4**K]$PF_6 \cdot$ 4MeOH, which, to our knowledge, is the *first* structural example of a bis-benzo-crown ether potassium intramolecular sandwich complex. A preliminary report on this work has recently been published.[19]

RESULTS AND DISCUSSION

Synthesis of 4 *and* 5

The condensation of respective 1,1′-bis(chlorocarbonyl)metallocenes **1** and **2**[24] with 2 mol of 4-aminobenzo-15-crown-5 (**3**)[25] in the presence of triethylamine gave, after column chromatography (alumina, 99% CH_2Cl_2, 1% MeOH), the ferrocene bis(crown ether) (**4**: 80% yield) and the ruthenocene analogue (**5**: 75% yield), Scheme 1 (preparative details are given in the Experimental).

The structures of both new air-stable metallocene bis(crown ethers) were characterized by elemental analysis, mass spectrometry and ^1H (Tables 1 and 2) and ^{13}C NMR spectroscopy (Tables 3 and 4).

Coordination studies

^{13}C NMR spectroscopy was used initially to investigate the complexation of **4** and **5** with alkali metal cations sodium, potassium and caesium.[26] The stepwise addition of an alkali metal nitrate salt to a methanol (65%)–acetone (35%) solution of **4** and a methanol (65%)–dichloromethane (35%) solution of **5** led to considerable shifts of the OCH_2 carbons of the respective bis(crown molecules). In all cases the $\Delta\delta$ ppm versus [alkali metal salt]/[metallocene bis(crown ether)] titration curves can

be interpreted as suggesting 1 : 1 stoichiometry of metallocene bis(crown ether) to guest alkali metal cation (Fig. 1). This result may lead to the proposition that both **4** and **5**, in solution, are adopting a conformation in which the amido-benzo-15-crown-5 units are lying either cofacial or in close proximity to one another and are acting co-operatively to form intramolecular sandwich complexes with the alkali metal cation guest species. In contrast to this observation, a recent publication reports the 18-crown-6 units of a related ferrocene bis(crown ether) to be acting independently of one another and complexing two alkali metal guest ions.[27]

Refluxing aqueous-methanolic solutions of **4** with an excess amount of sodium or potassium hexafluorophosphate led to the successful isolation of the respective [**4**M]$PF_6 \cdot H_2O$, M = Na, K, complexes (see Table 5 for elemental analyses).

The single-crystal structure of [**4**K]$PF_6 \cdot 4MeOH$ is illustrated in Fig. 2 with the space-filling representation of the structure in Fig. 3. The structure confirms the intramolecular sandwich complex with the potassium guest cation in the solid state. Selected bond lengths and bond angles are listed in Tables 6 and 7, respectively. The torsional angles associated with the crown ether rings are shown in Table 8. These values are similar to those of benzo-15-crown-5 itself[28] and one conformer in the $NaClO_4$ (benzo-15-crown-5)$_2$ sandwich.[29] The potassium guest cation is coordinated to all 10 oxygen atoms of the two benzo-crown ether moieties in an irregular pentagonal antiprismatic configuration with K—O contact distances ranging

from 2.82 to 2.97 Å (Table 9). These distances compare with 2.78–2.96 Å in the KI (benzo-15-crown-5)$_2$ crystal structure reported by Truter.[30] In contrast to Truter's structure, it is noteworthy that the two shortest K—O contact distances are *not* those from the catechol oxygens but are from K—O(4) and K—O(7) (Table 9). Unlike the centrosymmetrical arrangement of the two benzo-crown ligands in the KI (benzo-15-crown-5)$_2$ structure,[30] here the two components of the sandwich are related by a two-fold axis that passes through the Fe and K atoms with the benzo-crown moieties of **4** being *gauche* to each other. The cyclo-

pentadienyl rings of the ferrocene unit are almost parallel (3.4° between their mean planes and a mean inter-ring separation of 3.3 Å) and rotated from an eclipsed orientation by *ca* 7° (Fig. 4). Similar geometries are found in low temperature triclinic,[29] orthorhombic[30] forms of ferrocene, 1-acetyl-1′-benzoyl-ferrocene,[31] acetyl-ferrocene,[32] diacetyl-ferrocene[33] and ferrocene–carboxylic acid[34] where ring orientations range from eclipsed (0°) to 14° from eclipsed.[31] The cyclopentadienyl ring, the amide group and the benzo ring are not all coplanar there being small torsional rotations about the C(20)—C(21) [N(17), C(20), C(21), C(22) torsion angle 174.1(4)°] and the C(17)—N(17) [C(18), C(17), N(17), C(20) torsion angle −176.8(4)°] bonds.

There are four molecules of methanol for each molecule of the complex, forming strong hydrogen bonds to each other and more weakly to the amido linkages of the ligand. It is noteworthy that X-ray quality crystals of the complex rapidly degrade in air indicating that the methanol molecules are essential to the structure of the crystal.

Fast atom bombardment mass spectrometry selectivity studies

Fast atom bombardment (FAB) mass spectrometry, a new powerful semi-quantitative technique, has been used to study the selectivity of *monocyclic* crown ethers for metal cations in competition experiments.[37] It seemed reasonable to apply this method for the first time to bis(crown) ethers.

Individual FAB mass spectrometric experiments

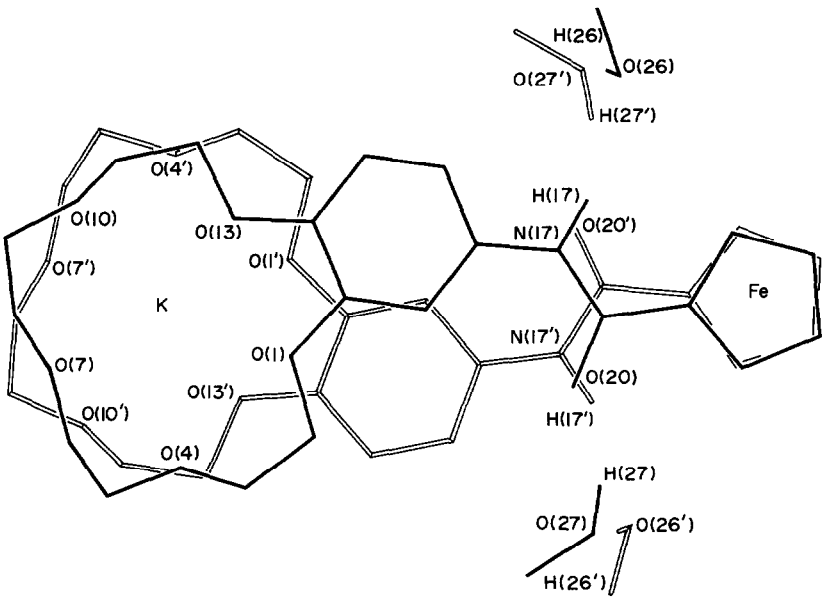

Fig. 4. View of the complex normal to the plane of the upper ("heavy bonds") cyclopentadienyl ring. Hydrogen bonding geometries: $O_{20}\cdots O_{27}$ 2.71 Å, $O_{20}\cdots H_{27}$ 1.79 Å, O···H—O < 154°, $O_{26}\cdots O_{27}$ 2.71 Å, $H_{26}\cdots O_{27}$ 1.73 Å, O···H—O < 175°, $N_{17}\cdots O_{26}$ 3.13 Å, $H_{17}\cdots O_{26}$ 2.19 Å, N—H···O < 161°.

of **4** (5×10^{-3} M; 0.5 cm^3 65% methanol–35% acetone) and **5** (5×10^{-3} M; 0.5 cm^3 65% methanol–35% dichloromethane) with the nitrates of sodium, potassium and caesium (5×10^{-3} M; 0.5 cm^3 water–1.0 cm^3 glycerol) gave gas-phase [bis(crown ether)+metal]$^+$ ions at *m/z* values of 1 : 1 stoichiometric formulations. Analogous competition experiments of **4** and **5** with an aqueous solution of sodium, potassium and caesium nitrates each at a concentration of 5×10^{-3} M gave the respective [**4**+potassium]$^+$ ion (*m/z* 843) and [**5**+potassium]$^+$ ion (*m/z* 889), exclusively.

The exclusive selectivity exhibited by both **4** and **5** towards potassium suggests that a well-defined cavity exists between the amido-benzo-15-crown-5 units which provides an optimal spatial fit[38] for the potassium guest cation (see Figs 2 and 3).

It is interesting to note that related bis(benzo-15-crown-5) and bis(benzo-18-crown-6) ether ligands linked together by various alkyl and alkoxy moieties, preferentially extract alkali metal cations larger than the hole size of the respective benzo-crown ether unit[39,40] (K^+ and Cs^+, respectively); this change of selectivity has been called the "bis crown effect".[41]

Electrochemical studies

The results of cyclic voltammetry measurements in acetonitrile of **4** and **5** are reported in Table 10. Addition of one or more equivalents of sodium or potassium hexafluorophosphate to the electrochemical acetonitrile solutions of **4** had little effect ($\Delta E_{1/2} \leqslant 20$ mV) on the reversible ferrocenyl oxidation wave. This result implies that the alkali metal cation complexed at the benzo-crown ether coordinating sites, is too far away to influence the electron density at the ferrocene iron atom, either inductively or through space.

Table 10. Electrochemical data

Compound	$E_{1/2}$[a] (V)	ΔE_p[b] (mV)
4	0.79	100(70)
5	0.55[c]	—

[a] Obtained from cyclic voltammetry studies in acetonitrile solvent containing 0.2 M $[Bu^n_4N]BF_4$ as supporting electrolyte. Solutions were *ca* 2×10^{-3} M in the compound and measurements were made at 21 ± 1°C at 0.2 V s^{-1} scan rate using a Pt bead working electrode with ferrocene internal reference. Values are quoted relative to the saturated calomel reference electrode.

[b] Separation between anodic and cathodic peak potentials, values for ferrocene under the same conditions in parentheses. No compensation was made for internal cell resistance.

[c] Anodic peak potential for an irreversible process.

We are currently synthesizing related Group 1A selective metallocene receptor molecules designed to have the cation binding site in closer proximity to the redox-active centre.

EXPERIMENTAL

Reactions were carried out under an atmosphere of dry nitrogen and solvents were distilled prior to use from an appropriate drying agent. ^{1}H NMR spectra were recorded at 400 MHz and ^{13}C NMR spectra at 100 MHz using tetramethylsilane (TMS) as internal standard. Electrochemical measurements were performed on a PAR 174A polarographic analyser. Positive ion FAB mass spectrometry was performed using a primary atom beam of Ar (6 keV) on a Kratos MS80 RF mass spectrometer coupled to a Kratos DS55 data system.

1,1′-Bis(chlorocarbonyl)ferrocene, 1,1′-bis(chlorocarbonyl)ruthenocene and 4-aminobenzo-15-crown-5 were prepared according to literature procedures.[24,25]

1,1′-*Bis*{[(2,3,5,6,8,9,11,12-*octahydro*-1,4,7,10,13-*benzopentaoxacyclopentadecin* - 15 - *yl*) - *amino*]-*carbonyl*}*ferrocene* (4)

A solution of 1,1′-bis(chlorocarbonyl)ferrocene (**1**) (0.5 g, 1.61 mmol) in dry toluene (70 cm^3) was added dropwise over 30 min to a stirred solution of 4-aminobenzo-15-crown-5 (**3**; 0.91 g, 3.2 mmol) in toluene (100 cm^3) containing triethylamine (0.32 g, 3.2 mmol). When addition was complete stirring was continued for 1 h and the solution filtered. After removal of solvent the crude product was chromatographed on a column of alumina using 99% dichloromethane–1% methanol eluant. An orange band was collected and after solvents were removed recrystallization from dichloromethane–hexane gave **4** (1.03 g, 80%) as orange crystals, m.p. 198–199°C; *m/z* 804.

1,1′-*Bis*{[(2,3,5,6,8,9,11,12-*octahydro*-1,4,7,10,13-*benzopentaoxacyclopentadecin* - 15 - *yl*) - *amino*]-*carbonyl*}*ruthenocene* (5)

The procedure for the preparation of **5** followed that described for **4**. A solution of 1,1′-bis(chlorocarbonyl)ruthenocene (**2**) (0.6 g, 1.68 mmol) in dry toluene (50 cm^3) was added dropwise over 30 min to a stirred solution of 4-aminobenzo-15-crown-5 (0.95 g, 3.3 mmol) in toluene (70 cm^3) containing triethylamine (0.34 g, 3.3 mmol). When addition was complete stirring was continued for 1 h and the solution filtered. Removal of solvent gave the crude product which was chromatographed on an alumina column using 99% dichloromethane–1% methanol. A pale yellow band was collected and removal of solvents followed by recrystallization from dichoromethane–hexane gave **5** (0.98 g, 75%) as pale yellow crystals, m.p. 206–207°C; *m/z* 850.

Preparation of sodium and potassium complexes of 4

To a methanolic solution of **4** (1 mmol) was added an excess amount of alkali metal hexafluorophosphate salt (5 mmol). The resulting solution was refluxed for 30 min and upon cooling an orange precipitate was collected and dried *in vacuo*. Recrystallization from methanol gave the respective complexes in quantitative yields.

^{13}C *NMR titration experiments*

The experimental procedure consisted of measuring $\Delta\delta_{obs}$ as a function of changing alkali metal nitrate salt concentrations while the metallocene bis(crown ether) ligand's concentration was kept constant. In a typical experiment, **4** (30 mg, 0.373 mmol) was dissolved in 65% methanol–35% acetone (4 cm^3) and the resulting solution transferred to a ^{13}C NMR tube. The ^{13}C NMR chemical shifts were measured versus tetramethylsilane (TMS) as internal standard after each addition of $NaNO_3$, KNO_3 and $CsNO_3$, respectively. Titration curves were obtained by plotting $\Delta\delta_{obs}$ (ppm) versus $[MNO_3]/[\mathbf{4}]$. See Fig. 1 in Results and Discussion.

*Crystal data**

$C_{40}H_{48}N_2O_{12}KFe \cdot PF_6 \cdot (CH_3OH)_4$, $M = 1116.9$, monoclinic, space group $C2/c$, $a = 14.283(3)$, $b = 25.726(5)$, $c = 14.438(2)$ Å, $\beta = 101.53(2)°$, $V = 5198$ Å^3, $Z = 4$ (the complex is disposed about a two-fold axis), $D_c = 1.43$ g cm^{-3}, $\mu = 41$ cm^{-1}, $F(000) = 2332$.

Data collection. 2672 unique independent reflections ($2\theta \leqslant 100°$C) were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator, $\lambda = 1.54178$ Å) using the ω-scan measuring routine. Of these, 2022 had $[|F_o| > 3\sigma(|F_o|)]$ and were considered observed.

Structure solution and refinement. The structure was solved by direct methods. A numerical absorption correction, based on a face-indexed crystal, was applied. The non-hydrogen atoms were refined anisotropically. The PF_6^- group was disordered, and refined as two distinct orientations, of occupancy 70 and 30%, respectively. The hydroxy hydrogen atoms on the methanols and the amide

* The atomic co-ordinates for this work are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

proton were located from a ΔF map and refined isotropically. The leading hydrogen atoms on the methyls of the methanols were also located from a ΔF map, and the groups refined as rigid bodies. The positions of the remaining hydrogen atoms were idealized (C—H 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2\ U_{eq}$ (C), and allowed to ride on their parent carbon atoms. Refinement converged to $R = 0.051$, $R_w = 0.046$ [$w^{-1} = \sigma^2(F) + 0.00032F^2$]. Refinement was by block-cascade full-matrix least-squares, carried out on an Eclipse S140 computer using the SHELXTL program system.[40]

(*Received* 3 *October* 1988, *accepted* 31 *October* 1988)

Abstract—The first metal carbonyl derivatives of a coordinated episulphide ring are reported. Two classes of complex have been obtained wherein the bisepisulphide behaves either as a bridging ligand between two metal pentacarbonyl moieties as in for example $[\{W(CO)_5\}_2(\overline{CHSCHCH_2CHSCHCH_2})]$, or as a chelating ligand in a mononuclear metal pentacarbonyl complex such as $[Cr(CO)_4(\overline{CHSCHCH_2CHSCHCH_2})]$, for which the X-ray crystal structure is reported.

The chemistry of organic episulphides is essentially dominated by the reactivity of the three-membered $\overline{C—S—C}$ ring. The ring strain present in such compounds, although less than their epoxide analogues, accounts for much of their known chemistry,[1] exemplified by the polymerization of ethylene sulphide in sunlight.[2]

Among the classes of reaction of episulphides is that of desulphurization by low oxidation state metal complexes. The first of such observations was the desulphurization of 3-chloropropylene episulphide and cyclohexene episulphide by di-iron-nonacarbonyl.[3] A subsequent study of episulphide desulphurization by $Fe_2(CO)_9$ showed the reactions to be highly stereospecific and a sulphur–metal coordinated intermediate has been proposed.[4] A wide variety of transition metal compounds has now been shown to desulphurize episulphides, but the mechanisms of such reactions are poorly understood.[1]

To date, only one transition metal–episulphide complex has been reported in which the episulphide retains its integrity.[5] This complex $[PtCl_2(\overline{SCMe_2CMe_2})_2]$ is not very stable in solution, and the palladium analogue could not be prepared. We have sought to investigate the reactions of the potential ligand (L), *cis*-1,4-cyclohexadiene bisepisulphide, Fig. 1. This has been already shown to participate in a template type of polymerization reaction;[6] it does however have sulphur atoms in a suitable conformation for the production of chelated complexes. We report herein the syntheses of the compounds $[\{Cr(CO)_5\}_2L]$, $[\{W(CO)_5\}_2L]$, $[Cr(CO)_4L]$ and $[Mo(CO)_4L]$ and the X-ray crystal structure of $[Cr(CO)_4L]$.

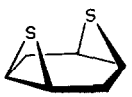

Fig. 1. *cis*-1,4-cyclohexadienebisepisulphide, $\overline{CHSCHCH_2CHSCHCH_2}$.

EXPERIMENTAL

Materials

cis - 1,4 - cyclohexadienebisepisulphide (L),[6] $[M(CO)_4(nbd)]$ (M = Cr, Mo[7] and W[8]), $[NEt_4][W(CO)_5Br]$,[9] Et_3OBF_4[10] and $Fe_2(CO)_9$[11] were prepared using literature procedures.

Complexes

$[Cr(CO)_4L]$. A cooled (−5°C) solution of $[Cr(CO)_4(nbd)]$ (0.16 g, 0.64 mmol) in toluene (20 cm^3) was added to a suspension of L (0.14 g, 0.94 mmol) in toluene (10 cm^3). The mixture was stirred for 3 h producing a bright yellow precipitate. After removal of solvent under low pressure the crude product was extracted into cold THF (20 cm^3) and filtered. The cloudy solution was then filtered through a pad of celite and the solvent removed under reduced pressure. This residue was dissolved in dichloromethane (15 cm^3) and hexane (7 cm^3). This solution was chilled to −20°C to yield deep yellow crystals of $[Cr(CO)_4L]$ (0.02 g).

$[Mo(CO)_4L]$. This was prepared in an analogous manner, except that dichloromethane replaced THF for the initial extraction of the crude product from the reaction mixture.

$[\{Cr(CO)_5\}_2L]$. Chromium hexacarbonyl (0.5 g, 2.27 mmol) in THF (20 cm^3) was subjected to UV irradiation through quartz for 8 h to produce an orange solution of $[Cr(CO)_5(THF)]$. Approximately one half of this solution was cooled to −20°C and added over a period of 40 min to L (0.23 g, 1.59 mmol). The reaction mixture was allowed to achieve ambient temperature and stirring was continued for a further 3 h. Solvent was removed *in vacuo* and the resulting oily residue was extracted into dichloromethane (10 cm^3). Chromatography on alumina with dichloromethane elution gave one bright yellow band. The volume of this band eluate was reduced to *ca* 4 cm^3 and the solution cooled to −20°C. The product $[\{Cr(CO)_5\}_2L]$ (0.2 g) was collected by filtration as small golden needles.

$[\{W(CO)_5\}_2L]$. This compound was obtained from the mixing of L (0.15 g, 1.04 mmol) and $[W(CO)_5Br][NEt_4]$ (0.54 g, 1.00 mmol) in the presence of an excess of triethyloxonium tetrafluoroborate in dichloromethane (30 cm^3). Chromatography of the crude product on alumina, with dichloromethane–hexane (1 : 1 by volume) elution gave a single, pale yellow band. Reduction of the eluate volume under reduced pressure to 10 cm^3 and cooling to −10°C produced yellow crystals of $[\{W(CO)_5\}_2L]$ (0.03 g).

All complexes synthesized were more or less air-sensitive, and all operations were performed under dry nitrogen using Schlenk techniques. Characterization data for the products are reported in Table 1.

Spectra

^1H NMR spectra were recorded on a Bruker AM250 spectrometer, operating at 250 MHz. IR spectra were recorded using either a Perkin–Elmer 299B or 398 spectrophotometer with 0.5 mm NaCl solution cells.

X-ray crystallography

The crystal used for X-ray work was mounted under nitrogen in a capillary. Following preliminary photography, unit cell and intensity data

were obtained using a CAD4 diffractometer and graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å), following standard procedures.[12a] The structure was solved via use of the heavy-atoms method and refined by full-matrix least-squares; non-hydrogen atoms were assigned anisotropic thermal parameters, hydrogen atoms were experimentally located and freely refined with group U_{iso} values.

Crystallographic data are as follows: $C_{10}H_8CrO_4S_2$, $M_r = 308.28$, orthorhombic, $a = 13.256(3)$, $b = 9.201(1)$, $c = 9.746(1)$ Å, $V = 1188.71$ Å^3, space group *Pnma*, $Z = 4$, $D_c = 1.722$ g cm^{-3}, μ(Mo-K_α) = 12.73 cm^{-1}, $T = 295$ K. 1236 data were recorded giving 1105 unique and 714 observed [$I > 1.5\sigma(I)$]. Empirical absorption correction was carried out as described in ref. 12b. Number of parameters in least-squares, 106 and weighting scheme $w = [\sigma^2(F) + 0.0002F_o^2]^{-1}$. Final R, $R_w = 0.0385$, 0.0377. Atomic scattering factors were calculated from the data in ref. 12c. Final atomic positional parameters, displacement factor coefficients and lists of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

General properties

The reactions of *cis*-1,4-cyclohexadienebisepisulphide (L) with [M(CO)$_4$(nbd)] (M = Cr and Mo) gave the tetracarbonyl products [M(CO)$_4$L], but attempts to prepare the analogous tungsten product have not been successful.

[{Cr(CO)$_5$}$_2$L] and [{W(CO)$_5$}$_2$L] have been synthesized by the action of L upon [Cr(CO)$_5$(THF)] and [W(CO)$_5$Br], respectively.

Whilst all four products were sensitive to oxygen in solution, the tetracarbonyl complexes were considerably more unstable than the pentacarbonyls.

X-ray studies

The novelty of a chelating bisepisulphide prompted us to make a single crystal X-ray structural determination of [Cr(CO)$_4$(CHSCH CH$_2$CHSCHCH$_2$)]. The molecular structure is illustrated in Fig. 2, and a selection of bond lengths and bond angles is given in Table 2. The molecule is an octahedral chelated species and possesses a crystallographic mirror plane which bisects the S—S vector and contains C(2), C(4), Cr, C(13), O(13), C(11) and O(11). The bisepisulphide ligand has retained its integrity after complexation. The sulphur-to-metal bonds are in the manner of thioethers, with Cr—S bond lengths of 2.339(3) Å. These are short compared[13,14] with the sum of the covalent radii of these atoms of 2.52 Å, supporting the suggestion[15] of an element of multiple bond π-character in the chromium–sulphur linkage. What appears to be a remarkably small C—S—C bond angle of 47.3(2)° in the coordinated bisepisulphide is nevertheless within the expected[1] range for the

episulphide ring system. More notable are the C—S bond lengths of 1.915(7) Å, which appear to be the longest observed to date in episulphide rings.

^{1}H *NMR studies*

Despite their very different stoichiometries the NMR spectra of the complexes $[M(CO)_4L]$ and $[\{M(CO)_5\}_2L]$ have similar features. In both types of complex, the methylene group protons give signals characteristic of the AB part of an ABX_2 spin system, while the methine protons give essentially singlet signals. The partially resolved vicinal couplings of the methylene signals are an aid to the individual assignment of the latter. The Karplus rules predict[16] that the coupling constant between H_a and H_c (Fig. 3) will be larger than between H_a and H_b. Thus, the protons showing the larger vicinal couplings will be H_c. It is striking that in the mononuclear chelate ligand complexes, **1** and **2**, these protons appear to the lower frequency side of the H_b protons, whereas in the dinuclear bridging ligand

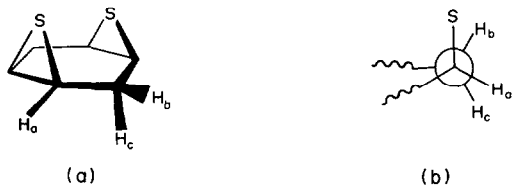

Fig. 3. The relationship between the vicinal protons in *cis*-1,4-cyclohexadienebisepisulphide and its metal complexes.

complexes, **3** and **4**, the relative chemical shifts of H_b and H_c are reversed (Table 3). In all cases the geminal coupling constants $^3J(H_b—H_c)$ are of the order of 18.5 Hz and the vicinal coupling constants $^3J(H_a—H_c)$ and $^3J(H_a—H_b)$ are *ca* 3.5 and 1 Hz, respectively. As these latter couplings were not fully resolved, their magnitudes were not known with any accuracy and therefore could not be used to provide any reliable information concerning the conformations of the six-membered carbocyclic rings in the two types of complex.

Table 3. ^{1}H NMR spectroscopic data for the group 6a metal complexes of *cis*-1,4-cyclohexadienebisepisulphide (L)

Complex	Solvent	Temperature (°C)	$\delta(H_a)$ (ppm)	$\delta(H_b)$ (ppm)	$\delta(H_c)$ (ppm)	$J(H_b—H_c)$ (Hz)
$[Cr(CO)_4L]$ (1)	CD_2Cl_2	25	3.16	3.02	3.01	18.6
$[Mo(CO)_4L]$ (2)	$C_6D_5NO_2$	25	3.47	3.22	2.99	18.7
$[\{Cr(CO)_5\}_2L]$ (3)	$CDCl_3$	25	3.24	3.08	3.21	18.2
$[\{W(CO)_5\}_2L]$ (4)	CD_2Cl_2	25	3.55	3.01	3.34	18.4

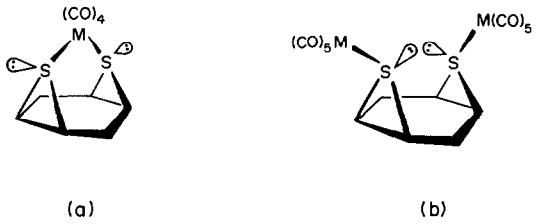

Fig. 4. The use of the "inner" and "outer" lone pairs of sulphur electrons in the formation of $[M(CO)_4L]$ and $[\{M(CO)_5\}_2L]$, respectively.

The isochronous nature of the CH group protons indicates the very high degree of symmetry in all four complexes. The structure determination of **1** demonstrates that the tetracarbonyl products can be thought of as utilizing the two inner lone pairs of the episulphide ligand as illustrated in Fig. 4(a). Model studies show that steric requirements make it impossible for the bis-metal pentacarbonyl species, **3** and **4**, to do other than use the two outer lone pairs of the ligand as in Fig. 4(b).

OTHER REACTIONS

Solutions of compounds **1** and **2** in several solvents, were heated to 45°C in sealed tubes, whereupon extensive decomposition took place. We were, however, unable to characterize any molecular product from the residues.

Ligand L reacted smoothly with di-ironnonacarbonyl in dichloromethane to give $[Fe_3(\mu_3\text{-}S)_2(CO)_9]$ in good yield. This product has been obtained previously by the desulphurization of episulphides[3] and other thioethers.[17] We have reacted $[Cr(CO)_4(nbd)]$ and $[W(CO)_4(nbd)]$ with ethylene sulphide and find no evidence for formation of isolable new metal complexes.

Abstract—In contrast to analogous complexes of smaller phosphines, which react with bromine to give platinum(IV) dibromo species, [$Pt(S_2N_2H)(PPh_3)_2$]BF_4 (**1**) reacts to give a mixture of $PtBr_2(PPh_3)_2$, $PtBr_4(PPh_3)_2$ and, if performed in the presence of [dbuH]Cl, the pentabromo complex [dbuH][$PtBr_5(PPh_3)$] (**2**). The X-ray crystal structure determination of the latter represents the first such analysis of a complex of this class.

We have recently reported on the reactions of [$Pt(S_2N_2H)(PR_3)_2$]BF_4 (PR_3 = PMe_2Ph and PMe_3) with stoichiometric quantities of bromine which lead to platinum(IV) dibromo complexes of the type [$Pt(S_2N_2H)(Br)_2(PR_3)_2$]$BF_4$, which in turn spontaneously decompose to the platinum(II) complexes $Pt(S_2N_2H)(Br)(PR_3)$.[1]

This type of reaction is sensitive to the nature of the phosphine present; here we report upon the reaction of the triphenylphosphine complex, [$Pt(S_2N_2H)(PPh_3)_2$]BF_4 (**1**), with bromine which leads, via loss of the sulphur–nitrogen fragment, to simple platinum–triphenylphosphine–bromo complexes. If the reaction is performed in the presence of [dbuH]Cl (a by-product of the preparation of the starting materials) a salt of the pentabromo anion [$PtBr_5(PPh_3)$]$^-$ is formed. Although complexes of this type have been made previously, the X-ray crystal structure of the latter is the first to be reported.

RESULTS AND DISCUSSION

Complexes of the type [$Pt(S_2N_2H)(PR_3)_2$]BF_4 are readily formed by reaction of BF_3 with the analogous $S_2N_2^{2-}$ complexes, which in turn are prepared in high yield by treatment of a mixture of *cis*-$PtCl_2(PR_3)_2$ and $S_4N_4H_4$ with the base dbu.[2] One by-product of the latter reaction is [dbuH]Cl which can only be completely removed by thoroughly washing the products with water. During our early investigations into the reaction of [$Pt(S_2N_2H)(PMe_2Ph)_2$]BF_4 with bromine, which yields the platinum(IV) dibromo complex [$Pt(S_2N_2H)(Br)_2(PMe_2Ph)_2$]$BF_4$,[1] the undoubted presence of small amounts of [dbuH]Cl as contaminants did not appear to affect the course of the reaction. However, upon extending the range of reactions to include the PPh_3 complex, it soon became clear that in this case the purity of the starting materials is more important.

The reaction of **1** with bromine proceeds much more slowly than that of the PMe_2Ph analogue; thus the ^{31}P NMR spectrum of the product after 30 min shows $\approx$ 50% of the platinum species unreacted. Also present in this solution is $PtBr_2(PPh_3)_2$, indicating that the reaction proceeds via a different route to that observed in the other cases, one which involves loss of the $S_2N_2H^-$ ligand. In addition, if the reaction is performed upon starting material which is contaminated with [dbuH]Cl, then another species is seen in the ^{31}P NMR spectrum. This new complex appears as a singlet at $\delta = -7.0$ ppm, together with ^{195}Pt sat-

ellites ($^1J(^{195}Pt—^{31}P)$ 2140 Hz). The low value of the ^1J coupling suggests the presence of platinum(IV). By slow diffusion into $CHCl_3$ solutions the platinum(IV) complex can be obtained as well-formed red crystals.

On first obtaining crystals of this complex we hoped that it would prove to be a platinum–sulphur–nitrogen species; however their IR spectrum showed none of the expected S—N stretches, and showed a peak at ≈ 1650 cm^{-1}, typical of dbu. Micro-analysis and X-ray crystallography confirmed the complex to be [dbuH][$PtBr_5(PPh_3)$].

A diagram of the unit cell contents is given in Fig. 1. Selected bond lengths and angles are listed in Table 1. The anion has the expected octahedral geometry with the unique Pt—Br distance being

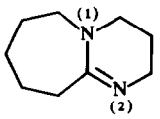
0.06 Å longer than the four equivalent "equatorial" Pt—Br distances, as a result of the *trans* influence of the phosphine. The hydrogen atoms on the dbu cation were not located and we cannot identify the point of protonation in this way. However, the bridgehead nitrogen, N(1), is nearly planar (sum of angles = 359.9°) so it is likely that N(2) carries the proton.



Complexes of this class have been reported previously; treatment of halogen-bridged complexes of the type [PtX$_2$(PR$_3$)]$_2$ with [^{n}Pr$_4$N]X yields salts of [PtX$_3$(PR$_3$)]$^-$ which can be oxidized with the appropriate halogen to give the corresponding platinum(IV) species.[3] This technique has been used to produce complexes of PMe$_3$, although to our knowledge none of the products has been analysed by X-ray crystallography.

The precise mechanism for the production of **2** in this case is unclear, as is the reason for the contrast between the reactions of the PMe$_2$Ph and PPh$_3$ complexes. However, the role of the [dbuH]Cl is crucial; if the reaction is performed upon a compound known to be completely free of the latter then no [PtBr$_5$(PPh$_3$)]$^-$ is formed. In this case, addition of excess bromine, followed by slow hexane diffusion yields a mass of micro-crystals which analyse as a mixture of PtBr$_2$(PPh$_3$)$_2$ and PtBr$_4$(PPh$_3$)$_2$. Possibly [dbuH]Cl can react with the latter platinum(IV) species to yield a salt of [PtBr$_4$Cl(PPh$_3$)]$^-$, via loss of triphenylphosphine, and this in turn reacts with the bromine in the system to give the final product. It is worth noting that although the precise mechanism for the reaction is unclear, and obviously our first preparation of **2** was totally fortuitous, the reaction is reproducible so long as care is taken to leave [dbuH]Cl in the system.

We have yet to fully characterize the products of the reaction of [Pt(S$_2$N$_2$H)(PPh$_2$Me)$_2$]BF$_4$ with bromine; ^{31}P NMR reveals the presence of a platinum(IV) complex, consistent with [Pt(S$_2$N$_2$H)(Br)$_2$(PPh$_2$Me)$_2$]BF$_4$, but this rapidly decomposes in a matter of minutes to give a mixture with a similar ^{31}P NMR spectrum to that of the decomposition products from the PMe$_2$Ph analogue. Thus, there appears to be two distinct effects brought about by the introduction of more phenyl groups into the phosphines present. The first of these is the destabilizing effect upon the resulting platinum(IV) dibromo species, as witnessed by the greater instability of the PPh$_2$Me complex, which is stable only for minutes, compared to the PMe$_3$ and PMe$_2$Ph analogues which are stable for days.

Another effect appears to be at work in the PPh$_3$ case, since ^{31}P NMR shows no evidence for the presence of [Pt(S$_2$N$_2$H)(Br)$_2$(PPh$_3$)$_2$]BF$_4$, even as a short lived species. Rather, it would seem that in this case the reaction proceeds via an entirely different mechanism, since it is slower and eventually results in the loss of the sulphur–nitrogen ligand. It may well be that the crucial factor is the steric influence of the bulky triphenylphosphine groups, although it is unclear why this should have the effect of labilizing the S$_2$N$_2$H$^-$ ligand.

EXPERIMENTAL

General reaction conditions and techniques were as described previously.[1] Compound **1** was prepared from Pt(S$_2$N$_2$)(PPh$_3$)$_2$, the latter from PtCl$_2$(PPh$_3$)$_2$ and S$_4$N$_4$H$_4$/dbu.[2] The bromine solution used consisted of 0.2 cm^3 of Br$_2$ in 20 cm^3 CH$_2$Cl$_2$ (i.e. 0.195 M w.r.t. Br$_2$).

Reaction of **1** *with* Br$_2$ *in the absence of* [dbuH]Cl

A solution of **1** (0.25 g, 0.28 mmol) in CH$_2$Cl$_2$ (20 cm^3) was treated with Br$_2$ in CH$_2$Cl$_2$ (1.5 cm^3, 0.29 mmol) and stirred for 30 min, during which time the solution gradually darkened from orange to light red and deposited some pale solid. The volume of the solvent was reduced to ≈ 5 cm^3 *in vacuo* and Et$_2$O (40 cm^3) added giving a bright orange precipitate. ^{31}P NMR of a CDCl$_3$ solution of the product showed the presence of the starting material together with PtBr$_2$(PPh$_3$)$_2$ (ratio ≈ 1 : 1.2).

The solution was treated with more bromine solution (0.75 cm^3, 0.15 mmol) and stirred overnight. The resulting red solution was reduced in volume and hexane (30 cm^3) layered on top. Slow diffusion of the hexane resulted in a mass of yellow microcrystals. Micro-analysis suggested a mixture of PtBr$_2$(PPh$_3$)$_2$ and PtBr$_4$(PPh$_3$)$_2$. Found: C, 47.2; H, 3.2. Calc. for dibromide: C, 49.2; H, 3.4 and for tetrabromide C, 41.6; H, 2.9%.

Reaction in the presence of [dbuH]Cl

A solution of **1** (0.25 g, 0.28 mmol), known to be contaminated with [dbuH]Cl, in CH$_2$Cl$_2$ (10 cm^3) was treated with bromine solution (1.5 cm^3, 0.29 mmol). After stirring for 30 min the solvent was reduced in volume; the ^{31}P NMR spectrum of the product showed the presence of PtBr$_2$(PPh$_3$)$_2$ and a platinum(IV) complex (ratio 2 : 1). The mixture was taken up in CH$_2$Cl$_2$ (10 cm^3) and treated with

toluene (20 cm^3). The rest of the CH_2Cl_2 was removed *in vacuo* and the resulting orange solid filtered off and washed with cold toluene followed by Et_2O. The solid obtained was redissolved in CH_2Cl_2 (3 cm^3) and hexane layered on top; slow diffusion yielded **2** as well-formed orange–red crystals. Found: C, 32.0; H, 3.0; N, 2.8. Calc. C, 32.1; H, 3.2; N, 2.8%.

Crystal data. $C_{27}H_{32}N_2Br_5Pt$, $M = 1010.1$, monoclinic, $a = 9.583(6)$, $b = 32.523(6)$, $c = 10.115(3)$ Å, $\beta = 94.74(4)°$, $U = 3141.7$ $Å^3$, space group $P2_1/n$, $Z = 4$, $D_c = 2.14$ g cm^{-3}, μ(Mo-K_α) 108.8, $\lambda = 0.71069$ Å, $F(000) = 1904$.

Data collection and processing. ($1.5\theta \leqslant 25°$), graphite monochromated Mo-K_α radiation; 5518 independent measured reflections, 3677 observed [$|F_o| > 6\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction.

Structure analysis and refinement. The structure was solved by the heavy-atom method and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned group isotropic thermal parameters $U(H) = 1.2U\text{eq}(C)$ and allowed to ride on their parent carbons. Refinement was by full-matrix least-squares to $R = 0.045$, ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.046$ ($w^{-1} = \sigma^2(F) + 0.00035F^2$). Computations were carried out on a VAX 11/750 computer using the SHELX76 program system.*

* Atomic coordinates, thermal parameters, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

REDISTRIBUTION REACTIONS OF PLATINUM(II) AND PALLADIUM(II) PHOSPHINE COMPLEXES

JEFFREY A. RAHN, MARK S. HOLT and JOHN H. NELSON*

Department of Chemistry, University of Nevada, Reno, NV 89557-0020, U.S.A.

(*Received* 28 *August* 1988; *accepted* 31 *October* 1988)

Abstract—Anion redistribution equilibria of the type $(R_3P)_2MX_2+(R_3P)_2MY_2 \leftrightarrows 2(R_3P)_2MXY$ (X, Y = Cl, Br, I, CN, N_3; R_3P = Me_2PhP, $MePh_2P$, $(Bzl)_3P$, $(CH_2{=}CH)_2PhP$, $(CH_2{=}CH)Ph_2P$ and 1-phenyl-3,4-dimethylphosphole; M = Pd, Pt) have been studied by $^{31}P\{^1H\}$ and in some cases $^{195}Pt\{^1H\}$ NMR spectroscopy. It was found that except for the two cases when R_3P = $MePh_2P$, M = Pd, X = Cl, Y = Br and R_3P = Me_2PhP, M = Pd, X = Cl, Y = Br, redistribution was in general instantaneous. The $(R_3P)_2PdCl_2+(R_3P)_2Pd(CN)_2$ reactions were slow but proceeded to completion. In contrast, when one of the anions is CN^- no anion redistribution was observed for the platinum complexes even after a month. The thermodynamic stabilities of the mixed anion species relative to the symmetric species is anion dependent showing that these are not random processes. The $(R_3P)_2PdXY$ complexes possess the *trans* geometry. The $(R_3P)_2PtXY$ complexes are generally *cis* but in some cases both the *cis* and *trans* isomers are present in solution. A mechanism is proposed for these reactions. Phosphine redistribution of the type $(R_3P)_2MX_2+(R'_3P)_2MX_2 \leftrightarrows 2(R_3P)(R'_3P)_2MX_2$ is general for palladium. It did not occur for platinum unless one or more of the R and R′ groups on each phosphine was unsaturated (allyl, vinyl or the butadiene moiety of a phosphole). In most of these cases the $(R_3P)(R'_3P)MX_2$ complexes underwent intramolecular [4+2] Diels–Alder cycloaddition reactions.

Ligand redistribution reactions [eq. (1)] are common for typical element compounds.[1]

$$MA+M'B \rightleftharpoons MB+M'A. \quad (1)$$

The theoretical aspects,[1,2] experimental methods for their study[1–4] and the various systems which undergo this class of reaction have been reviewed.[1–4] Redistribution reactions of transition metal complexes, although less studied,[4] may not be less common. We reported earlier[5,6] that neutral ligand redistribution is a general reaction for palladium(II) complexes. In this paper we extend that study to analogous platinum(II) complexes and consider as well, anionic ligand redistribution for both palladium(II) and platinum(II) phosphine complexes. This type of reaction is of fundamental importance to our understanding of the solution chemistry of "inert" transition metal complexes.

EXPERIMENTAL

Reagents and physical measurements

All chemicals used were reagent grade and were used as received or synthesized as described below. All solvents, when necessary, were dried by standard procedures and stored over Linde 4 Å molecular sieves. All reactions involving phosphines were conducted under a nitrogen atmosphere.

The $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectra were recorded at 40.26 and 21.28 MHz, respectively, on a JEOL FX-100 spectrometer in the FT mode. Phosphorus chemical shifts were relative to external 85% H_3PO_4, with a positive value being downfield of the reference. ^{195}Pt chemical shifts are referenced to a standard frequency of 21.4 MHz relative to the proton resonance of TMS at 100 MHz.[7,8] Concentration values for calculating "k_{eq}" were obtained by integration of the areas of the ^{31}P res-

onances, or by measurement of the peak heights. When both methods could be used, the "k_{eq}" values were within 5% of each other.

Synthesis

Most $(R_3P)_2MCl_2$ complexes were prepared by reacting 2 equivalents of the phosphine or phosphole with one equivalent of the $(PhCN)_2MCl_2$ complex in CH_2Cl_2 under a nitrogen atmosphere as reported previously.[9] When R_3P was Bu_3P or Et_3P, 2 equivalents of the phosphine were reacted with 1 equivalent of K_2PtCl_4 as described previously.[10] The bromide,[11] iodide,[11] cyanide[12] and azide[13] complexes were prepared by metathesis of the chloride complexes in a CH_2Cl_2–CH_3OH–H_2O solvent mixture for 1 to 7 days for the palladium and platinum complexes, respectively. Except for cyanide, a 4:1 molar ratio of NaX to chloride complex was employed. For the cyanide complexes, a 2:1 molar ratio of NaCN to chloride complex was employed. The $^{31}P\{^1H\}$ NMR data for the palladium and platinum complexes is contained in Tables 1 and 2, respectively. The physical properties of all complexes agreed with the literature data.[9–26]

Redistribution reactions

These were performed by dissolving a 1:1 molar ratio of the two complexes, 20–60 mg each, in approximately 3 cm^3 of $CDCl_3$. The resultant solution was then placed in a 10 mm NMR tube and spectra were recorded immediately at 300 K, after 2 and 48 h, then again after a week or more.

RESULTS AND DISCUSSION

Anion redistribution

Reaction of complexes containing two different anions, X and Y [eq. (2)], was generally very rapid.

$$(R_3P)_2MX_2+(R_3P)_2MY_2 \rightleftharpoons 2(R_3P)_2MXY. \quad (2)$$

In most cases, an equilibrium mixture of starting materials and either a *cis* or *trans* (in some cases both) mixed anion complex was formed. Equilibrium constants for eq. (2) were calculated from the equation:

$$K_{eq} = \frac{[(R_3P)_2MXY]^2_{total}}{[(R_3P)_2MX_2][(R_3P)_2MY_2]}$$

where $[(R_3P)_2MXY]_{total}$ is the total concentration of the *cis* and *trans* isomers of the mixed anion products.

Palladium reactions. The $(R_3P)_2PdX_2$ complexes generally exist as temperature dependent equilibrium mixtures of *cis* and *trans* isomers in solution.[11,14-20] Their $^{31}P\{^1H\}$ NMR spectra contain two resonances, one for each isomer, with that of the *trans* isomer generally being upfield of that for the *cis* isomer. The $^{31}P\{^1H\}$ NMR spectrum of a typical reaction mixture is shown in Fig. 1(C). The spectrum of the mixture contains, in addition to the resonances expected for the starting materials, a new singlet whose chemical shift lies between those of the *trans*-Cl_2 and *trans*-I_2 complexes. This resonance is assigned to the *trans*-$(MePh_2P)_2PdClI$ complex since the *cis* isomer should show two ^{31}P chemical shifts (*vide infra*). Similar spectra were observed for the 20 reactions listed in Table 1. The *trans* mixed anion complex formed in every case studied, except for the two Cl/Br combinations where only the two starting materials were present in solution after several days.

In several cases where the redistribution occurred, the K_{eq} values differ substantially from the statistical value of four, indicating that these equilibrium constants are influenced by the strengths of the Pd—X bonds[4] and are not random processes.

The reactions between the $(R_3P)_2PdCl_2$ and $(R_3P)_2Pd(CN)_2$ complexes were slower, but proceeded to completion. The *trans*-$(R_3P)_2Pd(CN)Cl$ complex was the only species present in solution after 1 week. Exchanges between the cyanide complexes and the complexes of other anions (Br, I, and N_3) all had equilibrium constants (K_{eq} = 21.1–490) that are much greater than for the non-cyanide containing exchanges. Reaction of the

azide complexes with the chloride, bromide and iodide complexes, except for the $(MePh_2P)_2PdI_2$+ $(MePh_2P)_2Pd(N_3)_2$ reaction ($K_{eq} = 1.7$), all had equilibrium constants which were less than one. The equilibrium constants for the chloride with iodide and bromide with iodide reactions were near the statistical value, ranging from 3.2 to 4.2. It should also be noted that the nature of the phosphine affects the value of the equilibrium constant, but that there is no regular trend that is easily discernible relating to either the size or the basicity of the phosphine.

Platinum reactions. The geometry of the $(R_3P)_2PtX_2$ complexes may be easily determined from the magnitude of the platinum–phosphorus coupling constant. For *cis* complexes ^1J(Pt—P) is generally greater than 3000 MHz, while for *trans* compounds ^1J(Pt—P) is generally less than 2500 Hz.[21,27-29] The $(R_3P)_2PtI_2$ complexes exist as temperature-dependent equilibrium mixtures of *cis* and *trans* isomers in solution. The chloride, bromide and azide complexes are wholly *cis* and the cyanide complexes wholly *trans* in solution.

The $^{31}P\{^1H\}$ NMR spectrum of a typical reaction mixture is shown in Fig. 2. This spectrum contains an AB quartet, in addition to the resonances expected for the starting materials. This AB pattern is assigned to the *cis*-$(R_3P)_2PtXY$ complex. The magnitudes of the two ^1J(Pt—P)s and ^2J(PP)[30,31] are all consistent with the *cis* geometry. In all cases, when both the symmetric complexes were *cis*, the mixed anion complex was also *cis*. If both the symmetric complexes were *trans*, then the mixed anion complex which formed was also *trans* [reactions (23), (24), (25)]. In some cases, when one of the symmetric complexes was an iodide complex, a mixture of *cis* and *trans* isomers of $(R_3P)_2PtXI$ [reactions (2), (5), (9), (13)] was formed, with the major species being the *cis* isomer. A similar study[32] with *cis*-$(MePh_2P)_2Pt(NO_3)_2$ and *cis*-$(MePh_2P)_2Pt(CH_3)_2$ showed that the *cis*-$(MePh_2P)_2Pt(NO_3)(CH_3)$ isomer was formed first and that it slowly isomerized to the *trans* isomer.

Most of the equilibrium constants for the anion redistribution reactions of the platinum complexes do not differ markedly from the statistical value of four. The redistribution occurs to the greatest extent when one of the anions is the pseudo-halide N_3^-. Anion redistribution does not occur when one of the anions is cyanide (even after a month) which is in stark contrast to the results of the palladium reactions where the cyanide reactions occurred to the greatest extent. Also, redistribution between chloride and bromide complexes occurred for platinum but not for palladium. Clearly, the metal has an influence on K_{eq}.

The $(Bzl_3P)_2PtX_2$ (X = Cl, Br and I) complexes are each *trans* isomers, probably because of the

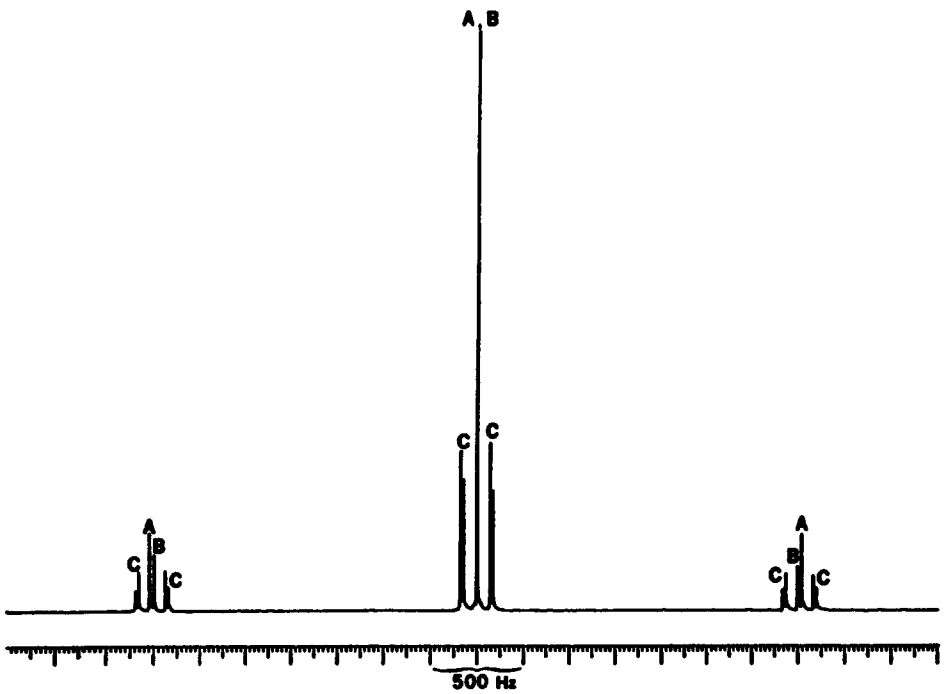

Fig. 2. 40.26 MHz $^{31}P\{^1H\}$ NMR spectrum of an equilibrium mixture of (A) $(Me_2PhP)_2PtCl_2$, (B) $(Me_2PhP)_2PtBr_2$ and (C) $(Me_2PhP)_2PtClBr$ in $CDCl_3$ at 300 K.

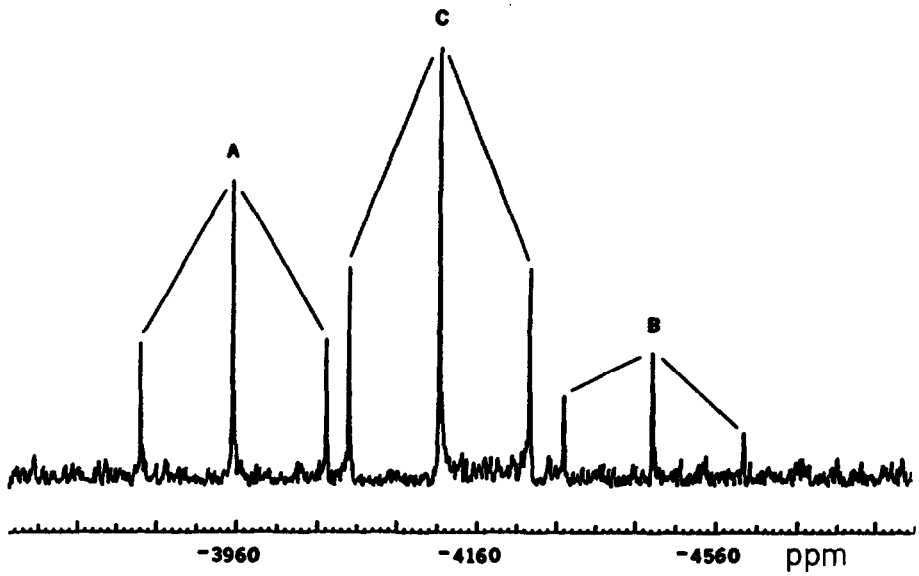

Fig. 3. 21.28 MHz $^{195}Pt\{^1H\}$ NMR spectrum of an equilibrium mixture of (A) $(Bzl_3P)_2PtCl_2$, (B) $(Bzl_3P)_2PtBr_2$ and (C) $(Bzl_3P)_2PtBrCl$ in $CDCl_3$ at 300 K.

steric bulk of Bzl_3P. Formation of *trans*-$(Bzl_3P)_2PtXY$ would then be expected. The $^{195}Pt\{^1H\}$ NMR spectrum for the reaction of $(Bzl_3P)_2PtCl_2$ with $(Bzl_3P)_2PtBr_2$ is shown in Fig. 3. For *trans*-$(Bzl_3P)_2PtCl_2$, $\delta^{195}Pt = -3954$ ppm and for *trans*-$(Bzl_3P)_2PtBr_2$, $\delta^{195}Pt = -4478$ ppm. The ^{195}Pt chemical shift of *trans*-$(Bzl_3P)_2PtBrCl$ is, as anticipated[33] due to the rough additivity of the halide influence on $\delta^{195}Pt$, intermediate between these two values ($\delta^{195}Pt = -4210$ ppm). Figure 4 shows the $^{195}Pt\{^1H\}$ NMR spectrum for the reaction of $(MePh_2P)_2PtBr_2$ with $(MePh_2P)_2PtI_2$ which displays the presence of both *cis*- ($\delta = -4931$ ppm) and *trans*- ($\delta = -5120$ ppm) $(MePh_2P)_2PtBrI$.

An unexpected trend was noted concerning the platinum–phosphorus coupling constants for the *cis* mixed halide complexes produced in reactions involving the chloride, bromide and iodide

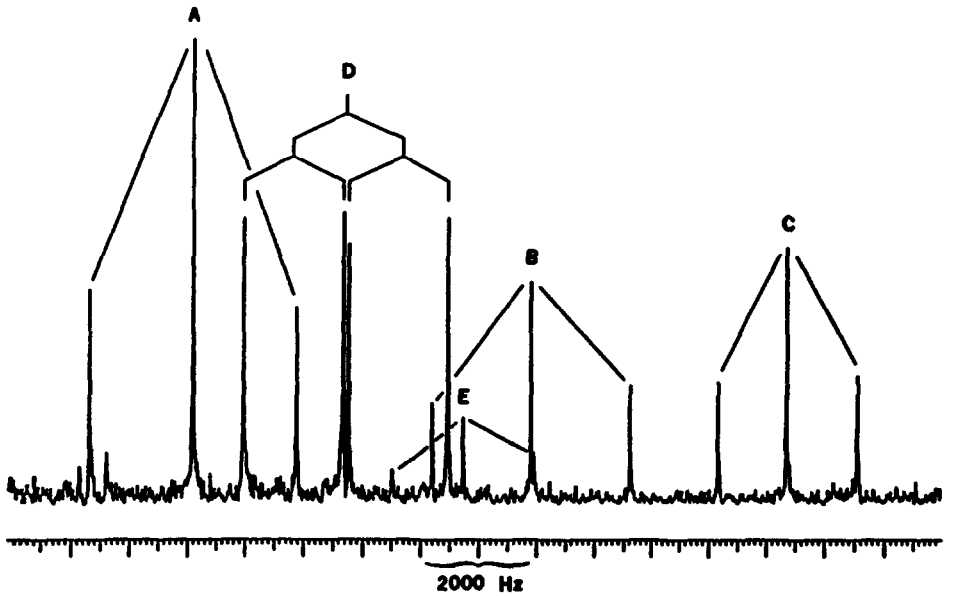

Fig. 4. 21.28 MHz $^{195}Pt\{^1H\}$ NMR spectrum of an equilibrium mixture of (A) *cis*-$(MePh_2P)_2PtBr_2$ ($\delta = -4685$ ppm), (B) *cis*-$(MePh_2P)_2PtI_2$ ($\delta = -5230$ ppm), (C) *trans*-$(MePh_2P)_2PtI_2$ ($\delta = -5648$ ppm), (D) *cis*-$(MePh_2P)_2PrBrI$ ($\delta = -4931$ ppm) and (E) *trans*-$(MePh_2P)_2PtBrI$ ($\delta = -5120$ ppm) in $CDCl_3$ at 300 K.

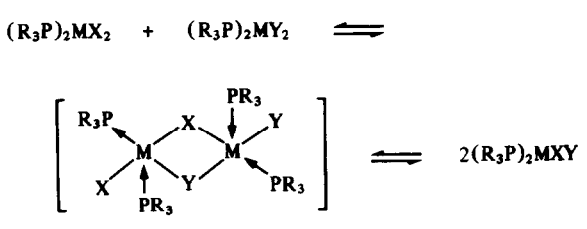
complexes. In most cases, there is a reversal in the magnitude of J(Pt—P). Reaction (5) is a typical example. For *cis*-$(Me_2Ph)_2PtBr_2$ and *cis*-$(Me_2PhP)_2PtI_2$, ^1J(Pt—P) is, respectively, 3500 and 3364 Hz. For the *cis*-$(Me_2PhP)_2PtBrI$ complex, the resonance assigned to the phosphorus *trans* to bromide has ^1J(Pt—P) of 3348 Hz and that assigned to the phosphorus *trans* to iodide has ^1J(Pt—P) of 3503 Hz. This is just opposite to our expectations. A reversal in the assignment of the phosphorus resonances for the *cis*-$(R_3P)_2PtXY$ complexes would give ^1J(Pt—P) coupling constants that are consistent with expectations, but then the chemical shifts would be difficult to explain.[34] Hence, the exact assignment of the chemical shifts in these cases is uncertain but the conclusions regarding the reactions remain the same, independent of the assignment.

Mechanism of anion redistribution. As with geometrical isomerizations[35] of L_2MX_2 complexes, both associative and dissociative mechanisms are possible for the anion redistribution reactions. We believe that the associative mechanism illustrated in eq. (3), which has been previously proposed,[36–38] is the most likely process. We do not wish to imply anything regarding the coordination geometry of the anion-bridged intermediate (i.e. either square-based pyramidal (SBP) or trigonal-bipyramidal (TBP)), or of the actual location of the ligands not involved in bridging. Based upon the limited amount of structural data[39] on L_3MX_2 complexes the geometry may be distorted between SBP and TBP.



(3)

Phosphine redistribution

Palladium reactions. We have previously reported[5,6] on the neutral ligand redistribution of palladium complexes and found it to be fairly general. Six new reactions, all involving phosphines with unsaturated substituents, were carried out between pairs of palladium(II) phosphine complexes (Table 3). In each case, the $(R_3P)(R'_3P)PdX_2$ complex was in equilibrium with $(R_3P)_2PdX_2$ and $(R'_3P)PdX_2$, but also in each case this mixed ligand complex underwent a subsequent Diels–Alder [4+2] cycloaddition reaction[40] as illustrated in eq. (4). For the chloride complexes, only the *cis* mixed

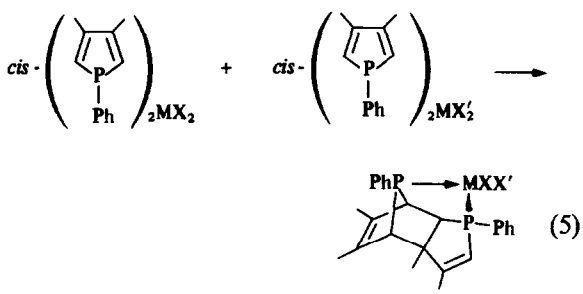
ligand complex was formed. For the bromide complexes, both the *cis* and *trans* mixed ligand complexes were formed and for the iodide complexes, only the *trans* mixed ligand complex was formed. This is in agreement with previous observations that the *cis* isomer stability decreases with increasing size of the halide.[11] In each case, ligand redistribution was instantaneous and the following Diels–Alder cycloaddition relatively slow. Because of the following Diels–Alder cycloaddition reaction, K_{eq} for the ligand redistribution could not be measured. We also observed slow Diels–Alder [4+2] reactions [eq. (5)] in reactions (20), (21) and (22) of Table



(5)

2. Details of these Diels–Alder reactions will be described in subsequent publications.

Platinum reactions. For all the platinum reactions listed in Table 4 there was no evidence of phosphine redistribution in $CDCl_3$ over a period of 4 weeks. In contrast, for each of the reactions listed in Table 5, phosphine redistribution not only occurred but did so instantaneously. It should be noted that all of the phosphines which participated in the redistribution reaction bear unsaturated substituents (allyl, vinyl, or the butadiene moiety of the phosphole ring). Most of the $(R_3P)(R'_3P)PtX_2$ complexes have the *cis* geometry. Reactions (39) and possibly (40) (both iodides) showed *trans* mixed ligand species. For reactions (35) and (36), equilibrium constants could be measured. For all other cases, [4+2] Diels–Alder cycloaddition occurred and equilibrium constants could not be measured.

Mechanism of phosphine redistribution. It is tempting to suggest that the mechanism for phos-

phine ligand redistribution is similar to that of anion redistribution. We propose the mechanism shown in eq. (6). This is not dissimilar from dimer formation and phosphine dissociation which has been proposed to occur in similar systems.[41,42] Platinum(II) is more inert than palladium(II) and platinum–ligand bond strengths are generally greater than palladium–ligand bond strengths for the same ligands. Hence, one may anticipate the equilibrium constant for equilibrium (2) [eq. (6)] to be smaller for platinum than for palladium and we propose then that neutral ligand redistribution should only occur with platinum for weakly bound ligands. We have shown that redistribution reactions, contrary to our initial expectations, are not only common but unexpectedly rapid for "inert" square-planar palladium(II) and platinum(II) complexes. It seems most likely that they occur by associative processes involving bridged intermediates. The spontaneous *cis–trans* isomerizations which are common[11,14,20] for $(R_3P)_2PdX_2$ complexes, may occur by similar processes.

(*Received* 3 *May* 1988; *accepted* 31 *October* 1988)

Abstract—Reactions between Cu^{II} and Ni^{II} salts and the ligand 1,9-bis-(2-pyridyl)-2,5,8-triazanonane at different stoichiometric relations produced two different complexes in the case of Cu^{II} and only one with Ni^{II}. The spectral properties of these complexes are discussed and the X-ray crystal structure of one of the Cu^{II} products is described. The compound consists of a Cu^{II} pentacoordinated complex cation (all the donor atoms in L are coordinated) and a tetrahedral $[CuCl_4]^{2-}$ group. The coordination geometry of the cation can be described as a distorted square-based pyramid.

Although the study of the coordination chemistry of macrocyclic polyamine ligands, especially the quadridentate, has received much attention, linear polydentate chelators have not been studied so extensively. Pentadentate ligands are stereochemically important both for the interest in the structural behaviour of pentacoordinate complexes in solution and in the solid state,[1] as well as for being potential sources for the synthesis of seven-coordinate transition metal complexes.[2,3]

A number of transition metal complexes with linear pentadentate ligands have been prepared and several spectroscopic structural, electrochemical and kinetic studies have been carried out with them.[4,5]

Various metal complexes of the potential pentadentate ligand 1,9-bis-(2-pyridyl)-2,5,8-triazanonane (PICDIEN) have been prepared. The acid dissociation and stability constants of the Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} complexes[6] and the oxygenation constants of the cobaltous chelates have been determined[7] and a series of Co^{III} isomeric complexes of PICDIEN have been characterized by X-ray diffraction.[8–10] In these last compounds, it can be observed that all five possible coordination sites of the ligand are bonded to the metal atom which has a near regular octahedral coordination sphere.

In this paper we report the reaction of Cu^{II} and Ni^{II} salts with PICDIEN using several M–L stoichiometric relations, the spectral properties of the products and the X-ray crystal structure of one of the copper complexes.

RESULTS AND DISCUSSION

The reactions between PICDIEN and the metal salts were first carried out in 1:1 stoichiometric relationships using nickel(II) and copper(II) chlorides and perchlorates. In the case of nickel, a violet complex was produced regardless of the salt used while both cupric salts yielded a blue compound.

Table 1 lists some spectroscopic results for the compounds synthesized.

From the analytical and spectroscopic information, the complexes derived from the chlorides were assigned the formulae [CuL][$CuCl_4$], **1**, and [NiL][$NiCl_4$], **3**, and those obtained from the perchlorates [CuL][ClO_4]$_2$, **2**, and [NiL][ClO_4]$_2$, **4**. Compound **2** had been previously prepared but very little information about it was given.

The IR spectra of the complexes show all the bands expected for both the ligand and the counterion. The electronic spectra both in solution and in the solid state were measured for all complexes, and the results are given in Table 2. Figure 1 shows the spectra of **1** and **2**.

The diffuse reflectance spectra are equivalent for both [Cu(PICDIEN)][$CuCl_4$] and [Cu(PICDIEN)][ClO_4]$_2$, indicating that the absorbing species in this region is the cation [Cu(PICDIEN)]$^{2+}$, which is in agreement with the data reported,[11] while the anionic species $[CuCl_4]^{2-}$ is described as absorbing at lower energies.[12]

Hathway *et al.*, in a series of papers,[11,13,14] have determined the absorbing region for copper(II) complexes in a variety of geometries. In this case the spectra obtained suggest that the complex has a square-based pyramid structure distorted towards a trigonal bipyramid.

[Cu(PICDIEN)][Cu_xCl_y]	619								700			

[a] In H_2O.

[b] There is a broad band near 800 nm.

[c] VS, very small.

Compounds **1** and **2** also give the same electronic spectra when they are dissolved in water or in 0.1 N HCl. This is indicative of the complex being stable and inert enough as to maintain their structure in solution even in an acidic medium.

The diffuse reflectance spectra of the two nickel complexes, **3** and **4**, are very similar. Even though it was not possible to run our spectra in the range of the visible spectrum which has been used as diagnostic of five-coordinate species ($\sim 7700\ cm^{-1}$), the part of the spectra that we can compare is similar to that reported by Sacconi *et al.*[15,16]

The spectra of an aqueous solution remains the same. However, when the complexes are dissolved in 0.1 N HCl, the originally pink tone solutions change to pale green and the UV–vis spectra change. This might be caused by a chloride ligand entering into the sixth coordinating position forming an octahedral complex. The final spectra support this suggestion since they are very similar to those reported for octahedral species.[17,18]

The magnetic moments for **1** and **2** are 1.94 and 2.03 BM, respectively, which are the normal values for Cu^{II} complexes indicating that, in the case of **1**, there is negligible spin–spin coupling. Nickel complexes **3** and **4** have magnetic moments of 3.78 and 3.0 BM, respectively. The first higher value might be due to an orbital contribution to the moment from the tetrahedral counterion $[NiCl_4]^{2-}$. The magnetic moment observed for tetrahedral species such as $[NiCl_4]^{2-}$,[19] or [Ni(hexamethyl phosphoramide)]$^{2+}$,[20] is above 4 BM. Pentacoordinate nickel complexes can assume both high or low spin configurations, regardless of the geometry attained. In the case of the complexes $[Ni\{((CH_3)_2NCH_2CH_2)_3N\}X]^{2+}$ prepared by Ciampolini,[21] the magnetic moment has a value of 3.42 BM and the complex has a trigonal bipyramid structure.[22] We are therefore proposing a similar structure for the cation in **3** and **4**.

Spectroscopic and magnetic data then suggested pentacoordinate complexes for the cations in **1** to **4**. The two idealized geometries for this coordination number are square-based pyramid, symmetry groups C_{4v} and trigonal bipyramidal, symmetry group D_{3h}. Many complexes in fact show geometries that are intermediate between these two.[23] In order to determine which was the case for the copper complex cation prepared in this work an X-ray crystal structure determination of **1** was undertaken.

Crystal structure of **1**

The structure of the compound consists of discrete $[Cu(PICDIEN)]^{2+}$ cations and $[CuCl_4]^{2-}$ anions. The structures of both cation and anion are shown in Fig. 2 together with the atom numbering scheme. Bond lengths and angles are given in Tables 3 and 4.

The cation is a five-coordinated species in which the five coordinating positions of the ligand are bonded to the copper atom in a distorted square-based pyramidal structure. N(1) and N(4) could be considered to occupy the axial positions of a trigonal bipyramid [N(1)—Cu—N(4) 176.2(2)°], indicating that the structure is really intermediate between these two geometries.

The Cu—N bond lengths, with the exception of Cu—N(2) (mean 2.0463 Å), are within the range of values reported in other similar complexes.[23,24] The distance Cu—N(2) of 2.243(4) Å is significantly

longer than the other Cu—N distances. Although values similar, or longer, to this one are not common, they have been observed in some complexes.[23] It is difficult to explain the reasons for this long bond although it has been reported[25] that a peculiar behaviour of the square-based pyramidal copper complexes is a relatively long bond between copper and the apical coordinating atom with bond lengths ranging from 2.41 to 2.76 Å. If we take N(2) as the apical vertex of a square-based pyramid, an examination of the angles between the remaining donor atoms clearly shows the distortions from the ideal geometry.

The spatial arrangement of the PICDIEN ligand in **1** is diffirent from those observed in the cobalt complexes of PICDIEN, for which crystal structures have been described.[8-10] This must be a consequence of the different steric requirements of the Cu^{II} ion where a pentadentate complex is preferred to the Co^{III} compounds where near regular octahedtral structures are favoured. The torsion angles about the non-rigid bonds of the PICDIEN ligand are presented in Table 5.

There are no significant distortions in the polyamine skeleton. C—C and C—N bond lengths are practically the same as the ones observed in other complexes of PICDIEN. Two of the three secondary nitrogen atoms of the ligand exhibit chirality, the configuration of N(2) is *S* while that of N(4) is *R* (or *R* and *S*).

The anionic group consists of a $CuCl_4$ tetrahedral group with Cu—Cl bond lengths ranging from 2.255(1) to 2.292(1) Å. Cl—Cu—Cl angles are all very close to the ideal value of 109° [106.7–114.3(1)°]. These results contrast with the flattened tetrahedral structure observed for several [alkylammonium]$_2$[$CuCl_4$] salts.[26,27] Those distorted structures have been related to N···Cl short interactions.

Table 5. Torsion angles (deg) for **1**

N(1)—C(5)—C(6)—N(2)	−17.8(6)
C(7)—N(2)—C(6)—C(5)	−92.4(5)
C(6)—N(2)—C(7)—C(8)	90.3(5)
N(2)—C(7)—C(8)—N(3)	50.8(5)
C(9)—N(3)—C(8)—C(7)	73.7(5)
C(8)—N(3)—C(9)—C(10)	−151.7(4)
N(3)—C(9)—C(10)—N(4)	49.9(6)
C(11)—N(4)—C(10)—C(9)	−168.3(4)
C(10)—N(4)—C(11)—C(12)	143.1(4)
N(4)—C(11)—C(12)—N(5)	−10.0(6)

In the case of **1** there are some short intermolecular contacts between some of the amine protons and the chlorine atoms of the anion. Distances for these contacts are given in Table 6.

It has been reported[28] that some linear polydentate ligands can conform so that the same ligand molecule coordinates to two metal atoms. With PICDIEN having a relatively long saturated chain, the ligand has a large flexibility and we decided to carry out reactions in which there was an excess of metal ions as to see if a polynuclear complex could also be obtained.

These reactions with the nickel(II) and copper(II) chlorides were carried out using metal–ligand stoichiometric ratios of 4 : 1. In the case of nickel, **3** was again obtained but in the case of copper a green compound resulted, **5**. It has not been possible to determine with certainty the exact formulation for this compound but we believe it to contain a polynuclear, halogen-bridged anion. A general formula would then be [CuPICDIEN][Cu_xCl_y]. Polynuclear species of this type have been reported.[27,29,30] The same reaction was also carried out with copper(II) acetate and adding $NaClO_4$ in order to precipitate the complex, but **2** was then obtained thus supporting the suggestion of a different anionic species causing the difference in analytical and spectroscopic results.

The diffuse reflectance spectrum of **5** shows a broad band which is believed to be formed by two unresolved overlapping bands. One should correspond to the cation and the other to the anion which could have either tetrahedral or square-based pyramidal geometries around the copper atoms.

When **5** is dissolved in water or in 0.1 N HCl, the electronic spectrum is the same as the one observed for **1**. However if the complex is dissolved in ethanol or dimethylformamide, the spectrum remains the same as that for the solid state.

Table 6. Short intermolecular contacts (Å)

				Symmetry relation		
H(3a)—Cl(1)	2.688	N(3)—Cl(1)	3.532	1.00−x	1.00−y	−z
H(4a)—Cl(3)	2.450	N(4)—Cl(3)	3.398	0.5−x	0.5+y	0.5−z
H(2a)—Cl(2)	2.817	N(2)—Cl(2)	3.419	0.5−x	0.5+y	0.5−z

The magnetic moment for **5** is 3.22 BM which is a very high value for a d^9 species. On the other hand, such a high value could be explained in terms of ferromagnetic interactions such as those reported for $[Cu_2Cl_6]^{2-}$.[31,32] Ferromagnetic or antiferromagnetic interactions can occur in polynuclear structures but further studies are necessary to determine if such effects are present in our complex.

EXPERIMENTAL

Elemental analyses were carried out on a Perkin–Elmer 240B microanalyzer and in Butterworth Ltd Laboratories in the U.K. The metal contents were measured, after decomposition of the complexes, by atomic absorption analyses on a Varian 475 equipment.

IR spectra in the range 4000–200 cm^{-1} were recorded in KBr pellets on a Perkin–Elmer 599B spectrophotometer. Far-IR spectra were obtained on a Perkin–Elmer 1330.

UV-vis spectra in solution and in the solid state were obtained on Bausch Lomb 2000 and Cary 17-D spectrophotometers, respectively.

Magnetic moments were measured at room temperature (23°C) by the Gouy method with a Cahn electromagnet, Model 6685 and a Cahn 2000 electrobalance.

Preparation of the compounds

The ligand 1,9-bis-(2-pyridyl)-2,5,8-triazanonane, L, was prepared as described in the literature.[7]

[CuL][$CuCl_4$]. The ligand, L (1.1107 g, 1 mmol) was dissolved in 25 cm^3 of ethanol and added to a solution of $CuCl_2 \cdot 2H_2O$ (0.6647 g, 1 mmol) in 10 cm^3 of ethanol. The precipitate formed was filtered off, washed with ethanol and dried under vacuum. Found: C, 35.3; H, 4.25; N, 11.5; Cu, 24.5. Analysis calculated for $C_{16}H_{23}N_5Cl_4Cu_2$: C, 34.5; H, 4.13; N, 12.6; Cu, 22.9%.

[CuL][ClO_4]$_2$. $Cu(CH_3COO)_2$ (0.2683 g, 1.47 mmol) was dissolved in 10 cm^3 of ethanol and added to a solution of the ligand (0.4213 g, 1.47 mmol) in ethanol. The complex was precipitated by adding some drops of perchloric acid. The resulting precipitate was filtered, washed and dried. Found: C, 35.5; H, 4.28; N, 12.4; Cu, 12.0. Analysis calculated for $C_{16}H_{23}N_5Cl_2O_8Cu$: C, 35.0; H, 4.23; N, 12.8; Cu, 11.6%.

[CuL][Cu_xCl_y]. This compound was prepared in the same way as the first complex, although 2.226 g (13.05 mmol) of $CuCl_2 \cdot H_2O$ and 0.9303 g (3.2 mmol) of ligand were used. The green precipitate was treated as the previous compounds. Found: C, 17.9; H, 2.71; N, 6.3; Cl, 35.7; Cu, 39.8. Analysis calculated for $C_{16}H_{23}N_5Cl_{12}Cu_6$: C, 17.6; H, 2.10; N, 6.4; Cl, 39.0; Cu, 34.9%.

[NiL][$NiCl_4$]. Same procedure as above using 0.5346 g, 2.2 mmol of $NiCl_2 \cdot 4H_2O$ and 0.627 g, 2.2 mmol of ligand. Found: C, 33.0; H, 4.65; N, 12.1. Analysis calculated for $C_{16}H_{23}N_5Cl_4Ni_2$: C, 33.3; H, 4.4; N, 12.0%.

[NiL][ClO_4]$_2$. $Ni(ClO_4)_2 \cdot 6H_2O$, (0.345 g, 0.94 mmol) and the ligand (0.268 g, 0.94 mmol) were made to react following the same procedure as above. Found: C, 34.2; H, 4.48; N, 12.2. Analysis calculated for $C_{16}H_{23}N_5Cl_2O_8Ni$: C, 34.3; H, 4.46; N, 12.3%.

Crystal structure determination

Crystal data. $Cu_2C_{16}H_{23}N_5Cl_4$, molecular weight = 554, monoclinic, $a = 11.822(2)$, $b = 13.845(3)$, $c = 13.619(3)$ Å, $\beta = 93.17(2)°$, $V = 2225.5(1.9)$ Å^3. Space groups $P2_{1/n}$, $Z = 4$; $\rho_c = 1.653$ g cm^{-3}; $F(000) = 1120$, $\lambda = 0.71069$ Å; μ(Mo-K_α) = 24.14 cm^{-1}.

Data collection and solution

Intensity data were collected on a crystal of dimensions $0.32 \times 0.36 \times 0.4$ mm using ω scans ($3 < 2\theta < 45.0°$) with a variable scan rate from 4 to 30 deg min^{-1} and a scan width of 1.0° on a Nicolet R3m four-circle diffractomer with graphite-monochromated Mo-K_α radiation. From a total of 2910 measured reflections, 2395 with [$F > 3\sigma(F)$] were considered observed and used in the structure solution and refinement. Two monitor reflections with constant intensity, $R_{merge} = 0.0164$ from merging equivalent reflections. Data were corrected for Lorentz and polarization effects. Maximum and minimum transmission factors for absorption corrections were 0.268 and 0.244, respectively.

The structure was solved by direct methods and Fourier difference maps using SHELXTL.[34] The refinement was carried out by the full-matrix least-squares method using anisotropic thermal parameters for all non-hydrogen atoms. Amine protons were localized in a Fourier map and included in the refinement. All the remaining hydrogen atoms were placed in idealized positions and included in the refinement. The weighting scheme used was $[\sigma^2(F_o) + G(F_o^2)]^{-1}$, where σ is the estimated standard deviation based on counting statistics, and G an adjustable variable; the final G value was 0.00028. A final difference Fourier synthesis indicated maximum residuals of 0.6 eÅ^{-3}. Scattering factors were taken from the *International Tables for X-Ray Crystallography*.[35] The calculations were performed on a Nova 4S computer. Final

$R = 0.0361$ and $R_w = 0.034$. Final atomic coordinate and other crystallographic data have been deposited with the Editor and atomic coordinates have been sent to the Cambridge Crystallographic Data Centre.

REACTIONS OF THE MOLYBDENUM COMPLEX $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ WITH ONE EQUIVALENT OF L {L = PPh_3, $AsPh_3$, $SbPh_3$, py, 3Br—py, 4Br—py AND $P(OPh)_3$} TO GIVE $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$. BRIDGE CLEAVAGE REACTIONS OF $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$

PAUL K. BAKER* and ADRIAN BURY

Department of Chemistry, University College of North Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 6 *July* 1988; *accepted after revision* 8 *November* 1988)

Abstract—The seven-coordinate molybdenum complex $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ reacts rapidly with 1 equivalent of L [L = PPh_3, $AsPh_3$, $SbPh_3$, py, 3Br—py, 4Br—py and $P(OPh)_3$], in acetone at room temperature, to afford the chloro-bridged compounds $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$. The triphenylphosphine dimer $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ reacts with 2 equivalents of L′ [L′ = PPh_3, $SbPh_3$, py and $P(OPh)_3$] to give the bridge-cleaved mononuclear compounds $[MoCl(SnCl_3)(CO)_3LL']$.

Recent interest in seven-coordinate complexes has been highlighted by Bencze *et al.*[1,2] They showed the seven-coordinate complexes $[MX_2(CO)_3L_2]$ (M = Mo or W; X = Cl or Br; L = PPh_3 or $AsPh_3$) to be active alkene metathesis catalysts for the ring-opening polymerization of norbornene and norbornadiene.[1,2] Although many examples of seven-coordinate dihalo complexes of the type $[MX_2(CO)_3L_2]$ (M = Mo or W; X = Cl, Br or I; L = neutral donor ligands) have been prepared,[3–11] very few analogous halotin compounds such as $[MX(SnX_3)(CO)_3L_2]$ have been reported.[12–14] Very recently we have described the preparation of the reactive seven-coordinate halotin complex, $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$, from reaction of the zero-valent complex $[Mo(CO)_3(NCMe)_3]$ *in situ* with an equimolar quantity of $SnCl_4$.[15]

In this paper we wish to describe the reactions of $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ with 1 equivalent of monodentate neutral donor ligand (L) to rapidly give the chloro-bridged complexes $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$. The bridge cleavage reactions of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ are also described herein.

EXPERIMENTAL

All reactions described in this paper were carried out under an atmosphere of dry nitrogen using standard Schlenk line techniques.

The complex $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ was prepared by the published method.[15] $[Mo(CO)_6]$ was generously donated by Amax Speciality Metals U.K. Ltd. All other chemicals were purchased from commercial sources.

Elemental analyses for carbon, hydrogen and nitrogen were recorded on a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer. Magnetic susceptibilities of the complexes were measured on a Johnson-Matthey Magnetic Susceptibility balance. The molecular weight of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(py)]_2$ (**4**) was determined by Rast's method[16] using camphor as the solvent.

$[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ (**1**)

To $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ (4.03 g, 7.7 mmol) dissolved in acetone (50 cm^3) with continuous stirring under a stream of dry nitrogen, was added PPh_3 (2.02 g, 7.7 mmol). After stirring for 30 s, filtration and removal of the solvent *in vacuo* gave light brown crystals of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ (**1**) (yield = 5.31 g, 98%), which were recrystallized from acetone.

Similar reactions of $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ with 1 equivalent of L [L = $AsPh_3$, $SbPh_3$, py, 3Br—py, 4Br—py and $P(OPh)_3$] in ace-

tone at room temperature after stirring for 30 s, afforded the analogous chloro-bridged complexes $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ (**2–7**) (see Table 1 for colour and yields). Molecular weight determination for $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(py)]_2$: Found: 872, Calc: 1039.

Reaction of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ *with 2 equivalents of* PPh_3

To $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ (0.70 g, 0.5 mmol) dissolved in acetone (15 cm^3) with continuous stirring under a stream of dry nitrogen, was added PPh_3 (0.26 g, 1 mmol). After stirring for 30 min, filtration and removal of the solvent *in vacuo* gave bright yellow crystals of $[MoCl(SnCl_3)(CO)_3(PPh_3)]_2$ (**8**) (yield = 0.66 g, 69%), which were recrystallized from acetone.

Similar reactions of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ with 2 equivalents of L′ [L′ = $SbPh_3$, py and $P(OPh)_3$] gave $[MoCl(SnCl_3)(CO)_3(PPh_3)L]$ (**8–11**) (see Table 1 for colours and yields).

RESULTS AND DISCUSSION

Equimolar quantities of the bisacetonitrile complex $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ and L [L = PPh_3, $AsPh_3$, $SbPh_3$, py, 3Br—py, 4Br—py and $P(OPh)_3$] react in acetone at room temperature to give good yields of the new chloro-bridged dimers $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ (**1–7**). The triphenylphosphine dimer $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ (**1**) reacts with 2 equivalents of L′ [L′ = PPh_3, $SbPh_3$, py and $P(OPh)_3$] in acetone at room temperature, to give the symmetrical bridge-cleaved products $[MoCl(SnCl_3)(CO)_3LL']$ (**8–11**). The complexes, **1–11**, were characterized by elemental analysis (C, H and N) (Table 1) and IR spectroscopy (Table 2). All the complexes were found to be diamagnetic, which was expected since the complexes obey the effective atomic number rule. The dimers **1–7** are photosensitive and thermally unstable, however they can be stored in the dark under a nitrogen atmosphere at 0°C for several days. The monomeric complexes, **8–11**, are more stable than the dimers, but are still stored in Schlenk tubes under nitrogen. The complexes, **1–11**, are only slightly soluble in chlorinated solvents such as $CHCl_3$ or CH_2Cl_2, however they are much more soluble in acetone (see Experimental).

Reaction of $[MoCl(SnCl)_3(CO)_3(NCMe)_2]$ with 1 equivalent of L [L = PPh_3, $AsPh_3$, $SbPh_3$, py, 3Br—py, 4Br—py and $P(OPh)_3$] probably initially affords the monoacetonitrile complexes $[MoCl(SnCl_3)(CO)_3(NCMe)L]$. Several attempts

[a] Spectra recorded as $CHCl_3$ thin films between NaCl plates.

were made to isolate these monoacetonitrile intermediates by rapid work-up procedures without success. Evidence to support the initial formation of these monoacetonitrile intermediates comes from related work we have carried out on the related diiodo system $[MI_2(CO)_3(NCMe)_2]$ (M = Mo and W). The complexes $[MI_2(CO)_3(NCMe)_2]$, react with 1 equivalent of L [L = PPh_3, $AsPh_3$, $SbPh_3$, PPh_2Cy and $P(OPh)_3$] in CH_2Cl_2 to give the monoacetonitrile complexes $[MI_2(CO)_3(NCMe)L]$, which were isolated and fully characterized.[17] The apparent greater ease of dimerization of $[MoCl(SnCl_3)(CO)_3(NCMe)L]$ compared to the diiodo analogues, may be due to the steric bulk of the $SnCl_3$ group. Seven-coordinate complexes of molybdenum(II) and tungsten(II) are highly crowded and coordinatively saturated, hence it is highly likely that the substitution reactions go via a dissociative mechanism. Hence, the bulky $SnCl_3$ group attached to the metal should facilitate easy loss of acetonitrile from $[MoCl(SnCl_3)(CO)_3(NCMe)L]$ to give the dimers $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$. The dimeric nature of the complexes $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ was confirmed by molecular weight measurements on $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(py)]_2$ (**4**) by Rast's method[16] (see Experimental).

It is highly likely that the dimeric complexes, **1**–**7**, are bridged via the chloride ion rather than the $SnCl_3$ group, since $SnCl_3$ does not possess a dative lone pair on the tin (apart from the attached chlorine atoms) to coordinate to the other molybdenum atom. It is improbable that chloride groups on the tin bridge, since there are no precedents for this type of behaviour. Several attempts were made to grow a single crystal for X-ray crystallography of the dimers $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ (**1**–**7**), but due to the instability of these complexes no success was achieved. However, since the structure of the bromide-bridged dimer $[W(\mu\text{-}Br)Br(CO)_4]_2$ shows the two tungsten atoms to be in capped octahedral environments,[18] it is highly likely that these $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3L]_2$ (**1**–**7**) complexes have this type of geometry.

Symmetric cleavage of the chloride bridges in the complexes $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(PPh_3)]_2$ (**1**), by L′ to give monomeric seven-coordinate complexes of the type $[MoCl(SnCl_3)(CO)_3(PPh_3)L']$, are similar to the symmetric bridge cleavage reactions carried out on the octacarbonyl halo-bridged dimers of the type $[M(\mu\text{-}X)X(CO)_4]_2$ (M = Mo or W; X = Cl, Br or I) described by Colton and his coworkers.[19] Since the IR spectra of the compounds $[MoCl(SnCl_3)(CO)_3(PPh_3)L']$ (**8**–**11**) show three carbonyl stretching bands (Table 2) with a similar pattern to analogous dihalo complexes of the type $[MX_2(CO)_3L_2]$ which have been shown to have capped octahedral geometry by X-ray crystallography,[20–28] it is likely that complexes **8**–**11** have this geometry.

Acknowledgements—We wish to thank Amax Speciality Metals Ltd for their generous gift of $[Mo(CO)_6]$, and we thank Mr A. Quinlan for measuring the molecular weight of $[Mo(\mu\text{-}Cl)(SnCl_3)(CO)_3(py)]_2$ by Rast's method.

Abstract—Studies of nine (α-diimine)Mo(CO)$_4$ complexes demonstrate the importance of metal-to-ligand charge-transfer contributions for the chemical shift in ^{95}Mo NMR spectroscopy. The $\delta(^{95}Mo)$ values, which occur in the range −847 to −1164 ppm, correlate with the calculated LUMO coefficients c_N^2 at the coordinating (chelate) nitrogen centres, with the McLachlan π-spin populations ρ_N^{ML} and with ESR coupling constants $a(^{14}N)$ of the anion radical complexes.

^{95}Mo NMR spectroscopy has already proven to be a very valuable tool for various areas of molybdenum chemistry[1,2] with the shift scale for this nucleus ($I = 5/2$, 15.7% natural abundance) encompassing more than 7000 ppm. There are usually relatively narrow lines [$Q = -0.015(4)\ 10^{-28}$ m^2] observed with coordination complexes, so that a number of structural and electronic effects can be studied by this method; e.g. long range electronic interactions,[3–5] stereochemistry in chiral complexes,[6] or chelate ring size contributions.[7] Chemical shift and coupling constant data are now available for an extensive range of substituted molybdenum carbonyl complexes.[1,8]

In order to gain an even more detailed understanding as to what factors influence the ^{95}Mo NMR chemical shift, we have now studied isostructural complexes between the Mo(CO)$_4$ fragment and a number of α-diimine chelate ligands, whose characteristics in terms of calculated molecular orbital and various related experimental data are well established.[9–17] Particularly interesting is the series of four isomeric bidiazine complexes complexes which have already allowed some insight into the mechanisms and consequences of charge-transfer interactions in coordination compounds.[9,11,17]

RESULTS AND DISCUSSION

The structures of the ligands employed are shown in Fig. 1: bpdz = 3,3′-bipyridazine, bpm = 4,4′-bipyrimidine, bpz = 2,2′-bipyrazine, bpym = 2,2′-bipyrimidine, abpy = 2,2′-azobipyridine, bptz = 3,6-bis(2′-pyridyl)-1,2,4,5-tetrazine. Spectroscopic results and relevant data for the ligands are summarized in Table 1, with the $\delta(^{95}Mo)$ data for the 2,2′-bipyridine (bpy) complex being taken from ref. 7. Starting with the most revealing comparison of the four isomeric bidiazine systems, these complexes exhibit a familiar pattern:[9] while the two mononuclear bipyrimidine compounds show spectra very similar to that of the bpy system, the two other complexes display a distinct low field shift and a detectable narrowing of the absorption signal. This result clearly rules out the ligand field strength as being solely responsible for the chemical shift. The HOMO–LUMO difference follows the order bpm < bpdz ~ bpz < bpym, as experimentally[9] indicated by metal-to-ligand (d–π^*) charge-transfer (MLCT) absorptions and by the respective differ-

† Authors to whom correspondence should be addressed.

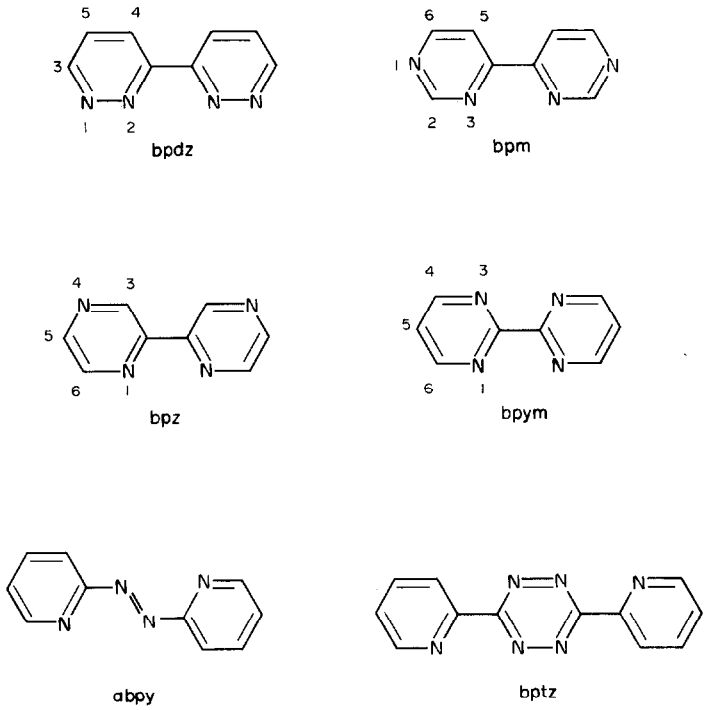

Fig. 1.

ences between the oxidation and reduction potentials. The observed $\delta(^{95}Mo)$ values also do not directly parallel the changes in the ground state basicity K_b of the ligand (bpz < bpm < bpym < bpdz),[9,16] which in any case is not expected to dominate the magnitude of the chemical shift.[1,8]

Instead, this observed pattern correlates with the calculated LUMO coefficients c_N^2 at the coordinating (chelate) nitrogen centres,[9] with the McLachlan π-spin populations ρ_N^{ML} and ^{14}N ESR coupling constants, a, of the anion radical complexes.[13] Although the $^{95,97}Mo$ coupling constants in the anion radicals could be observed in but a few cases, because of the low natural abundance of these isotopes (^{97}Mo: $I = 5/2$, 9.6%),[13-15] it may be safely assumed on the basis of the direct cor-

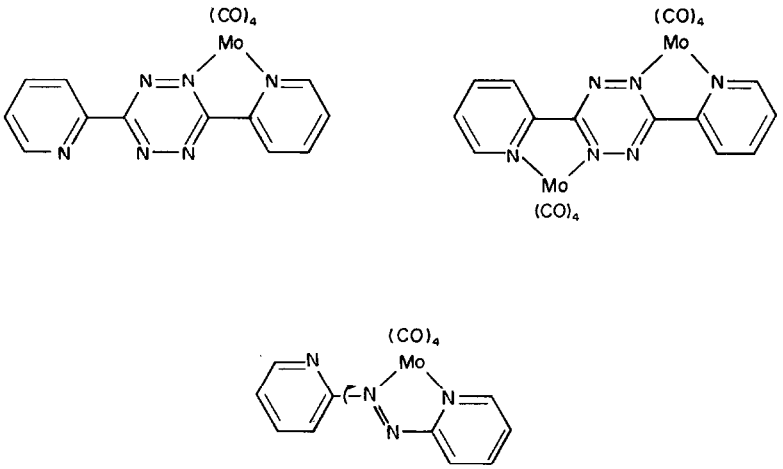

Fig. 2.

relation between $a(^{14}N)$ and $a(^{95,97}Mo)$[14] that the chemical shift correlates with the coupling constant of the metal in the singly reduced complex (see Table 1).

This relation also holds for complexes of the other two ligands, abpy and bptz (see Fig. 2). Large c_N^2, ρ_N^{ML} and $a(^{14}N)$ values for the coordinating azo nitrogen centres[10,14,15] correlate qualitatively with more deshielded values of $\delta(^{95}Mo)$. The value for the mononuclear abpy complex is a little more shielded than that for the bptz system, since the former cannot adopt a coplanar conformation,[10,18] thereby reducing the π-interaction as is also evident from a cathodically shifted reduction potential.[10] A double metal–ligand interaction in the binuclear bptz complex results in a further low field shift for the metals, in agreement with a strongly lowered LUMO, facilitated reduction and a very low-lying metal-to-ligand charge-transfer (MLCT) transition.[10] In the bpym series, on the other hand, the second coordination of $Mo(CO)_4$ does not cause a detectable shift in $\delta(^{95}Mo)$ (Table 1); bpym is a ligand with relatively poor π-acceptor capability.[9,10]

The line width $\Delta\nu_{1/2}$ seems to relate to the nearness of the second nitrogen atom to the coordinated nitrogen centre, the complex with the α-iminoazo ligand abpy, exhibiting a very low value of only 4 Hz. The narrowness of this line is surprising when compared to other *cis*-$Mo(CO)_4L_2$ values,[1,8] especially since the bite angle in $Mo(CO)_4$(abpy) (70.9°) is even less than that in α-diimine complexes (72.8°).[22] This lowering of the electric field gradient at the molybdenum nucleus is enhanced by the proximity of the second nitrogen atom and is consistent with the greater charge delocalization, but such a correlation with the line width must remain tentative.

CONCLUSION

The results obtained in this study of qualitatively isostructural $Mo(CO)_4$ complexes illustrate the significance of charge-transfer interactions for the ^{95}Mo NMR chemical shift. The factors affecting the magnitude of $\delta(^{95}Mo)$ are normally discussed with reference to a modified Ramsey expression for the paramagnetic term[1,8] that includes spectrochemical (ΔE) and nephelauxetic ($k'\langle r^{-3}\rangle$) factors. In the present case, neither the ground-state basicities of the ligands nor the MLCT absorption energies of the complexes properly account for the observed trends of $\delta(^{95}Mo)$; it is the amount of charge transferred from the low valent metal to the π-accepting ligand via the N(chelate) coordination centres which correlates with the chemical shift of the metal. This study has thus shown a correlation of NMR chemical shift data with ESR coupling constants in the singly reduced complexes,[23] an observation which may be of significance for other metal complexes as well.[24]

EXPERIMENTAL

Preparation of the ligands and complexes has been described previously.[9,10,15]

The ^{95}Mo NMR spectra were recorded at 26.08 MHz frequency on a Bruker WH 400 spectrometer at Guelph, using 10 mm sample tubes and dichloromethane solutions at ambient temperatures and with aq. 2 M K_2MoO_4 at pH 11 as external standard. The pulse width was normally 47 μs for the 90° pulse, with the resolution being better than 13 Hz per point.

ADDUCT FORMATION BY NICKEL(II) COMPLEXES OF S-METHYL HYDRAZINE CARBODITHIOATE SCHIFF BASES WITH 2,2′-BIPYRIDYL AND 1,10-PHENANTHROLINE

ALY M. A. HASSAAN,* EZZAT M. SOLIMAN and AHMED M. EL-ROUDI

Chemistry Department, Faculty of Science, Minia University, Minia, Egypt

(*Received* 11 *April* 1988; *accepted after revision* 8 *November* 1988)

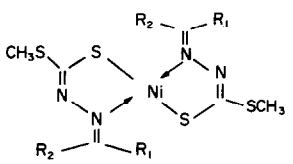
Abstract—The base-adducts of nickel(II) complexes of S-methyl hydrazine carbodithioate Schiff bases with 2,2′-bipyridyl and 1,10-phenanthroline are prepared and isolated in benzene and acetonitrile, and analysed. Structures are suggested on the basis of IR and electronic spectra. Adduct formation with 2,2′-bipyridyl has been studied in a dichloroethane solution, spectrophotometrically. The results obtained suggest the formation of the *cis*-octahedral monoadduct.

Schiff bases derived via the condensation of S-methyl hydrazine carbodithioate with some ketones and aromatic aldehydes were found to behave as monobasic bidentate ligands, giving bis-neutral complexes with the nickel(II) salt (**1**).[1] It was deduced that these complexes possess a square-planar structure with the basic coordination unit NiN_2S_2. The square-planar arrangement around nickel(II), as well as its coordinative unsaturation, make these complexes good Lewis acids.[1,2] These chelates were found to form different base-adducts with Lewis bases depending on the substituents (R_1 and R_2).[1,3]

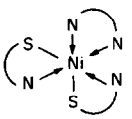
In the present work, base-adducts of nickel(II) chelates of the type (**1**) with 2,2′-bipyridyl and 1,10-phenanthroline have been isolated as solids in benzene and acetonitrile and their structures studied. In solution, adduct formation with 2,2′-bipyridyl has been studied in dichloroethane. Attention has been focused on the effect of both the solvents used and the substituents on the base-adduct formation.

RESULTS AND DISCUSSION

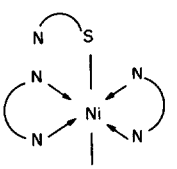
Reactions of neutral diamagnetic square-planar nickel(II) chelates of the type (**1**) ($R_1 = H$, $R_2 = C_6H_5$, *p*-BrC_6H_4 and *p*-$NO_2C_6H_4$) with 2,2′-bipyridyl or 1,10-phenanthroline, in benzene yield the corresponding crystalline solid bis-adducts (**3**) independent of the nickel chelate–base molar ratio. In the case of (**1**) ($R_1 = H$, R_2 = *p*-$OCH_3C_6H_4$ and *p*-$CH_3C_6H_4$), reaction with 2,2′-bipyridyl in benzene gives rise to mono- and bis-base-adducts (**2** and **3**, respectively) depending on the nickel chelate–base molar ratio. This disparity may be ascribed to the ability of *p*-Br, *p*-NO_2 and unsubstituted chelate derivatives to accept two molecules of bidentate Lewis base, due to their electron withdrawing substituent effects which can lead to rupture of the Ni ← N bond. Therefore, the N-arylidene S-methyl hydrazine carbodithioate acts as a monodentate ligand (Structure **3**). However, in the case of the electron releasing groups (CH_3, OCH_3), the Ni ← N bond is much stronger and resists the bond rupture.



(**1**)



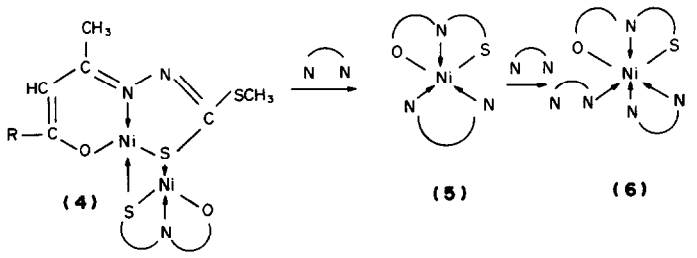
(**2**)



(**3**)

Reaction of (**1**) ($R_1 = CH_3$, $R_2 = CH_3$) with 1,10-phenanthroline in benzene yields bis-adducts

* Author to whom correspondence should be addressed.



(4) (5) (6)

(3) whether the nickel chelate–base molar ratio used is either 1 : 1 or 1 : 2, whereas reaction of this chelate with 2,2′-bipyridyl in benzene yields mono- and bis-adducts (**2** and **3**, respectively) depending on the molar ratio used. Such disparity in behaviour may be attributed to the high reactivity of 1,10-phenanthroline compared to 2,2′-bipyridyl.

Reaction of a dimeric molecule of the nickel(II) chelate of the S-methyl hydrazine carbodithioate Schiff base of acetyl and benzoyl acetone (**4**; R = CH_3 and C_6H_5, respectively) with 2,2′-bipyridyl in benzene, affords only the bis-adduct (**6**). This reaction is found experimentally to be independent of the chelate–base molar ratio used. The same reaction in acetonitrile gives only the mono-adduct (**5**) whatever the molar ratio used. An attempt to prepare the bis-adduct in acetonitrile was unsuccessful. This implies that acetonitrile retards the addition reaction of 2,2′-bipyridyl to these chelates, while benzene leads to the reverse situation. The bis-adduct of these chelates is only obtained in acetonitrile in the case of the reaction with the more reactive 1,10-phenanthroline. The bis-adduct molecule (**6**) may be suggested to contain two molecules of bidentate Lewis base, but one of them acts as a unidentate ligand. The different isolated base-adducts, together with their elemental analysis results, are listed in Table 1.

IR spectra

The mesomeric effect of the carbodithioate group adjacent to a nitrogen atom will give rise to a band due to (C=N), namely the thioureide band.[4] S-methyl hydrazine carbodithioate shows such an absorption at 1520 cm^{-1}. This band appears at 1510 cm^{-1} in the spectra of (**1**) $R_1 = CH_3$, $R_2 = CH_3$ and at 1490 cm^{-1} in the spectra of (**1**) $R_1 = H$, $R_2 = C_6H_5$, *para*-substituted C_6H_4 complexes. This band is found to shift to a lower frequency of 1480 cm^{-1} with splitting, in the corresponding base-adducts of 2,2′-bipyridyl or 1,10-phenanthroline with (**1**) $R_1 = CH_3$, $R_2 = CH_3$ and to 1440 cm^{-1} for the corresponding base-adducts with (**1**) $R_1 = H$, $R_2 = C_6H_5$, *para*-substituted C_6H_4. This may be attributed to the rearrangement of the in-plane ligand as a result of *cis*-octahedral formation. The band at 1600 cm^{-1} may be assigned to the azomethine group, C=N. This band is not shifted in the base-adducts, but its intensity is increased with splitting. This may be assigned to a contribution to the C=N stretching from the 2,2′-bipyridyl or 1,10-phenanthroline.

Electronic spectra

The electronic spectra of the isolated solid base-adducts of (**1**) ($R_1 = H$, $R_2 = C_6H_5$, *para*-substituted C_6H_4 and $R_1 = CH_3$, $R_2 = CH_3$) with 2,2′-bipyridyl and 1,10-phenanthroline recorded in the solid state as Nujol mulls are consistent with an octahedral coordination geometry. The spectra exhibit one broad band in the vicinity of 15,000–20,000 cm^{-1} due to the ν_2-transition, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ in an octahedral configuration. However, the appearance of a high intensity band in the region 23,000–28,000 cm^{-1} in the electronic spectra of the above base-adducts may be argued to be due to a charge-transfer transition rather than an $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transition.[5] The ν_1-transition, $^3A_{2g} \rightarrow {}^3T_{2g}(F)$, lies outside the range of the spectrophotometer used.

In an attempt to study the base-adduct formation by means of spectrophotometric titration,[6] it was found that the addition of 2,2′-bipyridyl to a dichloroethane solution of (**1**) ($R_1 = H$, $R_2 = p$-$CH_3C_6H_4$, p-$OCH_3C_6H_4$, C_6H_5 and p-$NO_2C_6H_4$) results in profound spectral changes (Fig. 1). The spectrophotometric results obtained suggest that the reaction of the above chelates with 2,2′-bipyridyl in dichloroethane affords the hexacoordinate monoadduct (**2**). The values of $\log K$ measured at 25°C ± 0.1 are 3.3, 4.0, 4.3 and 6.1, respectively. These values of $\log K$ have been found to be slightly greater than those measured in benzene.[7]

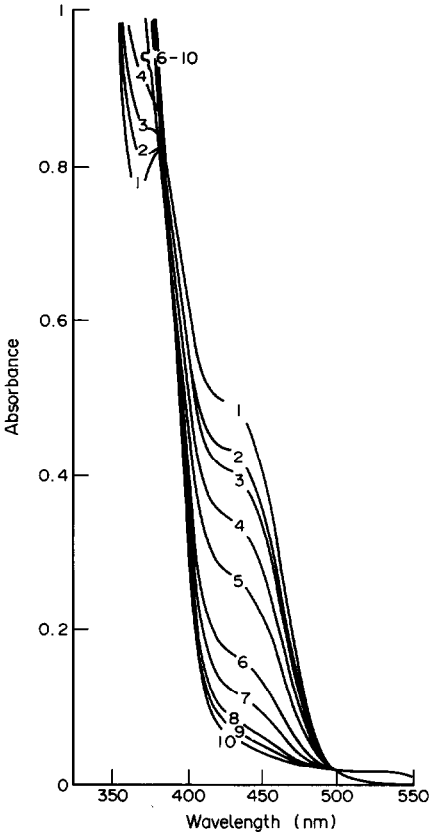

Fig. 1.

EXPERIMENTAL

Different molar ratios of 2,2′-bipyridyl or 1,10-phenanthroline were reacted with nickel(II) chelates of S-methyl hydrazine carbodithioate Schiff bases in benzene and acetonitrile to obtain the corresponding isolated solid base-adducts. The nickel content was determined gravimetrically. Electronic spectra and spectrophotometric titrations were recorded using a Spectronic 2000 spectrophotometer. A Shimazu 408 spectrophotometer was used for recording the KBr IR spectra.

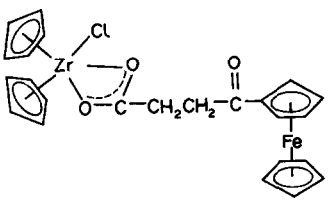
(*Received* 21 *April* 1988; *accepted after revision* 8 *November* 1988)

Abstract—Bis(η^5-cyclopentadienyl)chloro(4-oxoferrocenebutanoyloxy)zirconium(IV), η^5-$Cp_2ZrCl(OCOCH_2CH_2COFc)$ ($Cp = C_5H_5$, $Fc = C_5H_5FeC_5H_4$), has been synthesized by reaction of zirconocene dichloride with sodium 4-oxoferrocenebutanoate and has been characterized by elemental analysis, PMR and IR spectroscopy. The X-ray crystal structure of the title complex was determined using 2593 independent reflections with $I > 3\sigma(I)$. The complex crystallizes in the monoclinic space group $P2_1/c$ with four monomeric molecules in a cell of dimensions $a = 11.952(6)$, $b = 13.104(3)$, $c = 14.547(3)$ Å, $\beta = 108.2(3)°$, $V = 2164.5$ Å^3, $D_{calc} = 1.666$ g cm^{-3} and $\mu(K_\alpha) = 12.912$ cm^{-1}. The structure has been solved by direct methods and refined by Fourier and full-matrix least-squares methods to a conventional $R = 0.0465$. The carboxyl group in this complex is a bidentate ligand and the atoms, Zr, Cl, O(2), O(3), C(4) and C(3) lie in a quasi-mirror plane.

The chemistry, electronic structures and molecular geometries of bis(η^5-cyclopentadienyl) transition metal complexes, η^5-Cp_2ML_n have been widely studied.[1–8] A large number of metallocene derivatives of group IVB elements are 16-electron complexes with additional ligands.[9] But a small number of five-, six- and seven-coordinate complexes of zirconium(IV) have also been prepared.[7,8,10–13] The structure of some of the five-coordinate complexes, η^5-Cp_2ZrL_3, that contain chelating ligands has been determined by X-ray diffraction,[7,8,14,15] but the crystal and molecular structures of those complexes containing carboxyl ligands have not been studied so far. In this paper, a new five-coordinate, 18-electron complex of zirconium containing a carboxyl group (I) has been synthesized and the molecular geometry established by X-ray crystallography.



(I)

EXPERIMENTAL

Preparation of (I)

This complex was prepared by reaction of equimolar amounts of η^5-Cp_2ZrCl_2 and $FcCOCH_2CH_2COONa$ in anhydrous benzene under argon. The $FcCOCH_2CH_2COONa$ was obtained by the method described in the literature.[16] Recrystallization from a benzene–hexane solvent afforded orange crystals. Found: C, 53.7; H, 4.3; Cl, 7.1. Calc. for $C_{24}H_{23}ClFeO_3Zr$: C, 53.2; H, 4.3; Cl,

Crystal structure determination

Several clear, orange cubic crystals of dimensions $0.4 \times 0.25 \times 0.20$ mm, which were obtained by slow crystallization from benzene–hexane, were selected for the X-ray diffraction analysis. The data were collected on an Enraf–Nonius CAD-4 automatic four-circle diffractometer with graphite monochromated Mo-K_α radiation ($\bar{\lambda} = 0.71073$ Å), using the ω–2θ scan technique in the range $4° < 2\theta < 54°$ at *ca* 293 K. Three standard reflections were monitored every 3600 s to check both crystal and apparatus stability. The intensity data were converted to structure factor amplitudes by corrections for Lorentz, polarization and absorption effects. Of the 4897 independent reflections measured, 2593 reflections had net intensities I greater than $3\sigma(I)$ and were used in the subsequent analysis. The cell constants and other crystal data are shown in Table 1.

The structure was solved by direct methods and Fourier techniques. The 30 non-hydrogen atoms were refined by block-diagonal-matrix least-squares techniques using anisotropic thermal parameters. A difference Fourier synthesis revealed the positions of all the hydrogen atoms. These were assigned a fixed isotropic thermal parameter in the final refinement by full-matrix least-squares techniques. The discrepancy indices $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ ($w = 1/\sigma^2$) were 0.046 and 0.053, respectively. In the final cycle, the parameter shift converged almost to zero, except for those of hydrogen atoms which were less than the corresponding standard deviations. A final difference Fourier map showed no extra peaks.*

* Supplementary material available: a listing of structure factors and anisotropic thermal parameters (25 pages) has been deposited with the Editor at Queen Mary College and also with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The geometry of the molecule and the atom numbering scheme for η^5-$Cp_2ZrCl(OCOCH_2CH_2COFc)$ are shown in Fig. 1. The bond distances and bond angles are given in Table 2. The results of selected mean plane calculations are summarized in Table 3 and selected dihedral angles are listed in Table 4.

In this complex, the zirconium atom attaches to each carbon atom of two cyclopentadienyl rings, to the chlorine atom and two oxygen atoms of the 4-oxoferrocenebutanoyloxy group. Due to the crowding in the coordination group, the Zr—Cl bond length, 2.518(1) Å, is significantly longer

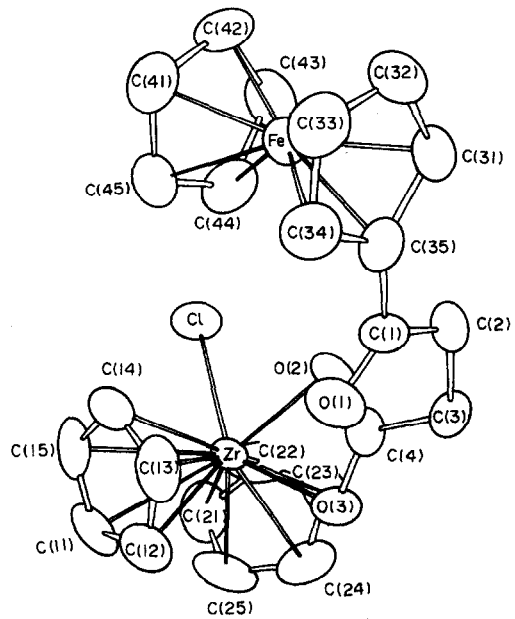

Fig. 1. A perspective drawing of the $Cp_2ZrCl(OCOCH_2CH_2COFc)$ molecule. Each atom is represented by an ellipsoid consistent with the thermal parameters.

C_1—C_2—C_3	113.0(5)		

Numbers in parentheses are estimated standard deviations in the last significant figure.

than the distance of 2.441 Å in η^5-Cp_2ZrCl_2.[5] The Zr—O(2) and Zr—O(3) bond lengths 2.248(3) Å and 2.287 Å, respectively, are longer than the Zr—O bond length in eight-coordinate $Zr[SOCN(C_2H_5)_2]_4$ (2.190 Å),[17] $[Zr(C_2O_4)_4]^{4-}$ (2.199 Å)[18] and $Zr(acac)_4$ (2.198 Å).[19] They are also much longer than Zr—O distances in the four-coordinate oxo-bridged dimeric complexes, $[\eta^5$-$Cp_2ZrCl]_2O$ (1.94 Å)[20] and $[\eta^5$-$Cp_2Zr(SC_6H_5)]_2O$ (1.968 Å).[21] The Zr—O(2) and Zr—O(3) bond lengths are equal to those in η^5-$Cp_2ZrCl[SOCN(CH_3)_2]$ (2.249 Å) and η^5-$Cp_2Zr(COCH_3)(CH_3)$ (2.290 Å),[22] respectively. The bond lengths of O(2)—C(4) and O(3)—C(4), which are almost equal (1.280 and 1.253 Å, respectively). are longer than the normal C=O distance (1.22 Å) and shorter than the C—O distance (1.43 Å). The C(1)—C(35) bond length, 1.473 Å, is shorter than standard C—C single bond (1.54 Å). It is shown that the double bond between C(1) and O(1) has been conjugated with the cyclopentadienyl ring in ferrocene.

The four molecules per unit cell occupy general positions of the space group $P2_1/c$ and are not required to have any symmetry. It can be seen from

Plane 6	C_{31}, 0.033; C_{32}, −0.029; C_{33}, −0.043; C_{34}, 0.021; C_{35}, 0.064; C_1, 0.016; C_2, −0.039; O_1, −0.023

Table 3 that the dihedral angle between two cyclopentadienyl ligands in the ferrocenyl group equals 2.9°, that is to say, planes 4 and 5 are parallel. It should be pointed out that the Fe—C(35) distance is the shortest in all of Fe—C bonds in the ferrocenyl group. The dihedral angles between planes 1 and 3, and 2 and 3 are 23.1 and 30.4°, respectively, and the sum of the two dihedral angles is 53.5°, which equals the dihedral angle between planes 1 and 2. It is shown that plane 3 inserts between planes 1 and 2.

The ferrocenyl group bends towards the zirconocenyl group and the chlorine atom is close to the iron atom. The Cl—Zr—O(3) bond angle (134.2°) is 37° larger than the Cl—Cr—Cl bond angle in η^5-Cp_2ZrCl_2,[5] but is 3° and 4° smaller than the Cl—Zr—S(2) (137.5°) in η^5-$Cp_2ZrCl[S_2CN(C_2H_5)_2]$ and Cl—Zr—O (138.1°) in η^5-$Cp_2ZrCl[SOCN(CH_3)_2]$, respectively. The average distances between the zirconium and the carbon atoms of the two cyclopentadienyl rings is equal to that in η^5-Cp_2ZrCl_2. The Cl···O(2) distance (2.982 Å) is 0.22 Å less than the sum of the van der Waals radii (3.20 Å).[23] Specifically, the O(2)···O(3) contact (2.166 Å) is 0.64 Å less than the van der Waals contact (2.80 Å). The C(3)—C(4) bond length, 1.495 Å, is shorter than that of normal C—C single bond. It can be seen from the above that the arrangement of atoms or coordination groups in this molecule is suitable and more crowded.

PREPARATION AND X-RAY CRYSTAL STRUCTURE OF BIS(1,8-NAPHTHYRIDINE-N-MONOXIDE)COPPER(II) NITRATE

GAN XINMIN, TANG NING, WANG XIN, ZHU YIN and TAN MINYU*

Department of Chemistry, Lanzhou University, Lanzhou, P.R.C.

(*Received* 24 *May* 1988; *accepted after revision* 8 *November* 1988)

Abstract—The title compound $Cu(napyo)_2(NO_3)_2$ was formed by the reaction of copper(II) nitrate with 1,8-naphthyridine-N-monoxide (napyo) in methanol. The complex crystallizes in the monoclinic space group $P2_1/n$ with $Z = 2$, $a = 7.768(2)$, $b = 13.976(2)$, $c = 9.045(3)$ Å, $\beta = 113.12(3)°$. The structure was determined from 1579 observed reflections and refined to $R = 0.035$. The copper atoms show a tetragonally distorted octahedral configuration, being bonded to two oxygen atoms (Cu—O, 1.951 Å) and two nitrogen atoms (Cu—N, 1.963 Å) of the two napyo ligands and to two oxygen atoms (Cu—O, 2.410 Å) of two nitrate groups.

A number of copper complexes with some aromatic amine N-oxides have been investigated,[1] but the copper complex with 1,8-naphthyridine-N-monoxide (napyo), which belongs to this kind of aromatic amine N—oxide, has never been reported. We recently synthesized this compound and determined its crystal and molecular structure.

EXPERIMENTAL

Preparation of $Cu(napyo)_2(NO_3)_2$

Copper nitrate hexahydrate (0.030 g, 0.1 mmol) and napyo[2] (0.029 g, 0.2 mmol) were dissolved in methanol (40 cm^3). The solution was placed in a desiccator with $CaCl_2$ at room temperature. After about 2 weeks dark blue needle-like crystals of the title compound were obtained. Found: C, 39.7; H, 2.9; N, 17.1; Cu, 13.1. Calc. for $C_{16}H_{12}CuN_6O_8$: C, 40.1; H, 2.5; N, 17.5; Cu, 13.2%.

Crystal structure determination of $Cu(napyo)_2(NO_3)_2$

Crystal data. $C_{16}H_{12}CuN_6O_8$, $M = 479.85$, monoclinic, space group $P2_1/n$, $a = 7.768(2)$, $b = 13.976(2)$, $c = 9.045(3)$ Å, $\beta = 113.12(3)°$. $V = 903.3$ $Å^3$, $Z = 2$, $D_c = 1.764$ g cm^{-3}, D_o (flotation in CCl_4/CH_2I_2) = 1.756 g cm^{-3}, λ(Mo-K_α) = 0.7109 Å, $\mu = 12.7$ cm^{-1}, $F(000) = 486$.

A single crystal of dimensions $0.2 \times 0.2 \times 0.4$ mm was selected for the data collection on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation, ω–2θ scan. 2183 reflections were collected in the range of $2° \leqslant 2\theta \leqslant 52°$, 1579 reflections with $I \geqslant 3\sigma(I)$ were used in the structure determination and refinement. Lorentz polarization and absorption correction were applied. The structure was solved by direct method and Fourier techniques, refined by full-matrix least-squares with anisotropic temperature parameters for all non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. Final $R = 0.035$, $R_w = 0.045$.

RESULTS AND DISCUSSION

Selected bond lengths and bond angles are given in Tables 1 and 2. Figure 1 shows the structure of the complex molecule and Fig. 2 shows the molecular packing arrangement in the unit cell. Final atomic coordinates, anisotropic thermal

parameters and lists of F_o/F_c values have been deposited with the Editor as supplementary material.

It can be seen from Fig. 1 that the copper atom is located on the inversion centre of the complex molecule and is bonded to two oxygen atoms (Cu—O, 1.951 Å) and two nitrogen atoms (Cu—N(2), 1.963 Å) of two napyo ligands and to two oxygen atoms (Cu—O(1), 2.410 Å) of two unidentate nitrate groups. The latter two distances are much greater than the other four and this phenomenon doubtlessly results from the Jahn–Teller effect of the Cu^{2+} ion with a d^9 electronic configuration. So the coordination configuration of the copper atom is a lengthened octahedron.

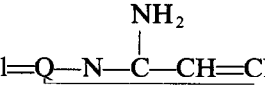
(*Received* 16 *May* 1988; *accepted after revision* 8 *November* 1988)

Abstract—The 3-aminoisoxazole (3-AI) copper(II) complexes, Cu(3-AI)$_n$X$_2$ · mH$_2$O (where $n = 2$, X = Cl, Br, NO$_3$, $m = 0$; $n = 4$, X = ClO$_4$, $m = 1$) have been synthesized and their IR, electronic and ESR spectral properties have been studied to obtain stereochemical information of these complexes both in solid and solution states. The metal appears to be four-coordinate in the bis-complexes and hexa-coordinate in the case of the tetrakis-complex. In DMF (N,N′-dimethylformamide) solutions two species are found to form, unlike in the solutions of pyridine.

From our previous IR, ESR and electronic spectral studies on isoxazolamine derivatives with metal ions, it was found that there is a competition between N_{ring}, O_{ring} and N of the exocyclic amino group atom, depending on the aminic and methylic group positions and the nature of the metal ion.[1–6] It was also found that some of the above copper(II) complexes possess fluxional geometry.[7] In view of the above important observations, we have synthesized and extended the studies to the polycrystalline and solute specimens of copper(II) complexes of unmethylated 3-aminoisoxazole



(3-Al=O—N—C—CH=CH), using the above three techniques to obtain information on the stereochemistry and solute–solvent interactions. The complex chosen for the present work has the general formula, Cu(3-AI)$_n$X$_2$ · mH$_2$O where $n = 2$ and $m = 0$ when X = Cl, Br, NO$_3$ and $n = 4$ and $m = 1$ when X = ClO$_4$.

EXPERIMENTAL

Materials

3-AI, CuCl$_2$ · 2H$_2$O, Cu(NO$_3$)$_2$ · 3H$_2$O were commercially available. CuBr$_2$, Cu(ClO$_4$)$_2$ · 6H$_2$O were prepared using literature methods.

Preparation of the complexes

The complexes were prepared from the reaction of the methanolic solutions of the ligand and the metal salt in the required stoichiometrical ratio. The precipitation is promoted by adding isopropanol. The compounds were purified by means of repeated washing with isopropanol. The dried complexes are either crystalline or powder-like. Nitrogen, carbon and hydrogen were analysed with a Perkin–Elmer 240 Elemental Analyser.

Physical measurements

Physical measurements were carried out as described earlier.[8]

RESULTS AND DISCUSSION

IR and electronic spectral studies

The analytical data and physical properties of these complexes are reported in Table 1. Table 2 gives the principal IR bands of nitrate and perchlorate compounds along with their assignment. The far IR bands are listed in Table 3. In the compound $Cu(3\text{-}AI)_4(ClO_4)_2 \cdot H_2O$, the absorption bands at 3580 cm^{-1} ν(OH) and at 1620 cm^{-1} δ(HOH) and the loss of water at 110°C show the presence of water of crystallization. The molar conductivity values are typical of non-conducting compounds. In the solid state the perchlorate and nitrate derivatives exhibit IR bands indicative of unidentate groups.[1] The bands at 316 cm^{-1} are assigned to the ν(Cu—$OClO_3$) stretching frequency and the bands at 306 cm^{-1} to the ν(Cu—ONO_2). The ν(Cu—X) band of the halide compounds is in good agreement with the terminal metal halide mode for square-planar stereochemistry.[9] The band present in these complexes in the 259–232 cm^{-1} range is attributed to ν(Cu—N_{ring}) vibrations. This confirms that 3-AI is monodentate N_{ring}-bonded. On the basis of reflectance spectra (Table 4), the $Cu(3\text{-}AI)_2X_2$ compounds have square-planar (CuN_2X_2) stereochemistry,[10] while the $Cu(3\text{-}AI)_4(ClO_4)_2 \cdot H_2O$ is distorted hexa-coordinate (CuN_4O_2).[11] On the other hand, in the bis-complexes of 3-AMI (3-amino-5methylisoxazole), this ligand acts as a bridging (N- and O-bonded) bidentate ligand and the complexes are found to be polymeric.[1] In the case of tetrakis-complexes of 3-AMI, this ligand acts as an N_{ring}-bonded monodentate ligand.

300 and 77 K and Q-band spectrum of Cu(3-AI)$_4$(ClO$_4$)$_2$·H$_2$O at 300 K respectively. In none of the present complexes, at both the above temperatures, are copper(II) hyperfine lines resolved at X-band, indicating strong dipolar and exchange interactions between copper(II) ions in the unit cell. The asymmetric ESR line obtained in perchlorate complex at X-band (Fig. 1) has been resolved partially at Q-band (Fig. 2), indicating that the order of exchange interaction among copper(II) ions is about 1 cm^{-1}. The principal g values are calculated using the procedure of Kneubuhl[12] and these values, along with the values of $G\{(g_3-2)/[(g_1+g_2/2)-2]\}$ and $R[(g_2-g_1)/(g_3-g_2)]$, are given in Table 4. From the value of G it is possible to know whether or not exchange coupling effects invalidate the use of observed g values to reflect the local copper(II) environment.[13] In the present studies, in all the complexes the G values lie between 3.5 and 5, which indicates that the influence of exchange effects to deviate the crystal g values from molecular g values is less. Hence, it appears that the magnetic misalignment of the molecules in the unit cell in all the complexes is not much.[13-16] In the nitrate and perchlorate complexes, since the chromophore around copper(II) has axial symmetry ($R = 0$) and $g_1 > 2.04$, the ground state of copper(II) is $d_{x^2-y^2}$. The rhombic g values and the values of R in the range 0.2–0.4 in the chloro and bromo complexes indicate that the ground state of copper(II) in the CuN_2X_2 entities is dominated by $d_{x^2-y^2}$ with a slight admixture of d_{z^2}. These g values are comparable to the values obtained in other N_{ring}-bonded copper(II) complexes of other heterocyclic ligands.[16-21] But before drawing conclusions on the slight temperature variations of the g values, one has to take into consideration the increased errors in the g values brought about by the broadening effects due to dipolar, exchange and unresolved hyperfine interactions.[13] Therefore these temperature variations in the g value may arise due to the fluxional

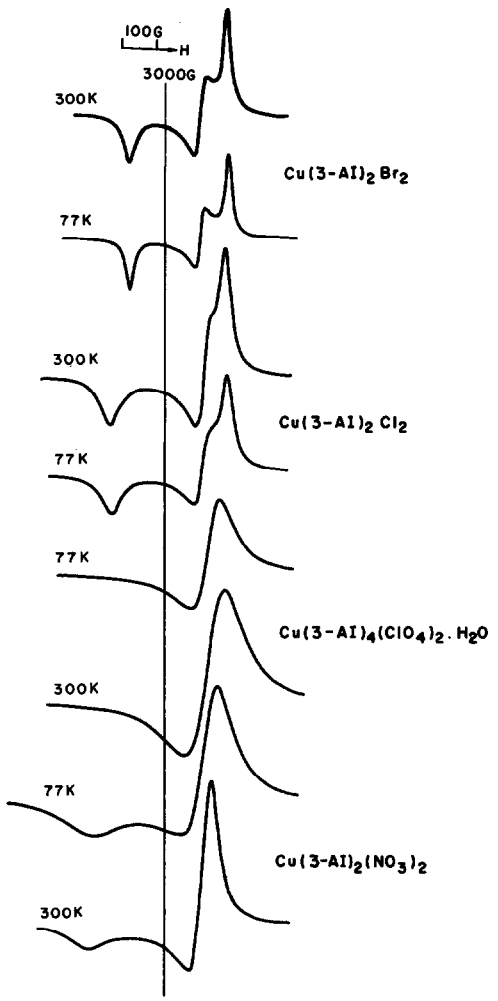

Fig. 1. ESR spectra of polycrystalline 3-AI copper(II) complexes of 9.07 GHz.

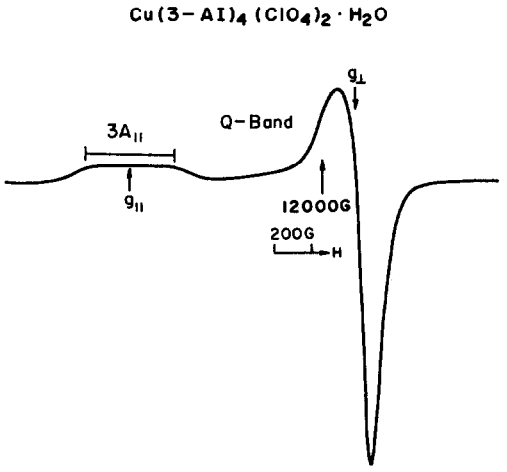

Fig. 2. ESR spectrum of polycrystalline $Cu(3\text{-AI})_4(ClO_4)_2 \cdot 2H_2O$ at 35.4 GHz.

nature of the geometries[22] or due to the inaccuracies in the g values induced by the above line broadening factors. A comparison of the g values of the bis-complexes of 3-AI and 3-AMI (Table 4) indicates that these values in the former complexes are more than in the latter complexes, which may arise probably due to the difference in the nature of coordination of 3-AI (monodentate N_{ring}-bonded) and 3-AMI (bridging bidentate) ligands. Since, in the case of the tetrakis-complex of 3-AI and 3-AMI, both the ligands are monodentate N_{ring}-bonded and hence g and A values of these complexes are comparable,[5] the difference in the symmetries (axial and rhombic) in the chromophores of $Cu(3\text{-AI})_4(ClO_4)_2 \cdot H_2O$ and $Cu(3\text{-AMI})_4(ClO_4)_2$ (Table 4) may arise most probably due to the fact that the former complex is hexa-coordinate (CuN_4O_2) and the latter one is penta-coordinate (CuN_4O).[1]

Solution spectra

Figures 3 and 4 show the ESR spectra in the frozen solutions of these complexes in DMF (dimethylformamide) and pyridine, respectively. Table 5 gives the g and A values obtained from these

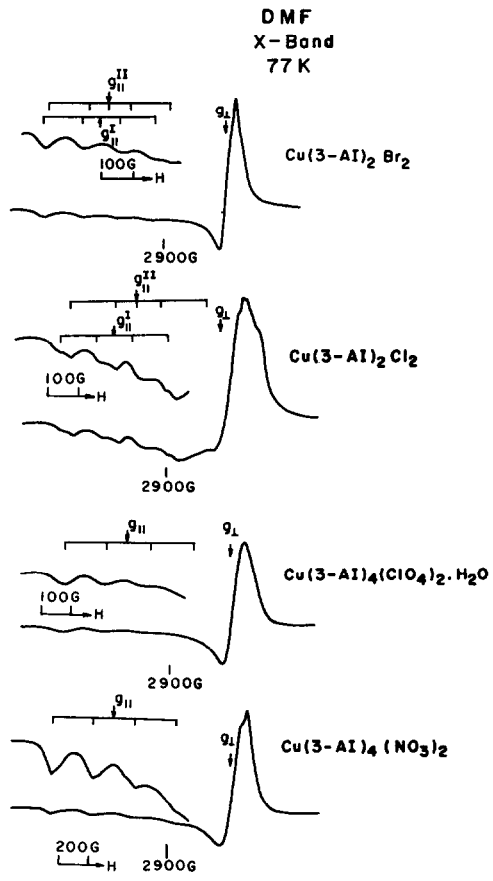

Fig. 3. ESR spectra of 3-AI copper(II) complexes in frozen DMF solutions.

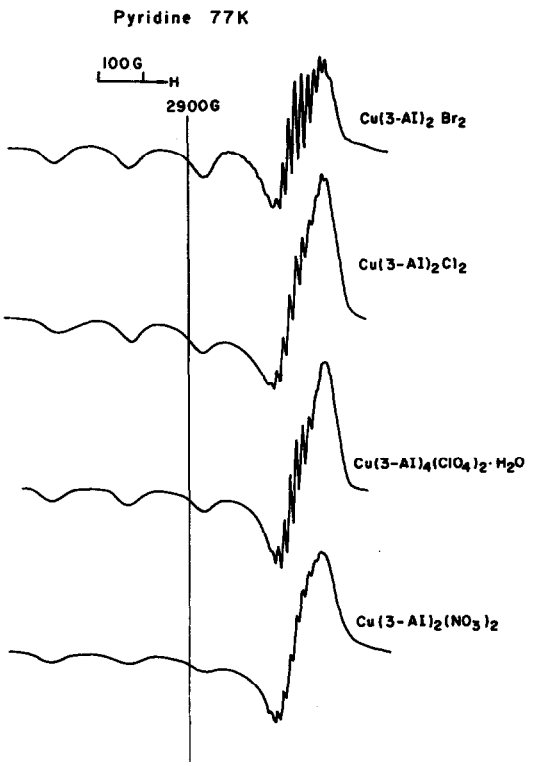

Fig. 4. ESR spectra of 3-AI copper(II) complexes in frozen pyridine solutions.

spectra. In the DMF solutions of chloro and bromo complexes, two species with different g and A values similar to 3-AMI complexes[6] are found to exist. The two species observed in the other two complexes are very close (Fig. 3) and hence only average g and A values of the two species are given in Table 5. In the case of the chloro complex the g and A values of species I and II are indicating oxygen and nitrogen coordinations, respectively.[16] Also the g values of species II of the above complex are comparable to the polycrystalline values: On the other hand the g (2.40–2.35) and A values (120–140 G) of the DMF species of the remaining complexes are indicating oxygen coordination. In pyridine solutions, the g and A values of all the species are the same within experimental error and indicate nitrogen coordination, which is supported by the ligand hyperfine structure on the perpendicular features. The above information suggests that the 3-AI ligands may most probably have been replaced by the solvent molecules in these solutions. This type of solute–solvent interaction is also observed in the copper(II) complexes of 3-AMI.[6]

CONCLUSIONS

Copper(II) complexes of 3-aminoisoxazole with general formula Cu(3-AI)$_n$X$_2$·mH$_2$O have been synthesized and their IR, electronic and ESR data obtained in polycrystalline and solution forms yielded the following information.

(a) IR and electronic spectral studies indicated that in all complexes 3-AI acts as a monodentate N$_{ring}$-bonded ligand, unlike the 3-AMI ligand which acts as a monodentate ligand in tetrakis-complexes and a bridging ligand (N- and O-bonded) in bis-complexes. The bis-complexes of 3-AI are mono-

Table 5. Spin-Hamiltonian constants obtained in DMF and pyridine solutions of 3-AI and 3-AMI copper(II) complexes

Complexes		Solvent	$g_\parallel$	$g_\perp$	$A_\parallel$ (G)	Reference

[b] The g and A values are the average values of the two species.

meric with CuN_2X_2 ($X = Cl^-$, Br^- and NO_3^-) geometries, unlike the corresponding 3-AMI complexes which are polymeric. The tetrakis-complexes of 3-AI are hexa-coordinate (CuN_4O_2), unlike the corresponding 3-AMI complexes which are penta-coordinate (CuN_4O).

(b) The G values calculated from the g values obtained in polycrystalline samples, indicate that the magnetic misalignment of molecules in the unit cell is only small. The partial resolution of the copper(II) hyperfine lines at Q-band in the case of $Cu(3\text{-AI})_4(ClO_4)_2 \cdot H_2O$ indicates that the exchange interaction amongst copper(II) ions in the unit cell is of the order of 1 cm^{-1}. The g values of the bis-complexes in the present case are found to be greater than that of the corresponding values in the 3-AMI complexes, indicating that the metal–ligand bond is weaker in the present complexes than in the 3-AMI complexes.

(c) Two species are found to exist in the DMF solutions of all the complexes unlike in the pyridine solutions. Large changes induced in the g values of the species in these solutions indicate that the coordinate positions in the complexes are occupied by solvent molecules.

(*Received* 7 *June* 1988; *accepted* 8 *November* 1988)

Abstract—The spectroscopic behaviour and the substitution kinetics of the (2,6 dimethyl pyrazine)pentacyanoferrate(II) complex in mixed water–organic solvents are strongly influenced by preferential solvation effects. The dissociation rate constants, obtained in the presence of a high excess of dimethyl sulphoxide as the incoming ligand, exhibit a linear dependence with respect to the acceptor number scale.

The solvent can play an extraordinary rôle in the kinetics and mechanisms of ligand substitution processes. These reactions usually proceed at overall rates much slower than the diffusion limits, and the diffusional encounter of the reactants can be treated as a pseudo-equilibrium followed by the rate determining step involving ligand exchange within the precursor complex.[1] The formation of the precursor complex and the substitution step are strongly influenced by the solvent composition, which may induce general changes in the free energies, or specific changes on the structure–reactivity behaviour of the reactants and activated complexes. On the other hand, in mixed solvents, the composition and reactivity of the precursor complex will depend on the extent of preferential solvation. We have previously shown[2] that this type of interaction has a dramatic influence in the solvatochromic properties of cyanoiron(II) complexes. We now report a detailed study of the preferential solvation effects in the substitution kinetics of the (2,6 dimethyl pyrazine)pentacyanoferrate(II) complex.

EXPERIMENTAL

The $Na_3[Fe(CN)_5(dmpz)]\cdot 3H_2O$ (dmpz = 2,6 dimethyl pyrazine) complex was synthesized and characterized previously.[3] $H_3Fe(CN)_5(dmpz)\cdot 3H_2O$ was obtained as a yellow solid, by rapidly mixing a saturated aqueous solution of $Na_3[Fe(CN)_5(dmpz)]\cdot 3H_2O$ with an equal volume of hydrochloric acid (37%), at 0°C, in a well-ventilated hood. The solid was collected on a filter, washed with diethyl ether and stored in a sealed flask, in the freezer. The tetrabutylammonium (TBA) salt was prepared by reacting $H_3Fe(CN)_5(dmpz)\cdot 3H_2O$ with stoichiometric amounts of tetrabutylammonium hydroxide in methanol, followed by the evaporation of the solvent under low pressure.

The electronic spectra of the complexes were recorded on a Cary 17 or a Hewlett–Packard model 8451-A diode-array spectrophotometer. The solvents were saturated with dry argon and transferred into the spectrophotometric cell with calibrated syringes. Serum caps or Teflon stoppers were used for syringe transfer, with special care to prevent the contact of the rubber with the solvents. The kinetics were carried out under an argon atmosphere, by monitoring spectrophotometrically the dissociation of the complex in the presence of a high excess of dimethyl sulphoxide (dmso) as the entering ligand.

RESULTS AND DISCUSSION

The $[Fe(CN)_5(dmpz)]^{3-}$ complex undergoes a dissociation reaction in solution, according to eq.

* Author to whom correspondence should be addressed.

(I), leading to a partial decay of the strong charge transfer band in the visible region (Fig. 1). The spectra are greatly influenced by the solvent, as observed in many cyanoiron(II) complexes.[2,5-8] The dissociation process can be repressed in the presence of an excess of the dmpz ligand, or driven to completion by adding an appropriate ligand, such as dmso, which has strong affinity for the pentacyanoferrate(II) ion.[9]

$$[Fe(CN)_5(dmpz)]^{3-} + S \rightleftharpoons [Fe(CN)_5S]^{3-} + dmpz. \quad (1)$$

In general, the substitution reactions in pentacyanoferrate(II) complexes proceed via a dissociative mechanism. The kinetics exhibit a saturation behaviour where the observed rate constants and the corresponding activation parameters are independent of the concentration and nature of the entering ligand.[10] Additional evidence for the dissociative mechanism has been obtained for the (3,5 dimethyl pyridine)pentacyanoferrate complex, based on measurements of the activation volumes.[11]

The kinetic constant measured at the saturation point, (versus [dmso]) for the dissociation of the $[Fe(CN)_5(dmpz)]^{3-}$ complex is 6.3×10^{-4} s^{-1}, in comparison to 1.3×10^{-3} s^{-1} (25°C) for the analogous 3,5 dimethyl pyridine complex.[10,11]

The substitution kinetics for the pentacyano(3,5 dimethylpyridine)ferrate(II) complex have already been investigated[12] in binary aqueous mixtures containing up to 40% by volume of methanol, ethanol, *t*-butyl alcohol, glycerol and tetrahydrofuran. The kinetics were consistent with the operation of a dissociative mechanism under all the conditions studied. The rates were also correlated with the Grunwald–Winstein *Y* values, showing only a low sensitivity to the solvent composition.

In the case of the pentacyano(2,6 dimethyl pyrazine) complex, the kinetics of substitution with dmso exhibited saturation behaviour in methanol, as illustrated in Fig. 2, with only 20% increase in the observed rate constants. In acetone and in acetonitrile, however, the rates were enhanced by two orders of magnitude. These results were unexpected, in view of the preceding results for the 3,5 dimethyl pyridine complex.[10] For this reason, we examined the detailed kinetic behaviour of the

dmpz complex in binary aqueous mixtures containing methanol, acetone and acetonitrile. Typical results are shown in Table 1.

The spectra of the $[Fe(CN)_5(dmpz)]^{3-}$ complex were also obtained under the conditions employed for the kinetics, for comparison purposes. The spectroscopic behaviour is strongly influenced by preferential solvation in the mixed solvents, as one can see in Fig. 3. When no preferential solvation occurs, the composition of the solvation shell should reflect

the composition of the bulk solvent, and the spectroscopic data are expected to follow a linear dependence with respect to the mole fraction of the mixture.[12] The deviation from the linear behaviour shown in Fig. 3(A) is consistent with a strong preferential solvation of the cyanoiron complex, with the water molecules predominating in the solvation shell in aqueous acetone or acetonitrile mixed solvents. A similar deviation from the ideal behaviour is observed in the plots of partial vapour pressure of water in acetonitrile solutions versus the mole fraction.[1] This means that water is transferred more easily from the bulk solvent to the complex solvation shell when it is in a weakly interacting medium, such as in acetonitrile.

The preferential solvation effects can be dealt with by means of the acceptor number scale (AN),[13–15] which is a combined measure of solvent polarity or polarizability and hydrogen bond donor ability.[16] As one can see in Fig. 3(B) the spectroscopic data for the pentacyano(2,6 dimethyl pyrazine)ferrate(II) complex are linearly correlated with AN.

The kinetic constants (k) for the dissociation reactions (Fig. 4) follow the trends observed for the spectroscopic behaviour, indicating strong preferential solvation effects. A linear correlation with the acceptor number scale is observed for each series of mixed solvents, as expressed by eq. (2):

$$\ln k = \ln k_o - b \cdot (AN), \qquad (2)$$

where $\ln k_o = -6.51$, -2.70, 0.16, and $b = -0.016$, -0.087, -0.140, for aqueous methanol, acetone and acetonitrile, respectively.

The $[Fe(CN)_5(dmpz)]^{3-}$ complex can interact strongly with the solvent via the cyanide and pyrazine ligands. The acceptor properties of the solvents

should enhance the backbonding capability of both ligands, leading to a greater stabilization of the solvated precursor complex, with respect to the pentacoordinated activated complex, decreasing the rates of the dissociation reactions. On the other hand, the solvent effects are probably not restricted to the stabilization of the precursor complex, otherwise the data in Fig. 4(B) would fit a single correlation with the acceptor number scale, as in the case for the spectroscopic behaviour.[2] The different slopes in Fig. 4(B) are associated with the kinetic behaviour in the pure solvents, which show some scattering in the correlation with the acceptor number scale. We presume that the scattering arises from solvent effects in the activated complexes, assisting the transfer of the leaving ligand to the solvation shell.

COMPARATIVE STUDY OF TUNGSTEN(V) COMPLEXES WITH 8-QUINOLINOL AND 2-METHYL-8-QUINOLINOL

R. LOZANO,* J. ROMÁN and F. DE JESUS

Departamento de Química Inorgánica, Facultad de Farmacia, Universidad Complutense, 28040 Madrid, Spain

(*Received* 20 *June* 1988; *accepted* 8 *November* 1988)

Abstract—The present paper reports a comparative study of a number of oxo- and sulphido bridge tungsten(V) oxo-complexes with 8-quinolinol and 2-methyl-8-quinolinol as ligands. The results obtained permit us to assign the following formulae to the complexes: $W_2O_3(LL)_4$, $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$ and $W_2O_3S(LL)_2$. All these complexes present very low values of the magnetic moment, according to a dimer structure with monoxo, dioxo, disulphido and oxo-sulphido bridges. We suggest that the low magnetic moments observed are due, at least in part, to intramolecular metal–metal interactions.

Oxo-complexes of the group (VI) elements play a central rôle in a variety of industrial and biological oxidation processes.[1]

In previous communications we have reported the isolation and study of monomeric and dimeric molybdenum(V) complexes with different ligands,[2–4] but such binuclear compounds are not so numerous in tungsten chemistry. However, recently we have reported the characterization of tungsten(V) dimeric complexes with dithiocarbamates as ligands.[5,6]

The object of the present study has been to obtain compounds of tungsten(V) with 8-quinolinol and 2-methyl-8-quinolinol as ligands, so as to observe the steric effect exercised by the methyl group.

The systematic changes upon bridge modification are useful in characterizing the compounds and in clarifying assignments of W—O and W—S bridge stretching frequencies. The results are discussed on the basis of structural information available for tungsten complexes.

These complexes were characterized by IR and electronic spectroscopy, magnetic susceptibility measurements and analytical data. The results obtained permit us to assign the following formulae to the complexes: $W_2O_3(LL)_4$, $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$ and $W_2O_3S(LL)_2$.

EXPERIMENTAL

(a) *Materials*

$Na_2WO_4 \cdot 2H_2O$, 8-quinolinol and 2-methyl-8-quinolinol were Merck commercial products.

The solvents used to prepare and to recrystallize the complexes were Carlo Erba or Merck. The solutions for absorption spectra were prepared using dimethylsulphoxide (DMSO) spectral grade (Merck–Uvasol).

(b) *Analytical procedures*

Elemental analyses were performed on a Perkin–Elmer model 240 B elemental analyser.

Tungsten was determined by atomic absorption with a Perkin–Elmer model 430 atomic absorption spectrophotometer, after decomposing the complexes with a 1 : 1 mixture of concentrated nitric and sulphuric acid.

The analytical data are given in Table 1. Results conform to proposed formulae.

(c) *Methods*

Magnetic susceptibility was determined by the Gouy method at room temperature using a Mettler H-51 AR balance and a type C Newport electromagnet. Molar susceptibilities have been cor-

rected for diamagnetism. Table 1 shows the results obtained.

The IR spectra were measured on a Perkin–Elmer recording spectrophotometer model 283 using KBr pellets. Important IR absorption peaks for the compounds prepared in this study are listed in Table 2.

The vis–near UV spectra of the compounds were measured in the range 220–1000 nm, on a Beckman recording spectrophotometer model 554, using complex solutions in DMSO. The results obtained are given in Table 3.

(d) *Preparation of the complexes*

$W_2O_3(C_9H_6NO)_4$. (3.30 g, 10 mmol) of $Na_2WO_4 \cdot 2H_2O$ was dissolved in 30 cm^3 of water and depolymerized with NaOH. Another solution of 8-quinolinol (2.90 g, 20 mmol) in 60 cm^3 of hot absolute ethanol was prepared. Once it was cold, this solution was added to the previous one, taking on a yellow colour—the resulting solution. A solution of 1 g of sodium dithionite was added, changing from yellow to green. Glacial acetic acid was added drop by drop and with vigorous stirring till reaching pH 5.

A brown solid was precipitated, which separated by filtration *in vacuo* and was washed repeatedly with a boiling water–ethanol mixture (50%). The residue was filtered hot and *in vacuo* so as to obtain a brown powder which was dried over P_4O_{10} (yield, 67%).

$W_2O_4(C_9H_6NO)_2$. A solution of $Na_2WO_4 \cdot 2H_2O$ (3.30 g, 10 mmol) in 50 cm^3 of water was prepared. 2 N NaOH was added till reaching pH 10, and the solution was heated by boiling for 10 min.

A second solution, 8-quinolinol (0.45 g, 10 mmol) dissolved in 40 cm^3 of hot absolute ethanol, was

prepared. The two solutions were combined and the resulting one was yellow in colour. A solution of 0.5 g of sodium dithionite in 20 cm^3 of water was added to it and the resulting solution turned green. Lastly, 2N HCl was added, drop by drop, and with continuous stirring till reaching pH 2 so that a greenish precipitate was obtained which was separated by filtration *in vacuo*.

The solid obtained was washed with a mixture of 20 cm^3 of water and 20 cm^3 of boiling ethanol, and filtered hot and *in vacuo* so as to obtain a greenish powder which was dried over P_4O_{10} (yield, 54%).

$W_2O_2S_2(C_9H_6NO)_2$. $Na_2WO_4 \cdot 2H_2O$ (3.30 g, 10 mmol) was dissolved in 50 cm^3 of water, and a concentrated sodium hydroxide solution was added, heating the solution by boiling for 10 min to avoid polymerization.

At the same time, 8-quinolinol (1.45 g, 10 mmol) was dissolved in 35 cm^3 of hot absolute ethanol. Once it was cold, this solution was added to the previous one and a new solution of 1 g of sodium dithionite in 40 cm^3 of water was added. The resulting solution changed from yellow to green. Hydrogen sulphide was passed through the resulting solution with simultaneous cooling in a freezing mixture for about 30 min. Glacial acetic acid was added, drop by drop, till reaching pH 6 and total precipitation. The solution was filtered and an orange residue was obtained which was washed with an acetic acid–ethanol mixture and was dried over P_4O_{10} (yield, 71%).

$W_2O_3S(C_9H_6NO)_2$. A solution of sodium tungstate (3.30 g, 10 mmol) dihydrated in 50 cm^3 of water was prepared, adding 10 cm^3 of concentrated boiling NaOH and dropping 2 N HCl until reaching pH 2. Another solution of 1 g of sodium dithionite in 40 cm^3 of water was added to the previous one. The resulting solution was heated lightly for 15 min. Once it was cold, hydrogen sulphide was bubbled slowly through the solution for about 60 min, changing it to a dark brown colour.

Another solution of 8-quinolinol (1.45 g, 10 mmol) in 60 cm^3 of hot absolute ethanol was prepared. The two solutions were combined and glacial acetic acid was added to it, drop by drop, till reaching pH 5 and total precipitation.

The solid precipitate was washed with a 2 N ethanol–acetic acid mixture (1 : 1), obtaining a brown-coloured powder which was dried over P_4O_{10} (yield, 68%).

Similar preparations for the tungsten(V) oxo-complexes with 2-methyl-8-quinolinol as the ligand were performed.

DISCUSSION

(a) *Structures of the complexes*

According to the results of the analytical, magnetic and spectroscopic data, the synthesized oxo-complexes are dimeric.

When precipitation occurred at pH 5 with acetic acid, the complexes had a monoxo bridge, the stoichiometry was 2 : 1 and the tungsten was six-coordinated. The formula which was most closely square with the analyses is $W_2O_3(LL)_4$. However, when

precipitation was carried out at pH 2, the stoichiometry of the compounds was 1 : 1, the tungsten was five-coordinated and the complexes had a dioxo bridge. The formula we assign to these complexes is $W_2O_4(LL)_2$.

By bubbling hydrogen sulphide through $Na_2WO_4 \cdot 2H_2O$ solution and the corresponding ligand, complexes were obtained with a 1 : 1 stoichiometry, and tungsten was five-coordinated with the formula $W_2O_2S_2(LL)_2$.

When the hydrogen sulphide was bubbled through $Na_2WO_4 \cdot 2H_2O$ solution in dil. HCl with posterior addition of the ligand, the union between the tungsten atoms is realized by means of an oxo-sulphido bridge, the formula of the complexes being $W_2O_3S(LL)_2$.

(b) *Magnetic properties*

All the complexes studied present very low values for the magnetic moments (1.3–0.0 BM), as occurs in similar tungsten(V) complexes,[5,6] which can probably be attributed to an interaction through the bridge atoms or the possible formation of a direct metal–metal bond, as has been proved for similar molybdenum(V) oxo-complexes.[7,8]

(c) *IR spectra*

The IR spectra show, in all cases, a very strong band in the range 962–925 cm^{-1}, which we attribute to the vibration of the terminal W=O bond.

If we compare the complexes of 2-methyloxine with the tungsten(V) complexes of oxine (see Table 2), we observe that the first ones exhibit the band of the symmetric stretching mode of the W=O bond, displaced to greater frequencies. This difference is due to the steric effect of the methyl group, which weakens the union of the 2-methyloxine ligand with the tungsten atom, strengthening the tungsten terminal oxygen bond.

Since the W=O bond is stronger in the 2-methyloxine complexes than in the oxine ones, the bonding of the tungsten atom to the oxygen bridge atoms should be less in the dimeric 2-methyloxine complexes.

In the IR spectra of the compounds with monoxo-, dioxo- and oxo-sulphido bridges, we assign the bands corresponding to the W—O—W bridge at 835–805 and 463–430 cm^{-1} which we attribute to the vibration of the antisymmetric and symmetric stretching modes, respectively, of the W—O bridge bond. These bands are displaced to lower frequencies in the 2-methyloxine complexes, in comparison with the analogous complexes with oxine.

Another two bands, which appear in the IR spectra of the complexes with disulphido and oxo-sulphido bridges in the regions of 470–465 and 372–360 cm^{-1}, can be attributed to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the W—S bridge bond. These bands are displaced to lower frequencies in the 2-methyloxine complexes as occurs with the W—O bridge bands, previously discussed.

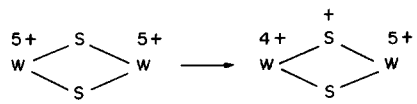
All the complexes studied exhibit two bands in the IR spectra in the 1115 and 330 cm^{-1} regions. We attribute the first one to a C—O—W vibration mode and the second one to the W—N bond stretching as has been observed in other tungsten(V) complexes.[9–11]

(d) *Visible and UV spectra*

The electronic spectra (Table 3) for all the complexes present two bands in the 14,005–14,455 and 17,921–18,315 cm^{-1} regions, which we attribute to *d–d* transitions. We assign the two bands to $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions, respectively, for a distorted octahedral structure[12] for the monoxo bridge complexes and for a square pyramidal structure[13] for the complexes with dioxo-, disulphido and oxo-sulphido bridges.

In the visible region we can detect two other bands over 20,000 and 27,000 cm^{-1} that we attribute to charge-transfer transitions.

In the complexes with disulphido and oxo-sulphido bridges another band appears in the visible region over 22,000 cm^{-1} that can be attributed to a charge-transfer:



as has been observed in other transition metal complexes with a sulphur bridge.[14,15]

In the UV region, two transitions are detected at 30,000 and 35,000 cm^{-1} attributable to intraligand transitions.

We have made these compounds which, on the basis of our physical measurements, are analogous to similar molybdenum compounds.

NITROSOTHIOUREA: ITS REACTIVITY WITH METAL IONS AND THEIR COMPLEXES

D. S. PANDEY and U. C. AGARWALA*

Department of Chemistry, Indian Institute of Technology, Kanpur 208 016, India

(*Received* 21 *June* 1988; *accepted* 8 *November* 1988)

Abstract—Reactions of nitrosothiourea with different metal ions in the presence of pyridine, 2,2′-bipyridyl, 1,10 phenanthroline and a few complexes of ruthenium, rhodium, iridium, palladium and platinum have been carried out under varying reaction conditions. Physical methods such as IR, magnetic measurements, melting points, mixed melting points and elemental analyses have been used for the identification of reaction products.

Werner[1] and Stedman *et al.*[2] have shown that the unstable S-nitrosothiourothonium ion formed during the reaction of HNO_2 with thiourea, dissociates according to mechanism (1) in low acidic conditions and mechanism (2) under higher acidic conditions:

$$H^+ + HNO_2 + SC(NH_2)_2 \rightleftharpoons (NH_2)_2CSNO$$

$$(NH_2)_2CSNO \rightleftharpoons NH_2CSNHNO \longrightarrow NH_2CS{-}N{=}NOH$$

$$NH_2C{-}S{-}N{=}NOH \longrightarrow H^+ + HNCS + N_2 + OH^- \quad (1)$$

$$2H^+ + HNO_2 + 2SC(NH_2)_2 \longrightarrow (NH_2)_2CSSC(NH_2)_2 + 2NO + 2H_2O. \quad (2)$$

Since the NO group in both mechanisms either migrates from sulphur to nitrogen, eq. (1), or is generated, during reaction (2), there is a possibility of it being trapped by the metal ions to form their nitrosyls. However, the preferential ligation of the ambidentate NCS^-, forming simultaneously in the reaction, may create a problem in the "*in situ* trapping" of NO. It will, therefore, be interesting to examine the reactivity of S-nitrosothiourothonium (NTU) as the nitrosylating agent, over a range of acidities (from 2 M to pH 7) with various metal ions. The metal ions chosen for the reactions are those whose nitrosyls are stable and are synthesized at room or at low temperatures only. Since these metal ions are also potential thiocyanate scavengers, the relative overall efficacy of "NO group trapping" by the metal ions to that of the thiocyanate group under given experimental conditions may also be compared. The present note reports some work in this area.

EXPERIMENTAL

Analar grade chemicals and freshly distilled solvents were used in the reactions. NTU and the complexes of Ru, Rh, Ir, Pd and Pt were prepared and purified by the literature methods.[3–7] Microanalytical measurements, IR spectra (KBr), m.p. and room temperature magnetic susceptibilities of the complexes were carried out as described elsewhere.[8,9]

(A) *Reaction of* NTU *with* Co^{II} *acetate in presence of pyridine*

A methanolic solution (25 cm^3) containing Co^{II} acetate (1.0 mmol) was cooled to about 0°C using an ice–salt bath. To this, 15 cm^3 of an aqueous solution of NTU (freshly prepared) and 4.5 mmol of pyridine were added with stirring and left for about 0.5 h at 0°C. A pink compound separated out which was filtered and washed with water and a little methanol. It was extracted with excess alcohol, and the deep blue alcoholic extract was slowly evaporated on a waterbath whereby pink needle shaped crystals crystallized out. These were filtered, washed with ether and dried *in vacuo*. They were analysed for $[Co(py)_3(NCS)_2]$.

Reactions of NTU with Cr^{II}, Mn^{II}, Fe^{II}, Ni^{II}, Cu^{II}, Ag^{I}, Zn^{II}, Cd^{II} and Hg^{II} salts in presence of pyridine; Co^{II}, Ni^{II} and Cu^{II} salts in presence of 2,2′-bipyridyl

and 1,10-phenanthroline and with $[Ru(NH_3)_5Cl]Cl_2$, $[Pd(PPh_3)_4]$ and $[Pt(PPh_3)_4]$ were carried out by the procedure similar to that described in the previous paragraph.

(B) *Reaction of* $[Co(py)_3(NCS)_2]$ *with* $[(CH_3)_4N]Cl$

The refluxing of 30 cm^3 of a methanolic solution containing $[Co(py)_3(NCS)_2]$ (1 mmol) with $[(CH_3)_4N]Cl$ (2 mmol) for 30 min followed by concentration of the resulting mixture to half its volume on a water bath, and finally cooling to room temperature, resulted in a deep blue oil. On repeated crystallization using CH_2Cl_2–petroleum ether, the oil afforded a deep blue complex which was filtered, washed with alcohol and ether and dried *in vacuo*. It was analysed for $[(CH_3)_4N]_2[CoCl_2(NCS)_2]$.

Reactions of tetraethyl and tetrabutyl ammonium chloride were also carried out by the same procedure.

(C) *Reaction of* NTU *with* $[RuCl_2(PPh_3)_3]$

An aqueous solution of NTU (15 cm^3; freshly prepared) was added to a refluxing solution (25 cm^3, 1:1 ethanol/CH_2Cl_2) containing $[RuCl_2(PPh_3)_3]$ (0.26 g). The resulting mixture was refluxed for 1.5 h. On cooling, a yellow–orange microcrystalline compound was precipitated which was filtered, washed with ethanol and diethyl ether and dried *in vacuo*. It was recrystallized from CH_2Cl_2–petroleum ether, and analysed for $[Ru(NO)(NCS)_2(PPh_3)_2Cl]1/2CH_2Cl_2$.

Reactions of $[RhCl(PPh_3)_3]$ and $[IrCl_3(PPh_3)_3]$ with NTU were carried out by the same procedure.

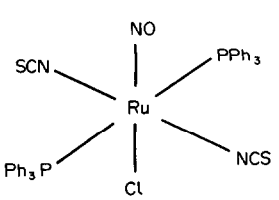
RESULTS AND DISCUSSION

The results (Table 1) show the formation of metal thiocyanato complexes in reasonably good yields (*ca* 60%). All products reported in the literature have been identified by their elemental analyses and by comparing their colours, melting points, mixed melting points, the IR spectra and the magnetic susceptibility data, with those of the authentic samples.

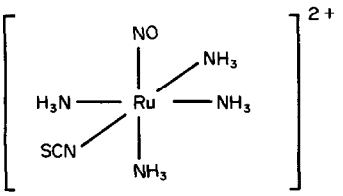
Reactions of NTU with the salts of Mn^{II}, Fe^{II}, Ni^{II}, Ag^{I}, Cd^{II} and Hg^{II} [10–17] in presence of pyridine; those of Co^{II}, Ni^{II} and Cu^{II} ions in the presence of 2,2′-bipyridyl and 1,10-phenanthroline,[18] and $[Pd(PPh_3)_4]$ and $[Pt(PPh_3)_4]$,[19] strictly under the reaction conditions used for their nitrosyl synthesis, yielded the literature-known thiocyanato complexes. Co^{II}, Cr^{II} and Zn^{II} under similar conditions yielded different complexes. Chromium(II) acetate in the presence of pyridine formed a white complex $[Cr(NCS)_3(py)_2 \cdot H_2O]$ whose IR spectrum displayed an intense split band around 1965 cm^{-1} (ν_{CN}), weak to medium intense bands around 760 cm^{-1} (ν_{CS}) and 450 cm^{-1} (δ_{NCS}) besides the characteristic bands of pyridine. The positions of these bands suggested the linkage of the NCS group through its nitrogen end.[20] Reactions with Co^{II} and Zn^{II} yielded $[Co(py)_3(NCS)_2]$ or $[Co(py)_6][Co(NCS)_4]$ and $[Zn(py)_3(NCS)_2 \cdot H_2O]$, respectively. The deep blue ethanolic solution of the cobalt complex gave, on slow evaporation, pink needle-shaped crystals containing cobalt in the anion. $[(CH_3)_4N]_2[CoCl_2(SCN)_2]$, $[(C_2H_5)_4N]_2[CoCl_2(SCN)_2]$ and $[(C_4H_9)_4N]_2[Co(SCN)_4]$ were obtained on treating the tetramethyl, tetraethyl or tetrabutyl ammonium chloride with the eluent which was obtained by passing a solution of the pink crystals through a column of cation exchanger in ethanol or methanol.

Although the formation of thiocyanato complexes by all the metal ions suggested the generality of the reaction course, the reactions of ruthenium and rhodium ions and their complexes which picked up NO along with SCN groups are of interest here. Considering the remarkable affinities of these metal ions for NO,[21] the products were not unexpected. $[Ru(NO)(NCS)_2Cl(PPh_3)_2]$ is the first mixed nitrosyl derivative of ruthenium of this type.

The bright yellow–orange crystalline diamagnetic Ru^{II} complex, $[Ru(NO)(NCS)_2Cl(PPh_3)_2]1/2CH_2Cl_2$, exhibited in its IR spectrum, intense bands at 1875 cm^{-1} (ν_{NO}) and 2080 cm^{-1} (ν_{CN}), and other characteristic bands of the NCS group around 860 cm^{-1} ($\nu_{C=S}$) and 470 cm^{-1} (δ_{NCS}), respectively. These positions suggested the bonding of the NCS group in the complex through its nitrogen atoms. Furthermore NO^+, being strongly *trans* directing,[22] will prefer to coordinate to the metal ion *trans* to a ligand having the weakest *trans* effect viz. Cl^- ion.[22] It is, therefore, suggested that NO^+ is bonded *trans* to the chloride ion. Besides under reaction conditions, the formation of $[Ru(NO)Cl(NCS)_2(PPh_3)_3]$ will be favoured over that of $[Ru(NO)(NCS)_3(PPh_3)_2]$. Since ν_{CN} and $\nu_{C=S}$ appeared as single bands, this indicated the *trans* positions of the NCS groups, and phosphine molecules in $[Ru(NO)Cl_3(PPh_3)_2]$.[23] The following structure is therefore tentatively suggested.



The reaction of $[Ru(NH_3)_5Cl]Cl_2$ with NTU in aqueous medium led to the formation of a yellow nitrosyl, $[Ru(NO)(NCS)(NH_3)_4]Cl_2$. In view of (1) the elemental analyses; (2) the IR spectra bands, [ν_{NO}, 1875 cm^{-1}, ν_{CN} 2080 cm^{-1} (strong sharp); ν_{CS} 860 cm^{-1} weak; δ_{NCS} (medium intensity) 880 cm^{-1} and the characteristic NH_3 bands]; (3) the ion exchange studies indicating the presence of the NCS group inside, the Cl^- outside the coordination sphere; and (4) the NO being a strong *trans* directing group, preferring to coordinate *trans* to the NH_3 molecule (weak *trans* directing group), the following structure is proposed.



However, other alternating structures may also be possible. The IR spectrum of the rhodium complex, $[Rh(NO)(NCS)Cl(PPh_3)]$, exhibited a band at 1630 cm^{-1} indicating the presence of coordinated NO^-. The reaction thus proceeds with the oxidation of Rh from +1 to +3. Presumably NO^+, the only oxidizing species present in the system, might have been picked up by Rh^I during the intramolecular *trans* migration of NO^+ from sulphur to nitrogen (cf. reaction 1) and oxidized the metal ion. During the process it also coordinated to the metal centre.

Since the preferred geometry of Rh^{III} complexes is octahedral, four coordination around the metal centre in $[Rh(NO)Cl(NCS)(PPh_3)]$ is highly unexpected. However, the position of the ν_{CN} band (2110 cm^{-1}) which appeared at relatively higher wave numbers along with the positions of $\nu_{C=S}$ and δ_{NCS}, span the range of the bridging NCS group. It is unfortunate that we are not in a position to confirm the ν_{Rh-Cl} band because of a large number of ligand bands present in the region. In view of these arguments, an octahedral geometry of the rhodium complex with bridging NCS^- and Cl^- ions, and with terminal NO^- and PPh_3 molecules in *trans* positions have been tentatively proposed. NO^- could also coordinate *trans* to bridging Cl^-. We do not, however, wish to decide in favour of any of the alternative structures possible for the complex.

The presence of the coordinated thiourea in the octahedral iridium complex, $[Ir(PPh_3)_2(NCS)_2Cl$ (thiourea)], have been confirmed by recrystallizing it a number of times from different solvents and allowing it to pass through Sephadex G-10 column (25 × 2 cm). In every case the complex was found to be identical to the starting material. As expected, the IR band positions of the NCS group (Table 1) suggested S-bonded thiocyanate because of the "b" character of the metal ion.

In all the reactions, a point of interest is the invariable coordination of the NCS group irrespective of NO being linked with the metal ion or not. This is understandable in the case of Pd and Pt complexes which have more tendency to form complexes in the zero valent state rather than their nitrosyls.[24] Besides, they (in +2 oxidation state) prefer to form $(N_2O_2)^{2-}$ complexes[25] which should be relatively unstable with respect to those of their thiocyanates, and particularly, when the NCS concentration is very high in the medium. The same argument may be put forward for the formation of NCS complexes by the first row transition metal ions. In most cases, the NO group is introduced only under special conditions in the first transition elements. It is therefore assumed that the greater affinity of the NCS group compared with that of NO for the first transition series elements may be one of the reasons why the NO group is not trapped by them.

CONCLUSION

The conclusion from the previous Results and Discussion is that NTU does not seem to have favourable potential for nitrosylation, except when the metal ion has relatively higher affinity for the NO group. The possible reason for this could be the very high rate of reaction (1) under these conditions. The NO group before being picked up by the metal ions, migrates to the nitrogen atom of thiourea which subsequently decomposes to NCS^- by destroying NO^+. Thus due to very large NCS concentration, the latter preferentially attacks the metal centre and forms thiocyanato complexes rather than nitrosyls.

NEUTRAL AND CATIONIC OXO-METHYL COMPLEXES OF RHENIUM(V); X-RAY STRUCTURE OF $ReOMe_2Cl(PMe_3)_2$

DAVID M. HOFFMAN* and DERK A. WIERDA

Department of Chemistry, Harvard University, 12 Oxford Street, Cambridge, MA 02138, U.S.A.

(*Received* 27 *August* 1988; *accepted* 9 *November* 1988)

Abstract—Reaction of $ReO(OEt)Cl_2(py)_2$ with 1 equivalent of $AlMe_3$ in the presence of 2 equivalents of PMe_3 or PMe_2Ph produces $ReOMe_2Cl(PMe_2R)_2$ (R = Me or Ph) and reaction of $ReOMe_2Cl(PMe_2R)_2$ with dmpe gives $ReOMe_2Cl(dmpe)$. Spectroscopic studies and an X-ray structure of the PMe_3 derivative show that the compounds are octahedral with a *trans*-[Cl—Re═O] group and *cis*-methyl ligands. Reactions of an excess of $ZnMe_2$ with $ReOMe_2Cl(PMe_2R)_2$ and $ReOMe_2Cl(dmpe)$ give square-pyramidal $ReOMe_3(PMe_2R)$ (R = Me and Ph) and octahedral $ReOMe_3(dmpe)$, respectively. The trimethyl complexes are unstable at room temperature ($t_{1/2} \approx 3$ h for $ReOMe_3(PMe_3)$ in C_6D_6). The complexes $ReOMe_2Cl(PMe_2R)_2$ and $ReOMe_2Cl(dmpe)$ react with $[Ag(CH_3CN)_2][BF_4]$ to give $[ReOMe_2(PMe_2R)_2(CH_3CN)][BF_4]$ (R = Me and Ph) and $[ReOMe_2(dmpe)(CH_3CN)[BF_4]$, respectively. The cations are octahedral and contain a *trans*-$[CH_3CN—Re═O]$ moiety. Both the PMe_3 and PMe_2Ph derivatives exist in solution as a mixture of *cis*- and *trans*-phosphine isomers; variable temperature NMR studies show that the *trans* isomer predominates at low temperatures.

We have established that d^2 square-pyramidal $ReO(CH_2SiMe_3)_3(PMe_3)$ reacts with a variety of small molecules, including CO,[1] HCCH,[2] CN^-, CH_2N_2 and bipyridine (bipy),[3] Scheme 1. Surprisingly, however, $ReO(CH_2SiMe_3)_3(PMe_3)$ does not react with ethylene.[1] This may be due to the large steric bulk of the trimethylsilylmethyl ligand. These observations prompted us to prepare d^2 oxo-methyl complexes in order to test the reactivity of the less hindered complexes with ethylene and other small organic molecules. Reported here are the results of our initial synthetic work which includes the preparation of $ReOMe_2Cl(PMe_2R)_2$ (R = Me and Ph); $ReOMe_2Cl(dmpe)$ (dmpe = $Me_2PCH_2CH_2PMe_2$); $ReOMe_3(PMe_2R)$ (R = Me and Ph); $ReOMe_3(dmpe)$; $ReOMe_3(bipy)$; $[ReOMe_2(CH_3CN)(PMe_2R)_2]^+$ (R = Me and Ph); and $[ReOMe_2(CH_3CN)(dmpe)]^+$.

RESULTS AND DISCUSSION

Neutral oxo-dimethyl rhenium(V) *complexes*

The reaction of $ReO(OEt)Cl_2(py)_2$ (**1**)[4] with 1 equivalent of $AlMe_3$ in the presence of 2 equivalents of trimethylphosphine or dimethylphenylphosphine gives $ReOMe_2Cl(PMe_3)_2$ (**2a**, yield 62%) and $ReOMe_2Cl(PMe_2Ph)_2$ (**2b**, yield 56%), respectively [eq. (1)]. If 1/3 equivalent of $AlMe_3$ is used in reaction (1), a mixture of starting material, and mono- and dimethylated products is obtained. Reaction of **1** with 1 equivalent of $AlMe_3$ in the absence of phosphine, or with 2 or 3 equivalents of $AlMe_3$ in presence of PMe_2Ph or PMe_3, gives paramagnetic products which have not yet been characterized.

These are presumably oxo-free complexes.

$$\underset{(\mathbf{1})}{ReO(OEt)Cl_2(py)_2} + AlMe_3 + 2PMe_2R \xrightarrow[CH_2Cl_2]{75°C\,12\,h}$$

$$ReOMe_2Cl(PMe_2R)_2 + Al(OEt)ClMe + 2py. \quad (1)$$

[R = Me (**2a**) and Ph (**2b**)]

Reaction of **2a** or **2b** with dmpe at room temperature gives $ReOMe_2Cl(dmpe)$ (**2c**) quantitatively by ^1H NMR (vs internal standard) and in 62 and 73% isolated yields, respectively [eq. (2)]. Surprisingly, the reaction of **1** with $AlMe_3$ and dmpe [cf. eq. (1)] does not give **2c**.

$$ReOMe_2Cl(PMe_2R)_2 + dmpe \xrightarrow[1\,h]{Toluene}$$

$$\underset{(\mathbf{2c})}{ReOMe_2Cl(dmpe)} + 2PMe_2R. \quad (2)$$

The compounds **2a**, **2b** and **2c** are red–brown crystalline solids, which are sparingly soluble in hexane and soluble in toluene and CH_2Cl_2. They are moderately air-sensitive, more so in solution than in the solid state.

The structure of **2a** has been determined by an X-ray crystallographic study; an ORTEP plot of the molecule is given in Fig. 1. Bond lengths and angles are presented in Table 1. The molecular geometry of **2a** is distorted octahedral. The Re=O,[1,2,5] Re—CH_3,[6] and Re—P[1,7] distances are normal, but the Re—Cl distance (2.607(3) Å) is long [e.g. it is 0.17 and 0.16 Å longer than the Re—Cl distances (Cl *trans* to Re=O) in $ReOCl_3(CNBu^t)_2$ and $ReOCl_3(PEt_2Ph)_2$, respectively].[5b,c] A possible explanation for the longer than normal Re—Cl distance is that electron donation from the strongly σ donating methyl groups makes an electron contribution from the chloride unnecessary and, given this, that steric interactions are minimized by pushing chlorine away from the rhenium centre.

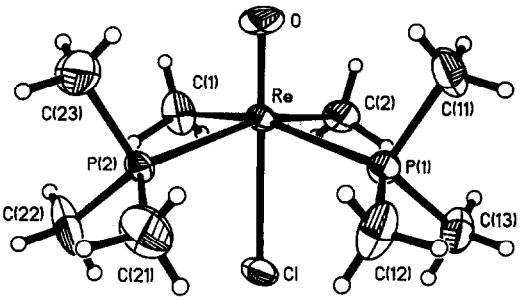

Fig. 1. ORTEP plot of $ReOMe_2Cl(PMe_3)_2$ (**2a**) showing the atom numbering scheme (50% probability level).

In **2a** the methyl groups are closer to the rhenium than the phosphines ($d_{Re-P} - d_{Re-C} = 0.25$ Å) and, because of this, the oxo and chloride ligands are repelled more by the methyl groups than the phos-

phine ligands, even though the phosphines are larger. This is indicated in the structure by angular distortions from an octahedral geometry. For instance, the O—Re—C angles [102.0(3) and 103.3(3)°] are slightly larger than the O—Re—P angles [96.6(2) and 97.0(2)°]. Also, the O—Re—Cl angle is 10° from linear and bent in the direction of a line bisecting the P—Re—P angle.

Spectroscopic data for **2a**, **2b** and **2c** are similar and consistent with the solid state structure of **2a**. For instance, in **2a** the protons of the Re—*Me* groups appear as a doublet in the ^{1}H NMR spectrum, and the carbons appear as a doublet of a doublet in the $^{13}C\{^1H\}$ NMR spectrum ($^2J_{CP}$ = 48 and 8 Hz). By analogy to what has been reported for $ReO(CH_2SiMe_3)_3(PMe_3)$,[1] the $^{31}P—^1H$ coupling observed for **2a** is attributed to the *cis*-[P—Re—CH_3] groups, and the large and small $^2J_{PC}$ values are assigned to the *trans*- and *cis*-[P—Re—CH_3] moieties, respectively. The methyl protons of the PMe_3 ligands in **2a** give rise to a doublet in the ^{1}H NMR spectrum, but the carbons appear as a complex multiplet in the $^{13}C\{^1H\}$ spectrum. To a first approximation the latter can be interpreted as one half of an AA′XX′ spectrum, but in order to simulate the spectrum successfully it is necessary to use an AXY spin system (Fig. 2). This takes into account that $ReO(^{12}CH_3)_2Cl[^{31}P(^{13}CH_3)(^{12}CH_3)_2][^{31}P(^{12}CH_3)_3]$ is the isotopomer actually observed by $^{13}C\{^1H\}$ NMR. A complete listing of all coupling constants is given in the Experimental.

^{18}O labelling studies show that the Re=O stretching bands for **2a**, **2b** and **2c** occur at 1004, 999 and 1000 cm^{-1}, respectively. These are normal values for neutral rhenium(V) mono-oxo complexes.[8] The ^{18}O labelled compounds were prepared by stirring the unlabelled complexes with an excess of degassed $H_2{}^{18}O$ (100 equivalents) for 24 h in toluene.

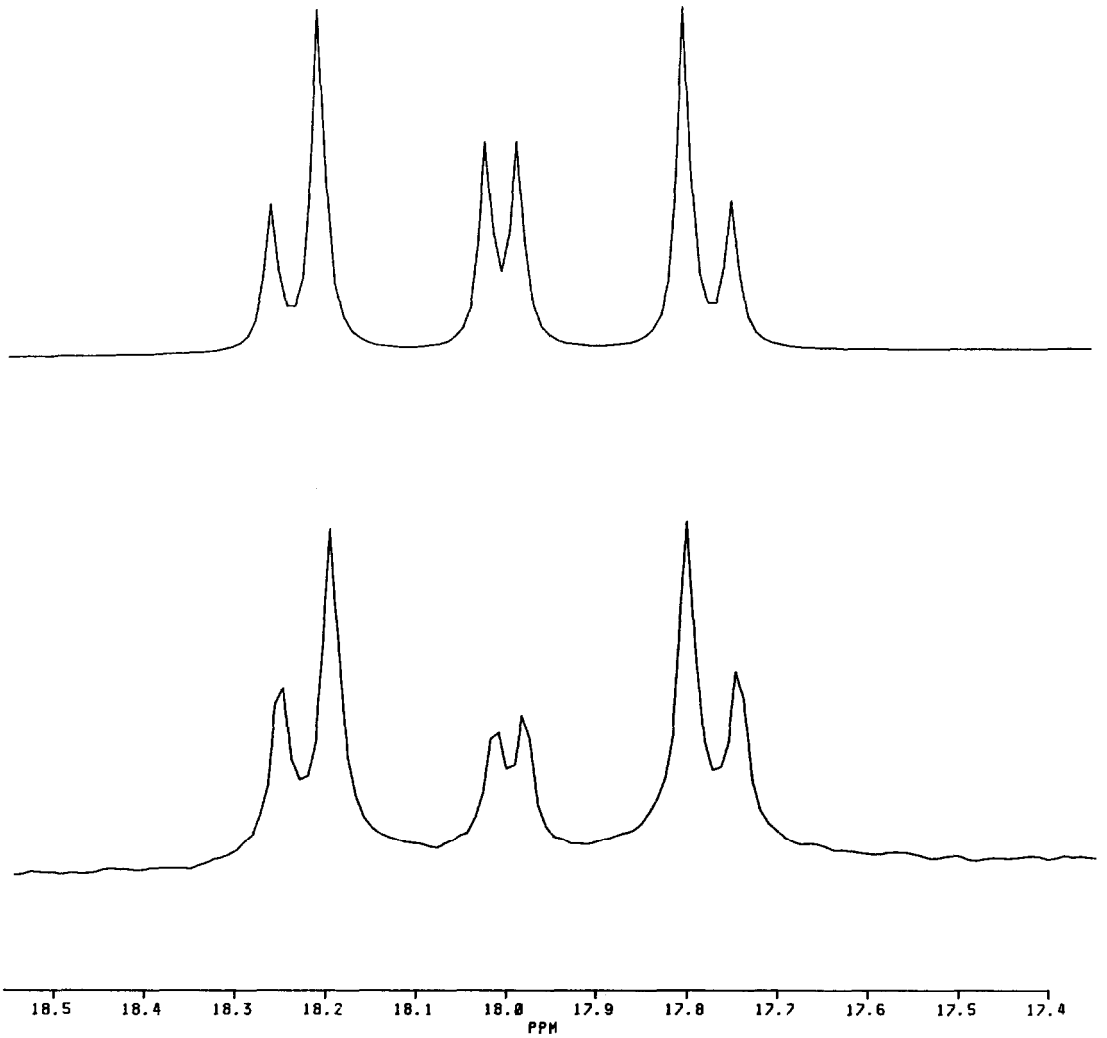

Fig. 2. Simulated (top) and experimental (bottom) $P(CH_3)_3$ region of the 75.5 MHz $^{13}C\{^1H\}$ spectrum for $ReOMe_2Cl(PMe_3)_2$ (**2a**).

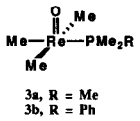
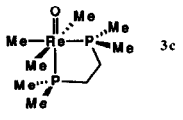
Neutral oxo-trimethyl rhenium(V) complexes

Reactions of **2a**, **2b** and **2c** with an excess of $ZnMe_2$ at 0°C give the corresponding trimethyl derivatives, $ReOMe_3(PMe_2R)$ [R = Me (**3a**) and Ph (**3b**)] and $ReOMe_3$(dmpe) (**3c**), eqs (3) and (4). Reactions (3) and (4) are quantitative by ^1H NMR (vs internal standard), and the isolated yields are 47, 51 and 31% for **3a**, **3b** and **3c**, respectively.



3a, R = Me
3b, R = Ph



3c

Complex **3b** can also be prepared by the reaction of $Re_2(\mu\text{-}O)O_2Me_6$[6a,c] with PMe_2Ph [eq. (5)], and complex **3c** by the reactions of dmpe with **3a** or **3b**.

$$ReOMe_2Cl(PMe_2R)_2 + ZnMe_2 \xrightarrow[\text{Toluene}]{0°C} ReOMe_3(PMe_2R) + ZnMeCl + PMe_2R \quad (3)$$

[R = Me (**3a**) and Ph (**3b**)]

$$ReOMe_2Cl(\text{dmpe}) + ZnMe_2 \xrightarrow[\text{Toluene}]{0°C} ReOMe_3(\text{dmpe}) + ZnMeCl \quad (4)$$

(**3c**)

$$Re_2(\mu\text{-}O)O_2Me_6 + 3PMe_2Ph \longrightarrow 2ReOMe_3(PMe_2Ph) + P(O)Me_2Ph. \quad (5)$$

Compounds **3a** and **3b** are green oils, and **3c** is a red solid. All of the compounds decompose at room temperature ($t_{1/2} \approx 3$ h for **3a** in C_6D_6) to give as yet, uncharacterized products. The decomposition rates depend qualitatively on the phosphine ligand, with the dmpe ligand complex being the slowest to decompose and the PMe_3 complex being fastest.

The facile decomposition of **3a**, **3b** and **3c** has hampered their complete characterization. In particular, chemical analyses could not be obtained for any of the compounds and reliable IR data have been collected only for **3c** (ν(Re=O) 1018 cm^{-1}). NMR data sets have been obtained for all three compounds, however, and they are consistent with the structures shown. The proposed structures for **3a** and **3b** are analogous to the structure reported for $ReO(CH_2SiMe_3)_3(PMe_3)$.[1]

Compounds **3a** and **3b** are fluxional on the NMR time scale at room temperature. In low temperature limiting ^1H NMR spectra recorded at −66°C, the methyl ligands in **3a** give rise to a doublet, which by the integral intensity is assigned to the methyl ligands *cis* to PMe_3, and a singlet (methyl ligand *trans* to PMe_3). The observation of P—H coupling due to the *cis*-[P—Re—CH_3] and not the *trans*-[P—Re—CH_3] groups is consistent with an earlier study of $ReO(CH_2SiMe_3)_3(PMe_3)$.[1]

In contrast to compounds **3a** and **3b**, **3c** is not fluxional on the NMR time scale. In the $^{31}P\{^1H\}$ NMR spectrum recorded for **3c**, two doublets are observed indicating that the phosphorus atoms are in different chemical environments and are both bound to the metal. The ^1H NMR spectrum also shows evidence for two bound phosphorus atoms in that each methyl ligand (2:1 integral ratio) appears as a doublet of a doublet. Doublet of doublet resonances are also observed for the carbons of the methyl ligands in the $^{13}C\{^1H\}$ NMR spectrum.

In addition to $ReO(CH_2SiMe_3)_3(PMe_3)$, two other compounds related to **3a**, **3b** and **3c**, $Re(NPh)Me_3(PMe_3)_2$[9] and $ReOEt_3(PPh_3)_2$,[10] have been reported in the literature. The existence of these two compounds, each containing two phosphine ligands, suggested to us that the bis-phosphine complexes $ReOMe_3(PMe_2R)_2$, R = Me and Ph, should exist.

In an effort to observe a bis-phosphine adduct, we recorded a low-temperature limiting ^1H NMR spectrum (−73°C, $C_6D_5CD_3$) for a mixture of **3a** and 5 equivalents of PMe_3. This spectrum was consistent with the presence of *cis,mer*-$ReOMe_3(PMe_3)_2$ and free PMe_3 in solution. An attempt to isolate the bisphosphine complex by reacting an excess of PMe_3 with **3a** on a large scale, however, resulted in recovery of only **3a** after work-up. Thus, two phosphine ligands do coordinate to **3a** at low temperature in solution, but the isolable species contains only *one* phosphine ligand. Obviously, two phosphine centres coordinate in **3c** because of the chelate effect, but it is unclear why two phosphines coordinate in $Re(NPh)Me_3(PMe_3)_2$ and $ReOEt_3(PPh_3)_2$, whereas only one coordinates in **3a** and **3b**.

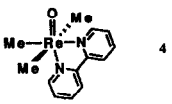
In addition to the NMR studies, there is also indirect evidence that the mono-phosphine formulation of **3b** is correct. The reaction of **3b** with bipyridine, carried out in an NMR tube and monitored by ^1H NMR, gave *one* free phosphine molecule and $ReOMe_3$(bipy) (**4**) [eq. (6), 80% yield by integration vs internal standard]. A large-scale reaction produced **4** in 35% isolated yield.

$$ReOMe_3(PMe_2Ph) + \text{bipy} \xrightarrow{C_6D_6} ReOMe_3(\text{bipy}) + PMe_2Ph. \quad (6)$$

(**4**)

Complex **4** is a blue crystalline solid which is air-stable in solution and in the solid state. The IR spectrum has a strong band at 970 cm^{-1} which can be assigned to the Re=O stretch. The ^1H NMR

spectrum reveals two methyl resonances in the integral ratio 2:1 as well as eight different resonances attributable to coordinated bipyridine. These data are consistent with the structure shown below.



4

Cationic oxo-methyl rhenium(V) *complexes*

Reactions of **2a**, **2b** and **2c** with $[Ag(CH_3CN)_2][BF_4]$ in acetonitrile give the cationic rhenium(V) complexes $[ReOMe_2(PMe_2R)_2(CH_3CN)]$ [R = Me (**5a**, yield 71%) and R = Ph (**5b**, yield 65%)], eq. (7) and $[ReOMe_2(dmpe)(CH_3CN)][BF_4]$ (**5c**, yield 68%), eq. (8), respectively. The cationic complexes are thermally stable red oils or oily solids which are insoluble in hydrocarbon solvents.

$$ReOMe_2Cl(PMe_2R)_2 + [Ag(CH_3CN)_2][BF_4] \xrightarrow{CH_3CN} [ReOMe_2(PMe_2R)_2(CH_3CN)][BF_4] + AgCl \quad (7)$$

[R = Me (**5a**) and Ph (**5b**)]

$$ReOMe_2Cl(dmpe) + [Ag(CH_3CN)_2][BF_4] \xrightarrow{CH_3CN} [ReOMe_2(dmpe)(CH_3CN)][BF_4] + AgCl. \quad (8)$$

(**5c**)

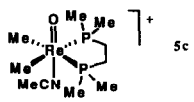
Variable temperature ^1H and ^{13}C NMR studies (CD_3COCD_3) reveal that **5a** and **5b** exist in solution as an equilibrium mixture of the *cis*- and *trans*-phosphine isomers shown below. For **5a** at 23°C, the ratio of *cis* to *trans* isomers (*cis–trans*) is approximately 1:1. At −33°C the *trans* isomer is dominant (1:6) and at +39°C the *cis* isomer is slightly favoured (1.7:1). The spectral changes are fully reversible. The solution behaviour of **5b** is similar to that of **5a** but, as expected on steric grounds, PMe_2Ph has a greater preference to be *trans* to PMe_2Ph (as opposed to *cis*) in comparison to the PMe_3 case.

5a, R = Me
5b, R = Ph

If the variable temperature ^1H NMR studies of **5a** and **5b** are repeated using CD_3CN as a solvent, the *cis–trans* ratio remains constant at temperatures below 23°C. This suggests that the isomerization is a two-step process involving acetonitrile dissociation followed by an intramolecular rearrangement of the resulting five-coordinate intermediate.

The *cis*- and *trans*-phosphine isomers of **5a** and **5b** are readily distinguished in ^1H NMR spectra. For instance, the *cis* isomer of **5a** gives rise to a doublet of a doublet for $ReCH_3$ and a doublet for the PMe_3 protons, whereas the *trans* isomer gives a triplet for $ReCH_3$ and a virtual triplet for the PMe_3 protons.

In contrast to **5a** and **5b**, NMR spectra recorded for **5c** are invariant with temperature. Two separate proton resonances for the dmpe methyl groups and only one ^{31}P resonance are observed for **5c**, and the ^1H NMR spectrum in the Re*Me* region resembles the spectra of *cis* **5a** and **5b**. These findings, as well as $^{13}C\{^1H\}$ NMR data, are consistent with the structure shown below.



5c

IR spectra recorded for **5a**, **5b** and **5c** show broad overlapping bands in the 950–1050 cm^{-1} region. This has prevented a definitive identification by labelling studies of the bands arising from the Re=O stretches. Oxo ligands are present, however, because the cations can be converted in the absence of air or water to their respective neutral compounds (**2a**, **2b** and **2c**) via reactions (9) and (10). It is noteworthy that only *cis*-dimethyl *cis*-diphosphine $ReOMe_2Cl(PMe_2R)_2$ complexes are obtained from eq. (9).

$$[ReOMe_2(PMe_2R)_2(CH_3CN)][BF_4] + NaCl \xrightarrow[1\,h]{CH_3CN} ReOMe_2Cl(PMe_2R)_2 + NaBF_4 \quad (9)$$

$$[ReOMe_2(dmpe)(CH_3CN)][BF_4] + NaCl \xrightarrow[1\,h]{CH_3CN} ReOMe_2Cl(dmpe) + NaBF_4. \quad (10)$$

CONCLUSION

We have prepared the neutral rhenium oxo-methyl complexes $ReOMe_2Cl(PMe_2R)_2$ (R = Me, Ph) and $ReOMe_2Cl(dmpe)$, and the cationic rhenium oxo-methyl complexes $[ReOMe_2(PMe_2R)_2(CH_3CN)]^+$ (R = Me, Ph) and $[ReOMe_2(dmpe)(CH_3CN)]^+$, in moderate yields. The latter compounds are the first examples of rhenium(V) mono-oxo cations.

The original synthetic targets of this study, $ReOMe_3(PMe_2R)$ compounds, are thermally unstable. This is in contrast to $ReO(CH_2SiMe_3)_3(PMe_3)$, which is stable at 23°C in the absence of air for months.[1] A related compound, $ReOEt_3(PPh_3)_2$, is also reported to be unstable at room temperature, but in this case the instability is

probably due to the presence of β-hydrogens in the molecule.[10] We are studying the decomposition reactions of $ReOMe_3(PMe_2R)$ in order to determine the ultimate products. Reactivity studies using $ReOMe_3(PMe_2R)$, which can be generated quantitatively *in situ*, are also in progress.

EXPERIMENTAL

Microanalyses were performed by Dornis and Kolbe, F.R.G. IR data were collected on a Perkin–Elmer 598 spectrophotometer (Nujol mulls (cm^{-1}), referenced externally to the 1601 cm^{-1} band of polystyrene). NMR data were collected using Bruker AM-500, AM-300, AM-250 and WM-300-WB (^{31}P NMR) spectrometers. ^1H NMR spectra were referenced to the ^1H impurities in the deuterated solvents (benezene-d_6, δ 7.15; acetonitrile-d_3, δ 1.93), ^{13}C NMR spectra to the ^{13}C triplet of benzene-d_6 (δ 128.0) or the septet of acetonitrile-d_3 (δ 1.3), and ^{31}P spectra to external H_3PO_4, with upfield shifts taken as negative. Molecular weights were determined by isothermal distillation (vs ferrocene).[11]

All operations were performed under oxygen-free nitrogen, argon or *in vacuo*. Solvents were purified by standard techniques and were dry and oxygen-free.

$^{13}C\{^1H\}$ NMR spectra obtained for the carbons of the phosphine ligands in **2a**, **2b**, **2c**, **3c**, **5a**, **5b** and **5c** were simulated using the program PANIC (Bruker). Initial ^{13}C coupling constants for **2a**, **2b**, **2c**, **5a**, **5b** and **5c** were obtained analytically by approximating the spin systems as AA′XX′ ($J_{CC'} = 0$).[12] Simulations with PANIC were carried out using an AXY spin system. In all cases, simulated and analytically determined coupling constants were in close agreement. The methyl region of the ^1H NMR spectrum of $ReOMe_3$(dmpe) (**3c**) was simulated as well.

(1) *Chlorodimethyloxobis(trimethylphosphine)rhenium*(V), $ReOMe_2Cl(PMe_3)_2$ (**2a**)

To a cold solution (−78°C) of $ReO(OEt)Cl_2(py)_2$ (1.50 g, 3.15 mmol) in methylene chloride (75 cm^3) $AlMe_3$ (1.6 cm^3, 3.20 mmol, 2.0 mol dm^{-3} in toluene) was added dropwise. The resulting green solution was frozen (−196°C) and the flask evacuated. PMe_3 (6.50 mmol) was then condensed into the flask via a calibrated vacuum manifold. After the mixture was allowed to warm to room temperature, the blue solution was heated (**Caution**: closed flask heating) at 75°C for 12 h. The volatiles were then removed *in vacuo*, and the residue was extracted with toluene (4 × 75 cm^3); the extracts were filtered and then evaporated to dryness *in vacuo*, and the residue was extracted with warm hexane (6 × 75 cm^3, 45°C). The hexane solution was filtered, reduced in volume, and cooled to −60°C to give red blocks. If necessary, the compound can be recrystallized from toluene. (Yield 0.82 g, 1.97 mmol, 62%.) Found: C, 23.1; H, 5.9; mol. wt (CH_2Cl_2) 404(30). Calc. for $ReClP_2OC_8H_{24}$: C, 22.9; H, 5.8%; mol. wt calc. 419.9.

^1H NMR (C_6D_6): δ 3.8 (d, 6, *cis*-J_{PH} = 7.4 Hz, Re*Me*), 1.6 (d, 18, J_{PH} = 9.2 Hz, P*Me*$_3$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 19.4 (dd, 2, *trans*-J_{CP} = 48 Hz, *cis*-J_{CP} = 8 Hz, Re*Me*), 18.0 (AXY, J_{CP} = 27.3, $^3J_{CP}$ = 2.7, J_{PP} = −11.4 Hz, $\Delta P_X - \Delta P_Y$ = 1.9 Hz, P*Me*$_3$). $^{31}P\{^1H\}$ (C_6D_6): δ −47.1 (s). (3) *Chlorodimethyloxo(bis(dimethylphosphino)ethane)rhenium*(V), $ReOMe_2Cl(Me_2PCH_2CH_2PMe_2)$ (**2c**)

To a solution of $ReOMe_2Cl(PMe_2Ph)_2$ (0.275 g, 0.51 mmol) in toluene (25 cm^3) dmpe (0.106 cm^3,

0.58 mmol) was added via syringe. The brown solution was stirred (1 h), filtered and concentrated *in vacuo* (to *ca* 3 cm^3). Cooling (−20°C) produced brown crystals. (Yield 0.162 g, 0.39 mmol, 76%.) This compound was also prepared from $ReOMe_2Cl(PMe_3)_2$ in 62% yield by an analogous procedure. A satisfactory carbon analysis was not obtained. Found: C, 25.5; H, 5.4. Calc. for $ReClP_2OC_8H_{22}$: C, 23.0; H, 5.3%.

^1H NMR (C_6D_6): δ 3.76 (d, 6, *cis*-J_{PH} = 6.8 Hz, Re*Me*), 1.79 (m, 2, —C*H*$_2$PMe$_2$), 1.40 (d, 6, J_{PH} = 11.4 Hz, —CH$_2$P*Me*$_2$), 1.07 (d, 6, J_{PH} = 8.0 Hz, —CH$_2$P*Me*$_2$), 0.93 (m, 2, —C*H*$_2$PMe$_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 32.9 (AXY, 2, J_{CP} = 41.0 Hz, $^3J_{CP}$ = 3.3 Hz, J_{PP} = −12 Hz, —*C*H$_2$PMe$_2$), 16.7 (AXY, 2, J_{CP} = 28.2 Hz, $^3J_{CP}$ = 10.1 Hz, J_{PP} = −4.3 Hz, $\Delta P_X - \Delta P_Y$ = 3.4 Hz, —CH$_2$P*Me*$_2$), 11.8 (AXY, 2, J_{CP} = 39.8 Hz, $^3J_{CP}$ = 7.1 Hz, J_{PP} = −5 Hz, $\Delta P_X - \Delta P_Y$ = 1.9 Hz, —CH$_2$P*Me*$_2$), 11.35 (AXY, 2, *trans*-J_{CP} = 37.5 Hz, *cis*-J_{CP} = 12.5 Hz, J_{PP} = −3.4 Hz, Re*Me*). $^{31}P\{^1H\}$ NMR (C_6D_6): δ 16.1 (s). IR: ν(Re═O) 1000(s) [ν(Re═^{18}O) 948], 1827(w), 1799(m), 1420(w), 1409(w), 1302(sh), 1288(m), 1246(w), 1180(br), 1107(w), 940(s), 919(w), 901(m), 867(w), 844(w), 748(m), 713(m), 650(m), 636(m), 510(m), 453(w), 362(w), 349(w).

(4) *Trimethyloxo(trimethylphosphine)rhenium*(V), $ReOMe_3(PMe_3)$ (**3a**)

To a cold solution (0°C) of $ReOMe_2Cl(PMe_2Ph)_2$ (0.050 g, 0.12 mmol) in toluene (20 cm^3) a toluene solution (5 cm^3) of $ZnMe_2$ (0.020 cm^3, 0.21 mmol) was added dropwise via an addition funnel over a period of 10 min. The solvent was then removed at 0°C under reduced pressure. The residue was extracted with cold pentane. Removal of the pentane under reduced pressure yielded a green oil. The yield was quantitative by ^1H NMR vs internal standard. The isolated yield was 47%. The material decomposed within days when stored at −20°C.

^1H NMR (C_7D_8, −57°C): 3.56 (s, 3, Re*Me*), 2.57 (d, 6, J_{PH} = 8.2 Hz, Re*Me*), 0.61 (d, 9, J_{PH} = 8.2 Hz, P*Me*$_3$). $^{13}C\{^1H\}$ NMR (C_7D_8, −66°C): 32.2 (d, 1, J_{CP} = 25.3 Hz, Re*Me*), 18.0 (s, 2, Re*Me*), 12.6 (d, 2, J_{CP} = 31.3 Hz, P*Me*$_3$). $^{31}P\{^1H\}$ NMR (C_7D_8, −23°C): δ −0.7 (s).

(5) *Trimethyloxo(dimethylphenylphosphine)rhenium*(V), $ReOMe_3(PMe_2Ph)$ (**3b**)

This compound was prepared by a procedure analogous to the one used for the preparation of $ReOMe_3(PMe_3)$. The yield was quantitative by ^1H NMR vs internal standard. The isolated yield was 51%.

^1H NMR (C_7D_8, −66°C): δ 7.26 (m, 2, PMe$_2$*Ph*), 7.04 (m, 3, PMe$_2$*Ph*), 3.66 (s, 3, Re*Me*), 2.62 (d, 6, J_{PH} = 8.7 Hz, Re*Me*), 0.85 (d, 6, J_{PH} = 9.1 Hz, P*Me*$_2$Ph). $^{13}C\{^1H\}$ NMR (C_7D_8, −66°C): δ 131.6 (d, 2, J_{CP} = 10.7 Hz, PMe$_2$*Ph*), 130.8 (s, 1, PMe$_2$*Ph*), 129.1 (2, PMe$_2$*Ph*), 31.8 (d, 1, J_{CP} = 24.9 Hz, Re*Me*), 18.9 (s, 2, Re*Me*), 12.5 (d, 2, J_{CP} = 30.7 Hz, P*Me*$_2$Ph). $^{31}P\{^1H\}$ NMR (C_7D_8, 23°C): δ −0.8 (s).

(6) *Trimethyloxo(bis(dimethylphosphino)ethane) rhenium*(V), $ReOMe_3$(dmpe) (**3c**)

This compound was prepared by a procedure similar to the one used for the preparation of $ReOMe_3(PMe_3)$. The compound is a red solid. (Yield 31%.)

^1H NMR (C_6D_6): δ 3.25 (dd, 3, J_{P_XH} = 7.8 Hz, J_{P_YH} = 6.6 Hz, Re*Me*), 2.94 (dd, 6, J_{P_XH} = 13.7 Hz, J_{P_YH} = 5.7 Hz, Re*Me*), 1.39 (d, 6, J_{PH} = 9.9 Hz, —CH$_2$P*Me*$_2$), 1.02 (m, 2, —C*H*$_2$PMe$_2$), 0.55 (m, 2, —C*H*$_2$PMe$_2$), 0.20 (d, 6, J_{PH} = 7.5 Hz, —CH$_2$P*Me*$_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 28.8 (m, 1, —*C*H$_2$PMe$_2$), 25.9 (dd, 1, J_{CP_X} = 20.5 Hz, J_{CP_Y} = 17.5 Hz, Re*Me*), 24.7 (m, 1, —*C*H$_2$PMe$_2$), 17.2 (m, 2, CH$_2$P*Me*$_2$), 17.0 (dd, 2, J_{CP_X} = 17.5 Hz, J_{CP_Y} = 12.5 Hz, Re*Me*), 7.7 (m, 2, CH$_2$P*Me*$_2$). $^{31}P\{^1H\}$ NMR (C_6D_6): δ −3.0 (d, J_{PP} = 29 Hz), −34.7 (d, J_{PP} = 29 Hz). IR: ν(Re═O) 1018(s), 1419(m), 1360(sh), 1299(m), 1283(m), 1239(m), 1252(m), 1221(m), 980(m), 938(s), 927(sh), 910(m), 894(m), 835(m), 793(w), 703(m), 649(w).

(7) *Trimethyloxo(bipyridine)rhenium*(V), $ReOMe_3$(bipy) (**4**)

To a cold (0°C) solution of $ReOMe_2Cl(PMe_2Ph)_2$ (0.050 g, 0.09 mmol) in toluene (30 cm^3) a toluene solution (5 cm^3) of $ZnMe_2$ (0.020 cm^3, 0.21 mmol) was added dropwise via an addition funnel. After the addition was complete, the solvent was removed at 0°C *in vacuo*. The residue was extracted with cold pentane, and the pentane solution added to a flask containing an excess of bipy (0.050 g, 0.32 mmol). The mixture slowly changed colour from green to blue (2 h). Solvent and the excess bipy were then removed *in vacuo*. Crystallization from pentane (−50°C) gave blue crystals. (Yield 0.013 g, 0.03 mmol, 35%.)

^1H NMR (C_6D_6): δ 8.81 (m, 1, *bipy*), 7.77 (d, 1, bipy), 7.25 (m, 1, bipy), 6.79 (d, 1, bipy), 6.50 (dt, 1, bipy), 6.23 (dq, 2, bipy), 5.34 (m, 1, bipy), 3.92 (s, 3, Re*Me*), 2.83 (s, 6, Re*Me*). IR: ν(Re═O) 970(s), 1602(m), 1588(m), 1579(sh), 1562(w), 1419(sh),

1312(m), 1260(m), 1239(m), 1150(w), 1010(w), 990(w), 957(sh), 900(m), 752(s), 511(w).

(8) *Dimethyloxo(acetonitrile)bis(trimethylphosphine) rhenium*V) *tetrafluoroborate*, $[ReOMe_2(PMe_3)_2(CH_3CN)][BF_4]$ (**5a**)

To a mixture of $ReOMe_2Cl(PMe_3)_2$ (0.100 g, 0.24 mmol) and $[Ag(CH_3CN)_2][BF_4]$ (0.065 g, 0.24 mmol) cold acetonitrile (25 cm^3, 0°C) was added. A white powder formed immediately. The solution was stirred (1 h), filtered, and then the solvent removed *in vacuo* to yield a red oil. (Yield 0.086 g, 0.17 mmol, 71%.) Two isomers were observed in solution (the *cis–trans* ratio at 24°C in CD_3CN is 3:1). Found: C, 23.4; H, 5.1; N, 2.9. Calc. for $ReP_2F_4ONC_{10}BH_{27}$: C, 23.4; H, 5.3; N, 2.7%.

IR: 2287(w), 1314(sh), 1292(m), 1235(s), 1120(br), 1030(br), 1010(m), 950(m), 905(m), 848(w), 761(w).

cis isomer. ^1H NMR (CD_3CN): δ 3.0 (dd, 6, *cis*-J_{PH} = 7.3 Hz, *trans*-$J_{P'H}$ = 2.3 Hz, Re*Me*), 1.9 (s, 3, C*H*$_3$CN), 1.83 (d, 18, J_{PH} = 10.3 Hz, P*Me*$_3$). $^{13}C\{^1H\}$ NMR (CD_3CN): δ 18.0 (AXY, 2, J_{CP} = 23 Hz, $^3J_{CP}$ = 10.5 Hz, J_{PP} = −17 Hz, $\Delta P_X - \Delta P_Y$ = 1.9 Hz, P*Me*$_3$), 14.4 (dd, 2, *trans*-J_{CP} = 15 Hz, *cis*-J_{CP} = 9 Hz, Re*Me*). $^{31}P\{^1H\}$: δ −36.1 (s).

trans isomer. ^1H NMR (CD_3CN): δ 3.73 (t, 6, J_{PH} = 6.3 Hz, Re*Me*), 1.95 (s, 3, C*H*$_3$CN), 1.73 (virtual triplet, 18, $J_{PH} = J_{P'H}$ = 5.1 Hz, P*Me*$_3$). $^{13}C\{^1H\}$ NMR (CD_3CN): 14.72 (virtual triplet, 6, $J_{CP} = {}^3J_{CP}$ = 17 Hz, P*Me*$_3$), −6.1 (t, 2, J_{CP} = 5 Hz, Re*Me*). $^{31}P\{^1H\}$ (CD_3CN): δ −32.9 (s).

(9) *Dimethyloxo(acetonitrile)bis(dimethylphenylphosphine)rhenium*(V) *tetrafluoroborate*, $[ReOMe_2(PMe_2Ph)_2(CH_3CN)][BF_4]$ (**5b**)

This compound was prepared by a procedure similar to the one used for the preparation of $[ReOMe_2(PMe_3)_2(CH_3CN)][BF_4]$. The compound was isolated as a red–orange oil. (Yield 65%.) Two isomers were observed in solution (the *cis–trans* ratio at 24°C in CD_3CN is 2:1).

IR: 2255(w), 2240(m), 1440(sh), 1308(m), 1289(w), 1236(m), 1060(vbr), 980(br), 956(w), 895(m), 870(sh), 838(w), 740(s), 690(m), 675(w), 518(m), 483(s), 412(m), 397(sh).

cis isomer. ^1H NMR (CD_3CN): δ 7.62 (m, 2, PMe_2*Ph*), 7.51 (m, 3, PMe_2*Ph*), 3.08 (dd, 6, *cis*-J_{PH} = 9.4 Hz, *trans*-$J_{P'H}$ = 2.0 Hz, Re*Me*), 1.95 (s, 3, C*H*$_3$CN), 1.90 (d, 6, J_{PH} = 10 Hz, P*Me*$_2$Ph), 1.85 (d, 6, J_{PH} = 9.9 Hz, P*Me*$_2$Ph). $^{13}C\{^1H\}$ NMR (CD_3CN): δ 132.1 (s, 2, PMe_2*Ph*), 131.82 (d, 2, J_{PC} = 3.5 Hz, PMe_2*Ph*), 131.77 (d, 2, J_{CP} = 3.5 Hz, PMe_2*Ph*), 131.46 (d, 2, J_{CP} = 3.7 Hz, PMe_2*Ph*), 131.41 (d, 2, J_{CP} = 3.7 Hz, PMe_2*Ph*), 130.15 (d, 2, J_{CP} = 4.5 Hz, PMe_2*Ph*), 16.25 (AXY, 2, J_{CP} = 30 Hz, $^3J_{CP}$ = 2.2 Hz, J_{PP} = −12.2 Hz, $\Delta P_X - \Delta P_Y$ = 2.0 Hz, P*Me*$_a$Me$_b$Ph), 14.96 (AXY, 2, J_{CP} = 32.2 Hz, $^3J_{CP}$ = 1.3 Hz, J_{PP} = −12.2 Hz, $\Delta P_X - \Delta P_Y$ = 2.4 Hz, PMe$_a$*Me*$_b$Ph), 16.5 (dd, 2, *trans*-J_{CP} = 16 Hz, *cis*-J_{CP} = 2 Hz, Re*Me*). $^{31}P\{^1H\}$ NMR (CD_3CN): δ −28.1 (s).

Crystallographic studies

Crystal data. $ReOClMe_2(PMe_3)_2$ at −80(1)°C: M = 419.9; monoclinic, space group $P2_1/n$, a = 6.632(4), b = 12.729(4), c = 17.495(6) Å, β = 93.08(4)°, Z = 4, D_c = 1.891 g cm^{-3}, μ(Mo-K_α) = 87.21 cm^{-1}.

Data collection. X-ray data were collected on a

Nicolet R3 four-circle diffractometer equipped with a LT-1 low-temperature device. Data collection was controlled using the Nicolet program P3. Raw diffractometer data were processed using the program XDISK. An empirical absorption correction was performed with the program PSICOR. $4 \leqslant 2\theta \leqslant 45°$, $T = 193$ K, 4366 data measured, 1930 unique, 1741 observed [$F_o > 6\sigma(F_o)$].

Structure solution and refinement. The structure was solved and refined using the SHELXTL-PLUS (microVax II) packages of programs. The rhenium atom was found by use of a Patterson synthesis. Standard difference map techniques were used to find the remaining non-hydrogen atoms. After all of the non-hydrogen atoms were located and refined anisotropically, a difference map revealed approximately one half of the hydrogen positions. The hydrogen atoms were therefore placed in calculated positions on the appropriate carbon atoms ($U_{iso}(H) = 1.2U_{iso}(C)$; d_{C-H} 0.96 Å) for refinement. Refinement was performed to convergence [$\Delta/\sigma(\max) < 0.001$] with this model. The values of R, R_w were 0.0335 and 0.0401, respectively, and the weighting scheme was $w = [\sigma^2(F) + 0.0018F^2]^{-1}$. The final difference map contained two peaks (1.63 and 1.44 eÅ^{-3}) within 1.00 Å of the rhenium. All other peaks were less than 0.90 eÅ^{-3}.

Final atomic coordinates, a table of anisotropic thermal parameters and a F_o/F_c listing have been deposited with the Editor as supplementary material.

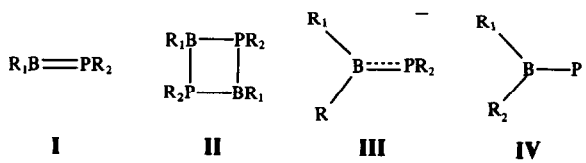
(*Received* 23 *September* 1988; *accepted* 9 *November* 1988)

Abstract—A portion of the potential energy surface of the [BH_2P] system has been studied in both the singlet and triplet electronic states using *ab initio* methods. Local minima corresponding to borylphosphinidene (H_2BP), boraphosphene (HBPH) and phosphinoborene (BPH_2) were obtained at the HF/6–31G** level. Transition structures linking these species via 1,2-hydrogen shifts were also located. Relative energies were estimated at the MP4/6–31++G**+ZPE level. The singlet HB=PH is the global minimum, while H_2B—P is the lowest energy on the triplet surface. Calculated results suggest that these two species are probably the only stable ones with respect to unimolecular rearrangement. Comparison between Iterative Extended Hückel (IEH) calculations on $(H_3CP)Fe(CO)_3$, $(H_2NP)Fe(CO)_3$ and $(H_2BP)Fe(CO)_3$ also suggests that the latter complex is somewhat weaker than the former, but complexation with a d^8 metal system might be a means of examining boraphosphinidenes.

Being members of the family of phosphorus compounds with lower coordination states, the boraphosphenes **I** (or phosphaborenes) featuring a boron–phosphorus double bond are of considerable current interest. In 1986, Cowley and co-workers[1] reported the first vapour phase synthesis of **I** (with R_1 = 2,2,6,6-tetramethylpiperidino; R_2 = 2,4,6-tri-*t*-butylphenyl) from thermolysis of the dimeric form **II** (diphosphadiboretanes) at 250°C.



I **II** **III** **IV**

The lithium salts of **I**, giving phosphinidene–borate anions **III**, have been described simultaneously by Power and co-workers[2] and Couret *et al.*[3] The transient existence of **I** during the synthesis of **II** has also been postulated by Nöth and collaborators.[4]

On the other hand, the isomeric forms **IV** (borylphosphinidenes), belong to a class of reactive species whose interactions with transition metal fragments have been studied extensively.[5,6]

As far as we know, apart from some preliminary SCF calculations[1] comparing linear and bent forms of the parent HB=PH species (with the split-valence 6–31G basis set), no theoretical work on these species has as yet been undertaken. As part of our continuing efforts on theoretical studies of low-coordinated phosphorus compounds[7] we now describe *ab initio* molecular orbital calculations on the potential energy surface of the simplest system, [BH_2P]. The latter was considered in both the lowest-lying singlet and triplet electronic states in order to obtain useful information on the relative stabilities between isomers with respect to 1,2-hydrogen shifts.

† Author to whom correspondence should be addressed.

In addition, the possibility of trapping borylphosphinidenes in a metal complex is also worth examining. Therefore, the second part of the present work consists of a comparative Iterative Extended Hückel (IEH) study of the ability of borylphosphinidene (H_2BP) to coordinate to a tricarbonylmetal moiety relative to amino- and methylphosphinidenes (H_2NP and H_3CP, respectively).

RESULTS AND DISCUSSION

(1) Ab initio *calculations on the* [BH_2P] *potential energy surface*

Ab initio calculations were carried out using the GAUSSIAN 82 package[8] on a VAX 11/780 computer. The equilibrium and transition structures were located using analytical energy derivatives at the single determinantal SCF level with the polarized 6–31G** basis set.[9] Harmonic vibrational frequencies were computed at the HF/6–31G** level in order to characterize stationary points and to estimate zero-point vibrational contributions to relative energies. The latter were obtained from single-point calculations (with HF/6–31G** geometries) at the Møller–Plesset perturbation theory[10] level employing an additional basis set, namely the 6–31++G** (++ denotes a set of diffuse *s* functions on H and *sp* functions on B and P).[11] The unrestricted formalism (UHF, UMP) was used for the triplet states.

(a) *Singlet states.* Five stationary points on the singlet [BH_2P] energy surface were located. These consisted of three minima including borylphosphinidene **1** (H_2B—P), boraphosphene **3** (HB=PH) and phosphinoborene **5** (B—PH_2), and the transition structures **2** and **4** for the 1,2-hydrogen shift connecting the isomers. The HF/6–31G** optimized geometries are displayed in Fig. 1, while the total and relative energies are collected in Table 1.

As seen in Table 1, the boraphosphene **3** has the lowest energy. At the HF level, there is a very small energy barrier between **1** and **3**. At higher levels, this barrier disappears indicating that the borylphosphinidene **1** does not exist as a discrete species in the closed-shell singlet state. A similar situation has previously been observed for the isovalent borylnitrene (H_2B—N).[12] For its part, the phosphinoborene **5** is calculated to be a high-level minimum lying 48.7 kcal mol^{-1} above **3**. The energy barrier for the **5**–**3** conversion amounts to only 9.2 kcal mol^{-1}. This value is thus much smaller than that of 18 and 33 kcal mol^{-1} previously obtained for the H_2P—CH → HP=CH_2[13] and H_2P—N → HP=NH[14] conversions, respectively, at similar levels of theory. Accordingly, boraphosphene **3** is probably the only observable species on the singlet potential energy surface.

Fig. 1. HF/6–31G** geometries of stationary points on the singlet energy surface. Bond lengths in Å and bond angles in degrees. ν_i are imaginary frequencies, associated with transition structures, given in cm^{-1}.

At the HF/6–31G** level, the harmonic B=P stretching frequency in **3** is 1043 cm^{-1}. This value lies close to those of 1260 cm^{-1} for P=N in HP=NH[14] and 1114 cm^{-1} for C=P in H_2C=PH[13] at a similar level. In contrast, it is larger than the stretching frequency of 709 cm^{-1} computed for P=P in HP=PH.[15] This indicates that the boron–phosphorus bond in boraphosphenes has a rather strong double bond character. In view of the systematic overestimation of vibrational frequencies at the HF level (by 10–15%), it can be expected that the B—P stretching frequencies of R_1B=PR_2 compounds lie in the region of 900–950 cm^{-1}.

It is also worth noting that the HOMO in **3** is B—P π-bonding, whereas the second HOMO is B—P σ-bonding. These orbitals are pictured in structures **3a** and **3b**, respectively.

[c] Estimated values using the additivity approximation: ΔE(MP4/6–31++G**) ≈ ΔE(MP4/6–31G**) + ΔE(MP2/6–31++G**) − ΔE(MP2/6–31G**).

[d] Including ΔE(MP4SDTQ/6–31++G**) and Δ(ZPE).

(b) *Triplet states.* The UHF/6–31G** optimized geometries for the triplet species **6**–**10** considered are recorded in Fig. 2. The total and relative energies are collected in Table 2. In order to facilitate the comparison, the final energy profile for both singlet and triplet electronic states is shown schematically in Fig. 3 (values at MP4SDTQ/6–31++G**+ZPE level).

At all levels of theory considered, the borylphosphinidene **6** (H_2B—P) turns out to be the triplet global minimum lying 31.1 and 53.7 kcal mol^{-1} below **8** (HB=PH) and **10** (B—PH_2), respectively. The triplet phosphinidene **6** possesses a C_{2v} symmetry ($^3A_2$ state) while the triplet boraphosphene **8** is planar and *cis*-bent ($^3A'$). The phosphinoborene **10** exhibits a flatter pyramidal configuration about phosphorus than that in the singlet **5**.

Parallel to the decrease of the B—P distances in the three minima (from **6** via **8** to **10**, Fig. 2), the corresponding harmonic stretching frequencies also increase monotonically from 696 cm^{-1} in **6** via 727 cm^{-1} in **8** to 833 cm^{-1} in **10**. The change occurring in the B—P distances of the triplets with respect to the singlets is thus in line with the orbital picture. For example, the triplet boraphosphene **8** is formally formed by taking an electron away from the B—P π-bonding orbital **3a** (becoming the orbital **8b** in structure **8**) and placing it in an orbital which

is primarily localized on boron and with B—P antibonding components (the orbital **8a**). This consequently reduces the B—P bond order in **8** and the stretching frequency by 316 cm^{-1} (with respect to that of the singlet **3**).

The three minima interconvert, respectively, through the two transition structures **7** and **9**. In the latter, the B—P distances are more contracted than in the equilibrium structures. Both conversions proceed via an out-of-plane migration with rather similar H—B—P angles (62.1° in **7** and 61.9° in **9**).

Our best energetic estimates (Table 2) suggest that the triplet borylphosphinidene **6** is quite stable with respect to unimolecular rearrangement. For instance, the conversion H_2B—P (**6**) → HB=PH (**8**) via the transition structure **7** requires a large barrier energy of 42.6 kcal mol^{-1}. In contrast, the conversion of either HB=PH (**8**) or B—PH_2 (**10**) to the more stable and directly connected isomer is a rather facile process, requiring only 10.4 kcal mol^{-1} for **10** and 11.5 kcal mol^{-1} for **8**. Accordingly, the "cascade effect" in the triplet potential energy surface (see Fig. 3) appears to favour the formation of borylphosphinidene **6** as the only stable triplet species. It is noted that the energy difference

between the most stable triplet structure **6** and the most stable singlet one, **3** (which is also the global minimum of the species considered), is calculated to be 15.3 kcal mol^{-1} (Fig. 3). This is slightly larger than the values of 10 and 6 kcal mol^{-1} previously obtained for the $CH_3P \rightarrow CH_2PH$[13] and $NH_2P \rightarrow HNPH$[16] systems, respectively (at comparable levels of theory).

In summary, the most significant chemical result of the present study of the $[BH_2P]$ potential energy surface is a prediction that the boraphosphene **3** and borylphosphene **6** are stable discrete species in the lowest-lying singlet and triplet electronic states, respectively. The remaining isomers are high-energy species and unstable with respect to unimolecular rearrangement.

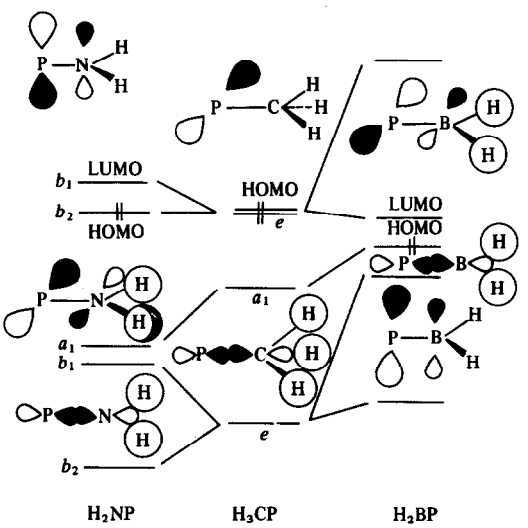

Fig. 4. Molecular orbital correlation digram for H_2NP, H_3CP and H_2BP.

(2) *Comparative extended Hückel study of the complexation of phosphinidenes with the* d^8 *metal fragment* $Fe(CO)_3$

In order to examine whether borylphosphinidenes are possible candidates for metal complexation, we also performed IEH calculations on the interaction of the model species NH_2P, CH_3P and BH_2P with the d^8 $Fe(CO)_3$ moiety. The three phosphinidenes are interesting because of the difference between them, with a π-donor in the α-position in H_2NP, almost none in H_3CP and a π-acceptor in the α-position in H_2BP. We used the *Forticon-8*[17] program for the IEH calculations. Details of the choice of semi-empirical parameters used are given in the Appendix. Calculations on the isolated ligands (Fig. 4) show that the HOMO–LUMO gap in borylphosphinidene (H_2BP) is quite similar to that in aminophosphinidene (H_2NP). From nitrogen to carbon to boron, the gap between the first and second HOMOs decreases, with the second HOMO moving to higher energy as the p_z(P) coefficient increases. A population analysis (Table 3) also indicates that there is greatest P—X charge-transfer in BH_2P. The P—X bond is strongest for X = B, with stronger σ- and π-components than in amino- and methylphosphinidenes. Such a difference obviously affects the interaction with metal fragments.

The interaction between CH_3P and $Fe(CO)_3$ has previously been discussed in some detail by Trinquier and Bertrand.[5a] However, for the purpose of comparison, we display again the interaction dia-

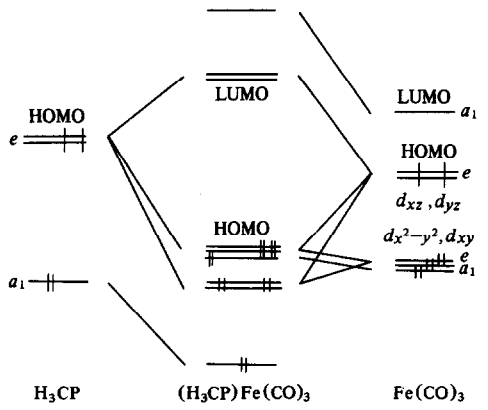

Fig. 5. Molecular orbital interaction diagram for $(CH_3P)Fe(CO)_3$.

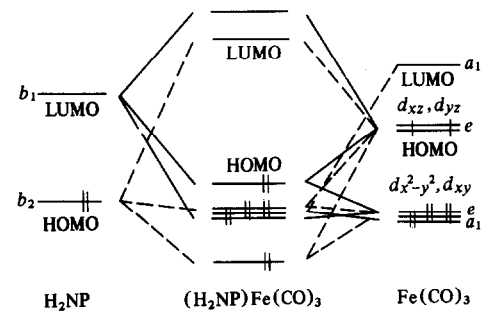

Fig. 6. Molecular orbital interaction diagram for $(NH_2P)Fe(CO)_3$.

gram in Fig. 5 along with that for $(H_2NP)Fe(CO)_3$ and $(H_2BP)Fe(CO)_3$ in Figs 6 and 7, respectively.

As seen in Fig. 7, the HOMO (e) of $Fe(CO)_3$ can overlap with the LUMO (b_2) of H_2BP. The analogous interaction in $(H_2NP)Fe(CO)_3$ is that with the empty b_1-orbital of H_2NP. The overlap is not as good in the former as in the latter. The HOMO and LUMO of H_2BP are at lower energy than those of H_2NP which should favour the H_2BP (LUMO)–$Fe(CO)_3$ (HOMO) interaction and operate against the H_2BP (HOMO)–$Fe(CO)_3$ (LUMO) one. Thus, the orbital overlap trend reduces Fe—P donation in going from H_2NP to H_2BP, while the molecular orbital energy trend favours it. In H_2BP, the HOMO (a_1) can also interact with the LUMO (a_1) of $Fe(CO)_3$, although the energy difference is large. The HOMO–LUMO gap in the complexes is largest in $(H_3CP)Fe(CO)_3$ (≈ 3 eV), smaller in $(H_2NP)Fe(CO)_3$ (≈ 2.5 eV) and further reduced to ≈ 1.5 eV in $(H_2BP)Fe(CO)_3$, suggesting a decreasing kinetic stability.

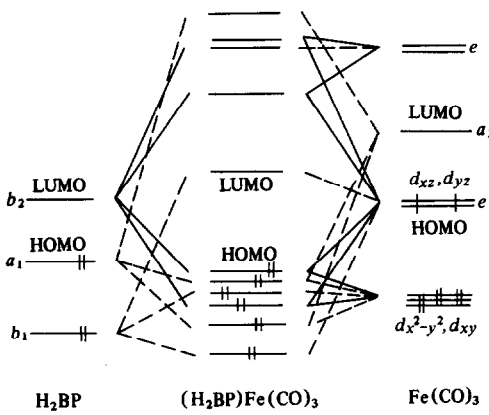

Fig. 7. Molecular orbital interaction diagram for $(H_2BP)Fe(CO)_3$.

The population analysis (Table 3) shows that there is greatest Fe → P electron transfer in the H_2BP complex (although boron retains little of this extra charge). In addition, the P—X ($\sigma+\pi$) and P—X (π) overlap populations *decrease* on complexation in all cases. These values are largest in $(H_2BP)Fe(CO)_3$. In contrast, the Fe—P overlap population is smallest in the latter. Thus, despite considerable Fe—P donation, the Fe—P turns out to be slightly weaker in the borylphosphinidene complex.

In summary, the IEH calculations suggest that the $(H_2BP)Fe(CO)_3$ complex is somewhat less stable than either $(H_2NP)Fe(CO)_3$ or $(H_3CP)Fe(CO)_3$, though the HOMO–LUMO gap is by no means negligible. The Fe—P bond is weaker, but the X—P becomes stronger for $X = BH_2$ than for $X = NH_2$ or CH_3. Thus complexation with a d^8 metal moiety might be a means of examining boraphosphinidenes. This is certainly better than complexation with other fragments such as d^6 systems.

APPENDIX

Parameters used in the IEH calculations

Geometrical parameters. For BH_2P, the geometry is given in Fig. 2. For CH_3P and NH_2P, the geometries were taken from refs 13 and 14, respectively. The $Fe(CO)_3$ fragment was assumed to be octahedral with r(Fe—C) = 1.820 Å and r(C—O) = 1.150 Å. The Fe—P distance used was fixed at 2.00 Å for all complexes.

Basis sets and diagonal coulomb terms. The basis set for iron consisted of valence Slater-type 3*d*, 4*s* and 4*p* atomic orbitals; for the first-row atoms, 2*s* and 2*p* atomic orbitals, and for phosphorus, 3*s* and 3*p* atomic orbitals, were used. 1*s* orbitals were included on hydrogen atoms. The radial wavefunctions computed by Fitzpatrick and Murphy[18] as a least-squares fit to the SCF functions of Herman and Skillman[19] were chosen (double-zeta functions were used to represent *d* orbitals). A value of 1.3 was used as the exponent for the hydrogen 1*s* orbitals. Valence orbital ionization energies of the atoms were taken from Basch *et al.*[20] as approximations to the diagonal terms of the coulomb matrix. Off-diagonal terms were calculated using the "weighted" Wolfsberg–Helmholz parameterization.[21]

(*Received* 27 *September* 1988; *accepted* 9 *November* 1988)

Abstract—Several new organoperoxo complexes of Zr^{IV}, Th^{IV}, Mo^{VI} and U^{VI} have been synthesized and characterized. The complexes have the general formulae, $[Zr(O_2)C_6H_4(CO_2)_2 \cdot 2C_5H_5NO]$, $[Th(O_2)_2L]$, $[Th(O_2)C_6H_4(CO_2)_2 \cdot 2OPPh_3]$, $[Th(O_2)L'_2]$, $[MO(O_2)_2L]$, $[MO(O_2)L'_2]$ and $[MO(O_2)L''H_2O]$ [L = bidentate, neutral; L′ = bidentate, uninegative and L″ = bidentate, dinegative ligands; M = Mo^{VI} and U^{VI}], respectively. The complexes were found to oxidize PPh_3 and $AsPh_3$ to their oxides. The IR spectra of the complexes indicate that the frequency of the ν_1 mode of the $M(O_2)$ grouping, which is essentially an O—O stretch, decreases with the increase in the atomic number of metals in a particular group.

The general field of peroxo complexes of transition metals has attracted considerable attention in recent years.[1–9] By introducing different ligands into metal peroxides, its properties can be modified so that more stable complexes are formed. In general, peroxo complexes containing multidentate ancillary ligands stabilize the metal peroxo moiety which precludes the transfer of active oxygens to organic and inorganic substrates.[5,9] In addition, the reactivity of peroxo complexes can be greatly modified by introducing metals of different sizes.[2,4–6,9,10] We have been interested in extending such a study to peroxo complexes of Zr^{IV}, Th^{IV}, Mo^{VI} and U^{VI} containing a number of bidentate organic ligands. We report here the synthesis of these complexes and their possible oxygen transfer reactions.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade and were used as supplied by Merck.

Physical measurements and elemental analyses

IR spectra (as KBr pellets) were recorded on a Pye-Unicam SP3-300 IR spectrophotometer. Conductivities of 10^{-3} M solutions in dimethyl sulphoxide (DMSO) were recorded at 298 K using a WPA CM35 conductivity meter and a dip-type cell with platinized electrodes.

Metals[4,6–8] were determined gravimetrically. Carbon and hydrogen analyses were carried out by Mikroanalytisches Labor Pascher, F.R.G.

Preparation of complexes: General method for the preparation of complexes **1** *and* **4**: $[M(O_2)C_6H_4(CO_2)_2 \cdot 2L]$ (M = Zr^{IV} *and* Th^{IV}; L = C_5H_5NO *or* $OPPh_3$)

$M(NO_3)_4 \cdot 4H_2O$ (0.005 mol) in water (25 cm^3) was added to a solution of phthalic acid (0.005 mol) in methanol (20 cm^3). To the mixture, 25 cm^3 of 30% H_2O_2 was added followed by the addition of a solution of L (0.01 mol) in acetone (50 cm^3). The resulting precipitate which separated out was filtered, washed with ethanol and dried *in vacuo* over P_4O_{10}.

Preparation of complexes **2** *and* **3**: $[Th(O_2)_2L]$ (L = $C_6H_4(NH_2)_2$ *and* $C_5H_4NNH_2$)

$Th(NO_3)_4 \cdot 4H_2O$ (0.005 mol) in water (25 cm^3) was added to a solution of the ligand L (0.005 mol) in ethanol (25 cm^3). To the mixture, 30 cm^3 of 30% H_2O_2 was added. The resulting mixture was heated on a steam bath for 10 min. The precipitate so obtained was processed and collected as before.

Preparation of **5**: $[Th(O_2)(C_6H_4NH_2O)_2]$

The same procedure was applied to $Th(NO_3)_4 \cdot 4H_2O$ (0.005 mol), $C_6H_4NH_2OH$ (0.01 mol) and 20 cm^3 of 30% H_2O_2, which gave the product **5**.

Preparation of **6**: $[Mo(O)(O_2)_2C_6H_4(NH_2)_2]$

MoO_3 (0.005 mol) was stirred and heated in 30% H_2O_2 (60 cm^3) at 50°C for 48 h. The solution was filtered and the filtrate added to a solution of $C_6H_4(NH_2)_2$ (0.005 mol) in ethanol (30 cm^3). The precipitate obtained was separated and stored as above.

Preparation of complexes **7–9**: $[Mo(O)(O_2)(NH_2CH_2CH_2O)_2]$ *and* $[Mo(O)(O_2)L''H_2O]$ ($L'' = CH_2CH_2O_2$ *and* $CH_2(CO_2)_2$]

These complexes were prepared similarly from MoO_3 (0.005 mol) in 50 cm^3 of 30% H_2O_2 and a stoichiometric amount of organic ligands in ethanol (25 cm^3).

Preparation of **10** *and* **11**: $[U(O)(O_2)_2L]$ ($L = C_6H_4(NH_2)_2$ *and* $C_5H_4NNH_2$)

To a solution of $UO_2(NO_3)_2 \cdot 6H_2O$ (0.005 mol) in ethanol (20 cm^3), was added successively a solution of L (0.005 mol) in the same solvent (25 cm^3) and 20 cm^3 of 30% H_2O_2. The product was separated and stored as above.

Preparation of complexes **12** *and* **13**: $[U(O)(O_2)L'_2]$ ($L' = NH_2CH_2CH_2O^-$ *and* $C_6H_4NH_2O^-$)

The same procedure was applied to $UO_2(NO_3)_2 \cdot 6H_2O$ (0.005 mol), L′ (0.01 mol) and 25 cm^3 of 30% H_2O_2, which yielded products **12** and **13**.

Preparation of **14**: $[U(O)(O_2)CH_2(CO_2)_2H_2O]$

Complex **14** was prepared similarly, from $UO_2(NO_3)_2 \cdot 6H_2O$ (0.005 mol), $CH_2(COOH)_2$ (0.005 mol) and 20 cm^3 of 30% H_2O_2.

Reaction of **10** *with triphenylphosphine* [*Reaction* (*a*)]

Triphenylphosphine (1.05 g, 0.004 mol) was added to a solution of **10** (0.85 g, 0.002 mol) in tetrahydrofuran (THF) (40 cm^3). The mixture was heated to 60°C for 72 h. TLC indicated that the reaction was complete. The solution was filtered and the residue collected. A yellowish-white product was recovered from the filtrate which was identified as $OPPh_3$, m.p. 156–157°C (literature 157°C).

Reaction of **6** *with triphenylarsine* [*Reaction* (*b*)]

A solution of triphenylarsine (0.28 g, 0.0009 mol) in THF (25 cm^3) was added to a suspension of **6** (0.13 g, 0.00045 mol) in the same solvent (50 cm^3). The mixture was refluxed for 48 h. TLC indicated that arsine was converted entirely into arsine oxide. The solution was filtered and the residue collected. Evaporation of the filtrate yielded the product, m.p. 186–188°C (literature 189°C).

Attempted reaction of **8** *and* **14** *with allyl alcohol* [*Reaction* (*c*)]

Refluxing **8** with allyl alcohol in a 1 : 1 molar ratio in THF medium for 48 h failed to produce any reaction. **8** was recovered unchanged. Refluxing of **14** with allyl alcohol in the presence of a large excess of 30% H_2O_2 in dioxane medium for 48 h at 90°C also failed to produce any reaction. The unaltered complex **14** was recovered.

RESULTS AND DISCUSSION

Elemental analyses and conductivity data of the complexes (**1–14**) are presented in Table 1. The conductivity data for solutions in DMSO indicate that **1–14** are non-electrolytes. IR spectral data are shown in Table 2. Complexes of phthalic acid, **1** and **4**, show a decrease in ν(C=O) by 22 and 45 cm^{-1}, respectively, compared to the free ligand value (1680 cm^{-1}), and those of malonic acid, **9** and **14**, show a decrease in ν(C=O) by 95 and 87 cm^{-1}, respectively, compared to the free ligand value (1725 cm^{-1}), indicating carboxylate binding in the complexes. In complex **1**, complexing causes a decrease in ν(N—O) by 32 cm^{-1} compared to the free pyridine oxide (1242 cm^{-1}).[11] In **4**, the ν(P=O) mode is decreased by 67 cm^{-1} from the free ligand value (1192 cm^{-1}).[12] Ethyleneglycol is potentially bidentate, dinegative. The ν(OH) mode, observed as a broad band at 3200–3600 cm^{-1}, disappears upon coordination in **8** which indicates deprotonation and coordination at the oxygen site. Complexes **2**, **3**, **5–7** and **10–13** show two bands (**2**, 3340 and 3280; **3**, 3280 and 3180; **5**, 3320 and 3200; **6**, 3210 and 3100; **7**, 3200 and 3140; **10**, 3160 and 3120; **11**, 3240 and 3100; **12**, 3100 and 3000; **13**, 3220 and 3165 cm^{-1}—significantly lower than the values for O-phenylenediamine (3400, 3380 cm^{-1}) (in **2**, **6** and **10**); 2-aminopyridine (3350, 3200 cm^{-1}) (in **3** and **11**); 2-aminophenol (3414,

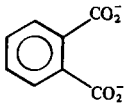
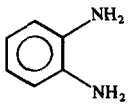
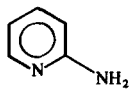
[a] The organic moieties for the compounds indicated are:



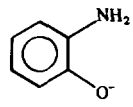
1 and **4**



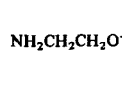
2,**6** and **10**



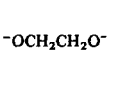
3 and **11**



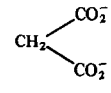
5 and **13**



7 and **12**



8



9 and **14**

3342 cm^{-1}) (in **5** and **13**); ethanolamine (3380, 3290 cm^{-1}) (in **7** and **12**), which indicate coordination by the amino nitrogen. This is also evident from the appearance of bands at 255–320 cm^{-1} which are tentatively attributed to the ν(M—N) mode[4–9] (M = Zr^{IV}, Th^{IV}, Mo^{VI} and U^{VI}).

Further, in complexes **3** and **11**, the ν(C=N) mode appears at 1570 and 1560 cm^{-1}, respectively, indicating that the ring nitrogen is coordinated to the metal atom.[10] In addition, the far IR spectra of **1**, **4**, **5**, **7–9**, **12–14** display bands at 360–460 cm^{-1} (Table 2) which are tentatively attributed to the ν(M—O′) modes[4–9] (O′ = oxygen in organic ligand). The metal peroxo grouping (local C_{2v} symmetry) gives rise to three IR- and Raman-active vibrational modes. These are predominantly (O—O) stretching (ν_1), the symmetric M—O stretch (ν_2) and the antisymmetric M—O stretch (ν_3). The characteristic ν_1(O—O) modes of **1–14** appear at 800–875 cm^{-1} (Table 2). In particular, the ν_1 mode of the present thorium peroxo complexes (**2–5**) occur at slightly lower frequencies than the zirconium analogue (**1**). This is more discernible in the peroxo complexes of the elements of group 6A; there is a decrease in ν_1 upon passing from molybdenum complexes (**6–9**) (865–875 cm^{-1}) to the corresponding uranium peroxo complexes (**10–14**) (800–830 cm^{-1}). The present data, thus show that for the M(O_2) grouping, the ν_1(O—O) modes decrease with the increase in the atomic number of metals in a particular group. In the present examples, the ν_3 and ν_2 modes appear at 600–695 and 500–555 cm^{-1}, respectively. These assignments are based on comparisons with other peroxo complexes of zirconium, thorium, molybdenum and uranium.[5–9,13,14] The complexes **6–14** display ν(M=O) modes[3,7] at 900–925 cm^{-1}. Complexes **8**, **9** and **14** show broad bands at 3160 cm^{-1} arising from coordinated water molecules.

Reactivity

So that the possible reactivity of the present peroxo complexes could be explored, compounds **10** and **6** were allowed to react with PPh_3 and $AsPh_3$, respectively. The reactions produced $OPPh_3$ and $OAsPh_3$. The products showed IR bands at 1192 and 880 cm^{-1}, assigned to ν(P=O) and ν(As=O) modes, respectively.[12,15] IR spectra of the metal residues of reactions (a) and (b) showed the disappearance of ν_1(O—O) bands, thereby indicating the transfer of peroxo oxygens to the substrates. In reaction (c), compounds **8** and **14** were allowed to react with allyl alcohol. These compounds failed to

oxidize allyl alcohol even when refluxing at 90°C was continued for 48 h. The negative results outline the enhanced stability of the metal peroxo moiety in the presence of bidentate, dinegative chelating ligands. We observed similar negative results with other peroxo complexes containing tridentate, bidentate–dinegative and quadridentate ligands.[5,6,9,16]

THE HYDROLYSIS OF THE PRASEODYMIUM(III) ION, Pr^{3+}, IN 3 m (Li)ClO_4 AT 60°C

LIBERATO CIAVATTA,† RAFFAELLA PORTO and ERMANNO VASCA

Dipartimento di Chimica dell'Università, Via Mezzocannone, 4, 80134 Napoli, Italy

(*Received* 28 *September* 1988; *accepted* 9 *November* 1988)

Abstract—The reaction of the Pr^{3+} ion with water has been studied at 60°C in 3 m (molal) (Li)ClO_4 ionic medium by measurements of the hydrogen ion concentration with a glass electrode. The metal concentration ranged from 0.03 to 1 m, while the acidity was varied from high values, where hydrolysis is negligible, to low enough values for a precipitate of praseodymium(III) hydroxide to form. Hydrolysed solutions were conveniently prepared by coulometric generation of OH^- ions. The potentiometric data, which indicate that less than 1% of the metal ion can be transformed into reaction products in clear solutions, have been explained in terms of $Pr(OH)^{2+}$, $Pr_2(OH)^{5+}$, $Pr_2(OH)_2^{4+}$ and $Pr_3(OH)_5^{4+}$ species. Their formation constants in the inert 3 m $LiClO_4$ medium are reported.

This work is part of a general programme aiming at the elucidation of the reaction with water of the tripositive lanthanide ions. In two previous investigations,[1,2] the hydrolysis equilibria of the La^{3+} ion at 60°C and of the Ce^{3+} at 50°C have been studied. Temperatures higher than 25°C, generally accepted as standard, were chosen in order to favour species of nuclearity lower than $La_5(OH)_9^{6+}$ and $Ce_3(OH)_5^{4+}$, which are the main complexes at room temperature.[3,4] In both cases, evidence was produced for intermediate complexes, $La_2(OH)_3^{3+}$ and $Ce(OH)^{2+}$. For easy comparison with previous results, we have adopted in the present study a temperature of 60°C.

Very little quantitative information has been reported as yet on the hydrolysis of the Pr^{3+} ion. The only attempt seems to be that made in 1946 by Moeller[5] who measured, at 25°C with a glass electrode, the acidity of $Pr_2(SO_4)_3$ solutions and concluded that mononuclear hydrolytic complexes cannot be the main reaction products. While sulphate complexing and medium changes prevented an accurate analysis of the data, the measurements in dilute solutions were explained by assuming the formation of $Pr(OH)^{2+}$ with $\log^* \beta_{11} = -9.0$. This result was based on the postulate that there were no appreciable amounts of protolytic impurities, as sulphuric acid, in the praseodymium(III) sulphate which he had prepared.

Symbols

- a_w activity of water;
- $^*\beta_{pq}$ equilibrium constant for the formation of $Pr_q(OH)_p^{3q-p}$ considering H_2O and not OH^- as reagent;
- m_H proton analytical excess, $=[ClO_4^-]+m_X-3m_M-[Li^+]$;
- m_M total concentration of the Pr^{3+} ion;
- m_X total concentration of the Cl^- ion;
- $\bar{n}$ average number of hydrogen ions set free per praseodymium atom, $=([H^+]-m_H)/m_M$;
- y_H, y_M, y_{pq} activity coefficients, respectively, of H^+, Pr^{3+}, $Pr_q(OH)_p^{3q-p}$.

Concentrations and equilibrium constants, if not otherwise stated, are expressed on the molal scale, m (mol/kg H_2O).

METHOD

The investigation was performed by measuring, with a glass electrode, the $[H^+]$ of a series of $Pr(ClO_4)_3$ solutions of various acidity. The concentration of ClO_4^- in all the test solutions was made up to 3 m by the addition of $LiClO_4$. Since the hydrolysis reaction becomes measurable at $\log[H^+] < -5$ and less than 1% of the praseodymium(III) can be transformed into hydrolysis products before the precipitation of solid hydroxides, rather concentrated metal solutions, in the

range from 0.03 to 1 m, were studied in order to attain sufficiently high buffer capacities. At the low values of $\bar{n}$ that need be measured, < 0.01, the deleterious effect of protolytic impurities, introduced in the system with strong base solutions, was minimized by coulometric generation of OH^- ions. The inherent accuracy of the coulometric method allowed the low $\bar{n}$ values to be affected by uncertainties not exceeding 1%.

The test solutions, abbreviated by TS in the following discussion, were of the general composition:

$$Pr^{III}\ m_M,\ H^+ m_H,\ Cl^-\ m_X,$$

$$Li^+\ (3-3\ m_M - m_H + m_X),\ ClO_4^-\ 3.00\ m,$$

where m_H in most of the hydrolysed solutions studied was negative. The auxiliary chloride ion, in the range $5 \times 10^{-3} \leqslant m_X \leqslant 0.05$ m, served the purpose of avoiding salt bridges in the electrolysis cell (I), employed for the coulometric generation of OH^-, as well as in the galvanic cell (II) for measuring $[H^+]$. Practically coinciding results, within the limits of experimental error, were obtained in experiments carried out at different m_X but constant m_M, thus indicating the negligible influence of Cl^- ions on the hydrolytic equilibria.

The acidity of TS was decreased in a stepwise fashion by the electrolysis cell (I), connected to a constant-current source

$$-Pt/TS/Ag+. \qquad (I)$$

When current is passed through (I), the reaction $Ag(s) + Cl^- + H_2O \rightarrow AgCl(s) + OH^- + (1/2)H_2(g)$ takes place on the right. However, small amounts of silver ions are reduced on the platinum cathode, proportional to the electrolysis duration. The side process occurs at a rate of $(5 \pm 1) \times 10^{-10}$ mol s^{-1}, thus an efficiency of OH^- generation better than 99.9% can be achieved only with currents exceeding 50 mA. On the other hand, at such high intensities it becomes difficult to avoid a local excess of base which might promote premature precipitation of praseodymium(III) hydroxides. Good results were attained with intensities in the interval 1–20 mA. To prevent the accumulation of strong base in the vicinity of the cathode, generations of less than 30 s were alternated with pauses of at least 60 s. The moles of electrons passed were corrected for the amount of silver ion reduced. For each experiment, the correction term was evaluated from the total silver deposited on the platinum cathode, which was determined afterwards as described previously.[1] The values of m_H could then be assessed with an uncertainty of less than 1%.

The hydrogen ion concentration in TS was determined using cell (II)

$$-Ag/AgCl/TS/GE+ \qquad (II)$$

where GE denotes the glass electrode. The EMF of cell (II) can be expressed at 60°C as eq. (1)

$$E = E'_0 + 0.06610 \log([H^+] m_X y_{HCl}^2), \qquad (1)$$

in which E'_0 is a constant in each experiment and y_{HCl} denotes the activity coefficient of hydrochloric acid. The standard states are so chosen that the activity of a solute species tends to its molality as the composition of TS approaches 3 m $LiClO_4$.

During a series of measurements, carried out conveniently at constant m_M as a potentiometric titration, the variations of y_{HCl}, owing to the small $\bar{n}$ values reached, are negligible. Therefore data of the same titration can be calculated using eq. (2)

$$E = E_0 + 0.06610 \log([H^+] m_X). \qquad (2)$$

The value of E_0 was determined in each titration by measurements in solutions with $m_H > 10^{-4}$ m, where hydrolysis is suppressed and, consequently, $[H^+] = m_H$. E_0 and m_H^*, the proton excess in the starting solution, were assessed simultaneously on the basis of Gran plots.[6] In each case, data in the acidity range from 2×10^{-3} to 10^{-4} m gave E_0 values constant to better than 0.05 mV and m_H^* values within $\pm 0.2\%$.

In constructing the $\bar{n}(\log[H^+])$ function, which forms the basis for the deduction of the composition of the main reaction products, we had to consider the effect of small but unavoidable amounts of protolytic impurities introduced with the reagents, mostly $LiClO_4$, present in high concentration. The acidity constant of the protolytic impurity as well as its concentration was determined by a potentiometric procedure developed recently.[7] The contaminant, supposed to be a monoprotic acid, was found to have $pK_a = 5.5 \pm 0.2$ at 60°C and a concentration of about 20×10^{-6} m in 3 m $LiClO_4$, the salt being purified by double crystallization. The quality of the preparation did not improve in subsequent crystallizations. However, better results were obtained by prolonged purging of the solutions with purified nitrogen gas. Hence, after two days of bubbling, the impurity level from 20×10^{-6} m recorded after 2 h purging, sank to $(5 \pm 1) \times 10^{-6}$ m in 3 m $LiClO_4$. Very likely, the impurity is carbon dioxide, whose last traces are removed sluggishly by the nitrogen stream.

On the basis of these figures we estimate that the $\bar{n}$ values for the lowest m_M are uncertain to about 1%. However, the error is less in the remaining reaction range.

Most of the measurements were performed by gradually decreasing the acidity of TS. Therefore doubts may arise whether a true equilibrium was

attained. To answer this essential question, experiments were also made by acidification of partially hydrolysed solutions with perchloric acid. The data (back titrations in Table 1) are seen to agree in Fig. 1 within the limits of experimental error with those of the forward titrations, thus indicating a real equilibrium.

EXPERIMENTAL

Materials and analysis

Praseodymium(III) *perchlorate solutions.* These were made from the oxide, Pr_6O_{11}, a Fluka product of 99.9% purity, and $HClO_4$, Merck p.a. The oxide was added portionwise to a hot, 4 m $HClO_4$ solution, until a pH value of 3 was reached. In acid media, the mixed Pr^{III}–Pr^{IV} oxide dissolves completely with a distinct ozone smell, indicating that the Pr^{IV} ion is reduced by water. In order to remove heavy metal impurities present in the reagents, the solution of Pr^{III} was made alkaline with OH^- ions, produced electrolytically on a platinum cathode, until a permanent precipitate of Pr^{III} hydroxide appeared. The solution, after standing for a week, was filtered and re-acidified to about pH = 3. No traces of the Pr^{IV} ion could be detected by the iodine–starch test.

The Pr concentration was established by titration with EDTA, using xylenol orange as the visual indicator.[8] The results agreed to 0.1%. The proton analytical excess was determined by coulometric acid–base titration with a glass electrode. The perchlorate ion concentration was calculated as the sum: $m_H + 3m_M$.

Lithium perchlorate, perchloric acid and lithium chloride solutions. These were prepared and analysed as described previously.[1,2]

Experimental details of the EMF measurements

The potentiometric titrations were carried out by immersing the vessel, containing the test solution, in a silicone oil thermostat kept at 60.00 ± 0.03°C. Glass electrodes manufactured by Jena Glasswerk were employed. They took 20 min after the addition of OH^- to acquire a steady value, which remained constant to ± 0.1 mV for several hours. Silver–silver chloride electrodes were obtained according to Brown.[9] Platinum gauze electrodes, 2×2 cm, were boiled in 1 : 1 HNO_3 and ignited in an alcohol flame. Platinum gauze, coated by a thick layer of silver, was used as the anode in cell (I). It was prepared by electrolysis from 0.05 m AgCl in 16 m LiCl. The electrodes were washed with concentrated ammonia, and then soaked for several days in water.

The sequence of operations: stepwise addition of OH^- by constant-current coulometry and EMF measurements was performed with an all automatic data acquisition system furnished by the Hewlett and Packard Company. The number of coulombs could be determined with an error of less than 0.02%. The EMF values were established to within ± 0.02 mV.

Before a titration was started, a stream of purified and presaturated nitrogen was passed for 2 days through the solutions kept at room temperature. Throughout the measurements at 60°C, the solution was protected from atmospheric contamination by

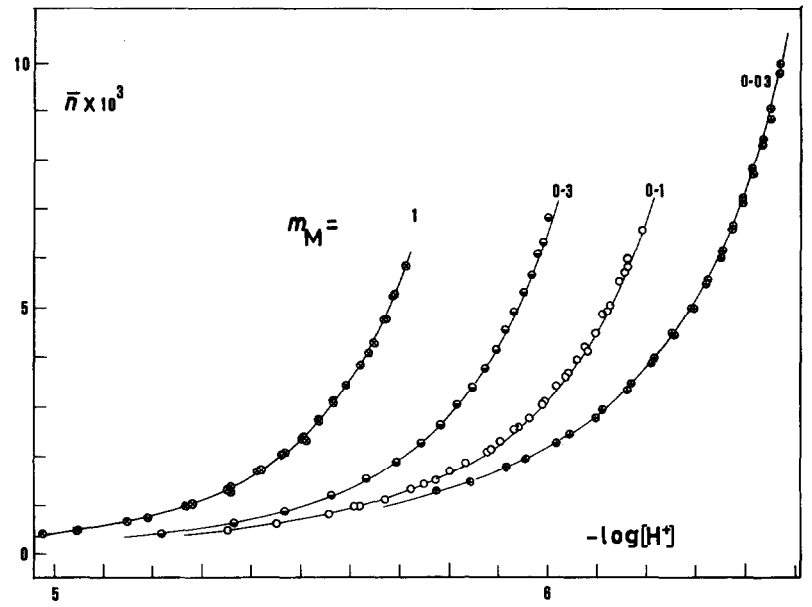

Fig. 1. $\bar{n}$, the average number of OH^- ions bound per praseodymium atom, as a function of $\log[H^+]$. The curves were calculated using the constants of Table 3 and expressions (9) and (10) for medium changes.

placing it in vessels fitted with high-vacuum ground glass stoppers.

In the back titrations, the test solution was acidified by stepwise addition of a standard $HClO_4$ solution.

THE COMPOSITION OF THE HYDROLYSIS PRODUCTS

The $\bar{n}(\log[H^+], m_M)$ data, which are given in Table 1 and are graphically represented in Fig. 1, were treated as follows. First, the number of OH ions, p, bound in the $Pr_q(OH)_p^{3q-p}$ complexes, and the conditional constants K_p, eq. (6), were deduced for each set at constant m_M. Subsequently, the main q values and the $^*\beta_{pq}$ constants were determined by examining the dependence of K_p on m_M. Medium changes, caused by the replacement of large portions of the solvent lithium ion with Pr^{3+}, were accounted for by the Specific Interaction Theory, SIT.[10] Finally, the equilibrium constants were refined with numerical procedures based on the principle of least-squares.

Evaluation of the prevailing p *values*

In solutions where a series of $Pr_q(OH)_p^{3q-p}$ complexes is formed, the concentration of OH^- ions bound in the hydrolysis products, is expressed as

$$\bar{n}m_M = [H^+] - m_H = \sum_p \sum_q p[Pr_q(OH)_p^{3q-p}]$$

$$= \sum_p \sum_q p^*\beta_{pq}[Pr^{3+}]^q[H^+]^{-p}a_w^r y_M^q y_H^{-p} y_{pq}^{-1}, \quad (3)$$

where the exponent r is a function of p, q and the structure of the $Pr_q(OH)_p^{3q-p}$ species. Since $\bar{n}$ could never be made to exceed 0.01, the composition of TS at constant m_M varies only slightly upon alkalification and hydrolysis. Therefore, as long as m_M is maintained constant, the changes in activity coefficients and water activity may be neglected. Furthermore, the calculations can be simplified by putting

$$[Pr^{3+}] \simeq m_M(1-\bar{n}). \quad (4)$$

Approximation (4) becomes exact either when $p = q$ or for $\bar{n} \to 0$. As the results of the next section will show, we are not very far from these conditions, so that no appreciable error is introduced by using eq. (4). Hence eq. (3) can be written with good approximation, as eq. (5)

$$\bar{n}m_M = \sum_p pK_p x^p, \quad (5)$$

where the conditional m_M-dependent constant K_p is defined by

$$K_p = \sum_q {}^*\beta_{pq} m_M^q y_M^q y_H^{-p} y_{pq}^{-1} a_w^r \quad (6)$$

and

$$x = (1-\bar{n})[H^+]^{-1}. \quad (7)$$

Comparison of the experimental points with normalized functions,[11] based on eq. (5) and representing various hypotheses, suggested the presence of complexes with $p = 1$ and 2, at the lowest $\bar{n}$. However, at least another value of p,p' must be

Table 2. Survey of the K_p constants

m_M	$-\log K_1$	$-\log K_2$	$-\log K_5$	p'
0.9988	8.56±0.02	14.15±0.02	32.4_4±0.1	4.9±0.5
0.3000	9.27±0.02	15.21±0.02	34.24±0.05	4.8±0.5
0.1000	9.74±0.02	16.19±0.02	35.7±0.1	4.6±0.5
0.0300	10.25±0.02	17.35±0.02	37.3±0.1	5.3±0.5

assumed to explain the systematic deviations at the highest $\bar{n}$. We postulated the formation of species with a single p' and analysed the function

$$\log R = \log(\bar{n}m_M - K_1x - 2K_2x^2) = \log(p'K_{p'}) + p'\log x. \quad (8)$$

First, from the plots $\bar{n}m_M x^{-1}$ vs x for the lowest $\bar{n}$, preliminary values of K_1 and K_2 were evaluated, which when introduced into eq. (8) yielded p' as slope of the $\log R$ against $\log x$. Then, temporary $K_{p'}-s$ values were estimated by taking for p' the nearest integer value, and better K_1 and K_2 constants were calculated after correcting $\bar{n}m_M$ for $p'K_{p'}x^{p'}$. The cycle was repeated until convergence. The final results summarized in Table 2 indicate the presence of a species with $p' = 5$, in addition to complexes with one and two OH^- ions. The uncertainties of the K_p constants represent maximum deviations from mean values.

Calculation of q

To find the main q values we have to confront data of different m_M, thus involving the estimate of the variations of the activity coefficients as well as of the water activity. Corrections for medium effects were made by SIT.[10] According to theory, as reagents and products are all positively charged and the anionic composition of the medium is essentially constant, the activity coefficient y_i of the "i" species of charge z_i in our medium scale, may be expressed as a function of the ionic strength, I, by

$$\log y_i = -z_i^2\{0.5452I^{0.5}/(1+1.5I^{0.5}) - 0.2624\} = -z_i^2 D. \quad (9)$$

Concerning the a_w variations, we assumed a linear dependence of $\log a_w$ with m_M between the value in 3 m $LiClO_4$, where $a_w = 1$ according to our choice of standard states, and that in 1 m $Pr(ClO_4)_3$ at 60°C. We get, using the isopiestic data published by Pitzer,[12]

$$\log a_w = 0.0199 m_M. \quad (10)$$

To deduce q and $^*\beta_{pq}$ from eq. (6) we have to make guesses about the coefficients r. For mononuclear $Pr(OH)_p^{3-p}$ species we set $r = 4p$, which means that H^+ is solvated by $4H_2O$, as suggested by experimental[13,14] and theoretical[15] evidence, and that the Pr^{3+} ion maintains its coordination in the hydrolysis products. The formation of hydroxide or oxide bridges in polynuclear complexes implies the removal of water from the coordination sphere of the metal ion. Consequently, r is less than $4p$ and its estimate requires some information on the structure of the complexes. At any rate, as the a_w values are not very different from unity, rough estimates of r seem adequate for the interpretation of data with the present accuracy.

For species with $p = 1$, eq. (6) gives

$$K_1 m_M^{-1} 10^{4D} a_w^{-4} = {}^*\beta_{11} + {}^*\beta_{12} m_M 10^{12D} a_w^{-1} + \cdots, \quad (11)$$

where we use $r = 3$ for the formation of $Pr_2(OH)^{5+}$. Within the limits of experimental error the left-hand side of eq. (11) was found to be constant for $m_M \leqslant 0.3$. On the other hand, a systematic deviation which greatly exceeds the estimated uncertainty of the data, was recorded at $m_M = 1$. This has been ascribed to the presence, in addition to $Pr(OH)^{2+}$, of small amounts of $Pr_2(OH)^{5+}$. The values of $^*\beta_{11}$ and $^*\beta_{12}$ are reported in Table 3.

Equation (6) yields for $p = 2$

$$K_2 = {}^*\beta_{21} m_M 10^{-6D} a_w^8 + {}^*\beta_{22} m_M^2 a_w^6 + \cdots. \quad (12)$$

The value of $r = 6$ for the $Pr_2(OH)_2^{4+}$ ion stems

Table 3. Values of the formation constants, $^*\beta_{pq}$

	$-\log {}^*\beta_{11}$	$-\log {}^*\beta_{12}$	$-\log {}^*\beta_{22}$	$-\log {}^*\beta_{53}$
Graphical	8.75±0.02	9.2±0.1	14.25±0.05	32.7±0.1
Least-squares	8.74±0.01	9.34±0.06	14.23_3±0.01_5	32.76±0.09

from the assumption that a double bridge of OH^- links the metal ions. Over the entire concentration range studied, the quantity $\log(K_2 m_M^{-2} a_w^{-6})$ is independent of m_M within ± 0.05 units. We may thus infer that the $Pr_2(OH)_2^{4+}$ species is formed. The mean $*\beta_{22}$ value is shown in Table 3.

An exploratory examination of the dependence of K_5 on m_M suggested that the main q is equal to three. The value of $\log *\beta_{53} = \log(K_5 m_M^{-3} 10^{6D} a_w^{-15})$ (Table 3) was found to be constant to within ± 0.1 units. The value of $r = 15$ was chosen according to a model in which three metal atoms are arranged in an equilateral triangle around a central O^{2-} ion, equivalent to two OH^-. Each of the remaining three OH^- groups links a pair of praseodymiums. Of the 20 water molecules bound to the five protons set free in the formation of $Pr_3(OH)_5^{4+}$, five originate from the water coordinated by the metal ions.

Refinement of the equilibrium constants

The calculations of the previous sections have furnished evidence for the presence of $Pr(OH)^{2+}$, $Pr_2(OH)_2^{4+}$ and $Pr_3(OH)_5^{4+}$ species and for small amounts of the $Pr_2(OH)^{5+}$ ion in the most concentrated praseodymium(III) solutions. As a check, the equilibrium constants $*\beta_{pq}$ were deduced by procedures founded on the principle of least-squares. The computation consisted in the minimization of the sum

$$U = \sum \{(\bar{n}_i - \bar{n}_c)/\bar{n}_i\}^2, \qquad (13)$$

where $\bar{n}_i$ stands for an experimental datum and $\bar{n}_c$ denotes a calculated $\bar{n}$ value with a given set of $*\beta_{pq}$s. Medium changes were accounted for by using eqs (9) and (10).

The minimum of U was found with the constants listed in Table 3. These are seen to agree fairly well with those evaluated above using graphical procedures based on approximation (4). The uncertainties of the constants are three times the standard deviation, defined by the "D-boundary",[16] and are smaller than maximum errors estimated by graphical procedures.

The method originating from the least-squares principle offers a quantitative measure of the fit between experimental data and proposed model. Of a total of 116 data points, 54 have shown positive deviations, whereas 62 have shown negative ones. The average of the positive deviations amounts to 2.8%, that of the negative ones to 2.1%. The magnitude and sign of the deviations do not exhibit appreciable trends with $\bar{n}$ and m_M.

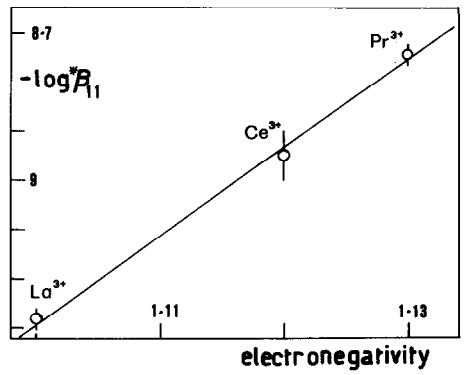

Fig. 2. The linear dependence of $\log *\beta_{11}$ on the electronegativity (χ) for the first lanthanide ions. The line expresses: $-28.85 \pm 17.79\ \chi$.

DISCUSSION

The main conclusion of the present investigation is that the hydrolytic complexes $Pr(OH)^{2+}$, $Pr_2(OH)^{5+}$, $Pr_2(OH)_2^{4+}$ and $Pr_3(OH)_5^{4+}$, are formed in the narrow reaction region, $\bar{n} < 0.01$, which connects the Pr^{3+} ion with colloidal praseodymium hydroxides. The short discussion is dedicated to trends and irregularities in the behaviour of the cations La^{3+} and Ce^{3+}, studied previously,[1,2] and Pr^{3+}.

An exact linear relation is verified between $\log *\beta_{11}$ and electronegativities, χ. This is illustrated in Fig. 2 where against χ values, taken from Allred's study,[17] are plotted the log of the constants of the initial hydrolysis step at 60°C in 3 m (Li)ClO_4. For Ce^{3+}, $\log *\beta_{11} = -8.95 \pm 0.05$ was calculated from the value determined at 50°C, -9.13, and the enthalpy change $\Delta *H_{11} = 33$ kJ mol^{-1}, estimated for $La^{3+} + H_2O \leftrightarrows LaOH^{2+} + H^+$. At increasing electronegativity the drainage of charges from the ligand oxygen to the metal ion raises the positive charge density on the periphery of the hydrated cation. The greater the charge density, the lower is the work required to remove a proton and to transfer it to a water molecule. A clear correlation seems to exist between aquo acidity and electronegativity within the same group, including cations of the same charge and of the same coordination number.

The difference in electronegativity within the same group provides a plausible explanation also in the trend of $*\beta_{12}/*\beta_{11}$, the equilibrium constant of the dimerization with a single hydroxo bridge. Below, along with electronegativity values[17] are summarized the $*\beta_{12}/*\beta_{11}$ constants for the first three lanthanides, 60°C and 3 m $LiClO_4$, and for dipositive cations of group 2b at 25°C in the specified media: $\log(*\beta_{12}/*\beta_{11})$ (χ): La^{3+} 0.36(1.10);

Ce^{3+} −0.35(1.12); Pr^{3+} −0.60(1.13); Zn^{2+} (3.2 m NaCl) 1.72(1.65); Cd^{2+} (3.47 m $LiClO_4$) 1.04(1.69); Hg^{2+} (3.5 m $NaClO_4$) 0.81(2.00). The constants for Zn^{2+}, Cd^{2+} and Hg^{2+} were obtained from ref. 18. The drainage of electrons from the oxygen donor atom by the more electronegative Pr^{3+} and Hg^{2+} ions will render the formation of a second oxygen–metal bond less probable.

Concerning the formation of $Pr_2(OH)_2^{4+}$ and $Pr_3(OH)_5^{4+}$, expressed as the polymerization from $Pr(OH)^{2+}$

$$Pr(OH)^{2+} \rightleftharpoons 1/2Pr_2(OH)_2^{4+}, \qquad \log(*\beta_{22}^{1/2}/*\beta_{11}) = 1.6$$

$$Pr(OH)^{2+} \rightleftharpoons 1/5Pr_3(OH)_5^{4+} + 2/5Pr^{3+}, \qquad \log(*\beta_{53}^{1/5}/*\beta_{11}) = 2.2,$$

the constants do not sensibly differ from those found for several cations of different charge, ion size and electronic structure.[19] As pointed out on many occasions,[19,20] the polymerization reaction is primarily a property of the oxygen atom and the hydroxide ion as ligand.

Apart from these similarities, some irregularities still persist in the behaviour of the lanthanide series. We recall that the dinuclear complexes, $La_2(OH)_2^{4+}$ as well as $Ce_2(OH)_2^{4+}$, do not attain detectable concentration levels under experimental conditions identical to those chosen for praseodymium(III). Presently, the limited amount of fairly reliable information on the hydroxide complexes of tripositive lanthanides does not allow definite conclusions on these anomalies.

Abstract—The compounds of the formula $CuCl_2$(4-aminobenzophenone) (hereinafter L) 0.5S (S = ethanol or methanol) were synthesized and characterized by means of thermogravimetric, electronic, IR spectra and magnetic susceptibility measurements. For the ethanol derivative, the structure was determined by a single crystal X-ray diffraction analysis. It crystallizes in the monoclinic system, space group $P2_1/a$ with $Z = 4$ in a unit cell having $a = 29.903(4)$, $b = 6.202(2)$, $c = 8.195(2)$ Å, $\beta = 92.88(4)°$. The structure is polymeric and consists of infinite chains of chlorine bridged copper(II) ions along the b axis: the repeating unit is $(L—CuCl_2—EtOH—CuCl_2—L)_n$. Although the two coppers are related through crystallographic inversion centres, they have different coordination geometries owing to the statistical positioning of the ethanol molecule. One is octahedrally coordinated to three chlorines in the square plane and to the nitrogen of L, while in the apical positions are the ethanol oxygen and a fourth chlorine atom; the second has a pyramidal coordination geometry, because of the missing ethanol oxygen in one apical position. (The same structure has been deduced for the methanol derivative.) Relevant bond distances are Cu—Cl(1), 2.593(5); Cu—Cl(1)′, 2.294(4); Cu—Cl(2)″, 2.450(4); Cu—N, 2.03(1); Cu—O, 2.06(2) Å.

Benzophenone and its derivatives have considerable chemical, physical and medical interest.

Of particular relevance are their applications in the pharmaceutical industry as starting products in the synthesis of cardiovascular[1] and hypotensive[2] drugs, and as intermediates for the preparation of psychotropic[1] and analgesic drugs.[3]

In addition, benzophenone has played an important role in the development of synthetic and mech-

† Author to whom correspondence should be addressed.

anistic photochemistry, since it is a good triplet sensitizer.[4] This characteristic property can be strongly affected by structural and environmental effects. The introduction of a one electron donor group, such as NH_2, into the aromatic ring, "switches" the reactive state $n\pi^*$ to a less reactive $\pi\pi^*$, or charge-transfer (CT) state,[5] and strongly decreases the coordinative reactivity of the carbonyl group.

In order to clarify the influence of the position of the NH_2 group on the coordinative ability of the benzophenones, we have previously studied the complexes of 2-aminobenzophenone with copper(II) halides.[6] In this paper we report the preparation and structural, magnetic and spectroscopic characterization of the title compounds.

EXPERIMENTAL

4-Aminobenzophenone in hexane solution was purified by chromatography on neutral alumina. AnalaR grade anhydrous copper chloride was used.

Synthesis of $CuCl_2$(4-*aminobenzophenone*)·0.5EtOH

An absolute ethanolic solution of copper(II) chloride was added slowly under continuous stirring to an ethanolic solution of 4-aminobenzophenone with metal-to-ligand molar ratios ranging from 1 : 1 to 1 : 2. Red–orange crystals separated out after 4–5 days. (Found: C, 47.3; H, 3.9; N, 4.0. Calc. for $C_{14}H_{14}NO_{1.5}Cl_2Cu$: C, 47.3; H, 3.9; N, 3.9%.)

Synthesis of $CuCl_2$(4-*aminobenzophenone*)·0.5MeOH

This compound was prepared as described above by using methanol in place of ethanol. (Found: C, 46.5; H, 3.8; N, 4.0. Calc. for $C_{13.5}H_{13}NO_{1.5}Cl_2Cu$: C, 46.6; H, 3.7; N, 4.0%.)

Physical measurements

IR spectra in Nujol mulls in KBr pellets as support, in KBr pellets (4000–250 cm^{-1}), in Nujol mulls in polythene as support and in polythene pellets (600–100 cm^{-1}), were recorded on a Perkin–Elmer 180 spectrophotometer. The electronic spectra of the solid samples were recorded on a Shimadzu MPS 50-L spectrophotometer. Samples were prepared by grinding the compounds on filter paper as support. The thermogravimetric analysis was performed at a rate of 10°C min^{-1} with a Netzsch Sta 409 thermobalance. The room temperature magnetic moments were measured by the Gouy method using $Ni(tu)_3S_2O_3$ as the calibrant and correcting for diamagnetism using Pascal's constants.

X-ray measurements and structure determination

A transparent red, prismatic, single crystal of $0.05 \times 0.15 \times 0.20$ mm was centred on a four-circle Philips PW 1100 diffractometer. Using graphite-monochromated Mo-K_α radiation, 2569 reflections ($2\theta_{max} = 46°$) were measured which, when merged, gave 996 unique reflections with $I \geqslant 3\sigma(I)$. The intensity data were corrected for Lorentz-polarization effects and for absorption.[7]

The structure was solved using three-dimensional Patterson and Fourier techniques and refined by full-matrix least-squares. Hydrogen atoms were introduced at calculated positions and were allowed to ride on associated carbon atoms during the least-squares refinement ($d_{C-H} = 0.95$ Å and $U_{iso} = 0.06$ $Å^2$). Atomic scattering factors were taken from ref. 8. Data processing and computation were carried out by using the *SHELX 76* program package.[9]

The refinement of the $CuCl_2L$ moiety reached convergency at $R = 0.065$. At this point three residual peaks in the range 2–3 e $Å^{-3}$ were evident in the Fourier difference map. They were interpreted as a statistically distributed one-half ethanol molecule per $CuCl_2L$ unit. The introduction of the ethanol molecule in the positions indicated by the electron density residuals, with a population factor of 0.5, gave the most significant lowering of the R value: $R = 0.053$. Geometrical calculations were made by using the *PARST* program,[10] while the structure illustrations were from *PLUTO*[11] and *ORTEP*.[12]

Tables of atomic coordinates, atomic thermal vibrations and calculated structure amplitudes are available as supplementary material; atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

Crystal data

$C_{14}H_{14}NO_{1.5}Cl_2Cu$, $M = 354.2$, monoclinic space group $P2_1/a$, $a = 29.903(4)$, $b = 6.202(2)$, $c = 8.195(2)$ Å, $\beta = 92.88(4)°$, $U = 1517.9$ $Å^3$, $Z = 4$, $D_c = 1.55$ Mg m^{-3}, $F(000) = 720$, μ(Mo-K_α) = 17.05 cm^{-1}.

RESULTS AND DISCUSSION

The solid complexes were obtained by treating a solution of $CuCl_2$ in ethanol (or methanol) with the ligand in the same solvent. Features of thermogravimetric analysis, electronic and IR spectra of the two compounds are summarized in Table 1.

The thermogravimetric analysis shows a sharp

Table 1. Room temperature (298 K), electronic (10^{-3} cm^{-1}) and IR (cm^{-1}) results for the ligand and the complexes in the solid state. Weight loss temperature range (K) and magnetic moments are also included

maximum in the temperature ranges 369–400 and 336–369 K, without decomposition, for the ethanol and methanol adducts, respectively, corresponding to the complete loss of the respective alcohol.

The room-temperature solid-state electronic and IR data of the methanol and ethanol derivatives are identical, suggesting the same structure for both complexes. In particular, the unresolved broad band, centred at 13,070 cm^{-1}, can be assigned to the simultaneous presence of two different chromophores, $CuCl_4NO$ and $CuCl_4N$, which present very small absorption energy differences. The very strong and broad CT bond at 22,470 cm^{-1} can be considered as responsible for the red colour of these unusual polymeric species.

The IR spectra in the low energy region show a strong band at about 274 cm^{-1}, which is in the region typically associated with the bridging Cu—Cl stretching mode.[13]

The structure is polymeric and consists of infinite chains where the repeating unit is (L—$CuCl_2$—EtOH—L—$CuCl_2$).

The chlorine bridged copper(II) ions run parallel to the *b* axis as shown in Fig. 1. The asymmetric unit is formed by the L—$CuCl_2$(ethanol)$_{0.5}$ moiety which is presented in Fig. 2 with the atom numbering scheme used. The crystallographic inversion centres at 1/2,0,1/2 and 0,1/2,1/2, connect the two copper ions which are bridged through Cl(1) and its equivalent, while O(1) of the ethanol molecule coordinated to a metal ion, must be considered statistically distributed between the two coppers around the crystallographic inversion centres and then assigned to only one of the two in order to avoid chemically impossible contacts between the carbon atoms of the ethyl groups. The crystallographic centres at 0,0,1/2 and 1/2,1/2,1/2 connect the copper ions bridged through Cl(2) and its equivalent. The 4-aminobenzophenone ligand coordinated via the nitrogen atom completes in one case (where the ethanol oxygen is bound to the metal) an octahedral coordination geometry, and in the second case a square pyramidal coordination

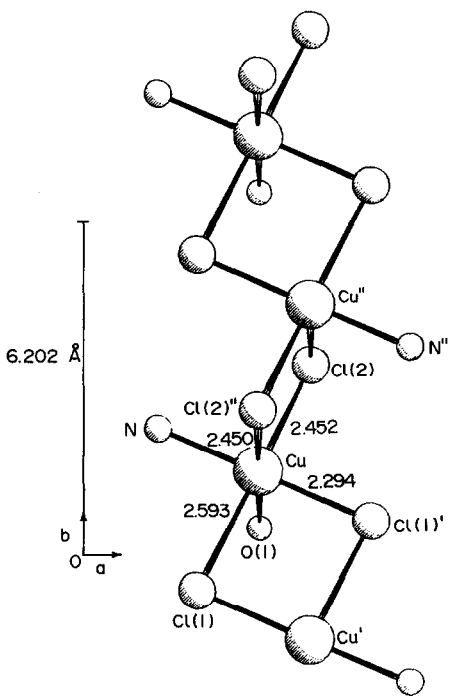

Fig. 1. View of the copper coordination polyhedrons along *b*. Neighbouring coppers are related by the crystallographic inversion centres at 1/2,0,0 (Cu···Cu' 3.434(3) Å) and 1/2,1/2,1/2 (Cu···Cu'' 3.403(3) Å). (' $1-x, -y, 1-z$ and '' $1-x, 1-y, 1-z$.)

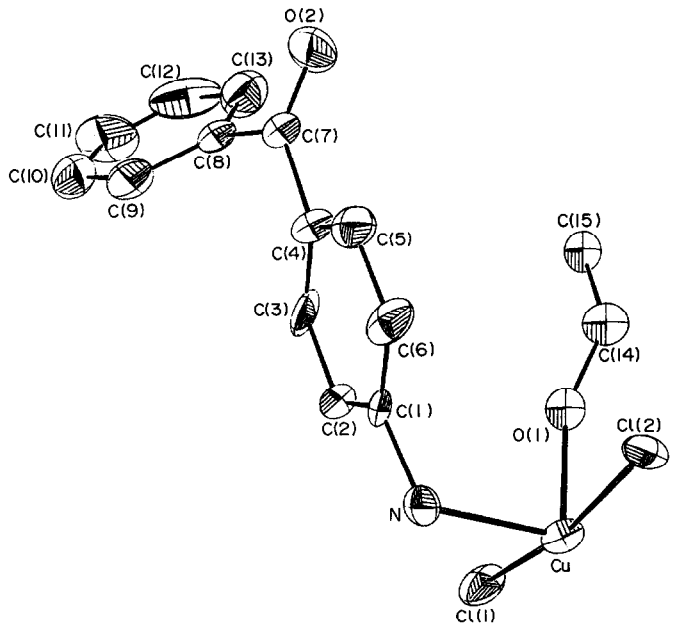

Fig. 2. The asymmetric unit, with H atoms omitted and 50% probability thermal ellipsoids.

geometry (the ethanol oxygen is missing here) as is shown in Fig. 1.

The square plane of both the octahedron and square pyramid coordination polyhedra comprise three chlorines and one nitrogen, while the ethanol oxygen and chlorine in the first polyhedron are in the apical positions and only a chlorine in the second polyhedron.

Representative bond lengths and angles are given in Table 2. The Cu—Cl bond distances, which are all bridging, range from 2.294(4) to 2.593(5) Å. In particular, the Cl(2) bridges are symmetrical, Cu—Cl(2) 2.452(6) and Cu—Cl(2)″ 2.450(4) Å, and a Cl(2)—Cu—Cl(2)″ angle of 92.1(3) and Cu—Cl(2)—Cu″ 87.9(3)°. The Cl(1) bridging distances are significantly different, Cu—Cl(1) 2.593(5) (the longest Cu—Cl distance) and Cu—Cl(1)′ 2.294(4) Å (the shortest) (Cu—Cl(1)—Cu′

Table 2. Selected bond lengths (Å) and angles (°) with ESDs in parentheses

(a) Bond lengths			
Cu—Cl(1)	2.593(5)	N—C(1)	1.45(1)
Cu—Cl(2)	2.452(6)	O(2)—C(7)	1.22(2)
Cu—O(1)	2.059(17)	C(4)—C(7)	1.51(2)
Cu—N	2.030(10)	C(7)—C(8)	1.49(2)
Cu—Cl(1)′	2.294(4)	C(14)—C(15)	1.57(4)
Cu—Cl(2)″	2.450(4)		
O(1)—C(14)	1.43(3)		
(b) Bond angles			
O(1)—Cu—N	92.2(5)	Cu—O(1)—C(14)	156(2)
Cl(2)—Cu—N	89.2(3)	N—C(1)—C(6)	120(1)
Cl(2)—Cu—O(1)	91.1(5)	N—C(1)—C(2)	118(1)
Cl(1)—Cu—N	88.4(3)	O(1)—C(14)—C(15)	140(2)
Cl(1)—Cu—O(1)	79.8(5)	O(2)—C(7)—C(4)	120(1)
Cl(1)—Cu—Cl(2)	170.4(1)	O(2)—C(7)—C(8)	121(1)
Cu—Cl(2)—Cu″	87.9(1)	C(4)—C(7)—C(8)	118(1)
Cl(2)—Cu—Cl(2)″	92.1(2)	Cu—Cl(1)—Cu′	89.1(2)
Cu—N—C(1)	117.0(8)	Cl(1)—Cu—Cl(1)′	91.0(2)

Equivalent positions: ′ $1-x, -y, 1-z$; ″ $1-x, 1-y, 1-z$.

is 89.1(2)°) are higher than the Cu—Cl(2)—Cu″ previously reported and consequently Cl(1)—Cu—Cl(1)′ 90.9(2)° is slightly smaller than the corresponding angle, Cl(2)—Cu—Cl(2)″. The two contact distances, Cu···Cu″ and Cu···Cu′ are 3.403(3) and 3.434(3) Å, being shorter when the Cu—Cl(2)—Cu″ angle is smaller. The octahedron square planes are distorted towards tetrahedral, the deviations with respect to the best mean plane calculated through N, Cl(1)′, Cl(1), Cl(2) being N −0.251(10), Cl(1)′ −0.028(4), Cl(1) 0.030(4), Cl(2) 0.038(4) Å. The copper deviates from this plane by −0.166(2) Å in the same direction as Cl(2)″, which is −2.613(4) Å away from the plane (O(1) is 1.88(2) Å distant in the opposite direction). The two *trans*-Cl(1) and -Cl(2) atoms form an angle Cl(1)—Cu—Cl(2) of 170.4(1)° and the bending is in the direction of the ethanol oxygen opposite to the Cl(2)″ position. The shorter Cu—Cl(1) bridging distance of 2.294(4) Å is *trans* to nitrogen and is close to the values of 2.270(3) and 2.318(3) Å for non-bridging distances in the di-μ-chloro-dodecachlorotricuprate(II) anion[14] and to the values of 2.297(1) and 2.278(1) Å for non-bridging chlorine in bis(2-aminobenzophenone)dichlorocopper(II);[6] while the other values for Cu—Cl bond distances which range from 2.450(4) to 2.593(5) Å are in agreement with the values normally found for chlorine bridges.[15] The Cu—N bond distance of 2.03(1) Å has a value comparable to that found for Cu—N(1) (2.028(3) Å) and Cu—N(2) (2.020(4) Å) in the bis(2-aminobenzophenone)dichlorocopper(II) complex[6] (where the two 2-aminobenzophenone ligands are, respectively, monodentate via N(1) and bidentate via N(2) and O(2) to the copper ion), and to the value of 1.984(4) Å in copper(2-aminobenzophenone)$_2$$(BF_4)_2$ where the two neutral ligands are both bidentate through nitrogen and oxygen donor atoms[16] and to the value of 1.992(5) Å in bis(4-chloro-1,2-benzoquinone-2-oximato)(methanol)copper(II).[17] The Cu—O(ethanol) bond distance of 2.059(17) Å is somewhat shorter when compared, for example, to the Cu—O(methanol) distance of 2.274(4) Å found in the previously quoted compound, or to the Cu—O distances in a series of N,N-bis(benzimidazol-2-ylmethyl) amine copper derivatives[18] which range from 2.266(6) to 2.461(6) Å. This is indicative of a relatively strong interaction between copper(II) and ethanol. The 4-aminobenzophenone ligand (see Fig. 2) has the two benzene rings rotated with respect to each other by 112.1(4)°, while the dihedral angles between the phenyls and the plane through C(7), C(8), O(2), C(4) are 19.9(5)° (for the 4-aminobenzene ring) and 125.8(5)° for the second phenyl. The two benzene rings ($C_1 \rightarrow C_6$) and ($C_8 \rightarrow C_{13}$) are rotated by 63.6(3) and 62.2(3)°, respectively, with respect to the copper coordination plane. The bond distances and angles in the ligand are generally close to those reported for the free 4,4′-diaminobenzophenone,[19] with the exception of the C(1)—N bond length which is, in the present case (1.45(1) Å), longer with respect to the value of 1.370(3) Å in the free ligand, due to the metal coordination. The twisted conformation of the ligand is maintained, but with different torsion of the two phenyls with respect to the previously quoted plane containing the C=O bond (24 and 33° in 4,4′-diaminobenzophenone).

There is a short intermolecular contact between N(1) and O(2)‴ at $x, y, 1+z$, N(1)···O(2)‴ 2.91(1) Å, N(1)—H(18)···O(2)‴ 1.96(1) Å, and the angle N(1)—H(18)···O(2)‴ is 174(1) °; the short distance between the NH_2 hydrogen and the ketonic oxygen is comparable to the value of 1.99 Å found in bis(2-aminobenzophenone)dichlorocopper(II)[6] for the intramolecular contact, ketonic oxygen–amine hydrogen. This contact, which can be considered as a hydrogen bond, connects the polymeric chains in the direction of the *c* axis, giving rise to a layer polymer as shown in Fig. 3.

In conclusion, we note that with respect to the 2-

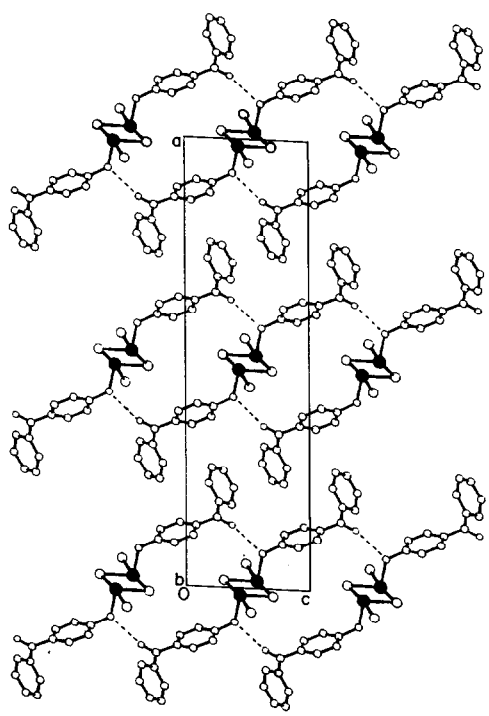

Fig. 3. Crystal packing down *b*, the polymeric columns are connected via hydrogen bonds between the carboxylic oxygen and one adjacent amino proton (one column is shown in Fig. 1), black circles are copper atoms.

aminobenzophenone ligand, the *para* position of the amino group is unfavourable for bidentate behaviour of the ligand itself. The amino coordination is preferred to the carbonyl coordination, and the possibility of polymeric chains being formed by the coordination of both the possible donor atoms (oxygen and nitrogen) on different copper ions, is overcome by the better donor ability of the chlorines which realize the polymeric structure just described.

The loss of the alcohol molecule in the sixth coordinative position of the copper inner sphere does not involve molecular rearrangements. In fact, the new coordination sphere around copper is the stable, square planar pyramidal geometry shown by the $CuCl_4N$ chromophore.

The stability of this type of environment can activate coordinative reactions at the sixth apical position, but it is rather rare that this is found only for one half of the copper ions, taking account also of the relatively strong Cu—O(ethanol) bond, probably because the driving force of the crystal packing is the formation of polymeric structures through the chlorine bridges. Indeed, copper halides with the simultaneous presence of octahedral six-coordinated and square pyramidal pentacoordinated species are known in the literature.[14]

(*Received* 12 *December* 1988; *accepted* 11 *January* 1989)

Abstract—Reaction of $[PtCl_2(PMe_2Ph)]_2$ (**1**) with S_4N_4 in CH_2Cl_2 leads to the platinum(IV) complex $PtCl_2(S_4N_4)(PMe_2Ph)$ (**2**), which contains the tridentate meridional $S_4N_4^{2-}$ ligand coordinating via two sulphurs and one nitrogen atom.

As part of a continuing study into metalla–sulphur–nitrogen chemistry, we have recently reported[1–3] on the preparation of complexes of $S_2N_2^{2-}/S_2N_2H^-$ and S_3N^-, starting from platinum–phosphine complexes of the type *cis*-$[PtCl_2(PR_3)]_2$. The variety of these reactions indicates the versatility of the latter complexes as starting materials. However, despite their ability to react with a range of reagents, such as $Na(S_3N_3)$, $[Me_2Sn(S_2N_2)]_2$ etc., they are inert towards S_4N_4 at room temperature. In contrast, we have found that dimeric complexes of the type $[PtCl_2(PR_3)]_2$ readily react with S_4N_4 to give a variety of species, the precise nature of which depends upon both the stoichiometry of the reaction and the nature of the phosphine group. Here we report on the reaction of $[PtCl_2(PMe_2Ph)]_2$ (**1**) with S_4N_4, in the molar ratio 1 : 2, which yields the platinum(IV) complex, $PtCl_2(S_4N_4)(PMe_2Ph)$ (**2**). This is only the second example of a complex containing the $S_4N_4^{2-}$ ligand, which in this case adopts a unique coordination geometry as established by X-ray crystallography.

In a typical reaction, a solution of **1** (0.12 mmol) in CH_2Cl_2 (20 cm^3) was slowly added to a solution of S_4N_4 (0.25 mmol) in CH_2Cl_2 (15 cm^3) with stirring. After 15 min the volume of the CH_2Cl_2 was reduced to 10 cm^3 and the red solution was passed down a bio-bead gel-permeation column. Elution with CH_2Cl_2 revealed an intense dark red band between two paler bands; this was collected and the volume reduced to 5 cm^3 *in vacuo*. Addition of hexane (60 cm^3) yielded a dark red solid which was filtered from the pale yellow solution and dried. Crystals suitable for X-ray crystallography were obtained by slow hexane diffusion into a CH_2Cl_2 solution.† Found: C, 16.5; H, 2.1; N, 9.1. Calc. for

$[PtCl_2S_4N_4\{P(CH_3)_2(C_6H_5)\}]$: C, 16.3; H, 1.9; N, 9.5%. ^{31}P NMR; singlet δ 5.0, $^1J(^{195}Pt-^{31}P)$ 2170 Hz.

The $^1J(^{195}Pt-^{31}P)$ coupling constant in the ^{31}P NMR spectrum of **2** is typical of compounds of platinum(IV), and this conclusion is confirmed by the X-ray structure of the compound (Fig. 1) which reveals an octahedral geometry, with the $S_4N_4^{2-}$ ligand coordinating through two sulphurs and one nitrogen in a meridional fashion. The ligand can be regarded as fused S_2N_2 and S_3N_2 groups. Comparison with the structure of $IrCl(CO)(S_4N_4)(PPh_3)$ (**3**), which can be prepared[4] by reacting $IrCl(CO)(PPh_3)_2$ with S_4N_4 and is the only previously reported complex of this ligand, reveals that although in both cases the ligand is coordinated through the same atoms, there is an important difference in the geometry of the ligand. Whereas in **3** the S_4N_4 undergoes relatively little reorganization upon coordination, in **2** a much more open geometry is adopted. The ligand in **2** deviates significantly from planarity and can be considered to comprise of one chelating S_2N_2 group forming a PtS_2N_2 metallacycle (as in $Pt(S_2N_2)(PMe_3)_2$)[2] fused at the Pt—S bond with a PtS_3N_2 metallacycle. The two rings are not coplanar but result in an overall *mer*-coordination, indicating that the $S_4N_4^{2-}$ ligand is potentially stable in a variety of conformations.

We have yet to establish a mechanism for the reaction of **1** with S_4N_4. However, it is interesting to note that under identical conditions the analogous palladium complex, $[PdCl_2(PMe_2Ph)]_2$, is inert to S_4N_4. It is possible that the first stage of the reaction involves oxidative addition of the S_4N_4 across an S—N bond, followed by cleavage of the chloro bridge by a second sulphur atom.

Acknowledgement—We are grateful to Johnson Matthey for loans of K_2PtCl_4.

Abstract—$Ce(OSiPh_3)_4 \cdot x$DME ($0.5 < x < 1$) was prepared from $Ce(OPr^i)_4$ by exchange reaction with Ph_3SiOH in dimethoxyethane (DME). Crystallization from a toluene–ether mixture yielded monocrystals of $Ce(DME)(OSiPh_3)_4 \cdot C_6H_5CH_3$, the crystal structure of which was determined by X-ray single-crystal techniques. It crystallizes in the monoclinic system, sp.gr. = $P2_1/c$, $a = 28.078(6)$ Å, $b = 14.628(2)$ Å, $c = 18.739(5)$ Å, $\beta = 92.24(2)°$, $V = 7.691$ Å^3, $Z = 4$, $R = 0.074$ for 4406 observations with $I > 3\sigma(I)$ and 319 variables. The Ce^{IV} ion exhibits a (4+2) coordination by oxygen atoms with four short metal–silyloxy bonds ($2 \times 2.10(1)$ Å; $2 \times 2.13(1)$ Å) and two long metal–DME bonds (2.58(1) Å; 2.59(1) Å).

Compounds of the type $M(OSiR_3)_n$, where $n = 3$ or 4, have been prepared first for Ti.[1] A more comprehensive study was made by Bradley and Thomas related to Ti, Zr, Nb and Ta.[2] The silyloxides of Gd and Er were reported in 1970[3] and they seem to be the only examples with the lanthanides.

The outcome of organic reactions involving tetravalent cerium being difficult to predict, we have undertaken a broad range study that began with the development of a simplified method for the synthesis of ceric alkoxides from ceric ammonium nitrate[4] and centred recently on the Ce^{IV} alkanoatoamine derivatives[5] and ceric silyloxides.

Among several Ce—O—Si bond compounds prepared in our Laboratory,[6] the tetrakis(triphenylsiloxy)cerium gave a good monocrystal suitable for crystal X-ray examination. We wish to report here on the synthesis and structural characterization of this product.

EXPERIMENTAL

Reagents and physical measurements

All manipulations were carried out under the exclusion of oxygen and moisture either in a N_2-filled, recirculating glove box or by the usual Schlenk technique using argon as an inert gas. The anhydrous solvents, dimethoxyethane (DME) and diethylether were purchased from Aldrich and were used without further purification. Ph_3SiOH was purchased from Petrarch Systems and was used without further purification. Ceric isopropoxide was prepared according to the published method.[4] ^1H, ^{13}C and ^{29}Si NMR spectra were recorded on a JEOL FX 90Q FT NMR spectrometer and the IR spectrum on a Perkin–Elmer 567 Grating IR spectrophotometer.

Preparation of $Ce(OSiPh_3)_4 \cdot x$DME (1)

Ceric isopropoxide (16 g, 42.5 mmol) was dissolved in 50 cm^3 of DME. Under stirring, 46.97 g

of triphenylsilanol (169 mmol) in 50 cm^3 DME was added slowly via a syringe. A white precipitate appeared after 10 s and stirring was continued during the next 15 min. The precipitate was filtered and washed with two portions of 50 cm^3 diethylether. After drying for 1 h *in vacuo* at 30°C, 50 g of a fine, white powder was obtained. It appears that depending on the extent of drying the amount of the coordinated DME varies from 0.5 to 1 mol. Found: C, 69.2; H, 4.7; Si, 9.1; Ce, 11.2. Calc. for $Ce(OSiPh_3)_4 \cdot 0.5DME$: C, 69.1; H, 5.0; Si, 8.7; Ce, 10.9. ^1H NMR ($CHCl_3$-d): 2.9 (s, CH_3); 3.0 (s, CH_2CH_2); 6.9; 7.0; 7.1; 7.86; 7.87 (phenyl). ^{13}C NMR ($CHCl_3$-d): 60.24 (—CH_3); 71.83 (—CH_2CH_2); 127.41; 128.83; 135.27; 138.47 (phenyl). ^{29}Si NMR (C_6H_6-d_6/THF: 1/2) 24.14 (s). IR (KBr, cm^{-1}): 3030 (w, —C—H, ring); 2950 (w, —C—H, DME); 1420 (m, Si—Ph); 1251 (m, C—O); 1090 (vs, C—O); 1010 (s, Si—Ph); 880 (vs, Ce—O—Si); 692 and 505 (s, C—H, ring).

Preparation of single crystals and X-ray structure analysis

Single crystals suitable for X-ray structure analysis were grown by dissolving 4 g of $Ce(OSiPh_3)_4$ (**1**) in a mixture of 60 cm^3 toluene and 25 cm^3 ether, and storing the solution for 24 h at −12°C, after which time, shiny, hexagonal-shaped crystals had been formed. After filtration via a Schlenk frit, the crystals were dried carefully by passing argon through the frit for *ca* 10 min.

A single crystal was sealed under dry nitrogen in a Lindeman-glass capillary and mounted on an Enraf-Nonius CAD4 computer-controlled four-circle diffractometer, using graphite-monochromatized Cu-K_α-radiation. Accurate unit-cell constants were derived from the setting angles of 25 reflections (Table 1). The intensity data were collected at room temperature up to a maximum Bragg angle $\theta = 53°$ (Table 1). The space group $P2_1/c$ was uniquely determined from the relevant systematic absences. The crystal was automatically reoriented each time the agreement factor between caculated and measured indices was larger than 0.12. The data were corrected for the corresponding periodic variations in intensity of about 5%, and for Lorentz and polarization effects. At the end of the data collection, the faces of the crystal were no longer smooth but covered with imbricated white shiny microcrystals.

The structure was solved by Patterson synthesis followed by alternating cycles of least-squares refinements and electron density calculations by means of Fourier and difference-Fourier synthesis, using the SHELX-76, SDP and ORTEP chains of programs.[7] The atomic scattering factors were taken from the usual tabulation,[8] and the effects of anomalous scattering were taken into account by using Cromer and Ibers' values of $\Delta f'$ and $\Delta f''$.[9] Throughout the refinements, the function minimized was $\Sigma w(F_o - |F_c|)/\Sigma F_o$, where F_o and $|F_c|$ are the observed and calculated structure factor amplitudes and w the weight. The phenyl groups were

[a] These parameters have been described in: A. Mosset, J. J. Bonnet and J. Galy, *Acta Crystallogr.* 1977, **B33**, 2633.

treated as rigid groups (C—C = 1.395 Å) with individual isotropic thermal parameters.

It rapidly appeared that besides four $OSi(C_6H_5)_3^-$ ligands, one DME molecule was coordinated to the cerium atom. Refining the non-H atoms using anisotropic thermal parameters for the Ce atom only and unit weights yielded a conventional agreement factor $R = 0.116$. After numerical absorption corrections were applied using a grid size of $4 \times 10 \times 18$, the R factor lowered to 0.094. At this stage of refinement, the difference-Fourier map showed two independent benzene rings which were attributed to solvent toluene molecules. Since they were lying at close proximity to inversion centres, they were given 50% occupancy factors. They were refined as rigid groups with free individual temperature parameters. Only one of the two corresponding methyl groups could be identified. Each H atom except for the "amputated" toluene molecule was located and introduced as a fixed contributor with an idealized position (C—H = 0.97 Å) and a thermal parameter equal to that of the atom to which it is attached. The methyl groups of both the toluene and DME molecules were treated as rigid bodies. The last cycles of refinement were run with anisotropic thermal parameters for all non-H and non-phenyl atoms. The unit weights were replaced by a non-Poisson contribution weighting scheme with a p factor of 0.01. In the final cycle of refinement, the largest (variable shift)/(esd) ratio was 0.26 for the atoms of the Ce $(DME)(OSiPh_3)_4$ molecule, and 0.90 for the atoms of the solvent molecules; the reliability factors stabilized at $R = 0.074$, $R_w = 0.082$, and the error in an observation of unit weight was $s = 1.02$ electron, for 4406 observations with $I > 3\sigma(I)$ and 319 variables. The final difference-Fourier map showed no significant peak. Final atomic positional and thermal parameters and lists of F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request.

SYNTHESIS AND PROPERTIES OF $Ce(OSiPh_3)_4$

Although ceric alkoxides were prepared by Bradley *et al.* as early as 1957,[2] the exchange reaction with silanols does not seem to have been carried out. Reaction of ceric isopropoxide with 4 moles of triphenylsilanol in DME resulted in the formation of a white, air stable powder:

$$Ce(OPr^i)_4 + 4Ph_3SiOH \longrightarrow Ce(OSiPh_3)_4 + 4i\text{-PrOH}. \quad (1)$$

NMR results and elemental analysis are in agreement with the expected formula for **1**. The product appears to be air stable and resistant towards hydrolysis. Reaction with acetylacetone forms immediately, dark red cerium(IV) acetylacetonate complex. The product is soluble in THF, $CHCl_3$ or toluene and not soluble in hydrocarbons. In close analogy to the corresponding Ti-complex, $Ti(OSiPh_3)_4$ (**1**), is heat resistant with a melting temperature of 330°C.

As shown by elemental analysis and NMR and IR spectroscopy, **1** contains variable amounts of DME which was used as solvent. Depending on the drying conditions the (DME)/Ce molar ratio varies between 0.5–1. The single crystals of **1** obtained from a mixture of 60 cm^3 toluene and 25 cm^3 ether, revealed to have the formula $Ce(DME)(OSiPh_3)_4 \cdot C_6H_5CH_3$ from the X-ray structure determination.

CRYSTAL AND MOLECULAR STRUCTURE OF $Ce(DME)(OSiPh_3)_4 \cdot C_6H_5CH_3$

The unit-cell has a volume of 7691 $Å^3$ and contains four $Ce(DME)(OSiPh_3)_4$ molecules located at about (1/4, 0, 3/8), (3/4, 0, 5/8), (1/4, 1/2, 7/8), (3/4, 1/2, 1/8) and four toluene molecules (t1 and t2) statistically distributed around the inversion centres at (0, 0, 0), (0, 1/2, 1/2), (1/2, 0, 0), (1/2, 1/2, 1/2) with 50% site occupancies. A stereoscopic view of the cell content is given in Fig. 1. A simplified view of the $Ce(DME)(OSiPh_3)_4$ molecule emphasizing the coordination geometry of the Ce^{IV} ion and showing the atom numbering scheme is shown in Fig. 2. The main bond lengths and angles are presented in Table 2. All the phenyl bond lengths and angles are equal to 1.395 Å and 120°, respectively, according to the rigid body mode of refinement.

The Ce^{IV} ion is bound to four triphenylsiloxy groups with oxygen atoms O1, O2, O3, O4 at distances ranging from 2.10(1) to 2.13(1) Å, and two chelating DME oxygen atoms (O5, O6) about 0.5 Å further: 2.58(1) and 2.59(1) Å. Muetterties' pairing dihedral angle criterion[10] did not allow to locate this six-fold coordination symmetry somewhere between octahedral and trigonal prismatic, even by using the modified version by Kouba and Wreford[11] to take into account large discrepancies in metal-to-ligand distances. The coordination would rather be considered as a (4+2) environment derived from a tetrahedral geometry. The part of environment reminiscent of a tetrahedron comprises the four siloxy oxygen atoms (O1 → O4). They are equidistant from the Ce atom within experimental error and define two perpendicular planes with the Ce atom: CeO1O3 and

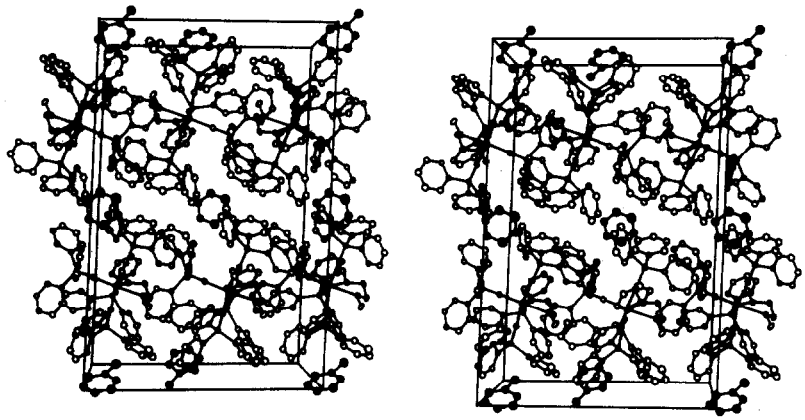

Fig. 1. Stereoscopic ORTEP view down the *b* axis (*a* is vertical) of the molecular packing of $Ce(DME)(OSiPh_3)_4 \cdot C_6H_5CH_3$. The origin of the represented unit-cell was translated by (0, −1/4, 0) with respect to the conventional one. Solvent toluene molecules t1 and t2 are blackened. Only one set of the positions they are statistically distributed on is represented. The methyl group was not located for t2. Atoms are drawn with their 10% probability thermal ellipsoids.

[a] C(1aj), C(1bj), C(1cj) are the three phenyl C atoms attached to atom Si(j).

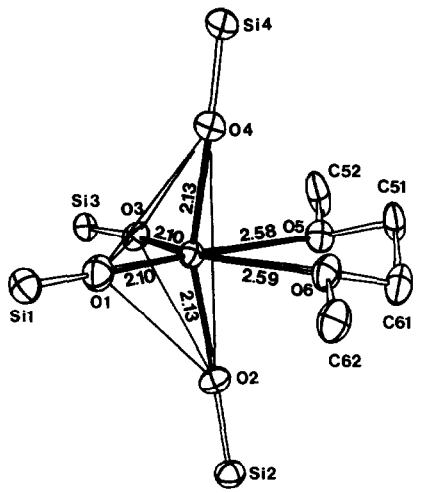

Fig. 2. The (4+2) coordination geometry of cerium(IV) in $Ce(DME)(OSiPh_3)_4$. For the sake of clarity the phenyl groups were not drawn. 20% Probability thermal ellipsoids are shown.

CeO2O4 make an angle of 89.8(4)°. All the relevant six O—Ce—O angles, which would equal 109.5° in an ideal tetrahedron, are indeed markedly larger than 90°: as a result of the intervention of the O5, O6 DME bite which occurs between atoms O2 and O4, right in the plane defined by atoms Ce, O1, O3 (the angle between planes CeO1O3 and CeO5O6 is 2°), the O2—Ce—O4 angle opens to 160.5(4)° and the other five "tetrahedral" angles shrink to 95–96° (Table 2).

The Ce—O—Si angles are nearly straight, ranging from 170.1(6) to 178.6(7)°. The Si—O and Si—C bond lengths ranging from 1.61(1) to 1.62(2) Å and 1.86(1) to 1.90(1) Å, respectively do not show unusual features, nor do bond lengths and angles in the DME chelating ligands.

The molecular packing may be described as layered with layers of $Ce(DME)(OSiPh_3)_4$ molecules at mean levels $x = 1/4$ and $x = 3/4$ alternating with layers of toluene molecules at mean levels $x = 0$ and $x = 1/2$ (Fig. 1).

SYNTHESIS AND X-RAY CRYSTALLOGRAPHIC CHARACTERIZATION OF THE DECAMETHYLSAMAROCENE SOLVATES $(C_5Me_5)_2Sm(OC_5H_8)_2$ AND $(C_5Me_5)_2Sm(OC_5H_{10})$

WILLIAM J. EVANS* and TAMARA A. ULIBARRI

Department of Chemistry, University of California, Irvine, Irvine, CA 92717, U.S.A.

(*Received* 22 *July* 1988; *accepted* 31 *October* 1988)

Abstract—The bis(dihydropyran) and mono(tetrahydropyran) solvates of $(C_5Me_5)_2Sm$ have been prepared by displacing THF from $(C_5Me_5)_2Sm(THF)_2$ and have been studied by X-ray diffraction. $(C_5Me_5)_2Sm(OC_5H_8)_2$ crystallizes from C_5H_8O in space group $P2_1/c$ with $a = 11.819(6)$, $b = 14.192(10)$, $c = 17.838(6)$ Å, $\beta = 95.26(4)°$ and $D_{calc} = 1.313$ g cm^{-3} for $Z = 4$. Least-squares refinement on the basis of 3168 observed reflections led to a final R value of 0.047. $(C_5Me_5)_2Sm(OC_5H_{10})$ crystallizes from hexane in space group $P2_1/a$ with $a = 14.900(5)$, $b = 16.263(7)$, $c = 10.732(3)$ Å, $\beta = 70.32(2)°$ and $D_{calc} = 1.376$ g cm^{-3} for $Z = 4$. Least-squares refinement of 3660 observed reflections led to a final R value of 0.046. Structural variations in the $(C_5Me_5)_2Sm(ether)_x$ series where $x = 0$, 1 and 2 are analysed.

Due to the strong reduction potential of samarium(II) ($Sm^{III}/Sm^{II} = -1.5$ V vs NHE[1]), divalent organosamarium chemistry is one of the major areas of study in the organolanthanide field.[2–4] Reactivity with a variety of substrates including organic halides, epoxides, ketones, alkynes, alkenes, azo compounds, CO, NO, N_2O and C_5H_5NO among others, has been observed.[2–4] To fully understand organosamarium(II) reactivity, it is important to know how similar this class is to trivalent lanthanide complexes. For example, is the special reactivity of samarium(II) species due just to the strong reduction potential, or are special metal–ligand bonding interactions present in these complexes which also affect the chemistry?

One source of information on this topic is X-ray crystal structure data. However, only a few organosamarium(II) complexes have been studied. The first structurally characterized organosamarium(II) complex was the disolvate $(C_5Me_5)_2Sm(THF)_2$ (**1**).[5,6] Subsequently, the unusual, bent, solvent-free $(C_5Me_5)_2Sm$ (**2**)[7,8] and the mono-ring complex $[(C_5Me_5)(THF)_2Sm(\mu\text{-}I)]_2$ (**3**),[6] were studied by X-ray diffraction. In the course of our studies on samarium(II) chemistry, we have obtained X-ray crystal structures on two additional $(C_5Me_5)_2Sm^{II}$ complexes, a bis(dihydropyran) derivative and a mono(tetrahydropyran) complex. These compounds, along with **1** and **2**, provide the data needed for a structural analysis of the complete series $(C_5Me_5)_2SmL_x$ where L = ether, $x = 0$–2.

EXPERIMENTAL

The complexes described below are extremely air- and moisture-sensitive. Therefore, both the syntheses and subsequent manipulations of these compounds were conducted under nitrogen with rigorous exclusion of air and water using Schlenk, vacuum line and glovebox (Vacuum/Atmospheres HE-553 Dri-Lab) techniques. Solvents were purified and physical measurements were obtained as previously described.[9] $(C_5Me_5)_2Sm(THF)_2$ was prepared according to the literature.[6]

$(C_5Me_5)_2Sm(OC_5H_8)_2$ (4)

In the glovebox, $(C_5Me_5)_2Sm(THF)_2$ (0.170 g, 0.300 mmol) was placed in a 50 cm^3 flask equipped with a Teflon stir bar and dissolved in *ca* 15 cm^3 of toluene. The toluene was removed by rotary evaporation and the process was repeated to yield a dark brownish-green solid which, by complexometric analysis, was the monosolvate, $(C_5Me_5)_2Sm(THF)$. The solid was then dissolved in *ca* 10 cm^3 of 3,4-dihydro-2H-pyran and the brownish-green–black solution was stirred for 30 min. The solvent was

* Author to whom correspondence should be addressed.

removed by rotary evaporation to yield a purple–black microcrystalline solid, $(C_5Me_5)_2Sm(OC_5H_8)_2$ (**4**), in quantitative yield. Found: Sm, 25.9. Calc. for $SmC_{30}H_{46}O_2$: Sm, 25.5%. $(C_5Me_5)_2Sm(OC_5H_8)_2$ can be recrystallized from a concentrated solution of 3,4-dihydro-2H-pyran by cooling to −32°C. ^1H NMR (benzene-d_6, 0.11 mM) δ 3.585 (s, C_5Me_5), definitive assignment of resonances associated with the dihydropyran group have not been made. ^{13}C NMR (benzene-d_6, 0.11 mM) δ 95.65 (q, C_5Me_5, $J = 120$ Hz), −94.01 (s, C_5Me_5). IR (KBr) 2915(s), 2860(s), 1665(w), 1450(m), 1420(w), 1230(w), 1195(w), 1060(w), 1040(m), 885(w), 860(w), 830(w), 810(w), 750(w), 725(w) cm^{-1}; $\chi_M = 5840 \times 10^{-6}$ (cgs); $\mu_{eff} = 3.75\ \mu_B$.

$(C_5Me_5)_2Sm(OC_5H_{10})$ (**5**)

In the glovebox, $(C_5Me_5)_2Sm(THF)$ (0.142 g, 0.288 mmol) was placed in a 20 cm^3 vial and dissolved in *ca* 8 cm^3 of tetrahydropyran to yield a deep maroon solution. The reaction was shaken vigorously. After 90 min, the solvent was removed by rotary evaporation to yield a dark maroon–brown solid. The maroon solid was dissolved in 10 cm^3 of toluene. The toluene was removed by rotary evaporation and this procedure was repeated to yield the dark brown solid, $(C_5Me_5)_2Sm(OC_5H_{10})$, in quantitative yield. Found: Sm, 30.5. Calc. for $SmC_{25}H_{40}$: Sm, 29.7%. This complex can be recrystallized from hexane. ^1H NMR (benzene-d_6, 0.05 mM) δ 4.05 (s, C_5Me_5), 9.15 v br s, −0.35 br s, −2.27 (br s, OC_5H_{10}). ^{13}C NMR (benzene-d_6, 0.05 mM) δ 96.23 (q, C_5Me_5, $J = 125$ Hz), −96.42 (s, C_5Me_5). IR (KBr) 2920(s), 2860(s), 1445(w), 1030(w), 915(w), 805(w) cm^{-1}; $\chi_M = 5143 \times 10^{-6}$ (cgs); $\mu_{eff} = 3.52\ \mu_B$.

X-ray data collection, structure determination and refinement for $(C_5Me_5)_2Sm(OC_5H_8)_2$

General procedures for data collection and reduction have been described previously.[10] A dark purple–black crystal measuring $0.62 \times 0.38 \times 0.042$ mm was sealed under nitrogen in a glass capillary and mounted on a Syntex $P2_1$ diffractometer. Lattice parameters were obtained from the settings of 15 computer-centred reflections. Monoclinic symmetry was indicated by the interaxial angles and confirmed by axial rotation photography. Data were collected by the θ–2θ scan technique in bisecting geometry. The p factor in the expression[11] for the standard deviation of the observed intensities was given a value of 0.05. Relevant crystal and data collection parameters are given in Table 1. All computations were carried out with a local version of the UCLA Crystallographic Computing Package.[12] The space group was determined as $P2_1/c$ (No. 14) from the systematic absences, $h0l$, $l \neq 2n$, and $0k0$, $k \neq 2n$.

During the data collection, the intensities of three standard reflections exhibited only random fluctuations within ±2%. Data were corrected for Lorentz, polarization and absorption effects. Patterson and difference Fourier techniques were used to locate all non-hydrogen atoms which were refined with anisotropic thermal parameters by the use of full-matrix least-squares methods. Hydrogen atoms were not included in the refinement. Atomic scattering factors were taken from ref. 13. A final difference map containing no recognizable features; its largest peak was of height 1.12 $eÅ^{-3}$ at a distance of 1.03 Å from the samarium atom.

X-ray data collection, structure determination and refinement for $(C_5Me_5)_2Sm(OC_5H_{10})$

A dark brown crystal measuring $0.40 \times 0.26 \times 0.26$ mm was handled as described above. Lattice parameters for a monoclinic cell were obtained from the settings of 15 computer-centred reflections. Relevant crystal and data collection parameters are given in Table 1. The space group was determined as $P2_1/a$ (alternate setting of $P2_1/c$, No. 14) from the systematic absences, $h0l$, $h \neq 2n$, and $0k0$, $k \neq 2n$. During the data collection, the intensities of three standard reflections measured every 100 reflections showed a linear decay of 8%. Data were corrected for Lorentz, polarization and absorption effects and for the decay of standards. Patterson and difference Fourier techniques were used to locate all non-hydrogen atoms which were refined with anisotropic thermal parameters by the use of full-matrix least-squares methods. Hydrogen atoms were not included in the refinement. The high thermal parameters for C(16) to C(20) indicate the presence of a large amount of thermal motion in the form of in-plane wagging for these pentamethylcyclopentadienyl methyl groups. A model containing two carbons at half occupancy for these methyl carbons was tried. The single site model presented in this paper was found to be a better model for the system. A final difference map contained no recognizable features; its largest peak was of height 2.69 $eÅ^{-3}$ at a distance of 1.10 Å from the samarium atom.

RESULTS AND DISCUSSION

Synthesis and characterization

Rotary evaporation of toluene solutions of $(C_5Me_5)_2Sm(THF)_2$ (**1**) reduces the amount of sol-

vated THF and forms the monosolvated species $(C_5Me_5)_2Sm(THF)$. This complex dissolves in 3,4-dihydro-2H-pyran, C_5H_8O, presumably to form a mixture of disolvated species $(C_5Me_5)_2Sm(OR_2)(OR'_2)$. Rotary evaporation of this solution removes the lower boiling THF preferentially and leaves $(C_5Me_5)_2Sm(OC_5H_8)_2$ (**4**). X-ray quality crystals of **4** recrystallize from C_5H_8O. The THF in **1** can be similarly displaced by tetrahydropyran. Rotary evaporation of toluene solutions of this product gives $(C_5Me_5)_2Sm(OC_5H_{10})$ (**5**). Recrystallization from hexane gives X-ray quality crystals.

The physical properties of **4** and **5** are consistent with the presence of samarium(II). The intense, dark colours are similar to those of other organosamarium(II) species and differ from the typical light yellow–orange colours of samarium(III) species.[2] The room temperature magnetic susceptibilities of **4** and **5** are in the samarium(II) range.[14] The ^{13}C NMR spectra of **4** and **5** are similar to those of **1–3** but different from $(C_5Me_5)_2Sm^{III}$ spectra in that the methyl carbon signals are at low field, ~ 96 ppm, and the ring carbon signals are at high field, −94 to −96 ppm. The complexometric analyses of **4** and **5** were consistent with their formulations as $(C_5Me_5)_2Sm(OC_5H_8)_2$ and $(C_5Me_5)_2Sm(OC_5H_{10})$, respectively, and definitive identification was made by X-ray crystallography.

X-ray crystal structures

Figures 1 and 2 show the molecular structures of **4** and **5**, respectively, and bond distances and angles are given in Tables 2 and 3. In complex **4**, the two C_5Me_5 ring centroids and the two OC_5H_8 oxygen atoms comprise a distorted tetrahedral geometry around the samarium atom. The six angles describing these five positions in **4** are very similar to the analogous angles in **1**. The O(1)—Sm—O(2) angle in **4** is 82.2(2) vs 82.7(4)° in **1**. The Cn(1)—Sm—Cn(2) angles [Cn(1) = ring centroid

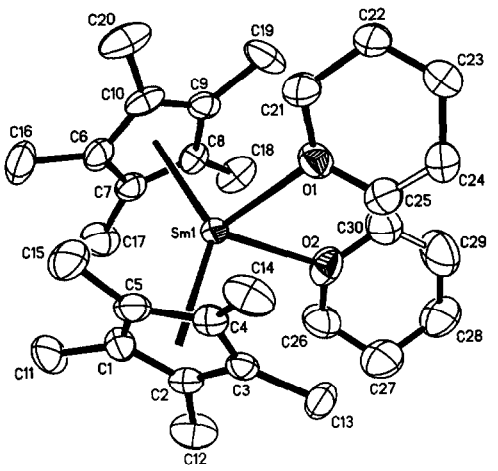

Fig. 1. Molecular structure of $(C_5Me_5)_2Sm(OC_5H_8)_2$ (**4**).

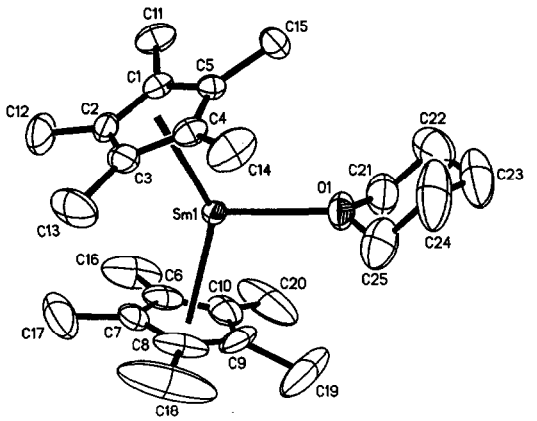

Fig. 2. Molecular structure of $(C_5Me_5)_2Sm(OC_5H_{10})$ (**5**).

for the C_5Me_5 ring comprised of carbon atoms (1)–(5)] are 138.2° in **4** and 136.5° in **1**. The four Cn—Sm—O angles in **4** are 103.0, 104.5, 106.9 and 107.9° compared to 103.8, 104.5, 107.8 and 108.3° in **1**.

As shown in Table 4, the Sm—C(C_5Me_5) average distance in **4** is slightly smaller than that in **1**, and the Sm—O distances are slightly longer than those in **1**. However, the differences are not statistically significant. The double bonds in the dihydropyran rings, C(24)—C(25) and C(29)—C(30), are both located on the inside of the O—Sm—O wedge although neither are oriented toward the samarium atom or toward each other.

In $(C_5Me_5)_2Sm(OC_5H_{10})$, the tetrahydropyran ligand is positioned almost symmetrically between the C_5Me_5 rings as shown by the C_5Me_5 centroid—Sm—O angles of 107.0 and 107.4°. The samarium atom lies 0.34 Å out-of-the plane defined by the two ring centroids and the oxygen atom. Hence, the formal coordination geometry is not perfectly trigonal planar. The (ring centroid)—Sm—(ring centroid) angle of 140.0° is slightly larger than those observed for the eight-coordinate complexes **1** and **4**. This is consistent with the smaller steric demand placed on the metal by the single solvate molecule. The average Sm—C(C_5Me_5) distance of 2.816(3) Å is smaller than those in **1** and **4**, which again is consistent with the lower coordination number in **5**. The Sm—O distance in **5** is between the two values found in $(C_5Me_5)_2Sm(THF)_2$ and is smaller than the analogous distances in $(C_5Me_5)_2Sm(OC_5H_8)_2$. The tetrahydropyran ligand adopts a chair conformation with normal bond distances and angles.[15]

Structural comparisons

Table 4 consists of a compilation of crystallographic data on divalent samarium complexes containing the C_5Me_5 ligand. The complexes are arranged in order of decreasing coordination number. For the six samarium complexes, a diminishing progression of average Sm—C(C_5Me_5) distances is observed as the coordination number decreases. This is sterically reasonable since fewer ligands can get closer to the metal. The trend follows the change in effective ion radius observed for metals, as a function of coordination number in halides and chalcogenides.[16] The difference in the averages in going from formal eight coordination to six coordination, 2.86(1)–2.79(1) Å, is not large and the ranges of individual values for complexes with different coordination numbers often overlap. For example, six-coordinate $(C_5Me_5)_2Sm$ and eight-coordinate $(C_5Me_5)_2Sm(THF)_2$ both have a 2.81 Å Sm—C(C_5Me_5) bond length. In comparison, Shannon shows that the ionic radius of Sm^{2+} varies from 1.22 to 1.27 to 1.32 Å in seven-, eight- and nine-coordinate samarium(II) complexes, respectively.[16]

The (ring centroid)–Sm–(ring centroid) angles also follow a regular pattern which is understandable in terms of steric factors. The increase in angle as coordination number decreases is reasonable since the additional ligands in the higher coordinate complexes will force the C_5Me_5 rings closer together (smaller angle). As was found in the Sm—C(C_5Me_5) distances, the range of samarium complexes is small, 136.5–140.5°.

In contrast to the data discussed above, the Sm—O distances do not follow a regular pattern with respect to coordination number. Given that the overall range is again small, that different ether ligands are involved and that only two coordination numbers can be compared, this may not be too surprising.

Comparison of the data in Table 4 with data on trivalent $(C_5Me_5)_2Sm$ complexes is also informative. In the past, average Sm—C(C_5Me_5) distances in trivalent $(C_5Me_5)_2Sm(X)(Y)$ complexes ranged from 2.72 to 2.77 Å[17] and did not overlap with averages of eight-coordinate Sm^{II}—C(C_5Me_5) lengths, 2.812(4)–2.86(1) Å (Table 4). Recently, however, the range for $(C_5Me_5)_2Sm(X)(Y)$ complexes has been extended from 2.68(1) Å for $[(C_5Me_5)_2Sm(\mu\text{-}Me)_2AlMe_2]_2$[18] to 2.80(1) Å for sterically crowded $[(C_5Me_5)_2Sm(CNCMe_3)]_2(\mu\text{-}O)$.[19] Hence, there is no longer such a clean distinction between the ranges. In general, however, for comparable coordination environments, Sm—C(C_5Me_5) distances can be valuable indicators of the valence of the metal centre.

The Sm—O distances also fall in distinct ranges for divalent vs trivalent $(C_5Me_5)_2Sm$ complexes. Table 4 shows a range of 2.62(2)–2.699(7) Å, whereas in published trivalent $(C_5Me_5)_2Sm(X)(THF)$ systems, Sm—O bonds range from 2.44(2)[20] to 2.511(4) Å.[21] The (ring centroid)–Sm–(ring centroid) angles, on the other hand, are not specific to the metal valence state. The samarium(II) range of 136.5–140.1° overlaps considerably with the 127[17]–141°[22] range observed for trivalent $(C_5Me_5)Sm$ complexes.

SUMMARY

Analysis of the structural data now available on the series $(C_5Me_5)_2Sm(OR_2)_x$, $x = 0$–2, shows that

$[(C_5Me_5)(THF)_2Sm(\mu\text{-}I)]_2$	7	2.81(2)	2.77(2)–2.84(3)	2.66(1) 2.62(2)	—	6
$(C_5Me_5)_2Sm$	6	2.79(1)	2.775(6)–2.815(6)	—	140.1	8

[a] Two of the metal ligand distances are quite long.

organosamarium(II) complexes show reasonable structural trends based on coordination number. Both the Sm—C(C_5Me_5) and the Sm—O(THF) distances have characteristic values for samarium(II) complexes which are distinct from trivalent values in complexes of comparable coordination environment. These data are similar to the structural trends found in trivalent organolanthanide complexes.[23]

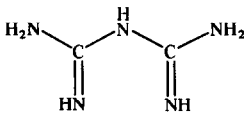
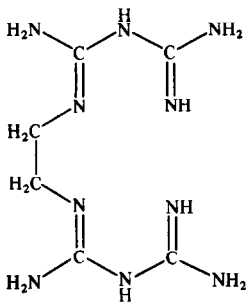
(*Received* 19 *July* 1988; *accepted after revision* 8 *November* 1988)

Abstract—(Amino acidato)dibiguanidecobalt(III) salts of the type $[Co(AB)en(bigH)_2]^{2+}$ have been prepared and characterized (ABH = DL-α-alanine, β-alanine, L-leucine, DL-valine and L-histidine; $en(bigH)_2 = N^1,N^1$-ethylenedibiguanide). A number of salts of each cation have been prepared, and their ionic nature has been confirmed by conductance measurements. IR spectra have furnished positive information regarding the bonding sites of the title ligands. Electronic spectra revealed expected trends. In the case of the $[Co(hist)en(bigH)_2]^{2+}$ cation, the histidinate (hist) anion behaves as a bidentate NN donor not as an NO donor.

Biguanide (**1**) and ethylenedibiguanide (**2**) are extremely powerful and formidable coordinating ligands which have played important roles in elucidating many interesting aspects of coordination chemistry.[1,2] Furthermore, by stabilizing many otherwise unfamiliar oxidation states of metal ions, these ligands have played significant roles in the development of ideas on the mechanism of racemization and on interesting reaction kinetics.[1–5] Dutta and his students[6–8] have prepared and characterized some cobalt(III) mixed chelates of the type $[Co(AB)(bigH)_2]^{2+}$ (ABH = glycine, DL-α-alanine, β-alanine, etc.; bigH = biguanide). A survey of metal dibiguanide complexes shows that although a number of studies have been made of homo-(dibiguanide) complexes of a variety of transition metal ions, none has been devoted to hetero-(dibiguanide) complexes.[1–5,7,9–11] In this paper we report a study of several mixed chelates of cobalt (III) containing one bidentate amino acid (with a donor set, NO for alanine, leucine and valine, and an NN donor set or NO donor set for histidine) and one quadridentate ligand (N^1,N^1-ethylenedibiguanide) in order to aid in the elucidation of the structure of $[Co(AB)en(bigH)_2]^{2+}$.



Biguanide (**1**)



Ethylenedibiguanide (**2**)

EXPERIMENTAL

Ethylenedibiguanide hydroxide sulphate and diamineethylenedibiguanidecobalt(III) hydroxide sulphate were prepared following known methods.[1,2]

Analysis

Cobalt and nitrogen were determined as $CoSO_4$ and by the combustion method, respectively. Carbon and hydrogen were analysed by CDRI (Lucknow, India). Chlorine, bromine and iodine were determined as the silver salts. Electrical conductances were measured with a Philips PR 9500 conducti-

* Author to whom correspondence should be addressed.

vity bridge. IR spectra were recorded at CDRI (Lucknow). Solution spectra were obtained with a Hilger Uvispec spectrophotometer over the range 320–600 nm.

DL - α - *Alaninatoethylenedibiguanidecobalt(III) sulphate*

Diamine ethylenedibiguanidecobalt(III) hydroxide sulphate-4-hydrate (1 g) was dissolved in water (15 cm^3), heated with α-alanine (0.2 g in 10 cm^3 of water), and the mixture digested on the steam bath. When evolution of ammonia had ceased, the solution was cooled, neutralized with cold, dilute H_2SO_4 (1 : 4) and filtered. After concentration and cooling, the filtrate deposited red–violet crystals, which were recrystallized from hot water and dried over $CaCl_2$ (yield, 0.8 g). Found: Co, 11.6; C, 20.8; H, 4.8; N, 30.4. Calc. for $[Co(\alpha\text{-alan-}\bar{O})en(bigH)_2](SO_4)\cdot 2H_2O$: Co, 11.6; C, 21.3; H, 5.12; N, 30.3%.

DL - α - *Alaninatoethylenedibiguanidecobalt(III) chloride*

The above sulphate salt (1 g) was dissolved in water (15 cm^3) and treated with excess aqueous barium chloride solution, whereupon insoluble barium sulphate was formed, which was removed by filtration. The filtrate was concentrated to a small volume and then cooled, whereupon red-violet crystals separated. These were purified by recrystallization from hot water (yield, 0.7 g). Found: Co, 11.8; C, 21.5; H, 5.3; N, 30.6. Calc. for $[Co(\alpha\text{-alan-}\bar{O})en(bigH)_2]Cl_2\cdot 3H_2O$: Co, 11.7; C, 21.5; H, 5.5; N, 30.7%.

DL-α-*Alaninatoethylenedibiguanidecobalt(III) iodide*

The above chloride salt (1 g) was dissolved in water (15 cm^3), and KI solution was added to this solution to precipitate red–violet crystals, which were purified by two recrystallizations, twice from hot water (yield, 0.9 g). Found: Co, 8.9; C, 16.3; H, 3.7; N, 23.3. Calc. for $[Co(\alpha\text{-alan-}\bar{O})en(bigH)_2]I_2\cdot 1.5H_2O$: Co, 8.9; C, 16.4; H, 3.8; N, 23.4%.

The following compounds were obtained by procedures similar to those for DL-α-alaninatoethylenedibiguanidecobalt(III) chloride and iodide.

β-Alaninatoethylenedibiguanidecobalt(III) chloride

Reddish-violet crystals, recrystallized from hot water. Found: Co, 11.7; C, 21.4; H, 5.3; N, 30.7. Calc. for $[Co(\beta\text{-alan-}\bar{O})en(bigH)_2]Cl_2\cdot 3H_2O$: Co, 11.7; C, 21.5; H, 5.5; N, 30.7%.

β-Alaninatoethylenedibiguanidecobalt(III) iodide

Reddish-violet crystals, recrystallized from hot water. Found: Co, 8.8; C, 16.2; H, 3.6; N, 23.4. Calc. for $[Co(\beta\text{-alan-}\bar{O})en(bigH)_2]I_2\cdot 1.5H_2O$: Co, 8.9; C, 16.4; H, 3.8; N, 23.4%.

L-*Leucinatoethylenedibiguanidecobalt(III) chloride*

Reddish-violet crystals, recrystallized from a (1 : 1) alcohol/water mixture. Found: Co, 11.3; C, 27.8; H, 6.0; N, 29.9. Calc. for $[Co(l\text{-leuc-}\bar{O})en(bigH)_2]Cl_2\cdot 1.5H_2O$: Co, 11.4; C, 27.9; H, 6.0; N, 29.9%.

DL-*Valinatoethylenedibiguanidecobalt(III) sulphate*

Reddish-violet crystals, recrystallized from a hot (1 : 1) alcohol/water mixture. Found: Co, 10.8; C, 23.8; H, 5.5; N, 28.3. Calc. for $[Co(val\text{-}\bar{O})en(bigH)_2](SO_4)\cdot 2.5H_2O$: Co, 10.8; C, 24.2; H, 5.7; N, 28.3%.

DL-*Valinatoethylenedibiguanidecobalt(III) chloride*

Reddish-violet crystals, recrystallized from a hot (1 : 1) alcohol/water mixture. Found: Co, 10.9; C, 24.3; H, 6.0; N, 28.7; Cl, 13.1. Calc. for $[Co(val\text{-}\bar{O})en(bigH)_2]Cl_2\cdot 3.5H_2O$: Co, 10.9; C, 24.5; H, 6.1; N, 28.6; Cl, 13.2%.

L - *Histidinatoethylenedibiguanidecobalt(III) sulphate*

Orange–red crystals, recrystallized from hot water. Found: Co, 9.8; C, 24.0; H, 4.8; N, 30.8. Calc. for $[Co(hist\text{-}\bar{O})en(bigH)_2](SO_4)\cdot 3H_2O$: Co, 9.9; C, 24.3; H, 5.0; N, 30.8%.

L-*Histidinatoethylenedibiguanidecobalt(III) chloride*

Orange–red crystals, recrystallized from hot water. Found: Co, 10.6; C, 26.1; H, 4.9; N, 33.1; Cl, 13.0. Calc. for $[Co(hist\text{-}\bar{O})en(bigH)_2]Cl_2\cdot 2H_2O$: Co, 10.7; C, 26.2; H, 5.1; N, 33.2; Cl, 12.9%.

L - *Histidinatoethylenedibiguanidecobalt(III) bromide*

Orange–red crystals, recrystallized from hot water. Found: Co, 9.1; C, 22.3; H, 4.1; N, 28.6; Br, 26.0. Calc. for $[Co(hist\text{-}\bar{O})en(bigH)_2]Br_2\cdot 2H_2O$: Co, 9.2; C, 22.6; H, 4.3; N, 28.5; Br, 25.0%.

L-*Histidinatoethylenedibiguanidecobalt(III) iodide*

Orange–red crystals, recrystallized from hot water. Found: Co, 8.3; C, 19.8; H, 3.4; N, 25.4; I,

RESULTS AND DISCUSSION

It is not known whether diamineethylenedibiguanidecobalt(III) hydroxide sulphate has a *cis* or *trans* configuration.[1,2] When the compound was treated with an amino acid, ammonia was not immediately evolved, but on warming the mixture, ammonia was evolved, and a reddish solution resulted. On concentrating the solution to a small volume and neutralizing it, the cations could be isolated. All the salts are highly crystalline, appear homogeneous under the microscope, and are very stable in aqueous solution. The molar conductances (Table 1) in aqueous solution at 25°C are 205–219 Ω^{-1} cm^2 mol^{-1}, which are within the range for bi-univalent electrolytes.[2]

In the IR spectra of all the cobalt(III) complexes, the bands in the 3 μ region, arising due to ν_{asy}(N–H) (3310–3385 cm^{-1}) and ν_{asy}(N–H) (3100–3150 cm^{-1}) modes of vibration of the guanyl group,[12] are observed almost in the same positions as those in the original ligand molecules, with slight decreases in intensities, suggesting participation of the ligand in complex formation without deprotonation. In the region of 1645–1660 cm^{-1}, the complexes exhibit strong bands, and these are assigned to ν(C=N) stretch, ν(N—H) deformation, and ν(O—H) deformation vibration.[13–15] In ethylenedibiguanide sulphate, the ν(C=N) stretch occurs at 1695 cm^{-1}, and the ν(N—C—N) stretch at 1585 cm^{-1}. A similar N—C—N stretching frequency of other cobalt(III) biguanide complexes was observed at ~1580 cm^{-1}.[15] The lowering of the ν(C=N) stretch (1660 cm^{-1}) and the ν(N—C—N) stretch (1545 cm^{-1}) in metal complexes is due to coordination with nitrogen atoms of =NH groups. The ν(C—N) stretch of the C—NH$_2$ group of both the ligand and the complexes, is assigned to about 1345–1375 cm^{-1}. A strong band in the region of 1190–1315 cm^{-1} corresponds to the formation of the chelate ring, which is absent in this region in the particular ligand.[16] Since the —C=N— stretch of the biguanide is in the region of antisymmetrical carboxyl stretching,[17] it frustrated attempts to demonstrate whether the carboxyl group is free or not. Attempts to protonate COO$^-$ by HCl to produce [Co(histH)en(bigH)$_2$]$^{3+}$, led to decomposition of the complex,[2,9,18] As expected for cobalt(III) complexes,[19] all the chelates exhibit two *d–d* absorption bands I and II (Table 1). The higher energy band, II, of the [Co(hist)en(bigH)$_2$]$^{2+}$ ion could not be located, presumably because it was covered by the charge-transfer transition arising from an interaction between cobalt(III) and the imidazole moiety.[20] Such a high energy band, II, was also not observed in compounds of ions like [Co(pic)(bigH)$_2$]$^{2+}$ [picH = picolinic acid (pyridine 2-carboxylic acid); bigH = biguanide], [Cu(lut)(bigH)$_2$]$^+$ [lutH$_2$ = lutidinic acid (pyridine 2,6-dicarboxylic acid)], [Co(DMG)(bigH)$_2$]$^+$ (DMGH$_2$ = dimethylglyoxime), [Co(en)(bigH)$_2$]$^{3+}$, and [Co(hist)(bigH)$_2$]$^{2+}$ (histH = histidine) ions.[8,21] Although histidine may act either as a bidentate NN[22,23] or as an NO donor,[24] the spectrum of the [Co(hist)en(bigH)$_2$]$^{2+}$ ion reveals that the histidinate ion functions in this particular complex as a bidentate NN ligand. Interestingly enough, band I for the [Co(hist)en(bigH)$_2$]$^{2+}$ ion is comparable to transitions in cobalt(III) complexes with [CoN$_6$] chromophores, e.g. [Co(bigH)$_3$]$^{3+}$ (λ_{max}, 495 nm; ε = 235), [Co(en)$_3$]$^{3+}$ (λ_{max}, 470 nm; ε = 72.5),

$[Co(en)(bigH)_2]^{3+}$ (λ_{max}, 475 nm; $\varepsilon = 165$), $[Co(en)_2(bigH)]^{3+}$ (λ_{max}, 480–490 nm; $\varepsilon = 158$), $[Co(o\text{-phen})(bigH)_2]^{3+}$ (λ_{max}, 470 nm; $\varepsilon = 177$), $[Co(dipy)(bigH)_2]^{3+}$ (λ_{max}, 465 nm; $\varepsilon = 172$), $[Co(dipy)en(bigH)_2]^{3+}$ (λ_{max}, 480–490 nm; $\varepsilon = 175$); (en = ethylenediamine, dipy = α,α′-dipyridyl).[8,21,25] It thus appears that the histidinate ion behaves as an NN bidentate donor in this mixed chelate, using the imidazole and NH_2 nitrogen for linking to cobalt (III).[2,8,23]

(*Received* 27 *September* 1988; *accepted* 9 *November* 1988)

Abstract—Aspartic and glutamic acids have been studied as ligands (L) for copper(II) at 25°C and in 1.00 M $NaClO_4$ (as a constant ionic medium), by measuring the electromotive force of galvanic cells containing glass and copper amalgam electrodes in a wide concentration range of the reagents, to elucidate the formation of the protonated species. The experimental data have accounted for the species CuL, CuL_2, CuHL, $CuHL_2$, CuH_2L_2, CuH_2L and, for aspartate, CuH_4L_2. The relative stability constants have been determined and compared with those of glycine and serine. The protonation constants of aspartate have also been determined under the same experimental conditions using an H_2 electrode.

The behaviour of amino acids as ligands (L) towards cations represents a subject of research in our laboratory. In previous papers, glycine[1] and serine[2,3] were studied, and experimental data were also explained by assuming the presence of protonated species.

In this paper the results obtained for the copper(II)–aspartate and copper(II)–glutamate systems are reported. These two amino acids, containing one amino and two carboxylic groups, can act as tridentate ligands.

Stability constants[4,5] and critical stability constants[6] represent the most important studies published until 1973. More recently, both systems have been more thoroughly investigated,[7–14] although equilibria involving glutamate have been studied in less detail than those with aspartate. Generally, from the limited amount of available data on the concentration ranges of the reagents, it seems that all the studies were carried out in only limited ranges. However, disagreement exists on the protonated species which are assumed to explain the experimental data.

Liang and Olin[14] have performed the most complete research on the copper(II)–aspartate system and accounted for their measurements of the electromotive force (e.m.f.) of cells containing glass electrodes by assuming the species CuL, CuHL, CuL_2, $CuHL_2$, CuH_2L_2 to exist. The system did not exhibit stereoselectivity.

Although Brookes and Pettit[9] studied the copper(II)–glutamate system in a very restricted reagent concentration range, they pointed out small quantities of protonated species, not found by other authors. To extend the study of Liang and Olin and to determine the existence and the stability constants of the protonated species, we planned to study both systems in a wide range of reagents by measuring the e.m.f. of cells containing glass and amalgam electrodes, so that it would be possible to obtain data on the existence of species not found previously, like CuH_2L, CuH_3L_2 and CuH_4L_2.[14]

The results will be used to compare the behaviour of aspartate, glutamate, serine and glycine as ligands towards copper(II).

METHOD

Method of investigation

The ions Cu^{2+}, H^+ and aspartate (asp^{2-}) or glutamate (glu^{2-}) are considered to be independent reagents at 25°C in solutions of the following general composition: B M in Cu^{2+}; H M in H^+; A M in L; $(1-2B-H)$ M in Na^+; $(1-A)$ M in ClO_4^-, where L indicates one of the ligands, B and A represent the total concentrations of copper(II) and ligands, respectively, H is the analytical excess of hydrogen ions with respect to 1 M $NaClO_4$, H_2O and asp^{2-} or glu^{2-}, respectively.

To study equilibria occurring in the above described solution S, the e.m.f. of the cells:

$$\text{R.E.}|\text{Solution } S|\text{G.E.} \qquad \text{(I)}$$

$$\text{Cu(Hg)}|\text{Solution } S|\text{R.E.} \qquad \text{(II)}$$

was measured at 25°C, R.E., G.E. and Cu(Hg) are reference, glass and copper amalgam electrodes, respectively.

According to Biedermann and Sillén,[15] in a constant ionic medium (1 M $NaClO_4$), the e.m.f. of cells (I) and (II) at 25°C and in mV units can be expressed as a function of h (free hydrogen ions concentration) and b (free Cu^{2+} concentration):

$$E_I = E_I^0 + 59.16 \log h + E_j$$

$$E_{II} = E_{II}^0 - 29.58 \log b - E_j.$$

E_I^0 and E_{II}^0 are two constants determined in the absence of the ligand, so that $H = h$ and $B = b$. The liquid junction potential $= E_j$, and, under the selected experimental conditions, we found $E_j = -62h$. The values of b and h for each point were obtained by a procedure similar to that described previously.[16] For each set of measurements B and H were kept constant, while A and consequently $-\log h$ gradually increased. Titrations were terminated at $-\log h \leqslant 8$ and back titrations agreed well with the direct ones.

EXPERIMENTAL

Chemicals and apparatus

Copper(II) perchlorate, perchloric acid, sodium hydroxide, sodium perchlorate were prepared and analysed as described in ref. 17. Copper amalgam ($\approx 0.01\%$ weight) was prepared by dissolving electrolytic copper (freshly deposited) in a weighed amount of mercury in the measurement vessel. L-Aspartic and L-glutamic acids (both C.Erba and Fluka p.a.) were recrystallized twice from double-distilled water and then dried at 110°C. The absence of water and the stoichiometric composition were checked by TGA (Thermo gravimetric analysis). All solutions were purged of O_2 by bubbling purified N_2 through them as described previously. The H_2 electrode and the apparatus were described in ref. 18.

CALCULATIONS AND RESULTS

Knowledge of the protonation constants of aspartate and glutamate was necessary in order to account for the e.m.f. data in terms of complex formation. The equilibrium

$$asp^{2-} + nH^+ \rightleftharpoons H_n asp^{+n-2} \quad \text{where } n = 1, 2, 3,$$

defined by the relationship

$$[H_n asp] = k_n h [H_{n-1} asp] \quad \text{(charges omitted)},$$

was investigated at 25°C and 1 M $NaClO_4$, by measuring the e.m.f. of the cell

$$Pt,H_2|\text{Solution } S_1|\text{R.E.} \qquad \text{(III)}$$

as a function of H and A in the ranges $0 \leqslant H \leqslant 0.1$ M and $5 \times 10^{-3} \leqslant A \leqslant 0.02$ M.

The results of e.m.f. measurements of cell (III), elaborated as described in ref. 19, gave the following values of the protonation constants: $\log k_1 = 9.625 \pm 0.01$; $\log k_1 k_2 = 13.31 \pm 0.02$; $\log k_1 k_2 k_3 = 15.42 \pm 0.03$. The error limits were estimated from the maximum shift possible for which agreement was still acceptable.

The k_n values of the glutamate, determined in another paper,[20] under the same experimental conditions, are $\log k_1 = 9.52 \pm 0.01$; $\log k_1 k_2 = 13.69 \pm 0.02$; $\log k_1 k_2 k_3 = 16.00 \pm 0.03$.

For both systems (copper(II)–aspartate and copper(II)–glutamate) e.m.f. measurements were performed at different H values (0.025, 0.035, 0.050, 0.070 and 0.100 M) and B values (0.5, 1.0 and 2.0×10^{-3} M). As the e.m.f. of cells (I) and (II) gave b and h, and B was analytically known, it was possible to calculate η ($= \log(B/b)$) and the data could be presented in the form $\eta\ (-\log h)_{H,B}$.

Figures 1 and 2 show the dependence of η on $-\log h$ for copper(II) aspartate and glutamate, respectively. In both cases, as expected, η is independent of B, and therefore polynuclear complexes in Cu^{2+} are not present in appreciable concentration. The prevailing species are of the type CuH_pL_r with the relative stability constants $\beta_{1,p,r}$, where $p \neq 0$ and $r \geqslant 1$. To evaluate the predominant values assumed by p and r the free concentration of the ligand, a, can be obtained from the material balance of H, written in the following form:

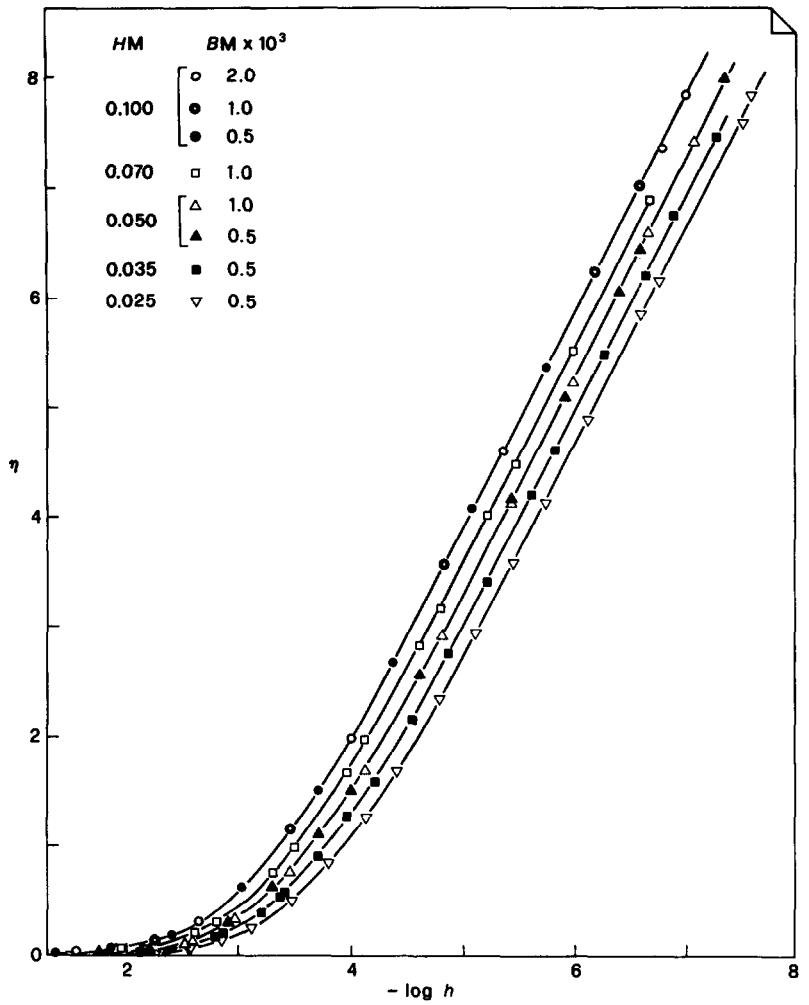

Fig. 1. Experimental data for the copper(II)–aspartate system plotted in the form η ($= \log(B/b)$) vs $-\log h$. Curves are calculated by means of the values collected in Table 1a.

$$H = h + k_1 ha + 2k_1k_2h^2a + 3k_1k_2k_3h^3a + \Sigma_p\Sigma_r p\beta_{1,p,r} bh^p a^r. \quad (1)$$

In eq. (1) and in those that follow, hydrolytic species of copper(II) are neglected on the basis of the obtained b and h and of the results of Berecki-Biedermann.[21] Since for all the points $H \geqslant 0.02B$, first approximation values of a can be calculated by neglecting the last term of eq. (1). It will be verified below that the first approximation and refined $\log a$ values coincide within ± 0.01.

In Figs 3 and 4, η is plotted against $\log a$ for aspartate and glutamate, respectively. As points obtained at different H fall on different curves, η is an increasing function of H, so that protonated species with $p \geqslant 0$ are present. However, in both cases, in the range $7 \leqslant -\log h \leqslant 8$, η is independent of H, so that species formed with loss of protons can be excluded.

At $-\log h \geqslant 5.5$, the quantity $\log[(10^{\eta}-1)b^{-1}a^{-2}]$ was constant within ± 0.03 and independent of B and H, so that the data could be explained by supposing the presence of CuL_2 alone (L is the aspartate or the glutamate, respectively) and the average value of the above quantity represented is its stability constant (see Table 1).

At a more acidic range ($2.5 \leqslant -\log h \leqslant 5$ for aspartate and $3.5 \leqslant -\log h \leqslant 5.5$ for glutamate), to find the prevailing values of p and r, the methods described for serine were applied.[2,3]

In these ranges, for both systems, the experimental data could be explained by assuming the presence of CuHL, CuL, $CuHL_2$ and CuH_2L_2 (where L indicates alternatively aspartate or glutamate). For all these complexes the stability constants were calculated.

Systematic deviations were observed for both systems at $-\log h \leqslant 2.5$ for aspartate and $-\log h \leqslant 3.5$ for glutamate. To verify the presence

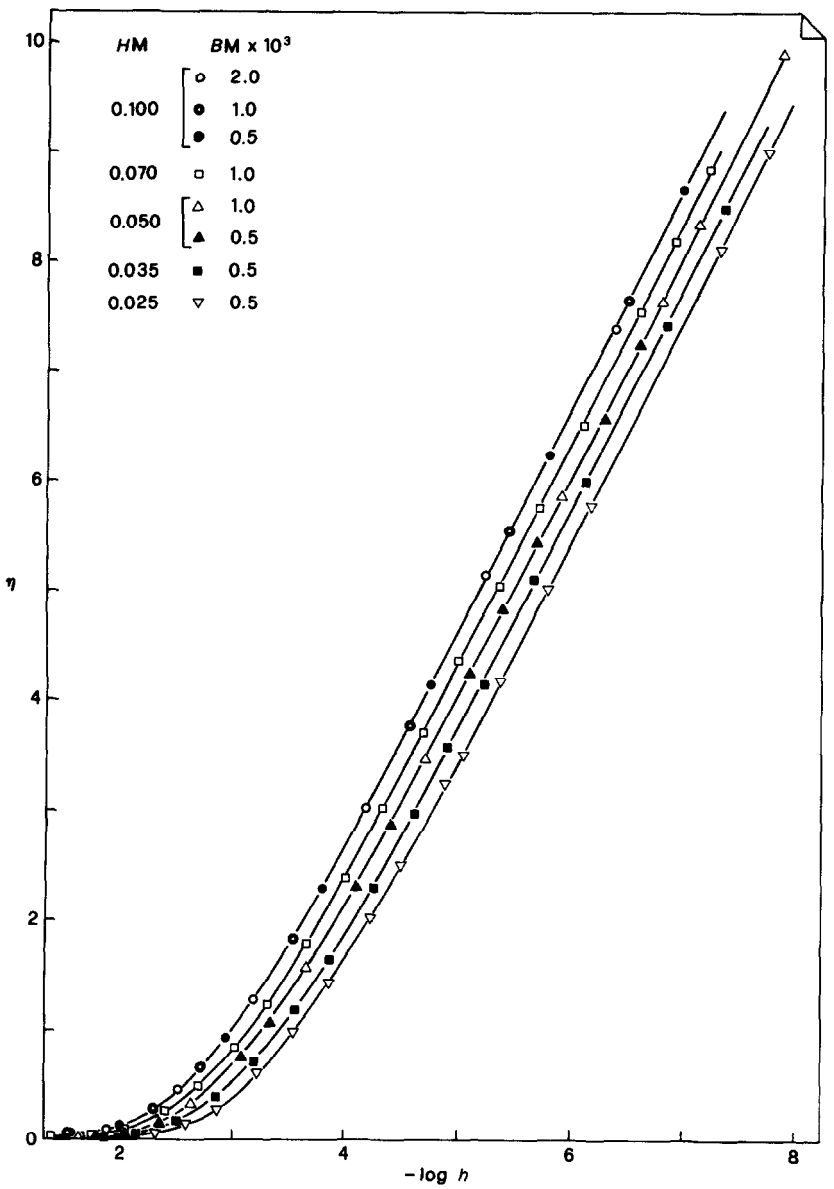

Fig. 2. Experimental data for the copper(II)–glutamate system plotted in the form η vs $-\log h$. Curves are calculated by means of the values collected in Table 1b.

of other species, the contribution of the complexes found at higher $-\log h$ was calculated by means of the already obtained constants assumed as correct and, by subtracting it from B, the following quantity was calculated for each point and for both systems:

$$B_c = B - \beta_{1,0,1}ba - \beta_{1,1,1}bha - \beta_{1,0,2}ba^2 - \beta_{1,1,2}bha^2 - \beta_{1,2,2}bh^2a^2. \quad (2)$$

Since in the $-\log h$ range reported above, the presence of other complexes was confirmed for all points $B_c > b$. To find the prevailing p' and r' of the species CuH_p, L_r present in this range, and their stability constants, η_c ($= \log(B_c/b)$) was calculated from eq. (2) and plotted against $-\log(h^2a)$.

In Fig. 5, the trend of η_c vs $-\log(h^2a)$ is shown for the system copper(II)–aspartate. Since the existence of CuH_2L alone does not explain the data, the hypothesis of the presence of CuH_2L and CuH_4L_2 was formulated, so that eq. (2) can be written as follows:

$$\eta_c = \log(1 + \beta_{1,2,1}h^2a + \beta_{1,4,2}h^4a^2).$$

According to the method of normalized curves proposed by Sillén,[22] the points of Fig. 5 were superimposed to a family of curves of equation:

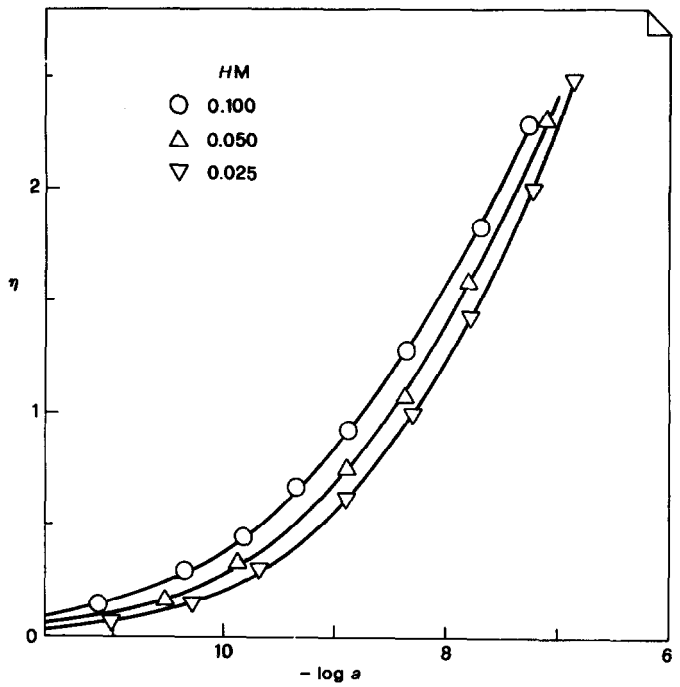

Fig. 3. The dependence of η on $-\log a$ at different H values, for the complexes formed by aspartate. Curves are calculated by means of the constants in Table 1a.

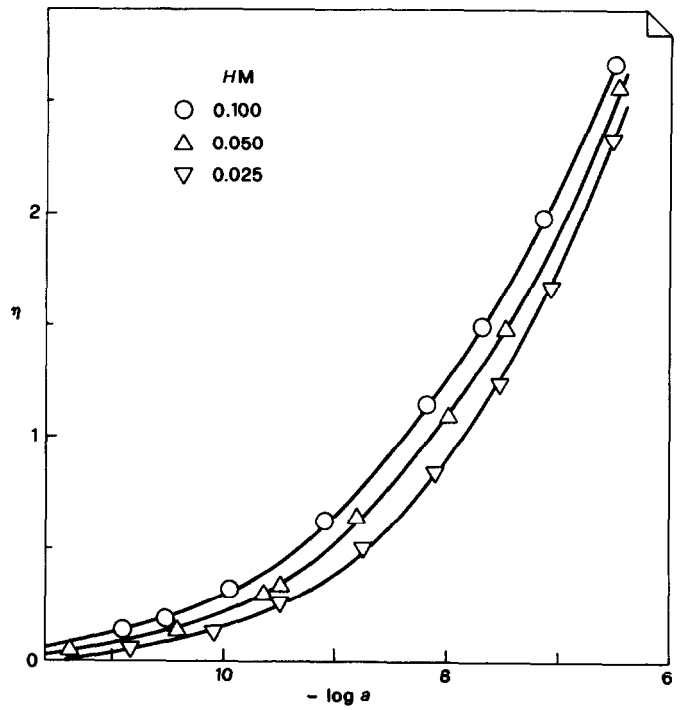

Fig. 4. The dependence of η on $-\log a$ at different H values, for the complexes formed by glutamate. Curves are calculated by means of the values in Table 1b.

Table 1. Values of the stability constants

$$y = \log(1+\alpha u+u^2)$$

where $u = h^2a\sqrt{\beta_{1,4,2}}$ and $\alpha = \beta_{1,2,1}/\sqrt{\beta_{1,4,2}}$. From the point of best fit obtained by moving experimental and theoretical plots parallel to the abscissa, the values of $\beta_{1,2,1}$ and $\beta_{1,4,2}$ were obtained. The good agreement between the normalized curve and points (Fig. 5) confirm the above hypothesis.

The same procedure was applied to the points obtained for copper(II)–glutamate. In this case the assumption of CuH_2L alone satisfactorily explains the experimental data. The value of the corresponding stability constant $\beta_{1,2,1}$ was obtained in a similar manner to the case for aspartate.

The data obtained in the whole $-\log h$ range studied could be explained by assuming the following species for the system copper(II)–aspartate:

CuL, CuHL, CuH_2L, CuL_2,

$CuHL_2$, CuH_2L_2 and CuH_4L_2,

and for the system copper(II)–glutamate:

CuL, CuHL, CuH_2L, CuL_2, $CuHL_2$ and CuH_2L_2.

The stability constants found above were refined by an iterative treatment and the obtained values are collected in Table 1 as results of approach I.

In approach II, the experimental data B, H, A and b and h were elaborated by means of a computer graphic program described in another paper[23] and the species found, with their corresponding stability constants, are collected in Table 1. The results show that for both approaches the same species explain the experimental data and the values of the stability constants are practically coincident.

The $\beta_{1,p,r}$ values collected in Table 1 explain data obtained at higher B (till $B = 0.01$ M) as well.

DISCUSSION

Experimental data relating to equilibria occurring at 25°C and in 1 M $NaClO_4$ between copper(II)

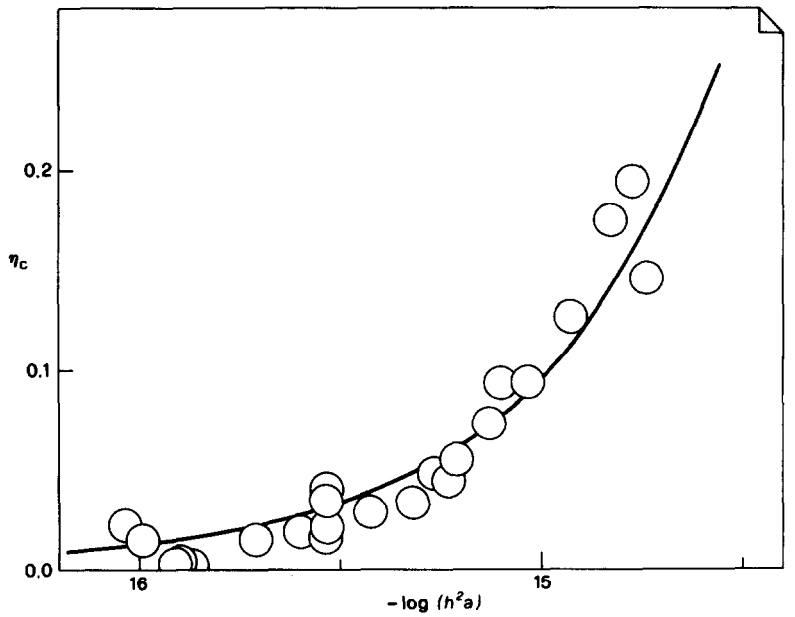

Fig. 5. The system copper(II)–aspartate. The plot η_c ($= \log(B_c/b)$ vs $-\log(h^2a)$ shows the presence of CuH_2L and CuH_4L_2. The curve is that normalized in the position of best fit.

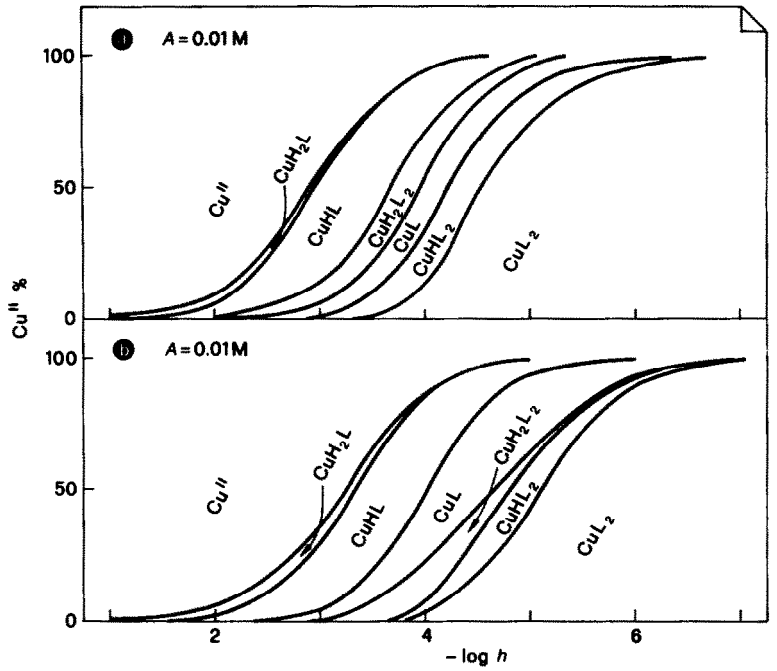

Fig. 6. Distribution of complexes as a function of $-\log h$ at $A = 0.01$ M and at $B = 0.5 \times 10^{-3}$ M for aspartate (a) and glutamate (b). Curves at higher B are practically coincident.

and aspartate or glutamate are well explained by assuming the species and relative stability constants collected in Table 1. Furthermore, the protonation constants of aspartate have been determined in the same experimental conditions.

From Table 1 and Fig. 6, it can be seen that aspartate is able to form several protonated species with copper(II). The first five complexes were found by Liang and Olin[14] and by Brookes and Pettit,[9] whereas CuH_2Asp and $CuH_4(Asp)_2$ were not found. By taking into account the different ionic medium, the stability constant for CuL here proposed approximately agrees with that proposed by Brookes and Pettit, that of CuHL agrees with the value proposed by Liang and Olin, while the other constants disagree with both works.[14,9]

Moreover, the constants of complexes containing two aspartates per species, do not agree with each other[9,14] probably because of either the limited concentration range investigated for the reagents or for the values of k_n determined by glass electrode or because the free concentration of the central group (*b*) was not measured.

By means of the observed $\beta_{1,p,r}$ distribution curves of the species existing in aqueous solutions of copper(II)–aspartate were calculated as a function of $-\log h$ at $A = 0.01$ M and plotted in Fig. 6. From the distribution curves relative to aspartate it is apparent that at $A = 0.01$ M, CuH_2L is only 2% of total copper(II) and CuH_4L_2 does not appear. By increasing A, their quantity increases so that CuH_2L reaches 5% at $A = 0.025$ M, whereas CuH_4L_2 appears at $A \geqslant 0.025$ (at $A = 0.025$ M it is about 1%).

To explain equilibria occurring between copper(II) and glutamate, the species CuL, CuL_2, CuHL, $CuHL_2$, CuH_4L_2 and CuH_2L have been proposed. No appreciable evidence for the existence of CuH_4L_2 was found. Our values cannot be compared with those of others because of the different experimental conditions, the limited ($\approx 1 \times 10^{-3}$ M) concentration ranges of the reagents and the values of the protonation constants of the ligand. At last no information is given on the way used to determine k_1, k_2 and k_3. The distribution curves of complexes found for copper(II)–glutamate are plotted in Fig. 6 at $A = 0.01$ M.

Only Brookes and Pettit[9] found the same species (except CuH_2L) but they calculated that CuH_2L_2 and $CuHL_2$, present in the range $3 \leqslant -\log h \leqslant 4.5$, constitute only 3–5% of total copper(II). This disagreement can be explained by taking into account that these researchers studied solutions containing copper(II) and glutamate only in a 1:1 ratio ($\approx 1 \times 10^{-3}$ M) and then the stability constants relative to the species containing two ligands are affected by a higher error.

Figure 6 shows that at $-\log h \approx 4$, $CuHL_2$ is $\approx 5\%$, CuH_2L_2 is 15%, and CuHL reaches 35%. At $-\log h = 3$, CuH_2L represents 5–6% of total

Table 2. A comparison between the values of $\log \beta_{1,p,r}$ for glycine, serine, aspartate and glutamate as ligands towards copper(II)

Species	Glycine	Serine	Aspartate	Glutamate
CuL	8.39	8.55	8.40	8.20
CuHL	10.62	10.90	12.40	12.40
CuH_2L	—	—	14.25	14.67
CuL_2	16.96	16.02	15.90	14.93
$CuHL_2$	—	—	20.15	19.60
CuH_2L_2	—	—	24.08	23.90
CuH_4L_2	—	—	28.26	—

The constants relative to glycine were earlier determined under the same experimental conditions,[24] while those corresponding to serine[2] were found in 3 M $NaClO_4$.

copper(II). It seems interesting to compare the behaviour of aspartate, glutamate, glycine and serine as ligands towards copper(II) (Table 2). All four ligands form with copper(II) CuL, CuL_2 and CuHL with differing stabilities.

Serine seems to be the strongest ligand and glutamate the weakest, whereas glycine and aspartate show approximately the same strength. The protonated complexes formed by the last two ligands of Table 2 are more stable than those that correspond to glycine and serine. The formation of CuH_2L, $CuHL_2$, CuH_2L_2 and CuH_4L_2 is reasonably attributed to the additional carboxylic group existing in the side chain of aspartic and glutamic acids.

To propose an explanation for the formation of protonated species, it is helpful to compare the constants relative to the following equilibria of the stepwise protonation of CuL and CuHL:

$$CuL + H^+ \rightleftharpoons CuHL \qquad (3)$$

with constant $K_1^H = [CuHL]h^{-1}[CuL]^{-1}$.

$$CuHL + H^+ \rightleftharpoons CuH_2L. \qquad (4)$$

with constant $K_2^H = [CuH_2L]h^{-1}[CuHL]^{-1}$.

Both (3) and (4) occur with aspartate and glutamate, while only equilibrium (3) can be formulated for serine and glycine. Completely different values of $\log K_1^H$ (2.2, 2.4, 4.0, 4.2, respectively) are obtained for all four ligands. On the contrary the values of $\log K_1^H$ obtained for serine and glycine (2.2 and 2.4) are similar and homogeneous with those of $\log K_2^H$ relative to aspartate and glutamate (1.9 and 2.3). As the $\log K_1^H$ and $\log K_2^H$ are determined by thermodynamic stability and by the kind of bond, it seems reasonable to suggest the following mechanism for the formation of the complexes.

For all the four ligands, first of all copper(II) is bound to the ligands through the amine group and the next carboxylic group to form CuL and CuL_2. In moderately acidic solutions ($-\log h \approx 5$) the carboxylic group of the side chain of aspartic and glutamic acids is protonated and the species CuHL, $CuHL_2$ and CuH_2L_2 are formed. Their respective quantities depend on the ratio ligand : copper(II) and on the $-\log h$ value. By further decreasing $-\log h$ (≈ 3), the proton displaces copper(II) from its bond with the $-NH_2$ group to form CuH_2L with the aspartic and glutamic acids, while CuHL appears in the case of glycine and serine. The formation of CuHL corresponds, in the case of glycine and serine, to the protonation of the aminic group, while for aspartate and glutamate, it relates to the protonation of the additional carboxylic group. Finally, the apparent higher stability of CuH_2L formed by glutamate can be explained by taking into account the basicity of the ligands, stronger for glutamate than aspartate.

SYNTHESIS AND CHARACTERIZATION OF SOME OXO-BRIDGED TRI- AND TETRANUCLEAR MANGANESE(III) SCHIFF BASE COMPLEXES

BANGLIN CHEN and KE CHEN*

Chemistry Department of Zhejiang University, Hangzhou, China

(*Received* 3 *October* 1988; *accepted* 9 *November* 1988)

Abstract—Some oxo-bridged tri- and tetranuclear manganese(III) Schiff base complexes $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$, $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS\cdot H_2O]$, and $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2\cdot 2H_2O]$, where $bzacipa^{2-}$ is the dianion of 2-(β-hydroxy-β-methylethyl-imine)-4-phenyl-butanone(4), have been synthesized and characterized by elemental analyses, IR and electronic spectra, and thermal analyses. The possible structures of the complexes are suggested.

It is generally believed that four atoms of manganese per photosystem II reaction centre are essential for oxygen evolution in green plants and photosynthetic bacteria.[1-2] The Mn_4 aggregate is capable of cycling between five oxidation levels (S_0–S_4) during the catalytic cycle,[3-6] but can also adopt an additional "super-reduced" oxidation level, labelled S_{-1}, under certain conditions.[7] It was recently reported that the complexes containing the $[Mn_4O_2]$ core have structural features similar to the enzyme and are isolable in three oxidation levels corresponding to the native S_{-1}, S_0 and S_1 levels.[8,9] Oxo-bridged trinuclear centres are likely intermediates in the formation of large polynuclear aggregates for manganese and iron complexes.[8-11] In the preceding report we have synthesized some trinuclear manganese(III) complexes containing the tridentate Schiff base ligand $bzacea^{2-}$, where $bzacea^{2-}$ is the dianion of 2-(β-hydroxyethylimine)-4-phenyl-butanone(4).[12] In this paper we describe the synthesis and characterization of $[Mn_3O(bzacipa)_2(O_2CCH_3)_2]$, $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS\cdot H_2O]$ and $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2\cdot 2H_2O]$, where $bzacipa^{2-}$ is the dianion of 2-(β-hydroxy-β-methylethyl-imine)-4-phenyl-butanone (4)

EXPERIMENTAL

Materials

The Schiff base $H_2bzacipa$ was prepared similarly to $H_2bzacea$.[13] $Mn(O_2CCH_3)_3\cdot 2H_2O$ was prepared according to ref. 14, then dried *in vacuo* over KOH. All other chemicals and solvents were reagent grade and used without further purification.

Preparation of $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$

The ligand $H_2bzacipa$ (3.0 g, 1.37×10^{-2} mol), dissolved in 15 cm^3 of hot 2-C_3H_7OH was added to a solution of $Mn(O_2CCH_3)_3\cdot 2H_2O$ (5.4 g, 2.06×10^{-2} mol) in 80 cm^3 of hot 2-C_3H_7OH. The resulting mixture was allowed to stand at 40°C for 3 h. The precipitated solids were collected on a filter, washed with small volumes of 2-C_3H_7OH and dried *in vacuo*. Yield: 2.7 g; 50% based on the $Mn(O_2CCH_3)_3\cdot 2H_2O$ used. Found: C, 48.7; H, 5.0; N, 3.2; Mn, 20.2. Calc. for $C_{32}H_{39}Mn_3N_2O_{11}$: C, 48.5; H, 5.0; N, 3.5; Mn, 20.8%.

Preparation of $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS\cdot H_2O]$

The complex $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ (0.7 g, 8.84×10^{-4} mol) in 10 cm^3 CH_3OH was treated with 50 cm^3 of aqueous solution of KNCS (8.84×10^{-3} mol). The precipitate was formed after stirring for several minutes. The solids were isolated on a filter, washed with 3×10 cm^3 of distilled water and dried *in vacuo* over silica gel. Yield: 5 g; 70% based on $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ used. Found: C, 46.2; H, 4.9; N, 4.6; Mn, 19.7. Calc. for $C_{31}H_{38}Mn_3O_{10}S$: C, 46.0; H, 4.7; N, 5.2; Mn, 20.4%.

* Author to whom correspondence should be addressed.

Preparation of $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2 \cdot 2H_2O]$

The complex $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ (0.7 g, 8.84×10^{-4} mol) in 10 cm^3 CH_3OH was treated with 50 cm^3 of aqueous solution of KNCS (8.84×10^{-3} mol). The precipitate was formed after stirring for several minutes and was extracted with 2×30 cm^3 of chloroform. The chloroform solution of the complexes was re-extracted into 2×50 cm^3 of distilled water. The chloroform phase was filtered and the pure solid was crystallized by the addition of petroleum ether. The solids were isolated on a filter, washed with ether and dried *in vacuo* over silica gel. Yield: 0.25 g; 40% based on the $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ used. Found: C, 40.2; H, 4.3; N, 5.5; Mn, 22.6. Calc. for $C_{32}H_{40}Mn_4N_4O_{12}S_2$: C, 40.2; H, 4.2; N, 5.9; Mn, 23.0%.

Physical measurements

Carbon, hydrogen and nitrogen analyses were carried out with a Perkin–Elmer 240 microanalyser. The manganese analysis was carried out by the formaldoxime method.[15] Electronic spectra were recorded with a Shimadzu UV-240 type spectrophotometer using CH_3OH solutions of the complexes. The IR spectra were obtained using KBr discs (4000–400 cm^{-1}) on a Nicolet 5DX IR spectrophotometer, and polyethylene discs (500–200 cm^{-1}) on a Nicolet 170SX IR spectrophotometer. The thermal analyses studies were obtained using a Peking PCT-1 thermobalance. Thermogravimetry and differential thermal analyses curves were obtained at a heating rate of 10°C min^{-1} in static air. The intermediate products isolated for $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS \cdot H_2O]$ and $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2 \cdot 2H_2O]$ were obtained by heating these compounds on the thermobalance until the weight loss is 63 and 55%, respectively.

RESULTS AND DISCUSSION

Synthetic method

When the method of synthesizing $[Mn_3O(bzacea)_2(O_2CCH_3)_3]$[12] was used to synthesize $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ (the solutions of H_2bzacipa and $Mn(O_2CCH_3)_3 \cdot 2H_2O$ in 2-propanol were refluxed and stirred for 3 h), only mixtures of large polynuclear manganese complexes were isolated (%Mn > 25) and the synthesis was difficult to repeat. Synthesis under mild conditions (the solutions were kept at 40°C for 3 h) produced $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$. The tendency of H_2bzacipa to form larger polynuclear manganese complexes was also found in the formation of $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2 \cdot 2H_2O]$. The complexes are slightly soluble in methanol and DMSO, but insoluble in other solvents.

IR spectra

The ligand H_2bzacipa shows a sharp O—H stretching vibration at 3320 cm^{-1} and exists mainly in the ketamine structure[16] (Fig. 1). When the complexes are formed, the ν(O—H) disappears and ν(C=O) shifts to a lower frequency, indicating the coordination of the oxygens in the ligand. The complex $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$ shows $\nu_{as}(CO_2^-)$ at 1610 cm^{-1} and $\nu_s(CO_2^-)$ at 1395 cm^{-1}, $\Delta\nu = 215$ cm^{-1}, indicating the existence of monodentate $CH_3CO_2^-$.[17] The complexes $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS \cdot H_2O]$ and $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2 \cdot 2H_2O]$ show ν(CN) at 2060 cm^{-1} indicating the presence of the N-bonded NCS^-.[18] Johnson *et al.*[19] have analysed the IR and Raman spectra of a series of complexes $[M^{III}_3O(O_2CR)_6L_3]X \cdot xH_2O$. The $\nu_{asym}(M_3O)$ would be expected to lie in the region 500–700 cm^{-1}. The complex $[Mn_3O(O_2CCH_3)_6Py_3]ClO_4$ shows $\nu_{asym}(Mn_3O)$ at 590 cm^{-1} and $\delta_s(Mn_3O)$ at 289 cm^{-1}. The complexes reported here show $\nu_{asym}(Mn_3O)$ at *ca* 530 cm^{-1} and $\delta_s(Mn_3O)$ at *ca* 280 cm^{-1}, indicating the presence of μ_3-O atoms. The trinuclear manganese complexes contain a Mn_3O unit and the complex $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2 \cdot 2H_2O]$ contains a Mn_4O_2 unit which includes two Mn_3O units sharing one edge. The Mn_4O_2 unit was found in tetranuclear manganese complexes such as $[Mn_4O_2(O_2CCH_3)_6(bpy)_2]$,[9] $[Mn_4O_2(O_2CCH_3)_7(bipy)_2]ClO_4 \cdot 3H_2O$ and $[Mn_4O_2(O_2CPh)_7(bipy)_2]$.[8] The IR spectral data are listed in Table 1.

Electronic spectra

The ligand H_2bzacipa shows two absorptions at 41.5×10^3 cm^{-1} (I) and 29.4×10^3 cm^{-1} (II) in CH_3OH and tentative assignments are made to the

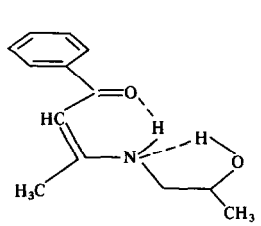

Fig. 1. The ketamine structure of H_2bzacipa.

Table 1. IR spectral data (cm^{-1}) of the complexes

Complex	C=O	C=C (aromatic)	C=C (non-aromatic)	Mn_3O (ν_{asym})	Mn_3O (δ_s)
H_2bzacipa	1600	1579	1540	—	—
$[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$	1590	1576	1511	540	284.5, 278.6
$[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS\cdot H_2O]$	1596	1570	1509	527	292, 272
$[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2\cdot 2H_2O]$	1590	1571	1508	524	286, 272

$\pi \rightarrow \pi^*$ transition of the benzene ring conjugated with carbonyl, and the $\pi \rightarrow \pi^*$ transition of C=C—C=O conjugated with benzene, respectively.[12] The complexes show two new absorptions at ca 27.0×10^3 cm^{-1} (III) and ca 21.5×10^3 cm^{-1} (IV) having similar energy to the $[Mn_3O(bzacea)_2(O_2CCH_3)_3]$ type complexes[12] and are tentatively assigned to charge-transfer and ligand-field transitions, respectively. The energy of band (IV) is comparable to that of the $^5E_g \rightarrow {}^5T_{2g}$ transition in the $[Mn_3O(O_2CCH_3)_6CH_3CO_2H]ClO_4$ and $[Mn_3O(O_2CCH_3)_6Py_3]ClO_4$ complexes.[20] The electronic spectral data and their assignments are listed in Table 2.

Thermal analysis

Figure 2 displays the TG and DTA curves of $[Mn_3O(bzacipa)_2(O_2CCH_3)_3]$. The thermal decomposition products are suggested and are listed in Table 3. The observed weight losses for these processes compare favourably with the theoretical values. The intermediate thermal decomposition products of $[Mn_3O(bzacipa)_2(O_2CCH_3)_2NCS\cdot H_2O]$ (weight loss: 62%) and $[Mn_4O_2(bzacipa)_2(O_2CCH_3)_2(NCS)_2\cdot 2H_2O]$ (weight loss: 57%) show ν(S=O) absorptions at 1120 cm^{-1}.[21] The thermal decomposition processes of the complexes show some similarity with the trinuclear manganese(III) carboxylic acid complexes.[22] The processes are as follows: reduce to the polymanganese complexes first, and then change to Mn_3O_4 (see Table 3). The residues from the thermal analyses of the complexes are confirmed to be Mn_3O_4 by manganese analyses and IR spectra, which show absorptions at 610, 490 and 415 cm^{-1}.[23]

Abstract—Toluene-3,4-dithiol ($TDTH_2$) reacts with [Mo(NO)LX_2] (X = OEt or I; L = HB(3,5-$Me_2C_3N_2H)_3$) to produce the chelate complex [Mo(NO)L(TDT)]. This complex is reduced at a potential more anodic than its non-chelated counterpart [Mo(NO)L$(SPh)_2$]. The reaction between [Mo(NO)LI_2] and 1,2-diaminobenzene affords the bimetallic complex [{Mo(NO)LI}$_2$(1,2-$(NH)_2C_6H_4$)]. This reaction and that of [Mo(NO)LI_2] with 2-aminobenzenethiol also produce products in which partial degradation of the tripodal ligand L has occurred with one dimethyl pyrazolyl group being lost.

The sterically demanding tripodal ligand hydrotris(3,5-dimethylpyrazolyl)borate (L) may be used to restrict both molybdenum(II), in the form of $\{Mo(NO)\}^{3+}$, and molybdenum(V), in the form of $\{MoO\}^{3+}$, to octahedral six-coordination.[1,2] In the case of the $\{Mo(NO)L\}^{2+}$ moiety, this results in the formation of formally 16-electron complexes of the general formula [Mo(NO)LXY] (X, Y are halide alkoxide, aryloxo, organoamide or thiolate). These coordinatively unsaturated species are stabilized by both steric and electronic factors.[1,3]

A surprising observation on the chemistry of the {MoL} moiety is that, whilst several examples of molybdenum(V) species containing five-membered chelate rings attached to the $\{Mo(O)L\}^{2+}$ core have been characterized,[2] no such examples have been reported for the molybdenum(II) $\{Mo(NO)L\}^{2+}$ core. Thus [Mo(O)L(Chel)] (Chel = OCH_2CH_2O, 1,2-$O_2C_6H_4$, 1,2-$ONHC_6H_4$, 1,2-$SNHC_6H_4$ or 3,4-$S_2C_6H_4Me$) have been prepared,[2] but the reaction of [Mo(NO)LI_2] with 1,2-NH_2—EH—C_6H_4 (E = NH, S or O) affords complexes of the formula [Mo(NO)L{NHC_6H_4EH}], in which only one donor atom of the bifunctional aryl ligand is bound to molybdenum. In the case of catechol, the reaction with [Mo(NO)LI_2] results in the destruction of the ligand L by deboronation to give [Mo(NO)(3,5-$Me_2C_3N_2H)_3(O_2$—$C_6H_4)$].[4] In addition, all attempts to prepare a chelate complex of {Mo(NO)L} with glycol have thus far failed;[5] although complexes containing large polyethylene glycol chelate rings are known.[6] A comparison of the structural data for [Mo(E)L$(SPh)_2$] (E = O or NO) reveals[2,7] that the Mo—N—(L) bond distances are slightly longer in the complex with E = O than with E = NO (averages: 2.243 Å for E = O and 2.222 Å for E = NO). This effect is especially pronounced if only the Mo—N(L) bonds *trans* to the E ligands are considered (2.367 Å for E = O and 2.244 Å for E = NO). The Mo—S distances are also longer (averages: 2.382 Å for E = O and 2.358 Å for E = NO). It would seem possible that in the nitrosyl complexes the reduced bond distances result in a closer approach of the non-donor chelate ring atoms to a 3-Me substituent in L. This in turn might give rise to a stronger interligand repulsion

* Author to whom correspondence should be addressed.

than occurs in the {Mo(O)} derivatives. The use of larger donor atoms such as sulphur in toluene-3,4-dithiol ($TDTH_2$) might relieve this interaction, allowing chelation to occur in the nitrosyl complex as well as the oxo complex.

In addition to these steric considerations, the formation of chelate rings with the $\{Mo(NO)L\}^{2+}$ moiety will have electronic consequences. In [Mo(NO)LXY], $p\pi$–$d\pi$ donation from the donor atoms of X and Y to the unfilled molybdenum *d* orbital can alleviate the electron deficiency of the molybdenum centre.[1] A similar situation arises in the related complex $[Mo(NO)(\eta^5\text{-}C_5H_5)(SPh)_2]$. Ashby and Enemark have shown[3] that the interaction between filled sulphur 3*p* orbitals and the molybdenum d_{xy} orbital elevates the energy of the LUMO, thus reducing the nucleophilic character of the complex. This accounts for the finding that $[Mo(NO)(\eta^5\text{-}C_5H_5)(SPh)_2]$ remains monomeric rather than dimerizing via sulphur bridges to give a formally 18-electron compound. The solid state structure[3] of this complex reveals that the thiophenolate ligands are orientated so as to maximize the overlap between sulphur 3*p* orbitals and the molybdenum d_{xy} orbital. The incorporation of a bridging group between the sulphur donor atoms to form a chelate would change the orientation of the sulphur 3*p* orbitals, thus reducing opportunities for their interaction with the unfilled molybdenum *d* orbital. The effect of this would be a destabilization of the higher energy filled orbitals and a stabilization of the LUMO.[3] This latter effect would be expected to give rise to an anodic shift in the reduction potential of a chelate complex as compared to a non-chelated analogue.

In order to examine the points raised above we have re-investigated the synthesis of chelate complexes containing the $\{Mo(NO)L\}^{2+}$ moiety. The ligands selected for this study were toluene-3,4-dithiol ($TDTH_2$) to provide two large donor atoms and 1,2-diaminobenzene ($DABH_2$) to provide two small donor atoms but reduce the risk of boron sequestration which arises with oxygen donors,[4] and finally 2-aminobenzenethiol ($ABTH_2$) to represent the intermediate situation.

EXPERIMENTAL

Synthetic studies

All reagents were used as supplied, $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I_2]$ and $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}(OEt)_2]$ were prepared according to previously described methods.[8,9] Silica gel 60 (70–230 mesh) was used as the stationary phase for column chromatography unless otherwise stated. All reactions were carried out under nitrogen but purification procedures were carried out in air. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

IR spectra were recorded using a PE 297 spectrometer as KBr discs unless otherwise stated. ^1H NMR spectra were obtained as solutions in $CDCl_3$ using Varian HA 100 or Jeol GX 270 (270 MHz) instruments. Cyclic voltammetric measurements were made using a Hitek PPR 1 waveform generator and DT 2101 potentiostat or a PAR 174A polarograph. Solutions in CH_2Cl_2 were *ca* 10^{-3} mol dm^{-3} in complex and 0.2 mol dm^{-3} in $[Bu^nN]BF_4$ as the base electrolyte. A platinum bead test electrode was used with an SCE reference electrode and ferrocene as internal standard. Potentials are quoted relative to the SCE and under these conditions E_f for the oxidation of ferrocene was found to be 0.56 V with a ΔE_p of 100 mV. The number of electrons associated with electrode processes was estimated by comparison with $[Mo(NO)LCl_2]$ and confirmed by coulometry where specified in the text.

[Mo(NO)L(TDT)]

Method I. A mixture of $[Mo(NO)LI_2]$ (0.5 g, 0.75 mmol) and toluene-3,4-dithiol (0.32 g, 1 mmol) was heated for 24 h in CH_2Cl_2 (100 cm^3) containing NEt_3 (10 drops) under reflux. The deep blue solution which formed was evaporated to dryness under reduced pressure and the solid obtained was purified by recrystallization from CH_2Cl_2–hexane mixtures. Further purification was effected by column chromatography using CH_2Cl_2 as the eluant. Yield 0.24 g (55%).

Method II. A mixture of $[Mo(NO)L(OEt)_2]$ (1 g, 1.95 mmol) and toluene-3,4-dithiol (0.32 g, 1 mmol) was heated for 24 h in toluene (60 cm^3) under reflux. The deep blue solution which formed was evaporated to dryness under reduced pressure and the solid obtained was purified by recrystallization from CH_2Cl_2–hexane mixtures. Further purification was effected by column chromatography using CH_2Cl_2 as the eluant. Yield 0.5 g (45%). This material was spectroscopically (^1H NMR and IR) identical to that obtained by method I. Found: C, 46.1; H, 5.0; N, 17.2. Calc. for $C_{22}H_{28}N_7BMoOS_2$: C, 45.8; H, 4.9; N, 17.0%.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$}(ABT)I]

A solution of $[Mo(NO)LI_2]$ (1 g, 1.5 mmol) and 2-aminobenzenethiol (185 mg, 1 mmol) was heated under reflux in toluene (30 cm^3) containing NEt_3 (10 drops) for 48 h. The red–brown reaction mixture

was evaporated to dryness under reduced pressure and the solid obtained was purified by recrystallization from CH_2Cl_2–hexane mixtures. Further purification was effected by column chromatography using CH_2Cl_2 as the eluant and collecting the principle purple fraction. Yield 0.4 g (47%). Found: C, 33.1; H, 3.7; N, 14.5; I, 21.4. Calc. for $C_{16}H_{20}N_6BIMoOS$: C, 33.2; H, 3.5; N, 14.5; I, 22.0%.

[{Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}I}$_2$(DAB)]

A solution of [Mo(NO)LI_2] (1 g, 1.5 mmol) and 1,2-diaminobenzene (160 mg, 1 mmol) was heated under reflux in toluene (100 cm^3) containing NEt_3 (10 drops) for 3 days. The red–purple reaction mixture was evaporated to dryness under reduced pressure and the solid obtained was purified by recrystallization from CH_2Cl_2–hexane mixtures. Further purification was effected by column chromatography using CH_2Cl_2 as the eluant and collecting the purple fraction. Yield 0.30 g (34%). Found: C, 36.2; H, 4.3; N, 17.7. Calc. for $C_{36}H_{52}N_{16}B_2I_2Mo_2O_2$: C, 35.8; H, 4.3; N, 18.6%.

[Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(DAB)}I]

A solution of [Mo(NO)LI_2] (1 g, 1.5 mmol) and 1,2-diaminobenzene (160 mg, 1 mmol) was heated under reflux in toluene (60 cm^3) containing NEt_3 (10 drops) for 24 h. The red–purple reaction mixture was evaporated to dryness under reduced pressure and the solid obtained purified by recrystallization from CH_2Cl_2–hexane mixtures. Further purification was effected by column chromatography using CH_2Cl_2 as the eluant and collecting the magenta fraction. Yield 0.25 g (30%). Found: C, 33.9; H, 4.3; N, 15.1. Calc. for $C_{16}H_{21}N_7BIMoO$: C, 34.2; H, 3.8; N, 17.5%.

RESULTS AND DISCUSSION

Synthetic studies

The previously reported[4] reaction between [Mo(NO)LI_2] and $TDTH_2$ in the absence of added base afforded a complex, [Mo(NO)LI{SC_6H_3(Me)SH}], containing a monodentate thiolate ligand. The reaction between [MO(NO)LI_2] and EtOH similarly produces the monoalkoxide [Mo(NO)LI(OEt)] under such conditions. However, if NEt_3 is added the bis-alkoxide, [Mo(NO)L$(OEt)_2$] is produced instead. Accordingly, we have repeated the reaction between [Mo(NO)LI_2] and $TDTH_2$ in the presence of NEt_3 and obtained a purple complex, **1**, in which both iodide ligands have been displaced. A spectroscopically (^{1}H NMR and IR) identical material may be obtained from the reaction between [Mo(NO)L$(OEt)_2$] and $TDTH_2$ in toluene under reflux. In this case the more acidic thiolate ligand serves to displace the alkoxide group in the form of EtOH, which is then displaced from the reaction mixture in boiling toluene. This reaction parallels the use of [Mo(O)L{OCH_2CH_2O}] as a precursor to complexes containing the {Mo(O)L}$^{2+}$ moiety.[2] The IR spectrum of **1** contained ν_{NO} at 1660 cm^{-1} and ν_{BH} at 2550 cm^{-1}. The ^{1}H NMR spectrum contained six singlets of relative areas 6 : 3 : 3 : 3 : 3 : 3 at δ_{TMS} = 2.51, 2.49, 2.43, 2.32, 2.29 and 1.53, which may be assigned to the six pyrazolyl methyl groups in L and the methyl group in the TDT ligand. The pyrazolyl 4-H signals appeared as two signals of relative area 1 : 2 at δ_{TMS} = 5.67 and 6.06 ppm, while the aryl protons of the TDT ligand appeared as an area 1 singlet at δ_{TMS} = 7.88 and two area 1 doublets at δ_{TMS} = 7.17 and 7.93 ppm (J_{HH} = 8 Hz). The mass spectrum of **1** contained a molecular ion envelope based at m/z = 579 (^{98}Mo, ^{11}B), in addition to an ion at m/z = 549 attributable to {M—(NO)}$^+$. On the basis of these data and the elemental analysis results we formulate **1** as the complex [Mo(NO)L(TDT)] in which both iodide or ethoxide ligands in the starting material have been replaced by a chelating TDT ligand.

A similar material containing ABT could not be prepared from [Mo(NO)LI_2] and $ABTH_2$. Instead a product, **2**, was isolated in which the ligand L was no longer present. The reaction between [Mo(NO)L$(OEt)_2$] and $ABTH_2$ in toluene afforded only intractable materials. The IR spectrum of **2** contained ν_{NO} at 1676 cm^{-1} and ν_{NH} at 3200 cm^{-1}. However, ν_{BH} appeared at 2485 cm^{-1} rather than the normal value of 2550 cm^{-1} generally found in complexes containing the {Mo(NO)L}$^{2+}$ moiety. The ^{1}H NMR spectrum of **2** revealed that one 3,5-dimethylpyrazolyl group had been lost from L. Only three pyrazolyl methyl resonances of relative areas 3 : 3 : 6 were observed at δ_{TMS} = 2.14, 2.25 and 2.36 ppm. The pyrazolyl 4-H protons appeared as two area 1 singlets at δ_{TMS} = 5.62 and 5.85 ppm, while the aryl protons of the ABT ligand appeared as two multiplets of relative areas 3 : 1 at δ_{TMS} = 7.3 and 7.7 ppm. A broad area 1 resonance attributable to the remaining NH proton in the ABT ligand was observed at δ_{TMS} = 4.6 ppm. The elemental analyses for **2** established the presence of iodine in the molecule and were in accord with the formulation [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$}(ABT)I]. The mass spectrum contained an ion envelope based at m/z = 580 (^{98}Mo, ^{127}I, ^{11}B) consistent with this formula, along with an ion at m/z = 550 attributable to {M—(NO)}$^+$. However, there was also an

ion at $m/z = 610$ which might be attributed to $\{M+(NO)\}^+$.

The spectroscopic data cannot fully define the structure of this compound and as yet crystals suitable for an X-ray diffraction study have not been obtained. A variety of structures may be proposed for **2** but we favour one in which a dimethylpyrazole moiety in L has been replaced by ABT. It might be expected that a B—N interaction would be of higher stability than a B—S one, and we would propose that the sulphur atom of the ABT ligand is bound to the molybdenum atom. This is in accord with the observed chemical shift of the aryl-NH proton which is not in the region associated with molybdenum arylamide derivatives of this type. As it stands, the formulation [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(ABT)}I] would leave the boron atom coordinatively saturated but the molybdenum centre would be formally five-coordinate. The complex might thus be expected to oligomerize through the formation of iodide or thiolate bridges and thus increase the molybdenum coordination number to six. An osmometric solution molecular weight determination,* carried out in $CHCl_3$, gave a value of 1633 which may be compared with the expected values for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(ABT)}I]$_n$ of 1155 ($n = 2$) and 1733 ($n = 3$). This result confirms the oligomeric nature of the complex and is more closely in accord with a trimeric rather than a dimeric formulation.

The reaction between [Mo(NO)LI_2] and $DABH_2$ affords two major products. The first of these is the bimetallic complex, **3**, and the second a magenta material, **4**, which proved difficult to obtain in a pure form. The reaction between [Mo(NO)L$(OEt)_2$] and $DABH_2$ afforded only intractable materials. The IR spectrum of **3** contained ν_{NO} at 1665 cm^{-1}, ν_{BH} at 2550 cm^{-1} and ν_{NH} at 3300 cm^{-1}. The ^1H NMR spectrum contained five singlets of relative area 6:6:6:12:6 at $\delta_{TMS} = 1.55$, 1.94, 2.35, 2.44 and 2.58 ppm attributable to the pyrazolyl methyl protons. The pyrazolyl 4-H protons appeared as three singlets of relative areas 2:2:2 at $\delta_{TMS} = 5.37$, 5.84 and 5.86 ppm and the aryl protons of the DAB moiety appeard as two multiplets each of relative areas 2 at $\delta_{TMS} = 7.53$ and 8.34 ppm; the NH protons of the DAB ligand were observed as a single broad resonance of relative area 2 at $\delta_{TMS} = 12.44$ ppm. On the basis of this data we formulate **3** as [{Mo(NO)LI}$_2$(DAB)].

The IR spectrum of **4** contained ν_{BH} at 2480 cm^{-1} and ν_{NH} at 3240 cm^{-1}. The ^1H NMR spectrum contained only four resonances, each of relative area 3, at $\delta_{TMS} = 2.18$, 2.32, 2.63 and 2.42 ppm attributable to the pyrazolyl methyl groups. Two area 1 resonances at $\delta_{TMS} = 5.63$ and 5.84 ppm were assigned to the pyrazolyl 4-H protons. A broad area 2 resonance at $\delta_{TMS} = 4.0$ ppm was assigned to the NH protons of the DAB ligand and the aryl protons of the DAB ligand appeared as multiplets of relative area 1:2:1 at $\delta_{TMS} = 6.74$, 7.06 and 7.42 ppm. However, in contrast to that of **2**, the solid state IR spectrum of **4** contained two ν_{NO} bands at 1670 and 1660 cm^{-1}. The mass spectrum of **4** contained an ion envelope based at $m/z = 563$ (^{98}Mo, ^{127}I, ^{11}B) attributable to a molecular ion for a complex of formula [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(DAB)}I], although this was not fully confirmed by the microanalytical data. It seems likely that **4** is similar in nature to **2**, but difficulties in obtaining analytically pure materials precluded a definitive characterization of this material.

Electrochemical studies

The cyclic voltammogram (CV) of [Mo(NO)L(TDT)] contained a reversible one-electron reduction wave at $E_f = -0.35$ V, with a separation between the cathodic and anodic peak potentials of $\Delta E_p = 130$ mV (CH_2Cl_2, SCE, F_c/F^+ 0.56 V, ΔE_p 120 mV). This may be compared with the value of −0.64 V reported for the reduction of [Mo(NO)L$(SPh)_2$] (MeCN, SCE).[10] The CV of [{Mo(NO)LI}$_2$(DAB)] contained a reversible reduction wave with $E_f = -0.44$ V and $\Delta E_p = 80$ mV (CH_2Cl_2, SCE, F_c/F^+ 0.55 V with $\Delta E_p = 80$ mV), which was shown by coulometry to be a one-electron process. A second irreversible two-electron wave was also observed at $E_p^c = -1.32$ V.

The electrochemical properties of the complexes containing the degraded polypyrazolylborate ligand were also investigated. Both exhibited a single formally one-electron reduction process in the range 0 to −1.5 V. In the case of [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(ABT)}I] this appeared at $E_f = -0.30$ V with $\Delta E_P = 60$ mV (MeCN, SCE, F_c/F^+ $E_f = 0.42$ V, $\Delta E_p = 60$ mV), while for [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(DAB)}I] this appeared at $E_f = -0.80$ V with $\Delta E_p = 80$ mV (MeCN, SCE). The more cathodic reduction potential found for this latter compound is in accord with its formulation as an analogue of [Mo(NO){HB(3,5-$Me_2C_3N_2H)_2$(ABT)}I] since the replacement of a thiophenolate ligand by an aryl amide ligand in [Mo(NO)LClX] (X = SPh, NHPh) similarly produces a cathodic shift of 480 mV.[10]

*We are indebted to Mrs S. Bradshaw, Department of Chemistry, University of Sheffield, for making this measurement.

CONCLUSION

The formation of the chelate ring in [Mo(NO)L(TDT)] establishes that, with larger donor atoms, five-membered chelate rings may form with the $\{Mo(NO)L\}^{2+}$ moiety. However, in the case of [Mo(NO)L(TDT)] this is associated with a substantial anodic shift in reduction potential compared to the non-chelate analogue,[10] [Mo(NO)L$(SPh)_2$]. This observation is in accord with the expected electronic consequences of the structural changes brought about by the incorporation of a bridging aryl group between the ligating sulphur atoms. In [Mo(NO)L$(SPh)_2$] the phenyl rings can orientate themselves so that filled sulphur $3p$ orbitals can lie in the xy plane. These filled sulphur $3p$ orbitals can then interact strongly with the unfilled molybdenum d_{xy} orbital as illustrated in Fig. 1. By analogy with [Mo(NO)$(\eta^5$-$C_5H_5)(SPh)_2$], S $p\pi \rightarrow$ Mo $d\pi$ charge donation would be expected to raise the energy of the LUMO which is largely d_{xy} in character.[3] In contrast, the formation of a chelate ring with the TDT ligand requires the rotation of the sulphur atoms about the Mo—S bond to give a C—S—Mo—NO torsion angle substantially different from 0 or 180°. This results in a rotation of the sulphur p orbitals out of the xy plane, reducing opportunities for the overlap of the sulphur p orbitals with the molybdenum d_{xy} orbital. This in turn leads to some destabilization of the complex as a whole, but to the stabilization of the LUMO as compared to the situation in the non-chelate complex.[3] These changes in the stability of the LUMO are reflected in the reduction potentials of the complexes, with the chelate complex exhibiting the more anodic potential.

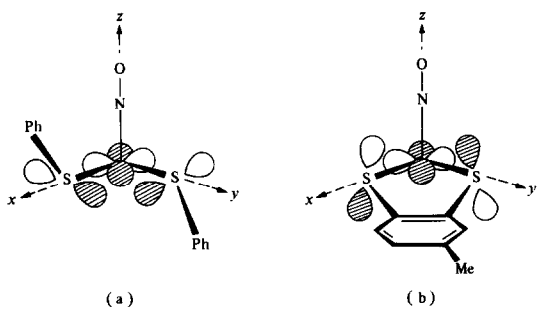

Fig. 1. A schematic representation of the orbital orientation in the $\{Mo(NO)Y_2\}$ ($Y_2 = (SPh)_2$ or TDT) fragment. (a) The situation in [Mo(NO)L$(SPh)_2$] where the phenyl rings are orientated so as to place the filled sulphur $3p$ orbitals in the xy plane. (b) The situation in [Mo(NO)L(TDT)] in which the chelate ring enforces a rotation of the sulphur $3p$ orbitals out of the xy plane and reduces the overlap with the unfilled molybdenum d_{xy} orbital.

The reactions between [Mo(NO)LI_2] and $DABH_2$ or $ABTH_2$, in the presence of base, result in some degradation of the ligand L. In these cases complete removal of the boron does not occur as found with catechol, **4**, and it seems likely that the compounds **2** and **4** represent intermediates in the deboronation reaction which goes to completion with catechol. It would appear that the $\{Mo(NO)L\}$ core does not readily form five-membered chelate rings when ligand donor atoms smaller than sulphur are involved. This contrast with the behaviour of the $\{Mo(O)L\}$ moiety could arise from steric effects or from differences in the reactivity of the two different molybdenum centres. The finding that chelate complexes of the $\{Mo(NO)L\}$ fragment form when two large sulphur donor atoms are involved in a five-membered chelate ring, or when smaller oxygen donor atoms are involved in a large chelate ring, would be consistent with the steric effect argument. However, the results described here also show that, for ligands with oxygen or nitrogen donor atoms, both boron and molybdenum represent potential reaction sites within the $\{Mo(NO)L\}$ moiety.

Acknowledgements—We are grateful to Mr T. Green for experimental assistance and to Mustansirigh University of Iraq for support (to N.AlO).

THE KINETIC COORDINATION TEMPLATE EFFECT OF AN *ORTHO*(2,2′-BIPYRIDYL) SUBSTITUENT IN THE METAL ION-CATALYSED FORMATION OF ARYLPHOSPHONIUM SALTS FROM AN ARYL HALIDE. X-RAY CRYSTALLOGRAPHIC CONFIRMATION AND AN UNUSUAL ASPECT OF LIGAND REACTIVITY IN COORDINATION COMPOUNDS

(*Received* 21 *September* 1988; *accepted* 10 *November* 1988)

Abstract—The reaction of 3-(2,4-dibromo-5-methylphenyl)-2,2′-bipyridyl with triphenylphosphine or tributylphosphine in the presence of either copper(II) acetate or nickel(II) bromide in ethanol, proceeds with regiospecific replacement of the bromine in the *ortho* position with respect to the 2,2′-bipyridyl group, which provides a kinetic coordination template for the metal catalyst. An intermediate bromocopper(I) complex derived from the aryl halide and bromo(triphenylphosphine)copper(I) has been characterized and shown to undergo conversion to the arylphosphonium salt on heating. An X-ray crystal structure of one of the arylphosphonium salts is also reported, providing unequivocal proof of the position of halogen replacement.

The reactions of aryl halides with tertiary phosphines to form arylphosphonium salts only proceed at high temperatures (150–200°C) and in the presence of a transition metal halide, e.g. $Ni^{II}Br_2$, as catalyst.[1–4] However, we have shown that when the aryl halide bears an *ortho* substituent which is able to provide an appropriate coordination template for the metal ion, the displacement of the halide by the phosphine proceeds in good yield under much less severe conditions in refluxing ethanol. Among effective kinetic template systems are the dyestuffs (**1**; X = Cl, Br, I; R = H or NHAc),[5] the Schiff's bases (**2**; X = Cl, Br, I)[6] and the benzimidazole (**3**).[7] In this paper, we report a study of the related reactions of the aryl halide (**4**), which bears a 2,2′-bipyridyl unit as the potential template system, together with an X-ray study of a phosphonium salt (**5**, R = Ph) derived therefrom.

RESULTS AND DISCUSSION

The bipyridyl template (**4**) was of interest in view of earlier observations made in studying the nickel(II) catalysed reactions of the above dyestuff (**1**) and Schiff's base systems (**2**) with phosphines which revealed that, when such template systems involved a *second* donor centre capable of interacting with the metal ion in a chelating manner, the formation of the phosphonium salt was significantly retarded or inhibited completely, presumably a consequence of the diversion of the metal ion in a mode of coordination inappropriate to the key catalytic steps. On this basis it was expected that the bipyridyl system (**4**) would not prove to be an effective template.

However, when the aryl halide (**4**) was heated with *either* triphenylphosphine *or* tributylphosphine in ethanol containing nickel(II) bromide, the related phosphonium salts (**5**, R = Ph or Bu) were formed in good yield over several hours. The reactions did not occur in the absence of the nickel(II) halide. The phosphonium salt formation reactions were also catalysed by copper(II) acetate, and in this respect the reactions of the halide (**4**) resemble those of the dyestuffs (**1**), rather than those of the Schiff's bases (**2**) or the benzimidazole (**3**), for which nickel(II) halides were found to be the only effective catalysts.

^{31}P NMR studies indicated that the products were free of phosphorus-containing impurities (e.g. $R_3P{=}O$ or R_3P), the salts having ^{31}P chemical

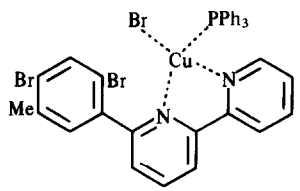
(5)

shifts of 23.8 ppm (**5**, R = Ph) and 32.6 ppm (**5**, R = Bu), respectively. ^{1}H NMR spectra were also consistent with the formation of a mono-phosphonium salt, thus implying that regiospecific replacement of the halogen *ortho* to the donor group had occurred, the *para*-halogen remaining unaffected. Proof of the structures of these compounds rests on microanalytical data, ^{1}H and ^{31}P NMR studies, and the results of an X-ray crystallographic study of (**5**, R = Ph) (see below).

The reaction of the halide (**4**) (1 mol equiv) with the preformed copper(I) complex (**6**) (1 mol equiv), together with triphenylphosphine (1 mol equiv), also gave the corresponding colourless phosphonium salt (**5**, R = Ph) in good yield (*ca* 60%).

$[Ph_3PCuBr]_4$

(6)

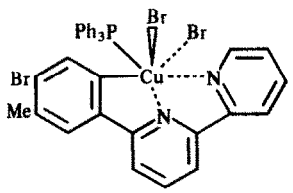


(7)

When this reaction was carried out using equimolar amounts of the halide (**4**) and the complex (**6**), but excluding the additional mole of triphenylphosphine, a red solution resulted, which, on standing overnight, deposited orange–red crystals. On the basis of microanalytical data, and the ^{31}P NMR spectrum which exhibited a signal at $\delta = -4.96$ ppm (indicating the presence of a PPh_3 ligand), it is proposed that this product is the tetrahedral copper(I) complex (**7**) formed from the halide (**4**) with the bromo(triphenylphosphine) copper(I) complex. Related copper(I) complexes of simple bipyridyl ligands and phosphines have been prepared by Jardine *et al.*[8] Prolonged heating of the red solution also led to the formation of the phosphonium salt (**5**, R = Ph) (isolated in 26% yield) and thus it would seem that the complex (**7**) is an early intermediate on the pathway to the phosphonium salt. An X-ray crystal structure of the complex (**7**) has been attempted, but was frustrated by the instability of the crystals in the X-ray beam.

In none of the other *ortho*-(template) aryl halides studied so far have we observed the formation of arylphosphonium salts from the reaction of the aryl halide with a halogen(triphenylphosphine) copper(I) complex. Thus, the isolation and subsequent conversion of the complex (**7**) into the phosphonium salt (**5**) is quite significant, and provides the first example of an isolable intermediate complex in reactions of this type.

The mechanism of subsequent conversion of the complex into the phosphonium salt remains unclear, but is likely to involve a coordination-assisted oxidative insertion of copper(I) into the carbon–halogen bond to form the related coordinatively stabilized arylcopper(III) complex (**8**).



(8)

Reductive elimination of the arylphosphonium salt from (**8**) would regenerate the copper(I) halide, which in the presence of additional phosphine would reform the initial halogeno(phosphine) copper(I) complex. Prior to the above reaction of the halide (**4**) with the copper(I) complex, all other reactions of template halides (**1**)–(**3**) were promoted by copper(II) and/or nickel(II), it being assumed that an initial electron transfer step occurred (probably via a phosphine molecule usually present in excess), leading to the generation of a copper(I) or nickel(I) species *in situ*.[6]

These kinetic coordination template reactions therefore provide an interesting group of examples which demonstrate the pronounced effect on the organic reactivity of the ligand as a result of its coordination to a metal ion, and contribute to the current discussion[9] of the principles of ligand reactivity in coordination compounds.

X-ray structural study of 3-(2-*triphenylphosphonio*-4-*bromo*-5-*methylphenyl*)-2,2′-*bipyridyl bromide dihydrate* (**5**, R = Ph)

Crystal data. $C_{35}H_{31}Br_2N_2O_2P_1$. $M_r = 701.8$. Monoclinic, space group $P2_1/c$, $a = 8.743(5)$, $b = 22.398(4)$, $c = 15.669(3)$ Å, $\beta = 94.0(0)$, $\alpha = \gamma = 90°$. $U = 3061.2$ Å^3, Mo-K_α $\lambda = 0.71069$ Å, $D_m = 1.52$, $D_c = 1.54$ g cm^{-3}, $Z = 2$, μ(Mo-K_α) = 13.25 cm^{-1}, $F(000) = 712$.

Data collection and recovery. Intensities were measured for a crystal, approximate dimensions 0.20 × 0.12 × 0.12 mm, mounted on a glass fibre rod with the *c* axis coincident with the rotation (ω) axis of a two circle Stoe Stadi 2 diffractometer. Monochromatic Mo-K_α radiation was used and the background-ω-scan background technique employed. Sixteen layers were collected giving 3169 independent reflections, of which 1704 had $I > 3\sigma(I)$ and were used for subsequent analysis. Corrections for Lorentz and polarization effects were applied, but no corrections for absorption were made.

Structure determination and refinement. The space group and unit cell parameters were obtained from oscillation and Weissenberg photographs. Systematic absences when $h0l$, $l = 2n+1$ and $0k0$, $k = 2n+1$, and density measurements indicate that the space group is $P2_1/c$. The approximate positions of the two bromine atoms were calculated using a three-dimensional Patterson synthesis. Multi-solution direct methods using *SHELX*[10] enabled the position of all non-hydrogen atoms to be readily located. Scattering factors were calculated using an analytical approximation[11] and the weighting scheme $w = 1.000[\sigma^2(F_o)+0.001265(F_o)^2]$ adopted. Full-matrix least-squares refinement for the ordered non-hydrogen atoms gave final $R = 0.0951$ and $R' = 0.0958$. Selected bond distances are listed in Table 1, and selected bond angles in Table 2. Full atomic parameters, thermal parameters, bond lengths, bond angles and mean plane data have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

Discussion of the structure. Although it has not proved possible to gain detailed structural data for this phosphonium salt, it is quite clear that the bromine atom in the *ortho* position with respect to the bipyridyl system has been replaced by phosphorus, and that the *para*-bromine atom contained in the same aryl ring remains unaffected.

The geometry around the phosphorus atom (Fig. 1) is approximately tetrahedral, with the bond angles ranging from 106 to 114° (Table 2). Both pyridine rings of the bipyridyl system are planar and are inclined to one another at an angle of 22.1°. The twisting of these rings to each other might be explained by the accommodation of the large triphenylphosphine group.

A feature worth noting in this crystal structure is that the pyridine ring C(51)—C(55) is inclined to the C(41)—C(46) phenyl ring, so that the overall configuration is such that the nitrogen atom N(1) is closely approached by the positively charged phosphorus atom, giving a N(1)—P distance of 3.03 Å, which is within the sum of their van der Waals'

radii (N = 1.55, P = 1.85 Å).[12] Such an interaction between N(1) and P may also be indicated by the increase in the P—C(41)—C(46) bond angle to 127.0° (compared to the other exocyclic angle P—C(41)—C(42), 114.1°).

Positions for the anionic bromide, Br(2), and two oxygens, O(1) and O(2), were identified and have subsequently been omitted from the crystal structure for clarity. No other atoms were identified as associating with the oxygen atoms and although no hydrogen atoms could be located on these atoms, it is believed that they are water molecules entrapped in the crystal lattice (confirmed by microanalysis). Although the bromide anion, Br(2), shows no sign of interaction with the cation ($P^+ \cdots Br^-$ 4.6 Å), it has been located within the sum of the van der Waals' radii ($Br \cdots O$ = 3.35 Å) for both O(1)—Br(2), 2.58 Å and O(2)—Br(2), 3.27 Å.

EXPERIMENTAL

^{31}P NMR spectra were recorded on a Bruker WP80 SY instrument. Chemical shifts are reported with respect to 85% *ortho*-phosphoric acid as external standard; shifts to high frequency are positive in sign. ^1H NMR spectra were recorded on the same instrument, and chemical shifts are reported on the δ scale with respect to tetramethylsilane as internal standard in deuteriochloroform solution. Mass spectra were recorded using a VG Micromass 305 Spectrometer.

3-(2,4-Dibromo-5-methylphenyl)-2,2′-bipyridyl (**4**) was obtained as a gift from Dr R. Price, ICI Organics Division, Blackley, Manchester. Tetrakis[bromo(triphenylphosphine)copper(I)] was prepared as previously described.[8]

Reaction of the halide (**4**) *with phosphines*

The halide (10^{-3} mol), tertiary phosphine (3×10^{-3} mol) and *either* nickel(II) bromide *or* copper(II) acetate (0.2×10^{-3} mol) were heated together under reflux in ethanol (10 cm^3) under nitrogen for 5–8 h. The reaction mixture was then poured into water (50 cm^3) containing potassium bromide (0.5 g) and extracted with ether to remove non-ionic impurities. The aqueous layer was then extracted with chloroform (3×10 cm^3). The chloroform extract was dried ($MgSO_4$) and evaporated. The oily residue was then triturated several times with sodium-dried ether until it solidified. The crude salts were then recrystallized. The following were characterized.

3 - (2 - *Triphenylphosphonio* - 4 - *bromo* - 5 - *methylphenyl*)-2,2′-*bipyridyl bromide* (**5**; R = Ph). (40%), m.p. 272°C (from $CHCl_3$–EtOAc). (Found: C, 60.5; H, 4.2; N, 4.0. $C_{35}H_{27}N_2Br_2P_1 \cdot 2H_2O$ requires C, 59.8; H, 4.1; N, 4.0%.) $\delta^{31}P(CDCl_3)$: 23.89 ppm; $\delta^1H(CDCl_3)$: 8.2–7.0 (m, 24ArH) 2.7 (s,3H) ppm. (Found: $(M—^{81}Br)^+$ 585.1079. $C_{35}H_{27}N_2Br_2P_1$ requires $(M—^{81}Br)^+$ 585.1095.)

3 - (2 - *Tributylphosphonio* - 4 - *bromo* - 5 - *methylphenyl*)-2,2′-*bipyridyl bromide* (**5**; R = Bu). (42%), m.p. 134°C (from $CHCl_3$–ether). (Found: C, 56.4; H, 6.4; N, 4.6. $C_{29}H_{39}N_2Br_2P_1 \cdot H_2O$ requires C, 55.8; H, 6.6; N, 4.5%.) $\delta^{31}P(CDCl_3)$: 32.79 ppm; $\delta^1H(CDCl_3)$: 8.8–7.4 (m,9ArH) 2.6 (m,9H) 1.4 (m,12H) 0.9 (m,9H) ppm.

Reaction of the halide (**4**) *with* $[Ph_3PCuBr]_4$

The halide (0.25 g) and the copper(I) phosphine complex (0.25 g) were heated together in ethanol (10 cm^3) to form an orange–red solution. On standing overnight, red crystals were isolated and recrystallized from ethanol to give bromo(triphenylphosphine)[3-(2,4-dibromo-5-methylphenyl)-2,2′-bipyridyl]copper(I) (**8**) (0.34 g, 62%), m.p. 202–204°C (Found: C, 51.5; H, 3.2; N, 3.4. $C_{35}H_{27}CuBr_3N_2$ requires C, 51.9; H, 3.3; N, 3.4%.) $\delta^{31}P(CDCl_3)$: −4.96 ppm; $\delta^1H(CDCl_3)$: 8.2–7.1 (m,24ArH) and 2.4 (s,3H) ppm.

SYNTHESIS AND REACTIVITY OF PALLADIUM(I) DERIVATIVES WITH BIS(DIPHENYLPHOSPHINO)AMINE. X-RAY CRYSTAL STRUCTURE OF $Pd_2(\mu\text{-dppa})_2Cl_2 \cdot (CH_3)_2CO$

(*Received* 21 *September* 1988; *accepted* 10 *November* 1988)

Abstract—$ClPd(\mu\text{-dppa})_2PdCl$ [dppa = bis(diphenylphosphino)amine] (**1**) has been prepared by treating $PdCl_2(NCPh)_2$ with $Pd_2(dba)_3 \cdot CHCl_3$ (dba = dibenzylideneacetone) and dppa in CH_2Cl_2. Substitution reactions allow the synthesis of the neutral $BrPd(\mu\text{-dppa})_2PdBr$ (**2**) and the cationic $[Ph_3PPd(\mu\text{-dppa})_2PdPPh_3](BPh_4)_2$ (**4**) derivatives. Complex **1** reacts with $SnCl_2$ yielding $Cl_3SnPd(\mu\text{-dppa})_2PdSnCl_3$ (**3**). The species R_2N^+ and SO_2 insert into the Pd—Pd bond of **1** to give the appropriate A-frame Pd^{II}–Pd^{II} complexes. Extrusion of SO_2 takes place at room temperature. CO does not react with **1** in CH_2Cl_2 at room temperature. The insertion–elimination reactions of **1** with isonitriles RNC (R = *p*-Tol, Cy) have been studied.

The molecular structure of $ClPd(\mu\text{-dppa})_2PdCl \cdot (CH_3)_2CO$ has been established by a single crystal X-ray study. The crystals are monoclinic, space group $P2_1/c$, with $a = 13.540(3)$, $b = 16.943(2)$, $c = 21.082(15)$ Å, $\beta = 105.257(42)°$ and $Z = 4$. The final R factor was 0.033 for 5091 observed reflections. The Pd—Pd distance is 2.6378(6) Å.

Bis(diphenylphosphino)amine (dppa) has received very little attention in palladium coordination chemistry. We have recently described the synthesis of dppa-containing Pd^{II} and Pd^{I} complexes in which the P-donor ligand acts as a terminal monodentate or bidentate chelating ligand, or bridges between two metal centres.[1] Here we report the synthesis of the homo binuclear Pd^{I} derivatives $XPd(\mu\text{-dppa})_2PdX$ (X = Cl, Br, $SnCl_3$) and the reactivity of $ClPd(\mu\text{-dppa})_2PdCl$ in respect to the formation of cationic complexes and insertion reactions into the Pd—Pd bond. The reactions of $ClPd(\mu\text{-dppa})_2PdCl \cdot (CH_3)_2CO$ with RNC (R = *p*-Tol, Cy) have also been studied.

The molecular structure of $ClPd(\mu\text{-dppa})_2PdCl \cdot (CH_3)_2CO$ has been established by a single crystal X-ray diffraction study. As far as we know, the molecular structures of only two dppa-containing transition metal complexes $Rh_2(\mu\text{-CO})(\mu\text{-Cl})(\mu\text{-dppa})_2(CO)_2 \cdot CH_3OH$[2] and $(C_6F_5)ClAu(\mu\text{-dppa})AuCl(C_6F_5)$[3] have been previously reported.

RESULTS AND DISCUSSION

The reaction of $PdCl_2(NCPh)_2$ with $Pd_2(dba)_3 \cdot CHCl_3$ (dba = dibenzylideneacetone) and dppa (molar ratio 2 : 1 : 4), in oxygen-free CH_2Cl_2 yields the homo-binuclear Pd^{I} derivative $ClPd(\mu\text{-dppa})_2PdCl$ (**1**):

$$PdCl_2(NCPh)_2 + \tfrac{1}{2}Pd_2(dba)_3 \cdot CHCl_3 + 2dppa \longrightarrow ClPd(\mu\text{-dppa})_2PdCl + 3/2dba + 2NCPh + CHCl_3. \quad (1)$$

Solutions of complex **1** in donor solvents give the corresponding $[ClPd(\mu\text{-dpa})_2PdCl]\cdot nS$ [S = acetone, $n = 1$ (**1a**); S = acetonitrile, $n = 2$ (**1b**)] which are slightly soluble in the solvent S. The thermogravimetric analyses of complexes **1a** and **1b** confirm the indicated stoichiometry; they loose solvent at 155 and 115°C, respectively. The structure of complex **1a** has been established by a single crystal X-ray diffraction study and is discussed below. Analytical and conductivity data are collected in Table 1.

Complex **1** reacts with $[NBu^n_4]Br$ in CH_2Cl_2 to give $BrPd(\mu\text{-dppa})_2PdBr$ (**2**); treatment of **1** with $SnCl_2$ in CH_2Cl_2 (molar ratio 1:2) produces insertion of $SnCl_2$ into the Pd—Cl bonds, yielding $Cl_3SnPd(\mu\text{-dppa})_2PdSnCl_3$ (**3**).

The IR spectra of complexes **1**, **2** and **3** show an absorption due to ν(N—H) [3310 cm^{-1} (**1**), 3310 cm^{-1} (**2**) and 3285 cm^{-1} (**3**)], *i.e.* at higher energies than in the spectrum of the free ligand [dppa = ν(N—H) 3230 cm^{-1}].

The ν(N—H) absorption appears in complex **1b** at 3220 cm^{-1}, shifted to lower energy than that of the free ligand and of complex **1**, probably due to the interaction between the $NCCH_3$ molecules and the N—H group of the bridging dppa.[4,5] Complex **1a** shows two ν(N—H) absorptions located at 3315 and 3185 cm^{-1} since only one of the two bridging dppa's is linked to acetone (see below, structure of **1a**). Complexes **1**, **1a** and **1b** show ν(Pd—Cl) absorptions in the 255–245 cm^{-1} region, in the same range as found for ν(Pd—Cl) in $ClPd(\mu\text{-dppm})_2PdCl$[6] and at lower energies than ν(Pd—Cl) for the Pd^{II} derivative $PdCl_2$(dppa) (290, 280 cm^{-1}),[7] suggesting a fairly high *trans* influence of the Pd—Pd bond. Complex **1a** shows a strong absorption at 1710 cm^{-1} corresponding to ν(CO) of the $(CH_3)_2CO$, while an absorption at 2255 cm^{-1} observed in the IR spectrum of **1b** is assigned to ν(C≡N) of the $NCCH_3$. Complex **3** shows absorptions at 315, 308 and 299 cm^{-1} due to ν(Sn—Cl).[8]

The $^{31}P\{^1H\}$ NMR spectra of complexes **1–3** in $CDCl_3$ show singlet signals at 58.96, 57.26 and 56.29 ppm respectively, due to the presence of four equivalent phosphorus atoms.

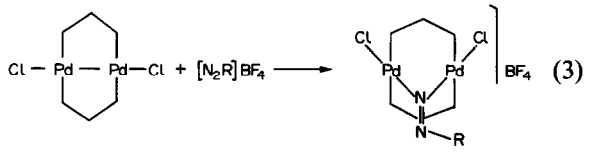
Addition of PPh_3 to a suspension of **1** in methanol (molar ratio 2:1) results in complete dissolution of the solid and, by adding $NaBPh_4$, the cationic $[Ph_3PPd(\mu\text{-dppa})_2PdPPh_3](BPh_4)_2$ (**4**) can be isolated:

$$ClPd(\mu\text{-dppa})_2PdCl + 2PPh_3 + 2NaBPh_4 \longrightarrow [Ph_3PPd(\mu\text{-dppa})_2PdPPh_3](BPh_4)_2 + 2NaCl. \quad (2)$$

The IR spectrum of complex **4** shows an absorption at 610 cm^{-1} due[9] to BPh_4^- and the $^{31}P\{^1H\}$ NMR spectrum shows two signals at 58.88 and 29.85 ppm, corresponding to the P(dppa) and $P(PPh_3)$ atoms.

Insertion reactions

Complex **1** reacts (in acetone at −30°C) with diazonium salts $[N_2R]BF_4$ (R = C_6H_4-*o*-NO_2, C_6H_4-*p*-CH_3) yielding the "A-frame" homo-bimetallic compounds $[ClPd(\mu\text{-dppa})_2(\mu\text{-}N_2R)PdCl]BF_4$ [R = C_6H_4-*o*-NO_2 (**5**), C_6H_4-*p*-CH_3 (**6**)]



(3)

in which the $[NNR]^+$ moiety inserted into the Pd—Pd bond.

The $^{31}P\{^1H\}$ NMR spectra of complexes **5** and **6** show two multiplets (**5** 61.06, 56.56; **6** 61.77, 59.20 ppm) corresponding to an AA'BB' system, consistent with a bridging diazenide ligand with an NNC angle less than 180°C.

The IR spectra of complexes **5** and **6** show a strong and broad absorption at ~ 1100 cm^{-1} due to the counterion BF_4;[10] complex **5** shows an absorption at 1530 cm^{-1} due to $\nu_{as}(NO_2)$ of the $[N_2(C_6H_4\text{-}o\text{-}NO_2)]^+$ group.[11]

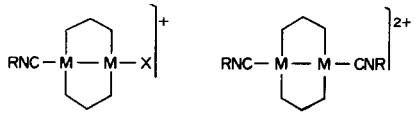
When SO_2 is bubbled through a CH_2Cl_2 solution of complex **1** (orange), a green solution is obtained, and by adding diethylether in the presence of SO_2 a green precipitate is obtained. This solid seems to be the A-frame derivative with SO_2 inserted into the Pd—Pd bond [ClPd(μ-dppa)$_2$(μ-SO_2)PdCl]; however, even in the solid state, it decomposes very rapidly, yielding the orange starting material **1**, and we have not been able to observe absorptions $\nu(SO_2)$ due to inserted SO_2. The $^{31}P\{^1H\}$ NMR spectrum of a $CDCl_3$ solution at room temperatue shows the signal due to the starting material **1** and a small singlet at 66.35 ppm which could be due to the SO_2 derivative.

The instability of ClPd(μ-dppa)$_2$(μ-SO_2)PdCl contrasts with the stability of the dppm derivative; in fact ClPd(μ-dppm)$_2$(μ-SO_2)PdCl has been prepared[12] and SO_2 is evolved when a CH_2Cl_2 solution of the complex is refluxed under N_2.

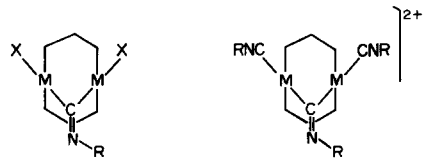
In contrast, although ClPd(μ-dppm)$_2$ PdCl reacts with CO in CH_2Cl_2 yielding ClPd(μ-dppm)$_2$(μ-CO)PdCl,[6] complex **1**, ClPd(μ-dppa)$_2$PdCl, does not react with CO under similar conditions.

Reactions with isonitriles

Palladium(I) and platinum(I) complexes of this type react with isonitriles and the nature of the reaction product (terminal **A**, **B**; bridging **C** or both **D**) is dependent on the starting M^I complex, the isonitrile and the solvent used.[6,9,13]



(A) (B)



(C) (D)

The reactions between ClPd(μ-dppa)$_2$PdCl·$(CH_3)_2CO$ (**1a**) and CNTol-*p* or CNCy have been studied and the results are different to those of ClPd(μ-dppm)$_2$PdCl.[6]

Complex **1a** reacts in dichloromethane with a stoichiometric amount of *p*-TolNC (molar ratio 1 : 1) giving a pale-orange solution and when benzene is added the colour of the solution turns red-orange (as far as we know, this change in colour could indicate the transformation of species **A** into species **C**). In a few seconds the colour of the solution fades (**C** → **A**) and a yellow solid precipitates. The IR spectra of this solid shows an absorption at 2170 cm^{-1} [ν(C≡N)] indicating that the isonitrile is coordinated as a terminal ligand to the metal centre (**A** or **B**) and that no inserted isonitrile (species **C**, **D**) is present. The analytical [found (calculated) for [ClPd(μ-dppa)$_2$PdCNR]Cl (**A**), C: 56.4(57.4); N: 3.5(3.6), H: 3.9(4.2)] and conductivity (Λ_M 57 ohm^{-1} cm^2 mol^{-1}) data indicate that the yellow solid could be a mixture of the starting material and the cationic species [ClPd(μ-dppa)$_2$CNR]Cl (**A**). However, the $^{31}P\{^1H\}$ NMR spectrum of a $CDCl_3$ solution of the yellow solid shows two singlets (58.86 and 49.34 ppm) and two complicated multiplets (centred at 56.67 and 53.77 ppm). The singlet at δ 58.86 ppm is assignable to the starting material (**1**); the multiplets, which corresond to an AA'BB' system, can be assigned to [ClPd(μ-dppa)$_2$PdCNR]Cl (**A**), and the other singlet (δ 49.34 ppm) seems to indicate the presence of [(RNC)Pd(μ-dppa)$_2$Pd(CNR)]Cl_2 (**B**), so that in solution ClPd(μ-dppa)$_2$PdCl and species **A** and **B** seem to be present.

By reacting **1a** with an excess of CNTol-*p* (molar ratio 1 : 30) in CH_2Cl_2 and in the presence of $NaClO_4$ (to facilitate the formation of the cationic complex) a red solid is obtained. The IR spectrum of this solid shows absorptions at 2160 cm^{-1} [ν(C≡N)] and 1620 cm^{-1} [ν(C=N)] indicating the presence of terminal and bridging isonitriles. The analytical data of the red solid are in agreement with the calculated values for [(RNC)Pd(μ-dppa)$_2$(μ-CNR)Pd(CNR)]$(ClO_4)_2$ [found (calculated), C: 56.3(56.4); N: 4.4(4.6); H: 4.1(4.1)]. The solution of this solid in $CHCl_3$ is orange-yellow with a perceptible smell of isonitrile, and the $^{31}P\{^1H\}$ NMR spectrum shows only a singlet

(δ 51.93 ppm), assignable to [(RCN)Pd(μ-dppa)$_2$Pd(CNR)](ClO$_4$)$_2$. These data indicate that in solution elimination of isonitrile takes place:

$$[(RNC)Pd(\mu\text{-dppa})_2(\mu\text{-CNR})Pd(CNR)](ClO_4)_2 \xrightarrow{CHCl_3} [(RNC)Pd(\mu\text{-dppa})_2Pd(CNR)](ClO_4)_2 + CNR. \quad (4)$$

The reaction between complex **1a** and CNCy (molar ratio 1 : 1) in CH_2Cl_2 shows a similar behaviour to that observed for CNTol-*p*. An orange-yellow solid can be isolated: [ClPd(μ-dppa)$_2$Pd(CNCy)]Cl [ν(C≡N) 2175 cm^{-1}], analytical data [found (calculated) C: 56.5(56.8); N: 3.7(3.6); H: 4.7(4.6)]; however, the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$) shows two singlets (δ 58.85 ppm and 49.88 ppm) and two complicated multiplets (centred at 56.79 ppm and 54.25 ppm), indicating that in solution the starting material and species **A** and **B** are present. If this reaction is carried out in the presence of $NaClO_4$, a yellow solid [ν(C≡N) 2175 cm^{-1}; analytical results: Found (calculated for [ClPd(μdppa)$_2$Pd(CNR)](ClO$_4$) C: 53.4(53.8); N: 3.5(3.4); H: 4.5(4.3)] is obtained. The $^{31}P\{^1H\}$ NMR spectrum shows a similar pattern to that observed for [ClPd(μ-dppa)$_2$Pd(CNR)]Cl [58.84(s); 52.62(s); 57.67(m); 54.97(m) ppm] indicating the presence of starting material and species **A** and **B**.

No complexes containing both inserted and coordinated isonitriles have been obtained even using a large excess (molar ratio 1 : 40) of CNCy, showing minimal tendency of CNCy to insert into the Pd—Pd bond.[13]

Structure of [Pd(μ-Cl)(dppa)]$_2$ · CH_3COCH_3 (**1a**)

The structure of complex **1a** has been solved by single crystal X-ray diffraction. Bond distances and angles are given in Table 2; Fig. 1 shows the molecular structure of the complex **1a**. Figure 2 shows the unit cell. The presence of an acetone molecule associated with only one of the NH ends of the [Pd$_2$(μ-dppa)$_2$Cl$_2$] should be noted.

The molecular structure involves two palladium centres with a Pd—Pd bond [2.6378(6) Å]; two dppa ligands bridge the metal–metal bond and there is one Cl ligand per palladium atom. The environment around each palladium is almost square planar with small tetrahedral distortions (*e.g.* the dihedral angles between the planes Cl(1)Pd(1)P(2), P(1)Pd(1)Pd(2) and Cl(2)Pd(2)P(3), P(4)Pd(2)Pd(1) are 4.93(4) and 3.03(4)° respectively. The angles between mutually *cis*-Pd(1)–ligand bonds are in the range 83.4–92.1°; the same parameters corresponding to the Pd(2) centre are in the range 88.1–

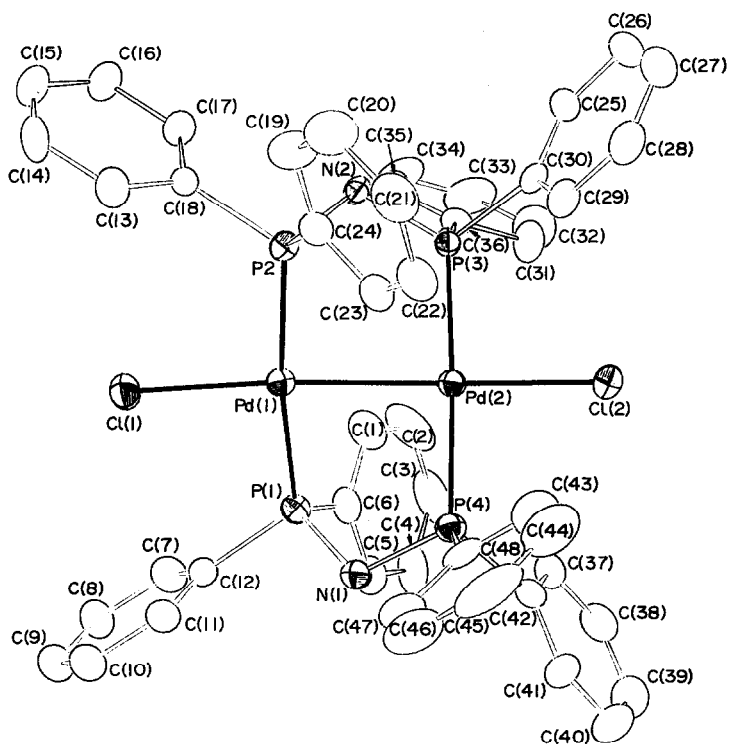


Fig. 1. Plan view of **1a**, excluding hydrogen atoms for the sake of clarity. Thermal ellipsoids are drawn at the 30% probability level.

92.1°. The square planar environment around the Pd(1) centre is more distorted than around the Pd(2) centre. The angles between mutually *trans*-palladium–ligand bonds are: 171.9°, 175.6° for Pd(1) and 176.4°, 177.9° for Pd(2) respectively. The chain Cl(1)Pd(1)Pd(2)Cl(2) is almost linear, the angle between the Cl(1)Pd(1) line and the Pd(2)Cl(2) line is 2.8°.

The Pd—P distances are in the range 2.263–2.292 Å, similar to those in dinuclear Pd—Pd derivatives with two bridging dppm ligands $BrPd(\mu\text{-dppm})_2PdBr$,[14] $ClPd(\mu\text{-dppm})_2PdSnCl_3$,[15] $(C_6Cl_5)Pd(\mu\text{-dppm})_2Pd(C_6Cl_5)$.[13b]

The Pd(1)—Cl(1) and Pd(2)—Cl(2) distances are 2.3991(13) and 2.4153(15) Å respectively.

The Pd—Pd distance, [2.6378(6) Å], is in the same range or somewhat shorter than the distances found in other Pd^I—Pd^I derivatives with two dppm's as bridging ligands; 2.644(2) Å in $ClPd(\mu\text{-dppm})_2PdSnCl_3$,[15] 2.670(2) Å in $(C_6Cl_5)Pd(\mu\text{-dppm})Pd(C_6Cl_5)$[13b] and 2.699(2) Å in $BrPd(\mu\text{-dppm})_2PdBr$.[14]

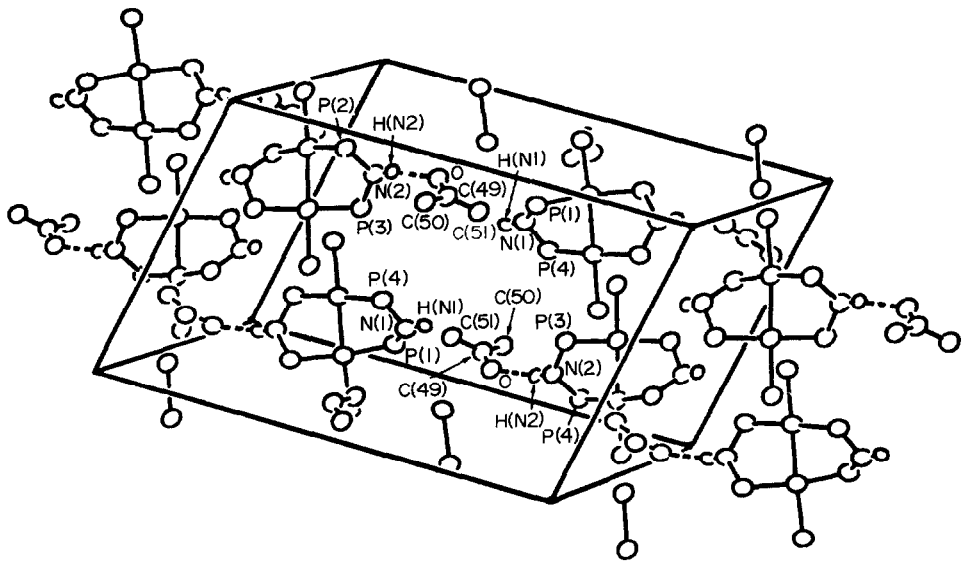

Fig. 2. Unit cell contents for **1a** · Me_2CO.

The environment around each N atom is almost trigonal planar. The PNP angles around N(1) and N(2) are 112.7(3) and 116.1(3)° respectively. The four P—N distances are similar [1.702(4)–1.690(4) Å]; these distances are shorter than the sum of the N and P covalent radii (1.80 Å), and this fact may suggest that the N—P bonds in the coordinated dppa ligands have partial double bond character.

The distance between the two P atoms of the same dppa group [P(1)—P(4) or P(2)—P(3)] are approximately 0.2 Å longer than the Pd(1)—Pd(2) distance.

The two coordination planes around the Pd atoms are twisted about the Pd(1)—Pd(2) bond, so that the dihedral angle between them is 36.83(4)° (see Fig. 3).

There is an acetone molecule for each ClPd(μ-dppa)PdCl molecule; the O atom of the solvent molecule is situated at only 2.10(9) Å from the H atom bonded to N(2) and 2.915(7) Å from the N(2) atom indicating the presence of typical hydrogen bond.[16] No analogous interaction is present for the H atom bonded to N(1).

EXPERIMENTAL

C, H and N analyses were carried out on a Perkin–Elmer 240 microanalyser. Conductivities were measured in approx. 5×10^{-4} M acetone solutions with a Philips PW 9501/01 conductimeter. The IR spectra were recorded (in the 4000–200 cm^{-1} range) on a Perkin–Elmer spectrophotometer. $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XL-200. Thermogravimetric studies have been carried out using a TGS-2 Perkin–Elmer system.

Standard methods were used to prepare the following complexes: $Ph_2PNHPPh_2$(dppa),[17] $PdCl_2(PhCN)_2$[18] and $Pd_2(dba)_3 \cdot CH_3Cl$.[19]

ClPd(μ-dppa)$_2$PdCl (1)

To a solution of dppa (0.600 g, 1.55 mmol) in 30 cm^3 of CH_2Cl_2, $PdCl_2(NCPh)_2$ (0.298 g, 0.78 mmol) and $Pd_2(dba)_3 \cdot CHCl_3$ (0.402 g, 0.39 mmol) were added; the mixture was refluxed for 1 h. After filtration the resulting red solution was evaporated to

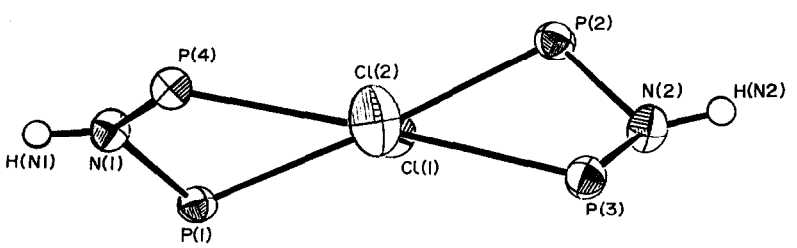

Fig. 3. View along the Pd—Pd bond showing the relative inclination of the two five-atom rings.

$\simeq 5\ cm^3$ and Et_2O (30 cm^3) was added. The orange-brown solid which separated was filtered off and this solid was stirred in 60 cm^3 of Et_2O for 3 h at room temperature (68% yield).

$[ClPd(\mu\text{-dppa})_2PdCl]\cdot(CH_3)_2CO$ (**1a**), $[ClPd(\mu\text{-dppa})_2PdCl]\cdot 2NCCH_3$ (**1b**). Complex **1** (0.4 g, 0.38 mmol) was dissolved in 20 cm^3 of acetone and stirred at room temperature. After a few minutes a yellow precipitate was formed. The solid was filtered off, and air dried (**1a**, 82% yield).

Complex **1b** was obtained in a similar way by using acetonitrile as solvent (65% yield).

$BrPd(\mu\text{-dppa})_2PdBr$ (**2**)

To a solution of $ClPd(\mu\text{-dppa})_2PdCl$ (0.200 g, 0.19 mmol) in 20 cm^3 of CH_2Cl_2, NBu^n_4Br (1.00 g, 3.10 mmol) was added. The mixture was stirred at room temperature overnight and then evaporated to dryness. The orange residue was washed with water ($2\times 10\ cm^3$) and extracted with CH_2Cl_2. The dichloromethane solution was evaporated almost to dryness and the addition of Et_2O (30 cm^3) renders an orange solid which was recrystallized from acetone/diethyl ether (**2**, 44% yield).

$SnCl_3Pd(\mu\text{-dppa})_2PdSnCl_3$ (**3**)

To a solution of $ClPd(\mu\text{-dppa})_2PdCl$ (**1**) (0.200 g, 0.19 mmol) in 20 cm^3 of CH_2Cl_2, a solution of $SnCl_2$ (0.189 g, 1.00 mmol) in 20 cm^3 of MeOH was added. The mixture was stirred for 4 h at room temperature. The solution was evaporated to 10 cm^3 giving a red precipitate, which was filtered, and air dried. Complex **3** (72% yield).

$[(Ph_3P)Pd(\mu\text{-dppa})_2Pd(PPh_3)]BPh_4$ (**4**)

PPh_3 (0.105 g, 0.40 mmol) was added to a suspension of $ClPd(\mu\text{-dppa})_2PdCl$ (**1**) (0.200 g, 0.189 mmol) in 15 cm^3 MeOH; stirring at room temperature for 10 min resulted in complete dissolution. After addition of $NaBPh_4$ (0.136 g, 0.4 mmol), an orange solid precipitated. The resulting solid was filtered off and air dried. Complex **4** (60% yield).

$[ClPd(\mu\text{-dppa})_2(\mu\text{-}N_2R)PdCl]$ $R = C_6H_4\text{-}o\text{-}NO_2$ (**5**), $C_6H_4\text{-}p\text{-}CH_3$ (**6**)

To a solution of $ClPd(\mu\text{-dppa})_2PdCl$ (**1**) (0.263 g, 0.25 mmol) in acetone (25 cm^3) (−30°C), $[o\text{-}NO_2C_6H_4N_2]BF_4$ was added. The solution was stirred at −30°C for 15 min and then allowed to reach room temperature over *ca.* 30 min. The resulting red solution was filtered and evaporated to *ca.* 5 cm^3. The addition of Et_2O (30 cm^3) afforded **5** (55% yield).

Complex **6** was obtained similarly by using $[p\text{-}CH_3\text{-}C_6H_4N_2]BF_4$ (57% yield).

Crystallographic study of (**1a**)

Crystal data (*at* 185 K). $Pd_2P_4Cl_2ON_2C_{50}H_{48}$, $M = 1100.54$. Monoclinic, $a = 13.540(3)$, $b = 16.943(2)$, $c = 21.082(15)$ Å, $\beta = 105.257(42)°$, $U = 4671(4)\ Å^3$, space group $P2_1/c$ (No. 14). $Z = 4$, $D_c = 1.565\ g\ cm^{-3}$, $F(000) = 2224$, graphite-monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu(\text{Mo-}K_\alpha) = 10.49\ cm^{-1}$, yellow crystal, $0.2\times 0.25\times 0.3$ mm.

Data collection and processing. CAD4 diffractometer with low temperature unit, ω–2θ scans, ω scan width $0.8+0.35\tan\theta$, 6145 reflections measured (θ_{max} 22°; h $-14\rightarrow 14$, k $0\rightarrow 17$, l $0\rightarrow 22$), giving 5091 reflections with $F \geqslant 5\sigma(F)$ for structure solution and refinement. No significant crystal movement or decay over 78 X-ray hours.

Structure analysis and refinement. Solution by Patterson and difference syntheses was followed by full-matrix least-square refinement with anisotropic thermal parameters for all atoms except H, using the SHELX 76 program system.[20] Empirical absorption correction[21] applied after isotropic convergence. The phenyl rings were refined as rigid groups with H atoms in calculated positions. H atoms bonded to N located and freely refined. Those of the solvent molecule set in idealized positions. Group U's for all H atoms [0.067(3) $Å^2$ at convergence]. Refinement of 476 parameters converged at $R = 0.0333$ and $R_w = 0.0486$ (weighting scheme $w^{-1} = [\sigma^2(F)+0.000006F^2]$. Largest peak 1.53 $e/Å^3$ at 1.07 from Pd(1).

(*Received* 17 *September* 1988; *accepted* 10 *November* 1988)

Abstract—A series of methoxy-substituted triarylphosphines $R_nPh_{3-n}P$ (n = 1–3), where R may be 2-(MeO)C_6H_4, 4-(MeO)C_6H_4, 2,6-(MeO)$_2C_6H_3$ and 2,4,6-(MeO)$_3C_6H_2$, have been prepared and employed as extractants for the gallium(III) ion from hydrochloric acid solutions. The extractabilities of these compounds are found to become more effective with an increase in their basicities, which are determined by non-aqueous titrimetry. Highly basic compounds, $\{(2,6\text{-}(MeO)_2C_6H_3)\}_3P$ and $\{(2,4,6\text{-}(MeO)_3C_6H_2)\}_3P$, possess the highest extractability amongst the triarylphosphines. The extraction mechanism is discussed on the basis of the ^1H and ^{31}P NMR spectroscopic data.

Triphenylphosphine (Ph_3P) is one of the most popular ligands which can coordinate with noble metal ions. Thus it has been applied to the extraction of such metal ions as gold, platinum and palladium from acidic media.[1–5] In these cases, triphenylphosphine acts as a neutral ligand or its phosphonium salt of hydrogen chloride, depending on both the nature of the metal ions and the concentration of hydrochloric acid.

In a previous paper,[6] we described that the basicities of the methoxy-substituted triarylphosphines, $R_nPh_{3-n}P$ [R = 2-(MeO)C_6H_4, 4-(MeO)C_6H_4, 2,6-(MeO)$_2C_6H_3$ and 2,4,6-(MeO)$_3C_6H_2$ (abbreviations: 2-MeOPh, 4-MeOPh, 2,6-MeOPh and 2,4,6-MeOPh, respectively); n = 1, 2 and 3], increase with increasing numbers of the introduced methoxy groups on the phenyl rings, and that tris(2,4,6-trimethoxyphenyl)phosphine (2,4,6-MeOPh)$_3P$ (pK_a = 11.02) possesses the highest basicity amongst them, which is comparable to that of piperidine (pK_a = 11.2).[7] In addition, this phosphine shows the most effective extractability for the gallium(III) ion from hydrochloric acid solutions. In this system, we have proposed that the gallium(III) ion is extracted through an anion-exchange mechanism.

In this paper, we describe the extraction behaviour of a series of methoxy-substituted triarylphosphines for the gallium(III) ion from acidic media and the relationship between their extractabilities and basicities. Moreover, the extraction mechanism will be discussed from the chemical shifts obtained in ^1H and ^{31}P NMR spectroscopy.

EXPERIMENTAL

Preparation of methoxy-substituted triarylphosphines

Triarylphosphines, $R_nPh_{3-n}P$, where R is 2,6-MeOPh and 2,4,6-MeOPh (n = 1–3), were prepared according to the method described in a previous paper.[8]

* Author to whom correspondence should be addressed.

$R_nPh_{3-n}P$, where R is 2-MeOPh and 4-MeOPh (n = 1–3), were prepared as follows. $(2\text{-MeOPh})_3P$: a tetrahydrofuran (THF) solution (10 cm^3) of chlorodiphenylphosphine (5.7 g) was added to a THF solution (30 cm^3) of Grignard reagent, $o\text{-}CH_3OC_6H_4MgBr$ at 0°C, which was prepared from *o*-bromoanisole (5.0 g). The mixture was refluxed for 3 h. After the reaction was complete, distilled water (25 cm^3) containing conc. H_2SO_4 (2.5 cm^3) was added to decompose an excess of the Grignard reagent. The reaction mixture was extracted twice with benzene (100 cm^3). The benzene extracts were washed with an aqueous solution of diluted $NaHCO_3$ (5%) and then several times with distilled water, and dried over Na_2SO_4. The benzene solution was evaporated to dryness under reduced pressure, and the residue was recrystallized from ethanol.

Other triarylphosphines were prepared by a similar method to the one described above. These compounds were obtained in 60–70% yield. Their analytical data, melting points, mass spectral data and pK_a values are listed in Table 1.

Reagents

An aqueous gallium(III) chloride solution was prepared by dissolving gallium metal (99.99%), which was obtained from Wako Chemical Co. Ltd, in conc. HCl and diluting with deionized water to the required concentration. Other reagents were of analytical grade.

Extraction and analytical procedure

Equal volumes (5 cm^3) of a chloroform solution of an extractant and a HCl solution of the gallium(III) ion were placed in a centrifuge glass tube (10 cm^3), followed by shaking for 15 min at 25 ± 0.1°C and centrifuging until phase separation. The concentration of the gallium(III) ion remaining in the aqueous phase was determined by atomic absorption spectrometry. The concentration of the gallium(III) ion transferred into the organic phase was calculated from mass balance, using that in the aqueous phase. Deuterochloroform was used as the organic phase for NMR measurements in place of chloroform.

pK_a *Measurements of phosphines*

The basicities of the triarylphosphines were measured by non-aqueous titrimetry in nitromethane according to the method reported by Streuli.[9] A standard HCl solution (0.004 mol dm^{-3}) and a glass calomel electrode system were used. Diphenylguanidine was used as the reference standard for all of the non-aqueous titrations. The pK_a (H_2O) values were calculated from the half-neutralization potential values obtained in the non-aqueous titrimetry.

Physical measurements

Atomic absorption measurements were made on a Nippon Jarrell Ash AA-8500 Mark II spectrometer using a $N_2O\text{–}C_2H_2$ flame. IR spectra were recorded on a JASCO 910 grating spectrophotometer between caesium iodide plates. A Horiba pH meter F-8 DP equipped with a glass calomel electrode was used for titrimetry. ^1H NMR spectra were obtained on a JNM-PS-100 spectrometer operating at 100 MHz using tetramethylsilane (TMS) as the internal standard. ^{31}P

Table 1. Elemental analyses and some properties of triarylphosphines

Compound	Mass [M^+]	Melting point (°C)	Elemental analyses Found (Calc.) (%) C	H	pK_a
$(2\text{-MeOPh})Ph_2P$	292	124–125	77.6(78.1)	5.9(5.8)	3.33

$(2,6\text{-MeOPh})_3P$	442	158–160	64.8(65.2)	6.2(6.1)	9.33
$(2,4,6\text{-MeOPh})Ph_2P$	352	105–106	71.4(71.6)	6.1(6.0)	5.77
$(2,4,6\text{-MeOPh})_2PhP$	442	150–151	64.8(65.2)	6.2(6.1)	8.22
$(2,4,6\text{-MeOPh})_3P$	532	166–168	60.6(60.9)	6.3(6.2)	11.02

NMR spectra were taken on a JEOL-GSX-270S spectrometer operating at 270 MHz using 85% H_3PO_4 as the external standard.

RESULTS AND DISCUSSION

Basicities of methoxy-substituted triarylphosphines

Previously, Streuli and Fritz and co-workers have determined the pK_a values of organic acids and bases such as substituted phosphines,[9] phenols,[10] and amines[11] by non-aqueous titrimetry. We determined the pK_a values of the methoxy-substituted triarylphosphines using almost the same procedure as described by them. These numerical data are summarized in Table 1. It can be seen that the pK_a values of the triarylphosphines are increased with an increase in the number of introduced methoxy groups on the phenyl rings. However, they are affected by the substituted position of the methoxy group on the phenyl ring: the substitution of the four-position on the phenyl ring resulted in a slightly higher basicity compared with that for the substitution of the two-position, and the pK_a value of (2,6-MeOPh)Ph_2P is higher than that of (2-MeOPh)$_2$PhP, in spite of involving two methoxy groups per one phosphine molecule. This pK_a difference between (2,6-MeOPh)Ph_2P ($pK_a = 5.39$) and (2-MeOPh)$_2$PhP ($pK_a = 4.01$) may arise from steric effects in addition to electronic effects. The 2,6-MeOPh group is more bulky than the 2-MeOPh group, so that free rotation, in solution, of the methoxy-substituted phenyl ring around the P—C bond might be more restricted for the former compared with the latter. Thus, (2,6-MeOPh)Ph_2P may statistically adopt a more effective configuration for electron releasing from the methoxy group on the phosphorus atom than (2-MeOPh)$_2$PhP.

The extraction isotherm

The extraction behaviour of the gallium(III) ion with the triarylphosphines from various concentrations of HCl is shown in Figs 1–4, where the concentration of the extractants in the organic phase is equal to the initial concentration of the gallium(III) ion in the aqueous phase (5.0×10^{-4} mol dm^{-3}). Figures 1 and 2 show the extraction isotherms obtained by using (2-MeOPh)$_n$Ph$_{3-n}$P and (4-MeOPh)$_n$Ph$_{3-n}$P ($n = 1$, 2 and 3), respectively. Figure 1 also includes the extraction isotherm obtained by using Ph_3P for comparison. It can be seen in both cases that maximum extractions of the gallium(III) ion are achieved at lower concentrations of HCl in the order of $n = 1 < 2 < 3$. This order is fairly consistent with the increasing

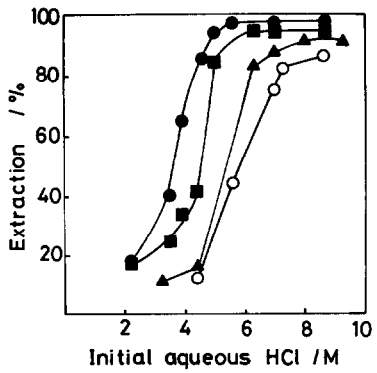

Fig. 1. Effects of HCl concentration on extraction of Ga^{III} (5×10^{-4} M) with (2-MeOPh)$_n$Ph$_{3-n}$P and Ph_3P (5×10^{-4} M). (▲): $n = 1$; (■): $n = 2$; (●): $n = 3$; (○): Ph_3P.

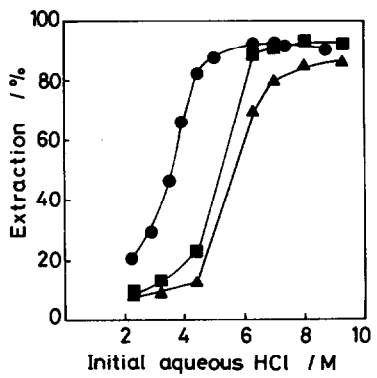

Fig. 2. Effects of HCl concentration on extraction of Ga^{III} (5×10^{-4} M) with (4-MeOPh)$_n$Ph$_{3-n}$P (5×10^{-4} M). (▲): $n = 1$; (■): $n = 2$; (●): $n = 3$.

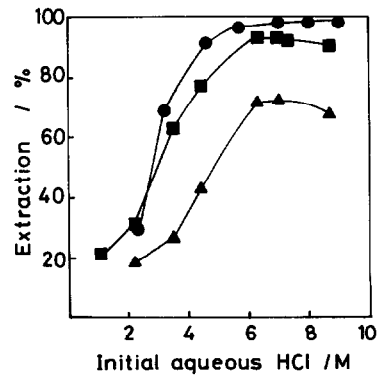

Fig. 3. Effects of HCl concentration on extraction of Ga^{III} (5×10^{-4} M) with (2,6-MeOPh)$_n$Ph$_{3-n}$P (5×10^{-4} M). (▲): $n = 1$; (■): $n = 2$; (●): $n = 3$.

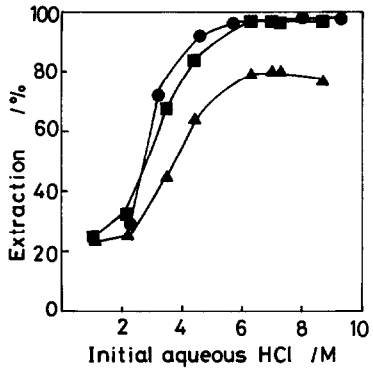

Fig. 4. Effects of HCl concentration on extraction of Ga^{III} (5×10^{-4} M) with (2,4,6-MeOPh)$_n$Ph$_{3-n}$P (5×10^{-4} M). (▲): $n = 1$; (■): $n = 2$; (●): $n = 3$.

order of their basicities. The percentage extraction of the gallium(III) ion with Ph_3P was only about 80% more than with 7.3 M HCl. The pK_a value of Ph_3P is 2.73,[9] being the lowest basicity examined in the present work.

Figures 3 and 4 show the extraction isotherms obtained by using (2,6-MeOPh)$_n$Ph$_{3-n}$P and (2,4,6-MeOPh)$_n$Ph$_{3-n}$P (n = 1, 2 and 3), respectively. A similar relationship was observed between their extractabilities and basicities. Moreover, extractions nearly equal to 100% were obtained in the cases of (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P, which are highly basic as shown in Table 1. These results indicate that they are the most effective extractants among the triarylphosphines investigated here.

^{1}H *and* ^{31}P *NMR*

In the extractions of platinum(II) and palladium(II) with Ph_3P from acidic media, it has been proposed[4] that Ph_3P can act as both a neutral ligand and an anion exchanger by forming its phosphonium cation [Ph_3P^+H].

In order to clarify the extraction mechanism for the present systems, we have measured the following ^{1}H and ^{31}P NMR spectra: (I) the $CDCl_3$ solutions of the triarylphosphines themselves, (II) those after shaking with conc. HCl and (III) those after extraction of gallium(III) from 6.0 M HCl, for which data are summarized in columns I, II and III, respectively, in Table 2 for the ^{1}H NMR spectra and in Table 3 for the ^{31}P NMR spectra.

^{1}H *NMR study*. The phenyl proton signals of the methoxy-substituted triarylphosphines split as expected, and those at the *ortho* and *para* positions vs methoxy group are observed at higher magnetic fields than those at the *meta* position. The ^{1}H NMR data for (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P, which are already reported in a previous paper,[8] are listed again in Table 2 for comparison. When the $CDCl_3$ solutions of the triarylphosphines were shaken with conc. HCl, all the proton signals shifted to lower magnetic fields as shown in column II in Table 2. This may be caused by the formation of their phosphonium salts from hydrogen chloride. The shift values of the phenyl protons are larger than those of the methyl protons of the methoxy groups; the former lies in the range 0.20–0.48 ppm and the latter in the range 0.08–0.24 ppm. However, the shift value of the phenyl protons of Ph_3P is the smallest amongst the triarylphosphines investigated here. On the other hand, when the $CDCl_3$ solutions of the triarylphosphines were shaken with a gallium(III) solution in 6.0 M HCl, their chemical shifts are observed at almost the same magnetic fields as those observed after shaking with conc. HCl, except for Ph_3P, whose proton signals are shifted to lower magnetic fields by *ca* 0.21 ppm. In particular, all the proton signals for (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P are observed at the same positions. These results will be discussed later in combination with those obtained in the ^{31}P NMR spectroscopy.

^{31}P *NMR study*. As shown in column I in Table 3, the ^{31}P chemical shifts of the triarylphosphines lie within a wide range of −4.84 ppm for Ph_3P to −69.36 ppm for (2,4,6-MeOPh)$_3$P, and are shifted to higher magnetic fields with an increase in the number of introduced methoxy groups per triarylphosphine molecule.

It should be noted that the chemical shifts of the triarylphosphines having a methoxy group in the two-position on the phenyl ring, are observed at higher magnetic fields than those in the four-position. A higher magnetic field shift like this has been reported for the compound (2-MeOPh)Ph_2P and explained in terms of an anisotropic effect.[12] It is particularly interesting that the shift values increase almost proportionally with an increase in the number of methoxy groups. For example, when the ^{31}P chemical shift of Ph_3P is a standard, the difference in the chemical shifts between Ph_3P and (2-MeOPh)Ph_2P is 11.28 ppm. That between (2-MeOPh)Ph_2P and (2-MeOPh)$_2$PhP is 11.18 ppm and that between (2-MeOPh)$_2$PhP and (2-MeOPh)$_3$P is 11.70 ppm. A similar behaviour is observed for a series of the 4-MeOPh derivatives, of which the shift values, however, are smaller than those of the 2-MeOPh derivatives.

The ^{31}P chemical shifts of the $CDCl_3$ solutions of the triarylphosphines after shaking with conc. HCl are given in column II (Table 3), and the differences in chemical shifts before and after shaking with it

Table 2. ^1H NMR data for methoxy-substituted triarylphosphines[a]

are also given in column (II–I). It can be seen that relatively large, lower magnetic field shifts are observed for (2,6-MeOPh)$_3$P, (2,4,6-MeOPh)$_3$P and the 2-MeOPh derivatives. On the contrary, the ^{31}P chemical shift of Ph_3P changes slightly, and the shift values for the 4-MeOPh derivatives are relatively small compared with those for the above 2-MeOPh derivatives. This trend is consistent with that observed in ^1H NMR spectroscopy. Such differences in the shift values between the 2- and 4-methoxy-substituted compounds may be ascribed to the difference in the anisotropic magnetic field effect between them, because their basicities are comparable, as shown in Table 1. In addition, the ^{31}P NMR spectra of the $CDCl_3$ solutions of (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P were observed as

Table 3. ^{31}P NMR data of methoxy-substituted triarylphosphines[a]

Compound	Chemical shift (ppm) I[b]	II[c]	III[d]	(II–I)	(III–II)
Ph_3P	−4.84	−4.82	4.87	0.02	9.69
$(2\text{-MeOPh})Ph_2P$	−16.12	−9.48	−3.75	6.64	5.73
$(2\text{-MeOPh})_2PhP$	−27.30	−11.87	−8.51	15.43	3.36
$(2\text{-MeOPh})_3P$	−39.00	−17.18	−16.94	21.82	0.24
$(4\text{-MeOPh})Ph_2P$	−6.47	−4.03	0.61	2.44	4.64

[c] After shaking with conc. HCl.
[d] After extraction of Ga^{III} from 6.0 M HCl.

clearly split signals after shaking with conc. HCl, as shown in Fig. 5. These split signals may arise from coupling with the proton nucleus (^1H), by the formation of their phosphonium salts with HCl. However, such a clearly split signal was not observed for $(2\text{-MeOPh})_2PhP$ and $(2\text{-MeOPh})_3P$, although their shift values are comparable with those observed for $(2,6\text{-MeOPh})_3P$ and $(2,4,6\text{-MeOPh})_3P$. This may be related to the difference in their basicities: the latter two compounds have such high basicities that they can easily form their stable phosphonium salts with HCl.

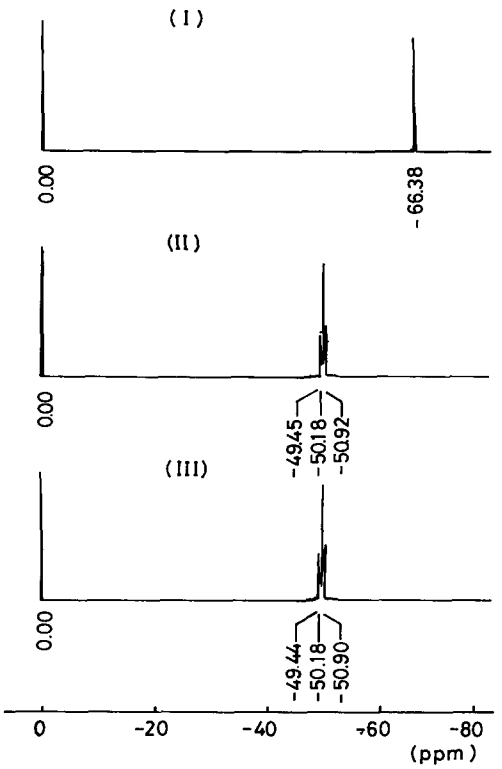

Fig. 5. ^{31}P NMR spectra of $(2,6\text{-MeOPh})_3P$ in $CDCl_3$. (I): $(2,6\text{-MeOPh})_3P$; (II): after shaking with conc. HCl; (III): after extraction of Ga^{III} ion. 0.00 ppm is for the external standard (85% H_3PO_4).

Next, the ^{31}P chemical shifts of the $CDCl_3$ solutions of the triarylphosphines after extraction of gallium(III) from 6.0 M HCl are given in column III (Table 3), and also the differences in the chemical shifts between columns II and III are presented in column (III–II). The differences in column (III–II) are almost zero for the compounds $(2\text{-MeOPh})_3P$, $(2,6\text{-MeOPh})_3P$ and $(2,4,6\text{-MeOPh})_3P$. Moreover, as shown in Fig. 5, the spectral features of $(2,6\text{-MeOPh})_3P$ between after shaking with conc. HCl and after extraction of gallium(III) are very similar. From these results, it can be concluded that the extraction of gallium(III) with these compounds proceeds via the ion-pair formation in which they act as an anion-exchanger, as shown in the following equation;

$$R_3P + HCl \rightleftharpoons [R_3P^+H][Cl^-]$$

$$[R_3P^+H][Cl^-] + H[GaCl_4] \rightleftharpoons [R_3P^+H][GaCl_4^-] + HCl,$$

where R_3P denotes a triarylphosphine.

On the other hand, with other triarylphosphines, relatively large lower magnetic field shifts are observed after the extraction of gallium(III). The following two reasons, responsible for the lower magnetic field shifts, are considered: (1) these triarylphosphines react with $H[GaCl_4]$, which is a main species in 6.0 M HCl, to give their phosphonium salts with a tetrachlorogallate(III) ion,

$[R_3P^+H][GaCl_4^-]$ and (2) they coordinate to the gallium(III) ion as a neutral ligand.

$$(R_3P) + H[GaCl_4] \rightleftharpoons [R_3P^+H][GaCl_4^-] \quad (1)$$

$$n(R_3P) + H[GaCl_4] \rightleftharpoons H[GaCl_4(R_3P)_n]. \quad (2)$$

From only the shift values, we can not conclude that either of the above two processes takes place in the extraction of gallium(III) with this group of triarylphosphines. However, in the extraction of H_2PtCl_6 with (2,6-MeOPh)$_3$P in $CDCl_3$ from neutral aqueous solution (not hydrochloric acid), its ^{31}P NMR spectrum shows a close similarity to that for the $CDCl_3$ extract of gallium(III); the chemical shift of the ^{31}P signals is observed at -50.13 ppm with splitting. This result may support the extraction process of the ion-pair formation (1), rather than the coordination of the extractant (2). However, the ^{31}P NMR spectra of the $CDCl_3$ extracts of this group of triarylphosphines show a single peak which is different from those of (2-MeOPh)$_3$P, (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P. These ambiguous data might be explained by taking the existence of the following rapid equilibrium, which is beyond the NMR time scale, into consideration: $[R_3P^+H][GaCl_4^-] \rightleftharpoons [H][GaCl_4(R_3P)]$. In addition, the coupling constants (J_{P^+-H}) observed for the extraction systems with (2,6-MeOPh)$_3$P or (2,4,6-MeOPh)$_3$P are calculated to be *ca* 80 Hz, which are smaller than those observed for the isolated phosphonium salts; 546 Hz for [(2,6-MeOPh)$_3P^+H$][ClO_4^-] and [(2,6-MeOPh)$_3P^+H$][Cl^-]. This may be caused by hydration of the extracted phosphonium salts, because the $CDCl_3$ extracts always include the saturated H_2O.

In the present work, the extraction mechanisms for the methoxy-substituted triarylphosphines–gallium(III) systems are discussed on the basis of ^1H and ^{31}P NMR spectroscopic data in connection with their basicities and extractabilities. It can be concluded that highly basic compounds, (2,6-MeOPh)$_3$P and (2,4,6-MeOPh)$_3$P, act as anion-exchangers by forming their phosphonium salts with hydrogen chloride in the extraction of gallium(III) from hydrochloric acid.

Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, 1040 Sofia, Bulgaria

(*Received* 1 *August* 1988; *accepted* 10 *November* 1988)

Abstract—A magnesium hydroxide nitrate, $Mg_2(OH)_3NO_3$, with lattice parameters $a_0 = 3.16$ and $c_0 = 6.98$ Å has been prepared by precipitation from $Mg(NO_3)_2$ and NaOH solutions. Its hydrothermal treatment in the mother liquor at 150°C leads to crystallization of a new phase with lattice parameters $a_0 = 5.46$ and $c_0 = 6.96$ Å. Transmission electron microscope and selected area electron diffraction studies have shown that the formation of the MgO phase during the decomposition of $Mg_2(OH)_3NO_3$, is a topotactic process. On the basis of the general formulae, lattice parameters and decomposition mechanisms, it has been assumed that the structures of the magnesium hydroxide nitrates are related to the single-layered brucite-like type.

In previous studies[1] on the formation of mixed crystals of Mg—Co hydroxide nitrates it was established that $Co_2(OH)_3NO_3$ is tolerant with respect to the isomorphous replacement of Co^{II} by Mg^{II} ions. The possibility of obtaining a pure magnesium hydroxide nitrate by precipitation, on which there are no data in the literature, was also considered. It should be noted that there are only a few investigations on the conditions of preparation, composition and structure of magnesium hydroxide nitrates.[2–5]

Recently, the interest in the decomposition mechanism of the hydroxide nitrates of divalent metals has considerably increased. The crystal structures of the largest part of these compounds proved to be of a layered, brucite-like type.[6–9] The strong cation–anion intralayer interaction and the weak interlayer hydrogen bonding in these structures facilitate the diffusionless formation of the final oxide product during thermal treatment.[10,11] In this connection, the preparation of each new hydroxide nitrate phase and the study of its decomposition is of definite interest.

The present paper contains results from studies of the preparation, characterization and thermal decomposition of magnesium hydroxide nitrate synthesized by precipitation.

EXPERIMENTAL

Magnesium hydroxide nitrate was prepared by adding a 0.5 M NaOH solution with intense stirring to a boiling 3 M $Mg(NO_3)_2$ solution saturated with respect to $NaNO_3$. The initial volume in the reaction vessel was maintained constant during the precipitation by evaporation and regulation of the rate with which the NaOH solution was added. The suspension obtained was cooled to 0°C, then washed with iced water until the elimination of nitrate ions in the washing water, and subsequently washed with ethanol. The precipitate was first dried at room temperature, then at 60°C for 1 h.

To elucidate the ageing processes of the magnesium hydroxide nitrate in its mother liquor, the following experiments were carried out: on stopping the addition of the precipitant, the suspension was subjected to hydrothermal treatment in an autoclave (described in ref. 12), then at 150°C for 96 h.

The magnesium content of the samples was determined complexometrically, the nitrate ions content, by the method of Dewarda, and the hydroxide, acidimetrically. XRD analyses were carried out with a powder diffractometer using Co-K_α radiation and a scintillation counter. The diffraction patterns were indexed by the method of Lipson.[13] The unit cell parameters were calculated using the least-

squares method. The IR spectra of the samples were obtained on a KBr tablet. DT and TG analyses were carried out in air with a heating rate of 10°C min^{-1}. Transmission electron microscope (TEM) and selected area electron diffraction (SAED) studies were performed on samples deposited on a carbon substrate. The decomposition of the samples under electron irradiation in the microscope chamber was also examined.

RESULTS AND DISCUSSION

During precipitation of Mg^{II} ions from a $Mg(NO_3)_2$ solution with alkaline hydroxide, unstable magnesium hydroxide nitrates were formed which readily hydrolysed to $Mg(OH)_2$ during the precipitation. Complete hydrolysis was hindered by increasing the concentration of nitrate ions in the initial solution of $Mg(NO_3)_2$ with the addition of $NaNO_3$. When the hydroxyl ratio (moles of NaOH added to those of $Mg(NO_3)_2$ in the initial solution) varied in the range $0.3 < OH/NO_3 < 1.5$, an unknown magnesium hydroxide nitrate phase was precipitated. With a hydroxyl ratio above 1.5, the precipitate obtained was two-phase, i.e. a second phase of $Mg(OH)_2$ appeared.

The hydrothermal treatment of precipitated magnesium hydroxide nitrate proved to be accompanied by structural changes leading to the formation of a new crystalline phase.

1.024	1.024	1	211

of the two phases. The crystals of freshly precipitated hydroxide nitrate are needles and have no well-shaped faces. After the hydrothermal ageing, crystallization processes take place which lead to the growth of ribbon-like crystals.

The chemical analyses of the two phases obtained in a series of experiments, show that magnesium hydroxide nitrates are non-stoichiometric compounds with varying compositions. Further studies were carried out with samples having the following compositions: $Mg_2(OH)_{3.24}(NO_3)_{0.76}(H_2O)_{0.24}$ for the fresh phase, sample I; and $Mg_2(OH)_{3.14}(NO_3)_{0.86}(H_2O)_{0.19}$ for the hydrothermally obtained phase, sample II.

Both kinds of magnesium hydroxide nitrate are indexed on the basis of a hexagonal unit cell, space group $P3m1$ ($a_0 = 3.165 \pm 0.003$ and $c_0 = 6.982 \pm 0.001$ Å for sample I; and $a_0 = 5.460 \pm 0.0017$ and $c_0 = 6.958 \pm 0.005$ Å for sample II).

The interlayer spacings, the relative intensities and the diffraction indices of both kinds of hydroxide nitrates (the freshly precipitated and the hydrothermally treated) are presented in Tables 1 and 2, respectively.

The lattice parameters of magnesium hydroxide nitrates are very close to those of the hydroxide nitrates of cobalt, nickel and copper with the composition $M_2(OH)_3NO_3$,[8,14,15] for which a layered brucite-type structure is found.

On the basis of data from chemical analysis, the similarity of unit cells, and the maximum hydroxyl ratio (1.5) up to which a single phase product is precipitated, the magnesium hydroxide nitrates are to be considered as salts with an idealized composition, $Mg_2(OH)_3NO_3$. They might have structures similar to the brucite. In this case, the interlayer spacings would correspond to the values of the parameter c_0, i.e. 6.982 and 6.958 Å for samples I and II, respectively.

The IR spectra of magnesium hydroxide nitrates are presented in Fig. 2. The bands at 770 (ν_4), 835 (ν_2), 1022 (ν_1), 1333, 1384 and 1488 cm^{-1} (ν_3) correspond to the stretching modes of the NO_3 groups of sample I. The appearance of the band ν_1 and the splitting of ν_3 show that the symmetry of nitrate groups is lower than D_{3h} which is characteristic of a free nitrate ion.[16] Hence, oxygen atoms from the nitrate groups participate in the formation of the oxygen surroundings of magnesium ions which is established for isotypic hydroxide nitrates.[8] The

remaining spectral bands are attributed to the following vibrations: 609 (ν_{Mg-O}), 1632 (δ_{H_2O}), 3677 and 3703 cm^{-1} (ν_{OH}). Sample II has an analogous spectrum.

DTA, TG and DTG curves of decomposition of the two samples are shown in Fig. 3. The thermal destruction of the samples was also studied by X-ray phase analysis of intermediate products obtained by isothermal treatment of the initial phases at 150, 300 and 400°C for 1 h.

Both samples decompose endothermally in two steps at 250–450°C. From the studies of the isothermally treated phases, it is established that up to 150°C the intercalated water is eliminated. At this step the OH/NO_3 ratio does not change. No alterations can be observed in the X-ray diffraction patterns either. At 300°C, i.e. in the region of the endoeffects, nitrogen oxides and water evolve. The X-ray diffraction patterns indicate the presence of MgO. The complete decomposition of both samples to MgO ends at 400°C.

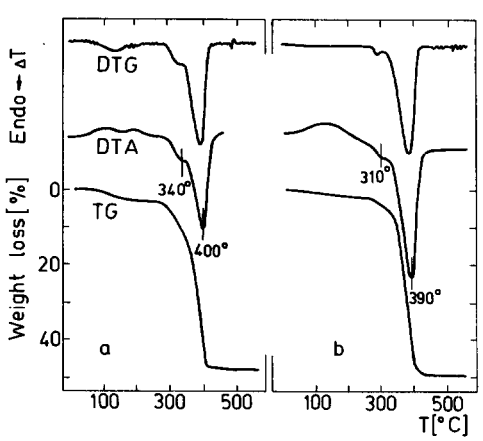

Fig. 3. DTA, TG and DTG curves of the magnesium hydroxide nitrate samples I and II, (a) and (b), respectively.

The assumption about a brucite-like structure of the magnesium hydroxide nitrates and the relatively low decomposition temperatures (below 400°C) presuppose the proceeding of structural transformations of a shear-collapse type with conservation of the two-dimensional metal–oxygen layers. In a number of cases of this kind of structural transformations there is a definite crystallographic relationship between the crystal structures of parent and product phases.[17]

TEM and SAED studies *in situ* were performed with sample II due to the higher morphological perfection of this hydroxide nitrate (see Fig. 1). Figure 4 shows TEM photographs of an initial crystal and another one decomposed under electron beam irradiation, as well as the SAED pattern of the decomposed crystal. The initial crystals of the sample proved to be very unstable towards irradiation, owing to which it was impossible to obtain the SAED pattern of an initial crystal. The diffraction spots on the SAED pattern of the decomposed crystal are smeared probably due to the disorientation of the subcrystallites, which makes exact crystallographic indexing impossible.

The above difficulties imposed the use of an indirect approach to the elucidation of the orientation relationship during the decomposition process. This approach was based on the following facts known from the literature: (1) hydrolysis of the hydroxy salts to the corresponding hydroxides under mild conditions, e.g. in a weakly alkaline medium, is a topotactic process leading to the formation of a pseudomorphous product;[17] (2) the structural transformation of $Mg(OH)_2$ to MgO is also topotactic

$$\langle 111\rangle_{MgO} \| \langle 001\rangle_{Mg(OH)_2},$$

$$\langle 110\rangle_{MgO} \| \langle 001\rangle_{Mg(OH)_2}.$$[10]

Taking into consideration these facts, some additional experiments were carried out on the hydrolysis of magnesium hydroxide nitrate to $Mg(OH)_2$ and the decomposition of the latter in the microscope chamber.

It was established that the hydroxide nitrate was hydrolysed in water medium to a hydroxide. Figure 5 shows TEM photographs and a SAED pattern of the $Mg(OH)_2$ obtained. Obviously, the hydrolysis

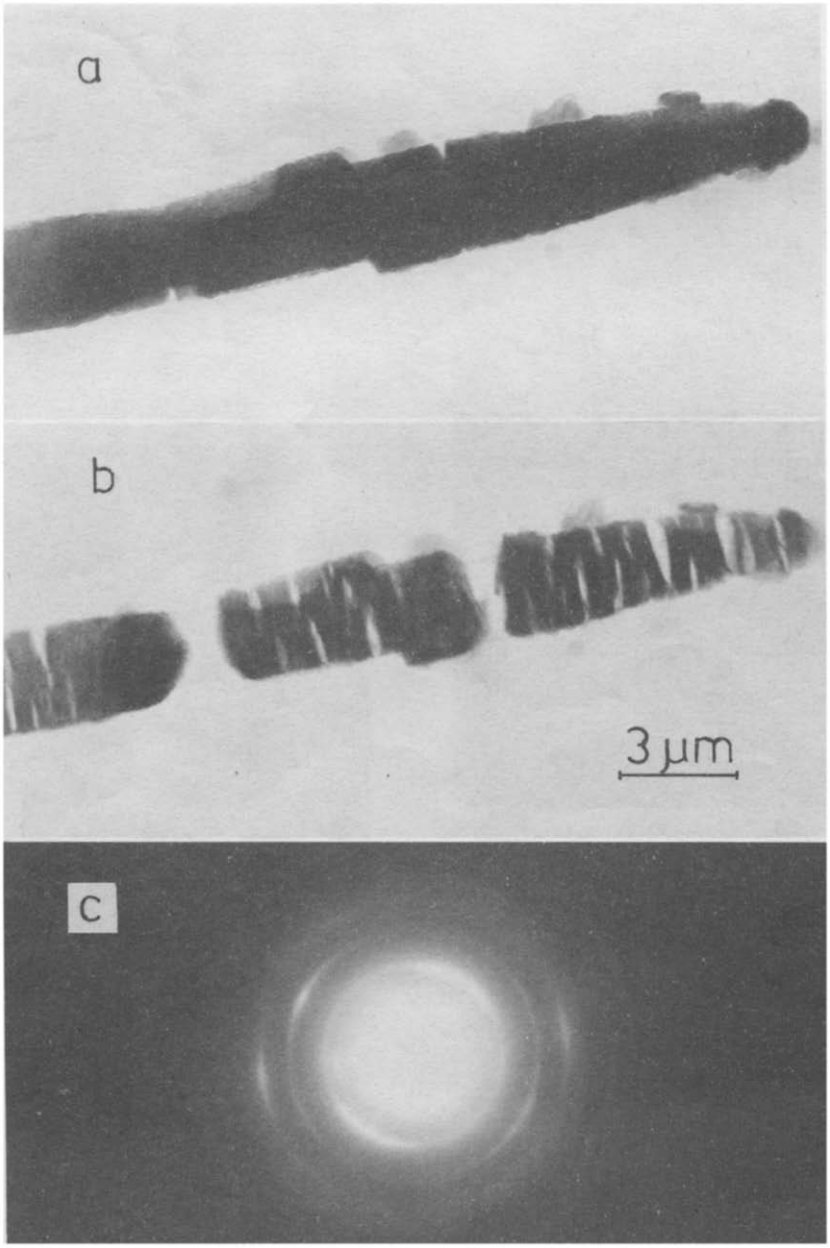

Fig. 4. TEM photographs of sample II: (a) initial, (b) decomposed crystal, (c) SAED pattern of the product.

in this case leads to no change in crystal habit, i.e. the product is pseudomorphous. The SAED pattern contains only (001) reflections of the hexagonal lattice. Therefore, the long axis of the crystals coincides with the crystallographic direction ⟨001⟩. The absence of spots with indices hkl, $0kl$ and $hh0$ indicates a pronounced turbostratic disorder in the structure of magnesium hydroxide.

The decomposition of $Mg(OH)_2$ in the microscope chamber proceeds similarly to that of the hydroxide nitrate (Fig. 6). The SAED pattern of the sample shows spots which can be indexed on the basis of a cubic unit cell with a lattice parameter $a_0 = 4.20$ Å. These data show that $Mg(OH)_2$ is decomposed to MgO. The crystallites of the product were oriented along the direction ⟨110⟩ which is parallel to the electron beam, and again, the dependence

$$\langle 001\rangle_{Mg(OH)_2} \| \langle 111\rangle_{MgO},$$

is established.

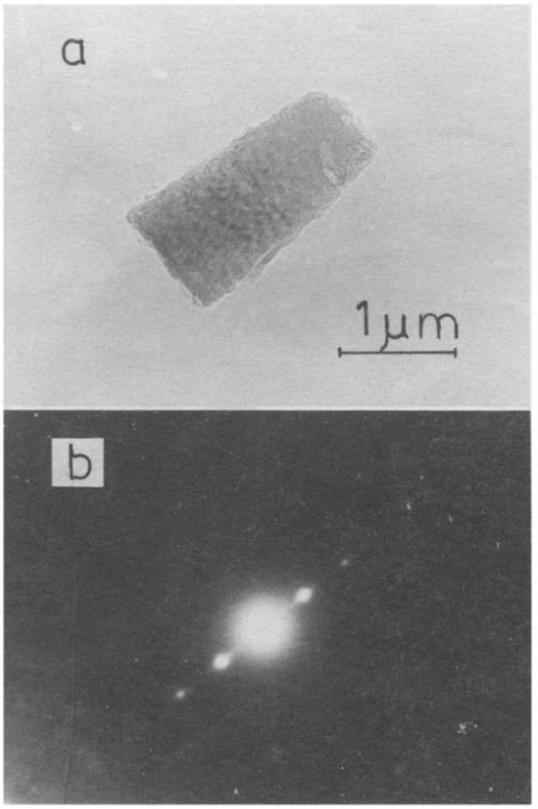

Fig. 5. (a) TEM photograph and (b) SAED pattern of magnesium hydroxide obtained by hydrolysis of sample II.

The SAED pattern of decomposed magnesium hydroxide nitrate is similar to that of the hydroxide obtained. Hence, the above crystallographic correlations can also be valid for magnesium hydroxide nitrate and the oxide obtained from it, i.e.

$$\langle 001\rangle_{Mg_2(OH)_3NO_3} \| \langle 111\rangle_{MgO}.$$

This means that for the hydroxide nitrate phase the direction $\langle 001\rangle$ coincides with the long axis of the crystals. This assumption is confirmed by the TEM photograph of the decomposed initial crystal [Fig. 4(b)]. The evolution of water and nitrogen oxides during the decomposition produces strains in the decomposing crystal, which leads to the appearance of cracks spreading in the (001) plane.

On the basis of the experimental results, the magnesium hydroxide nitrates obtained can be regarded as brucite derivatives. This conclusion is confirmed by comparison of the lattice parameters and the IR spectroscopy data with those concerning the hydroxide nitrates with the formula $M_2(OH)_2NO_3$ and by the decomposition mechanism. Similarly to $Mg(OH)_2$, the magnesium hydroxide nitrates form the lattice of the oxide product by a diffusionless shear-collapse mechanism.

(*Received* 19 *September* 1988; *accepted* 10 *November* 1988)

Abstract—The interaction of the cyclometallated complex $[(Me_3P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$ with the mono or bidentate N- and P-donor ligands C_5H_5N (py), $Me_2NCH_2CH_2NMe_2$ (tmen), PMe_2Ph and $Me_2PCH_2CH_2PMe_2$ (dmpe), has been studied. Of these, only py and dmpe afford the substitution products, $[(C_5H_5N)(Me_3P)\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$ (**2**) and $[(dmpe)\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$ (**4**), in clean, high yield reactions. Isolation of the tmen derivative has proved unattainable, while the PMe_2Ph complex $[(PhMe_2P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$ (**3**), is best obtained by alkylation of $[NiCl_2(PMe_2Ph)_2]$ with $Mg(CH_2CMe_2Ph)Cl$, in the presence of I^-. The new compounds **2–4** have been characterized by analytical and spectroscopic studies, and in the case of **2**, an X-ray structural determination has also been undertaken. Compound **2** is monoclinic, space group $P2_1/c$, with unit cell parameters $a = 9.154(2)$, $b = 10.810(2)$, $c = 19.240(10)$ Å, $\beta = 102.3(1)°$ and $D_{calc} = 1.23$ g cm^{-3} for $Z = 4$. The nickel centre is in a slightly distorted square-planar environment, with Ni—C(aryl) and Ni—C(alkyl) distances of 1.917(5) and 1.935(5) Å, respectively.

Transition metal–metallacycles have been subjected to numerous studies in recent years, due mainly to their intermediacy in a number of catalytic reactions,[1] e.g. alkene metathesis,[2] diene oligomerization,[3] telomerization of butadiene and carbon dioxide,[4] etc. In addition, use of cyclometallated compounds allows the study of some transformations of transition metal complexes which undergo facile decomposition reactions. Work by Whitesides and co-workers has demonstrated that for many such systems[5] the β-hydrogen elimination reaction can be suppressed by constraining the M—C_α—C_β—H dihedral angle to values far from the optimal 0°. Other metallacycles undergo decomposition by this well-known pathway, but their thermal stability is generally much higher than that displayed by their acyclic analogues.

We have reported recently[6a] the formation of the nickelacyclopentene complex $[(Me_3P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$ (**1**). Many cyclometallated complexes of nickel are known[7–10] and the simplest of the nickelacyclopentane units, $\overline{Ni(CH_2CH_2CH_2CH_2)}$, is known to undergo[11] three major decomposition pathways: β-hydrogen elimination, carbon–carbon bond cleavage to ethylene, and reductive elimination. Since the latter process is very often favoured in L_nNiRR' compounds (R,R′ = alkyl or aryl groups) by addition of a phosphine or other ligand,[12] we have attempted the elimination of cyclobutene by addition to compound **1** of N- and P-containing ligands. Instead we have found that the nickelacyclopentene complex **1**, $[(Me_3P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}]$, undergoes sub-

stitution of one of the two PMe_3 ligands. This substitution chemistry is the subject of this paper, which describes also the results of a single-crystal X-ray structural determination, carried out with the mixed PMe_3–py derivative, $[(C_5H_5N)(Me_3P)Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)]$ (**2**).

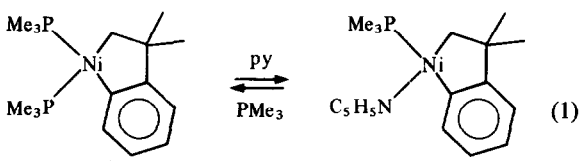
RESULTS AND DISCUSSION

We have recently shown that the cyclometallated complex **1** can be readily prepared by reacting $[NiCl_2(PMe_3)_2]$ with 2 equiv of $Mg(CH_2CMe_2Ph)Cl$, in the presence of I^- as a catalyst. Since this metallacyclic compound exhibits a very rich insertion chemistry, the synthesis of similar cyclic units, containing different co-ligands, has been undertaken.

An X-ray structural determination carried out on compound **1** has shown[6b] that, in spite of the different *trans*-influence of the alkyl and aryl groups, the two Ni—P bonds have nearly equal lengths. Both groups have good *trans*-directing properties and indeed the fluxional behaviour observed for **1** can be explained in terms of a fast intermolecular exchange between coordinated and traces of free PMe_3. NMR data suggest the interchange process to be faster for the PMe_3 ligand *trans* to the Ni—C(alkyl) bond. On this basis, it is reasonable to expect facile substitution of one of the two PMe_3 ligands, with formation of new metallacycles. Since, on the other hand, cyclometallated **1** is stable towards reductive elimination of the organic fragment, even in the presence of added phosphine ligands, simple substitution reactions should provide access to the desired compounds. We have studied the interaction of **1** with two N-containing ligands, pyridine (py) and tmen ($Me_2NCH_2CH_2NMe_2$) and with two P-donors, PMe_2Ph and dmpe ($Me_2PCH_2CH_2PMe_2$). Clean reactions are only observed for py and dmpe, while tmen fails to give the corresponding substitution product and the PMe_2Ph derivative is best prepared by direct alkylation of $[NiCl_2(PMe_2Ph)_2]$, as discussed below.

Reaction of **1** *with pyridine. Formation of* **2** *and its molecular structure*

Treatment of **1** with an excess of py at room temperature, affords, after work-up, a yellow crystalline material of composition $[(C_5H_5N)(Me_3P)Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)]$ (**2**). The new complex has solubility and reactivity towards oxygen and moisture very similar to those of **1**, but at variance with the behaviour found for the latter complex, it has rigid structure in solution. NMR data strongly suggest that the py ligand is occupying the position *trans* with respect to the Ni—CH_2 bond. In accord with this, the methylene carbon nucleus, Ni—CH_2, gives rise to a doublet in the $^{13}C\{^1H\}$ NMR spectrum, with a coupling constant, $^2J_{CP}$, of 13.7 Hz. In the related metallacyclobutene $[(R_3P)_2Ni(CH_2\text{-}o\text{-}C_6H_4)]$,[13] values of *ca* 23 and 55 Hz are found for *cis*- and *trans*-$^{13}CH_2$—Ni—^{31}P couplings, respectively. Formation of **2** can therefore be represented as indicated in eq. (1). The reaction can be readily reversed by addition of PMe_3 to solutions of **2**. As already mentioned, the facile substitution of the ligand which is *trans* with respect to the Ni—alkyl bond is not unexpected and follows from the higher *trans* effect of this group, as compared with the aryl ligand. Note however, that this kinetic effect does not seem to be related to any appreciable weakening of the corresponding bond in the ground state of the molecule, since the Ni—P bonds in **1** have nearly equal lengths.[6b]



(1)

1 **2**

The geometry proposed for **2** on the basis of spectroscopic data has been confirmed by a single-crystal X-ray study. Figure 1 shows an ORTEP view of the molecule of **2** and Tables 1 and 2 include relevant structural data. The coordination around nickel is slightly distorted square-planar, with some distortion being imposed by the relatively small bite angle of the chelating organic ligand which constrains the C(1)—Ni—C(6) angle to 82.4(2)°. The remaining angles between pairs of *cis*-ligands are close to the ideal 90° value (Table 2). The square-planar arrangement is further emphasized by angles between *trans*-ligands, C(6)—Ni—P and C(1)—Ni—N of 172.4(2) and 175.2(2)°, respectively. The Ni—P distance is somewhat longer than the corresponding distance in **1** (2.197(1) vs 2.192(4) Å), but the Ni—C(alkyl) bond length of 1.935(5) Å and the Ni—C(aryl) separation of 1.917(5) Å, are slightly shorter than the corresponding values of 1.96(1) and 1.93(1) Å, found respectively in the parent complex **1**. These bond lengths are not exceptional and fall in the range observed for other alkyl and aryl complexes of nickel(II).[14] The Ni—N separation, 1.963(4) Å, is close to the 1.957(8) Å value reported for $[Ni(CH_2SiMe_3)_2(py)_2]$,[15] and appreciably smaller than the distance of *ca* 2.08 Å observed in bis(pyridine) octahedral complexes of nickel(II).[16–18]

Reaction of **1** *with the phosphine ligands*, PMe_2Ph *and* dmpe

Two synthetic routes can in principle be used for the preparation of the metallacyclic derivatives containing PMe_2Ph and dmpe ligands: reaction of the chlorides, $[NiCl_2P_2]$ (P = PMe_2Ph; P_2 = dmpe), with an excess of the Grignard reagent, $Mg(CH_2CMe_2Ph)Cl$, in the presence of I^-, and substitution of the PMe_3 ligands in **1** by the corresponding phosphine. Rather interestingly, the PMe_2Ph complex, $[(PhMe_2P)_2Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)]$ (**3**), can only be obtained in good yields by the first procedure, while formation of $[(dmpe)Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)]$ (**4**), is only accomplished by dmpe substitution of the PMe_3 groups in **1**, eqs (2) and (3).

$$NiCl_2(PMe_2Ph)_2 + 2Mg(CH_2CMe_2Ph)Cl \xrightarrow{[I^-]} (PhMe_2P)_2Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4) + C_6H_5CMe_3 + MgCl_2 \quad (2)$$

$$(Me_3P)_2Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4) + dmpe \longrightarrow (dmpe)Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4) + 2PMe_3. \quad (3)$$

Reaction (2) affords high yields of cyclometallated **3**, which can be isolated as a yellow, moderately air-stable, crystalline solid. Its characterization as a metallacycle analogous to **1** follows from microanalysis, and IR and NMR spectroscopy. As for the PMe_3 analogue, it is reasonable to assume[6]

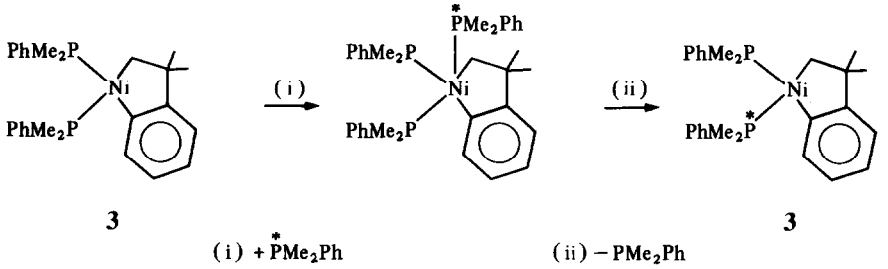
that the cyclometallation proceeds through an unstable dialkyl intermediate, $[Ni(CH_2CMe_2Ph)_2(PMe_2Ph)_2]$, which undergoes a rapid δ-hydrogen abstraction reaction.

Complex **3** is fluxional; the room temperature $^{31}P\{^1H\}$ NMR spectrum consists of two broad singlets centred at 4.3 and 0.2 ppm. Upon cooling, the spectrum somewhat narrows, but no coupling between the two anisochronous ^{31}P nuclei can be observed, even at -80°C. These and other observations suggest the existence of a phosphine-exchange process and, as for **1**, the NMR spectra can be explained in terms of an exchange between coordinated and traces of free phosphine, by means of a five-coordinate intermediate species, as shown in Scheme 1. In the $^{13}C\{^1H\}$ NMR spectrum, recorded at 20°C, the two phosphine ligands give well-resolved doublets, and the Ni—CH_2 resonance also appears as a doublet ($^2J_{CP}$ = 16 Hz), as a result of the coupling with only one of the ^{31}P nuclei. These results contrast with those found for **1**, whose room temperature ^{13}C NMR spectrum exhibits a broad



3 **3**

(i) + $\overset{*}{P}Me_2Ph$ (ii) − PMe_2Ph

Scheme 1.

signal for the two PMe_3 ligands and a singlet for the Ni—CH_2 nucleus. It can therefore be concluded that the phosphine exchange process is faster for the PMe_3 derivative **1**. The low value of 16 Hz found for $^2J_{CP}$ is typical of a *cis*-coupling (*trans*-^{13}C–^{13}P coupling constants in complexes of this type have much higher values (*ca* 40–70 Hz), see refs 6 and 13 and the discussion of the NMR spectra of **4**). This suggests that at this temperature the PMe_2Ph ligand *trans* to the Ni—C(alkyl) bond is undergoing fast exchange with traces of free PMe_2Ph via a phosphine association–dissociation process, while for the other coordinated phosphine ligand the rate of exchange is slow on the NMR time scale. These observations are in agreement with the already mentioned higher *trans*-effect of the alkyl group, as compared with the aryl ligand, and are also in accord with the behaviour reported for **1**.[6b] Cooling to −50°C and below causes broadening of the Ni—CH_2 resonance, but the expected doublet of doublets is not observed even at −80°C.

As already indicated, complex **1** undergoes a smooth reaction with dmpe, with complete replacement of the PMe_3 ligands [eq. (3)]. The resulting compound **4** is a highly crystalline material, sparingly soluble in petroleum and diethyl ether, but readily soluble in other common organic solvents. As with the related metallacycles, **1–3**, complex **4** displays high thermal stability, which contrasts with the propensity of complexes of the type [(dmpe)Ni(alkyl)(aryl)] to undergo reductive elimination reactions.[19] The metallacyclic nature of **1–4** is doubtless responsible for this enhanced stability.

In contrast with **1** and **3**, and clearly due to the chelating nature of the dmpe ligand, **4** is a rigid molecule whose structure can be readily deduced from NMR studies. Thus, the $^{31}P\{^1H\}$ NMR consists of an AX pattern (δ_A 26.9, δ_X 34.8, $^2J_{AX}$ 9 Hz), in accord with the existence of two different moieties in the metallacyclic unit. In the ^{13}C NMR spectrum, the methylene group gives rise to the expected doublet of doublets, with *trans* and *cis*, $^2J_{CP}$, coupling constants of 65.8 and 18 Hz, respectively. Similar features are observed for the aromatic quaternary carbon bound to nickel, which also appears as a doublet of doublets.

As discussed above, complex **4** cannot be prepared by direct cyclometallation, but occurs by dmpe replacement of the PMe_3 ligands in **1**. This is not surprising since the putative dialkyl intermediate, [(dmpe)$Ni(CH_2CMe_2Ph)_2$], which can be obtained[20] by addition of dmpe to the unstable tmen derivative [$Ni(CH_2CMe_2Ph)_2$(tmen)],[15] does not metallate by moderate heating (60°C, 4 days, toluene solution). These results are in accord with those found previously by other workers[21] in related platinum systems and may be accounted for by reference to the chelating nature of the dmpe ligand.

EXPERIMENTAL

Microanalyses were carried out by the Pascher Microanalytical Laboratory, Bonn, and the Microanalytical Service of the University of Sevilla. The spectroscopic instruments used were Perkin–Elmer models 557 and 684 for IR spectra and Varian XL-200 for ^1H, ^{13}C and ^{31}P NMR spectra. All preparations and other operations were carried out under oxygen-free nitrogen, following conventional Schlenk techniques. Solvents were dried and degassed before use. The light petroleum used had b.p. 40–60°C. Complex **1** was prepared according to ref. 6.

Synthesis of [$(C_5H_5N)(Me_3P)\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}$] (**2**)

0.34 g of complex **1** (1 mmol) were dissolved in 10 cm^3 of Et_2O and to the resulting solution pyridine (2 cm^3, excess) was added. The mixture was stirred for 2 h at room temperature, during which time it was occasionally exposed to vacuum to remove the replaced PMe_3 from the solution. The solvent was then pumped-off and the residue extracted with Et_2O (25 cm^3). Cooling at −20°C furnished yellow–orange crystals of the desired compound (0.24 g, 70% yield). Found: C, 61.4; H, 7.6; N, 3.8. Calc. for $C_{18}H_{26}NPNi$: C, 62.5; H, 7.5; N, 4.0%. ^1H NMR (C_6D_6, 200 MHz): δ 0.63 (d, J_{HP} = 6 Hz, PMe_3), 1.48 (d, J_{HP} = 11 Hz, Ni—CH_2), 1.82 (s, CMe_2), 6.31–7.29 (m, aromatics). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 13.1 (d, J_{CP} = 19 Hz, PMe_3), 38.9 (d, J_{CP} = 14 Hz, Ni—CH_2), 35.0 (s, CMe_2), 121.4, 123.4, 123.5, 134.3, 134.7, 150.7, 168.1 (aromatics). $^{31}P\{^1H\}$ NMR (C_6D_6): δ −15.0 s.

Reaction of [$(C_5H_5N)(Me_3P)\overline{Ni(CH_2CMe\text{-}o\text{-}C_6H_4)}$] (**2**) *with* PMe_3

To a suspension of [$(C_5H_5N)(Me_3P)\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}$] (**2**) (0.34 g, 1 mmol) in Et_2O (10 cm^3), PMe_3 (0.5 cm^3, 5 mmol, excess) was added and the mixture stirred at room temperature for 2 h. Evaporation of the solvent until a final volume of 2 cm^3 and cooling at −20°C provided 0.28 g of [$(Me_3P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}$].[6] This crystalline material may sometimes contain small amounts of the unreacted pyridine derivative, that can be separated by fractional crystallization or additionally reacted with more PMe_3.

Synthesis of [$(PhMe_2P)_2\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}$] (**3**)

To a stirred suspension of [$NiCl_2(PMe_2Ph)_2$] (1.84 g, 4.5 mmol) in 60 cm^3 of Et_2O, cooled to −30°C, $Mg(CH_2CMe_2Ph)Cl$ was added (7.2 cm^3 of a 1.25 N solution in Et_2O, 9 mmol). The mixture was stirred at low temperature for 15 min and then warmed and stirred at 30°C for an additional 3 h. The solvent was removed *in vacuo* and the residue extracted with a petroleum ether–diethyl ether mixture (20:70 cm^3). After centrifugation, concentration to 30 cm^3 and cooling at −20°C for 10 h, 1 g of the crude product was obtained. This material was purified by extraction with Et_2O and filtration. Partial evaporation of the solvent and cooling at −30°C provided pure samples of the title compound as yellow needles (Yield 40%). Found: C, 67.01; H, 7.32. Calc. for $C_{26}H_{34}P_2Ni$: C, 66.85; H, 7.28%. ^1H NMR (C_6D_6, 200 MHz): δ 0.99 (d, J_{HP} = 15.8 Hz, P—Me), 1.84 (s, CMe_2), 1.95 (d, J_{HP} = 9.3 Hz, Ni—CH_2), 6.9–7.5 (m, aromatics). $^{13}C\{^1H\}$ NMR (THF–CD_3COCD_3): δ 13.8 (d, J_{CP} = 22 Hz, P_A—Me), 16.4 (d, J_{CP} = 21 Hz, P_B—Me), 34.4 (s, CMe_2), 50.8 (d, J_{CP} = 11 Hz, CMe_2), 53.0 (d, J_{CP} = 16 Hz, Ni—CH_2), 119.9, 121.9, 122.2 and 138.4 (s, s, d, J_{CP} = 6 Hz, and s, nickelacycle CH aromatics), 167.0 (s, C_{Ar}—CMe_2), 169.6 (d, J_{CP} = 79 Hz, Ni—$C_{aromatic}$). $^{31}P\{^1H\}$ NMR (THF–CD_3COCD_3): δ 4.3 (s, P_A), 0.2 (s, P_B).

Preparation of [(dmpe)$\overline{Ni(CH_2CMe_2\text{-}o\text{-}C_6H_4)}$] (**4**)

Complex **1** (0.64 g, 1.87 mmol) was dissolved in Et_2O (15 cm^3) and the solution cooled at −20°C. Dmpe (0.37 cm^3, 1.87 mmol) was then added. After stirring at this temperature for a few minutes, a yellow crystalline product precipitated. The mixture was warmed and stirred at room temperature for 30 min, the solvent partially evaporated to half of the initial volume and the resulting suspension cooled to −30°C and filtered. The title compound was obtained in almost quantitative yield. Recrystallization from Et_2O provided yellow crystals of analytical purity. Found: C, 55.8; H, 8.2. Calc. for $C_{16}H_{28}P_2Ni$: C, 56.3; H, 8.2%. ^1H NMR (C_6D_6, 200 MHz): δ 0.91 (d, J_{HP} = 8 Hz, P_A—Me), 1.01 (d, J_{HP} = 7 Hz, P_B—Me), 0.80–1.00 (m, P—CH_2), 1.69 (s, CMe_2), 1.88 (dd, J_{HP_A} = 11 Hz, J_{HP_B} = 3 Hz, Ni—CH_2), 7.2–7.3 (m, aromatics). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 11.9 (d, J_{CP} = 22 Hz, P_A—Me), 13.2 (d, J_{CP} = 15 Hz, P_B—Me), 27.1 (dd, J_{CP_A} = 25 Hz, J_{CP_B} = 20 Hz, P_A—CH_2), 28.6 (dd, J_{CP_B} = 27 Hz, J_{CP_A} = 21 Hz, P_B—CH_2), 35.8 (d, J_{CP} = 5 Hz, CMe_2), 48.3 (dd, J_{CP_A} = 66 Hz, J_{CP_B} = 18 Hz, Ni—CH_2), 51.0 (dd, J_{CP_A} = 9 Hz, J_{CP_B} = 3 Hz, CMe_2), 122.1, 122.2, 123.5 and 140.0 (s, s, s and dd, J_{CP_A} = 14 Hz, J_{CP_B} = 4 Hz, CH aromatics), 167.3 (dd, J_{CP_B} = 85 Hz, J_{CP_A} = 14 Hz, Ni—$C_{aromatic}$), 169.4 (d, J_{CP} = 5 Hz, C_{Ar}—CMe_2). $^{31}P\{^1H\}$ NMR (C_6D_6): δ 26.9 (d, P_A), 34.8 (d, P_B, J_{PP} = 9 Hz).

Structure solution and refinement

The crystal data and the parameters used during the collection and refinement of the diffraction data are summarized in Table 1. A yellow crystal was coated with an epoxy resin and mounted on the diffractometer. The cell dimensions were refined by a least-squares fit of the θ values of 25 reflections. There was appreciable change in the periodically monitored standard reflections because the crystal became damaged by radiation. The intensities were corrected for decay and for Lorentz and polarization effects.

Scattering factors for neutral atoms and anomalous dispersion corrections for nickel and phosphorus were taken from the *International Tables for X-ray Crystallography*.[22]

The structure was solved by Patterson and Fourier methods, and an empirical absorption correction[23] was applied at the end of the isotropic refinement.

The final refinement was made with anisotropic thermal motion for the non-hydrogen atoms and fixed isotropic temperature factors and calculated coordinates for hydrogen atoms.†

Most of the calculations were carried out with *XRAY80* system.[24]

(*Received* 19 *September* 1988; *accepted* 10 *November* 1988)

Abstract—The crystal and molecular structure of the $[Cu(BPCA)(OH_2)(O_2CCH_3)]\cdot H_2O$ complex (BPCA = *N*-2-pyridinylcarbonyl-2-pyridinecarboximidate anion) has been determined by X-ray diffraction methods. It crystallizes in the triclinic space group $P\bar{1}$ with two formula units in a cell of dimensions: $a = 7.416(2)$, $b = 8.632(4)$, $c = 13.034(3)$ Å, $\alpha = 74.55(3)$, $\beta = 84.84(3)$, $\gamma = 81.04(5)°$. Least-squares refinement of 2534 reflections with $I > 2.5\sigma(I)$ and 218 parameters gave a final $R = 0.047$ and $R_w = 0.049$. The structure consists of discrete $[Cu(BPCA)(OH_2)(O_2CCH_3)]$ neutral units linked through hydrogen bonding. The coordination geometry around copper ions can be described as tetragonal square pyramidal, the oxygen atom from the coordinated water molecule occupying the axial position. The compound loses both coordinated and lattice water upon heating, and quickly rehydrates to the initial form when it cools down to room temperature. The powder X-band ESR spectra of both the hydrated and the anhydrous forms exhibit the $\Delta M_s = 2$ absorption, indicating magnetic exchange between two copper(II) ions. The nature of this coupling is discussed on the basis of the structural features.

In the course of our study of the interactions between copper(II) and easily stackable ligands,[1] we have recently reported the synthesis and characterization of a set of copper(II)–BPCA (BPCA = *N*-2-pyridinylcarbonyl-2-pyridinecarboximidate anion) complexes which include di- and polynuclear species.[2,3] BPCA is a tridentate rigid quasi-planar N-donor ligand whose monoanionic character makes it different from other related ligands like terpy (2,2′:6′,2″-terpyridine), paphy (pyridine-2-aldehyde-2′-pyridyl hydrazone), or TPT [2,4,6-tris(2-pyridyl)-1,3,5-triazine].[1–5] This renders possible the isolation of neutral Cu(BPCA)X entities (X = monoanion). When X is a potentially bridging ligand, condensed systems may result.[2,3] Such an ability is well established for simple carboxylates,[6] and we have analysed it in the copper(II)–terpy system.[7] To progress on this subject, we are now approaching the study of the interactions between carboxylate monoanions and the $[Cu(BPCA)]^+$ entities. In this work we present the results concerning the Cu(BPCA)–acetate system.

EXPERIMENTAL

Preparation of $[Cu(BPCA)(OH_2)(O_2CCH_3)]\cdot H_2O$

A blue solution of $Cu(O_2CCH_3)\cdot 2H_2O$ (1 mmol) in water (12 cm^3) was mixed while stirring with a

* Author to whom correspondence should be addressed.

colourless solution of TPT (1 mmol) in ethanol (10 cm^3). The deep green colour of the resulting solution is consistent with the formation of a copper(II)–TPT complex.[5] This solution was heated to gentle boiling and became blue after *ca* 1 h, thus indicating TPT hydrolysis and consequent formation of $[Cu(BPCA)]^+$ entities.[2] The solution was allowed to stand at room temperature and dark blue crystals appeared after several days. These were separated by filtration, washed with small portions of cold ethanol and stored in a desiccator over silica gel. Found: C, 44.0; H, 4.0; Cu, 16.5; N, 11.0. Calc. for $C_{14}H_{15}CuN_3O_6$: C, 43.7; H, 3.9; Cu, 16.5; N, 10.9%.

Physical measurements

IR spectra were obtained on KBr pellets in the 4000–250 cm^{-1} region using a Pye Unicam SP 2000 spectrophotometer. Diffuse reflectance electronic spectra were recorded on a Perkin–Elmer Lambda 9 UV/VIS/NIR spectrophotometer. ESR spectra were recorded on a Bruker ER 200D X-band spectrometer equipped with a variable temperature device. Water was determined thermogravimetrically using a Setaram B70 simultaneous TGA–DTA thermobalance. X-Ray powder diffraction patterns ($2° < 2\theta < 50°$) were performed in a Kristalloflex 810 Siemens diffractometer, equipped with a variable temperature device, using Cu-K_α radiation and silicon powder as internal reference.

Crystallographic study

Crystal data. Blue prismatic crystals of $C_{14}H_{15}CuN_3O_6$, M = 384.5, triclinic, space group $P\bar{1}$, $a = 7.416(2)$, $b = 8.632(4)$, $c = 13.034(3)$ Å, $\alpha = 74.55(3)$, $\beta = 84.84(3)$, $\gamma = 81.04(5)°$, $V = 793.4(9)$ $Å^3$, $Z = 2$, $D_c = 1.609$ g cm^{-3}, $F(000) = 390$, μ(Mo-K_α) = 13.8 cm^{-1}.

Data collection. A well formed crystal of dimensions $0.16 \times 0.18 \times 0.20$ mm was selected and mounted on an Enraf–Nonius CAD-4 diffractometer equipped with a graphite monochromator. The cell dimensions were obtained by least-squares refinement of 25 well-centred reflections ($14° < 2\theta < 27°$) using Mo-K_α radiation ($\lambda = 0.70926$ Å). The space group $P\bar{1}$ was assumed throughout the structure analysis and was confirmed by the successful refinement of the structure. Examination of four standard reflections, monitored after each 50 reflections, showed no substantial intensity decay. A total of 2926 reflections were measured ($2° < 2\theta < 50°$; $-8 < h < 8$, $-10 < k < 10$, $0 < l < 15$) with the variable-speed ω–2θ technique, of which 2534 were unique with $I > 2.5\sigma(I)$ and used in the determination of the structure. Lorentz and polarization corrections were applied, but not for absorption.

Structure solution and refinement. The position of copper and 14 non-hydrogen atoms were obtained by direct methods (*MULTAN* 11/84).[8] The remaining non-hydrogen atoms were located from subsequent Fourier syntheses. The model obtained was refined with the *SHELX76* system[9] by weighted anisotropic full-matrix least-squares methods. After refinement of positional and anisotropic thermal parameters for all non-hydrogen atoms, difference maps indicated the positions of all the hydrogen atoms (excepting one associated to one water molecule and another associated to the BPCA ligand), and were included in the final refinement with common fixed isotropic thermal parameters ($U = 0.075$ $Å^2$). The final R values were $R = 0.047$ and $R_w = 0.049$ (218 parameters refined); $\Sigma w(|F_o| - |F_c|)^2$ was minimized, where $w = 1/[\sigma^2(F_o) + 0.028834(F_o^2)]$ with $\sigma^2(F_o)$ from counting statistics. In the final difference map the residual maxima were less than 0.65 e $Å^{-3}$. Atomic scattering factors and corrections for anomalous dispersion for the copper atom were taken from ref. 10. The geometrical calculations were performed with *XANADU*[11] and *DISTAN*[12] and molecular illustrations were drawn with *PLUTO*.[13] Final atomic coordinates, thermal parameters and F_o/F_c values have been deposited with the Editor as supplementary data.

RESULTS AND DISCUSSION

Crystal structure

Figure 1 shows a perspective view of the molecule with the atomic numbering scheme, and Fig. 2 shows a view of the crystal packing in the solid. Selected bond distances and angles are listed in Table 1. The coordination sphere of copper(II) is best described as a tetragonal square pyramid. The basal positions are occupied by the three nitrogen atoms from the BPCA ligand and one oxygen atom from the monodentate acetate anion, while the apical position is occupied by the oxygen atom from the coordinated water molecule. The Cu—N bond distances, ranging from 1.947 to 2.000 Å, are very similar to those found in the Cu(BPCA)Br and other copper(II) complexes with related *N*-heterocyclic ligands,[1,2] while the Cu—O(basal) and the Cu—O(apical) bond distances are 1.942(2) and 2.338(3) Å, respectively. The four basal atoms are coplanar within ±0.01 Å, and the copper atom is

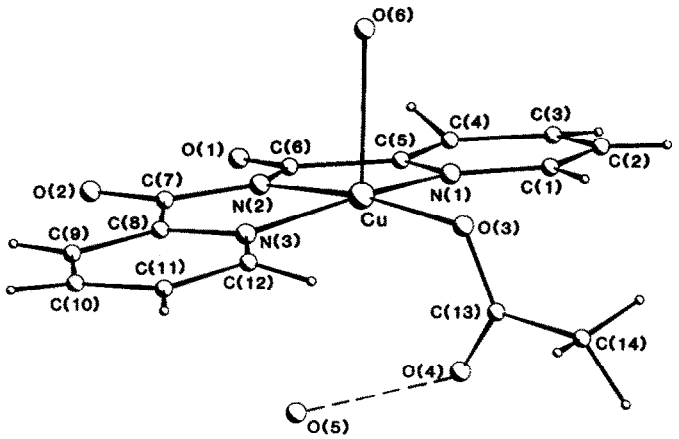

Fig. 1. Perspective view of [Cu(BPCA)(O$_2$CCH$_3$)(OH$_2$)]·H$_2$O with atomic numbering.

displaced 0.15 Å above the mean plane. The plane defined by the Cu, O(3) and O(6) atoms makes an angle of 87.4° with the basal plane. If the second oxygen atom of the acetate group is considered as "semicoordinated" [Cu—O(4) = 2.790(3) Å], the environment of the copper(II) could be described as an elongated and strongly distorted octahedron because the O(3)—Cu—O(4) angle is 51.4(1)°. This kind of coordination has been also found in other carboxylate, nitro and nitrite copper(II) complexes.[7,14–16] Otherwise, the oxygen atom of the second water molecule is located 3.506(4) Å below

the copper(II) atom in the apical direction. Owing to this rather large distance, the second water molecule could not be considered coordinated to the copper atom.

The BPCA ligand is nearly planar (within ±0.12 Å), although if the two pyridinylcarbonyl halves are viewed separately, the respective deviations from planarity are less then 0.04 Å, with their mean planes making an angle of 6.6°. Another feature to note in the conformation of the BPCA ligand is the values of the angles around the carbon atoms involved in the carbonyl groups (see Table 1). As previously noted,[17] the need for short copper–nitrogen bonds introduces such a large angular strain.

As the contact distances shown in Table 1 indicate, the crystal packing is achieved by intermolecular hydrogen bonding. Indeed, the non-coordinated water molecule is hydrogen bonded to oxygen atoms [O(4) and O(4)‴] from two acetate groups (related by an inversion centre) belonging to adjacent molecules (see Fig. 2). On the other hand, the coordinated water molecule is hydrogen bonded simultaneously to two [O(1)′ and O(2)′] and one [O(2)″] carbonyl-oxygen atoms from two different BPCA ligands (see Table 1). Therefore, it is to be noted that this extended hydrogen bonding network gives rise to a lamellar structure. Thus, every pair of [Cu(BPCA)(O_2CCH_3)] entities linked through the coordinated water molecules yields a double layer unit which, in turn, is interconnected with the adjacent ones by means of the hydrogen bonds involving the non-coordinated water molecules. Then a sequence of alternate H_2O and [Cu(BPCA)(O_2CCH_3)] layers result.

Vibrational and electronic spectra

Concerning the IR bands due to BPCA ligand, we note the presence of a strong band assignable to the ν(C=O) vibrations of the imide group located at 1710 cm^{-1}, which agrees with that observed for other Cu^{II}–BPCA derivatives.[2] Between 3200 and 3700 cm^{-1} there appears a relatively broad and medium-intensity absorption showing well defined maxima at 3430 and 3500 cm^{-1} and a shoulder at 3300 cm^{-1}. These bands can be assigned to the O—H stretching vibrations of hydrogen-bonded, not clustered, water molecules.[18] Bands corresponding to $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ from the acetate group are identified at 1590 and 1415 cm^{-1}, respectively, in spite of the complexity of the vibrational spectrum or BPCA in the 1200–1700 cm^{-1} region.

The reflectance electronic spectrum exhibits one broad unresolved band in the visible region with

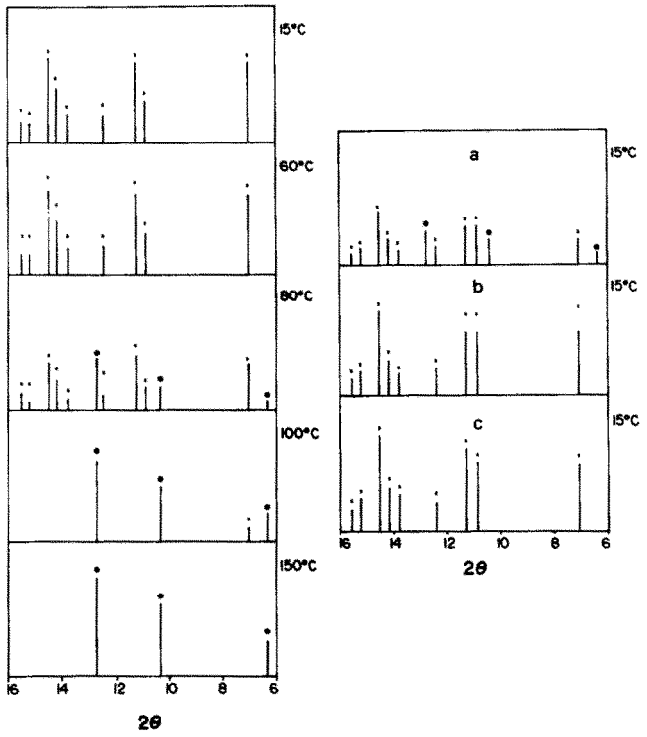

Fig. 3. Temperature variation of polycrystalline powder X-ray patterns of [Cu(BPCA)(O$_2$CCH$_3$)(OH$_2$)]·H$_2$O (left), and time variable polycrystalline powder X-ray patterns of [Cu(BPCA)(O$_2$CCH$_3$)] at (a) $t = 0$, (b) $t = 5$ min and (c) $t = 10$ min (right). the maximum in the absorption envelope located near 16,200 cm^{-1}, in agreement with the geometry of the [CuN$_3$OO'] chromophore.[19]

Dehydration–rehydration processes

An unexpected result is that concerning the thermal behaviour of the title compound. In fact, TGA–DTA curves show a single endothermic dehydration step (peak temperature = 115°C) in which two water molecules per mol of complex are evolved in a single step. Moreover, variable temperature X-ray powder diffraction patterns (Fig. 3) do not show the formation of any crystalline intermediate phase between the starting [Cu(BPCA)(OH$_2$)(O$_2$CCH$_3$)]·H$_2$O complex and the resulting anhydrous product. On the other hand, the anhydrous phase quickly rehydrates at room temperature to give again the initial phase (Fig. 3). Thus it seems that the reversible equilibrium

$$[Cu(BPCA)(OH_2)(O_2CCH_3)]\cdot H_2O(s) \overset{\Delta T}{\rightleftharpoons} [Cu(BPCA)(O_2CCH_3)](s) + 2H_2O(g)$$

would occur through a concerted process in whose evolution it is not possible to discern non-coordinated and coordinated water molecules.

The X-ray powder diffraction pattern of the anhydrous derivative can be indexed[20] to a triclinic cell of dimensions $a = 6.38(4)$, $b = 8.80(8)$, $c = 14.26(8)$ Å, $\alpha = 85.0(6)$, $\beta = 91.8(7)$, $\gamma = 88.9(3)°$, $V = 797(1)$ Å^3. The main changes with respect to the initial cell are observed in the *ac* plane, in accordance with the directionality of the hydrogen bonding network. At this stage, it would be unreliable to argue about the actual structure evolution. Notwithstanding, given that dehydration occurs without appreciable colour change, it may be thought that the copper(II) environment remains essentially "4+1" in the anhydrous phase. This might be achieved through the apical coordination of the O(4) oxygen atom from the acetate group (see below), although the formation of acetate bridges could not be fully excluded *a priori*. Nevertheless, this last possibility seems unlikely because of the great structural changes required and the easiness of water displacement.

In short, such a pseudo-topotactic reversible water dissociation could be described as an acid–base intercalation reaction in the interlayer space of the [Cu(BPCA)(O$_2$CCH$_3$)] host lattice.

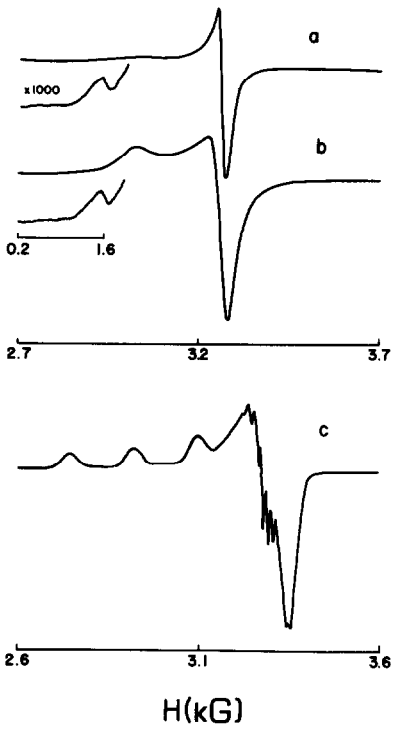

Fig. 4. X-Band ESR spectra of (a) polycrystalline powder samples of $[Cu(BPCA)(O_2CCH_3)(OH_2)]\cdot H_2O$, (b) $[Cu(BPCA)(O_2CCH_3)]$, and (c) frozen solution (ethanol, 125 K) of $[Cu(BPCA)(O_2CCH_3)(OH_2)]\cdot H_2O$.

ESR spectroscopy

X-Band ESR spectra of polycrystalline $[Cu(BPCA)(OH_2)(O_2CCH_3)]\cdot H_2O$ samples show axial-type signals which remain unchanged from room temperature down to 125 K [Fig. 4(a)]. The resulting g values ($g_\parallel = 2.23$, $g_\perp = 2.06$) indicate a mainly copper(II) $d_{x^2-y^2}$ orbital ground state, which agrees with the above statements. The spectra show also a weak absorption at half field value associated to a $\Delta M_s = 2$ forbidden transition. This implies a magnetic interaction between two copper(II) ions. Most dimeric copper(II) complexes of known structure, exhibiting exchange interactions, contain a bridging atom or group of atoms through which a magnetic interaction may be propagated. However, a few examples have been recently reported where the exchange pathway must be considered as purely dipolar ("through space") in origin.[21,22] In our case, the "dimeric spectra" could be then understood on the basis of two potential interaction pathways: (i) a "through space" dipolar path, and (ii) a superexchange path through an extended bridging network involving the hydrogen bonded water molecules. Actually, the possibility of the propagation of the magnetic exchange between copper(II) ions through hydrogen bond frameworks has been previously shown.[1,23] From the hydrogen bonding scheme in Table 1 it might be thought of three possible superexchange dimeric pathways connecting Cu—Cu′, Cu—Cu″ and Cu—Cu‴, which involve spin–spin distances of 6.75, 7.42 and 8.28 Å, respectively (the symmetry relations are indicated in Table 1). The only additional pair involving a comparable copper–copper distance (6.93 Å) is the Cu—Cu^{iv} (Cu^{iv} is generated from Cu after $-x, -y, 2-z$). In any case, the Cu—Cu′ pair shows both the shortest intermetallic distance and a simple hydrogen bonding network. Accordingly, it is reasonable to assume that the interaction in this pair causes the $\Delta M_s = 2$ signal.

On the other hand, the ESR spectrum of the anhydrous form $[Cu(BPCA)(O_2CCH_3)]$ [Fig. 4(b)], also shows the weak intensity $\Delta M_s = 2$ absorption. Besides, this spectrum is axial and leads to g values identical to those corresponding to the hydrated form. Whereas this last observation is clearly consistent with the above statement on the "4+1" copper(II) coordination mode in the anhydrous form, it is evident that now the magnetic exchange cannot proceed through any hydrogen bonding network. In this case, a "through space" dipolar path would be the only way to propagate the magnetic interaction if, as suggested above, dimerization through acetate bridges does not occur.

Finally, the $[Cu(BPCA)(OH_2)(O_2CCH_3)]\cdot H_2O$ solution ESR spectra (nitromethane, ethanol, chloroform) do not show signs of coupling apart from the copper and nitrogen hyperfine structure. The room temperature spectrum yields isotropic $g = 2.11$ and $A(Cu) = 0.0074$ cm^{-1} parameters. The frozen-solution spectrum (ethanol or chloroform, 125 K) shows an axial signal [Fig. 4(c)] leading to $g_\parallel = 2.24$, $g_\perp = 2.06$ ($g_{ave} = 2.12$). The copper hyperfine splitting in the $g_\parallel$ part is well defined yielding $[A_\parallel(Cu)] = 0.018$ cm^{-1}, whereas the $[A_\perp(Cu)]$ is not resolved, although it can be estimated to be less than 0.0025 cm^{-1}. On the $g_\perp$ component, a seven line superhyperfine structure due to the three nitrogen atoms from BPCA ligand is detected. This structure is also present but poorly resolved in the high-field hyperfine component of $g_\parallel$. Since the principal direction of the superhyperfine ^{14}N tensor is along the Cu—N bond, we can estimate values of $A_\parallel(^{14}N) = 0.0016$ cm^{-1} and $A_\perp(^{14}N) = 0.0011$ cm^{-1}. According to the literature,[24] all these values are those expected for a monomeric copper(II) complex with a basically $d_{x^2-y^2}$ orbital ground state.

In the light of these results, the determination of the structure of the anhydrous species becomes a very interesting challenge because this compound might constitute one of the scarce examples of pair-

wise dipolar coupling in copper(II) systems. In this sense, new experiments on the structure and the Lewis acid–base intercalation chemistry in the [Cu(BPCA)(O$_2$CCH$_3$)] host lattice are in progress.

(*Received* 21 *July* 1988; *accepted* 11 *November* 1988)

Abstract—New complexes with an Rh—Hg bond of the type $RhX(HgX)(pyC)PR_3$ (**A**) and $RhCl(HgPh)(pyC)(CO)(PR_3)$ (**A′**) (X = Cl, Br, I; pyC = 2-C_5NH_4COO; R = 4-$CH_3OC_6H_4$, 4-$CH_3C_6H_4$, 4-FC_6H_4, 4-ClC_6H_4) have been prepared by the reaction of $Rh(pyC)(CO)(PR_3)$ with HgX_2 (X = Cl, Br, I) and PhHgCl.

The reactivity of the above bimetallic derivatives towards $SnCl_2$ yielding new complexes with Hg—Rh—Sn bonds is also reported.

Synthetic and structural aspects of the chemistry of complexes containing bonds between dissimilar metal atoms are of continuing interest.[1,2] In particular, the reactions of mercury(II) compounds with complexes of transition metals have been extensively studied[2] and different types of reactions have been found. Thus, when the transition metal complex is an electron-rich one, a donor–acceptor complex with mercuric derivatives is usually formed.[3–5] However, when the transition metal complex is less nucleophilic and amenable to oxidation, oxidative addition products were obtained. For this reason, Vaska's complex is easily oxidized by mercury(II) halides or pseudohalides,[6] but a similar reaction does not occur for analogous Rh^I complexes.

Nevertheless, a series of Rh—Hg bonded compounds has been prepared by oxidation of $RhCl(CO)(L)_2$ complexes with $HgCl_2$, with more basic ligands than PPh_3, such as L = PPh_2Et, PPh_2Pr^i, L_2 = Ph_2PCH_2SPh and $Ph_2PCH_2CH_2SPh$.[7] Recently, the reactivity of $HgCl_2$ towards binuclear rhodium–rhodium complexes was studied yielding new compounds with Rh—Hg—Rh bonds.[7,8]

In previous work,[9] we have reported the high basicity of the $Rh(pyC)(CO)(PR_3)$ complexes in their reactions with I_2, Br_2 and ICH_3. Herein we report the analogous reactions with Hg^{II} derivatives HgX_2 (X = Cl, Br, I) and PhHgCl, to form six-coordinated Rh^{III} complexes, $RhX(HgX)(pyC)(CO)(PR_3)$ (**A**; **I–XII**) and $RhCl(HgPh)(pyC)(CO)(PR_3)$ (**A′**; **XIII–XVI**) with HgX and X or HgPh and Cl as the additional ligands. It is noteworthy that for Rh^I complexes containing N—O ligands, only one related compound, Rh(moq)(CO)[P(4-$CH_3C_6H_4)_3$]$HgCl_2$ has been described.[10]

In the second part of this study we have synthesized trimetallic complexes, $Rh(SnCl_3)(HgCl)(pyC)(CO)(PR_3)$ (**B**; **XVII–XX**) and $Rh(SnCl_3)(HgPh)(pyC)(CO)PR_3$ (**B′**; **XXI–XXIV**), by insertion reactions of $SnCl_2$ in the above Rh—Hg complexes.

EXPERIMENTAL

IR spectra were recorded on a 1300 Perkin–Elmer spectrophotometer (over the 4000–200 cm^{-1} range) with KBr pellets.

* For part I, see ref. 9.

† Author to whom correspondence should be addressed.

Conductance measurements were performed in $\sim 3 \times 10^{-4}$ M acetone solution with a Philips PR 9500 conductimeter. Analyses (C, H, N) were carried out by Elemental Microanalyses Laboratories Ltd (Devon, England). ^{31}P-NMR spectra were recorded on a Varian XL-200 spectrometer at room temperature using 85% H_3PO_4 as the external standard. The reactions were carried out normally at room temperature.

Complexes of Rh(pyC)(CO)(PR_3) were prepared by our published methods.[9] The solvents were distilled before use. The other reagents were commercially obtained.

RhCl(HgCl)(pyC)(CO)(PR_3)·$2HgCl_2$ (R = 4-$CH_3OC_6H_4$, 4-$CH_3C_6H_4$, 4-FC_6H_4, 4-ClC_6H_4) *complexes* (**I–IV**)

A slight excess over the Rh/Hg (1 : 3) stoichiometric ratio of mercury(II) chloride was added to an acetone solution (15 cm^3) of the corresponding Rh(pyC)(CO)(PR_3)[9] (0.1 mmol) complex. The starting yellow solution immediately changed to a deep yellow colour. The stirring was continued for 5 min. Addition of cold Et_2O lead to the complete precipitation of the yellow complex, which was filtered off, recrystallized from CH_2Cl_2/Et_2O (10 : 20 cm^3), washed with acetone–diethylether and dried *in vacuo* (yield, $\sim$ 75%).

The analogous compounds, RhBr(HgBr)(pyC)(CO)(PR_3)·$HgBr_2$ (**V–VIII**), were prepared by a procedure similar to the above. In these cases the time of reaction changes depending on the phosphine ligand and it is 6 to 10 h for P(4-$CH_3OC_6H_4)_3$ and P(4-$ClC_6H_4)_3$, respectively.

RhI(HgI)(pyC)(CO)(PR_3)·HgI_2 (R = 4-$CH_3OC_6H_4$, 4-$CH_3C_6H_4$, 4-FC_6H_4, 4-ClC_6H_4) *complexes* (**IX–XII**)

In these cases, the reaction occurred in absolute ethanol (10 cm^3) and the mixture was stirred for 24 h, at room temperature in darkness. The solvent was reduced to *ca* 2 cm^3 and cooled light petroleum (15 cm^3) was added. The orange precipitate was filtered off, washed with ethanol (5 cm^3) and dried *in vacuo* (yield, 60%).

RhCl(HgPh)(pyC)(CO)(PR_3) (R = 4-$CH_3OC_6H_4$, 4-$CH_3C_6H_4$, 4-FC_6H_4, 4-ClC_6H_4) *complexes* (**XIII–XVI**)

Rh(pyC)(CO)(PR_3)[9] (0.15 mmol) was dissolved in ethanol (20 cm^3), and PhHgCl (0.45 mmol) was added. The solution was stirred and refluxed for 15 min. It was then filtered through Kieselguhr, to eliminate the metallic mercury forming during the reaction. The solvent was removed and the crude solid was recrystallized from dichloromethane–light petroleum giving a yellow solid (yield, 92%).

Rh($SnCl_3$)(HgX)(pyC)(CO)(PR_3) (R = 4-CH_3OC_6H, 4-$CH_3C_6H_4$, 4-FC_6H_4, 4-ClC_6H_4, X = Cl, Ph) *complexes* (**XVII–XXIV**)

A slight excess ($\sim$ 10%) of $SnCl_2$ was added to an acetone solution of the corresponding bimetallic compound (**I–IV** and **XIII–XVI**). Immediately the colour changed from yellow to red–orange. The solution was stirred for 5 min, then the solvent was removed and the solid was dissolved in dichloromethane (10 cm^3) and reduced in volume to 5 cm^3. Addition of cold light petroleum (10 cm^3) gave, quantitatively, the orange solid, which was recrystallized from acetone–diethylether (1 : 2). The Rh($SnBr_3$)(HgBr)(pyC)(CO)(4-$CH_3OC_6H_4$) complex is prepared by a procedure similar to the above, by addition of $SnBr_2$ to the RhBr(HgBr)(pyC)(CO)(4-$CH_3OC_6H_4$) complex.

RESULTS AND DISCUSSION

Reactions of Rh(pyC)(CO)PR_3 *complexes with* HgX_2 (X = Cl, Br, I) *and* ClHgPh

In contrast to the lack of reaction of $HgCl_2$ with *trans*-RhCl(CO)($PRh_3)_2$[6,7] in acetone, solutions of the Rh(pyC)(CO)(PR_3) complexes reacted with HgX_2 to form by oxidative addition, the RhX(HgX)(pyC)(CO)(PR_3) (**A**) complexes (**I–XII**) (Table 1).

The reaction is complete only when a Rh/Hg molar ratio of 1 : 3 or higher is employed. The compounds are air-stable for long periods, but show very low solubility in the most common solvents, in which partial decomposition to Hg^0 and decarbonylated products is observed. The conductivity measurements of freshly prepared acetone solutions are consistent with the neutral character of the compound (Table 1).

Analogous reactions with PhHgCl were carried out in refluxing ethanol under nitrogen atmosphere for short reaction times. New yellow microcrystalline products were obtained and characterized as the oxidative addition complexes, RhCl(HgPh)(pyC)(PR_3) (**A′**, **XIII–XVI**) (Table 1). These compounds are air-stable, soluble in common organic solvents, and non-electrolytic in acetone solution.

The IR spectra of all complexes of type (**A**) and (**A′**) (Table 2) exhibit a strong band in the carbonyl stretching region, 2075–2033 cm^{-1}. This band is shifted $\sim$ 100–70 cm^{-1} towards higher frequencies, with respect to the parent compounds,[9]

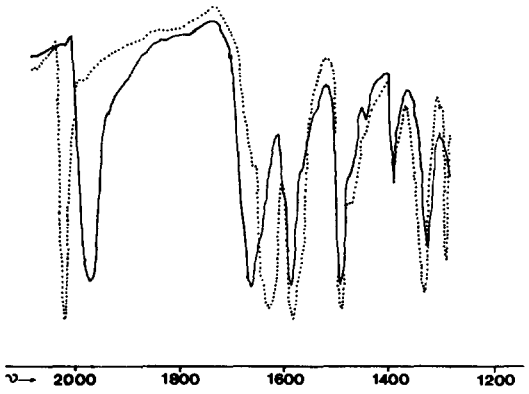

Fig. 1. IR spectra of: ——, Rh(pyC)(CO)[P(4-$FC_6H_4)_3$]; ···, RhCl(HgCl)(pyC)(CO)[P(4-$FC_6H_4)_3$]·$2HgCl_2$.

and is consistent with a carbonyl ligand in an oxidized Rh^{III} complex. An example is shown in Fig. 1.

The presence of a single sharp $\nu(C{\equiv}O)$ absorption seems to point to the presence of only one isomer in the solid state. It can be reasonably argued that the isomer obtained comes from the *trans* addition of the X and HgX groups to the square-planar Rh(pyC)(CO)(PR_3) complexes,[9] as a result of the considerable bulkiness of these groups.[11]

However, for the *trans* oxidative addition of PhHgCl, two isomers are possible depending upon the dissociation of the organomercuric derivative in HgCl and Ph or HgPh and Cl, respectively. A possible explanation is considered below.

In the lower frequency region, the addition products with $HgCl_2$ (**I–IV**) exhibit three new bands with respect to monocarbonyl starting compounds (Table 2). A band at *ca* 370 cm^{-1}, assigned to ν(Hg—Cl), is attributed to the presence of additional lattice molecules of $HgCl_2$ in the compounds.[3,12–15]

The bands at *ca* 300 and 260 cm^{-1}, are consistent with ν(metal–halogen) vibrations. In a tentative assignment it is possible to consider the band at 260 cm^{-1} as due to the ν(Hg—Cl) of HgCl group bonded to transition metal, while the band at *ca* 300 cm^{-1} is attributed to the ν(Rh—Cl). A value of ~ 300 cm^{-1} for ν(Rh—Cl) vibration is also found in Rh^{III} complexes.[16,17] On the other hand, in hexacoordinate Ir^{III} halocomplexes[18] it has been shown that the ν(Ir—Cl) is only modified by the nature of the ligand *trans* to the halogen, the influence of the *cis* ligands being negligible.

If the above assignment for ν(Rh—Cl) is correct, the value of these vibrations is only very slightly modified for the different phosphine ligands, the assignment would be consistent with the above proposed *trans* addition of the groups HgCl and Cl to the parent compounds.

The assignment of metal–halogen vibration bands for the derivatives with PhHgCl is complicated by the numerous bands which appear in this region. However, it is noteworthy that absorption at ~ 260 cm^{-1} attributed to ν(Hg—Cl) is absent in all cases.

As expected, the derivatives with $HgBr_2$ and HgI_2 did not show bands in the region studied above.

The presence of the asymmetric ν(OCO) band (1670–1625 cm^{-1}) and the corresponding symmetric ν(OCO) band (1345–1330 cm^{-1}) show that the carboxylic group would be monodentate for all the above-mentioned complexes, as it is in the parent compounds.[9,19,20]

A shift of the asymmetric ν(OCO) band by *ca* 30–15 cm^{-1} towards the lower frequency region, with respect to the parent compounds, is observed for derivatives with HgX_2 (X = Cl, Br, I) (**I–XII**). This result may be due to interactions with the additional mercury halide molecules through the free oxygen of the carboxylate group. Figure 1 shows this shift in the IR spectra of the Rh(pyC)(CO)[P(4-$FC_6H_4)_3$] complex.

Reactions of RhCl(HgCl)(pyC)(CO)(PR_3) *and* RhCl(HgPh)(pyC)(CO)(PR_3) *with* $SnCl_2$

We have synthesized trimetallic complexes of composition Rh($SnCl_3$)(HgCl)(pyC)(CO)(PR_3) (**B**, **XVII–XX**) and Rh($SnCl_3$)(HgPh)(pyC)(CO)(PR_3) (**B′**, **XXI–XXIV**) (Table 1).

The insertion reactions of $SnCl_2$ in haloorganometallic complexes provide a useful method for the synthesis of M—Sn compounds.[21]

For the above Rh—Hg compounds (**A** and **A′**) we have proposed a *trans* disposition of groups HgX and X in which two kinds of M—halogen bonds (M = Rh, Hg) are present. First of all the insertion of $SnCl_2$ should be possible in both kinds of bonds, however, we have no previous evidence of this insertion into the Hg—X bond.[21]

The new compounds are yellow–orange solids, air-stable, and sparingly soluble in common organic solvents. Analytical data and some of their properties are listed in Table 1.

The IR spectra (Table 2) show only a carbonyl band whose position is not substantially different from that of the parent complexes. This fact suggests that the addition of $SnCl_2$ does not appreciably modify the rhodium oxidation state. On the other hand, the ν_{as}(OCO) band is shifted *ca* 50 cm^{-1} towards the higher frequency region, with respect to the mercuric derivatives, coming back to an analogous position to the starting Rh^{I} derivatives. This fact is consistent with the absence of interactions between the carboxylic group and the mercury of

the additional molecules which are not present in **B** and **B′** compounds. An example of this behaviour is illustrated in the IR spectra of Fig. 2.

In the low frequency region some other differences are also observed. One broad band, centred at 330 cm^{-1}, is tentatively assigned to the sum of asymmetric and symmetric ν(Sn—Cl) vibrations of the $SnCl_3$ group. This value is similar to that found for ν(Sn—Cl) in the $Ir(SnCl_3)(HgCl)(CO)(PR_3)$[22,23] complex. One other band appears as a shoulder at *ca* 298–290 cm^{-1}. This value is not substantially different from those ν(Hg—Cl) of the above **A** complexes.

Based on these observations, it is reasonable to formulate the **B** and **B′** complexes as the products of the hypothetical oxidative addition of $SnCl_3$ and HgCl or HgPh groups to the $Rh(pyC)(CO)(PR_3)$ complexes. This interpretation is also supported by the linear relation between ν(C≡O) and the sum of the electron affinities of both groups (Table 3).

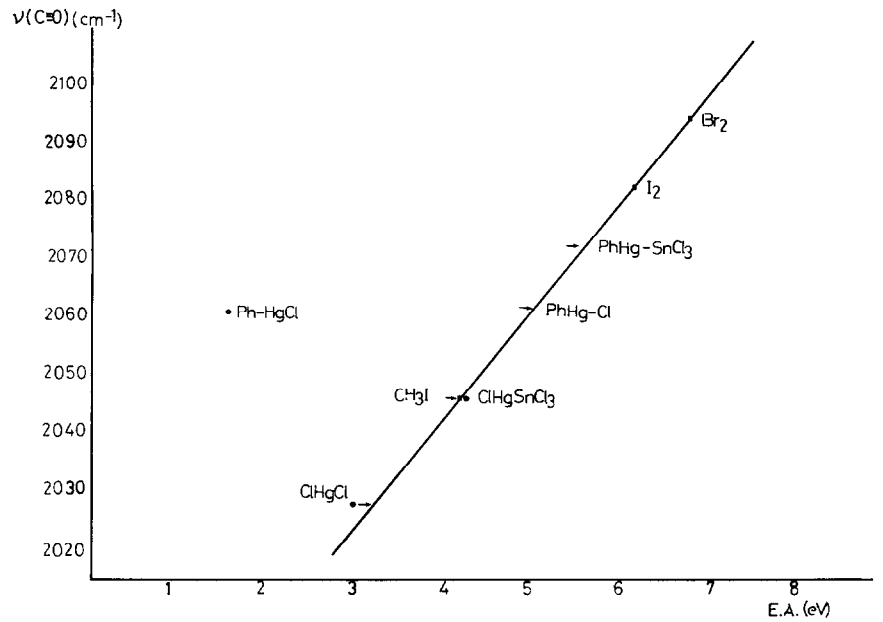

Fig. 3. Linear relation between the ν(C≡O) and the sum of electron affinities values given in Table 3.

Vaska[24] found a singular behaviour of the ν(CO) frequencies on oxidative addition of X—Y molecules, when the addition occurs with breaking of the X—Y bond to form *trans* adducts.[23] For these reactions a linear correlation between the sum of electron affinities (EA) of X and Y and the ν(CO) was found. Using this correlation, Pregosin *et al.*[23] estimated the EAs of $HgCl^+$ and $SnCl_3^-$ groups based on the ν(C≡O) of $IrCl_2(HgCl)(CO)(PPh_3)_2$ and $IrH(SnCl_3)Cl(CO)(PPh_3)_2$, giving values of −0.61 and 4.80 eV, respectively. The sum of these values compares favourably with the estimated values obtained by us in the **B** and **B′** complexes by the correlation shown in Fig. 3.

Also, the sum of the values for electron affinities of HgCl and Cl in the Pregosin complexes, is in good accordance with those estimated by us for the complexes of type **A**. In the same way, the behaviour of the ν(CO) for the addition complexes with PhHgCl is consistent with the addition of PhHg and Cl groups to the rhodium. These facts also support the view that the suggested *trans* addition of (Cl)(HgCl) and (PhHg)(Cl) groups to the complexes $Rh(pyC)(CO)(PR_3)$ really occurs.

The reaction products with $SnCl_2$ can similarly be formulated as the result of a *trans* addition of hypothetical $ClHgSnCl_3$ or $PhHgSnCl_3$ species to the rhodium(I) starting complexes.

^{31}P-*NMR*

The ^{31}P-NMR spectra are a source of information about the coordinated phosphorus ligands. The chemical shifts,[25] and especially, the *J*(Rh—P) coupling constants, are very sensitive to electron density variations on the rhodium atom.

We have recorded the ^{31}P-NMR of Rh(pyC)(CO)(PR_3) complexes in Cl_3CD and C_6D_6, and the data are given in Table 4.

In the case of oxidative addition products with $HgCl_2$, the very low solubility prevents the utilization of this technique, however, we have some results for the complexes with PhHgCl, $HgBr_2$ and some tin derivatives (Table 4). The data indicate that in the starting Rh(pyC)(CO)(PR_3) complexes, the changes in the phosphine ligand, or in the solvent used, cause only a small modification in the coupling constants. In all cases the *J*(Rh—P) are *ca* 160 Hz, representative of Rh^I square-planar complexes.

For the complex with $P(4\text{-}FC_6H_4)_3$, the spectrum exhibits two doublets of almost identical *J*(Rh—P) coupling constant values. Since only one $P(4\text{-}FC_6H_4)_3$ molecule is present, this fact could be attributed to the presence of two isomers. Although the highest *trans* influence of the nitrogen to oxygen in the N—O ligand would be responsible in the formation of only one isomer, we have observed two isomers in related Rh^I complexes with 2-quinaldinate as the N—O ligand, only when the phosphine ligand exhibits a lower basicity.

The observation that the values in *J*(Rh—P) for the addition products with HgX_2 or PhHgCl is lower than in the parent four coordinate complexes, is consistent with an increase in the oxidation state of the rhodium atom.

It is remarkable that in the mercury–tin deriva-

		34.5	136.0	Acetone

[a] 1H decoupled: chemical shifts in ppm downfield from 85%H_3PO_4, coupling constants in Hz.

tives (**B** and **B'**) the coupling constant values exceeded those of the mercuric derivatives (**A** and **A'**). This fact could be attributed to the highest oxidative character of chlorine with respect to $SnCl_3$ ligands. However, the J(Rh—P) is not substantially different for complexes of the types **A** and **B**, and this fact is indicative that the Rh oxidation state hardly varies.

ENTHALPY OF SUBLIMATION OF ADDUCTS—AN EVALUATION INVOLVING $MX_2 \cdot nL$ (M = Zn, Cd, Hg; X = Cl, Br, I; n = 1, 2, 3; L = ORGANIC BASE CONTAINING CO OR PO GROUPS) ADDUCTS

AÉCIO PEREIRA CHAGAS* and CLAUDIO AIROLDI

Instituto de Química, Universidade Estadual de Campinas, 13081 Campinas (SP), Brazil

(*Received* 30 *August* 1988; *accepted* 11 *November* 1988)

Abstract—The approximation that the molar enthalpy of sublimation of an adduct is equal to the molar enthalpy of sublimation or vaporization of the ligand, has been applied to the calculation of the mean enthalpy of dissociation of the metal–ligand bond, $\bar{D}$(MO), for adducts of the type $MX_2 \cdot nL$ (M = Zn, Cd, Hg; X = Cl, Br, I; n = 1, 2, 3; L = ligand containing PO or CO groups) and for other similar compounds. Based on a thermochemical cycle, a linear equation $\bar{D}(MO) = A\,\Delta_r H(a) + B$ was obtained, with $A = 1/n$ and $\Delta_r H$(a) derived from the enthalpy of the reaction $MX_2 \cdot nL(s) = MX_2(g) + nL(g)$, whose thermochemical value was calculated from experimental data. By using data from nearly 80 compounds and calculating $\bar{D}$(MO) for various approximations, it was verified through linear regression that the cited approximation is the one which correlates the best with the stoichiometries of the compounds. This result is a good argument for the use of this approximation in $\bar{D}$(MO) calculations.

Knowledge of the interactions of metal ions with ligand atoms of nitrogen and oxygen groups is of great importance in the understanding of biological and industrial processes. Thus, a simple illustration is shown by haemoglobin, where the nitrogen atoms of the porphyrin ring hold the iron atom in forming iron–nitrogen bonds. Moreover, the photosynthetic process in green plants is carried out by chlorophyll, which has a magnesium atom centred in a ring, very similar to the porphyrin system. Nitrogen fixation in plants by microorganisms involving enzymes, has as an active centre, the Mo—S—Fe group. DNA polymerase and a series of enzymes, such as carbonic anhydrase, carboxypeptidase A, etc., the so-called zinc enzymes, have an active site on the metal, which is free to accept a pair of electrons from a donor atom of the substrate, leading the reaction to a determined function. Normally, this process is dependent on the formation of a zinc–oxygen bond.[1–3]

These few examples illustrate models of a huge class of enzymes, whose activity can be better understood if the energies involved in the formation or breakage of bonds during the process of the reaction are known. However, there is a shortage of available thermochemical data for such complexes which could be applied to the enzyme. In addition, the majority of these data were obtained in aqueous solution and the suitable energies for metal–ligand interactions should be calculated from gaseous data.[1]

For a less complex system comprising a generic compound $MX_2 \cdot nL$ (M = metal, X = halogen, L = organic ligand), the enthalpy of dissociation in the gaseous phase is given by:

$$MX_2 \cdot nL(g) \longrightarrow MX_2(g) + nL(g). \qquad (1)$$

The enthalpy of this reaction is a measure of the strength of the metal–ligand bond, whose value can be given by:

$$\Delta H(1) = n\bar{D}(MY)$$

where $\bar{D}$(MY) is the mean enthalpy of dissociation of MY, with Y being the donor atom bonded to M.

A thermochemical cycle (Cycle 1) might be established to determine $\Delta H(1)$ or $\bar{D}$(MY) for solid complexes.

* Author to whom correspondence should be addressed.

$$\begin{array}{ccc} MX_2 \cdot nL(g) & \xrightarrow{\Delta H(1)} & MX_2(g) + nL(g) \\ \uparrow \Delta_{sub}H(a) & & \uparrow \Delta_{sub}H(h) \quad \uparrow n\Delta^g_{cd}H(l) \\ MX_2 \cdot nL(s) & \xrightarrow{\Delta H(2)} & MX_2(s) + nL(cd) \end{array}$$

(Cycle 1)

$\Delta H(2)$ is experimentally determined through solution–reaction calorimetry. Normally, $\Delta_{sub}H(h)$ and $\Delta^g_{cd}H(l)$ are determined from various techniques such as calorimetry, vapour pressure measurements, etc. and are available in the literature. The term $\Delta_{sub}H(a)$ is not usually available experimentally, since the adducts are not stable outside of the solid state.

The main purpose of this publication is to further the discussion initiated by Burkinshaw and Mortimer[1,4] and to present some empirical correlations which support the method utilized to determine $\Delta_{sub}H(a)$.

An extra thermodynamic assumption has been used for non-sublimable complexes. In this approximation, it is established that the enthalpy of sublimation of the adduct is equal to the enthalpy of sublimation or vaporization of 1 mol of ligand,[1,5] i.e.: $\Delta_{sub}H(a) = \Delta^g_{cd}H(l)$. The validity of this approximation is shown to be reasonable, as, from the few complexes of this kind which do sublime, the enthalpy values displayed are close to those of the ligand, varying within a 10 kJ mol^{-1} range. (Table 1 lists some examples.) The sparse data show that the assumption is valid within the experimental error. It is concluded that this approximation is valid since the intermolecular forces in the complex and the ligand are very similar; namely, the crystalline structures of the ligand complex remain virtually unchanged.[4]

Table 1. Sublimation enthalpies at 298 K of some adducts and their respective ligands

[a] The deviation of ref. 6 was re-evaluated.

Correlations

An interesting thermochemical cycle (Cycle 2) similar to Cycle 1, which is very useful to the acquisition of correlations, is presented below:

$$\begin{array}{ccc} MX_2 \cdot nL(g) & \xrightarrow{\Delta H(1)} & MX_2(g) + nL(g) \\ \uparrow \Delta_{sub}H(a) \quad \nearrow \Delta_rH(a) & & \uparrow \Delta_{sub}H(h) \quad \uparrow n\Delta^g_{cd}H(l) \\ MX_2 \cdot nL(s) & \xrightarrow{\Delta H(2)} & MX_2(s) + nL(cd) \end{array}$$

(Cycle 2)

The application of Hess' law to this cycle gives:

$$\bar{D}(MY) = 1/n[\Delta_rH(a)] + 1/n\Delta_{sub}H(a) \qquad (1)$$

with $\bar{D}(MY) = 1/n\,\Delta H(1)$ and $\Delta_rH(a) = \Delta H(2) + \Delta_{sub}H(h) + n\Delta^g_{cd}H(l)$. All the parameters on the right-hand side of this last equality are experimentally determined and, consequently, $\Delta_rH(g)$ is an exact parameter calculated without approximation. $\bar{D}(MY)$ is calculated from eq. (1), by means of the approximation

$$\Delta_{sub}H(a) = \Delta^g_{cd}H(l). \qquad (A\text{-}1)$$

The experimental and calculated data can be fit to a straight line equation $y = ax + b$, where $y = \bar{D}(MY)$; $a = 1/n$; $X = \Delta_rH(a)$ and $b = 1/n\,\Delta_{sub}H(a)$.

If one considers eq. (1) not as a functional relationship but as a statistical relationship, it makes sense to find a correlation between $\bar{D}(MY)$ and Δ_rH, as indicated by eq. (1) itself. Other approximations can be found to estimate $\Delta_{sub}H(a)$, as will be described further.

The correlation shown in Fig. 1 was obtained from published data, by using the compounds $MX_2 \cdot nL$, with M = Zn, Cd, Hg; X = Cl, Br, I; n = 1, 2 or 3; and L an organic ligand containing a CO or PO group. The compounds and references are in Table 2. Table 3 lists the parameters calculated by the least-squares method.[18]

Taking into account the approximation

$$\Delta_{sub}H(a) = \Delta_{sub}H(h) \qquad (A\text{-}2)$$

used to calculate $\bar{D}(MY)$, the same correlation can be seen in Fig. 2. The parameters obtained are listed in Table 3. Other approximations were also employed:

$$\Delta_{sub}H(a) = [n\Delta^g_{cd}H(l) + \Delta_{sub}H(h)]/n + 1 \qquad (A\text{-}3)$$

and

$$\Delta_{sub}H(a) = \{[\Delta^g_{cd}H(l)]^n\,\Delta_{sub}H(h)\}^{1/n+1}. \qquad (A\text{-}4)$$

In these approximations, the arithmetic and geometric means of the enthalpies of vaporization or sublimation of the ligands and of the halides were

used. The calculated parameters are given in Table 3.

DISCUSSION

From an inspection of the correlations obtained, it is noted that the best correlation was that of the (A-1) approximation, which reproduced practically all the stoichiometric relationships of the complexes ($1/n = 0.5$) within the estimated standard deviation. The same behaviour was not observed for the (A-2) approximation. Although the (A-3) and (A-4) approximations gave reasonable results, these values are not better than those of the (A-1) approximation. All adducts are metal–oxygen bonded ligands, having halide–ligand stoichiometries in the proportions 1 : 1, 1 : 2 and 1 : 3. With the exception of diacetamide (da), all other ligands are monodentate. Therefore, the above stoichiometries are associated with the presence of one, two or three metal–oxygen bonds in the adducts, respectively. However, for these compounds there are always two metal–oxygen bonds. An interesting conclusion can be extracted from the (A-1) results

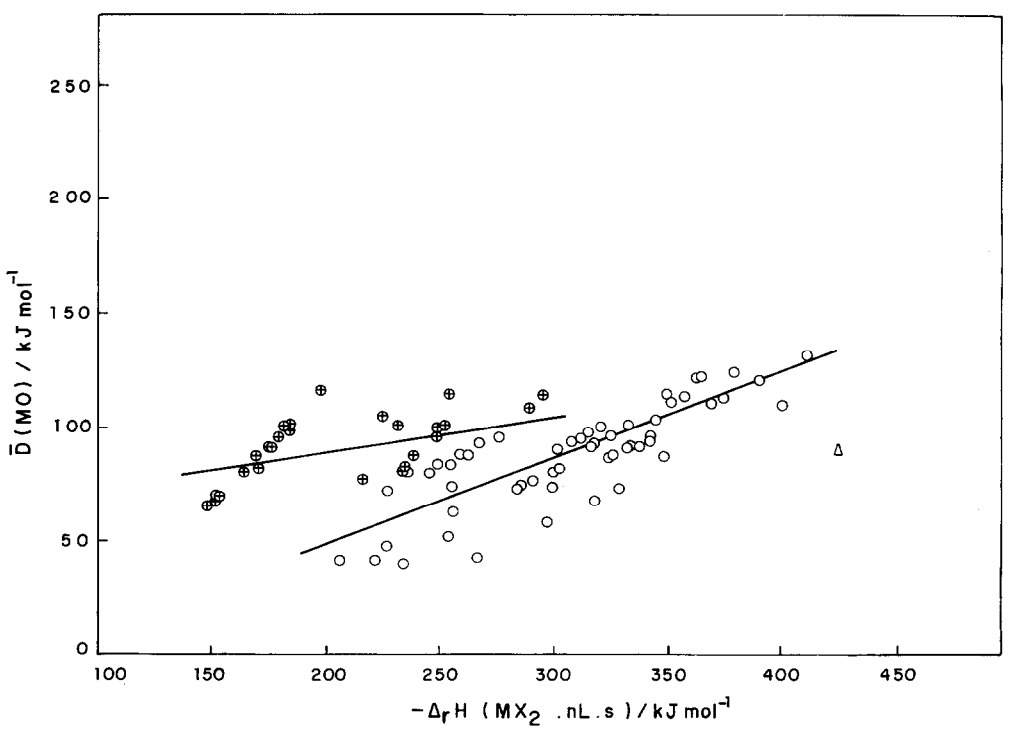

Fig. 2. Correlation between $\bar{D}$(MO) vs $\Delta_r H$(a) for the (A-2) approximation. Compounds with one, ⊕; two, ○; and three, △, metal–oxygen bonds.

Table 4. Some $\bar{D}$(MY) values in $MCl_2 \cdot nL$ compounds

[e] Reference 6.

in Fig. 1, which still permit the distinguishing of two separate sets, with one and with two metal–oxygen bonds. However, the tris-adduct is represented as a single point (triangle in Fig. 1). Consequently, the diacetamide compounds are fitted into the two metal–oxygen bonds set. On the other hand, from the (A-2) approximation (Fig. 2) this kind of discernment is not possible, since, there is an overlapping of the plotted points.

All these correlations can be considered as a strong argument in favour of the (A-1) approximation, and certainly the differences and variations in $\bar{D}$(MY) values for all these series of compounds, more than 80, are corrected, except in case of a constant term.

In addition, a summary of the selected values of $\bar{D}$(MY) are given in Table 4, calculated by considering that the (A-1) approximation is valid. This table lists the mean values of bonds for some compounds and the respective standard deviations of the mean. Except for the cadmium–oxygen bond ($n = 1$), the standard deviation of the mean is of the order of the quantity of the calculated values of $\bar{D}$(MY), estimated as ±8 kJ mol^{-1}. Note also that, in general, $\bar{D}$(MY, $n = 1$) is bigger than half of $\bar{D}$(MY, $n = 2$), characterizing a competitive interaction between the halide and ligand. For comparison, $\bar{D}$(ZnN) and $\bar{D}$(ZnS) values are also included. An inspection of $\bar{D}$(MY) values (Table 4) suggests the sequence: Zn ≃ Cd > Hg for the mean enthalpy of the metal–ligand bond.

IDENTIFICATION OF A LOWEST EXCITED STATE IN THE $Cr(CO)_5PBu_3$ COMPLEX

C. DÍAZ† and N. YUTRONIC

Department of Chemistry, Faculty of Sciences, University of Chile, Casilla 653, Santiago, Chile

(*Received* 5 *October* 1988; *accepted* 11 *November* 1988)

Abstract—Electronic absorption data are reported for the $Cr(CO)_5PBu_3$ complex. The absorption band at the lowest energy value is assigned to a metal → ligand charge-transfer transition (MLCT) on the basis of the solvent effect. Data for this effect on $M(CO)_5PBu_3$ (M = Mo and W) are also discussed.

The UV–vis absorption spectra of the $M(CO)_5L$ complexes (M = Cr, Mo and W, L = neutral donor ligand) have been extensively studied.[1–4] The lowest absorption energy in these compounds has been assigned to the ligand field transition $^1A(e^2b_2^2) \rightarrow {}^1E(e^1b_2^2a_1^1)$.[4,5] As we have shown recently,[4] this transition is sensitive to the π-acceptor ability of the L ligand. For phosphine ligands, the band corresponding to this transition appears in the range 310–360 nm[6] and hence the compounds $M(CO)_5PR_3$ are generally colourless or pale yellow.[7,8] In contrast to this, the $Cr(CO)_5PBu_3$ complex presents a strong red-wine (Chartreuse) colour, suggesting an unusual absorption behaviour.

In this article we discuss the assignment of the absorption band at the lowest energy for the $Cr(CO)_5PBu_3$ complex using solvent effect. Data for the $M(CO)_5PBu_3$ complexes are also reported.

RESULTS AND DISCUSSION

In Fig. 1 the absorption spectrum of $Cr(CO)_5PBu_3$ in *n*-hexane is shown. Evidently the band at 555 nm explains the red colour of the complex. This band shows a characteristic displacement to higher energy as the polarity of the solvent is increased (Table 1). The band moves within a range of 85 nm on going from *n*-hexane to acetonitrile, as is shown in Fig. 2.

For the hydroxylic solvents, in addition to the polarity effects, hydrogen bond interactions must also be considered. From Table 1, a displacement

[c] Probably hidden under $M \rightarrow (CO)^*$MLCT.

to higher energy is observed for alcohol solvents. This can be understood by considering the limiting structures **I** and **II** given below, usually applied to describe carbonyl compounds:

$$O{=}C{=}M{-}L \qquad \overset{\delta+}{O}{\equiv}C{-}M{-}\overset{\delta-}{L}.$$
(I) **(II)**

Hydroxylic solvent should stabilize the oxygen lone pair electron in the carbonyl ground state through structure **I**, by hydrogen bonding:

$$\begin{matrix} & & H\cdots O{=}C{=}M{-}PR_3. \\ RO & \diagup & \end{matrix}$$

The solvent dependence is comparable to the shift of 59 nm observed for the lowest CTML transition in $Cr(CO)_5(RN{=}NR)$ complexes[9] on substituting *n*-hexane for acetonitrile. Thus, the transition is strongly dependent on the metal; for the $M(CO)_5PBu_3$ complexes, see Table 1, the energy varies in the order Mo > W > Cr, the behaviour is similar to that observed for the lowest absorption band in the complexes, $M(CO)_5(RN{=}NR)$[9] and $M(CO)_4$(1,10-phen).[10]

† Although this band has a low extinction coefficient ($\varepsilon = 302$), it can be assigned to a charge-transfer transition. These bands are generally, but not always very intense. For instance rhodium(I) and iridium(I) complexes exhibit charge-transfer transitions of relatively low intensity (see refs 11 and 12).

On the basis of the above observations we have assigned the lowest energy band in the solution spectra of $Cr(CO)_5PBu_3$ to a metal–ligand charge-transfer transition.†

The next lowest energy absorption band observed as a shoulder in the spectra of $Cr(CO)_5PBu_3$ is only slightly influenced by the polarity of the solvent (see Fig. 1 and Table 1). This behaviour is typical of *d–d* bands as observed for other complexes.[9] Thus, we have estimated a value of $\lambda = 328$ nm for the ligand field transition from the relation $\varepsilon_{max} = -137.7\pi + 407.2$ valid for *d–d* transition in $Cr(CO)_5L$ complexes.[4] This value is very close to that observed in Fig. 1 at $\simeq 332$ nm. Therefore, it is possible to assign this absorption band to a metal centred $d_{yz,xz} \rightarrow d_{x^2-y^2,z^2}$ transition. For the complexes, $M(CO)_5PBu_3$ (M = Mo and W), this band is observed at about 350 nm and shows no shift by solvent effects.

Now the question is why $Cr(CO)_5PBu_3$ exhibits a lowest excited state that is not observed in other $Cr(CO)_5PR_3$ compounds. Comparison of IR,[7,8] ^{31}P NMR[8] and ESCA[13] spectral data of tributylphosphine chromium complexes with other alkylphosphine complexes does not reveal significant differences that could be used to explain such behaviour. The steric effect of PR_3 appears not to be related to the absorption differences mentioned above; the steric parameter of Tolman[14] for PBu_3 and other phosphines such as PMe_3, PEt_3, PPr_3, etc. are similar. Nonetheless, we have noted that tributylphosphine is a much stronger σ-

donor than trimethylphosphine, triethylphosphine and other alkylphosphines. This is also evidenced by Valence Photoelectron Spectroscopy,[15] as well as by ^{95}Mo NMR spectroscopy of $Mo(CO)_{5-n}(PR_3)_n$ complexes.[16] Also, the ionization potential of the free phosphine ligands is consistent with PBu_3 having a higher donor ability than PR_3 ($R = C_2H_5$, C_6H_5, CH_3, H) and PX_3 compounds ($X = OC_2H_5$, OC_4H_9, OCH_3, Br, Cl, F).[17]

The fact that alkylphosphines have a weaker donor ability than PBu_3 can considerably affect the energy of the metal–ligand antibonding orbitals. Figure 3 shows a partial view of MO levels for the C_{4v} $M(CO)_5L$ complexes;[9,18,19] the levels are labelled according to their metal *d* orbital character. The greatest donor ability of PBu_3 should destabilize the a_1 MO. The π^*-level indicated in the diagrams, has a higher energy than the a_1 and b_1 MOs in the majority of the $M(CO)_5L$ complexes.[9,20] However, when the L ligand has a low energy vacant orbital, this π^*-level decreases in energy in some cases[20] to the level between the *e*, b_2 and b_1, a_1 orbitals. For the $Cr(CO)_5PBu_3$ complex, a low energy π^*-level is postulated as is shown in Fig. 3. This level probably arises from contributions of filled metal *d* orbitals and the LUMO of tributylphosphine. Comparison of ionization data,[17,18] as well as theoretical studies[21,22] for PX_3, PH_3, PR_3 (R = other than butyl) with those of PBu_3, certainly suggests that the LUMO of tributylphosphine may have a lower energy. In the $Cr(CO)_5PR_3$ ($R \neq n$-Bu) and $Cr(CO)_5PX_3$ compounds, the LUMO of the phosphorus compounds is too high in energy[18] and hence a low energy π^*-state is not possible. In fact the pentacarbonylchromium complexes with PR_3 ($R \neq n$-Bu) and PX_3 ligands[5,6] do not absorb above 360 nm.

The lowest energy excited state in the $Cr(CO)_5PBu_3$ complex also should be π^*-(CO) in nature, but this is improbable because the Cr → (CO)* charge-transfer transition for complexes $Cr(CO)_5L$ (L = N donor, P donor) appears in the range 220–290 nm.[5,6]

With regard to the current interest in low-lying MLCT states of transition metal compounds, we note that the $Cr(CO)_5PBu_3$ complex constitutes the fourth class of the compound type $M(CO)_5L$ having MLCT lowest excited states.

The other examples known are $W(CO)_5$(4-R-pyridine),[20] $Cr(CO)_5ArC(OCH_3)$[23] and $M(CO)_5$(RN=NR).[9]

EXPERIMENTAL

Preparation of $Cr(CO)_5PBu_3$

A solution of 3 mmol $Cr(CO)_6$ in *ca* 60 cm^3 of THF was irradiated (UV lamp Hanau medium pressure 150 W) for 90 min at room temperature. A solution of 3 mmol of tributylphosphine in *ca* 20 cm^3 of THF was then added and the mixture stirred for 20 min. After removing the solvent under reduced pressure, the excess of hexacarbonyl was sublimed from the residue *in vacuo* at room temperature. The oily residue was then redissolved in an *n*-pentane–benzene mixture (10 : 1), filtered through kieselguhr, and the solvent evaporated *in vacuo*. The product obtained was a wine-red liquid. Found: C, 52.2; H, 7.6. Calc. for $C_{17}H_{27}O_5PCr$; C, 51.8; H, 6.8%. ^1H NMR; $\delta_H(CCl_4$, from TMS) 1.0 (3H, m, CH_3), 1.6 (6H, m, $(CH_2)_3$). IR: ν(CO) *n*-hexane

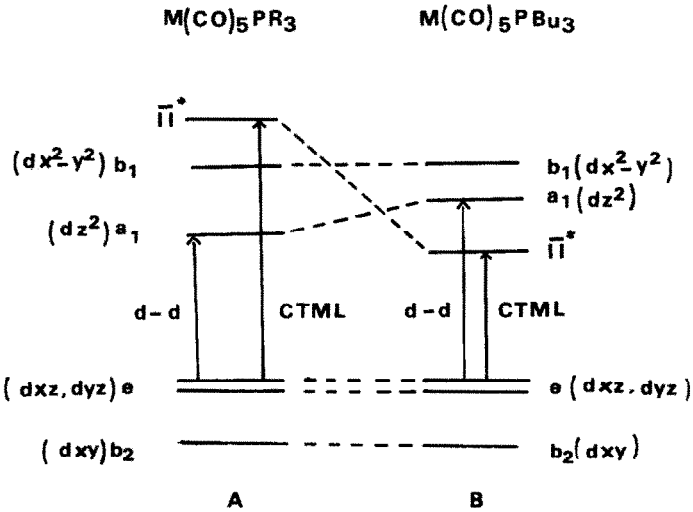

Fig. 3. Partial MO diagram for $Cr(CO)_5PBu_3$ complexes: (A) L = PR_3, (B) L = PBu_3.

solution 2061 s (A_1^2), 1985 vw (B_1), 1944 vs, 1930 vs (E), 1915 m,sh (A_1^1); δ(MCO) 671 s (E), 650 s (A_1). The main bands in the ligand region (liquid between plates) were 2960 vs, 2937 vs, 2878 vs, 1460 s, 1416 m, 1089 m, 905 m, 790 w, 770 w, 718 m. For comparison, the spectral data for the free tributylphosphine are: ^{1}H NMR: δ_H 0.96 (3H, m, CH_3); 1.55 (6H, m $(CH_2)_3$). IR: 2959 vs, 2924 vs, 2878 vs, 1465 s, 1415 m, 1091 m, 895 m, 785 w,br, 721 m.

The $M(CO)_5PBu_3$ complexes (M = Mo, W) were prepared in a similar way and their ^{1}H NMR and IR spectral properties were in agreement with those cited in the literature for authentic samples.[8] UV–vis absorption spectra were recorded with Cary 17 and Varian-DMS 90 spectrophotometers.

Abstract—Reactions of copper(I) bromide with heterocyclic thiones (L) [L = pyridine-2-thione (py2SH), pyridine-4-thione (py4SH), pyrimidine-2-thione (pymtH), 1,3-thiazolidine-2-thione (tzdtH), 1-methyl-1,3-imidazoline-2-thione (meimtH), benz-1,3-imidazoline-2-thione ($bzimtH_2$), benz-1,3-oxazoline-2-thione (bzoxtH), 5-nitro-2-benz-1,3-imidazoline-2-thione ($nbzimtH_2$), benz-1,3-thiazoline-2-thione (bztzH) and quinazolinone-2-thione ($qnotH_2$)] in the presence of triphenylphosphine yields mononuclear complexes of the general formula $[Cu(L)(PPh_3)_2Br]$. The complexes have been characterized by elemental analysis, IR, UV-vis and NMR spectroscopy. The crystal structure of $[Cu(PPh_3)_2$(pymtH)Br] has been determined by single-crystal X-ray diffraction methods. The yellow–orange crystals are monoclinic, space group $P2_1/n$ with $a = 13.035(2)$, $b = 43.660(9)$, $c = 13.446(2)$ Å, $\beta = 90.68(2)°$, and $D_{calc} = 1.352$ g cm^{-3}, $V = 7652$ Å^3, $R(F) = 0.067$; $R_w(F) = 0.069$, $GOF = 1.19$. In both molecules of the asymmetric unit, the pymtH molecule acts as a monodentate ligand through the S atom (Cu—S = 2.352(3) Å).

Heterocyclic thiones as ligands are potentially ambidentate or multi-functional donors with either the exocyclic S or heterocyclic N (or S or O) atom available for coordination.[1] The aim of the present paper is to further our present knowledge in the field of these ligands which exhibit a thione–thiol (—N=C—SH ⇋ —NH—C=S) equilibrium. Recently, the complexing properties of these ligands with copper(I) in the presence of triphenylphosphine have been studied, and a variety of interesting complexes (monomeric or dimeric) with the thione ligands acting as S-donors have been obtained.[2,3] More recently, monomeric complexes formulated as $[Cu(PPh_3)_2(L)_2]NO_3$ have been obtained via a simple method of preparation by direct reaction of $Cu(PPh_3)_2NO_3$ with the ligands investigated.[4] As a part of the examination of the ligation behaviour of these ligands, we report in this paper the preparation and characterization of a series of mononuclear Cu^I complexes of general formula $[Cu(PPh_3)_2(L)Br]$.

EXPERIMENTAL

Physical measurements

Elementary analyses were performed on a Perkin–Elmer 240 B elemental analyser. IR spectra

were recorded in the 4000–250 cm^{-1} region on a Perkin–Elmer 467 spectrophotometer using KBr pellets. Electronic spectra in chloroform solutions were obtained on a Cary 17 DX spectrophotometer. NMR spectra were recorded on a Brucker AW 80 spectrometer. Conductivity measurements were taken in a Wheatstone bridge Model RC 216 B2 using 10^{-3} M solutions in acetonitrile or chloroform. Melting points were determined with a Büchi apparatus and are uncorrected. Magnetic susceptibility measurements were taken employing the Faraday technique at different magnetic field strengths. $Hg[Co(SCN)]_4$ was used as the calibrand.

Starting materials

All thione ligands, supplied by EGA or Aldrich, were purified by recrystallization from ethanol. Anhydrous copper(I) bromide, triphenylphosphine and all solvents were of reagent grade and were used without further purification in synthetic work.

Preparation of the complexes

CuBr (1 mmol) was suspended in 10 cm^3 THF and treated with a 40 cm^3 solution of 1 mmol of the appropriate ligand and 2 mmol PPh_3 in the same solvent. The reaction mixture was stirred for 1 h at 40°C, filtered and cooled to room temperature. Slow evaporation of the solvent at room temperature gave a microcrystalline solid, which was filtered off, washed with ethanol and ether and dried *in vacuo*. The yield in this procedure was about 65–85%.

Crystal and molecular structure determination

A suitable crystal of $[Cu(PPh_3)_2(PymtH)Br]$ was obtained from recrystallization of the complex in THF. Preliminary Weissenberg photographs revealed a monoclinic cell and systematic conditions (*h*0*l*: $h+l = 2n$, 0*k*0: $k = 2n$) led to space group $P2_1/n$. The experimental conditions are given in Table 1. The scattering factors were taken from refs 6 and 7. The structure was solved by the heavy atom method by interpretation of the Patterson map and was refined by standard least-squares and Fourier techniques. Due to thermal motion or disorder problems, the C(31)—C(36) phenyl ring was refined as a rigid group; all the coordinates of the hydrogen atoms linked to the carbon atoms were calculated and kept fixed during the refinement process. The two N—H hydrogen atom coordinates used were those found in the difference Fourier map in order to distinguish between the two nitrogens of the pyrimidine ring. Main bond distances and angles are given in Table 2. Fractional coordinates, standard deviations, equivalent temperature factors, anisotropic thermal parameters of the atoms, least-squares planes, other bond lengths and structure factors have been deposited as supplementary material with the Editor from whom copies are available on request.*

RESULTS AND DISCUSSION

Recently, the mononuclear complex, $[Cu(PPh_3)_2(py2SH)Br]$, has been isolated by the reaction

*Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

of $Cu(PPh_3)_3Br$ with $Zr(py2S)_4$ in THF.[3] However, we report in this study a more simple and general method for the preparation of such complexes, namely, the reaction between the heterocyclic thiones and a 1 : 2 mixture of CuBr and PPh_3. Table 3 lists the compounds with their colours, melting points and analytical data. The results of the elemental analyses for all complexes show good agreement with the formula $[Cu(PPh_3)_2(L)Br]$. The magnetic susceptibility measurements at room temperature indicate that the complexes are diamagnetic, consistent with a d^{10} configuration. They can be handled in air without evident decomposition, decompose slowly in water, are soluble in chloroform, acetone and acetonitrile, slightly soluble in methanol and benzene but insoluble in ether. Their conductivity measurements in chloroform or acetonitrile show, as expected, a non-electrolytic nature.

Description of the crystal structure

A stereographic projection of the two molecules of the asymmetric unit is given in Fig. 2. Figure 1 is a PLUTO drawing of the molecule with the numbering scheme used for the main atoms. In both molecules the Cu atom is four-coordinated by a bromide atom, two triphenylphosphine ligands and one monodentate pymtH molecule coordinating through the sulphur atom; the Cu—L bond lengths in both molecules are similar (Table 2). However, the coordination polyhedra of both molecules of the asymmetric unit are different due to the P—Cu—P coordination angles: The Cu(1) coordination polyhedron is close to a regular tetrahedron ($106.5 \leqslant L—Cu—L' \leqslant 112.9°$), whereas in the Cu(2) polyhedron, the $P_3—Cu_2—P_4$ angle is 124.3(1)°. This demonstrates the flexibility of these coordination angles in this class of compounds. However, all these angles fall within the range reported for other tetrahedral complexes of copper(I).[8–12] A possible explanation for the large value of the $P_3—Cu—P_4$ angle is the π–π interaction between the phenyl ring C(49)···C(54) and the pymtH ($N_3 \cdots N_4$) entity: the angles between their least-squares planes is 16° and the distances of atoms C(51), C(50), C(49), C(52) are, respectively, 3.04, 3.02, 3.35 and 3.34 Å from the pymtH plane.

The average Cu—S bond length is 2.352 Å as usually found for tetrahedrally coordinated copper(I) complexes with thione–sulphur donors.[4,13]

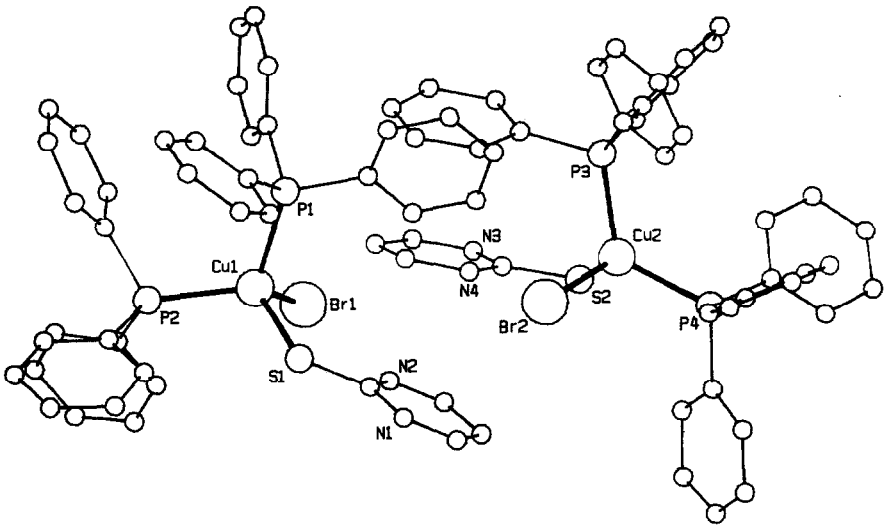

Fig. 1. PLUTO drawing of the two molecules of the asymmetric unit.

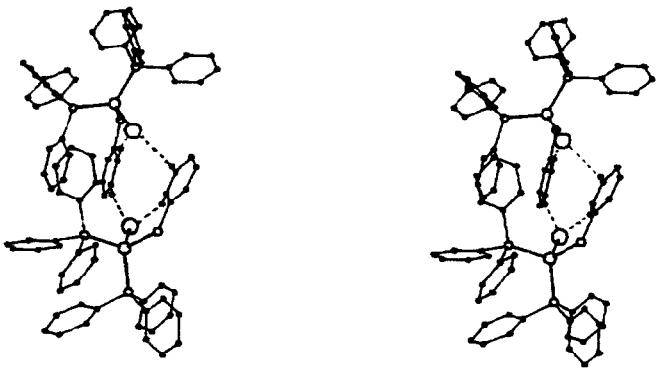

Fig. 2. ORTEP stereoview of the molecules.

The Cu—P bond lengths are normal (see, for example refs 4, 14, 15). The average Cu—Br bond lengths of 2.515 Å are significantly longer than those observed in $Cu(PPh_3)_3Br$ (2.35 Å).[15] Moreover, it is slightly longer than the corresponding Cu—Br distance of 2.462 Å in $Cu(PPh_3)_2$ (py2SH)Br_3, and it compares well with that found in $(TTTCu_2Br_4)$[16] (TTT = tetrathiotetracene) (2.490 Å) and in $[Cu(PPh_3)Br]_4$[17] (2.495 Å).

Hydrogen bonds and intermolecular contacts

As described in the Experimental section, the hydrogen atoms linked to N_2 and N_4 were found in difference Fourier maps and no peak at a distance of about 1 Å of N_1, N_3 was visible. Furthermore, the bond distances in the pymtH ring agree with this assignment (Table 2) and are close to those found in most pyrimidine-2-thione complexes.[18,19] As shown in Fig. 2, intramolecular hydrogen bonds between the bromide atoms (Br_1, Br_2) and the HN_2, HN_4 hydrogen occur ($Br_1 \cdots N_2 = 3.205(7)$ Å, $Br_2—N_4 = 3.300(8)$ Å). These hydrogen bonds are of different strength, as shown also by the least-squares planes formed by the Cu, Br, S, C, N atoms (Table 4). Furthermore, short van der Waals contacts exist between one H—C hydrogen atom of the pymtH ring of one molecule, with the bromide atom of the other molecule, giving rise to an almost dimeric molecule (Br_1—C(83) = 3.67(1) Å, Br_2—C(41) = 3.462(9) Å). Then the strongest hydrogen bond to one bromide atom is associated with the weakest van der Waals contact. As a consequence of this dimer formation, Br_1, Br_2, N_2, N_4, C(83), C(41) form a plane within 0.6 Å (Table 4). Finally, no other intermolecular contact is smaller than 3.5 Å.

[a] Calculated values in parentheses.

IR spectra

IR spectra, in the region 4000–250 cm^{-1}, provide information concerning the mode of coordination. Some selected bands and their assignments are given in Table 5.

The solid-state IR spectra of complexes studied, exhibit the dominance of the thione form of the ligands investigated with the presence of ν(NH) bands at 3180–3130 cm^{-1},[20–22] the absence of any evidence for ν(SH) bands in the 2500–2600 cm^{-1} region,[23–24] and the production of characteristic "thioamide" bands.[23]

All the pymtH ligands are bonded to the metal through the sulphur atom, as shown by the shifts of the "thioamide" bands observed by comparing the IR spectra of the complexes with those of the free ligands. Of the four "thioamide" bands, those showing the most significant changes upon coordination are (III) and (IV). "Thioamide(III)" undergoes downward shifts ranging from 10 to 60 cm^{-1}. "Thioamide(IV)" shows similar behaviour, although here, the shifts are generally greater (30–100 cm^{-1}), and the absorptions are in many cases pertly masked by strong triphenylphosphine bands.

In agreement with the X-ray crystal structure there is no positive evidence that in the complexes discussed here, the ligands behave as bidentate. In fact, "thioamide(I)" occurred at the same wavenumbers, or showed small ($\pm$5 cm^{-1}) shifts, signifying that the ligands are not N-bonded to the metal.

The N—H stretching frequency in the complexes tends to lie at a lower wavenumber than in the free ligands, but the shifts of this band are small, suggesting that the nitrogen atoms are not involved in bonding.[24] The directions of the shifts in the position of all the bands in the spectra of the complexes are the same, indicating that the binding pattern in all the complexes must be similar.

The monodentate nature of the ligands is further confirmed by the presence of a band around 350 cm^{-1}, which is assigned to the ν(Cu—S) vibration.[25]

Electronic and NMR spectra

The UV-vis spectra of the compounds in $CHCl_3$ solutions, as expected, show only two absorption bands at 310–360 and 240–280 nm, which can be assigned as intraligand transitions.

The ^{1}H NMR spectra of the complexes in $CDCl_3$ solution also provided proof that ligands are (NH) protonated. The absence of any evidence for the thiol (SH) proton (δ 3–5 ppm) and the presence of a peak for the NH group at $\sim$ 10–14 ppm (sometimes very broad) indicate the thione tautomer as the dominant species in the complexes studied.

STUDIES ON EXTRACTION OF LANTHANUM(III), CERIUM(III), EUROPIUM(III), THORIUM(IV) AND URANIUM(VI) WITH 3-PHENYL-4-ACETYL-5-ISOXAZOLONE (HPAI)

A. JYOTHI and G. N. RAO*

Department of Chemistry, Indian Institute of Technology, New Delhi-110016, India

(*Received* 21 *September* 1988; *accepted* 23 *November* 1988)

Abstract—The extraction of lanthanum(III), cerium(III), europium(III), thorium(IV) and uranium(VI) from aqueous solutions into 4-methyl-2-pentanone (MIBK), containing 3-phenyl-4-acetyl-5-isoxazolone (HPAI), has been investigated. The mechanism of extraction and the species extracted have been identified. Extraction constants in each system have been calculated and compared with those of the corresponding systems using 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (HPMBP) and thenoyltrifluoroacetone (HTTA). It is found that, in general, HPAI extracts these metals better than HPMBP and HTTA. Solid complexes of these metals with HPAI have been isolated and characterized by using elemental analysis, IR and NMR spectroscopic techniques.

β-Diketones have been used extensively for the extraction of metals. Thenoyltrifluoroacetone (HTTA) has received special attention in the separation of elements like uranium, thorium and zirconium.[1] However, it is difficult to prepare and rather unstable during storage. Acyl pyrazolones have been found effective for the efficient extraction of lanthanides,[2,3] actinides[4,5] and other metals.[6–8] Similar to acyl pyrazolones, β-diketones derived from 4-acyl derivatives of isoxazolones are considered to be attractive as chelating reagents. Recently we have reported the extraction of manganese(II), iron(II), nickel(II), cobalt(II), copper(II), zinc(II), palladium(II) and cadmium(II) with 3-phenyl-4-acyl-5-isoxazolones.[9,10] We now report on the extraction of lanthanum(III), cerium(III), europium(III), thorium(IV) and uranium(VI) with 3-phenyl-4-acetyl-5-isoxazolone (HPAI). The solid complexes isolated were characterized by elemental analysis, IR and ^{1}H NMR spectral studies. HPAI can exist in four tautomeric forms (Fig. 1) and has been shown to behave like a bidentate enol forming neutral metal complexes of the type shown in Fig. 2. The effectiveness of the ligand HPAI in the separation of metals is discussed.

EXPERIMENTAL

Reagents

All the reagents used were of analytical grade. The ligand HPAI was prepared according to the method of Korte and Storiko,[11] using 3-phenyl-5-isoxazolone and acetic anhydride in the presence of sodium acetate and its purity checked by elemental analysis. 4-Methyl-2-pentanone (MIBK) was used as solvent for the extraction. Stock solutions of metals were prepared by using spec-pure quality metal oxide/nitrate and standardized by titration with EDTA or gravimetrically. A constant ionic strength in the aqueous phase was maintained by using potassium nitrate solution. The pH of the aqueous phase was maintained by using mixtures of potassium chloride–hydrochloric acid for pH 1–3 and sodium acetate–acetic acid for pH 3–6.

Extraction procedure

10 cm^3 of the aqueous phase containing an aliquot of metal solution, 5 cm^3 of buffer solution and 1 cm^3 of 1 M KNO_3 was equilibrated with 10 cm^3 of MIBK, containing the required concentration of HPAI, in a stoppered bottle. The mixture was shaken in a mechanical shaker for 1 h at 25 ± 1°C.

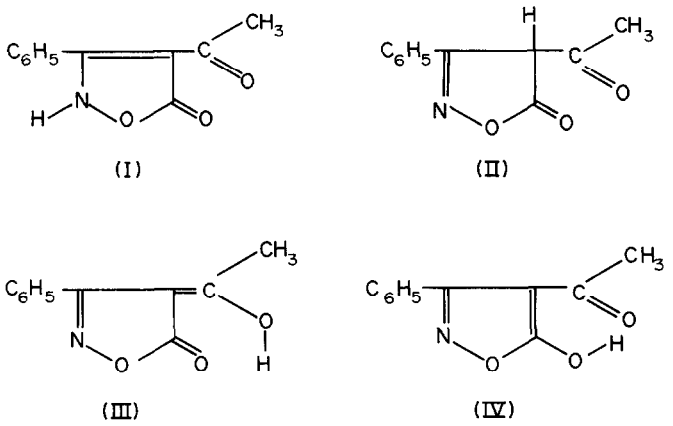

Fig. 1.

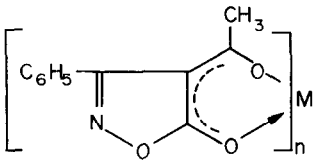

Fig. 2.

Preliminary studies showed that this period is sufficient for attaining the equilibrium. After equilibration, the two phases were separated and the pH of the aqueous phase was measured by using ELICO MODEL L1-120 digital pHmeter. The concentration of metal ion in the aqueous phase was determined spectrophotometrically by developing colour with Alizarin Red-S[12] for lanthanum(III), cerium(III) and europium(III), thoran for thorium(IV)[13] and dibenzoylmethane (DBM) for uranium(VI),[14] using a Pye Unicam SP-500 visible spectrophotometer. Preliminary experiments showed that the colour of Alizarin Red-S metal ion is very sensitive to changes in the hydrogen ion concentration, hence it was necessary to destroy the acetate ion which makes it difficult to attain the desired pH. A 5 cm^3 aliquot of the aqueous phase was evaporated and fused twice with perchloric acid to destroy the acetate ion, and the residue was dissolved in distilled water and the metal content was determined spectrophotometrically by developing colour with Alizarin Red-S.[12] Occasionally the organic phase was back-extracted with 2 M HNO_3 and the metal content was similarly determined.

Preparation of metal complexes

The metal complexes were prepared by the following general procedure: an ethanolic solution of the ligand prepared by dissolving 5 mmol in a minimum quantity of 95% ethanol was added dropwise, with stirring, to a hot solution of 1 mmol of metal nitrate or chloride in water. The reaction mixture was heated on a water bath for 10 min. The precipitates formed were filtered, washed with a 1 : 1 ethanol and water mixture and dried in a desiccator over fused calcium chloride. Analytical data, colour and melting points of the complexes prepared are given in Table 1.

Table 1. Physical and analytical data of HPAI and its metal complexes

RESULTS AND DISCUSSION

The extraction of La^{3+}, Ce^{3+}, Eu^{3+}, Th^{4+} and UO_2^{2+} as a function of the pH of the aqueous phase is shown in Fig. 3. The extraction behaviour of these metals can be understood by the variation of the distribution ratio "K_d" (defined as the concentration of metal ion in the organic phase divided by the concentration of metal ion in the aqueous phase) as a function of the aqueous phase acidity and as a function of the extractant concentration. The plots of $\log K_d$ vs pH (Fig. 4), at constant ligand concentration (0.01 M), gave straight lines with a slope around two for UO_2^{2+}, three for La^{3+}, Ce^{3+} and Eu^{3+}, while the slope is four for Th^{4+}. This suggests the release of two, three and four hydrogen ions, respectively, during the extraction process.

To calculate the number of ligand molecules coordinated with the extracted species, the concentration of HPAI was varied at constant pH. The log–log plots of distribution ratio vs ligand concentration (Fig. 5) were linear with slopes

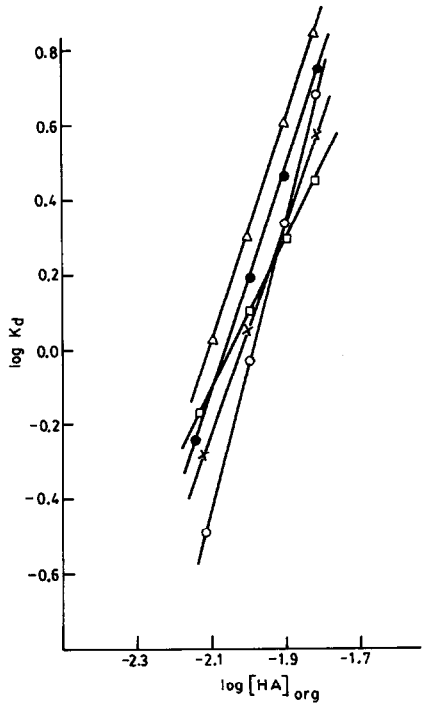

Fig. 5. Plot of $\log K_d$ vs $\log[HA]_{org}$: ○ = Th^{4+}; □ = UO_2^{2+}; △ = Eu^{3+}; × = Ce^{3+}; ● = La^{3+}.

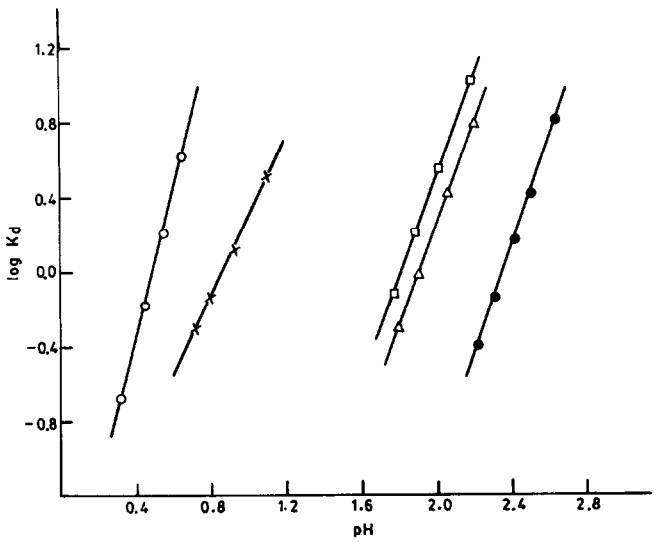

Fig. 4. Plot of $\log K_d$ vs pH: ○ = Th^{4+}; × = UO_2^{2+}; □ = Eu^{3+}; △ = Ce^{3+}; ● = La^{3+}; 0.01 M HPAI in MIBK.

around two for UO_2^{2+}, three for La^{3+}, Ce^{3+} and Eu^{3+}, and four for Th^{4+}, indicating that two, three and four molecules of the ligand, respectively, are incorporated in the extracted species. Hence, the extraction equilibria can be represented as

$$Ln^{3+} + 3HPAI \rightleftharpoons Ln(PAI)_3 + 3H^+$$

$$Th^{4+} + 4HPAI \rightleftharpoons Th(PAI)_4 + 4H^+$$

$$UO_2^{2+} + 2HPAI \rightleftharpoons UO_2(PAI)_2 + 2H^+$$

where, Ln represents lanthanum, cerium and europium, and PAI is the anion of 3-phenyl-4-acetyl-5-isoxazolone. The extraction constant K_{ex} is given as:

$$\log K_{ex} = \log K_d - n\text{pH} - n \log [\text{HPAI}]_{org}$$

where, $n = 2$, 3 or 4 for UO_2^{2+}, La^{3+}, Ce^{3+}, Eu^{3+} and Th^{4+}, respectively.

The values of the extraction constants ($\log K_{ex}$) have been calculated for all the systems and are summarized in Table 2. The extraction constant values obtained for the present systems have been compared with those available in the literature using HPMBP and HTTA (Table 2). It can be seen from the table that HPAI gives much higher extraction constant values than HPMBP and HTTA. This can be attributed to the lower pK_a value of this reagent (1.31) as compared to those of HTTA (6.23)[1] and HPMBP (4.10).[17]

In order to understand the mechanism of the extraction process and nature of the species extracted, physico-chemical studies on solid complexes of these metals have been carried out. Analytical data, together with some physical properties of the complexes, are given in Table 1. The elemental analyses correspond to the general formula $M(PAI)_n \cdot xH_2O$, where, for M = La, Ce and Eu, $n = 3$ and $x = 2$; for M = Th, $n = 4$ and $x = 0$; for $M = UO_2$, $n = 2$ and $x = 0$. The presence or absence of coordinated water molecules in the metal complexes was confirmed by IR and ^1H NMR spectral studies.

Table 2. Comparison of extraction constant values (log K_{ex}) of metal–HPAI systems with metal–HPMBP and metal–HTTA systems

Metal	Ligand HPAI[a]	HPMBP[b]	HTTA[c]
Lanthanum	−0.88	−7.28	−9.90
Cerium	+0.21	−6.71	−9.60
Europium	+0.69	−5.33	−8.99
Thorium	+5.93	−1.00	+1.00
UO_2	+2.36	−1.15	−2.40

IR spectra

IR spectra were recorded on a Unicam SP-1200 IR spectrophotometer and Nicolet 5-DX-FTIR spectrophotometer. The chelates of lanthanum, cerium and europium showed a broad peak in the 3300–3500 cm^{-1} region, which is assigned to the ν(O—H) of coordinated water. This region is free of absorption for the complexes of thorium and UO_2^{2+}, indicating the absence of coordinated water. Of interest are the C=O and C=C stretching frequencies of the chelate ring; these are known to be very sensitive to substitution in β-diketonates.[18] The intense band located between 1680 and 1640 cm^{-1}, in the spectra of chelates, are assigned to the ν_{as}(C=O) mode. The other strongest absorption occurring around 1515–1480 cm^{-1} in the spectra, are assigned to the ν_{as}(C=C). These agree well with the similar assignments in acetylacetonates[19] and acyl pyrazolones.[20] The chelate of UO_2^{2+} showed an intense band at 935 cm^{-1}, which is assigned to the ν(O=U=O).

The following points are of structural significance:

(i) The intense broad band centred around 2600 cm^{-1}, which is assigned to the ν(O—H) in the spectrum of the ligand, is absent in the spectra of complexes, indicating the ionization of the enolic O—H group and the involvement of oxygen of the hydroxyl group in chelation.

(ii) The stretching frequencies of the C=O group have shifted from 1780 cm^{-1} in the ligand to ν(C=O): 1660 (La)–1648 cm^{-1} (Th) in the complexes, which suggests that the carbonyl group is involved in bonding.

(iii) The absence of any band between 3100 and 3600 cm^{-1} in the anhydrous complexes (e.g. Th), indicates the absence of ν(N—H). Thus the possibility of any amino–diketo tautomeric form or reacting only through the carbonyl groups, or forming a coordinate link to metal through the nitrogen of its secondary amino group, is eliminated.

(iv) The presence of bands in the 400–500 cm^{-1} region, typical of metal-β-diketonates ν(M—O), suggests that the bonding of the metal to the ligand is through the oxygen atoms.

Proton NMR spectra

The ^1H NMR spectral data of the ligand and some of its metal complexes are shown in Table 3.

Table 3. ^{1}H NMR spectral data of HPAI and its metal complexes[a]

Compound	Phenyl protons	Methyl protons	Water molecule protons	Hydroxyl proton	Solvent
HPAI	7.03–7.51(m)	2.49(s)	—	11.6	$CDCl_3$
$C_{33}H_{28}O_{11}N_3La$	7.43–7.10(m)	2.02(s)	3.38(s)	—	DMSO-d_6
$C_{44}H_{32}O_{12}N_4Th$	7.81–6.42(m)	2.10(s)	—	—	DMSO-d_6
$C_{22}H_{16}O_8N_2U$	7.53–6.74(m)	2.27(s)	—	—	DMSO-d_6

[a] Chemical shifts in δ (ppm) relative to TMS.
m—multiplet; s—singlet.

The spectra were obtained using a JEOL-JNM-FX-100 FT-NMR spectrometer.

The spectrum of the ligand showed a sharp singlet at δ 2.49 ppm relative to TMS, which is assigned to the methyl protons, a multiplet at δ 7.93–7.51 ppm due to the phenyl protons and a broad peak at δ 11.6 ppm assigned to a hydroxyl proton, indicating that the ligand exists in the enolic form. The enolic ^{1}H resonance present in the ligand is absent in the spectra of metal chelates, indicating that the hydroxyl proton has been lost and the enolic form of the ligand is involved in chelation. In the spectra of metal chelates, both the methyl and phenyl proton signals have been shifted upfield compared to that of the ligand, and a slight broadening of the signals was observed. The shift of these signals may be attributed to contact and pseudocontact interactions, while the broadening may be attributed to spin–spin relaxation processes. The spectrum of the lanthanum complex shows a resonance attributable to coordinated water molecules.

Thus, the results of elemental analysis, IR and ^{1}H NMR spectral studies confirm that the ligand HPAI in these metal chelates is behaving as a bidentate, forming the extractable species of the type depicted in Fig. 2.

Separations

The possibility of utilizing the reagent HPAI for the separation of metals, has been investigated by calculating the separation factor "S", which is the ratio of the distribution coefficients of the elements to be separated.[21] A separation in which not more than 1% of one element is co-extracted, will be obtained if $S \geqslant 10^4$ and the product of distribution coefficient is unity.[21] The separation of thorium from lanthanum, cerium and europium is perfect around pH 1.0, where the separation factor is "∞", because the extraction of lanthanum, cerium and europium is negligible around pH 1.0 (Fig. 3). Similarly, UO_2^{2+} can be separated from lanthanum, cerium and europium around pH 1.0, where the separation factor is "∞". Thus under these conditions, it is possible to separate the actinides (thorium and uranium) from the lanthanides studied. It is evident from the results presented in the text, that these acyl isoxazolones represent a new group of chelating reagents which have great potential in solvent extraction.

AN UNUSUAL EXAMPLE OF INTERMOLECULAR COUPLING BETWEEN METAL–METAL BONDED DIMERS: CRYSTAL AND MOLECULAR STRUCTURE OF $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot C_5H_5N$

HOLLY J. McCARTHY and DEREK A. TOCHER*

Department of Chemistry, University College London, 20 Gordon Street, London WC1H 1AJ, U.K.

(*Received* 24 *October* 1988; *accepted* 24 *November* 1988)

Abstract—The reaction of $Rh_2(O_2CCH_3)_4$ with 1,1,1-trifluoro-2,4-pentanedionate in water, gives two isomers of $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot 2H_2O$. Addition of pyridine and elution from a silica column gives isomerically pure $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot C_5H_5N$. The structure of the crystalline product was obtained by X-ray diffraction. The crystals belong to the monoclinic space group $P2_1/n$ with $a = 9.660(2)$, $b = 19.976(3)$, $c = 13.202(2)$ Å, $\beta = 106.54(2)°$, $V = 2442(1)$ Å^3 and $z = 4$. The structure was refined on 2708 independent reflections to $R_w = 0.0604$. The asymmetric unit contains a single dinuclear unit in which only one rhodium atom is bound by an axial pyridine molecule. The Rh—Rh bond is 2.534(1) Å and the Rh—N bond, 2.133(10) Å. Surprisingly, pairs of dinuclear units are linked together in the solid state via two long, 3.106 Å, Rh—C interactions, between the axial site on the metal and the γ-carbon atom of the β-diketonate ligand.

The vast majority of the classical metal–metal bonded dimers of the type $M_2(XYZ)_4$ (where XYZ is a monoanionic three-atom bridging ligand) exist as discrete dinuclear units, or simple bis-adducts $M_2(XYZ)_4L_2$ (L = pyridine, H_2O, PR_3 etc.), both in the solid state and in solution. Relatively few of these compounds exist as polymeric materials, the best characterized examples being the ruthenium compounds $Ru_2(O_2CR)_4Cl$ and $Ru_2(HN(O)CR)_4Cl$, in which dinuclear cations are linked in chains by bridging axial chloride ions,[1–4] and the so-called "unsolvated" $Cr_2(O_2CR)_4$ molecules, which associate in the solid state via oxygen bridge bonding.[5,6] In the course of our studies into the products formed on reaction of dirhodium(II) tetracarboxylate molecules with a number of β-diketone ligands, we have encountered an unusual molecule $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot C_5H_5N$, which in the solid state dimerizes through a pair of weak rhodium–carbon interactions.

EXPERIMENTAL

Synthesis

$Rh_2(O_2CCH_3)_4 \cdot 2CH_3OH$ (0.156 g, 0.31 mmol) was refluxed in H_2O (20 cm^3) with $CF_3C(O)CH_2C(O)CH_3$ (0.5 cm^3) for 6 h. The green precipitate formed was filtered off and air-dried. The solid was suspended in CH_3OH (10 cm^3) to which C_5H_5N (0.1 cm^3) was added. The mixture was stirred for 1 h, in which time a red solution was obtained. The CH_3OH was removed under reduced pressure and the red gum redissolved in CH_2Cl_2 (5 cm^3). This was loaded onto a silica gel (60–120 mesh) column and a green band eluted with a mixture of CH_2Cl_2 (80%), *n*-hexane (12%) and diethyl ether (8%). Slow evaporation of this solution resulted in the deposition of a homogeneous mass of green crystalline material. Yield 0.167 g, 70%. Found: C, 32.2; H, 2.7; N, 1.8. Calc. for $C_{19}H_{19}NO_8F_6Rh_2$: C, 32.2; H, 2.7; N, 2.0%. IR spectrum (KBr disc): 3449(w), 1607(m), 1542(s), 1512(m), 1481(m) 1443(s), 1420(w), 1340(m),

1267(s), 1210(s), 1198(s), 1152(s), 1137(s), 1095(m), 1064(w), 1003(w), 946(w), 819(w), 789(m), 754(w), 697(s), 624(w), 598(w), 530(w), 350(w) cm^{-1} (key: s, strong; m, medium; w, weak). Mass spectrum: m/z 630, $[Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2]^+$. Proton NMR ($CD_2Cl_2$ solvent, $(CH_3)_4Si$ reference): 17°C, pyridine, δ 8.48, 7.96, 7.52 ppm; $CF_3C(O)CHC(O)CH_3$, 5.54 ppm; O_2CCH_3, 2.08 ppm; $CF_3C(O)CHC(O)CH_3$, 1.90 ppm; −79°C, pyridine, δ 8.41, 7.97, 7.53 ppm; $CF_3C(O)CHC(O)CH_3$, 5.63 and 5.44 ppm; O_2CCH_3, 2.10 and 2.06 ppm; $CD_3C(O)CHC(O)CH_3$, 1.89 and 1.84 ppm.

X-ray studies

Green needle crystals were obtained as described above.

Crystal data. $C_{19}H_{19}NO_8F_6Rh_2$, monoclinic, space group $P2_1/n$, $a = 9.660(2)$, $b = 19.976(3)$, $c = 13.202(2)$ Å, $\beta = 106.54(2)°$, $U = 2442$ Å^3, $z = 4$, $M = 709.20$, $D_c = 1.93$ g cm^{-1}, μ(Mo-K_α) = 13.8 cm^{-1}, $F(000) = 1392$.

Measurements. Refined unit cell parameters were obtained by centring 50 reflections on a Nicolet R3mV diffractometer. A total of 4322 unique data were measured in the range $5° \leqslant 2\theta \leqslant 50°$ with Mo-K_α radiation (graphite monochromator). Of these, 2708 reflections had $I > 2.0\sigma(I)$ and were considered to be observed. Three standard reflections were remeasured every 97 scans and showed no significant loss (< 2%) in intensity during the data collection. The data were corrected for Lorentz and polarization factors, and an empirical absorption correction was applied.

Structure analysis. The positions of the two rhodium atoms were derived using direct methods and the remaining non-hydrogen atoms were found by iterative application of difference Fourier synthesis and least-squares refinement. The fluorine atoms are disordered over two sites. A satisfactory model for the disorder was found by assuming a 75% occupancy of one site [fluorines F(1a)—F(6a) attached to C(9) and C(14)] and a 25% occupancy of the alternative site [fluorines F(1b)—F(6b) attached to C(8) and C(13)]. No attempt was made to locate the hydrogen atoms. All atoms [except F(3b)] were refined anisotropically. The final cycle of refinement included 374 parameters and converged to give $R = 0.0776$ and $R_w = 0.0604$ ($w^{-1} = \sigma^2(F) + 0.00088F^2$), and did not shift any parameter by more than 0.026 times its estimated standard deviation. The final difference Fourier map was featureless with the largest peak being 1.01 e Å^{-3}. Computations were carried out on a Microvax II computer using the SHELXTL PLUS program package.

Final atomic coodinates, thermal parameters and structure factor tables have been deposited with the Editor and with the Cambridge Crystallographic Data Centre, as supplementary material.

RESULTS AND DISCUSSION

Some 20 years ago, the reaction of $Rh_2(O_2CCH_3)_4$ with β-diketones was reported to give complexes with the stoichiometry $[Rh(O_2CCH_3)(\beta\text{-diketonato})L]_2$, where L is the neutral donor ligand, H_2O or pyridine.[7] Several structures were proposed for these molecules. However, the most likely one contained a $[Rh_2]^{4+}$ core, two cisoid bridging acetato ligands, one chelating β-diketonato ligand on each metal ion, and one donor ligand, L, on each metal ion in the coordination site *trans* to the rhodium–rhodium single bond. We have recently confirmed this geometry for the molecule $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot 2C_5H_5N$.[8]

When $Rh_2(O_2CCH_3)_4$ is treated with an aqueous solution of the unsymmetrical β-diketone, $CH_3C(O)CH_2C(O)CF_3$, two isomers of the compound $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot 2H_2O$ are formed.[7] Although these isomers were not separated by Cenini *et al.* they were identified by ^1H NMR spectroscopy. In the *cis* isomer the β-diketonate ligands are arranged such that the $—CF_3$ substituents are approximately eclipsed, leading to inequivalent acetato ligands, while in the *trans* isomer each $—CF_3$ group is eclipsed with the $—CH_3$ substituent on the other β-diketonate, giving rise to an equivalence of the two acetato ligands in the NMR spectrum.

If the crude reaction mixture described earlier is treated with pyridine, which displaces the axially coordinated water molecules, and is then eluted from a silica column, an efficient separation of the two isomers can be effected.

The first fraction to be eluted from the column was shown, by ^1H NMR spectroscopy, to be the *trans* isomer. Surprisingly however, integration of the ^1H NMR spectrum was in the ratio pyridine–acetate–β-diketonate of 1:2:2. Given the propensity for the $[Rh_2]^{4+}$ unit to interact strongly with two axial ligands, this observation could not be easily rationalized and therefore we deemed it necessary to determine unequivocally the structure of this molecule in the solid state by X-ray crystallography.

Green needle crystals of $Rh_2(O_2CCH_3)(CF_3C(O)CHC(O)CH_3)_2 \cdot C_5H_5N$ are readily obtained

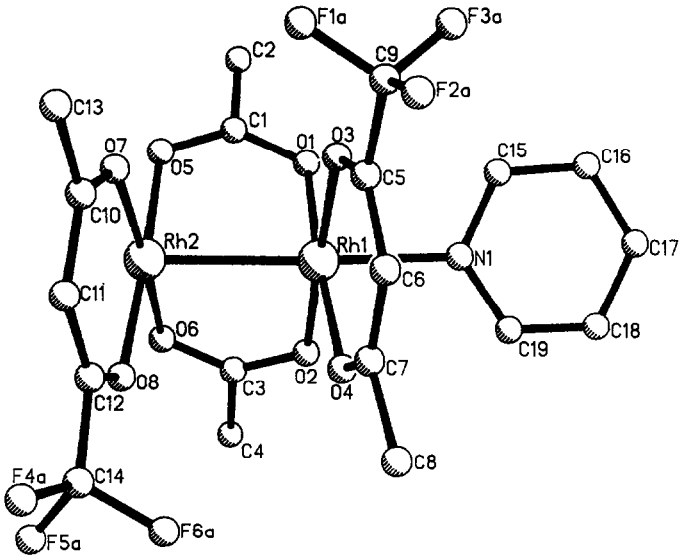

Fig. 1. Molecular structure of $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot C_5H_5N$ defining the atom labelling scheme.

by the slow evaporation of the solvent mixture used to elute the chromatography column. Data collection, structure solution and refinement used routine procedures described previously.[9]

The molecular structure of $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CH_3)_2 \cdot C_5H_5N$ is shown in Fig. 1, while the coupling of the dinuclear units is illustrated in Fig. 2. Selected bond lengths and angles are presented in Table 1. The two rhodium atoms in the dinuclear core are bridged by two acetate ligands and each rhodium is also coordinated by a chelating $[CF_3C(O)CHC(O)CH_3]^-$ ligand. The coordination site on Rh(1) *trans* to the Rh—Rh bond is occupied by a pyridine molecule. The Rh—Rh bond length, 2.534(1) Å, is very similar to the one observed in $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot 2C_5H_5N$, 2.523(2) Å,[8] and is much greater than that observed for the tetracarboxylate complex, $Rh_2(O_2CCH_3)_4 \cdot 2C_5H_5N$, 2.396(1) Å.[10] This Rh—Rh bond distance is not dissimilar to that observed in $Rh_2(O_2CCH_3)_2(phen)_2$ complexes (mean: 2.558(3) Å), which also contain only two acetate ligands bridging the metal–metal single bond.[11] One closely related molecule, $Rh_2(O_2CCH_3)_2(dmg)_2 \cdot 2PPh_3$, has been observed to have a significantly longer Rh—Rh bond, 2.618(5) Å.[12] The Rh—Rh and Rh—N bonds are not colinear: angle Rh(2)—Rh(1)—N(1) =

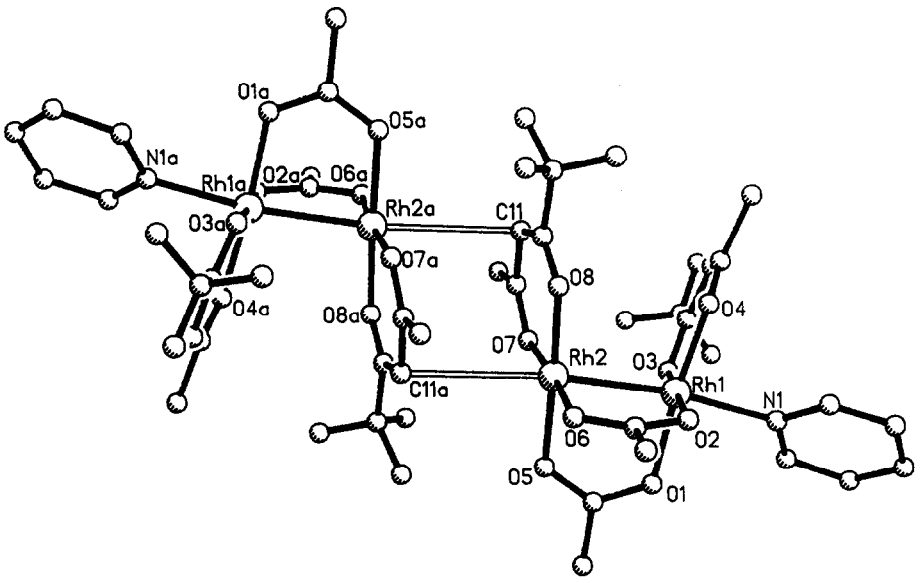

Fig. 2. Coupling of the dinuclear units (atoms labelled "a" are generated by an inversion centre).

O(8)—Rh(2)—O(7)	93.6(4)		

171.8(3)°. This angle is similar to those observed in $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot 2C_5H_5N$[8] and $Rh_2(O_2CC(CH_3)_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot 2C_5H_5N$,[13] and can almost certainly be attributed to unfavourable steric interactions between the axial ligands and the $-CF_3$ substituent(s) on the chelating β-diketonate ligands. Although the deviation from linearity is significant, it is markedly less than that observed in $Rh_2(O_2CR)_2[(C_6H_4)PR'R'']_2 \cdot 2L$ molecules, which also exhibit similarly distorted structures.[14,15] The rhodium–carboxylate–oxygen bonds are longer than those to the β-diketonate oxygen atoms (mean values of 2.029 and 2.000 Å, respectively). In addition, the Rh—Rh—O(carboxylate) angles average 85.5°, while those involving the β-diketonate ligands average 97.8°. The dihedral angle between the least-square planes defined by the atoms Rh(1)—O(3)—C(5)—C(6)—C(7)—O(4) and Rh(2)—O(7)—C(10)—C(11)—C(12)—O(8) is 29.3°. These distortions from the idealized octahedral geometry about the metal ions must be attributed to the unfavourable steric interactions between the substituent groups on the two chelating β-diketonate ligands. The two β-diketonate ligands are rotated about the Rh—Rh axis by *ca* 7° from the eclipsed configuration (torsion angles O(3)—Rh(1)—Rh(2)—O(7) 7.6°; O(4)—Rh(1)—Rh(2)—O(8) 6.6°). Similarly, the two bridging acetate ligands are distorted with torsion angles about the Rh—Rh bond of 6.2 and 7.4°. This twisting of one end of the dinuclear molecule with respect to the other is much reduced from that observed in $Rh_2(O_2CCH_3)_2(CF_3C(O)CHC(O)CF_3)_2 \cdot 2C_5H_5N$,[8] where the four independent torsion angles fall in the range 11–15°.

Initial inspection of the molecular structure indicated that one rhodium atom per molecule was coordinatively unsaturated. However, when the crystal packing was examined, it became apparent that in the solid state the binuclear units are associated in pairs, see Fig. 2. The open site on Rh(2) is blocked by a γ-carbon atom of a β-diketonate ligand on an adjacent molecule. The rhodium-to-carbon distance, 3.106 Å, is too long to be considered as a formal bond. However, the interaction must be relatively strong, otherwise we would expect to observe the axial ligation of a second pyridine molecule. Similar long metal–carbon interactions have been observed in the homoleptic β-diketonate com-

pounds of mercury(II) and iron(II).[16,17] We believe that the separation between the two metallocyclic rings is principally a function of the unfavourable steric interactions. There is no evidence of metal–metal interactions between the dinuclear units, the Rh(2)—Rh(2a) distance being > 4.8 Å.

The ^1H NMR spectra recorded in CD_2Cl_2 at 290 K (see Experimental), show only averaged β-diketonate and acetate ligands. When spectra were recorded at 194 K, each class of ligand has two sets of resonances consistent with a steady-state structure in which only one rhodium ion is ligated by pyridine. The low temperature NMR data do not conclusively establish that binuclear units are linked in pairs in solution. However, even though neither signal due to the proton on the γ-carbon atom exhibits resolved coupling to rhodium, we believe that the chemical shift difference, which is much larger than that for any other pair of proton environments, may be attributed to a structure in solution closely similar to that which is observed in the crystal lattice.

Acknowledgements—We thank Johnson Matthey plc for their generous loans of rhodium trichloride and the SERC for provision of the X-ray equipment.

Abstract—The compounds $Ru_3(CO)_9(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**1**) and $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**2**) are decarbonylated when heated to 68°C and condense to form the dimers $[Ru_3(CO)_8(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**3**) and two isomers of $[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**4**) and (**5**), respectively. Compounds **2**, **3**, **4** and **5** were characterized by single-crystal X-ray diffraction. Compounds **1** and **2** are open clusters that have a triply bridging sulphido ligand and a triply bridging HC_2Ph ligand. Compounds **3**, **4** and **5** are dimers of the decarbonylated forms of **1** and **2** that are joined by two S → Ru donor–acceptor bonds, one from each cluster to the other. Compounds **3** and **4** are centrosymmetric and were formed by the combination of enantiomers of the cluster precursors. Compound **5** is chiral but has overall C_2 symmetry and was formed by the combination of enantiomerically similar monomeric units. Compound **5** is converted to **4** when heated, but the reverse does not occur.

Recent studies have demonstrated the value of bridging sulphido ligands in facilitating the addition of metal containing groups to cluster complexes[1–9] [e.g. eq. (1)[10]]. In the absence of addition reagents, ligand elimination processes may result in self-condensation of the clusters, (e.g. dimerization, eq. (2);[11] cyclotrimerization, eq. (3)[12]). This is facilitated by coordination of the lone pair of electrons of the bridging sulphido ligand to the vacant site on the metal atom of a second cluster. Further ligand elimination can lead to the formation of metal–metal bonds between the clusters.[11]

We have recently reported the preparation and structural characterization of the sulphur- and alkyne-bridged cluster complex, $Ru_3(CO)_9(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**1**), from the reaction of $Ru_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)$ with HC_2Ph.[13] Compound **1** is easily enlarged by the sequential addition of ruthenium carbonyl fragments generated from $Ru(CO)_5$.[14] We have now found that **1** and its PMe_2Ph derivative, **2**, readily undergo the elim-

ination of 1 mole of CO when heated and the resultant ligand deficient species will combine with a second cluster to yield dimers joined by bridging sulphido ligands. The results of this study are reported herein.

EXPERIMENTAL

General data

All reactions were performed under a nitrogen atmosphere, unless otherwise specified. Reagent grade solvents were dried over 4 Å molecular sieves. $Ru_3(CO)_{12}$ was purchased from Strem Chemical Co. and was used as received. Phenylacetylene was purchased from Aldrich Chemical Co. and was vacuum distilled before use. Dimethylphenylphosphine was purchased from Aldrich Chemical Co. and used as received. CP grade carbon monoxide was purchased from Linde Co. and was used without further purification. $Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**1**) was prepared as previously reported.[13]

All chromatographic separations were performed in air. TLC separations were performed on plates of 0.25 mm Kieselgel 60 F_{254}, E. Merck, F.R.G. IR spectra were recorded on a Nicolet 5DXB FT-IR spectrophotometer. ^1H NMR spectra were recorded on a Brüker AM-300 spectrometer operating at 300 MHz. Elemental analyses were performed by Desert Analytics, Tucson, Arizona.

Preparation of $Ru_3(CO)_8(\mu_3\text{-}\eta^2\text{-}HC_2Ph)(PMe_2Ph)(\mu_3\text{-}S)$ (**2**)

100 mg (0.145 mmol) of compound **1** and 0.022 cm^3 (0.154 mmol) of PMe_2Ph were dissolved in cyclohexane (75 cm^3). The reaction solution was then stirred for 30 min at 25°C, and the solvent was removed *in vacuo*. The residue was dissolved in a minimum of CH_2Cl_2 and was chromatographed by TLC by using a hexane–CH_2Cl_2, 8:2 solvent mixture. Yield: 74.3 mg of $Ru_3(CO)_8(PMe_2Ph)[\mu_3\text{-}HC_2Ph](\mu_3\text{-}S)$ (**2**), 64% as a yellow band. IR for **2**: (ν(CO) cm^{-1} in hexane) 2082(s), 2050(vs), 2018(vs), 1997(w,br), 1982(m), 1974(w,sh), 1967(w,sh). ^1H NMR (δ in $CDCl_3$) 8.95 (s, 1H), 7.40–6.66 (m, 10H), 1.88 (d, 3H, J_{PH} = 9.54 Hz), 1.72 (d, 3H, J_{PH} = 10.47 Hz). Found: C, 36.5; H, 2.1. Calc. for $Ru_3PSO_8C_{24}H_{17}$: C, 36.0; H, 2.1%.

Decarbonylation of $Ru_3(CO)_9(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**1**)

50 mg (0.0725 mmol) of compound **1** was dissolved in hexane (50 cm^3) and then heated to a reflux for 30 min. During this time, the yellow solution changed to a cloudy orange colour. The hexane was removed *in vacuo*, the residue was dissolved in a minimum of CH_2Cl_2 and was chromatographed by TLC, using a hexane–CH_2Cl_2, 95:5, solvent mixture. Yield: 47.0 mg of orange $[Ru_3(CO)_8(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**3**), 98%. IR for **3**: (ν(CO) cm^{-1} in hexane) 2087(vs), 2060(vs), 2041(vs), 2024(m), 2016(w), 2010(vw), 2001(w), 1974(w). ^1H NMR (δ in $CDCl_3$) 8.30 (s, 1H), 7.16–6.87 (m, 5H). Found: C, 29.0; H, 0.90. Calc. for $Ru_6S_2O_{16}C_{32}H_{12}$: C, 29.0; H, 0.91%.

Reaction of **3** *with* CO

9.0 mg (0.0068 mmol) of compound **3** was dissolved in heptane (10 cm^3). The solution was heated to reflux (98°C) for 30 min under a CO purge. Work-up as described above yielded 9.1 mg of **1**, 97%, as a yellow band.

Reaction of **3** *with* PMe_2Ph

5.0 mg (0.0038 mmol) of **3** was dissolved in CH_2Cl_2 (10 cm^3). To this solution was added 1 equivalent of PMe_2Ph. The reaction mixture was then stirred for 30 min at 25°C and the solvent was removed *in vacuo*. The residue was dissolved in a minimum of CH_2Cl_2 and was chromatographed by TLC, using a hexane–CH_2Cl_2, 8:2, solvent mixture. Yield: 5.1 mg of **2**, 84%.

Decarbonylation of **2**

51.8 mg (0.075 mmol) of compound **2** was dissolved in hexane (50 cm^3) and was then heated to a reflux for 3.5 h. The solution turned from bright yellow to orange. The hexane was removed *in vacuo*. The residue was dissolved in a minimum of CH_2Cl_2 and was chromatographed by TLC using a hexane–CH_2Cl_2, 75:25, solvent mixture. This yielded 2.7 mg of compound **2**, 21.2 mg of *R,S*-$[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**4**), 45% as an orange band, and 24.5 mg of *R,R*- and *S,S*-$[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**5**), 52.0% as a bright orange band. For **4**: IR (ν(CO) cm^{-1} in hexane) 2052(s), 2028(vs), 1996(w), 1972(m), 1953(w). ^1H NMR (δ in $CDCl_3$) 7.59–6.57 (m, 11H), 1.98 (d, 3H, J_{PH} = 10.83 Hz), 1.96 (d, 3H, J_{PH} = 10.86 Hz). Found: C, 36.0; H, 2.2. Calc. for $Ru_6P_2S_2O_{14}C_{46}H_{34}$: C, 35.8; H, 2.2%. For **5**: IR (ν(CO) cm^{-1} in hexane) 2067(s), 2054(m), 2029(vs), 2006(vw), 1982(m), 1971(w), 1967(w,sh), 1951(m). ^1H NMR (δ in $CDCl_3$) 7.64–6.57 (m, 11H), 2.04 (d, 3H, J_{PH} = 10.29 Hz), 2.01 (d, 3H, J_{PH} = 10.47 Hz). Found: C, 35.7; H, 1.93. Calc. for $Ru_6P_2S_2O_{14}C_{46}H_{34}$: C, 35.8; H, 2.22%. The yields of

compounds **4** and **5** were calculated from the amount of **2** that was consumed.

Isomerization of **5** *to* **4**

48.8 mg (0.0369 mmol) of compound **5** was heated to reflux in octane (50 cm^3). The reaction solution was refluxed for 2.5 h. Work-up as described above yielded 27.1 mg of compound **4**, 60%, and 3.8 mg of compound **5**. The yield of compound **4** was calculated from the amount of **5** consumed.

Crystallographic analyses

Crystals of **2** were grown by slow evaporation of hexane solutions at −20°C. Crystals of **3** were grown by slow evaporation of solvent from hexane–CH_2CL_2, 8 : 2, solutions at 25°C. Crystals of **4** and **5** were grown by slow evaporation of benzene solutions at 25°C. The data crystals were mounted in thin-walled glass capillaries. Diffraction measurements were made on a Rigaku AFC6 automatic diffractometer by using Mo-K_α radiation. Unit cells were determined and refined from 25 randomly selected reflections obtained by using the AFC6 automatic search, centre, index and least-squares routines. Crystal data and results of the analyses are listed in Table 1. All data processing was performed on a Digital Equipment Corp. MICROVAX II computer by using the TEXSAN structure solving program library (v 2.0) obtained from the Molecular Structure Corp., College Station, Texas. Neutral atom scattering factors were obtained from the standard sources.[15a] Anomalous dispersion corrections were applied to all non-hydrogen atoms.[15b] Full-matrix least-squares of refinements minimized the function:

$$\sum_{hkl} w(|F_{obs}| - |F_{calc}|)^2 \quad \text{where}$$

$$w = 1/\sigma(F)^2, \quad \sigma(F) = \sigma(F^2_{obs})/2F_{obs}$$

$$\text{and} \quad \sigma(F^2_{obs}) = [\sigma(I_{raw})^2 + (PF^2_{obs})^2]^{1/2}/Lp.$$

All four compounds crystallized in the triclinic crystal system.

The space group $P\bar{1}$ was assumed and confirmed in each case by the successful solution and refinement of the structure.

For **2**, the structure was solved by a combination of Patterson and difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were located and refined with isotropic thermal parameters.

The structures of compounds **3**–**5** were solved by combinations of direct methods and difference Fourier syntheses. Compound **3** contains two symmetry independent molecules in the unit cell, and each molecule contains a crystallographically imposed centre of symmetry. Compound **4** contains only one complete molecule in the unit cell and it contains a crystallographically imposed centre of symmetry. For **3** and **4**, all non-hydrogen atoms were refined with anisotropic thermal parameters. For **3**, the acetylenic hydrogen atoms were located and refined. The hydrogen atom positions of the phenyl groups were calculated and included in the structure factor calculations, but they were not refined. For **4**, all hydrogen atom coordinates were calculated and their scattering contributions were added to the structure factor calculations, but their positions were not refined. For **5**, only the atoms larger than oxygen were refined with anisotropic thermal parameters. Hydrogen atom coodinates were calculated and their scattering contributions were included in the structure factor calculations, but their positions were not refined.*

RESULTS AND DISCUSSION

Compounds **1** and **2** undergo decarbonylation when solutions in hexane solvent are refluxed. The decarbonylated species then couple in pairs to yield the hexaruthenium complexes **3**, and **4** and **5** in reasonably good yield from **1** and **2**, respectively. Compound **3** can be reconverted to **1** by treatment with CO at 97°C, and converted to **2** by treatment with PMe_2Ph at 25°C. As determined from the crystallographic characterizations, *vide infra*, compounds **4** and **5** are isomers. It was found that **5** is converted to **4** when refluxed in octane solutions, but the reverse does not occur. This is in accord with the finding that the yield of **4** relative to **5** increases as the reaction period decreases.

Description of the structures

$Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**2**). An ORTEP diagram of the molecular structure of **2** is shown in Fig. 1. Selected bond distances and angles are listed in Tables 2 and 3. The molecule consists of an "open" triangular cluster of three ruthenium atoms that contains two ruthenium–ruthenium bonds. Structurally, compound **2** is very similar to that of **1**.[13] However, unlike **1**, in which the two ruthenium–ruthenium bonds are nearly equal in length, 2.798 vs 2.776 Å,† the Ru(2)—Ru(3) bond that lies approximately *trans* to the phosphine ligand in **2** is significantly longer than the Ru(1)—Ru(2) bond, 2.8077(5) vs 2.7482(4) Å. A similar difference that was attributed to a σ-inductive effect of the phosphine ligand was observed between the two open osmium cluster complexes $Os_3(CO)_9(\mu_3\text{-}S)_2$ and $Os_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$.[16] Compound **2** contains a triply bridging sulphido ligand and a triply bridging HC_2Ph ligand analogous to **1**. The alkyne ligand has adopted the $2\sigma+\pi$ or μ_3-|| bonding mode and serves as a four electron donor.[17] The hydrogen atom on the alkyne ligand was located and refined. In the ^1H NMR spectrum of **2**, it was observed in the characteristically low-field shift region at $\delta = 8.95$. The carbonyl ligands on Ru(2) differ from the relative positions observed in **1**. In **2**, one carbonyl ligand C(23)—O(23) lies essentially in the plane of the three metal atoms and displays a weak semibridg-

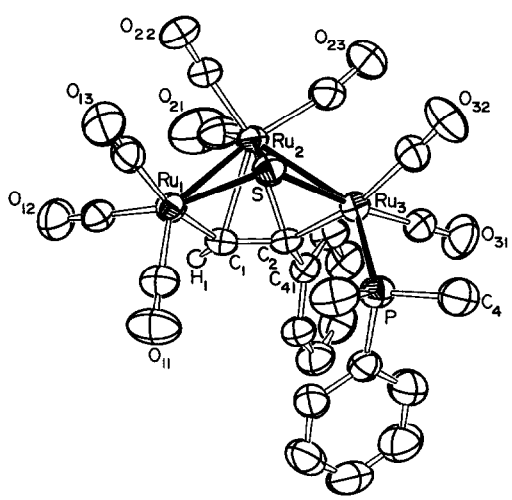

Fig. 1. An ORTEP diagram of $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ (**2**).

*Complete tables of bond lengths, angles, atomic positional and thermal parameters, and observed and calculated structure factors for **2**–**5** have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have been submitted to the Cambridge Crystallographic Data Centre.

† These are averaged values.

Angles are in degrees. Estimated standard deviations in the least significant figure are given in parentheses.

ing character to Ru(3), Ru(2)—C(23)—O(23) = 170.6(3)°. This ligand lies in the region approximately *trans* to the phosphine ligand on Ru(3). The development of the semibridging character could be a result of the greater concentration of electron density on Ru(3) due to the substitution of a carbonyl ligand with the PMe_2Ph ligand. All the other carbonyl ligands are linear. Overall, the molecule contains no symmetry and the crystal consists of a racemic mixture of the two enantiomers.

$[Ru_3(CO)_8(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**3**). An ORTEP drawing of the molecular structure of **3** is shown in Fig. 2. Selected bond distances and angles are listed in Tables 4 and 5. In the crystal, compound **3** contains two symmetry independent dimers of the monomeric unit $Ru_3(CO)_8(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$ and each dimer contains a crystallographically-imposed centre of symmetry. The basic monomeric unit is structurally very similar to that of its parent **1**. Unlike **1**, **3** does not have a carbonyl ligand on the metal atom Ru(3), at the site approximately *trans* to the phenyl-substituted end of the bridging alkyne ligand. Instead, this site is filled by the donation of a lone pair of electrons from the sulphido ligand of the second monomeric unit of the dimer. This S → Ru donor–acceptor bond is significantly longer,

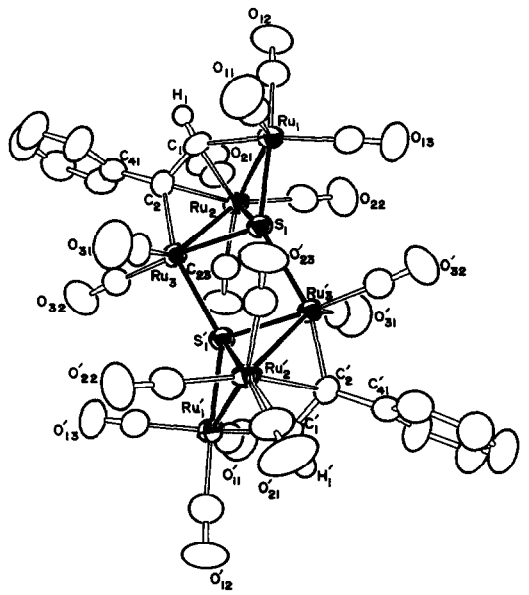

Fig. 2. An ORTEP diagram of the molecular structure of $[Ru_3(CO)_8(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**3**).

2.478(2) Å, than the Ru—S bonds within the monomeric unit which range from 2.337(2) to 2.418(2) Å. A similar difference in Ru—S bonding was observed in the cyclotrimer $[Ru_3(CO)_8(\mu\text{-}H)_2(\mu_4\text{-}S)]_3$ (**6**) in

Angles are in degrees. Estimated standard deviations in the least significant figure are given in parentheses.

which the monomeric units were also joined by S → Ru donor–acceptor bonds.[12] The sulphido ligand in the first monomeric unit is similarly coordinated to the corresponding ruthenium atom of the second cluster and this completes joining of the two clusters. A planar Ru—S—Ru—S ring is formed. The alkyne hydrogen atoms were located and refined. It exhibits the characteristic low-field shift, $\delta = 8.30$, but is shifted upfield slightly (0.53 ppm) from that observed in **1**.

R,S-$[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**4**). An ORTEP drawing of the molecular structure of **4** is shown in Fig. 3. Selected bond distances and angles are listed in Tables 6 and 7. The unit cell contains one formula unit of **4** and like **3** it contains a crystallographically-imposed centre of symmetry. Thus **4** consists of a combination of the *R*- and *S*-enantiomers of the monomeric cluster unit. The configuration of the cluster can be defined uniquely from the configuration of the chiral sulphido ligand. The monomeric unit, $Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$, is structurally very similar to that of its parent **2**, *vide supra*, except that the two Ru—Ru bond distances are nearly equal, Ru(1)—Ru(2) by TLC, using a hexane–CH_2Cl_2, 95:5, solvent = 2.803 (1) Å and Ru(2)—Ru(3) = 2.799(2) Å. The dimer is linked through two S → Ru donor–acceptor bonds similar to those in **3**. As in **3**, these donor–acceptor bonds are significantly longer, 2.500(3) Å, than those within the monomeric cluster unit, range 2.348(3)–2.427(3) Å. As in **3**, the Ru—S—Ru—S ring is planar by symmetry.

R,R- and S,S-$[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**5**). An ORTEP drawing of the molecular struture of **5** is shown in Fig. 4. Selected bond distances and angles are listed in Tables 8 and 9. Compound **5** is an isomer of **4**. It is also a dimer of **2**, but was formed by the coupling of two enantiomerically similar monomers. The structure of the monomeric unit, $Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_3\text{-}S)$, in **5** is essentially the same as that in **4**. The two monomeric units are joined by two S → Ru donor–acceptor bonds, Ru(3)—S(2) and Ru(6)—S(1), that are similar in length to those in **4**, 2.490(4) and 2.510(4) Å, and are significantly longer than the Ru—S bonds within the cluster unit. Overall, the molecule has C_2 symmetry (not crystallographically imposed). The Ru—S—Ru—S ring is not planar but has a slight fold. The dihedral angle is 16.5°. Since the crystal of **5** is centrosymmetrical, it must contain an equal mixture of the two enantiomeric dimers (i.e. the *R,R* and *S,S* combinations of the monomers).

The irreversible isomerization of **5** to **4** indicates that **5** is a kinetically stable product of the decarbonylation of **2**. Evidently, for reasons that are not apparent to us, enantiomerically similar monomeric units undergo dimerization more readily than enantiomerically dissimilar monomeric units, but the *meso* isomer **4** is thermodynamically more stable.

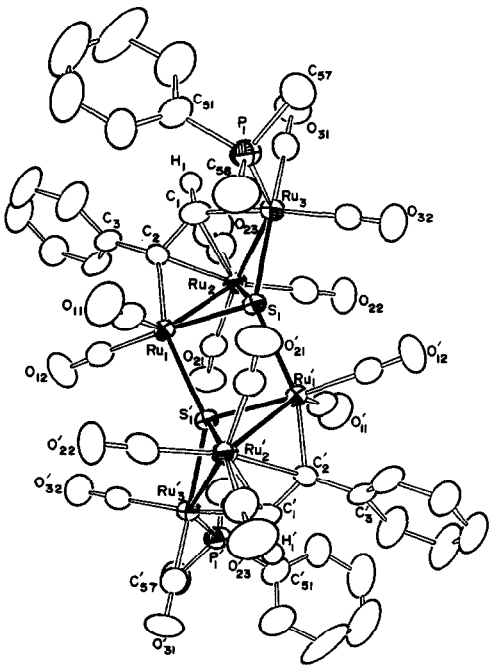

Fig. 3. An ORTEP diagram of *R,S*-$[Ru_3(CO)_7(PMe_2P)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**4**).

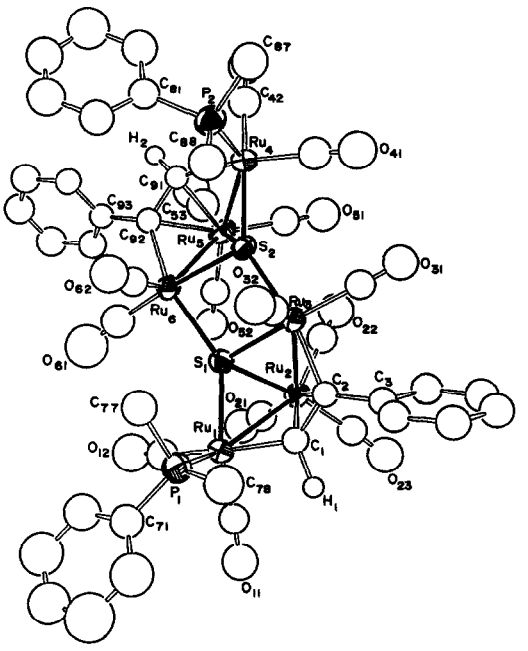

Fig. 4. An ORTEP diagram of $[Ru_3(CO)_7(PMe_2Ph)(\mu_3\text{-}HC_2Ph)(\mu_4\text{-}S)]_2$ (**5**). The *R,R*-enantiomer is shown.

This study clearly shows the importance of the bridging sulphido ligand to the first step in cluster self-condensation. Unfortunately, our attempts to induce further condensation by the formation of metal–metal bonds between the two triruthenium groups have not yet been successful. In the osmium system, eq. (2), further condensation was achieved.[11] These two systems seem to differ from that of the decarbonylation and dimerization of $Os_3(CO)_9(\mu_3\text{-}S)_2$.[18] In the dimer, $[Os_3(CO)_8(\mu_3\text{-}S)_2]_2$ (7), the monomeric units are joined by metal–metal bonds only. However, it is possible that unobserved sulphur-bridged intermediates were traversed en route to 7.

Acknowledgements—These studies were supported by the National Science Foundation under Grant CHE-8612862. NMR measurements were made on a Brüker AM-300 spectrometer purchased with funds from the National Science Foundation under Grant No. CHE-8411172.

(*Received* 8 *November* 1988; *accepted* 12 *December* 1988)

Abstract—Extended Hückel calculations on the model complexes $(C_6H_6)_2Cr$, $(C_6H_6)CrP_6$, $(C_5H_5)_2Cr^{2-}$, $(C_5H_5)CrP_5^{2-}$, $(C_5H_5)_2Fe$ and $(C_5H_5)FeP_5$ showed that the complexes containing P_5 and P_6 ring systems may show stabilities comparable to, or even stronger than, their carbon analogues, despite large differences between the free cyclic fragments. Although the HOMO–LUMO energy gaps in both P and C complexes are often similar, the pattern of MO interactions differ significantly for P and C rings and there is less distinct MO binding in P complexes.

It is now established that the P_x units can act as two, four, six and eight electron donors to metal fragments.[1] Among those P-containing complexes recently synthesized are several triple- and double-decker sandwich complexes with cyclic and planar P_6[2] and P_5[3] layers which lie parallel to other arene ligands. While the existence of the *free* hexaphosphabenzene (**I**) is, up to now, only theoretically postulated,[4] the cyclic anion (**II**), the all-phosphorus analogue of the cyclopentadienide anion ($C_5H_5^-$), has recently been generated in solution and characterized spectroscopically.[5] The shape of the experimental UV spectrum, which exhibits two $\pi^* \leftarrow \pi$ absorption bands and a $\pi^* \leftarrow n$ band, suggests a strongly aromatic character for **II**.

(I)

(II)

In this context, an interesting problem is to consider to what extent can the P_x rings, **I** and **II**, be compared with their carbon analogues in complexation with metal fragments. In this particular work we attempt to consider this question in a simple way by carrying out self-consistent charge and configuration extended Hückel[6] calculations on the double-decker complexes formed from the interaction of P_6 and C_6H_6 with $(C_6H_6)Cr$, and of P_5^- and $C_5H_5^-$ with both $(C_5H_5)Cr^-$ and $(C_5H_5)Fe^+$, respectively. Such a comparative study enables some qualitative information about the P_x complexes to be found.

The calculations were carried out using the FORTICON-8 program[7] and the MO correlation diagrams were constructed using a program developed in our laboratory. The calculation on the moieties were non-iterative, using the coulomb terms from the self-consistent results. Details of the choice of semi-empirical parameters used for the iterative calculations were given in previous papers.[8] The geometries employed were derived from the crystal structures where possible and the following distances were taken (values in Å):

(a) $(C_6H_6)Cr$, $(C_6H_6)_2Cr$ and $(C_6H_6)CrP_6$: r(Cr—C) = 2.19; r(C—C) = 1.38; r(Cr—P) = 2.54 and r(P—P) = 2.17 (refs 2 and 9).

* Author to whom correspondence should be addressed.

(b) $(C_5H_5)Cr^-$, $(C_5H_5)_2Cr^{2-}$ and $(C_5H_5)CrP_5^{2-}$: r(Cr—C) = 2.30; r(C—C) = 1.43; r(P—P) = 2.17 and r(Cr—P) = 2.30 (refs 3(a) and 10);

(c) $(C_5H_5)Fe^+$, $(C_5H_5)_2Fe$ and $(C_5H_5)FeP_5$: r(Fe—C) = 2.03; r(C—C) = 1.43; r(P—P) = 2.10 and r(Fe—P) = 2.34 (refs 3(c) and 11).

Molecular orbital correlation diagrams are displayed in Figs 1–3.

The $(C_6H_6)_2Cr$ *and* $(C_6H_6)CrP_6$ *complexes*

From Fig. 1, it can be seen that there is a considerable difference between the free P_6 and C_6H_6 moieties. There is in fact a large HOMO–LUMO separation ($\approx$ 5 eV) in the latter, while in P_6 the gap is only about 1.2 eV. In both, the LUMO is of π^*-character (2e).

The $(C_6H_6)Cr$ moiety has a small HOMO–LUMO gap (0.5 eV). In $(C_6H_6)_2Cr$, the gap becomes larger (1.8 eV). The principal interaction (which is well known) is that of the LUMO-(C_6H_6) with the 2nd-HOMO-(C_6H_6)Cr. The latter is mainly of Cr($d_{x^2-y^2}$, d_{xy}) origin. There is also interaction between the filled π-(C_6H_6) level and the empty 1st-LUMO-(C_6H_6)Cr. The resulting antisymmetric MO thus constitutes the complex LUMO. The HOMO-$(C_6H_6)_2Cr$ is essentially the HOMO-(C_6H_6)Cr with strong Cr(d_{z^2}) character.

In the P_6 complex, the HOMO–LUMO separation is somewhat smaller (1.5 eV). Here, as with C_6H_6, a strong interaction between the 2nd-HOMO-(C_6H_6)Cr and LUMO-P_6 occurs, with mixing-in of the HOMO-P_6 level. These interacting MOs lie closer in energy than those in $(C_6H_6)_2Cr$, so that the resulting interaction is expected to be stronger.

The charges on benzene in the two complexes differ little. In $(C_6H_6)CrP_6$, the P charge is -0.029 and the C and H charges are -0.031 and -0.034. Thus, the overall Cr $\rightarrow$ P_6 charge-transfer is less than the Cr $\rightarrow$ CH transfer. The atomic populations reveal that the metal gives electrons to the vacant π^*-hexaphosphabenzene orbitals. The results also show large donation to the metal from the P_6 ring.

In summary, it may be said that both $(C_6H_6)_2Cr$

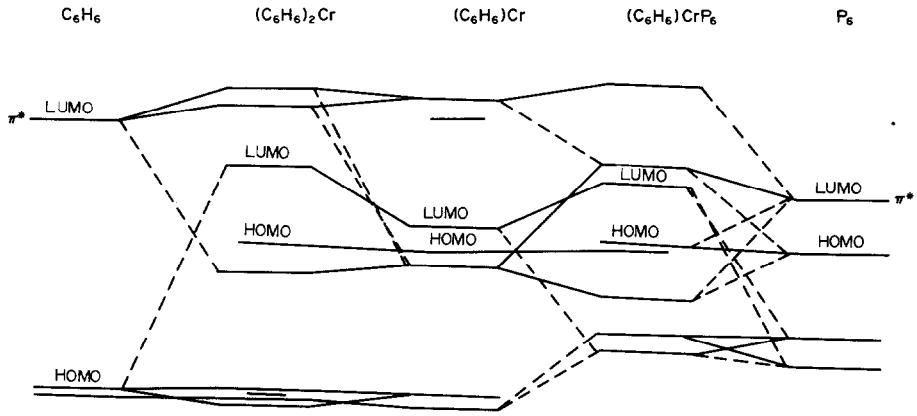

Fig. 1. MO correlation diagram comparing the $(C_6H_6)_2Cr$ and $(C_6H_6)CrP_6$ complexes.

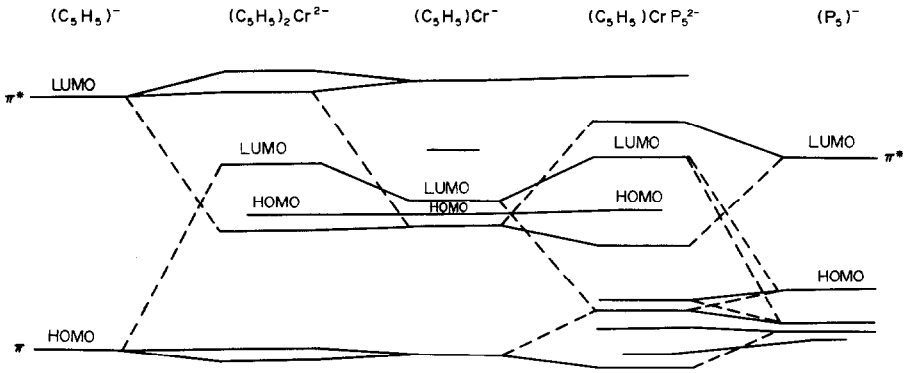

Fig. 2. MO correlation diagram comparing the $(C_5H_5)_2Cr^{2-}$ and $(C_5H_5)CrP_5^{2-}$ complexes.

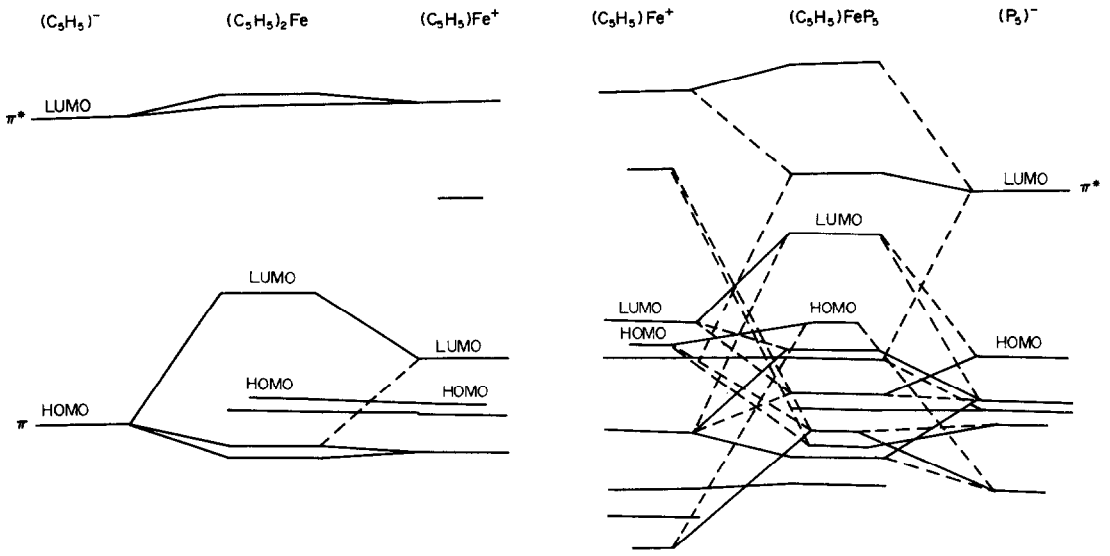

Fig. 3. MO correlation diagram comparing the $(C_5H_5)_2Fe$ and $(C_5H_5)FeP_5$ complexes.

and $(C_6H_6)CrP_6$ have a number of similarities. In particular, the LUMO–HOMO energy separation is of the same order in both, which suggests comparable kinetic stabilities. In the P_6-complex, the main interaction is $P(\sigma) \rightarrow Cr$ donation with weaker $Cr \rightarrow P(\pi^*)$ donation than in the C_6H_6 case. Overall, while free P_6 is much less stable than free benzene,[4] it appears that with such systems as a d^6 arenechromium fragment, the P_6 ring may be trapped.

The $(C_5H_5)_2Cr^{2-}$ *and* $(C_5H_5)CrP_5^{2-}$ *complexes*

There are some differences between the free $C_5H_5^-$ and P_5^- moieties. The HOMO–LUMO gap in the former is large ($\approx$ 5.5 eV) and is smaller in the latter ($\approx$ 2.5 eV). The LUMO is of π^*-character (2e) in both, but in $C_5H_5^-$, the HOMO is π, whereas in P_5^-, the HOMO is not and the π (1e) orbital lies less than 1 eV lower in energy. Thus, the LUMO of $C_5H_5^-$ lies higher in energy than that of P_5^- while a reverse ordering occurs for the HOMOs (Fig. 2). Despite such differences, the HOMO–LUMO energy gap levels becomes similar in both complexes ($\approx$ 1 eV).

In $(C_5H_5)CrP_5^{2-}$, the principal stabilization arises from a strong interaction between the LUMO-$(P_5)^-$ and the 2nd-HOMO-$(C_5H_5)Cr^-$ giving rise to the 2nd-HOMO of the complex. Owing to the more favoured HOMO–LUMO energy separation, this interaction is stronger than the corresponding one in $(C_5H_5)_2Cr^{2-}$. The non-bonding HOMO of $(C_5H_5)Cr^-$ remains the principal contribution to the HOMOs of both complexes. There is also an additional stabilizing interaction between the HOMO-$(P_5)^-$ and the LUMO-$(C_5H_5)Cr^-$ (Fig. 2). This would enhance the stability of the P_5 system. In going from the $C_5H_5^-$ to the P_5^- complex, a decreasing overlap thus does not operate against a greater interaction with the metal as much as with the six-membered ring analogues discussed above.

From a population analysis, we note that the $Cr \rightarrow$ ring charge-transfer occurs in both complexes. The $C_5H_5^-$ ring charges become more negative and that of Cr more positive in $(C_5H_5)_2Cr^{2-}$. The two way electron flow in $(C_5H_5)CrP_5^{2-}$ also involves a larger amount of electrons than that in the C_5H_5 counterpart. In $(C_5H_5)CrP_5^{2-}$ the $d_{x^2-y^2}/d_{zy}$ populations are 1.506, and in $(C_5H_5)_2Cr^{2-}$ the corresponding value is 1.754, thus increased donation from Cr is indicated in the P complex. Also in the P complex the $d_{xz/yz}$ population is 0.445, while in $(C_5H_5)_2Cr^{2-}$ it is 0.274. Thus in the P complex there is more donation to the Cr. This is a further illustration of the difference between the complexes and indicates appreciable stability for $(C_5H_5)CrP_5^{2-}$.

An investigation of the eclipsed forms of the complexes showed very similar interactions and energies to those for the staggered complexes examined here.

In summary, the calculations indicate that donation to and from the metal are larger in $(C_5H_5)CrP_5^{2-}$ than in $(C_5H_5)_2Cr^{2-}$. As the HOMO–LUMO energy separations differ little, the kinetic stability of both complexes may be expected to be similar. Thus, the existence of cyclo-P_5^- in the complexed form is perhaps not as surprising as originally thought. However, this complex is di-anionic, therefore a consideration of the corres-

ponding neutral Fe complex was undertaken for comparative purposes.

The $(C_5H_5)_2Fe$ *and* $(C_5H_5)FeP_5$ *complexes*

The isolated $C_5H_5Fe^+$ moieties in the two complexes differ slightly, thus in Fig. 3 they are represented separately. Firstly, we note that the LUMOs of the cyclopentadienide rings are not involved in bonding in ferrocene. The HOMO–LUMO energy differences amount to about 2.0 eV in both complexes, which are larger (Fig. 3) than in the anionic chromium species. As previously, there is significant mixing-in of lower-lying orbitals into the HOMO-$(P_5)^-$ and LUMO-$(C_5H_5)Fe^+$ interaction. The $C_5H_5^-/P_5^-$ donation to the $(C_5H_5)Fe^+$ fragment is the major feature in both complexes, and there is little evidence (from a population analysis) for Fe → C or Fe → P charge-transfer. The pronounced charge drift in $(C_5H_5)FeP_5$ can be seen in the transfer of electron from the P(s, p_x, p_y) orbitals to the Fe(d_{xy}, d_{yz}) ones, which in turn increases the Fe → C donation. Because the HOMO-$(P_5)^-$ lies closer energetically to the LUMO of $(C_5H_5)Fe^+$ than does the HOMO-$(C_5H_5)^-$, the P_5 complex is expected to be somewhat more stable.

In conclusion, it may be deduced from this preliminary study that complexes containing P_5^- and P_6 ring systems may, in a number of cases, show stabilities comparable to (or even better than) their C analogues, despite large differences between the free ring fragments. This study also suggests that the pattern of MO interactions signficantly differ for P and C rings.

REACTIONS OF CARBONYL SULPHIDE AND CARBON DISULPHIDE WITH RUTHENIUM COMPLEXES

KRISHNA KUMAR PANDEY* and SHARAD KUMAR TEWARI

Department of Chemistry, Devi Ahilya University, Indore 452001, India

(*Received* 20 *May* 1988; *accepted* 6 *July* 1988)

Abstract—The reaction of COS with $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ under various experimental conditions resulted in the formation of chloro-bridged complexes $[(Ph_3P)Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)]$ and $[(PPh_3)_2Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)_2]$ which reacted with excess PPh_3 under reflux to form $[Ru(CO)Cl_2(PPh_3)_3]$. CS_2 reacted with $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ in the presence of PPh_3 to give $[(Ph_3P)_2Cl(CS)Ru(\mu\text{-}Cl)_2Ru(CS)Cl(PPh_3)_2]$. Reactions of COS with $[RuH(CH_3COO)(PPh_3)_3]$, $[Ru(CO)Cl(CH_3COO)(PPh_3)_2]$, $[RuH(CO)Cl(AsPh_3)_3]$ and $[Ru(CO)Cl_2(AsPh_3)_3]$ resulted in the formation of the complexes $[Ru(CO)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$, $[(Ph_3P)_2Cl(CO)Ru(\overset{O}{\overset{\|}{C}})S\text{—}Ru(CO)Cl(PPh_3)_2]$, $[RuH(CO)_2Cl(AsPh_3)_2]$ and $[Ru(CO)_2Cl_2(AsPh_3)_2]$, $[(Ph_3As)_2Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(AsPh_3)_2]$, respectively. CS_2 reacted with $[RuH(CH_3COO)(PPh_3)_3]$ and $[RuH(CO)Cl(AsPh_3)_3]$ to give $[Ru(CS)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$ and $[RuH(CO)(CS)Cl(AsPh_3)_2]$, respectively. The complexes were characterized by elemental analysis, magnetic measurements, IR and electronic spectral studies.

The coordination properties of triatomics such as CO_2, COS and CS_2, which are the potential source of C_1 chemistry, are interesting, especially from a synthetic view point. The interesting reactions, especially of CO_2 and CS_2, are those which are related to (a) the formation of organometallic compounds, (b) the facile insertion into the M—H, M—C, M—N etc. bonds and (c) the catalytic synthesis of various types of organic compounds.[1–20] Since the first report of the reaction of COS, which is structurally similar to CO_2 and CS_2, with a metal complex by Baird and Wilkinson,[21] it has received little attention.[22] Herein, we wish to report the reactions of COS and CS_2 with ruthenium complexes.

EXPERIMENTAL

All the reagents were of analytical or chemically pure grade. Benzene, toluene, hexane and diethyl ether were dried over sodium, dichloromethane over P_4O_{10} and methanol over CaO. All the solvents were purged with nitrogen and distilled immediately before use. All reactions were performed under pure dry nitrogen atmosphere. $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$, $[RuH(CH_3COO)(PPh_3)_3]$, $[RuH(CO)ClL_3]$ (L = PPh_3, $AsPh_3$), $[Ru(CO)Cl_2(AsPh_3)_3]$ and COS were prepared by literature methods.[23–27]

The analyses for sulphur and chloride in the complexes were carried out by the standard methods.[28] Carbon and hydrogen analyses were performed using a Carlo Erba 1106 Thomas CH Analyser 35. For the estimation of phosphorus and arsenic, samples were decomposed with sodium peroxide, sugar and sodium nitrate in the ratio 20 : 1 : 3 in a Parr bomb crucible and extracted with water. Then the solution was neutralized with dilute H_2SO_4 and an excess of concentrated H_2SO_4 (0.5 cm^3) added. It was heated until the evolution of SO_3 fumes ceased, then cooled and diluted with water. From the filtrate of the solution, phosphorus and arsenic were estimated by standard methods.[29] The results are reported in Table 1.

The IR spectra were recorded in the range 4000–250 cm^{-1} with a Perkin–Elmer 580 spectrophotometer from the R.S. Instrument Centre at the Indian Institute of Technology, Bombay. Samples were prepared as KBr pellets. Important IR frequencies are given in Table 2. The electronic

spectra have been recorded with Shimadzu 160 spectrophotometer. Magnetic measurements were carried out by Gouy's method at room temperature (25°C) using mercury tetrathiocyanato cobaltate(II) as calibrant. All the complexes were found to be dimagnetic. Melting points were determined by the capillary method and are uncorrected.

Synthesis of $[(Ph_3P)Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)]$ (**1**)

COS was bubbled into a solution of $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ (0.2 g) in toluene (30 cm^3) for 30 min and the reaction mixture was stirred for 1 h. This was then evaporated to 5 cm^3 under reduced pressure. On the addition of *n*-hexane (40 cm^3), a green complex (**1**) precipitated which was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield 0.08 g, 67%).

Synthesis of $[(Ph_3P)_2Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)_2]$ (**2**)

COS was bubbled into a solution of $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ (0.2 g) and PPh_3 (0.4 g) in toluene (40 cm^3) for 30 min and the reaction mixture was refluxed for 2 h. This was evaporated to 5 cm^3 and slow addition of *n*-hexane (40 cm^3) precipitated a red complex (**2**) which was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield 0.065 g, 34%).

Synthesis of $[Ru(CO)Cl_2(PPh_3)_3]$ (**3**)

A solution of $[(Ph_3P)Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)]$ (0.2 g) and PPh_3 (0.4 g) in benzene (30 cm^3) was refluxed for 8 h whereby the colour of the solution changed from green to orange. The resulting orange solution was reduced in volume and *n*-hexane was added to give orange crystals of **3**.

Synthesis of $[(Ph_3P)_2Cl(CS)Ru(\mu\text{-}Cl)_2Ru(CS)Cl(PPh_3)_2]$ (**4**)

A solution of $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ (0.2 g) and PPh_3 (0.6 g) in CS_2 (20 cm^3) was refluxed for 3 h. The colour of the solution changed to red. The solution was diluted with diethyl ether (80 cm^3) and cooled to 5°C. The red precipitate of **4** that formed was collected by filtration, washed with diethyl ether and dried *in vacuo* (yield 0.1 g, 52%).

Synthesis of $[Ru(CO)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$ (**5**)

COS was bubbled into a solution of $[RuH(CH_3COO)(PPh_3)_3]$ (0.2 g) in toluene (20 cm^3) for 30 min and the reaction mixture was stirred for a further 1 h. Complex **5** was isolated by a similar procedure to that given for complex **1** (yield 0.12 g, 78%).

Synthesis of $[Ru(CS)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$ (**6**)

A mixture of CS_2 (2 cm^3) and $[RuH(CH_3COO)(PPh_3)_3]$ (0.2 g) in toluene (20 cm^3) was allowed to reflux for 1 h. The reaction mixture was evaporated to 5 cm^3 under reduced pressure. On addition of 40 cm^3 of *n*-hexane, complex **6** was precipitated which was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield 0.1 g, 64%).

Synthesis of $[Ru(CO)Cl(PPh_3)_2]_2(\mu\text{-}COS)$ (**7**)

COS was bubbled into a solution of $[Ru(CO)Cl(CH_3COO)(PPh_3)_2]$ (0.2 g) in toluene (30 cm^3) for 30 min and the reaction mixture was stirred for 1 h. Complex **7** was isolated by a similar procedure to that given for complex **1** (yield 0.13 g, 67%).

Synthesis of $[RuH(CO)_2Cl(AsPh_3)_2]$ (**8**)

COS was bubbled into a solution of $[RuH(CO)Cl(AsPh_3)_3]$ (0.2 g) in toluene (30 cm^3) for 30 min and the reaction mixture was stirred for 1 h. Complex **8** was isolated by a similar procedure to that given for complex **1** (yield 0.08 g, 54%).

Synthesis of $[RuH(CO)(CS)Cl(AsPh_3)_2]$ (**9**)

A solution of $[RuH(CO)Cl(AsPh_3)_3]$ (0.2 g) in toluene (30 cm^3) was treated with CS_2 (4 cm^3) for 3 h. Complex **9** was isolated by a similar procedure to that given for complex **5** (yield 0.1 g, 65%).

Reaction of COS *with* $[Ru(CO)Cl_2(AsPh_3)_3]$

COS was bubbled into a solution of $[Ru(CO)Cl_2(AsPh_3)_3]$ (0.2 g) in toluene (30 cm^3) for 30 min. The reaction mixture was refluxed for 1 h. The solvent was removed under reduced pressure and the residue was dissolved in a minimum of dichloromethane. On the addition of methanol, a cream white complex $[Ru(CO)_2Cl_2(AsPh_3)_2]$ (**10**) separated, which was filtered, washed with methanol and diethyl ether and dried *in vacuo* (yield $\approx$ 5%).

The filtrate was reduced to half the volume and cooled to 5°C. The red complex $[(Ph_3As)_2Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(AsPh_3)_2]$ (**11**) which separated was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield 0.04 g, 43%).

RESULTS AND DISCUSSION

COS reacts with $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ at room temperature to give a green complex (**1**):

$$2Ru(CH_3CN)_2Cl_2(PPh_3)_2 + 2COS \rightarrow [(Ph_3P)Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(PPh_3)] + 2SPPh_3.$$

The reaction of COS with $[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ under reflux in the presence of PPh_3 yields an orange complex (**2**):

$$2Ru(CH_3CN)_2Cl_2(PPh_3)_2 + 2COS + 2PPh_3 \rightarrow [(Ph_3P)_2Cl(CO)Ru(\mu\text{-}Cl)_2(CO)Cl(PPh_3)_2] + 2SPPh_3.$$

The green complex (**1**) or orange complex (**2**) reacts with excess PPh_3 under reflux to give orange complex $[Ru(CO)Cl_2(PPh_3)_3]$ (**3**).

$[Ru(CH_3CN)_2Cl_2(PPh_3)_2]$ in CS_2 under reflux in the presence of PPh_3 affords a red complex (**4**).

$$Ru(CH_3CN)_2Cl_2(PPh_3)_2 + 2CS_2 + 2PPh_3 \rightarrow [(Ph_3P)_2Cl(CS)Ru(\mu\text{-}Cl)_2(CS)Cl(PPh_3)_2] + 2SPPh_3.$$

Reaction of $[RuH(CH_3COO)(PPh_3)_3]$ with COS and CS_2 results in the formation of sulphur bridged carbonyl and thiocarbonyl complexes, respectively:

$$[RuH(CH_3COO)(PPh_3)_3] + SCX \rightarrow [Ru(CX)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S) + \cdots$$

(**5**), X = O; (**6**), X = S.

COS reacts with $[Ru(CO)Cl(CH_3COO)(PPh_3)_2]$ to give the bridged carbonyl sulphide complex (**7**):

$$2Ru(CO)Cl(CH_3COO)(PPh_3)_2 + COS \rightarrow (Ph_3P)_2Cl(CO)Ru{-}\overset{\overset{O}{\|}}{C}{-}S{-}Ru(CO)Cl(PPh_3)_2 + \cdots$$

Reactions of SCX with $[RuH(CO)Cl(AsPh_3)_3]$ give hydridodicarbonyl ruthenium complexes:

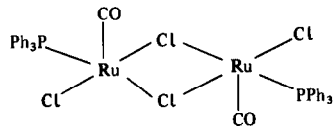
$$RuH(CO)Cl(AsPh_3)_3 + SCX \rightarrow RuH(CO)(CX)Cl(AsPh_3)_2 + \cdots$$

(**8**), X = O; (**9**), X = S.

COS reacts with $[Ru(CO)Cl_2(AsPh_3)_3]$ to give a cream–white complex, $[Ru(CO)_2Cl_2(AsPh_3)_2]$ (**10**) and a red complex, $[(Ph_3As)_2Cl(CO)Ru(\mu\text{-}Cl)_2Ru(CO)Cl(AsPh_3)_2]$ (**11**).

IR spectra

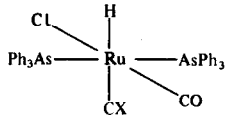
Important IR data are summarized in Table 2. The IR spectrum of the green complex, $[Ru(CO)Cl_2(PPh_3)]_2$, shows absorption bands at 1950, 330 and 260 cm^{-1} in addition to the characteristic bands of triphenylphosphine.[30] The band at 1950 cm^{-1} is due to the characteristic stretching frequencies of the terminal carbonyl group. The band at 330 cm^{-1} is typical of ν(Ru—Cl) (Cl *trans* to Cl) while the band at 260 cm^{-1} could be due to either ν(Ru—Cl) (Cl *trans* to P) or to bridging chlorine modes, or to both.[31] The green complex (**1**) may, therefore, be dimeric in the solid state with bridging chlorines.



(**1**)

The IR spectrum of the orange complex $[Ru(CO)Cl_2(PPh_3)_2]_2$ shows absorption bands at 1960 cm^{-1} due to ν(CO),[32] 330 cm^{-1} due to ν(Ru—Cl) and 255 cm^{-1} due to ν(Ru—Cl) (bridging Ru—Cl modes). The IR spectrum of $[Ru(CO)Cl_2(PPh_3)_3]$ contains carbonyl bands at 2025, 1982 and 1945 (same as the literature values)[32] indicating the presence of two isomers which could not be separated. One isomer of complex (**3**) has been reported previously with ν(CO) at 1950 cm^{-1}.[33,34] The IR spectrum of the thiocarbonyl complex $[Ru(CS)Cl_2(PPh_3)_2]_2$ shows absorption bands at 1290 cm^{-1} due to ν(CS) (literature value 1290 cm^{-1}),[35] and at 335 and 265 cm^{-1} due to ν(Ru—Cl). The IR spectra of sulphide bridged complexes, $[Ru(CX)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$ (X = O, S), exhibit absorption bands at 1940 cm^{-1} due to ν(CO), at 1290 cm^{-1} due to ν(CS), at *ca* 460 cm^{-1} due to ν(Ru—S) and in the regions 1510, 1460 cm^{-1} due to ν(CO) of the acetate group, suggesting that the acetato ligand present is bidentate.[36] The IR spectrum of the carbonyl sulphide complex $[(Ph_3P)_2Cl(CO)Ru{-}\overset{\overset{O}{\|}}{C}{-}S{-}Ru(CO)Cl(PPh_3)_2]$ contains a broad band at 1950 cm^{-1} due to ν(CO), a broad band at 1540 cm^{-1} and a weak band at 850 cm^{-1} due to the ν(CO) and ν(CS) of the COS group, respectively.[37] The IR spectrum of $[RuH(CO)_2Cl(AsPh_3)_2]$ shows absorption bands at 2065 and 2005 cm^{-1} due to ν(CO) (literature: 2060, 200 cm^{-1}), the bands at 1985 cm^{-1} may be due to ν(Ru—H) and those at 340 cm^{-1} are due to ν(Ru—Cl). The IR spectrum of $[RuH(CO)(CS)Cl(AsPh_3)_2]$ contains bands at 2030 cm^{-1} due to ν(CO), at 1320 cm^{-1} due to ν(CS), the

one at 1985 cm^{-1} may be due to ν(Ru—H) and the one at 340 cm^{-1} is due to ν(Ru—Cl). The ν(Ru—Cl) at 340 cm^{-1} in these complexes indicates a chloride *trans* to carbonyl rather than to triphenylarsine. Therefore structures of complexes **8** and **9** tentatively may be given.



(8) X = O
(9) X = S

The structure for $[RuH(CO)_2Cl(AsPh_3)_2]$ has been established by Harris and Robinson,[26] and for the analogous triphenylphosphine complex $[RuH(CO)_2Cl(PPh_3)_2]$ by James and Markham.[38] $[Ru(CO)Cl_2(AsPh_3)_2]$ contains strong bands at 2060 and 2000 cm^{-1} due to ν(CO) which are in the range reported previously for a *cis–trans–cis* type of isomer.[33,39-41] The IR spectrum of the complex, [di - μ - chlorobis(chlorocarbonylbistriphenylarsine) ruthenium], exhibits absorption bands at 1970 cm^{-1} (broad) due to ν(CO) and at 350 and 275 cm^{-1} due to ν(Ru—Cl). One isomer of this complex has been previously reported with ν(CO) at 1955 cm^{-1}.[26]

Electronic spectra

The ground state of Ru^{II} in an octahedral field (t_{2g}^6 configuration) is $^1A_{1g}$. The excited states corresponding to the $t_{2g}^5 e_g^1$ configuration are $^3T_{1g}$, $^3T_{2g}$, $^1T_{1g}$ and $^1T_{2g}$ in increasing order of energy. Thus one should expect four transitions, $^1A_{1g} \rightarrow {}^3T_{1g}$; $^1A_{1g} \rightarrow {}^3T_{2g}$; $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$. In the electronic spectra of Ru^{II} complexes, three bands in some cases, four or five bands in other cases, appear in the visible region (Fig. 1). The positions of these bands and their respective assignments are given in Table 3. From the band positions, the

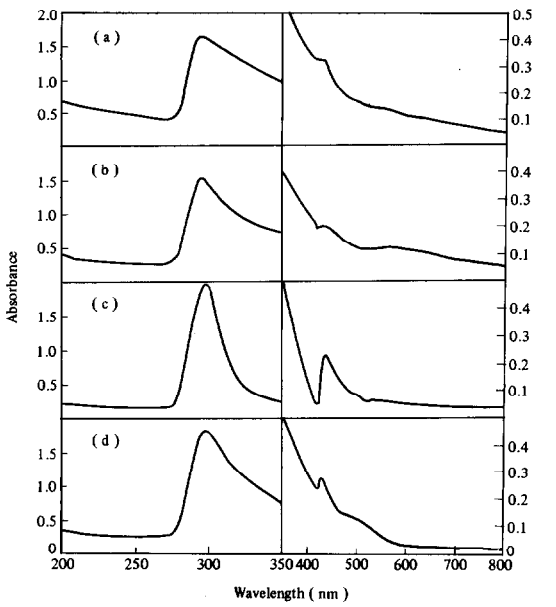

Fig. 1. Electronic absorption spectra of: (a) $[Ru(CO)(CH_3COO)(PPh_3)_2]_2(\mu\text{-}S)$; (b) $[Ru(CS)(CH_3COO)(PHh_3)_2]_2(\mu\text{-}S)$; (c) $[Ru(CO)Cl(PPh_3)_2]_2(\mu\text{-}COS)$; (d) $[Ru(CO)Cl(AsPh_3)_2]_2(\mu\text{-}Cl)_2$.

values of $10Dq$, B, β and C have been calculated.[42] The values of the molar extinction coefficients for the bands in the range 400–500 nm were found to be more than those of the usual *d–d* transitions. This may be due to: (i) mixing of the energy levels with those corresponding to the neighbouring intense charge-transfer bands, (ii) the covalent nature of the complexes and (iii) the lowering of the symmetry to the molecule whereby the centre of symmetry is lost.

(*Received* 30 *June* 1988; *accepted* 8 *November* 1988)

Abstract—Rhodium(II) hydrocinnamate has been prepared by the reaction of hydrocinnamic acid with rhodium(II) acetate and has been used to prepare complexes of probable formula $[Rh_2(C_6H_5CH_2CH_2CO_2)_4L_2]$ (L = imidazole, 2-methylimidazole, pyridine, dimethylamine). IR, Raman, electronic, XPE and NMR (^1H) spectra and magnetochemical and thermal analysis data are reported.

Interest in the synthesis of new rhodium carboxylates has existed since the discovery, by Bear *et al.*, of the anti-tumor properties of those compounds in 1972.[1] Many studies on the catalytic activity of the rhodium carboxylates have already been reported, as for example hydrogenation of olefins;[2] the synthesis of aza-β-lactams from diazo compounds[3] and the synthesis of the benzyl ketones from benzene and α-diazoketones[4] are some of the applications of the rhodium carboxylates in this field. Cotton and co-workers have contributed with a notable number of articles with regard to binuclear complexes, not only concerning the structures, but also the synthesis of new compounds.[5–8] In this paper, we describe the synthesis and the characterization of rhodium hydrocinnamate and some of its adducts.

EXPERIMENTAL

Reagents

$RhCl_3 \cdot 3H_2O$ was purchased from Aldrich Chemical Co. Diethyl ether (Merck) was distilled and dried over sodium. Chloroform, ethanol and other chemicals were analytical grade and used as supplied. Hydrocinnamic acid[9] and rhodium(II) acetate[10] were prepared by literature methods.

Synthesis

$Rh_2(HCin)_4$. Anhydrous rhodium(II) acetate (0.5 g, 1.1 mmol) and hydrocinnamic acid (1.8 g, 12 mmol) were ground in a mortar and transferred to a test tube, which was maintained between 90–94°C for 3 h. Afterwards, the resultant solid was washed several times with hot water until the supernatant was colourless. The residual green solid was dissolved in anhydrous ethyl ether (100 cm^3). After filtering, the ether was evaporated and the product dried in a vacuum desiccator over anhydrous calcium chloride. Finally, it was heated *in vacuo* at 78°C for 24 h. The excess of hydrocinnamic acid was sublimed and condensed (yield, 65–70%).

$Rh_2(HCin)_4(Im)_2$. Rhodium hydrocinnamate (0.1 g, 0.12 mmol) was dissolved in 30 cm^3 of ether. This solution was added to another containing 0.017 g (0.25 mmol) of imidazole in 2 cm^3 of acetone. During the reaction, the initially pink solution gradually gave a suspension of a pink solid. After some hours, the supernatant was removed with a pipette and the solid residue was washed

*Author to whom correspondence should be addressed.

several times with ether and dried in a vacuum desiccator, over anhydrous calcium chloride (yield, ~ 95%).

$Rh_2(HCin)_4(mIm)_2$. Rhodium hydrocinnamate (0.1 g, 0.12 mmol) was dissolved in 30 cm^3 of ethanol and added slowly to a suspension containing 0.021 g (0.25 mmol) of 2-methylimidazole in 10 cm^3 of ethanol, under stirring. The colour of the resulting solution changed from green to pink and a pink solid precipitated. The supernatant was removed with a pipette, the solid residue was washed with ethanol and ether and the final product was dried in a vacuum desiccator, over calcium chloride (yield, ~ 90%).

$Rh_2(HCin)_4(py)_2$. Pyridine (0.03 cm^3, 0.3 mmol) was added slowly with stirring to 0.1 g (0.12 mmol) of $Rh_2(HCin)_4$ dissolved in 20 cm^3 of ether and the solvent was removed by evaporation. The residue was washed with water several times and dried in a vacuum desiccator, over anhydrous calcium chloride (yield, ~ 92%).

$Rh_2(HCin)_4(DMA)_2$. Rhodium hydrocinnamate (0.1 g, 0.12 mmol) was dissolved in 30 cm^3 of anhydrous ethyl ether and slowly added, under stirring, to a 40% aqueous solution of dimethylamine. The precipitate was washed with water and afterwards with ether. Finally, it was dried in a vacuum desiccator, over calcium chloride (yield, ~ 65%).

Elemental analyses were carried out by the Microanalytical Laboratory (Instituto de Química, Universidade de São Paulo). The solid state IR absorption spectra were obtained using a Perkin–Elmer 180 spectrometer with fluorolube mulls between KBr windows or KBr discs.

The Raman spectra were obtained with a Jarrell–Ash 25-300 double monochromator fitted with a photomultiplier tube detector (ITT-Fw 130) and using a rotating-sample cell. The exciting radiation was 514.5 nm for rhodium acetate and rhodium hydrocinnamate, while for the adducts, 647.1 nm was used, with 30–35 mW of power. The emergent radiation was detected perpendicular to the laser beam. The spectral resolution in all measurements was 10 cm^{-1}. The electronic spectra were recorded on a Zeiss DMR-10 spectrometer, using millimolar $CHCl_3$ solutions. ^1H NMR measurements were obtained on a Bruker AC 80 spectrometer. The samples were dissolved in $CDCl_3$ and the chemical shifts were referred to Me_4Si as an internal standard. X-ray photoelectron spectra (XPE) were obtained using a Shimadsu ESCA 750 with Mg-K_α exciting irradiation. The magnetic susceptibility at 298 K was measured using the Gouy method. Mercury tetrathiocyanocobaltate(II) was used as the calibrant, and diamagnetic corrections were estimated from Pascal's constants. The effective magnetic moment was calculated from the expression: $\mu_{eff} = 2.84(X_M \cdot T)^{1/2}$. X-ray powder patterns were obtained using a Norelco apparatus and diffractometer from Philips Electronic Instruments with Cu-K_α radiation. The thermogravimetric studies were carried out on a Perkin–Elmer TGS-1 apparatus, at a heating rate of 10 deg min^{-1} under a nitrogen atmosphere.

RESULTS AND DISCUSSION

Table 1 shows the elemental analyses for rhodium hydrocinnamate and its adducts. These results are in compliance with the general formula $Rh_2(HCin)_4 \cdot 2L$. The rhodium hydrocinnamate is an amorphous (according to X-ray powder pattern) green solid, water insoluble but soluble in acetone, chloroform, ethyl ether, methanol, ethanol and tetrahydrofuran. Thermogravimetric analyses indicated that the compound and its adducts are stable up to *ca* 100°C. At higher temperatures, fast decomposition occurs which is not so clear for the adducts but in all cases the final product is Rh_2O_3.

IR spectra

The IR spectra show bands in the region of 1405–1413 cm^{-1} (ν_{sym} OCO) and 1560–1591 cm^{-1} (ν_{asym} OCO). These absorptions are not very conclusive with regard to the coordination mode of the carboxylate group, but allow us to exclude

Table 1. Analytical data

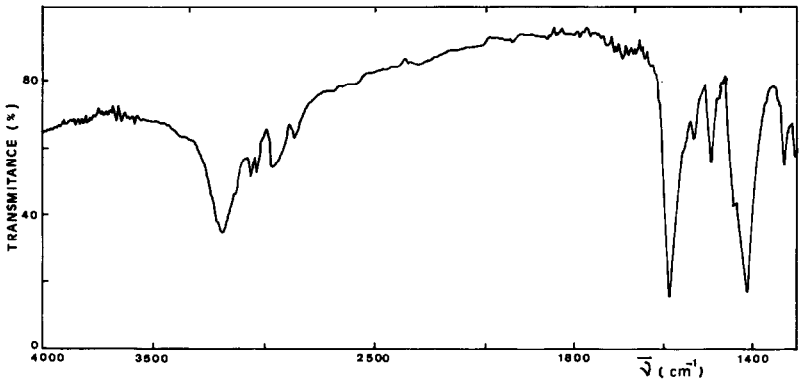

Fig. 1. IR spectrum of the imidazole adducts.

the monodendate hypothesis of coordination, because in this case the difference between the asymmetric and symmetric stretching modes is generally $\geqslant 200$ cm^{-1}.[11] In all spectra we can observe a medium sharp band at 1490 cm^{-1} that may be assigned to ring vibrations. In the adducts, the band that refers to the asymmetric stretching is shifted to higher wave numbers relative to anhydrous rhodium hydrocinnamate ($\Delta \simeq 25$–30 cm^{-1}, Fig. 1).

Raman spectra

Raman spectroscopy has been used to study the Rh—Rh bond, but the complexity of the spectra in the region below 500 cm^{-1} and the low intensity bands expected for such interactions prevent a clear assignment. The rhodium hydrocinnamate Raman spectrum presents a medium line at 179 cm^{-1} and a weak line in the 345 cm^{-1} region, respectively, assigned to the Rh—Rh and Rh—O vibrations.[12–14] In the adducts, the region at *ca* 170 cm^{-1} could not be studied due to the presence of strong plasma lines. When the axial ligands are changed, we can see a shift from 345 cm^{-1} in the anhydrous rhodium hydrocinnamate to 334, 330 and 322 cm^{-1} in the pyridine, imidazole and 2-methylimidazole adducts, respectively. Those shifts are probably related to the increased donor strength of the axial ligands, as had been observed by Ketteringham and Oldham.[15]

Electronic spectra

The absorptions in chloroform solutions for rhodium hydrocinnamate and its adducts confirm the behaviour expected for such typical dimeric rhodium carboxylates, with two bands (or one band and a shoulder) in this region, the lower energy one sensitive to the change of the axial ligands.[16] It is interesting to observe that the change is according to the rhodium cinnamate derivatives,[17] where the λ_1 shifts to higher frequencies with axial ligands of increasing acceptor power. It becomes evident from the less intense shift of the λ_1 band for the methylimidazole than for imidazole. The hyper-conjugative effect of the methyl group which reduces

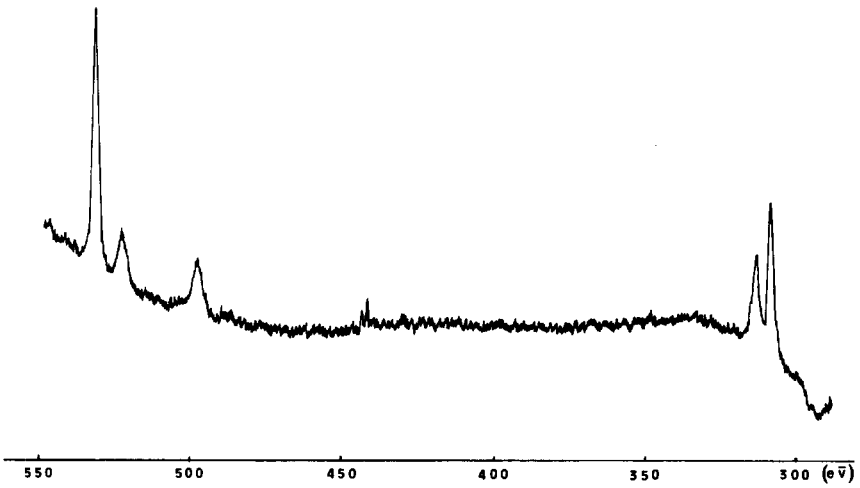

Fig. 2. X-ray photoelectron spectrum of $Rh_2(HCin)_4$.

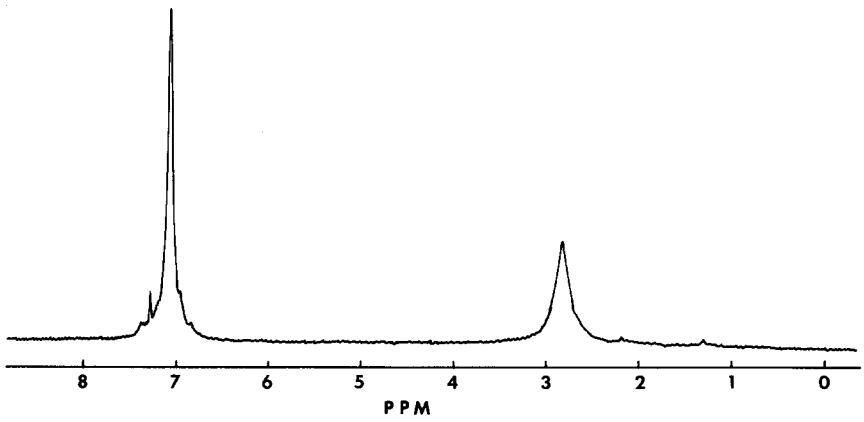

Fig. 3. ^{1}H NMR of rhodium hydrocinnamate.

the π-acceptor capability of the imidazole ring is probably responsible for this effect.

XPE

Changes in the electron density about an atom are reflected in changes in the binding energies of the core electrons. Larger binding energies are associated with smaller electron densities, so, Rh^{III} has larger $3d_{5/2}$ energy than Rh^{II}, and the latter larger than Rh^{I}. The rhodium(II) carboxylates have generally the $3d_{5/2}$ binding energy in the range of 308.5–309 eV.[18,19] The photoelectron spectrum of the rhodium hydrocinnamate (Fig. 2) shows a single Rh $3d_{5/2}$ peak at 308.5 eV, consistent with identical rhodium ions in each dimeric unit and a single O_{1s} peak at 331 eV, indicating eight equivalent oxygen atoms.

^{1}H *NMR*

The ^{1}H NMR spectrum of the anhydrous rhodium hydrocinnamate (Fig. 3) does not show any signals at 11.4 ppm, indicating the absence of the hydroxylic proton of the carboxylic group and a single line at *ca* 7.05 ppm, suggesting that all the phenyl groups are equivalent. The broad line at 2.7 ppm corresponds to the multiplet of the hydrocinnamic acid in the 2.6–3.0 ppm region, and the weak peak at *ca* 7.2 ppm should be an impurity of $CHCl_3$.

Magnetic susceptibility

Rhodium carboxylates are generally characterized by the coupling of spins between two rhodium(II) ions, giving rise to magnetic moments lower than those expected for a magnetically dilute Rh^{II} (d^7) compound. Rhodium hydrocinnamate is essentially diamagnetic, with $\mu_{eff} = 0.4$ BM.

CONCLUSION

All the measurements we have made suggest that rhodium hydrocinnamate and its adducts have the typical structure of the rhodium(II) carboxylates, with two rhodium ions held together by bridging carboxylate groups, and the core presenting a D_{4h} symmetry.

OPTICALLY ACTIVE COORDINATION COMPOUNDS—XLIX.* THE *CIS*-BIS-AQUO-BIS-1,2-DIAMINOETHANERHODIUM(III) SYSTEM

R. D. GILLARD† and JULIO D. PEDROSA DE JESUS‡

Inorganic Research Laboratories, University College, P.O. Box. 78, Cardiff CF1 1XL, Wales, U.K.

(*Received* 18 *July* 1988; *accepted after revision* 8 *November* 1988)

Abstract—Resolved *cis*-$[Rh(en)_2(OH)_2]^+$ or *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ were formed by base or acid hydrolysis, respectively, of resolved oxalato bisethylenediamine rhodium(III); acid dissociation constants, determined using circular dichroism, are given by $pK_1 = 5.02$ and $pK_2 = 9.04$, and these are compared with values from pH titration. *Cis*-$[Rh(en)_2(H_2O)(OH)]^{2+}$ shows marked enhancement of circular dichroism in solution (relative to its own conjugate acid and base) similar to that for its cobalt(III) analogue. The possible micro-species responsible are discussed in terms of bridging by $(H_3O_2)^-$.

Isomeric compounds of the type $[M(en)_2XY]^{n+}$, where en signifies 1,2-diaminoethane and M = Co^{III}, Cr^{III}, Rh^{III} or Ir^{III} have been well studied. For M = Rh^{III}, the current situation is fully summarized.[2] The optical activity of the *cis* isomers has not been so extensively used as for homologues with M = Co, so here we report some applications of the stereochemical method for determining solution properties for M = Rh^{III}.

A good way of making *cis* complexes is through the oxalato species, $[Rh(en)_2(C_2O_4)]^+$, itself best made by a catalytic route developed here,[3] and widely validated[4] as giving high yields. Also in high yield, the anations of this oxalato ion with hydrohalic acids (presumably via hydrolysis) have been used[5,6] to prepare *cis*-dichloro and dibromo ions. These hydrolyses themselves have been explored as routes to other *cis* compounds of rhodium(III), in particular to those containing ions of the type *cis*-$[Rh(en)_2X_2]^{n+}$, where X = OH or OH_2.

EXPERIMENTAL

The apparatus and detailed findings are described in the Ph.D. thesis of J. D. P. D. Jesus ("Stereochemical Aspects and Photochemistry of Compounds of Rhodium(III)", University of Wales, at University College, Cardiff (1977)). The parent oxalato-compound was prepared[3] and resolved[5] optically by established methods. Its hydrolysis was studied by spectrophotometry and circular dichroism (CD).

When the perchlorate of the oxalato complex was used in basic hydrolysis, the final CD spectrum was that of a solution of (−)-*cis*-$[Rh(en)_2(OH)_2]^+$ at the same concentration as the starting solution. However, when the *chloride* was treated in the same manner in sodium hydroxide solution, a different final CD spectrum was observed. Tipping also produced[7] anomalous behaviour for the CD spectra of similar aquorhodium(III) complexes in the presence of chloride ions. This is perhaps due to strong ion pairing between the complexed cation and the Cl ions, although Poë and Vuik[8] thought that the values of K_{IP} for the ion pairs *trans*-$[Rh(en)_2Cl_2]Cl$ and *cis*-$[Rh(trien)Cl_2]Cl$ at concentrations of 25 and 60 M^{-1} derived[9] from radiochloride exchange rates, were "unreasonably large" for an aqueous solution.

Reaction with NO_2^-

(a) *Cis*-diaquobis(ethylenediamine)rhodium(III), treated with an excess of nitrite ion at 100°C gave the *cis*-dinitro-bis(ethylenediamine)rhodium(III)

* For part XLVIII see ref. 1.

† Author to whom correspondence should be addressed.

‡ Present address: Chemistry Department, University of Aveiro, Aveiro 3800, Portugal.

ion, whose circular dichroism spectrum has a lowest energy absorption at 300 nm.

(b) *Cis-O*-nitrito-aquo-bis(ethylenediamine)rhodium(III) was obtained by addition of sodium nitrite to the cold (4°C) acidic (pH 3.5) solution of the diaquo compound (molar ratio of complex: NO_2^- = 1 : 1). A new band immediately developed around 335 nm; this increased in intensity on heating (333 K) to a maximum after 30 min. The pH changed from 3.50 to 4.35.

(c) Acid–base properties. The pK_a was 8.5 ± 0.4, by titration against NaOH. The conjugate base, *cis*-$[Rh(en)_2(ONO)(OH)]^+$ at pH = 11.1 shows a CD band at a lower energy (345 nm) than for the corresponding conjugate acid (as expected for aquo ⇌ hydroxo ligand). Another well defined absorption appears (for pH 11.1) in the region (297 nm) where a shoulder was observed for the *O*-nitritoaquo parent at pH = 4.35. On reacidification to pH = 4.3, the CD spectrum of the starting solution (at the same pH) is restored.

(d) *Cis*-$[Rh(en)_2(H_2O)_2]^{3+}$ reacted with NO_2^- (in a 1 : 1 ratio as in part (b)) at pH 6, but at a slower rate than at pH 3. On reacting the resultant solution of *cis*-$[Rh(en)_2(ONO)(OH_2)]^{2+}$ with an excess of NaCl, the lower energy CD band moves to 335 nm and a better defined absorption develops around 300 nm, characteristic of *cis*-$[Rh(en)_2(NO_2)Cl]^+$.

(e) The reacidified solution from (c) was treated with more nitrite, at 330 K. The CD band at 340 nm, which is due to *cis*-$[Rh(en)_2(ONO)_2]^+$, decreases in intensity relative to the shoulder around 300 nm, which then develops into the well-defined absorption of *cis*-$[Rh(en)_2(NO_2)_2]^+$ with an approximately two-fold increase in the intensity, at 345 nm. Scheme 2 represents the probable reactions taking place.

Reaction with IO_3^-

(a) Aqueous *cis*-diaquobis(ethylenediamine)rhodium(III) nitrate, at pH = 2.6 (adjusted with HNO_3) has a CD maximum at 322 nm; on adding sodium iodate, a very fast shift to 337 nm occurs. On leaving the solution at room temperature for 24 h, the band moves to 342 nm.

(b) The addition of IO_3^- to a starting solution of diaquo rhodium(III) ion acidified to pH = 1.0 with HNO_3, also causes a very fast CD shift to 342 nm, which does not change significantly over 24 h at room temperature.

(c) The reaction is more rapid as the concentration of H^+ increases.

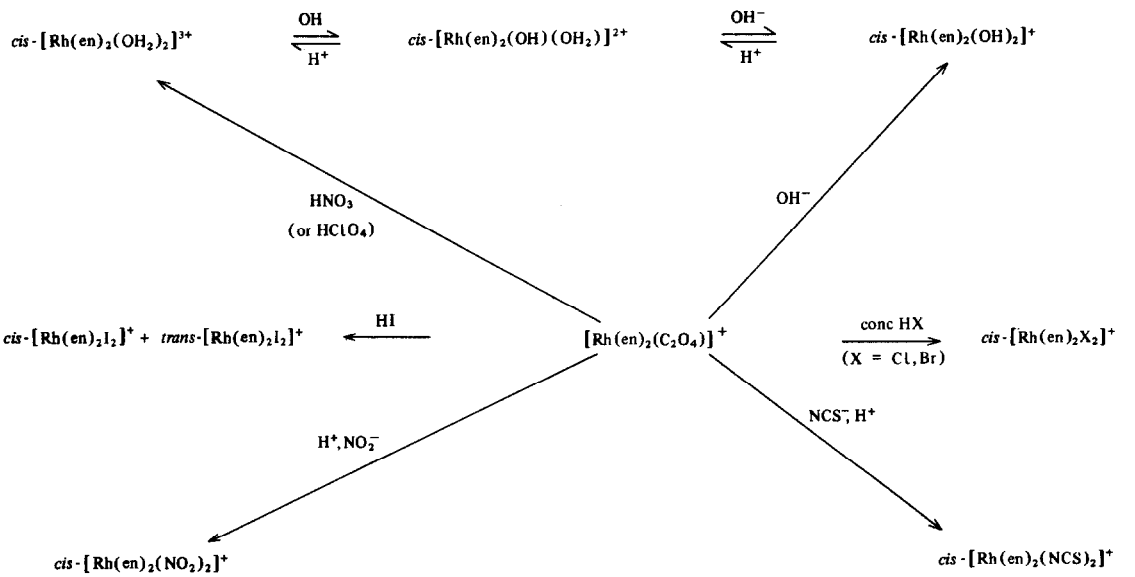
(d) We assume that the rapidly formed species with a CD absorption maximum at 342 nm is *cis*-$[Rh(en)_2(OH_2)(OIO_2)]^{2+}$, akin to the *cis*-$[Co(en)_2(OH_2)(OIO_2)]^{2+}$ complex known to form from a similar rapid addition of iodate to the racemic cobalt(III) congener.

RESULTS AND DISCUSSION

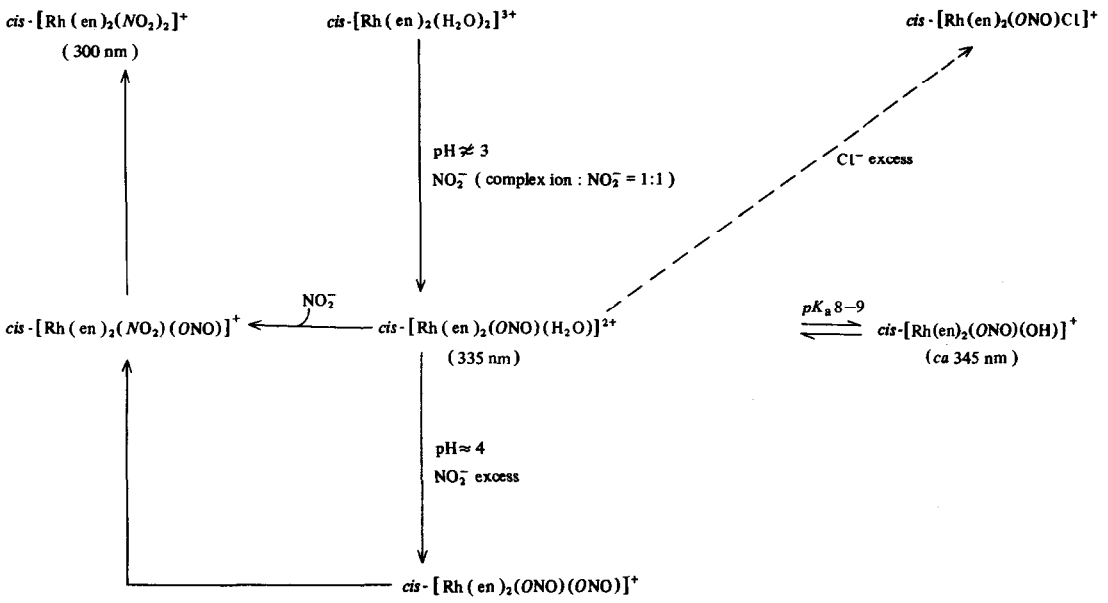
Hydrolysis

Scheme 1 shows several hydrolyses centred on this accessible oxalato-ion.

The $[Rh(en)_2(C_2O_4)]^+$ ion reacts quite rapidly with nitric acid.[10] It gives *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ on reaction with either nitric or perchloric acid. The reaction of $[Rh(en)_2(C_2O_4)]^+$ with hydroxide gives *cis*-$[Rh(en)_2(OH)_2]^+$. The corresponding aquo-



Scheme 1.



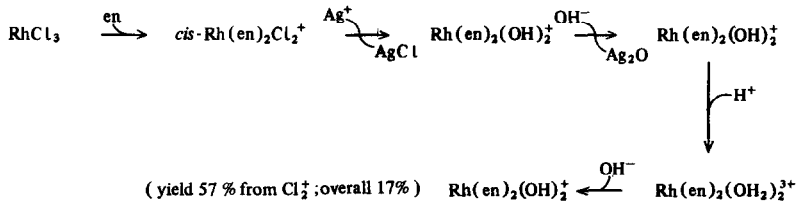
Scheme 2.

complexes were obtained by acidifying the solution of dihydroxo-[Rh^{III}] ion.

Although the preparation of *cis*-$[Rh(en)_2(NO_2)_2]^+$ involves[11] reacting *cis*-$[Rh(en)_2Cl_2]^+$ with nitrite, we find that $[Rh(en)_2(C_2O_4)]^+$ is nevertheless a suitable starting material. This reaction can be performed obtaining very good yields, by reacting the oxalato-complex with $NaNO_2$ in acid (pH ~ 4). Details of intermediates and their circular dichroism changes are given in the Experimental section and in Scheme 2. Similar reactions with NaI result[11] in a mixture of *cis*- and *trans*-$[Rh(en)_2I_2]^+$ ions. In similar acidic conditions (pH 4), NCS^- also gives some *cis*-$[Rh(en)_2(NCS)_2]^+$. However, this reaction is not straightforward and the yield was poor. A better synthesis, along with the properties of this thiocyanate and its linkage isomers are discussed in detail elsewhere.[12] All these reactions (see Scheme 1) take place with 100% retention of the *cis* configuration with the mentioned exception[11] of the reaction with iodide (where *cis–trans* isomerization is swift). The products, *cis*-$[Rh(en)_2X_2]^{n+}$, from the optically active oxalato-species, are also optically active, for all X = OH^-, H_2O, NO_2^-, Cl^-, Br^-.

Base hydrolysis of $[Rh(en)_2(C_2O_4)]^+$

Aquo and hydroxo compounds containing the *cis*- or *trans*-$[Rh(en)_2]^{3+}$ moiety have been prepared using various routes.[5,10,13,14] Since $[Co(en)_2(C_2O_4)]^+$ is known[15,16] to undergo hydrolysis in a wide range of basic conditions, we studied the reactivity of the Rh^{III} analogue in alkaline solution. The reaction of the rhodium(III) oxalato ion with OH^- gives *cis*-$[Rh(en)_2(OH)_2]^+$, and is first order with respect to the hydroxide and the complex at 333 K, for $0.05\,M < [OH^-] < 0.2$ M. Using optically active $[Rh(en)_2(C_2O_4)]^+$, no isomerization occurred. The *cis*-aquohydroxo and the diaquo ions could then be prepared in solution by appropriate adjustment of the pH of the solution containing *cis*-$[Rh(en)_2(OH)_2]^+$. The *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ ion could of course also be prepared by a reaction of $[Rh(en)_2(C_2O_4)]^+$ with $HOClO_3$ or $HONO_2$, and isolated as *cis*-$[Rh(en)_2(OH_2)_2](NO_3)_2ClO_4$. The other salt usually isolated as a solid was *cis*-$[Rh(en)_2(OH)(OH_2)](ClO_4)_2$, which has been synthesized by a laborious route (via the *cis*-dichloro ion) by Palmer *et al.*[17] via:



Those authors did succeed in increasing the notoriously low yield of the *cis*-dichloro ion made by this older method[11] to 30%, giving an overall yield around 17%.

The reaction of $[Rh(en)_2(C_2O_4)]^+$ with the base can be easily followed spectrophotometrically. The product, *cis*-$[Rh(en)_2(OH)_2]^+$, was identified by its electronic spectrum in the final solution, by the spectrum of *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ resulting from the acidification of that solution, and by measuring the CD spectrum when optically active $[Rh(en)_2(C_2O_4)]ClO_4$ was employed; the reaction then took place with the conservation of optical activity. The overall reaction can thus be described by

$$(-)\text{-}[Rh(en)_2(C_2O_4)]^+ + 2OH^- \rightleftharpoons (-)\text{-}[Rh(en)_2(OH)_2]^+ + C_2O_4^{2-}.$$

Values of absorbance at 285 (and 325 nm) were used to obtain pseudo-first order rate constants for four different concentrations of hydroxide (Table 1): the reaction is first order with respect to the hydroxide ion. The rate law can then be written as

$$\text{Rate} = k[OH^-][Rh(en)_2(C_2O_4)]^+$$

with $k = 4.55 \times 10^{-3}$ mol^{-1} dm^3 s^{-1} at 333 K.

There is no *cis–trans* isomerization in the basic hydrolysis of $(-)$-$[Rh(en)_2C_2O_4]^+$; this is as expected from the higher stereo-inertness of *cis*-Rh^{III} relative to *cis*-Co^{III} compounds. However, a scheme similar to that offered for the cobaltic compound[15,16] (also where rate = k[complex][OH^-], with $k = 2.8(\pm 0.5) \times 10^{-2}$ mol^{-1} dm^3 s^{-1}) would be expected for the reaction of $[Rh(en)_2(C_2O_4)]^+$, *viz*

$$cis\text{-}[Rh(en)_2(C_2O_4)]^+ + OH^- \longrightarrow cis\text{-}[Rh(en)_2(C_2O_4)(OH)]^0$$

$$cis\text{-}[Rh(en)_2(C_2O_4)(OH)]^0 + OH^- \longrightarrow cis\text{-}[Rh(en)_2(OH)_2]^+ + C_2O_4^{2-},$$

where the ring opening is the rate determining step.

Acidic properties of cis-$[Rh(en)_2(OH_2)_2]^{3+}$

Cis-$[Rh(en)_2(OH_2)_2]^{3+}$ in aqueous solution is a diprotic acid, with acidity constants K_1 and K_2.

$$n H_2O + cis\text{-}[Rh(en)_2(OH_2)_2]^{3+} \overset{K_1}{\rightleftharpoons} cis\text{-}[Rh(en)_2(OH)(OH_2)]^{2+} + H^+(OH_2)_n$$

$$cis\text{-}[Rh(en)_2(OH)(OH_2)]^{2+} + n H_2O \overset{K_2}{\rightleftharpoons} cis\text{-}[Rh(en)_2(OH)_2]^+ + H^+(OH_2)_n.$$

Previously reported values are given in Table 2. Values of pK_a have been measured for the *trans* and *cis* isomers. One set of results for the *cis* compounds was most likely obtained from compounds which were not geometrically pure, as the value of pK_1 obtained was abnormally small.[5] We have therefore repeated the determination of the two acidity constants for the *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ ion, using circular dichroism (and, for comparison, a pH titration).

Figure 1 shows how the circular dichroism of a solution of *cis*-$[Rh(en)_2(OH)_2]^+$ varies as titration

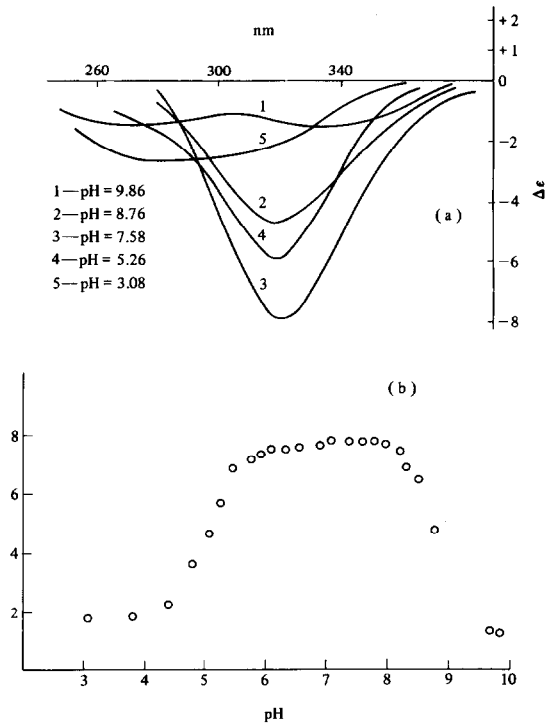

Fig. 1. CD spectra during titration of *cis*-$[Rh(en)_2(OH)_2]^+$ with 5 M HNO_3. (a) Typical spectra measured at: (1) pH 9.86; (2) pH 8.76; (3) pH 7.58; (4) pH 5.26; and (5) pH 3.08. (b) The variation with pH of molar circular dichroism, $\Delta\varepsilon$, at 320 nm. From measurements as in (a) $\Delta\varepsilon_{320}$ has been multiplied by -1.

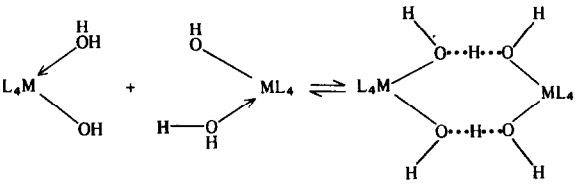
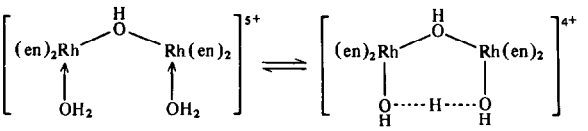
with HNO_3 progresses. By following the change in intensity of the CD spectra at 320 nm, as in Fig. 1b, the presence of three species is clear. Until pH ~ 9.5, the intensity (i.e. the molar circular dichroism per mole of rhodium ion, in whatever form) is about the same as that of the starting *cis*-$[Rh(en)_2(OH)_2]^+$ solution. Between pH 9.5 and pH 8, the intensity increases substantially and then stays constant until *ca* pH 5.5. This region of pH, between 8 and 5.5, corresponds stoichiometrically to the presence of mainly *cis*-$[Rh(en)_2(OH)(OH_2)]^{2+}$. Below pH ~ 5.5, there is again a very pronounced change (decrease) in intensity until pH 4.5. This corresponds to the protonation of the intermediate ion(s) to give the diaquo complex. The changes in intensity were used to calculate the pK_a values. This effect, that the circular dichroism of the aquohydroxo ion was larger than that for either the diaquo or the dihydroxo ion, was previously found for the analogous cobalt(III) system.[19] The *g*-factor ($\Delta\varepsilon/\varepsilon$) increases because, roughly speaking, chirality at the metal ion has increased more than has distortion of the local centrosymmetry which increases the intensity of the *d–d* transitions in isotropic spectra. This can arise from the formation of an additional flexible ring, and, in species containing the *cis*-$M(H_2O)(OH)$ moiety, such a formation of new rings has indeed been suggested as a general phenomenon,[20] occurring by dimerization through strong hydrogen bonds in $\mu(HOHOH)^-$ as shown (L is any ligand, here $\frac{1}{2}$en).



Such a dimerization would have little effect upon the allowedness of *d–d* bands in the metal ions (which are rather remote from each other) but confers an extra element of conformational flexibility in the dimer.

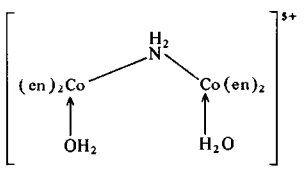
Among existing cases of effects attributed to a bridging by $(H_3O_2)^-$, are several in systems reminiscent of the present one:

(i) pK_{A1} and pK_{A2} of the ol-bridged *meso*-dimer (**I**) are very well separated; Hancock attributes[21] the anomalous stability of the first conjugate base (**II**) to the structure shown:

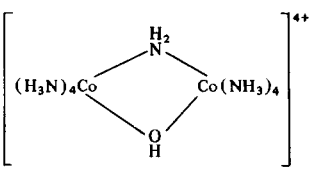


(**I**) (**II**)

This suggestion recalls an earlier debate[22,23] attempting to distinguish between the oxygen ligands in (**III**) and (**IV**):

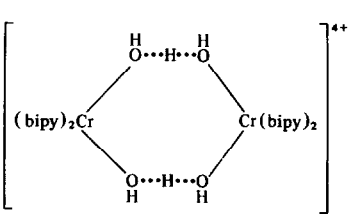


III



IV

(ii) In addition to crystallographic proof[24] of the existence of the centric species in its tetra-iodide dihydrate, where bipy = 2,2′-bipyridyl, vapour tensiometry also supported[25] the reality of the species in aqueous solutions.



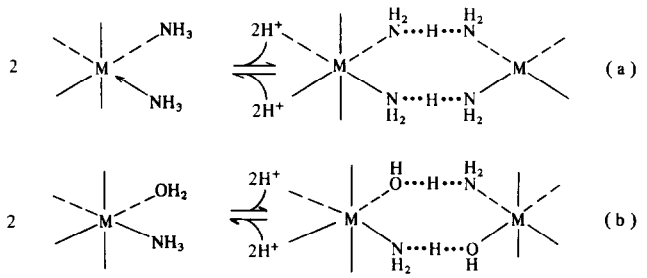
(iii) The bridging role of $(H_3O_2)^-$ in tri-tungsten species has been demonstrated by X-ray methods,[20,26] not only in the crystalline phase but also in aqueous solution[27] by employing differential anomalous X-ray scattering.

(iv) To account for an extra Mössbauer active species, Meagher[28] has very recently suggested the possibility that the well known hydrolysed dimers of aquo-iron(III) include some novel ones with $\mu(H_3O_2^-)$. In a similar way, an extra Mössbauer signal in the more complicated system Fe(EHGS) had been assigned to the $Fe^{III}\mu(H_3O_2)Fe^{III}$ fragment.[29]

(v) A recent example is perhaps provided by the system $[Pd(phen)(OH_2)_2]^{2+}$. Discrepancy between the interpretation of the careful titrations by Anderegg and Wanner[30] and later magnetic resonance experiments[31] may arise from the presence of the dimeric $\mu(H_3O_2)^-$ species under the greater concentration found in spectrometry.

Ardon and Bino[24] point out that the major difficulty in proving the presence of the $\mu(H_3O_2)^-$ species in solution lies in distinguishing it from its anhydride, the μ(OH) species. The instant enhancement of molar circular dichroism on crossing the pK_A observed for (+)-*cis*-$[Rh(en)_2(H_2O)(OH)]^{2+}$ and, several years ago,[19] for (+)-*cis*-$[Co(en)_2(H_2O)(OH)]^{2+}$, offer a novel method for making this distinction, at least for kinetically inert resolvable compounds.

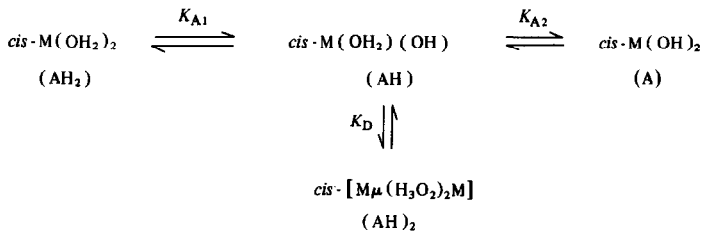
While, in monomeric complex ions, the possibility of such bridging through strong hydrogen bonds is greatest in the *cis*-hydroxo-aquo systems, (because of the relative strength of OHO bonds), any other *cis* arrangement of a hydrogen bond donor and a hydrogen bond acceptor may give rise to similar bridging, as in the *cis*-diammine species or the *cis*-aquo-ammines, as shown below.



Many similar situations involving substituted hydroxo or amido species, are possible. Indeed, for any unidentate protic ligand (which is a hydrogen bond donor), in the position *cis* to its own conjugate base (which is a hydrogen bond acceptor) the bridge may form.

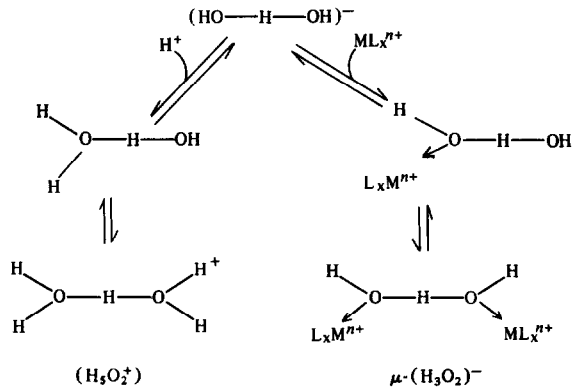
Grinberg[32] pointed out the special effects on pK_A of the *cis*-diammine platinum(IV) moiety; and (a) above may now help to account for these.

Quite apart from such anomalies in the absolute size of acidity constants, the extra equilibrium involving dimerization may also have an effect upon measured pK_A, as shown schematically below (for clarity, charges are omitted).



The apparent values of pK_A will vary with concentration (this may help to explain the large spread in results of Table 2); properties like circular dichroism will not vary linearly with total metal concentration; and there may be stereoselective effects in racemic as against optically active systems (as observed[33] for other dimeric bridged complexes like tartrato-vanadate(IV) or copper(II) tartrates). For example, in (+)-*cis*-$[M(en)_2H_2O)(OH)]^{2+}$, the only possible dimer is non-centric $(+)(\mu H_3O_2)(+)$, whereas for the (±) complex ion, the possible dimers comprise the non-centric pair $(+)(\mu H_3O_2)(+)$ and its enantiomer $(-)(\mu\text{-}H_3O_2)(-)$, and the centric (*meso*) isomer $(+)(\mu\text{-}H_3O_2)(-)$ which should have quite different properties from the racemate. Experiments are in hand on this stereoselectivity.

The classical analogy between protonation of a Bronsted base and its co-ordination extends to $(H_3O_2)^-$, as in Scheme 4:



The transformation from the short O–O contact (2.29 Å) of free $(H_3O_2)^-$ to the much larger separation (*ca* 2.5 Å) of $(H_5O_2)^+$ or that in the $\mu(H_3O_2)^-$ bridge linking two metal ions, is in line with many other changes of O–O distance from two co-ordinated oxygen systems like $[(DMSO)_2H]^+$ to three co-ordinated oxygen atoms, as in $[(R_2O)_2H]^+$. In addition, and at present unique to the aquo system, there is the charge effect on O–O distance.

Reactions with carbon dioxide

It is convenient to summarize our CD results on the resolved compounds in the light of the careful work by Palmer *et al.*[17] on the racemic system. They showed that, in rapid reactions with carbon dioxide, *cis*-$[Rh(en)_2(OH)_2]^+$ and *cis*-$[Rh(en)_2(OH)(OH_2)]^{2+}$ formed *cis*-$[Rh(en)_2(CO_3)(OH)]^0$ and *cis*-$[Rh(en)_2(CO_3)(OH_2)]^+$ respectively: these were related by a pK_a of 8.45. $[Rh(en)_2(CO_3)]^+$ had $\lambda = 327$ (312 M^{-1} cm^{-1}) (cf. the oxalato-species; Table 3).

In the titration of carbonato-free solutions of *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$ with sodium hydroxide, the circular dichroism spectra change through formation of aquohydroxo- and dihydroxo-Rh^{III} species. In the presence of CO_2, the changes in spectra

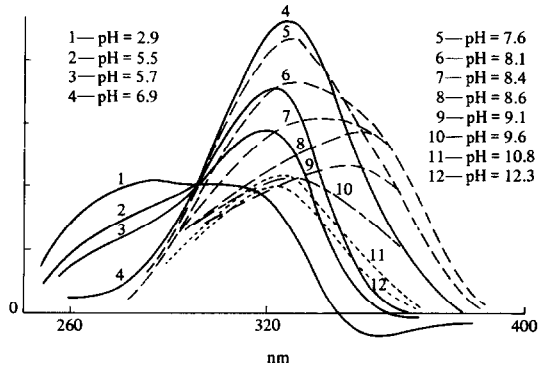


Fig. 2. Variation of circular dichroism for (−)-$[Rh(en)_2(OH_2)_2]^{3+}$ during titration (in the presence of CO_2) with NaOH. Spectra were measured at the following pHs: (1) 2.9; (2) 5.5; (3) 5.7; (4) 6.9; (5) 7.6; (6) 8.1; (7) 8.4; (8) 8.6; (9) 9.1; (10) 9.6; (11) 10.8; and (12) 12.3.

[a] This work.
[b] pH 8.85.
[c] pH 7.1.
[d] These values are approximate, based on an analysis of spectra like those in Fig. 3.
[e] This species may have one or more of a variety of possible structures, including aquocarbonato—as preferred in ref. 17—or the tautomeric hydroxo-hydrogencarbonato-, or some hydrogen bonded (intra- or intermolecular) variant.

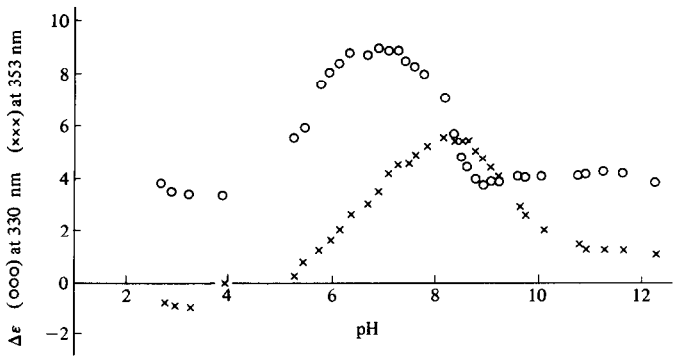

Fig. 3. Variation of $\Delta\varepsilon_{330}$ (○○○) and $\Delta\varepsilon_{353}$ (× × ×) for (−)-$[Rh(en)_2(OH_2)_2]^{3+}$ during titration with NaOH in CO_2.

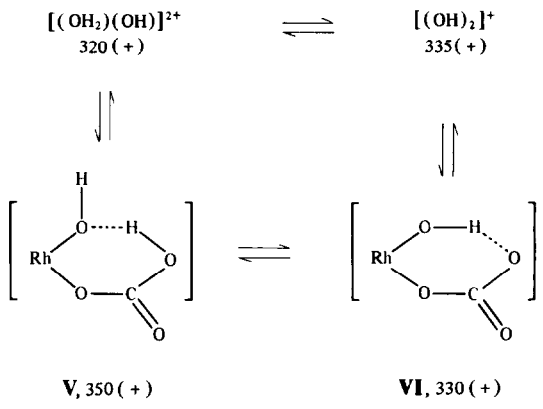
(Fig. 2) are similar to those in the carbonate-free situation until pH ~ 7 (cf. Fig. 1a). But, as the pH is increased above 7, a new band develops around 350 nm. This is better shown in Fig. 3, where the intensities at 330 and 353 nm are plotted as a function of pH. Up to pH ~ 4.5, the intensity at 330 nm is about equal to that of the starting solution of *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$. At the same time, the intensity at 350 nm changes slightly from a negative value to approximately zero. From pH 4.5 to 6, the intensity at 330 nm increases substantially to its maximum value, whereas the intensity at 350 nm shows a much smaller increase. The intensity at 330 nm does not then change significantly until pH 7, although the Cotton effect at 350 nm continues to increase until it reaches a maximum at pH 8.5. From pH 7 to 8.5 the intensity at 330 nm again changes very substantially and then maintains an approximately constant value for pH > 8.5. The intensity of the band at 350 nm decreases from pH 8.5 to 10.5 and then stays constant at higher pH. The spectrum of the final solution is distinctly different from that of *cis*-$[Rh(en)_2(OH)_2]^+$ obtained in the titration of carbonate-free solutions. It shows only one absorption band with $\lambda \simeq 330$ nm, instead of two (less intense) bands shown by the *cis*-dihydroxo compound, at 340 and 270 nm. If that final alkaline solution is titrated back with acid, the new band at 350 nm is even more clear. The solution finally obtained for pH 3.06 gives the circular dichroism spectrum of *cis*-$[Rh(en)_2(OH_2)_2]^{3+}$. The development of the band around 350 nm is observed between pH 5.5 and 8.5. The dominant aquorhodium(III) species in this range of pH is the *cis*-$[Rh(en)_2(OH)(OH_2)]^{2+}$ ion. Therefore, the compound responsible for the highly intense absorption at 350 nm arises from the reaction of this complex ion with HCO_3^-. As the titration proceeds, both the carbonato complex and the aquohydroxo ion are titrated, and the final product is not *cis*-$[Rh(en)_2(OH)_2]^+$ alone. It shows a CD spectrum of higher intensity than would be expected for this compound. The reactions suggested by these features are in Scheme 3, which is, in essence, the same as that derived for the racemic system.[17]



Scheme 3.

The formation of compound (V) explains the very high intensity of the new band at 350 nm, even stronger than that corresponding to the aquohydroxo compound (itself anomalously high). In fact, the six membered chelate ring formed within the molecule is expected to contribute strongly to the optical activity.[34] All the reactions are fast, as expected for reactions not involving M–O bond cleavage, so all species involving the unidentate ligands OH^-, OH_2 CO_3^{2-} of Table 3 and Scheme 3 have chemically correlated optical configurations.

(*Received* 30 *August* 1988; *accepted* 11 *November* 1988)

Abstract—The equilibria in aqueous solution in the systems L-serine and L-threonine $+VO^{2+}$ have been studied by a combination of pH-potentiometric and spectroscopic methods (EPR, visible absorption and circular dichroism) in the pH range 1.5–13.6. For pH > 4, high ligand-to-metal ratios were used. The results of the various methods are made self-consistent, then rationalized assuming an equilibrium model including species, MLH, ML, MLH_{-2}, MLH_{-3}, ML_2H_2, ML_2H, ML_2, ML_2H_{-1}, ML_2H_{-2}, $M_2L_2H_{-2}$ and $M_2L_2H_{-3}$ (where HL denotes L-serine or L-threonine) and several hydrolysis products; their formation constants and individual electronic spectra (isotropic and circular dichroism) are given. Plausible isomeric structures for each of the stoichiometries are discussed.

Knowledge of the complex equilibria of VO^{2+} in the presence of amino acids is relevant in understanding its possible interaction with likely biological ligands; few reliable data exist.

The first part of this study[1] introduced our work and gave detailed results for the system L-Ala+VO^{2+} in the pH range 2–12. This work involves the study of the L-serine and L-threonine+VO^{2+} systems by combining the results of potentiometric and spectroscopic techniques. A part of this has been presented in a preliminary form.[2] No other reliable data have been published for these systems.[3] Several general experimental difficulties in the study of oxovanadium(IV) +amino acid systems were discussed in Part I.[1]

The L-Ser and L-Thr systems have an additional coordinating group (–CHROH, hereafter designated by –ROH) but—to our knowledge—no reliable data for pK_{a3} of the –ROH group are available. Examples of published values for this pK_a(–ROH) (= pK_{a3}) of L-Ser include: 11.02 (I = 0.10 M KNO_3),[4] 11.45 (I = 1 M $NaClO_4$),[5] 13.6 (I = ?)[6] and 16 (I = ?).[7] However, pH potentiometric titrations performed in this work suggest that (at least for I = 2.25 M $NaNO_3$ and t = 25°C) the pK_{a3} of L-Ser is greater than 12. NMR experiments even suggest that pK_{a3} may be in the range 13–14.

Our results suggest that for pH > 6.5, several species form that involve the coordination of the $-RO^-$ group of L-Ser and L-Thr. Since pK_{a3} is not available, exactly as for the *bidentate* L-Ala+VO^{2+} system, the formation constants calculated[1] correspond to the general reaction:

$$xVO^{2+} + yL^- + zH^+ \rightleftharpoons (VO)_x(L)_y(H^+)_z. \quad (1)$$

In common with biochemical studies, we abbreviate L-alanine as HA, L-serine as HS and L-threonine as HT, and their conjugate bases, the singly charged alaninate, serinate and threoninate ions are then A^-, S^- and T^-, respectively. L^- will denote both S^- and T^-.

* For Part I, see ref. 1.

EXPERIMENTAL

Reagents

All solutions were prepared in an inert atmosphere (high purity dinitrogen passed through soda lime and glass wool). All measurements were performed at 25°C with solutions containing 2.25 M $NaNO_3$.

L-Serine (BDH), L-threonine (BDH) and L-serine methyl ester hydrochloride (Sigma) were dried for several days (vacuum desiccator with silica gel). All results refer to optically pure amino acids only.

Instrumentation

The instruments used were described in Part I.[1] Several potentiometric titrations were made with a Metrohm 655 Dosimat, instead of the Radiometer Autoburet ABU12.

Calibration procedure for pH measurements

This was described in Part I.[1] The maximum pH value for the titration curves of solutions containing L-Ser (and L-Thr)+VO^{2+} was 7.5. Several visible and circular dichroism spectra recorded in the pH range 10.5–13.6, and a combined electrode (Radiometer GK2351B—low sodium-error electrode) was used for this purpose. The interference of the Na^+ was corrected using factors supplied by the manufacturer. The accuracy of these pH measurements is obviously not as good as for pH < 10.

General experimental conditions

Five titration curves ($C_{\text{amino-acid}} = 3\text{–}10 \times 10^{-2}$ M) were obtained for each amino acid to determine the protonation constants in 2.25 M $NaNO_3$; NaOH (2.2 M) was used.

For both L-Ser (and L-Thr)+VO^{2+}, 10 titration curves were measured with initial total concentrations of oxovanadium(IV) in the range 2.6–50×10^{-3} M and L-amino acid 0.012–0.36 M. Titrations involving pH measurements in the pH range 2–4 and 4.0–7.5 were performed using ligand-to-metal (L/M) ratios of 0.5–6.4 and 30–113.

A total of 40 visible spectra and 80 CD spectra (visible region) were recorded for each system, with total concentrations of oxovanadium(IV) and amino acid in the range $1.5\text{–}26 \times 10^{-3}$ and 0.01–0.31 M, respectively. Ligand-to-metal ratios were in the range 4–100.

RESULTS

EPR studies

The EPR spectra recorded with frozen "solutions" containing VO^{2+} and L-Ser or L-Thr at 77 K are typical VO^{2+} axial spectra. The field region that corresponds to $A_\parallel$ and $M_I = 5/2$ and 7/2 gives more information about the type and number of species present.

In Fig. 1, we include the high-field region of the EPR spectra of frozen "solutions" containing L-Ser and VO^{2+} with ligand-to-metal ratios of 38.0 at several values of pH. The results obtained for the L-Thr+VO^{2+} system are similar. SI to SVII represent distinct components detected in the EPR spectra. Each corresponds to a given set of g and A values ($\parallel$ and $\perp$): there may of course be more than one vanadium complex with approximately the same g and A parameters.

Analysing Fig. 1, we make the following general observations:

(i) For pH $\lesssim$ 6, the spectra obtained with L-Ser+VO^{2+} and L-Thr+VO^{2+} are similar to those for the L-Ala+VO^{2+} system,[1] except that the pH range where species of the type L_I and L_{II} (L = S, T, A) predominate is narrower and is shifted by $\sim$ 0.5 pH units to lower pH.

(ii) At pH $\sim$ 6, essentially one component only is detected (designated by S_{III} or T_{III}). The EPR spectra of S_{III} and T_{III} are identical and coincide with the spectra of MA_2.[1] This suggests that, for all three systems, the same type of species is responsible for the observed spectra.

(iii) For pH $\gtrsim$ 6 the EPR spectra for the L-Ser (and L-Thr)+VO^{2+} systems differ completely from those in the L-Ala+VO^{2+} system in similar conditions, in that a clearly seen component (designated by S_{IV} or T_{IV}) for pH 6.4 has $A_\parallel(L_{III}) > A_\parallel(L_{IV})$. The component S_{IV} in Fig. 1 corresponds to at least two different species, S_{IV} and $S_{IV'}$; Their experimental spectra are indistinguishable; $S_{IV'}$ predominates for pH $\gtrsim$ 9 (see below).

As the pH increases, the intensity of the peak in the region of L_{III} decreases. The modifications with pH in these peaks also suggest that a new component (designated by L_V) forms, with $A_\parallel(L_V)$ slightly smaller than $A_\parallel(L_{III})$. For pH $\gtrsim$ 10, L_{III} has probably disappeared—the peak observed in this region may correspond to L_V only.

(iv) For pH $\gtrsim$ 11, the intensity of the peaks in the region of L_V increases, suggesting formation of a new component—L_{VI}. As pH increases above about 12, shoulders in the peaks corresponding

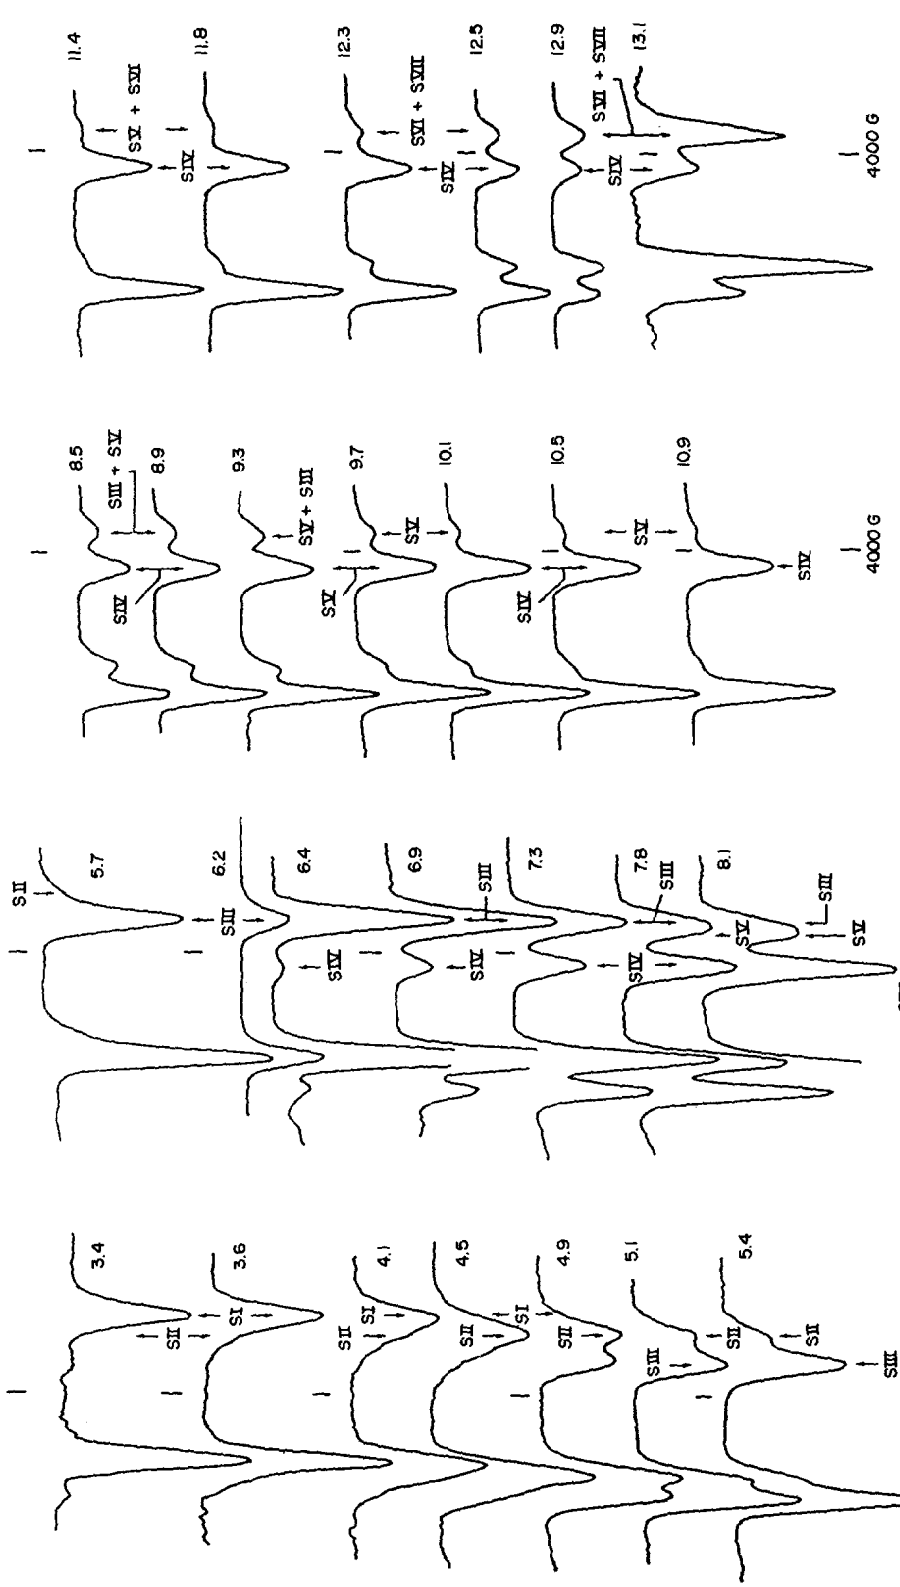

Fig. 1. High field range (3800–4200 Gauss) of the first derivative EPR spectra at 77 K of frozen "solutions" containing L-Ser and VO^{2+} with L/M = 38.0. The total vanadium concentration is in the range $1.3–2.2 \times 10^{-2}$ M. pH values are indicated.

to $M_I = 7/2$ and a slight decrease in $A_\parallel$ also suggest the formation of another component—L_{VII}. CD spectra in similar conditions also indicate at least two (probably three) distinct species.

Several spectra were recorded at fixed pH values, varying L/M by progressively adding stock VO^{2+} solution. For example, for the L-Ser + VO^{2+} system at pH 9.3, three components may be detected—S_{III}, S_V and S_{IV}, with $A_\parallel(S_{IV}) \ll A_\parallel(S_V) \lesssim A_\parallel(S_{III})$. Their positions and relative intensities are essentially unchanged as L/M varies from 38 to 10. The signal due to S_{III} appears as a shoulder on the signal of S_V.

At pH ~ 13.4, S_{IV}, and another component—S_{VI} and/or S_{III}, are detected. The relative intensity of S_{IV} may slightly decrease as L/M varies from 38 to 12.

In spectra at pH ~ 12.5 for the L-Thr + VO^{2+} system, at least two components occur: T_{IV} and T_{VI} (and/or T_{VII}), with relative intensities independent of L/M from 35 to 10. CD spectra in similar conditions point to at least three distinct species.

Circular dichroism and visible absorption spectra

As for EPR, the CD and visible spectra and their changes as the pH varies are similar for both L-Ser + VO^{2+} and L-Thr + VO^{2+} systems. We will, in the main, present results (and calculations) for the L-Ser + VO^{2+} system.

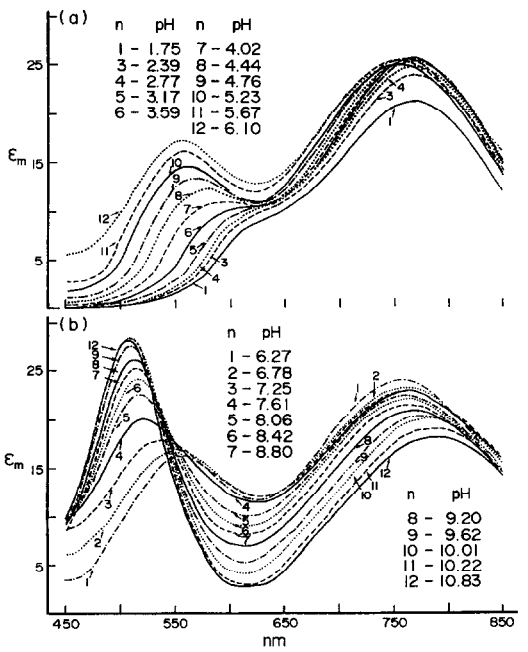

Fig. 2. Visible spectra of solutions containing L-Ser + VO^{2+} with L/M = 38.0 and $C_{VO} = 7.2$–8.3×10^{-3} M. The pH corresponding to each spectrum is indicated. The CD spectra for the same solutions are in Figs 4 and 5.

Figure 2 includes visible spectra of L-Ser + VO^{2+} solutions with an L/M ratio of 38.0. For pH $\lesssim$ 6.1 (Fig. 2a), the results are similar to those in the L-Ala + VO^{2+} system for L/M = 53.9.[1] For pH $\gtrsim$ 3, the spectra also reveal a progressive increase in the ligand field around VO^{2+}.

For pH $\gtrsim$ 6.3, on the other hand, the evolution of the visible spectra is completely different from that for the L–Ala + VO^{2+} system, with a ligand-to-metal ratio of 53.9 (Fig. 2 of ref. 1) and as pH increases:

(i) Band II increases in intensity and further shifts to lower wavelengths.
(ii) Band I shows a progressive decrease in ε_m and shifts to longer wavelengths.

Figure 3 includes visible spectra for pH $\gtrsim$ 10.7. For pH $\gtrsim$ 12.3, the general increase in ε_m (especially in the range 450–600 nm) suggests extensive hydrolysis of VO^{2+}; these spectra are akin to those observed in the L-Ala + VO^{2+} system for pH $\gtrsim$ 8.

As for the L-Ala + VO^{2+} system, the CD spectra of solutions of L-Ser (and L-Thr) + VO^{2+} vary enormously in the pH range 1–14. Up to pH 6, the spectra are relatively similar to those for L-Ala + VO^{2+}, in that $|\Delta\varepsilon_m|$ values gradually increase and band II shifts to longer wavelengths. The $|\Delta\varepsilon_m|$ values are of the same order of magnitude: e.g. at pH ~6 and ~760 nm, $\Delta\varepsilon_m$(Ser) ~ $1.4 \times \Delta\varepsilon_m$(Ala). Figure 4 includes some spectra of L-Ser + VO^{2+} solutions for pH $\lesssim$ 6.

As for EPR and visible spectra, for pH $\gtrsim$ 6 the CD spectra in the system L-Ser or L-Thr + VO^{2+} (Figs 5 and 6) differ completely from those for the L-Ala + VO^{2+} system in similar conditions. Namely:

(i) In the range 400–800 nm the $|\Delta\varepsilon_m|$ values continue to increase till pH ~ 8.8.
(ii) In the range 650–800 nm: $\Delta\varepsilon_m$(pH 8.4) ~ $3.5 \times \Delta\varepsilon_m$(pH 6.3).
(iii) In the range 450–550 nm: $\Delta\varepsilon_m$(pH 8.4) ~ $2.2 \times \Delta\varepsilon_m$(pH 6.3).

For pH $\gtrsim$ 8.5 (Fig. 5):
In the range 650–800 nm, the $\Delta\varepsilon_m$ still increase till pH ~ 10.7.
In the range 450–550 nm, the $|\Delta\varepsilon_m|$ decrease and for pH $\gtrsim$ 10, $\Delta\varepsilon_m > 0$.

For pH $\gtrsim$ 10.7 (Fig. 6), by contrast:
In the range 650–800 nm, $\Delta\varepsilon_m$ wanes and at high pH a species exists which has $\Delta\varepsilon < 0$.
In the range 450–550 nm, the $\Delta\varepsilon_m > 0$ waxes till pH ~ 12.6 (Fig. 6).
For pH $\gtrsim$ 12.6, all $|\Delta\varepsilon_m|$ decrease.

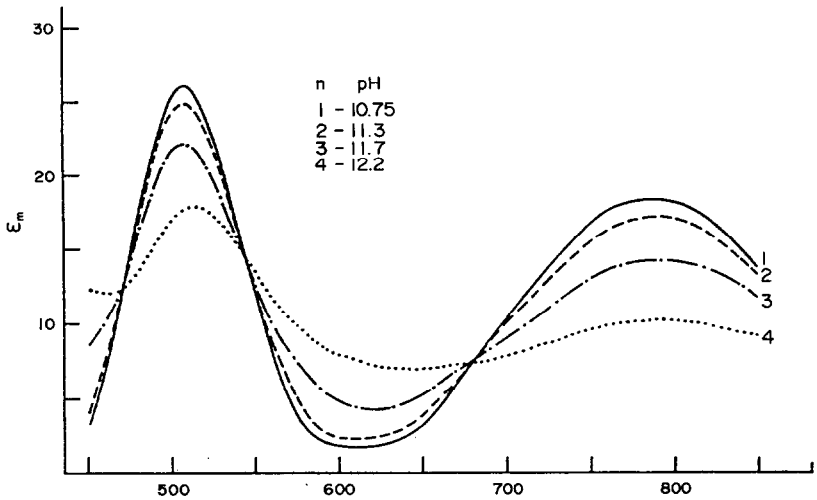

Fig. 3. Visible spectra of solutions containing L-Ser+VO^{2+} for pH $\gtrsim$ 10.7 with L/M = 38.0 and $C_{VO} = 6.7–7.7 \times 10^{-3}$ M. The pH corresponding to each spectrum is indicated and the CD spectra for the same solutions are in Fig. 6.

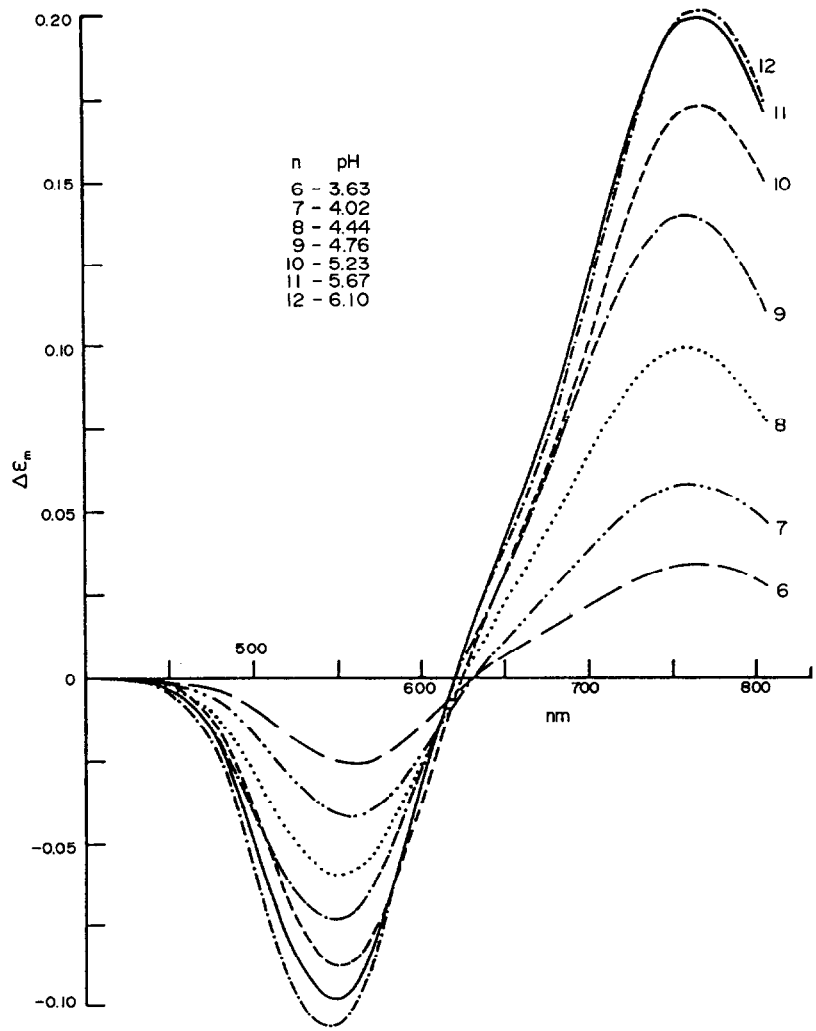

Fig. 4. CD spectra of solutions containing L-Ser+VO^{2+} with L/M = 38.0 and $C_{VO} = 7.2–7.9 \times 10^{-3}$ M. The isotropic absorption spectra of these solutions are in Fig. 2.

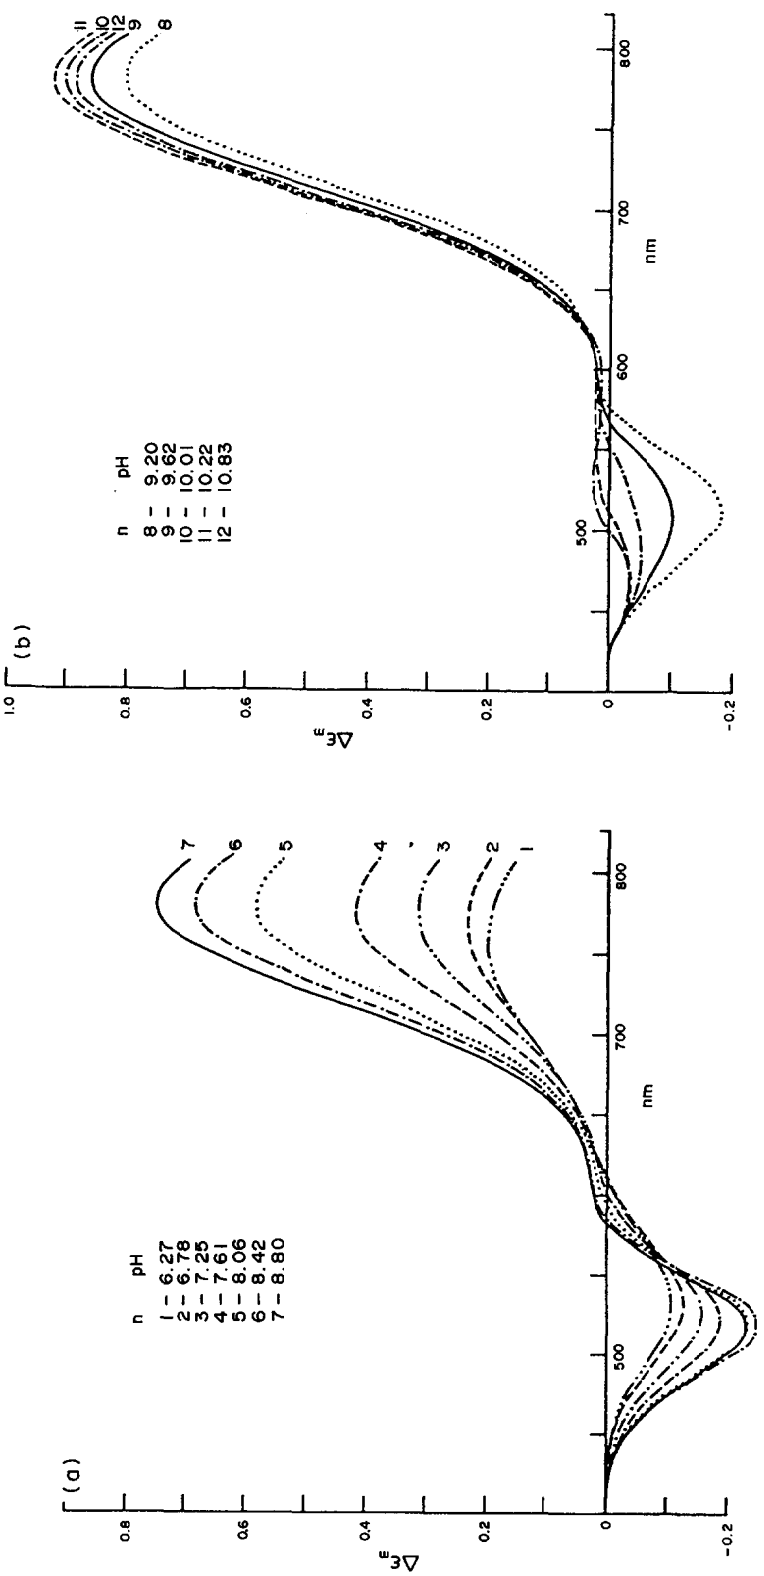

Fig. 5. CD spectra of solutions containing L-Ser + VO^{2+} with L/M = 38.0 and C_{VO} = 7.5–8.3 × 10^{-3} M. The isotropic absorption spectra of these solutions are in Fig. 2.

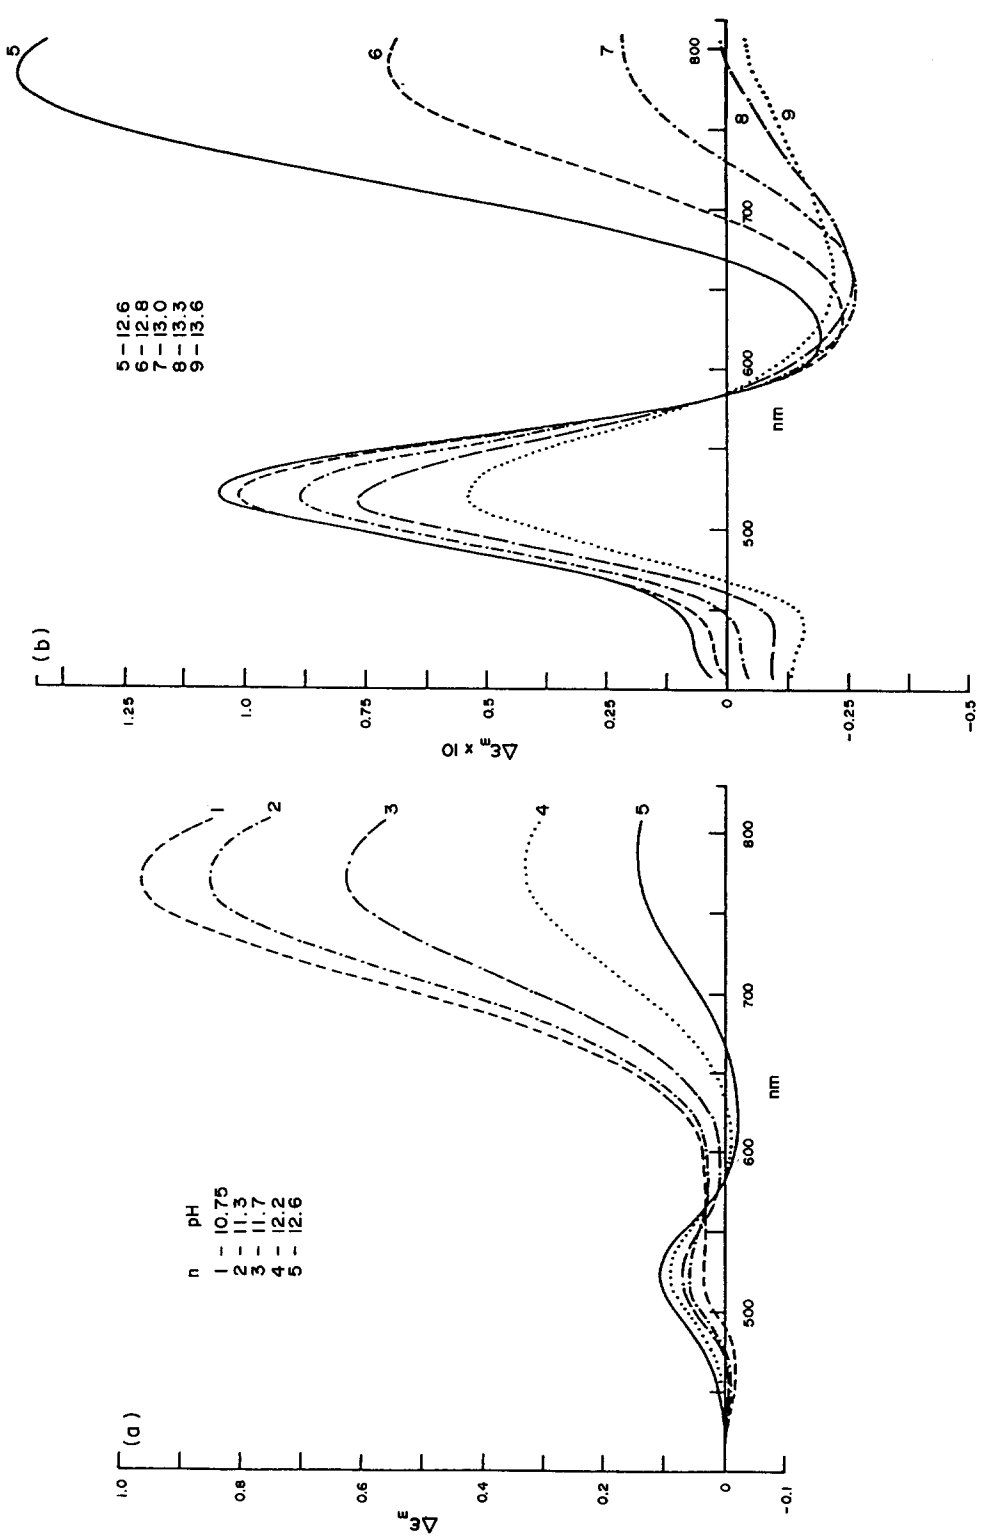

Fig. 6. CD spectra of solutions containing L-Ser + VO^{2+} with L/M = 38.0 and C_{VO} = 7.5–8.3 × 10^{-3} M. The isotropic absorption spectra of the solutions with pH < 12.3 are in Fig. 3. Note the different scales for a and b.

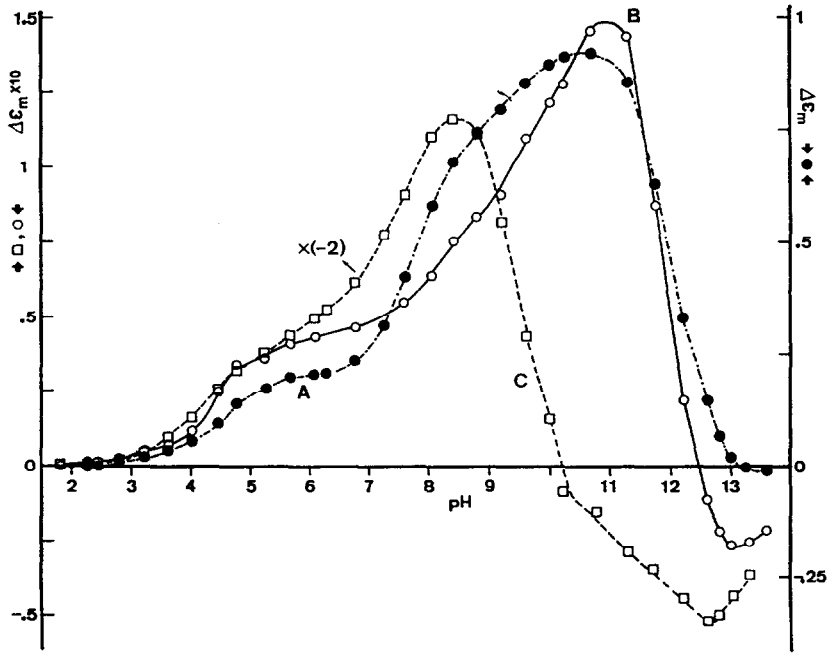

Fig. 7. Change with pH of the $\Delta\varepsilon_m$ values of L-Ser + VO^{2+} solutions with L/M = 38.0 from Figs 4–6 at three wavelengths. A: 767 nm, B: 632 nm and C: 527 nm ($\Delta\varepsilon_m \times -2$).

Between pH 4 and 8, oxovanadium(IV) must be coordinated mainly to amino acids, otherwise $VO(OH)_2$ would precipitate. However, the soluble product of hydrolysis of oxovanadium(IV) is clearly not as important for L-Ser (and L-Thr) + VO^{2+} as for L-Ala + VO^{2+} in similar conditions. Likewise, the solutions for L-Ser (and L-Thr) + VO^{2+} were violet or pink-violet in the pH range 7–13.3, and the ligand-to-metal ratios were lower, whereas L-Ala + VO^{2+} solutions with L/M ~ 54 were already brown for pH $\gtrsim$ 8.4.

Besides these qualitative observations, the EPR, visible and CD spectra show clearly that the $-RO^-$ group is involved in the coordination to VO^{2+} at pH > 7 in L-Ser (and L-Thr) + VO^{2+} solutions with high L/M ratios. The coordination of the $-CH_2O^-$ group of malate must similarly be assumed to explain the EPR, visible and CD spectra for pH > 7, in solutions containing L-malic acid and VO^{2+} with high L/M ratios.[8]

CD spectra have also been recorded at fixed pH (pH = 4.5, 7.2, 9.2 and 13.3 for solutions containing L-Ser + VO^{2+} and pH = 4.5, 7.4, 9.4, 12.4 and 13.6 for solutions containing L-Thr + VO^{2+}) at varying but high amino acid-to-vanadium ratios. For each pH, two types of experiments were performed: (i) the total concentration of the amino acid is approximately constant and that of VO^{2+} is varied or, (ii) the total vanadium concentration is kept approximately constant but that of amino acid is varied (not done for pH = 12.4 and 13.6).

At pH 4.5, the CD spectra show minor changes between amino acid : vanadium = 97 (C_{VO} ~ 0.0021 M) and 21 (C_{VO} ~ 0.0086 M) [C_{VO} = total concentration of oxovanadium(IV)]. For lower L/M, the CD spectra change more, probably due to hydrolysis. At pH 7.2 (L-Ser, Fig. 8a) and pH 7.4 (L-Thr), the CD spectra change quite drastically as L/M varies between 97 (C_{VO} = 0.0017 M) and 19 (C_{VO} = 0.0083 M). At pH 9.2 (L-Ser) and 9.4 (L-Thr), the CD spectra again show minor changes between amino acid : vanadium = 97 (C_{VO} = 0.0016 M) and 19 (C_{VO} = 0.0083 M).

At pH ~ 12.4 (L-Thr), the CD spectra show gross changes as L/M varies between 35 and 10 (Fig. 9a); similar but less marked behaviour may be observed at pH ~ 13.3 (L-Ser, Fig. 8b). At pH ~ 13.6 (L-Thr, Fig. 9b), $|\Delta\varepsilon_m|$ values decrease a little as L/M varies between 35 and 12.

At pH ~ 13.3, solutions containing L-Ser + VO^{2+} with L/M = 35 (CD spectrum 1 in Fig. 8b) are light violet. Nevertheless solutions used to record CD spectra 2 and 3 in the same figure differ, being brownish-yellow, and those used for CD spectra 4–7 were brown, becoming browner as the VO^{2+} concentration increased.

As with L-Ala + VO^{2+}, the results in Figs 8 and 9b can be explained only by assuming equilibria between at least two vanadium-containing species differing in their degree of polymerization. On the other hand, if CD spectra recorded at fixed pH and varying but high L/M ratios almost coincide, that

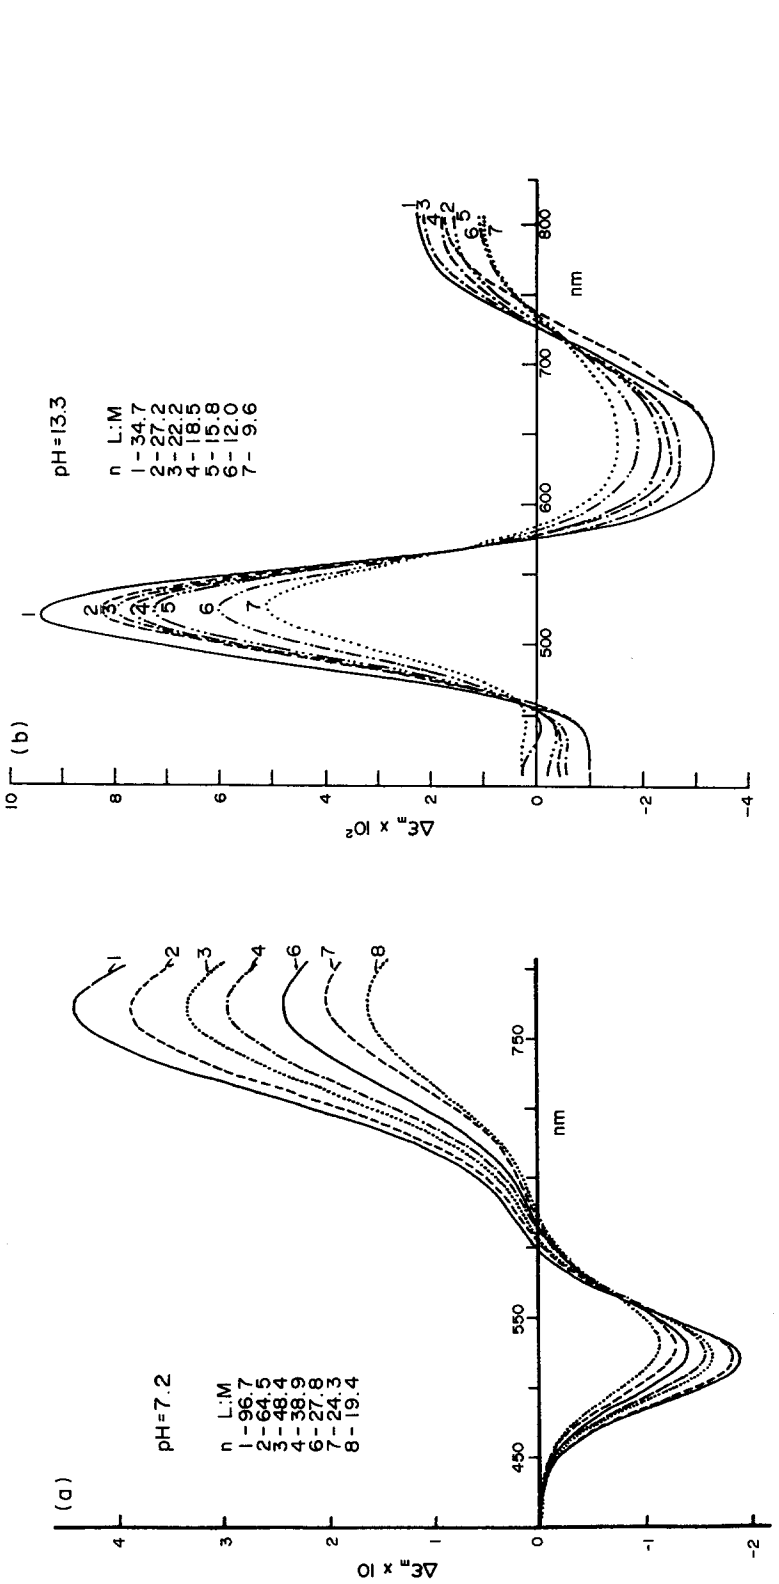

Fig. 8. CD spectra of solutions containing L-Ser and oxovanadium(IV) with (a) $C_{VO} = 1.7–8.3 \times 10^{-3}$ M and (b) $C_{VO} = 8.8–26 \times 10^{-3}$ M. The solutions were prepared by varying the volume of the VO^{2+} stock solution. For each group of spectra, the total L-Ser concentration is approximately the same.

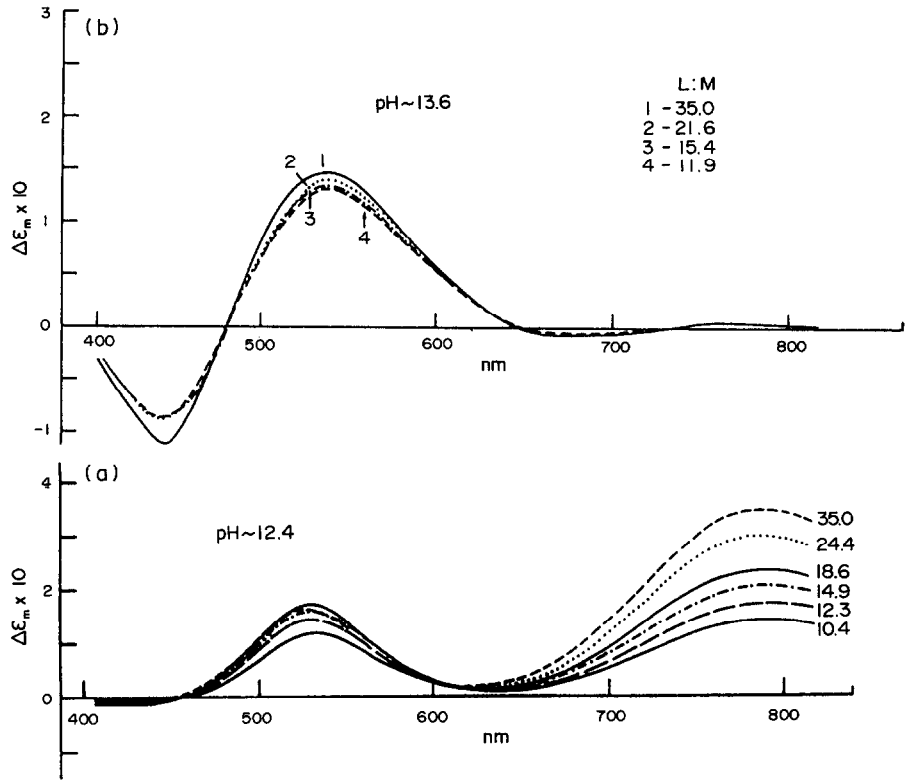

Fig. 9. CD spectra of solutions containing L-Thr and oxovanadium(IV) with (a) $C_{VO} = 8.5–25 \times 10^{-3}$ M and (b) $C_{VO} = 6.8–18 \times 10^{-3}$ M. The solutions were prepared by varying the volume of the VO^{2+} stock solution. For each group of spectra, the total L-Thr concentration is approximately the same.

can be explained only by assuming that in those conditions species predominate with the same degree of polymerization.

"Very basic" (originally brown) solutions containing L-Ser (or L-Thr)+VO^{2+} acidified to pH ~ 10–11 remain brown for some time. However, if acid is added till pH $\lesssim$ 7–8, fast equilibration occurs to the colour characteristic of that pH. More or less similar behaviour was found in the L-Ala+VO^{2+} system,[1] consistent with extensive polymerization of vanadium(IV) in brown solutions. In the conditions used for the spectra in Fig. 6, no great polymerization occurs until at least pH 13.3. Distinct from all other known amino acid+VO^{2+} systems,[1,2,9–11] L-Ser and L-Thr are unique in preventing polymerization of VO^{2+} at high pH. The malic acid+VO^{2+} system[8] behaves in a similar way.

CD spectra for solutions containing L-serine methyl ester and VO^{2+} (with total ligand and metal concentrations similar to those used in Figs 5 and 6) have shapes in the pH range 7–13 resembling those for the L-Ser (and L-Thr)+VO^{2+} systems, but values of $|\Delta\varepsilon_m|$ are some ten times lower. For pH ~ 12.3–12.8, the CD spectra are similar to spectra 8 and 9 in Fig. 6b, except that band I shifts to longer wavelengths (e.g. ~ 710 nm and ~ 760 nm for pH ~ 12.3 and 12.8, respectively). Further, while in the pH range 6–13.3 the L-Ser (and L-Thr) solutions were violet or pink-violet, in the system involving L-serine methyl ester+VO^{2+}, solutions were brownish-green with a slight bluish shade till pH ~ 9 and brown for pH > 9.7.

Hydrolysis of the methyl ester cannot be ruled out in explaining the spectra. However, from these experiments, one may at least conclude that for the L-Ser (and L-Thr)+VO^{2+} systems the carboxylate group is involved in coordination in the pH range 7–12, since the different results (much lower $|\Delta\varepsilon_m|$ values and colours of the solutions) for the L-serine methyl ester+VO^{2+} system would otherwise be inexplicable.

Potentiometry

Protonation constants calculated by the MINIQUAD[12] and SUPERQUAD[13] programs almost coincide. From SUPERQUAD, for L-serine in solutions containing 2.25 M $NaNO_3$ (at 25°C): $pK_{a1} = 2.322 \pm 0.004$ and $pK_{a2} = 9.274 \pm 0.002$ and

for L-threonine $pK_{a1} = 2.326 \pm 0.004$ and $pK_{a2} = 9.187 \pm 0.002$.

As for L-Ala the titration curves involving "low" ligand-to-metal ratios demonstrate the formation of amino acid complexes with VO^{2+}, but $VO(OH)_2$ precipitates for pH $\gtrsim$ 4.

Also as for L-Ala, the titration curves obtained using high L/M ratios show a progressive increase of pH as base is added in the pH range 4.0–7.5. In formation curves calculated for these curves:

(i) $\bar{n} \sim 2$ for the pH range 5–7; this means that ML_2 complexes make an important contribution.
(ii) The calculated formation curves do not coincide with each other but the observed differences are not as important as those found in the L-Ala system—this probably means that hydrolysis and formation of polymeric species are not as important.
(iii) In the "high" pH region $\bar{n} > 2$, an effect which is more important for curves with lower L/M ratios.
(iv) The $\bar{n}$ values for titration curves in the L-Thr+VO^{2+} system exceed those for L-Ser, especially for pH $\lesssim$ 5 and pH $\gtrsim$ 7.

As in the case of L-Ala, the systems are quite complex. Calculations involving the refinement of β_{xyz} values of all possible species (i.e. $M_xL_yH_z$ with x, y and z quite general) gave results with no physical meaning. As for the L-Ala+VO^{2+} system,[1] we therefore chose the following strategy:

(i) From titration curves of solutions with "low" L/M, "titration points" were selected to correspond to "solutions" where only MLH and ML (and VO^{2+}) co-exist. Several iterations were needed to select these "titration points" and because the pK_{a1} of L-Ser and L-Thr are $\sim$ 0.2 pH units lower than the pK_{a1} of L-Ala, this particular selection was difficult.
(ii) Taking β_{111} and β_{110} as known, the MINIQUAD and SUPERQUAD programs were used to calculate the β_{xyz} of other species now including the full set of the "complete" titration curves.

Our best model (model I) from this procedure is in Table 1. For each of the $\log \beta_{xyz}$ values, plausible ranges are also given, established by a critical examination of all the calculations.

Beside the usual criteria used to select equilibrium models for such programs (CHI[2] and R values, standard deviations, etc.) we compare with spectroscopic values. This self-consistency between

Table 1. Composition and formation constants of the species in the L-Ser (and L-Thr) systems, assuming various equilibrium models. Values for $\log \beta_{xyz}$ of eq. (1) are given[a]

[a] The type of vanadium(IV) hydrolysis products considered and the corresponding formation constants are in Table 1 of ref. 1.

[b] In the calculations performed with MINIQUAD and SUPERQUAD, formation constants could be refined for stoichiometries like $M_2L_2H_{-4}$, ML_2H_{-2}, MLH_{-2} and MLH_{-3}. However, the calculated β substantially differ depending on the formation constants included; besides, the β values obtained in these calculations were such that it would not be possible to rationalize these with the visible and CD spectra.

[c] ML_2H_2 is specially important for solutions with high ligand-to-metal ratios for pH $\lesssim$ 4.5. This is the reason why the β_{122} values are given with a relatively high uncertainty.

thermodynamic and spectroscopic results constitutes the novelty and power of our method of speciation.

One main problem in calculations with MINIQUAD and SUPERQUAD for the L-Ala + VO^{2+} system was the importance of hydrolysis products of VO^{2+} in the pH range 5–8. The nature of such products and their formation constants are not accurately known (for a brief discussion of oxovanadium(IV) hydrolysis, see ref. 3). Hydrolysis in the L-Ser (and L-Thr) + VO^{2+} systems is much less important. Consequently, the calculations are more reliable and the χ^2 values (10–40) of the models contributing to Table 1 are quite reasonable, considering: the complexity of the systems; the many titration curves included; the several NaOH concentrations used and the two pH ranges included (2–4.0 and 4.0–7.5).

As we found in the L-Ala + VO^{2+} system, models excluding ML_2H_2 and $M_2L_2H_{-3}$ are also acceptable. The statistical parameters including $M_2L_2H_{-3}$ clearly improve but the results including ML_2H_2 are not so clear-cut. However, calculations involving CD and visible spectra in the pH ranges 2.5–4.5 and 6–9 show that both species should be included. Recent potentiometric and calorimetric measurements for the Gly + VO^{2+} system[14] for pH < 3 were also interpreted with a model including MG_2H_2.

Spectrometry

In solutions of VO^{2+} and L-Ser or L-Thr, only vanadium complexes contribute to ε_m or $\Delta\varepsilon_m$ in the visible region. This fact removes the limitation of potentiometry to those regions of pH where the ligand has no significant buffer effect. Therefore, when calculating formation constants based on visible or CD spectra, we are better off for species like ML_2H_2, which predominates in the pH range 2–4.5. Also, solutions with pH > 7.5 may be used, which are especially valuable in the L-Ser (and L-Thr) + VO^{2+} systems.

As for the L-Ala + VO^{2+} system, the SQUAD program was used to check that the visible and CD measurements were consistent with the potentiometric results in the pH range 1.8–5.3. For visible and CD spectra, calculations were performed on results for 450–830 and 405–805 nm, respectively. For the species MSH, MS_2H_2, MS, MS_2H, MS_2 and $M_2S_2H_{-2}$, ε (or $\Delta\varepsilon$) are considered as parameters to be refined, and the β_{xyz} for the several species were calculated either individually or in sets of two (except β_{22-2}, since in this pH range $M_2S_2H_{-2}$ is never an important species).

The values so calculated are within the range obtained with MINIQUAD and SUPERQUAD. Therefore, the values for β_{111}, β_{110}, β_{121} and β_{120} given in model IA in Table 1 may be accepted as correct and $\log\beta_{122} = 19.9 \pm 0.3$ taken as consistent with both potentiometry and spectrophotometry. Similar calculations in the pH range 1.8–7 but now including MS_2H_{-1} and $M_2S_2H_{-3}$ gave values for β_{12-1} and β_{22-3} also within the range in model IA (Table 1).

Taking β_{111}, β_{122}, β_{110}, β_{121}, β_{120} and β_{22-2} as known, the visible and CD spectra of MSH, MS_2H_2, MS, and MS_2H were calculated using SQUAD based on experimental spectra in the pH range 1.8–5.3. As had been done for the L-Ala + VO^{2+} system,[1] we used a step-by-step procedure, now following the order:

visible spectra:
(i) MSH and MS_2H_2, (ii) MS_2H and (iii) MS,
CD spectra:
(i) MS_2H_2 (1st iteration), (ii) MS_2H, (iii) MSH (1st iteration), (iv) MS (1st iteration), (v) MSH, (vi) MS_2H_2 and (vii) MS.

For example, in the calculation of the CD spectra of MLH [step (iii)], after including the CD spectra of MS_2H_2 (1st iteration) and MS_2H in the input file [they were calculated in steps (i) and (ii)], a set of experimental spectra was first chosen; then the CD spectra of MSH, MS, MS_2 and $M_2S_2H_{-2}$ were calculated using SQUAD. The values obtained for $\Delta\varepsilon_{111}$ were then included in the input file of SQUAD as known parameters. Step (iv) (calculation of the CD spectra of ML) was then executed. In order to get a second version of a spectrum calculated in a previous step, the 1st version is removed from the input file. The calculated visible and CD spectra are in Fig. 10.

Once the visible and CD spectra of MSH, MS_2H_2, MS and MS_2H were known and included in the input file of SQUAD, the visible spectra of MS_2, $M_2S_2H_{-2}$ and MS_2H_{-1} were also calculated by a step-by-step procedure that also involved an expansion of the pH range of the experimental spectra included. The sequence of these calculations is summarized in Table 2 and the calculated spectra are in Fig. 11a.

The calculated spectra in Fig. 12a of MS_2, $M_2S_2H_{-2}$ and $M_2S_2H_{-3}$ from a calculation with SQUAD[15] used experimental spectra in the pH range 3.6–7.2.

Once the visible and CD spectra of most of the species that may be important for pH < 7.5 are known and included in the input file of SQUAD, calculations may be performed for pH > 7.5.

One main difficulty in the calculations for pH > 11–12 is that the K_{a3} of L-Ser and L-Thr is unknown. Probably, this accounts in part for no

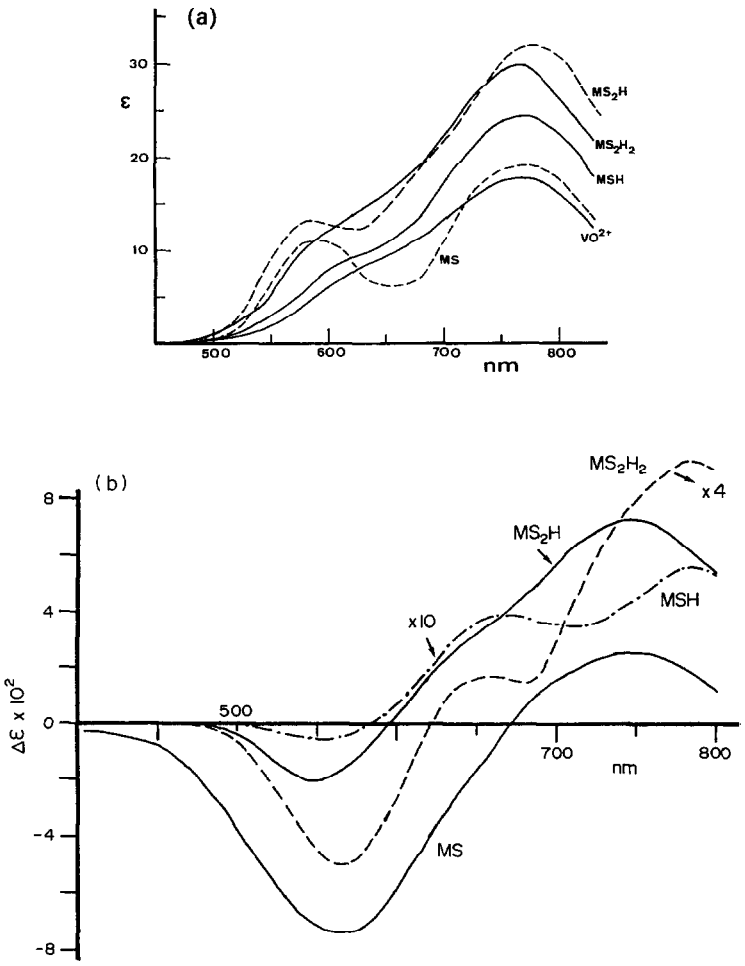

Fig. 10. Visible absorption (a) and circular dichroism (b) spectra (calculated using the SQUAD[15] program—see text for details) for species MSH, MS_2H_2, MS and MS_2H ($\log \beta_{xyz}$ in Table 1) which are only important for pH < 5.5 in solutions with high L/M ratios.

Table 2. Sequence of calculations used to obtain the visible spectra of MS_2, $M_2S_2H_{-2}$ and MS_2H_{-1}[a]

Spectra included in the input file of SQUAD	pH range of experimental spectra	Spectra calculated	Spectrum considered to be satisfactory
MSH, MS_2H_2 MS, MS_2H	1.8–5.7	MS_2 and $M_2S_2H_{-2}$	MS_2
The same and MS_2	1.8–7.2	MS_2H_{-2}, $M_2S_2H_{-2}$ and $M_2S_2H_{-3}$	$M_2S_2H_{-2}$
The same and $M_2S_2H_{-2}$	1.8–7.7	MS_2H_{-1} and $M_2S_2H_{-3}$	MS_2H_{-1}
The same and MS_2H_{-1}	Further calculations are described in the text and Table 3.		

[a]The experimental spectra used were chosen from solutions where there is no significant contribution from oxovanadium(IV) hydrolysis products and vanadium–amino acid complexes (e.g. MSH_{-2}) important for higher pH.

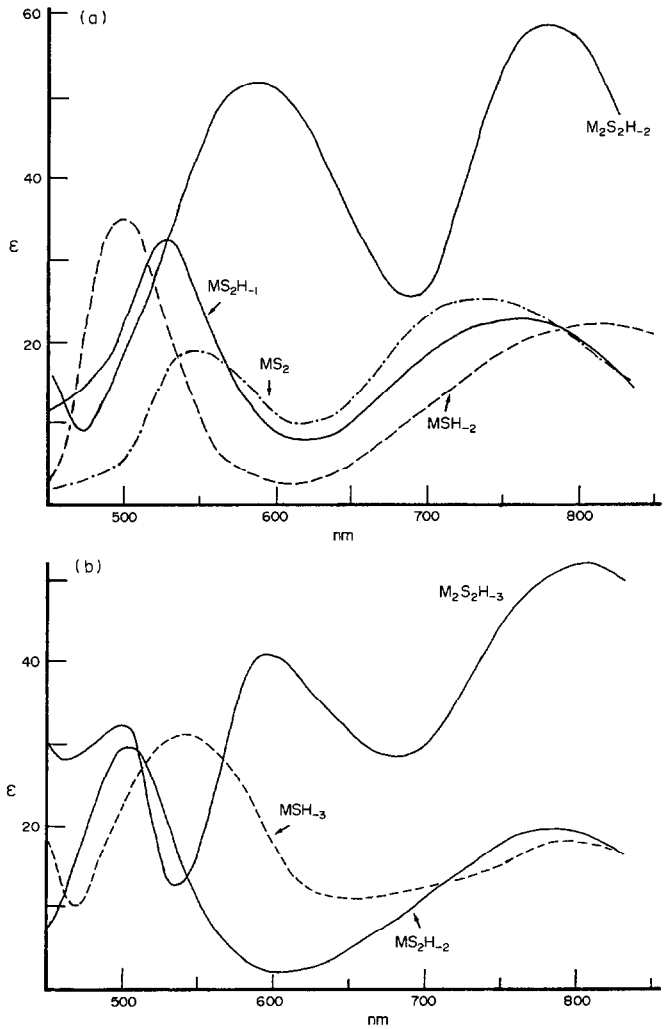

Fig. 11. Visible absorption spectra (calculated using the SQUAD[15] program—see text for details) for species that may form in solutions containing L-Ser+VO^{2+} (high L/M ratios) for pH > 6 using the formation constants in model IIA—Table 1 and experimental visible spectra in the pH range 6.4–11.7. (a) MS_2, $M_2S_2H_{-2}$, MS_2H_{-1} and MSH_{-2}. (b) $M_2S_2H_{-3}$, MS_2H_{-2} and MSH_{-3}.

results being obtained using the SQUAD program when the spectra of solutions with pH > 12.8 were included; it was impossible to pass beyond the intermediate calculations of the program. Even when pK_{a3} values were assumed (in the range 11–13.5) and all formation constants corrected accordingly, it was again not possible to get to the start of the 1st iteration cycle of SQUAD.

Tables 3–5 summarize some results obtained with SQUAD for the visible and CD spectra of L-Ser+VO^{2+} solutions and Figs 11 and 12 include the visible and CD spectra calculated for the several species assuming model IIA (Table 1) as correct.

A feature common to all calculations is that β_{12-2} (the formation constant for ML_2H_{-2}) is a constant to be refined; consistently, $\log\beta_{12-2}$ is in the range -5.0 ± 0.3. This ML_2H_{-2} is important only for pH $\gtrsim$ 8, explaining why β_{12-2} is not refined consistently with MINIQUAD and SUPERQUAD; titration curves always had pH $\lesssim$ 7.5.

While it was never possible to refine simultaneously β_{12-2}, β_{11-2} and β_{11-3} from the CD measurements, it was however possible for the visible spectra, but the value for β_{11-3} seems too high. However, plausible values may be obtained for these constants in calculations involving β_{12-2} and β_{11-2}, β_{12-2} and β_{11-3} or β_{12-2}, β_{11-3} and β_{10-3}. Results are always better if β_{11-2} is included and β_{11-3} not, than vice versa. However, excluding K_{a3} of the amino acid certainly gives more problems in calculations involving β_{11-3} than β_{11-2}.

For basic aqueous solutions, $VO(OH)_3^-$ is detected[16] from pH $\gtrsim$ 12, consistent with $\log\beta_{10-3}$ being -18 to -19.[3] Most calculations in Table 3 and involving this species agree. However, we emphasize that if a pK_{a3} for the amino acid and/or

Table 3. Calculations of visible spectra and/or formation constants of species MS_2H_{-2}, MSH_{-2}, MSH_{-3} and MH_{-3} using SQUAD,[15] based on experimental visible spectra (450–830 nm) of L-Ser + VO^{2+} solutions (high L/M ratios) in the pH range 6.4–11.3[a,b]

Calculation number	VIS1	VIS2	VIS3	VIS4
$\log\beta_{12-2}$ (SD)	−5.147 (0.023)	−5.272 (0.045)	−4.641 (0.071)	−5.162 (0.054)
$\log\beta_{11-2}$ (SD)	−5.842 (0.018)	−5.874 (0.018)	[c]	−5.792 (0.026)
$\log\beta_{11-3}$ (SD)	—	[c]	−15.72[d] (0.16)	−16.225[d] (0.091)
$\log\beta_{10-3}$ (SD)	—	−18.497 (0.42)	−15.836[e] (0.034)	—
pH range of experimental spectra (No. iteration cycles)	6.4–11.3 (4)	6.4–11.8 (7)	6.4–11.8 (14)	6.4–11.3 (7)

[a] Spectra for species MSH, MS_2H_{-3}, MS, MS_2H, MS_2, $M_2S_2H_{-2}$, $M_2S_2H_{-3}$ and MS_2H_{-1} are considered to be known and are included in the input file of SQUAD.

[b] So long as the K_{a3} of L-Ser is unknown, calculations involving the stoichiometry MSH_{-3} may have a doubtful meaning.

[c] When the four formation constants were all considered as parameters to be refined, the calculation does not converge—$\log\beta_{10-3}$ diverges.

[d] The β_{11-3} calculated seems too high.

[e] The β_{10-3} calculated is too high.

a VO^{2+} hydrolysis product that may form for pH higher than $VO(OH)_3^-$ are not included, speciations necessarily give "parallel" concentrations for MH_{-3} and MLH_{-3}. Therefore, not only is it not possible to explain the general decrease of $|\Delta\varepsilon_m|$ values for pH > 13 (this of course, clearly indicates that oxovanadium(IV)–amino acid complexes are hydrolysing to products containing no coordinated amino acid), but all calculations involving β_{11-3} are doubtful.

DISCUSSION

The proposed equilibrium model—the set of species (with plausible values for their formation constants), to explain all the experimental potentiometric and spectroscopic results is in Table 1 (model II). For low L/M ratios, other complex species might be important.

Figure 13 gives the concentration distribution estimated from EPR spectra (Fig. 1 and similar for L-Thr + VO^{2+}). Figure 11 should be compared with the distribution in the L-Ser + VO^{2+} system, Fig. 14, calculated for L/M = 38.0 and a total vanadyl concentration close to those corresponding to the EPR, visible and CD spectra of Figs 1–6.

(i) Species $S_I + S_{II}$ correspond to several stoichiometries: M, MSH, MS_2H_2, MS_2H and MS. The L-Ala + VO^{2+} system presented a similar situation.[1] The EPR peaks show only gradual (but apparent) changes in positions as H_2O in $VO(OH)_5^{2+}$ is substituted by the 1st and 2nd R–COO^- group or by a R–NH_2 group.

(ii) Species S_{III} corresponds to MS_2 ($M_2S_2H_{-2}$ is probably EPR silent). The crossing point with $S_I + S_{II}$ and S_{III} at pH 5 in Fig. 13 approximately coincides with the crossing point with $MS_2H + MS$ and MS_2 in Fig. 14.

(iii) As mentioned before, S_{IV} and $S_{IV'}$ have very similar g and A parameters and correspond to MS_2H_{-1} and MS_2H_{-2}, respectively.

(iv) S_V could correspond to $M_2S_2H_{-3}$, but there are other plausible hypotheses which are discussed below.

(v) S_{VI} could correspond to MSH_{-2} and/or MSH_{-3} and S_{VII} probably corresponds to MH_{-3} (or to MSH_{-3}).

On a semi-quantitative basis, the concentration distribution shown also explains the evolution of visible and CD spectra of Figs 2–6, namely:

(i) The increase of $|\Delta\varepsilon_m|$ until pH ~ 6, as in the L-Ala + VO^{2+} system.[1]

(ii) The further increase of $|\Delta\varepsilon_m|$ in the range 400–800 nm until pH ~ 8, which coincides with the formation of MS_2H_{-1} (and $M_2S_2H_{-3}$).

(iii) The CD spectra for pH > 8, rationalized either considering only MS_2H_{-2} and MSH_{-2} as being important for pH > 8 or taking these and MSH_{-3} as important species for pH $\gtrsim$ 9.

The spectra (visible and CD) calculated by SQUAD using the formation constants of Table 1

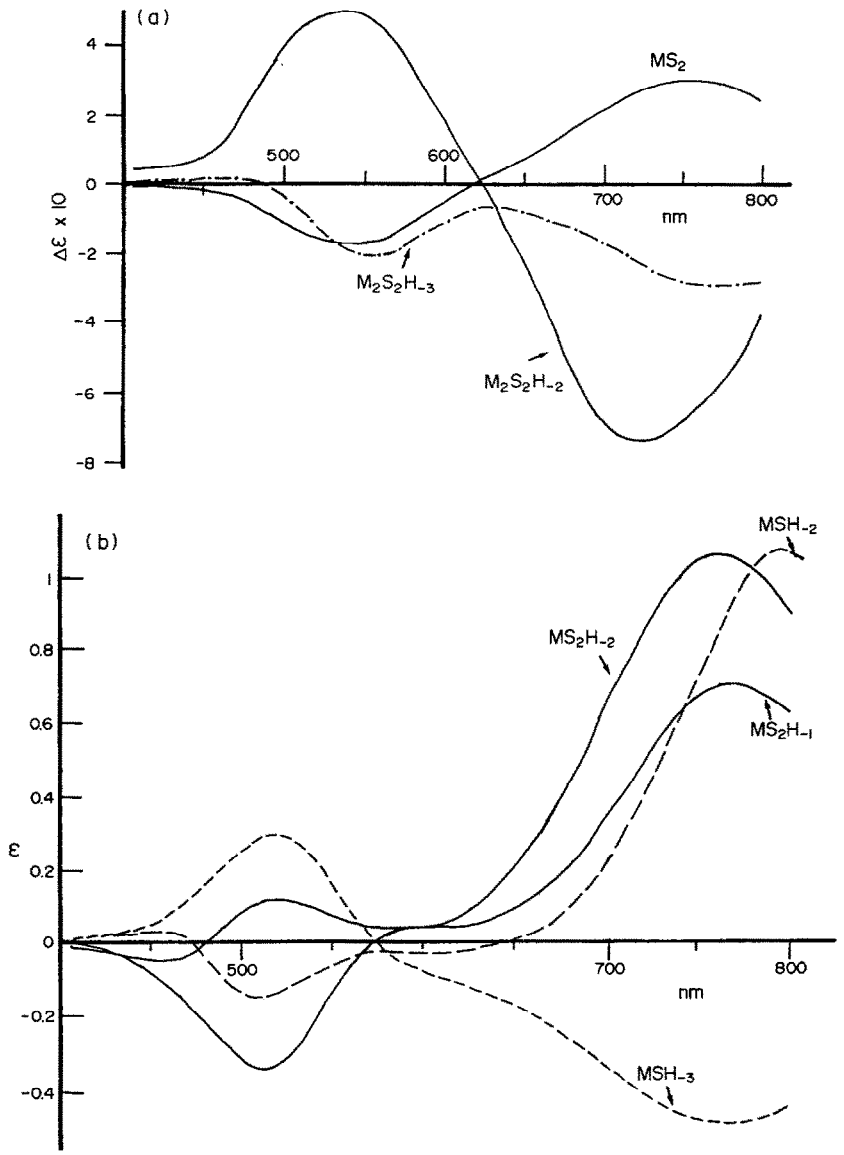

Fig. 12. Circular dichroism spectra (calculated using the SQUAD[15] program—see text for details) for species that may form in solutions containing L-Ser + VO^{2+} (high L/M ratios) for pH > 6 using the formation constants in model IIA—Table 1 and experimental CD spectra in the pH range 6.7–12.8.

and the visible and CD spectra of Figs 10–12 almost coincide with the experimental spectra.

Correlation of formation constants

Figure 15 represents $\log \beta^S$ vs $\log \beta^T$ from this work as well as $\log \beta^S$ vs $\log \beta^A$. Such linear plots are expected as long as the coordination geometry around VO^{2+} is the same for a given stoichiometry. If the plot of ($\log \beta^S_{xyz}$, $\log \beta^A_{xyz}$) is not nearly linear, this indicates that the coordination geometries in $M_xS_yH_z$ and $M_xA_yH_z$ differ.

Constants for the L-Thr + VO^{2+} system are such that its degree of complex formation is greater, and VO^{2+} hydrolysis, $M_2T_2H_{-2}$ and $M_2T_2H_{-3}$ are less important than in the other systems.

Structures

Because the vanadyl ion is lopsided, many of its chelates may form more isomers than do apparently analogous monoatomic metal centres; refs 1 and 3 briefly discuss this.

Stoichiometry MLH probably corresponds to complexes with the R–COO^- group coordinated equatorial. Writing the formation of such complexes as ($n = 1$):

$$VO^{2+} + nHL \overset{K_n}{\rightleftharpoons} VO(HL)_n^{2+}. \qquad (2)$$

K_1(L-Ser) = 12.5 and K_1(L-Thr) = 12.9, to be compared with K_1(L-Ala) = 15.6[1] and K_1(Gly) = 14.8[17] or K_1(Gly) = 11.5[14] (the Gly values in a different medium, 1 M $NaClO_4$).

Table 4. Calculations of CD spectra and/or formation constants using SQUAD, based on experimental CD spectra (405–805 nm) of L-Ser + VO^{2+} solutions (high L/M ratios) in the pH range 6.7–12.8[a]

[a] Approximate asymmetry factor calculated for each band according to: $\Delta\varepsilon$ (at λ_{max})/ε (at λ_{max}).

[b] Two bands are observed in the CD spectrum of opposite signs; these partly cancel each other so that no *g*-factor is presented.

[c] Presumably the bands in the visible spectrum at ~ 500 and 595 nm correspond to the CD bands at 470 and 560 nm, respectively.

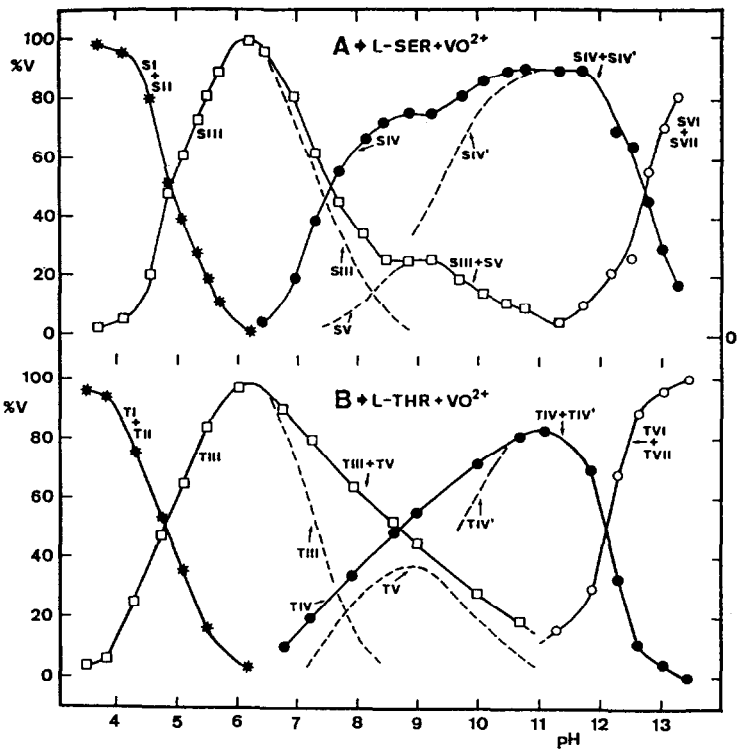

Fig. 13. Concentration distribution of the species L_I–L_{VII} detected in the EPR spectra. These distributions should be considered only as approximate. EPR silent species are obviously not included. (A) L-Ser+VO^{2+} system—estimated from the EPR spectra of Fig. 1. (B) L-Thr+VO^{2+} system—estimated from the EPR spectra of solutions containing L-Thr and VO^{2+} with L/M = 25.1 and C_{VO} in the range $1.2–1.5 \times 10^{-2}$.

The visible and CD spectra calculated for MSH (Fig. 10) and for MAH are similar; one would not expect major differences in these spectra for complexes involving different amino acids coordinated as monodentate ligands by the carboxylate group.

The calculated CD spectra and the K_1 value suggest that probably there is no such direct interaction between the oxygen of the –ROH group and the metal centre as was suggested for $Cu(HS)^{2+}$.[4] However, although there is no clear indication of it, there may be some interaction of the –ROH group and coordinated water.

The stoichiometry ML_2H_2 probably corresponds

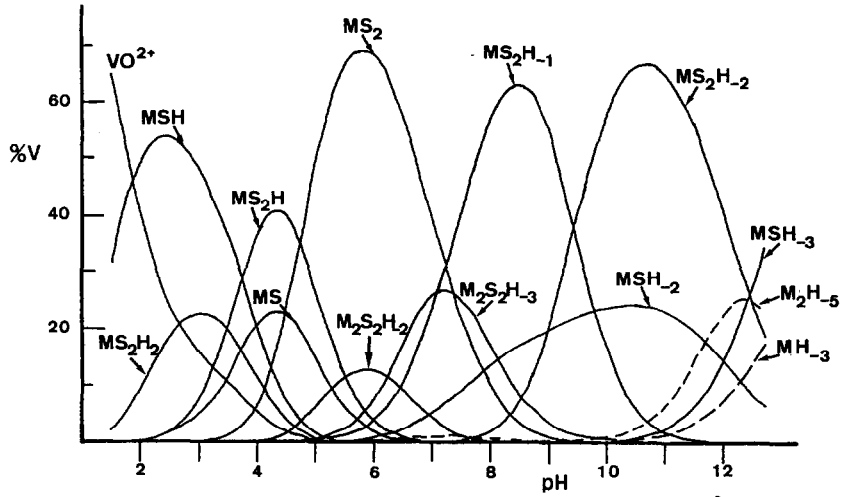

Fig. 14. Concentration distribution of the complexes formed in the L-Ser+VO^{2+} system in solutions with $C_{VO} = 8.0 \times 10^{-3}$ M and L/M = 38.0, calculated using the β_{xyz} of model IIA in Table 1 and $\log \beta_{20-5} = -22.22$ and $\log \beta_{10-3} = -18.8$. This speciation is on a molar basis, while the concentration distribution of fig. 11 in Part I[1] was calculated on an atomic basis.

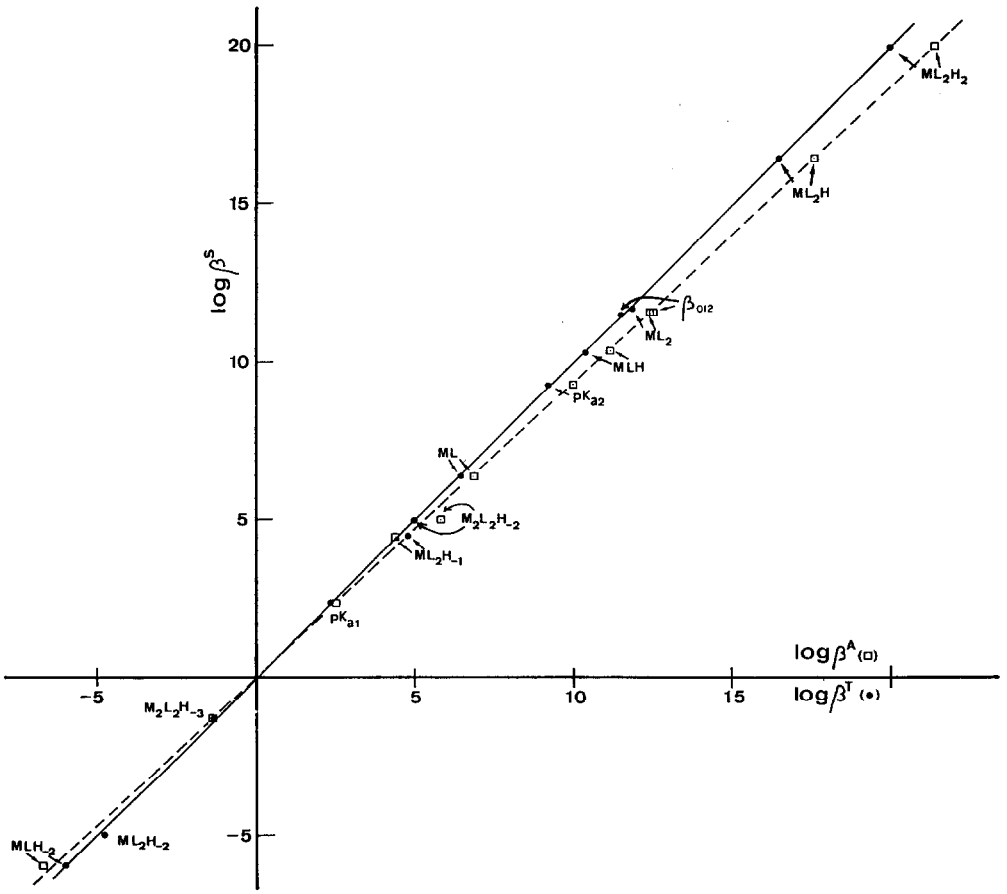

Fig. 15. Representation of $\log \beta^{S}_{xyz}$ vs $\log \beta^{T}_{xyz}$ (●) obtained in this work and of $\log \beta^{S}_{xyz}$ vs $\log \beta^{A}_{xyz}$ (□) obtained in part I[1]. The pK_{a1}, pK_{a2} and $\log \beta_{012}$ are also represented.

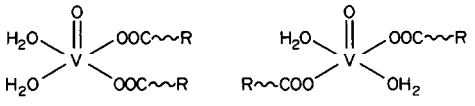
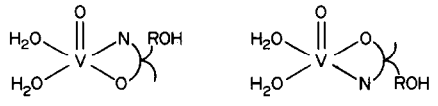
to complexes with two monodentate carboxylate groups coordinated equatorial. From Table 1, K_1K_2(L-Ser) ~ 24. The corresponding value for L-Ala is 30.2.[1] Apart from differences in the ε_{122} and $\Delta\varepsilon_{122}$ values, spectra calculated for MS_2H_2 (Fig. 10) are similar to those calculated for MA_2H_2.[1] The differences may be a mathematical artefact (because the systems are quite complicated), or they may originate in differing proportions of *cis* and *trans* isomers, (I) and (II), in MA_2H_2 as against MS_2H_2.



At this point, we emphasize that more than one isomer corresponds to the particular stoichiometry for each "species" $M_xL_yH_z$. Relative isomeric concentrations are independent of concentrations of metal, ligand and H^+, so our experimental techniques do not distinguish between them (in some cases, the EPR spectra could ultimately help). Therefore not only each formation constant, but also the calculated visible and CD spectra reflect the features of each isomer in proportion to its relative importance. For example, in the case of ML_2H_2 stoichiometry, the value for β_{122} is the weighted sum of $\beta_{122}(cis)+\beta_{122}(trans)$ and the calculated visible and CD spectra may involve contributions from structures (I) and (II).

Stoichiometry ML may correspond to structures (III) and (IV) (not considering the possibility of one group being axial). These are not enantiomers (as they would be if the amino acid were glycine).



The β_{110} obtained ($\log\beta$ ~ 6.4) is the weighted sum of β_{110}(III) and β_{110}(IV). As for L-Ala we note that for L-Ser and L-Thr: $\beta_{110}(Ni^{2+}) < \beta_{110}(VO^{2+}) < \beta_{110}(Cu^{2+})$ (as $\log\beta_{110}(Ni^{2+})$ ~ 5.4 and $\log\beta_{110}(Cu^{2+})$ ~ 8).[4,5]

The visible spectrum calculated for VO(S) is very similar to that for VO(A).[1] CD spectra are also similar. The different relative intensities for bands I ($\Delta\varepsilon > 0$) and II ($\Delta\varepsilon < 0$) may be a mathematical

artefact or real: they may also reside in slightly different positions of the maxima for bands I and II.

Because the vanadyl ion is lopsided, four structures may be envisaged for MS_2H with one S^- (or T^-) bidentate and the other coordinated only via the R–COO^- group, all equatorial (monodentate coordination involving the $-NH_2$ or $-RO^-$ is unlikely). Additional structures may naturally be envisaged where one group is coordinated axial.

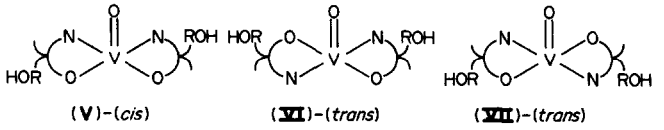
The visible and CD spectra calculated for MS_2H are remarkably like those for MA_2H.[1] The type and relative proportions then of species in these systems with stoichiometry MS_2H are the same. There is then practically no interaction between the oxygen of the ROH group and the metal centre or a water molecule coordinated to it.

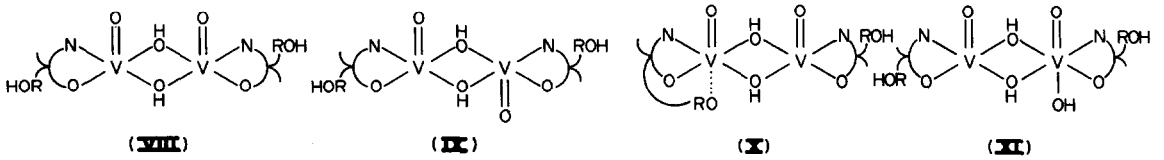
For stoichiometry ML_2, assuming equatorially coordinated R–NH_2 and R–COO^- groups, three isomers (V)–(VII) may form in differing concentrations.

the metal centre. This would favour isomers (V) and (VII).

Two *d–d* bands are found for MS_2 in the range 500–800 nm instead of the three bands in many complexes with *trans* geometry.[3] There have been proposals that for VO^{2+} complexes the *cis* geometry is favoured. However, several stereochemical effects may operate and this argument cannot be definitive. Nevertheless, the correlation between the number of *d–d* bands detected and the geometry is reasonably established, suggesting that ML_2 (L = Ala, Ser and Thr) would be predominantly *cis* complexes.

In the L-Ser and L-Thr systems, the stoichiometry $M_2L_2H_{-2}$ is less important than for L-Ala+VO^{2+}. Several dimeric structures may be envisaged with two OH groups bridging the vanadium atoms and N, O coordination in equatorial positions, e.g. (VIII) and (IX). The V=O groups may be "parallel" or "antiparallel" and the structures might be quite distorted from those idealized as (VIII) and (IX).





Spectra of these isomers should differ. However, not only was there no evidence in EPR spectra at pH ~ 6 for isomers, but the EPR spectra of VO(L-SerO)$_2$, VO(L-ThrO)$_2$ and VO(L-AlaO)$_2$ are identical ($g_\parallel = 1.944$, $g_\perp = 1.976$, $A_\parallel = 164$ and $A_\perp = 55 \times 10^{-4}$ cm^{-1}), within the small experimental error.

The calculated visible spectrum of MS_2 is similar to that for MA_2[1] but the ε_{120} values are normally higher. The calculated CD spectra of MS_2 and MA_2 are also similar except that $|\Delta\varepsilon_{120}$(L-Ser)$| > |\Delta\varepsilon_{120}$(L-Ala)|, especially for band II. As for other stoichiometries, this may either be a mathematical artefact or arise from a real difference in the relative importance of isomers (V)–(VII) in the two systems.

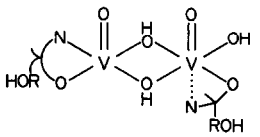
The interaction of the oxygen of $-CH_2OH$ with a water ligand (proposed for Cu(L-SerO)$_2$[4]) may also be envisaged for VO(L-SerO)$_2$. Alternatively, a ROH of L-Ser (or L-Thr) directly could interact with

High $\Delta\varepsilon$ values may be expected for such structures and are indeed observed (Fig. 12). The calculated CD spectrum for $M_2S_2H_{-2}$ (pattern: +, −) is reasonably different from that for $M_2A_2H_{-2}$ (pattern: +, −, −) and $|\Delta\varepsilon_{22-2}|$ are much higher for $M_2S_2H_{-2}$. This either originates in a mathematical artefact or may result from a different proportion of isomers. Any interaction of the O atom of the –ROH group with vanadium might either have a direct effect on the spectra, or an indirect one through the stabilization of certain isomers.

Many different dimeric structures may be envisaged for stoichiometry $M_2L_2H_{-3}$, with two bridging OH groups:

(i) With one $-RO^-$ group coordinated in either equatorial or axial position [e.g. (X)].
(ii) With no coordination of $-RO^-$, but with one OH^- group axial [e.g. (XI)] or equatorial [e.g.

(**XII**)]. Some direct or indirect effect of the –ROH group may operate as mentioned for $M_2S_2H_{-2}$.



(**XIII**)

High $\Delta\varepsilon$ values would be expected for both types, as observed (Fig. 12). The calculated CD spectrum for $M_2S_2H_{-3}$ is similar to that for $M_2A_2H_{-3}$: the sign pattern is the same: (+, −, −) and the λ_{max} and $\Delta\varepsilon$ values do not differ much. This suggests that the type of complexes in the two systems is not too different, although the isomeric proportions may differ. These considerations suggest that, for the $M_2S_2H_{-3}$ stoichiometry, isomers which involve the coordination of one $-RO^-$ group [eg. (**X**)] do not form in appreciable amount.

Both $M_2S_2H_{-2}$ and $M_2S_2H_{-3}$ are probably EPR silent. Both are dimers with two OH^- as bridging groups, so ε values higher than for monomeric complexes are expected. This is indeed so, since the ε values in visible spectra of stoichiometries $M_2S_2H_{-2}$ and $M_2S_2H_{-3}$ are two or more times those for other species (namely MS).

For pH $\gtrsim$ 6.5, spectra of solutions (per metal ion) containing L-Ser (and L-Thr)+VO^{2+} differ from those of L-Ala+VO^{2+}. One most noticeable difference involves the components designated by L_{IV} and $L_{IV'}$ in the EPR (Figs 1 and 13). Components designated by L_V correspond to $A_\parallel \sim 163\times10^{-4}$ cm^{-1} and approximately coincide with L_{III}.

Comparing Figs 13 and 14, L_{IV} and L_V correspond to ML_2H_{-1}. The EPR spectra of L_{IV} and $L_{IV'}$ are indistinguishable (at least in our experimental conditions) and correspond to $A_\parallel = (150–154)\times10^{-4}$ cm^{-1} and $g_\parallel = 1.955–1.961$. This suggests that the groups involved in the coordination and their arrangement around the VO^{2+} are the same in L_{IV} and $L_{IV'}$. Notwithstanding this, the visible and CD spectra calculated for stoichiometries ML_2H_{-1} both differ.

The visible, CD and EPR spectra observed for pH $\gtrsim$ 6.5 can be explained only by assuming that the $-RO^-$ group of L-Ser (and L-Thr) coordinates to VO^{2+}. Such coordination starts around two pH units lower than for the L-Ser (and L-Thr)+Cu^{2+} systems[5,7,20,21] (note that the L/M ratios are quite different), consistent with the preference of VO^{2+}, relative to Cu^{2+}, for oxygen-containing ligands.

The stoichiometry ML_2H_{-1} probably corresponds to at least two different complexes: one involving coordination of the $-RO^-$ group, corresponding to L_{IV} in the EPR spectra and the other involving coordination of OH^- ("similar" to MA_2H_{-1} in the L-Ala+VO^{2+} system), corresponding to L_V in the EPR spectra.

The structure of ML_2H_{-2} ($L_{IV'}$ in the EPR spectra) can either be similar to the first type for ML_2H_{-1}, but involving the dissociation of the second uncoordinated –ROH group, or can involve the coordination of this group, implying quite a different structure. Alternatively, an OH^- group could be involved. For the former case one might indeed expect that the EPR spectra of L_{IV} and $L_{IV'}$ should be indistinguishable. For the two last structures mentioned, the observed similarity of the EPR spectra would be a coincidence.

Structures for ML_2H_{-1} and ML_2H_{-2} must account for:

(i) The high $\Delta\varepsilon$ values.
(ii) The high "stability" of the complexes, explaining why hydrolysis does not occur at "high" pH as it does in the case of the L-Ala+VO^{2+} system.[1]

This suggests that L_{IV} and $L_{IV'}$ do not involve coordination of OH^-, but (instead) terdentate coordination of one ligand and bidentate coordination of the other.

Using the contributions of R–COO^-, R-NH_2, RO^- and OH^- to $g_\parallel$ and $A_\parallel$ proposed by Chasteen,[19] these EPR spectral parameters may be estimated for each possible structure for ML_2H_{-1} and ML_2H_{-2}, assuming equatorial coordination. Such calculated values for $A_\parallel$ ($\times10^4$ cm^{-1}) are given hereafter for many structures. These calculations imply axially coordinated H_2O. As discussed above, this is probably not true for the complexes predominant in this pH range, and no safe conclusions can be made based on calculated $A_\parallel$.

Figure 16 gives structures for complexes corresponding to stoichiometries ML_2, ML_2H_{-1} and ML_2H_{-2}. Several other structures can be envisaged for each.

The visible and CD spectra calculated for each stoichiometry include contributions from all the structures of the complexes that may form. Thus, ML_2H_{-1} includes contributions from L_{IV} and L_V and one may note the resemblance of the CD spectra calculated for MS_2H_{-1} and the one obtained for MA_2H_{-1}.[1]

In Fig. 15, the point for [$\log\beta_{12-1}$(Ser), $\log\beta_{12-1}$(Ala)] is quite near the line, notwithstanding that one structure expected to contribute to this stoichiometry (corresponding to L_{IV}) is quite different from the structures expected for MA_2H_{-1}. This coincidental goodness-of-fit probably results from: (i) the contribution of S_V to

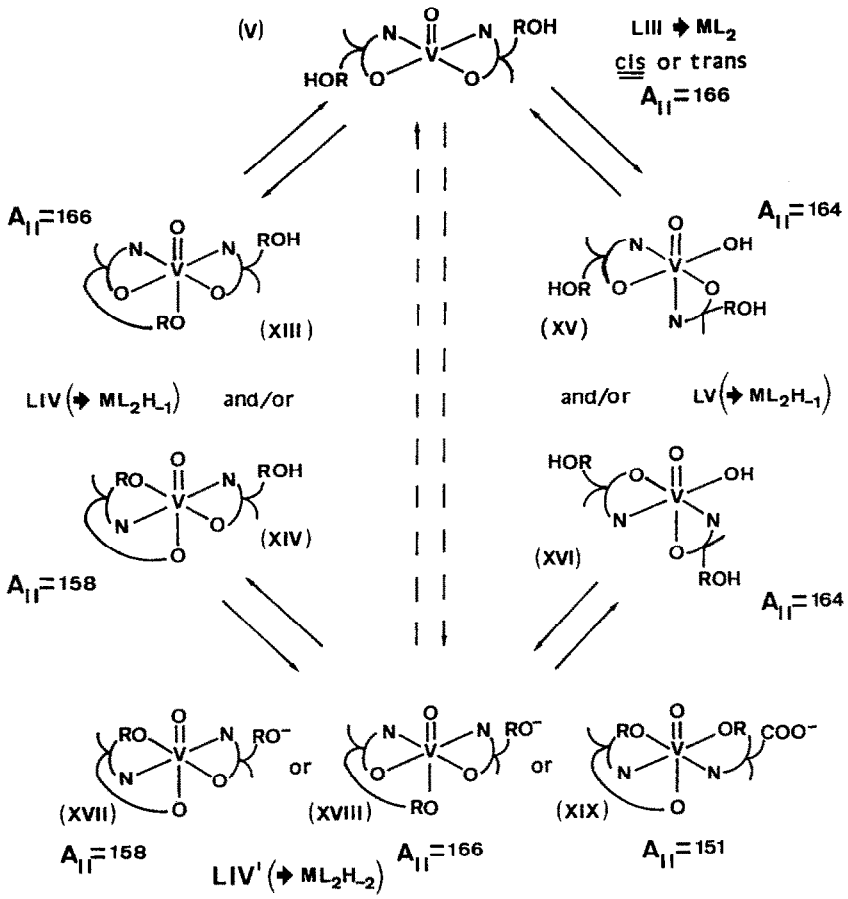


Fig. 16. Plausible structures for the main species that predominate in the pH range 7–12 in solutions containing L-Ser (and L-Thr) + VO^{2+} with high L/M ratios. Estimated values for $A_{\parallel}$ ($\times 10^4$ cm^{-1}) are also included[19] not considering the influence of the axial ligands (see text).

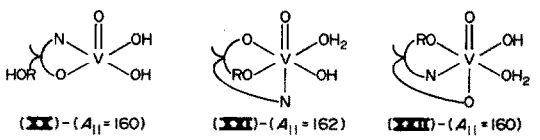
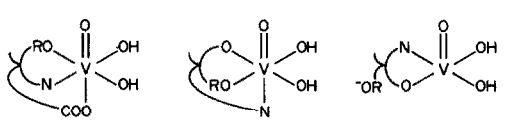
MS_2H_{-1}; (ii) the pK_a of the –ROH group followed by coordination of $-RO^-$ is around 8 (this may be compared with CuS_2 where the corresponding pK_a is ~ 10).[5,20,21]

Several different structures could be envisaged for the stoichiometry MLH_{-2}. The CD spectrum calculated for MSH_{-2} (Fig. 12) is reasonably similar to that for MAH_{-2} and could indicate complexes such as **(XX)**. However, the calculated visible spectrum (Fig. 11) suggests that isomers like **(XXI)** and/or **(XXII)** may be more important.



The MSH_{-3} stoichiometry may be important for pH $\gtrsim$ 11 and the calculated CD spectrum (Fig. 12) is what one would expect from the evolution of the experimental CD spectra in the high pH range (Fig. 6). As for the MSH_{-2} stoichiometry, structures like **(XXIII)** and **(XXIV)** seem more reasonable than **(XXV)** to explain the calculated visible and CD spectra and the "high" stability of the vanadium–amino acid complexes that exist for pH $\gtrsim$ 12.



The components L_{VI} and L_{VII} in the EPR spectra at high pH (Fig. 1) correspond to $A_{\parallel} = 168$ and 164×10^{-4} cm^{-1}, respectively. The calculated $A_{\parallel}$ include only contributions from groups coordinated equatorially. As L_{VI} probably corresponds to MLH_{-2} and/or MLH_{-3} and L_{VII} to MLH_{-3} and/or MH_{-3} ($A_{\parallel}$(calc.) $= 162 \times 10^{-4}$ cm^{-1}), we assume that axial coordination of $-RO^-$, RNH_2, $RCOO^-$ or OH^- affects the EPR spectra differently from H_2O.

Although the experimental CD spectra obtained for L-Ser+VO^{2+} solutions at pH ~ 13.3 (Fig. 8b) are akin to those for L-Thr+VO^{2+} solutions at pH ~ 13.6 (Fig. 9b) and the band pattern is the same (−, +, −, +), the relative intensities of the bands are not the same and values of $|\Delta\varepsilon_m|$ are larger for the L-Thr+VO^{2+} system. Therefore, hydrolysis of ML_2H_{-2} to MLH_{-3} and other complexes not involving coordinated amino acid occurs at a higher pH in this system.

Except for differences ascribed to slightly different concentration distributions in the two systems, like that just described, no clear distinctions were noticed in the experimental CD spectra of the L-Ser+VO^{2+} and of the L-Thr+VO^{2+} solutions that could be attributed to the existence of two dissymmetric centres in L-Thr as against one in L-Ser.

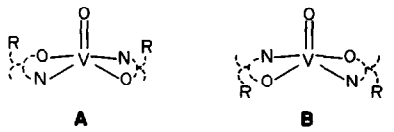
While the two methylene hydrogen atoms of the alkoxo function of serinate are inequivalent in the vanadyl-bonded species, their difference is small and the $-CH_2O^-$ moiety is almost symmetrical, so we are concerned with understanding the *failure* of the corresponding asymmetric carbon atom of the threonine side chain to manifest its asymmetry in the vanadyl electronic manifold. The explanation of this failure may be electronic or steric and we consider these in turn.

This failure arises because the $-RO^-$ group is inefficient at inducing dissymmetry to the VO^{2+} bands. Restating this, the new element of chirality (arising from $-*CH(CH_3)-O^-$ of L-threoninate) may be able to influence only some orbitals of the vanadyl ion, transitions between which are of low asymmetry factor (g-factor). Recalling that the rotational strength of any electronic transition is given by $\mu_m\mu_e\cos\theta$, where μ_m and μ_e are the magnetic-dipole and electric-dipole moments of transition respectively and θ is the angle between them, we see that, if the chiral ligand $-*CH(CH_3)-O^-$ occupies a position such that d-orbitals affected by it participate only in magnetic-dipole-forbidden transitions, no great influence of this centre on CD in the visible d–d region would be expected.

For example if the $-RO^-$ groups always coordinate axially (affecting mainly the d_{z^2} level) and to a less extent d_{x^2} and d_{y^2}, the transition $d_{xy} \leftrightarrow d_{x^2-y^2}$ will be insensitive to it.

The alternative steric explanation is that for complexes forming for pH > 7, the vicinal effect is less important than effects arising from dissymmetric arrangement of the ligating atoms and a dissymmetric deviation of ligating atoms from a regular structure.[22]

For example, for the structures **A** and **B** (where vanadium is above the plane of its four equatorial ligands),



A **B**

if, for some reason, their concentrations differ, [**A**] ≠ [**B**], there is—beside the vicinal and conformational contributions—an effect resulting from these differing concentrations. Two contributions to the overall measured Cotton effect may then be considered (separating them as in ref. 22):

—dissymmetric arrangement of the ligating atoms,
—dissymmetric deviation of ligating atoms from regular structure.

According to ref. 22, the latter contribution can be as important as the configurational contribution in determining the magnitude of the Cotton effect. In the present case, for alkaline solutions where terdentate coordination is likely to occur, structure **B** is favoured. The two contributions just mentioned become dominant.

*Comments on the equilibria at high p*H

The most remarkable feature of the L-Ser (and L-Thr)+VO^{2+} systems is the existence of a relatively high proportion of vanadium(IV)–amino acid complexes in the high pH range. A similar situation is found in L-Ser (and L-Thr)+Cu^{2+} systems.[23,24]

For pH $\gtrsim$ 11, models II in Table 1 predict that vanadium(IV)–amino acid complexes with stoichiometries ML_2H_{-2}, MLH_{-2} and MLH_{-3} predominate. However, other stoichiometries could be envisaged for the high pH range, e.g. $M_2L_2H_{-4}$ and $M_2L_2H_{-5}$: if MLH_{-2} and/or MLH_{-3} are not included in the calculations with SQUAD, spectra can be obtained for such species, although the results cannot be considered as "good" as those obtained for model II. For lower L/M ratios and/or higher vanadium concentrations, $M_2L_2H_{-4}$ and $M_2L_2H_{-5}$ probably make a greater contribution. However, such solutions are not easy to study; vanadyl hydrolysis and/or oxidation and sluggish equilibration become nuisances. As the pK_{a3} of L-Ser and L-Thr are unknown, it is impossible to make accurate calculations for pH > 11–12. Thus, both experimental possibilities and good computational criteria are lacking to test the importance of such stoichiometries.

Nevertheless, some general conclusions may be drawn from CD spectra at very high pH. In fact, since in such CD spectra for high L/M ratios at pH ~ 13.3 (Fig. 8b) and 13.6 (Fig. 9b), there are differences in $\Delta\varepsilon_m$, an equilibrium is postulated between species with different degrees of poly-

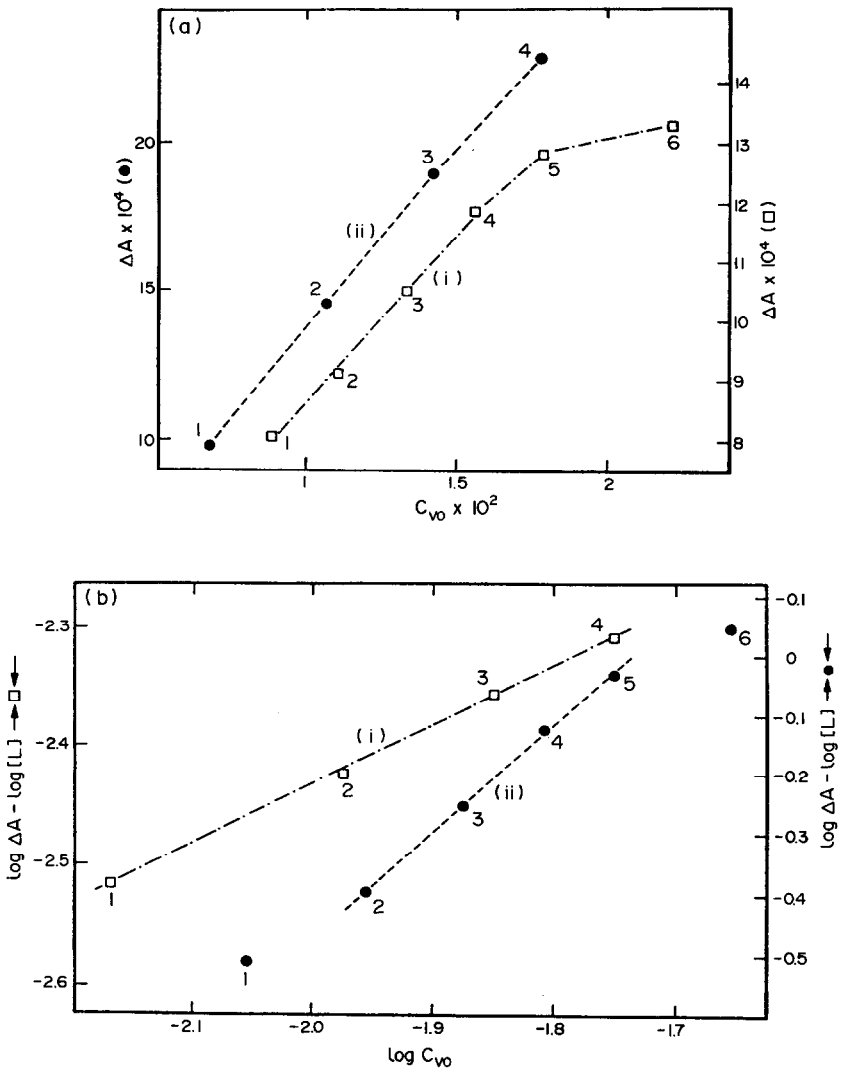


Fig. 17. Representation of: (a) ΔA vs C_{VO} for the CD spectra of (i) L-Ser+VO^{2+} solutions at pH ~ 13.3 for λ = 532 nm (□) (from Fig. 8b); (ii) L-Thr+VO^{2+} solutions at pH ~ 13.6 for λ = 527 nm (●) (from Fig. 9b). The total ligand concentration may be considered as being constant. (b) $\log \Delta A - \log [L]$ vs C_{VO} corresponding to (i) and (ii) in (a).

merization, especially for L-Ser+VO^{2-} at pH ~ 13.3.

At these pH values, a substantial amount of vanadium is uncoordinated by amino acid and this is probably one species involved in the above mentioned equilibrium.

Figure 17a gives a representation of ΔA vs C_{VO} for two wavelengths at pH 13.3 and 13.6. Two types of situations will be considered—A and B—and the corresponding models are described and discussed in Table 6.

Hypothesis A: From eq. (6A) of Table 6, the plot to test this is Y_A vs $\log C_{VO}$. However, $[M_2]$, part of Y_A is not known, so $\alpha(M_2)$ cannot be calculated. However, when C_{VO} increases, $[M_2]$ and $\sqrt{[M_2]}$ (< 1) also increase, so that $\alpha(M_2)$ and $\log \alpha(M_2)$ decrease. Therefore, if—instead of representing Y_A vs $\log C_{VO}$—we take $(\log \Delta A - \log [L])$ vs $\log C_{VO}$, a "straight line" with slope greater than 1/2 is expected and indeed found. Thus, plotting in this way $(\log \Delta A - \log [L])$ vs $\log C_{VO}$ (Fig. 17b) (or $\log \Delta A - 2 \log [L]$) vs $\log C_{VO}$ (ΔA values from Fig. 17a), gives straight lines with slopes 0.878 and 0.986 for (i) and (ii) respectively.

Hypotheses B: According to eq. (6B) of Table 6 the best plot is of Y_B vs $\log C_{VO}$. Again [M] is unknown, so α(M) cannot be calculated. However, as C_{VO} increases, α(M) and $\log \alpha$(M) increase (α(M) > 1). Again, plotting $(\log \Delta A - \log [L])$ (or $\log \Delta A - 2 \log [L]$), a slope greater than 2 would be expected.

The slopes obtained are less than 1. This suggests

Table 6. Two models for explaining CD spectra of solutions with high L/M ratios, fixed (and high) pH and variable C_{VO}[a]

Hypothesis A

dimer	$\rightleftharpoons$	monomer
("free" metal)		(responsible for the CD spectra)

$$M_2+2L \rightleftharpoons 2ML^{b}$$

$$\beta'_{ML}=\frac{[ML]^2}{[M_2][L]^2}\longrightarrow [ML]=\sqrt{\beta'_{ML}}[L]\sqrt{[M_2]}$$

Multiplying by $\Delta\varepsilon_{ML}$: $\Delta A=\sqrt{\beta'_{ML}}\Delta\varepsilon_{ML}[L]\sqrt{[M_2]}$ or

$$\Delta A=(K)_1[L]\sqrt{[M_2]} \qquad (3A)$$

Applying logarithms:

$$\log\Delta A-\log[L]=\log(K)_1+1/2\log[M_2] \qquad (4A)$$

Representing $(\log\Delta A-\log[L])$ vs $\log[M_2]$ one should obtain a straight line with slope 1/2.

$[M_2]$ is not known but

$$C_{VO}=2[M_2]+[ML]=[M_2]\underbrace{|2+(\sqrt{\beta'_{ML}}[L])/(\sqrt{[M_2]})|}_{\alpha(M_2)}$$

or: $$[M_2]=C_{VO}/\alpha(M_2) \qquad (5A)$$

Substituting (5A) in (4A), one gets:

$$\underbrace{\log\Delta A-\log[L]+1/2\log\alpha(M_2)}_{Y_A}=\log(K)_1+1/2\log C_{VO} \qquad (6A)$$

Conclusion: Representing Y_A vs $\log C_{VO}$ should give a straight line, slope 1/2.[c]

Hypothesis B

monomer	$\rightleftharpoons$	dimer
("free" metal)		(responsible for the CD spectra)

$$2M+2L \rightleftharpoons M_2L_2$$

$$\beta'(M_2L_2)=\frac{[M_2L_2]}{[M]^2[L]^2}\longrightarrow [M_2L_2]=\beta'(M_2L_2)[L]^2[M]^2$$

Multiplying by $\Delta\varepsilon(M_2L_2)$: $\Delta A=\beta'(M_2L_2)\Delta\varepsilon(M_2L_2)[L]^2[M]^2$ or

$$\Delta A=(K)_2[L]^2[M]^2 \qquad (3B)$$

Applying logarithms:

$$\log\Delta A-\log[L]=\log(K)_2+2\log[M] \qquad (4B)$$

Representing $(\log\Delta A-2\log[L])$ vs $\log[M]$ one should obtain a straight line with slope 2.

[M] is not known but

$$C_{VO}=[M]+2[M_2L_2]=[M]\underbrace{\{1+2\beta'(M_2L_2)[L]^2[M]\}}_{\alpha(M)}$$

or: $$[M]=C_{VO}/\alpha(M) \qquad (5B)$$

Substituting (5B) in (4B), one gets:

$$\underbrace{\log\Delta A-\log[L]+2\log\alpha(M)}_{Y_B}=\log(K)_2+2\log C_{VO} \qquad (6B)$$

Conclusion: Representing Y_B vs $\log C_{VO}$ should give a straight line, slope 2.

[a] For both A and B, if the equilibria are shifted towards the formation of the optically active complex, if C_{VO} varies, as one has an excess of ligand all vanadium would yield the complex, the ΔA would be proportional to C_{VO} and $\Delta\varepsilon_m$ = constant, which is not the case (although one is nearer to that situation in Fig. 9b than in Fig. 8b). Therefore, if the experimental results may be explained by either A or B, as the $\Delta\varepsilon_m$ are not constant this means that an appreciable amount of "free" metal exists.

[b] If the equilibrium is of the type $M_2+2L\rightleftharpoons 2MLH_{-3}+3H^+$, since one is considering groups of CD spectra at fixed pH, the treatment would be similar. If the equilibrium is of the type $M_2+4L\rightleftharpoons 2ML_2$, instead of eq. (3A) one would get: $\Delta A=\Delta\varepsilon_{ML_2}\sqrt{\beta'_{ML_2}}[L]^2\sqrt{[M_2]}$ and the treatment is also similar. If the equilibrium involves simultaneously ML and ML_2 complexes, as long as L/M is high their relative proportions are almost invariant with C_{VO} and the treatment is still valid.

[c] If the equilibrium is of the type $M_n+nL\rightleftharpoons nML$, the slope corresponding to eqs (4A) and (6A) would be $1/n$.

that equilibria of the type included in hypothesis B (Table 6) are unsuitable to describe the experimental CD spectra at high pH and variable C_{VO}. However, the results are consistent with expectation for hypothesis A. Therefore, at high pH, a fair description involves optically active monomeric complexes in equilibrium with dimeric (or oligomeric) non-optically active vanadium(IV) hydrolysis products. This agrees with the results obtained with SQUAD for pH $\lesssim$ 12.8 and is consistent with the present knowledge of vanadium(IV) aqueous chemistry at very high pH, where one expects to have $VO(OH)_3^-$ in equilibrium with other oligomeric species.[3]

MIXED-LIGAND COMPLEXES OF TECHNETIUM—III. SYNTHESIS AND CHARACTERIZATION OF [BIS(DIPHENYLPHOSPHINO)ETHANE]TETRAKIS(TRIMETHYL PHOSPHITE)TECHNETIUM(I) HEXAFLUOROPHOSPHATE, $[Tc(DPPE)(TMP)_4]PF_6$

(*Received* 1 *September* 1988; *accepted* 10 *November* 1988)

Abstract—The diamagnetic technetium(I) complex $[Tc(DPPE)(TMP)_4]PF_6$ was prepared from $[Tc(N_2)H(DPPE)_2]$ and characterized by elemental analysis, ^1H- and ^{99}Tc-NMR spectroscopy and fast atom bombardment mass spectrometry. $[Tc(DPPE)(TMP)_4]PF_6$ is a prototype compound for technetium complexes with mixed phosphine–phosphite coordination spheres.

In a recent report[1] we showed that hydridobis [bis(diphenylphosphino)ethane] dinitrogentechnetium(I), $[Tc(N_2)H(DPPE)_2]$,[2,3] is a useful starting material for the preparation of technetium mixed-ligand complexes with the metal in low oxidation states which may have a potential use as radiopharmaceuticals in diagnostic nuclear medicine.[1,4,5] With isocyanides (^{t}BuNC, cyclohexylNC), ligand exchange takes place by substitution of the hydride and the dinitrogen ligand to yield $[Tc(DPPE)_2(RNC)_2]^+$ cations.[1]

In this paper, we report ligand exchange reactions of this compound using trimethylphosphite (TMP).

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All operations were carried out in a fume cupboard, using gloves to avoid contamination. The weak β-emission of ^{99}Tc is retained by the glass of the reaction vessels. Secondary X-rays (bremsstrahlung) only become important if handling a larger scale of ^{99}Tc.

The procedures are performed in an atmosphere of dry nitrogen.

Preparation

$[Tc(N_2)H(DPPE)_2]$ (37 mg; 40 μmol) were suspended in 10 cm^3 MeOH. After addition of 2 cm^3 TMP, the mixture was refluxed for 1 h to obtain a

clear solution. The volume was reduced in vacuum to 1 cm^3, and 0.5 cm^3 of a saturated KPF_6 solution was added. Addition of 0.5 cm^3 water and cooling results in the formation of a colourless solid which was filtered and twice washed with ether. After recrystallization from acetone–water, 36 mg (80%) of colourless crystals were obtained; m.p. 182–186°C dec. Elemental analysis: Found: C, 41.5; H, 5.5; P, 20.7; Tc, 8.3. Calc. C, 40.1; H, 5.3; P, 19.9; Tc, 8.7. ^{1}H-NMR (without ^{31}P-decoupling): phenyl, 7.3 ppm *m* (20H); CH_3, 3.86 ppm *m* (18H) and 2.86 ppm *m* (18H); CH_2, 2.22 ppm *m* (4H). ^{99}Tc-NMR: −1664 ppm *m*.

Physical measurements

Fast atom bombardment mass spectra were recorded on a VG-ZAB-HSQ spectrometer. Argon was used as primary beam gas. The ion gun was operated at 8 keV and 100 μA. Glycerol was used as matrix. CID spectra could be obtained with argon as the collision gas.

The ^{1}H- and ^{31}P-NMR spectra were obtained in acetone-d_6 on a WX 90 DS spectrometer. The ^{99}Tc-NMR spectrum was recorded in CD_2Cl_2 on a AM 250 instrument with a measuring frequency of 56.3 MHz for ^{99}Tc. The chemical shifts are relative to TMS and TcO_4^- in D_2O, respectively.

RESULTS AND DISCUSSION

In contrast to the ligand exchange reaction between $[Tc(N_2)H(DPPE)_2]$ with isocyanides,[1] the reaction with trimethylphosphite does not result in the formation of $[Tc(DPPE)_2(TMP)_2]^+$, but yields another colourless complex, $[Tc(DPPE)(TMP)_4]^+$, which can be precipitated as the hexafluorophosphate salt. The compound is soluble in polar organic solvents, sparingly soluble in ether and insoluble in hydrocarbons and water. As a solid, it is stable in air, whereas in solution, a slow decomposition occurs if allowed to stand in the atmosphere over a longer period.

In the IR spectrum there is no evidence for frequencies arising from the N_2 and H^- ligand, respectively. The vibrational frequencies due to the P—O bonds of the TMP ligands are hypsochromically shifted in the complexes (by about 40 cm^{-1}), indicating their coordination to technetium.

More detailed information about the structure of the complex can be derived from the mass spectrometric investigations. Figure 1 shows the FAB mass spectrum of the mixed-ligand complex. The peak with the highest *m/z* value, 993, which represents the complex ion, corresponds to $[Tc(DPPE)(TMP)_4]^+$ cations. The structure of the $m/z = 993$ ion is supported by the more intense peaks at *m/z* 869, 745, 621 and 497, respectively, which indicate a stepwise loss of the TMP ligands. This assumption is confirmed by MIKE (mass analysed ion kinetic energy) spectra of the corresponding ions. As illustrated in Fig. 2, each of the mass selected ions, starting with $[Tc(DPPE)(TMP)_4]^+$, decomposes under metastable conditions (without collision gas) by elimination of one TMP ligand. The decomposition of the finally formed $[Tc(DPPE)]^+$ ion yields typical fragment ions by loss of, e.g. C_2H_4 (469), C_6H_6 (419), and $P(C_6H_5)_2$ (311).

Collision activation increases the number of

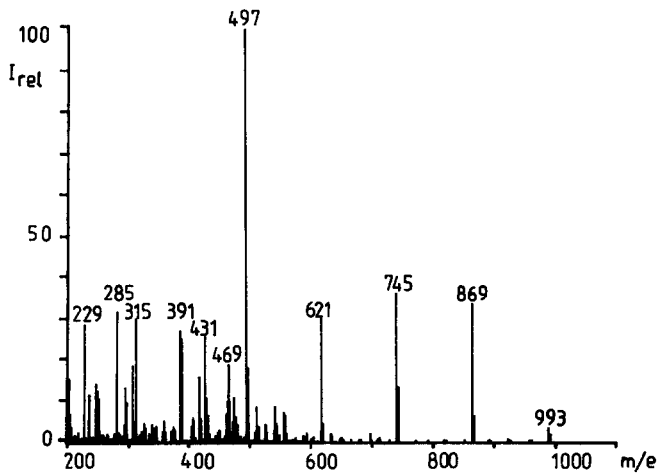

Fig. 1. Positive FAB mass spectrum of $[Tc(DPPE)(TMP)_4]^+$; matrix: glycerol.

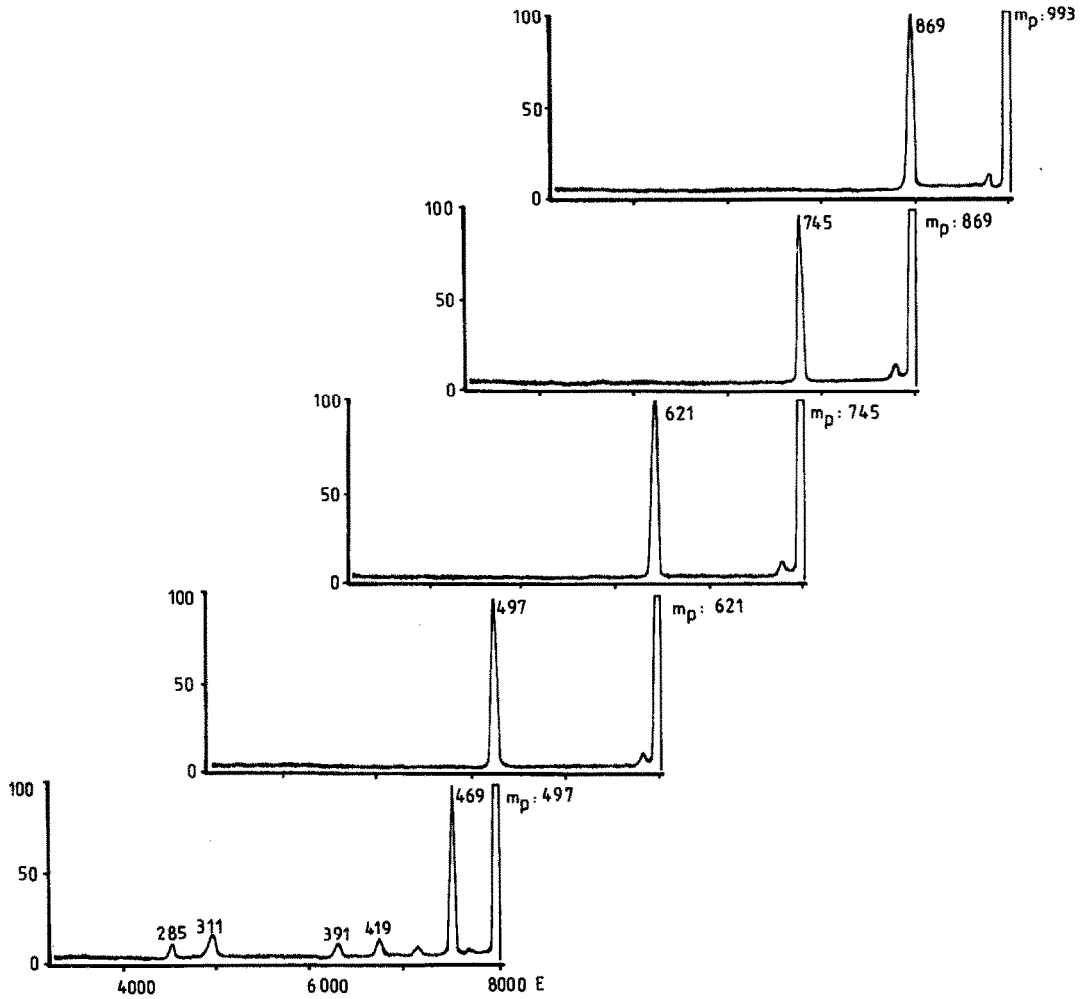

Fig. 2. MIKE spectra showing the fragmentation of metastable *m/z* 993, 869, 745, 621 and 497 ions.

ions formed. The MIKE spectrum of $[Tc(DPPE)(TMP)_4]^+$ ions recorded at 50% main beam reduction due to the collision gas (argon), contains all peaks which can be observed in the corresponding spectra obtained under metastable conditions (see Fig. 2). However, the most important fragmentation pathway, which allows the determination of the structure, is given by the loss of the ligands. This was also found in the MS–MS spectra of similar phosphine containing cationic Tc complexes.[6,7]

NMR spectroscopic results characterize $[Tc(DPPE)(TMP)_4]PF_6$ to be diamagnetic, as expected for the corresponding d^6 configuration. The proton spectrum confirms the stated structure showing two signals for the methyl protons of the differently bonded phosphite ligands. The ^{99}Tc-NMR spectrum (Fig. 3) shows a multiplet signal at -1664 ppm. This upfield chemical shift is in accordance with the values measured for $[Tc(TMP)_6]^+$ and $[Tc(DMPE)_3]^+$, which give ^{99}Tc-NMR signals at -1657 and -1837 ppm.[8] The larger line width in the $[Tc(DPPE)(TMP)_4]^+$ is due to its lower symmetry and the resulting quadrupole relaxation effects (quadrupole moment of ^{99}Tc: $Q = -0.2 \times 10^{-28}$ m^2).[9] Nevertheless, a multiplet structure of the ^{99}Tc-NMR signal could be resolved, arising from coupling with the ^{31}P nuclei of the ligands (three different groups each with two P-atoms). Individual coupling constants could not be derived due to many line overlappings. Obviously, the ^{99}Tc-^{31}P(phosphite) couplings are smaller than those found for $[Tc(TMP)_6]^+$ (910 Hz) and come in the range of corresponding ^{99}Tc-^{31}P(phosphine) values (574 Hz for $[Tc(dmpe)_3]^+$).[8,10] The ^{31}P-NMR spectrum of the mixed-ligand complex shows the expected high order pattern which is difficult to analyse.

DICHLORO AND AMINO ACID COBALT(III) COMPLEXES OF ETHYLENEDIAMINE-N,N′-di-S-α-PROPIONIC ACID

MOO-JIN JUN,* YOUN BONG PARK and SUNG RACK CHOI

Department of Chemistry, Yonsei University, Seoul, Korea

(*Received* 16 *May* 1988; *accepted* 11 *November* 1988)

Abstract—The dichloro cobalt(III) complex of ethylenediamine-N,N′-di-S-α-propionic acid (SS-eddp), [Co(SS-eddp)Cl_2], has yielded the Δ-s-*cis* isomer only. Chloro-aqua and diaqua cobalt(III) complexes of SS-eddp, Δ-s-*cis*-[Co(SS-eddp)Cl·H_2O] and Δ-s-*cis*-[Co(SS-eddp)$(H_2O)_2]^+$, have also been prepared. Reactions of the s-*cis*-[Co(SS-eddp)$Cl_2]^-$ complex with amino acids have yielded the s-*cis*-[Co(SS-eddp)(aa)]$^{n+}$ complexes (aa = L-alanine, S-methyl-L-cysteine or L-cysteine). The L-alanine or S-methyl-L-cysteine cobalt(III) complex of SS-eddp has been obtained as the s-*cis*-meridional isomer only. The S-methyl-L-cysteine is coordinated to the cobalt(III) ion via the nitrogen and oxygen donor atoms, while the cysteine is found to coordinate to the cobalt(III) ion via the nitrogen and sulphur donor atoms.

Ethylenediamine-N,N′-di-S-α-propionic acid (SS-eddp), the configuration of which is shown below, was first prepared by Liu and co-workers.[1]

The SS-eddp ligand is a flexible tetradentate ligand of the N_2O_2 system and can occupy four-coordinate sites with three geometrical isomers possible, s-*cis* (symmetric *cis*), uns-*cis* (unsymmetric *cis*) and *trans* in [Co(SS-eddp)$X_2]^{n+}$ type complexes as shown in Fig. 1. Both s-*cis* and uns-*cis* geometrical isomers can have either Δ or Λ absolute configurations.

Liu and co-workers have prepared the cobalt(III) complexes of SS-eddp, [Co(SS-eddp)L]$^{n+}$, where L is ethylenediamine (en) or *R*-propylenediamine (*R*-pn). The [Co(SS-eddp)(en)]$^+$ and [Co(SS-eddp)(*R*-pn)]$^+$ complexes have yielded Λ-s-*cis*, Δ-s-*cis*, and Δ-uns-*cis* isomers.[1] Recently, the rhodium(III) complexes of SS-eddp of the type [Rh(SS-eddp)L]$^{n+}$ (L = Cl_2, en, *R*- or *S*-alanine, glycine) have been prepared.[2–4] The dichloro complex of [Rh(SS-eddp)$Cl_2]^-$ has yielded only Δ-s-*cis* and Λ-uns-*cis* isomers. The ethylenediamine rhodium(III) complex of SS-eddp has also yielded only Δ-s-*cis* and Λ-uns-*cis* isomers.

It will be of interest to see which isomers would be obtained in the diacido cobalt(III) complexes of SS-eddp. It will be shown here that only one isomer, the Δ-s-*cis* isomer, has been yielded for the complexes of [Co(SS-eddp)$L_2]^{n+}$ (L = Cl or H_2O). There have been no reports on the SS-eddp or any N_2O_2 type tetradentate ligand cobalt(III) complexes of amino acids containing the sulphur atom. Our work on the SS-eddp cobalt(III) complexes of amino acids containing the sulphur atom, S-methyl-L-cysteine (mcy) and cysteine (cy), show rather an interesting result: the coordination of S-methyl-L-

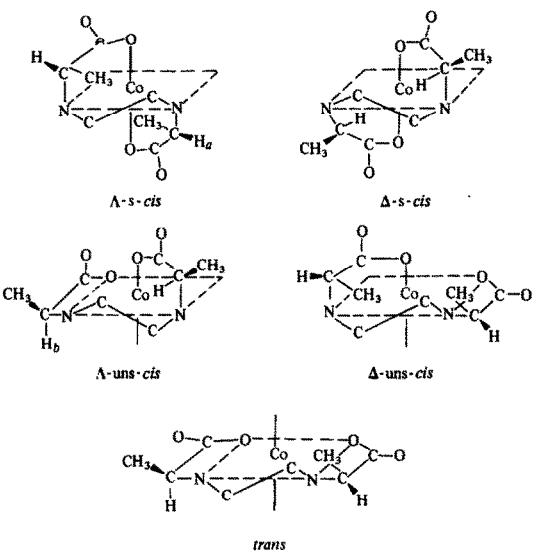

Fig. 1. The possible isomers of [Co(SS-eddp)$X_2]^{n+}$ complexes.

* Author to whom correspondence should be addressed.

cysteine in [Co(SS-eddp)(mcy)] is through the amino and carboxylate groups, whereas the cysteine is coordinated through the amino and mercaptide groups in $[Co(SS\text{-}eddp)(cy)]^+$. The synthesis of the *S*-alanine cobalt(III) complex of SS-eddp is also described.

EXPERIMENTAL

Physical measurements

Electronic absorption spectra were obtained with a Shimadzu UV-240 spectrophotometer. PMR spectra were recorded on a Varian EM 360L spectrometer. IR spectra were taken with a Shimadzu IR-435 spectrophotometer. Circular dichroism spectra were obtained with a J-500C spectropolarimeter. Elemental analyses were performed by Micro-Tech Analytical Laboratory, Skokie, Illinois.

Preparation of ethylenediamine-N,N′-*di*-S-α-*propionic acid* (SS-eddp)

This was prepared by the reported method.[1]

Preparation of s-cis-*hydrogen dichloro(ethylenediamine*-N,N′-*di*-S-α-*propionato)cobaltate*(III), s-cis-H[Co(SS-eddp)Cl_2]

To a solution of ethylenediamine-N,N′-di-S-α-propionic acid (1.0 g) in 35 cm^3 of water were added sodium hydroxide (0.4 g) and cobalt(III) chloride hexahydrate (1.2 g). The brown solution was aerated with carbon dioxide-free air for 5 h. Concentrated hydrochloric acid (20 cm^3) was added to the oxidation product and the reaction mixture was concentrated on a steam bath with continuous stirring to about 30 cm^3. The colour changed to a dark bluish-green and a dark green precipitate appeared. After cooling, the precipitate was collected on a filter, and washed with MeOH and ether. More of the green compound was obtained from the filtered solution by adding a small amount of conc. HCl and evaporating the solution. Separation of any isomers using an ion exchange resin column yielded only one isomer. Yield: 0.45 g. Found: C, 27.4; H, 4.6; N, 8.0. Calc. for H[Co(SS-eddp)Cl_2]·H_2O: C, 27.4; H, 4.8; N, 8.0%.

Preparation of s-cis-[Co(SS-eddp)Cl·H_2O] in situ

s-*cis*-H[Co(SS-eddp)Cl_2]·H_2O (15 mg) was dissolved in 20 cm^3 of 0.01 N perchloric acid. The solution was allowed to stand at 20°C for 70 min. The colour of the solution changed from dark green to blue, and at this point the electronic absorption and CD spectra were obtained.

Preparation of s-cis-$[Co(SS\text{-}eddp)(H_2O)_2]^+$ in situ

Sodium bicarbonate (0.05 g) was added to the s-*cis*-[Co(SS-eddp)Cl·H_2O] solution obtained above. The resultant solution was allowed to stand at room temperature for 30 min and the colour changed to light purple. Perchloric acid was added to the solution until the pH of the solution reached 2. The colour of the solution then changed to violet, and the electronic absorption and CD spectra were taken.

Preparation of s-cis-L-*alaninato(ethylenediamine*-N,N′-*di*-S-α-*propionato)cobalt*(III), s-cis-[Co(SS-eddp)(L-ala)]

s-*cis*-[Co(SS-eddp)Cl_2]·H_2O (0.70 g) was dissolved in 20 cm^3 of water and heated at 60°C for 20 min. L-alanine (0.19 g) was added and the pH of solution was adjusted to 8 with 1 N NaOH. After adding 0.1 g of activated charcoal, the solution was heated at 60°C in a water bath with stirring for 5 h. The activated charcoal was filtered and washed with hot water. The washings and filtrate were combined, and then concentrated on a rotatory evaporator to a volume of 5 cm^3. The resulting violet solution was poured into a column containing cation-exchange resin (Dowex 50W-X4, 200–400 mesh, H^+ form). The solution was separated into two bands using water as the eluent. The upper band, the unreacted $[Co(SS\text{-}eddp)(H_2O)_2]^+$, was retarded without elution. From the electronic absorption and ^1H NMR spectra, the eluate of the lower band was identified as the s-*cis* isomer. By fractional crystallization, the s-*cis*-[Co(SS-eddp)(*S*-ala)] was obtained. Yield: 0.49 g. Found: C, 37.9; H, 5.6; N, 11.8. Calc. for $CoC_{11}H_{20}N_3O_6$: C, 37.8; H, 5.7; N, 12.0%.

Preparation of s-cis-S-*methyl*-L-*cysteinato(ethylenediamine*-N,N′-*di*-S-α-*propionato)cobalt*(III), s-cis-[Co(SS-eddp)(mcy)]

s-*cis*-H[Co(SS-eddp)Cl_2]·H_2O (1.0 g) was dissolved in 30 cm^3 of water and heated at 60°C for 20 min. S-methyl-L-cysteine (0.4 g) was added and the pH of solution was adjusted to 10 with 1 N NaOH. Activated charcoal (0.1 g) was added and the reaction mixture was heated and stirred at 60°C on a water bath for 8 h. The charcoal was removed by filtration and washed with hot water. The combined filtrate and washings were concentrated to 5

cm^3 using a rotatory evaporator. The solution was passed through an ion-exchange column (Dowex 50W-X4, 200–400 mesh, H^+ form) with water as eluent. Two bands were formed. The upper band was the unreacted $[Co(SS\text{-}eddp)(H_2O)_2]^+$. The product was obtained by fractional crystallization of the lower band solution. Yield: 0.64 g. Found: C, 36.4; H, 5.6; N, 10.7. Calc. for $CoC_{12}H_{22}N_3O_6S$: C, 36.5; H, 5.6; N, 10.6%.

Preparation of s-cis-*sodium* S-*cysteinato(ethylenediamine*-N,N′-*di*-S-α-*propionato)cobaltate*(III), s-cis-Na[Co(SS-eddp)(cy)]

s-*cis*-H[Co(SS-eddp)Cl_2]·H_2O (1.0 g) was dissolved in 60 cm^3 of water and the solution was heated at 60°C for 20 min. The colour of solution turned from green to red–violet. After the solution was cooled to 0°C, 0.36 g of *S*-cysteine was added, and the pH of solution was adjusted to 10 by the addition of a 1 N NaOH solution. The solution was maintained at 0°C for 5 h with stirring on an ice bath. The reaction mixture was concentrated to 20 cm^3 using a rotatory evaporator. When 20 cm^3 of absolute ethanol was added, black precipitates were formed. The precipitates were removed by filtration and washed with absolute ethanol. The combined filtrate and washings were concentrated to 15 cm^3. The resulting reaction mixture was allowed to stand at 0°C for 1 day. The dark brown crystals which settled at the bottom of the beaker were filtered, washed with absolute ethanol and ether, and air-dried. More of the dark brown compound was obtained from the filtrate by evaporating the solution and adding absolute ethanol. Yield: 0.57 g. Found: C, 31.4; H, 4.9; N, 11.1. Calc. for $CoC_{10}H_{17}N_3O_6S \cdot H_2O$: C, 31.6; H, 5.0; N, 11.0%.

RESULTS AND DISCUSSION

Preparation of the dichloro cobalt(III) complex of SS-eddp has yielded only one geometrical isomer, the s-*cis* isomer. Attempts to isolate other isomers including ion-exchange chromatography have failed. In the electron absorption spectrum of $[Co(SS\text{-}eddp)Cl_2]^-$ shown in Fig. 2 bands I and II, which are due to the *d–d* transitions in the octahedral $CoN_2O_2Cl_2$ system, appear between 400 and 650 nm. The shape of the first band is nearly symmetrical, indicating an s-*cis* configuration. If the complex has the *trans* configuration a splitting of band I should be observed.[5–7] If the complex has an uns-*cis* geometry, two atoms of the same kind (Cl—Cl, N—N, O—O) are at the *cis* positions, and a very intense absorption of band II would be expected, since the ligand field around the central atom is highly unsymmetrical.

The PMR spectrum shown in Fig. 3 clearly indicates that the $[Co(SS\text{-}eddp)Cl_2]^-$ complex has a s-*cis* geometry. A single methyl doublet is shown at 1.7 ppm and a single α-carbon proton quartet is seen at 3.5 ppm. If the complex has an uns-*cis* geometry, the same methyl should show two doublets and the α-carbon proton should show two quartets, because the two carboxylate arms are not equivalent in the uns-*cis* geometry.

Figure 4 shows portions of the PMR spectra of s-*cis*-[Co(edda)(en)]$^+$, Λ-s-*cis*-[Co(SS-eddp)(en)]$^+$, Δ-s-*cis*-[Co(SS-eddp)(en)]$^+$, and Δ-s-*cis*-[Co(SS-eddp)Cl_2]$^-$, where edda is ethylenediamine-N,N′-diacetic acid. The chemical shifts of the protons of edda (labelled H_a and H_b) can be distinguished because of the magnetic anisotropic shielding of the C—N bond,[1,8,9] and the H_a protons resonate at a lower field than the H_b protons. From the known

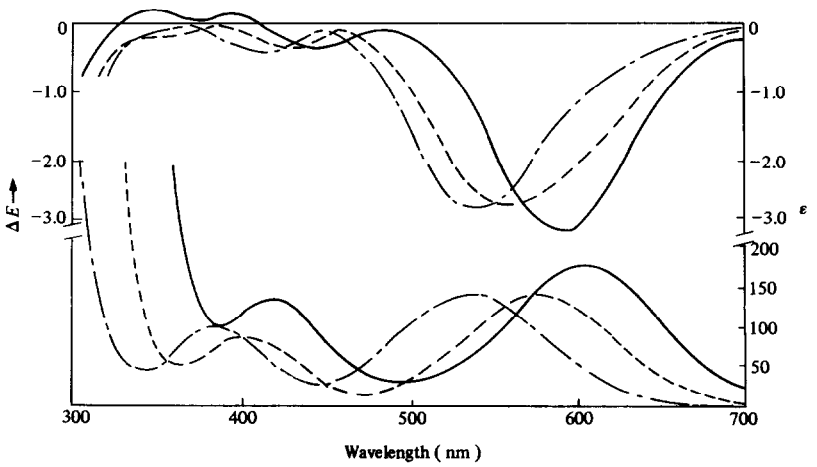

Fig. 2. Circular dichroism and electronic absorption spectra of Δ-s-*cis*-[Co(SS-eddp)Cl_2]$^-$ (——), Δ-s-*cis*-[Co(SS-eddp)Cl(H_2O)] (– – – –), and Δ-s-*cis*-[Co(SS-eddp)$(H_2O)_2$]$^+$ (—·—·—).

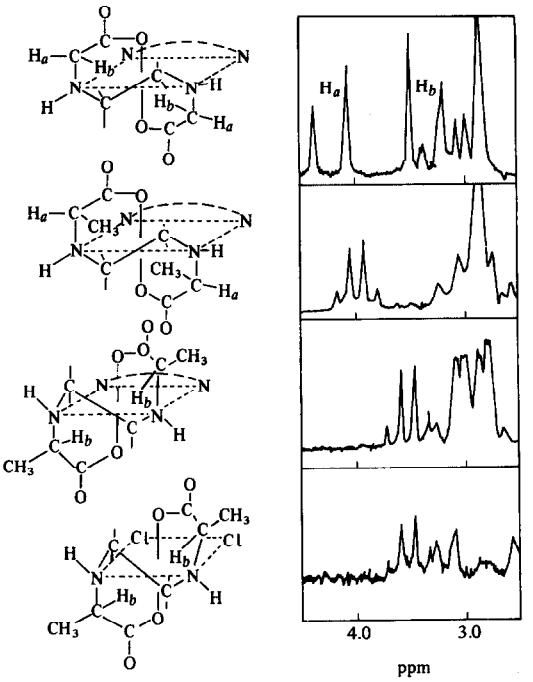

Fig. 4. PMR spectra of (from top to bottom) s-*cis*-[Co(edda)(en)]$^+$, Λ-s-*cis*-[Co(SS-eddp)(en)]$^+$, Δ-s-*cis*-[Co(SS-eddp)(en)]$^+$, and Δ-s-*cis*-[Co(SS-eddp)Cl_2]$^-$. Stereochemical representations are shown on the left.

absolute configuration of SS-eddp the absolute configuration of the s-*cis*-[Co(SS-eddp)Cl_2]$^-$ complex can be assigned based on its PMR spectrum. Only an H_a proton signal is exhibited in the Λ-s-*cis* isomer at 4.0 ppm, while only an H_b proton signal appears in the Δ-s-*cis* isomer at 3.5 ppm. The s-*cis*-[Co(SS-eddp)Cl_2]$^-$ shows only the H_b quartet at 3.5 ppm, and a Δ-absolute configuration is assigned to this complex. Such an assignment of the Δ-absolute configuration is also substantiated by its CD spectrum shown in Fig. 2. The dominant negative Cotton effect shown near 600 nm indicates the Δ-absolute configuration, as in the case for Δ-(−)-s-*cis*-[Co(SS-eddp)(en)]$^+$ or Δ-(−)-s-*cis*-[Co(SS-eddp)(*R*-Pn)]$^+$ complex.[1]

Figure 2 also indicates the electronic absorption spectra for Δ-s-*cis*-[Co(SS-eddp)Cl·H_2O] and Δ-s-*cis*-[Co(SS-eddp)$(H_2O)_2$]$^+$ and their spectra data are summarized in Table 1. Two observations can generally be made: the peaks of band I are symmetrical indicating s-*cis* configurations, and the λ_{max} is shifted towards the shorter wavelength as the chloro ligands are substituted by the aqua ligands, which is in accordance with the spectrochemical series. The CD spectra in Fig. 2 show the negative Cotton effect for the band I absorption, indicating Δ-absolute configurations for those complexes.

It is interesting to find out that only the s-*cis* isomer has been obtained during the preparation of the [Co(SS-eddp)Cl_2]$^-$ complex. In octahedral complexes of the type [M(edda-type ligand)L_2]$^{n+}$, the s-*cis* configuration is generally favoured, while the uns-*cis* configuration is also formed in low yield

Table 1. Electronic absorption spectral data for the cobalt(III) complexes with the SS-eddp ligand

Na[Co(SS-eddp)(cy)]	500sh(40)	370(250)

[a] In nm.
[b] In M^{-1} cm^{-1}.

when L_2 is a bidentate ligand.[10] Thus, only the s-*cis* isomer has been found for [Co(SS-eddiv)$(NO_3)H_2O$] and [Co(pren)$(H_2O)_2]^+$ complexes, while both s-*cis* and uns-*cis* isomers have been obtained for $[Co(SS\text{-}eddiv)(en)]^+$ and $[Co(pren)(en)]^+$ complexes,[11,12] where SS-eddiv and pren are, respectively, ethylenediamine-N,N′-di-S-α-isovaleric acid and 2S,2′S-1,1′-(ethane-1,2-diyl) bis(pyrrolidine-2-carboxylate). Ring strain and non-bonded interactions between chelate rings have been cited for the preference for the s-*cis* configuration. On the other hand, the extra stability due to the chelation effect of the bidentate ligands makes the existence of the uns-*cis* configuration possible.[10–13] Octahedral complexes of $[Co(SS\text{-}eddp)L_2]^{n+}$ have yielded both s-*cis* and uns-*cis* isomers when L is a bidentate ligand such as en or amino acid.[1,10] Diacido cobalt(III) complexes of SS-eddp prepared in this work, are the only octahedral complexes of $[Co(SS\text{-}eddp)L_2]^{n+}$ where L is a unidentate ligand.

The substitution reactions of Δ-s-*cis*-$[Co(SS\text{-}eddp)Cl_2]^-$ with L-alanine, S-methyl-L-cysteine and L-cysteine in aqueous media, have resulted in the isolation of the corresponding amino acid complexes with retention of configuration. Three geometrical isomers, s-*cis*-*mer* (meridional), uns-*cis*-*mer*, and uns-*cis*-*fac* (facial) occur (Fig. 5) when an amino acid (aa) is coordinated in the $[Co(SS\text{-}eddp)(aa)]^{n+}$ complex.

The electronic absorption spectrum is useful in differentiating between the facial and meridional isomers: the loss of symmetry from facial (cubic holohedrized symmetry) to meridional (rhombic holohedrized symmetry) is expected to cause a splitting or at least a broadening of the first absorption band.[14] In the electronic absorption spectrum of [Co(SS-eddp)(L-ala)] (Fig. 6), band I and band II appear between 350 and 550 nm. The splitting pattern of the first band having a shoulder near 500 nm indicates that the [Co(SS-eddp)(L-ala)] complex has a meridional geometry of either s-*cis* or uns-*cis*. The PMR spectrum of the [Co(SS-eddp)(L-ala)] complex (Fig. 7) clearly shows an s-*cis* geometry. The methyl regions of this complex show

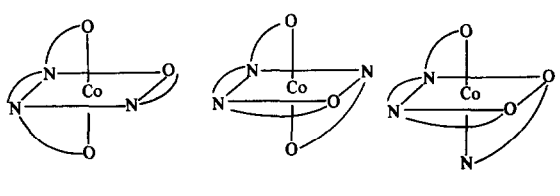

Fig. 5. The configuration isomers of [Co(edda-type)(aa)]$^{n+}$ complexes.

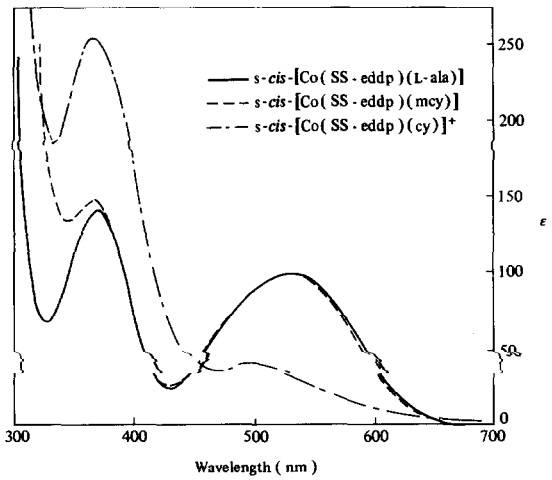

Fig. 6. Electronic absorption spectra of the amino cobalt (III) complexes of SS-eddp.

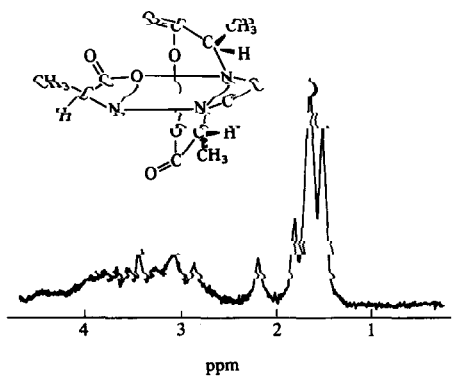

Fig. 7. PMR spectrum of s-*cis*-[Co(SS-eddp)(*S*-ala)].

two methyl doublets with a 2 : 1 intensity, indicating that the loss of C_2 symmetry going from the s-*cis* dichloro cobalt(III) complex to the s-*cis* alanine cobalt(III) complex causes two of the propionato arms of SS-eddp to be no longer equivalent. The doublets at 1.7 and 1.5 ppm are due to the methyl groups of the unequivalent propionato arms. The doublet at 1.5 ppm is distinctive of the L-alanine methyl group in this s-*cis* isomer.

Although S-methyl-L-cysteine has three donor atoms (N, O, S), the IR spectrum of the [Co(SS-eddp)(mcy)] complex shows the coordination of nitrogen and oxygen donor atoms. The C=O stretching band occurs at 1650 cm^{-1} (Table 2), as is typical of the coordinated carboxylate groups. The electronic absorption spectrum (Fig. 6) of this complex shows a similar pattern as the alanine complex; a typical CoN_3O_3 system with a meridional configuration. The PMR spectrum of the complex shown in Fig. 8 presents the methylene protons in the S-methyl-L-cysteinato chelate ring at 3.0 ppm

Table 2. The CO stretching frequencies of the SS-eddp ligand and cobalt(III) complexes

Compound	ν^a(C=O)	Group
SS-eddp	1580	$-CO_2-$
Δ-s-*cis*-H[Co(SS-eddp)Cl_2]H_2O	1620	$-CO_2Co$
s-*cis*-[Co(SS-eddp)(*S*-ala)]	1640	$-CO_2Co$
s-*cis*-[Co(SS-eddp)(Smcy)]	1650	$-CO_2Co$
Na[Co(SS-eddp)(cy)]	1610	$-CO_2-$

[a] In cm^{-1}.

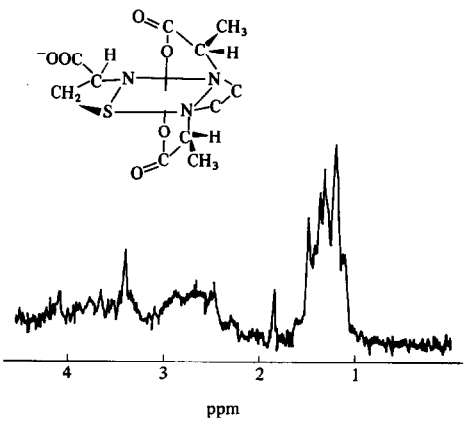

Fig. 9. PMR spectrum of Na[Co(SS-eddp)(cy)].

as a doublet along with the S-methyl protons at 2.1 ppm as a singlet. The methyl groups in the two propionato arms are shown as doublets at 1.4 and 1.6 ppm. If the complex has an uns-*cis* configuration, the PMR spectrum would have been much more complicated.

The IR spectrum provides definite evidence as to which groups of the cysteine are coordinated in Na[Co(SS-eddp)(cy)]. There is no band observed in the 2500 cm^{-1} region (S—H stretching mode), suggesting that the mercaptide group is coordinated at one of two coordination sites. The other site may be occupied by the amino or the carboxylate group. An intense C=O stretching band occurs at 1610 cm^{-1} in the IR spectrum of Na[Co(SS-eddp)(cy)]. This value is consistent with the presence of the free carboxylate ions. The presence of the strong N—H stretching band near 3200 cm^{-1} indicates the fact that the cysteine is coordinated to the cobalt(III) ion through the nitrogen and sulphur atoms.

The electronic absorption spectrum (Fig. 6) of the $[Co(SS\text{-}eddp)(cy)]^-$ complex shows the splitting pattern of the CoN_3O_2S system which is very different from that of the CoN_3O_3 system. The *d–d* spectral data of Table 1 are consistent with pseudooctahedral symmetry, band I corresponding to the low symmetry split components of $^1A_{1g}$–$^1T_{1g}$ and band II to those of $^1A_{1g}$–$^1T_{2g}(O_h)$.[15] In spite of the low position of the mercaptide ion in the spectrochemical series, it coordinates strongly to cobalt(III), but in other cobalt(III) complexes of cysteine the mercaptide group is not always coordinated and there is competition among the three functional groups.[16,17] The PMR spectrum of the $[Co(SS\text{-}eddp)(cy)]^-$ complex (Fig. 9) shows the methyl groups in the two carboxylate arms at 1.2 and 1.4 ppm as doublets, the pattern of which is consistent with the s-*cis* configuration.

(*Received* 23 *August* 1988; *accepted after revision* 23 *November* 1988)

Abstract—Reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ with 3-hydroxy-2-butanone (acetoin) in methanol yields $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]\cdot 0.5(C_2H_5)_2O$, a complex with the $[Mo_2O_5]^{2+}$ core and a coordinated 2,3,4,5-tetrahydroxy-2,3,4,5-tetramethylfuranose ring, formed by Aldol condensation and oxidation of acetoin groups. Crystal data: triclinic space group $P\bar{1}$, $a = 11.824(2)$, $b = 12.033(2)$, $c = 12.677(3)$ Å, $\alpha = 83.65(1)$, $\beta = 71.30(1)$, $\gamma = 88.71(1)°$, $V = 1698.0(6)$ Å^3, $Z = 2$, $D_{calc} = 1.37$ g cm^{-3}; 3826 reflections to give $R = 0.0588$.

Coordination complexes of polyoxomolybdates are of interest as models for surface-bound intermediates in heterogeneous catalysis employing solid molybdenum oxides.[1–5] Structurally characterized examples of polyoxomolybdate complexes incorporating simple organic substrate units include $[Mo_8O_{26}(HCO_2)_2]^{6-}$,[6] $[Mo_4O_{14}(OH)CH_2]^{3-}$,[7] $[Mo_8O_{24}(OCH_3)_4]^{4-}$,[8] $[Mo_4O_8(OC_2H_5)_2\{CH_3C(CH_2O)_3\}_2]$[9] and $[Mo_4O_{10}(OCH_3)_6]^{2+}$,[10] and the alkoxy and siloxy derivatives of $[MoO_3(P_3O_9)]^{2-}$[11] and $[Mo_3O_7\{CH_3C(CH_2O)_3\}_2]^{2-}$,[12] and of the niobotungstate $[Nb_2W_4O_{19}]^{4-}$.[13] In the course of our investigations of polyoxomolybdate–carbonyl interactions,[14] we have examined the chemistry of acetoin. As anticipated, the organic substrate is incorporated into a polyoxomolybdate core; however, the acetoin group has undergone an Aldol condensation and oxidation to provide an unusual 2,3,4,5-tetrahydroxy-2,3,4,5-tetramethylfuranose ring coordinated to the $[Mo_2O_5]^{2+}$ core of the product, $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]\cdot 0.5(C_2H_5)_2O$. A closely related dimolybdo–furanose structure has been reported for the lyxose–dimolybdate, $(NH_4)[Mo_2O_5(C_4H_5O_5)]$, formed by the epimerization and ligation of xylose in the presence of ammonium molybdate.[15]

Reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ with an equimolar amount of acetoin in methanol, followed by addition of ether, gives colourless, transparent blocks of $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]\cdot 0.5(C_2H_5)_2O$ in 55% yield.† The IR spectrum is characterized by strong bands at 952 and 940 cm^{-1} assigned to ν_s(Mo=O) and ν_{as}(Mo=O), respectively, and a number of features in the 650–900 cm^{-1} range associated with ν(Mo—O—Mo) and ν(Mo—O—alkoxy). The complex crystallizes in the triclinic space group $P\bar{1}$ with $a = 11.824(2)$, $b = 12.033(2)$, $c = 12.677(3)$ Å, $\alpha = 83.65(1)$, $\beta = 71.30(1)$, $\gamma = 88.71(1)°$, $V = 1698.0(6)$ Å^3, $D_{calc} = 1.37$ g cm^{-3}. Structure solution and refinement based on 3826 reflections with $F_o \geqslant 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å) converged at $R = 0.0588$.‡

The structure of $[Mo_2O_5(C_8H_{13}O_5)]^{1-}$ is shown in Fig. 1, and selected bond lengths and angles are presented in the caption. The structure of the binuclear complex monoanion consists of the well-

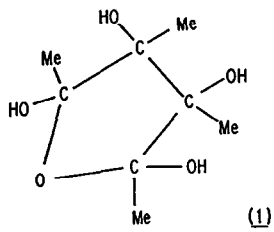
documented $[Mo_2O_5]^{2+}$ core,[16] ligated to an organic moiety formally derived from 2,3,4,5-tetrahydroxy-2,3,4,5-tetramethylfurane (**1**). The tetradentate



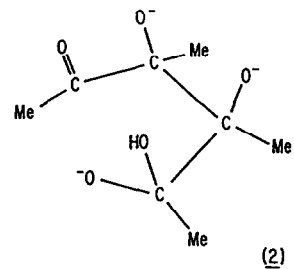
(1)

ligand coordinates to the Mo centres through four alkoxy oxygen donors, two of which, O(7) and O(9), are terminal, while O(6) and O(8) assume bridging modes.

The most unusual feature of the structure is the geometry associated with O(8), which exhibits unsymmetrical bridging with unusually long bond distances of 2.485(4) and 2.709(5) Å to Mo(2) and Mo(1), respectively. Such Mo—O bond distances are outside the range of 2.10–2.20 Å, characteristic for bridging alkoxides and clearly indicate that O(8) is present as the protonated alcohol form.[17] This observation is also consistent with the charge requirements for a mononegative anion $[Mo_2O_5(C_8H_{13}O_5)]^-$, which require that the ligand be trinegative $(C_8H_{13}O_5)^{3-}$, rather than the fully deprotonated form. The ^1H NMR spectrum of $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]$ exhibits a singlet at 8.63 ppm, integrating for a single proton, which confirms the presence of the alcoholic proton.

Although the overall coordination geometry may be most simply described in terms of two $[MoO_6]$ octahedra sharing a face defined by O(5), O(6) and O(8), the detailed geometry about the molybdenum centres suggests an alternative description based on edge-sharing square-pyramids, with an additional weak axial interaction. In fact, the bond strengths associated with Mo(1)—O(8) and Mo(2)—O(8) are *ca* 0.1 and 0.2, respectively.[18]

The ligand exhibits a number of unusual bond lengths: C(2)—O(7) is significantly shorter than the average of other C—O(alkoxy) distances (1.37(1) vs 1.44(1) Å), while the C(2)—O(10) distance of 1.475(10) Å is considerably longer than C(7)—O(10), 1.395(9) Å. This observation suggests some contribution from the acyclic form (**2**) to the over-



(2)

all ligand structure, a feature possibly related to the ring closure via an Aldol condensation.

It is noteworthy that acetoin undergoes spontaneous dimerization in organic solvents to give the six-membered cyclic bis-hemiacetal, 2,5-dihydroxy-2,3,5,6-tetramethyldioxane (**3**).[19] In contrast, the

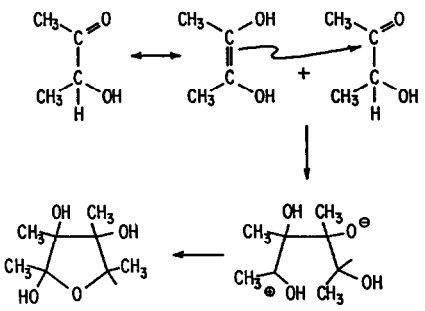
ligand moiety observed in the structure of $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]$ implicates an Aldol



Scheme 1.

condensation mechanism to produce the furanose ring, coupled to oxidation of a carbon site by the dimolybdate precursor (see Scheme 1). Thus, the polyoxomolybdate not only serves to oxidize the ligand substrate, but also to promote the Aldol condensation pathway. We are investigating the chemistry of related α-hydroxyketones and α-diketones, where such oxidation processes and enolate mechanisms appear to be general.[6,14]

THE YTTRIUM ION AS A TEMPLATE IN THE SYNTHESIS OF THE MACROCYCLIC AND ACYCLIC COMPLEXES FORMED IN THE REACTIONS WITH 2,6-DIACETYLPYRIDINE AND HYDRAZINE*

WANDA RADECKA-PARYZEK

Faculty of Chemistry, Adam Mickiewicz University, 60-780 Poznań, Poland

(*Received* 3 *November* 1988; *accepted* 24 *November* 1988)

Abstract—The macrocyclic tetradentate NNNN donor yttrium nitrate complex of formula $[YL^1(NO_3)_3]\cdot 2H_2O$, where L^1 is 2,5,11,14-tetramethyl-3,4,12,13,19,20-hexaazatricyclo[13.3.1.1^{6,10}]eicosa-1(19),2,4,6,8,10(20),11,13,15,17-decaene, has been prepared by the condensation of 2,6-diacetylpyridine with hydrazine in the presence of a metal ion template and characterized by spectral and analytical data. Different experimental conditions (the type of counterion, ratio of starting materials) lead to the isolation of acyclic tetradentate NNNO or terdentate NNN donor complexes of yttrium with uncondensed carbonyl or amino groups. They are formulated as $[YL^2(H_2O)_2]Cl_3\cdot 2H_2O$ and $[YL^2(H_2O)_2](ClO_4)_3\cdot 2H_2O$, where L^2 is (6-acetyl-pyrid-2-yl)methyl ketone azine, and $[YL^3(NO_3)_3]\cdot 2H_2O$, $[YL^3_2]Cl_3\cdot 2H_2O$ and $[YL^3_2](ClO_4)_3\cdot 2H_2O$, where L^3 is 2,6-diacetylpyridinedihydrazone. The 2,6-diacetylpyridine (L) complexes isolated as minor products, are regarded as possible intermediates in the formation of macrocyclic L^1 and ring-opened L^2 complexes of yttrium.

Interest in exploring the encapsulation of the rare earth elements by polyoxa- and polyaza-macrocycles like coronands and cryptands, has continually increased since they can be used for lanthanide separation, for the stabilization of unusual oxidation states, for the systematic investigation of the coordinating properties of these elements and for probing the metal ion binding sites of biological macromolecules.[1]

The coordination of yttrium by polyoxa-macrocycles has been little studied. The synthetic and structural results of research on complexation of yttrium with crown ethers were recently reported.[2]

In previous papers we reported the preparation and characterization of scandium and heavier lanthanide (Tb–Lu) complexes containing the 14-membered tetradentate hexaaza macrocyclic ligand.[3] The lighter lanthanides (La–Gd) have been found to be ineffective as templates for the synthesis of this macrocycle under similar conditions, but effective in the synthesis of N donor macrocycles with greater ring size.[4] We have concluded that the important factor which must be taken into account in the synthesis of the macrocyclic compounds with the aid of a metal ion is the ratio of cation diameter to ligand cavity size. As a continuation of our studies on the effectiveness of metal ions of varying radius and electron configuration in the synthesis of polyaza-macrocyclic compounds with different ring size, we extended our investigations to the yttrium ion, which has not so far been examined in this respect. We now report what we believe to be the first example of the template action of yttrium ion (which is similar in size to Dy and Ho) in the synthesis of a macrocyclic compound. We have found that different experimental conditions lead to the isolation of macrocyclic (coronate) or acyclic (podate) complexes of yttrium.

EXPERIMENTAL

The hydrated yttrium salts (chloride, perchlorate or nitrate) were prepared by dissolving the 99.99% Y_2O_3 in the appropriate acid. The solutions were

evaporated and precipitates recrystallized from methanol.

Preparation of the yttrium complexes. General procedure

The complexes were prepared by the template synthesis of the yttrium chloride, perchlorate or nitrate with 2,6-diacetylpyridine and hydrazine in ethanol, in the reactant ratios 2 : 1 : 1, 1 : 1 : 2, 1 : 2 : 4 and 1 : 3 : 6. The reaction mixtures were heated under reflux with stirring for 24 h. The resulting precipitates were filtered off, washed with hot ethanol and ether, and dried under vacuum.

The macrocyclic complex of L^1 is formed only in the reaction of yttrium nitrate with 2,6-diacetylpyridine and hydrazine in the 2 : 1 : 1 molar ratio of starting materials. Under the same reaction conditions, yttrium chloride and perchlorate gave the acyclic 1 : 1 complexes (6-acetyl-pyrid-2-yl)methyl ketone azine (L^2). Small amounts of yttrium nitrate, chloride or perchlorate complexes of 2,6-diacetylpyridine (L) were also obtained from these reactions.

From the reactions of yttrium nitrate, chloride and perchlorate with 2,6-diacetylpyridine and hydrazine in the molar ratios 1 : 1 : 2, 1 : 2 : 4 and 1 : 3 : 6, the 2,6-diacetylpyridinedihydrazone (L^3) complexes were isolated with the metal-to-ligand stoichiometry of 1 : 1 for nitrate and 1 : 2 for chloride and perchlorate as counteranions, irrespective of the molar proportions of starting materials.

Table 1 reports analytical data of the compounds.

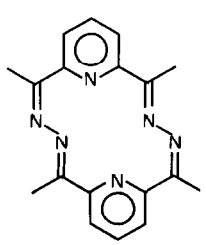
Measurements

These were as previously described.[2]

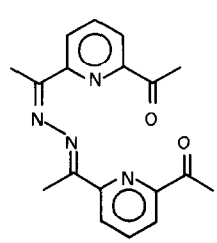
RESULTS AND DISCUSSION

The 14-membered hexaaza-macrocyclic complex of yttrium has been prepared via template condensation of 2,6-diacetylpyridine with hydrazine in the presence of $Y(NO_3)_3\cdot 6H_2O$ in the ratio of reactants 1 : 1 : 2. Less than the stoichiometric amounts of 2,6-diacetylpyridine and hydrazine were required to prevent the formation of 2,6-diacetylpyridinedihydrazone. The formulation of this complex as $[YL^1(NO_3)_3]\cdot 2H_2O$ follows from spectral data (IR, UV–vis, ^1H NMR and MS) and thermal and elemental analysis. The complex is a yellow air-stable solid, soluble in CH_3CN and DMSO.

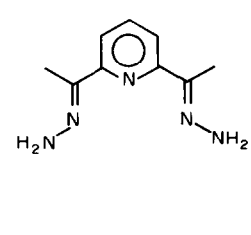
The IR spectrum of this complex in the 4000–200 cm^{-1} region confirms the formation of the macrocyclic compound by the absence of uncondensed functional group (NH_2, C=O) stretching modes of starting materials and the appearance of a strong absorption band at 1620 cm^{-1}, attributable to the coordinated C=N stretching frequencies. The high and low energy pyridine bands are observed at 1575, 1460, 630 and 420 cm^{-1} suggesting coordination of pyridine.[5] A broad diffuse band of strong intensity in the 3700–3200 cm^{-1} region may be assigned to the O—H stretching vibration for lattice water. The



L^1



L^2



L^3

absorption characteristic of coordinated water does not appear. The thermogravimetric analysis confirms this observation indicating the loss of two molecules of water at 40–70°C.

The IR spectrum of this complex demonstrates the presence of coordinated nitrates. The band characteristic of ionic nitrates at 1390 cm^{-1} does not appear. The two new bands associated with the asymmetric stretch appear near 1320 and 1495 cm^{-1}. The magnitude of the separation (175 cm^{-1}) is typical of bidentate bonding of the nitrates.[6]

The electronic spectra of acetonitrile solution of the complex exhibit bands at *ca* 268 and 333 nm, attributable to the $\pi \rightarrow \pi^*$ transitions of coordinated macrocycle.

The ^1H NMR spectrum of the yttrium complex of L^1 obtained in DMSO-d_6 solution shows the pyridine protons at δ 7.9–8.2 and methyl protons at δ 2.28 and 2.56. The integrated relative intensities are in good agreement with the required ratio 1 : 1 : 1, consistent with the proposed formulation of this complex.

The mass spectrum of this complex provides strong evidence for the presence of a macrocyclic compound showing the highest fragment at m/z 318, corresponding to the molecular weight of the uncoordinated macrocycle.

On the basis of the spectral data and thermogravimetric analysis, along with molecular model inspection, it seems reasonable to assign the tentative coordination number of 10 for the yttrium ion in this complex. The metal ion is presumably coordinated to the four nitrogen atoms of the hexaaza 14-membered macrocycle and to oxygen atoms of three bidentate nitrate groups. The synthesis and crystal structure of the 12-membered crown ether complex of yttrium nitrate with such a high coordination number was recently reported.[7]

Attempts to prepare this macrocyclic compound with the aid of yttrium chloride or perchlorate was unsuccessful. In the reactions in which 2,6-diacetylpyridine was allowed to react with hydrazine in the presence of yttrium chloride or perchlorate, the ring closure did not occur. Instead, the ring-opened complexes of (6-acetyl-pyrid-2-yl)methyl ketone azine (L^2) were formed. The complexes are yellow solids, moderately soluble in acetonitrile. They have the composition $[YL^2(H_2O)_2]Cl_3 \cdot 2H_2O$ and $[YL^2(H_2O)_2](ClO_4)_3 \cdot 2H_2O$.

It should be noted, here, that ligand L^2 appears to be identical with the compound isolated earlier, as an intermediate in the preparative route to the free L^1 macrocycle.[8]

The IR spectra of the two complexes of L^2 are very similar and analysed similarly to that of the free ligand. The band characteristic of the C=N stretching mode, indicating the partial condensation reaction, is shifted by *ca* 30 cm^{-1} from 1600 cm^{-1} in the free ligand to lower frequencies, suggesting the coordination by the nitrogen atom. The profile of the pyridine ring vibration observed in the 1600–1400 cm^{-1} region and the strong band at 1000 cm^{-1} are characteristic of coordinated pyridine. An important feature is the occurrence of the medium absorption bands at 1700 and 1670 cm^{-1}, assigned to the C=O stretching modes. In the IR spectrum of the free ligand this absorption appears at 1695 cm^{-1}. The shift of this band to lower frequencies in the complexes indicates the coordination through the oxygen atom. The position of the other C=O band at a slightly higher frequency than in the free ligand suggests that one of the two carbonyl groups remain uncoordinated.

The ^1H NMR spectra of these complexes in acetonitrile-d_3 solution confirm this observation. The appearance of two methyl proton signals of the CH_3CO groups at δ 2.72 and 2.85, instead of one signal observed at δ 2.72 for the free ligand, and the small downfield shift of the CH_3CN methyl and pyridine proton resonances from δ 2.4 and 7.7–8.3, respectively, in the free azine to δ 2.45 and 7.9–8.4 in the complexes, is assumed to be a consequence of coordination of the ligand to the yttrium ion through the three nitrogen donor atoms and one oxygen atom of the two carbonyl groups.[9]

The presence of uncoordinated perchlorates is inferred from the absence of the degenerate stretching and bending modes of ClO_4^- at 1100 cm^{-1}. A broad diffuse band in the 3500–3200 cm^{-1} region and weak absorptions at 860 and 540 cm^{-1} suggest the presence of lattice and coordinated water. This is supported by the results of the thermogravimetric analysis, which indicates a loss of two molecules of water at 35–65°C and two water molecules at 140–190°C for these complexes.

The electronic spectra of yttrium chloride and perchlorate complexes of L^2, for solutions in acetonitrile, consist of three bands at 238–240, 258–262 and 296–300 nm. The differences in the spectra of the complexes and free ligand can be attributed to changes in energy levels of the ligand orbitals on coordination.

The tentative coordination number of six is proposed for podate yttrium chloride and perchlorate complexes of (6-acetylpyrid-2-yl)methyl ketone azine. The coordination sphere is filled by the tetradentate NNNO donor ligand with sufficient interaction of two water molecules.

The failure of the 2,6-diacetylpyridine and hydrazine system to undergo complete condensation and cyclization, in the presence of yttrium chloride and perchlorate, is presumably attributed to the greater

flexibility of the podands than coronands and to the different complexing properties of the counterions involved in the template synthesis. The nitrate ions, contrary to the chlorides and perchlorates, are known to be very good complexing agents towards the rare earth elements. The yttrium ion has therefore been found to be effective for the synthesis of the 14-membered hexaaza-macrocyclic ligand, but the interaction between the metal ion and the counteranion seems to play the decisive role in the stabilization of the macrocyclic complex.

In addition to the ring-closed and ring-opened complexes discussed above, a small number of 2,6-diacetylpyridine (L) complexes were isolated from the reactions of 2,6-diacetylpyridine with hydrazine in the presence of yttrium nitrate, chloride and perchlorate in the reactant ratio 1 : 1 : 2. They are yellow microcrystalline compounds, soluble in polar solvents. The complexes have the compositions $[YL(NO_3)_3]\cdot 2H_2O$, $[YL_2(H_2O)_2]Cl_3\cdot 2H_2O$ and $[YL_2(H_2O)_2](ClO_4)_3\cdot 2H_2O$.

The evidence for the coordination of the carbonyl oxygen atoms and pyridine nitrogen atom to the yttrium ion comes from the IR and ^1H NMR spectra of the complexes.

The most diagnostic feature is the shifting of the C=O absorption band to lower wavenumbers by about 40 cm^{-1} relative to the ligand (1700 cm^{-1}), resulting from a decrease in the C=O double bond character owing to coordination. The band assigned to the pyridine ring vibrations are shifted to higher frequencies, which is a good indication of the coordination of the heterocyclic nitrogen atom.

The signals of methyl protons at δ 2.75 and pyridine protons at δ 8.18 observed in the ^1H NMR spectrum of 2,6-diacetylpyridine appear at δ 2.88–2.90 and δ 8.2–8.6 in the spectra of yttrium complexes.

The IR spectra of the complexes indicate the presence of ionic perchlorate and chloride (unsplit band at 1100 cm^{-1} and absence of the band at *ca* 230 cm^{-1} characteristic of Ln—Cl interaction) and coordinated bidentate nitrato groups (bands at 1310 and 1465 cm^{-1}).

The absorptions characteristic of lattice water at 3700–3200 cm^{-1} occur in the IR spectra of nitrate, chloride and perchlorate complexes of yttrium. In addition, in the spectrum of the nitrate complex, a weak absorption is found at *ca* 880 and 540 cm^{-1} as expected for coordinated water. The thermogravimetic analysis confirms this observation indicating the loss of two molecules of water at 40–80°C for all the complexes and, additionally, in the case of the chloride and perchlorate complexes, the loss of two water molecules at 150–190°C.

Treatment of the yttrium complexes of L with hydrazine in ethanol at 75°C for 24 h leads to isolation of the L^1 complex of yttrium nitrate and L^2 complexes of yttrium chloride and perchlorate. Thus the yttrium complexes of 2,6-diacetylpyridine are regarded as possible intermediates in the partial or total condensation reaction leading to the formation of coronate L^1 or podate L^2 complexes. The coordination of the metal ion to the pyridine nitrogen and the two oxygen atoms of the carbonyl groups makes the carbonyl more susceptible to nucleophilic attack by the hydrazine nitrogen atom.

From the reaction of yttrium nitrate, chloride and perchlorate with 2,6-diacetylpyridine and hydrazine in 1 : 1 : 2, 1 : 2 : 4 and 1 : 3 : 6 molar ratios of starting materials, the yellow air-stable complexes of 2,6-diacetylpyridinedihydrazone (L^3) were isolated. They are formulated as $[YL^3(NO_3)_3]\cdot 2H_2O$, $[YL_2^3]Cl_3\cdot 2H_2O$ and $[YL_2^3](ClO_4)_3\cdot 2H_2O$.

The IR spectra of these complexes were analysed in comparison with that of the free ligand, which was prepared and described previously.[10] These three complexes all give very similar spectra except for anion and water vibrational modes, but they are different from the spectra of the free ligand. The C=N absorption band observed in the spectrum of the ligand at 1600 cm^{-1} is shifted by 50–60 cm^{-1} to lower wavenumbers upon complexation, suggesting the involvement of the nitrogen lone pair in coordination with the yttrium ion. The N—N frequency found at 1150 cm^{-1} in the free ligand, increased by 50 cm^{-1} in the complexes. It may be explained by the coordination of one of the nitrogen atoms from each N—N bond to the metal.[11] Bonding of the pyridine nitrogen atom is shown by the increase in frequency of higher and lower energy pyridine ring vibrations (1570, 950, 640, 400 cm^{-1}) by about 20–45 cm^{-1} in the complexes. The non-bonding of the NH_2 nitrogen atom is confirmed by the persistence of the NH_2 vibration occurring at 1635 cm^{-1} in the free ligand, and the shifting of the antisymmetric and symmetric stretching vibrations of the NH_2 groups from 3360 and 3200 cm^{-1} to higher frequencies in the metal complexes. The weak absorption band at 375–385 cm^{-1} may be assigned to the metal–nitrogen stretching vibrations.

The ^1H NMR spectra of these complexes indicate the bonding mode discussed above, showing a small downfield shift of the methyl and pyridine proton resonances from δ 2.25 and 7.82, respectively, in the free ligand, to δ 2.32–2.38 and δ 8.12–8.25 in the complexes.

The broad diffuse band in the 3600–3500 cm^{-1} region is observed for all these complexes and is assigned to the stretching and bending modes for lattice water. The thermogravimetric analysis in-

dicates for yttrium complexes of 2,6-diacetylpyridinedihydrazone, loss of two molecules of water at 30–60°C.

The spectra of the chloride and perchlorate complexes of L^3 do not show absorption bands characteristic of coordinated counterions. An IR absorption attributable to the ClO_4^- anion occurs as unsplit bands at 1100 and 626 cm^{-1}. The spectrum of the yttrium nitrate complex of L^3 indicates the presence of the nitrato groups coordinating in a bidentate fashion by the appearance of two bands at 1310 and 1480 cm^{-1}, instead of one band at 1390 cm^{-1} typical for ionic nitrates.

The electronic spectra of L^3 complexes of yttrium recorded in acetonitrile, show similar features and contain intense and medium absorption bands with maxima at 285–287 nm and 352–360 nm. The free ligand shows an intense band at 273 nm with a shoulder at 305 nm. The differences between the spectra of the complexes and free ligand can be attributed to the metal–ligand interaction.

On the basis of available evidence, it can be concluded that 2,6-diacetylpyridinedihydrazone acts as a terdentate NNN donor ligand. The stoichiometry of the complexes depends on the type of counterion. The coordination number of six is assigned for the yttrium complex of hydrazone with non-coordinating chlorides and perchlorates, assuming that the coordination sphere is filled by two molecules of ligand. With the small but strongly coordinating nitrates as counterions, the yttrium forms a complex with a 1 : 1 metal to hydrazone ratio, and the coordination number of nine is achieved by the incorporation of three bidentate nitrato groups into the coordination sphere.

ACCELERATION OF LIGAND EXCHANGE BY COORDINATED NITRATE IN POLYPYRIDYL RUTHENIUM COMPLEXES

JERRY L. WALSH* and CREGG C. YANCEY†

Department of Chemistry, University of North Carolina at Greensboro, Greensboro, NC 27412, U.S.A.

(*Received* 19 *September* 1988; *accepted* 30 *November* 1988)

Abstract—The rate of substitution of L by a chloride ion or acetonitrile in *cis*-$[Ru(bpy)_2(L)(X)]^+$ (X = NO_3; L = pyridine, acetonitrile; bpy = 2,2′-bipyridine) in low polarity solvents, is greatly enhanced over the rates observed for complexes with X = Cl, NO_2, CF_3CO_2 and *p*-$CH_3C_6H_4SO_3$. For X = NO_3, rate constants and a mechanism for formation of the final product, *cis*-$Ru(bpy)_2Cl_2$ or *cis*-$[Ru(bpy)_2(CH_3CN)_2]^{2+}$, are presented. The rate enhancement for the nitrato complex is attributed to its ability to act as a bidentate ligand.

The influence of non-exchanging ligands on the rate of ligand substitution in coordination complexes has been studied extensively.[1] Often the influence can be related to the effect of donor or acceptor properties of the non-exchanging ligand on the electronic nature of the metal centre. The thermal and photochemical substitution reactions of polypyridyl ruthenium complexes are usually predictable and well-behaved, exhibiting trends expected in comparison to other systems.[2–4] In general, ruthenium(II) and ruthenium(III) complexes are relatively inert.[3] Facile ligand exchange occurs thermally only for solvent complexes, especially oxygen donor solvents, and complexes with weakly coordinating anions in polar solvents.[2]

The facile substitution of nitrato ligands of the complexes, $[Ru(bpy)_2(L)(NO_3)]^+$ (L = CH_3CN, pyridine (py); bpy = 2,2′-bipyridine), by anions in low polarity solvents is described here. However, surprisingly, the nitrato ligand induces rapid substitution of relatively inert ligands, such as acetonitrile and pyridine, in the subject complexes.

EXPERIMENTAL

Ruthenium complexes were prepared by literature methods.[4–6]‡ Acetonitrile and dichloromethane were purified by standard methods.[7] Other chemicals were reagent grade and used as received.

Spectral and kinetic data were obtained on a Varian DMS-100 spectrophotometer equipped with a thermostatable, programmable multicell holder and a Houston Model 164 recorder; temperature was controlled with a Neslab RTE-8 bath/circulator. Cyclic voltammetry experiments were performed with a Bioanalytical Systems model CV-1B analyzer using electrolyte solutions of 0.1 M tetraethylammonium perchlorate in acetonitrile, or 0.2 M tetrabutylammonium hexafluorophosphate in dichloromethane. All manipulations were performed under reduced light conditions because of the light sensitivity of these compounds.[4]

Rate constants at 25.0 ± 0.2°C were determined from absorbance (A) vs time (t) data taken from recorded spectra at appropriate wavelengths. Data showed that all reactions were first-order in ruthenium complex for two or more half-lives. Linear least-squares fitting at $\ln(A - A_0)$ vs t was used to obtain first-order rate constants. Where consecutive reactions occurred, the rate constants were different enough to avoid interference when data was carefully selected. Reported rate constants are the average of three or more trials with a typical standard deviation of < 20% of the reported values.

For the reaction of $[Ru(bpy)_2(py)(NO_3)]^+$ with Cl^-, the infinity values for runs with less than a stoichiometric amount of chloride were obtained

‡ Spectral analyses suggest that all ruthenium complexes involved are in the *cis* configuration.

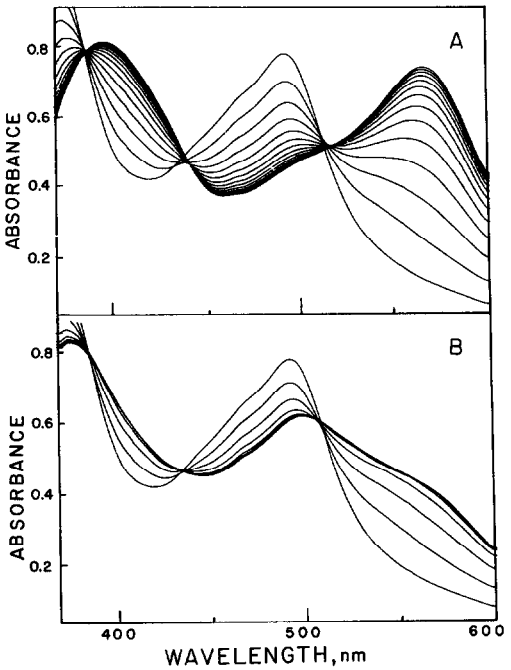

Fig. 1. Reaction of *cis*-$[Ru(bpy)_2(py)(NO_3)]^+$ with chloride ion in acetone at 25°C, recorded at 44 min intervals. Concentration of *cis*-$[Ru(bpy)_2(py)(NO_3)]^+ = 1.2 \times 10^{-4}$ M. (A) $[Cl^-] = 4.8 \times 10^{-4}$ M; (B) $[Cl^-] = 0.96 \times 10^{-4}$ M.

from identical runs with more than the stoichiometric amount of chloride, such that the infinity values are those expected for complete transformation to $Ru(bpy)_2Cl_2$. In doing so, the data fit first-order behaviour very well.

RESULTS

When tetrabutylammonium chloride is added to dichloromethane or acetone solutions of $[Ru(bpy)_2(py)(NO_3)]^+$, the solution spectrum (Fig. 1) changes smoothly from that of the nitrato complex ($\lambda_{max} = 486$ nm) to that of $Ru(bpy)_2Cl_2$ ($\lambda_{max} = 562$ nm), with isosbestic points at 365, 422 and 510 nm. This suggests that the one step transformation shown in the following equation has occurred.

$$[Ru(bpy)_2(py)(NO_3)]^+ + 2Cl^- \longrightarrow Ru(bpy)_2Cl_2 + py + NO_3^-.$$

The reaction is first-order ($k = 7.3 \times 10^{-5}$ s^{-1} at 25.0°C) in ruthenium complex but zero-order in chloride. An interesting feature of the reaction kinetics is that with less than a 1:2 mole ratio of ruthenium to chloride, the spectral changes follow typical first-order behaviour until all chloride is depleted. The reaction then comes to an immediate halt [Fig. 1(B)]. The reaction is not influenced by elimination of atmospheric oxygen, the presence of hydroquinone or ascorbic acid as reducing agents, by solvent purification, or by use of different samples of the ruthenium complex. Under the same conditions, $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ reacts extremely rapidly with the chloride ion and two well separated steps are observable. The first is complete on an ordinary mixing time scale, giving an intermediate with $\lambda_{max} = 535$ nm. This species reacts more slowly with chloride by a first-order reaction ($k = 3.0 \times 10^{-4}$ s^{-1} at 25°C) to give $Ru(bpy)_2Cl_2$. With more polar solvents, like ethanol, solvolysis of the nitrato ligand occurs rapidly and $[Ru(bpy)_2(L)(S)]^{2+}$ (S = solvent) and/or $[Ru(bpy)_2(L)Cl]^+$ are obtained as the products.

Other anions, such as Br^- and SCN^-, substitute similarly to chloride giving $Ru(bpy)_2X_2$ (X = Br, SCN) as final products. Related complexes, $[Ru(bpy)_2(py)(X)]^+$ (X = Cl, *p*-$CH_3C_6H_4SO_3$, CF_3CO_2, NO_2) are unreactive or at least much less reactive ($t_{1/2} > 5$ days) than the nitrato complex under the same conditions.

The reaction of $[Ru(bpy)_2(L)(NO_3)]^+$ (L = CH_3CN, py) with chloride in acetonitrile solution yields a mixture of products but, in pure acetonitrile, $[Ru(bpy)_2(CH_3CN)_2]^{2+}$ ($\lambda_{max} = 425$ nm) is the observed product. For L = CH_3CN, a one step reaction is observed. With L = py, two steps are observed (Fig. 2) with an intermediate which has a spectrum very similar to that of $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ in acetonitrile. The rate of the first step ($k = 7.2 \times 10^{-5}$ s^{-1}) is identical to that for chloride substitution. The rate at which the intermediate is transformed to $[Ru(bpy)_2$

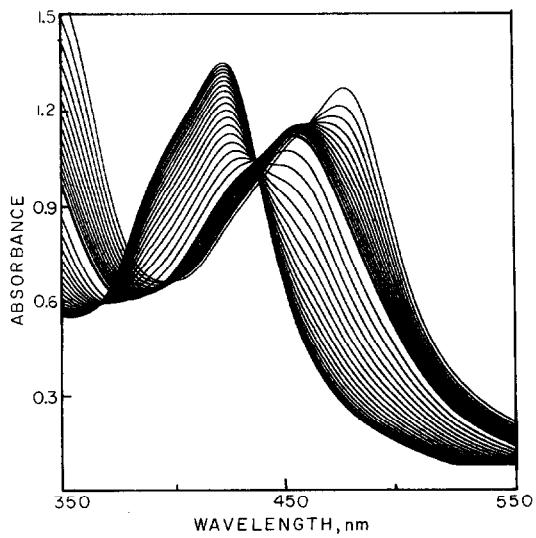

Fig. 2. Reaction of *cis*-$[Ru(bpy)_2(py)(NO_3)]^+$ with acetonitrile solvent at 25°C, recorded at 30 min, then 120 min intervals.

$(CH_3CN)_2]^{2+}$ is the same as for $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ ($k = 7.5 \times 10^{-6}$ s^{-1}).

Each of the above reactions was also monitored by cyclic voltammetry.* All species involved exhibit at least pseudo-reversible behaviour. The cyclic voltammetry results confirmed the spectral analyses. Reaction of $[Ru(bpy)_2(py)(NO_3)]^+$ ($E_{1/2} = 0.94$ V) with chloride in dichloromethane, showed a one step transformation to $Ru(bpy)_2Cl_2$ ($E_{1/2} = 0.36$ V). The same reaction for $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ exhibits an intermediate ($E_{1/2} = 0.56$ V) which then reacts to form $Ru(bpy)_2Cl_2$ at rates consistent with spectral data. In acetonitrile, $[Ru(bpy)_2(py)(NO_3)]^+$ reacts to form an intermediate ($E_{1/2} = 0.98$ V) which then produces $[Ru(bpy)_2(CH_3CN)_2]^{2+}$ ($E_{1/2} = 1.41$ V). In this case, a second product, probably $[Ru(bpy)_2(py)(CH_3CN)]^{2+}$ ($E_{1/2} = 1.3$ V) is observed, possibly the result of the higher ruthenium complex or supporting electrolyte concentration used for cyclic voltammetry compared to spectral analysis. A one step reaction is observed for the reaction of $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ ($E_{1/2} = 0.98$ V) with acetonitrile to form $[Ru(bpy)_2(CH_3CN)_2]^{2+}$ ($E_{1/2} = 1.41$ V).

In pure dichloromethane or acetone, $[Ru(bpy)_2(py)(NO_3)]^+$ is stable for days. However, $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$ is reasonably stable in acetone but a significant amount of green oxo-bridged species is formed in a matter of hours in dichloromethane. Chloride ion substitution into $[Ru(bpy)_2(py)(H_2O)]^{2+}$ in acetone occurs in a reaction which is first-order in complex and zero-order in chloride ($k = 1.0 \times 10^{-3}$ s^{-1}).

DISCUSSION

The nitrato complexes $[Ru(bpy)_2(L)(X)]^+$ (L = py, CH_3CN; X = NO_3) undergo relatively rapid ($t_{1/2} < 200$ min) ligand exchange, as shown in the following equation,

$$[Ru(bpy)_2(L)(NO_3)]^+ + 2L' \longrightarrow [Ru(bpy)_2(L')_2]^{n+} + L + NO_3^-$$

[L = py, CH_3CN; L′ = Cl ($n = 0$); L′ = CH_3CN ($n = 2$)],

whereas, similar species (L = py; X = Cl, NO_2, CF_3CO_2, p-$CH_3C_6H_4SO_3$) are unreactive, showing little to no reaction in 5 days. The spectral data and kinetic results are consistent with the mechanism shown in Scheme 1.

$$[Ru(bpy)_2(L)(NO_3)]^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{I} + L \quad (1)$$

$$\mathbf{I} + L' \xrightarrow{k_2} [Ru(bpy)_2(L')(NO_3)]^+ \quad (2)$$

$$[Ru(bpy)_2(L')(NO_3)]^+ + L' \xrightarrow{k_3} [Ru(bpy)_2(L')_2]^{2+} + NO_3^- \quad (3)$$

Scheme 1.

Reaction (1) represents reversible formation of a short-lived intermediate, **I**. No net reaction occurs for $[Ru(bpy)_2(py)(NO_3)]^+$ when L′ is absent. For L = CH_3CN, **I** may provide a pathway for decomposition to oxo-bridged products as well as substitution. When L′ is present, reaction (1) becomes rate-controlling as **I** reacts rapidly with L′. The rate of this reaction depends on the identity of L but very little on L′. For L = py, k_1 (L′ = Cl) is 7.3×10^{-5} s^{-1} and k_1 (L′ = CH_3CN) is 7.2×10^{-5} s^{-1}. For L = CH_3CN, k_1 is very fast. For L = py and L′ = Cl, k_2 and k_3 are presumably greater than k_1, so only starting complex and final product are spectrally observable. For L = CH_3CN and L′ = Cl, k_1 and k_2 are greater than k_3, so the intermediate, $Ru(bpy)_2(Cl)NO_3$, accumulates during the reaction.

For acetonitrile substitution (L′ = CH_3CN), k_3 is slower than for chloride substitution, probably a reflection of the charge effect in low polarity solvent. In this case, steps (1) and (2) lead to no net reaction for L = CH_3CN. For L = py, steps (1) and (2) lead to the formation of $[Ru(bpy)_2(CH_3CN)(NO_3)]^+$, which then undergoes the same transformation as when this species is the starting material.

The question arises as to what feature of the nitrato ligand leads to such facile substitution of pyridine and acetonitrile in $[Ru(bpy)_2(L)(NO_3)]^+$. Since the spectral properties of $[Ru(bpy)_2(py)(NO_3)]^+$ are very similar to those of the other $[Ru(bpy)_2(py)(X)]^+$ complexes,[4] the electronic nature of the ruthenium centre in the ground state reactants appears to be similar. The rates of various reactions would be consistent with solvation of the nitrato ligand followed by anation. However, the products are not the same for the nitrato reaction as for reaction of the aquo complex. Thus, this reaction pathway can be ruled out.

Two features which distinguish nitrate from the other X ligands are its ability to act as a bidentate ligand and its behaviour as an oxidizing agent. Nitrate has been shown to be capable of oxidizing $[Ru(bpy)_2(py)(H_2O)]^{2+}$ in aqueous acidic solution.[8] Thus, a short-lived ion-paired redox species, such as $[Ru(bpy)_2(L)(O)^{2+},NO_2^-]$, may be generated. Ion pairing is undoubtedly important in the low polarity

* Reduction potentials differ by small amounts from literature values due to differences in solvent and/or added electrolyte.

solvents used. Following substitution by L′, recombination of the oxo moiety with NO_2^- would lead to the net substitution observed, including the absence of oxidized products. Substitution reactions carried out by redox intermediates are quite common in coordination chemistry.[9] Many are characterized by unusual kinetic features,[2c,9] but the net process involves unusually rapid substitution. The lack of influence by reducing agents and what appears to be a reasonably robust[5] coordination sphere in $[Ru(bpy)_2(py)(O)]^{2+}$ would argue against this mechanism.

Although nitrite and trifluoroacetate may behave as bidentate ligands, the tendency of these and other X ligands to do so is less than that of nitrate.[10] With the relatively small bite angle of the nitrato ligand, the monodentate nitrato ligand of $[Ru(bpy)_2(py)(NO_3)]^+$ may bind to produce a pseudo-seven coordinate transition state. Loss of L and formation of a bidentate nitrato ligand leads to a six coordinate intermediate, **I**. The intermediate would then accept L′ to generate $[Ru(bpy)_2(L')(NO_3)]^+$. A strongly ion-paired chloride or an acetonitrile from the solvent cage is readily available for coordination. Further substitution of the nitrato ligand by L′ would give the final product. Other examples[11,12] of nitrate acceleration of *cis* ligand substitution have been reported for chromium(III)–amine and cobalt(III)–amine and –oxalato complexes. It is not obvious in all cases that a nitrato ligand in the coordination sphere of the metal is the active species.[12] When coordinated nitrate is thought to be present, a chelating mechanism similar to that proposed for **I** in Scheme 1 was proposed. In the present case, there appears to be no doubt that nitrate is coordinated during L substitution, since it remains in the coordination sphere after L substitution, and the presence of coordinated nitrate accelerates the rate of L substitution.

In summary, the nitrato ligand induces significant labilization of the ligands *cis* to it in *cis*-$[Ru(bpy)_2(L)(NO_3)]^+$ complexes. A three step mechanism, involving an intermediate which is extremely susceptible to ligand addition, leads to facile substitution of the nitrato ligand and its neighbour.

(*Received* 25 *July* 1988; *accepted* 12 *December* 1988)

Abstract—On investigating the relation between optical activity of aminocarboxylato cobalt(III) complexes and aminocarboxylato chelate ring conformation, it was found that the diastereomers of *cis*(NO_2),*trans*(NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt(III) exhibit almost symmetrical circular dichroic (CD) spectra, indicating a weak vicinal and conformational contribution of the *R*-alaninato ligand to the optical activity of the diastereomers. The crystal structure analyses revealed that in both diastereomers, the *R*-alaninato chelate ring adopts a strained envelope conformation, with the side methyl group in an equatorial position.

The vicinal contribution of the diastereomers of aminocarboxylatocobalt(III) complexes to the optical activity has been considered as an important one, while the conformational effect of an α-aminocarboxylato ring was considered to be of little importance.[2] However, we have recently shown[1] that in the complexes containing bulky nitro ligands, unequal steric constraints imposed on aminocarboxylato chelates in a diastereomeric pair produce quite different conformations of the chelates, which are reflected in different conformational and vicinal contributions to the optical activity. Specifically, we have established that in the Λ-*cis*(NO_2),*trans*(NH_2)-bis(*S*-aminocarboxylato)dinitrocobaltate(III) diastereomers, the δ-envelope conformation of a chelate ring and the equatorial position of the corresponding ring

† For part I, see ref. 1.

‡ Author to whom correspondence should be addressed.

side group result in a weak conformational and vicinal contribution to the optical activity. Contrary to this, in the Δ-isomer the λ-twist conformation of an *S*-aminocarboxylato chelate ring and the axial position of the corresponding ring side group induce a considerably greater contribution to the optical activity. Hence, the aminocarboxylato chelate ring conformation is of utmost importance for the optical activity of diastereomers. Therefore, we are now undertaking extensive examination of the influence of the aminocarboxylato chelate ring conformation on the optical activity of cobalt(III) complexes. In the investigation we are dealing with mixed ligand complexes which contain, in addition to an aminocarboxylato chelate, sterically demanding ligands. Such ligands are expected to force the aminocarboxylato ring to adopt a strained conformation, the geometry of which is then reasonably insensitive to intermolecular interactions. This is very necessary when the solution optical activity is going to be related to the conformation of a chelate in a solid complex.

In the present work we are investigating the *cis* (NO_2),*trans*(NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt(III) diastereomers which contain sterically demanding nitro and 1,3-diaminopropane ligands. These complexes are closely related to the previously examined *cis*(NO_2),*trans* (NH_2)-bis(aminocarboxylato)dinitrocobaltate(III) complexes,[1] but in the former ones a greater strain is expected to be exerted on the aminocarboxylato chelate. To establish the chelate rings conformations, we have undertaken the crystal structure determination of Λ-*cis*(NO_2),*trans* (NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt(III) dihydrate. The crystal structure of the corresponding Δ-isomer has been reported by us earlier.[3]

RESULTS

Optical activity

CD spectra in the region of the first *d–d* transition of the investigated diastereomers are presented in Fig. 1. For comparison, CD spectra of the related bis(*R*-alaninato) and bis(1,3-diaminopropane) complexes are also given. It is seen that by substituting one *R*-alaninato ligand by 1,3-diaminopropane in the *cis*(NO_2),*trans*(NH_2)-bis(*R*-alaninato)dinitrocobaltate(III) diastereomers, the optical activity of the resulting isomers is considerably reduced and the corresponding CD curves become almost symmetrical.

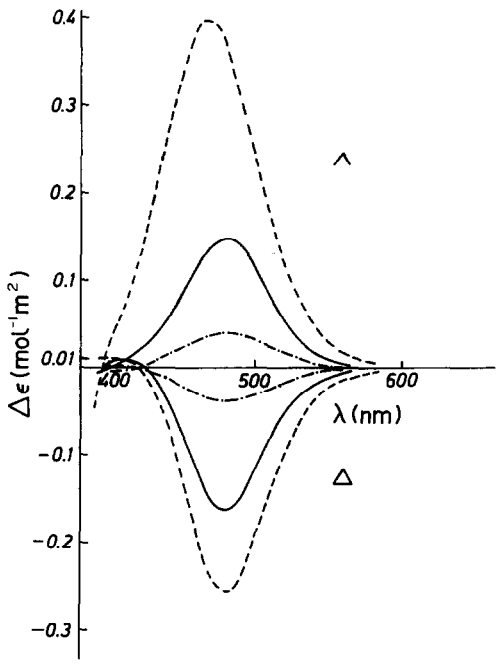

Fig. 1. CD spectra of the Λ- and Δ-isomers of the *cis*(NO_2),*trans*(NH_2)-$[Co(NO_2)_2(R\text{-ala})_2]^-$ (– – –), *cis* (NO_2),*trans*(NH_2)-$[Co(NO_2)_2(R\text{-ala})(tn)]$ (——) and *cis* (NO_2)-$[Co(NO_2)_2(tn)_2]^+$ (– · – · –) complexes.

Crystal structure

The crystal structure of Λ-*cis*(NO_2),*trans*(NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt (III) dihydrate consists of discrete neutral complex molecules and water molecules, joined together by the system of O—H···O and N—H···O weak hydrogen bonds. An ORTEP drawing of the complex molecule with the numbering scheme of the atoms is given in Fig. 2. Bond distances and angles are given in Table 1. Atomic coordinates, anisotropic thermal parameters, intermolecular contacts involving hydrogen atoms, and observed and calculated structure factors are presented as supplementary material.

The geometry of the complex molecule is in agreement with previously reported data for related complexes.[3,4] All the bond lengths and angles in the coordination polyhedron of cobalt(III), as well as in the *R*-alaninato and 1,3-diaminopropane ligands, are unexceptional. The same holds for the nitro groups. The angle between the least-squares mean planes through the cobalt atom and the corresponding nitro group is 106°. The Co—NO_2 distance *trans* to the carboxylato oxygen is significantly shorter than this one *trans* to an amino group, in accordance with our previous observations of π-bond participation in NO_2-bonding in cobalt(III) complexes.[5]

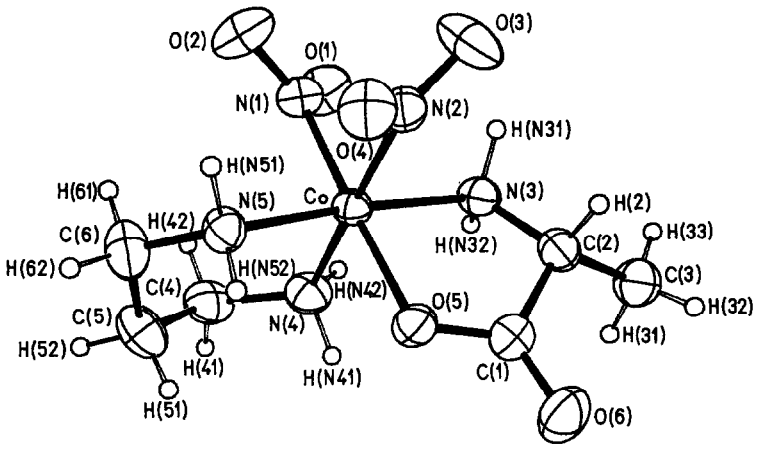

Fig. 2. ORTEP drawing of the complex molecule with the atomic numbering scheme.

The conformation of *R*-alaninato five-membered and 1,3-diaminopropane six-membered rings, expressed by the relevant conformational parameters,[6] are given in Table 2. The analysis of these data shows that *R*-alaninato chelate adopts the λ-envelope conformation, with the methyl group in the equatorial position. The same conformation of the *R*-alaninato chelate was found earlier in the Δ-diastereomer.[3]

Due to the strong repulsion between 1,3-diaminopropane and the methyl group from the *R*-alaninato ligand, the conformation of the 1,3-diaminopropane ring in the investigated Λ-isomer is a distorted highly strained chair.

DISCUSSION

From the crystal structures of the two diastereomers, it can be seen that the *R*-alaninato che-

late ring adopts a strained λ-envelope conformation in both. This is a consequence of the repulsion of the *R*-alaninato methyl group from the nitro group in the Δ-isomer, and from 1,3-diaminopropane in the Λ-isomer. Hence, the nitro group and 1,3-diaminopropane ligands have fixed the amino-carboxylato chelate ring conformations. This gave the opportunity for the interpretation of the solution CD spectra on the basis of the crystal structures.

CD spectra of the examined diastereomers could be well explained by means of the Quadrant Rule for the conformational and vicinal contributions to the optical activity of octahedral complexes.[7] According to the rule, the *R*-alaninato λ-envelope conformation is expected to induce a weak negative contribution to the optical activity, as it may be concluded from Fig. 3. 1,3-Diaminopropane adopts different conformations in the two diastereomers. In the investigated Λ-isomer the conformation is a highly strained distorted chair, while in the Δ-isomer it is an almost ideal chair. However, according to the same rule, no significant conformational contribution to the optical activity is expected (Fig. 3). Therefore, almost symmetrical CD spectra of the diastereomers are observed, with only slightly stronger negative dichroism of the Δ-isomer, due to the *R*-alaninato λ-envelope chelate conformation.

Especially interesting is the large change of the optical activity when in the Λ-*cis*(NO_2),*trans*(NH_2)-bis(*R*-alaninato)dinitrocobalt(III) diastereomers one *R*-alaninato ligand is substituted by 1,3-diaminopropane (Fig. 1), which is connected with the change of the *R*-alaninato conformation from the

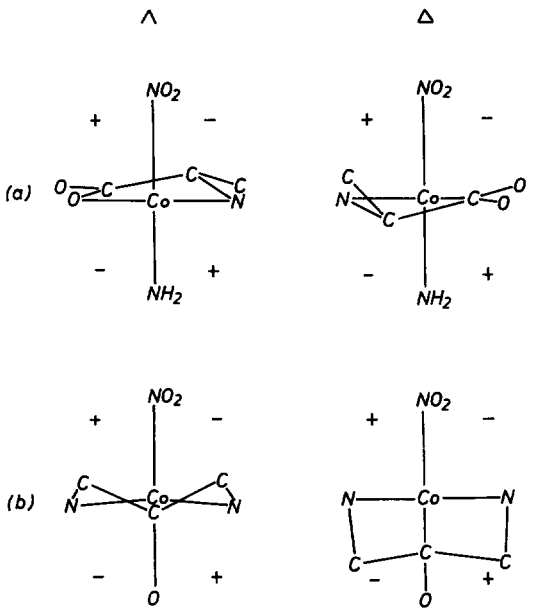

Fig. 3. Skeletal atom projection of the *R*-alaninato (a) and 1,3-diaminopropane (b) ligands in the investigated isomers according to the Quadrant Rule for ligand conformational and vicinal contributions to the optical activity of octahedral complexes.

δ-twist to λ-envelope one. This is in accordance with the findings in our previous paper,[1] in which we have concluded that the λ-twist conformation of an *S*-aminocarboxylato chelate ring induces a large negative contribution to the optical activity, or consequently, by symmetry, that the δ-twist conformation of the *R*-alaninato aminocarboxylato chelate ring has a large positive contribution.

In the Λ-isomer the λ-envelope conformation of the *R*-alaninato chelate ring is preserved upon the substitution of an *R*-alaninato by a 1,3-diaminopropane ligand, and the resulting optical activity of the Λ-*cis*(NO_2),*trans*(NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt(III) isomer is an almost average value of those in the corresponding bis(*R*-alaninato) and bis(1,3-diaminopropane) complexes (Fig. 1).

EXPERIMENTAL

Preparation

Λ-*cis*(NO_2),*trans*(NH_2)-(*R*-alaninato)(1,3-diaminopropane)dinitrocobalt(III) dihydrate was obtained by the procedure previously described by us.[3]

CD spectra

Spectra of the investigated complexes were recorded by a JASCO Dichrograph Model 500 A, using 2×10^{-3} M aqueous solutions.

X-ray analysis

The specimen used for X-ray crystal structure analysis was an orange crystal of dimensions $1.08 \times 0.52 \times 0.68$ mm. All measurements were made at room temperature (~ 22°C) with Mo-K_α radiation, $\lambda = 0.71069$ Å, on an Enraf–Nonius CAD 4F diffractometer equipped with a graphite monochromator.

Crystal data: $[Co(NO_2)_2(C_3H_6NO_2)(C_3H_{10}N_2)] \cdot 2H_2O$, $M_r = 349.2$; orthorhombic; space group $P2_12_12_1$; $a = 9.369(1)$, $b = 10.567(1)$, $c = 14.231(1)$ Å; $U = 1408.9(2)$ Å^3; $Z = 4$; $D_o = 1.56$, $D_c = 1.657$ g cm^{-3}; $F(000) = 728$; μ(Mo-K_α) = 12.57 cm^{-1}.

Unit cell dimensions were determined by a least-squares fit to the setting angles of 23 reflections with $13 < \theta < 17°$. The space group was determined from the systematic absences and confirmed by the shape of a Patterson function and structure analysis.

The intensities of 4447 reflections with $2 < \theta < 30°$ were measured from θ–2θ scans of $(0.80 + 0.35 \tan\theta)°$ in θ, and background was estimated by extending the scans of both ends by 25%. The scans speeds were adjusted to give $\delta I/I > 0.03$ subject to a time limit of 90 s. A standard reflection remeasured every 2 h showed a continuous drop in intensity, amounting to 17% at the end of data collection. All reflections in the h range from −13 to 13, k from 0 to 14 and l from 0 to 20 were measured. Corrections were made for decomposition, Lorentz polarization and absorption effects, the latter by an empirical method,[8] which gave transmission factors on F of 0.84–1.38. Rejecting systematic absences and merging duplicate measurements gave 4082 hkl and $\bar{h}kl$ structure amplitudes, $I \geqslant \sigma(I)$, which were used in subsequent calculations.

The structure was solved by Patterson and difference Fourier methods and refined by full-matrix least-squares, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(|F_o|)$. After isotropic refinement of all non-hydrogen atoms, the structure amplitudes were calculated for values of polarity factor, η,[9] 1 and −1, giving R factors of 0.082 and 0.089, respectively. The model of the correct absolute configuration, which was also in accordance with the configuration deduced from the configuration of *R*-alanine, was further refined. The hydrogen atoms of the complex molecule were included in the structural model in the calculated positions, with C—H and N—H bonds of 0.96 Å, while those belonging to the water molecules were calculated at the positions from the difference Fourier map. All hydrogen atoms were allowed to ride on the atoms to which they are bonded, with $U(H) = 1.2U$ of the corresponding atom. The refinement of 183 parameters including the polarity factor, η, and extinction coefficient, r^*, defined by Larson,[10] converged at $R = 0.041$ and $R_w = 0.047$, with $\eta = 1.04(3)$ and $r^* \times 10^{-3} = 0.72(7)$, and the largest parameter/shift error ratio was 0.05. In the final difference electron density synthesis, the function values varied from −0.47 to 0.54 e Å^{-3}, with most of the largest positive peaks situated in the vicinity of the cobalt atom. Neutral atom scattering factors and complex anomalous dispersion corrections were taken from ref. 11.

All calculations were performed on a GOULD SEL 32/27 minicomputer using the GX program package.[12]

Abstract—Electronegativity of atoms, based on Allred and Rochow's method, has been re-estimated by calculating the effective nuclear charge by using the experimental values of the binding energies of the inner and valence states obtained from X-ray photoelectron spectroscopic data. The present method has the advantage that no arbitrary method of determining the screening constants is involved.

Pauling[1] originally defined electronegativity as "the power of an atom in a molecule to attract electrons to itself", and also set up its relative scale based on bond energies from thermochemical data. Several other workers have also correlated electronegativity with different atomic or molecular properties and have given a quantitative measure of it by several empirical relations based on ionization potential and electron affinity,[2] bond order,[3] bond stretching force constants,[4] stability ratio,[5] electrostatic force and covalent radius,[6] molecular orbital,[7] and dipole moment,[8] etc. The concept of electronegativity has been of considerable help in the calculation of a number of important parameters, such as partial ionic character of bonds,[9] effective charge per atom,[10,11] equilibrium length of polar bonds[12] and ionicity,[13] etc.

A scale of electronegativity based on the force of electrostatic attraction between the nucleus and an electron from a bonded atom has been constructed by Allred and Rochow.[6] This force of electrostatic attraction at the electron due to the nucleus and other surrounding electrons is given by

$$F = \frac{e}{r} Z_{\text{eff}} \qquad (1)$$

where r represents the distance between the electron and the nucleus and eZ_{eff} is the charge which is effective at the electron due to the nucleus and its surrounding electrons. The effective nuclear charge is always less than the actual nuclear charge due to the screening by the other electrons in the atom. Allred and Rochow[6] have made use of Slater's rule,[14] for determining the value of the screening constant and have thus estimated the $Z_{\text{eff}} = [Z - \sigma]$.

The effective force F, given by eq. (1), is an approximate measure of the extent to which an atom in a molecule attracts electrons to itself, and hence it was proposed as a measure of the absolute electronegativity of an atom. The electronegativity scale due to Allred and Rochow,[6] and that of Pauling, bear the following relation

$$Xp = a + b\frac{Z_{\text{eff}}}{r} \qquad (2)$$

where $a = 0.744$ and $b = 0.35$.

Mande and Damle[15,16] have pointed out that though the assumption of Allred and Rochow[6] is reasonable, their electronegativity values do not always compare very well with the values of Pauling, which are based on experimental values of thermochemical data. The reason for this disagreement, is because they have calculated the effective nuclear charge or screening constant by Slater's[14] method, which is simply an empirical method.

* Author to whom correspondence should be addressed.

Mande and Damle[15,16] have given a method for calculating the effective nuclear charges for different inner shells with the help of experimental X-ray term values and Dirac's relativistic equation.[17] According to Schiff,[17] the total relativistic energy of an electron in any orbital is given by

$$E = mc^2\left[1+\frac{\gamma^2}{(s+n')^2}\right]^{-1/2} \tag{3}$$

where

$$\gamma = \frac{Ze^2}{\hbar c} = \alpha Z, \quad \alpha = \frac{e^2}{\hbar c}$$

$$= \text{fine structure constant}, \tag{4}$$

where $n = n' + |k|$ = total quantum number.

$$s = \sqrt{k^2-\gamma^2} = \sqrt{k^2-\alpha^2Z^2} \tag{5}$$

and

$$k = l(l+1)-j(j+1)-1/4$$

$$= -l-1 \quad \text{for } j = l+1/2$$

$$= l \qquad \text{for } j = l-1/2. \tag{6}$$

Thus from eq. (6) for the $s_{1/2}$ term, $l = 0, j = 1/2$, $k = -1$, for the $p_{1/2}$ term, $l = 1, j = 1/2, k = 1$, for $p_{3/2}$, $l = 1$, $j = 3/2$, $k = -2$, and for $d_{3/2}$, $l = 2$, $j = 3/2, k = 2$.

Now subtracting the energy corresponding to the rest mass from eq. (3), we get

$$E = mc^2\left[1+\frac{\alpha^2Z^2}{\{(k^2-\alpha^2Z^2)^{1/2}+n-|k|\}^2}\right]^{-1/2} - mc^2.$$

Thus the energy of the electron in terms of Rydberg's constant

$$R = \frac{2me^4\pi^2}{ch^3} = \frac{\alpha^2mc}{2h}$$

is given by

$$\frac{\nu}{R} = -\frac{E}{hcR} =$$

$$-\frac{mc^2}{hcR}\left[\left\{1+\frac{\alpha^2Z^2}{\{n-|k|+(k^2-\alpha^2Z^2)^{1/2}\}^2}\right\}^{-1/2}-1\right], \tag{7}$$

but

$$\frac{mc^2}{hcR} = \frac{mc^2}{\frac{hc(\alpha^2mc)}{2h}} = \frac{2}{\alpha^2}. \tag{8}$$

Thus

$$\frac{\nu}{R} =$$

$$-\frac{2}{\alpha^2}\left[\left\{1+\frac{\alpha^2Z^2}{[n-|k|+(k^2-\alpha^2Z^2)^{1/2}]^2}\right\}^{-1/2}-1\right]. \tag{9}$$

Now introducing the screening constant, we can write Z as $[Z-\sigma]$ in eq. (9) and we get

$$\frac{\nu(nlj)}{R} =$$

$$-\frac{2}{\alpha^2}\left\{1+\frac{\alpha^2(Z-\sigma)^2}{[n-|k|+\{k^2-\alpha^2(Z-\sigma)^2\}^{1/2}]^2}\right\}^{-1/2}-\frac{2}{\alpha^2}. \tag{10}$$

Therefore, the energy of any emission line can be expressed as

$$\left(\frac{\Delta\nu}{R}\right)_{(\text{line})} = \frac{\nu(n_il_ij_i)}{R} - \frac{\nu(n_fl_fj_f)}{R}. \tag{11}$$

Let us put $|k| = j'$ and

$$K = n-|k|+\varepsilon$$

$$= n-|j'|+\varepsilon$$

where

$$\varepsilon = \sqrt{j'^2-\alpha^2(Z-\sigma)^2}.$$

Thus eq. (10) can be written as

$$\frac{\nu(n,l,j)}{R} = -\frac{2}{\alpha^2}\left\{1+\frac{\alpha^2(Z-\sigma)^2}{K^2}\right\}^{-1/2}-\frac{2}{\alpha^2}. \tag{12}$$

Mande and co-workers[16,18] have calculated $(Z-\sigma)$ for inner levels by using experimental data of X-ray spectroscopy for the ν/R term values in eq. (12), but for the valence state they have extrapolated the term values in a very crude manner to get $(Z-\sigma)$ from eq. (12) and therefore their values for the electronegativity of valence state cannot be taken as being very accurate. Their expression for electronegativity normalized to Pauling's scale is expressed by the following relation.

$$X_M = 0.778\frac{Z_{\text{eff}}}{r^2}+0.5. \tag{13}$$

In order to overcome the above mentioned shortcoming for the evaluation of the term values, we have used the binding energies of the valence states of the atoms obtained from X-ray photoelectron spectroscopic data[19] to calculate the screening constant.

To find the screening constant σ and Z_{eff}, eq. (12) has been simplified for computational convenience as

$$\sigma = Z-\sqrt{X-\frac{X^2\alpha^2}{4}}\left\{P\left(1-\frac{\alpha^2X^2}{2}\right)\right.$$

$$\left.+\sqrt{j'^2-\alpha^2p^2\left(X-\frac{X^2\alpha^2}{4}\right)}\right\}, \tag{14}$$

where Z is the atomic number of the atom concerned, $X = \nu/R$, the term values for the valence state and $p = n - |j'|$. From eq. (14) we have

$$Z - \sigma = \sqrt{X - \frac{X^2\alpha^2}{4}}\left\{P\left(1 - \frac{X^2\alpha^2}{2}\right) + \sqrt{j'^2 - \alpha^2 p^2\left(X - \frac{X^2\alpha^2}{4}\right)}\right\}. \quad (15)$$

With the help of eq. (15), Z_{eff} for atoms with Z lying in the range $1 < Z < 92$, have been computed with a computer.

The electronegativities of all those atoms for which the covalent radii[5] r are given, have been calculated by feeding the values of Z_{eff} into eq. (15) (Table 1). On calculating the electronegativities, the authors have given different values to the constants a and b, occurring in eq. (2), to fit Pauling's electronegativity values, which have been assumed by all workers to be the standard ones. The modified form of eq. (3) is as follows.

$$X = 0.77\frac{Z_{eff}}{r^2} + 0.24. \quad (16)$$

By using eq. (16), the electronegativity values of atoms have been calculated and it is found that these values are in better agreement with Pauling (Table 1).

DETERMINATION OF FORMATION CONSTANTS OF COPPER(II) DI-CARBOXYLATES WITH A SOLID STATE COPPER(II) ION-SELECTIVE ELECTRODE

C. J. COETZEE

Department of Chemistry, University of the Western Cape, Private Bag X17, Bellville, 7535, South Africa

(*Received* 14 *November* 1988; *accepted* 12 *December* 1988)

Abstract—Formation constants for 1 : 1 complexes of copper(II) with oxalate, malonate, succinate, glutarate and adipate, respectively, have been determined at 25°C and 0.10 M ionic strength using a copper(II) ion-selective electrode.

Ion-selective electrodes have attained wide acceptance for analytical and general chemical measurement purposes. One of the chief advantages of these electrodes is that they respond only to free uncomplexed ions in solution. This property makes them extremely useful as analytical tools for the study of complexes and especially for the determination of formation constants. Copper(II) ion-selective electrodes of both the liquid–liquid membrane[1] and the solid membrane[2–4] design have been successfully used for the determination of formation constants of copper(II) complexes.

Although formation constant values for a large number of copper(II) complexes are known, they were determined under a variety of conditions. In this work an Orion Cupric ion electrode Model 94-29 was used for the re-evaluation of values of formation constants of 1 : 1 complexes between the copper(II) ion and oxalate, malonate, succinate, glutarate and adipate, under controlled and comparable conditions.

EXPERIMENTAL

Copper(II) solutions were prepared by the treatment of excess basic copper(II) carbonate (Merck extra pure) with a perchloric acid solution (Merck G.R.). After double filtration the solutions were diluted with distilled water obtained from an all-glass still, standardized and diluted to suitable volumes. Sodium perchlorate monohydrate, oxalic and succinic acid (Merck G.R.) were used as such, malonic acid (Merck LAB), glutaric acid (Merck ORG) and adipic acid (Merck) were twice recrystallized from water. The experimental procedure was carried out as follows: potentiometric measurements were made at 25±0.5°C using the electrochemical cell:

Cu^{2+} electrode / sample solution / saturated calomal electrode. (Beckman 39170)

EMF values were measured with a Beckman Research model pH-meter. Prior to equilibria measurements, the copper(II) electrode was calibrated by means of standard copper(II) solution prepared in sodium perchlorate medium to give an ionic strength of 0.10 M. The cell EMF is given by $E = E^{\ominus} + 0.0296 \log a_{Cu}$. The electrode gave a linear response between pCu values of 2 and 4.8. Because $E^{\ominus}$ varied from time to time, the calibration of the electrode was checked before each set of equilibrium measurements were made.

The equilibrium concentration of the free copper ion in solution was measured at a constant pH of 6 and constant ionic strength of 0.10 M after mixing appropriate volumes of solutions of a known concentration of copper ion and ligand. The pH of the solutions was adjusted by means of sodium hydroxide or perchloric acid solutions which were also 0.10 M in sodium perchlorate.

The formation constant K for the reaction $Cu^{2+} + L^{2-} \rightleftharpoons CuL$ is given by the equation

$$K = \frac{[CuL] f_{CuL}}{[Cu^{2+}][L^{2-}] f_{Cu} f_{L}}.$$

In order to calculate the K values the following must be taken into consideration. At pH 6, the copper ion in solution is hydrolysed to a certain

extent according to the reaction $Cu^{2+}+H_2O \rightleftharpoons Cu(OH)^{+}+H^{+}$. By using the known value of the hydrolysis constant[5] the calculated ratio of $[Cu(OH)^{+}]/[Cu^{2+}]$ at pH 6 is found to be equal to 0.3388, which implies that about 25% of the free copper ions in solution are hydrolysed. This has to be taken into account and cannot be ignored as in a previous study.[1] At pH 6 the ligands being diprotic carboxylic acids will also be protonated to a certain extent. The free $[L^{2-}]$ can be calculated using their respective pK_1 and pK_2 values.[6,7] The values $[Cu^{2+}]_e$, [CuL] and $[L^{-2}]$ which were used to calculate the formation constant K, were calculated as follows:

$$[Cu^{2+}]_e = \text{measured directly by potentiometry}$$

$$[CuL] = [Cu^{2+}]_{total} - 1.3388[Cu^{2+}]_e$$

$$[L^{2-}] = [L^{2-}]_{total} - [CuL] - [HL^{-}] - [H_2L].$$

Activity coefficients were calculated by using the extended Debye–Hückel equation $\log f = -0.51Z^2\mu^{1/2}(1+\mu^{1/2})^{-1}$. The values for the formation constants are listed in Tables 1–5. In Table 6 the experimental values are compared with

available literature data, which were determined under comparable conditions by different authors. The results show a weakening of complexation with increasing ring size of the formed chelate. The method used in this study, where free copper(II) concentrations are measured directly, is thought to be superior to the conventional methods because of its simplicity and potential applicability to a wide range of ionic media.[1]

COMMUNICATION

AN EFFICIENT SYNTHETIC ROUTE TO PERIPHERALLY-SUBSTITUTED AND LACUNAR NICKEL(II) COMPLEXES OF DIBENZOTETRAAZA[14]ANNULENES

JULITA EILMES

Faculty of Chemistry, Jagiellonian University, Karasia 3, 30-060 Cracow, Poland

(*Received* 12 *December* 1988; *accepted* 5 *January* 1989)

Abstract—An aminolytic cleavage of γ,δ-unsaturated-δ-lactonic substituents of disubstituted nickel(II) complexes of dibenzotetraaza[14]annulenes (**1** and **2**) has been accomplished by means of aliphatic amines and diamines. The reaction led to amide groups containing derivatives having either pendant open-chain γ,γ'-substituents or γ,γ'-bridging groups. The products were characterized by ^{1}H NMR and IR data.

The synthesis of the substituted Jäger complexes, **1** and **2**, and the transformations of the lactonic rings into the new substituents carrying carboxyl and ester functions have already been described.[1,2]

Further experiments revealed that the unsaturated δ-lactonic substituents of complexes **1** and **2** are susceptible to an aminolytic cleavage, giving rise to new disubstituted derivatives.

This paper reports the results of the reactions of complexes **1** and **2** with primary and secondary aliphatic amines and diamines.

RESULTS

An aminolysis of the lactonic substituents of the macrocyclic complexes was accomplished by refluxing the starting compounds **1** and **2** in benzene solution with an excess of appropriate amine. The reaction led to the new products in reasonable yield (70–88%).

The products of the reaction with aliphatic amines have amide groups containing pendant arms on the ligand periphery (compounds **3–8**). The same synthetic route when applied to aliphatic diamines gives rise to the lacunar complexes (**9–12**), with bridging groups connected to opposite γ-positions on the macrocyclic ring.

The procedure extended to a variety of amines and diamines provides a convenient method for the macrocyclic ligand modifications.

Scheme 1 outlines the performed reactions. ^{1}H NMR and IR data are given in Table 1.

EXPERIMENTAL

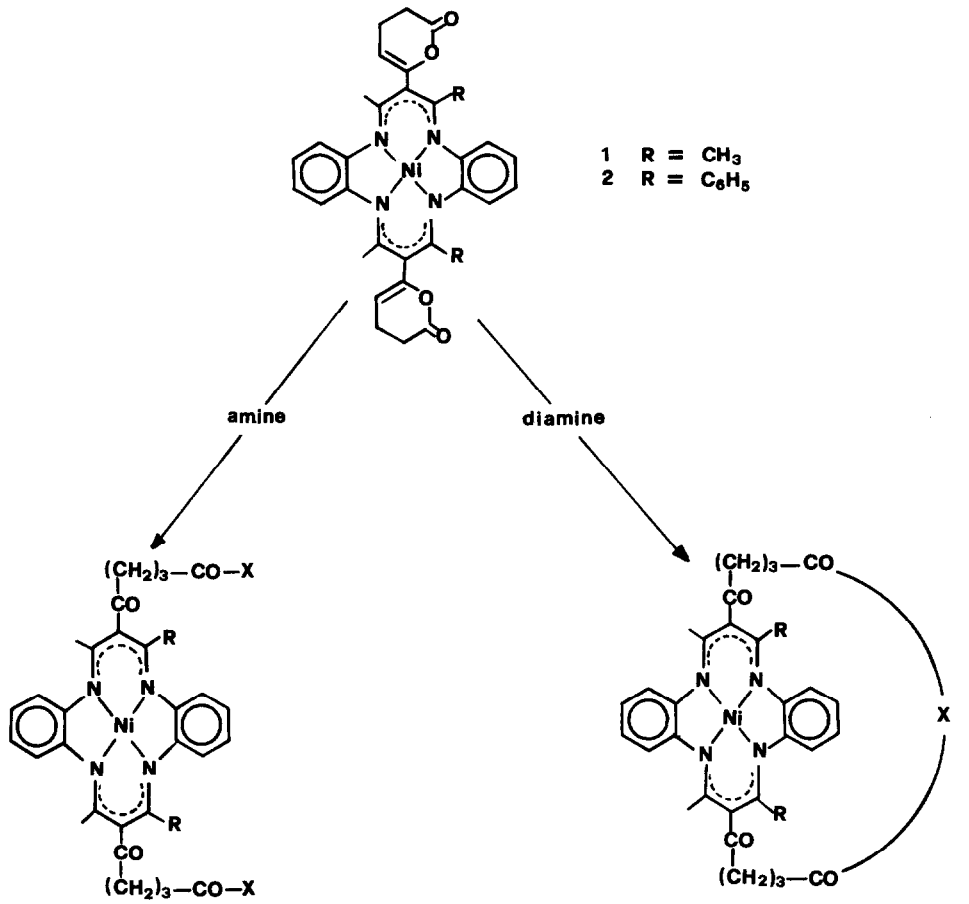
Melting points are uncorrected. IR spectra were recorded in Nujol and hexachlorobutadiene on a Zeiss UR-10 spectrometer. ^{1}H NMR spectra were taken on a Brüker AM500 MHz instrument using TMS as internal standard.

Parent complexes **1** and **2** were prepared by a procedure described earlier.[1]

Syntheses of the complexes **3–12** *(general procedure)*

An appropriate amine (30 mmol) was added to a slurry of the parent complex (1 mmol) in benzene (30 cm^3). The reaction mixture was heated under gentle reflux for 30 min, then left overnight at room temperature. The solvent and excess reagent were distilled off on a rotatory evaporator. A green residue was triturated with water, filtered off and then washed carefully with water.

Further purification was accomplished according to one of the methods given below (see Table 2):



3 R = CH_3 X = NH–CH_2– 

4 R = C_6H_5 X = NH–CH_2– 

5 R = CH_3 X = NH– 

6 R = C_6H_5 X = NH– 

7 R = CH_3 X =

8 R = C_6H_5 X =

9 R = CH_3 X = NH–CH_2–C(CH_3)(CH_3)–CH_2–NH

10 R = C_6H_5 X = NH–CH_2–C(CH_3)(CH_3)–CH_2–NH

11 R = CH_3 X = 

12 R = C_6H_5 X =

(*Received* 8 *January* 1989; *accepted* 10 *February* 1989)

Abstract—The reaction of $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ with 4 equivalents of HO-2,6-$Bu^t_2C_6H_3$ in toluene at 100°C provides orange U(O-2,6-$Bu^t_2C_6H_3)_4$ in high yield. U(O-2,6-$Bu^t_2C_6H_3)_4$ has been characterized by NMR, magnetic susceptibility (μ_{eff} = 2.68 BM), and X-ray crystallography. It is the first structurally characterized homoleptic uranium(IV) aryloxide complex. The UO_4 core is nearly tetrahedral with U(1)—O(2) = 2.135(4) Å, O(2)—U(1)—O(2′) = 110.2(1)° and O(2)—U(1)—O(2″) = 108.0(2)°; the U(1)—O(2)—C_{ipso} angle is 154.0(6)°.

We recently reported the synthesis and characterization of two uranium(III) phenoxide complexes, $\{U(O\text{-}2,6\text{-}R_2C_6H_3)_3\}_x$ (R = Pr^i, $x = 2$; R = Bu^t, $x = 1$).[1] The uranium(IV) analogues of these complexes have not been reported, although $[Li(THF)_4][U(O\text{-}2,6\text{-}Pr^i_2C_6H_3)_5]$ has been isolated from the reaction of UCl_4 and LiOAr in THF and structurally characterized.[2] Lappert and co-workers[3] were unable to prepare U(O-2,6-$Bu^t_2C_6H_3)_4$ from $[U(NEt_2)_4]_2$ and excess phenol. Instead, the $U(NEt_2)$(O-2,6-$Bu^t_2C_6H_3)_3$ was isolated according to eq. (1):

$$0.5[U(NEt_2)_4]_2 + \geqslant 3HO\text{-}2,6\text{-}Bu^t_2C_6H_3 \xrightarrow{C_5H_{12}} U(NEt_2)(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3 + 3HNEt_2. \quad (1)$$

We have repeated this reaction in our laboratory and find that, even in refluxing toluene, the fourth diethylamide ligand [eq. (1)] cannot be metathesized.

Several years ago, Dormond *et al.*[4] described the reactions of the uranium(IV) metallacycle $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$,[5] with both HOBu^t and HO-2,6-$Me_2C_6H_3$. They observed rapid protonation of the uranium–carbon bond and isolated two U(OR)$[N(SiMe_3)_2]_3$ complexes [eq. (2)]:

$$[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2} + HOR \xrightarrow{C_6H_6} U(OR)[N(SiMe_3)_2]_3 \quad (2)$$

(R = Bu^t, 2,6-$Me_2C_6H_3$).

They also noted that cleavage of uranium–nitrogen bonds occurred but was not competitive with attack on the metal–carbon bond.

In agreement with Dormond *et al.*, we find that the reaction of one equivalent of HO-2,6-$Bu^t_2C_6H_3$ with $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ in hexane at room temperature for 1 h, provides orange

* Author to whom correspondence should be addressed.

$U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)[N(SiMe_3)_2]_3$ in essentially quantitative yield. This hydrocarbon soluble, air-sensitive compound has been characterized by elemental analyses and ^1H NMR.* The room temperature ^1H NMR spectrum shows non-equivalent silyl amide ligands indicative of restricted rotation about the U—O bond and/or U—N bonds.

The reaction of $[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2}$ with slightly greater than 4 equivalents of $HO\text{-}2,6\text{-}Bu^t_2C_6H_3$ in toluene at 100°C for 6 h provides, after solvent removal and recrystallization from hexane, an orange, air-sensitive crystalline solid in 80% yield [eq. (3)]:

$$[(Me_3Si)_2N]_2\overline{UN(SiMe_3)SiMe_2CH_2} + 4HO\text{-}2,6\text{-}Bu^t_2C_6H_3 \xrightarrow{PhCH_3,\Delta} U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4 + 3HN(SiMe_3)_2. \quad (3)$$

The ^1H NMR spectrum shows one type of phenoxide ligand and elemental analyses were consistent with the formula $U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4$.† The solid follows Curie–Weiss behaviour from 60 to 300 K with $\mu_{eff} = 2.68$ BM, consistent with the presence of two unpaired electrons (U^{4+} has a $5f^2$ ground-state configuration).

X-ray quality crystals, in the form of orange cubes, were grown from a concentrated THF solution at −40°C, and the structure was determined from X-ray diffraction data collected at −145°C.‡ The uranium lies on a crystallographic $\bar{4}$ site (i.e. the molecule has S_4 symmetry) and is coordinated by the oxygen atoms [U(1)—O(2) = 2.135(4) Å] of the four phenoxide ligands in a nearly tetrahedral fashion: angles O(2)—U(1)—O(2′) and O(2)—U(1)—O(2″) are 110.2(1) and 108.0(2)°, respectively (Fig. 1). The U(1)—O(2)—C(3) angle is 154.0(6)°. $U(NEt_2)[O\text{-}2,6\text{-}Bu^t_2C_6H_3]_3$, which also adopts a tetrahedral geometry, has an average U—O distance of 2.143(4) Å.[3] In the trigonal bipyramidal uranium(IV) anion, $[U(O\text{-}2,6\text{-}Pr^i_2C_6H_3)_5]^-$, the U—O distances range from 2.15(1) to 2.19(1) Å.[2]

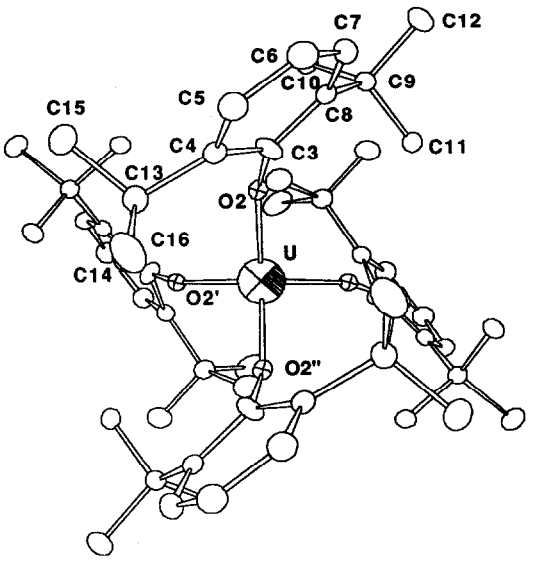

Fig. 1. ORTEP drawing of $U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4$. U(1)—O(2) = 2.135(4) Å; O(2)—C(3) = 1.344(14) Å; U(1)—O(2)—C(3) = 154.0(6)°; O(2)—U(1)—O(2′) = 110.2(1)°; O(2)—U(1)—O(2″) = 108.0(2)°.

The reason that $U(NEt_2)(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ does not react with $HO\text{-}2,6\text{-}Bu^t_2C_6H_3$ to form $U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4$ is most likely a consequence of the enhanced π-basicity of NEt_2^- relative to $N(SiMe_3)_2^-$. For the latter, N → Si $p\pi$–$d\pi$ bonding is possible and this will compete with N → U π-bonding. In this context, we note that the U—N bond length of 2.162(5) Å in $U(NEt_2)(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_3$ is significantly shorter than the terminal U—N bonds of $[U(NEt_2)_4]_2$, which range from 2.21(1) to 2.24(1) Å,[6] and that the average U—N bond length in $HU[N(SiMe_3)_2]_3$ is 2.237(9) Å.[7]

Schrock and co-workers[8] have structurally characterized the d^2 tungsten(IV) phenoxide complexes, $W(O\text{-}2,6\text{-}R_2C_6H_3)_4$ (R = Me and Pr^i), and found the coordination geometries to be nearly square-planar. The latter has been explained in terms of oxygen lone-pair → tungsten π-donation, which stabilizes the square-planar geometry relative to the tetrahedral geometry.[8,9] For $U(O\text{-}2,6\text{-}Bu^t_2C_6H_3)_4$, it is unclear whether the tetrahedral geometry is the

A NEW TYPE OF CATENAND: INTERLOCKED MACROCYCLES HELD TOGETHER BY INTRAMOLECULAR SANDWICH BENZO-15-CROWN-5 POTASSIUM COMPLEXES

PAUL D. BEER* and ANNE S. ROTHIN

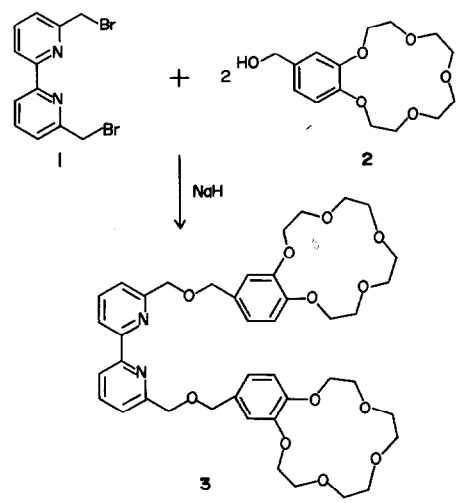
Department of Chemistry, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, U.K.

(*Received* 27 *September* 1988; *accepted after revision* 10 *February* 1989)

Abstract—The synthesis of a new type of catenand ligand (**6**) containing two interlocked 6,6′-bis(benzo-15-crown-5)-2,2′-bipyridine moieties held together via intramolecular sandwich benzo-15-crown-5 potassium complexes is reported.

The catenands[1,2] are a new class of ligand that display unusual coordinating properties towards transition metals, such as the exceptional stabilization of transition metals in low oxidation states. For example nickel(I)[3] and formally copper(0)[1] catenates have both been successfully prepared. These properties are attributed to the novel molecular architecture of the catenands, the interlocking of macrocyclic ligands creating a unique topological environment favourable for a low valent transition metal. We report here the synthesis and preliminary coordination chemistry of a new type of catenand ligand (**6**) in which the interlocked macrocycles are held together by intramolecular sandwich benzo-15-crown-5 potassium complexes.

The condensation of 6,6′-bis(bromomethyl)-2,2′-bipyridine (**1**)[4] and 2 equivalents of 4-hydroxymethylbenzo-15-crown-5 (**2**)[5] in the presence of sodium hydride gave the new bis crown ether ligand (**3**) in 72% yield (Scheme 1). Its structure was characterized by elemental analysis, mass spectrometry and ^{1}H and ^{13}C NMR spectroscopy. The reaction of $Cu^I(CH_3CN)_4PF_6$[6] with 2 equivalents of **3** gave the deep orange air-stable crystalline complex, **4**. Reacting **4** with an excess amount of KPF_6 gave the new catenate, **5**.



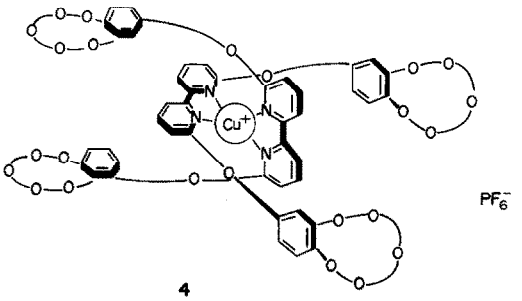
Scheme 1.

Copper(I) demetallation of **5** was achieved quantitatively on addition of either potassium or tetramethylammonium cyanide to produce the novel catenand **6** as a white solid.

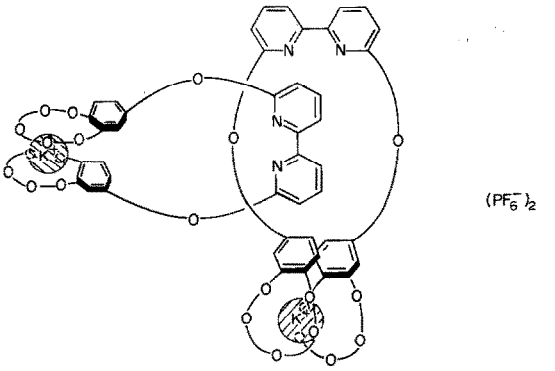
The catenane structure of **6** was established by a combination of conductivity measurements (acetonitrile $\Lambda = 226\ \Omega^{-1}\ cm^2\ mol^{-1}$),† FAB mass spectrometry and ^{1}H NMR. The FAB mass spectrum of **6** displays the $[(\mathbf{6})-PF_6]^+$ molecular ion at 1776. The 270 MHz ^{1}H NMR spectrum of **5** showed the respective CH_2 absorptions at 4.35 and 4.58 ppm. These relatively high field positions may be attributed to the mutual ring current effects of the respective bipyridyl subunits in **5**. On removal of

* Author to whom correspondence should be addressed.

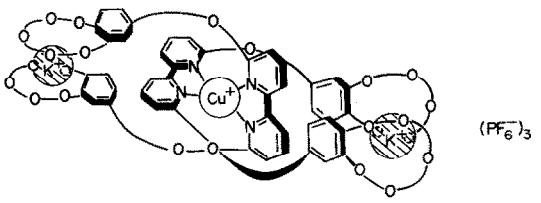
† Ligand **3** forms a 1 : 1 **3**·KPF_6 complex with excess KPF_6, whose conductivity (acetonitrile) $\Lambda = 118\ \Omega^{-1}\ cm^2\ mol^{-1}$ under identical experimental conditions.



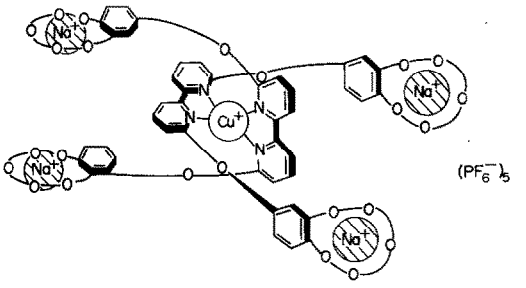
4



6



5



7

the copper(I) cation these ring current effects are negated and consequently the CH_2 absorptions of **6** are observed at lower field, 4.52 and 4.64 ppm, respectively. Similar ^{1}H NMR spectral characteristics are observed with the 1,10-phenanthrolene catenands and metallocatenates reported by Sauvage and co-workers.[1]

The electrochemical properties of the copper(I) complexes, **4** and **5**, were studied using cyclic voltammetry in dry DMF with SCE as reference. Neither complex could be electrochemically oxidized, the interlocked ligands stabilizing the tetrahedral coordination environment around the copper(I) metal centre. However, in contrast to the copper(I) catenates reported by Sauvage and co-workers,[1] both **4** and **5** exhibited *irreversible* reduction waves at -1.62 and -1.58 V, respectively, suggesting that copper demetallation occurs under these conditions.

In contrast to the potassium cation, Na^+ does *not* form a catenate structure with **4**, instead the polymetallic complex **7** was isolated.

Abstract—Highly hygroscopic, black, prism-like crystals separated out from CH_3CN solutions containing $(Et_4N)_2NiCl_4$ and 3-dimethylamino-1-propanethiol at several mole ratios. Crystals of $[Ni_6\{S(CH_2)_3N(CH_3)_2\}_{12}]$ are orthorhombic, space group $P2_12_12$ with $a = 30.197(6)$, $b = 29.231(4)$, $c = 10.649(1)$ Å and $Z = 4$. The Ni_6S_{12} core of each molecular unit constitutes a hexagonal prism whose rectangular faces are NiS_4 coordination planes (Ni—S = 2.19 Å; S—Ni—S = 82.2°, 98.05°). Approximate diameters for the Ni_6 and S_6 rings are 5.85 and 6.60 Å, respectively. The allowed molecular symmetry for the Ni_6S_{12} core, D_{6h}, is reduced to D_{3d} when the axial and equatorial S—C bonds are included.

Since the report in 1965 of the hexagonal "tiara" structure of $[Ni_6(SEt)_{12}]$,[1] one of the first discrete homothiolate compounds,[2] several cyclic nickel(II) thiolate complexes with different degrees of oligomerization have been described. Thus, a square cyclic structure, $[Ni_4\{\mu\text{-}SC_5H_9N(CH_3)\}_8]$,[3] hexagonal molecular cycles, $[Ni_6(\mu\text{-}SR)_{12}]$, R = Et,[1] CH_2CH_2OH,[4] $(CH_2)_3\dot{N}H(CH_3)_2$,[5] and an octogonal cyclic molecule, $[Ni_8(\mu\text{-}SCH_2COOEt)_{16}]$[6] have been characterized structurally by X-ray diffraction prior to the recent publication of the first pentanuclear complex, $[Ni_5(\mu\text{-}SEt)_{10}]$, together with another tetrameric species, $[Ni_4(\mu\text{-}SC_6H_{11})_8]$.[7] The thiol ligand in the pentametallic complex is the same as that in the hexameric unit $[Ni_6(SEt)_{12}]$, already mentioned.

Considering the rest of the metals in the nickel group, cyclic structures have only been found in the case of palladium, and the two examples known, $[Pd(SR)_2]_n$, R = CH_2CH_2OH[4] and $CH_2CH_2CH_3$,[8] correspond to hexameric molecular units ($n = 6$). The M_nS_{2n} core of the macrocyclic molecules, $[Ni(SR)_2]_n$, $4 \leqslant n \leqslant 8$, can always be described as a regular prism with as many faces as number of metal atoms, each face having the metal atom in its centre and linking to each other by means of the doubly-bridging sulphur atoms that lie on the vertices.

By reacting different nickel compounds with 3-dimethylamino-1-propanethiol at varying metal-to-ligand ratios under anhydrous conditions and inert atmosphere, we have obtained, as a side product, a black highly hygroscopic crystalline complex of the empirical formula $[Ni\{S(CH_2)_3N(CH_3)_2\}_2]$. A compound with the same composition had already been found in this laboratory,[5] and it had been proposed that its structure could consist of hexanuclear cyclic molecules analogous to those found in $[Ni_6\{\mu\text{-}S(CH_2)_3NH(CH_3)_2\}_{12}](ClO_4)_{12}\cdot 2H_2O$.[5] The facts that the reaction medium was completely different in both syntheses of $[Ni\{S(CH_2)_3N(CH_3)_2\}_2]$, that the γ-mercaptoamine complex of known structure has the ligand in a zwitterionic form, and that rings of different nuclearity have been found for the com-

plex $[Ni(SEt)_2]_n$,[1,7] prompted us to determine the structure of the complex $[Ni\{S(CH_2)_3N(CH_3)_2\}_2]$, synthesized in organic medium.

EXPERIMENTAL

Preparation of compounds

3-Dimethylamino-1-propanethiol was synthesized according to a known procedure[9] and purified by vacuum distillation until its purity, checked by iodometric determination of the SH group, was > 99.5%. The corresponding sodium salt was prepared by mixing a methanolic solution of NaOMe, always less than 1 cm^3, with an equivalent amount of the thiol in 20 cm^3 of CH_3CN. $(Et_4N)_2NiCl_4$ was obtained by following a standard procedure.[10] In the following preparations, degassed solvents were used and all manipulations were performed under an atmosphere of dry and pure nitrogen.

$[Ni_6\{S(CH_2)_3N(CH_3)_2\}_{12}]$. A solution of $(Et_4N)_2NiCl_4$ in 25 cm^3 of CH_3CN was slowly added with constant stirring to the sodium thiolate solution indicated above. The colour rapidly turned dark red–brown. After the mixture was stirred for 2 h, NaCl was removed by filtration. Cooling the filtrate to −20°C afforded a brown solid, which is now being characterized. Further cooling of the filtrate at −20°C for 1 week afforded large shiny black prisms of pure product, independently of whether the ligand-to-metal mole ratio in the initial reaction mixture had been 4:1, 6:1 or 8:1. The crystals were filtered very rapidly at approximately −15°C because of the strong temperature dependence of their solubility, then dried *in vacuo* and stored under nitrogen. Found: C, 39.8; N, 9.1; S, 21.2. Calc. for $C_{10}H_{24}N_2NiS_2$: C, 40.7; N, 9.5; S, 21.7%.

Physical measurements

The IR spectrum of the complex (4000–400 cm^{-1}), recorded as KBr pellet on a Perkin–Elmer 1710 spectrophotometer, shows no difference to that of the free ligand, the 3000–2700 cm^{-1} region indicating very clearly that the nitrogen atom is not involved in coordination.[5]

Microanalyses were performed with a Carlo–Erba N.A. 1500 analyser.

X-ray data collection, solution and refinement of the structure

A suitable crystal was wedged into a glass capillary and sealed under an atmosphere of nitrogen. The main characteristics of the crystallographic analysis are given in Table 1. The structure was solved, as far as the heavy atoms are concerned, by difference direct methods (DIRDIF), starting from a square planar nickel atom surrounded by four sulphur atoms. A hexanuclear Ni_6S_{12} cage has been established unambiguously as well as the corresponding geometric parameters, although the disorder present in the aliphatic chains has prevented the total completion of the structure. Atomic coordinates and thermal parameters for all nickel, sulphur and carbon atoms linked to sulphur atoms and lists of F_o and F_c values have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Selected bond distances and angles are given in Table 2.

RESULTS AND DISCUSSION

Synthesis

$[Ni_6\{S(CH_2)_3N(CH_3)_2\}_{12}]$ was always obtained as a final pure by-product when mixing nickel(II) and the sodium thiolate with excess ligand. It is extremely hygroscopic and also very soluble in all common organic solvents.

Owing to the fact that different ligand-to-metal ratios have been tried and that in all cases a significant amount of pure $[Ni(SR)_2]$ complex is collected after another solid has separated out from solution, it can be concluded that the hexameric nickel complex is very stable and probably present in solution from the time the reactants are mixed. Its very high solubility, which is consistent with the molecular structure, agrees with the facts that it appears as the final product and also that it requires low temperature while separating it from solution.

Despite the common feature for all cyclic $[Ni(SR)_2]_n$ complexes, that they show an appreciable solubility in different organic solvents, it is difficult to find a relationship between the synthetic method followed in each case ($n = 4$,[3,7] $n = 5$,[7] $n = 6$[1,4,5] and this work, $n = 8$[6]) and the nuclearity of the complex species isolated.

Description of the structure of $[Ni_6\{\mu\text{-}S(CH_2)_3N(CH_3)_2\}_{12}]$

The crystal structure of the title compound consists of neutral cyclic molecules, each of them containing a regular hexagon of nickel atoms, Table 3, bridged over the edges by pairs of doubly-bridging thiolate ligands, Fig. 1. The Ni_6S_{12} core, that shows D_{6h} symmetry, can thus be described as a hexagonal prism with nickel atoms at the centres of its rectangular faces and sulphur atoms at the vertices.

Dihedral angle, mean value: 120°; Nickel, mean value: 0.002 Å

[a] Atom labelling is given in Fig. 1.

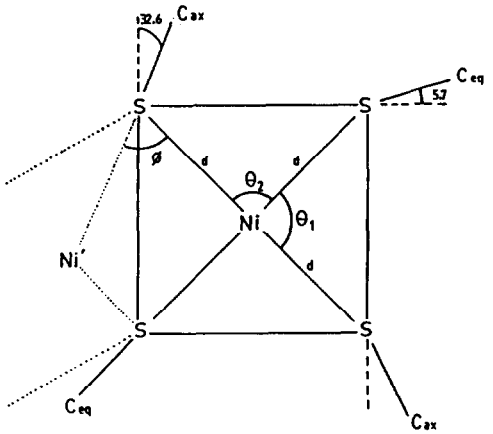
[b] Displacement of nickel atoms from NiS_4 planes (in Å).

Calculated mean values for distances and angles in each face, given in Fig. 2, agree very well with other literature data for cyclic $[Ni(SR)_2]$ complexes.[6,7]

Coordination around the metal is essentially square planar. The mean displacement of nickel from the S_4 coordination plane, calculated from values given in Table 3, is only 0.002 Å. Atoms corresponding to the Ni_6 hexagon, as well as those of the parallel and larger S_6 hexagons above and below, deviate very slightly from the planes they define. The mean distance between the Ni_6 and S_6 planes is 1.44 Å. These values together with the dihedral angles between adjacent NiS_4 planes are shown in Table 3.

The position of each carbon linked to a sulphur atom, Fig. 1, shows that the ligand chains depart from the S_6 hexagons alternately, according to axial and equatorial configurations. Thus, it can be assumed that six C—S vectors are practically parallel to the S_6 planes, while the others are divided into two sets, each having opposite directions roughly along the S—S lateral edges of the hexagonal prism (see Fig. 2). The idealized symmetry of the Ni_6S_{12} core after including these 12 carbon atoms is D_{3d}. Calculated mean values for the Ni—S—Ni′, Ni—S—C_{ax}, Ni—S—C_{eq}, C_{ax}—S—Ni′ and C_{eq}—S—Ni′ angles, Fig. 2, are 83.6, 110.3, 106.5, 112.5 and 106.4°, respectively.

The Ni—Ni distance between adjacent faces, 2.92 Å, precludes any metal–metal interaction. Approximate diameters for Ni_6 and S_6 rings are 5.85 and 6.60 Å, respectively. These data agree very well with the corresponding values of other hexameric nickel–thiolate complexes.[1,4,5]



$d = 2.193$ Å (24 values)
$\theta_1 = 82.2°$ (12 values)
$\theta_2 = 98.1°$ (12 values)

[a] In case there are several values, mean values are given.
[b] The pentameric cycle reported recently is included for comparison.
[c] Defined in Table 3.
[d] Not reported.

The similarity of the main geometric parameters in $[Ni(SR)_2]_6$ complexes with known structures is noteworthy, Table 4, since it clearly indicates that the substituents on the aliphatic chain of the thiol have no influence on the geometry of the Ni_6S_{12} core. This could also explain why there is no important difference between the structures of $[Ni_6\{S(CH_2)_3\overset{+}{N}H(CH_3)_2\}_{12}]^{12+}$ [5] and $[Ni_6\{S(CH_2)_3N(CH_3)_2\}_{12}]$ (this work), where the ligand is, respectively, in a zwitterionic or an anionic form. Despite the fact that complexes with a different degree of oligomeration may exist in solution,[15] and that there must be a relation between solid complex species formed and solubility in a particular medium, all existing data seem to favour the hexameric cyclic nickel(II) thiolates if steric repulsions between ligand substituents[3,7] or inclusion of coordinating groups on the toroid axis[6] are absent. However, the report on the pentanuclear $[Ni_5(SEt)_{10}]$ complex[7] enhances the need for finding an explanation for experimental data.

TUNGSTEN COMPLEXES WITH STRONG π-DONOR AND π-ACCEPTOR LIGANDS: $W(E)Cl_2(L)(PR_3)_2$ (E = O, NR, S, AND L = CO, CNR, CH_2=CHR AND O=CHMe)

FU-MIN SU, JEFFREY C. BRYAN, SOONHEE JANG and JAMES M. MAYER*

Department of Chemistry, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 17 *September* 1988; *accepted* 23 *November* 1988)

Abstract—The synthesis and characterization of a series of tungsten complexes, $W(E)Cl_2(L)(PR_3)_2$, containing both a π-donor group (E = oxo, imido, or sulphido) and a π-acceptor ligand (L = CO, CN^{t}Bu, CH_2=CHR, O=CHMe) is reported (PR_3 = PMe_3, $PMePh_2$). The compounds are prepared by substitution of a phosphine ligand in $W(E)Cl_2(PR_3)_3$ by L and by oxidative addition of heterocumulenes E=L, epoxides or episulphides to $WCl_2(PMePh_2)_4$. All of the compounds have an octahedral structure with the π-donor and π-acceptor ligands *cis*, according to spectroscopic data and X-ray crystal structures of oxo–carbonyl (**4**), oxo-ethylene (**7**) and imido–carbonyl (**25**) complexes. The ethylene ligands are oriented perpendicular to the tungsten–oxygen, –nitrogen, or –sulphur multiple bond, and are non-fluxional by NMR. These geometrical features are a direct result of the electronic structure of the d^2 metal centre. The dihapto coordination of acetaldehyde shows the substantial π-basicity of the tungsten(IV)–oxo centre. The CO stretching frequencies indicate that the donor abilities are in the order: oxo < sulphido < imido (< alkylidene < alkylidyne). Complexes **4**, **7** and **25** are significantly distorted from octahedral geometry, also due to the electronic influence of two π-bonding ligands. The structure of $WCl_2(PMePh_2)_4$ (**1**) shows smaller distortions, a result of the steric bulk of the four phosphine ligands. Crystallographic data for **1**: $P\bar{1}$, a = 11.7401(13), b = 14.2555(12), c = 17.5922(12) Å, α = 76.226(6), β = 70.891(7), γ = 83.476(8)°, Z = 2; for **25**: *Pbcn*, a = 17.764(2), b = 15.821(6), c = 23.829(3) Å, Z = 8.

Metal–ligand π-bonding can be divided into two types. π-Donor ligands, such as terminal oxo (O^{2-}), imido (NR^{2-}), and sulphido (S^{2-}) groups, form multiple bonds with transition metal centres, formally by donation of electrons to empty metal d orbitals.[1] Because of the need for empty d orbitals, these groups are found as terminal ligands predominantly in high oxidation state complexes, with d^0, d^1 or d^2 electronic configurations. In contrast, the π-acceptor (π-acid) ligands: carbon monoxide, isonitriles and olefins require filled d orbital(s) of π-symmetry for productive π-bonding.[2] The filled d_π orbital must in addition be high enough in energy to interact strongly with the ligand acceptor orbital(s), so that π-acid ligands are found mostly in low-valent complexes. Since the two classes of ligands have conflicting requirements, few examples of complexes containing both types have been reported.[3]

This report describes the synthesis and characterization of a series of tungsten(IV) complexes with both a π-donor oxo, imido, or sulphido group and a π-acid carbonyl, isonitrile or ethylene ligand.[4] These are the first isolated examples of olefin complexes with terminal oxo, sulphido or imido ligands,[5] and of oxo–carbonyl and sulphido–carbonyl species. The compounds are prepared by substitution and/or by oxidative addition to a tungsten(II) complex. The electronic structure of these compounds is discussed in light of their structure and reactivity, with the conclusion that the d^2 configuration is ideal for molecules with both classes of ligands.

The oxo- and imido–olefin complexes are of particular interest because species of this kind have been suggested as intermediates in olefin oxidation reactions by metal reagents (osmium tetroxide,

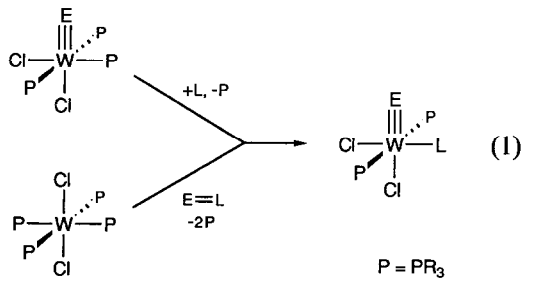
* Author to whom correspondence should be addressed.

chromyl chloride, etc.) and by metalloenzymes.[1,6] Similarly, oxo–carbonyl species may be intermediates in the oxidation of CO by metal oxides.[7] Indeed, the oxidative addition of epoxides and carbon dioxide to form oxo–olefin and oxo-carbonyl complexes reported here is the reverse of olefin or CO oxidation.

RESULTS

Synthesis

Two synthetic routes have been used to prepare the tungsten(IV) oxo, imido, and sulphido complexes: substitution of a phosphine ligand in the tris-phosphine complexes $W(E)Cl_2(PR_3)_3$ (E = O, S, NR) and oxidative addition of epoxides, episulphides and heterocumulenes to $WCl_2(PR_3)_4$ (**1**) [eq. (1)].



(1)

E = O, S, N^{t}Bu, NPh, N-*p*-Tol, $NSiMe_3$; PR_3 = $PMePh_2$, PMe_3; L = CO, CN^{t}Bu, $CH_2{=}CH_2$, $CH_2{=}CHR$, $PhC{\equiv}CH$.

Many of the compounds have been prepared by both routes. The molybdenum oxo–carbonyl complex $Mo(O)Cl_2(CO)(PMePh_2)_2$ is also formed by displacement of a phosphine ligand in $Mo(O)Cl_2(PMePh_2)_3$ with CO. The isolated compounds are listed in Table 1, together with the compound numbers and the method(s) of synthesis. The last column indicates the reagent used in the oxidative addition reaction.

Ligand substitution is the most straightforward procedure, since facile routes to $W(O)Cl_2(PR_3)_3$ [PR_3 = $PMePh_2$ (**2**), PMe_3 (**3**)][8] and $W(NPh)Cl_2(PR_3)_3$ [PR_3 = $PMePh_2$ (**19**), PMe_3 (**20**)][9] have been reported. Preparation of the sulphido complex $W(S)Cl_2(PMePh_2)_3$ (**13**) is reported below. Carbon monoxide, *t*-butylisonitrile and ethylene all readily displace $PMePh_2$ from $W(E)Cl_2(PMePh_2)_3$ (E = O, S, NPh). The reactions are equilibria, however, and addition of excess $PMePh_2$ to the CO, CN^{t}Bu and $CH_2{=}CH_2$ complexes in a sealed NMR tube in general forms a small amount of the tris-$PMePh_2$ complexes. The formation of PMe_3–carbonyl and –ethylene complexes from **3** is less favourable: $W(O)Cl_2(CH_2{=}CH_2)(PMe_3)_2$ has been observed in the presence of excess ethylene, but we have been unable to isolate it because the equilibrium is unfavourable. In contrast, PMe_3 is readily displaced from the imido complex **20** by ethylene.

Terminal olefins such as propylene do not bind as strongly to the tungsten–oxo centre and can be completely displaced by excess $PMePh_2$. Internal olefins do not react with $W(O)Cl_2(PMePh_2)_3$ (**2**). This pattern of binding $CH_2{=}CH_2$ > $CH_2{=}CHR$ > $RHC{=}CHR$, is typical of transition metal olefin complexes.[10] Butadiene, vinyl fluoride and allyl alcohol displace phosphine from **2**, but the electron rich olefin ethyl–vinyl–ether does not, indicating that π-backbonding is important in stabilizing the olefin complexes (see below). The π-basicity of the tungsten(IV) centre is especially evident in the formation of the η^2-acetaldehyde complex, **12**, by reaction of **2** with $O{=}CHMe$. η^2-Aldehyde complexes are rare;[11] the η^2-form is favoured over the η^1-linkage isomer only by metal centres that have a strong preference for a π-acid ligand.

The oxidative addition reactions of $WCl_2(PMePh_2)_4$ (**1**)[12] generally require a few hours at ambient temperatures in benzene solution. $PMePh_2$ is the ligand of choice because its large size favours dissociation; PMe_3 is more difficult to substitute because of its small size and greater donor ability.[13] The difference between the two ligands is observed both in the thermodynamics of the ligand substitution reactions, as described above, and in the reaction kinetics. $WCl_2(PMe_3)_4$ reacts very slowly at ambient temperatures with CO_2, and reactions of $W(NPh)Cl_2(PR_3)_3$ occur at 25°C for PR_3 = $PMePh_2$ but only at elevated temperatures for the PMe_3 derivative.

Epoxides react with **1** to give an apparent equilibrium mixture of tungsten(IV) oxo complexes. Thus ethylene oxide gives predominantly the oxo–ethylene complex **7**, propylene oxide gives a mixture of the propylene and phosphine complexes **8** and **2**, and epoxides of internal olefines (2-butene oxides, tetramethylethylene oxide) give only the tris-phosphine complex **2**. The rate of equilibration among the oxo complexes is comparable to or faster than the rate of oxidative addition. Ethylene sulphide reacts with **1** to give the sulphido ethylene complex **16** as the major product when the stoichiometry is 1 : 1, but ethylene sulphide reacts further with **16** to give unidentified tungsten product(s) and $MePh_2PS$.

Heterocumulenes X=C=Y react with **1** with cleavage of one double bond, forming a tungsten–X multiple bond and a C≡Y ligand. When X and

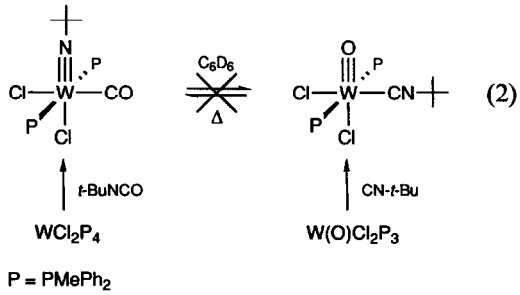
[a] Reference 8.
[b] Also formed from 1+ sterically crowded epoxides, see text.
[c] Formed together with **2**.
[d] A number of products are formed in the reaction.
[e] Reference 9.

Y are different the reactions are regioselective: isocyanates yield only tungsten–imido–carbonyl complexes, and SCO and SCN^tBu give the sulphido–carbonyl and sulphido–isonitrile compounds. The weaker double bond of the heterocumulene appears to be cleaved in each case. The reaction of **1** with CS_2 gave only $MePh_2PS$ and uncharacterized tungsten product(s).

The oxidative addition of heterocumulenes is an irreversible reaction. Isomeric oxo–isonitrile (**6**) and imido–carbonyl (**17**) species have been isolated and they do not interconvert, even after a week at 70°C [eq. (2)].



(2)

^{13}C enrichment of the oxo–carbonyl complex **4** is not observed on reaction with $^{13}CO_2$ for a week at 25°C.

The oxidative addition reaction appears to be a powerful route to high oxidation state tungsten compounds. We have, for instance, recently reported the addition of ketones to **1**, forming oxo–alkylidene compounds.[14] This route has also been used to prepare the sulphido tris(phosphine) complex **13** from the phosphine sulphide [eq. (3)]:

$$WCl_2(PMePh_2)_4 + MePh_2PS \longrightarrow \underset{\textbf{(1)}}{} \quad W(S)Cl_2(PMePh_2)_3 + 2PMePh_2. \quad (3)$$
$$\textbf{(13)}$$

Phosphinimines (e.g. $MePh_2P{=}N$-*p*-Tol) also react with **1** to form imido complexes, but oxygen atom transfer from phosphine oxides has not been observed.

Characterization

Compounds **2–27** have been characterized by NMR and IR spectroscopies (Table 2), analytical data, and by X-ray crystal structures of **4**, **7** and **25**. The data are consistent with a common geometry for all the complexes: octahedral with *trans*-phosphines, *cis*-chlorides and *cis*-π-donor and -acceptor ligands. Thus all the compounds (except those with unsymmetrical olefin, acetylene and aldehyde ligands **8–12**) show a virtual triplet for the phosphine methyl groups, indicative of two *trans*-phosphine ligands. The ^{13}C resonances for the carbonyl and isonitrile carbons are binomial triplets. The phenyl groups of $PMePh_2$ are observed to be diastereotopic (when not obscured by overlapping resonances), consistent with the only molecular symmetry element being a mirror plane that relates the two phosphines. The α-olefin, phenylacetylene and acetaldehyde complexes **8–12**, which contain no symmetry element, shown an AB pattern in the ^{31}P NMR and the phosphorus methyl groups appear as two doublets in the ^1H NMR.

The butadiene ligand in **9** is bound in an η^2-fashion, as indicated by its NMR spectra. For instance, four ^{13}C signals are observed for the butadiene, two in the olefinic region and two quite close to those observed for the propylene complex, **8**.

The ^1H NMR spectra of the ethylene complexes **7**, **16**, **23** and **24** all show two signals for the ethylene hydrogens, indicating that the ethylene ligands do not rotate on the NMR timescale. The barriers to ethylene rotation are significant, greater than 16 kcal mol^{-1} from variable temperature NMR data.[15] The phenylacetylene complex is also non-fluxional at 25°C.

The presence of a single ^{13}C resonance for the ethylene carbons shows that these carbons are related by the mirror plane. Therefore the ethylene ligands are oriented perpendicular to the metal–oxo, –sulphido and –imido multiple bonds, consistent with the structure of **7** in the solid state (Fig. 2).

The fluxionality of the complexes of α-olefins and acetaldehyde (**8–10**, **12**) cannot be determined from the NMR spectra. The substituted carbon is a chiral centre so the phosphines are diastereotopic, independent of olefin or aldehyde rotation. Two isomers are possible: the substituent can either point towards the oxo group or away. The observation of only one species by NMR seems to indicate that one isomer is strongly preferred, although it is possible that rotation, which would interconvert the isomers, is much more facile for these ligands. Rapid isomer interconversion via olefin or aldehyde dissociation is ruled out by the presence of inequivalent phosphines and by separate resonances for bound and free ligands.

The dihapto bonding mode of acetaldehyde in **12** is indicated by the lack of a high energy (> 1500 cm^{-1}) C=O stretching mode in its IR spectrum and by its NMR spectra. An η^1-structure would be expected to have free rotation about the W—OCHMe bond and would therefore show equivalent phosphine ligands, in contrast to the asymmetric structure observed. Both the aldehyde carbon and hydrogen atoms show coupling to the phosphorus atoms that are bound to tungsten, indicative of W—C bonding. The observed C—H and H—H coupling shows that the acetaldehyde group is intact in **12**, ruling out, for instance, an alternative hydrido–acyl structure.

Compounds **4**,[4b] **7**[4a] and **25** have been characterized by X-ray crystal structures (Figs 1–3): a comparison of the bond distances and angles is given in Table 3. The three complexes adopt similar octahedral structures, with an approximate mirror plane containing the tungsten and the *cis*-chlorides. The presence of this mirror plane is consistent with the spectroscopic data, which indicate equivalent phosphine ligands. The tungsten–oxygen distances of 1.689(6) (**4**) and 1.714(6) Å (**7**) are typical of mono-oxo tungsten compounds: the mean W—O distance in 34 mono-oxo structures is 1.699 Å[16] (compare also the value of 1.67(1) Å in **3**[17]). The W—N distance of 1.754(6) Å and W—N—C angle of 171.6(5)° in **25** are very similar to those in the phenylimido complex **20** (1.755(3) Å, 179.5(3)°).[18] On the basis of tungsten–chloride distances, the order of the *trans* influence appears to be: oxo > imido > carbon monoxide ≈ ethylene, consistent with previous suggestions.[19] A shorter tungsten–carbonyl distance is found in the imido complex (1.983(8) Å) than in the oxo species (2.029(9) Å),

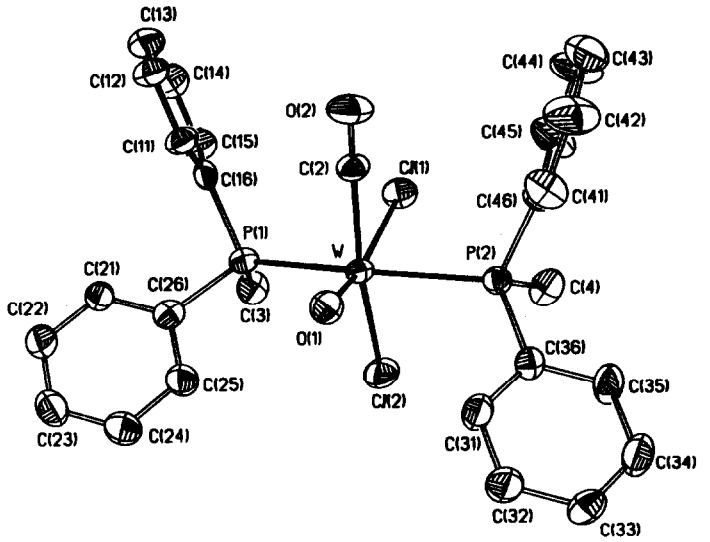


Fig. 1. Perspective drawing of $W(O)Cl_2(CO)(PMePh_2)_2$ (**4**) with hydrogen atoms omitted for clarity.

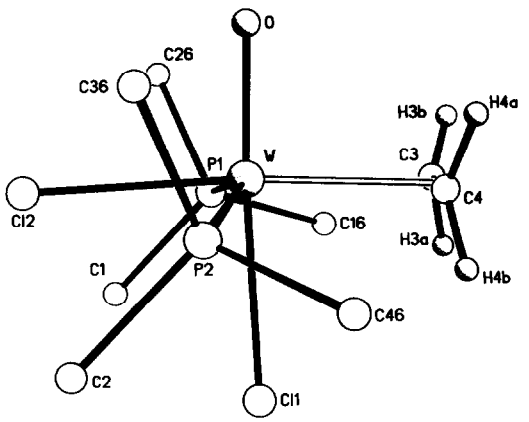

Fig. 2. Perspective drawing of $W(O)Cl_2(CH_2{=}CH_2)(PMePh_2)_2$ (**7**) with hydrogen atoms (except on the ethylene ligand) omitted and only the *ipso*-carbons of the phenyl rings shown.

indicating stronger backbonding in the imido derivative (see Discussion).

The coordination geometries in **4**, **7** and **25** are best described as distorted octahedral, with *cis* angles varying from 75.5(3) to 104.1(2)° and *trans* angles as low as 154.7(1)°. In all three structures the π-acid ligand lies almost exactly at a right angle to the metal–oxo/imido multiple bond ($\angle$E—W—L = 88.9(3)–90.7(4)°, E = oxo or imido), but the phosphines and the *cis*-chloride ligand have moved away from the oxo or imido group ($\angle$E—W—L = 93.0(2)–104.1(2)°). Thus the "*trans*" P—W—P angles are significantly less than 180° (154.7(1)–168.5(1)°). In **4** and **25** the phosphines bend primarily away from the oxo or imido ligand; in **7** the distortion is away from the ethylene as well. The Cl—W—Cl angle is approximately 90° in all three structures, presumably to keep the Cl···Cl non-bonded distance at ~3.5 Å. The movement of Cl(2) away from the oxo or imido thus results in Cl(1) being close to the carbonyl or ethylene ligands, with Cl(1)—W—$C_{carbonyl}$ angles of 75.5(3) (**4**) and 78.0(2)° (**25**).

$WCl_2(PMePh_2)_4$ (**1**) has a more regular octahedral structure, with *trans*-chlorides ($\angle$Cl—W—Cl = 179.6(1)°) and four phosphines in the equatorial plane (Fig. 4, Table 4). The steric crowding caused by the presence of four large $PMePh_2$ ligands (cone angle 136°[13]) is partially relieved by a ruffling of the four phosphines. Two phosphines lie above the equatorial plane and two below, with Cl(1)—W—P angles of 94.8, 84.7, 95.4 and 84.8(1)°. This gives an approximate S_4 axis, and the molecule as a whole has roughly D_{2d} symmetry. Similar structures have been reported for a number of $MoCl_2L_4$ molecules (L = PMe_3, L_2 = diphos, dmpe, 1,2-$C_6H_4(PPh_2)_2$) and the disordered $MCl_2(PMe_3)_4$—$M(N_2)_2(PMe_3)_4$ (M = Mo, W).[20] The facile loss of $PMePh_2$ from **1**, and therefore its high reactivity, is undoubtedly due to this steric crowding.

The $PMePh_2$ cone angle is not a good measure of the crowding in **1** because the phenyl rings interleave and stack [Fig. 4(a)]. The eight phenyls form four pairs in which the rings are roughly parallel, with interplanar distances from 3.2 to 3.5 Å. These distances indicate an attractive stacking interaction; the interlayer distance in graphite, for example, is 3.35 Å.[21]

Reactions

The oxo–carbonyl, oxo–isonitrile and oxo–ethylene complexes are thermally stable, exhibiting less than 10% decomposition after a day at 90°C in C_6D_6 solution. Solutions of the α-olefin complexes, however, are substantially decomposed within 24 h at 40°C, and the acetaldehyde complex decomposes within a few hours at 25°C. These processes appear to occur via loss of the π-acid ligand. Reaction of complexes **4–10** with an excess of CO, CN^{t}Bu, or C_2H_4 results in ligand exchange, consistent with the suggestion above that the ligand exchange reactions are equilibria.

Dissociation of coordinated carbon monoxide or ethylene in **4** or **7** can also be promoted photochemically. Irradiation of **7** in the presence of $PMePh_2$, for instance, gives **2** [eq. (4)]:

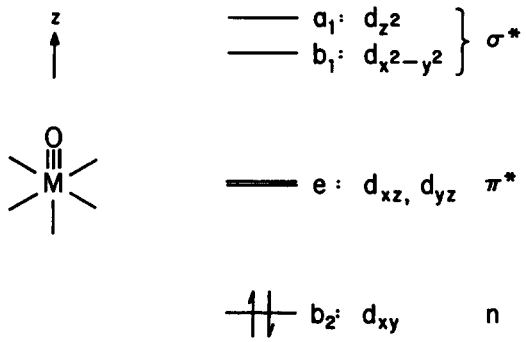
[a] Bond distances in Å, angles in degrees.

The carbonyl and isonitrile complexes **4** and **6** do not react with $AlMe_3$, although the ethylene ligand in **28** can be substituted for CO and CN^{t}Bu to form $W(O)(Me)Cl(L)(PMePh_2)_2$ [L = CO (**29**); CN^{t}Bu (**30**)]. The methyl derivatives are less stable than the dichloride analogues, decomposing in solution at ambient temperatures. A major product of the decomposition of the methyl–ethylene complex **28**, is the *di*chloride–ethylene complex, **7**. The ^{1}H NMR of **28–30** show a triplet for the tungsten methyl groups (J_{PH} = 10 Hz), in addition to resonances similar to those for **4**, **6** and **7**. The methyl group is believed to be *trans* to the oxo ligand, given the large oxo *trans* influence, but this cannot be determined from the spectral data.

DISCUSSION

The stability of this wide range of tungsten(IV) olefin and carbonyl complexes is remarkable, given that these ligands do not often form high oxidation state complexes.[3,22] The tungsten(IV)–oxo, –sulphido, or –imido centre clearly has a high affinity for a π-acid ligand. This is perhaps most evident in the formation of the η^2-acetaldehyde complex **12**. The origin of this stability lies in the electronic structure of the tungsten(IV) d^2 centre.

The electronic configuration of d^2 mono-oxo and related species is well established.[23] The two d electrons are paired in the HOMO, which is the d_{xy} orbital (the z axis is taken as coincident with the metal–ligand multiple bond, Scheme 1). The LUMO is usually the metal–ligand π^*-orbitals, the antibonding combination of the metal d_{xz} and d_{yz} with the ligand p_π orbitals. Oxo, sulphido and imido ligands form strong triple bonds in octahedral symmetry only in electron counts of d^0, d^1 or d^2, because additional d electrons would have to occupy strongly antibonding[24] π^*-orbitals.[23] The



Scheme 1.

d^2 configuration is therefore ideal for the π-donor/π-acceptor molecules reported here: a W≡E triple bond can be formed and two electrons (one pair) are available for backbonding to the π-acid ligand.

Since the two d electrons are in the d_{xy} orbital, the π-acid ligand (carbon monoxide, ethylene, etc.) must bind *cis* to the tungsten–E multiple bond. In addition, an olefin ligand with only one acceptor orbital has only one orientation that allows favourable overlap with d_{xy}:

Thus, the unsaturated organic ligand lies perpendicular to the tungsten–E bond, as observed in complexes **7–12**, **16**, **23** and **24**. The large barrier to ethylene rotation is due to loss of the π-backbonding interaction on turning the ethylene 90°. This orbital description is similar to that used to explain the geometry and lack of rotation in d^2 oxo–acetylene[25] and oxo–carbene compounds,[26] and is supported by two recent theoretical studies.[27]

The high barriers to olefin rotation indicate that π-backbonding is an important interaction for these complexes. Significant backbonding is also implied by the CO stretching frequencies (Table 5). This conclusion is somewhat surprising since the tungsten centre is in the +4 oxidation state, with two chloride ligands and an oxo, sulphido, or imido group. However, the tungsten(IV) centre is a reasonable reducing agent,[28a] implying that the two *d* electrons are at fairly high energy and are available for backbonding. Weaker backbonding is seen in the molybdenum oxo–carbonyl complex **27** (compare ν(CO) = 2130 cm^{-1} for **27**, 2006 cm^{-1} for **4**), because molybdenum is a less electropositive metal and molybdenum(IV) is a poorer reducing agent than tungsten(IV).[28]

The CO stretching frequency can be used as a measure of the electron density at the metal centre. For instance, because PMe_3 is a stronger donor than $PMePh_2$, the PMe_3 complexes **5** and **22** have lower CO stretching frequencies than **4** and **21**, by 11 and 18 cm^{-1}. This enables a comparison of the electron donor abilities of the multiply bonded ligands (Table 5). The oxo ligand is the least electron donating, then sulphido, and the imido group is the most donating. This order does not simply parallel the donor atom electronegativity, O (3.5) > N (3.0) > S (2.5).[29] It is reasonable that oxygen is the weakest donor, but the poor donation from the sulphido ligand is surprising. The presence of the imido substituent may complicate the comparison, but the substituent does not seem to have a substantial influence on ν(CO). The poor donation from the sulphido ligand may indicate that π-bonding involving the third row element sulphur is not as effective as π-interactions involving oxygen and nitrogen. This is also suggested by the electronic spectra: the lowest energy transition, believed to be $d_{xy} \rightarrow d_{xz}d_{yz}$ ($n \rightarrow \pi^*$),[23] is in the range 492–544 nm in the oxo- and imido–carbonyl complexes, but is at much lower energy (696 nm) in the sulphido–carbonyl compound **14**.

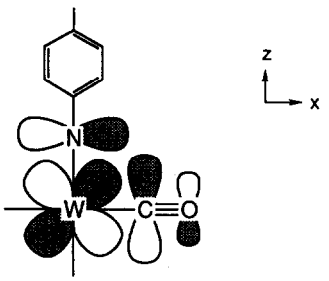
Table 5 also contains CO stretching frequencies for related alkylidene and alkylidyne complexes. Because of the low electronegativity of carbon (2.5), an alkylidene would be expected to be a very strong donor, but phenylimido is almost as donating as benzylidene. The difference in bond polarity is probably offset by the difference in bond order, an M≡NPh triple bond versus an M=CHPh double bond. The alkylidyne ligand provides a comparison of triple bonds but, because the alkylidyne is a trivalent group, the compounds are not strictly analogous. One of the alkylidyne complexes in Table 5 has an unusual phosphinium–alkylidyne moiety, and in the other a phosphite ligand is in place of one of the chlorides. The list of analogous compounds illustrates the similarities among metal–ligand multiple bonds. Imido and carbene or alkylidene ligands are not as different as is implied by the oxidation state formalism of NR^{2-} as a π-donor and CR_2, a neutral π-acid ligand.

The above discussion used the electronic structure of the parent oxo, sulphido or imido complex and added the π-acid ligand as a small perturbation. The solid state structures and the spectroscopic data are consistent with this approach: The molecules are not distorted towards bound epoxide, η^2-CO_2 or η^2-OCNR forms—there is no evidence for bonding between the π-donor and π-acceptor ligands. The angle between the ligands is very close to 90° in all three cases, and the carbonyl ligands are essentially linear (W—C—O = 177.0(7), 178.5(7)° for **4** and **25**).

There is, however, a short contact between the carbonyl carbon and the oxo or imido nitrogen atom in **4** and **25**, due to the short W—CO and W≡O or W≡NR bonds. These distances, O···C = 2.63 Å and N···C = 2.62 Å, are much longer than a bond (compare 1.163 Å in CO_2),[30] but are substantially shorter than the sum of the van der Waals radii (C, 1.7; N, 1.55; O, 1.5 Å).[31] Thus, there is probably overlap of the oxygen or nitrogen p_x orbital with the carbonyl π^*-orbital in the *xz* plane, in addition to the overlap with the tungsten d_{xz} (Scheme 2). One effect of this three orbital–two electron situation is to lower the energy of the filled W—O or W—N π_x-orbital compared to the π_y. This is consistent with the orientation of



Scheme 2. A schematic drawing of the interaction of the tungsten d_{xz}, nitrogen p_x and carbonyl π^* orbitals in W(N-*p*-Tol)Cl_2(CO)$(PMePh_2)_2$ (**25**).

the tolyl group in **25**, in the *xz* plane: the empty aromatic π^*-orbital(s) of the tolyl ring overlap better with the filled M—N π_y-orbital than the lower energy π_x. This is a weak interaction, however, since rapid rotation about the C—N bond is observed in the ^{1}H NMR at $-90°C$ ($\Delta G^{\ddagger} < 9$ kcal mol^{-1}). The π-donor acetylene ligand in **11**, *cis* to the oxo, has a larger effect: in this three orbital–*four* electron case the acetylene competes for the tungsten d_{xz} orbital, as noted in other oxo–acetylene compounds.[25] As a result, the W—O bond order is lower and complex **11** has the lowest W—O stretching frequency of the oxo compounds reported here.

The presence of two π-bonding ligands also seems to be the origin of the significant distortions from octahedral geometry. Closely related d^0 dioxo[32] and d^4 dicarbonyl[33] complexes also adopt highly distorted structures, the distortions resulting from the presence of *cis*-π-bonding ligands.

EXPERIMENTAL

General considerations

All manipulations were carried out using either high vacuum line or glovebox techniques except as indicated. Solvents were vacuum transferred from sodium benzophenone (diethyl ether, THF), calcium hydride (benzene, toluene, petroleum ether, heptane and pentane), or 4 Å sieves (methylene chloride) immediately before use. Deuterated solvents were dried and transferred from activated 4 Å sieves. Gaseous reagents were obtained from Matheson and used without further purification. Complexes **1**,[12] **2**, **3**,[8] **20**,[9] and Mo(O)Cl_2(P$MePh_2)_3$[34] and $MePh_2PS$[35] were prepared following literature procedures.

Elemental analyses were performed by Canadian Microanalytical Service Ltd, Vancouver, British Columbia. NMR spectra were taken using Varian CFT-20 and VXR-300, and Bruker CXP-200 and WM-500 spectrometers. Variable temperature NMR was performed on the VXR-300. IR spectra were obtained as Nujol mulls (unless otherwise noted) using Perkin–Elmer 225, 283 or 1640 spectrometers, and are reported in cm^{-1}. Selected NMR and IR spectra are given in Table 2, the remainder below. The NMR data are reported below as: chemical shift (multiplicity, integral, coupling constant in Hz, assignment). UV–vis spectra were recorded on a Hewlett–Packard 8450A spectrophotometer, and are reported as: UV–vis: λ_{max} (ε).

W(O)Cl_2(CO)$(PMePh_2)_2$ (**4**)

This was prepared from CO in 70% yield as red–purple crystals following the procedure for **7**. Complex **4** was also observed in > 95% yield (together with < 5% **2**) by NMR when CO_2 (127 torr in 7.5 cm^3) was was exposed to **1** (27 mg) for 3 h in C_6D_6 in a sealed NMR tube. IR: ν(CO) = 2006, $\nu(^{13}CO)$ = 1985. Found: C, 46.6; H, 3.9. Calc. for $C_{27}H_{26}Cl_2O_2P_2W$: C, 46.4; H, 3.7%. UV–vis: 498 nm (86). **4**—^{13}CO was prepared in a sealed NMR tube from 10 mg of **2** in C_6D_6 and ^{13}CO (Cambridge Isotope).

W(O)Cl_2(CO)$(PMe_3)_2$ (**5**)

This was prepared in a sealed tube containing 10 mg of **3** in C_6D_6 and 20 equivalents of CO.

W(O)Cl_2(CN^{t}Bu)$(PMePh_2)_2$ (**6**)

CN^{t}Bu (0.02 cm^3, 0.26 mmol) was added to a stirred solution of **2** (0.2 g, 0.23 mmol) in benzene (15 cm^3). The purple solution was filtered and the volume was reduced to 1 cm^3. Petroleum ether (5 cm^3) was added. The purple crystals were isolated and dried *in vacuo*; yield 0.11 g (70%). ^{1}H NMR: 7.02–7.95 (br m, 12, PMe*Ph*$_2$, *p* and *m*), 7.70 (m, 4, PMe*Ph*Ph′, *o*), 8.11 (m, 4, PMePh*Ph*′, *o*). UV–vis: 552 nm (110).

W(O)Cl_2(CH_2=CH_2)$(PMePh_2)_2$ (**7**)

A suspension of **2** (0.35 g, 0.4 mmol) in benzene (20 cm^3) was stirred at 40°C under 1 atm of ethylene for 30 min. Filtration, evaporation of most of the solvent and addition of petroleum ether gave 0.25 g (74%) of yellow crystals. **7** was also formed in ~ 80% yield (together with ~ 10% of **2**, by NMR) when ethylene oxide (6 torr in 25 cm^3) was exposed to **1** (9 mg) for 3 h in C_6D_6 in a sealed NMR tube.

^{1}H NMR: 6.94 (m, 6, PMe*Ph*Ph′, *p* and *m*), 7.04 (m, 6, PMePh*Ph*′, *p* and *m*), 7.40 (m, 4, PMe*Ph*Ph′, *o*), 7.98 (m, 4, PMePh*Ph*′, *o*). Found: C, 48.5; H, 4.5. Calc. for $C_{28}H_{30}Cl_2OP_2W$: C, 48.1; H, 4.3%. UV–vis: 358 nm (240).

$W(O)Cl_2(C_2H_4)(PMe_3)_2$

The compound was detected by ^{1}H NMR in a sealed tube when $W(O)Cl_2(PMe_3)_2$ (10 mg) dissolved in C_6D_6 was exposed to 20 equivalents of C_2H_4. IR (C_6D_6): 960 br [ν(WO)]. ^{1}H NMR: 1.42 (t, J_{PH} = 4, P*Me*$_3$), 2.60 (m, 2, C*H*H′C*H*H′), 2.64 (m, 2, CH*H*′CH*H*′).

$W(O)Cl_2(CH_2{=}CHMe)(PMePh_2)_2$ (8)

Compound **8** was prepared from propylene and **2** in 65% yield as yellow crystals following the procedure for **7**. **8** was also formed in ~ 15% yield (together with ~ 75% of **2**, by NMR) when propylene oxide (10 torr in 25 cm^3, Aldrich) was exposed to **1** (9 mg) for 3 h in C_6D_6 in a sealed NMR tube. ^{1}H NMR: 6.94–7.11 (br m, 12, PMe*Ph*$_2$, *p* and *m*), 7.43 (m, 2, PMe*Ph*$_2$, *o*), 7.67 (m, 2, PMe*Ph*$_2$, *o*), 8.02 (m, 4, PMe*Ph*$_2$, *o*). Found: C, 48.8; H, 4.7. Calc. for $C_{29}H_{32}Cl_2OP_2W$: C, 48.4; H, 4.5%.

$W(O)Cl_2(CH_2{=}CHCH{=}CH_2)(PMePh_2)_2$ (9)

Compound **9** was prepared from butadiene and **2** in 50% yield as yellow crystals following the procedure for **7**. ^{1}H NMR: 2.61 (m, 1, WC*H*H′CH CHCH$_2$), 3.00 (m, 1, WCH*H*′CHCHCH$_2$), 3.68 (d, 1, J = 17, WCH$_2$CHCHC*H*H′), 4.25 (m, 1, WCH$_2$ C*H*CHCH$_2$), 4.28 (d, 1, J = 11, WCH$_2$CHCH CH*H*′), 5.97 (dt, 1, J = 17, 10, WCH$_2$CHC*H*CH$_2$), 6.94–7.11 (br m, 12, PMe*Ph*$_2$, *p* and *m*), 7.36 (m, 2, PMe*Ph*$_2$, *o*), 7.69 (m, 2, PMe*Ph*$_2$, *o*), 7.91 (m, 4, PMe*Ph*$_2$, *o*). ^{13}C{^{1}H} NMR: 57.8 (s, W*C*H$_2$ CHCHCH$_2$), 71.7 (s, WCH$_2$*C*HCHCH$_2$), 113.9 (s, WCH$_2$CHCH*C*H$_2$), 145.7 (s, WCH$_2$CH*C*HCH$_2$). Found: C, 50.3; H, 4.6. Calc. for $C_{30}H_{32}Cl_2OP_2W$: C, 49.7; H, 4.4%.

$W(O)Cl_2(CH_2{=}CHCH_2OH)(PMePh_2)_2$ (10)

Compound **10** was prepared from allyl alcohol (0.05 cm^3) in 45% yield as pale yellow crystals following the procedure for **6**. IR: 3450 (br, OH). ^{1}H NMR: 1.0 (br m, 1, CH$_2$CHCH$_2$O*H*), 2.35 (br m, 1, C*H*H′CHCH$_2$OH), 2.70 (br m, 1, CH*H*′CH CH$_2$OH), 3.52 (br m, 2, CH$_2$CHC*H*$_2$OH), 4.36 (br m, 1, CH$_2$C*H*CH$_2$OH).

$W(O)Cl_2(PhC{\equiv}CH)(PMePh_2)_2$ (11)

Compound **11** was prepared from phenylacetylene (0.05 cm^3) in 65% yield as light yellow crystals following the procedure for **6**.

$W(O)Cl_2(O{=}CHMe)(PMePh_2)_2$ (12)

Acetaldehyde (0.5 cm^3, Aldrich) was added to a suspension of **1** (0.20 g) in benzene (1 cm^3). On stirring for 2 h, some blue solids were observed to form on the reaction walls. Pentane (5 cm^3) was added and the resulting white solids filtered and dried *in vacuo* for 3 h, yielding 0.045 g (27%) of **12**. IR: 1192, 1113 vs, 1076 s, 953 s, 923 s, 896 vs, 746, 722, 692 vs.

$W(S)Cl_2(PMePh_2)_3$ (13)

Complex **1** (0.41 g) was added to $MePh_2PS$ (0.09 g) in 10 cm^3 of toluene and stirred for 3 h. The reaction mixture was concentrated to 2 cm^3 and heptane (10 cm^3) was added. The resulting solids were filtered, washed with pentane (5 cm^3) and dried *in vacuo* for 18 h, yielding 0.245 g (71%) of green **13**. Found: C, 51.9; H, 4.4. Calc. for $C_{39}H_{39}Cl_2P_2SW$: C, 52.8; H, 4.4%. IR: 1282, 1095, 1028, 1000 w, 890 vs, 741 s, 694 vs, 507 vs, 480, 441 w.

$W(S)(CO)Cl_2(PMePh_2)_2$ (14)

Carbonyl sulphide (66 torr in 25 cm^3, K&K) was added to a suspension of **1** (75 mg) in benzene (12 cm^3) and stirred for 1 h. Volatiles were pumped away and Et_2O (2 cm^3) was added to dissolve the residue, and pentane (15 cm^3) was added. The resulting solids were filtered and dried *in vacuo* for 2 h, yielding 17 mg (33%) of green **14**. Found: C, 45.0; H, 3.9. Calc. for $C_{27}H_{26}Cl_2OP_2SW$: C, 45.3; H, 3.7%. IR: 1986 [ν(CO)], 1280 w, 1092, 1034, 893 vs, 741 s, 729 s, 689 s, 524 s ν(W=S), 508 s, 480, 457 s, 291 w ν(WCl). UV–vis: 696 nm (82).

$W(S)(CN^tBu)Cl_2(PMePh_2)_2$ (15)

t-Butyl isothiocyanate (0.011 cm^3, Aldrich) was added to a suspension of **1** (89 mg) in benzene (10 cm^3) and stirred for 2.5 h. The reaction mixture was concentrated to 4 cm^3 and pentane (10 cm^3) was added. The resulting solids were filtered and dried *in vacuo* for 2 h, yielding 44 mg (68%) of yellow–green **15**. Found: C, 48.2; H, 4.6; N, 1.7; S, 4.4. Calc. for $C_{31}H_{35}Cl_2NP_2SW$: C, 48.3; H, 4.6; N, 1.8; S, 4.2%. IR: 2127 [ν(CN)], 1239, 1190, 1101, 1090, 1028, 893 vs, 795 s, 739 vs, 695 s, 519 s ν(W=S), 510 s, 488, 480, 420, 347 w, 277 ν(WCl).

$W(S)(CH_2{=}CH_2)Cl_2(PMePh_2)_2$ (**16**)

Complex **13** (0.125 g) was stirred under 1 atm of ethylene in toluene (8 cm^3) for 1 h. The reaction mixture was concentrated to 2 cm^3 and heptane (10 cm^3) was added. The resulting solids were filtered and dried *in vacuo* for 18 h, yielding 0.075 g (74%) of grey **16**. Found: C, 46.9; H, 4.2. Calc. for $C_{28}H_{30}Cl_2P_2SW$: C, 47.0; H, 4.2%. IR: 1284, 1186, 1100, 1027 w, 965 w, 901 s, 890 vs, 753, 737 s, 693 vs, 515 s, 447.

$W(N^tBu)(CO)Cl_2(PMePh_2)_2$ (**17**)

t-Butyl isocyanate (0.013 cm^3, Strem) was added to a suspension of **1** (0.14 g) in benzene (10 cm^3) and stirred for 90 min. Volatiles were pumped away and Et_2O (4 cm^3) and pentane (5 cm^3) were added. The resulting solids were filtered and dried *in vacuo* for 2 h, yielding 0.055 g (55%) of red **17**. Found: C, 49.5; H, 4.7; N, 1.6. Calc. for $C_{31}H_{35}Cl_2NOP_2W$: C, 49.4; H; 4.7; N, 1.9%. IR: 1966 vs ν(CO), 1281 w, 1252 s, 1098 ν(WNC), 1029 w br, 893 vs, 740 s, 727 s, 690 s, 508 s, 489, 454 w, 287 w, 254 w. UV–vis: 501 nm (56).

$W(N^tBu)(CN^tBu)Cl_2(PMePh_2)_2$ (**18**)

t-Butyl carbodiimide (0.002 cm^3, Aldrich) was exposed to **1** (15 mg) for 1 week in C_6D_6 in a scaled NMR tube. IR (C_6D_6): 2090 s ν(CN), 1262, 1185 br, 1120 s br, 1100 s br, 890 vs br, 740 vs, 693 vs.

$W(NPh)Cl_2(PMePh_2)_3$ (**19**)

This complex was prepared following the reported procedure for **20**.[9] Excess $PMePh_2$ (2.2 cm^3, 11.7 mmol) was added by syringe to a benzene solution of $W(NPh)Cl_4$ (1.18 g, 2.83 mmol). Sodium amalgam (Na 0.196 g, 8.52 mmol; Hg 19.8 g) was then added by syringe. The solution was stirred at room temperature for 12 h, filtered, and most of the volatiles were removed *in vacuo*. Petroleum ether was added and 2.0 g (75%) of brown **19** was isolated by filtration. IR: 1279 w, 1094 w, 1025 w, 892, 748, 738, 724, 695, 506. UV–vis: 542 nm (260).

$W(NPh)Cl_2(CO)(PMePh_2)_2$ (**21**)

Following the procedure for **22**, 0.4 g (0.43 mmol) of **19** was stirred under 1 atm of CO at room temperature for 2 days. Evaporation of the solvent and addition of petroleum ether gave 0.27 g (83%) of purple **21**. IR: 1964 ν(CO), 1101, 906, 893, 770, 746, 736, 723, 696, 505, 483, 455, 446. UV–vis: 508 nm (100).

$W(NPh)Cl_2(CO)(PMe_3)_2$ (**22**)

A suspension of **20** (0.25 g, 0.44 mmol) in benzene (25 cm^3) was stirred under 1 atm CO at 65°C for a day. Evaporation of most of the solvent and addition of Et_2O gave 0.11 g (69%) of purple **22**. IR: 1946 ν(CO), 1303, 1282, 1070, 950, 773, 743, 723, 555, 465, 379. Found: C, 29.8; H, 4.3; N, 2.5. Calc. for $C_{13}H_{23}Cl_2NOP_2W$: C, 29.7; H, 4.4; N, 2.7%. UV–vis: 492 nm (220).

$W(NPh)Cl_2(CH_2{=}CH_2)(PMePh_2)_2$ (**23**)

Following the procedure for **20**, 0.3 g (0.32 mmol) of **19** gave 0.14 g (49%) of **23**. IR: 1653, 1582, 1188, 1156, 1104, 1093, 1072, 999, 990, 891, 767, 739, 697, 618, 507, 484, 446, 437.

$W(NPh)Cl_2(CH_2{=}CH_2)(PMe_3)_2$ (**24**)

A solution of **24** (0.35 g, 0.9 mmol) in benzene (15 cm^3) was stirred at 70°C under 1 atm of ethylene for 1 h. Evaporation of most of the solvent and addition of petroleum ether gave 0.18 g (38%) of yellow **24**. IR: 1282, 1168, 1069, 1023, 950, 861, 773, 743, 723, 691, 567, 555, 542. Found: C, 31.8; H, 5.1; N, 2.6. Calc. for $C_{14}H_{27}Cl_2NOP_2W$: C, 31.9; H, 5.1; N, 2.7%.

$W(N\text{-}p\text{-}Tol)(CO)Cl_2(PMePh_2)_2$ (**25**)

p-Tolyl isocyanate (0.015 cm^3, Aldrich) was added to a suspension of **1** (105 mg) in benzene (12 cm^3) and stirred for 4 h. The volatiles were pumped away, Et_2O (1 cm^3) was added to dissolve the residue, and pentane (8 cm^3) was added. The resulting solids were filtered and dried *in vacuo* for 2 h, yielding 45 mg (57%) of purple **25**. Found: C, 51.4; H, 4.2; N, 1.7. Calc. for $C_{34}H_{33}Cl_2NOP_2W$: C, 51.8; H, 4.2; N, 1.8%. IR: 1964 vs ν(CO), 1587 w, 1158, 1099 ν(WNC), 892 vs, 821 s, 758 s, 740 s, 731 s, 720 s, 690 vs, 559 w, 515 s, 480, 450 w, 290, 255 w. UV–vis: 544 nm (160).

$W(NSiMe_3)(CO)Cl_2(PMePh_2)_2$ (**26**)

Trimethylsilyl isocyanate (0.030 cm^3, Aldrich) was added to a suspension of **1** (0.20 g) in benzene (15 cm^3) and stirred for 21 h. The volatiles were pumped away and Et_2O (1 cm^3) and pentane (15 cm^3) were added. The resulting solids were filtered and dried *in vacuo* for 2 h, yielding 0.110 g (75%) of red **26**. IR: 1976 vs ν(CO), 1249, 1129 s, 1118 s, 1098, 890 vs, 838 br, 739 s, 690 vs, 506 s, 455, 273 w, 255 w.

$Mo(O)Cl_2(CO)(PMePh_2)_2$ (**27**)

This complex was prepared from CO and $Mo(O)Cl_2(PMePh_2)_3$ in 65% yield as brown crystals following the procedure for **4**, except petroleum ether was added through the side arm of the Schlenk flask instead of by vacuum transfer. ^1H NMR: 6.94–7.03 (br m, 12, PMe*PH*$_2$, *p* and *m*), 7.55 (m, 4, PMe*Ph*Ph′, *o*), 7.92 (m, 4, PMePh*Ph*′, *o*).

$W(O)Me(Cl)(CH_2{=}CH_2)(PMePh_2)_2$ (**28**)

A solution of **7** (0.20 g, 0.28 mmol) was dissolved in benzene (20 cm^3), cooled to 10°C, and $AlMe_3$ (1.0 M in benzene, 0.33 cm^3, 0.33 mmol) was added with stirring. The mixture was filtered and the volume was reduced to 1 cm^3. Ether (10 cm^3) was added and yellow crystals were isolated upon stirring the mixture; yield 0.08 g (40%). IR: 960 *ν*(W—O). ^1H NMR: 1.35 (t, 3, $^3J_{PH}$ = 11, WC*H*$_3$), 2.23 (t, 6, J_{PH} = 4, P*Me*Ph$_2$), 2.47 (m, 2, C*H*H′C*H*H′), 2.58 (m, 2, CH*H*′CH*H*′), 6.94–7.06 (br m, 12, PMe*PhPh*′, *p* and *m*), 7.57 (m, 4, PMe *Ph*Ph′*o*), 7.78 (m, 4, PMePh*Ph*′, *o*). ^{13}C NMR: 11.5 (q of t, J_{PC} = 17, J_{CH} = 116, WCH_3), 20.65 (q of t, J_{PC} = 9, J_{CH} = 121, PCH_3Ph$_2$), 48.99 (t, J_{CH} = 158, C_2H_4). $^{31}P\{^1H\}$ NMR: 19.5 (s, J_{WP} = 274).

$W(O)Me(Cl)(CO)(PMePh_2)_2$

This complex was prepared in a sealed tube containing **28** (10 mg) in C_6D_6 and 1 atm CO. IR (C_6D_6): 1985 *ν*(CO), 960 *ν*(WO). ^1H NMR: 1.72 (t, 3, $^3J_{PH}$ = 10, WCH_3), 2.17 (t, 6, J_{PH} = 4, P*Me*Ph$_2$), 6.94–7.07 (br m, 12, PMePh*Ph*′, *p* and *m*), 7.67 (m, 4, PMe*Ph*Ph′, *o*), 7.75 (m, 4, PMePh*Ph*′, *o*). $^{13}C\{^1H\}$ NMR: 236.6 (s, J_{PC} = 5, *C*O). $^{31}P\{^1H\}$ NMR: 15.7 (s, J_{WP} = 323, J_{PC} = 4). The ^{13}C and ^{31}P spectra were determined for W(O)Me(Cl)(^{13}CO)$(PMePh_2)_2$.

$W(O)Cl(Me)(CN^tBu)(PMePh_2)_2$

CN^tBu (0.015 cm^3, 0.20 mmol) was added to a stirred solution of **28** (0.10 g, 0.23 mmol) in 15 cm^3 of benzene. The purple solution was filtered and the volume was reduced to 1 cm^3. Petroleum ether (5 cm^3) was added and the purple crystals were isolated and dried *in vacuo*; yield 0.35 g (45%). IR: 2110 *ν*(CN), 955 *ν*(WO). ^1H NMR: 0.80 (s, 9, CNC*Me*$_3$), 2.07 (t, 3, J_{PH} = 9, WCH_3), 2.40 (t, 6, J_{PH} = 4, P*Me*Ph$_2$), 6.97–7.14 (br m, 12, PMe*Ph*$_2$, *p* and *m*), 7.70 (m, 4, PMe*Ph*Ph′, *o*), 8.11 (m, 4, PMePh*Ph*′, *o*). $^{13}C\{^1H\}$ NMR: 15.35 (t, J_{PC} = 15, P*Me*Ph$_2$), 15.45 (t, J_{PC} = 6, WCH_3), 30.69 (s, CNC*Me*$_3$), 57.83 (s, CH*C*Me$_3$), 145.50 (t, J_{PC} = 19, *C*NCMe$_3$). $^{31}P\{^1H\}$ NMR: 16.8 (s, J_{WP} = 327).

X-ray structure determinations for W(N-*p*-Tol)(CO)$Cl_2(PMePh_2)_2$ (**25**) *and* $WCl_2(PMePh_2)_4$ (**1**)

Data were collected at room temperature (295 K) on a crystal sealed in a glass capillary (**25**) and on

a crystal mounted on a glass fiber (**1**) using a CAD4 diffractometer operating in the θ–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), as previously described.[36] The structures were solved using standard heavy atom methods and refined with full-matrix least-squares, with scattering factors and anomalous dispersion terms taken from standard compilations.[37] All non-hydrogen atoms were refined anisotropically, hydrogen atom positions were calculated (C—H = 0.95 Å). Crystallographic data are given in Table 6. Positional and thermal parameters, complete tabulations of bond lengths and angles, and observed and calculated structure factors are available as supplementary material from the Editor.

Acknowledgements—We would like to thank Lauren Atagi for the photochemical experiments and Don McAlister for his many contributions. This work was supported by the Donors of the Petroleum Research Fund, administered by the American Chemical Society, the University of Washington Graduate School Research Fund (GSRF), the National Science Foundation (CHE-8617965), and the Chevron Research Company. We also acknowledge support for X-ray equipment from the National Science Foundation (CHE-8617023) and the University of Washington GSRF (PHS grant PR-07096).

(*Received* 7 *November* 1988; *accepted* 5 *January* 1989)

Abstract—Reaction of 3,3′-iminobispropylamine with trimethylaluminium affords the crystalline complex $[Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2$. The title compound crystallizes in the monoclinic space group $P2_1/n$, with unit cell parameters $a = 8.334(2)$, $b = 11.099(3)$, $c = 14.264(4)$ Å, $\beta = 90.99(2)°$, $V = 1319.2$ Å^3, and $\rho = 1.14$ g cm^{-3} for $Z = 2$. Least-squares refinement based on 1018 observed reflections [$I > 3\sigma(I)$] converged at $R = 0.048$, $R_w = 0.053$. The title compound, consisting of two amine units bridged by four organoaluminium moieties, has extensive Al—N association. The two central aluminium atoms are five-coordinate residing in trigonal bipyramidal environments. The compound contains three Al_2N_2 rings with a mean Al—N distance of 1.990(4) Å. The shortest Al···Al contact of 2.830(2) Å does not suggest significant metal–metal interactions.

The utilization of organo-main group compounds as organometallic precursors to ceramic materials is currently a very popular area of study. Organoaluminium–nitrogen compounds are noteworthy as potential single source organometallic precursors to aluminium nitride. While much of the recent emphasis in this area has concerned the condensation reactions of aluminium alkyls with ammonia,[1] Smith performed a considerable amount of seminal work concerning the organoaluminium chemistry of primary and secondary monodentate amines.[2–10] The corresponding organoaluminium chemistry of nitrogen-based macrocyclic ligands and multidentate open-chain amines has received less attention. Here, we report the synthesis and molecular structure of $[Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2$ isolated from reaction of 3,3′-iminobispropylamine ($C_6H_{17}N_3$) (Fig. 1) with trimethylaluminium. The title compound is noteworthy in that it contains an extensive aluminium–nitrogen network, in addition to accommodating two five-coordinate aluminium atoms residing in trigonal bipyramidal environments.

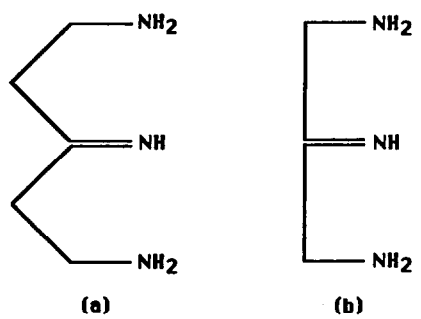

Fig. 1. (a) 3,3′-iminobispropylamine and (b) diethylenetriamine.

EXPERIMENTAL

Synthesis

Standard Schlenk techniques were employed in conjunction with an inert atmosphere dry box (Vacuum Atmospheres HE-43 Dri-Lab). Trimethylaluminium and 3,3′-iminobispropylamine, both purchased from Aldrich Chemical Company, were used as received. Single crystal, X-ray data were collected on a Nicolet R3m/V diffractometer. ^{1}H NMR data were recorded on a JOEL-FX90Q

* Author to whom correspondence should be addressed.

NMR spectrometer. Solvents were purified and degassed in the usual manner.

Inside the dry box, a reaction vessel was charged with 3,3′-iminobispropylamine (7.15 mmol) and a mixture of methylene chloride and pentane (5 cm^3: 10 cm^3, respectively). Trimethylaluminium (14.3 mmol) was slowly added via syringe. Reaction was immediate and quite exothermic. The resulting clear mixture was heated overnight in an oil bath (90°C). The system was vented frequently to allow release of CH_4. After allowing the system to stand undisturbed for several hours at room temperature, a multitude of small, colourless, extremely air-sensitive crystals were obtained. ^1H NMR ($CDCl_3$): δ −0.529 [s, 3H, Al(CH_3)], −0.665 [s, 3H, Al(CH_3)], −0.798 [s, 6H, Al(CH_3)$_2$], −0.842 [s, 6H, Al(CH_3)$_2$], −0.924 [s, 6H, Al(CH_3)$_2$], −0.943 [s, 6H, Al(CH_3)$_2$], 1.69–2.69 [m, 24H, (N(CH_2)$_3$)$_2$N]. The six peaks representing the alkyl aluminium protons are indicative of solution isomerization of the title compound.

X-ray structural solution and refinement

A single crystal of [Al(CH_3)]$_2$[$C_{12}H_{28}N_6$][Al(CH_3)$_2$]$_2$ was mounted in a thin-walled glass capillary under an inert atmosphere of argon. Cell constants and an orientation matrix for the setting angles of 26 carefully centred reflections in the range $15.07 < 2\theta < 29.61°$ corresponded to a monoclinic cell with dimensions $a = 8.334(2)$, $b = 11.099(3)$, $c = 14.264(4)$ Å, $\beta = 90.99(2)°$, $V = 1319.2$ Å^3, and $\rho = 1.14$ g cm^{-3} for $Z = 2$. The space group was determined to be $P2_1/n$. The structure was solved by direct methods and refined, based on 1018 observed reflections [$I > 3\sigma(I)$], using SHELXTL.[11] Hydrogen atoms, located from difference Fourier maps, were placed in idealized positions with fixed isotropic temperature factors. Refinement converged at $R = 0.048$, $R_w = 0.053$. Relevant crystallographic data are given in Table 1.

RESULTS AND DISCUSSION

Particularly significant in the design of organoaluminium single source aluminium nitride precursors is the optimization of Al—N interactions throughout the source molecule. We have endeavoured to address this premise by exploring the organoaluminium chemistry of macrocyclic[12–14] and multidentate open-chain amines.[15–18] Multidentate open-chain amines are notably attractive in this regard for two reasons: (1) reaction of N—H and Al—R species results in alkane elimination and reaction products with considerable Al—N association; (2) due to their inherent flexibility, multidentate open-chain amines offer various modes of coordination about an aluminium atom, thereby potentially saturating the coordination sphere via extensive Al—N contacts. The tridentate open-chain amine 3,3′-iminobispropylamine was allowed to react with trimethylaluminium; [Al(CH_3)]$_2$[$C_{12}H_{28}N_6$][Al(CH_3)$_2$]$_2$ was the only product isolated. The overall reaction is given in eq. (1). The X-ray crystal structure of the compound is given in Fig. 2.

$$4Al(CH_3)_3 + 2(H_2NCH_2CH_2CH_2)_2NH \longrightarrow [Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2 + 6CH_4. \quad (1)$$

Several points are worthy of note regarding the structure and bonding in [Al(CH_3)]$_2$[$C_{12}H_{28}N_6$][Al(CH_3)$_2$]$_2$. The title compound consists of a dimer, in that two amine units are bridged by four organoaluminium species. The molecule, residing about a crystallographic centre of symmetry, contains two dimethylaluminium species and two methylaluminium species. Furthermore, [Al(CH_3)]$_2$[$C_{12}H_{28}N_6$][Al(CH_3)$_2$]$_2$ contains three Al_2N_2 ring fragments. The coordination environment of the aluminium atoms is particularly significant. The two outermost aluminium atoms, Al(2) and Al(2a), are in the usual organoaluminium coordination of four-coordinate tetrahedral. However, the two central aluminium atoms, Al(1) and Al(1a), are clearly five-coordinate, being bonded to two nitrogen atoms of each amine

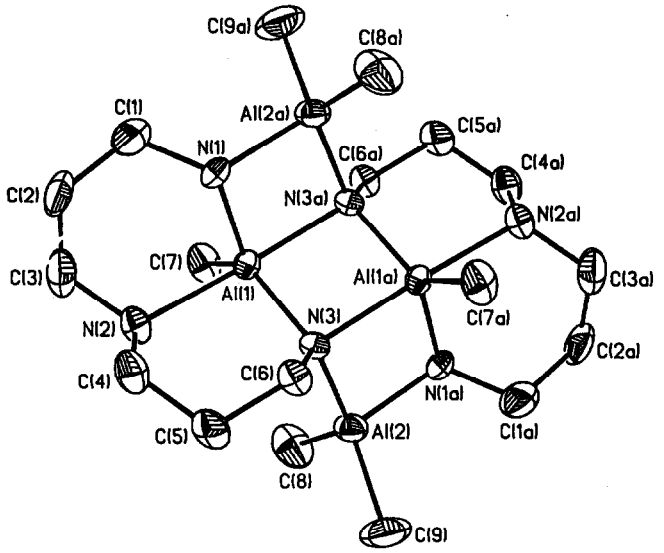

Fig. 2. A view of the $[Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2$ molecule showing the atom labelling scheme. Thermal ellipsoids show 35% probability levels; hydrogen atoms have been omitted. Selected bond distances (Å) and angles (°): Al(1)—N(1), 1.967(4); Al(1)—N(2), 2.193(4); Al(1)—N(3), 1.878(4); Al(1)—N(3a), 2.065(4); Al(1)—C(7), 1.988(6); Al(2)—N(3), 1.891(4); Al(2)—N(1a), 1.944(4); Al(2)—C(8), 1.974(7); Al(2)—C(9), 1.987(7); Al(1)···Al(2a), 2.830(2); Al(1)···Al(1a), 2.883(3). N(2)—Al(1)—N(3a), 169.0(2); N(1)—Al(1)—C(7), 117.1(2); N(3)—Al(1)—C(7), 127.9(2); N(2)—Al(1)—C(7), 89.8(2); N(2)—Al(1)—N(3), 91.6(2); N(3)—Al(2)—N(1a), 90.6(2); C(8)—Al(2)—C(9), 111.0(3); Al(1)—N(3)—C(6), 116.3(3); Al(2)—N(3)—C(6), 111.7(3); Al(2)—N(3)—Al(1a), 91.2(2); Al(1)—N(3)—Al(1a), 93.8(2).

unit in addition to a methyl carbon atom. The aluminium atom, Al(1), is coplanar with C(7), N(1), and N(3). The N(2)—Al(1)—N(3a) bond angle is 169.0(2)° while the N(2)—Al(1)—C(7), N(2)—Al(1)—N(3) and N(1)—Al(1)—N(2) are determined to be 89.8(2), 91.6(2) and 86.2(2)°, respectively. The Al(1)—N(2) and Al(1)—N(3a) bond distances are 2.193(4) and 2.065(4) Å, respectively. The coordination of both Al(1) and Al(1a) may thus be described as five-coordinate trigonal bipyramidal. A perspective view of the coordination geometry about Al(1) is given in Fig. 3.

The title compound is easily compared to the previously reported $[Al(CH_3)]_2[C_8H_{20}N_6][Al(CH_3)_2]_2$ complex[18] isolated from reaction of trimethylaluminium with diethylenetriamine (Fig. 1). While this complex bears a resemblance to the title compound in that both compounds contain two five-coordinate aluminium atoms, there are fundamental differences between the two. In the organoaluminium–diethylenetriamine complex the two five-coordinate aluminium atoms are in square-pyramidal environments, while the two five-coordinate aluminium atoms

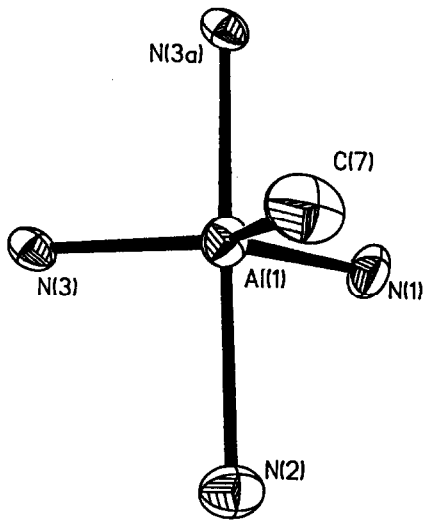

Fig. 3. A perspective view of the coordination geometry about Al(1) in $[Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2$.

in the title compound are in trigonal bipyramidal geometries. This may be viewed as a consequence of the greater inherent flexibility of 3,3′-iminobispropylamine relative to diethylenetriamine. In-

deed, in two other recently reported organoaluminium compounds containing penta-coordinate aluminium atoms, $[Al(CH_3)][C_{18}H_{19}N_4][Al(CH_3)_2]$[15] and $[Al(CH_3)][Ph_2P(O)C]_2[Al(CH_3)_2]_2$,[19] the five-coordinate aluminium atoms were found to be in trigonal bipyramidal environments. Notably, both of these compounds involved flexible multidentate ligands. It thus appears that the coordination geometry of five-coordinate aluminium species depends markedly on the associated ligand(s). It may thus be suggested that if the associated multidentate ligand(s) is sufficiently flexible, a trigonal bipyramidal coordination of aluminium may be favoured. Conversely, if the associated ligand(s) is sufficiently rigid, a square bipyramidal coordination geometry may be observed.

Another notable difference between the title compound and the organoaluminium–diethylenetriamine complex is the coordination environment of the nitrogen atoms. Each nitrogen atom in the previously reported organoaluminium–diethylenetriamine complex, including the two central nitrogen atoms, is bonded to two aluminium atoms. The single hydrogen atom on both central nitrogen atoms of the free tridentate amine was utilized in alkane elimination during the course of the reaction with trimethylaluminium. A similar situation was not observed in the title compound. Surprisingly, the central secondary amine nitrogen atoms, N(2) and N(2a) in $[Al(CH_3)]_2[C_{12}H_{28}N_6][Al(CH_3)_2]_2$, each retained their single hydrogen atom, while both hydrogen atoms of two primary amine nitrogen atoms, N(3) and N(3a), were utilized in the alkane elimination. The remaining primary nitrogen atoms, N(1) and N(1a), each donated one of their hydrogen atoms to alkane elimination. This all results in the central nitrogen atoms in the title compound being bonded to only one aluminium atom, whereas the two nitrogen atoms that lost both of their hydrogen atoms are bonded to three aluminium atoms. This appears to be a consequence of the increased length in the hydrocarbon linkages of the multidentate open-chain amines (3,3′-iminobispropylamine relative to diethylenetriamine), in that the $-(CH_2)_3-$ hydrocarbon fragments are too long to facilitate substantial interaction of the organoaluminium moieties with the central N—H units. Consequently, the terminal primary amine units are in better positions to be involved in the Al—N network. Importantly, this is the first observation by this laboratory where both hydrogen atoms of a $-NH_2$ fragment were cleaved resulting in the nitrogen atom bonding to three aluminium atoms.

The organoaluminium chemistry of multidentate open-chain amines has proven to be a particularly fruitful area of study. Small changes in the length of the hydrocarbon fragments of these amines profoundly affect the coordination geometry of aluminium. Indeed, we have recently observed a six-coordinate aluminium atom in a macrocyclic amine complex.[20] Related studies with multidentate open-chain amines and alkylaluminium halides and hydrides are forthcoming.

Acknowledgement—We are grateful to the National Science Foundation for support of this work to G.H.R. (RII-8520554).

Supplementary material available. A summary of data collection and refinement, tables of bond distances and angles, and tables of fractional coordinates, in addition to a listing of observed and calculated structure factors have been deposited with the Cambridge Crystallographic Data Centre. Complete structural information is available from the Editor.

CYCLOPENTADIENYL SUBSTITUTED DIETHYLAMINOCARBYNE COMPLEXES OF TUNGSTEN IN A HIGHER OXIDATION STATE

A. C. FILIPPOU

Institut für Anorganische Chemie, Technische Universität München, Lichtenbergstraße 4, D-8046 Garching, F.R.G.

(*Received* 9 *November* 1988; *accepted* 5 *January* 1989)

Abstract—The reaction of an equimolar mixture of $(\eta^5\text{-}C_5H_5)(I)_2(CO)W{\equiv}CNEt_2$ (**1**) and $t\text{-}C_4H_9NC$ in THF at 50°C, results in the replacement of the CO ligand by isocyanide and formation of $(\eta^5\text{-}C_5H_5)(I)_2(t\text{-}C_4H_9NC)W{\equiv}CNEt_2$ (**2**). Complex **2** reacts further with $t\text{-}C_4H_9NC$ in refluxing THF with displacement of the iodide ligand from the coordination sphere to give the cationic carbyne complex $[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)_2W{\equiv}CNEt_2]^+I^-$ (**3**). A new route to **2** in three steps has also been developed. The starting material, *mer*-$I(t\text{-}C_4H_9NC)_3W{\equiv}CNEt_2$ (**4**), is transformed with KC_5H_5 in refluxing THF to $(\eta^5\text{-}C_5H_5)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2$ (**5**). Complex **5** is then oxidized with elemental iodine in CH_2Cl_2 to give $[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2]^+I^-$ (**6**), the first cationic, carbonyl-containing carbyne complex of tungsten in a higher oxidation state. Finally, **6** is decarbonylated thermally in boiling THF to **2**. The composition and structure of the new complexes **2**, **3**, **5** and **6** have been determined by total elemental analyses and IR, ^1H NMR, ^{13}C NMR spectroscopies, as well as by mass spectrometry. The non-ionic nature of **2** and ionic nature of **6** in solution, have been confirmed by conductivity measurements.

Complexes containing a metal–carbon triple bond are divided into two classes. Class (a) includes compounds of low valent metals, which are known as Fischer type carbyne complexes. In these complexes, the electron-rich metal is stabilized by good π-acceptor ligands such as CO, e.g. *trans*-$X(CO)_4M{\equiv}CR$ (X = halogen; M = Cr, Mo, W; R = aryl or alkyl group).[1] Class (b) contains complexes of high valent metals, i.e. Schrock type alkylidyne complexes. In these complexes, the electron-deficient metal is stabilized by good π-donor ligands, such as halogen or alkoxy ligands, e.g. $X_3(dme)W{\equiv}CCMe_3$ (X = halogen; dme = 1,2-dimethoxyethane).[2]

Striking differences in the reactivity exist between class (a) and (b) compounds. This is most impressively demonstrated by their reactions with alkynes. Fischer type carbyne complexes catalyse alkyne polymerization, while Schrock type alkylidyne complexes function as alkyne metathesis catalysts.[3,4]

In our development of the chemistry of substituted tungsten carbyne complexes with the general formula $I(CO)_2L_2W{\equiv}CNEt_2$ (L = C_5H_5N, PMe_3, $t\text{-}C_4H_9NC$, L_2 = 2,2′-bipy, *o*-phen), we have demonstrated that their oxidative decarbonylation with iodine gives $(I)_3(CO)L_2W{\equiv}CNEt_2$ in high yield.[5–8]

These complexes are unique, because they combine features of both Fischer type carbyne complexes, such as π-acceptor CO ligands, and Schrock type alkylidyne complexes, i.e. a high valent metal centre. Therefore, new, interesting reactivity patterns are expected. We first studied their reactions with nucleophiles and found two reaction pathways to be predominant: (a) Substitution of the labile CO ligand and one iodide ligand by the nucleophile to form cationic carbyne complexes, e.g. the reaction of $(I)_3(CO)L_2W{\equiv}CNEt_2$ with $t\text{-}C_4H_9NC$ to give $[(I)_2(t\text{-}C_4H_9NC)_2L_2W{\equiv}CNEt_2]^+I^-$ (L_2 = 2,2′-bipy, *o*-phen; L = $t\text{-}C_4H_9NC$)[7,8] and (b) reductive elimination of iodine to give low valent, neutral or cationic carbyne complexes, e.g. the reaction of $(I)_3(CO)(PMe_3)_2W{\equiv}CNEt_2$ or $(I)_3(CO)L_2W{\equiv}CNEt_2$ (L_2 = 2,2′-bipy, *o*-phen) with PMe_3 to give *mer*-$I(PMe_3)_3(CO)W{\equiv}CNEt_2$ or $[(PMe_3)_2(CO)L_2W{\equiv}CNEt_2]^+I^-$ (L_2 = 2,2′-bipy, *o*-phen).[5,6] To

extend our studies on cyclopentadienyl (cp) substituted carbyne complexes, we have first developed a high yield route to $(\eta^5\text{-}C_5R_5)(CO)_2W{\equiv}CNEt_2$ (R = H, Me) and subsequently decarbonylated these complexes to give $(\eta^5\text{-}C_5R_5)(X)_2(CO)W{\equiv}CNEt_2$ (R = H, Me; X = Br, I).[9,10] We have found differences in the reactivity of $(\eta^5\text{-}C_5H_5)(I)_2(CO)W{\equiv}CNEt_2$ compared to the corresponding $(I)_3(CO)L_2W{\equiv}CNEt_2$ complexes (L_2 = 2,2′-bipy, *o*-phen; L = PMe_3, *t*-C_4H_9NC). Thus a reaction with PMe_3 occurs only at elevated temperatures; it leads to the displacement of the Cp ligand and reductive elimination of iodine to form low valent trimethylphosphine-substituted carbyne complexes. The expected product, $(\eta^5\text{-}C_5H_5)(PMe_3)(CO)W{\equiv}CNEt_2$, was not observed.[11] This result has prompted us to investigate the reaction of $(\eta^5\text{-}C_5H_5)(I)_2(CO)W{\equiv}CNEt_2$ with *t*-C_4H_9NC.

RESULTS AND DISCUSSION

The reaction of **1** with *t*-C_4H_9NC (molar ratio 1 : 1.2) in THF at 50°C, yields quantitatively the substitution product **2** [eq. (1)]. This product is isolated as a purple, microcrystalline solid, which is only slightly sensitive to air and moisture, soluble in CH_2Cl_2, THF and toluene, but insoluble in Et_2O and *n*-pentane (m.p. 110°C).

Complex **2** reacts with *t*-C_4H_9NC in boiling THF with the elimination of one iodide ligand from the coordination sphere and formation of the yellow, cationic carbyne complex **3** [eq. (2)]. This product is soluble in CH_2Cl_2, sparingly soluble in cold THF and toluene, but insoluble in Et_2O and *n*-pentane. Complex **3** undergoes decomposition in a sealed capillary at 135°C. A slow halogen exchange (iodide for chloride) occurred in a solution of **3** in CH_2Cl_2 at room temperature. This reaction is accelerated in boiling CH_2Cl_2 and leads to mixed halogen substitution products.[11]

A different route to **2** has been developed requiring three steps. The first step involves the reaction of the easily available *mer*-$I(t\text{-}C_4H_9NC)_3(CO)W{\equiv}CNEt_2$ (**4**)[12] with KC_5H_5 in refluxing THF to give **5** [eq. (3)]. Complex **5** is an extremely air-sensitive, yellow oil, which is very soluble in CH_2Cl_2, THF, Et_2O and *n*-pentane. Complex **5** is then quantitatively transformed with elemental iodine to **6**, the

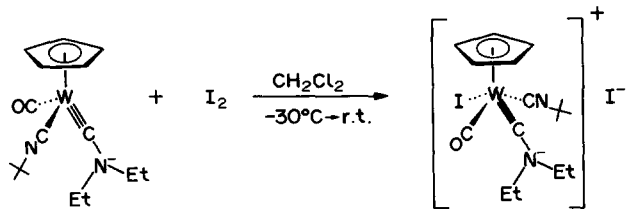
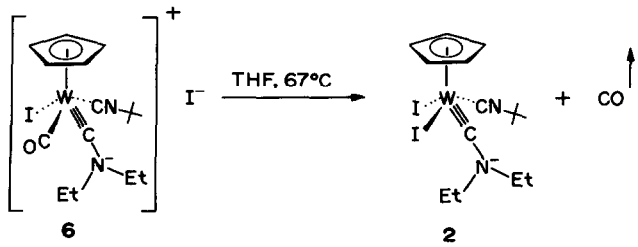
first carbonyl containing, cationic carbyne complex of tungsten in a higher oxidation state [eq. (4)]:



5 6 (4)

This product is obtained as an orange, microcrystalline powder, which is very soluble in CH_2Cl_2, sparingly soluble in cold THF and toluene, but insoluble in Et_2O and *n*-pentane. Decomposition of **6** is observed in a sealed capillary at 108°C.

In the last step, **6** is thermally decarbonylated to quantitatively give **2** [eq. (5)]:



6 2 (5)

We assume a piano-stool geometry for complexes **2**, **3** and **6**, in agreement with MO-calculations on $CpML_4$ complexes, which favour energetically this structure over an alternative C_5H_5-capped trigonal bipyramidal structure.[13] The solution IR spectra of the new compounds, **2**, **3**, **5** and **6**, show characteristic absorptions for the stretching vibrations of the coordinated isonitrile and carbonyl ligands (Table 1).
