A shift of the $\nu(C{\equiv}N{-})$ absorptions to higher frequency is observed when the IR data of **2**, **3** and **6** are compared. This shift can be attributed to a reduction of the electron density at the metal, and the simultaneous weakening of the metal isonitrile back-bonding. The same trend is observed for the $\nu(C{\equiv}O)$ band of compound **1** ($\nu(C{\equiv}O)$ in CH_2Cl_2, 2008 cm^{-1})[9] and **6** ($\nu(C{\equiv}O)$ in CH_2Cl_2, 2053 cm^{-1}), due to the weaker metal carbonyl back-bonding in **6** compared with **2**. In KBr, the complexes exhibit a strong band around 1600 cm^{-1}, which may be assigned to a $\nu(C{=}N)$ vibration. This

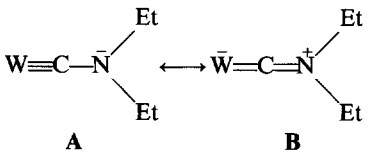

Fig. 1. Resonance forms for the bonding in the carbyne ligand.

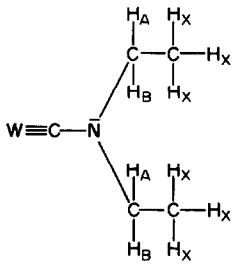
band displays the strong interaction of the metal–carbon triple bond with the lone pair of nitrogen (Fig. 1, resonance form **B**).

The contribution of resonance form **B** to the bonding description of the carbyne ligand is diminished in **2** compared with **3** and **6**, due to an enhancement of the electron density at the metal centre. Therefore, a shift of the ν(C≡N) vibration to lower frequency is observed. A similar trend has already been reported for other diethylaminocarbyne complexes of tungsten in both lower and higher oxidation states.[5,6,8,14]

The triplets for the methyl protons of the diethylamino group observed in the ^{1}H NMR spectra of **2**, **3**, **5** and **6**, confirm the free rotation of the ethyl groups around the carbyne–carbon–nitrogen bond (Table 2). A singlet is obtained for the *t*-butyl groups of the isonitrile ligands in **3**, showing their *trans*-orientation. Complexes **5** and **6** are chiral, therefore, the protons of the methylene groups in the carbyne ligand are diastereotopic and give a signal of four overlapping quartets, which may be assigned in an ABX_3 spin system:



The same splitting is observed for the signals of the methylene protons in **2**, which must, therefore, also be diastereotopic. These facts suggest a structure of low symmetry with a *cis*-orientation of the iodide ligands. In contrast, the *t*-C_4H_9NC ligands in **3** are *trans*-oriented and the molecule contains a plane of symmetry; the methylene protons are therefore homotopic and give rise to a quartet.

Resonances, expected for the carbyne carbons in cyclopentadienyl-substituted diethylaminocarbyne

complexes of tungsten, are observed in the $^{13}C\{^1H\}$ NMR spectra of **2**, **3**, **5** and **6** (Table 3).[9,10]

The isonitrile carbons appear as broad singlets, because of the quadrupol relaxation of nitrogen. Therefore any ^{13}C–^{14}N coupling cannot be resolved. Comparing the data of **2**, **3** and **6**, an upfield shift of the isonitrile carbon resonance is observed. This can be explained by the weaker metal–isonitrile back-bonding ($6 < 3 < 2$) and is in agreement with results obtained earlier for other tungsten isonitrile complexes.[8,12,14,15] For the same reason, the strong metal–isonitrile back-bonding in **5** causes an extremely large downfield shift of the isonitrile carbon signal. This is independently demonstrated by the shift of the $\nu(C\equiv N\rightarrow)$ vibration in the IR spectrum of **5** to a considerably lower frequency ($\nu(C\equiv N\rightarrow)$ in CH_2Cl_2, 1925 cm^{-1}) compared with that of the free ligand ($\nu(C\equiv N\rightarrow)$ in CH_2Cl_2, 2140 cm^{-1}).

The conductance of **6** in 1,2-dichloroethane is of the same magnitude ($c = 4.6 \times 10^{-4}$ mol dm^{-3}, $t = 19.8$°C, $\Lambda = 31\ \Omega^{-1}\ cm^2\ mol^{-1}$) as that of $NR_4^+X^-$ (R = "bu, "pr; X = Br, I, PF_6) and other ionic diethylaminocarbyne complexes of tungsten in low and high oxidation states.[6–8,16] The conductivity increases with decreasing concentration of the complex, and proves independently the ionic nature of **6** in solution. In contrast, 1,2-dichloroethane solutions of **1** and **2** are not conducting.

The mass spectral data of **2**, **3**, **5** and **6** (Table 4) reveal characteristic fragmentation patterns of isonitrile-substituted diethylaminocarbyne complexes. Loss of I or t-C_4H_9NC, elimination of isobutylene ($Me_2C{=}CH_2$) from the t-C_4H_9NC ligand or C_2H_5 from the carbyne ligand are observed. Using the SIMS method for complex **3**, the parent cation $[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)_2W{\equiv}CNEt_2]^+$ (K^+: $m/z = 626$) is observed. Complex **6** decom-

poses under EI conditions with elimination of CO and formation of $[(\eta^5\text{-}C_5H_5)(I)_2(t\text{-}C_4H_9NC)W{\equiv}CNEt_2]^+$ (m/z = 670), the molecular ion of **2**. This ion could not be detected in the mass spectrum of **2** under EI conditions.

CONCLUSION

Starting from $(\eta^5\text{-}C_5H_5)(CO)_2W{\equiv}CNEt_2$, the precursor of $(\eta^5\text{-}C_5H_5)(I)_2(CO)W{\equiv}CNEt_2$, and $(\eta^5\text{-}C_5H_5)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2$, we were able to isolate by high yield methods, neutral and cationic cyclopentadienyl-substituted tungsten carbyne complexes containing isocyanide ligands. The oxidative decarbonylation of the electron-rich complex $(\eta^5\text{-}C_5H_5)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2$, enabled us to synthesize $[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2]^+I^-$, the first cationic diethylaminocarbyne complex of high-valent tungsten containing a carbonyl ligand. Its decarbonylation leads to the first neutral, carbonyl-free diethylaminocarbyne complex of high-valent tungsten. Based upon the spectroscopic data, the mass spectral data and the conductivity measurements, we suggest a neutral structure with a *cis*-orientation of the two iodide ligands for **2** and an ionic structure with a *trans*-orientation of the two isonitrile ligands for **3**. In both molecules an iodide ligand, acting as a π-donor, is located in the *trans*-position relative to the carbyne ligand. Therefore, we assume that the same orientation is retained in the ionic compound **6**, although we cannot exclude stereoisomers with a different orientation.

The new complexes are useful starting materials for the investigation of isonitrile carbyne coupling reactions induced by electrophiles or reducing agents.[17]

EXPERIMENTAL

KC_5H_5 was prepared from KH and C_5H_6 in THF. $(\eta^5\text{-}C_5H_5)(I)_2(CO)W{\equiv}CNEt_2$ and *mer*-$I(t\text{-}C_4H_9NC)_3(CO)W{\equiv}CNEt_2$ were synthesized as described previously.[9,12] t-C_4H_9NC was distilled and stored under nitrogen. All operations were carried out under nitrogen or argon atmospheres using Schlenk tube techniques. The solvents were dried by standard methods (*n*-pentane, toluene, Et_2O and THF over Na; CH_2Cl_2 over P_4O_{10} and Na/Pb alloy). The Al_2O_3 used for filtration (Merck Darmstadt, neutral, activity *I*, 0.063–0.2 mm) was degassed and dried at room temperature *in vacuo*, and then saturated with nitrogen. Elemental analyses were determined by the Microanalytical Laboratory of this department. IR spectra were measured with a Nicolet DX5 FT spectrophotometer, NMR spectra with a Jeol GX 270 FT instrument and mass spectra with a Varian MAT CH7 spectrometer using EI conditions for **2**, **5** and **6** and the SIMS method for **3**. Conductance measurements were carried out as described previously.[6–8,16]

$(\eta^5\text{-}C_5H_5)(I)_2(t\text{-}C_4H_9NC)W{\equiv}CNEt_2$ (2)

A purple solution of **1** (180 mg, 0.29 mmol) and t-C_4H_9NC (0.04 cm^3, 0.35 mmol) in THF (60 cm^3) was heated for 1 h at 50°C until the ν(C≡O) band in the IR spectrum of **1** at 2000 cm^{-1} disappeared. The red–purple solution was reduced in volume and an Et_2O–pentane mixture (1 : 2) was added. The supernatant, almost colourless solution was removed and the purple, microcrystalline solid dried *in vacuo* (190 mg, 97% relative to **1**). (Found: C, 27.0; H, 3.5; I, 38.1; N, 4.2; W, 28.2. $C_{15}H_{24}I_2N_2W$ (670.03) requires: C, 26.9; H, 3.6; I, 37.9; N, 4.2; W, 27.4%.)

$[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)_2W{\equiv}CNEt_2]^+I^-$ (3)

A red–purple solution of **2** (140 mg, 0.21 mmol) and t-C_4H_9NC (0.032 cm^3, 0.28 mmol) in THF (50 cm^3) was refluxed for 5 h. The colour of the solution turned brown–yellow. The solvent was reduced in volume and *n*-pentane was added. The supernatant light brown solution was decanted and the yellow, microcrystalline solid dried *in vacuo* (140 mg, 89% relative to **2**). (Found: C, 31.9; H, 4.5; I, 32.6; N, 5.5; W, 24.6. $C_{20}H_{33}I_2N_3W$ (753.16) requires: C, 31.9; H, 4.4; I, 33.7; N, 5.6; W, 24.4%.)

$(\eta^5\text{-}C_5H_5)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2$ (5)

A mixture of **4** (280 mg, 0.42 mmol) and KC_5H_5 (0.70 mmol) was refluxed in THF (60 cm^3) for 6 h. The solvent was then evaporated *in vacuo* and the residue extracted with Et_2O (3 × 30 cm^3). The extracts were filtered through Al_2O_3 (2 × 3 cm) and the solvent removed *in vacuo* to give a yellow oil. Upon cooling a saturated solution of the yellow oil in *n*-pentane to −78°C, yellow crystals of **5** were obtained, which melt below room temperature (150 mg, 81% relative to **4**). (Found: C, 43.0; H, 5.4; N, 6.2. $C_{16}H_{24}N_2OW$ (444.23) requires: C, 43.3; H, 5.4; N, 6.3%.)

$[(\eta^5\text{-}C_5H_5)(I)(t\text{-}C_4H_9NC)(CO)W{\equiv}CNEt_2]^+I^-$ (6)

To a yellow solution of **5** (110 mg, 0.25 mmol) in CH_2Cl_2 (30 cm^3) was added at −30°C, a purple solution of I_2 (62 mg, 0.24 mmol) in CH_2Cl_2 (20 cm^3). The colour of the iodine solution disappeared immediately and the reaction solution turned first

to red and then, upon warming up to room temperature, to orange. The solvent was reduced in volume *in vacuo* and an Et_2O–pentane mixture (1 : 2) was added. The supernatant, almost colourless liquid was decanted, and the microcrystalline, orange residue dried *in vacuo* (165 mg, 95% relative to **5**). (Found: C, 27.6; H, 3.5; I, 36.1; N, 4.0; O, 2.3; W, 26.5. $C_{16}H_{24}I_2N_2OW$ (698.04) requires: C, 27.5; H, 3.5; I, 36.4; N, 4.0; O, 2.3; W, 26.3%.)

$(\eta^5\text{-}C_5H_5)(I)_2(t\text{-}C_4H_9NC)W{\equiv}CNEt_2$ (**2**) *from* **6**

An orange suspension of **6** (140 mg, 0.20 mmol) in THF (50 cm^3) was refluxed for 1.5 h. Upon warming, **6** dissolved in THF to give first an orange solution, which then changed colour through red to red–purple. When all of **6** had been consumed (monitoring by IR) the solution was concentrated *in vacuo* and an Et_2O–pentane mixture (1 : 2) was added. The supernatant liquid was decanted and the microcrystalline, purple precipitate dried *in vacuo* (130 mg, 97% relative to **6**).

2 was characterized by the ^1H NMR and IR spectra.

THE INTERACTION OF $FeCl_3$ WITH PPh_3 IN CHLOROFORM. X-RAY CRYSTAL STRUCTURE OF $[Ph_3PCH_2PPh_3][FeCl_4]_2$

J. DAVID WALKER and RINALDO POLI*

Department of Chemistry and Biochemistry, University of Maryland, College Park, MD 20742, U.S.A.

(*Received* 12 *December* 1988; *accepted* 18 *January* 1989)

Abstract—Interaction of $FeCl_3$ and PPh_3 in $CHCl_3$ yields complex mixtures containing unstable adducts. The compound $[Ph_3PCH_2PPh_3][FeCl_4]_2 \cdot CHCl_3$ was isolated from the solution after the decomposed mixture had been allowed to interact with air. Crystal data: triclinic, space group $P\bar{1}$, $a = 11.459(4)$, $b = 12.102(2)$, $c = 18.109(4)$ Å, $\alpha = 105.15(2)$, $\beta = 102.14(2)$, $\gamma = 94.91(2)°$, $V = 2347(2)$ Å^3, $Z = 2$, $d_c = 1.49$ g cm^{-3}, μ(Mo-K_α) = 13.49 cm^{-1}, $R = 0.045$ ($R_w = 0.054$) for 487 parameters and 5256 observed reflections with $F_o^2 > 3\sigma(F_o^2)$.

We have recently studied the interaction of iron(III) chloride with monodentate phosphine ligands and we have obtained the mononuclear $FeCl_3(PR_3)_2$ (R = Ph, Me, Cy) derivatives.[1] These compounds exhibit a trigonal bipyramidal geometry with the phosphine ligands occupying the axial positions. We have also conducted an EPR study of the $FeCl_3$–PPh_3 interaction in different molar ratios and shown that a reactive four-coordinate $FeCl_3(PPh_3)$ compound, presumably with tetrahedral geometry, is formed when a 1 : 1 ratio is used. This compound decomposes at room temperature in aromatic solvents according to two competitive pathways, the first involving reduction to iron(II) species by the solvent, and the second being a disproportionation to an ionic iron(III) material.[1] We were interested in understanding the relationship between our reactive 1 : 1 adduct and a reported[2] yellow crystalline solid, described as $FeCl_3(PPh_3)$, that had been obtained from $Fe_3(CO)_{12}$ and PPh_3 in $CHCl_3$. An EPR spectroscopic study of the $FeCl_3$–PPh_3 interaction in $CHCl_3$ shows[1] that the $FeCl_3(PPh_3)$ species also forms in this solvent, but it subsequently decomposes according to the same pathways observed in the aromatic solvents. However, while we were trying to crystallize the ionic iron(III) product from the $CHCl_3$ solution, we obtained evidence that yet another decomposition path is available in these conditions. The results of this study are reported here.

EXPERIMENTAL

All operations were carried out under an atmosphere of dinitrogen, unless otherwise specified. Solvents were dried by conventional methods and distilled under dinitrogen prior to use. $FeCl_3$ was dehydrated by treatment in $SOCl_2$ and PPh_3 was recrystallized from absolute ethanol.

Reaction of $FeCl_3$ *with* PPh_3 *in* $CHCl_3$. *Synthesis of* $[Ph_3PCH_2PPh_3][FeCl_4]_2$

PPh_3 (0.92 g, 3.51 mmol) was added to a suspension of anhydrous $FeCl_3$ (0.85 g, 5.26 mmol) in 35 cm^3 of $CHCl_3$ and stirred at room temperature for 1 day. The black solution slowly lightened to produce a yellow solution and a greyish white solid. The solid was filtered and the solution allowed to sit for 1 week. At this point, exposure of this solution to air caused yellow crystals to form within several hours. A single crystal for the X-ray analysis was selected from this batch. The air-stable crystals were filtered and dried under vacuum, yielding 0.21 g (11%) of product, which retained one molecule of interstitial crystallization solvent ($CHCl_3$). Found: C, 43.3; H, 3.0; Cl, 36.7. Calc. for $C_{38}H_{33}Cl_{11}Fe_2P_2$: C, 43.3; H, 3.2; Cl, 37.0%. IR (Nujol mull, cm^{-1}): 1585 w, 1435 s, 1110 m, 995 s,

X-ray crystallography for $[Ph_3PCH_2PPh_3][FeCl_4]_2 \cdot CHCl_3$

A single crystal was glued on the tip of a glass fibre and mounted on the diffractometer. The cell constant determination, data collection and reduction were routine. A semi-empirical absorption correction was applied according to the method described by North *et al.*[3] Crystal data are assembled in Table 1. The structure was solved by direct methods and refined by alternating cycles of full-matrix least-squares and difference Fourier maps. Hydrogen atoms were included at calculated positions and used for structure factor calculations, but not refined. An interstitial chloroform molecule was also found. This had the carbon atom disordered among two equally populated positions, above and below the plane containing the three chlorine atoms.

Oxidation state, ionic charge, and synthetic methodology considerations led us to believe initially that the atom bridging the two phosphine moieties in the cation was an oxygen atom. Refinement with all the non-hydrogen atoms, including those of the interstitial chloroform molecule, treated anisotropically, converged to an agreement factor $R = 0.049$ ($R_w = 0.058$). The equivalent isotropic thermal parameter for the bridging atom was 7.5(2) Å^2, much larger than those of the neighbouring atoms (around 3.00 Å^2), but still acceptable. However, the results of the elemental analysis, together with this high thermal parameter for the bridging atom, convinced us that we did not have an oxygen atom but rather a carbon atom of a methylene functionality holding together the two PPh_3 moieties. Refinement on the appropriately modified model converged to a lower agreement factor

RESULTS AND DISCUSSION

(a) *Chemical studies*

The dark brown solutions obtained at low temperature by interacting anhydrous $FeCl_3$ and PPh_3 in a 1 : 1 molar ratio, and containing the unstable $FeCl_3(PPh_3)$ species,[1] rapidly changed colour to yellow when warmed to room temperature. We repeatedly tried to work up these solutions under a dinitrogen atmosphere with the hope of crystallizing the yellow decomposition product.

This is believed to be an ionic compound with empirical formula $FeCl_3(PPh_3)$,[2] possibly $[FeCl_2(PPh_3)_2]^+[FeCl_4]^-$. These solutions show high electric conductance, consistent with the production of ionic species. In addition, most of the known derivatives of iron(III) with soft donor ligands, and also a few with hard donor ligands, are ionic. Examples are $[Fe(L—L)_2X_2][FeX_4]$ [X = Cl or Br, L—L = *o*-$C_6H_4(AsMe_2)_2$;[4] X = Cl, L—L = methylenebis(diphenylphosphine oxide) or tetramethylenebis(diphenylphosphine oxide)[5]] and $[FeCl_2L_4][FeCl_4]$ (L = N-methylimidazole,[6] pyridine-N-oxide,[7] dimethylsulphoxide[8]). Unfortunately all of these materials correspond to the empirical formula $FeCl_3L_2$ or $FeCl_3(L—L)$. No ionic compound with an empirical formula $FeCl_3L$, that is with structure $[FeCl_2L_2][FeCl_4]$, seems to have been positively characterized. Four-coordinate tetrahedral iron(III) is common in anionic species, such as $[FeX_4]^-$ (X = Cl, Br, SR[9]) and has been suggested for the neutral $FeCl_3(THF)$ compound,[10] but, to the best of our knowledge, never found in cationic complexes.

While our attempts to obtain a crystalline material under dinitrogen were unsuccessful, we sampled an aliquot of the solution for a gas chro-

* A full list of bond distances and angles, positional parameters, anisotropic displacement parameters and F_o/F_c data have been deposited with the Editor as supplementary material. The atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

matographic analysis[1] and observed that a crystalline material was rapidly obtained upon exposure to air. We then decided to expose the rest of the solution to air, and we obtained the product, later proven to be $[Ph_3PCH_2PPh_3][FeCl_4]_2 \cdot CHCl_3$ by elemental and X-ray structural analysis (*vide infra*), in low yield. The solution had been exposed to air 8 days after the initial $FeCl_3$–PPh_3 interaction.

We have repeated the preparation of this crystalline material several times in consistently reproducible low yields. During one of these preparations, the solution was exposed to air shortly after the change of colour to yellow was completed, and *no crystalline product was obtained.*

The presence of a methylene functionality in the cation suggests that interaction with the solvent has occurred. The interaction of PPh_3 with haloforms is documented in the literature. With CHI_3, an ill-characterized 1 : 1 adduct was obtained.[11] PPh_3 and $CHBr_3$ do not react at room temperature, but under thermal or photochemical conditions $[Ph_3PCHBr_2]^+Br^-$ is obtained.[12] The reaction of PPh_3 and $CHCl_3$ has been reported to produce $Ph_3P{=}CCl_2$ in the presence of a strong base. This reaction has been described as proceeding through the free dichlorocarbene.[13] From these data, it would appear that the nucleophilic attack of PPh_3 on $CHCl_3$ is not a facile process. However, the presence of the strong Lewis acid, $FeCl_3$, should provide additional driving force by coordinating the chloride leaving group to form the stable $FeCl_4^-$ anion [eq. (1)]:

$$PPh_3 + CHCl_3 + FeCl_3 \longrightarrow [Ph_3PCHCl_2]^+[FeCl_4]^- \quad (1)$$

This type of reactivity has also been described for the PPh_3–CCl_4 system, where $[Ph_3PCCl_3]Cl$ is obtained without the aid of a Lewis acid.[14]

$FeCl_3$ could as well promote an additional nucleophilic attack to the quaternary carbon, according to eq. (2):

$$PPh_3 + [Ph_3PCHCl_3]^+[FeCl_4]^- + FeCl_3 \longrightarrow [Ph_3PCH(Cl)PPh_3][FeCl_4]_2 \quad (2)$$

Since this reaction is in large excess of $CHCl_3$, this second nucleophilic attack will occur only if reaction 2 is faster than reaction 1.

This reactivity pattern would parallel the one observed for the interaction of PPh_3 with CH_2Br_2, where $[Ph_3PCH_2PPh_3]Br_2$ has been obtained.[15] In addition, the reaction[16] of PPh_3 and CCl_4 in a 3 : 1 ratio, reported to yield $[Ph_3PC(Cl)PPh_3]Cl$, presumably proceeds through $[Ph_3PCCl_2PPh_3]Cl_2$.

The product of eq. (2) is the closest compound to the observed product of which we can rationalize the formation. It is completely obscure to us how the action of oxygen could replace the chlorine atom with a hydrogen atom in $[Ph_3PCH(Cl)PPh_3][FeCl_4]_2$, assuming that the latter is indeed an intermediate. It initially occurred to us, in view of the synthetic methodology, that the two PPh_3 units might be bridged by an oxygen atom, but this hypothesis has been subsequently ruled out by accurate elemental analysis determinations and by the results of the crystal structure refinement (see Experimental).

We do not have a better explanation as to how the observed product is formed. The only conclusion that can be safely drawn is that the intermediate species upon which oxygen is operating is only slowly produced in the reaction conditions, since no product is obtained when oxygen is introduced promptly after the interaction of $FeCl_3$ and PPh_3 has occurred. We have not further investigated the mechanism of this curious transformation, nor have we altered the reaction conditions in an attempt to maximize the yield of the product.

(b) *Crystallographic study*

The $[Ph_3PCH_2PPh_3][FeCl_4]_2$ compound crystallizes with one formula unit plus an interstitial $CHCl_3$ molecule in the asymmetric unit. No significant intermolecular interactions are observed, and the different ions are well separated from each other.

The $FeCl_4^-$ anions display fairly regular tetrahedral geometries, the one containing Fe(2) being slightly more distorted [average Cl—Fe—Cl angles are $109.47 \pm 0.8°$ for Fe(1) and 109.47 ± 1.6 for Fe(2)]. The Fe—Cl distances (average 2.18(2) Å) compare with those found in other $FeCl_4^-$ salts, for instance 2.182(1) Å in the $AsPh_4^+$ salt, 2.175(5) (av.) Å in the PPh_3Me^+ salt and 2.184(5) (av.) in the $[Fe(MeCN)_6]^{2+}$ salt.[17]

Figure 1 shows a view of the dication. This is arranged in a conformation where the atoms P(1), P(2), C(1), C(20) and C(60) approximately lie in the same plane. This allows the P(1)—C(1)—P(2) angle to close to the observed value of 123.4(2)° without major steric repulsions between the phenyl groups on adjacent phosphorus atoms. This angle is smaller than that found in the $[Ph_3PCHPPh_3]^+$ cation [128.2(3)°],[18] albeit larger than that observed for $Ph_2P(Se)CH_2P(Se)Ph_2$ [117.9(6)°],[18] in agreement with a different hybridization state in the former case and with a decreased steric repulsion and/or with the absence of an electrostatic repulsion in the latter one. The P—C(1) distances (average 1.819(4) Å) are in the expected range for a phos-

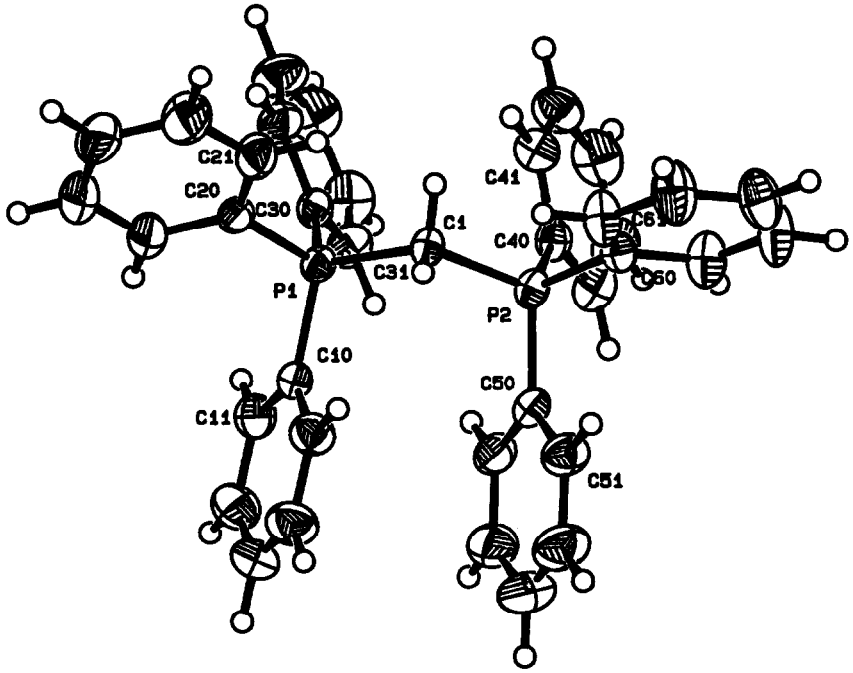

Fig. 1. An ORTEP view of the dication of compound $[Ph_3PCH_2PPh_3][FeCl_4]_2 \cdot CHCl_3$. Hydrogen atoms are drawn with arbitrary radii for the sake of clarity.

phorus–carbon (sp^3) single bond, and compare favourably with those observed in $Ph_2P(Se)CH_2P(Se)Ph_2$ (av. 1.84(1) Å), the slight decrease being consistent with the presence of positive charges.

(*Received* 25 *October* 1988; *accepted after revision* 18 *January* 1989)

Abstract—The reduction of $Ag(OH)_4^-$ by sulphite ion to give silver(I) and sulphate in strong base has been studied by stopped-flow spectrophotometry. The reaction was found to fit a second-order rate law with a rate constant $k = (9.1 \pm 0.1) \times 10^2\ M^{-1}\ s^{-1}$ ($T = 25°C$, $\mu = 1.2$ M). The estimated enthalpy and entropy of activation are 27 kJ mol^{-1} and -153 J K^{-1} mol^{-1} respectively. Variation of rate with ionic strength is consistent with the interaction between mononegative $Ag(OH)_4^-$ and dinegative SO_3^{2-}. The redox reaction appears to proceed by a one-step oxygen atom transfer. Two kinetically indistinguishable pathways are discussed. The first involves initial attack of a sulphite oxygen at an axial silver(III) site. The second pathway involves initial interaction between sulphur(IV) and a bound hydroxyl. Sulphite oxidation by silver(III) is about 10^4 times faster than that of phosphite, while no reaction is observed with NO_2^-.

Silver(III) is a spin paired d^8 system like gold(III), copper(III), nickel(II) and palladium(II).[1,2] It forms diamagnetic square-planar complexes with ligands including hydroxide,[3] triglycine, tetraglycine,[4] dimethylglyoximate,[5] tellurate and periodate.[6] Although octahedral geometry is rare, it is found in paramagnetic complexes with the general formula M_3AgF_6[7] (M = K, Na, Rb or Cs). Diamagnetic tetragonal silver(III) fluoro complexes ($MAgF_4$) have been successfully prepared by direct fluorination of 1 : 1 mixtures of MCl and $AgNO_3$.[8] Pale yellow, diamagnetic silver(III) complexes of tetraazamacrocyclic substrates have been extensively studied.[9] Silver(III) porphyrin complexes have also been investigated. For instance, Kadish *et al.* found that oxidation of the octaethylporphynatosilver(II) leads to the corresponding silver(III) complex.[10] Ethylene-bridged biguanide complexes of silver(III) were first prepared in 1944 by Chakravorty and Ray[11] as $Ag(enBigH)_2X_3$ (X = $0.5SO_4$, NO_3, ClO_4 or H). A thorough investigation of the kinetics of formation and decomposition of these complexes has been reported.[12] Simple, stable silver(III) biguanide and methyl biguanide complexes also have been synthesized.[13] Silver(III) complexes of triglycine and tetraglycine were successfully prepared by Kirschenbaum and Rush[4] by direct mixing of $Ag(OH)_4^-$ and the ligands in aqueous basic media. There are striking spectral and kinetic similarities of these complexes with those of analogous copper(III) polypeptide systems obtained by Margerum *et al.*[14]

$Ag(OH)_4^-$ has a half life of about 1.5 h in 1.2 M hydroxide at room temperature and has a UV–vis maximum at 267 nm in aqueous alkaline media. In recent years, we have studied the reaction of $Ag(OH)_4^-$ with a number of complexing and reducing substrates.[5,15–17]

Substitution reactions of $Ag(OH)_4^-$ with various oxygen donor ligands—periodate, tellurate,[3] phosphate, borate, pyrophosphate, carbonate and arsenate[18]—have been investigated. In the case of

* Author to whom correspondence should be addressed.

periodate and tellurate ions, the kinetically stable complexes $Ag(H_2IO_6)_2^{3-}$ and $Ag(H_4TeO_6)_2^-$, respectively, were formed. However, the substitution reactions of $Ag(OH)_4^-$ with the other oxoanions were partial and occurred only at reduced OH^-.

The formation of silver(III) complexes often provides a path for $Ag(OH)_4^-$ reduction,[16,19] but offers some increased stability under conditions where the highly reactive $Ag(OH)_3(H_2O)$ ion is otherwise formed [eq. (1)][20]

$$Ag(OH)_4^- \overset{H_2O}{\rightleftharpoons} Ag(OH)_3(H_2O) + OH^- . \quad (1)$$

Redox reactions of the tetrahydroxyargentate(III) ion have been studied with reductants including ethylenediamine (en),[21] H_2O_2,[22] $Mo(CN)_8^{4-}$, $Fe(CN)_6^{4-}$, MnO_4^{2-},[19] N_3^-,[16] $S_2O_3^{2-}$ [17] and arsenites.[15] It was found that an inner-sphere two-electron transfer process was involved in the cases of azide, thiosulphate, en, and arsenite. By contrast, a silver(II) intermediate was inferred for the other substrates.

The reduction of transition metals by sulphite in aqueous alkaline medium has been studied for $Mo(CN)_8^{3-}$, $Mn(P_2O_7)_3^{9-}$, $Fe(CN)_6^{3-}$ [23,24] and deprotonated copper(III) tetraglycine ($Cu(H_{-3}G_4)^-$).[25] Margerum *et al.*[25] recently showed that the kinetics of the reaction of $Cu(H_{-3}G_4)^-$ with excess sulphite is first-order in sulphite at pH 9.2. In addition, the reduction reaction goes stoichiometrically ($\Delta Cu(H_{-3}G_4)^- : \Delta SO_3^{2-} = 2:1$) via two reversible one-electron transfer steps, generating a sulphite radical anion in the first step. Brown and Higginson[23] showed that substitution-inert complexes which behave as one-equivalent oxidants can give quantitative sulphate products. However, those substitution labile complexes which react with a lower non-integral stoichiometry, give a mixture of sulphate and dithionate. In the particular case of the ferricyanide–sulphite reaction, Swinehart[26] suggested an outer-sphere mechanism involving sulphite radicals and dithionate and sulphate as major products. On the other hand, Veprek-Siska and Wagnerova[27] favoured an inner-sphere process with sulphate the only significant sulphur-containing product. Lancaster and Murray,[24] have shown that the reaction proceeds via the intermediates $Fe(CN)_5(CNSO_3)^{5-}$ and $Fe(CN)_5(CNSO_3)^{4-}$, followed by hydrolysis of the latter to ferrocyanide and sulphate. They thought that the reaction pattern lies somewhere between inner- and outer-sphere, a compromise between the two contradictory explanations mentioned above.

The reaction of $Ag(OH)_4^-$ with thiosulphate at low concentrations ($< 1.0 \times 10^{-3}$ M) proceeds via the aquated species $Ag(OH)_3(H_2O)$, giving a monothiosulphato complex, $Ag(OH)_3S_2O_3^{2-}$, which undergoes internal redox.[17] At thiosulphate concentrations above 1×10^{-3} M, silver(III) is reduced in a five-coordinate intermediate without hydroxyl replacement. In the case of the reaction of $Ag(OH)_4^-$ with arsenite, the reaction appears to proceed by a one-step oxygen atom transfer.[15] We have studied the reaction of $Ag(OH)_4^-$ with sulphite ion to see if its reduction mechanism is similar to either the thiosulphate or arsenite systems.

EXPERIMENTAL

Reactant solutions

For all experiments, sulphite stock solutions were freshly made in doubly distilled water, or in 1.2 M base by exact weighing of reagent grade anhydrous sodium sulphite (J. T. Baker). All sulphite reactant solutions were then made by serial dilution. Sodium hydroxide solutions were prepared from 50% low carbonate NaOH (Fisher). Lithium hydroxide solutions were made from solid hydrated LiOH (Matheson Coleman and Bel). A 1.2 M $NaClO_4$ or $LiClO_4$ solution was used for ionic strength adjustment when appropriate. $NaClO_4$ was prepared from NaOH and $HClO_4$ (Fisher), adjusted to pH 7, followed by filtration. Similarly, $LiClO_4$ was obtained from LiOH and $HClO_4$. $Ag(OH)_4^-$ solutions were prepared by anodic oxidation as previously described.[4] About 200 cm^3 of 1.2 M NaOH or LiOH solution were placed in a 250 cm^3 polyethylene beaker containing a silver foil anode. Argon was bubbled through the silver(III) solution during electrolysis from a capillary placed near the anode to provide constant stirring of the solution. In order to minimize spontaneous oxidation of sulphite to sulphate[28] by atmospheric oxygen, solutions used to prepare SO_3^{2-} solutions were also degassed with argon. In addition, great care was taken to avoid trace metal and multivalent cation catalytic auto-oxidation[25] of sulphite by using very clean glassware.

For the purpose of comparison, we also studied the reduction of silver(III) by NO_2^- and HPO_3^{2-}. The nitrite stock solutions were prepared by direct weighing of reagent grade $NaNO_2$ (Mallinckrodt). The phosphite solutions were made from a 50% solution of phosphorous acid (Allied Chemical) by potentiometric titration with 1.2 M NaOH.

An Aminco–Morrow stopped-flow apparatus was used in the kinetic runs.[4] Large excesses of reductant were used for all experiments. The reactions were monitored as $Ag(OH)_4^-$ disappearance at 267 nm ($\varepsilon = 1.17 \times 10^4\ M^{-1}\ cm^{-1}$). At this wavelength, neither sulphite, nitrite, nor phosphite

showed any significant absorbance. The reactions were followed on a Tektronix 564B storage oscilloscope coupled to a Radio Shack TRS-80 computer which recorded and processed the kinetic data. All observed pseudo-first-order rate constants are reproducible within 5%. Spectral analysis was done on a Cary 15 UV–vis spectrophotometer.

Product analysis

Known concentrations of sulphite and $Ag(OH)_4^-$ were mixed together. Immediately upon completion of the reaction, a saturated solution of barium nitrate was added to precipitate the product and excess sulphite where excess reductant was used. After filtration, the precipitates were dried and their IR spectra recorded on a Perkin–Elmer 1310 spectrophotometer. Blank sulphite and sulphate solutions were also analysed to check for possible contamination. To test for reactions between reactants and products, parallel experiments were done for the systems silver(I)–sulphite and silver(II)–sulphate.

RESULTS

Identification of the reaction product

At excess $Ag(OH)_4^-$, only sulphate IR peaks were observed. When excess reductant was used, sulphate and sulphite peaks were obtained. We therefore conclude that the reaction product is sulphate.

Reaction stoichiometry

The stoichiometry of the reaction was determined at excess silver(III) by measuring the difference between initial and final absorbances in the stopped-flow apparatus. The value for $\Delta[Ag^{III}]$ thus obtained when compared with the amount of sulphite present, indicated a stoichiometry of 1 : 1.

Attempts to determine the reaction stoichiometry at excess sulphite by iodometric back titration were not conclusive. Indeed, scattered ratio values were obtained. The difficulty in getting good stoichiometric data at excess sulphite is probably due to air-oxidation of sulphite or sulphate.[29] The detection of sulphate at moderate and large excess sulphite concentrations, however, leads us to conclude that the 1 : 1 stoichiometry is also operative under the kinetic conditions.

Based on the 1 : 1 stoichiometric ratio and the product analysis at excess SO_3^{2-}, the reaction goes as follows [eq. (2)]:

$$Ag(OH)_4^- + SO_3^{2-} \xrightarrow{k} Ag(OH)_2^- + SO_4^{2-} + H_2O. \quad (2)$$

Kinetics

When an excess of sulphite is mixed with yellow $Ag(OH)_4^-$, the colour is immediately discharged. A rapid first-order decrease in absorbance in the stopped-flow apparatus over the region 230–400 nm was observed, with no indication of intermediate complex formation. The dependence of the reaction rate on the sulphite ion concentration (5×10^{-4} M $\leqslant [SO_3^{2-}] \leqslant 5\times10^{-3}$ M) was studied at 25°C and $\mu = 1.2$ M, with initial silver(III) concentrations ranging from 1×10^{-5} to 1×10^{-4} M. As illustrated in Fig. 1, the reaction shows a first-order dependence in excess sulphite as given in eq. (3):

$$-d[Ag(OH)_4^-]/dt = k_{obs}[Ag(OH)_4^-] = k[SO_3^{2-}][Ag(OH)_4^-]. \quad (3)$$

A least-squares treatment of the data gives a straight line with an intercept that is close to zero (Fig. 1). The second-order rate constant obtained from this treatment is $k = (9.1\pm0.1)\times10^2\ M^{-1}s^{-1}$. Agreement between observed and calculated pseudo-first-order rate constants is generally better than 5% (Table 1).

Temperature dependence

The reaction was carried out over the range 10–53°C with a 1×10^{-3} M sulphite solution at $[OH^-] = 1.2$ M and $\mu = 1.2$ M. A plot of the data using eq. (4)[30] is linear (Fig. 2).

$$\ln(k_{obs}Nh/RT) = -\Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R. \quad (4)$$

The enthalpy and entropy of activation calculated from the slope and intercept of the least-squares treatment of eq. (4) are 27 kJ mol^{-1} and -153 J K^{-1} mol^{-1}, respectively. The recalculated temperature dependent rate constants are in good agreement with the observed rate constants.

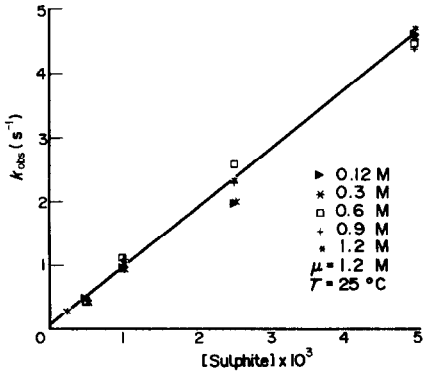

Fig. 1. Variation of the observed pseudo-first-order rate constants with sulphite at different hydroxide concentrations.

[a] Calculated from the least-squares line of $k = 0.07 + 9.10 \times 10^2 [SO_3^{2-}]$.

Ionic strength dependence

The kinetics were followed in the ionic strength range from 0.12 to 1.2 M in both LiOH and NaOH at $[SO_3^{2-}] = 5 \times 10^{-3}$ M. A hydroxide concentration of 0.12 M was maintained for all reactions. A net increase of the pseudo-first-order rate constant with ionic strength was observed. A Debye–Hückel–Brönsted–Davies[31] equation plot of $\log k_{obs}$ vs $\mu^{1/2}/(\mu^{1/2}+1) - 0.05\mu$ was linear in the case of LiOH, with a slope of 1.9 (Fig. 3). This is close to the value of two predicted for the interaction of mononegative $Ag(OH)_4^-$ with dinegative SO_3^{2-}. However, at high ionic strengths (≥ 0.6 M), a small deviation from this line was observed for the NaOH data.

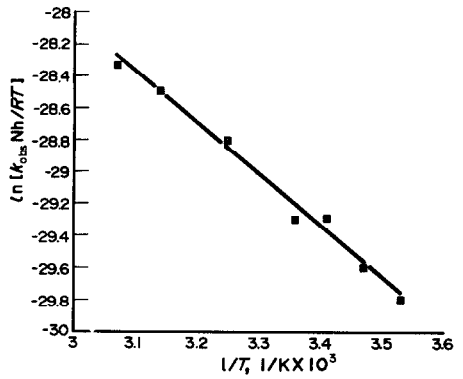

Fig. 2. Temperature dependence for the reaction between sulphite ($[SO_3^{2-}] = 1 \times 10^{-3}$ M) and $Ag(OH)_4^-$.

Reaction of silver(III) *with nitrite and phosphite*

When a nitrite solution is mixed with silver(III) in 1.2 M NaOH, the rate of decrease of the silver(III) absorbance cannot be distinguished from the expected spontaneous decomposition of $Ag(OH)_4^-$,[3,6] even at $[NO_2^-] = 1$ M.

For the system silver(III)–phosphite, the reaction was first carried out over the range 0.01–0.08 M $[HPO_3^{2-}]$, $[OH^-] = 0.96$ M, $\mu = 1.2$ M at 25°C. A slight acceleration in the decomposition of $Ag(OH)_4^-$ was observed. Attempts to account for this change by kinetic means were unsuccessful. There seems to be a competition between the spontaneous decomposition of $Ag(OH)_4^-$ and the oxidation of phosphite, which we were unable to separate because of the complex product-catalysed kinetics of the former reaction.* However, when

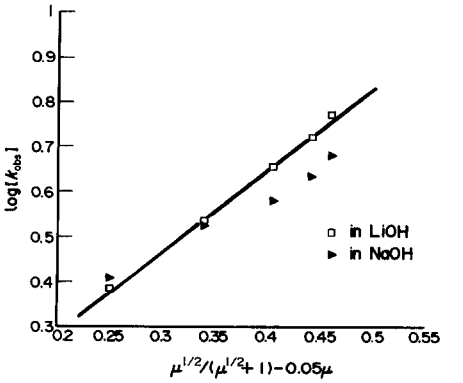

Fig. 3. Ionic strength dependence in aqueous perchlorate media at $[SO_3^{2-}] = 5 \times 10^{-3}$ M and $[OH^-] = 0.12$ M.

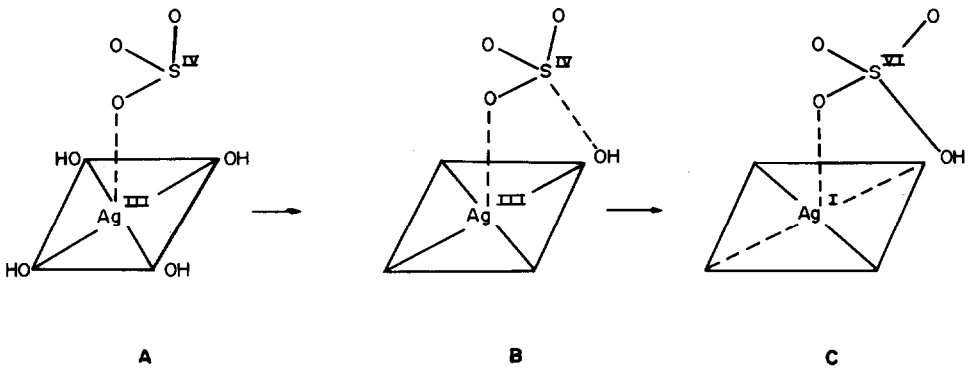
* The decomposition half-life of $Ag(OH)_4^-$ in electrolysed 1.2 M NaOH is about 90 min. However, when mixed in the stopped-flow apparatus with solutions which have not been pre-electrolysed to remove trace impurities, the decomposition rate of this complex is significantly faster. Therefore, higher phosphite concentrations and higher ionic strength were required in order to separate the reaction of phosphite with $Ag(OH)_4^-$ from spontaneous decomposition.



Scheme 1.

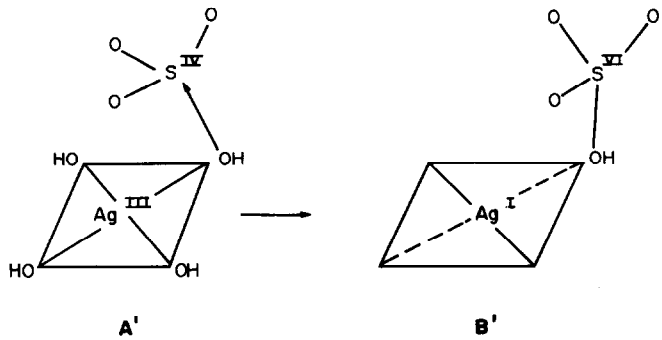
three concentrations of phosphite in the range 0.2–0.4 M (μ = 1.88 M, $[OH^-]$ = 0.72 M) were used, the decrease in absorbance at 267 nm was indeed first-order. The plot of k_{obs} vs $[HPO_3^{2-}]$ over this limited range was linear with a zero intercept. The slope of this line corresponds to a second-order rate constant of 1.0×10^{-1} M^{-1} s^{-1}.

DISCUSSION

Sulphite has been found to be an effective complexing agent for transition metal ions such as palladium(II),[32] cobalt(III),[33] and tellurium(I).[34] In the reduction of ferricyanide by sulphite, two iron sulphite intermediate complexes were reported.[4] In the present study, however, there is no kinetic or spectral evidence for a silver(III)–sulphite transient complex. In previous studies, it has been reported that the product of the reduction of transition metals by sulphite is either dithionate or sulphate, or both.[23,26,35] According to the product analysis, sulphate appears to be the only oxidation product of this reaction. The possibility of sulphate resulting from the disproportionation of the dithionate in base can be excluded. Although dithionate is thermodynamically unstable[36] in base, it is kinetically inert with respect to disproportionation.[37]

In blank experiments with $Ag^{III}+SO_4^{2-}$ and $Ag^{I}+SO_3^{2-}$, no reactions were observed, indicating that reactants and products do not react with one another. Furthermore, the stoichiometry observed in this study supports that sulphate is the only product of the reaction.

As is inferred in the two-electron transfer reaction of arsenite with $Ag(OH)_4^-$,[15] the oxidation of sulphite by silver(III) probably proceeds via a one-step oxygen atom transfer. Two kinetically indistinguishable pathways that account for our results are in Schemes 1 and 2. Scheme 1 involves attack by a sulphite oxygen on an axial site of the square-planar silver(III) complex. In Scheme 2, three-coordinate sulphur(IV) undergoes a nucleophilic attack by a hydroxyl ligand followed by oxygen transfer in either a singly-bridged or chelated (as in Scheme 1) intermediate. Both these schemes depend on the expansion of the sulphur(IV) coordination sphere with the fourth oxygen in the sulphate product deriving from $Ag(OH)_4^-$. The insignificant intercept observed in Fig. 1 indicates that there is no participation by $Ag(OH)_3(H_2O)$ in the reduction process as is in the thiosulphate reaction.[17] The lack of any hydroxide dependence on the rate, is as expected since SO_3^{2-} is the only sulphurous acid species in alkaline media (pKa_1 = 1.91,



Scheme 2.

pKa_2 = 7.18).[38] The possibility of a rapid transfer of a hydroxyl ligand to sulphite, concurrent with donation of its electron pair to silver(III) via the empty $d_{x^2-y^2}$ orbital (oriented in the equatorial plane of the complex), appears reasonable. Support of the possibility that redox occurs through a five-coordinate intermediate as in Scheme 1 is provided by the results of other $Ag(OH)_4^-$ reactions. For instance, the presence of third-order terms in the reaction of en,[21] HO_2^- [22] and thiourea[39] implies the formation of five-coordinate transients.

Activation parameters for silver(III) complexation reactions have been interpreted in terms of an associative mechanism for ligand exchange. The activation parameters reported here are similar to those obtained in the reduction of silver(III) by arsenite[15] species, $H_2AsO_3^-$ and $HAsO_3^{2-}$, where a five-coordinate silver(III) intermediate was postulated. The reaction is likely to proceed by (1) ion association, (2) axial attack by negative sulphite on the positive silver(III) centre, (3) changes in bond lengths of the two reactants and reconstruction of their solvation spheres and (4) a fast electron transfer step involving the rupture of a silver–oxygen bond to yield the products. The observed rate seems to be due to the formation of a bridged precursor intermediate (A or A′) which is then followed by a fast redox process. This is consistent with a large negative entropy as is observed.

The good agreement for the ionic strength dependence in LiOH–$LiClO_4$ with expectations indicates the absence of substantial ion pairing in the intimate step of the reaction, as is reported for similar reactions.[26,40] We note that at 1.2 M OH^-, there is no difference in rate between NaOH and LiOH (Table 1). Thus sodium (but not lithium) ion pairing is probably not responsible for the deviation in Fig. 3.

If we presume that the reduction of silver(III) by phosphite is, like the sulphite reaction, independent of [OH^-] and has the expected ionic strength variation, we may correct the second-order rate constant obtained at μ = 1.88 M[31] and compare the rates of the two reactions. The rate constant corrected to μ = 1.2 M for phosphite is 9.5×10^{-2} M^{-1} s^{-1} which is about four orders of magnitude smaller than the value of 9.1×10^2 M^{-1} s^{-1} obtained for the reaction of silver(III) with sulphite (25°C). The difference in reactivity between sulphite and phosphite, which are isoelectronic, may stem from the fact that sulphite has a lone pair of electrons on sulphur that is readily available in the electron transfer process. On the other hand, there is no such pair of electrons on the phosphite phosphorus which is bound to a non-labile hydrogen.[41] Ghosh *et al.*[42] reported that although phosphite is a powerful reducing agent, the reduction of the chromium(V) chelate bis(2-ethyl-2-hydroxybutyrato) oxochromate(V) by phosphite is immeasurably slow. This is consistent with the sluggish reactivity of phosphite.

Kinetics of nitrite ion oxidation by metal ions have been recently reported.[42–44] For example, the reduction of chromium(V) by nitrite was inferred to proceed by an $NO_2^{\cdot}$ radical intermediate.[42] Wilmarth *et al.*[44] reported rate constants for oxidations of $Fe(bpy)_3^{3+}$ by nitrite and sulphite of 3.3×10^4 and 4.6×10^6 M^{-1} s^{-1}, respectively. However, there is no evidence of a nitrite–silver(III) reaction even at [NO_2^-] = 1 M. An explanation for the non-reactivity of nitrite may be found in the inability of nitrogen to accept electrons into *d* orbitals. Before the bound hydroxyl oxygen can be transferred, an additional electron pair must coordinate to the central atom of the oxoanion (*vide supra*). While the availability of *d* orbitals permits an expanded number of valence electrons in arsenite, sulphite and phosphite, nitrite cannot coordinate to oxygen while it is also bound to silver. One-electron transfer to form $NO_2^{\cdot}$ and a silver(II) intermediate, while a potential alternative to oxygen atom transfer, would have a high activation energy. The $NO_2^{\cdot}/NO_2^-$ potential is just over 1 V.[45] We have estimated the $Ag(OH)_4^-/Ag(OH)_4^{2-}$ one-electron reduction to be about 3/10 V less than this,[46] thus posing a thermodynamic barrier to the electron transfer. Therefore, the non-reactivity of NO_2^- with $Ag(OH)_4^-$ is entirely consistent with the oxidation of the other oxoanions via an atom transfer mechanism.

LIQUID–LIQUID EXTRACTION OF SOME M^{II} AND M^{III} IONS WITH 2-ETHYLHEXYLHYDROGENPHENYLPHOSPHONATE

EMMANUEL O. OTU and ALAN D. WESTLAND*

Ottawa–Carleton Chemistry Institute, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5

(*Received* 9 *November* 1988; *accepted* 18 *January* 1989)

Abstract—The extraction of zinc(II), cadmium(II), bismuth(III) and some lanthanide ions from aqueous perchloric acid into hexane solutions of 2-ethylhexylphenylphosphonic acid, HEHϕP, has been studied. The extracted species contain varying numbers of extractant molecules and phosphonate groups as ligands, depending upon the size and charge of the ions. High loadings of the extractant with the metal ion resulted in suppression of the extraction. Alkali ions were not extracted but alkali perchlorate suppressed the extraction through the effect of ionic strength on the metal ion activity.

Phosphorus-based extractants, especially tributyl phosphate, are commonly employed for the isolation of higher valent metal ions such as the lanthanides and actinides. Mono-acidic extractants such as diesters of phosphoric acid have been the subject of several studies.[1–7] Mono esters of phosphonic acids have been reported to possess high separation factors for successive members of the lanthanide and actinide series.[8–12] Despite this advantage, these have been less studied.

The highest separation factors have been observed with 2-ethylhexylhydrogenphenylphosphonate (HEHϕP).[8] We therefore decided to study the extraction parameters (acid and extractant dependencies) of this extractant. Because it shows an especial affinity for larger ions such as the lanthanides, we have compared its behaviour in complexing lanthanides with its reactivity towards other M^{III} ions as well as M^{II} ions both large and small. Having determined some of the parameters of extraction, we are able to suggest possible extraction mechanisms.

EXPERIMENTAL

Materials

Lanthanum nitrate (99.99%) was obtained from Johnson Matthey Co. Praseodymium, neodymium, samarium, gadolinium, dysprosium, erbium and lutetium atomic absorption standard solutions were obtained from Aldrich Chemical Co. Bismuth nitrate and calcium carbonate were Baker reagent grade, and technical grade zinc powder was obtained from Fisher Scientific Co. Analar grade perchloric acid was supplied by BDH Chemicals. The hexane was practical grade.

Synthesis of HEHϕP

HEHϕP was prepared according to the method of Kantipuly.[13] This entailed the alcoholysis of phenylphosphonic dichloride with 2-ethyl-1-hexanol. Both reagents were obtained from Aldrich Chemical Co. A 1:1.5 molar ratio, respectively, of the above reagents in benzene was mixed in a pressure bottle and stirred for 48 h at room temperature. The pressure was released carefully and the mixture washed several times with water to remove unesterified phenylphosphonic acid. The mixture was taken up in ether and shaken with 10% NaOH solution. The aqueous phase was scrubbed with benzene to remove alcohol and any diester, and then acidified with concentrated hydrochloric acid to liberate the monoester, HEHϕP. This was taken up in anhydrous diethyl ether, dried with $MgSO_4$ and filtered. Solvent was removed under reduced pressure. The structure and purity of the product was confirmed by ^1H and ^{13}C NMR, and mass spectrometry. Found: C, 62.1; H, 8.6. Calc. for $C_{14}H_{23}O_3P$: C, 62.2; H, 8.6%.

Preparation of metal ion solutions

Aliquots of the metal ions in nitric acid medium were evaporated to dryness. The residues were taken up in 70% $HClO_4$ and re-evaporated to dryness. The dissolution in $HClO_4$ and evaporation was repeated and the resulting perchlorate salts were finally dissolved in $HClO_4$ and diluted with water to the required volume. The acidity was determined by titration.

Determination of the distribution ratio, K_d

The extractant phases had concentrations in the range 0.01–0.1 M HEHϕP in hexane. Normally, a 5 cm^3 volume of extractant was stirred magnetically with 5 cm^3 of metal ion solution in vials held in a thermostat bath at 25.0±0.5°C. Equilibrium was attained in 5 min but routine stirring times were rather longer than this. After equilibration, the phases were allowed to settle for 15 min before separating. Analyses of both aqueous and organic fractions yielded mass recoveries of greater than 98%. Therefore, for much of the data that follows, the aqueous phase was analysed and the metal content of the organic phase found by difference.

The lanthanides were determined by direct-coupled plasma emission spectrometry. The aqueous phases were run without treatment but the organic phases were wet-ashed with $HClO_4$ prior to analysis. Zinc and calcium were determined by atomic absorption spectrometry. Bismuth was determined by spectrophotometry as the complex, BiI_4^-.[14] Phosphate formed by wet-ashing the extractant was shown not to interfere.

Analyses were run in duplicate. Some, but not all, of the equilibrations were run in duplicate as well. The distribution ratio, K_d, was calculated by dividing the concentration of the ion in the organic phase by that in the aqueous phase.

RESULTS AND DISCUSSION

Figure 1 shows extraction isotherms for Dy^{3+} and Zn^{2+}. As the plots are not linear, it is evident that the ions do not obey Henry's Law in one or both of the phases in each case. The ionic strength of the aqueous phases is very largely determined by the fixed concentration of acid present. The aqueous phases containing rather low concentrations of metal ion should therefore obey Henry's Law to a good approximation. The situation is otherwise for

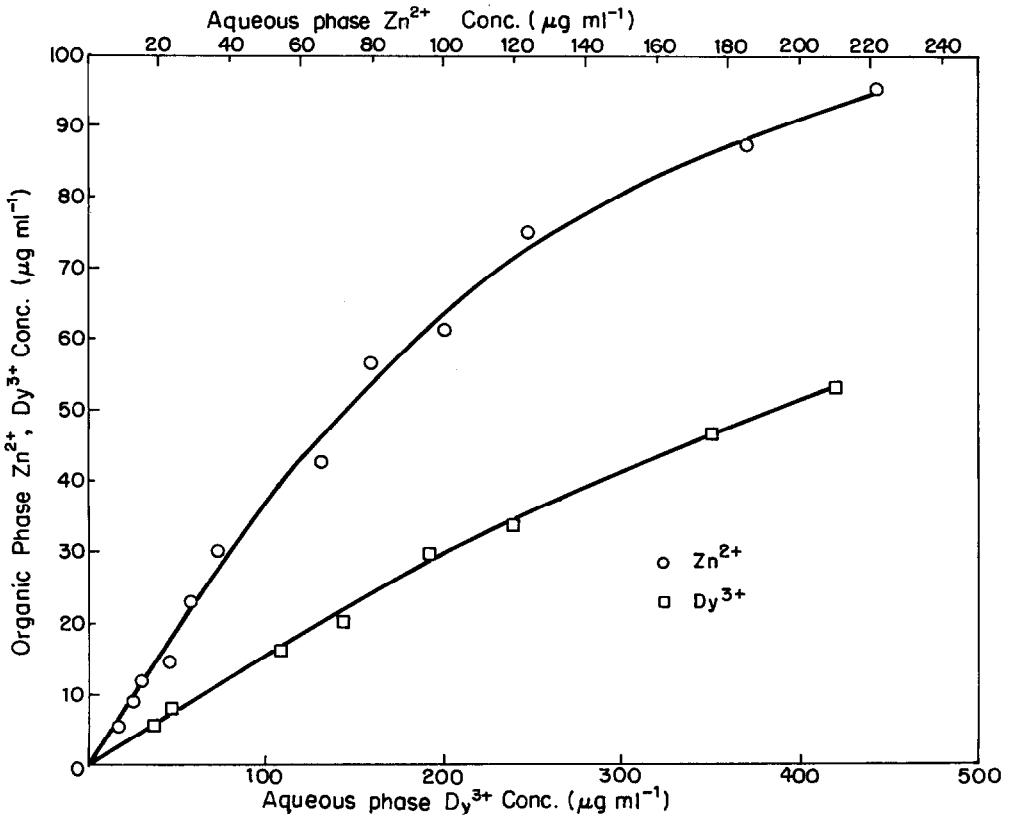

Fig. 1. Extraction isotherms for Zn^{2+} from 0.01 M $HClO_4$ and Dy^{3+} from 1.0 M $HClO_4$ into 0.01 M HEHϕP in hexane at room temperature.

the organic phase, however. It is shown later that the stoichiometric ratios of HEHϕP to Dy^{3+} and Zn^{2+} are 5:1 and 3:1, respectively, when the extractant is in large excess. As the extractant concentration was only 0.01 M, a large fraction of the extractant was bound to the metal ions in the organic phases that were relatively concentrated in metal ion. For example, in the most concentrated zinc solution (0.0015 M), with a 3:1 mole ratio of HEHϕP to zinc, 45% of the extractant would be bound to zinc. The curvature of the extraction isotherm suggests that with such a high degree of loading, the stoichiometry of the extracted species cannot be maintained at 3:1.

There is an additional reason for the curvature. As the extractant is deprotonated upon complexing, the acidity of the aqueous phase is increased. This would have a considerable effect in the case of zinc extraction where the initial acid concentration of the aqueous phase was 0.01 M. However, in the dysprosium case, the high acidity would not be changed appreciably by the complexing.

In the experiments described below, the metal ion concentrations were kept small relative to the extractant concentration so that both phases invariably obeyed Henry's Law.

Acid dependencies

Double logarithmic plots of the distribution coefficient against acid concentration appear in Figs 2 and 3. The slopes indicate that K_d is inversely second power and third power dependent upon the initial aqueous phase acidity for the M^{II} and M^{III} ions, respectively. The ionic strength was adjusted to a constant value with $NaClO_4$ throughout each series of measurements.

Peppard *et al.*[8] obtained the same third power dependence in the extraction of M^{III} ions with HEHϕP in toluene. Second power dependence has been reported for the extraction of Ca^{2+} with *n*-octyl esters of phenyl and chloromethyl phosphonic acids.[15]

The results suggest that neutral complexes enter the organic phase and the ion charge is neutralized by the extractant in anionic form. It follows that the perchlorate ion does not enter the complex.

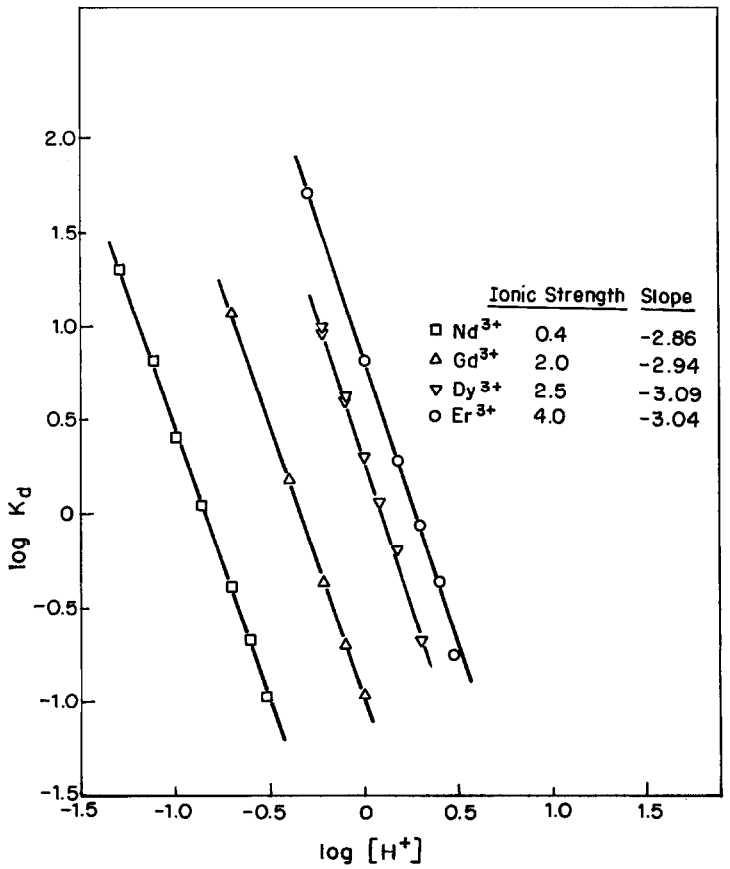

Fig. 2. Hydrogen ion dependence of the extraction of Nd^{3+}, Gd^{3+}, Dy^{3+} and Er^{3+} into 0.025 M HEHϕP in hexane; aqueous phase $HClO_4 + NaClO_4$ at 25°C.

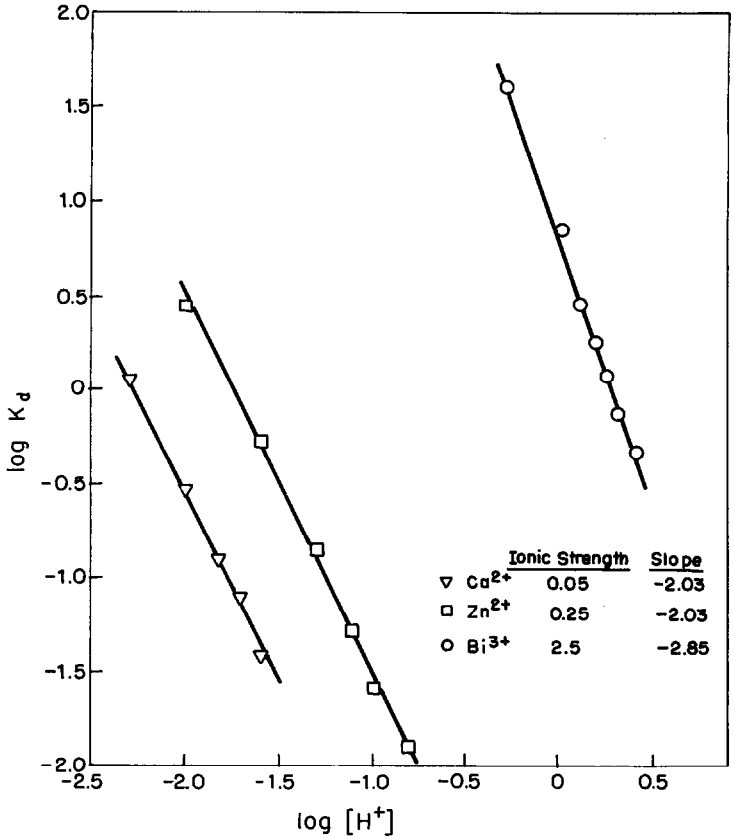

Fig. 3. Hydrogen ion dependence of the extraction of Ca^{2+}, Zn^{2+} and Bi^{3+} into 0.025 M HEHϕP in hexane; aqueous phase $HClO_4+NaClO_4$ at 25°C.

Were it to do so, the order of dependence upon acid concentration would be less than that observed.

Extractant dependencies

Studies of the dependence of extraction upon extractant concentration provide information about the composition of the extracted complexes. From the slopes of plots in Figs 4 and 5 it can be seen that the extraction of lanthanum and praseodymium is third power dependent upon extractant concentration, while the order drops to 2.5 for the heavier lanthanides. The neodymium and samarium plots are intermediate with slopes of 2.8 and 2.7, respectively. The plots in Fig. 6 indicate third order dependence for Ca^{2+} and Bi^{3+} and an order of 1.5 for Zn^{2+}. Peppard *et al.* reported third order dependence for M^{III} ions when treated with the extractants mentioned above.[8] Calcium exhibited an order of 2.5 when extracted with *n*-octylhydrogenchloromethylphosphonate and 3.0 with *n*-octylhydrogenphenylphosphonate.[15] An extractant dependence of order 1.5 has been observed for the extraction of Zn^{2+} with bis(2-ethylhexyl) phosphonic acid (HDEHP).[16] The order is thus variable, depending upon the ion charge and size and upon the particular choice of extractant.

The extractions with HEHϕP follow the equations:

$$La^{3+}(\text{or } Bi^{3+})+3(HY)_2 \rightleftharpoons M(HY_2)_3+3H^+$$

$$Ln^{3+}+2.5(HY)_2 \rightleftharpoons LnY(HY_2)_2+3H^+$$

$$Ca^{2+}+3(HY)_2 \rightleftharpoons Ca(HY_2)_2(HY)_2+2H^+$$

$$Zn^{2+}+1.5(HY)_2 \rightleftharpoons ZnY(HY_2)+2H^+,$$

in which the charged species and uncharged species are in aqueous and organic media, respectively, and $(HY)_2$ is the dimer of HEHϕP.[17,18] It is owing to the dimeric nature of the extractant that either integral or half-integral powers, n, arise in an equilibrium relation. For the reaction

$$M^{z+}+n(HY)_2 \rightleftharpoons \text{complex}+zH^+,$$

the equilibrium relation is

$$K_s=\frac{[\text{complex}][H^+]^z}{[M^{z+}][(HY)_2]^n}=\frac{K_d[H^+]^z}{[(HY)_2]^n}.$$

The number of extractant molecules that react with a given ion appears to decrease with the electric

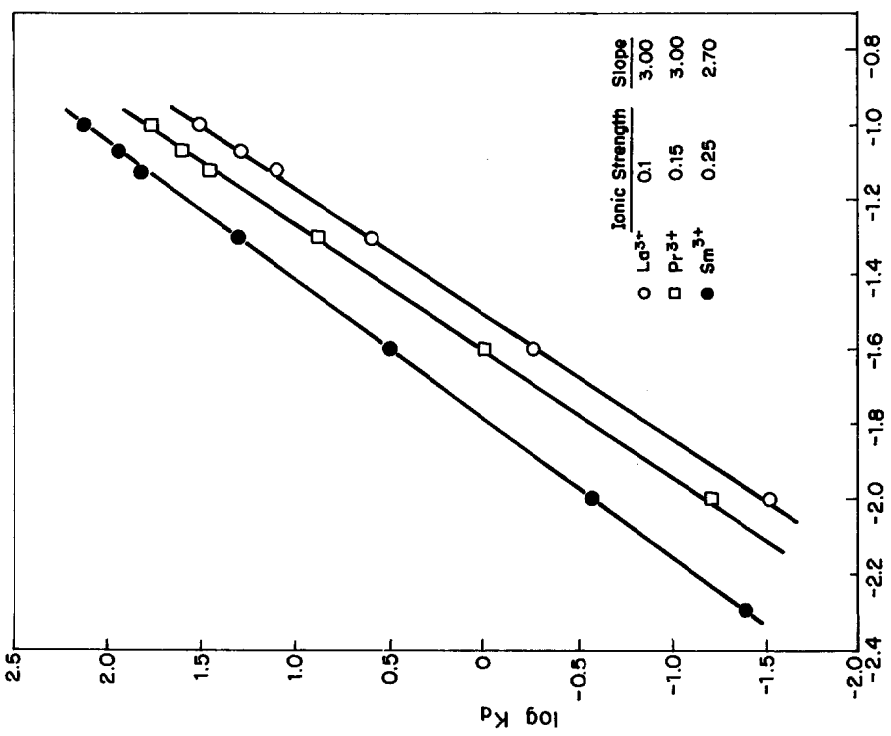

Fig. 4. Extractant dependence of the extraction of La^{3+}, Pr^{3+} and Sm^{3+} from aq. $HClO_4$ into hexane containing HEHφP at 25°C.

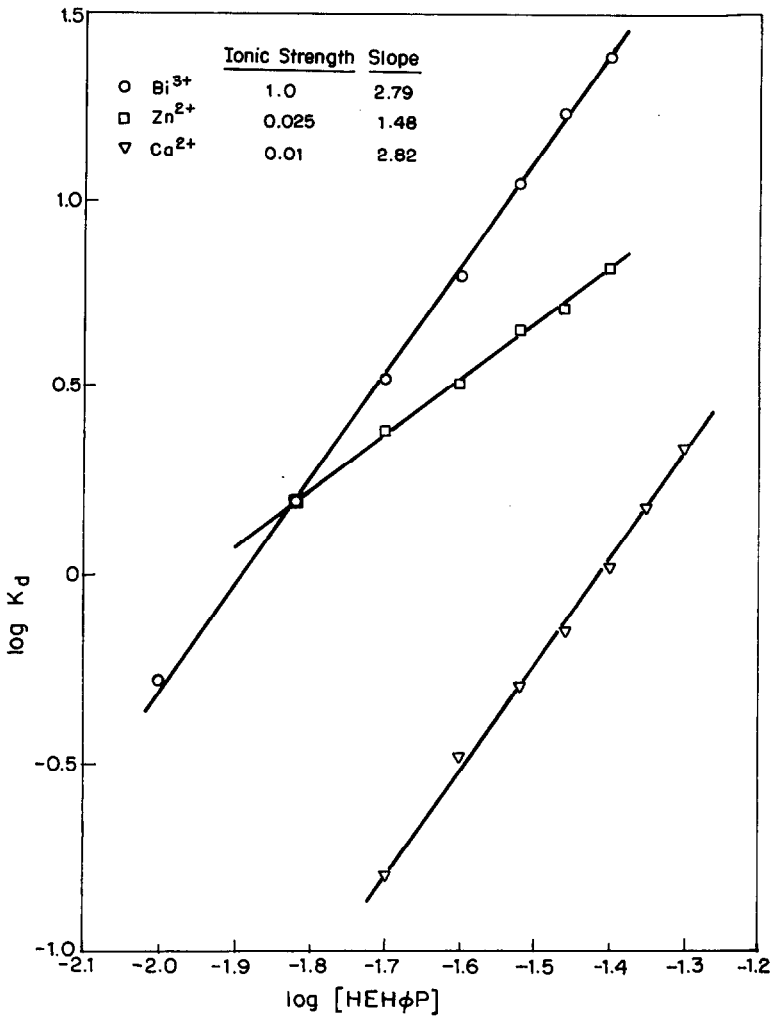

Fig. 6. Extractant dependence of the extraction of Ca^{2+}, Zn^{2+} and Bi^{3+} from aq. $HClO_4$ into hexane containing HEHϕP at 25°C.

field about that ion. The field is given approximately by the ionic function, ze/r, where ze is the charge and r the radius of that ion. Thus the largest rare earth ion, La^{3+}, binds three extractant dimers. With a decrease in radius, the later lanthanides replace one of the dimers with a monomer unit.

The radius of the calcium ion is about equal to that of Dy^{3+} but it carries only a double charge. Evidently the smaller electrical field permits the Ca^{2+} ion to react with additional, i.e. three, $(HY)_2$ molecules. The smaller radius of the Zn^{2+} ion combined with the fact that it is of the pseudo rare gas type, gives this ion a considerably stronger field. It consequently accommodates only 1.5 $(HY)_2$ molecules.

Effect of alkali salt

As HEHϕP is a liquid cation exchanger, it was thought that it might extract some of the alkali ion used in some of the experiments to adjust the ionic strength. Sodium perchlorate added to the aqueous phase at concentrations as high as 3 M had a large inhibitory effect on extractions. However, we were able to relate the effect of alkali salt solely to the reduction of the activity of the other ions in solution. The influence is quite large as can be seen from Fig. 7, which shows the effect of ionic strength on the distribution coefficient of Nd^{3+}. The solutions are too concentrated to allow the use of the Debye–Hückel equation, but the behaviour is compatible with plausible values of the activity of Nd^{3+} ion. Organic phases that had been equilibrated with 1 M alkali perchlorate in 0.01 M perchloric acid were found to contain less than 1 $\mu g\ cm^{-3}$ of alkali ion.

The phosphonate half ester shows extremely little affinity for univalent ions but a strong affinity for trivalent and quadrivalent ions. This difference is much less pronounced with sulphonate-type ion

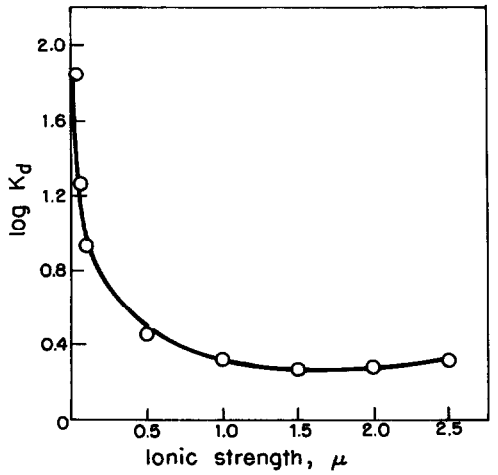

Fig. 7. Effect of ionic strength, $\mu(HClO_4+NaClO_4)$, on the extraction of Nd^{3+} into 0.025 M HEHϕP in hexane at 25°C.

exchangers. It follows that the phosphonate will display better selectivity between ions of differing charge. It is to be expected that there will also be better selectivity between ions of the same formal charge but differing effective charge. This is indeed observed in the separation factors for successive members of the lanthanide and actinide series.

We have measured enthalpies and entropies of extraction for a selection of ions of various effective charges by both HEHϕP and dinonylnaphthalene sulphonic acid. In all cases, there was a greater difference in free energy in the extraction of a given pair of ions when the phosphonate extractant was used. The results will appear elsewhere.

PHOSPHATE COMPLEXATION OF GADOLINIUM(III) IN AQUEOUS SOLUTION

L. S. BINGLER and R. H. BYRNE*

Department of Marine Science, University of South Florida, St. Petersburg, FL 33701, U.S.A.

(*Received* 11 *October* 1988; *accepted* 18 *January* 1989)

Abstract—Examination of the distribution of high specific activity Gd^{153} between tributyl phosphate and a 0.68 M aqueous phase at 25.0°C permits investigation of lanthanide phosphate complexation within rigorous solubility constraints. Our experiments provide the following formation constants with estimated standard errors: $\beta'_1 = [GdHPO_4^+][Gd^{3+}]^{-1}[HPO_4^{2-}]^{-1} = (8.05 \pm 0.7) \times 10^3$; $\beta'_2 = [Gd(HPO_4)_2^-][Gd^{3+}]^{-1}[HPO_4^{2-}]^{-2} = (8.1 \pm 1.9) \times 10^6$; $\beta'_H = [GdH_2PO_4^{2+}][Gd^{3+}]^{-1}[H_2PO_4^-]^{-1} = 50.4 \pm 6.8$. Our results indicate that phosphate complexation of lanthanide ions and trivalent actinides is significant in natural systems, and that the use of phosphate salts as pH buffers in laboratory examinations of metal hydrolysis is generally inadvisable.

Previous investigations of lanthanide ion aqueous equilibria have examined the formation of $LnH_2PO_4^{2+}$,[1,2] but apparently no previous studies have characterized the formation of $LnHPO_4^+$. Lanthanide ion equilibria of the form

$$Ln^{3+} + HPO_4^{2-} \rightleftharpoons LnHPO_4^+, \qquad (1)$$

are of environmental interest because of occasionally high phosphate concentrations (10^{-6}–10^{-4} M) in marine diagenetic systems, and because HPO_4^{2-} is present at much higher concentrations than $H_2PO_4^-$ within the normal pH range of sea water[3] and marine sediments. $LnHPO_4^+$ formation is of direct chemical interest because of the previous use of phosphate as a buffer in chemical systems composed for investigations of lanthanide ion hydrolysis equilibria. Bilal and Kob[4] investigated the hydrolysis of Ce^{3+}, Eu^{3+}, Tb^{3+} and Yb^{3+} in aqueous solutions containing phosphate at high concentrations. The hydrolysis constants reported in their work considerably exceed values[5] obtained in the absence of phosphate.

Examination of Fe^{3+} and Eu^{3+} linear free energy relationships for a variety of ligands (Fig. 1) indicates that rare earth phosphate complexation may be significant at relatively high concentrations of HPO_4^{2-}. The $FeH_2PO_4^{2+}$ formation constant obtained by Galal-Gorchev and Stumm,[13] $\log\beta_1 (H_2PO_4^-) = 3.47$, in conjunction with the plot shown in Fig. 1, provides a $EuH_2PO_4^{2+}$ formation constant estimate of the order 10^2. This is in reason-

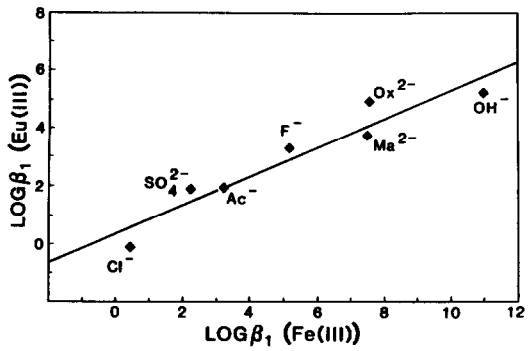

Fig. 1. Formation constants for europium(III) complexes are shown vs iron(III) complexation constants reported for similar conditions. Our thermodynamic data were obtained from the following sources: ($EuCl^{2+}$, 25°C, 1 M);[6] ($FeCl^{2+}$, 25°C, 0.7 M);[7] ($EuSO_4^+$, 25°C, 0.5 M; $FeSO_4^+$, 25°C, 0.5 M);[6] (Eu^{3+} acetate, 20°C, 0.5 M; Fe^{3+} acetate, 20°C, 1 M);[8] (EuF^{2+}, 25°C, 0.7 M);[9] (FeF^{2+}, 25°C, 0.5 M);[6] (europium(III) malonate, 25°C, 1 M);[10] (iron(III) malonate, 25°C, 1 M);[8] (europium(III) oxalate, 25°C, 0.7 M);[11] (iron(III) oxalate, 25°C, 1 M);[10] ($EuOH^{2+}$, 25°C, 1 M; $FeOH^{2+}$, 25°C, 1 M).[12]

ably good agreement with the reported values of Borisov *et al.*[1] and Rao *et al.*[2] The $FeHPO_4^+$ formation constant $\log\beta_1(HPO_4^{2-}) = 8.3$, obtained by Galal-Gorchev and Stumm,[13] indicates that $\log\beta_1(EuHPO_4^+)$ should be of the order 10^4. In order to obtain direct information on the significance of lanthanide ion complexation by the ligand HPO_4^{2-}, in both natural and synthetic systems, we have undertaken investigations of lanthanide ion complexation through phase distribution measurements. Gadolinium was used in our investigations because Gd^{153} is available as a high specific activity radionuclide, greatly limiting the total gadolinium concentrations in our experiments [$(Gd^{3+})_T < 10^{-9}$ mol dm^{-3}], and thereby reducing the possibilities of precipitation in our work. The existence of phosphate minerals as important lanthanide bearing ores attests to the low solubility of lanthanide element phosphates. We suspect that the absence of previously reported $LnHPO_4^+$ stability constants is a direct consequence of the substantial stability of lanthanide phosphate minerals.

EXPERIMENTAL

Our experiments examined the influence of HPO_4^{2-} ions on the distribution of Gd^{3+} between 0.68 M $NaClO_4$ and tributyl phosphate (TBP). The procedures used in our phosphate complexation experiments closely follow the procedures used by Lundqvist[5] and Cantrell and Byrne[11] in the examination of lanthanide and actinide complexation by carbonate ions.

Prior to each experiment, concentrated stock solutions of $NaClO_4$ (Aldrich Chemical Co., anhydrous 99$^+$%) were prepared and allowed to stand at pH 8.5–9.5 for approximately 24 h. The solutions were subsequently filtered with a 0.45 μ polycarbonate filter (Nuclepore Corp.) and diluted to 0.68 M. Before use, each filter was rinsed with acid, followed by deionized water. Prior to each experiment, approximately 120 cm^3 of TBP (Fluka, puriss p.a.) and 120 cm^3 of 0.68 M NaOH (Baker, CO_2 free) were combined in a separatory funnel, shaken for 5 min and then allowed to separate for 20 min. The TBP was next transferred into 25 cm^3 plastic tubes and centrifuged at 12,000 rpm, 25°C ± 1°C for 15 min. The TBP in each tube was then carefully removed and returned to a separatory funnel via an Eppendorf pipette. Approximately 120 cm^3 of 0.68 M $NaClO_4$ was added to the separatory funnel, the mixture was shaken for 5 min and then allowed to separate for 20 min. The $NaClO_4$ was then discarded and the process repeated. Subsequent to these pre-equilibration procedures, our Gd^{153} organic–aqueous phase equilibrations were conducted in a 250 cm^3 jacketed beaker maintained at 25°C ± 0.1°C. This beaker contained 100 cm^3 of both TBP and a 0.68 M $NaClO_4$ aqueous phase.

Our phase distribution measurements were conducted over a pH range such that total phosphate was partitioned dominantly between $H_2PO_4^-$ and HPO_4^{2-}. The concentration of each chemical form was determined from total phosphate and pH using the equations

$$(PO_4)_T = M_{HPO_4^{2-}}(1 + (K_2')^{-1}[H^+]) \quad (2)$$

and

$$(PO_4)_T = M_{HPO_4^{2-}} + M_{H_2PO_4^-}, \quad (3)$$

where $(PO_4)_T$ is the total phosphate concentration in the aqueous solution, $M_{HPO_4^{2-}}$ and $M_{H_2PO_4^-}$ indicate the molar concentration of each chemical form, $[H^+] = 10^{-pH}$ is the free hydrogen ion concentration, and K_2' is the $H_2PO_4^-$ dissociation constant:

$$K_2' = \frac{[H^+]M_{HPO_4^{2-}}}{M_{H_2PO_4^-}}. \quad (4)$$

Measurements of pH on the free hydrogen ion concentration scale[14–16] were obtained using a Ross combination pH electrode (Orion No. 810200) and a Corning model 150 pH meter. In titrations of 0.68 M $NaClO_4$ with strong acid, our electrode exhibited Nernstian behaviour. Measurements in perchlorate media required use of a 3 M NaCl filling solution to prevent $KClO_4$ precipitation at the electrode–liquid junction. Titrations of test solutions containing phosphate indicated that, in 0.68 M $NaClO_4$ at 25°C, $\log K_2' = -6.38$.

Aqueous–organic phase distribution measurements were obtained by measuring the net counts (counts above background) of Gd^{153} in each phase. Constant geometry was maintained for each sample. Gamma spectroscopy analyses were performed with a Bicron 2 × 2 inch well type NaI detector (2m WQ/2) and a Tracor Northern Multichannel analyser (TN-1710).

Phase distribution measurements, performed in the absence of phosphate, demonstrated a constant distribution coefficient, of the order 0.09, over the pH range between 4.0 and approximately 8.0. Using spectrophotometric procedures, in the absence of Gd^{153}, no measurable loss of phosphate to the organic phase was observed within the range of pH ($4.0 \leqslant pH \leqslant 7.0$) employed in our phosphate complexation determinations.

Two distinct procedures were used in our phase distribution measurements. (a) In the first case,

prior to the addition of radiotracer, 1 cm^3 of equimolar $NaH_2PO_4 \cdot H_2O$ (J. T. Baker) and Na_2HPO_4 (Fisher Scientific) in 0.68 M $NaClO_4$ was added to 100 cm^3 of 0.68 M $NaClO_4$ in the jacketed beaker, providing a total phosphate concentration equal to 2×10^{-4} M. TBP was added to the beaker and the mixture was subsequently acidified with 0.68 M $HClO_4$ and bubbled with N_2 for 30 min at pH $\simeq$ 4.0. The pH was adjusted to a desired initial value using 0.68 M NaOH and approximately 0.03 cm^3 of Gd^{153} (Isotopes Products Laboratories) was added to the organic–aqueous solution while stirring, providing a 1.3×10^{-10} M solution. Subsequent to bubbling vigorously with N_2 for 30 min, followed by a 30 min period for phase separation, 1 cm^3 samples were taken from each phase for gamma spectroscopy analysis. The solution was then slightly acidified, re-equilibrated while bubbling, and sampled after the 30 min allocated for phase separation. Repetition of this procedure resulted in a total of 19 titration points in two experiments at constant total PO_4 (2×10^{-4} M) within the pH range $4.0 \leqslant pH \leqslant 5.9$. (b) In a second procedure, Gd^{153} was added to the TBP–0.68 M $NaClO_4$ mixture prior to the addition of phosphate. Our phosphate titrant was equimolar $NaH_2PO_4 \cdot H_2O$ and Na_2HPO_4 in 0.68 M $NaClO_4$. Using the previous equilibration procedure (30 min of vigorous bubbling plus 30 min for phase separation) a series of distribution measurements were obtained between 0.0 M total PO_4 and approximately 4×10^{-3} M total PO_4. In two experiments using this procedure, we obtained a total of 22 titration points within the pH range $4.0 \leqslant pH \leqslant 5.4$.

RESULTS

The distribution of Gd^{153} between our tributyl phosphate organic phase and 0.68 M $NaClO_4$ can be described in terms of HPO_4^{2-} and $H_2PO_4^-$ complexation, using an expression identical in form to that used by Cantrell and Byrne[11] in descriptions of Ce^{3+}, Eu^{3+} and Yb^{3+} complexation by CO_3^{2-} and HCO_3^-:

$$D/D^0 = 1 + \beta'_1 M_{HPO_4^{2-}} + \beta'_2 M^2_{HPO_4^{2-}} + \beta'_H M_{H_2PO_4^-}, \quad (5)$$

where D^0 and D are distribution coefficients determined in the absence and presence of phosphate. D and D^0 are expressed as Gd^{153} (aqueous activity/g)/Gd^{153} (organic activity/g), and the parameters β'_1, β'_2 and β'_H are conditional stability constants appropriate to the 0.68 M aqueous medium at 25°C:

$$\beta'_1 = [GdHPO_4^+]/([Gd^{3+}]M_{HPO_4^{2-}})$$

$$\beta'_2 = [Gd(HPO_4)_2^-]/([Gd^{3+}]M^2_{HPO_4^{2-}})$$

$$\beta'_H = [GdH_2PO_4^{2+}]/([Gd^{3+}]M_{H_2PO_4^-}), \quad (6)$$

where $M_{HPO_4^{2-}} = [HPO_4^{2-}] + [NaHPO_4^-]$ and brackets denote the molar concentration of each indicated species.

In the first of our two experimental procedures, no distribution coefficients were obtained prior to the addition of phosphate. Since the total phosphate concentration in the first of our two procedures was only 2×10^{-4} M and β'_H is expected to be on the order of 10^2 or less, the term $\beta'_H M_{H_2PO_4^-}$ was neglected in our data analyses. In these experiments, conducted at constant total phosphate, our distribution data indicated that $[Gd^{3+}]/Gd_T$ was less than 0.60 for only one of 18 data points. Since $Gd(HPO_4)_2^-$ formation should be relatively small compared to $GdHPO_4^+$ under these conditions, our experiments at constant total phosphate were analysed by excluding our highest $M_{HPO_4^{2-}}$ data point and using the following truncated version of eq. (5):

$$D = D^0(1 + \beta'_1 M_{HPO_4^{2-}}). \quad (7)$$

Using eq. (7), our distribution data in the form (D, $M_{HPO_4^{2-}}$) were analysed through least-squares minimization of the residual sum of squares function $RSS = \Sigma_i(D(\text{observed})_i - D(\text{predicted})_i)^2$. The best fit parameters, D^0 and β'_1, obtained in our analyses are shown in Table 1.

Our experiments conducted using variable total phosphate concentrations produced data of the form (D/D^0, $M_{HPO_4^{2-}}$, $M_{H_2PO_4^-}$) where, in contrast to our first two experiments at constant $(PO_4^{3-})_T$, both $M_{HPO_4^{2-}}$ and $M_{H_2PO_4^-}$ varied over wide ranges. Consequently, these data were analysed directly using eq. (5) through minimization of the residual sum of squares function $RSS = \Sigma_i\{D/D^0(\text{observed})_i - D/D^0(\text{predicted})_i\}^2$. Our results obtained in these two experiments are shown in Table 2.

DISCUSSION

Our phosphate complexation determinations were designed primarily to provide quantitative characterizations of $GdHPO_4^+$ formation. The average estimate for β'_1 shown in Table 2 is $\log\beta'_1 = 3.91$. We regard the estimates shown in Table 1 as upper bound values due to the possible presence of $Gd(HPO_4)_2^-$ at low concentrations. As such, our Table 1 results indicate that $\log\beta'_1 \leqslant 4.07$. Our Table 1 results can be examined for the influence of $Gd(HPO_4)_2^-$ formation in two ways. In the first case, rather than eliminating the single high data point (D, $M_{HPO_4^{2-}}$) from our analyses, we included this point in an analysis using the following equation:

$$D = D^0(1+\beta'_1 M_{HPO_4^{2-}} + \beta'_2 M^2_{HPO_4^{2-}}). \quad (8)$$

The best fit β'_1 result obtained in this analysis, $\log\beta'_1 = 3.93$, is in very good agreement with our Table 2 results. In a second type of analysis we examined our experiments conducted at constant total phosphate by using eq. (7) and successively eliminating our highest $M_{HPO_4^{2-}}$ data. With one point eliminated from each of our experiments, we obtained the average $\log\beta'_1 = 3.98$ for the two experiments. With two points eliminated from each data set we obtained an identical result, $\log\beta'_1 = 3.98$. Both of these estimates are in good agreement with our Table 2 results.

Our estimates for β'_H, shown in Table 2, are in fair agreement with previous work. Our results indicate that $\beta'_H \leqslant 66$. The single relatively well-defined estimate shown in Table 2, $\log\beta'_H = 1.70$, can be compared with the estimates for $AcH_2PO_4^{2+}$ and $LaH_2PO_4^{2+}$ obtained at 25°C and 0.5 M ionic strength:[2] $\log\beta'_H = 1.59$ and $\log\beta'_H = 1.61$. In addition, at 25°C and 0.5 M ionic strength, Borisov *et al.*[1] obtained the estimates, $\log\beta'_H(Ce^{3+}) = 1.52$, $\log\beta'_H(Pm^{3+}) = 1.69$, $\log\beta'_H(Am^{3+}) = 1.69$ and $\log\beta'_H(Y^{3+}) = 1.89$.

Our β'_2 results are unique in the sense that apparently no other $M(HPO_4)_2^-$ formation constant results have previously been obtained for the lanthanides or any other element. As a check on the internal consistency of our results, it should be noted that for the stepwise stability constants K'_1 and K'_2 (where $K'_1 = \beta'_1$ and $K'_2 = \beta'_2/\beta'_1$), our Table 2 results indicate that $K'_2/K'_1 = \beta'_2/(\beta'_1)^2 \simeq 0.12$. This observation is in good accord with results obtained for lanthanide oxalate complexation: $K'_2/K'_1 = 0.10\pm0.01$ for Ce^{3+}, Eu^{3+} and Yb^{3+} [11] at 25°C and 0.68 M ionic strength.

Activity coefficients appropriate to Gd^{3+} and HPO_4^{2-} at 0.68 M ionic strength and 25°C can be calculated[17] as approximately 0.049 and 0.157. Following our previous activity coefficient choices for $LnCO_3^+$ and $Ln(CO_3)_2^-$,[11] we have chosen $\gamma(LnHPO_4^+) = \gamma Ln(HPO_4)_2^- \simeq 0.5$ for both phosphate complexes. Consequently, our best estimates for β'_1 and β'_2 at zero ionic strength are

$$\log\beta^0_1 = 5.7 \quad \text{and} \quad \log\beta^0_2 = 9.5. \quad (9)$$

The only previous quantitative characterizations obtained for HPO_4^{2-} complexation of trivalent metals are apparently those obtained for $FeHPO_4^+$ [13] and $GaHPO_4^+$.[18] It is noteworthy, however, that the Pm^{3+} distribution data of Borisov *et al.*[1] suggested to these authors "the appearance of appreciable amounts of the complex ions, containing HPO_4^{2-} as addends". While the pH 2.0 and 3.0 data of Borisov *et al.*[1] provided the estimate $\log\beta'_H = 49\pm3$, their pH 4.0 distribution data cannot be interpreted solely in terms of complexation by $H_2PO_4^-$. An appropriate analytical equation for the pH = 4.0 data of Borisov *et al.*[1] can be expressed as

$$D/D^0 = 1+\beta'_H[H_2PO_4^-]+\beta'_1[HPO_4^{2-}]. \quad (10)$$

Consequently,

$$\beta'_H+\beta'_1\left(\frac{[HPO_4^{2-}]}{[H_2PO_4^-]}\right) = (D/D^0-1)[H_2PO_4^-]^{-1} = \Psi_1. \quad (11)$$

Using the Ψ_1 data compilation of Borisov *et al.*[1] for points such that $(PO_4)_T \geqslant 0.005$, plus the estimate $\beta'_H = 49$, we obtain the result $\Psi_1 \simeq 83.7$ and thereby, $\beta'_1 = 34.7$ ($[H_2PO_4^-]/[HPO_4^{2-}]$). Since $-\log K'_2 \simeq 6.5$ at 25°C and $\mu = 0.5$ M, β'_1 can then

be estimated from the data of Borisov *et al.*[1] as

$$\log \beta'_1 \simeq \log 34.7 + 2.5 = 4.05 \pm 0.22, \quad (12)$$

where the listed uncertainty is one half the range of five calculated ${}^1\Psi_1$ estimates. Since Pm^{3+} is a relatively close neighbour of Gd^{3+}, the results obtained in this calculation seem to be in good agreement with the present work.

Due to the similarities noted for trivalent lanthanide and actinide complexation, the results of Rao *et al.*[19] for $AmHPO_4^+$ at 0.5 M ionic strength and 30°C, are of potential interest for direct comparison with the results obtained in the present work. Unfortunately, a variety of features of the Rao *et al.*[19] data analyses renders their reported $AmHPO_4^+$ formation constant result of limited quantitative significance. In order to partition total phosphate among various forms, including HPO_4^{2-} and PO_4^{3-}, Rao *et al.*[19] made use of expressions such as

$$\frac{[PO_4^{3-}]a_H}{[HPO_4^{2-}]} = D_3\left(\frac{\gamma_2}{\gamma_3}\right), \quad (13)$$

where $[PO_4^{3-}]$ and $[HPO_4^{2-}]$ represent species concentrations, a_H is the hydrogen ion activity, D_3 is a dissociation constant at zero ionic strength, and γ_2 and γ_3 are activity coefficients appropriate at 0.50 M ionic strength. In calculating the PO_4^{3-} and HPO_4^{2-} activity coefficients (γ_3 and γ_2), as well as activity coefficients for other species, it is important to note that the parameters γ_2 and γ_3 shown in eq. (13) are individual ion activity coefficients which can be calculated using the Davies equation in the form

$$\log \gamma_i = -AZ_i^2\left(\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.2\mu\right), \quad (14)$$

where μ is the ionic strength, Z_i is ionic charge and $A \simeq 0.5$ at 25°C.[3] Using the Davies equation, γ_3 and γ_2 are calculated as 0.036 and 0.23. Employing a form of the Davies equation appropriate to the calculation of mean ionic activity coefficients,[20] Rao *et al.*[19] calculated $\gamma_3 = 0.34$ and $\gamma_2 = 0.49$. Other problems which have a strong bearing on the reported results of Rao *et al.*[19] include their use of an Am^{3+} hydrolysis constant substantially larger than other reported values,[21,5] and their performance of experiments under conditions ($7.0 \leqslant pH \leqslant 8.0$; $0.005 \leqslant (PO_4^{3-})_T \leqslant 0.03$) which are likely to produce mixed ligand species such as $AmHPO_4(OH)^0$. Due in part to these factors, we regard the apparent agreement between our results and the reported result of Rao *et al.*[19] as fortuitous.

Our lanthanide phosphate complexation results, in conjunction with the carbonate complexation results of Cantrell and Byrne,[11] indicate that environmental phosphate complexation of the trivalent lanthanides and actinides is of modest importance relative to carbonate complexation. Stability constants for lanthanide carbonate complexation are approximately two orders of magnitude greater than for phosphate complexation, and the CO_3^{2-}–HPO_4^{2-} concentration ratio in natural systems is generally between 10 and 1000. Even in the interstitial waters of marine sediments where HPO_4^{2-} concentrations may be as high as 1×10^{-4}, our results indicate that $[Gd^{3+}] \geqslant [GdHPO_4^+]$. In spite of the limited extent of phosphate complexation in most natural systems, our results indicate that phosphate is a poor buffer choice for hydrolysis constant determinations. In the experiments of Bilal and Kob,[4] $Na_xH_{3-x}PO_4$ constituted between 0.2 and 2% of the components used to provide a 1.0 M total ionic strength. This implies, for $pH > 7.5$, the HPO_4^{2-} concentrations in Bilal and Kob's[4] experiments are between 0.0007 and 0.007 M. Rare earth complexation by phosphate is substantial under these conditions and may contribute to substantial hydrolysis constant misestimates. Based on a variety of investigations for the reaction

$$Yb^{3+} + H_2O \overset{\beta_1^*}{\rightleftharpoons} YbOH^{2+} + H^+ \quad (15)$$

at 25°C and 1 M ionic strength, Baes and Mesmer[12] estimate $\log \beta_1^*(Yb^{3+}) = -8.42$. Through direct solubility measurements in the absence of buffers, Kragten and Decnop-Weever[22] obtained the result, $\log \beta_1^* = -7.7$. Bilal and Kob[4] produced the result, $\log \beta_1^*(Yb^{3+}) = -5.30$.

THREE COORDINATED COPPER(I) COMPLEXES OF CHELATING LIGANDS DERIVED FROM 2,6-DIACETYLPYRIDINE AND PHENYLALANINE OR TYROSINE

W. L. KWIK* and ALICE W. N. TAY

Department of Chemistry, National University of Singapore, Lower Kent Ridge Road, Singapore 0511

(*Received* 7 *June* 1988; *accepted after revision* 18 *January* 1989)

Abstract—Copper(I) complexes of Schiff-base ligands, L_1 and L_2, derived from condensation of 2,6-diacetylpyridine with phenylalanine methyl ester or tyrosine ethyl ester have been prepared. On the basis of various spectroscopic data, it is proposed that these complexes in the solid-state have mononuclear structures in which the trimethine group acts as tridentate while retaining its planarity. In methanol, spectroscopic properties suggest at least partial dissociation of one-side arm leading to a two-coordinate copper(I) which then interacts with a free imino nitrogen of a second molecule of the copper(I) complex. This results in a more effective overlap of the copper(I) orbital with p_{π^*} of the ligand and hence an increase in absorption intensities.

Interesting examples of copper(I) Schiff-base complexes (Scheme 1) displaying reactivities towards dioxygen have recently been reported.[1–6] The Schiff-base ligands involved (Scheme 1) are those obtained from condensation of 2,6-diacetylpyridine and various amines, and span both the pentadentate types[1–5] (L^1, L^2) as well as those with only three nitrogen donors[6] (L^3, L^4, L^5). It has been noted[6] that some of the chemical behaviours of the five nitrogen and the three nitrogen Schiff bases are distinctly different.

We have previously reported[7] the synthesis and spectral properties of the copper(II) and zinc(II) complexes of the Schiff bases (Scheme 1) derived from condensation of 2,6-diacetylpyridine and phenylalanine methyl ester (L_1), or tyrosine ethyl ester (L_2) containing three nitrogen donor atoms as well as ester carboxylate groups in the side chain. In the following, the isolation and various chemical properties of the corresponding copper(I) complexes [**1** for $CuL_1(BF_4)$ and **2** for $CuL_2(BF_4)$] are presented.

EXPERIMENTAL

Synthesis

All solvents were deoxygenated and stored under nitrogen over molecular sieves (4 Å). Methanol, acetonitrile and dichloromethane were treated according to published procedures prior to use. Spectrochemical grade dimethyl sulphoxide (Aldrich, Gold Label) was used for electronic, electrochemical and conductivity measurements. Deuterated dimethyl sulphoxide (Aldrich, Gold Label) used for NMR spectral studies was stored under nitrogen in a dry-box.

2,6-Diacetylpyridine and 2-(2-aminoethyl)pyridine (Aldrich Chemical Company) were used as received. Phenylalanine methyl ester hydrochloride, tyrosine ethyl ester hydrochloride (Sigma Chemical Company) were treated to remove the hydrochloride by the method described by Casella *et al.*[5] Tetra(acetonitrile) copper(I) tetrafluoroborate was prepared by the method of Hemmerich and Sigwart. Electrochemical grade tetraethylammonium perchlorate (Eastman Chemicals) was used without further purification.

The ligand solution was prepared by refluxing 2,6-diacetylpyridine (2 mmol) and the base (4 mmol) (phenylalanine methyl ester/tyrosine ethyl ester) under nitrogen in dry, deoxygenated MeOH (100 cm^3) for about 20 h, whereupon an intense yellow colour developed.

Freshly prepared $[Cu(CH_3CN)_4]BF_4$ (2 mmol) was dissolved in deoxygenated CH_3CN (50 cm^3) and the solution filtered to remove trace amounts of blue copper(II) salt present. The colourless filtrate was warmed before being added to the hot ligand solution. The ensuing blood-red solution was then reduced to near dryness at 85°C by rotary evaporation, to yield a hygroscopic, dark red solid. This was recrystallized twice from deoxygenated MeOH in a dry-box. The final, dark red solid was dried *in vacuo* at 80°C for 6 h prior to elemental analysis.

Compound **1**. Found: C, 53.4; H, 4.9; N, 6.4; Cu, 9.6. Calc. for $C_{29}H_{33}N_3O_5CuBF_4$: C, 53.2; H, 5.0; N, 6.4; Cu, 9.6%. IR data (KBr, cm^{-1}): 1636 ($\nu_{C=N}$); 1740 ($\nu_{C=O}$); 1267 (ν_{C-OR}); 1636 ($\nu_{COO(as)}$); 1385 ($\nu_{COO(s)}$). Λ_M = 76 (MeOH); 37 (DMSO); 149 (CH_3CN) S cm^2 mol^{-1}.

Compound **2**. Found: C, 50.9; H, 5.0; N, 6.1; Cu. 8.6. Calc. for $C_{31}H_{39}N_3O_8CuBF_4$: C, 50.8; H, 5.3; N, 5.7; Cu, 8.7%. IR data (KBr, cm^{-1}): 1615 ($\nu_{C=N}$); 1734 ($\nu_{C=O}$); 1268 (ν_{C-OR}); 1615 ($\nu_{COO(as)}$); 1373 ($\nu_{COO(s)}$). Λ_M = 87 (MeOH); 36 (DMSO); 151 (CH_3CN) S cm^2 mol^{-1}.

Measurements

IR spectra in the 4000–400 cm^{-1} region were recorded on a Perkin–Elmer Model 1710 Fourier Transform IR spectrometer. Spectra extending into the far-IR region of 200 cm^{-1} were recorded on a Perkin–Elmer Model 567 spectrometer calibrated with polystyrene film. CsI and KBr pellets were employed throughout. Electronic spectra were recorded on a Perkin–Elmer Lambda 9 UV–vis–near-IR spectrophotometer. Conductivities of 10^{-3} M solutions of the complexes were measured at 30°C using a CM-115 conductivity meter (Kyoto Electronics). The ^1H and ^{13}C NMR spectra were obtained for samples in DMSO-d_6 solutions at 90 MHz using a Jeol Fx90 Q FT NMR spectrometer. Cyclic voltammograms were obtained in DMSO solutions at room temperature under a constant flow of N_2, using a Pine Instrument RDE 4 potentiostat. A three-electrode system was employed, with a glassy carbon ring-disc electrode (disc radius = 0.382 cm) serving as the working electrode, a platinum foil as the counter electrode, and a saturated calomel electrode (SCE) as the reference electrode. All solutions were 0.1 mol dm^{-3} in tetraethylammonium perchlorate and 10^{-3} mol dm^{-3} in the complex.

RESULTS AND DISCUSSION

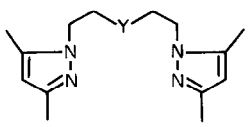
IR spectral study

The IR spectra of **1** and **2** are similar in important aspects to those of the free ligands, though there

Table 1. Chemical shifts (ppm) of ^{1}H NMR signals

Compound/complex	Protons H(1)	H(2)	H(7)	H(10)	H(11)	H(12)	H(14)	H(8)
2,6-diacetylpyridine	8.16	2.73	—	—	—	—	—	—
Phenylalanine methyl ester		—	3.58	7.21	7.21	7.21	3.58	3.58
Tyrosine ethyl ester		—	3.40	6.65	6.95	—	4.00	2.68 2.74
L_1	8.15	2.73	3.70	7.25	7.25	7.25	3.60	3.10
L_2	8.15	2.71	3.50	6.70	7.00	—	4.00	3.00
1	8.14	2.75	4.20	7.30	7.30	7.30	3.60	3.15
2	8.14	2.72	4.20	6.74	7.04	—	4.10	3.00

are distinct shifts of the characteristic bands. Both display strong IR absorptions at: (i) 1740, 1286 and 1240 cm^{-1} of the ester carbonyl (COOR),[8-10] (ii) 1636 cm^{-1} for **1** and 1625 cm^{-1} for **2** of the imino $\nu_{C=N}$[11] and (iii) 1050 cm^{-1} for the BF_4^- ion. As there is no significant difference in the IR absorption characteristics of the two copper(I) complexes, it is tentatively concluded that there is no significant structural difference between the two complexes. The presence of only one distinct absorption band due to the imino stretching ($\nu_{C=N}$) in the 1600–1660 cm^{-1} region, suggests that both complexes assume a structure in which the two imino (C=N) groups are equivalent. It appears that a dinuclear structure in which the two imino (C=N) nitrogen atoms are bonded to different copper centres can be excluded for these two copper(I) complexes.[6] It would seem reasonable to assume that the trimethine group functions as a tridentate chelating group to a single copper(I) ion, thus retaining planarity upon complexation. Moreover, a comparison of the IR spectra of these complexes shows that they closely resemble those of other metal complexes where trimethine group planarity has been proven by X-ray analysis.[5] These considerations lead us to propose that in **1** and **2**, the copper(I) ions are mononuclear and three-coordinate. This is consistent with the presence of uncoordinated ester groups as suggested from the IR absorption characteristics.[8-10] The most probable disposition of the donor atoms in L_1 and L_2 is such that the metal ion has a T-shaped geometry. Such a geometry, though unusual, has been observed in the ligand systems,[6] bis[2-(3′,5′-dimethylpyrazol-1-yl)ethyl]ether (Y = O) and the corresponding sulphide (Y = S) and amine (Y = NH), see Structure 1.



Structure 1.

^{1}H *NMR spectral study*

Both the copper(I) complexes display broad ^{1}H NMR signals at 25°C, most likely due to the presence of trace amounts of copper(II) ions. As the temperature is raised to 100 and 150°C, the spectra became better resolved.

A comparison of the spectra of the free ligands versus those of the complexes and those reported by Nelson,[6] reveals that the effect of complexation on the chemical shift is most significant for H(7) yielding a change in δ_H values of *ca* 0.5–0.7 ppm (Table 1). This is consistent with the proximity of H(7) to the imino nitrogen and similar changes in δ_H values have been observed for the zinc(II) analogues.[7,12] It is also of interest to note that the protons of the carboxylate group of the amino acid components are only marginally affected by condensation and complexation. This observation further points to the absence of any interaction between the carboxylate oxygen and the copper(I) ion in these complexes, in contrast to the case of the analogous zinc(II) complexes.[7,12]

^{13}C *NMR spectral study*

The ^{13}C NMR spectra of **1** and **2**, as well as those of the ligands L_1 and L_2, are generally of well-resolved peaks (Table 2). Assignments were made with the aid of the "off-resonance" technique, whereby the number of protons bound to each unique carbon atom could be determined without loss of the nuclear overhauser enhancement.[13,14] Reference was also made to values of ^{13}C chemical shifts reported for similar complexes.[6]

Comparison of the chemical shifts of L_1 and L_2 and those of the corresponding copper(I) complexes showed that the largest change is observed for the imino carbon, C(4). The shift of C(4) from 198.5 to 166.8–175 ppm upon condensation and complexation is not only supported by reported values

Table 2. Chemical shifts (ppm) of ^{13}C NMR signals

Compound/complex	C(1)	C(2)	C(3)	C(4)	C(7)	C(8)	C(9)	C(10)	C(11)	C(12)	C(13)	C(14)	C(15)
2,6-diacetylpyridine	138.8	124.4	152.1	198.5	—								
Phenylalanine methyl ester					41.0	55.9	137.7	128.6	129.5	126.8	175.5	51.7	
Tyrosine ethyl ester					40.0	55.8	127.5	115.0	130.0	155.6	174.9	59.8	14.0
1	138.5	126.6	152.2	170.0	54.6	55.5	138.5	128.1	128.8	127.9	170	52.1	
2	139.1	124.0	152.2	170.4	53.9	55.1	128.0	115.5	130.3	156	170	65.1	14.0

but also consistent with the lower electronegativity of nitrogen in comparison to that of oxygen.

The proximity of C(7) to the imino nitrogen is expected to induce significant changes in the chemical shifts upon condensation and complexation. Indeed, changes of 13.6–13.9 ppm have been observed for both copper(I) complexes. The larger changes of these three nitrogen systems, in comparison to the five nitrogen complexes (Table 2), would seem to indicate stronger imino nitrogen–metal interactions in the former.

Cyclic voltammetric studies

1 and **2** display a small cathodic wave at 0–40 mV and a larger wave at −450 to −500 mV, but there is only one anodic wave at +300 to +460 mV. The range of values into which these waves fall indicate that they are most likely attributable to the electrode processes of $Cu^{2+} \rightarrow Cu^{+}$ and $Cu^{+} \rightarrow Cu^{0}$ for the cathodic wave, and of $Cu^{+} \rightarrow Cu^{2+}$ for the anodic wave. Moreover, the larger ΔE_p for the first process means that the electron transfer is irreversible in each case.

That the $Cu^{2+} \rightarrow Cu^{+}$ process was detected as a small but distinct wave is not unexpected in view of the ease with which **1** and **2** undergo oxidation. That the anodic process of $Cu^{0} \rightarrow Cu^{+}$ is not detected is probably a manifestation of a coupled chemical reaction which occurs after the electrode reduction steps in the forward cathodic scan.

Electronic spectral study: nature of the complexes in solution

At room temperature, as well as at 80 K, solution and solid-state (KBr/Nujol mull) electronic spectra measured over the range 30,000–10,000 cm^{-1} (Table 3) are found to be solvent dependent. Whereas absorption maxima at ~ 35,700 cm^{-1}, attributable to the ligands $\pi \rightarrow \pi^*$ transition, are observed in MeOH, DMSO and CH_3CN and intense well-defined bands at ~ 22,730 and ~ 22,220 cm^{-1} for **1** and **2**, respectively (Fig. 1), are displayed only in MeOH and DMSO. In CH_3CN, a shoulder of much lower intensity appeared at 25,000 cm^{-1}. The high molar absorptivities of these lower energy bands in MeOH and DMSO (Table 3) clearly indicate that these are due to the charge-transfer transitions (CT) from filled *d*-orbitals of the copper(I) to the vacant π^* orbital of the trimethine group.[11] These bands are further characterized by a steady increase in intensity over a time period of ~ 30 and 60 min in carefully deoxygenated MeOH and DMSO, respectively.

Similar increases in absorbances with time were observed over a five-fold concentration range, 2×10^{-4}–1×10^{-3} M [Fig. 2(a)]. The apparent "ε"s

calculated for these absorption maxima are seen to be fairly constant, within some inherent experimental error, due to oxidation/decomposition of the complexes in solution.

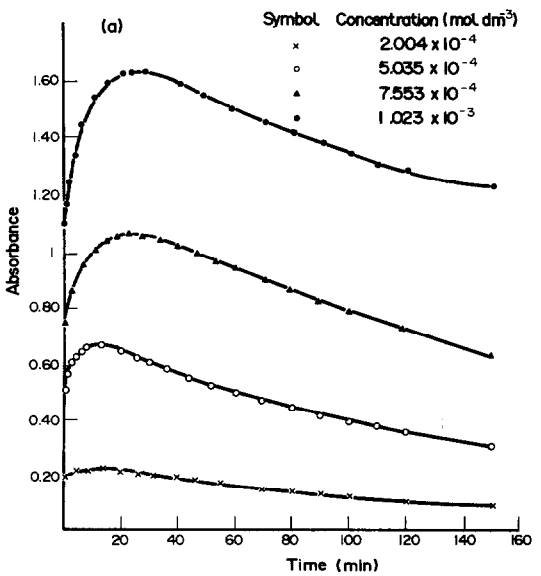

Fig. 2(a). Plot of absorbance of **1** vs *t* (min) at different concentrations in MeOH.

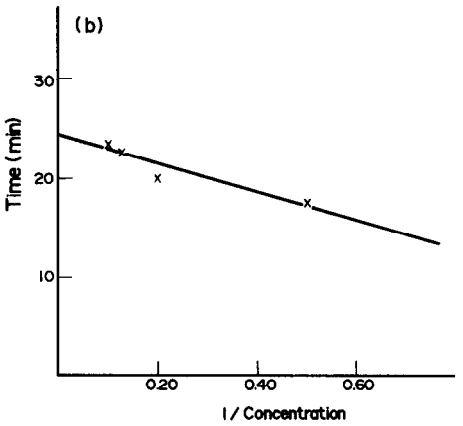

Fig. 2(b). Plot of $1/C$ vs *t* (min).

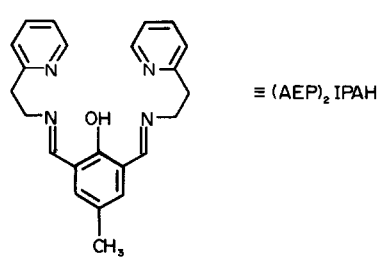
The plot of $1/C$ (with C being the concentration of the respective complex) vs *t* (the time taken to reach maximum absorbance at each concentration) [Fig. 2(b)], was found to be linear for both complexes in MeOH over the concentration range, 2×10^{-4}–1×10^{-3} M. This is an interesting observation, although no further conclusions could be drawn at this stage because of the complexities of possible decompositions due to the ease of oxidation of these complexes in solution. Moreover, the remarkably similar behaviour of **1** and **2** suggests that the process does not involve the phenolic OH in the tyrosine component to any significant extent.

In the following, an attempt will be made to account for: (i) the markedly different absorption spectra at 25,000–20,000 cm^{-1} in CH_3CN and in MeOH/DMSO; (ii) the remarkable increases in intensities of the absorption maxima at 22,700/22,200 cm^{-1} for **1** and **2**, respectively, in MeOH, as well as in DMSO.

Proposed mechanism for (i)

It must be mentioned that such markedly different absorption behaviour in CH_3CN and MeOH–DMSO are not unique for **1** and **2**. Urbach and coworkers[15,16] reported similar solvent dependence of electronic absorptions for a mononuclear copper(I) complex with the ligand shown in Structure 2.



Structure 2.

Thus the copper(I) complex of $(AEP)_2IPAH$ displays only one band at 22,600 cm^{-1} in MeOH and DMSO, but two bands at 22,400 and 28,300 cm^{-1} in MeCN, with the first band being reduced in intensity relative to that in MeOH. This behaviour was interpreted as a competition between the ligand and acetonitrile for coordination of the copper(I) according to the equilibrium:

$$[Cu(AEP)_2IPAH]^+ + CH_3CN\,(excess) \longrightarrow (AEP)_2IPAH + [Cu(CH_3CN)_n]^+.$$

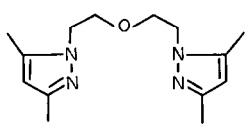
This equilibrium is reasonable in light of the known affinity of copper(I) for acetonitrile.[16] It was also found in this case, that addition of excess $[Cu(CH_3CN)_4]BF_4$ to an acetonitrile solution of the $[Cu(AEP)_2IPAH]^+$ produces a dramatic increase in intensity for the 22,400 cm^{-1} band which was associated with the complex, while the 28,300 cm^{-1} band, due to the free ligand, disappeared.

For **1** and **2** it was found that addition of excess $[Cu(CH_3CN)_4]BF_4$ to a methanolic solution containing 10% CH_3CN brought about a significant increase in absorbances at 22,200–22,700 cm^{-1}. Such behaviour suggests the relatively weaker binding of L_1 and L_2 as compared to $(AEP)_2IPAH$. This is not surprising in view of the binding of copper(I) by two more pyridine rings in the latter.[16]

Proposed mechanism for (ii)

The electronic absorption spectra of the copper(I) complexes of L^3 and similar Schiff-base bands reported by Nelson *et al.*,[6] comprise absorptions at 22,200–22,700 cm^{-1} appearing only as a shoulder of relatively weak intensity. On the other hand, the five-coordinated copper(I) complexes of Schiff-base ligands L^1 and L^2 due to Wilson *et al.*,[4] display well-defined absorptions similar to those of **1** and **2**.

The weaker CT band as observed for complexes of L^4 and L^5, can be rationalized by consideration of the coordination geometry of the copper(I) complexes due to the disposition of donor atoms in these complexes. It was found that the metal ion would in fact have a T-shaped geometry. Such an unusual geometry has been observed in a few copper(I) complexes[17–19] with ligands such as bis[2-(3′,4′-dimethylpyrazol-1-yl)ethyl]ether (pze) (Structure 3).

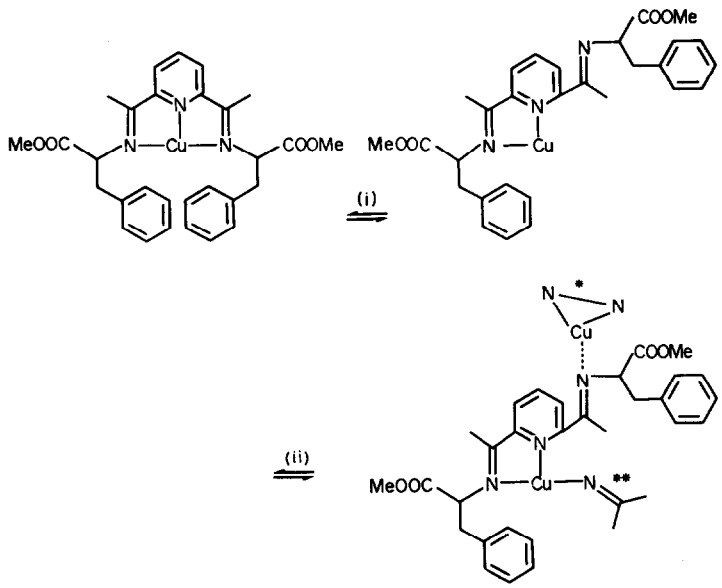


Structure 3.

The X-ray structure of the Cu^I–pze complex shows that the copper(I) is essentially two-coordinate with a weak interaction by the oxygen atom. Thus it is expected that the T-shaped disposition in copper(I) complexes of L^4 and L^5 ensues in poor overlap of the pyridine *p*-orbital with the filled *d*-orbital of copper(I). This, in turn, leads to CT bands of relatively lower intensity. The stronger CT band in the five-coordinated copper(I) complexes reported by Wilson *et al.*[4] is probably due to stronger binding brought about by the two imidazyl/pyridyl nitrogen donors (in addition to the DAP pyridine nitrogen) in these ligands. In fact as shown recently,[4] the trimethine group assumes a highly distorted, non-T-shaped disposition, the bond angle between the two imino to copper(I) bonds being 148° and significantly different from the 180° expected of the T-shaped geometry. Such distortion from T-shaped geometry in turn allows for better overlap between the pyridyl (trimethine) nitrogen *p*-orbital and the filled *d*-orbital of copper(I) and thus the observed intense CT band.

A consideration of electronic spectral behaviour in relation to the structures of the two series of copper(I) complexes mentioned above, leads to a possible explanation of the observed increase in intensities of the CT bands for **1** and **2** with time in MeOH–DMSO. It appears that such an increase must be related to a change in geometry around copper(I), so that more efficient overlap of the respective orbitals of the ligand L_1/L_2 and of copper(I) can be brought about. Taking all experimental data available into consideration, the equilibrium indicated in Scheme 2 appears most favourable.

In the above equilibrium it is proposed that one of the imino nitrogen swings open leaving a two-coordinated copper(I); the driving force for step (i) probably arises from the strong hydrogen bonding ability, particularly of MeOH, with which the free imino nitrogen can form hydrogen bonds, as first suggested by Urbach.[12] Step (ii) is proposed on the basis that the rate of increase in absorbance is inversely proportional to the concentration of the complex. It would seem reasonable that at least two copper(I) centres must be involved. These copper(I) centres may attain four-coordination through bonding with a MeOH molecule; alternatively it may remain three-coordinate but with more efficient overlap of the filled *d*-orbital on copper(I) with pyridyl nitrogen *p*-orbital. Furthermore, as step (ii) is statistically unfavourable, there is a slow increase over a time period of 30–60 min. It should



Scheme 2. * N | N only the part of the trimethine group that binds to the two-coordinate copper(I) is shown: ** N< only the bound N donor of the trimethine group is shown.

be emphasized that these time periods are only approximate upper limits, as the processes suggested in steps (i)/(ii) are competing against decomposition of the complexes produced by slow oxidation. Finally, the involvement of hydrogen bonding in step (i) is consistent with the order of observed increases in absorbances at 22,700–22,200 cm^{-1} for MeOH > DMSO > acetone; in the last case the increase lasted for only 7 min.

The proposed equilibrium is also consistent with the observed ^{1}H and ^{13}C NMR spectra described above. Thus the peak due to the methyl protons, C(5), was found to be extremely broadened, probably the result of an average of the two sets of imino methyl protons. Likewise, the imino C(5) appears as a broad peak in the ^{13}C NMR spectra of **1** and **2**. The fact that no separate signals were observed for the protons and carbons associated with the two imino nitrogens could be due to rapid exchange of the bound and unbound imino groups.

In addition, such a change in coordination geometry, brought about by opening up of one of the side arms in solution, is also consistent with the observed differences in spectra of samples dispersed in KBr/Nujol mull and of methanol/DMSO solutions. In KBr/Nujol mull, the absorption at 22,700 cm^{-1} appears only as a broad shoulder (Table 3). In glassed solution the bands at 22,200–22,700 cm^{-1} become better defined. This is in no way contradictory to the proposed equilibrium, as some of the copper(I) is already in the geometry type resulting from step (ii) of the above equilibrium in such a glassed solution.

Finally solvation by MeOH/DMSO to give rise to four-/five-coordinated copper(I), as well as participation of the phenyl ring of the tyrosine/phenylalanine residue in L_1/L_2 have been considered. However, mechanisms involving these processes could not fully account for the observed experimental findings.

Reactions with dioxygen

Both **1** and **2** have reasonable air stabilities over periods of days in the solid-state. The solutions in the presence of air, however, develop green or green–brown colours at rates dependent on the nature of the complex and of the solvent.

As the intensely red coloration was retained in DMSO over a significantly longer time than in MeOH, this was selected to be the solvent used for studying the oxygenation. Upon exposure to dioxygen (1 atm), the red coloration of a solution of **1** and **2** in deoxygenated dry DMSO at room temperature disappears, yielding a green–yellow solution. The change is complete in about 1.5 h and can be partially reversed by gentle heating of the oxygenated solution under a stream of dry nitrogen (Fig. 1). The degree of reversibility of the reaction determined spectrophotometrically is about 70%

and the oxy–deoxy cycle process can be repeated 2–3 times until the solution became brown and did not show any further colour change upon further exposure to dioxygen.

The change of colour of a methanolic solution of **1** or **2** upon exosure to dioxygen was found to be completely irreversible. A similar finding has previously been reported by Ibers and co-workers.[5]

Reactions with carbon monoxide

In view of the similarity in structure of the ligands L_1 and L_2 to those reported by Nelson *et al.*,[6] **1** and **2** are expected to interact with CO. Upon introduction of 1 atm of CO to a degassed DMSO solution of **1** or **2**, the solution changed from a red to yellow–brown colour. The spectral changes were found to be only partially reversible. Similar spectral changes have been reported by Nelson *et al.*[6] in a study of the carbonylation reaction of the copper(I) complex of the Schiff-base ligands, L^3–L^5. However, further investigation of the carbonylation of **1** and **2** was rendered difficult due to the strong IR absorption of DMSO in the region of interest.

(*Received* 5 *June* 1988; *accepted after revision* 18 *January* 1989)

Abstract—Nickel(II) complexes of the general formula $NiL_2 \cdot nH_2O$ have been prepared with various N-protected amino acids and characterized by thermogravimetric, magnetic susceptibility, IR and UV spectroscopy. The crystal structure of bis(N-acetylglycinato) tetraaquonickel(II) has been determined. The coordination around nickel is octahedral with two acetylglycine ligands *trans* to each other. Acetylglycine coordinates with nickel through a single oxygen of the carboxylate group, and the remaining four coordination sites are occupied by four water molecules. The structure is held together by strong intermolecular hydrogen bonding. Spectroscopic studies indicate that all complexes are octahedral in structure.

Simple amino acids, having no side chains, coordinate to metal ions through the amino nitrogen and carboxyl oxygen. This results in the formation of five- or six-membered chelate rings with the metal ions in α- and β-amino acids, respectively.[1] If the amino nitrogen is substituted by an acetyl or benzoyl group, the affinity of the amino nitrogen for the metal ion decreases. In such cases, the coordination takes place through the carboxylate group only. The carboxylate group can act as a symmetrical or unsymmetrical bridging bidentate,[2] symmetric or unsymmetric chelating bidentate[2a,3,4] or non-chelating unidentate ligand[5] towards the metal ion. Marcotrigiano and co-workers have prepared nickel (II) complexes with †N-Ac—Gly,[6] N-Bz—Gly,[6] N-Ac—DL-Val,[7] N-Ac—DL-Trp,[8] N-Ac—DL-Ala[9] and N-Ac—DL-Leu[10] and characterized them by magnetic and spectral studies. They have suggested that in the complexes of N-protected amino acids with nickel(II), the coordination occurs through the carboxyl group only. This fact still awaits the confirmation by crystal structure analysis of any of the nickel(II) complexes with N-protected amino acids. The crystal structure of the title compound has been undertaken for this reason. Other related complexes have been synthesized and characterized by electronic, IR and magnetic susceptibility data.

EXPERIMENTAL

All chemicals were reagent grade and used as received. The magnetic susceptibilities of powdered samples of metal complexes were measured by Gouy's method. The diamagnetic corrections for ligands and the metal ions were applied by using appropriate Pascal's constants. The IR spectra were recorded on a SP3-300, Pye Unicam spectrophotometer. The reflectance spectra were recorded in the range 300–1000 nm using magnesium oxide as the standard reflector. The electronic spectra of the solutions of the complexes in methanol were

* Author to whom correspondence should be addressed.
† Expansion of abbreviations given in Table 1.

recorded in the range 300–1500 nm using a VSU2-P Carl Zeiss spectrophotometer.

Freshly prepared nickel hydroxide (approximately 0.0012 mol) was added to hot solutions of N-acetyl amino acids (0.002 mol) dissolved in 25 cm^3 of water. The reaction mixture was heated on a water bath for about 1 h and unreacted nickel hydroxide was removed by filtration. The resulting light green coloured solutions were concentrated to a semi-solid state. The semi-solid residues were kept in a sulphuric acid dessicator for a few days and allowed to solidify. The complexes were powdered and dried *in vacuo* at room temperature. In the case of N-benzoylamino acids a 1 : 3 water–ethanol mixture was used as solvent.

The crystals of $Ni(Ac\text{–}Gly)_2(H_2O)_4$ were obtained by the liquid diffusion method, by layering acetone on top of the water solution of the complex. Small, green coloured, prismatic crystals with well-defined faces were obtained after 24 h.

Crystal data

$C_8H_{20}N_2O_{10}Ni$, $M = 362.96$, monoclinic space group $P2_1/a$, $a = 14.460(2)$, $b = 10.776(4)$, $c = 4.809(5)$ Å, $\beta = 96.95(3)°$, $D_{calc} = 1.625$ g cm^{-3} for $Z = 2$, $D_{meas} = 1.602$ g cm^{-3}, $\mu(Cu\text{-}K_\alpha) = 23.41$ cm^{-1}.

Data were collected by the multiple exposure, multiple film equi-inclination method. A total of 912 reflections were collected by visual methods using integrated Weissenberg photographs. Data were corrected for Lorentz and polarization effects, but not for absorption. The structure was solved by the heavy-atom method and positions of all the non-hydrogen atoms were determined by subsequent Fourier Maps.* Hydrogen atoms were calculated on geometric considerations. Full-matrix least-squares refinements converged to final $R = 0.11$ and $R_w = 0.11$. All the atoms were refined anisotropically and unit weights were used as they gave the best convergence. Hydrogens of the water molecules could not be located from the difference Fourier synthesis. Therefore, the hydrogen bonds were derived from the short intermolecular contacts between the atoms. The high R value is due to the fact that intensity data were measured from photographs and absorption corrections were not applied.

* Programs for structure determination and refinement were written by Dr G. M. Sheldrick. The program for molecular structure interpretation was written by Dr M. Nardelli of Universita di Parma.

RESULTS AND DISCUSSION

Eighteen complexes of nickel(II) with N-protected amino acids have been prepared. Their analytical data are given in Table 1. All of these complexes possess the 1 : 2 metal–ligand stoichiometry. The analytical data corresponds to the general formula $NiL_2 \cdot nH_2O$, where n ranges from 2 to 5. The protecting groups on N(amino) are simple groups (Ac, Bz and Form) and highly electron-withdrawing groups (MCA, TCA and TFA). All complexes are non-electrolytes as expected.

Description of the structure

The coordination around nickel is octahedral with two N-Ac—Gly ligands *trans* to each other. N-Ac—Gly coordinates to the metal ion only through one carboxyl oxygen. The second carboxyl oxygen does not take part in the coordination and remains free. The remaining four positions around the metal ion are occupied by four water molecules. Figure 1 shows the perspective view of the structure and its labelling scheme. Bond lengths and bond angles are given in Table 2. Non-chelating monodentate coordination through the carboxyl group has been found for the first time in the case of nickel(II). A similar type of structure[11] has been found in the case of $[Fe(Gly)_2(H_2O)_4]^{2+}$. The Ni—O(2), Ni—O(10) and Ni—O(11) bond lengths agree well with the bond lengths found in other octahedral complexes of nickel(II) with amino acid ligands.[12–14] Mean Ni—O(carboxyl) and Ni—O(water) bond lengths are 2.13(1) and 2.12(5) Å, respectively, as given by Freeman[15] in the amino acid complexes of nickel(II).

17	$Ni(Form—Val)_2 \cdot 2H_2O$	37.8 (37.6)	6.4 (6.3)	7.5 (7.3)	15.8 (15.3)
18	$Ni(Form—Leu)_2 \cdot 2H_2O$	40.3 (40.9)	6.3 (6.8)	7.3 (6.8)	14.6 (14.3)

[a] Calculated values are given in parentheses.

[b] AC = acetyl, Bz = benzoyl, Form = formyl, MCA = monochloroacetyl, TCA = trichloroactyl, TFA = trifluoroacetyl, Gly = glycine, Phe = phenylalanine, Leu = leucine, Ala = alanine, Val = valine, Trp = tryptophan.

The dimensions of the N-Ac–Gly residue are not significantly different from those found in the refined crystal structure of N-Ac–Gly,[16] except in the case of the carboxyl group. The C(3)—O(4) bond distance 1.27(2) Å is slightly longer than a normal C=O double bond distance. It may be due to the strong hydrogen bonding in the complex involving O(4). The C(7)—O(9) bond is lengthened and the C(7)—N(6) bond is shortened from their normal values, showing a considerable amount of resonance in the amide group.[17] The atoms O(2)—C(3)—O(4)—C(5) lie in an approximate plane with C(3) deviating from the plane by 0.03 Å. The group of atoms C(5)—N(6)—C(7)—C(8)—O(9) does not deviate significantly from planarity. The deviations of the individual atoms from the respective planes are given in Table 3. The dihedral angle between the two planes is 85.0° compared to 5.2° in (Ac—Gly), 6.6° in* $Cu(Ac—Gly)_2(phen)$,[3b] 79.3° in $Cu(Ac—Gly)_2(H_2O)_4$[3a] and 76.3 and 22.8° in $[Cu(Ac–Gly)_2(H_2O)]_2$. It shows that in the nickel(II)

* phen = 1,10-phenathroline.

O(4)—C(3)—C(5)—N(6)	3.6(7)	−18(2)
C(3)—C(5)—N(6)—C(7)	−178.4(5)	−77(1)
C(5)—N(6)—C(7)—C(8)	−178.1(5)	−177(1)
C(5)—N(6)—C(7)—O(9)	1.0(8)	1(2)

complex there is a greater twist around the C(3)—C(5) bond than in the copper(II) complexes.

Table 4 gives the calculated torsion angles for the structures of Ac—Gly and the present complex. All the torsion angles are almost the same except for C(3)—C(5)—N(6)—C(7). In Ac—Gly, N(6)—C(7) is nearly anti to the C(3)—C(5) bond. But in the complex, this angle has reduced by about 100°, showing that during complexation there is a rotation along C(5)—N(6) bond. Therefore the free ligand is in a somewhat expanded form, while during complexation it acquires a folded form.

There is an extensive network of hydrogen bonds involving free carboxyl oxygen O(4), peptide oxygen O(9), peptide nitrogen N(6) and oxygens of both the water molecules O(10) and O(11). The types of hydrogen bonds and their distances are given in Table 5. The main packing interaction is the hydrogen bond $O(4)\cdots H(6)—N(6)^{I}$ of length 2.97(1) Å and $O(4)\cdots H(6)—N(6)^{I} = 151(1)°$ ($I = -x, -y+1, -z$). The O(4) atom is also hydrogen bonded to the water molecules.

Spectroscopic and magnetic studies

The band positions in the electronic absorption spectra of the complexes are given in Table 6. Three

Table 5. Hydrogen bonding distances (Å)

$O(4)\cdots N(6)^{I}$	2.97(1)	$O(9)\cdots O(10)^{III}$	2.65(1)
$O(4)\cdots O(10)^{II}$	2.65(1)	$O(10)\cdots O(11)^{II}$	2.98(1)

[a] Triplet–singlet transition.
[b] Not sufficiently soluble.

main absorption bands have been observed. The molar extinction coefficients of these bands lie in the ranges 2.9–5.9, 2.9–5.9 and 7.3–16.2 $dm^3\ mol^{-1}\ cm^{-1}$, respectively. These values support that the complexes have a NiO_6 chromophore.[18] The Dq values of all the complexes fall into the range 800–900 cm^{-1}, which are close to the values found for the NiO_6 chromophore. This indicates that the ligand field strength of N-acyl amino acids are almost equal to that of water ($Dq = 850\ cm^{-1}$). By comparing the Dq values of N-acyl derivatives, the following spectrochemical series can be proposed:

(1) TFA—Gly > Bz—Gly > MCA—Gly = Ac—Gly

(2) TCA—Ala > TFA—Ala > Bz—Ala > MCA—Ala

(3) MCA—Phe > Form—Phe > Ac—Phe

(4) MCA—Leu > Bz—Leu > Form—Leu

(5) TFA—Val > Bz—Val > Form—Val.

It has been observed that the amino acids having stronger electron-withdrawing groups on the terminal amino group are placed higher in the spectrochemical series. The calculated numerical values of the inter-electric repulsion parameter, B', supports partial covalent bonding.

The magnetic moment values were obtained at room temperature and vary in the range 3.11–3.56 BM. Due to the lack of data at variable temperature, diagnostic conclusions cannot be arrived at.

The IR data indicate that in N-protected amino acids the N—H stretching frequencies in these complexes do not show coordination of this group with the metal ion. The shift of the amide I band to higher frequencies in the complexes also supports its non-participation in coordination. The analysis of ν(COO) frequencies indicates that in all compounds, except bis(acetylglycinato)tetraaquonickel(II), the carboxylate group acts as a bidentate group.

COMPLEXING PROPERTIES OF SQUARIC ACID WITH IRON IN BUTAN-2-OL

L. A. HALL

Department of Chemistry, The University of the West Indies, St. Augustine, Trinidad, West Indies

(*Received* 11 *August* 1988; *accepted after revision* 18 *January* 1989)

Abstract—The distorted octahedral iron(II) squarate, $[Fe(HC_4O_4)(OH)]_2 \cdot C_4H_9OH$, has been synthesized by reacting solutions of $FeCl_2 \cdot 4H_2O$ and squaric acid in butan-2-ol under anaerobic conditions. The characterization of the complex was achieved by elemental and spectroscopic analyses.

The iron(II) squarates prepared from ethanol and propan-2-ol are five-coordinate.[1,2] However, the complex prepared from butan-2-ol apparently has a layered structure with butan-2-ol molecules loosely held between the layers, such that the iron shows distorted octahedral coordination. So far, this is the only first row transition metal squarate prepared in an alcoholic medium and under anaerobic conditions that is six-coordinate.[1-4]

EXPERIMENTAL

The squaric acid was obtained from Sigma Chemical Company. The butan-2-ol, obtained from BDH (Poole, U.K.), was dried with anhydrous calcium sulphate and distilled prior to use.

Approximately 0.52 g (2.6 mmol) of $FeCl_2 \cdot 4H_2O$ was dissolved in 200 cm^3 of hot deaerated butan-2-ol. A hot deaerated solution (150 cm^3) containing 0.30 g (2.6 mmol) of squaric acid was then added to the iron(II) chloride solution and the mixture allowed to cool in an inert atmosphere. The yellow complex was collected as described elsewhere,[1] except that after the initial evacuation of the drying pistol, the vacuum pump was disconnected from the system. Continuous evacuation resulted in the decomposition of the complex. Yield: 0.21 g (35%). Found: C, 32.6; H, 4.6; Fe, 24.9. Calc. for $C_{12}H_{14}O_{11}Fe_2$: C, 32.3; H, 3.1; Fe, 25.0%.

The IR spectrum between 4000 and 600 cm^{-1} was recorded on a Pye Unicam SP 3-200 spectrophotometer using Nujol as the mulling agent. The spectrum between 600 and 300 cm^{-1} was recorded on a Perkin–Elmer 983 spectrophotometer using a Nujol mull and AgBr as window material. The reflectance spectrum was carried out on a Perkin–Elmer spectrophotometer equipped with a reflectance attachment. The room temperature magnetic moment was determined by the Gouy method using a Newport magnetic balance and $Hg[Co(SCN)_4]$ as standard.

The carbon, hydrogen analyses were carried out by Huffman Laboratories, Colorado, U.S.A., and the iron determination by atomic absorption spectrophotometry using a Pye Unicam SP 9 spectrophotometer.

The Mössbauer spectra were obtained under similar conditions to those described elsewhere.[5]

RESULTS AND DISCUSSION

The O—H stretch in the IR spectrum of the complex, occurs at 3330 cm^{-1} (Table 1). No C=O absorption is observed and this has been attributed to the extent of electron delocalization on the squarate rings. This delocalization is also responsible for the absence of the carbonyl absorption in the IR spectra of the potassium salt of squaric acid[6] and a number of iron(II) squarates synthesized by Wrobleski and Brown.[7] The absorptions at 1500 and 710 cm^{-1} are characteristic squarate absorptions.[8] The bands between 900 and 1150 cm^{-1} have been assigned to the vibrations of the butan-2-ol molecules coordinated to the iron atoms in the complex.[9] The absorption at 1100 cm^{-1} is assumed to be due to the bending O—H vibration in the hydroxyl bridge.[10] The Fe—O bands occur between 400 and 600 cm^{-1}.[10,11] Four of the five peaks attri-

1100 m	O—H bending
720 m	C—O deformation due to squarate
590 m, 550–580 m, 500–530 m, 450–470 m, 417–440 m	Fe—O stretching

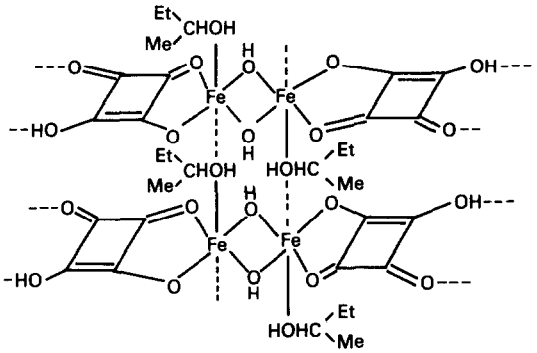
[a] s = strong, w = weak, vw = very weak, m = medium.

buted to the Fe—O vibrations are split. The split peaks occur at 417–440 cm^{-1}, 450–470 cm^{-1}, 500–530 cm^{-1} and 550–580 cm^{-1}, while the unsplit peak appears at 590 cm^{-1}. The number of Fe—O bands and the splitting observed, may be due to differences in Fe—O bond distances and the existence of both symmetric and asymmetric stretching Fe—O modes.[11]

The Mössbauer spectra of the complex at 78 and 293 K show chemical shifts of 1.35(1) and 1.23(1) mm s^{-1}, respectively, with corresponding quadrupolar splittings of 2.82(1) (78 K) and 2.22(1) mm s^{-1} (293 K). These chemical shifts and the quadrupole splitting temperature dependence are typical of high spin iron(II) in a tetragonally distorted octahedral environment[12,13] (Figs 1 and 2). The Mössbauer spectra show that the complex has a high recoil-free fraction. This is interpreted to be indicative of the complex being polymeric.

The electronic spectrum of the complex shows a sharp absorption at 10,000 cm^{-1}, a broad band at 6550 cm^{-1}, and two small peaks at 4650 and 4350 cm^{-1}. These absorptions are consistent with high-spin iron(II) in ligand fields of less than O_h symmetry.[14]

Elemental analysis of the complex allows for only one butan-2-ol molecule per iron(II) squarate dimer. Therefore, in order to accommodate a distorted octahedral environment around the iron atoms, a layer structure, in which pairs of dimers share butan-2-ol molecules, is proposed (see Structure 1).



Structure 1.

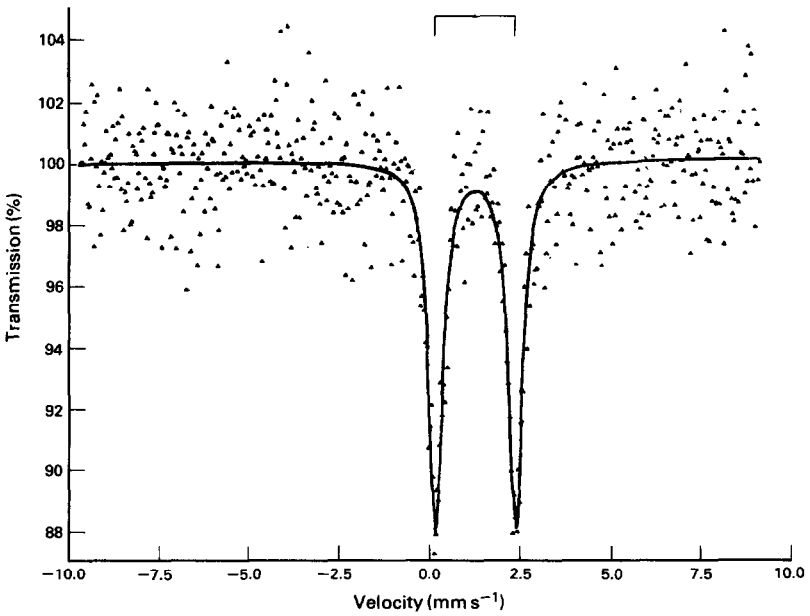


Fig. 1. Mössbauer spectrum of $[Fe(HC_4O_4)(OH)]_2 \cdot C_4H_9OH$ at 293 K.

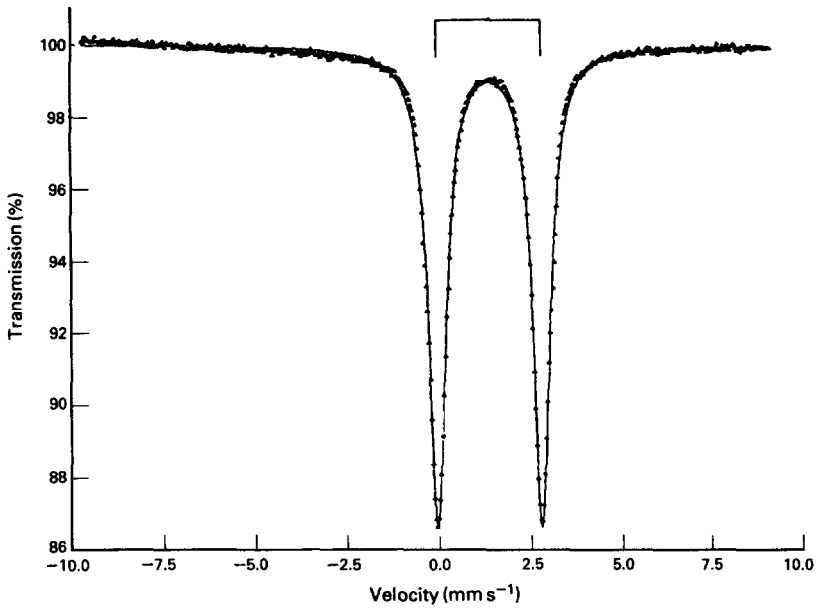

Fig. 2. Mössbauer spectrum of $[Fe(HC_4O_4)(OH)]_2 \cdot C_4H_9OH$ at 78 K.

In such a structure, layers of iron(II) squarate dimers, hydrogen-bonded together, are stacked on each other with butan-2-ol molecules being loosely held between the layers and shared by iron atoms, in accordance with the apparent polymeric nature of the complex suggested by the analysis of the Mössbauer spectra. Drying the complex *in vacuo* at room temperature for more than about 5 min, results in its decomposition which is accompanied by oxidation. This is most likely because the alcohol molecules, being only loosely held between the layers, are easily removed by vacuum drying at room temperature leaving the iron atoms in an unstable square-planar environment. Square-planar iron(II) normally requires macromolecular ligands to achieve stability.[15] Thus, after the removal of the alcohol molecules, the structure collapses and the decomposition/oxidation of the complex occurs. If the complex is simply exposed to the atmosphere at room temperature, decomposition occurs very slowly.

It is possible that the increase in size of the butan-2-ol molecule, compared to the ethanol and propan-2-ol molecules, forces the complex to adopt this structure instead of the five-coordinate ones proposed for the complexes prepared from ethanol and propan-2-ol.

The room temperature magnetic moment (298 K) of the complex is 4.72 BM, which is consistent with high spin octahedral iron(II).

The complex, like other squarates, is insoluble in most common solvents[7] and therefore, recrystallization was not possible. The poor quality of the hydrogen analysis has been attributed to this and solvent contamination which has been observed in other squarates.[1,3,16] A layered structure, like the one proposed for the complex, would be susceptible to solvent contamination between layers.

Acknowledgements—I wish to thank Mr A. Kuperman and Dr W. Tinto for their help in obtaining the reflectance spectrum, and Dr J. Silver for his assistance in obtaining the Mössbauer spectra.

PREPARATION AND CHARACTERIZATION OF NEW TERDENTATE AMINODIPHOSPHINES AND CORRESPONDING VANADIUM(III) DIALKYLAMIDES

A. A. DANOPOULOS and P. G. EDWARDS*

School of Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 12 *October* 1988; *accepted* 18 *January* 1989)

Abstract—The new amines, $HN(CH_2CH_2PR_2)_2$ (R = Me, Et), have been prepared by the nucleophilic substitution of halide in $HN(CH_2CH_2Cl)_2 \cdot HCl$ or the free amine by the corresponding dialkylphosphido anions. The new amines are readily deprotonated by the action of alkyl lithium reagents. Action of the amido anion, $^-N(CH_2CH_2PMe_2)_2$, on $VCl_3 \cdot 3THF$ leads to the new ternary amide $Cl_2VN(CH_2CH_2PMe_2)_2$, from which a new class of organovanadium amido complexes can be obtained by reaction with alkyl or aryl lithium reagents.

The use of polyphosphine ligands in coordination and organometallic chemistry is not widespread, but is increasing. Interest in polyphosphines as ligands is encouraged by the recent development of rational synthetic methods for some of them[1] and since the wide variability of the chelate bite, denticity and functionalization available enables rational modification of the metal ion environment.[2] Some interesting results from using terdentate amidophosphines have recently appeared[3] and we have reported on the stabilization of vanadium and titanium amides with similar linear amidoamines.[4] Since partial substitution of halide ligands on metal centres is possible with this amine, without the common event of redistribution to binary amido complexes[5] that occurs with other amido ligands, we now have potential access to a wide variety of tractable derivatives in oxidation states previously rare or unattainable. In view of this, we are interested in studying similar applications of terdentate amidophosphine ligands, as the tertiary phosphine functions may further aid stabilization of low oxidation states. To this end, we report herein the preparation and characterization of the new amines $(R_2PCH_2CH_2)_2NR'$ (R′ = H, R = Me, Et; R′ = $PhCH_2$, R = Me) and vanadium(III) halide, methyl and phenyl derivatives of the corresponding amide (R = Me). To our knowledge, the only similar ligand system that has been used for the stabilization of transition metal amido complexes, although not for vanadium(III), is the series $(R_2PCH_2Si(Me)_2)_2NH$ (R = alkyl or aryl).[3] There are a number of transition metal amino complexes containing neutral ligands of the type $(Ph_2PCH_2CH_2)_2NR$ (R = H, alkyl).[6]

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

Synthesis of $(Me_2PCH_2CH_2)_2NR$ (R = H, CH_2Ph)

Our preparation of bis(dimethylphosphinoethyl)amine is based on the nucleophilic substitution of chloride in bis-2-chloroethylamine [eq. (1)] by the dimethylphosphido anion in liquid ammonia. This method is similar to the preparation of the phenyl analogue, $(Ph_2PCH_2CH_2)_2NH$, reported by Sacconi[6a] in excellent yields.

$$HN(CH_2CH_2Cl_2)_2 + 2NaPMe_2 \longrightarrow HN(CH_2CH_2PMe_2)_2 + 2NaCl. \quad (1)$$

In contrast, our yields are moderate to low (based on amine). The variability in yield may be due to variations in basicity of the nucleophiles. Thus $^-PMe_2$ is a stronger base than $^-PPh_2$, which results in competitive proton abstraction from the secondary amine [eq. (2)] and subsequent intramolecular reactions.

$$Me_2P^- + HNR_2 \longrightarrow Me_2PH + R_2N^- \quad (2)$$
$$(R = CH_2CH_2Cl).$$

Support for this comes from the following observations:

(1) When the reaction is carried out using $NaPMe_2$ and $PhCH_2N(CH_2CH_2Cl)_2$ instead of $HN(CH_2CH_2Cl)_2$, $PhCH_2N(CH_2CH_2PMe_2)_2$ is obtained in almost quantitative yield (> 92% redistilled product) without detection of any side products (NMR). To date, we have been unable to cleave the benzyl–nitrogen bond under reductive conditions ($Na/NH_3(l)$ or $H_2/HCOOH/Pd/C$).

(2) Addition of the amine hydrochloride to solutions of 3 mole equivalents of $NaPMe_2$ in $NH_3(l)$ enable higher (up to 60%), although more variable, yields of $(Me_2PCH_2CH_2)_2NH$ to be isolated. Variation in yield is likely due to difficulties encountered in the careful control of the solid addition. This becomes more difficult as the scale is increased and yields as low as 25% have been obtained. This method is also wasteful in phosphide, since 1 mole equivalent is required to sacrificially neutralize the hydrochloride salt. It appears that substitution of halide competes favourably with neutralization of the ammonium function in liquid ammonia, such that the hydrochloride acts as a somewhat protected secondary amine. This is highlighted by the total failure of the attempted syntheses of the diethylphosphino and di-isopropylphosphino analogues from the free amine in liquid ammonia or THF. The ethyl homologue may be prepared in variable but low yields from the hydrochloride in THF [eq. (3)]

$$ClH_2N(CH_2CH_2Cl)_2 + 3LiPEt_2 \longrightarrow$$
$$HN(CH_2CH_2PEt_2)_2 + HPEt_2 + 3LiCl, \quad (3)$$

in a manner similar to Whiteside and co-workers' preparation[7] of the phenyl analogue, although they use *t*-butoxide rather than phosphide to neutralize the ammonium function. Again this fails for the isopropyl.

The new phosphines are effectively characterized by ^1H and ^{31}P NMR (Table 1). The spectra display patterns consistent with the assigned structures, thus protons adjacent to nitrogen are shifted from 1 to 2 ppm downfield, relative to those adjacent to phosphorus and $^3J_{P—H} > {}^2J_{P—H}$. The IR spectrum of the secondary amine shows the N—H stretch at 3280 cm^{-1}.

Preparation of $LiN(CH_2CH_2PMe_2)_2$

The lithium amide may be prepared by deprotonation of the amine with alkyl lithium reagents such as MeLi in diethyl ether and Bu"Li in hexane. The latter is more convenient since the solubility of the product is considerably less in aliphatic hydrocarbons than in ethers, and pure microcrystalline material is more readily isolated. The white pyrophoric amide is characterized by the absence of ν(N—H) in the IR and by broadened resonances in the ^1H NMR (C_6D_6). These are of the appropriate

intensity ratios and not significantly shifted from those of the free amine (Table 1). The broadening is presumably due to fluxionality in solution at ambient temperatures.

Vanadium(III) *derivatives*

Routes to the new complexes described below are collected in Scheme 1. All the following compounds are ESR silent in solid, solution or glass (290 and 99 K) and except for **II** below, analytical data are consistent with the proposed formulations. Magnetic susceptibilities (see Experimental) confirm the d^2 paramagnetic state of the vanadium(III) ions.

Interaction of $Cl_3V \cdot 3THF$ with $LiN(CH_2CH_2PMe_2)_2$ in THF, enables the isolation of the purple crystalline $Cl_2VN(CH_2CH_2PMe_2)_2$ (**I**). An identical material may be isolated from $VCl_3(NMe_3)_2$ by a similar procedure. Attempts to obtain crystals suitable for X-ray crystallography have so far been unsuccessful. It is likely, however, that the stereochemistry about vanadium is similar to that in the analogous amine complex $Cl_2VN(CH_2CH_2NEt_2)_2$,[4a] where the three anionic donors occupy the equatorial sites of a distorted trigonal bipyramid, with the neutral donors in the apical positions.

I may be readily converted to organometallic derivatives by the action of organolithium reagents. Thus with methyl lithium, an oil, $Me_2VN(CH_2CH_2PMe_2)_2$ (**II**), may be obtained from petroleum ether. The compound decomposes upon attempted distillation and is very soluble in apolar solvents. More definitive characterization of this material is difficult since we have been unable to obtain reliable microanalytical data, however in light of the magnetic susceptibility, the absence of chloride in the product ($AgNO_3$ using compound **I** as control) and the similarity of this system with the analogous $Me_2VN(CH_2CH_2NEt_2)_2$,[4b] we believe there is little doubt as to the nature of **II**. We are presently investigating reactions of **II**, as well as other compounds reported herein, in order to shed more light on this and other chemical properties.

With aryl lithium reagents, **I** provides the similar diarylvanadium amides $Ar_2VN(CH_2CH_2PMe_2)_2$ [Ar = Ph (**III**), 2-CH_3-C_6H_4 (**IV**)]. **III** and **IV** are both readily prepared from **I** in THF, and both may be obtained as emerald green crystals in good yield from petroleum ether. Attempts to obtain X-ray crystallographic data have so far failed. The compounds are very air-sensitive, especially in solution, becoming brown and eventually yellowish, presumably due to oxidation to vanadium(V) species. As well as by analytical data, **III** and **IV** are additionally identified by IR spectra that show characteristic aryl absorbancies (ν(C⋯C) at 1558 cm^{-1} for **III** and 1568 cm^{-1} for **IV**).

EXPERIMENTAL

Materials and methods

The following materials were either purchased from Aldrich [$(ClCH_2CH_2)_2NH_2Cl$, $PSCl_3$, Bu^nLi in hexane] or prepared following literature methods (Me_2PPMe_2,[8] $HPEt_2$,[9] $VCl_3 \cdot 3THF$,[10] $VCl_3 \cdot 2NMe_3$[11] and $PhCH_2N(CH_2CH_2Cl)_2 \cdot HCl$[6c]). PBu^n_3 was dried over and distilled from CaH_2 under nitrogen prior to use. Ammonia was condensed onto and distilled from sodium directly into the reaction vessel. Solvents were dried over the appropriate drying agents and distilled under nitrogen immediately prior to use.

Manipulations of all the new compounds reported here, were performed using standard Schlenk-line or dry-box techniques under purified nitrogen atmospheres or *in vacuo*. The quality of the nitrogen used has a significant bearing on the success of the preparation of the metal complexes described herein. Instruments used were: IR, Perkin–Elmer 783; NMR, Bruker WM 360 (^{1}H, 360 MHz; ^{31}P, 145 MHz); magnetic susceptibility, Johnson Matthey magnetic susceptibility balance. Analyses were carried out by Butterworth Laboratories Ltd, Teddington, U.K.

(1) *Preparation of* $PhCH_2N(CH_2CH_2PMe_2)_2$

$PhCH_2N(CH_2CH_2Cl)_2$ was liberated from the hydrochloride (8.6 g, 0.0032 M) by addition of diethyl ether (50 cm^3), followed by aqueous NaOH (2.5 g, 0.046 M, as a 10% w/w solution) and the organic phase dried over $MgSO_4$. This solution was deoxygenated and added dropwise to a solution of $NaPMe_2$ (from Me_2PPMe_2, 3.9 g, 0.032 M and Na, 1.47 g, 0.064 M) in ammonia (100 cm^3) at −60°C, until the orange colour had faded to pale yellow. Care was taken not to over-run the endpoint. The ammonia was allowed to warm and then evaporate. Diethyl ether (100 cm^3) was added to the white residue, followed by deoxygenated water (50 cm^3). The aqueous phase was separated and washed with diethyl ether (3 × 50 cm^3). The combined organic phase was distilled at atmospheric pressure to remove solvent, followed by low pressure. The fraction boiling at 120°C/0.05 mm was collected and was found to be pure by ^{1}H NMR. Yield: 8.5 g, 95% based on $PhCH_2N(CH_2CH_2Cl)_2 \cdot HCl$. IR (neat): 3080 w, 3055 w, 3020 m, 2945 s, 2880 s, 2800 s br, 1650 m, 1600 w, 1490 m, 1449 s, 1414 s br, 1360 m, 1289 m, 1105 m br, 1090 m, 1028 m, 990 m, 933 s, 881 m, 812 w, 727 s, 694 s, 662 w, 610 w, 465 w.

(2) *Preparation of* (a) $(Me_2PCH_2CH_2)_2NH$ *and* (b) $(Et_2PCH_2CH_2)_2NH$

The most reproducible results (best average yields based on phosphorus) were obtained by the following methods.

(a) To a solution of sodium (8.8 g, 0.38 M) in ammonia (500 cm^3) held at −78°C, was added dropwise with efficient mechanical stirring, Me_2PPMe_2 (22 g, 0.18 M) over 15 min. The resultant green solution was stirred for 1 h at −78°C. A solution of $HN(CH_2CH_2Cl)_2$ was prepared in the following way. To a suspension of $ClH_2N(CH_2CH_2Cl)_2$ (32.1 g, 0.18 M) in diethyl ether (100 cm^3), was added dropwise with cooling (0°C), an aqueous solution of NaOH (18 g in 100 cm^3, 2.5-fold mole excess). The two phases were separated, the aqueous phase was washed with ether (3 × 50 cm^3) and the combined ether phase dried over $MgSO_4$. Since the free amine slowly quaternizes in solution, the drying process was limited to approximately 2 h. The efficiency of this drying becomes critical since traces of moisture will destroy $NaPMe_2$ and deplete the resultant yield of the next step. We suggest using generous portions of $MgSO_4$ and stirring or shaking this mixture. The dried filtered solution of $HN(CH_2CH_2Cl)_2$ was degassed by boiling under reduced pressure and was then added dropwise to the ammonia solution of $^-PMe_2$. Addition of amine was stopped when the colour of the ammonia solution became pale yellow. The quantity of amine added was normally less than that expected on a stoichiometric basis. Addition of excess amine seriously depletes the yield. Following this addition, the mixture was allowed to warm to −33°C over 1 h. The ammonia was then allowed to evaporate, ether (200 cm^3) was added and the white slurry hydrolysed by careful addition of deoxygenated water (100 cm^3). The two phases were separated, the aqueous phase washed with ether (3 × 50 cm^3) and the combined organic phase dried over $MgSO_4$. Filtration followed by atmospheric pressure distillation, through a 20 cm Vigreux column, left a high boiling residue that was fractionated at reduced pressure. The fraction boiling at 60–65°C/0.01 mm Hg consists mainly of $(Me_2PCH_2CH_2)_2NH$ and was redistilled providing a fraction boiling at 63–65°C/0.01 mm Hg of pure (NMR) phosphine. Yield: 12.2 g, 35% based on Me_2PPMe_2. IR (neat): 3280 m br, 2955 s, 2920 s, 2895 s, 2815 s, 1630 w br, 1455 m br, 1425 s br, 1360 w, 1332 m, 1291 m, 1277 m, 1118 s, 992 m, 939 s, 889 m, 860 w, 814 w, 785 w, 708 s, 687 m, 676 m.

(b) A solution of Et_2PLi (prepared from Et_2PH and PhLi, 25.4 g, 0.26 M) in THF (300 cm^3) held at −40°C, was treated with small portions of $ClH_2N(CH_2CH_2Cl)_2$ (15.7 g, 0.088 M in total) over 2 h with vigorous stirring. The mixture was allowed to warm to room temperature and was stirred (24 h). After hydrolysis with deoxygenated water (100 cm^3), the two phases were separated and the aqueous phase washed with ether (3 × 50 cm^3). After drying ($MgSO_4$), the combined organic phase was distilled at atmospheric pressure through a 20 cm Vigreux column to remove solvents and the residue was vacuum distilled. The fraction boiling at 100–104°C/0.04 mm Hg was collected. Yield: 4.4 g, 20% based on amine hydrochloride. IR (neat): 3275 m, 2910 s br, 2810 s, 2730 w, 1605 w br, 1455 s, 1415 s, 1375 s, 1330 m, 1290 w, 1275 w, 1230 m br, 1175

w, 1115 s, 1038 s, 755 s br, 690 m, 669 s, 630 w, 613 w.

(3) *Preparation of* $LiN(CH_2CH_2PR_2)_2$

(a) (R = Me). To a solution of $HN(CH_2CH_2PMe_2)_2$ (4.6 g, 0.024 M) in petroleum ether (90 cm^3) cooled to −78°C, was added a solution of Bu^nLi (9 cm^3, 2.5 M in hexane, 5% molar excess) dropwise with stirring. Upon warming to ambient temperature, a white precipitate of the lithium amide appeared. Recooling (−78°C), followed by filtration and washing the precipitate with cold (−78°C) petrol, enables the isolation of a white microcrystalline material after drying *in vacuo*. Yield: 4.18 g, 88% based on $HN(CH_2CH_2PMe_2)_2$. This material may be recrystallized from toluene to give large colourless prisms, although the microcrystalline material is pure enough for the applications described below. The material is very air-sensitive in both the solid and in solution, as are the derivatives below. IR (Nujol): 1292 m, 1277 m, 1156 m, 1125 w, 1097 m, 1070 m, 942 s, 926 m, 916 m, 882 w, 871 w, 842 w, 809 w, 719 s, 708 m, 693 m, 656 w, 628 w, 610 w, 423 w, 370 m br, 318 w br.

(b) (R = Et). The ethyl derivative may be prepared in a manner similar to that described in (a) above, except that after warming to room temperature, the amide was obtained as an oil after removal of solvent *in vacuo*. Yield: 85% based on $HN(CH_2CH_2PEt_2)_2$.

(4) *Preparation of* $Cl_2VN(CH_2CH_2PMe_2)_2$ (I)

(a) To a solution of $VCl_3 \cdot 3THF$ (2.5 g, 6.7 mmol) in THF (70 cm^3), cooled to −78°C, was added with vigorous stirring, a solution of $LiN(CH_2CH_2PMe_2)_2$ (64 cm^3, 0.015 M in toluene) over 15 min. The colour of the solution changed from light orange to deep red–brown. The solution was allowed to warm to ambient temperature when it was stirred for a further 1 h. The volatile materials were removed *in vacuo* and the brown residue extracted into toluene (50 cm^3). The deep red solution was filtered through celite and the filtrate concentrated (to approximately 10 cm^3). Cooling slowly (to −20°C) gave purple needles that were isolated, washed with petrol and dried *in vacuo*. Yield 1.1 g, 48% based on $VCl_3 \cdot 3THF$. The compound is soluble in aromatic hydrocarbons and ethers, and sparingly soluble in aliphatic hydrocarbons.

(b) **I** may alternatively be prepared from $VCl_3 \cdot 2NMe_3$ using a procedure identical to that described in (a) above except for the substitution of $VCl_3 \cdot 3THF$ for the same molar quantity of $VCl_3(NMe_3)_2$. Found (Calc.): C, 31.6 (30.6); H, 6.0 (6.4); N, 4.2 (4.5%). $\mu_{eff} = 2.61$ BM. IR (Nujol): 1278 w, 1180 w, 1075 m, 1055 m, 979 m, 953 s, 927 m, 909 m, 868 w, 839 w, 738 m, 720 m, 663 w, 644 m, 393 m, 328 m, 295 w.

(5) *Preparation of* $(C_6H_5)_2VN(CH_2CH_2PMe_2)_2$ (III)

To a solution of $VCl_3 \cdot 3THF$ (0.27 g, 0.72 mmol) in THF (30 cm^3), was added a solution of $LiN(CH_2CH_2PMe_2)_2$ (9.5 cm^3, 0.076 M in toluene, 0.7 mmol) with stirring at −78°C. The resultant red–brown solution was allowed to warm to ambient temperature and then recooled to −78°C. At this point a solution of C_6H_5Li (1.2 cm^3, 1.25 M in Et_2O, 1.5 mmol) was added dropwise with stirring. The solution was allowed to warm to 0°C and the volatile materials were then removed *in vacuo*. The brown–green residue was extracted into petrol (3×20 cm^3), filtered through celite and concentrated to approximately 5 cm^3. Cooling to −20°C provides bright green plates which were isolated by filtration. Yield: 0.17 g, 60% based on $VCl_3 \cdot 3THF$. The compound is very soluble in hydrocarbons and ethers. Found (Calc.): C, 59.7 (60.5); H, 7.8 (7.5); N, 3.1 (3.5%). $\mu_{eff} = 2.59$ BM. IR (Nujol): 3100 m, 3030 s, 1558 m, 1325 m, 1293 m, 1280 m, 1237 w, 1210 m, 1188 w, 1151 m, 1083 m, 1066 m, 1050 m, 1019 w, 996 m, 975 m, 942 s, 918 m, 857 w, 830 m, 770 w, 739 m, 718 m, 700 s, 519 m, 484 m, 448 m, 345 m, 280 w, 250 w.

(6) *Preparation of* $(2\text{-}CH_3C_6H_4)_2VN(CH_2CH_2PMe_2)_2$ (IV)

The preparation of **IV** is identical to that of **III**, except for the substitution of C_6H_5Li with the equivalent molar quantity of $2\text{-}MeC_6H_4Li$. The product is obtained as green plates from petrol as for **III** and has similar properties to **III**. Yield: 58%. Found (Calc.): C, 62.7 (62.1); H, 8.2 (8.0); N, 3.4 (3.3%). IR (Nujol): 3050 m, 1592 w, 1568 m, 1323 m, 1294 m, 1280 m, 1260 m, 1244 m, 1212 m, 1189 w, 1164 w, 1090 s, 1078 s, 1031 s, 998 m, 979 m, 944 s, 920 m, 861 w, 799 m br, 747 s, 736 s, 720 m, 660 m, 541 m, 519 w, 484 m, 432 m, 399 m, 320 w, 288 w.

(7) *Preparation of* $Me_2VN(CH_2CH_2PMe_2)_2$ (II)

II may be prepared by a similar procedure to that described for **III** above, with $VCl_3 \cdot 3THF$ (0.5 g, 1.34 mmol) in THF (50 cm^3), and a solution of lithium amide in toluene (17.6 cm^3, 1.34 mmol) followed by a solution of MeLi in Et_2O (2.5 cm^3, 2.68 mmol). The product can be obtained as a

green–brown oil by evaporation of the filtered hexane extract. Attempts to distil and crystallize this oil have failed. $\mu_{eff} = 2.55$ BM.

CHIRAL HETEROCYCLIC LIGANDS—VI.* (4*S*,7*R*)-7,8,8-TRIMETHYL-4,5,6,7-TETRAHYDRO-4,7-METHANO-1H(2H)-INDAZOLE AND X-RAY STRUCTURE OF A COPPER(II) COMPLEX

ANDREW A. WATSON, DONALD A. HOUSE and PETER J. STEEL†

Chemistry Department, University of Canterbury, Christchurch, New Zealand

(*Received* 17 *October* 1988; *accepted* 19 *January* 1989)

Abstract—Dichlorobis[(4*S*,7*R*)-7,8,8-trimethyl-4,5,6,7-tetrahydro-4,7-methano-2H-indazole]copper(II), $C_{22}H_{32}Cl_2N_4Cu$, crystallizes in the monoclinic space group $C2$ with $a = 23.110(5)$, $b = 7.533(1)$, $c = 7.041(1)$ Å, $\beta = 105.25(2)°$ and $Z = 2$. The structure was refined to $R = 2.9\%$. The copper atom lies on a crystallographic two-fold rotation axis and has coordination geometry intermediate between tetrahedral and square-planar. A system of bifurcated (intra- and intermolecular) N—H···Cl hydrogen bonds connects the molecules in chains. The crystal structure and NMR studies of a palladium(II) complex show that the title ligand complexes through the more sterically hindered N(1) nitrogen. It is proposed that for unsymmetrical pyrazoles, the relative stabilities of the tautomers of the ligand is an important factor in determining the choice of the site of coordination to metal ions.

The coordination chemistry of pyrazoles and of pyrazole-derived ligands has expanded rapidly over the last decade and has been the subject of a recent review.[1] Simple neutral pyrazoles readily coordinate through the unsubstituted (pyridine-like) nitrogen to form complexes (**1**) with various transition metals, while the pyrazolide anion can act as a 1,2-exobidentate ligand (**2**), which bridges two metals or metalloids.[1] Numerous multidentate ligands which contain pyrazole groups have also been synthesized and their coordination chemistry studied.[1,2] Of these, the polypyrazolylmethanes and polypyrazolylborates are the most well studied.[3]

The most commonly used pyrazoles are the commercially available ligands, pyrazole (**3**), 3,5-dimethylpyrazole (**4**) and the unsymmetrical 3(5)-methylpyrazole (**5**), which exists in solution as two tautomers (**5a**, **5b**).[4] Also well studied is the readily available unsymmetrical ligand indazole (**6**) which exists in solution as the 1-H tautomer (**6a**).[4] It is generally accepted[1] that the unsymmetrical ligands **5** and **6** coordinate to metal ions through the less sterically hindered nitrogen. Thus, **5** coordinates as the 5-methyl tautomer (**5b**), and **6** as the 1-H tautomer (**6a**), as has been confirmed by X-ray crystal structure determinations of metal complexes.[5–8]

Despite extensive research into the coordination chemistry of pyrazoles and the importance of chiral ligands in asymmetric catalysis, the coordination chemistry of non-racemic chiral pyrazoles is completely unexplored. We have previously reported[9–13] the synthesis and study of diverse multidentate ligands derived from the chiral ligand (**7**), which is readily available[14,15] in optically pure form from (+)-camphor, a common source of chirality in numerous important chiral auxiliaries.[16,17] We herein describe the first transition metal complexes of **7**. NMR studies of a palladium(II) complex and the X-ray crystal structure of a copper(II) complex reveal the surprising result that **7** coordinates through the more hindered [N(1)] nitrogen, that is as the 2-H tautomer (**7b**).

RESULTS AND DISCUSSION

The ligand **7** was prepared by formylation of camphor and subsequent condensation with hydra-

(7)

zine, as previously reported.[14] Comparison of the ^1H and ^{13}C NMR spectra of **7** with the spectra of substituted derivatives,[10–13] indicates that in solution, **7** exists preferentially as the 2-H tautomer (**7b**). Particularly diagnostic in this respect are the chemical shifts for C(3) and the quaternary carbons C(3a) and C(7a), which are sensitive to the position of N-substitution in tetrahydroindazoles.[18,19] The greater stability of **7b** relative to **7a**, parallels the tautomerisms of other tetrahydroindazoles and the carbocyclic analogue isodicyclopentadiene.[20]

Reaction of **7** with MCl_2 (M = Pd, Cu) led to the isolation of complexes of stoichiometry $M(7)_2Cl_2$. The N—H IR stretching frequencies suggested the existence of N—H···Cl hydrogen bonds in both complexes, as have been observed in related pyrazole complexes of copper(II)[21] and palladium(II).[22] The Pd—Cl stretch at 350 cm^{-1} suggests *trans* coordination at the square-planar palladium as was observed[11] in a related complex of a substituted derivative of **7**. Because of the non-equivalence of the two nitrogens in **7**, two modes of coordination are possible corresponding to whether the ligand complexes as the 1-H tautomer (**7a**) or as the 2-H tautomer (**7b**). By analogy with the accepted tendency for coordination to occur through the less hindered nitrogen,[1] it would be expected that **7** should coordinate through the less hindered N(2) nitrogen, that is as the 1-H tautomer (**7a**). However, this expectation is not supported by the NMR spectra of the palladium complex. In particular, the ^{13}C NMR spectrum showed similar chemical shift values to those of the free ligand which, as stated above, exists as the 2-H tautomer (**7b**). Furthermore, the C(7) methyl protons experience a marked downfield shift in the complex (1.94 ppm) relative to the free ligand (1.33 ppm). This can be attributed to deshielding by an adjacent chlorine atom (as observed in related complexes[10]) only if coordination occurs through the N(1) nitrogen, that is as tautomer (**7b**).

In order to unambiguously determine the mode of coordination of **7**, a single crystal X-ray structure determination of the copper complex was undertaken. This structure was also of interest in order to determine the nature (intra- or intermolecular) of the hydrogen bonding in the complex and to determine the coordination geometry at the copper atom. Related CuN_2X_2 complexes exhibit a variety of coordination geometries at the copper atom, commonly involving expansion of the coordination number by association of square-planar monomeric

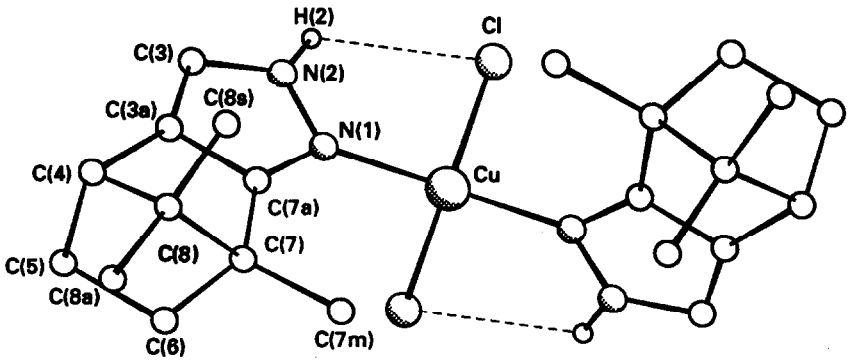

Fig. 1. Perspective view and atom labelling of the crystal structure. C—H hydrogens omitted for clarity.

units through axial interaction to adjacent molecules.[23–27]

Figure 1 shows a perspective view and atom labelling of the complex, which crystallizes in the monoclinic space group $C2$ with the copper atom lying on a crystallographic two-fold rotation axis. Table 1 lists bond lengths and angles for the complex. The geometry at the four-coordinate copper atom is intermediate between tetrahedral and square-planar, with the N(1)—Cu—C(1) mean planes mutually inclined at an angle of 57.0(2)° (cf. tetrahedral, 90°; square-planar, 0°). There is no expansion of the CuN_2Cl_2 core, as has been frequently observed in related structures which have square-planar coordination at the copper and weak axial interactions to atoms in adjacent molecules. The geometry at the copper atom probably results[28] from a combination of steric repulsion between the bulky bornyl groups of the ligand and the constraints imposed by hydrogen bonding. As shown in Fig. 2, H(2) is involved in bifurcated inter- and intramolecular hydrogen bonds, which connect molecules in chains perpendicular to the b axis (N(2)···Cl, 3.174(3) Å; H(2)···Cl, 2.67(2) Å; N(2)—H(2)···Cl, 113(2)°; N(2)···Cl*, 3.256(3) Å; H(2)···Cl*, 2.57(2) Å; N(2)—H(2)···Cl*,

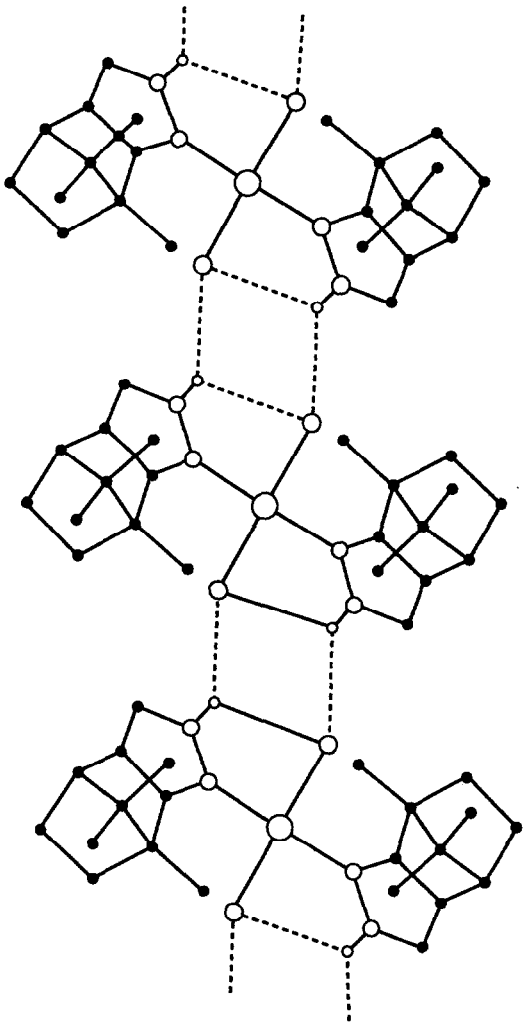

Fig. 2. Molecular packing projected down the *b* axis and showing hydrogen bonds as dashed lines.

128(2)° where Cl* is related to Cl by the transformation $-x, y, 2-z$). Both these forms of hydrogen bonding are common in complexes of pyrazoles.[5,7,29-32] The pyrazole ring is planar (maximum deviation from the mean plane: 0.004(5) Å) and the pyrazole rings are mutually inclined at an angle of 91.8(2)°. The geometry of the bornyl moiety is normal[9,13] and no close intermolecular contacts exist, other than those associated with the hydrogen bonding.

In accord with the conclusions drawn from the NMR studies, the crystal structure determination unambiguously demonstrates that the ligand coordinates through the more hindered N(1) nitrogen and hence as the 2-H tautomer. This is at variance with the generally accepted belief that steric factors control the site of coordination of unsymmetrical pyrazoles. Since we have shown above that the 2-H tautomer (**7b**) is the more stable tautomer, it is possible that this is a controlling factor in determining the mode of coordination of **7**.

For unsymmetrical pyrazoles the relative stabilities of the tautomers depend on a number of factors.[4,33] For **5**, the energy difference between the two tautomers is small,[4,33,34] and although a preference in favour of the 5-methyl tautomer was observed by low temperature ^{1}H NMR spectroscopy[35] and solid state ^{13}C NMR,[36] the fact that this ligand coordinates as the 5-methyl tautomer (**5b**) is probably indeed controlled by steric factors. A similar argument applies to **8**,[36,37] which has been reported to coordinate to gold(I) in both tautomeric forms[38] and to copper(II) as **8a**.[32] Highly significant however, is the report[8] of an X-ray structure of a platinum(II) complex of **9** in which coordination occurs as the 5-methyl tautomer (**9b**), which is expected to be the more stable tautomer.[33] Steric arguments would predict that coordination should occur as the 3-methyl tautomer (**9a**). Indazole (**6**) is well known[4,39] to exist as the 1-H tautomer (**6a**) and hence its preference for N(2) coordination may reflect the greater stability of **6a** rather than to be due to steric factors. Recent calculations[40] on tetrahydroindazoles (**10**) suggest a slight preference for the 2-H tautomer (**10b**). Introduction of the 4,7-methano bridge present in **7** should further stabilize the 2-H tautomer (**7b**), as the NMR studies show. These results lead us to propose that for unsymmetrical pyrazoles, the relative stabilities of the tautomers of the ligand is an important factor in determining the choice of the site of coordination to metal ions.[41]

EXPERIMENTAL

Physical methods

IR and UV spectra were recorded with Shimadzu IR27G and Varian DMS100 spectrophotometers, respectively. Optical rotations were recorded with

a JASCO ORD/CD5 spectropolarimeter. ^1H and ^{13}C NMR spectra were recorded with a Varian XL300 spectrometer, operating at 299.930 and 75.426 MHz, respectively, for $CDCl_3$ solutions with Me_4Si as internal standard. Microanalyses were performed by the Chemistry Department, University of Otago.

Syntheses

The ligand **7** was prepared from (+)-camphor as previously described.[14] ^1H NMR: δ 0.66, s, 3H, *syn*-8-CH_3; 0.96, s, 3H, *anti*-8-CH_3; 1.33, s, 3H, 7-CH_3; 2.78, d, 1H, H(4); 7.09, s, 1H, H(3). ^{13}C NMR: δ 10.8, 7-CH_3; 19.2, *anti*-8-CH_3; 20.4, *syn*-8-CH_3; 27.8, C(5); 33.7, C(6); 47.1, C(4); 50.0, C(8); 61.0, C(7); 119.9, C(3); 125.8, C(3a); 166.0, C(7a).

Palladium complex of **7**. A mixture of palladium(II) chloride (0.05 g, 0.29 mmol), dichloromethane (10 cm^3) and **7** (0.10 g, 0.56 mmol) was stirred at room temperature for 5 days. The resulting yellow solution was filtered and concentrated to give a solid which was recrystallized from methanol–dichloromethane to give orange crystals. Yield: 33%. ν_{max} 3200 (NH), 2900, 1460, 1140, 1050, 660, 560, 350 cm^{-1}. λ_{max} ($CHCl_3$) 382 nm ($\varepsilon = 217$ M^{-1} cm^{-1}). λ ($\Delta\varepsilon$) 406 nm (+2.59 M^{-1} cm^{-1}), 380 (0). λ ([M]) 430 nm (+208.3° M^{-1} m^{-1}), 413 (0), 361 (−488), 340 (0). ^1H NMR: δ 0.65, s, 3H, *syn*-8-CH_3; 0.97, s, 3H, *anti*-8-CH_3; 1.94, s, 3H, 7-CH_3; 2.65, d, 1H, H(4); 6.56, s, 1H, H(3). ^{13}C NMR: δ 11.5, 7-CH_3; 19.2, *anti*-8-CH_3; 20.5, *syn*-8-CH_3; 27.9, C(5); 32.4, C(6); 46.8, C(4); 51.8, C(8); 62.0, C(7); 122.0, C(3); 128.3, C(3a); 166.5, C(7a). Found: C, 49.1; H, 6.1; N, 10.5. Calc. for $C_{22}H_{32}Cl_2N_4Pd$: C, 49.9; H, 6.1; N, 10.6%.

Copper complex of **7**. An ethanolic solution of **7** (0.41 g, 2.33 mmol) was added to an ethanolic solution of cupric chloride dihydrate. The resulting yellow crystals were filtered and air-dried. Yield: 60%. M.p. 218–220°C. ν_{max}(KBr) 3375, 2950, 1580, 1430, 1390, 1270, 1160, 1120, 1060, 830, 660, 560, 300 cm^{-1}. λ_{max}($CHCl_3$) 728 nm. Found: C, 53.8; H, 6.8; N, 11.3. Calc. for $C_{22}H_{32}Cl_2N_4Cu \cdot H_2O$: C, 54.3; H, 6.6; N, 11.5%.

Crystallography

Intensity data were collected with a Nicolet R3m four-circle diffractometer using monochromatized Mo-K_α radiation ($\lambda = 0.7107$ Å) and a yellow crystal measuring $0.35 \times 0.16 \times 0.08$ mm. Cell parameters were determined by least-squares refinement, the setting angles of 25 accurately centred reflections ($2\theta > 23°$) being used. Throughout data collection the intensities of three standard reflections were monitored at regular intervals and this indicated no significant crystal decomposition. The intensities were corrected for Lorentz and polarization effects, but no correction for absorption was deemed necessary. Reflections with $I > 3\sigma(I)$ were used for structure solution and refinement.

The structure was solved by conventional Patterson and Fourier methods, and refined by blocked-cascade least-squares procedures. The absolute configuration employed was that consistent with the known[42] absolute configuration of (+)-camphor from which the ligand was synthesized. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions with isotropic thermal parameters equal to the isotropic equivalent of their carrier atoms. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with $w = [\sigma^2(F_o) + 0.00026F_o^2]^{-1}$. All calculations (including diagrams) were performed on a Nova 4X computer using SHELXTL.[43] Final atom coordinates, thermal parameters and structure factors have been deposited with the Editor as supplementary data. Atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Crystal data at −120°C: $C_{22}H_{32}Cl_2N_4Cu$, M_r 487.0, monoclinic, space group $C2$, $a = 23.110(5)$, $b = 7.533(1)$, $c = 7.041(1)$ Å, $\beta = 105.25(2)°$, $V = 1182.5(4)$ Å^3, $F(000)$ 510, D_c ($Z = 2$) 1.37 g cm^{-3}, $\mu = 11.7$ cm^{-1}, θ–2θ scans, $2\theta_{max} = 55°$, $N = 1464$, $N_0 = 1330$, 131 parameters, $S = 1.17$, $R = 0.029$, $R_w = 0.033$.

(*Received* 1 *November* 1988; *accepted* 19 *January* 1989)

Abstract—Treatment of bis(cyclooctadiene)nickel with carbon monoxide and trialkylphosphines in a 2:3:2 ratio provides a high-yield route to the clusters, $Ni_4(\mu\text{-}CO)_6L_4$ ($L = PMe_3$, PBu^n_3). The clusters are cleaved by PPh_3 and I_2, and are oxidized electrochemically in two successive one-electron steps; only the first oxidation step to a monocation is reversible. The molecular structure of $Ni_4(CO)_6(PMe_3)_4$ consists of a regular Ni_4 tetrahedron with edge-bridging CO and terminally coordinating PMe_3 ligands.

Whereas there are numerous carbonyl phosphine clusters of palladium and platinum,[1,2] related nickel clusters are rare, but examples include $Ni_4(CO)_6[P(CH_2CH_2CN)_3]_4$, isolated in low yield by thermolysis of $Ni(CO)_2[P(CH_2CH_2CN)_3]_2$[3] and $Ni_3(\mu\text{-}CO)_3(CO)_3[HC(PPh_2)_3]$.[4] Our recent serendipitous isolation and structural characterization of the unusual co-crystallization compound, $\{[Ni(PMe_3)_4]\cdot BF_4\cdot[Ni_4(\mu\text{-}CO)_6(PMe_3)_4]\}$, as one of the products formed during the carbonylation of $[NiMe(PMe_3)_4]BF_4$,[5] prompted us to synthesize similar nickel carbonyl phosphine clusters by a more rational route and in a pure form. We report here the preparation of the clusters, $Ni_4(\mu\text{-}CO)_6L_4$ [$L = PMe_3$ (**1**) and $L = PBu^n_3$ (**2**)].

EXPERIMENTAL

General procedures

All experiments were carried out under nitrogen using standard vacuum-line techniques. Solvents were distilled from sodium benzophenone (diethyl ether, THF), sodium (toluene) or calcium hydride (dichloromethane, acetonitrile). Perkin–Elmer 297 and 684 (IR) and Jeol PMX-60 and FX-100 (^1H, ^{31}P NMR) spectrometers were used. Melting points were determined in sealed capillaries under nitrogen and are uncorrected. $Ni(1,5\text{-}COD)_2$ was prepared as described.[6]

Preparation of $Ni_4(\mu\text{-}CO)_6(PMe_3)_4$ (1)

A solution of bis(1,5-cyclooctadiene)nickel (2.75 g, 10.0 mmol) was stirred at room temperature in 200 cm^3 toluene containing trimethylphosphine (1.04 cm^3, 10 mmol) in a partially evacuated flask. Carbon monoxide (400 cm^3, 16 mmol) was admitted from a gas burette. After the initial rapid gas uptake, the solution was stirred until no further carbon monoxide was consumed (*ca* 6 h). During this time, the colour of the solution changed from yellow to orange–brown. Volatiles were then removed *in vacuo* and the residue was washed with 2×20 cm^3 of cold methanol, dissolved in 50 cm^3 toluene, filtered and left to crystallize at $-20°C$.

* Author to whom correspondence should be addressed.

The product was obtained as orange rods (1.06 g, 1.53 mmol, 61%), m.p. 136–137°C.

IR (Nujol mull) 1800 vs, br, 1760 vs, br, 1420 m, 1305 m, 1288 s, 951 vs, br, 735 s, 678 m, 515 vs, br, 385 vs, br cm^{-1}. Found: C, 30.9; H, 5.1. Calc. for $C_{18}H_{36}Ni_4O_6P_4$: C, 30.6; H, 5.1%.

Preparation of $Ni_4(\mu\text{-}CO)_6(PBu^n_3)_4$ **(2)**

This compound was obtained in a fashion similar to **1**. The greenish-orange reaction mixture was filtered through Kieselguhr prior to vacuum removal of volatiles. The product is best recrystrallized from diethyl ether and obtained as orange prisms (1.5 g, 1.25 mmol, 50%), dec. 90°C.

IR (Nujol mull) 1800 vs, 1450 s, 1410 s, 1350, 1309, 1218, 1095, 1050, 970, 792, 730 cm^{-1}. Found: C, 53.6; H, 9.1. Calc. for $C_{54}H_{108}Ni_4O_6P_4$: C, 53.5; H, 9.0%.

Thermolysis of **1**

A solution of **1** in refluxing toluene, darkens to deep brown over a period of 4 h and yields **4** as overgrown black needles as the sole product, dec. > 150°C.

IR (Nujol mull) 2000 m, 1770 vs, 1748 vs, 1690 vs, 1420, 1301, 1285 m, 960 vs, 832, 675, 520 w, br, 470 w, br cm^{-1}; solution spectrum in Et_2O: 2002, 1781, 1755, 1719, 1694 cm^{-1}. Found: C, 29.4; H, 5.0. Calc. for $C_{23}H_{45}Ni_6O_8P_5$: C, 28.9; H, 4.7%.

X-ray crystallography

All X-ray measurements were made on a crystal of dimensions $0.5 \times 0.2 \times 0.2$ mm using an Enraf–Nonius CAD4 diffractometer and graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å), following previously detailed procedures.[7] The structure was solved via the application of direct methods and refined by full-matrix least-squares. Non-hydrogen atoms were refined anisotropically; hydrogens were included in idealized positions and refined as components of rigid groups with group U_{iso} values. Experimental details are as follows.

Crystal data. $C_{18}H_{36}Ni_4O_6P_4$, $M_r = 707.11$, orthorhombic, $a = 10.062(1)$, $b = 16.347(3)$, $c = 18.079(2)$ Å, $V = 2973.7$ Å^3. Space group *Pnma*, $Z = 4$, $D_c = 1.58$ g cm^{-3}, μ(Mo-K_α) = 26.27 cm^{-1}, $F(000) = 1456$.

Data collection. $1.5 \leqslant \theta \leqslant 25°$, $+h$, $+k$, $+l$, ω–2θ scan, data measured: 2978, unique: 2625, observed: 1643 [$I > 1.5\sigma(I)$].

Refinement. 170 parameters, weights = $[\sigma^2(F) + 0.00002F_o^2]^{-1}$, $R = 0.048$, $R_w = 0.043$.

Tables of atomic coordinates and displacement factor coefficients, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as Supplementary Data with the Editor.

Electrochemistry

Electrochemical measurements were carried out using a Princeton Applied Research 170 electrochemical system. The electrochemical cell contained a 0.002 cm^{-2} platinum disk working electrode, a platinum wire auxiliary electrode and a silver/silver chloride reference electrode (ferrocene/ferrocinium: $E_{1/2} = +0.55$ V vs silver/silver chloride). The variable temperature studies were performed using a Haacke Q thermostated bath.

Spectroelectrochemical data were collected as before[8] using a Metrohm E506 potentiostat and an optically transparent electrode (platinum/rhodium gauze) cell located directly in the beam of a Perkin–Elmer Lambda 9 spectrophotometer.

RESULTS AND DISCUSSION

Treatment of a 1:1 mixture of bis(1,5-cyclooctadiene)nickel and trimethylphosphine in toluene at room temperature with 1.5 equivalents of carbon monoxide gives $Ni_4(\mu\text{-}CO)_6(PMe_3)_4$ **(1)**, together with some $Ni(CO)_2(PMe_3)_2$; the former is obtained as orange crystals in 40–60% yield [eq. (1)].

The IR spectrum of **1** in hexane solution indicates the presence of a single type of bridging CO ligand by a single sharp band at 1796 cm^{-1}. The ^1H and ^{31}P NMR spectra in C_6D_6 consist of singlets at δ 1.1 and 4.6 ppm, respectively. The analogous cluster $Ni_4(\mu\text{-}CO)_6(PBu^n_3)_4$ **(2)** is prepared similarly, as orange air-stable crystals and is characterized by an IR band at 1798 cm^{-1} (hexane solution) and a singlet at δ 27.5 ppm in the ^{31}P NMR spectrum.

$$4Ni(COD)_2 + 4L + 6CO \longrightarrow Ni_4(\mu\text{-}CO)_6L \quad (1)$$

(1) L = PMe_3
(2) L = PBu^n_3.

Attempts to synthesize a similar tricyclohexylphosphine cluster were unsuccessful. The poorly soluble, brown solid which was obtained did contain bridging CO ligands as indicated by several IR bands between 1830 and 1760 cm^{-1}, but could not be separated from the more stable $Ni(CO)_2(PCy_3)_2$. The reaction with PPh_3 gives $Ni(CO)_2(PPh_3)_2$ exclusively.

By contrast to the reactions with nickel, we found recently that the application of this synthetic approach to palladium gives rise to the cluster, $Pd_8(\mu_3\text{-}CO)_2(\mu\text{-}CO)_6(PMe_3)_7$.[2] The analogous reac-

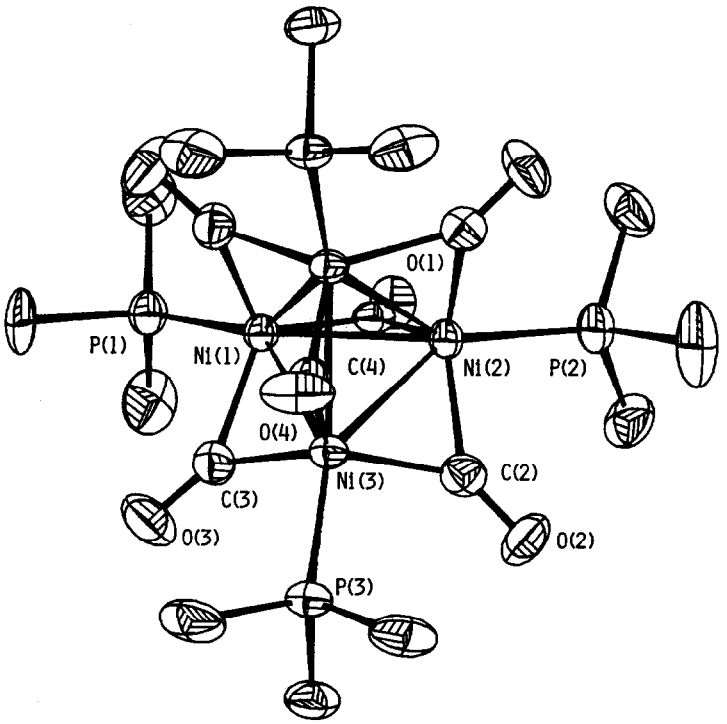

Fig. 1. The molecular structure of **1**, showing the atomic numbering scheme. Ellipsoids correspond to 50% probability.

tion between $Pt(1,5\text{-}COD)_2$, PMe_3 and CO produces a black, insoluble, microcrystalline material which contains both terminal and bridging CO ligands (ν(CO) 2000, 1825, 1775 cm^{-1}), but could not be identified.

The structure of **1** (Fig. 1) is based on a regular Ni_4 tetrahedron and resembles the Ni_4 cluster in $\{[Ni(PMe_3)_4]\cdot BF_4\cdot[Ni_4(CO)_6(PMe_3)_4]\}$ (**3**).[5] Selected bond lengths and angles are given in Table 1. The molecule lies on a crystallographic mirror plane which contains Ni(1), P(1), Ni(2), P(2), C(1), O(1), C(4) and O(4). The average Ni—Ni distance of 2.492(4) Å in **1**, compares well with the Ni—Ni bond length of 2.476(6) Å in **3**. The edges of the Ni_4 tetrahedron are bridged by six CO ligands. The average Ni—C distances in **1** (1.921 Å) are 0.12 Å longer than in **3**, while the C—O distances are shorter by about the same amount, and the Ni—C—Ni angles in **1** (81°) are consequently 6° more acute. These structural differences are reflected in the slightly higher CO stretching frequency of **1** (1796 cm^{-1}), compared to **3** (1780 cm^{-1}). The previously reported $P(CH_2CH_2CN)_3$ analogue of **1** has slightly longer Ni—Ni bonds (2.509 Å) and intermediate average Ni—C distances (1.886 Å) and Ni—C—Ni angles (83.4°).[3b]

Compounds **1** and **2** belong to a family of 60-valence electron (VE) clusters with tetrahedral metal frameworks, for example $[Fe_4(\mu_3\text{-}CO)(\mu\text{-}CO)_3(CO)_9]^{2-}$,[9] $M_4(CO)_{12}$ (M = Co, Rh),[10,11] $Ir_4(\mu\text{-}CO)_3(CO)_5(PMe_3)_4$[12] and $Ni_4(\mu\text{-}CO)_6[P(CH_2CH_2CN)_3]_4$.[3] The cobalt, rhodium and iridium clusters all have planar triangular bases $M_3(\mu\text{-}CO)_3L_3$, similar to the basal $Ni_3(\mu\text{-}CO)_3L_3$ unit in **1**, but are capped by ML_3 fragments. Thus the apical–basal M—M distances are longer than the bonds between the basal metal atoms. In $Ir_4(CO)_8(PMe_3)_4$, the steric effect of packing the four PMe_3 and eight CO ligands around the Ir_4 core results in the lengthening of one basal Ir—Ir distance. No such distortions are present in the nickel compounds.

No 60-VE clusters of the $M_4(CO)_6L_4$ structure are known for palladium and platinum, which instead form the 58-VE clusters $M_4(\mu\text{-}CO)_5(PMe_2Ph)_4$, in which the metal core adopts a butterfly structure.[13,14]

No reaction occurs between **1** or **2** and diphenyl acetylene or dimethyl acetylenedicarboxylate, in contrast to the reactivity of the isoelectronic $Co_4(CO)_{12}$ which gives $Co_4(CO)_{10}(C_2R_2)$ or $Co_2(CO)_6(C_2R_2)$, depending on the alkyne used.[15] Treatment of the clusters with triphenylphosphine cleaves the Ni—Ni bonds and gives $Ni(CO)_2(PPh_3)_2$,[16] again in contrast to $Co_4(CO)_{12}$ where ligand substitution takes place.[17] If **1** is reacted with only one equivalent of PPh_3, a mixture of $Ni(CO)_2(PPh_3)_2$ and unreacted **1** is formed. There is no reaction with H_2 or $LiBEt_3H$, or with $AgBF_4$ in THF and trimethylamine N-oxide in acetonitrile. The addition of elemental sulphur or selenium leads to the evolution of CO and the formation of unidentified insoluble products, while **1** reacts with iodine to give the known[18] complex $NiI_2(CO)(PMe_3)_2$.

Electrochemical oxidation of **1** *and* **2**

There is no observable redox process of **1** in THF solution in the reductive range, whereas an irreversible oxidative process is observed at a modest positive potential. The oxidation process is still irreversible at −40°C. In dichloromethane, however, the oxidation is fully reversible with a half-wave potential $E_{1/2} = +0.28$ V vs silver/silver chloride (0.3 M $NBu^n_4BF_4$ as supporting electrolyte). Coulometry confirms that this oxidation is a one-electron process. A further, irreversible oxidation step is observed at +0.78 V. For complex **2**, the reversible oxidation step is found at $E_{1/2} = +0.35$ V. Evidently, removal of one electron from the metal-centred HOMO of the cluster leaves the Ni_4 core intact, while the second oxidation step induces fragmentation:

$$Ni_4(CO)_6L_4 \underset{}{\overset{+0.28\,V}{\rightleftharpoons}} [Ni_4(CO)_6L_4]^+ \xrightarrow{+0.78\,V} \text{Fragmentation.}$$

This interpretation is confirmed by spectroelectrochemistry results in the 5000–30,000 cm^{-1} region. On oxidation of **1** in dichloromethane at −40°C at a constant potential of +0.5 V, the spectrum of **1** is gradually replaced by the spectrum of $\mathbf{1}^+$ (Figs 2 and 3), with the disappearance of the absorption at 21,700 cm^{-1} and an increase in intensity of weak bands at 8600 and 13,600 cm^{-1}. The presence of an isosbestic point (Fig. 3) indicates a clean conversion of **1** into $\mathbf{1}^+$. The first electron-transfer step is totally reversible, since reversal of the electrogeneration potential to 0 V results in the complete recovery of the absorption spectrum of the starting material **1**, that is $\mathbf{1}^+$ is a stable species in dichloromethane.

There is no evidence for intervalence bands in the spectrum, in accord with the assumption that the positive charge in $\mathbf{1}^+$ is delocalized over the Ni_4 core.

Thermolysis of **1**

At prolonged reaction times (24 h) the formation of **1** from $Ni(COD)_2$ is accompanied by small amounts of a dark brown material (**4**) which crys-

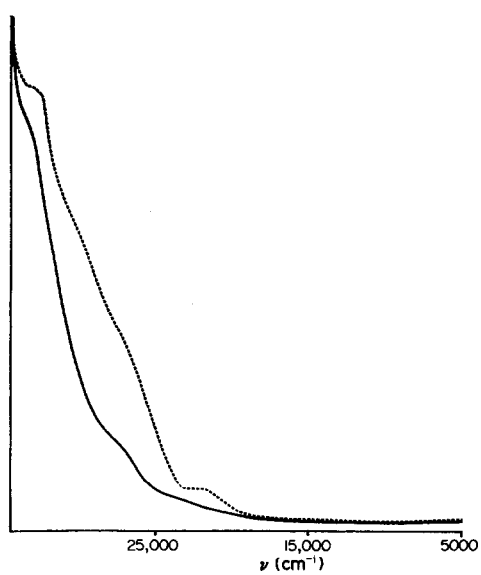

Fig. 2. Electronic spectrum of **1** (···) and of electrochemically generated $\mathbf{1}^+$ (——) in CH_2Cl_2 solution at −40°C, in the range of 5000–30,000 cm^{-1}. Supporting electrolyte: 0.2 M $NBu^n_4BF_4$.

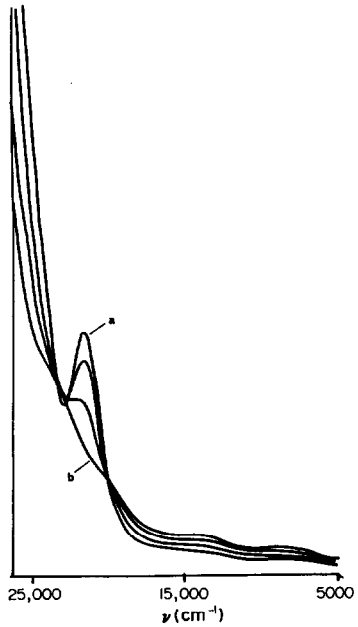

Fig. 3. Electrochemical generation of 1^+ (a) initial spectrum of **1**; (b) spectrum of 1^+. Recording conditions were as for Fig. 2.

tallizes as fine black needles. An identical material is obtained as the sole product by refluxing **1** in toluene for 4 h. The IR spectrum indicates the presence of a terminal CO and several bridging CO ligands. Attempts to grow crystals suitable for X-ray diffraction were unsuccessful. The positive-ion fast atom bombardment mass spectrum (FAB–MS) shows the ion grouping of the highest mass at *m/e* 957. Assuming that this mass corresponds to the parent peak, the result would suggest the presence of the 86-VE cluster $Ni_6(CO)_8(PMe_3)_5$. Four successive losses of CO are seen, in addition to peaks due to $[Ni_6(CO)_5(PMe_3)_4]^+$ (*m/e* 795) and $[Ni_5(CO)_4(PMe_3)_4]^+$ (*m/e* 709). The formulation of **4** as an 86-VE cluster is consistent with the existence of the trigonal-antiprismatic cluster anion $[Ni_6(CO)_{12}]^{2-}$.[19] Other 86-VE clusters are $[M_6(CO)_{18}]^{2-}$ (M = Ru,[20] Os[21]), $M_6(CO)_{16}$ (M = Co,[22] Rh[23]) and $[Re_6C(CO)_{18}H_2]^{2-}$;[24] all have an octahedral M_6 core.

(*Received* 16 *November* 1988; *accepted* 19 *January* 1989)

Abstract—The uranyl complexes, $UO_2(NO_3)_2(HL)_2$ (**1**) and the new complexes, $UO_2L_2(HL)_2$ (**2**) and $UO_2(ClO_4)_2(HL)_4 \cdot 2H_2O$ (**3**) (HL = $Ph_2P(O)CH_2C(O)Ph$), have been prepared. Spectroscopic studies of **1** and **3** indicate that the ligand is bound via the phosphoryl oxygen atom and that the carbonyl oxygen is not involved in bonding to the uranium. The crystal structure of the uranyl nitrate complex (**1**) has been determined, and confirms this bonding mode. The coordination about the uranium atom is distorted hexagonal-bipyramidal. The structure is compared with that of the analogous triphenylphosphine oxide complex and the differing U—O—P bond angles discussed. Solvent extraction studies of uranyl nitrate from aqueous media have been carried out using HL in dichloromethane solution as the extractant. Uranium is extracted as **1** from 4 M HNO_3, but as **2** from neutral aqueous solution.

There is considerable interest in the use of β-ketophosphonates as extractants for a variety of metals.[1–4] Coordination of the neutral ligand can occur in a monodentate[4] or bidentate fashion.[5] They also have the capacity to act as acidic ligands and have been shown to bond in a similar manner to β-diketones.[6,7]

In many cases, the exact nature of the complexes responsible for the extraction process is uncertain. Extraction of uranyl ions with $(BuO)_2P(O)CH_2C(O)Ph$ (HL′) has been interpreted in terms of the formation of $UO_2(NO_3)_2(HL')_2$ and $UO_2L'_2HL'$ from nitric and perchloric acid media, respectively,[4] although the complexes were not isolated. Structural studies of a number of uranium complexes of relevance to solvent extraction have been determined, but these were not demonstrated to be involved in any extraction processes.[8] With this in mind, we have studied the solvent extraction reactions of HL with uranyl nitrate to characterize the complexes involved in the extraction process.

RESULTS AND DISCUSSION

Equilibration of a CH_2Cl_2 solution of HL with uranyl nitrate in 4 M HNO_3 imparted a yellow

* Author to whom correspondence should be addressed.

colouration to the organic phase, indicative of uranium extraction. Solution IR spectral characteristics of the extract were identical to those of **1** in the same solvent. Furthermore, the solid complex which can be isolated from the organic phase had spectroscopic properties identical with those of an authentic sample.[9]

The single crystal X-ray structure of **1** was determined to fully characterize the solvent extraction complex and since no structures of β-ketophosphine oxide metal complexes have been reported.

The complex crystallizes with two molecules in the asymmetric unit, the structure of one of these is shown in Fig. 1 and selected bond lengths and angles are collected in Table 1. The coordination of the uranium atom is based on a distorted hexagonal-bipyramid with the oxygens of the uranyl ion occupying the axial positions. The nitrate ion is bidentate, whilst the ketophosphine oxide is clearly monodentate with the carbonyl oxygens situated symmetrically above and below the equatorial plane at distances of over 4 Å from the uranium atom. The six oxygens of the nitrate and phosphine oxide ligands lie within 3° of the equatorial plane through the uranium atom perpendicular to the O=U=O axis. Other bond lengths and angles are essentially the same as those found in the analogous triphenylphosphine oxide complex,[10] except for the U—O—P angle which is 165° compared with 160° in the Ph_3PO complex. The U—O—P angle would be governed by electrostatic repulsion between the positively-charged uranium and phosphorus centres and the steric requirements of the complex, both tending to widen the angle. Simple models show that HL can adopt less sterically demanding positions than Ph_3PO when coordinated to uranium. However in **1**, the carbonyl oxygens are oriented towards the uranium, presumably by weak electrostatic attraction. In this conformation, HL is bulkier than Ph_3PO and this increase in steric requirements is presumably responsible for the widening of the U—O—P angle in **1**.

Equilibration of neutral aqueous uranyl nitrate

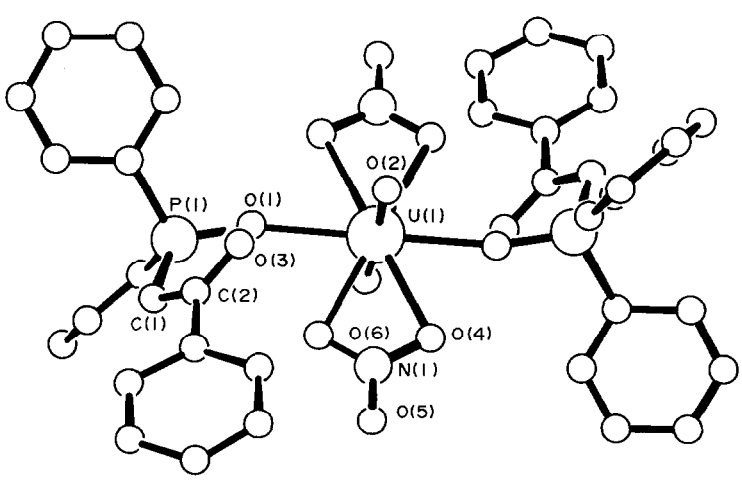

Fig. 1. Structure of $UO_2(NO_3)_2(HL)_2$.

with HL in dichloromethane also leads to the extraction of uranium into the organic phase. In this case, however, **1** is not found in the organic layer as evidenced by the solution IR spectrum which shows no strong bands due to nitrate ions and a shift in the U=O stretch from 935 cm^{-1} in **1** to 920 cm^{-1}. It was not possible to isolate the extraction complex free from HL from this system. It was noted, however, that equilibration of a CH_2Cl_2 solution of **1** with water led to the formation of the same extraction species in the organic layer (solution IR evidence) whilst distributing $UO_2(NO_3)_2$ and HNO_3 into the aqueous layer as shown in eq. (1):

$$2UO_2(NO_3)_2(HL)_{2(Org)} + (Aq) \longrightarrow UO_2L_2(HL)_{2(Org)} + UO_2(NO_3)_{2(Aq)} + 2HNO_{3(Aq)}. \quad (1)$$

Isolation and characterization of the extraction complex was possible in this case due to the absence of excess HL. The elemental analysis for **2** indicates contamination by a small quantity of HL. This is presumably present due to competing equilibria such as that shown in eq. (2):

$$UO_2(NO_3)_2(HL)_{2(Org)} \longrightarrow 2HL_{(Org)} + UO_2(NO_3)_{2(Aq)}. \quad (2)$$

The IR spectrum of the isolated complex shows bands typical of monodentate HL, with an additional absorption at 1510 cm^{-1} consistent with the presence of the anionic ligand L. The position of this band is in the accepted region for the C···O stretch in metal acetylacetonate complexes.[11] Most striking, however, is the absence of any bands due to the nitrate ion. The probable structure of the extraction complex **3** is shown in Fig. 2, where the ligand is acting as a neutral monodentate ligand and as an anionic chelating ligand.

Confirmation of the nature of **2** was obtained by equilibration of a dichloromethane solution of the perchlorate complex **3** with water. Here, the uranium-to-ligand ratio is 1 : 4 and it would be expected that the extraction would proceed predominantly according to eq. (3) with little uranium distributed into the aqueous layer:

$$UO_2(ClO_4)_2(HL)_{4(Org)} \longrightarrow UO_2L_2(HL)_{2(Org)} + 2HClO_{4(Aq)}. \quad (3)$$

The acidity of the aqueous phase increased during the extraction and little uranium was extracted from the organic layer. Solution IR analysis of the CH_2Cl_2 confirmed the presence of **2** and there were no absorptions due to perchlorate ions observable, indicating that the forward reaction of eq. (3) is favoured for the perchlorate complex.

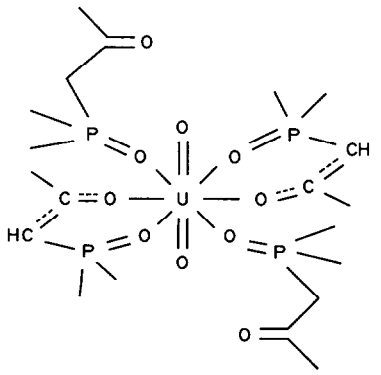

Fig. 2. A possible structure of $UO_2L_2(HL)_2$ (phenyl groups omitted).

EXPERIMENTAL

Preparation of $Ph_2P(O)CH_2C(O)Ph$ (HL)

The ligand was prepared by a literature procedure;[12] spectroscopic and physical properties were identical to the literature values.

Preparation of $UO_2(NO_3)_2(HL)_2$ (**1**)

Uranyl nitrate was dissolved in ethanol and a solution of HL in ethanol added. The mixture was heated under reflux for 2 h and allowed to cool to room temprature. The yellow crystals were filtered and dried to give a quantitative yield. Physical and spectroscopic data were identical to those reported in the literature.[12] Crystals for the structure determination were grown by slow evaporation from a toluene–ethanol solution.

Preparation of $UO_2(ClO_4)_2(HL)_4 \cdot 2H_2O$ (**3**)

Uranyl perchlorate and excess HL were refluxed in ethanol for 2 h. The solvent was evaporated and the resulting oil recrystallized from ethanol–diethyl ether at 0°C, to give the product as a pale yellow powder in 50% yield. Found: C, 53.9; H, 3.9. Calc. for $UO_2(ClO_4)_2(HL)_4 \cdot 2H_2O$: C, 53.8; H, 4.1%. IR data [cm^{-1} (KBr)]: C=O 1680, P=O 1150, 1130 Cl—O 1080, U=O 935.

Preparation of $UO_2L_2(HL)_2$ (**2**)

$UO_2(NO_3)_2(HL)_2$ (0.5 g, 0.48 mmol) in 5 cm^3 of CH_2Cl_2 was equilibrated with 5 cm^3 of water. The organic layer was separated, dried ($MgSO_4$) and evaporated to give 0.32 g (85%) of the product as a yellow–orange solid. Found: C, 63.8; H, 4.3; N,

0. Calc. for $UO_2L_2(HL)_2$: C, 62.0; H, 4.3; N, 0%. IR data [cm^{-1} (KBr)]: C=O 1680, C···O 1510, P=O 1178, 1145, U=O 920.

Extraction of $UO_2(NO_3)_2$ *from* 4 M HNO_3

10 cm^3 of 2M $UO_2(NO_3)_2$ was equilibrated with 10 cm^3 of 2 M HL in CH_2Cl_2. The dichloromethane layer was separated, dried ($MgSO_4$) and evaporated. The resulting solid was recrystallized from ethanol to give 0.66 g of $UO_2(NO_3)_2(HL)_2$; 64% based on HL originally in the organic phase.

Crystal data

$UC_{40}H_{34}N_2O_{12}P_2$, $M = 1034.69$, triclinic space group $P\bar{1}$, $a = 11.877(1)$, $b = 15.999(2)$, $c = 11.362(40)$ Å, $\alpha = 89.78(10)$, $\beta = 94.70(10)$, $\gamma = 110.23(2)°$, $U = 2018.5$ Å^3, $Z = 2$, (Mo-K_α) = 0.7107 Å, $\mu = 39.55$ cm^{-1}, $d_x = 1.702$ g cm^{-3}, $F(000) = 1011.9$.

The unit cell dimensions of the crystal were determined from an oscillation photograph for the rotation axis c, and from the refined data of the zero layer reflections for a, b and γ.

The intensities of 8382 reflections with $2\theta < 54°$ and ($\pm h$, $\pm k$, l) were measured on a Stoe STADI-2-Weissenberg diffractometer with graphite monochromated Mo-K_α radiation using an ω-scan technique. The data were corrected for Lorentz and polarization effects to yield 4701 reflections with $I \geqslant 3\sigma(I)$.

The uranium atoms were located on special positions using the Patt option of SHELXS 84.[13] All subsequent calculations were carried out using the SHELX computer program.[14] An absorption correction was carried out on the data, maximum and minimum transmission factors were 0.730 and 0.228, respectively. All non-hydrogen atoms were refined in the latter stages as anisotropic. Phenyl and methylene hydrogen atoms were included in calculated positions with C—H fixed at 1.08 Å and constrained isotropic thermal parameters.

Final cycles of refinement employed a weighting parameter $g(0.0009)\{w = 1/[\sigma^2(F)+gF^2]\}$ and gave the final residual indices $R\{= \Sigma(|F_o|-|F_c|)/\Sigma|F_o|\} = 0.043$ and $R_w\{[= \Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}\} = 0.044$. The final difference Fourier map was featureless, the highest residual peak of 1.4 e at approximately 1 Å from uranium. An analysis of the weighting scheme over $|F_o|$ and $\sin\theta/\lambda$ was satisfactory.

Final atomic positional and thermal parameters and lists of $|F_o|$ and $|F_c|$ values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Acknowledgement—The authors wish to thank Dr M. A. Beckett for many helpful discussions.

BOOK REVIEWS

Organometallic Chemistry: An Overview. John S. Thayer. Published by VCH Publishers, New York, 1988. ISBN 0-89573-121-5, 170 pp., $35.00.

This is an introductory text for those with a good background in chemistry who are interested in this important and industrially relevant topic.

The text itself is easily comprehensible and well indexed. The first chapter deals largely with the historical development of organometallic chemistry but also gives notes on nomenclature. The next chapter indicates general synthetic methods (concentrating on M—C σ-bonds), and following ones deal with more specific types: ionic and radical carbanions; and "electron deficient" compounds, with short sections on specific elements (Li, Mg, Be and Al). At the beginning of Chapter 5 the σ-bonded organometallics are categorized, apparently largely on the basis of reactivity, into (1) reactive metals, (2) heavy metals and (3) metalloids. Although this subdivision has some chemical basis, I found this taxonomy rather clumsy and may obscure some important chemical truths, especially for those unfamiliar with the field, for whom this book was intended. The separation of the "metalloids" (e.g. B, Si, Ge, P, As, Se, Te) is reasonable, but the grouping of Zn, Cd, Be, Mg and Al with transition metals (group (1), the reactive metals) seems strange, as does placing Ga in group (1) and In in group (2). Furthermore, I was not entirely satisfied that the term "reactive" was adequately explained. There is also a tendency to compartmentalize unwisely: for example, Section 5.3 on Grignard reagents; 5.4 on M—C bond lability, a concept perhaps best illustrated by highlighting more specifically the Schlenk reaction in the previous section or by the Ziegler–Natta polymerization reactions referred to in Section 5.5.

Chapters 8–10 concern M—C synergistic bonds: first those with "divalent" carbon, then those involving unsaturated hydrocarbons, and finally polynuclear species both with and without M—M bonds.

Most of the remainder of the book deals with biological aspects of organometallics: in medicine, toxicology, biosynthesis and environmental aspects. There is a short final chapter on more recent advances in the field (covering the literature up to 1986) which arose after earlier chapters had been completed.

In conclusion, despite reservations about the organization of material, this book does give a clear introduction to the field. It could be recommended as an introductory undergraduate text provided that it is read *in toto* (or almost so) rather than as a reference work on specific topics; a task facilitated by it being both readable and relatively brief.

DARIO M. FRIGO

The Chemistry of the Semiconductor Industry. Edited by S. J. Moss and A. Ledwith. Published by Blackie, Glasgow and London, 1987. ISBN 0-216-92005-1.

This book gives an account of the electronics industry with specific reference to the role played by chemistry.

It begins with an overview of the electronics industry itself, including a general history and a brief indication of where the future probably lies. The next three chapters concern, respectively, the three principal types of material used: silicon, with accounts of extraction and purification of polysilicon and thence conversion to single-crystal wafers; III–V compounds, with concentration on GaAs and InP; and II–VI compounds, which includes a useful section on phase equilibria. The next four chapters deal with the techniques of crystal growth: chemical vapour deposition (CVD), plasma-enhanced CVD, metal–organic vapour phase epitaxy (MOVPE), and liquid phase epitaxy (LPE). Subsequent sections concern processing techniques to produce devices, specifically photoresists, electron beam and X-ray resists, the chemistry of wet etching, and later on (apparently out of sequence) plasma etching and an account of the properties of polymers in plasmas. Sandwiched between these sections are ones on the polyimides, a general view of molecular electronics, and a more theoretical chapter on computer modelling of semiconductor interfaces. Certain aspects of the industry have been omitted on the grounds that chemistry plays only a minor role.

Although the book has been written by some 20 authors, the result is pleasingly free of repetition of material but inevitably, as with any compartmentalized pot-pourri, it suffers from a lack of cross-referencing between chapters which might indicate a greater wholeness of subject. Another inevitable criticism is that in a field that is so fast moving the most up to date expose is substantially old-hat by the publishing date; this book covers the literature up to 1986. On the other hand, the book is (on the whole) well done: most sections are fairly clearly written and authoritative. It can therefore be highly recommended to those who require background reading upon one or more topics covered, or a foundation upon which to read further in the appropriate journals.

2,5-TOLUENEDIAMINE-N,N′-DISUCCINIC ACID. PREPARATION, DISSOCIATION CONSTANTS AND COORDINATING CAPACITY WITH DIVALENT CATIONS

J. FUENTES,* R. REBOSO and A. RODRIGUEZ

Departamento de Química Inorgánica, Universidad de La Laguna, Tenerife, Canary Islands, Spain

(*Received* 17 *October* 1988; *accepted* 9 *November* 1988)

Abstract—2,5-Toluenediamine-N,N′-disuccinic acid (2,5-TDDS) was obtained for the first time and identified, and a formula is proposed on the basis of the results of analytical, potentiometric, conductimetric and spectrophotometric analyses. Its dissociation constants were determined potentiometrically, in an aqueous solution of 0.5 M NaCl and at 25 ± 0.05°C, by means of the Schwarzenbach criterion and the MINIQUAD program. The values obtained for $\log \beta_i$ are as follows: $\log \beta_1 = 6.52$, $\log \beta_2 = 11.06$, $\log \beta_3 = 14.75$, $\log \beta_4 = 17.75$ and $\log \beta_5 = 19.74$. The stability constants of the complexes formed by 2,5-TDDS with the divalent cations Mg, Ca, Mn, Co, Ni, Zn and Cd were determined potentiometrically, at $\mu = 0.5$ M NaCl and at 25 ± 0.05°C.

From the work reported in the literature[1] on the complexing capacity of aromatic diamines, it is deduced that upon introducing carboxymethyl groups their coordinating action is enhanced by metallic cations. This prompted us to prepare a large number of such derivatives with a view to utilizing them as chelating agents of di- and trivalent metallic ions.[2,3] In this work we report on the preparation, identification and determination of the dissociation constants of the new ligand, 2,5-toluenediamine-N,N′-disuccinic acid (2,5-TDDS), as well as the calculation of its stability constants with divalent metal cations. This ligand possesses two coordination spheres in *para* positions which should facilitate the formation of binuclear complex species of the M_2Y or mixed MM′Y types. This fact, together with the presence of asymmetric chains joined to the benzene ring, making its utilization possible in stereospecific syntheses of metallic complexes, renders it additionally interesting.

EXPERIMENTAL

Preparation of 2,5-*toluenediamine*-N,N′-*disuccinic acid*

To an aqueous solution of 0.75 M of 2,5-toluenediamine sulphate, previously neutralized with NaOH and kept at 90°C, an identical volume of a further solution of 1.5 M sodium bromosuccinate was added. The reaction mixture was kept under an inert atmosphere, continuously stirred and 2 M NaOH was added so that the pH of the solution was maintained between 7 and 8. Once the pH (~ 7) was stabilized, an excess (20%) of sodium bromosuccinate was added and the addition of 2 M NaOH was renewed until stabilization was again attained. The solution was filtered and concentrated hydrochloric acid was added to pH 6.5. Then a saturated aqueous solution of $Cd(NO_3)_2 \cdot 4H_2O$ in excess was added to precipitate a pale pink product whose yield became more copious upon adding methanol to the solution. The product was separated by filtering, washed with water to remove Cl^- and NO_3^- and then suspended in a small amount of water through which a H_2S current was passed. The filtrate, after separation of the CdS precipitate, was concentrated in a rotary evaporator and taken to dryness in a desiccator *in vacuo* over P_4O_{10}. The product is a pale beige solid which is highly soluble in water, and melts at 145°C with decomposition; it may be kept unaltered in a desiccator with P_4O_{10}.

Apparatus and experimental techniques

The experimental device utilized in the potentiometric study of 2,5-TDDS alone and in the pres-

* Author to whom correspondence should be addressed.

ence of metal cations has been described in ref. 2. The titrations were carried out in an aqueous solution of 0.5 M NaCl and at 25 ± 0.05°C, 100 cm^3 being the initial volume and the initial concentration of the acid was of the order 10^{-3} M. The measurements were recorded with a Radiometer potentiometer (the 64pHM type) with an accuracy of the order of 0.1 mV, and using glass and calomel electrodes, G202B and K401, respectively, from the same company. The cell used was of the type: Glass electrode/soln of 2,5-TDDS/M^{II}; ($\mu = 0.5$; $T = 25 \pm 0.05$°C)/Calomel electrode; the standard potential of which and the $[H^+]$ were determined in a similar manner to that described in ref. 4. Conductimetric measurements of the acid alone and in the presence of the cations studied were performed as indicated for the potentiometric determinations, utilizing the same experimental device and temperature and without adjusting the ionic strength. The metal–acid ratios were 1:1, 2:1 and 15:1 for all the cations and the initial concentration of the acid was of the order 10^{-3} M. The measurements were recorded in a Radiometer conductimeter, model CDM 83, equipped with a CDC 304 conductivity cell from the same company.

The high and low resolution mass spectra were performed on a VG Micromass spectrometer, model ZAB-1F, at 15 eV, by direct insertion of the sample. The UV spectrum was taken on a Perkin–Elmer 550S spectrophotometer using quartz cells and thermostated at 25°C. The IR spectrum was taken in the range 4000–600 cm^{-1} on a Beckman 20-AX spectrophotometer, using KBr pellets as support. Elemental analysis was determined with a Carlo Erba 1106 elemental analyser.

The solutions of the metal chlorides were prepared at a concentration of approx. 0.1 M and were calculated as indicated in ref. 4, as were those of EDTA, HCl and carbonate-free NaOH.

RESULTS AND DISCUSSION

Identification of the product

Found: C, 49.9; H, 5.7; N, 7.7. Calc. for $C_{15}H_{18}N_2O_8 \cdot 1/2H_2O$: C, 49.6; H, 5.3; N, 7.7%.

The mean value obtained for the equivalent of the acid was 90.75. The substitution of a hydrogen from each of the two $—NH_2$ groups of the 2,5-toluenediamine by HOOC—CH(COOH)—CH_2—COOH groups would give rise to a molecular mass of 363.32, which is in agreement with the formula $C_{15}H_{18}N_2O_8 \cdot 1/2H_2O$ with four carboxylic groups.

The results of the conductimetric titration of a 10^{-3} M aqueous solution of 2,5-TDDS with 0.1 M NaOH are plotted in Fig. 1 [conductivities, λ, vs values of a (mols of NaOH/mol of acid)]. The presence of four defined points at $a = 1$, 2, 3 and 4 seems to confirm the existence of four acidities in the product obtained.

As also seen in the case of 1,4-phenylenediamine-N,N′-disuccinic acid,[2] the signal corresponding to the molecular ion is not observed in the mass spectrum. However, a peak appearing at m/z 266 was interpreted as corresponding to $M^+ - 2CO_2$. In ref. 2 we discussed the fact that this type of "apparent molecular ion" is presented in molecules with little thermal stability, or in those which readily lose neutral molecules.[5] The fragments at m/z 207 and 161, whose elemental analyses were determined by high resolution, may be interpreted as successive losses of $—CH_2CO_2H$ and HCO_2H from the $M^+ - 2CO_2$ ion.

The UV spectrum of 2,5-TDDS acid in a 2×10^{-5} M aqueous solution shows three absorption bands at 207, 253 and 293 nm which were assigned to the allowed spin transitions (180, 200 and 260 nm) typical of the benzene ring.[6] The bathochromic shifts, observed in the three bands of the acid relative to those of benzene, are caused by substitution in the benzene ring of the two $—NH(C_4H_5O_4)$ auxochromic groups that produce, according to Braude,[7] the π–p conjugation between the non-shared electrons of the substituent and the π-system of the ring.

The IR spectrum shows a 1,2,5-substituted aromatic ring (812 cm^{-1}),[8] secondary aromatic amine groups (3409 cm^{-1}),[9] $—CO_2^-$ (1404, 1620 and 1565 cm^{-1}),[10] $—CO_2H$ in non-monomeric acids (3000–2500 and 1725 cm^{-1})[10,9] and the OH of the crystallization water (3600–3300 cm^{-1}).[11] The similarity of the IR spectrum of this compound with those of 1,3- and 1,4-phenylenediamine-N,N′-disuccinic acids led us to propose a dimerization by the way of intermolecular hydrogen bonds.[2]

Determination of the dissociation constants of 2,5-TDDS *acid*

Since 2,5-TDDS is tetrabasic, we have designated it as H_4Y for simplification purposes. The dissociation equilibria that permit the corresponding constants to be defined are:

$$H_4Y \rightleftharpoons H_3Y^- + H^+ \quad (1)$$

$$H_3Y^- \rightleftharpoons H_2Y^{2-} + H^+ \quad (2)$$

$$H_2Y^{2-} \rightleftharpoons HY^{3-} + H^+ \quad (3)$$

$$HY^{3-} \rightleftharpoons Y^{4-} + H^+. \quad (4)$$

In order to determine these constants, several solu-

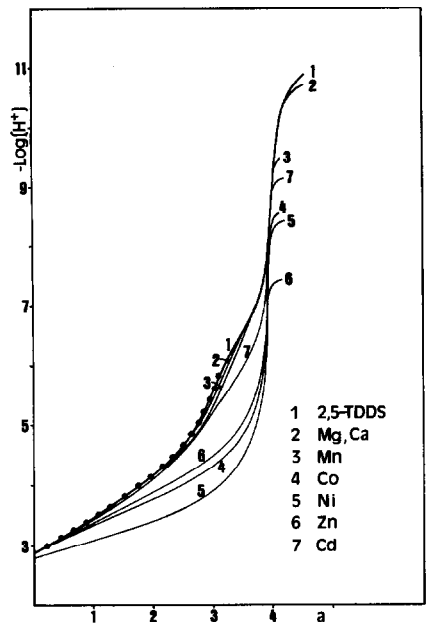

Fig. 1. Potentiometric curves of free acid 2,5-TDDS (—— experimental, ····· calculated) and in the presence of different divalent cations in the ratio $[M^{II}]/[2,5\text{-TDDS}] = 1:1$.

tions of the acid at concentrations of the order of 10^{-3} M, at ionic strength 0.5 M in NaCl and 25 ± 0.05°C, were titrated potentiometrically with NaOH. The values of $-\log[H^+]$ vs a are plotted in Fig. 1, where two potentiometric jumps are observed, one of which is well defined at $a = 4$ and the other less defined and with inflection at $a = 3$. Between $a = 0$ and $a = 3$ the curve does not present inflections, which proves that the first three equilibria are simultaneous and that, consequently, the ΔpK_s must be smaller than two units, whereas the last two equilibria must be successive or at least not totally simultaneous. For the calculation of the dissociation constants the graphical criteria of Bjerrum[12] and Schwarzenbach *et al.*[13] were employed, and refined with the MINIQUAD program.[14,15]

The values found for $\log \beta_i$ and pK_i are presented in Table 1, the standard deviations in the significant number are indicated in parentheses. The Bjerrum values given in Table 1 were refined by means of successive approximations,[16] since the relation between two successive constants was below 10^4. In addition to the four constants defined earlier, the value for a fifth constant appears in Table 1, which has been designated as K_0 and corresponds to the equilibrium:

$$H_5Y^+ \overset{K_0}{\rightleftharpoons} H_4Y + H^+.$$

As indicated in our study of 1,4-phenylenediamine-N-succinic acid,[17] the existence of the H_5Y^+ species can be interpreted as proceeding from the following self-dissociation equilibrium:

$$2H_4Y \rightleftharpoons H_5Y^+ + H_3Y^-.$$

The good fit between the curve of the experimental potentiometric titration and that calculated upon refining the dissociation constants of the acid can be observed in Fig. 1.

Stability constants

The process of formation of a metal complex, in which the ligand is a weak organic acid, can be represented by the equation:

$$H_mY + xM^{q+} \rightleftharpoons M_xH_{m-n}Y^{qx-n} + nH^+. \quad (5)$$

In this type of reaction new species are formed in solution, which can be detected by conductimetric and/or potentiometric techniques.

The conductimetric titration curves of the acid in the presence of the divalent cations under study for the ratio $[M^{II}]/[\text{acid}] = 1:1$ are plotted in Fig. 2. The curve corresponding to the titration of the free acid has been included for comparison purposes. For the cations Mg^{2+} and Ca^{2+} a decrease in the slope is observed only in the interval $3 < a < 4$ (the shift in those of Sr^{2+} and Ba^{2+} is negligible), which can be interpreted if it is assumed that in addition to equilibrium (4) of dissociation of the acid, the fol-

Table 1. Dissociation constants of 2,5-TDDS acid at 25°C and $\mu = 0.5$ M NaCl

	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$	$\log \beta_4$	$\log \beta_5$
MINIQUAD	6.52(1)	11.06(1)	14.75(1)	17.75(1)	19.74(1)
	pK_0	pK_1	pK_2	pK_3	pK_4
Schwarzenbach	—	3.08	3.61	4.60	6.53
Bjerrum	—	3.16	3.59	4.62	6.53
MINIQUAD	1.99	3.00	3.68	4.54	6.52

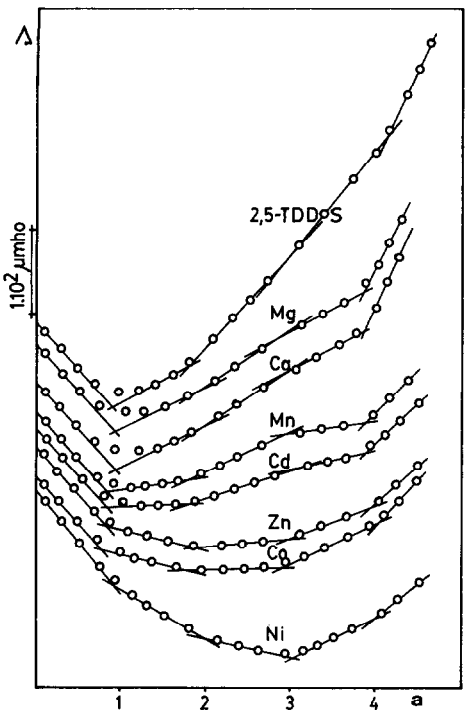

Fig. 2. Conductimetric curves of free acid 2,5-TDDS and in the presence of different divalent cations in the ratio $[M^{II}]/[2,5\text{-TDDS}] = 1:1$.

lowing equilibria come about:

$$\begin{aligned} Y^{4-} + M^{2+} &\overset{K_c}{\rightleftharpoons} MY^{2-} \quad 3 < a < 4 \\ HY^{3-} + M^{2+} &\rightleftharpoons MY^{2-} + H^+. \end{aligned} \tag{6}$$

For the cations Mn^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+} and Ni^{2+} (which deviate the curve of the acid from $a = 1$) these deformations are explained by means of the formation equilibria (7), (8) and (6):

$$H_2Y^{2-} + M^{2+} \overset{K''}{\rightleftharpoons} MH_2Y \quad 1 < a < 2 \tag{7}$$

$$HY^{3-} + M^{2+} \overset{K'}{\rightleftharpoons} MHY^- \quad 2 < a < 3, \tag{8}$$

where K'', K' and K_c are the corresponding stability constants.

The potentiometric curves in the ratio 1 : 1 plotted in Fig. 1 are deformed with respect to that of the acid from $a = 1$, with the exception of those corresponding to Mg^{2+} and Ca^{2+} which are only deformed between $a = 3$ and $a = 4$. The decrease observed in the pH from $a = 1$ is in agreement with the formation of complex species described earlier and which, in accordance with the shift equilibria:

$$H_3Y^- + M^{2+} \rightleftharpoons MH_2Y + H^+ \quad 1 < a < 2$$

$$H_2Y^{2-} + M^{2+} \rightleftharpoons MHY^- + H^+ \quad 2 < a < 3$$

$$HY^{3-} + M^{2+} \rightleftharpoons MY^{2-} + H^+ \quad 3 < a < 4,$$

induce 2,5-TDDS acid to behave like a strong acid.

In the case of the curves with excess of metal a greater deformation is observed, both in the conductimetric and potentiometric curves, with respect to the ratio 1 : 1, due to the fact that the concentration of metal ion shifts the equilibria defined by eq. (5) towards the right. In the interval $3 < a < 4$, the deformation of the curve of the acid is even more marked as a consequence of the additional shift of protons by the metal cation:

$$MHY^- + M^{2+} \rightleftharpoons M_2Y + H^+$$

and formation of the bimetallic particle M_2Y:

$$MY^{2-} + M^{2+} \overset{K_M}{\rightleftharpoons} M_2Y.$$

For the determination of the stability constants, solutions of 2,5-TDDS acid in 0.5 M NaCl were potentiometrically titrated in the presence of a metal cation in the ratios $[M^{II}]/[2,5\text{-TDDS}] = 1:1$, 1 : 2, 2 : 1 and 15 : 1. For the calculation of such constants the graphical criterion of Schwarzenbach[13] was used, and the values obtained were refined by means of the MINIQUAD program.[14,15] The models used in the calculation are in agreement with the results foreseen in the qualitative study and the best fits were achieved, after testing several hypotheses considering the exis-

tence of MH_2Y, MHY^- and MY^{2-} for Mn^{2+}, of the above species plus the bimetallic particle, M_2Y, for the cations Co^{2+}, Zn^{2+} and Cd^{2+} and of all the above mentioned species plus MY_2^{6-} only in the case of Ni^{2+}. The existence of the species MY^{2-} was only taken into account for Mg^{2+} and Ca^{2+}. The calculated values of the logarithms of the stability constants are presented in Table 2.

The species distribution diagrams as a function of $-\log[H^+]$ for the system $[Ni^{II}]/[2,5\text{-TDDS}]$ in the ratios 1:2 and 15:1 are plotted as an example in Fig. 3.

(*Received* 28 *October* 1988; *accepted* 6 *December* 1988)

Abstract—The new complexes $K_3[M(O_2)_3(tart)]\cdot H_2O$ (M = Nb, Ta; tart = tartrate), $K_3[M(O_2)_3(L)]\cdot 2H_2O$ [M = Nb, Ta; L = glycollate (glyc), citrate (cit)], $K_3[Nb(O_2)_3(mal)]\cdot 2H_2O$ (mal = malate), $K[M(O_2)_2(dipic)(H_2O)]\cdot 2H_2O$ (M = Nb, Ta; dipic = dipicolinate), $K_6[M_2(O_2)_6(tart)]\cdot 2H_2O$ (M = Nb, Ta), $K_2[M(O_2)(ox)_2]\cdot 2H_2O$ (M = Zr, Hf) and $K_2[M(O_2)_2(cit)]\cdot H_2O$ (M = Zr, Hf) have been prepared and characterized on the basis of the Raman and IR spectra of the solids, the Raman spectra of their aqueous solutions and, in some cases, their ^{13}C NMR spectra. They are likely to contain eight-coordinate metal atoms with the peroxo groups side-bonded to the metal atoms.

Transition metal peroxo complexes are of current interest because many of them are efficient stoichiometric or catalytic oxidants for organic substrates;[2] however, they tend, unless stabilized by suitable co-ligands, to be unstable towards heat or impact. Such co-ligands are hard donors such as the oxo (O^{2-}), fluoro (F^-) or hydroxo (OH^-) ligands; we have recently shown[3] that carboxylate anions capable of forming five-membered rings with the metal atom are excellent co-ligands for coordinated O_2^{2-} in molybdenum and tungsten complexes of the form $K_2[MO(O_2)_2L]$ (M = Mo, W; L = citrate, malate, tartrate, tartronate, quinate, glycollate). In this paper we extend our studies on carboxylato peroxo complexes to the Group V and Group IV elements niobium, tantalum, zirconium and hafnium.

RESULTS AND DISCUSSION

Niobium and tantalum complexes

Although salts of the fluoroperoxo complexes $[M(O_2)F_5]^{2-}$ (M = Nb,[4,5] Ta[6]) and $[M(O_2)_2F_4]^{3-}$ (M = Nb,[7] Ta[8]) have received much attention, there are relatively few carboxylato peroxo complexes of niobium and tantalum. The oxalato peroxo complexes $(NH_4)_3[Nb(O_2)(ox)_3]$,[9] $K_3[M(O_2)_2(ox)_2]\cdot H_2O$ (M = Nb, Ta;[10] the X-ray crystal structure of the niobium complex has been determined[11]) and the salts of $[Nb(O_2)_3(ox)]^{3-}$[12] have been prepared. The aminocarboxylato peroxo species $[M(O_2)_3(EDTA)]^{3-}$[13] and $[M(O_2)_2(pic)_2]^-$[14] (M = Nb, Ta; EDTA = ethylenediamine tetraacetate, pic = picolinate) are also known.

(i) *Mononuclear complexes.* We find that reaction of aqueous solutions of the tetraperoxo species $K_3[M(O_2)_4]$ (M = Nb, Ta) with the carboxylic acid in a 1:1 mole ratio in the presence of excess H_2O_2 leads to the new complexes $K_3[M(O_2)_3(tart)]\cdot H_2O$, $K_3[M(O_2)_3(cit)]\cdot 2H_2O$, $K_3[M(O_2)_3(glyc)]\cdot 2H_2O$, $K[M(O_2)_2(dipic)(H_2O)]\cdot 2H_2O$ and $K_3[Nb(O_2)_3(mal)]\cdot 2H_2O$. The presence of excess H_2O_2 in the reaction mixture serves to increase the yield of the product. As was the case with reaction of $[M'O_4]^{2-}$ with H_2O_2 and carboxylic acids H_2L to give the complexes $[M'O(O_2)_2L]^{2-}$ (M' = Mo, W), only those carboxylic acids capable of forming five-membered rings with the metals reacted. Reactions with species such as malonic acid and succinic acid, which would give six-membered rings, were unsuccessful. Mandelic acid gave no isolable product despite its potential ability to form a five-membered ring; presumably the phenyl group is sufficiently electron-

† For Part VIII, see ref. 1.

‡ Author to whom correspondence should be addressed.

withdrawing to prevent formation of a stable complex. The tridentate dipicolinato ligand in coordination can form two five-membered rings (as in $[VO(OO^tBu)(dipic)]$[14]); presumably, in the cases of these diperoxo dipicolinato complexes, a water molecule occupies the eighth coordination site.

Despite many attempts, it was in no instance possible to obtain crystals large or well enough formed for an X-ray crystal structure determination.

In Table 1 we list those Raman and IR bands which can clearly be assigned to the three typical modes of the coordinated (side-bonded) peroxo ligand,[1,3,15] viz. the O—O stretch (ν(O—O) near 880 cm^{-1}, the symmetric metal–peroxo stretch $\nu_{sym}[M(O_2)]$ near 650 cm^{-1} (both giving rise to polarized Raman bands for the aqueous solutions), and the asymmetric metal–peroxo stretch $\nu_{asym}[M(O_2)]$ near 600 cm^{-1}, depolarized for aqueous solutions. As in other peroxo complexes, ν(O—O) is strong and sharp both in the Raman and the IR; $\nu_{sym}[M(O_2)]$ is weak in the Raman and strong in the IR; and $\nu_{asym}[M(O_2)]$ is strong in the Raman and weak in the IR. Thus, the vibrational characteristics of these complexes suggest that the peroxo ligand is side-bonded to the metal atom. The similarity in band profiles of Raman spectra of the solids and of their aqueous solutions suggests that the structures of the species in the solid state are retained in aqueous solution.

The relatively low solubility of the salts in water made measurement of ^{13}C NMR spectra difficult; only in the cases of $[M(O_2)_3(glyc)]^{3-}$ (M = Nb, Ta) and $[Ta(O_2)_3(tart)]^{3-}$ were satisfactory spectra recorded. The niobium glycollato complex shows ^{13}C bands at δ 182.3 and 73.0 ppm, and analogous bands at δ 183.4 and 73.7 ppm were observed for solutions of $K_3[Ta(O_2)_3(glyc)]\cdot 2H_2O$. The resonances near δ 183 ppm are likely to arise from the carboxylic carbon atom (δ 178.8 ppm for free glycollic acid) and those near δ 73 ppm from the hydroxyl-bearing carbon atom (δ 62.0 ppm for the free acid). The downfield shift in resonance, observed also in $[MoO(O_2)_2(glyc)]^{2-}$ (M = Mo, W),[3] is expected since donation of electrons from the oxygen atoms adjacent to these carbon centres will effect deshielding of the latter. The ^{13}C NMR spectrum of $[Ta(O_2)_3(tart)]^{3-}$ shows a group of resonances centred around δ 180 ppm and another centred around δ 80 ppm, likely to arise from the carboxylate- and hydroxyl-bearing carbon atoms, respectively (they are observed in the free acid at δ 176.8 and 74.4 ppm). Again, similar downfield shifts were observed in $[MO(O_2)_2(tart)]^{2-}$ (M = Mo, W),[3] due to complexation as with the glycollate, but the complexity of the resonances suggests that some decomposition to $[Ta_2(O_2)_6(tart)]^{6-}$ may have occurred.

We suggest that all these complexes involve eight-coordinate niobium or tantalum; dodecahedral coordination has been demonstrated by X-ray crystallography for the anion in $KMg[Nb(O_2)_4]\cdot 7H_2O$[16] and $(NH_4)_3[Nb(O_2)_4]$.[9]

(ii) *Binuclear complexes.* We have reported the isolation of unusual binuclear tartrato-bridged peroxo complexes, $K_4[M_2O_2(O_2)_4(C_4H_2O_6)]\cdot 4H_2O$ (M = Mo, W), and established the X-ray crystal structure of the molybdenum salt.[3,17] It is therefore of interest to establish whether niobium and tantalum will form such species. We find that reaction of $[M(O_2)_4]^{3-}$ and (+)-tartaric acid in a 1:2 mole ratio in the presence of excess H_2O_2 gives sparingly soluble salts which analyse as $K_6[M_2(O_2)_6(tart)]\cdot 2H_2O$ (M = Mo, W). They are too insoluble for ^1H or ^{13}C NMR measurements, but the Raman and IR spectra suggest that they contain side-bonded peroxo ligands. The Raman and IR bands assignable to tartrate vibrations are similar in position and profile to those observed for $K_4[M_2O_2(O_2)_4(tart)]\cdot 4H_2O$ (M = Mo, W),[3,17] and we suggest that these new species contain eight-coordinated metal centres, probably having dodecahedral coordination as in other niobium and tantalum peroxo complexes. In this, each metal atom carries three side-bonded peroxo ligands and a bridging tartrate group, as in $K_4[Mo_2O_2(O_2)_4(tart)]\cdot 4H_2O$.[3,17] The deprotonated hydroxo and carboxylato oxygens of one half of the tartrate ligand give a five-membered ring with the metal.

Zirconium and hafnium complexes

Far fewer peroxo complexes of zirconium and hafnium are known than of niobium and tantalum, and X-ray data on only one of these are reported in the literature. Salts of $[Zr(O_2)_4]^{4-}$ (but not $[Hf(O_2)_4]^{4-}$) have been reported[18] and evidence presented for the existence of $[Zr_2(O_2)_3(SO_4)(H_2O)_4]$.[19] The fluoro complex $(NH_4)_3[Zr(O_2)F_5]$ has been made[15] and shown by X-ray structure analysis to contain a pentagonal bipyramidal anion;[20] salts of $[Zr_2(O_2)_2F_7]^{3-}$ are also known.[21] The known carboxylato peroxo complexes are $[Zr(O_2)(ox)(H_2O)_2]\cdot nH_2O$,[22] $[Zr(O_2)L_2]$ and $[Zr(O_2)L'(H_2O)]$ (L = picolinato, 8-hydroxyquinolinato, aniline-2-carboxylato, 2-aminophenoxido; L′ = N-(2-carboxyphenyl)salicylideneaminato).[23]

We have attempted to prepare peroxo complexes of these metals with oxalic, citric, tartaric and glycollic acids, the anions of which have proven complexing ability and the capability of forming five-membered rings with metals.

Reaction of the soluble oxychlorides $ZrOCl_2 \cdot 8H_2O$ and $HfOCl_2 \cdot 8H_2O$ with potassium oxalate (1 : 2 metal–ligand ratio) in the presence of H_2O_2 gave the new complexes $K_2[M(O_2)(ox)_2] \cdot 2H_2O$ as white, sparingly soluble salts; the pHs of formation were 3(Zr) and 2(Hf), values low enough to suppress hydrolysis of the zirconyl and hafnyl reactants. A similar procedure with potassium citrate gave $K_2[M(O_2)_2(cit)] \cdot H_2O$. With potassium tartrate no carboxylato complexes could be isolated, but glycollic acid and $MOCl_2 \cdot 8H_2O$ with KOH (mole ratio 1 : 1 : 2) in the presence of excess H_2O_2 gave white materials with analyses falling midway between the formulations $K_2[M(O_2)(glyc)_2] \cdot 2H_2O$ and $K_2[M(O_2)_2(glyc)] \cdot H_2O$. The IR spectra of these materials showed broad bands in the region 900–1000 cm^{-1}, which may arise from polymeric zirconyl or hafnyl moieties.

The low solubility of the $K_2[M(O_2)(ox)_2] \cdot 2H_2O$ and $K_2[M(O_2)_2(cit)] \cdot H_2O$ salts prevented study of their ^1H or ^{13}C spectra. Their vibrational spectra showed, in addition to bands typical of coordinated oxalate and citrate modes, bands typical of side-bonded peroxo ligands. The stoichiometries suggest six-coordination (assuming side-on coordination for peroxide) or seven-coordination if one molecule of water participates in the coordination sphere. On the basis of the known pentagonal bipyramidal symmetry of the anion in $(NH_4)_3[Zr(O_2)F_5]$[20] we suggest that these salts could also contain pentagonal pyramidal anions, viz. $[M(O_2)(ox)_2(H_2O)]^{2-}$ and $[M(O_2)_2(cit)(H_2O)]^{2-}$. The presence of only one citrate group rather than two is likely to arise from the steric crowding that would occur in a bis citrato complex.

EXPERIMENTAL

Preparation of $K_3[Nb(O_2)_4] \cdot \frac{1}{2}H_2O$

A sample of fresh Nb_2O_5 was obtained by addition of $NbCl_5$ (5.0 g) to a 2 M solution of KOH (50 cm^3) at 0°C. The Nb_2O_5 was filtered off, washed with cold water and dried. It was then fused (2.0 g, 7.52 mmol) with KOH pellets (3.4 g, 60.6 mmol) in a nickel crucible. The cooled melt was taken up in a minimum of water, and treated with 30% H_2O_2 (5 cm^3). The cloudy solution was heated for 15 min at 75°C on a water bath and filtered when hot. On cooling, the filtrate gave yellow–white crystals of $K_3[Nb(O_2)_4] \cdot \frac{1}{2}H_2O$, which are filtered off, washed with ethanol and air-dried. Found: K, 33.6; $(O_2)^{2-}$, 37.4. $HK_3NbO_{8.5}$ requires: K, 33.9; $(O_2)^{2-}$, 37.0%. Infrared (IR) and Raman (R) data (cm^{-1}): IR (Nujol mull): 813vs, 598s, 548s, 463br, 295m; R (solid, KBr disc): 841(10), 815(2), 600(1), 548(8), 521(3), 459(2), 300(2), 271(5).

A similar sample was obtained by the alkali fusion of potassium niobate followed by the same work-up. The sodium salt was prepared by using NaOH instead of KOH.

Preparation of $K_3[Ta(O_2)_4] \cdot \frac{1}{2}H_2O$

Fresh Ta_2O_5 (2.0 g, 4.53 mmol) [prepared by the addition of $TaCl_5$ (5.0 g) to a 2 M solution of potassium hydroxide (50 cm^3)] and potassium hydroxide pellets (2.0 g, 35.6 mmol) were fused in a nickel crucible. The cooled melt was taken up in a minimum of water, treated with 30% H_2O_2 (5 cm^3) and heated to 75°C for 15 min. The cloudy suspension was filtered when hot. On cooling at room temperature, the filtrate gave white crystals of $K_3[Ta(O_2)_4] \cdot \frac{1}{2}H_2O$, which were filtered off, washed with ethanol and air-dried. Found: K, 26.2; $(O_2)^{2-}$, 28.9. $HK_3O_{8.5}Ta$ requires: K, 26.9; $(O_2)^{2-}$, 29.4%. Infrared (IR) and Raman (R) data (cm^{-1}): IR (Nujol mull): 847m, 808vs, 621m, 594m, 560m, 531vs, 441s; R (solid, KBr disc): 836(10), 815(4), 633(2), 577(3), 558(4), 340(2).

A similar sample was obtained by alkali fusion of potassium tantalate. The sodium salt was prepared by using NaOH instead of KOH.

Preparation of $K_3[M(O_2)_3(tart)] \cdot H_2O$ (M = Nb, Ta) *and* $K_3[M(O_2)_3(L)] \cdot 2H_2O$ (M = Nb, L = glyc, cit, mal; M = Ta, L = glyc, cit)

$K_3[M(O_2)_4] \cdot \frac{1}{2}H_2O$ (1.44 mmol) and H_2L (1.44 mmol) were dissolved in water (25 cm^3). The solution was treated with excess 30% H_2O_2 (10 cm^3) with stirring. Addition of ethanol (*ca* 20 cm^3) and storage at 5°C yielded a light yellow (M = Nb) or white (M = Ta) solid, which was filtered off, washed with ethanol and air-dried.

Preparation of $K[M(O_2)_2(dipic)(H_2O)] \cdot 2H_2O$ (M = Nb, Ta)

$K_3[M(O_2)_4] \cdot \frac{1}{2}H_2O$ (1.48 mmol) and dipicolinic acid (pyridine-2,6-dicarboxylic acid) (1.48 mmol) were dissolved in water (15 cm^3) and the solution treated with 30% H_2O_2 (5 cm^3). Addition of ethanol (15 cm^3) and storage at 5°C gave a yellow (M = Nb) or white (M = Ta) solid, which was filtered off, washed with ethanol and air-dried.

Preparation of $K_6[M_2(O_2)_6(tart)]\cdot 2H_2O$ (M = Nb, Ta)

$K_3[M(O_2)_4]\cdot \frac{1}{2}H_2O$ (2.88 mmol) and (+)-tartaric acid (1.44 mmol) were dissolved in water (30 cm^3) and the solution treated with 30% H_2O_2 (10 cm^3), with stirring. Addition of ethanol and storage at 0°C yielded a light yellow (M = Nb) or white (M = Ta) solid, which was filtered off, washed with ethanol and air-dried.

Attempted preparation of other carboxylato peroxo complexes

The reactions of malonic, salicylic, succinic and mandelic acids with $K_3[M(O_2)_4]\cdot \frac{1}{2}H_2O$ (M = Nb, Ta), in the presence of H_2O_2, each yielded only the unreacted potassium tetraperoxometallate(V) salt upon precipitation with ethanol.

Preparation of $K_2[M(O_2)(ox)_2]\cdot 2H_2O$ (M = Zr, Hf)

Zirconyl chloride, $ZrOCl_2\cdot 8H_2O$ (1.00 g, 3.10 mmol) and potassium oxalate (1.14 g, 6.20 mmol) were dissolved in water (15 cm^3). Addition of 30% H_2O_2 (10 cm^3) with stirring, followed by storage overnight at 0°C, gave a white solid, which was filtered off, washed with cold ethanol (3 × 10 cm^3) and dried in a vacuum desiccator over silica gel. The solid proved to be slightly hygroscopic and was therefore stored in a desiccator permanently.

The analogous hafnium complex was similarly prepared and isolated as a white hygroscopic solid by the reaction of hafnyl chloride, $HfOCl_2\cdot 8H_2O$, with potassium oxalate and excess H_2O_2.

Preparation of $K_2[M(O_2)_2(cit)]\cdot H_2O$ (M = Zr, Hf)

The oxychloride, $MOCl_2\cdot 8H_2O$ (3.10 mmol) and potassium citrate (3.10 mmol) were dissolved in water (25 cm^3), and the solution treated with 30% H_2O_2 (10 cm^3) with stirring. Addition of ethanol and storage at 0°C gave white hygroscopic solids (M = Zr, Hf) which were collected, washed with ethanol and dried in a vacuum desiccator over silica gel. Both compounds were stored in a desiccator.

Preparation of glycollato peroxo complexes of Zr^{IV} *and* Hf^{IV}

Zirconyl chloride (1.00 g, 3.10 mmol) and glycollic acid (0.47 g, 6.2 mmol) were dissolved in water (15 cm^3), and 30% H_2O_2 (5 cm^3) added, followed by a solution of KOH (0.35 g, 6.2 mmol) in water (5 cm^3). A yellow–white solid appeared at 5°C and was collected, washed with cold ethanol and air-dried. (Found: C, 8.5; H, 2.3; K, 21.3; $(O_2)^{2-}$, 10.1%.) A similar compound was obtained using a 1:1:2 zirconium–glycollate–KOH molar ratio. Similarly, the analogous white hafnium compound was prepared using both 1:2:2 and 1:1:2 hafnium–glycollate–KOH ratios. (Found: C, 7.9; H, 2.2; $(O_2)^{2-}$, 11.2%.)

General experimental

Raman spectra were recorded on a Spex Ramalog 5 instrument with a Spex Datamate data acquisition unit, using the exciting lines at 568.2 and 530.9 nm from a Coherent model 52 krypton-ion laser, at 568.2 nm from a Coherent Innova 90 krypton-ion laser and at 514.5 nm from a Coherent Innova 70 argon-ion laser. Spectra of solids were taken as spinning discs on a potassium bromide base and of aqueous solution in spinning cells. IR spectra were measured on a Perkin–Elmer 683 spectrometer as liquid paraffin mulls between potassium bromide plates. The ^{13}C NMR spectra were recorded by Miss Sue Johnson on a Brüker WM250 Fourier transform spectrometer at 62.9 MHz. Carbon, nitrogen and hydrogen analyses were carried out by Mr K. Jones of the Microanalytical Department, Imperial College. Peroxide analyses were performed by iodometric titration and potassium was analysed gravimetrically (as the tetraphenylborate).

STUDIES ON TRANSITION METAL PEROXO COMPLEXES—X.* THE NATURE OF PEROXOVANADATES IN AQUEOUS SOLUTION

NICHOLAS J. CAMPBELL, ANDREW C. DENGEL and WILLIAM P. GRIFFITH†

Inorganic Chemistry Laboratories, Imperial College of Science and Technology, London SW7 2AY, U.K.

(*Received* 6 *December* 1988; *accepted* 19 *December* 1988)

Abstract—The nature of the species formed in solutions of $[VO_4]^{3-}$, in excess H_2O_2 from pH 14 to acid, has been studied by Raman spectroscopy and ^{51}V NMR; polymerization processes are far simpler in the presence than in the absence of H_2O_2. The principal species present are likely to be $[V(O_2)_4]^{3-}$, $[VO(O_2)_3]^{3-}$, $[V(OH)(O_2)_3]^{2-}$, *cis*-$[VO_2(O_2)_2(H_2O)]^{3-}$, $[V_2O_3(O_2)_4]^{4-}$ or $[V_2(OH)O_2(O_2)_4]^{3-}$, $[VO(O_2)_2(H_2O)]^{-}$ and $[VO(O_2)(H_2O)_4]^{+}$. A brief Raman study is also reported of spectra of $[M(O_2)_4]^{3-}$ (M = Nb, Ta) in excess H_2O_2 from pH 11 to 7.

The nature of the species formed when aqueous solutions of the orthovanadate ion $[VO_4]^{3-}$ are acidified has been studied by a number of techniques,[2–7] including Raman spectroscopy,[4,5] ^{51}V NMR[6,7] and ^{17}O NMR.[6] The reaction sequence is complex, involving monomers, dimers, tetramers and decamers.[2] We have recently shown[8] by the combined use of Raman and NMR (^{95}Mo, ^{183}W) that polymerization processes for molybdate, $[MoO_4]^{2-}$, and tungstate, $[WO_4]^{2-}$, in the presence of aqueous H_2O_2, are far less complex than those in aqueous solution alone. Here, we present similar data for the $[VO_4]^{3-}$–H_2O_2–H_2O system, using as a guide the ^{51}V[9,10] and ^{17}O[9] NMR data of Howarth *et al.* with new ^{51}V NMR results; we have previously reported a very restricted Raman study of peroxovanadates in solution.[4] Although in such systems, NMR can give valuable information on the number of species present in solution, we seek to show here that, as with molybdenum peroxo complexes, the *combined* use of NMR and Raman can give useful information on the nature of such species. The technique of comparing profiles of Raman spectra of species with known structures together with profiles of solute species has been used, so we report first the vibrational spectra of some solid oxoperoxovanadates which have already been structurally characterized, and also attempt an assignment of vibrational modes for the $[V_2(OH)O_2(O_2)_4]^{3-}$ ion using isotopic substitution.

RESULTS AND DISCUSSION

(A) *Raman and IR spectra of peroxovanadates of known structures*

The structures of $(NH_4)_4[V_2O_3(O_2)_4]$[11,12] and $(NH_4)_3[V_2(OH)O_2(O_2)_4]$[13] have been studied by X-ray single crystal analysis, and there is a brief mention of the X-ray crystal structure of $(NH_4)_3[V(O_2)_4]$.[12]

For assignments of Raman and IR bands we use commonly accepted mode descriptions: stretching vibrations [ν(V=O)] of terminal V=O bonds in VO and *cis*-VO_2 units will occur near 900 cm^{-1} with their deformations δ(V=O) near 320 cm^{-1}.[14] For the triangular $V(O_2)$ unit, the O—O stretch [ν(O—O)] is expected near 880 cm^{-1}, with the asymmetric and symmetric $V(O_2)$ stretches {ν^{as}[$V(O_2)$] and ν^{s}[$V(O_2)$]} near 600 cm^{-1}.[15,16] For binuclear complexes containing bent  units, the asymmetric and symmetric V—O stretches, $\nu^{as}(V_2O)$ and $\nu^{s}(V_2O)$, might be expected to lie near 700 and 500 cm^{-1}, respectively, by analogy with the corresponding modes in $[Cr_2O_7]^{2-}$[17] and in $[M_2O_3(O_2)_4(H_2O)_2]^{2-}$ (M = Mo, W).[8] The IR

spectra of oxomono- and diperoxovanadates have been discussed by Schwendt.[18]

$K_3[V(O_2)_4]$. The Raman and IR spectra of this unstable purple compound are reported in Table 1; the IR spectrum has already been reported.[18]

The vibrational spectra are very simple, with ν(O—O), $\nu^{as}[V(O_2)]$ and $\nu^{s}[V(O_2)]$ appearing at 859, 623 and 571 cm^{-1} in the Raman. The IR band at 373 cm^{-1} may be a $V(O_2)$ deformation.

$(NH_4)_3[V_2(OH)O_2(O_2)_4]$ *and* $K_4[V_2O_3(O_2)_4]$. Salts containing $[V_2(OH)O_2(O_2)_4]^{3-}$ and $[V_2O_3(O_2)_4]^{4-}$ can be isolated from peroxovanadate solutions using the appropriate pH control.[19] Although our attempts to prepare the claimed $(NH_4)_4[V_2O_3(O_2)_4]$[11,12] gave either the known complexes $(NH_4)_3[V_2(OH)O_2(O_2)_4]$[13] or $(NH_4)[VO(O_2)_2(NH_3)]$,[20] we did succeed in making $K_4[V_2O_3(O_2)_4]\cdot 2H_2O$. By using ^2H_2O or $H_2{}^{18}O$ as solvent we were also able to isolate $K_3[V_2(O^2H)O_2(O_2)_4]$ and $(NH_4)_3[V_2(^{18}OH)^{18}O_2(O_2)_4]$, although partial deuteration only was achieved in the former case. By comparison of the Raman and IR spectra of the normal and isotopically substituted complexes and also by using our previous data[8] on the vibrational spectra of normal and isotopically substituted (^2H, ^{18}O) $K_2[M_2O_3(O_2)_4(H_2O)_2]$ (M = Mo, W), tentative assignments of some of the vibrational modes in $[V_2(OH)O_2(O_2)_4]^{3-}$ and $[V_2O_3(O_2)_4]^{4-}$ can be made. There are reports on the IR spectra of $M_4[V_2O_3(O_2)_4]$ (M = K,[16,18,19] NH_4[18,19]) and of $M_3[V_2(OH)O_2(O_2)_4]$ (M = K, NH_4 and Cs with deuteration data[18,19]), but no Raman spectra have been reported.

There is unlikely to be $^{18}O/^{16}O$ exchange for the peroxo ligands during isolation of $(NH_4)_3[V_2(^{18}OH)^{18}O_2(O_2)_4]$ from $H_2{}^{18}O$, so Raman and IR bands near 880, 610 and 520 cm^{-1} are assigned to ν(O—O), $\nu^{as}[V(O_2)]$ and $\nu^{s}[V(O_2)]$, respectively, since they are unaffected by ^{18}O-substitution. The greater intensity of the 520 cm^{-1} Raman band compared with that near 610 cm^{-1} suggests that the former arises from the symmetric $\nu(O_2)$ stretch (for molybdenum and tungsten peroxo complexes $\nu^{s}[M(O_2)]$ lies at high wavenumbers than $\nu^{as}[M(O_2)]$,[8] but for vanadium peroxo complexes the reverse situation obtains). In $K_3[V_2(OH)O_2(O_2)_4]\cdot 2H_2O$, an IR band at 1055 cm^{-1} shifts to 770 cm^{-1} on deuteration and we assign this to a V—O—H deformation mode, δ[V(OH)]; Wieghardt and Quilitzsch have similarly assigned a band at 996 cm^{-1}, shifting to 730 cm^{-1} on deuteration, for $Cs_3[V_2(OH)O_2(O_2)_4]$.[19] The bands near 970 and 320 cm^{-1} shift by some 50 and 6 cm^{-1}, respectively, on ^{18}O substitution and so are assigned to V=O stretches and deformations ν(V=O) and δ(V=O), respectively; similar bands and shifts were noted for $K_2[M_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ (M = Mo, W).[8] The assignments of $\nu^{as}(V_2O)$ and $\nu^{s}(V_2O)$ (the asymmetric and symmetric stretches of the V(OH)V bridge) are more difficult; we tentatively assign the IR band in $(NH_4)_3[V_2(OH)O_2(O_2)_4]$ at 635 cm^{-1} to $\nu^{as}(V_2O)$, since it shifts to 621 cm^{-1} on ^{18}O substitution, and the weak Raman band at 460 cm^{-1}, shifting on ^{18}O substitution to 446 cm^{-1}, to $\nu^{s}(V_2O)$. Assignments for $M^{I}_4[V_2O_3(O_2)_4]\cdot nH_2O$ (M = K, Cs) then follow. The profiles of their Raman and IR spectra are like those of $K_2[M_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$,[8] as might be expected in view of their structural similarities. Raman spectra of these species in solution are discussed below.

(B) *Raman and* ^{51}V *NMR spectra of peroxovanadates in aqueous solutions*

Solutions studied were from 1.0 to 0.1 M in vanadium and $[VO_4]^{3-}$; H_2O_2–V ratios were 5:1, 2:1 and 1:1. Most studies were carried out on solutions of 0.5 M in $[VO_4]^{3-}$ with a five-fold excess of H_2O_2 and, unless otherwise stated, it is on those solutions that the work described below was carried out, since Raman spectra for lower vanadium concentrations are difficult to measure. The pH of solutions was adjusted by the addition of HCl, though the use of $HClO_4$ or H_2SO_4 produced very little change in the positions of ^{51}V NMR resonances. Data for 0.5 M $[VO_4]^{3-}$ in 2.5 M H_2O_2 at different pH are summarized in Table 2.

It seems likely that, with the exception of the dodecahedral[12] $[V(O_2)_4]^{3-}$ ion, all the peroxovanadates involved are seven-coordinated;[11-13] in order to achieve this, the species postulated below have, in some cases, coordinated water molecules in their formulae, though it is not possible using the methods employed here to detect the presence of aqua ligands.

pH > 13.5. At these high pHs it seems likely that the unstable purple $[V(O_2)_4]^{3-}$ is the dominant species.[21] Although Raman spectra of such solutions were very difficult to record owing to the colour and decomposition, polarized bands at 883, 855 and 572 cm^{-1} were observed, likely to be due to ν(O—O) of $[V(O_2)_4]^{3-}$, ν(O—O) of OOH^- and $\nu^{s}[V(O_2)]$, respectively, while a depolarized band at 621 cm^{-1} may be due to $\nu^{as}[V(O_2)]$. These values are reasonably close to those observed for the Raman spectrum of solid $K_3[V(O_2)_4]$. No ^{51}V NMR spectra could be recorded at these high pHs owing to problems of solution decomposition, but Howarth assigned a shift of δ −737.6* to the species.[9] This

* Relative to $VOCl_3$ (δ = 0 ppm). All ^{51}V spectra are quoted relative to this standard.

[a] Frequencies in cm^{-1}; Raman data or *IR. Relative Raman intensities in parentheses; polarized bands underlined, otherwise depolarized.
[b] Shifts (δ) in ppm relative to $\delta = 0$ for $VOCl_3$. Line intensities at halfwidth in italicized parentheses.

tetraperoxovanadate is likely to be the most highly peroxidated species present; the existence of the reported bright-red "$NH_4 \cdot VO_3 \cdot 6H_2O_2$"[22] could not be verified.

pH 13.5–10. At pH 13.5 a number of new Raman bands appear: polarized bands at 981 and 975 cm^{-1}, clearly due to ν(V═O), and a depolarized band at 316 cm^{-1} probably arising from δ(V═O). The ν(O—O) band at 883 cm^{-1} shifts to 891 and 881 cm^{-1}, and $\nu^s[V(O_2)]$ to 536 cm^{-1}. Both 0.5 and 0.1 M $[VO_4]^{3-}$ solutions show ^{51}V NMR shifts at −838, −763 and −742 ppm at pH 13, with the −838 and −742 ppm shifts apparent only when excess H_2O_2 is present. Howarth *et al.* have assigned shifts close to these values to $[VO(O_2)_3]^{3-}$, $[VO_2(O_2)_2]^{3-}$ and $[V(O_2)_4]^{3-}$, respectively.[10] Although we have shown that the claimed "triperoxo" species $K_3[V(O_2)_3ox] \cdot H_2O$ and $(NH_4)[V(O_2)_3bipy] \cdot 3H_2O$,[23] are perhydrates containing $[VO(O_2)_2ox]^{3-}$ and $[VO(O_2)_2bipy]^-$ anions,[24] there is an X-ray crystal structure of $(Me_4N)_2[V(OH)(O_2)_3] \cdot 4H_2O$.[25] There is also spectrophotometric evidence for the existence in solution of yellow $[VO(O_2)_3]^{3-}$ and $[V(OH)(O_2)_3]^{2-}$ species.[26] Therefore we agree with Howarth *et al.*[9,10] in assigning the δ −838 ppm resonance to $[VO(O_2)_3]^{3-}$ and suggest that the Raman bands at 981, 891, 536 and 316 cm^{-1} arise from this species. The δ −742 ppm resonance is very narrow, suggesting a very symmetrical environment about the metal, and could arise from the dodecahedral $[V(O_2)_4]^{3-}$.

As the pH drops below 13 these −838 and −742 ppm ^{51}V peaks give way to the resonance centred near −763 ppm, and this persists to pH 8. At these pH the Raman spectra in the ν(V═O) region show two polarized bands at 976 and 963 cm^{-1} (seen also in IR spectra of solutions), together with a new depolarized band near 950 cm^{-1}. For a species containing a VO_2 moiety, a *cis*-arrangement of the oxo ligands is likely, and for such a *cis*-VO_2 unit two Raman active ν(V═O) bands, one polarized and one depolarized, are expected.[14] Although the diperoxo complexes of vanadium so far examined by X-ray crystal structure analysis contain $VO(O_2)_2$ rather than $VO_2(O_2)_2$ units (e.g. the anions in $(NH_4)[VO(O_2)_2(NH_3)]$[20] and $K_3[VO(O_2)_2ox] \cdot H_2O$[27]) there is no intrinsic reason why complexes containing *cis*-$VO_2(O_2)_2$ units should not exist. We suggest that the species responsible for the relatively sharp δ −763 ppm resonance and the Raman bands near 963, 950, 890, 623 and 535 cm^{-1} arise from *cis*-$[VO_2(O_2)_2(H_2O)]^{3-}$, a coordinated water molecule bringing the coordination sphere to the normal seven for vanadium(V) peroxo complexes. IR spectra of solutions at these high pHs are difficult to record owing to decomposition in the beam.

In solutions with an H_2O_2–V ratio of 1 : 1, a ^{51}V shift at −621 ppm is seen, from pH 13 to 8. It disappears if more H_2O_2 is added and so could arise from a monoperoxo species such as $[VO_3(O_2)]^{3-}$ or a protonated form of this.

pH 10–1. Near pH 10 the sharp −764 ppm resonance gives way to a broader shift near −757 ppm and a new feature appears near −730 ppm, both persisting down to pH 4. Peaks in this region were also observed for aqueous solutions of $K_4[V_2O_3(O_2)_4]$ over the pH range 8–4, with a new peak appearing in the latter solution at −695 ppm. The broad −757 ppm feature is concentration-dependent, increasing in relative intensity with increasing vanadium concentration and so may arise from $[V_2O_3(O_2)_4]^{4-}$ or $[V_2(OH)O_2(O_2)_4]^{3-}$ (a resonance near −767 ppm has been assigned to $[V_2(OH)O_2(O_2)_4]^{3-}$[9]). Raman spectra of solutions of 0.5 M $[VO_4]^{3-}$ in 2.5 M H_2O_2, from pH 10 to 4, do not change drastically with pH, but the spectra of solutions of $K_4[V_2O_3(O_2)_4]$ or $(NH_4)_3[V_2(OH)O_2(O_2)_4]$ in water near pH 6 are similar in profile to those of the parent solids; three bands (978, 958 and 948 cm^{-1}) are observed in the ν(V═O) region, and bands at 890, 617 and 530 cm^{-1} are due to ν(O—O), $\nu^{as}[M(O_2)]$ and $\nu^s[M(O_2)]$, respectively, but no bands near 630 and 460 cm^{-1} assignable to $\nu^{as}(V_2O)$ and $\nu^s(V_2O)$ were seen. The −730 ppm peak is difficult to assign, but could perhaps arise from $[VO(OH)(O_2)_2(H_2O)]^{2-}$.

At pH 6.5 a new ^{51}V resonance appears near −697 ppm, persisting until pH 0.8, while the −757 and −729 ppm features become progressively less prominent and disappear near pH 4.5. We propose that this −697 ppm peak arises from $[VO(O_2)_2(H_2O)]^-$ (alkali metal salts of this have been isolated[28]) rather than the $[V(OH)_2(O_2)_2]^-$ suggested by Howarth *et al.*[9,10] (Russian workers have noted a resonance at −710 ppm assigned to $[VO(O_2)_2]^-$).[29] At pH 4, where this species becomes predominant, the Raman spectra become much simpler: there is only one polarized ν(V═O) band near 985 cm^{-1} with no depolarized band in the region, suggesting the absence of *cis*-VO_2 units. The polarized bands near 890 and 535 cm^{-1} may be assigned to ν(O—O) and $\nu^s[V(O_2)]$, respectively, while a depolarized band near 632 cm^{-1} is likely to arise from $\nu^{as}[V(O_2)]$. These bands are close in wavenumber to the IR and Raman bands observed for solid $K_3[VO(O_2)_2ox] \cdot H_2O_2$ and $(NH_4)[VO(O_2)_2bipy] \cdot 4H_2O$,[24] IR bands for solid $M[VO(O_2)_2(H_2O)]$ (M = K,[18,28] Cs,[18] NMe_4[18]), and in the IR spectrum of $K[VO(O_2)_2(H_2O)]$ in aqueous solution.[28] In further support of

our assignment of the −697 ppm peak to $[VO(O_2)_2(H_2O)]^-$, we note that aqueous solutions of another mono-oxodiperoxovanadate, $(NH_4)[VO(O_2)_2(NH_3)]$, show a single ^{51}V resonance at −695 ppm from pH 7 to 1. It has been observed that solutions of $[VO_4]^{3-}$ in excess H_2O_2 will epoxidize maleic and fumaric acids at pH 6;[30] the species responsible could well be $[VO(O_2)_2(H_2O)]^-$.

There is good evidence also from kinetic and mechanistic data for the existence in aqueous solutions of species containing $[VO(O_2)_2]^-$ units;[31,32] such a species may be responsible for the catalytic oxidation of diphenylsulphide by $[VO_4]^{3-}$ in excess H_2O_2.[31]

Below pH 1. As the pH drops below 3, the solutions of 0.5 M $[VO_4]^{3-}$ in 2.5 M H_2O_2 become markedly redder in colour, a change associated with the formation of the red complex containing the $VO(O_2)^+$ unit.[32] The Raman spectra of such solutions show polarized bands near 977, 890 and 542 cm^{-1} assigned to ν(V=O), ν(O—O) and $\nu^s[V(O_2)]$, respectively, and depolarized bands at 589 and 340 cm^{-1} assigned to $\nu^{as}[V(O_2)]$ and δ(V=O). At pH 1, two ^{51}V resonances are observed, at δ −665 and −543 ppm.

The origin of the −665 ppm resonance is not clear; Howarth tentatively assigned a shift at −650 ppm to $[V_2O(O_2)_4(H_2O)_2]$,[10] while Makarov *et al.* assign it to $[VO(O_2)]^+$.[29] It is only observed when excess H_2O_2 is present, disappearing if H_2O_2–V ratios of 2 : 1 or less are used, suggesting that it is a diperoxo species. The second resonance at −543 ppm may be assigned with confidence to a $VO(O_2)^+$ unit.[9,10] A number of oxomonoperoxovanadates containing the unit have been studied by X-rays (e.g. $[VO(O_2)pic(H_2O)_2]$[33] and $[VO(O_2)(pic)bipy]\cdot H_2O$;[34] pic = pyridine-2-carboxylate), and species containing $VO(O_2)^+$ have been implicated in oxidation reactions.[30] It is probably present in our system as $[VO(O_2)(H_2O)_4]^+$, which in concentrated HCl may well give species such as $[VO(O_2)Cl_n]^{1-n}$.

We conclude that several peroxovanadate species are formed when $[VO_4]^{3-}$ (or V_2O_5) are dissolved in excess aq. H_2O_2 over a wide pH range. However, the system is much simpler than that of $[VO_4]^{3-}$ over the same range in the absence of H_2O_2,[2-7] while being more complex than the corresponding $[MoO_4]^{2-}$–H_2O_2 and $[WO_4]^{2-}$–H_2O_2 systems.[8] Our Raman and ^{51}V NMR results are on the whole in agreement with those of Howarth *et al.*,[9,10] the main exception being the species giving a ^{51}V NMR resonance at −697 ppm; this they assign to $[V(OH)_2(O_2)_2]^-$, but we assign it on the strong evidence of the Raman spectra to $[VO(O_2)_2(H_2O)]^-$.

The span of ^{51}V NMR shifts for these peroxo- and oxoperoxovanadates is remarkable; possible reasons for its origin have been discussed.[9,35]

(C) *Raman spectra of peroxoniobates and peroxotantalates in aqueous solution*

Very high concentrations of H_2O_2 are needed to dissolve M_2O_5 or $K_8[M_6O_{19}]\cdot 16H_2O$ (M = Nb, Ta). However, we have prepared the known tetraperoxo salts $K_3[Nb(O_2)_4]\cdot 1/2H_2O$[36-39] and $K_3[Ta(O_2)_4]\cdot 1/2H_2O$,[37,38] repeated our earlier Raman and IR measurements on the solid salts[40] (see Table 1) and measured the Raman spectra of aqueous solutions of the salts from pH 11 to 7 in the presence of excess H_2O_2.

As with $K_3[V(O_2)_4]$, the spectra of the solids are easily assigned. At pH 11 the Raman spectrum profile of the aqueous solution (in the presence of H_2O_2) of $K_3[Nb(O_2)_4]$ is very similar to that of the solid; there is a single polarized band at 845 cm^{-1} assigned to ν(O—O), a polarized band at 540 cm^{-1} from $\nu^s[Nb(O_2)]$ and a depolarized band at 520 cm^{-1} from $\nu^{as}[Nb(O_2)]$. Unlike the vanadium system, though, there is little change in the Raman spectrum of the solution at pH 9 (pH was adjusted using HCl). However, at this pH, a gelatinous pale yellow precipitate starts to form; this precipitation is complete by pH 7. The Raman spectra of the supernatant solution remains essentially unchanged to pH 7, though the intensities of the peaks decrease, finally disappearing at pH 7. The precipitate is likely to be a complex containing the $[NbO_2(O_2)]^-$ moiety.[36-39] With $K_3[Ta(O_2)_4]\cdot 1/2H_2O$ the Raman spectrum of the aqueous solution at pH 10.7 is similar in profile to that of the solid salt, with polarized bands at 850 and 550 cm^{-1} assigned to ν(O—O) and $\nu^s[Ta(O_2)]$, respectively; $\nu^{as}[Ta(O_2)]$ appears at around 525 cm^{-1} as a shoulder. However, precipitation occurs at pH 10, presumably due to a species containing $[TaO_2(O_2)]^-$.[37,38] Thus, at relatively high pH at least, the peroxoniobate and peroxotantalate systems appear to be simpler than the peroxovanadates.

EXPERIMENTAL

$K_3[V(O_2)_4]$

This was prepared by a method based on that of Fergusson *et al.*[41] A solution of $K_3[VO_4]$ (2.0 g) in 30% H_2O_2 (12 cm^3) was cooled to ice-bath temperatures. The purple solution was added dropwise to ice-cold ethanol and the purple precipitate was filtered off, washed with ether and air-dried.

(Found: K, 39.3; O_2^{2-}, 42.8. Calc. for K_3VO_8: K, 39.5; O_2^{2-}, 43.2%.)

$(NH_4)[VO(O_2)_2(NH_3)]$

This was prepared by a method based on that of Drew and Einstein.[20] Divanadium pentoxide, V_2O_5 (1.82 g, 0.01 mol), was dissolved in 30% H_2O_2 (50 cm^3). To the deep red solution obtained, ammonium nitrate (1.60 g, 0.02 mol) was added, followed immediately by concentrated ammonium hydroxide, which was added dropwise until a bright yellow solution was obtained. This solution was allowed to stand for 12 h, after which bright yellow crystals were obtained. (Found: N, 16.6; H, 4.1; O_2^{2-}, 38.5. Calc. for $VO_5N_2H_7$: H, 16.9; H, 4.3; O_2^{2-}, 38.6%.)

$K_4[V_2O_3(O_2)_4]\cdot 2H_2O$

This was prepared by the method of Schwendt and Uskert.[42] Potassium vanadate, $K_3[VO_4]$ (0.69 g, 5 mmol), was dissolved in H_2O (20 cm^3), and 1 M KOH (5 cm^3) and 30% H_2O_2 (3 cm^3) were added. The yellow solution formed was mixed with ethanol (50 cm^3) and the resulting yellow precipitate was washed with ethanol and ether. (Found: K, 32.8; O_2^{2-}, 27.2. Calc. for $K_4V_2O_{13}H_4$: K, 33.2; O_2^{2-}, 27.2%.)

$K_3[V_2(OH)O_2(O_2)_4]\cdot 2H_2O$

This was prepared by the method of Wieghardt and Quilitzsch.[19] Divanadium pentoxide, V_2O_5 (0.91 g, 5 mmol), was dissolved with stirring in 30% H_2O_2 (30 cm^3) and H_2O (30 cm^3) and the solution filtered. The red solution was cooled in an ice bath and 1 M KOH (20 cm^3) slowly added. The yellow solution obtained was allowed to stand at 2°C for 24 h, after which a yellow solid was filtered off, washed with ethanol and ether, and air-dried. (Found: K, 26.8; O_2^{2-}, 29.8. Calc. for $K_3V_2O_{13}H_5$: K, 27.1; O_2^{2-}, 29.6%.)

$K_3[V_2(O^2H)O_2(O_2)_4]\cdot 2H_2O$

$K_3[V_2(OH)O_2(O_2)_4]\cdot 2H_2O$ (0.3 g) was dissolved in ^2H_2O (25 cm^3) with gentle warming and the yellow solution allowed to stand for 24 h. The solution was slowly evaporated to dryness on a vacuum line.

$Cs_3[V_2(OH)O_2(O_2)_4]$

This was prepared by the method of Wieghardt and Quilitzsch.[19] Divanadium pentoxide (0.91 g, 5 mmol) was dissolved, with stirring, in 30% H_2O_2 (30 cm^3). The solution was filtered and 0.5 M Cs_2CO_3 (20 cm^3) and 1 M CsCl (10 cm^3) solutions were added at room temperature. The solution was allowed to stand at 2°C for 24 h, after which a yellow powder was filtered off, washed with ethanol and ether, and air-dried. (Found: Cs, 57.8; O_2^{2-}, 18.8. Calc. for $Cs_3V_2O_{11}H$: Cs, 58.8; O_2^{2-}, 18.8%.)

$(NH_4)_3[V_2(OH)O_2(O_2)_4]\cdot 2H_2O$

This was prepared by the method of Wieghardt and Quilitzsch.[19] Ammonium metavanadate, $NH_4[VO_3]$ (2.35 g, 0.02 mol), was dissolved in concentrated ammonia (10 cm^3) and H_2O (80 cm^3) and cooled in an ice bath. 30% H_2O_2 (10 cm^3) and ethanol (30 cm^3) were added and the solution allowed to stand for 24 h. Yellow crystals were filtered off, washed with ethanol and ether, and air-dried. (Found: N, 11.6; H, 4.2; O_2^{2-}, 34.3. Calc. for $N_3H_{17}V_2O_{13}$: N, 11.4; H, 4.6; O_2^{2-}, 34.7%.)

$(NH_4)_3[V_2(^{18}OH)^{18}O_2(O_2)_4]\cdot 2H_2{}^{18}O$

$(NH_4)_3[V_2(OH)O_2(O_2)_4]\cdot 2H_2O$ (0.07 g) was dissolved under N_2 gas in $H_2{}^{18}O$ (98.4%, 1.0 cm^3) with very gentle warming. The solution was allowed to stand under nitrogen at room temperature for 24 h to facilitate exchange and was then evaporated to dryness *in vacuo*. The solid rapidly decomposed in air.

$K_3[Nb(O_2)_4]\cdot 1/2H_2O$

A sample of fresh Nb_2O_5 was obtained by the careful addition of $NbCl_5$ to an aqueous solution of KOH at 0°C. The Nb_2O_5 was filtered off, washed with cold H_2O and dried. Nb_2O_5 (2.0 g) and KOH pellets (3.4 g) were fused in a nickel crucible. The cooled melt was taken up in a minimum of H_2O and treated with 30% H_2O_2 (5 cm^3). The cloudy solution was heated for 15 min at 75°C on a water bath and filtered when hot. On cooling, the filtrate gave yellow–white crystals of the potassium tetraperoxoniobate, which were filtered off, washed with ethanol and air-dried. (Found: K, 33.6; O_2^{2-}, 37.4. Calc. for $HK_3NbO_{8.5}$: K, 33.9; O_2^{2-}, 37.0%.)

$K_3[Ta(O_2)_4]\cdot 1/2H_2O$

Fresh Ta_2O_5 (prepared by the careful addition of $TaCl_5$ to an aqueous solution of KOH at 0°C; 2.0 g) and KOH pellets (2.0 g) were fused in a nickel crucible. The cooled melt was taken up in minimum H_2O, treated with 30% H_2O_2 (5 cm^3) and heated at 75°C for 15 min. The cloudy suspension was filtered when hot. On cooling, the filtrate yielded

white crystals of potassium tetraperoxotantalate, which were filtered, washed with ethanol and air-dried. (Found: K, 26.2; O_2^{2-}, 28.9. Calc. for $HK_3O_{8.5}Ta$: K, 26.9; O_2^{2-}, 29.4%.)

Raman spectra were measured for solids on a KBr matrix as spinning discs or in solutions in spinning cells using a Spex Ramalog 5 spectrometer and a Coherent Radiation Innova 90 krypton-ion laser, with excitation at 6471 and 5648 Å. IR spectra were measured on a Perkin–Elmer 683 instrument, for solids as liquid paraffin films between caesium iodide plates or as aqueous solutions between calcium fluoride plates. ^{51}V NMR spectra were measured on a Brüker WM250 instrument at 65.7 MHz in 10 mm NMR tubes, with 5 mm inserts containing ^2H_2O for locking purposes.

Acknowledgements—We thank the SERC and Interox Chemicals Ltd for a CASE award to one of us (A.C.D.), and Mr R. Sheppard and Miss Sue Johnson for the NMR measurements.

(*Received* 24 *November* 1988; *accepted* 19 *December* 1988)

Abstract—For the complexing reactions: $MoO_4H^- + LH_n^q \rightleftarrows C$; a linear correlation of the form: $\log k = 4.50 + 0.42 \times pK$, is found for all kinetic data available (pK corresponds to the reaction $LH_{n+1}^{q+1} \rightleftarrows LH_n^q + H^+$). This empirical correlation is interpreted on the basis of a linear free energy relation. From the values of the slope, it is possible to infer that these reactions should proceed via I_a mechanisms. Similar results are found for WO_4H^-.

Much attention has been devoted to the investigation of complexing of molybdenum(VI) with different ligands.[1] The kinetics and mechanisms of complex formation between MoO_4^{2-} and several chelating ligands in aqueous solutions have been reported.[2–6] The formation of 1:1 complexes involves two reactive species of molybdenum(VI): MoO_4^{2-} and MoO_4H^-.

It is known[2] that the reaction pathways with no proton transfer do not contribute to reaction rates. This means that the interaction between MoO_4^{2-} and a fully deprotonated ligand, or between MoO_4H^- and a completely protonated ligand, do not take place.

Then all possible reaction pathways can be included in one of the following two groups of reactions:

Group I:

$$MoO_4^{2-} + LH_n^q \rightleftarrows C \quad n > 1 \qquad (1)$$

Group II:

$$MoO_4H^- + LH_n^q \rightleftarrows C \quad m > n > 0. \qquad (2)$$

Here LH_m and L will denote the fully protonated and deprotonated ligand species, respectively.

The experimental rates of complexation with unprotonated oxyanions—group I—decrease with increasing ligand basicity.[2] Empirical correlations between the rate and the ligand basicity can be found in the literature.[2–3] A correlation accounting for this behaviour based on theoretical considerations has been recently proposed by us.[4]

Whenever the comparison is possible, the same species of ligand reacts more rapidly,[7] about two to six orders of magnitude, with the protonated oxyanion than it does with the deprotonated one.

The difference in the orders of magnitude between rate constants for both groups of reactions has been explained as follows: the molybdate ion MoO_4^{2-} has a tetrahedral configuration.[8] Adding ligands to molybdate changes its configuration from tetrahedral to octahedral. Therefore reaction (1) involves an expansion of the coordination sphere. There are several evidences for the octahedral configuration of MoO_4H^- in solution.[9–12] Then it should be expected that reactions belonging to group II would be by a substitution mechanism.

The principal aim of this contribution is to find a correlation between the rate constants for group II reactions with the ligand basicity, through pK, and to propose an interpretation of such a correlation on the basis of linear free energy relations (LFER).

RESULTS AND DISCUSSION

All available experimental rate constants for group II reactions are listed in Table 1. The reacting ligand species LH_n and the pK value for the reaction $LH_{n+1}^{q+1} \rightleftarrows LH_n^q + H^+$ are also shown in this table.

Inspection of the values in Table 1 shows that

the rate increases with increasing ligand basicity. A linear regression fits the following equation:

$$\log k = 0.42\times \mathrm{p}K + 4.50. \quad (3)$$

Figure 1 shows a plot of log k vs pK.

For metal complexes it is well recognized that high thermodynamic stability is not necessarily correlated with kinetic inertness.[13] However, within a series of related reactions proceeding by a common mechanism, it is reasonable to expect a correlation between free energy of activation, $\Delta G^{\ddagger}$, and standard free energy, $\Delta G^{\ominus}$.[14] So, within the LFER approximation, the following expression can be written:

$$\Delta G^{\ddagger} = \alpha \Delta G^{\ominus} + \text{constant}, \quad (4)$$

where α is a parameter from which information regarding the reaction mechanism can be inferred.

For a series of octahedral substitutions, the α parameter of the Brønsted relationship (4), allows us to discriminate I_d or O mechanisms from the I_a mechanism. For the first two, $\alpha = 1$, while for the latter, $\alpha = 0.5$.[15]

Since ΔH makes a far larger contribution to ΔG than does $T\Delta S$, wherever a free energy relationship exists, the following relationship will also hold:[15]

$$\Delta H^{\ddagger} = \alpha \Delta H^{\ominus} + \text{constant}. \quad (5)$$

From the Arrhenius equation, $d\ln k/dT = E_m/RT^2$, with $E_m = \Delta H^{\ddagger} + RT$, and eq. (5), it is possible to obtain

$$d\ln k/dT = (\alpha \Delta H^{\ominus} + \text{constant})/RT^2. \quad (6)$$

A reaction equilibrium constant, K, and $\Delta H^{\ominus}$ are related through the Van't Hoff equation

$$d\ln k/dT = \Delta H^{\ominus}/RT^2. \quad (7)$$

By substituting eq. (7) into eq. (6) and integrating at constant temperature:

$$\log k = A - \alpha \log K. \quad (8)$$

In order to compare eq. (8) with eq. (3), where the ligand pK is involved, it should be assumed that the differences in the rate constant values in Table 1 arise from the enthalpy of ligand protonation, other contributions to $\Delta H^{\ominus}$ remaining constant. Therefore, by taking $\mathrm{p}K = -\log K$, the value of 0.42 is obtained for α.

Moreover, according to the α value, the octahedral substitutions should proceed via an I_a mechanism. This correlation could be accidental, but very similar results can be found for the series of octahedral substitutions in WO_4H^-. By employing

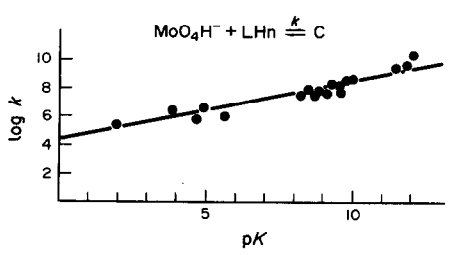

Fig. 1. Linear correlation between log k and pK values for the reaction of MoO_4H^- with different ligands.

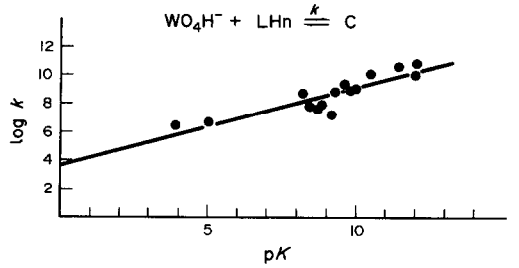

Fig. 2. Linear correlation between log k and pK values for the reaction of WO_4H^- with different ligands.

Kustin's data[2] a linear regression can be obtained with a slope of 0.54. A plot of $\log k$ involving WO_4H^- vs the ligand pK is shown in Fig. 2.

These results support an I_a mechanism for octahedral substitution in reactions of group II for MoO_4H^- and WO_4H^-.

(*Received* 7 *October* 1988; *accepted* 5 *January* 1989)

Abstract—Synthetic routes were developed for the preparation of clathrochelate complexes of ruthenium(II) utilizing a totally encapsulating ligand derived from dioxime ligands (1,2-cyclohexanedione dioxime, diphenylglyoxime and dimethylglyoxime) and various boron capping agents (boronic acids, borate esters, and boron halides). These complexes were fully characterized by ^{1}H NMR, UV–vis and IR spectroscopies. Cyclic voltammetric electrochemical experiments were performed and indicate that the stability of a ruthenium(III) clathrochelate complex is dependent on the nature of the substituent attached to the boron cap. Specifically, the stability increases with the length of the linear chain alkoxy groups attached to boron, and decreases for bulky alkoxy groups.

There has been extensive research concerning the coordination chemistry of ruthenium,[1–3] especially in the utilization of polydentate nitrogen donors.[4–16] In particular, the development of synthetic conditions for tris-diimine ruthenium(II) complexes, particularly tris-bipyridine ruthenium(II) complexes, has been of great current interest due to their chemical stability,[17] redox stability,[17,19,21,23,26,27] photochemical,[17–21,24,25] photocatalytic [17,20,22] and DNA cleaving properties.[27] Despite this focus on tris-diimine complexes, there are only three reported examples of totally encapsulated complexes of ruthenium(II) derived from polydentate nitrogen donors,[28–30] even though they offer possible increases in thermodynamic and kinetic stability.[31] It has been suggested that the reason for the scarcity of ruthenium(II) caged complexes is the synthetic difficulties encountered when utilizing a substitutionally inert metal centre such as ruthenium.[28–30] We wish to report the synthesis and characterization of a series of clathrochelate complexes of ruthenium(II), which utilize various dioxime ligands (1,2-cyclohexanedione dioxime, diphenylglyoxime and dimethylglyoxime) and boron capping agents containing aryl, halide, alkyl and alkoxy substituents (Fig. 1).

The clathrochelate structures were chosen as the totally encapsulating ligands because of their kinetic and thermodynamic stability,[32] their proven

utility in electron transfer reactions[33–36] and because of the variety of structural modifications on dioxime clathrochelates that are possible.[35,37–43] The ability to readily modify these clathrochelate ligands is important, because it allows for the correlation between ligand modification and complex stability.

EXPERIMENTAL

Materials

$Ru^{II}(DMSO)_4Cl_2$ and methylboronic acid were prepared as previously described.[44,25] All other chemicals were obtained commercially: phenylboric acid (Aldrich Chemical Co.), *n*-butylboronic acid (Lancaster Synthesis Ltd), boric acid (Fisher Scientific Co.), sodium borate (Fisher Scientific Co.), boron trifluoride diethyl etherate (Lancaster Synthesis Ltd), 1,2-cyclohexanedione dioxime (Aldrich Chemical Co.), diphenylglyoxime (Aldrich Chemical Co.) and dimethylglyoxime (Lancaster Synthesis Ltd). All solvents were purified by passage through a column of activated basic alumina immediately before use. All syntheses were carried out under nitrogen unless otherwise stated.

Measurements

Elemental analyses were conducted by Atlantic Microlabs. IR spectra in Nujol mulls were measured with a Perkin–Elmer 710 B IR spectrophotometer. Electronic absorption spectra were measured with a Bausch and Lomb Spectronic 2000 spectrophotometer equipped with a Houston Instrument Model 200 recorder, and the ^1H NMR spectra were recorded with a JEOL FX90Q Fourier transform NMR spectrometer. Cyclic voltammetric experiments were performed using methylene chloride as the solvent and tetra-*n*-butylammonium tetrafluoroborate as the supporting electrolyte, which was prepared by standard methods.[46] A platinum working electrode (Bioanalytical Systems), a platinum auxiliary electrode and a saturated sodium chloride calomel reference electrode (SSCE) were used for all electrochemical experiments. Cyclic voltammetry was conducted with an IBM EC/225 polarographic analyser equipped with a Houston Instruments Model 100 recorder.

Preparation of the complexes

Tris(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *diphenyldiborato*(2−)-N,N′,N″,N‴,N⁗,N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(BC_6H_5)_2$ (**1**).* A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and 90 mg of 1,2-cyclohexanedione dioxime ($NOXH_2$) (0.633 mmol) were added to 20 cm^3 of degassed THF, and were heated at reflux for 20 h, yielding a dark brown solution which was cooled to room temperature and reduced to dryness by rotary evaporation. To the brown residue, 10 cm^3 of methanol and 0.50 mg of phenylboric acid (0.410 mmol) were added, and the resulting mixture was stirred at room temperature for 2 h. The mixture was then rotary evaporated to dryness and purified by column chromatography, with neutral alumina as the stationary phase and methylene chloride as the eluent. The first yellow band was collected, reduced to a volume of 1 cm^3 by rotary evaporation and diluted with 2 cm^3 of hexanes to induce precipitation. Orange microcrystals were collected by vacuum filtration and washed with hexanes; yield (65 mg) 45%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di*-n-*butylborato*(2−)-N,N′,N″,N‴,N⁗,N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}n\text{-}C_4H_9)_2$ (**2**). This complex was prepared and purified as described for **1**, whereby 50 mg of *n*-butylboric acid (0.490 mmol) instead of phenylboric acid were used to yield the complex as orange microcrystals; yield (35 mg) 26%. Found: C, 46.8; H, 6.4. Calc. for $C_{26}H_{42}N_6O_6B_2Ru(0.5H_2O)$: C, 46.9; H, 6.5%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *dimethyldiborato*(2−)-N,N′,N″,N‴,N⁗,N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(BCH_3)_2$ (**3**). This complex was prepared and purified as described for **1**, whereby 25 mg of methylboronic acid (0.417 mmol) instead of phenylboric acid were used to yield the complex as an orange powder; yield (18 mg) 15%. Found: C, 42.0; H, 5.3. Calc. for $C_{20}H_{30}N_6O_6B_2Ru$: C, 41.9; H, 5.3%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato*-O : O′) *dimethoxydiborato*(2−)-N,N′,N″,N‴,N⁗,N⁗′] *ruthenium*(II), $Ru^{II}(NOX)_3(BOCH_3)_2$ (**4**). 100 mg of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and 90 mg of $NOXH_2$ (0.633 mmol) were added to 20 cm^3 of degassed methanol, and heated at reflux for 24 h. The transparent red solution was cooled to room temperature, treated with 25 mg boric acid (0.412 mmol) and heated to reflux for 15 min. While still under reflux, a suspension of 39 mg of sodium borate (0.103 mmol) in 10 cm^3 of methanol was then added dropwise over a period of 1 min through the top of the reflux condenser. Heating was continued for an additional 45 min. The solution was cooled and stirred at room temperature for 8 h. The existing solution was rotary evaporated to dryness and purified as for **1**. Orange microcrystals were collected by vacuum filtration;

* Improvement of synthesis reported in ref. 29.

yield (39 mg) 31%. Found: C, 39.6, H, 5.0. Calc. for $C_{20}H_{30}N_6O_8B_2Ru$: C, 39.7; H, 5.0%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *diethoxydiborato* (2−) - N, N′, N″, N‴, N⁗, N⁗′] *ruthenium*(II), $Ru^{II}(NOX)_3(BOC_2H_5)_2$ (**5**). This complex was prepared and purified as described for **4**, except a total of 30 cm^3 of ethanol was used instead of methanol, yielding the complex as orange microcrystals; yield (48 mg) 37%. Found: C, 41.8; H, 5.4. Calc. for $C_{22}H_{34}N_6O_8B_2Ru$: C, 41.7; H, 5.4%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di* - i - *propoxydiborato*(2−) - N,N′,N″,N‴,N⁗, N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}i\text{-}OC_3H_7)_2$ (**6**). A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol), 90 mg of $NOXH_2$ (0.633 mmol) and 25 cm^3 of 2-propanol were added to a round bottom flask, equipped with a reflux condenser and a Soxhlet extractor filled with activated 4 Å molecular sieves. The solution was heated at reflux for 20 h, cooled to room temperature, treated with 25 mg boric acid (0.412 mmol) and then heated at reflux for 15 min. While still under reflux, a suspension of 39 mg of sodium borate in 5 cm^3 of 2-propanol was rapidly poured directly into the reaction vessel, with continued heating for an additional 45 min. The final orange solution was cooled, and stirred at room temperature for 8 h. The existing suspension was vacuum filtered and the orange solid was purified as for **1**. Orange microcrystals were collected by vacuum filtration; yield (36 mg) 26%. Found: C, 43.5; H, 5.8. Calc. for $C_{24}H_{38}N_6O_8B_2Ru$: C, 43.6; H, 5.8%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di* - n - *propoxydiborato*(2−) - N,N′,N″,N‴,N⁗, N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}n\text{-}OC_3H_7)_2$ (**7**). A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and a 90 mg sample of $NOXH_2$ were added to 20 cm^3 of degassed THF, and were heated at reflux for 20 h yielding a dark brown solution that was rotary evaporated to dryness. The brown residue was treated with 20 cm^3 of 1-propanol and 25 mg of boric acid (0.412 mmol). The resulting solution was heated at 75°C for 15 min, and then 39 mg of sodium borate suspended in 5 cm^3 of 1-propanol were added dropwise over a period of 1 min directly to the reaction vessel. Heating was then continued for an additional 45 min. After heating, the dark brown solution was stirred at room temperature for 8 h. The solution was then rotary evaporated to dryness and purified as for **1**. The product was collected by vacuum filtration as orange microcrystals; yield (48 mg) 35%. Found: C, 43.7; H, 5.8. Calc. for $C_{24}H_{38}N_6O_8B_2Ru$: C, 43.6; H, 5.8%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di* - n - *butoxydiborato*(2−) - N,N′,N″,N‴,N⁗, N⁗′] *ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}n\text{-}OC_4H_9)_2$ (**8**). This complex was prepared as described for **7**, except a total of 25 cm^3 of 1-butanol was used instead of 1-propanol, and was removed by vacuum distillation instead of rotary evaporation. The product was purified as for **1**. The product was collected by vacuum filtration as dark orange microcrystals: yield (66 mg) 46%. Found: C, 45.2; H, 6.2. Calc. for $C_{26}H_{42}N_6O_8B_2Ru$: C, 45.3; H, 6.1%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di* - n - *pentoxydiborato*(2−) - N,N′,N″,N‴,N⁗, N⁗′]*ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}n\text{-}OC_5H_{11})_2$ (**9**). This complex was prepared as described for **7**, except a total of 25 cm^3 of 1-pentanol was used instead of 1-propanol. The product was collected by vacuum filtration as a yellow powder; yield (42 mg) 28%. Found: C, 46.9; H, 6.5. Calc. for $C_{28}H_{46}N_6O_8B_2Ru$: C, 46.9; H, 6.7.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *di*-n-*decoxydiborato*(2−)-N,N′,N″,N‴,N⁗,N⁗′] *ruthenium*(II), $Ru^{II}(NOX)_3(B\text{-}n\text{-}OC_{10}H_{21})_2$ (**10**). This complex was prepared as described for **7**, except a total of 25 cm^3 of 1-decanol instead of 1-propanol was used. The product was purified as for **1**. The product was collected as an orange powder; yield (45 mg) 25%. Found: C, 53.3; H, 7.8. Calc. for $C_{38}H_{66}N_6O_8B_2Ru$: C, 53.2; H, 7.8%.

[*Tris*(μ - 1,2 - *cyclohexanedione dioximato* - O : O′) *difluorodiborato*(2−) - N,N′,N″,N‴,N⁗,N⁗′] *ruthenium*(II), $Ru^{II}(NOX)_3(BF)_2$ (**11**). A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and 90 mg of $NOXH_2$ (0.633 mmol) were added to 20 cm^3 of degassed THF, and heated at reflux for 20 h. The existing brown solution was cooled to room temperature, treated with 1 cm^3 of distilled boron trifluoride diethyl etherate (25.32 mmol) and heated at reflux for 1 h. The existing suspension was cooled to room temperature and vacuum filtered. The orange solid was purified as for **1**. The product was collected by vacuum filtration as a yellow powder; yield (38 mg) 32%. Found: C, 36.6; H, 4.1. Calc. for $C_{18}H_{24}N_6O_6B_2Ru(0.5H_2O)$: C, 36.6; H, 4.3%.

[*Tris*(μ - 1,2 - *diphenyl* - 1,2 - *ethanedione dioximato* - O : O′)*di* - n - *buryldiborato*(2−) - N,N′,N″, N‴,N⁗,N⁗′]*ruthenium*(II), $Ru^{II}(DPG)_3(B\text{-}n\text{-}C_4H_9)_2$ (**12**). A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and 149 mg of diphenylglyoxime (0.633 mmol) were added to 40 cm^3 of degassed methanol. The solution was heated at reflux for 12 h, cooled to room temperature and treated with 0.50 mg of *n*-butylboronic acid (4.90 mmol). The existing brown solution was stirred at room temperature for 2 h, then rotary evaporated to dryness and purified as for **1**. The product was

collected by vacuum filtration as red microcrystals; yield (17 mg) 8.6%. Found: C, 63.0; H, 5.1. Calc. for $C_{50}H_{48}N_6O_6B_2Ru$: C, 63.1; H, 5.1%.

[*Tris*(μ - 1,2 - *diphenyl* - 1,2 - *ethanedione dioximato* - O:O′)*dimethoxydiborato*(2−) - N,N′,N″,N‴,N⁗,N⁗⁗]*ruthenium*(II), $Ru^{II}(DPG)_3(BOCH_3)_2$ (**13**). This complex was prepared as described for **4**, whereby 149 mg of diphenylglyoxime (0.633 mmol) instead of 1,2-cyclohexanedione dioxime and a total of 50 cm^3 of methanol were used, and the initial reflux time was 12 h. The product was purified as for **1**. The product was collected by vacuum filtration as a red powder; yield (25 mg) 14%. Found: C, 58.6; H, 4.1. Calc. for $C_{44}H_{36}N_6O_8B_2Ru$: C, 58.7; H, 4.0.

[*Tris*(μ - 2,3 - *butanedione dioximato* - O:O′)*di* - n - *butyldiborato*(2−) - N,N′,N″,N‴,N⁗,N⁗⁗] *ruthenium*(II), $Ru^{II}(DMG)_3(B\text{-}n\text{-}C_4H_9)_2$ (**14**). A 100 mg sample of $Ru^{II}(DMSO)_4Cl_2$ (0.206 mmol) and 72 mg of dimethylglyoxime (0.633 mmol) were added to 20 cm^3 of degassed methanol, and heated at reflux for 24 h. The solution was cooled to room temperature and treated with 0.50 mg of *n*-butylboronic acid (4.90 mmol). The existing dark orange solution was stirred at room temperature for 2 h, then rotary evaporated to dryness and purified as for **1**. The product was collected as yellow powder by vacuum filtration; yield (10 mg) 8.5%. Found: C, 41.3; H, 6.3. Calc. for $C_{20}H_{36}N_6O_6B_2Ru$: C, 41.5; H, 6.3%.

[*Tris*(μ - 2,3 - *butanedione dioximato* - O:O′) *dimethoxydiborato*(2−) - N,N′,N″,N‴,N⁗,N⁗⁗] *ruthenium*(II), $Ru^{II}(DMG)_3(BOCH_3)_2$ (**15**). This complex was prepared as described for **6**, whereby 72 mmol of dimethylglyoxime (0.633 mmol) instead of 1,2-cyclohexanedione dioxime and a total of 30 cm^3 of methanol were used, and the initial reflux time was 24 h. The product was purified as for **1**. The product was collected by vacuum filtration as orange microcrystals; yield (24 mg) 22%. Found: C, 32.0; H, 4.6. Calc. for $C_{14}H_{24}N_6O_8B_2Ru$: C, 31.9; H, 4.6%.

RESULTS AND DISCUSSION

Synthesis

The starting material $Ru^{II}(DMSO)_4Cl_2$ was a useful source of ruthenium(II), because of the substitutional lability of the DMSO and Cl^- ligands,[18,44] and because of the ease of $Ru^{II}(DMSO)Cl_2$ synthesis relative to $[Ru^{II}(DMF)_6](CF_3SO_3)_2$, which has been employed in the synthesis of other ruthenium(II) caged complexes.[28]

* Improvement of synthesis reported in ref. 29.

Notably, the use of $Ru^{II}(DMSO)_4Cl_2$ in place of $Ru^{III}Cl_3 \cdot 3H_2O$ in the synthesis of $Ru^{II}(NOX)_3(BC_6H_5)_2$ increased the product yield from 12 to 45%.*

The following equations depict the variety of reaction conditions necessary for the synthesis of ruthenium(II) clathrochelate complexes.

$$Ru^{II}(DMSO)_4Cl_2 + 3NOXH_2 \xrightarrow[THF]{\Delta}$$

$$\xrightarrow[40\,BF_3\cdot(OEt)_2]{} Ru^{II}(NOX)_3(BF)_2 \quad (1)$$

$$\xrightarrow[2n\text{-}C_4H_9B(OH)_2]{MeOH} Ru^{II}(NOX)_3(B\text{-}n\text{-}C_4H_9)_2 \quad (2)$$

$$\xrightarrow[2B(OH)_3,\ 0.5Na_2B_4O_7\cdot 10H_2O\ n\text{-}C_4H_9OH]{\Delta} Ru^{II}(NOX)_3(BO\text{-}n\text{-}C_4H_9)_2. \quad (3)$$

The general synthesis of transition metal clathrochelate complexes involves a template reaction among the transition metal, three dioxime ligands and a Lewis acid which caps the dioxime oxygens.[38] New reaction conditions were developed for some of the alkoxy-boron capped ruthenium(II) clathrochelate complexes (complexes **7**–**10**), since the alkoxide of the boron cap has a large effect on the overall reaction, in contrast to iron(II) clathrochelates.[38–43] These alkoxy-boron capped ruthenium(II) clathrochelates were synthesized in two separate reactions, employing the insertion of the dioxime ligands in THF, and the capping step in the appropriate alcohol. All alkoxy-boron capped ruthenium(II) clathrochelate complexes employed $B(OH)_3$ in combination with an alcohol to produce an alkoxy-borane capping agent. For the synthesis of $Ru^{II}(NOX)_3(BO\text{-}i\text{-}C_3H_7)_2$ (**6**) and $Ru^{II}(DMG)_3(BOCH_3)_2$ (**15**), it was necessary to remove the water liberated in the reaction through the use of a Soxhlet extractor filled with 4 Å molecular sieves, a safer and convenient method of water removal compared to water removal with a benzene–water–alcohol azeotrope.[38] Finally, the synthesis of $Ru^{II}(NOX)_3(BF)_2$ (**11**) involved the reflux of excess boron trifluoride diethyl etherate in THF. Attempts to prepare this complex by the methods employed by Rose[38] and Grzybowski[42] utilizing 1-butanol or methylene chloride, failed to yield the desired boron–halide capped clathrochelate.

^1H *NMR spectroscopy*

The ^1H NMR data for all complexes are reported in Table 1. The proton spectra provide data concerning the dioxime ligand used, and the substituents attached to the boron cap (Fig. 2). Firstly,

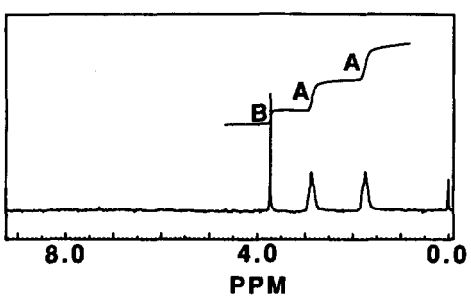

Fig. 2. ^{1}H NMR spectrum of $Ru^{II}(NOX)_3(B—OCH_3)_2$ in $CDCl_3$, where A = methylene protons, B = methyl protons.

the ^{1}H spectra for all ruthenium(II) clathrochelates complexes containing 1,2-cyclohexanedione dioxime complexes show two broad singlets, the first in the range 1.67–1.74 ppm and the other in the range of 2.80–2.88 ppm. These resonances are assigned to the methylene protons of the cyclohexane ring, which is consistent with the spectra of the free ligand and other clathrochelate complexes.[29,38,42] Similarly assigned is the multiplet associated with the diphenylglyoxime ligands ($\approx$ 7.3 ppm) and the singlet associated with dimethylglyoxime ligands ($\approx$ 2.3 ppm). Secondly, the other resonances present are from the aryl, alkyl and alkoxy moieties attached to the boron cap. The protons of the alkyl or aryl substituents show only slight variation in chemical shift compared with the alkyl boronic acid starting materials. The two resonances centred at 7.36 and 7.89 ppm of the ^{1}H spectrum of $Ru^{II}(NOX)_3(BC_6H_5)_2$ have been previously assigned to the phenyl hydrogen atoms.[29] In all ruthenium(II) clathrochelates which contain boron n-butyl substituents, the upfield multiplet can be assigned to the α-methylene and terminal methyl protons, while the downfield multiplet can be assgned to the β- and γ-methylene protons. This assignment is consistent with the ^{1}H NMR spectrum of n-butyl boronic acid, and the assignments made for iron(II) clathrochelate complexes.[42] The ^{1}H spectra of alkoxy-containing complexes show resonances reminiscent of the free alcohol, but with a downfield shift of 0.2–0.4 ppm, which suggests the ruthenium complex is more electron withdrawing than the hydrogen atom. This observation is consistent with that observed for alkoxy-boron capped iron(II) complexes.[38]

Electronic spectroscopy

The UV–vis spectral data for all complexes are given in Table 2. Complexes containing either 1,2-cyclohexanedione dioxime or dimethylglyoxime display similar electronic spectra which are dominated by an intense and complex absorbance

(ε = 16,000 M^{-1} cm^{-1}) in the region 382–399 nm (Fig. 3). The electronic spectra of ruthenium(II) clathrochelates containing diphenylglyoxime are quite different (Fig. 4), where two distinct, very intense bands ($\varepsilon \approx$ 24,000 and 23,000 M^{-1} cm^{-1}) centred in the ranges 409–410 and 456–459 nm, respectively, are observed. All of the ruthenium(II) clathrochelate complexes reported here display absorption bands in which neither the λ_{max} nor the extinction coefficient show great sensitivity to the various boron substituents. The electronic spectra of other tris-diimine ruthenium(II) complexes, such as $[Ru(bpy)_3]^{2+}$, also show intense complex absorption bands ($\varepsilon \approx$ 15,000 M^{-1} cm^{-1}) centred at 454 nm.[47] These absorbances are attributed to a Ru($d\pi$) → π^* (ligand) MLCT transition,[48] and by analogy, the absorbances present in the electronic

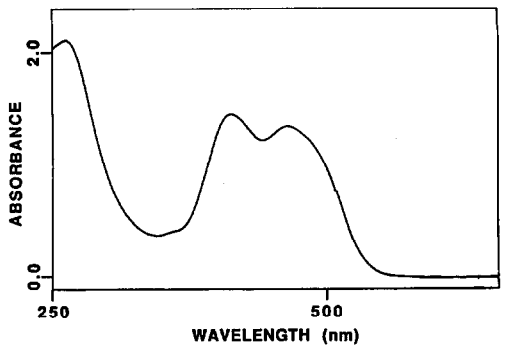

Fig. 4. UV–vis spectrum of $Ru^{II}(DPG)_3(B—OCH_3)_2$ (6.4×10^{-5} M) in CH_2Cl_2.

spectrum of ruthenium(II) clathrochelates can be assigned to charge-transfer bands. This assignment is reminiscent of those made for iron(II) clathrochelates.[38,43] It has also been observed that extinction coefficients of tris-diimine complexes are generally smaller than those of clathrochelate complexes,[49] which is also consistent with our results.

IR spectroscopy

Selected bands and their assignments are presented in Table 3. The assignments of the C=N (1500–1540 cm^{-1}), N—O (1210–1255 and 1060–1100 cm^{-1}) and B—O (1185–1200 cm^{-1}) stretches are consistent with assignments made for cobalt(II), cobalt(III) and iron(II) clathrochelate complexes.[32,38–40,43] The data in Table 3 demonstrate that there is virtually no effect on the frequency or the intensity of the N—O stretches when the substituents attached to the boron atom are varied from alkyl to fluoride or alkoxy groups (Fig. 5). It has also been observed that the absorbance for the C=N stretch appears at approximately the same frequency (1540 cm^{-1}) for the complexes containing either 1,2-cyclohexanedione dioxime or dimethylglyoxime, but for complexes containing diphenylglyoxime there is a slight shift to lower frequencies ($\Delta\nu \approx$ 40 cm^{-1}). All of the above observed trends have also been observed for analogous iron(II) clathrochelate complexes.[38,42,43] The absorbances for the B—O stretches for complexes containing alkyl or fluoride boron substituents could not be assigned because of their weak intensity and their masking by the absorbances for the N—O stretches.

Electrochemistry

The results of all cyclic voltammetric experiments are given in Table 4. The cyclic voltammetric exper-

[b] NOX = 1,2-cyclohexanedione dioxime, DPG = diphenylglyoxime, DMG = dimethylglyoxime.

iments were conducted to determine purity and as a method to correlate steric and electronic effects to the stability of the ruthenium(II) and ruthenium(III) metal centres associated with the clathrochelate complexes. To measure the stability of the electrochemically generated ruthenium(III) clathrochelates, the ratios of the cathodic current ($i_{p,c}$) and anodic current ($i_{p,a}$) associated with the ruthenium(III/II) quasi reversible couple were determined (Fig. 6). The $i_{p,c}/i_{p,a}$ ratio is a useful technique for determining stability, since this ratio approaches a value of one with increasing reversibility or stability associated with the oxidized species.[46]

From examination of Table 4 it is clear that the 1,2-cyclohexanedione dioxime complexes containing alkyl substituents attached to the boron atom (complexes **2**, **3**) have similar $i_{p,c}/i_{p,a}$ ratios (≈ 0.86) and therefore the ruthenium(III) centres possess similar stability characteristics. In examining the effect of varying the alkoxy-substituted boron cap on ruthenium 1,2-cyclohexanedione

[a] $E_{1/2} = (E_{p,a}+E_{p,c})/2$; ΔEp = peak separation; $i_{p,c}/i_{p,a}$ = peak current ratio. Conditions: 0.1 M n-Bu_4NBF_4 in CH_2Cl_2; Pt working electrode; SSCE reference electrode; scan rate = 100 mV s^{-1}.

[b] NOX = 1,2-cyclohexanedione dioxime, DPG = diphenylglyoxime, DMG = dimethylglyoxime.

dioxime complexes, the $i_{p,c}/i_{p,a}$ ratio increases in the order: O-n-$C_{10}H_{21}$ > O-n-C_5H_{11} > O-n-C_4H_9 > O-n-C_3H_7 > OC_2H_5 > OCH_3 ≈ O-i-C_3H_7; therefore the electrochemically generated ruthenium(III) clathrochelate complexes containing alkoxy-boron caps increase in stability with increasing length of the linear alkoxy chain. This phenomenon does not appear to be associated with electronic or steric size effects associated with the alkoxy substituents. Electronic effects are similar for the alkoxy substituents, where the $E_{1/2}$ values for the alkoxy-boron capped clathrochelate complexes are within 2 mV of each other. The observation that $Ru^{II}(NOX)_3(BO\text{-}n\text{-}C_3H_7)_2$ has a $i_{p,c}/i_{p,a}$ ratio of 0.86, and $Ru^{II}(NOX)_3(BO\text{-}i\text{-}C_3H_7)_2$ has a value of 0.77, suggests that bulky alkoxy substituents attached to boron decrease the ruthenium(III) stability. The effect of the dioxime ligand on the ruthenium(III) stability is seen upon observing the $E_{1/2}$ and $i_{p,c}/i_{p,a}$ ratios for analogous 1,2-cyclohexanedione dioxime (NOX), diphenylglyoxime (DPG), and dimethylglyoxime (DMG) complexes. The $E_{1/2}$ values increase in the following order: DPG > DMG ≈ NOX, and $i_{p,c}/i_{p,a}$ ratios are essentially identical (complexes **2**, **4**, **12**–**15**). These results demonstrate that the boron substituents have a distinct effect on the stability of the ruthenium(III) centre, while dioxime ligands show little effect.

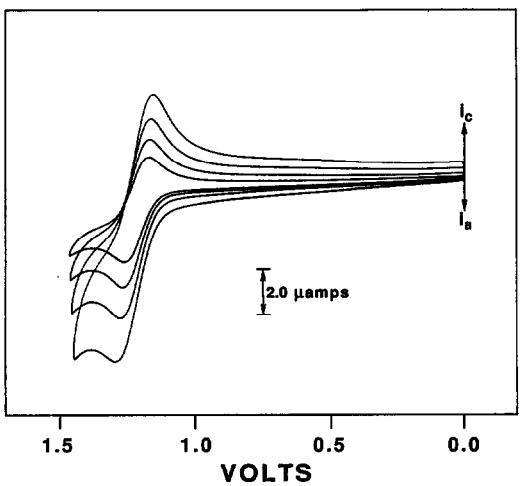

Fig. 6. Cyclic voltammogram of $Ru^{II}(NOX)_3(B\text{-}n\text{-}OC_{10}H_{21})_2$ in 0.1 M n-Bu_4NBF_4 in CH_2Cl_2. Scan rates: 50 mV s^{-1}, 100 mV s^{-1}, 200 mV s^{-1} and 400 mV s^{-1}; Pt working electrode, SSCE reference electrode.

CONCLUSIONS

In order to further investigate the chemistry of ruthenium(II) closed cage diimine complexes, synthesis methods have been developed for the preparation of a series of novel ruthenium(II) clathrochelate complexes. Characterization of these complexes by elemental analysis, ^1H NMR,

UV–vis and IR spectroscopies demonstrate that these complexes are closed cage diimine complexes containing ruthenium(II), three dioxime ligands and two boron capping ligands.

FORMATION OF PRIMARY AMIDE COMPLEXES OF Fe^+, Co^+ AND Rh^+ IN THE GAS PHASE

STEVEN W. BUCKNER† and BEN S. FREISER‡

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 29 *July* 1988; *accepted after revision* 18 *January* 1989)

Abstract—Primary amide complexes, M^+–NH_2, of Fe^+, Co^+ and Rh^+ are formed in thermal ion–molecule reactions using a Fourier transform mass spectrometer. Contrary to previous belief, these complexes have relatively high M—N bond strengths. These complexes were generated in reactions of various metal–ligand cations with NH_3. Collision-induced dissociation was used to probe the structures of these complexes. Mechanisms for the formation reactions are all proposed to proceed via oxidative addition of N—H bonds in NH_3 to the various metal centres, followed by reductive elimination of either H_2O or H_2.

Amide complexes of later transition metals are rare.[1–8] This has been attributed to the unfavourable interaction between the *p* electron density on the nitrogen atom and the filled *d* orbitals on the metal. However, the weak bond strength in these types of complexes which makes them so rare could be useful for catalytic reactions which involve transferring the NR_2 group. Many recent efforts to prepare amide complexes for later transition metals have involved placing electron-withdrawing substituents on the nitrogen to withdraw $p\pi$ electron density to help stabilize the M—N bond.[9,10] Though these types of complexes are interesting, it is also important to investigate complexes in which R is hydrogen or a hydrocarbon.

Recently, we have been investigating the chemistry of M—N bonds in gas-phase complexes. Initially, bond dissociation energies were obtained for $FeNH_2^+$ and $CoNH_2^+$ using ion–molecule bracketing techniques.[11] Surprisingly, these species were observed to have relatively high M—N bond strengths. In another study, the chemistry of MNH^+ (M = V, Fe) was investigated.[12] As expected, $D(V^+—NH)$ is much higher than $D(Fe^+—NH)$ [which is comparable to $D(Fe^+—NH_2)$]. The reactions of $FeNH^+$ with alkenes proceed by transfer of the NH group, which is the last step in a catalytic cycle for generating organic imines from NH_3, N_2O and alkenes.

Oxidative addition of N—H bonds has been a topic of renewed interest in recent years.[4,12–17] This type of reaction may have use in catalytic activation of NH_3. In the present paper, the preparation of some primary amide complexes of Rh^+, Fe^+ and Co^+ in the gas phase are reported along with mechanisms for their formation. These reactions are proposed to involve oxidative addition of N—H to the metal centres.

EXPERIMENTAL

All experiments were performed on a Nicolet FTMS-1000 Fourier transform mass spectrometer.[18] Briefly, the instrument is equipped with a 5.2 cm cubic trapping cell in a 0.9 T magnetic field produced by a Varian 15 in. electromagnet.

MOH^+,[19] FeH^+,[20] $MC_5H_6^+$[21] and MCH_3^+[22] were synthesized via reactions (1)–(4).

$$M^+ + CH_3NO_2 \longrightarrow MOH^+ + CH_2NO \quad (M = Fe, Co) \quad (1)$$

$$Fe^+ + CH_3NO_2 \xrightarrow{-NO} FeOCH_3^+ \xrightarrow[(Ar)]{CID} FeH^+ + CH_2O. \quad (2)$$

$$M^+ + c\text{-}C_5H_{10} \longrightarrow MC_5H_6^+ + 2H_2 \quad (M = Fe, Co, Ni, Rh) \quad (3)$$

† Present address: Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

$$M^+ + CH_3I \longrightarrow MCH_3^+ + I \quad (M = Fe, Co) \quad (4)$$

Neutral reagents for reactions (1)–(4) were admitted to the cell via a pulsed solenoid valve inlet system[23] and pumped away by a 5 in. diffusion pump in about 400 ms, permitting further interrogation of the selected metal–ligand ion. The product ions from reactions (1)–(4) were isolated by swept double resonance ejection pulses[24] prior to reaction with NH_3. Argon was always present at a static background pressure of $\approx 1 \times 10^{-5}$ torr to serve as a collision gas for collision-induced dissociation (CID) experiments. The FTMS–CID experiment has previously been described in detail.[25] Since it is a multi-collision process, rearrangements can occur prior to dissociation. Therefore, CID, as used in the present study, is only suggestive of likely structures and not conclusive for structural identification.[26a] The uncertainty in ion kinetic energy in the CID experiment is 35% at 1 eV, 10% at 10 eV and 5% at 30 eV.[26b]

Metal ions were produced by laser desorption–ionization of a pure foil of the appropriate metal using the fundamental output of a Quanta Ray Nd:YAG laser (10 ns pulse duration, $\approx$ 100 mJ pulse^{-1}).[27] Metal ions produced by this method have been shown to be kinetically and electronically excited.[28] The high static background pressure of argon used for CID also served to thermalize the ions prior to reaction.

RESULTS AND DISCUSSION

Singly-charged first row groups 6–12 atomic metal ions react at thermal energies with NH_3 only via slow condensation,[12] reaction (5).

$$M^+ + NH_3 \longrightarrow MNH_3^+. \quad (5)$$

However, Cr^+ which has been directly laser desorbed and not collisionally and radiatively cooled, reacts with NH_3 via reactions (6)–(8). After trapping the Cr^+ in $\approx 2 \times 10^{-5}$ torr argon for 1 s, the remaining Cr^+ reacts with NH_3 only via slow condensation.

$$(Cr^+)^* + NH_3 \longrightarrow CrNH_3^+ \quad (6)$$
$$\longrightarrow CrNH_2^+ + H^\cdot \quad (7)$$
$$\longrightarrow CrNH^+ + H_2. \quad (8)$$

Kinetic excitation of the cooled Cr^+ with an R.F. pulse at its cyclotron frequency (up to 140 eV lab energy) results in the reopening of pathways (7) and (8). Kinetic excitation results in formation of less than 0.1% of the bond cleavage products, whereas directly laser desorbed Cr^+ forms 0–4% of these products (depending on day-to-day fluctuations in experimental conditions). The higher reaction efficiency of directly laser desorbed Cr^+, relative to kinetically excited Cr^+, indicates it is reacting through a metastable electronic state. Cr^+ has previously been shown to react through metastable electronic states to dehydrogenate CH_4 in the gas phase.[29,30] Several cases have been documented in which specific electronic states have been observed to be much more effective at promoting endothermic reactions than kinetically excited metal ions.[31,32]

$FeNH_2^+$ and $CoNH_2^+$ can be synthesized by reaction of MOH^+ with NH_3, reaction (9)

$$MOH^+ + NH_3 \longrightarrow MNH_2^+ + H_2O \quad (9)$$
$$(M = Fe, Co).$$

Observation of reaction (9) together with ligand displacement reactions of MNH_2^+ indicate 79 kcal mol^{-1} > $D(Fe^+—NH_2)$ > 55 kcal mol^{-1} and 73 kcal mol^{-1} > $D(Co^+—NH_2)$ > 57 kcal mol^{-1}.[11] Interestingly, CH_3CN displaces $CH_3^\cdot$ from $CoCH_3^+$, but does not displace $NH_2^\cdot$ from $CoNH_2^+$, suggesting $D(Co^+—NH_2)$ is greater than $D(Co^+—CH_3)$, which in turn, is greater than $D(Co^+—H)$.[33] This is in contrast to saturated metal complexes in which M—N bond strengths are weaker than M—H or M—C bonds.[33,34]

FeH^+, which reacts with alkanes by initial C—H insertion followed by elimination of H_2 to form an activated Fe^+–alkyl complex,[20] reacts with NH_3 to form $FeNH_2^+$, reaction (10)

$$FeH^+ + NH_3 \longrightarrow FeNH_2^+ + H_2. \quad (10)$$

However, $FeCH_3^+$ is unreactive with NH_3. $FeCH_3^+$ has also been observed to be unreactive with alkanes.[35] It has been proposed that absence of reactivity of $FeCH_3^+$ with alkanes is due to an energetic barrier to oxidative addition to form an Fe^+–methyl–alkyl–hydride complex. A similar barrier may exist for the reaction of $FeCH_3^+$ with NH_3. Interestingly, $CoCH_3^+$ reacts with NH_3 only via displacement of $CH_3^\cdot$, reaction (11)

$$CoCH_3^+ + NH_3 \longrightarrow CoNH_3^+ + CH_3^\cdot. \quad (11)$$

$CoCH_3^+$ reacts with alkanes larger than ethane by initial insertion into a C—H bond, followed by elimination of CH_4 to form an activated Co^+–alkyl complex. The absence of bond insertion processes in reaction (11) is most likely due to rapid displacement of $CH_3^\cdot$ prior to bond insertion.

The bond activation processes presented in this paper can be rationalized by initial oxidative addition of an N—H bond to the metal centre.

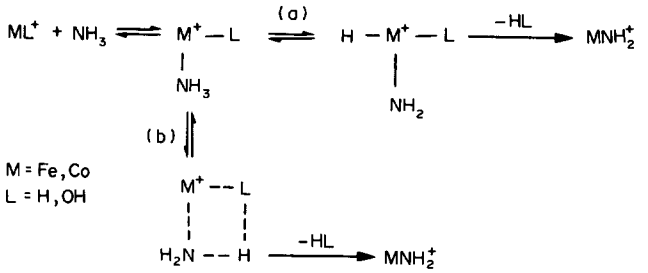

Fig. 1. Mechanism for formation of MNH_2^+ (M = Fe, Co).

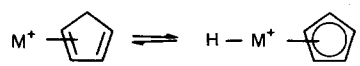
Oxidative addition of N—H bonds in NH_3 is rare and has only been reported twice in solution studies, for trinuclear osmium clusters[13] and recently for an iridium(I) complex.[8] Oxidative addition may also be occurring in the reactions of $CpTiC_5H_4TiCp_2$ and Cp_2MH_2 with NH_3.[14] In a recent gas-phase study from our laboratory, groups 3–5 metal ions were observed to exothermically dehydrogenate NH_3 via a mechanism which was proposed to include oxidative addition of N—H bonds.[12] A mechanism for reactions (9) and (10) is shown in Fig. 1. Route (a) proceeds by oxidative addition of an N—H bond, followed by reductive elimination of HL (L = ligand on the reactant). Route (b) involves concerted loss of HL through a four-centred σ-metathesis intermediate.[36] The highly unsaturated electron-rich nature of the metal centres used in the present study would greatly favour reaction pathway (a).

The reactions of $M(c\text{-}C_5H_6)^+$ (M = Fe, Co, Ni, Rh) with NH_3 are shown in eqs (12)–(15). $FeC_5H_6^+$ and $CoC_5H_6^+$ undergo bond insertion, reaction (13), whereas $RhC_5H_6^+$ and $NiC_5H_6^+$ only undergo attachment and ligand displacement reactions. The differences in reactivity can be rationalized by considering the structures of the reactant ions.



I II

Ion–molecule reaction studies have indicated $Fe(c\text{-}C_5H_6)^+$ and $Co(c\text{-}C_5H_6)^+$ exist in equilibrium between the cyclopentadiene (I) and the hydrido–cyclopentadienyl (II) complexes, while $Ni(c\text{-}C_5H_6)^+$ and $Rh(c\text{-}C_5H_6)^+$ only exist in the cyclopentadiene form.[37,38] Once the complex is in structure II, an incoming NH_3 can displace $H^\cdot$ or, after N—H bond insertion, can reductively eliminate H_2. Figure 2 shows a mechanism for reactions (13) and (14). CID of $Fe(c\text{-}C_5H_5)(NH_2)^+$ proceeds by reactions (16)–(19). Loss of NH_2 and C_5H_5 is consistent with the product ion structures proposed in Fig. 2.

Rh(propene)$^+$, generated in reaction (20), has been observed to undergo five H/D exchanges with D_2.[39]

	Fe	Co	Ni	Rh	
	3	34	65	100	(12)
	79	9	0	0	(13)
	15	2	0	0	(14)
	3	55	35	0	(15)

	10 eV	80 eV	
$Fe(C_5H_5)(NH_2)^+ \xrightarrow{Ar} FeC_5H_5^+ + NH_2$	83	38	(16)
$\rightarrow FeC_5H_4^+ + NH_3$	17	26	(17)
$\rightarrow FeNH_2^+ + C_5H_5$	0	15	(18)
$\rightarrow Fe^+ + NH_2 + C_5H_5$	0	21	(19)

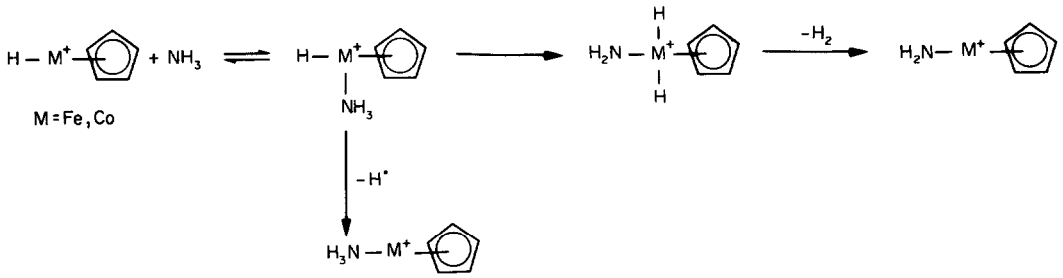


Fig. 2. Mechanism for the reaction of $M(c\text{-}C_5H_6)^+$ with NH_3.

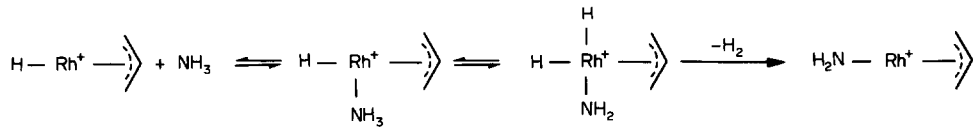

Fig. 3. Mechanism for the reaction of $RhC_3H_6^+$ with NH_3.

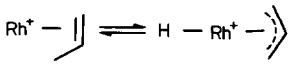
$$Rh^+ + C_3H_8 \longrightarrow Rh(C_3H_6)^+ + H_2 \quad (20)$$

This is due to the presence of an equilibrium between the propene (**III**) and hydrido–allyl (**IV**) structures for $Rh(C_3H_6)^+$. The D_2 can dissociate on the Rh^+ centre, and H/D exchange can occur via structure **IV**.



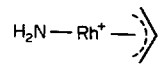
III **IV**

The only non-exchangeable H• is the secondary H atom on the propene ligand. Though Rh^+, Rh(butadiene)$^+$, and Rh(cyclopentadiene)$^+$ only react with NH_3 via slow attachment, Rh(propene)$^+$ reacts rapidly with NH_3 via reactions (21) and (22):

$$RhC_3H_6^+ + NH_3 \longrightarrow RhNH_3^+ + C_3H_6 \quad 75\% \quad (21)$$

$$\longrightarrow RhC_3H_5NH_2^+ + H_2 \quad 25\%. \quad (22)$$

The observation of reaction (21) indicates $D(Rh^+—NH_3) > D(Rh^+—C_3H_6) > 30$ kcal mol^{-1}.[40] The presence of the hydrido–allyl structure makes reaction (22) possible, as shown in Fig. 3. After initial attachment of NH_3 to the metal centre, an N—H bond dissociates on the metal centre. When $Rh(C_3H_6)^+$ is in the hydrido–allyl form, H_2 can be eliminated after dissociation of NH_3 on the metal centre. The final structure in this mechanism is an allyl–amide (**V**).

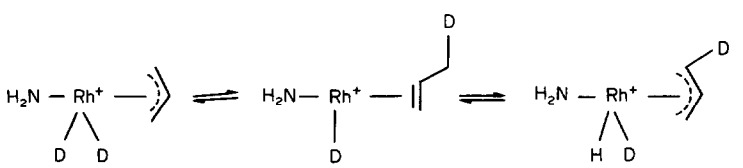


V

CID of the product ion from reaction (22) gives a variety of products, reactions (23)–(27).

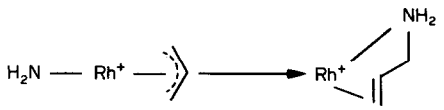
	24 eV lab energy	
$RhC_3H_7N^+ \xrightarrow{Ar} Rh^+ + C_3H_7N$	14%	(23)
$\longrightarrow RhNH_3^+ + C_3H_4$	17%	(24)
$\longrightarrow RhHCN^+ + C_2H_6$	9%	(25)
$\longrightarrow RhC_3H_4^+ + NH_3$	30%	(26)
$\longrightarrow RhC_3H_5N^+ + H_2$	30%.	(27)

The fragment ions do not include NH_2 or C_3H_5, which would be diagnostic for an allyl–amide structure. However, $RhC_3H_7N^+$ reacts with D_2 to undergo four H/D exchanges, which is indicative of an allyl–amide structure. A mechanism for the four H/D exchanges is illustrated in reaction (28). After initial dissociative attachment of D_2, a D• can migrate onto the allyl ligand to form propene. A terminal H• can migrate back onto the metal centre followed by elimination of HD. All four of the terminal hydrogen atoms on the allyl ligand are exchangeable.



(28)

Absence of direct cleavage in the CID results indicates that isomerization of $Rh(allyl)(NH_2)^+$ occurs prior to dissociation. Reaction (29) shows a rearrangement for the allyl–amide structure which would be expected to have a low barrier. This rearrangement is similar to the equilibrium between the hydrido–allyl and propene structures.



(29)

CONCLUSION

The synthesis of the three primary amide complexes, MNH_2^+ (M = Fe, Co), $M(c\text{-}C_5H_5)(NH_2)^+$ (M = Fe, Co) and $Rh(allyl)(NH_2)^+$, all proceed by reaction of NH_3 with a metal ion complex containing a σ-bound group, either $OH^\bullet$ or $H^\bullet$. CID proceeds by direct cleavage of $NH_2^\bullet$ for MNH_2^+ and $M(c\text{-}C_5H_5)(NH_2)^+$, but $Rh(allyl)(NH_2)^+$ under goes rearrangement prior to dissociation and direct cleavage of NH_2 is not observed.

MANGANESE COMPLEXES WITH 2-HYDROXY-3(3-METHYL-2-BUTENYL)-1,4-NAPHTHOQUINONE (LAPACHOL). REDOX CHEMISTRY AND SPECTROSCOPY IN DIMETHYLSULPHOXIDE

MARIO E. BODINI* and VERÓNICA ARANCIBIA

Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 6177, Santiago, Chile

(*Received* 7 *September* 1988; *accepted after revision* 18 *January* 1989)

Abstract—The redox behaviour of the ligand Lapachol has been studied in dimethylsulphoxide, and the conditions for the formation of the corresponding semiquinone have been determined. The combination of this semiquinone with manganese(II) in a 1 : 1 mole ratio forms a green complex which has been characterized by cyclic voltammetry, controlled-potential electrolysis, optical spectroscopy and magnetic susceptibility measurements. The metal centre in this complex has the characteristics of manganese(III), indicating an intramolecular charge-transfer between the metal and the ligand. The formation constant for the [Mn^{III}(TA)] complex (TA represents the trianion of the fully reduced ligand) has been evaluated voltammetrically and turns out to be 1.8×10^{15} M^{-1}. The direct interaction of manganese(III) with semiquinone leads to disproportionation yielding manganese(II) and the free ligand. These results may be relevant to the mechanism of the oxygen evolution reaction in photosystem II of green plant photosynthesis.

For many years it has been known that manganese is an essential co-factor in a number of biological systems,[1] and it is particularly necessary for the catalysis of oxygen evolution in photosystem II.[2–5] In this case, manganese appears to serve as an electron-transfer agent in reactions with molecular oxygen. Because quinones are present in significant quantities in chloroplasts[6] and are thought to be involved in the primary reactions of Photosystem II,[7–9] a mechanism has been proposed in which manganese exists in the oxidation states II, III and IV, and a catechol–semiquinone–*ortho*-quinone system is bound to this metal centre.[1]

Considering that the most abundant naturally occurring quinones are *para*-quinones,[10] we have decided to study the redox chemistry of a series of manganese complexes with these quinones in order to understand the interaction of these ligands with manganese.[11]

In this work, we report our results for the manganese complexes with 2-hydroxy-3(3-methyl-2-butenyl)-1,4-naphthoquinone (Lapachol), a naturally occurring *para*-quinone with a hydroxyl group in position 2, which enhances its binding ability. The manganese(II) complex in its reduced form has been evaluated.

All the studies have been carried out in dimethylsulphoxide, which is a solvent that stabilizes the radical species formed after the reduction of the quinone.

The electron delocalization in the deprotonated form of the ligand may lead to resonant structures corresponding to the *ortho*- and *para*-quinone configurations. Therefore, the redox chemistry of these complexes may correlate with the catechol analogues reported in the literature.[12–15]

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Tacussel Model PRT 20-2X potentiostat/galvanostat with Model GSTP wave generator) was used for the cyclic voltammetric and controlled-potential electrolysis experiments.

* Author to whom correspondence should be addressed.

A current integrator based on operational amplifiers was used as a coulometer in the controlled-potential electrolyses. Cyclic voltammograms were recorded on a Hewlett–Packard Model 7004 A X-Y recorder.

The electrochemical cell was equipped with a Beckman platinum-inlay working electrode (area 0.23 cm^2), a platinum coil auxiliary electrode, and an Ag/AgCl reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.000 V vs SCE.[16] The latter was contained in a Pyrex tube with a soft-glass cracked tip; this electrode was placed inside a Luggin capillary. For controlled-potential electrolysis, a platinum mesh working electrode was employed.

A Beckman Model ACTA CV spectrophotometer was used for UV–vis spectrophotometric measurements. The magnetic susceptibility measurements were made with a Varian XL-100 NMR spectrometer using the method of Evans,[17] as modified by Retting.[18] Diamagnetic corrections were made.[19]

Air-sensitive compounds were handled in a glove bag (Aldrich) under a nitrogen atmosphere and the oxygen content was monitored with a Beckman Model Monitor II oxygen analyser.

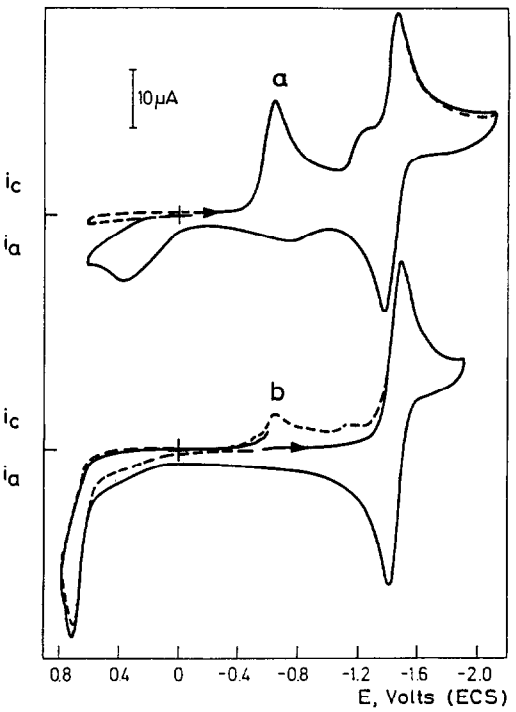

Fig. 1. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of solutions that are 1 mM in Lapachol (a); and 1 mM in Lapachol and 1 mM in TEAOH (b).

Reagents

The reagents for the investigation and syntheses included $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), 2-hydroxy-3(3-methyl-2-butenyl)-1,4-naphthoquinone (Lapachol) (Aldrich), tetraethylammonium hydroxide (TEAOH) (25% in methanol, Eastman), tetramethylammonium chloride (Aldrich), and tetraethylammonium perchlorate (TEAP) (G. Frederick Smith). Aldrich Gold Label grade solvents were used without further purification for all of the experiments. High purity argon gas was used to deaerate solutions.

Because the solvation water of the $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ salt interfered with the stoichiometric formation of the complexes under study, $[Mn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea)[20] was used in all the experiments in which the manganese(II) complexes were formed *in situ*. As a source of manganese(III), $[Mn^{III}(Urea)_6][ClO_4]_3$[21] was used in all the experiments.

RESULTS AND DISCUSSION

In DMSO, the cyclic voltammetric behaviour of Lapachol (HONQ), and of its corresponding monoanion (ONQ^-) in the presence of an equimolar amount of TEAOH is illustrated in Fig. 1.

The ligand exhibits an irreversible reduction peak at −0.65 V vs SCE [Fig. 1(a)], a sort of shoulder which can be associated with a second irreversible reduction process at −1.27 V vs SCE, and then a couple with a cathodic peak at −1.47 V vs SCE, and the corresponding anodic peak at −1.38 V vs SCE. The latter couple can be considered as a quasi-reversible system, because the peak separation is not the theoretical value predicted for a one-electron reversible process.

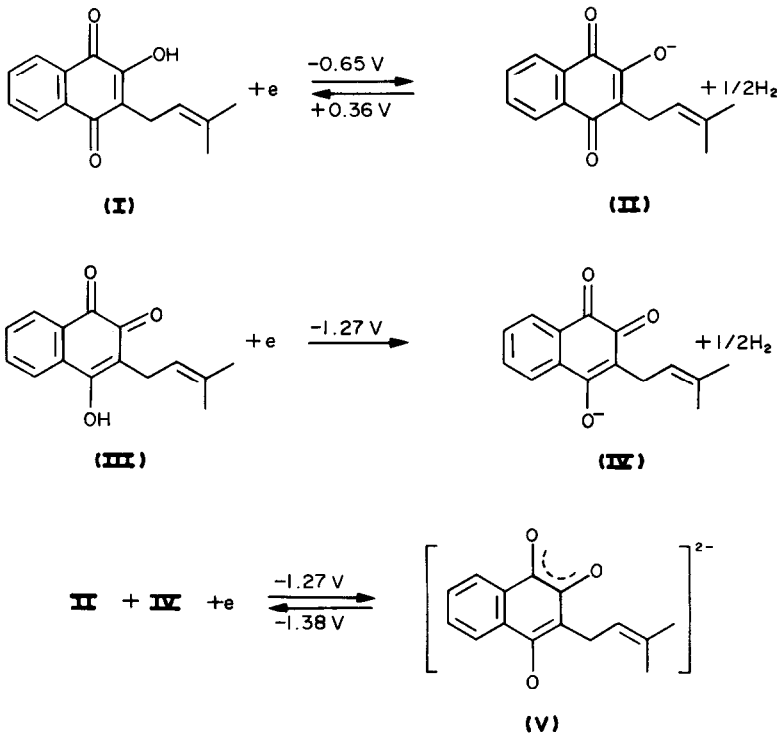
In the cyclic voltammogram, an irreversible anodic peak shows up at +0.36 V vs SCE, which corresponds to the oxidation of the product generated on the surface of the electrode after the reduction at −0.65 V vs SCE. If the potential scan direction is reversed at −1.00 V vs SCE, the anodic peak at 0.36 V vs SCE is observed as well. Upon addition of 1 equivalent of base [Fig. 1(b)], the reduction peak at −0.65 V vs SCE disappears, and so does the small reduction process at −1.27 V vs SCE. The redox process observed appears to be more reversible, with a peak separation of 60 mV ($E_c = 1.48$ V, $E_a = 1.42$ V vs SCE).

On the other hand, an irreversible anodic peak shows up at 0.70 V vs SCE, which is also present when the potential scan is made initially in the positive direction. Therefore, it must be concluded that it corresponds to the oxidation of the

monoanion of Lapachol, leading probably to a radical species which decomposes very readily.

Controlled-potential electrolysis at −0.85 V vs SCE of a solution of the ligand (HONQ) yields partially the monoanion, with 0.7 equivalents of charge transferred. After the electrolysis is complete, the cyclic voltammogram of the solution still shows the small cathodic peak at −1.27 V vs SCE. Further electrolysis of the resulting solution at −1.70 V vs SCE yields a brown solution, with 1.3 equivalents of charge transferred.

From these results we can conclude that the redox chemistry of this ligand can be represented by the following set of equations:



(1)

(2)

(3)

The presence of the *ortho*- and *para*-quinone isomeric forms of the ligand has also been observed in previous work carried out by our group with Lawsone,[11] indicating that in these cases the coexistence of the two isomers is inevitable in the solid compounds. A tautomeric equilibrium is not very likely, because after the complete reduction of the proton of one isomer, the cyclic voltammogram shows only the presence of the other form of the ligand and not a mixture of the two isomers.

When the two isomers are deprotonated, the anions correspond to resonance structures of a singles species, and that is the reason why only one cathodic peak is observed for the reduction to the corresponding semiquinone [Fig. 1(a) and (b)].

Figure 2(a) illustrates the cyclic voltammograms of Lapachol after controlled-potential electrolysis at −0.85 V vs SCE (monoanion), and Figs 2(b)–(d) illustrate the cyclic voltammograms for 1 : 3, 1 : 2 and 1 : 1 combinations of $[Mn^{II}(DMU)_6][ClO_4]_2$ and deprotonated Lapachol in DMSO. The results indicate that reduction of the ligand in the presence of an equimolar quantity of manganese(II) occurs at a peak potential that is 0.76 V (−0.71 V vs SCE) more positive than that for the ligand in a metal-free solution. The corresponding oxidation is observed at −0.48 V vs SCE. Therefore, the peak separation is 0.23 V, which can be considered to correspond to a quasi-reversible process. Controlled-potential electrolysis at −1.1 V vs SCE of a solution containing a 1 : 1 mole ratio of the anion of the quinone and manganese(II) indicates that one equivalent of charge is being transferred. So, a very stable complex of the semiquinone and manganese(II) is being formed. With respect to the stoichiometry, the cyclic voltammograms show that a 1 : 1 complex is formed, because in any other mole ratio the excess of the ligand is observed.

The other peaks in the cyclic voltammograms correspond to the excess of the ligand.

Figure 3 illustrates the UV–vis spectra of the different forms of this ligand. It can be observed that Lapachol presents absorption maxima at 225 nm (ξ = 20,000 cm^{-1} M^{-1}) corresponding to the benzene ring, another maximum at 248 nm (ξ = 13,400 cm^{-1} M^{-1}) associated to the quinonoid

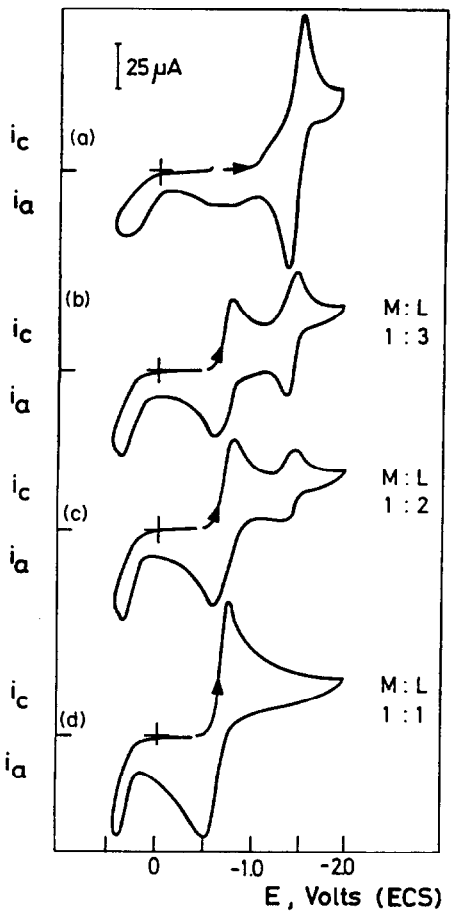


Fig. 2. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of a 3 mM solution of Lapachol after complete electrolysis at −0.7 V vs SCE ($n = 0.7$), and after the addition of 1, 1.5 and 3 mM $[Mn^{II}(DMU)_6][ClO_4]_2$.

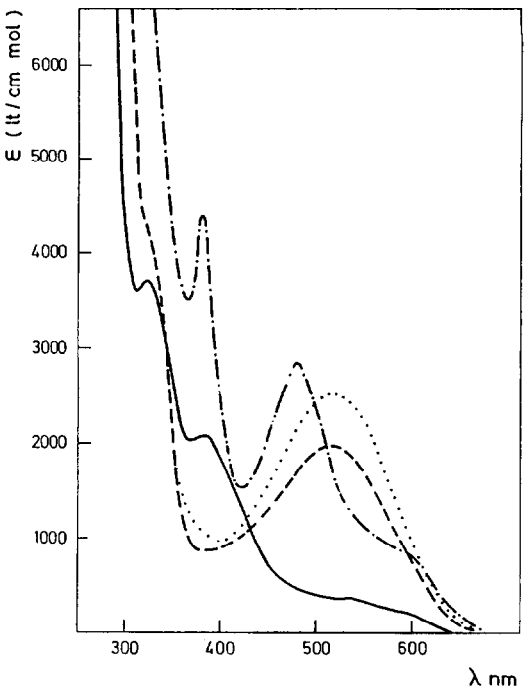

Fig. 3. Absorption spectra in Me_2SO of: (——) 1 mM Lapachol; (– – – –) 1 mM Lapachol after complete electrolysis at −1.1 V vs SCE ($n = 0.7$); (-----) 1 mM Lapachol after complete electrolysis at −1.5 V vs SCE ($n = 1.0$).

system,[22] and two less intense absorption maxima at 325 nm ($\xi = 3700\ cm^{-1}\ M^{-1}$) and at 385 nm ($\xi = 2100\ cm^{-1}\ M^{-1}$). The monoanion shows a well-defined visible absorption band at 515 nm ($\xi = 2500\ cm^{-1}\ M^{-1}$) which is responsible for the red colour of the solution. On the other hand, the semiquinone species shows well-defined absorption maxima at 236 nm ($\xi = 17{,}000\ cm^{-1}\ M^{-1}$), 305 nm ($\xi = 13{,}800\ cm^{-1}\ M^{-1}$), 380 nm ($\xi = 4000\ cm^{-1}\ M^{-1}$) and 480 nm ($\xi = 3000\ cm^{-1}\ M^{-1}$).

In the presence of manganese(II) in a 1 : 1 mole ratio, the UV–vis spectrum of the monoanion of Lapachol looks exactly the same, indicating that there is a very weak or no interaction at all between the metal ion and the ligand under these conditions.

Figures 4 and 5 show the UV–vis spectra of solutions of the semiquinone, and of this form of the ligand in the presence of 1/3, 1/2 and 1 equivalent of the metal ion. It can be observed that in both figures the spectra do not show the absorption maxima

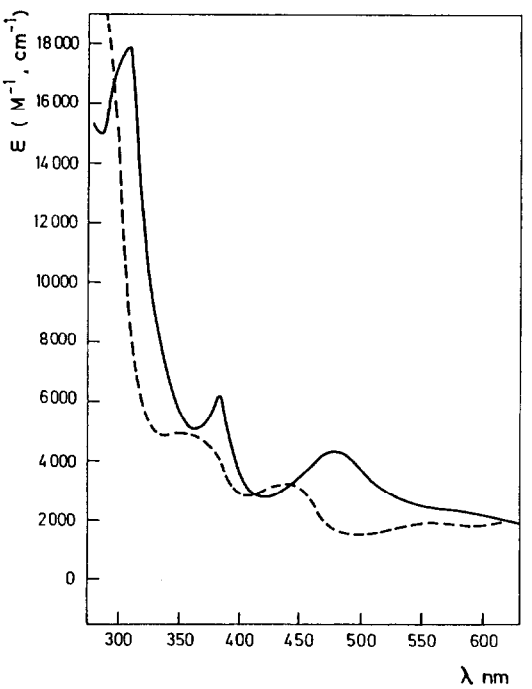

Fig. 4. Absorption spectra in Me_2SO of: (——) 1 mM semiquinone of Lapachol; (– – – –) 1 mM semiquinone of Lapachol + 1 mM $[Mn^{II}(DMU)_6][ClO_4]_2$

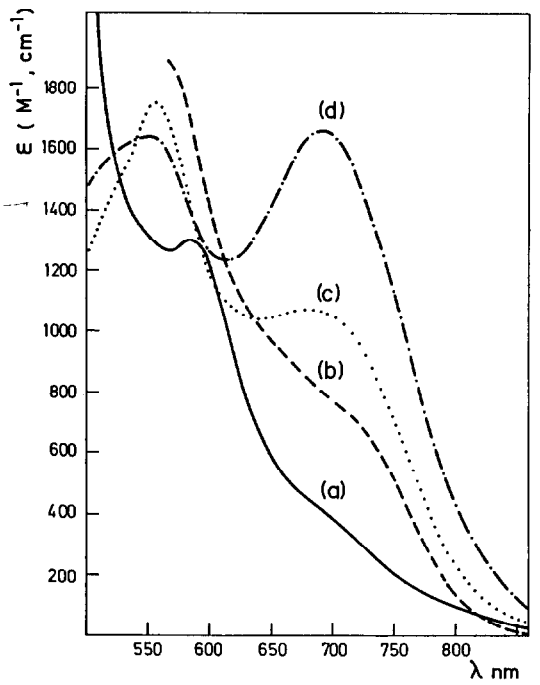

Fig. 5. Visible spectra in Me_2SO of: (a) 1 mM semiquinone of Lapachol; (b) same as a plus 1/3 mM $[Mn^{II}(DMU)_6(ClO_4)_2]$, (c) same as a plus 1/2 mM $[Mn^{II}(DMU)_6(ClO_4)_2]$, (d) same as a plus 1 mM $[Mn^{II}(DMU)_6][ClO_4]_2$.

corresponding to the presence of free semiquinone: 305, 380, 480 nm (Fig. 4) and 590 nm (Fig. 5), but instead present absorption maxima at 360 nm ($\xi = 4800$ cm^{-1} M^{-1}), 440 nm ($\xi = 3300$ cm^{-1} M^{-1}) and 683 nm ($\xi = 2200$ cm^{-1} M^{-1}), which are due to the bound semiquinone.

The magnetic susceptibility measurements for solutions that contain 5 mM $[Mn^{II}(DMU)_6][ClO_4]_2$ in DMSO are 5.9 μB as expected for a high-spin (d^5) manganese(II) ion. For a 5 mM solution of the semiquinone in DMSO (prepared by controlled-potential electrolysis) in the presence of 5 mM of manganese(II), the solution obtained presents a magnetic moment of 5.11 μB which indicates that the species in solution is a high-spin manganese(III) complex.

These results indicate that the metal centre is manganese(III) in the 1 : 1 complex. This is consistent with observations of Sawyer[23] and Pierpont[24] for manganese complexes with 3,5-di-*tert*-butyl-catechol. In these cases, the presence of a counter-ligand is needed to raise the energy of the filled manganese(II) *d* orbitals slightly above the semiquinone partially filled π^* orbitals, and cause electrons localized on the metal ion to move to the lower energy ligand-localized level. In the case of the ligand Lapachol, this effect is observed with no counter-ligand present in the complex, probably due to the lower energy of the semiquinone π^* orbitals as a consequence of the high delocalization of the π-system.

Therefore, the semiquinone binds to manganese(II) forming a 1 : 1 complex (green), which is generated on the surface of the electrode at -0.71 V vs SCE [Fig. 2(d)]:

$$ONQ^- + Mn^{II} + e^- \underset{-0.48\ V}{\overset{-0.71\ V}{\rightleftharpoons}} [Mn^{II}(ONSQ^-)] \downarrow [Mn^{III}(TA)], \quad (4)$$

or in solution when manganese(II) is combined with the semiquinone.

$$Mn^{II} + ONSQ^- \longrightarrow [Mn^{II}(ONSQ^-)] \longrightarrow [Mn^{III}(TA)].$$

Consideration of the voltammetric data for free $ONSQ^{2-}$ and ONQ^- (Fig. 1) and eq. (3), indicates that the thermodynamic redox potential for the $ONSQ^{2-}/ONQ^-$ couple ($E^{0\prime}_{12}$) has a value between $E_{p,a} = -1.38$ V vs SCE and $E_{p,c} = -1.47$ V vs SCE, a reasonable estimate is that:

$$E^{0\prime}_{12} \approx E_{p,a} - (\Delta E_{p/2});$$

$$-1.38 - 0.03 = -1.41 \text{ V vs SCE.}$$

In the case of the $[Mn(ONSQ^{2-})]^0/Mn^{II} + ONQ^-$ couple [Fig. 2(b)–(d)] and eq. (4), the thermodynamic redox potential ($E^{0\prime}_{22}$) must have a value between $E_{p,a} = -0.48$ V vs SCE and $E_{p,c} = -0.71$ V vs SCE. Therefore,

$$E^{0\prime}_{22} \simeq E_{p,a} - (\Delta E_{p/2});$$

$$-0.48 - 0.03 = -0.51 \text{ V vs SCE.}$$

Subtraction of eq. (4) from eq. (3) (with these estimated values for $E^{0\prime}_{12}$ and $E^{0\prime}_{22}$) gives:

$$Mn^{II} + ONSQ^{2-} \longrightarrow [Mn(ONSQ)]^0 \quad K_{f[MnONSQ]}.$$

The difference in formal potentials, $\Delta E^{0\prime}_{12,22}$, provides a direct measure of $K_{f[MnONSQ]}$:

$$\Delta E^{0\prime}_{12,22} = -0.90 = -0.059 \log K_{f[MnONSQ]}$$

and

$$K_{f[MnONSQ]} = 1.8 \times 10^{15} \ (25°C).$$

Cyclic voltammetry and spectroscopy of solutions in which manganese(III) is combined with the semiquinone indicate that there is a direct interaction that leads to the formation of manganese(II) and quinone.

In the cyclic voltammograms of Lapachol in the presence of manganese(III), the reduction of manganese(III) to manganese(II) is observed previously

and from then on the process is analogous to that described for manganese(II) and Lapachol.

The results of this study show that the redox behaviour of manganese complexes with *para*-quinones with a hydroxy group in position 2 is analogous to that found previously with *ortho*-quinone complexes. Manganese(II) binds strongly to the semiquinone, leading to the formation of a 1 : 1 complex in which the electrons in the metal–ligand molecular orbitals are localized closer to the ligand, giving manganese(III) character to the metal centre. This interesting property shown by a naturally occurring quinone such as Lapachol, may be relevant to the mechanism of the water evolution reaction of photosystem II of green plant photosynthesis.

SYNTHESIS AND PROPERTIES OF ORGANOTIN(IV) COMPLEXES OF DIMETHYLDITHIOCARBAMATE. THE CRYSTAL STRUCTURE OF $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)Cl_2$

OK-SANG JUNG, JONG HWA JEONG and YOUN SOO SOHN*

Division of Chemistry, Korea Advanced Institute of Science and Technology, Seoul 136-791, Korea

(*Received* 8 *November* 1988; *accepted* 19 *January* 1989)

Abstract—Organotin(IV) complexes, $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_xCl_{3-x}$ ($x = 1$–3), have been synthesized and characterized. The crystal structure of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)Cl_2$ (**1**) (monoclinic $P2_1/c$ space group; $a = 8.115(2)$, $b = 17.800(2)$, $c = 10.375(2)$ Å, $\beta = 111.41(2)°$, $Z = 4$, $R = 0.0396$) shows that the tin atom adopts a distorted octahedral geometry via the chelating dithiocarbamate ligand and intramolecular carbonyl oxygen-to-tin coordination. Spectral data (IR, and ^1H, ^{13}C and ^{119}Sn NMR) along with the cryoscopic data indicate that complex **1** has the same molecular structure both in the solid state and in solution. Other complexes, $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_2Cl$ (**2**) and $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_3$ (**3**), have also been characterized in terms of their spectroscopic properties. The spectral data suggest that in complexes **2** and **3** the intramolecular carbonyl oxygen-to-tin coordination is not allowed in order to accommodate two or three bidentate dithiocarbamate ligands.

Since the Hutton group [1,2] developed a novel route to "estertin" compounds they have received considerable attention because of the variety of coordination geometries about the tin atom and also their applicability as a PVC stabilizer with low mammalian toxicities.[3–6] The crystal structure of $CH_3OOCCH_2CH_2SnCl_3$[7] revealed that the central tin atom was penta-coordinated with the intramolecular carbonyl oxygen-to-tin coordination. However, the intramolecular coordination can be broken on coordination by external donor molecules, e.g. 2,2′-bipyridyl, 1,10-phenanthroline, etc.[8–10] In an effort to extend this chemistry, we have prepared the organotin(IV) complexes with the dimethyldithiocarbamate ligand (Me_2NCS_2), which is potentially bidentate.[11–14] In this paper, structural features of the isolated complexes both in the solid state and in solution are discussed based on their spectral properties together with the crystal structure of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)Cl_2$.

EXPERIMENTAL

All manipulations were performed under a dinitrogen atmosphere with the use of the standard Schlenk techniques. All chemicals were of reagent grade and used without further purification. The solvents used were dried by reflux over appropriate reagents and distilled before use. Chemical analyses were carried out by the Chemical Analysis Laboratory at KAIST. The molecular weights were determined cryoscopically in benzene using a Cryette A automatic cryoscope. The IR spectra in the 4000–400 cm^{-1} region were measured on KBr pellets with a Analect Instrument fx 6160 FT–IR spectrometer. All the NMR spectra were measured in chloroform solution. ^1H NMR spectra were recorded on a JEOL JNM–DMX 60 spectrometer, and ^{13}C and ^{119}Sn NMR spectra on a Bruker AM-200 operating at 50.32 MHz (^{13}C) and 74.63 MHz (^{119}Sn) in the pulse mode with Fourier transform at ambient temperature ($23 \pm 2°C$). The chemical shifts determined are relative to external Me_4Si (^{13}C) and Me_4Sn (^{119}Sn) for the indicated nuclei.

Preparation of $CH_3OOCCH_2CH_2SnCl_3$

This compound was prepared by the literature method.[1] Melting point: 69–70°C (ref. 1, 70°C). Found: C, 15.3; H, 2.2; Cl, 34.1. Calc. for $C_4H_7Cl_3O_2Sn$: C, 15.4; H, 2.3; Cl, 34.1%.

Preparation of $Na \cdot S_2CNMe_2 \cdot 2H_2O$

To an aqueous solution of $Na \cdot S_2CNMe_2$ prepared in the standard manner,[15,16] was added ethanol (ethanol/water = 3), and the mixture was left overnight. The white crystalline solid thus obtained was recrystallized from a H_2O–EtOH solvent pair (1 : 2) resulting in the dihydrate. Melting point: 108°C (ref. 16, 108°C). Found; C, 20.1; H, 5.6; N, 7.8. Calc. for $C_3H_6NS_2Na \cdot 2H_2O$: C, 20.1; H, 5.6; N, 7.8%.

Preparation of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)Cl_2$ (**1**)

A solution of $Na \cdot S_2CNMe_2 \cdot 2H_2O$ (0.90 g, 5 mmol) dissolved in 50 cm^3 of ethanol was added dropwise to an equimolar solution of $CH_3OOCCH_2CH_2SnCl_3$ (1.56 g, 5 mmol) in 50 cm^3 of ethanol. The reaction mixture was cooled to about 0°C, and the NaCl formed was removed by filtration. The solvent from the filtrate was removed under reduced pressure at 30°C. The resultant solid was recrystallized from a chloroform–petroleum ether solvent pair (1 : 1). The colourless crystalline solid (m.p. 165–167°C) was obtained in 85% yield. Molecular weight measured: 410.4 (theory: 396.9). Found: C, 21.1; H, 3.3; N, 3.5. Calc. for $C_7H_{13}Cl_2NO_2S_2Sn$: C, 21.2; H, 3.3; N, 3.5%.

Preparation of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_2Cl$ (**2**)

$Na \cdot S_2CNMe_2 \cdot 2H_2O$ (1.80 g, 10 mmol) in 100 cm^3 of ethanol was reacted with $CH_3OOCCH_2CH_2SnCl_3$ (1.56 g. 5 mmol) in 50 cm^3 of ethanol, in the same manner as used for the preparation of **1**. The resultant solid was recrystallized from a chloroform–petroleum ether solvent pair (1 : 1). The pale yellow crystalline solid (m.p. 119–120°C) was obtained in 82% yield. Molecular weight measured: 477.5 (theory: 469.6). Found: C, 25.4; H, 4.0; N, 5.9. Calc. for $C_{10}H_{19}ClN_2O_2S_4Sn$: C, 25.6; H, 4.1; N, 6.0%.

Preparation of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_3$ (**3**)

Reaction of $CH_3OOCCH_2CH_2SnCl_3$ (1.56 g, 5 mmol) with $Na \cdot S_2CNMe_2 \cdot 2H_2O$ (2.70 g, 15 mmol) in the mole ratio of 1 : 3 according to the same method as used for the preparation of **1**, followed by recrystallization from a chloroform–petroleum ether solvent pair (1 : 1), resulted in an orange crystalline solid (m.p. 169–170°C) in 81% yield. Molecular weight measured: 557.5 (theory: 548.3). Found: C, 28.0; H, 4.4; N, 7.5. Calc. for $C_{13}H_{25}N_3O_2S_6Sn$: C, 28.5; H, 4.6; N, 7.7%.

Crystallographic analysis of $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)Cl_2$

All X-ray crystallographic data were obtained on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated molybdenum radiation ($\lambda(K_{\alpha 1}) = 0.70930$ Å, $\lambda(K_{\alpha 2}) = 0.71359$ Å) at an ambient temperature of 23 ± 2°C. A well-formed crystal was glued to the interior of a thin-walled glass capillary, which was then sealed. Preliminary diffractometric investigations indicated monoclinic symmetry. From the observed extinctions $0k0$, $k = 2n+1$, and $h0l$, $l = 2n+1$, the space group was uniquely determined as $P2_1/c$ (C_{2h}^5 No. 14).[17] The lattice constants were determined by least-squares refinement of the diffraction geometry for 25 intense reflections having $13 \leqslant \theta_{Mo\text{-}K_\alpha} \leqslant 21$. Crystal parameters and procedural information corresponding to data collection and structure refinement for the complex are given in Table 1. The structure of complex **1** was solved by the conventional heavy atom method and difference Fourier techniques. Non-hydrogen atoms were refined by use of full-matrix least-squares procedures using SHELX-76, a system of computer programs for X-ray structure determination by G. M. Scheldrick.[18] All atoms were anisotropically refined. The final R indices were $R = 0.0396$, $R_G = 0.0508$.

RESULTS AND DISCUSSION

Reaction of $CH_3OOCCH_2CH_2SnCl_3$ with the dithiocarbamate ligand in appropriate molar ratios, followed by recrystallization, afforded the solid products, $CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_xCl_{3-x}$ ($x = 1$–3) (as established by chemical analysis, molecular weight determination and spectral data of IR, ^1H, ^{13}C and ^{119}Sn NMR), due to the metathesis reaction represented by the following equation:

$$CH_3OOCCH_2CH_2SnCl_3 + xNa \cdot S_2CNMe_2 \longrightarrow CH_3OOCCH_2CH_2Sn(S_2CNMe_2)_xCl_{3-x} + xNaCl \quad (x = 1\text{–}3).$$

All the products are crystalline solids with sharp melting points, which are soluble in benzene and in polar organic solvents such as chloroform, dichloromethane, acetone, tetrahydrofuran and dimethylsulphoxide, but insoluble in water and in saturated aliphatic hydrocarbons. These complexes have shown to be monomeric in benzene and are fairly air-stable.

Table 1. Crystal parameters and experimental details for CH_3OOC $CH_2CH_2Sn(S_2CNMe_2)Cl_2$

Formula	$C_7H_{13}Cl_2NO_2S_2Sn$
Formula weight	396.92
Crystal system	Monoclinic
Space group	$P2_1/c$

med via ester carbonyl oxygen-to-tin coordination, and a four-membered chelate ring from the bidentate dithiocarbamate ligand. Thus the tin atom is hexa-coordinate with the coordinating atoms S(1), S(2), C(4), Cl(2), Cl(1) and O(1) in a distorted octahedral arrangement. The small bite angle (70.1(1)°) of the dithiocarbamate ligand is in part responsible for the distortion of the octahedral geometry. The dithiocarbamate ligand is bonded to the tin atom in an anisobidentate fashion: Sn—S(1) and Sn—S(2) distances of 2.462(2) and 2.657(2) Å, respectively, are comparable with those of 2.48(1) and 2.79(1) Å in $Me_2Sn(S_2CNMe_2)Cl$.[13] The bond distances Sn—O(1) (2.436(6) Å), Sn—Cl(1) (2.413(2) Å) and Sn—Cl(2) (2.428(2) Å) are slightly longer than those (2.347(5), 2.357(2) and 2.303(2) Å, respectively) in $CH_3OOCCH_2CH_2SnCl_3$.[7] This indicates weak coordination, presumably due to the low Lewis acidity of the tin atom in the hexa-coordinate, compared with penta-coordinate complexes in the solid-state.

Spectroscopic properties of complexes **1**, **2** *and* **3**

The characteristic IR bands of complexes **1**–**3** relevant to their molecular structures are listed in Table 3.

Among the stretching modes, the ν(C=O) band in the 1650–1750 cm^{-1} region is known to depend on the nature of coordination of the carbonyl oxygen-to-metal.[8–10] The ν(C=O) bands of complexes **2** (1724 cm^{-1}) and **3** (1727 cm^{-1}) are in the same region as that of the free organic ester, CH_3OOCCH_3 (1740 cm^{-1}),[9] in which the carbonyl group is not coordinated, whereas the band of complex **1** (1652 cm^{-1}) exhibits a remarkable red shift from that of the organic ester. Such results clearly indicate that the coordination of the carbonyl oxygen-to-tin is maintained in complex **1** (see its crystal structure), but such a coordination is broken to accommodate two or three potentially bidentate dithiocarbamate ligands. The blue shifts of the ν(C—N) mode of complexes **1** and **2**, compared to that of the complex **3**, may be ascribed to the increase of Lewis acidity of the tin(IV) atom by the presence of the electronegative group (Cl). The appearance of the single band for ν(C—S) in the 950–1050 cm^{-1} region is indicative of the bidentate behaviour of the dithiocarbamate ligand.[19,20]

The ^1H and ^{13}C NMR data listed in Table 4, along with ^{119}Sn NMR data, also support the presence of carbonyl oxygen-to-tin coordination in complex **1**: $\delta(^1H) = 4.0$ ppm for $—OCH_3$ in complex **1** shows a downfield shift by 0.3 ppm compared to that of complexes **2** and **3**, and $\delta(^{13}C)$ values for the C=O and $—OCH_3$ in complex **1** are deshielded by approximately 6 ppm (C=O) and 3 ppm ($—OCH_3$), respectively, relative to those of complexes **2** and **3**.

^{119}Sn NMR spectroscopy has recently been found to be very useful for the elucidation of the nature of coordination in the dithiocarbamatotin(IV) complexes.[21-26] Even though for each complex with the same coordination number, some wide range of $\delta(^{119}Sn)$ values are observed depending on the different organic and dithiocarbamate groups attached to the tin atom, there is an approximate linear relationship between the $\delta(^{119}Sn)$ values and the coordination numbers of the complexes. Thus for the known dithiocarbamatotin(IV) complexes, $\delta(^{119}Sn)$ have been found to lie between -150 and -250 ppm in penta-coordinate, between -300 and -500 ppm in hexa-coordinate, and between -700 and -800 ppm in hepta-coordinate compounds.[21-27] The relationship $\delta(^{119}Sn) = -386.4$ ppm for complex **1** indicates that the tin atom is hexa-coordinated, implying that both the dithiocarbamate and ester groups act as chelating ligands. Assuming from the above-mentioned spectroscopic data that the ester group acts as monodentate in complexes **2** and **3**, the low $\delta(^{119}Sn)$ values of the complexes (-605.5 and -804.5 ppm, respectively) suggest that all the dithiocarbamate groups are bidentate, resulting in the hexa- and hepta-coordinate complexes, respectively. Although complexes **1** and **2** have the same hexa-coordinated tin atom, the ^{119}Sn chemical shift in complex **2** appears much further upfield than that in complex **1** owing to the partial change of donor atoms coordinated to tin(IV).

In conclusion, the spectroscopic and cryoscopic data in solution are completely in accordance with the crystal structure for complex **1**, and the similar complexes, **2** and **3**, are monomeric in solution and presumably are hexa- and hepta-coordinate, respectively, both in solution and in the solid-state.

PREPARATION AND CHARACTERIZATION OF MIXED AMIDO–PHOSPHIDO COMPOUNDS OF MOLYBDENUM(IV). A COMPARISON OF π-DONATING LIGANDS IN $Mo(NMe_2)_4$, $Mo(PCy_2)_4$ AND $[Mo(NMe_2)_2(PPh_2)_2]$ BASED ON X-RAY STUDIES

MALCOLM H. CHISHOLM,* CHARLES E. HAMMOND and JOHN C. HUFFMAN

(*Received* 23 *August* 1988; *accepted* 25 *January* 1989)

Abstract—Two preparative routes to mixed amido–phosphido complexes $[M(NMe_2)_{4-x}(PR_2)_x]$ have been investigated involving the addition of either R_2PH or $LiPR_2$ to hydrocarbon solutions of $Mo(NMe_2)_4$. The former method has allowed the replacement of two NMe_2 ligands and the isolation of the crystalline compound $[Mo(NMe_2)_2(PPh_2)_2]$. The latter synthetic approach has allowed the isolation of $[Mo(NMe_2)_3P(t\text{-}Bu)_2]$. Both compounds are monomeric in solution and in the solid-state $[Mo(NMe_2)_2(PPh_2)_2]$ adopts a structure closely related to those seen for $Mo(NMe_2)_4$ and $Mo(PCy_2)_4$. Specifically, the Mo—N (1.941(9) and 1.913(9) Å) and the Mo—P distances (2.260(3) and 2.264(3) Å) are (within the criteria of 3σ) identical to those seen in $Mo(NMe_2)_4$ and $Mo(PCy_2)_4$, respectively. Furthermore, the $Mo(NC_2)_4$, $Mo(PC_2)_4$ and $Mo(NC_2)_2(PC_2)_2$ units are all arranged in a common manner allowing the pnictinide-containing ligands to π-donate to the d^2 Mo(4+) centre. In this instance, NMe_2^- and PPh_2^- are both acting as 4-electron donors ($\sigma^2+\pi^2$) and only subtle distinctions based on the angles at nitrogen and phosphorus imply that the relative π-donor ability is $Me_2N^- > Ph_2P^-$. This result is compared to $[1,2\text{-}M_2(PR_2)_2(NMe_2)_4]$ structures where, based on M—P and M—N distances together with the angles subtend at nitrogen and phosphorus, the order is clearly established, $Me_2N^- > Ph_2P^-$. Crystal data for $[Mo(NMe_2)_2(PPh_2)_2]$ at −156°C: $a = 11.151(6)$, $b = 29.156(2)$, $c = 9.682(5)$ Å, $\beta = 119.99(2)°$, $Z = 4$, $d_{calc} = 1.351$ g cm^{-3} and space group $P2_1/c$

We recently reported the preparation and characterization of $[1,2\text{-}M_2(PR_2)_2(NMe_2)_4]$ (M≡M) compounds (M = Mo and W).[1] These exist in *anti*- and *gauche*-rotamers, both in solution and in the solid-state, and based on both considerations of M—P bond lengths and pyramidality at the phosphorus atom we determined that the relative π-donor ability of the ligands was in the order $Me_2N^- > R_2P^-$. In these compounds there are two metal *d* orbitals at each metal atom capable of accepting ligand p_π electrons, namely the d_{xy} and $d_{x^2-y^2}$ orbitals. The M≡M bond utilizes primarily metal d_{z^2} and d_{xz}/d_{yz} to form M—M σ and π_x/π_y orbitals, respectively.

In the case of the monomeric compounds of Mo(4+), $Mo(NMe_2)_4$[2] and $Mo(PCy_2)_4$,[3] the M—N/M—P distances are entirely consistent with formal double bonds and the sum of the angles at N and P are close to 360°. Moreover, the symmetry of the $M(EC_2)_4$ skeleton allows the N/P p_π orbitals to interact with vacant Mo d_{z^2}, d_{xy}, d_{xz} and d_{yz} atomic orbitals giving an effective 18-valence-shell electron-count at the metal centre.

In the compound $Cp_2Hf(PEt_2)_2$, there is only one metal hybrid orbital available for π-bonding and one phosphorus atom is trigonal planar and the other pyramidal with short, 2.488(1) Å, and long, 2.682(1) Å, M—P distances, respectively.[4] It should be noted that in this case the two C_2P planes are aligned such that only one phosphorus p_π orbital can interact with the Hf d_π orbital.

We were interested in comparing the metal–ligand bonding in mixed amido–phosphido compounds of formula $[Mo(NMe_2)_{4-x}(PR_2)_x]$. A number of hypothetical scenarios can be envisaged, including dimerization by either phosphido or amido bridge formation giving Mo≡Mo bonds. The latter are seen, for example, in the compounds $Mo_2(OPr^i)_8$[5] and $[Mo_2(NMe_2)_4(OR)_4]$, where R = 4-methylcyclohexyl and diisopropylmethyl, which rather interestingly choose to form NMe_2 bridges rather than OR bridges.[6] We describe here our preparation and characterization of mixed phosphido–amido compounds of Mo(4+).

RESULTS AND DISCUSSION

Synthesis

Two synthetic strategies were attempted. In one, R_2PH and $Mo(NMe_2)_4$ were allowed to react in a hydrocarbon solvent. This proved successful in the case of R = Ph but not R = Bu^t or Cy, presumably reflecting the acidity of the P—H bond.[7] In this way $[Mo(NMe_2)_2(PPh_2)_2]$ was isolated by crystallization. The second method involved the addition of $LiPR_2$ to a hydrocarbon solution of $Mo(NMe_2)_4$. Rather interestingly, and for reasons that are not apparent, this allowed PR_2-for-NMe_2 exchange when R = Bu^t but not when R = Ph. In any event, substitution only occurred once—quite probably for steric reasons—yielding $[Mo(NMe_2)_3P(t\text{-}Bu)_2]$.

Both new compounds are air-sensitive and must be handled in dry and oxygen-free atmospheres and solvents. They are monomeric in solution and may be crystallized from hexane.

Solid-state and molecular structure of $[Mo(NMe_2)_2(PPh_2)_2]$

A ball-and-stick drawing of the molecule is given in Fig. 1 and selected bond distances and bond angles are given in Table 1. The atom numbering scheme used in Table 1 is shown in Fig. 2.

The molecule has a virtual C_2 axis of symmetry and the geometry about molybdenum is similar to that found in $Mo(NMe_2)_4$ and $Mo(PCy_2)_4$. The $M(EC_2)_4$ units in the latter compounds (E = N and P) are oriented in an identical manner and the same arrangement is found for the $Mo(NC_2)_2$ unit in $[Mo(NMe_2)_2(PPh_2)_2]$. The C_2N and C_2P planes face one another in $[Mo(NMe_2)_2(PPh_2)_2]$ and are related by the virtual C_2 axis of symmetry. The M—N and M—P distances are short, indicative of double bonds, and are essentially identical to those found in $Mo(NMe_2)_4$ and $Mo(PCy_2)_4$, respectively. Evidently, since there are four available metal d_π

orbitals, these are used equally well by both NMe_2 and PPh_2 ligands. Only in an examination of the angles at the pnictinide atoms is there any evidence for differences in ligand-to-metal bonding and here the difference is extremely subtle.

A pyramidal (pseudo-tetrahedral) atom has 328.5° as the sum of its three angles, while for a trigonal planar atom the sum is, of course, 360°. These parameters are compared for all the compounds $Mo(NMe_2)_4$, $Mo(PCy_2)_4$ and $[Mo(NMe_2)_2(PPh_2)_2]$ in Table 2 and provide a consistent trend. For the mixed amido–phosphido compound, the sum of the angles at nitrogen (358.2°) is greater than in $Mo(NMe_2)_4$ (357.0°) and at phosphorus the sum (353.9°) is smaller than in $Mo(PCy_2)_4$ (355.5°).

Two other related measures of pyramidality are: (i) the angle between the M—P or M—N line and the respective PC_2 or NC_2 plane and (ii) the P or N atom distance out of the plane containing the MC_2 atoms. These parameters are compared in Table 3. It is worthy of note that even though the P—C bond distances are shorter for the PPh_2 ligand than the PCy_2 ligand, the distance that P deviates from the MoC_2 plane is greater for the $[Mo(NMe_2)_2(PPh_2)_2]$ compound than for $Mo(PCy_2)_4$.

Concluding remarks

In the mixed ligand compound $[Mo(NMe_2)_2(PPh_2)_2]$, both the amide and phosphide compete equally well as π-donor ligands, at least as can be judged by M—N or M—P distances. Only the very subtle changes noted in Tables 2 and 3 can be argued to support the view that the π-donating ability is in the order $NMe_2^- > PPh_2^-$. The difference between the bonding at the $(M{\equiv}M)^{6+}$ and Mo(4+) centres reflects the relative number of available metal d_π orbitals.

EXPERIMENTAL

Dry and oxygen-free solvents and atmospheres were used throughout. Manipulations and syntheses were carried out using standard dry-box and Schlenk techniques. NMR spectra were recorded in toluene-d_8 or benzene-d_6 on a Nicolet 360 (^{31}P) and a Varian 300 (^1H and ^{13}C) spectrometer. IR were recorded as Nujol mulls between CsI plates on a Perkin–Elmer 283 spectrophotometer. Elemental analyses were obtained from Alfred Bernhardt Mikroanalytische Laboratorium.

$[Mo(NMe_2)_2(PPh_2)_2]$

A flask was charged with $Mo(NMe_2)_4$ (509 mg), $HPPh_2$ (1.00 cm^3) and pentane (10 cm^3) and a stir bar. The purple solution of $Mo(NMe_2)_4$ in pentane changed colour to a red–brown solution. After 2 days of stirring the pentane was removed *in vacuo*. Aliquot analysis by NMR spectroscopy indicated the presence of $Mo(NMe_2)_4$, $HPPh_2$ and $Mo(NMe_2)_3PPh_2$. Upon standing for 1 day in a nitrogen atmosphere dry-box, crystals of $[Mo(NMe_2)_2(PPh_2)_2]$ had formed. These were coated with $HPPh_2$ and trace amounts of $[Mo(NMe_2)_3PPh_2]$, as identified by NMR spectroscopy. After liberal washings with pentane and benzene, 40 mg of pure crystals were isolated. Found: C, 60.9; H, 5.8; N, 4.8. Calc. for $MoC_{28}H_{32}N_2P_2$: C, 60.6; H, 5.8; N, 5.0%.

IR data (cm^{-1}): 1580(m), 1565(w), 1415(m), 1366(m), 1297(w), 1243(w), 1185(w), 1158(w), 1145(w), 1114(w), 1095(w), 1083(w), 1064(w), 1040(w), 1025(w), 939(w), 737(s), 690(s), 673(w) 661(w), 523(m), 477(w), 462(w), 456(w), 435(w), 320(w).

NMR data: ^1H, 25°C, C_6D_6: δ 3.23 (t), $^4J_{PH} = 2.7$ Hz (NMe_2); δ 7.64 (br), 7.08 (m), 6.99 (d) (Ph); ^{13}C, 25°C, C_6D_6: δ 49.0 (t), $^3J_{C—P} = 5$ Hz, ^{31}P δ 190 vs 85% H_3PO_4 in D_2O external lock.

NMR data for $Mo(NMe_2)_3(PPh_2)$: ^1H, 22°C, C_6D_6: δ 3.31 (d), $^4J_{PH} = 1.8$ Hz (NMe_2); ^{13}C, 25°C, C_6D_6: δ 50.8 (d), $^3J_{PC} = 4$ Hz; ^{31}P δ 154 (s) vs 85% H_3PO_4 in D_2O external lock.

$[Mo(NMe_2)_3P(t\text{-}Bu)_2]$

THF (15 cm^3) was added to the solids, $Mo(NMe_2)_4$ (400 mg) and $LiP(t\text{-}Bu)_2$ (240 mg). Reaction was immediate and the solution had a red–violet colour. The solvent was removed *in vacuo* and the residue extracted with pentane, filtered and the solvent again removed *in vacuo*. (The filtered solid has an identical IR spectrum of $LiNMe_2$.) A second extraction of 367 mg with pentane and crystallization from pentane gave 215 mg of red–violet crystals. Found: C, 44.8; H, 9.5; N, 11.1. Calc. for $MoC_{14}H_{36}N_3P$: C, 45.0; H, 9.7; N, 11.2%.

IR data (cm^{-1}): 1409(s), 1354(s), 1240(m), 1231(m), 1170(m), 1155(m), 1147(s), 1112(m), 1030(m), 1017(w), 943(s), 938(vs), 928(s), 805(m), 565(s).

NMR data: ^1H, 22°C, C_6D_6: δ 3.31 (d), $^4J_{PH} = 1.2$ Hz (NMe_2); δ 1.16 (d), $^3J_{PH} = 12$ Hz (P—*t*-Bu); ^{13}C, C_6D_6: δ 51.6 (d), $^3J_{P—C} = 3$ Hz (NMe); δ 44.8 (d), $^1J_{PC} = 13$ Hz ($PCMe_3$); δ 34.7 (d), $^2J_{P—C} = 5$ Hz ($PCMe_3$); ^{31}P, 22°C, pentane: δ 237 (s) vs 85% H_3PO_4 in D_2O: ^{95}Mo δ 3355 (d), $^1J_{Mo—P} = 322$, $\Delta\nu^{1/2} = 70$ Hz. Sample run in pentane and δ relative to external Na_2MoO_4, 2M in D_2O.

Crystallographic studies

General operating procedures and a listing of programs have been given previously.[8] A summary of crystal data is given in Table 4. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the IUMSC and cooled to −155°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/c$. Subsequent solution and refinement of the structure confirmed this choice.

Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. The data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. Refinement progressed smoothly, with a difference Fourier phased on the non-hydrogen atoms revealing the positions of most of the hydrogen atoms. The positions of the latter were fixed in their

idealized positions for the remainder of the refinement. Although a final difference Fourier was featureless (maximum peak = 0.45 e Å^{-3}), the residuals remained quite high (R(F) = 0.0896 and R_w(F) = 0.0941). ψ scans for several reflections indicated no significant absorption problems. It was observed that some decomposition of the sample had occurred during the sample transfer process, and it may be that this decomposition affected the quality of the data. There were no significant voids in the lattice, indicating solvent loss was not a problem.

Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Centre.

(*Received* 11 *January* 1989; *accepted* 25 *January* 1989)

Abstract—The protonation constants (α's) and the stability constants (*K*'s) of diethylenetriamine-N,N,N′,N″-tetraacetic acid-N″-propionic acid (DTTAP) and its anion–lanthanide complexes, respectively, have been determined experimentally, providing information about the nature of chelation across the lanthanide series. The stability constants indicate that DTTAP can participate in a successful separation of Am from the lanthanides.

The safe disposal of high-level wastes from nuclear power plants is a growing concern. Nearly all of the components of the high-level waste can be managed safely.[1,2] The ideal disposal process for the waste will involve the removal of the transuranic actinides. Once these elements are removed, they can be transmuted in a high-flux reactor, or disposed in other ways.

Sufficient methods have been developed for removing the actinides from all the waste components, except the lanthanides. Separation from the lanthanides is necessary for effective transmutation.

The key to a successful An/Ln separation is the existence of a chelating agent that will bind the transuranic An^{III} ions more tightly than any of the trivalent lanthanides.

Two major factors affect the value of a chelating agent for use in Am/Ln separations. It is favourable for the ligand to exhibit maximum Ln–ligand complex stability near Nd. Since Am^{III} and Nd^{III} possess nearly identical radii, all Ln–ligand complex stabilities should be lower than that of Nd^{III} for the maximum Am–Ln separation factor (α_{Ln}^{Am}) to be realized. Secondly, if the overall stabilities of the Ln–ligand complexes could be near $K = 10^{19}$–10^{20}, then the selection of the ligand for actinide ions over lanthanide ions would be enhanced over that of ligands with lower overall stability. Also, in this range the exchange kinetics would be favourable in a cation exchange separation of Am^{III} from the lanthanides using the chelating agent in the mobile phase.

This work describes the experimental determination of the protonation constants (α's) and the stability constants (*K*'s) of diethylenetriamine-N,N,N′,N″-tetraacetic acid-N″-propionic acid (DTTAP) and its anion–Ln complexes, respectively. The values were obtained from pH measurements in a simulated potentiometric titration described below.

The results provide some information about chelation across the lanthanide series. The stability constant values indicate that DTTAP is a candidate for participation in the disposal of high-level radioactive waste.

EXPERIMENTAL

Materials

All chemicals were of reagent-grade. Deionized water in this laboratory was prepared by passing

* Author to whom correspondence should be addressed. Present address: Department of Chemistry, Arizona State University, Tempe, AZ 85287-1604, U.S.A.

condensed steam through a mixed bed of anion- and cation-exchange resins.

Trivalent lanthanide nitrate solutions

Approximately 0.1 M lanthanide nitrate solutions were prepared by the dilution of concentrated stock solutions, which were prepared from Ln_2O_3 samples of 99.999% purity using the method described by Adolphson.[3]

Ligand solution

A 0.01110 M standard solution of DTTAP was prepared by dilution of the pure concentrated solution. The solution was standardized by several potentiometric titrations with standard KOH solution. The synthesis of this ligand is described elsewhere.[4]

pH_c *measurements*

All pH_c measurements were carried out using a Beckman model 1019 research pH meter equipped with a Phoenix Model 5733928 pH electrode. Standard solutions with known hydrogen-ion concentrations were prepared ($\mu = 0.100$ M) so that the pH_c could be measured directly.[5]

Procedure

Determination of protonation constants. The five protonation constants (α's) for DTTAP were determined using two separate sets of DTTAP solutions. Solutions prepared at high pH (8.7–10) were used to determine α_1 and α_2, and solutions prepared at low pH (2.8–6) were used to determine α_3, α_4 and α_5. Nineteen solutions were prepared in all; twelve of which were low pH solutions, and seven of which were high pH solutions.

Each of the nineteen solutions was prepared by combining 4.00 cm^3 of ligand solution, a measured amount of standard KOH solution, and an appropriate amount of KNO_3 solution to produce 0.100 M ionic strength. The required amount of KNO_3 was calculated for each solution using the computer program ALPHA, described elsewhere.[5] The solutions were all diluted to $25.00 \pm .01$ cm^3 with deionized water. The solutions were then equilibrated for 8 h in a constant temperature water bath at 25.00 ± 0.05°C, prior to the measurement of pH_c.

The five α values were calculated from the pH_c data using the computer program OMEGA, developed by Johnson[6] and Miller.[7] The least-squares analysis employed by this program has been described in detail by Tse.[8]

Determination of stability constants

The values of K_{ML} and K_{MHL} were determined for the complexes formed by DTTAP with the trivalent elements La–Lu, excluding Pm, using 8–10 carefully prepared solutions for each metal–DTTAP system.

Each of the solutions was prepared by combining 4.00 cm^3 of ligand solution, a measured amount of KOH solution, a measured amount of metal nitrate solution, and an appropriate amount of KNO_3 solution to produce 0.100 M ionic strength. The required amount of KNO_3 was calculated for each solution using the computer program BETA, described elsewhere.[5] The volume of metal nitrate solution was selected to provide a 1:1 ratio of metal–ligand. The solutions were diluted to 25.00 ± 0.01 cm^3 with deionized water, and then equilibrated for 12–16 h in a constant temperature water bath at 25.00 ± 0.05°C, prior to the measurement of pH_c.

The values of K_{ML} and K_{MHL} for each lanthanide–DTTAP system were calculated from the pH_c data using the computer program HCMPLX, developed by Potter.[9]

RESULTS AND DISCUSSION

Protonation constants

The protonation constants for DTTAP are displayed in Table 1 along with the logarithms of the five stepwise protonation constants (pK_a values).

The values of the fourth and fifth stepwise protonation constants indicate that DTTAP is a weaker acid than DTPA in the lower pH region (see Fig. 1).[10] These results are expected, when con-

sidering that the only difference between the two ligands is that in DTTAP a propionate group has replaced one acetate group on one end of the DTPA ligand. The propionate group, being less acidic, retains a proton at higher pH values than does the acetate group.

It is also observed that three protons are dissociated at low pH and the two remaining protons are dissociated at high pH. These two most tightly bound protons are each stabilized by association with two carboxylate groups and one nitrogen atom, at opposite ends of the molecule.

Metal–anion stability constants

The Ln–DTTAP stability constants are reported in Table 2. A plot of the $\log K_{ML}$ values vs metal cationic radius is shown in Fig. 2 for DTTAP and several other ligands.[10–12] The DTTAP ligand shows an overall stability with the lanthanides of about 10^3 times lower than that of DTPA. The maximum ligand affinity at Eu for DTTAP represents a shift of the maximum relative to DTPA.

The overall magnitude of the Ln–DTTAP complex stability constants is expected. A 10^3-fold attenuation is also observed when comparing the Ln–ligand stabilities of DETAP with EEDTA. The attenuation is explained in both cases by the replacement of an acetate group, capable of forming stable five-membered chelate rings, with a propionate group which will form less stable six-membered rings upon chelation. Furthermore, if the acetate group bonded to the *middle* nitrogen of DTPA is replaced with a propionate group, a more drastic 10^6-fold attenuation in complex stabilities is observed. This attenuation is shown by comparing the DTPA and CEDTA Ln–ligand complex stability constant values. The less drastic attentuation for the DTTAP system is expected because a bulky chelate ring at an end nitrogen is not expected to affect the rest of the molecule as much as a bulky chelate ring in the middle of the molecule.

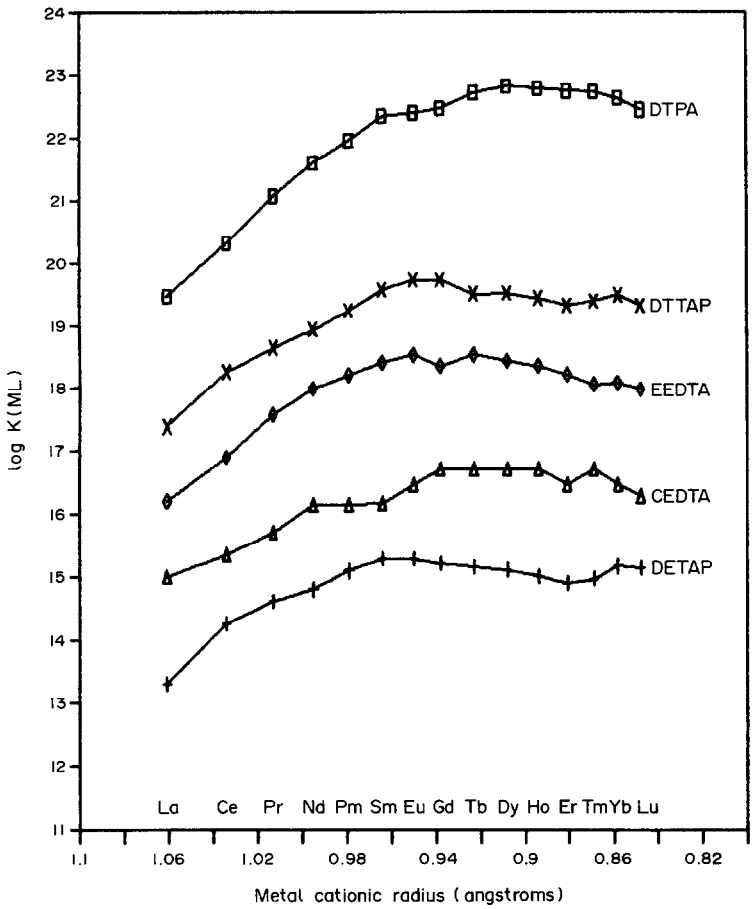

Fig. 2. Stability constants of some Ln–anion complexes as a function of the metal cationic radius.

The shift of the Ln–ligand complex stability maximum from right to left is also expected for the DTTAP function relative to the DTPA function. A similar shift is observed in the DETAP function relative to the EEDTA function. Both shifts are explained by a change in dentate character of the ligand across the lanthanide series. The size of the coordination sphere of the trivalent lanthanides diminishes significantly from La to Lu. It is reasonable to assume that a large ligand such as DTTAP or DPTA would coordinate in an octadentate fashion to the larger lanthanide ions and be forced to coordinate in a lower-dentate fashion to the smaller lanthanide ions.

In progressing from La to Lu, the large polyaminopolycarboxylate ligands most likely experience a breaking of at least one of the chelate rings in order to coordinate the smaller ions with a minimum of steric hindrance. This decrease in coordination number of aqueous lanthanide ions across the series is generally agreed upon by experts in this field.[13–15] By replacement of an acetate with a propionate moiety, a ligand will have a more strained six-membered chelate ring that will be likely to "fail" faster than the more stable five-membered ring offered by the acetate group. DTTAP, therefore, shows an earlier turnover in the $\log K_{ML}$ vs ionic radius function, due to an earlier failure of its octadentate character relative to that of DTPA.

The minimum Am–Ln separation factor (α_{Ln}^{Am}) for DTTAP can be estimated by interpolation, as explained by Powell and Ling.[11] As shown in Fig. 3, the estimated value for $\log \alpha_{Nd}^{Am}$ is 0.98. If one subtracts the difference ($\log K_{EuL} - \log K_{NdL}$) from 0.98, the value for $\log \alpha_{Eu}^{Am}$ is estimated:

$$\log \alpha_{Eu}^{Am} = 0.17$$

$$\alpha_{Eu}^{Am} = 1.48.$$

The estimated minimum separation factor of 1.48 for Am and the strongest complexing lanthanide ion does not represent the largest separation factor known for these systems. EEDTA provides a known value of 1.71,[16] which is the largest known to date.

The value of 1.48 for α_{Eu}^{Am}, estimated in this work, suggests that DTTAP is a chelating agent capable of

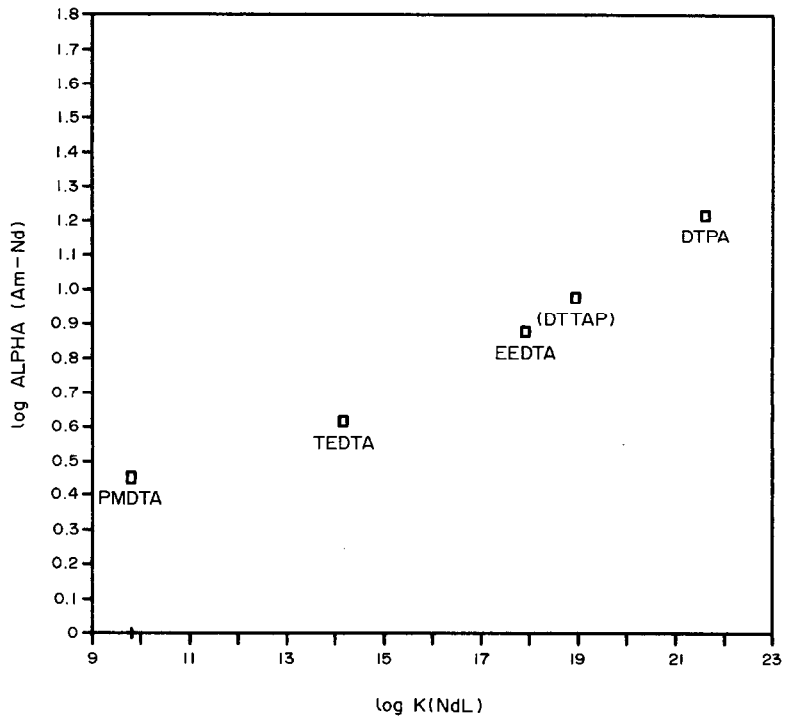

Fig. 3. Am^{3+}–Nd^{3+} separation factors as a function of affinity.[11]

effecting a separation of Am from the lanthanides.

Although the value for α_{Ln}^{Am} estimated here for the DTTAP system is slightly less than the value observed for the EEDTA system, one should keep in mind that 1.48 is the minimum estimated value for α_{Ln}^{Am}, and that the actual value may be larger. The value of $\log \alpha_{Nd}^{Am}$ for DTTAP could be more of the order of 1.22. This would result in a value of 2.57 for α_{Eu}^{Am}.

There is some precedent for considering the higher value of α_{Nd}^{Am} for the DTTAP system. In 1985, Powell and Ling[11] reported a value of 0.73 for $\log \alpha_{Y}^{Ho}$ for the DETAP system. This value is very close to the value observed for $\log \alpha_{Y}^{Ho}$ for the EEDTA system, despite the considerable difference in stabilities of the Ho–EEDTA and the Ho–DETAP complexes. While the replacement of an acetate by a propionate moiety resulted in a decrease in the overall stability of the Ho–L and Y-L complexes, the Ho–Y separation factor was virtually *unchanged.* Since Ho^{III} and Y^{III} have nearly identical radii, the Am^{III} and Nd^{III} system is expected to behave similarly; and it is not unreasonable to consider the possibility of a $\log \alpha_{Nd}^{Am}$ value for the DTTAP system close to that of the DTPA system. This consideration would result in a very attractive value for α_{Ln}^{Am} of 2.57; far superior to any separation factors observed to date for these systems.

SELECTIVE HOMOGENEOUS HYDROGENATION OF BENZOTHIOPHENE AND QUINOLINE CATALYSED BY RUTHENIUM, OSMIUM, RHODIUM AND IRIDIUM COMPLEXES

ROBERTO A. SÁNCHEZ-DELGADO* and EDGAR GONZÁLEZ

Chemistry Centre, Instituto Venezolano de Investigaciones Científicas, I.V.I.C., Apartado 21827, Caracas 1020-A, Venezuela

(*Received* 4 *January* 1989; *accepted* 25 *January* 1989)

Abstract—The homogeneous selective hydrogenation of benzothiophene to 1,2-dihydrobenzothiophene and of quinoline to 1,2,3,4-tetrahydroquinoline is efficiently achieved by the use of $RuCl_2(PPh_3)_3$, $[RuHCl(CO)(PPh_3)_3]$, $[OsHCl(CO)(PPh_3)_3]$, $RhCl(PPh_3)_3$, $[Rh(cod)(PPh_3)_2]PF_6$, and $[Ir(cod)(PPh_3)_2]PF_6$ (cod = cyclooctadiene) at 170°C and 115 bar and 150°C and 30 bar H_2, respectively.

Homogeneous hydrogenation of organic compounds by transition metal complexes has been an area of continuously growing interest, since it has proved to be of great utility in many practical applications and has played a key role in the fundamental understanding of catalytic reactions in general. Although a great proportion of the published papers have dealt with the hydrogenation of C=C bonds, a wide variety of other substrates have been investigated.[1]

One area which has received little attention is the hydrogenation of sulphur- and nitrogen-containing compounds, which is important in connection with industrially important reactions.

Heavy petroleum, tar sands and coal derived liquids contain organic nitrogen and sulphur in varying levels. Nitrogen and sulphur compounds are poisons for cracking and reforming catalysts, and produce polluting oxides on combustion; therefore they must be removed by hydrodesulphurization (HDS) and hydrodenitrogenation (HDN) processes.[2] HDS and HDN are conventionally carried out over molybdenum or tungsten sulphides supported on alumina and promoted by cobalt or nickel.[2] However, it has been reported that sulphides of ruthenium, rhodium, osmium and iridium show the highest activity of all the *d*-block elements for HDS reactions.[3]

It is thus of considerable interest to study the fundamental aspects of the reactions of model sulphur and nitrogen compounds with hydrogen in the presence of these and other transition metals.

Continuing our research programme on the homogeneous hydrogenation of polar organic molecules,[4] in this paper we report our results on the homogeneous hydrogenation of benzothiophene and quinoline catalysed by a series of transition metal complexes. Related work on quinoline hydrogenation has been previously published by Fish *et al.*,[5] by Lynch *et al.*[6a] and by Laine *et al.*[6b] Hydrogenation of benzothiophene (or any S-heterocycle) has been very little studied; while our work was in progress, Fish mentioned this reduction catalysed by $RhCl(PPh_3)_3$[5b] and $RuCl_2(PPh_3)_3$.[5d] There are, to our knowledge, no other reports on this reaction.

RESULTS

The metal complexes used in this work were chosen on the basis of their known catalytic activity for the hydrogenation of polar and/or aromatic molecules. Benzothiophene and quinoline were selected as substrates since they are generally considered as adequate models of petroleum and coal constituents, and have been frequently used as mechanistics probes in heterogeneous HDS and HDN reactions, respectively.[2]

After proper screening, the reaction conditions were chosen as in Tables 1 and 2. Under these

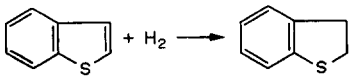
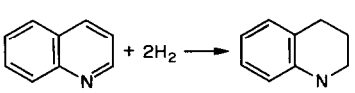
conditions, efficient and regiospecific hydrogenation to 1,2-dihydrobenzothiophene and to 1,2,3,4-tetrahydroquinoline (*ca* 100% selectivity for all the complexes) is achieved [eqs (1) and (2)].



(1)



(2)

Representative examples of the catalytic runs are shown in Figs 1 and 2; values of the initial rate (in turnover frequency units) were obtained from the slopes of these straight lines, and are collected in Tables 1 and 2. The observed kinetics in both cases may be expressed by the simple equation $-d[substrate]/dt = k_{obs}[substrate]$, where $k_{obs} = k[H_2][catalyst]$. The integrated form of this equation was plotted as $\log([substrate]_0/[substrate]_t)$ vs t; from the slopes of the straight lines values of $k'_{obs} = k[H_2][catalyst]/2.3$ were obtained. These values were then normalized for comparison purposes by dividing by the concentration of the catalyst, to yield the values of k_n collected in Tables 1 and 2; these values were used to calculate the relative catalytic activities also collected in Tables 1 and 2, where Wilkinson's catalyst, $RhCl(PPh_3)_3$, was arbitrarily assigned a value of 1.0.

Further experiments were carried out in the case of quinoline hydrogenation catalysed by $[RuHCl(CO)(PPh_3)_3]$, in order to gain some insight

into the influence of other reaction parameters such as the nature of the solvent, additives and the reducing gas on the catalytic activity. These data are collected in Table 3.

DISCUSSION

The catalytic precursors used in this work were chosen on the basis of their known activity for other hydrogenation reactions. The $RhCl(PPh_3)_3$ and $RuHCl(PPh_3)_3$ complexes developed by Wilkinson and co-workers have attracted a great deal of attention over the years and are probably the most widely used homogeneous hydrogenation catalysts today.[7]

We have recently shown that complexes of the type $[MHX(CO)(PPh_3)_3]$ (M = Ru, Os) display a rich catalytic chemistry; they are, for instance, amongst the most efficient systems known to hydrogenate C=O bonds.[4]

Finally, the catalytic potential of cationic rhodium and iridium complexes has been successfully exploited by several groups.[1,8] Particularly interesting for our purposes are the kinetic and mechanistic investigations conducted by Halpern and co-workers on the hydrogenation of polynuclear aromatic hydrocarbons.[9]

With these precedents in mind we decided to test these types of compounds as potential catalysts for

the hydrogenation of heterocyclic aromatic substrates, a subject which has been little developed in the literature.

Analysis of the data collected in Tables 1 and 2 reveals several interesting points: all the ruthenium, osmium, rhodium and iridium complexes tested are indeed very efficient catalysts precursors for the specific hydrogenation of the heterocyclic ring in benzothiophene and quinoline. Fish has previously reported the catalytic activity of $RuCl_2(PPh_3)_3$ and $RhCl(PPh_3)_3$ for these reactions,[5] but to our knowledge, this is the first report on the use of iridium or osmium complexes, or of cationic rhodium derivatives in this type of hydrogenation.

Reduction of the sulphur heterocycle requires more drastic conditions than that of the nitrogen-containing ring. Decomposition of the complexes is not apparent in the time range investigated; prolonged ($\sim$ 24 h) reaction in the hydrogenation of benzothiophene does lead to some decomposition and a consequent loss in catalytic activity. Also, small amounts ($< 1\%$) of ethylbenzene (a product of benzothiophene HDS most likely promoted by metallic particles) are observed in these prolonged reactions.

The relative activities are somewhat different for the two substrates. For benzothiophene (BT) hydrogenation (Fig. 1 and Table 1), the cationic rhodium and iridium diolefin complexes are considerably more active than Wilkinson's catalyst. From the known chemistry of these cationic complexes of rhodium and iridium,[10] we infer that the diene is rapidly hydrogenated and replaced by a substrate molecule, which then enters the catalytic cycle [eq. (3)]:

$$[M(cod)(PPh_3)_3]^+ + BT + 2H_2 \longrightarrow [M(BT)(PPh_3)_2]^+ + \text{cyclooctane.} \quad (3)$$

For chlorophosphine complexes we note that $RuCl_2(PPh_3)_3$ (which generates $RuHCl(PPh_3)_3$ *in situ*) is also more active than $RhCl(PPh_3)_3$. Incorporation of a carbonyl ligand in the coordination sphere as in $[RuHCl(CO)(PPh_3)_3]$ results in a marked drop in the hydrogenation rate. The osmium complex $[OsHCl(CO)(PPh_3)_3]$ is slightly more active than the ruthenium analogue, which is an unusual but not unprecedented observation.[4a]

For quinoline, which is hydrogenated under milder conditions, higher turnover frequencies as well as greater differences in catalytic activities are observed (Fig. 2 and Table 2).

The cationic rhodium complex shows the highest activity also in this case, but the iridium analogue is less active than $RhCl(PPh_3)_3$. Since the mechanism of quinoline reduction is probably very similar to that of benzothiophene, this indicates that iridium requires higher temperatures and H_2 pressures to reach hydrogenation activities comparable to those of rhodium.

$RuCl_2(PPh_3)_3$ is also in this case rapidly transformed into $[RuHCl(PPh_3)_3]$, and hydrogenates quinoline more efficiently than $RhCl(PPh_3)_3$, in agreement with data reported by Fish.[5] As for benzothiophene, incorporation of a CO ligand in the $[RuHCl(CO)(PPh_3)_3]$ complex causes a drop in catalytic activity. The osmium complex, $[OsHCl(CO)(PPh_3)_3]$, is in this case less active than the ruthenium analogue, probably also related to the more forced conditions necessary to activate osmium. It is, however, still a reasonably efficient catalyst, and this adds to the series of homogeneous organic reactions previously reported by us for this type of osmium compound.[4b]

Hydrogenation of the benzene ring does not take place to any detectable extent during hydrogenation of benzothiophene or quinoline, or if pure 1,2-dihydrobenzothiophene or 1,2,3,4-tetrahydroquinoline are used as substrates under the same reaction conditions. Interestingly, isolated heterocycles such as thiophene or pyridine were not hydrogenated by the same metal complexes. This indicates that although the benzene ring is unreactive towards hydrogen under our reaction conditions, its presence is essential in order to activate the heterocyclic rings towards catalytic reduction. This activation may be due to either an electronic effect of the arene making the heterocycle more susceptible to attack by hydrides, or to coordination to the metal centre through the benzene ring, placing the heterocycle in a convenient position to undergo hydrogenation.

On the other hand, the high selectivity for the reduction of the sulphur- and nitrogen-containing rings could be taken as an indication that both benzothiophene and quinoline bind to the metal through the heterocycle and not through the arene ring. We have recently demonstrated that thiophene is π-bonded in the complexes $[M(\eta\text{-thiophene})(PPh_3)_2]PF_6$ (M = Rh, Ir),[10b] and Chaudret and Jalon have shown that both S- and N-heterocycles can be π-bonded to ruthenium in $[C_p^*Ru(arene)]^+$ complexes.[11] Also, Spies and Angelici have reported π-bonded thiophene ruthenium complexes[12] and rhodium and iridium cyclopentadienyl derivatives containing benzothiophene π-coordinated through the arene ring.[13] In the case of quinoline, a further likely coordination mode would be through a metal–nitrogen σ bond, as described recently by Fish in the case of $[Cp^*Rh(quinoline)]^+$ complexes.[14]

For the $[RuHCl(CO)(PPh_3)_3]$-catalysed reduction of quinoline, the data in Table 3 indicate that

strongly coordinating solvents such as CH_3CN totally inhibit the reaction, probably by blocking the coordination sites necessary to activate the substrate. In methanol, a polar, but less strongly coordinating solvent, moderate activity is observed, whilst in THF a much higher conversion is reached. The best solvent seems to be toluene, in terms of activity, solubility and stability.

Addition of water to the reaction mixture causes no effect on the hydrogenation rates, in contrast to other catalytic hydrogenations which are promoted by small amounts of water.[15] On the other hand, addition of acid (HCl) or bases (Et_3N or KOH) produced adverse effects on the catalytic rates. Virtually no hydrogenation was detected if the reactions were carried out under syngas instead of pure hydrogen, or under water gas shift conditions, in opposition with our previous observations that nitro compounds can be efficiently reduced by $[RuHCl(CO)(PPh_3)_3]$, and other metal complexes under H_2, H_2/CO or CO/H_2O.[4d]

EXPERIMENTAL

The complexes $[M(cod)(PPh_3)_2](PF_6)$,[16] $RuCl_2(PPh_3)_3$,[17] $RhCl(PPh_3)_2$,[18] $[RuHCl(CO)(PPh_3)_3]$,[19] and $[OsHCl(CO)(PPh_3)_3]$[20] were prepared by literature procedures. Solvents and quinoline were distilled from appropriate drying agents. Benzothiophene was purified by recrystallization.

A typical hydrogenation run was as follows: the substrate, the catalyst, the solvent and tetrahydronaphthalene (as internal standard) were introduced into a glass-lined stainless steel autoclave fitted with a valve for sampling the solution during the run; the whole operation was carried out inside a nitrogen-filled glove bag or dry box. The sealed autoclave was then taken out and charged to the desired pressure and subsequently introduced into a thermostatted silicone-oil bath. During the run, samples of the reaction mixture were periodically extracted via the sampling valve, and the total pressure of the system was continuously adjusted to a constant value by admitting hydrogen from a high pressure reservoir. Reaction conditions are shown in Tables 1 and 2. The samples were immediately analysed by use of a Varian 3700 gas chromatograph fitted with a flame ionization detector and a Varian CDS-401 Vista data system. A 3 m 20% SP-2100 0.1 CW on 100/200 Supelcoport column at 110°C, and a combination of two columns: 3 m 20% SP-2100 0.1 CW on 100/120 Supelcoport at 55°C for 10 min, then 80°C min^{-1} to 155°C for 28 min, were used for the analysis of benzothiophene and quinoline reactions, respectively.

Each run was repeated at least three times in order to ensure reproducibility. The data were plotted with the aid of conventional graphic computer programs.

CLUSTER CONDENSATIONS. THE DIMERIZATION OF $[Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$

RICHARD D. ADAMS* and JIN-GUU WANG

Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 5 *December* 1988; *accepted* 27 *January* 1989)

Abstract—UV irradiation of $[Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$ (**1**) under a CO atmosphere has yielded the new hexaosmium cluster complex $[Os_6(CO)_{20}(\mu_3\text{-}S)(\mu_4\text{-}S)]$ (**2**) in 13% yield (30% based on the amount of **1** consumed). Compound **2** is a dimer of **1** based on its formula, but its structure is considerably different. Compound **2** was characterized by a single-crystal X-ray diffraction analysis. Crystal data: $Os_6S_2O_{20}C_{20}\cdot 1/3CHCl_3\cdot H_2O$, $M = 1759.0$, rhombohedral, $R\bar{3}$ (No. 148), $a = 43.333(9)$, $c = 10.203(1)$ Å, $V = 16592(9)$ Å^3, $D_c = 3.17$ g cm^{-3}, $Z = 18$, λ(Mo-K_α) = 0.71069 Å (graphite monochromator) $\mu = 202.4$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 2754 reflections [$F^2 \geqslant 3\sigma(F^2)$], ($1 \leqslant 2\theta \leqslant 43°$), gave R and R_w values of 0.041 and 0.042, respectively. Data/parameters ratio = 11.1, highest peak in final difference Fourier = 1.60 e Å^{-3}. The molecule consists of one cluster of four metal atoms arranged in the form of a planar spiked-triangle, that is linked to a second group of two metal atoms by one quadruply-bridging sulphido ligand and one triply bridging sulphido ligand. The dimerization involved the transfer of one metal atom from one cluster to the second cluster. When **2** is photolysed under an atmosphere of nitrogen, it loses 3 mol of CO and condenses to the known cluster complex $[Os_6(CO)_{17}(\mu_4\text{-}S)_2]$ (**3**).

Sulphido ligands have been shown to promote the formation of cluster compounds by facilitating the aggregation of metal atoms about the sulphur site, and by stabilizing the molecules by serving as bridging ligands.[1–3] We have shown that sulphido ligands can promote the oligomerization of clusters forming both dimers [eqs (1)–(3)][4–6] and cyclotrimers [eq. (4)][7] joined through bridging sulphido ligands. Ligand eliminations from these oligomers can lead to further condensation by the formation of metal–metal bonds. In one case, this was observed to occur by a sequential shift of the metal atoms from one cluster to the other, eq. (5).[6]

We have now investigated the nature of the photo-induced dimerization of $[Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$ (**1**) under a CO atmosphere. The dimeric product $[Os_6(CO)_{20}(\mu_4\text{-}S)(\mu_3\text{-}S)]$ (**2**), was isolated and has been characterized by a single-crystal X-ray diffraction analysis. The results of this study are reported herein.

EXPERIMENTAL

General

$[Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$ (**1**) was prepared as previously reported.[8] CP grade CO was purchased from Linde and was used without further purification. All chromatographic separations were performed in air. TLC separations were performed on silica gel plates (0.25 mm Kieselgel 60 F254, E. Merck, F.R.G.). IR spectra were recorded on a Nicolet 5DXB FT–IR spectrophotometer.

Preparation of $[Os_6(CO)_{20}(\mu_4\text{-}S)(\mu_3\text{-}S)]$ (**2**)

Compound **1** (80 mg) was dissolved in 30 cm^3 of CH_2Cl_2 and photolysed for 12 h under a CO atmosphere. During this time, the yellow solution turned to a red–brown colour. The solvent was then removed *in vacuo* and the residue was chromatographed by TLC. Elution with a hexane–CH_2Cl_2 (9:1) solvent mixture yielded (in order of elution): yellow $[Os_3(CO)_9(\mu_3\text{-}S)_2]$[9] (1.2 mg), red $[Os_4(CO)_{13}(\mu_3\text{-}S)_2]$[10] (1.7 mg), orange $[Os_4(CO)_{13}(\mu_3\text{-}S)]$[11] (2.7 mg), unreacted **1** (45.5 mg) and red–brown **2** (10.4 mg, 13%). IR for **2**: (ν(CO) in hexane) 2137(w), 2108(s), 2079(s), 2064(vs), 2048(m), 2037(m), 2031(m), 2010(m), 2004(s), 1987(w), 1980(w), 1974(w). Compound **2** can also be obtained, albeit in a lower yield by the UV photolysis of **1** under a N_2 atmosphere for 3.5 h.

Conversion of **2** *to* $[Os_6(CO)_{17}(\mu_4\text{-}S)_2]$ (**3**)

Compound **2** (10.0 mg) was dissolved in 20 cm^3 of CH_2Cl_2 and photolysed for 1 h under a N_2 atmosphere. The red–brown solution turned to a greenish-brown. After removal of the solvent *in vacuo*, the residue was chromatographed by TLC. Elution with a hexane–CH_2Cl_2 (9:1) solvent mixture yielded (in order of elution): $[Os_3(CO)_9(\mu_3\text{-}S)_2]$ (0.7 mg), $[Os_4(CO)_{13}(\mu_3\text{-}S)_3]$ (0.8 mg), $[Os_4(CO)_{13}(\mu_3\text{-}S)]$ (1.5 mg) and green **3** (5.5 mg, 58%).

Crystallographic analysis

Dark brown crystals of **2** were grown from hexane–$CHCl_3$ solutions at −20°C. The data crystal was mounted in a thin-walled glass capillary. Diffraction measurements were made on a Rigaku AFC6 automatic diffractometer using graphite-monochromatized Mo-K_α radiation. The unit cell was determined from 25 randomly selected reflections obtained by using the AFC6 automatic search, centre, index and least-squares routines. Crystal data, data collection parameters and results of the analyses are listed in Table 1. All data processing was performed on a Digital Equipment Corp. MICROVAX II computer by using the TEXSAN structure solving program library (v 2.0), obtained from Molecular Structure Corporation, The Woodlands, Texas. Neutral atom scattering factors were calculated by the standard procedures.[12a] Anomalous dispersion corrections were applied to all atoms.[12b] Full-matrix least-squares refinements minimized

the function:

$$\sum_{hkl} w(|F_{obs}| - |F_{calc}|)^2,$$

where

$$w = 1/\sigma(F)^2, \quad \sigma(F) = (F_{obs}^2)/2F_{obs}$$

and

$$\sigma(F_{obs}^2) = [\sigma(I_{raw})^2 + (PF_{obs}^2)^2]^{1/2}/Lp.$$

Compound **2** crystallized in the rhombohedral crystal system. A statistical analysis of the data indicated a centrosymmetrical space group. The space group, $R\bar{3}$, was selected and confirmed by the successful solution and refinement of the structure. The structure was solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses. All atoms larger than oxygen were refined using anisotropic thermal parameters. In the final stages of the refinement a molecule of $CHCl_3$ from the crystallization solvent was located in the lattice. Its carbon atom was located on a three-fold symmetry site. An additional peak was observed in a general position about 3 Å from the chlorine atoms. It was approximately the size of an oxygen atom, and was suspected to be an H_2O of crystallization. It was satisfactorily refined with this assignment although its hydrogen atoms were not located. Error analyses were calculated from the inverse matrix obtained on the final cycle of refinement.*

RESULTS AND DISCUSSION

The new compound $[Os_6(CO)_{20}(\mu_4\text{-}S)(\mu_3\text{-}S)]$ (**2**), was obtained as the principal product, 13% yield (30% yield based on the amount of reagent consumed), when solutions of $[Os_3(CO)_9(\mu_3\text{-}CO)(\mu_3\text{-}S)]$ (**1**) were irradiated (UV) for 12 h under a CO atmosphere. Small amounts of the known cluster complexes $[Os_3(CO)_9(\mu\text{-}S)_2]$,[9] $[Os_4(CO)_{13}(\mu_3\text{-}S)_2]$[10] and $[Os_4(CO)_{13}(\mu_3\text{-}S)]$[11] were also obtained. The molecular structure of **2** was established by a single-crystal X-ray diffraction analysis. An ORTEP drawing of the structure of **2** is shown in Fig. 1. Selected intramolecular bond distances and angles are listed in Tables 2 and 3, respectively. The six osmium atoms in **2** are arranged in two groups consisting of four and two atoms. The group of four consists of a triangle of three with the fourth bonded only to one of the three and lying in the plane of the triangle. Two of the Os—Os distances within the triangular group are nearly equal in length, Os(1)—Os(3) = 2.955(2) Å and Os(2)—Os(3) = 2.945(2) Å, but are much longer than the third distance, Os(1)—Os(2) = 2.803(2) Å. The Os—Os distances in $Os_3(CO)_{12}$, 2.878(3) Å,[13] lie approximately midway between these limiting

*Complete tables of bond lengths, angles, atomic coordinates, thermal parameters, and observed and calculated structure factors for **2** have been deposited as supplementary material with the Editor, from whom copies are available upon request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

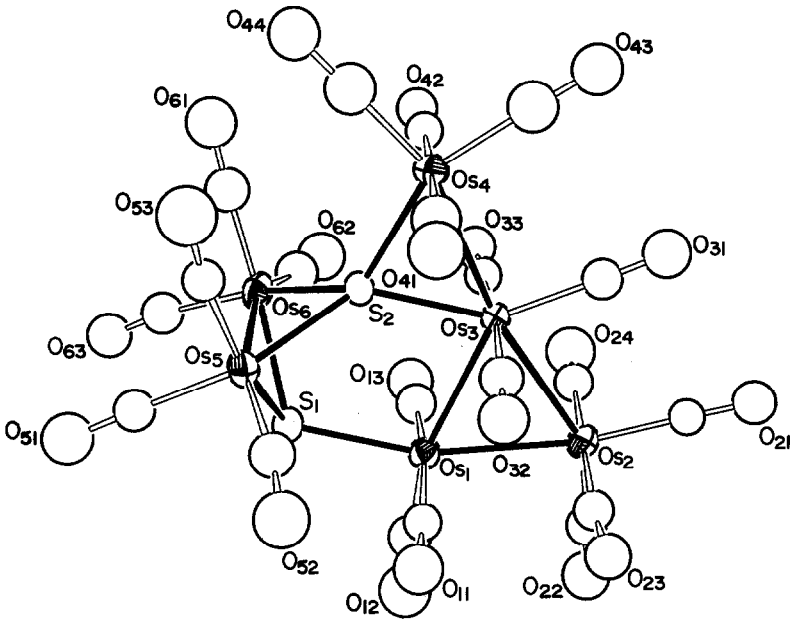

Fig. 1. An ORTEP drawing of $[Os_6(CO)_{20}(\mu_4\text{-}S)(\mu_3\text{-}S)]$ (**2**) showing 50% probability thermal ellipsoids.

values, while the sulphur-bridged bond Os(3)—Os(4) = 2.878(2) Å is identical to that in $Os_3(CO)_{12}$. The metal atoms in the two-atom group are mutually bonded at the short distance of 2.716(2) Å. The shortness of this bond may be due to contraction effects from the two bridging sulphido ligands. Similarly short Os—Os distances have been observed in other doubly-bridged diosmium groupings.[6,14] The two groups of metal atoms are held together by two bridging sulphido ligands. Ligand S(2) is a quadruple bridge that bridges both atoms of the two-atom group and Os(3)—Os(4) of the four-atom group. The Os—S(2) bond distances are normal, 2.360(7)–2.404(7) Å. The Os—S(2)—Os angles between metal atoms that are bonded are small, 74.6(2) and 68.9(2)°, while those between non-bonded metal atoms are very large, range 129.1(3)–132.3(3)°. Similar values were observed for the sulphido ligands in the compound $[Os_6(CO)_{18}(\mu_4\text{-}S)_2(\mu\text{-}HC{=}NPh)_2]$.[14] Ligand S(1) is a triple bridge that bridges both atoms of the two-atom group, but extends only to Os(1) of the four-atom group. The Os—S(1) bond distances are all slightly longer than those to S(2), 2.464(7), 2.423(8) and 2.435(7) Å. The Os(5)—S(1)—Os(6) angle is similar to the Os—S—Os angles between the bonded metal atoms and S(2), but the angles between the non-bonded metal atoms are much smaller than those about S(2), 114.5(3) and 114.3(3)°. The osmium atoms of the four-atom group all lie in a plane within ±0.002 Å, while the vector between Os(5) and Os(6) is nearly perpendicular to this. The molecule contains 20 linear terminal carbonyl ligands distributed among the metal atoms as shown in Fig. 1. Assuming that S(1) serves as a four-electron donor and S(2) serves as a six-electron donor, then all of the metal atoms can achieve 18 electron configurations. The most interesting feature about the formation of **2** is that one

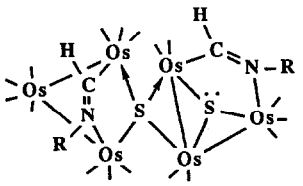
metal atom was shifted from one triosmium cluster to the other to produce the 4 : 2 distribution of metal atoms. Clearly, the sulphido ligands have played a key role in the linking of the two triosmium clusters and in the redistribution of the metal atoms. Since **2** contains 20 CO ligands there was overall no loss of CO, nevertheless, it is believed that the UV irradiation initiates the reaction by the decarbonylation of one of the two clusters of **1** involved in the formation of **2**. This paves the way for the linking of the two clusters through a sulphido bridge by the formation of a donor–acceptor bond, by using the lone pair of electrons on the sulphido ligand of one cluster and the vacant site generated by the loss of CO on the second cluster. Such a complex is represented by the intermediate **A** shown in Scheme 1. Intermediate **A** could reasonably isomerize to **B** by shifting S(2) into a bridging position across Os(5) and Os(6) and shifting the triply bridging CO ligands to terminal positions on Os(2)

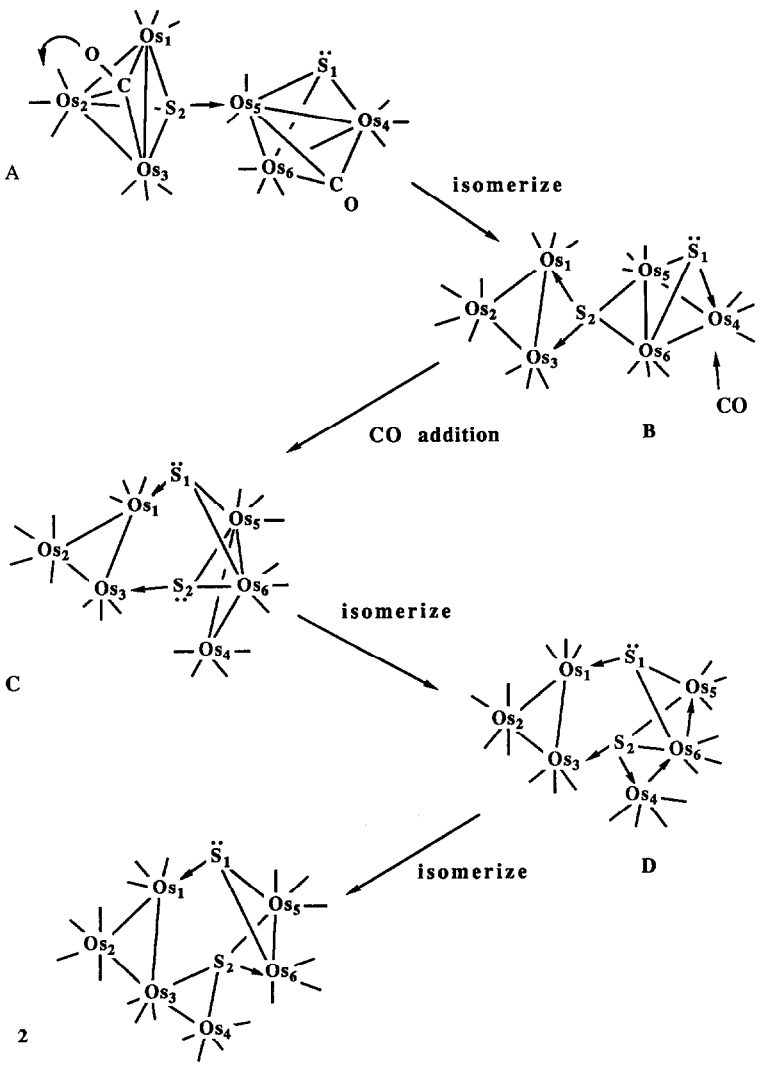
and Os(5). Intermediate **B** has a close structural similarity to the compound $[Os_6(CO)_{17}(\mu\text{-}HC{=}NC_6H_4\text{-}p\text{-}F)_2(\mu_3\text{-}S)(\mu_4\text{-}S)(\mu\text{-}H)_2]$ (**4**).[6] Addi-



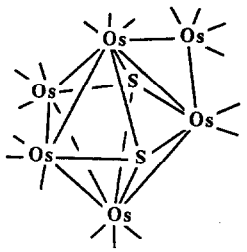
4

tion of CO to **B** at Os(4) could cause cleavage of the Os(4)—S(1) bond, which could then transform to **C** by formation of a donor–acceptor bond between Os(1) and S(2). Intermediate **C** contains two triply-bridging sulphido ligands. The formation of a donor–acceptor bond between S(2) and Os(4) would induce the opening of the Os(4)—Os(5)—Os(6) cluster by cleavage of the Os(4)—Os(5) bond and yield **D**. The formation of **2** would be completed by an isomerization that would involve cleavage of the Os(4)—Os(6) bond and formation of a bond between Os(3) and Os(4). This could be facile, since the Os(4)—Os(6) bond in **D** could be viewed as a donor–acceptor metal–metal bond.

When solutions of **2** were photolysed in the absence of CO, **2** lost three moles of CO and was converted into the known compound $[Os_6(CO)_{17}(\mu_4\text{-}S)_2]$ (**3**) in 58% yield.[14] Small amounts of $[Os_4(CO)_{13}(\mu_4\text{-}S)_2]$, $[Os_4(CO)_{13}(\mu_3\text{-}S)]$ and $[Os_3(CO)_9(\mu_3\text{-}S)_2]$ were also obtained. Compound **3** can be obtained in 44% yield directly by



Scheme 1.



3

UV irradiation of solutions of **1**.[8] The transformation of **2** to **3** has involved a considerable rearrangement of the structure of **2**. We have not observed any of the intermediates that must have been traversed in this process. Thus, we do not, at this time, wish to propose a mechanism for this process.

THE STRUCTURES OF Ph_3PICl AND Ph_3PIBr

KEITH B. DILLON* and JAMES LINCOLN

Chemistry Department, University of Durham, South Road, Durham DH1 3LE, U.K.

(*Received* 5 *July* 1988; *accepted after revision* 27 *January* 1989)

Abstract—The compounds Ph_3PICl and Ph_3PIBr, formed by reaction between Ph_3P and ICl or IBr, respectively, in non-polar solvents, have been shown to have the ionic structures $Ph_3PI^+X^-$ by means of solid state ^{31}P NMR spectroscopy.

Tertiary phosphines react readily with halogens to form phosphorus(V) derivatives, eq. (1):

$$R_3P + X_2 \longrightarrow R_3PX_2. \quad (1)$$

When R = Ph and X = Cl, Br or I, the products have ionic phosphonium salt structures $R_3PX^+X^-$, as has been demonstrated by solid state ^{31}P NMR spectroscopy.[1,2] Conductometric studies in MeCN as solvent have also shown the formation of ionic products at a 1:1 molar ratio of reactants.[3] Previous solution work on reactions of interhalogens with Ph_3P has led to rather confusing results, however. Conductance measurements on the Ph_3P–IBr systems in MeCN showed a break in the plot at a 1:1 molar ratio of reactants, but the yellow solid isolated from the solution analysed as $Ph_3PI_{1.5}Br_{0.5}$.[3] A 1:2 reaction product $Ph_3P(IBr)_2$, could also be isolated, and this, too, was a 1:1 electrolyte. Structures were suggested for these complexes of $[Ph_3PBr]^+[Ph_3PI]^+(I^-)_2$ and $[Ph_3PBr]^+[I_2Br]^-$, respectively. The related compounds Ph_3PI_3Br and Ph_3PIBr_3 were similarly obtained from 1:1 reactions of Ph_3PI_2 with IBr, and of Ph_3PBr_2 with IBr. These, too, were assigned ionic structures, with the cation containing the halogen of lower atomic number. The 1:1 product Ph_3PIBr was not described. More recently, the Ph_3P:ICl system in MeCN has been shown to give breaks in the conductance plot at 3:2 and 3:4 molar ratios of the reactants, and an explanation for this behaviour has been proposed.[4] The compound Ph_3PICl was isolated as a yellow crystalline solid, however, by adding anhydrous diethyl ether to a 1:0.5 mixture of Ph_3P and ICl_3 in MeCN. It gave good elemental analyses, but its structure was not discussed.

We have now prepared the compounds Ph_3PICl and Ph_3PIBr as yellow solids by stoichiometric reactions between Ph_3P and ICl or IBr, respectively, in non-polar solvents. They have been shown to have the ionic structures $Ph_3PI^+X^-$ (X = Cl or Br) by means of solid state ^{31}P NMR spectroscopy.

EXPERIMENTAL

All manipulations including NMR sample preparation were carried out either under an inert atmosphere of dry nitrogen or *in vacuo*. Diethyl ether was dried over sodium, and other solvents were dried over molecular sieve. Triphenylphosphine was recrystallized from toluene. Other reagents were obtained commercially and were used without further purification. The compound Ph_3PICl was prepared by treating a solution of Ph_3P in diethyl ether with an equimolar quantity of ICl dissolved in benzene. The yellow solid which precipitated was separated in an inert atmosphere box. For Ph_3PIBr, which had not been described previously in the literature, equimolar quantities of Ph_3P and IBr were dissolved separately in dichloromethane and the solutions were mixed, with stirring. The bright yellow solid was separated and dried *in vacuo*. (Found: C, 47.5; H, 4.2; P, 6.6; I, 26.9; Br, 16.8. $C_{18}H_{15}BrIP$ requires: C, 46.1; H, 3.2; P, 6.6; I, 27.1; Br, 17.0%.) The NMR results indicate that it should be named and formulated as iodotriphenylphosphonium bromide, $Ph_3PI^+Br^-$.

Elemental analyses and ^{31}P NMR spectra were obtained as described in previous papers.[2,5,6] ^{31}P chemical shifts were measured relative to external 85% H_3PO_4, with the downfield (higher frequency) direction taken as positive.

RESULTS AND DISCUSSION

The compounds Ph_3PICl and Ph_3PIBr were both isolated as yellow solids, as described above. Their solid state ^{31}P NMR spectra were recorded and the results are shown in Table 1, together with the previously reported solid state data for Ph_3PCl_2,[2] Ph_3PBr_2[1] and Ph_3PI_2.[1] The results show conclusively that Ph_3PICl has the ionic phosphonium salt structure $Ph_3PI^+Cl^-$ in the solid state. This deduction is consistent with solution state NMR results for the Ph_3PCl^+ cation, which gives shifts of 64.2 ± 2.2 ppm, irrespective of both counter-ion and solvent,[2,7-18] apart from one report of a value of 56.3 ppm in $MeNO_2$.[14]

The results for Ph_3PIBr are less clear-cut, since the shift difference between Ph_3PBr_2 and Ph_3PI_2 in the solid state is quite small. Nevertheless, the value obtained (Table 1) is clearly compatible with the formulation of this compound, too, as a salt of the Ph_3PI^+ cation. This conclusion is again consistent with solution data for the Ph_3PBr^+ cation, for which values of 48.3 ± 0.2 in $PhNO_2$[1] and 49.0 in 25 oleum[18] have been reported. It is also noteworthy that freshly-prepared Ph_3PI_2 is yellow, whereas Ph_3PCl_2 and Ph_3PBr_2 are white. We therefore conclude that the halogen with the higher atomic number is present in the cation in both instances, unlike some of the species deduced to be present from conductance studies in MeCN.[3,4] This discrepancy may be readily rationalized, however, since the compounds isolated in this work are unlikely to be stable in polar solvents. They are stabilized by precipitation as solids from less polar media, but the weakness of the P—I bond makes it susceptible to attack by lighter halide ions if the compound is brought into solution. In keeping with this premise, an attempt to obtain a solution ^{31}P NMR spectrum from Ph_3PICl in $PhNO_2$ resulted in the appearance of three resonances, at 66.0 ± 0.1 (Ph_3PCl^+), 34.7 ± 0.2 (possibly Ph_3PI^+), and -21.8 ± 0.3 ppm, the third peak remaining unassigned. A solution of Ph_3PIBr in $PhNO_2$ showed a single peak only, at 40.5 ± 0.4 ppm, in good agreement with the solid state value and probably due to the Ph_3PI^+ cation. This result suggests that Ph_3PIBr is more stable in solution than Ph_3PICl, which does not seem unreasonable since there will be a much larger difference in bond strength between P—Cl and P—I bonds than between P—Br and P—I bonds. Hence attack by Cl^- ions on the Ph_3PI^+ cation is expected to be more facile than attack by Br^- ions.

Table 1. δ ^{31}P (ppm) for solid Ph_3PXY and Ph_3PX_2 compounds

Compound	δ ^{31}P	Reference
Ph_3PICl	40.5 ± 2	This work
Ph_3PIBr	41.7 ± 2	This work
Ph_3PCl_2	62.0 ± 8	2
Ph_3PBr_2	48.6 ± 0.5	1
Ph_3PI_2	42.5 ± 1.0	1

Acknowledgement—We thank Dr A. Royston for assistance in recording the ^{31}P NMR spectra.

SYNTHESIS AND SPECTRAL STUDIES OF METALLOPORPHYRINS OF IRON, COBALT, COPPER AND RHODIUM WITH CARBON, NITROGEN AND SULPHUR DONOR LIGANDS

MORTEZA MASSOUDIPOUR, SHARAD KUMAR TEWARI and KRISHNA KUMAR PANDEY*

Department of Chemistry, Devi Ahilya University Indore, Khandwa Road, Indore 452 001, India

(*Received* 27 *September* 1988; *accepted after revision* 27 *January* 1989)

Abstract—[Rh(TPP)Cl] (TPP = *meso*-tetraphenylporphyrin) was prepared by reaction of [$RhCl_3 \cdot 3H_2O$] with HCHO in the presence of H_2TPP. Reaction of this complex with COS yielded [Rh(TPP)(CO)Cl]. $S_3N_3Cl_3$ reacted with [Fe(TPP)Cl] in THF in the presence of iron powder to give the air-sensitive complex [Fe(TPP)(NS)]. Reaction of $SOCl_2$ with [Fe(TPP)Cl] in the presence of zinc dust yielded [Fe(TPP)(SO_2)]. [Cu(TPP)(COS)] was prepared by interaction of COS with [Cu(TPP)]. Reaction of the blue solution of S_7NH with [M(TPP)] (M = Cu, Co) and [Co(TNPP)] (TNPP = *meso*-tetrakis(2-nitrophenyl)porphyrin) yielded [Cu(TPP)(S_3N)], [Co(TPP)(S_3N)] and [Co(TNPP)(S_3N)] complexes. Reaction of C_5H_6 with [Fe(TPP)Cl] in the presence of zinc dust yielded [Fe(TPP)(C_5H_5)], which reacted with NO to afford [Fe(TPP)(C_5H_5)(NO)]. These complexes have been characterized by elemental analysis, IR and electronic spectroscopy.

The reactions of the diatomic molecules O_2, NO and CO with metalloporphyrins and their relationship to the corresponding haemoprotein complexes have been intensively investigated.[1–8] Synthesis, structure and bonding of the transition metal complexes with ligands such as NS,[9–13] NSO,[14–16] NSO_2,[17] NS_2,[18] NS_3[19–25] and COS[26,27] have been a subject of much current interest. However, the complexes of metalloporphyrins with these ligands have not yet been described. We have recently reported for the first time the synthesis and characterization of a disulphidothionitrato(tetraphenylporphyrinato)iron(III) complex.[21] Herein we wish to report reactions of S_7NH, $S_3N_3Cl_3$, COS, $SOCl_2$, NO and C_5H_6, in the presence of zinc, with metalloporphyrins. A simple synthetic route for [Rh(TPP)Cl] by reaction of [$RhCl_3 \cdot 3H_2O$] with HCHO in the presence of H_2TPP has also been reported.

EXPERIMENTAL

All the reagents used were AnalaR or of chemically pure grade. The solvents were dried by standard procedures and were freshly distilled and degassed before use. Every reaction was carried out under dry nitrogen. H_2(TPP), H_2(TNPP), [Co(TPP)], [Cu(TPP)], S_7NH, $S_3N_3Cl_3$, COS and NO were prepared as previously described.[28–35]

The analyses for sulphur and chloride in the complexes were carried out by using standard methods.[36,37] Carbon and hydrogen in the complexes were analysed by the microanalytical section of the Central Drug Research Institute, Lucknow and the Indian Institute of Technology, Kanpur. The results are reported in Table 1. The IR spectra of samples were recorded with a Perkin–Elmer Model 580 spectrometer using KBr pellets. The electronic spectra of the samples were recorded with a Varian 634S and Simadzu-160 spectrophotometer. Important IR frequencies and the electronic data of the complexes are given in Table 2.

(a) *Chloro*(meso-*tetraphenylporphyrinato*)*rhodium* (III), [Rh(TPP)(Cl)]

To a solution of [$RhCl_3 \cdot 3H_2O$] (0.2 g, 0.76 mmol) in ethylene glycol (20 cm^3), formaldehyde (10 cm^3) was added and the resulting solution was refluxed until the colour of solution changed to pale yellow.

		(77.0)	(9.2)	(4.3)		

This was then reduced to 10 cm^3 and was added dropwise over the course of 30 min to a hot, stirred solution of H_2(TPP) (0.204 g, 0.33 mmol) in ethylene glycol (40 cm^3). It was then refluxed for 25 h. On addition of distilled water (100 cm^3), the brown complex [Rh(TPP)Cl] separated out. This was centrifuged, washed several times with water and dried *in vacuo* (yield: 0.14 g, 56%).

(b) *Chloro-carbonyl*(meso-*tetraphenylporphyrinato*) *rhodium*(III), [Rh(TPP)(CO)(Cl)]

To a solution of [Rh(TPP)Cl] (0.1 g, 0.13 mmol) in toluene (30 cm^3), COS was bubbled for 8 h. The solution was kept overnight, then reduced to 5 cm^3 under reduced pressure. On addition of *n*-hexane (30 cm^3), the [Rh(TPP)(CO)Cl] complex separated out. This was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield: 0.09 g, 87%).

(c) *Thionitrosyl*(meso-*tetraphenylporphyrinato*) *iron*(I), [Fe(TPP)(NS)]

A solution of $S_3N_3Cl_3$ (0.04 g, 0.16 mmol) in 25 cm^3 of tetrahydrofuran (THF) was added to a stirred solution of [Fe(TPP)Cl] (0.30 g, 0.43 mmol) in the presence of iron powder (1.0 g) and the reaction mixture was stirred for 3 h. It was then filtered, evaporated to dryness under reduced pressure and extracted with 20 cm^3 of dichloromethane. On the addition of methanol (60 cm^3), the dark blue complex [Fe(TPP)NS] separated out, which was filtered, washed with methanol and dried *in vacuo* (yield: 0.18 g, 58%).

(d) *Sulphur-dioxide*(meso-*tetraphenylporphyrinato*) *iron*(II), [Fe(TPP)(SO_2)]

$SOCl_2$ (2 cm^3) was added to a solution of [Fe(TPP)Cl] (0.2 g, 0.28 mmol) in benzene (40 cm^3) and zinc dust (4.0 g) added. The reaction mixture was stirred for 5 h. It was then filtered and reduced to 5 cm^3 under reduced pressure. On addition of methanol (30 cm^3), a greenish violet complex [Fe(TPP)(SO_2)] separated out, which was centrifuged, washed with methanol and dried *in vacuo* (yield: 0.098 g, 47%).

(e) *Disulphidothionitrato*(meso-*tetraphenylporphyrinato*)*cobalt*(III), [Co(TPP)(S_3N)]

A blue solution of S_7NH (0.12 g, 0.5 mmol) in 5 cm^3 of dimethylformamide (DMF) was added to a stirred solution of [Co(TPP)] (0.33 g, 0.5 mmol) in DMF (15 cm^3). The reaction mixture was further stirred for 8 h. It was then filtered and concentrated

to 5 cm^3 under reduced pressure. On addition of methanol (50 cm^3), a brownish violet complex [Co(TPP)S_3N] separated out, which was filtered, washed with methanol and dried *in vacuo*. It was recrystallized from CH_2Cl_2–CH_3OH (yield: 0.23 g, 60%).

(f) *Disulphidothionitrato*(meso-*tetraphenylporphyrinato*)*copper*(III), [Cu(TPP)(S_3N)]

A blue solution of S_7NH (0.12 g, 0.5 mmol) in 5 cm^3 of dimethylformamide (DMF) was added to a stirred solution of [Cu(TPP)] (0.34 g, 0.5 mmol) in DMF (15 cm^3). The reaction mixture was stirred for 8 h. The reddish violet complex [Cu(TPP)(S_3N)] was isolated by a procedure similar to that given in (e) (yield: 0.2 g, 51%).

(g) *Disulphidothionitrato*[meso-*tetrakis*(2-*nitrophenyl*)*porphyrinato*)]*cobalt*(III), [Co(TNPP)(S_3N)]

To a stirred solution of [Co(TNPP)] (0.212 g, 0.25 mmol) in DMF (15 cm^3), was added a blue solution of S_7NH (0.06 g, 0.25 mmol) in DMF (5 cm^3). The reaction mixture was stirred for 8 h and the brownish violet complex [Co(TNPP)(S_3N)] was isolated by a procedure similar to that given in (e) (yield: 0.124 g, 52%).

(h) *Carbonylsulphide*(meso-*tetraphenylporphyrinato*)*copper*(II), [Cu(TPP)(COS)]

To a solution of [Cu(TPP)] (0.1 g, 0.148 mmol) in toluene (30 cm^3), COS was bubbled for 10 h. It was kept for 50 h, then reduced to 5 cm^3 under reduced pressure. On addition of *n*-hexane, the pinkish brown complex [Cu(TPP)COS] separated

out. This was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield: 0.085 g, 78%).

(i) *Carbonyl*(meso-*tetraphenylporphyrinato*)*iron*(II), [Fe(TPP)(CO)]

To a solution of [Fe(TPP)] (0.1 g, 0.15 mmol) in benzene (30 cm^3), COS was bubbled for 8 h. It was kept for 2 days, then reduced to 5 cm^3 under reduced pressure. On addition of *n*-hexane (30 cm^3), the blue complex [Fe(TPP)(CO)] separated out. This was centrifuged, washed with *n*-hexane and dried *in vacuo* (yield: 0.09 g, 86%).

(j) *Cyclopentadienyl*(meso-*tetraphenylporphyrinato*) *iron*(III), [Fe(TPP)(C_5H_5)]

Freshly distilled monocyclopentadiene (C_5H_6) (1 cm^3) and zinc dust (1.0 g) were added to a stirred solution of [Fe(TPP)Cl] (0.2 g, 0.284 mmol) in benzene (50 cm^3). The reaction mixture was stirred for 5 h. It was then filtered and reduced to 5 cm^3 under reduced pressure. On addition of methanol (25 cm^3), the brown complex [Fe(TPP)(C_5H_5)] separated out. This was centrifuged, washed with methanol and dried *in vacuo*, and the product was recrystallized from dichloromethane and methanol (yield: 0.108 g, 52%).

(k) *Nitrosyl-cyclopentadienyl*(meso-*tetraphenylporphyrinato*)*iron*(II), [Fe(TPP)(NO)(C_5H_5)]

To a solution of [Fe(TPP)(C_5H_5)] (0.1 g, 0.136 mmol) in chloroform (20 cm^3), nitric oxide was bubbled for 30 min. It was reduced to 5 cm^3 under reduced pressure. On addition of methanol (50 cm^3), the brown complex [Fe(TPP)(NO)(C_5H_5)] separated out. This was centrifuged, washed with methanol and dried *in vacuo* (yield: 0.056 g, 54%).

RESULTS AND DISCUSSION

[Rh(TPP)Cl] was prepared by the interaction of the carbonyl complex of rhodium (prepared by refluxing formaldehyde with [$RhCl_3 \cdot 3H_2O$] in ethylene glycol) with H_2TPP. The IR spectrum of [Rh(TPP)Cl] is similar to that reported previously and prepared by other methods.[38] The reaction of COS with [Rh(TPP)Cl] resulted in the formation of [Rh(TPP)(CO)Cl]. The IR spectrum of this complex showed an absorption band at 2055 cm^{-1} due to the carbonyl stretching frequency.

Reaction of a green solution of trithiazyltrichloride in THF with $Fe^{II}TPP$, afforded [Fe^{III}(TPP)Cl]. When the same experiment was carried out in the presence of an excess of iron powder, the dark blue complex [Fe(TPP)(NS)], was isolated. The reaction system and the product [Fe(TPP)(NS)], are highly moisture-sensitive. From the six preparative experiments, only twice was the [Fe(TPP)(NS)] complex isolated.

$$Fe^{II}TPP + (NSCl)_3 \xrightarrow{THF} [Fe(TPP)(NS)] + \cdots.$$

The IR spectrum of [Fe(TPP)(NS)] showed a peak at 1270 cm^{-1} due to the thionitrosyl stretching vibration, which is in the range of thionitrosyl stretching frequencies observed in linearly bonded thionitrosyl complexes.[13,39]

Reaction of $SOCl_2$ with [Fe(TPP)] in the presence of zinc dust in benzene resulted in the formation of a green complex, [Fe(TPP)(SO_2)]. A plausible mechanism involved the prior formation of sulphur monoxide which disproportionated to sulphur dioxide and sulphur, and the resulting sulphur dioxide coordinated to the metal centre,[40,41] The IR spectrum of [Fe(TPP)(SO_2)] showed absorption bands at 1235 and 1080 cm^{-1} due to the η'-planar (sp^2) coordinatd SO_2 group.[42]

Heptasulphurimide reacted with [M^{II}(P)] to afford the disulphidothionitrato complexes [M^{III}(P)(S_3N)].

M = Fe, Cu, CO P = TPP
M = Co P = TNPP.

The IR spectra of the complexes [Cu(TPP)(S_3N)], [Co(TPP)(S_3N)] and [Co(TNPP)(S_3N)] show absorption bands in the regions, 912–940 cm^{-1} and 720–749 cm^{-1} due to ν(NS) and 595–620 cm^{-1} due to ν(S—S), which are in close agreement with the values for the coordinated bidentate S_3N^- ligand.

Reaction of COS with [Cu(TPP)] at room temperature in toluene, yielded a pinkish brown complex [Cu(TPP)(COS)], in which COS was bonded to the metal through carbon and sulphur. This is supported by its IR spectrum which exhibited a band at 1712 cm^{-1}, the characteristic IR frequency of a bidentate COS group.[26] Reaction of COS with [Fe(TPP)] resulted in the formation of [Fe(TPP)(CO)], which in its IR spectrum showed an absorption band at 1972 cm^{-1} due to ν(CO) (cf. literature value, 1973 cm^{-1}).[43,44]

Monocyclopentadiene (C_5H_6) in the presence of zinc dust reacted with [Fe(TPP)] giving a brown complex [Fe(TPP)(C_5H_5)]. The IR spectrum of this complex exhibited absorption bands at 852, 875 and 1405 cm^{-1} due to the cyclopentadienyl ligand. NO

reacted with [Fe(TPP)(C_5H_5)] to give the nitrosyl complex [Fe(TPP)(C_5H_5)(NO)]. The IR spectrum of this complex exhibited an absorption band at 1705 cm^{-1} due to the nitrosyl stretching frequency. The corrected stretching frequency (ν'(NO) 1655 cm^{-1}) of NO, calculated according to Ibers' rules,[45] falls above 1610 cm^{-1}. This is evidence for the presence of a linear nitrosyl group in this complex.

EQUILIBRIA IN COMPLEXES OF N-HETEROCYCLIC MOLECULES—XLVII.* SPECIATION IN AQUEOUS $[Cr(2,2'\text{-BIPYRIDYL})_3]^{3+}$

P. S. CARTWRIGHT and R. D. GILLARD†

Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL, U.K.

(*Received* 13 *June* 1988; *accepted after revision* 15 *February* 1989)

Abstract—Solutions of the salts $[Cr(bipy)_3]X_3$ ($X = Cl^-$ or ClO_4) in water, show reversible pH-dependence of luminescence. The circular dichroism is independent of pH.

The nature of the species actually present in solutions in protic media containing the complex ions $[M(LL)_3]^{n+}$ [e.g. M = Cr, $n = 3$; M = Ru, $n = 2$ or 3; LL = a di-imine like 2,2-bipyridine (bipy) or 1,10-phenanthroline (phen)] and of intermediates in solvolyses, has been hotly debated.[2] For example, the variation of species with pH has been much studied.

We comment here on some simple but illuminating observations on aqueous solutions of $[Cr(LL)_3]X_3$, where LL = 2,2′-bipyridine or 1,10-phenanthroline and X is the conjugate base of a very strong acid like HCl or $HOClO_3$.

The apparent variability or irreproducibility of properties (such as quenching of luminescence) often observed in such compounds, may usually be traced to impurity. (For example, in the photophysics[3] of $[Ir(phen)_2Cl_2]^+$ or the rates of decay of luminescence of $[Cr(phen)_3]^{3+}$, where apparently identical samples behaved differently.)[4] It is, in this field of work, consequently more than ever vital to be sure of the nature of solid compounds.

Figure 1 shows the variations (fully reversible) of luminescence for $[Cr(bipy)_3]^{3+}$ with pH. In a similar experiment, Kane-Maguire and Langford reported[5] the partial quenching of luminescence of $[Cr(phen)_3]^{3+}$ at high concentration of hydroxide. They interpreted this decrease in intensity with no shift of wavelength, as being consistent with attack by hydroxide on an aromatic ring of ground or excited state $[Cr(phen)_3]^{3+}$.

The variation with pH of the rates of several reactions of $[Cr(bipy)_3]^{3+}$ (solvolysis, racemization, photoracemization) follow such a common profile[2,6a] that the intermediacy of a 1 : 1 adduct of the cation with the hydroxide ion is accepted. The vari-

ation of luminescence intensity (I) varies with pH in the same way (particularly clear from plotting I^{-1}).

Quenching of luminescence (a term used to denote any emission of a photon from any excited state, i.e. fluorescence and/or phosphorescence) can arise[7] in several ways. These are (a) energy transfer, (b) excited donor–quencher chemical reaction, (c) catalysed deactivation without energy transfer or chemical reaction and (d) exciplex formation. The catalytic effects —(c)— are ruled out for the hydroxide ion, since these arise either from a heavy atom affecting spin-orbit coupling or from a paramagnetic quencher. Energy transfer —(a)— is ruled out since hydroxide has no low-lying energy levels. Exciplex formation —(d)— with $[Cr(LL)_3]^{3+}$ requires some other interacting π-system (not present). As pointed out[7] by Demas and Addington, mere ion-pairing between an excited donor and a quencher cannot itself quench (the possibility of energy or electron transfers must still be present for quenching to occur).

Hydroxide [in the related context of quenching photo-aquations of ions of chromium(III)] has been described[8] in a vague phrase as a "non-innocent quencher", i.e. not acting by electronic energy transfer. However, it was also said that "quenching by OH^- . . . has to take place by means of some kind of chemical reaction".

The only possible mechanism for the luminescence of $[Cr(LL)_3]^{3+}$ to be quenched by hydroxide is indeed by chemical reaction, and we (like Kane-Maguire and Langford in relation to $[Cr(phen)_3]^{3+}$) take this to be covalent addition[2] to one ligand, rather than to the metal ion.

From the presently available measurements of electronic spectra, the presence of pH-dependent speciation is obvious only in emission. We agree with Serpone that[6a,9] the electronic absorption spectrum of $[Cr(bipy)_3]^{3+}$ is independent of pH from 0 to 10.7, and we add the independence of the circular dichroism (a property often more sensitive than isotropic absorption) of resolved salts of both ions (bipy and phen) over the pH range from 2 to 11. However, despite the earlier observation[5] by Kane-Maguire and Langford of the pH dependence of luminescence of $[Cr(phen)_3]^{3+}$, Serpone and his associates found[9] no change of the luminescence of $[Cr(bipy)_3]^{3+}$ in the pH range 0–10.7. The change we find, reproducibly (Fig. 1), is about a 25% "quenching" from pH 2.0 to 10.8 and about a third of the intensity of the luminescence arising from "chrome doublet" states is quenched from pH 2.0 to 12.2 (the higher limit in our own study). It is, of course, common enough experience for other chromophores that fluorescence and phosphorescence are much more sensitive to change than are absorption spectra.

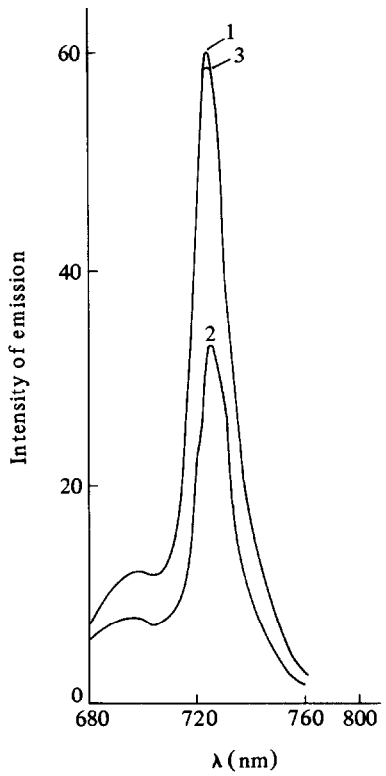

Fig. 2. Quenching of luminescence of $[Cr(phen)_3]^{3+}$ and its reversibility: (1) original solution at pH *ca* 4.5; (2) pH changed to *ca* 12 by conc. NaOH; (3) pH restored to *ca* 2 by conc. $(HO)_2SO_2$.

The yellow colour (absorption spectrum) of $[Cr(LL)_3]^{3+}$ salts in MeCN or DMSO does change (to red–violet) on adding base (Bu_4NOH in H_3COH–toluene) but not with full reversibility—the yellow *colour* reappears with HCl treatment, but the electronic spectrum (and CD for the resolved species) differ from the original. The basic solutions racemize quickly (for LL = bipy faster than for LL = phen). It is not yet clear that this change of species with base is related to those in water.

In conclusion, the notion advanced[10] in 1969 that di-imines coordinated to metal ions behave like quaternized imines, offers a good account of the simple properties of aqueous solutions. It has been taken up recently. Srivatsa and Sawyer invoke[11] exactly such nucleophilic attack of hydroxyl on a bound pyridine as being intermediate in the hydroxide-induced reduction of tetraphenylporphinato-iron(III) in pyridine. Others, studying the thermal and light-induced reductions of aqueous $[Ru(bipy)_3]^{3+}$, have repeated[12] a prior suggestion[13] that a pseudobase is an intermediate.

In the context of the present chromium(III) species, it is worth remarking that a simple theoretical analysis[6c] of whether coordinated N-heterocycles (as opposed to quaternized ones) would ever undergo nucleophilic attack, concluded that if any triply charged ion might polarize the ligands enough to induce this, chromium(III) was the one (although we doubt[14] the conclusion itself: our more extensive calculations point to a clear similarity between the electronic populations of coordinated and of quaternized N-heterocycles).

EXPERIMENTAL

Complex compounds were made, resolved and characterized as previously described.[15] Luminescence measurements used an Aminco–Bowman spectrofluorimeter with excitation at 430 nm. The several classes of experiment were:

(a) Reversibility: a freshly made solution (typically 10^{-3} M) had its luminescence measured (640–800 nm, spectrum 1), was treated with one drop of strong base (pH > 12) giving spectrum 2, quite different from 1 in intensity, then with conc. $(HO)_2SO_2$ back to pH 1–2, giving spectrum 3 coincident with 1, as in Fig. 2.

(b) Detailed pH profiles, as in Fig. 1.

(c) Time course, to establish possible interference from products of solvolysis. An aqueous solution (10^{-3} M) of $[Cr(bipy)_3]^{3+}$ at pH 12 was left and its luminescence (640–780 nm) recorded at times 0, 5, 6, 15 and 19 min. The measured intensities at peak emission 726.5 nm were (arbitrary scale) respectively as: 42.5; 39.4; 38.9, 33.3, 12.1. After acidification, the final solution had intensity 16.5. The sole luminescing species in base is the adduct of hydroxide with $[Cr(bipy)_3]^{3+}$, since the luminescence profile is constant with time. The rate of disappearance of the luminescing species at the particular pH of the time measurement, agrees quite well with the known rate of solvolysis of $[Cr(bipy)_3]^{3+}$. The growth of intensity by about a third on re-acidification of the residual pH 12 solution jibed well with Fig. 1.

Acknowledgements—We wish to thank SERC for a Quota Studentship, Dr E. D. Owen for help with spectrofluorimetry and Dr H. P. J. M. Dekkers (University of Leiden) for some valued comments on emission spectroscopy.

(*Received* 26 *January* 1989; *accepted* 15 *February* 1989)

Abstract—New complexes of titanium(III) and vanadium(III) stabilized by a chelating terdentate amido ligand have been prepared, providing access to the study of a rare class of compounds; the crystal structure of the aryl vanadium(III) derivative has also been determined. In addition, preliminary studies indicate that chromium(III) behaves in a different manner when forming complexes with this ligand.

We are currently interested in the study of dialkylamido complexes of *d*-block elements in groups IV and V, containing metal–carbon bonds, since organometallic complexes of these metals are well known to catalyse various organic transformations. Vanadium aryls, for example, are active as alkene polymerization or oligomerization catalysts.[1] There are, however, few well characterized examples of such compounds,[2] especially for vanadium(III), as isolation of products is typically hampered by marked tendencies towards disproportionations and oxidations. Consequently, this area of study for electropositive metals has been largely limited to cyclopentadienyl, neutral phosphino[2a] or bulky ligands.[2b] The few examples of metals in groups IV and V coordinated to both aryl (or alkyl) and dialkylamido ligands,[3] illustrate that these compounds are an important class in terms of their reactivity, and are non-trivial to synthesize in a rational manner. We have recently reported[4] routes to new dialkylamido complexes of these metals that contain halide ligands available for substitutions. We now present preliminary studies of these complexes that demonstrate access to new reactive methyl and phenyl derivatives of titanium and vanadium stabilized by chelating terdentate amido ligands. We also report the X-ray crystal structure of $Ph_2VN(CH_2CH_2NEt_2)_2$, the first organometallic derivative of a vanadium amido complex to be so characterized. The new compounds described here are represented in Scheme 1.

Preparation of these compounds is by interaction of alkyl or aryl lithium reagents with the amido metal dihalide complex in tetrahydrofuran. The new compounds may be prepared more conveniently by a "one pot" procedure where the amido metal dihalide precursor is generated as an intermediate (from $MCl_3 \cdot 3THF$[4]) *in situ* prior to the addition of the organolithium reagent. They may be recrystallized from petroleum ether and are soluble in apolar solvents. The compounds have provided satisfactory elemental analyses (Butterworth Laboratories Ltd, Teddington, U.K.).

Both titanium compounds are d^1 paramagnets that give rise to ESR spectra† and consistent solid-state magnetic susceptibilities;‡ are monomeric in

benzene solution (cryoscopy) and molecular ions are not observed in the mass-spectrum, although typical ligand fragmentations are.

For vanadium, both the methyl and phenyl derivatives appear to have two unpaired electrons (d^2, magnetic susceptibility) and both compounds are ESR silent in solution, solid or glass at 20 or −110°C. Again both compounds are monomeric in solution (cryoscopy, benzene) and unlike their titanium analogues, both display molecular ions in their mass spectra (295 amu for the dimethyl and 419 amu for the diphenyl).

Crystals of $Ph_2VN(CH_2CH_2NEt_2)_2$ suitable for X-ray crystallography were obtained from petroleum ether. The structure of the molecule is shown in Fig. 1.* The dimensions of comparable parts of the structure are similar to those of the precursor $Cl_2VN(CH_2CH_2NEt_2)_2$.[4] The vanadium–carbon average bond lengths (2.151(8) Å) are somewhat longer (by 0.07 Å) than that

*Crystal data: $C_{24}H_{38}N_3V$, $M_r = 419.52$, orthorhombic, $a = 14.075(1)$, $b = 18.095(5)$, $c = 18.778(3)$ Å, $V = 4782.9$ Å^3. Space group: *Pbca*, $Z = 8$, $D_c = 1.17$ g cm^{-3}, $F(000) = 1808$, μ(Mo-K_α) = 4.13 cm^{-1}, λ(Mo-K_α) = 0.71069 Å. Structure solved via routine procedures, refined by least-squares with non-hydrogens anisotropic, idealized phenyl rings, hydrogen atoms refined but with group U_{iso} values. $R = 0.079$, $R_w = 0.087$ for 269 parameters and 1977 observed [$F_o > 3\sigma(F_o)$] data from 4198 measured.

$$LTiR_2 \longleftarrow LiR \longrightarrow LVR_2$$

L = $-N(CH_2CH_2NEt_2)_2$

Scheme 1. All organometallic derivatives were prepared by the action of 2 mole equivalents of the organolithium reagent on the corresponding $LMCl_2$ in THF. Yields (based on $MCl_3 \cdot 3THF$) after crystallization from hexane are: $LTiR_2$: R = Me, 60%; R = Ph, 83%; LVR_2: R = Me, 70%; R = Ph, 61%.

reported in the only other vanadium(III) aryl for which such data is available.[5]

In the diphenyl complex, the vanadium–amido nitrogen bond is longer (1.874(8) Å) than in the analogous dichloride (1.834(8) Å), but is still considerably shorter than the vanadium–amino nitrogen bonds (acerage 2.271(8) Å), indicating substantial metal–nitrogen multiple bonding. The coordination around vanadium can be described as trigonal bipyramidal with the amino nitrogens axial and distorted towards the equatorial amido nitrogen. Since the structures of the present compound and its precursor are very similar, although the steric demands of phenyl groups are different to those of chloride, the distortion must largely be due to the steric constraints of the chelating nitrogen ligand, especially in view of the fact that purely electronic constraints of stereochemistry appear to provide more regular structures in similar environments, as demonstrated by the regular trigonal-bipyramidal $VCl_3(NMe_3)_2$.[6]

The reaction of $LiN(CH_2CH_2NEt_2)_2$ with $CrCl_3 \cdot 3THF$ in THF provides the dark green crystalline and hydrocarbon soluble complex, $[(Et_2NCH_2CH_2)_2NCrCl_2]_n$. Analytical data are consistent with this compound being empirically analogous to the titanium and vanadium compounds, however, there are significant differences in physical properties. In the mass spectrum, a peak corresponding to the monomeric unit is observed, however peaks at higher m/z values are also present and are consistent with fragments arising from a dimeric unit. All these peaks show an isotope envelope indicative of the presence of both chloride and chromium. In addition to the mass-spectral data, the magnetic susceptibility (20°C, $\mu_{eff} = 3.23$ BM, Gouy method) is lower than would be expected for a monomeric d^3 chromium(III) compound of this nature. It is likely that this compound is not structurally analogous to the titanium and vanadium compounds, probably as a result of the preference of d^3 compounds for six-coordinate rather than five-coordinate stereochemistries. These observations point to it being a dimer, with either two bridging chlorides or bridging amido nitrogens. Further studies into the nature of the chromium compound are in progress. We are currently investigating extensions of this chemistry to the heavier congeners of titanium and vanadium. Indications are that these materials are very reactive with numerous substrates and investigations of chemical properties are being undertaken.

SYNTHESIS AND PROPERTIES OF N-BIS(TRIFLUOROMETHYL)NITROXY-IMINOARSINE $(CF_3)_2NON{=}AsH$: THE FIRST TWO-COORDINATE IMINOARSINE CONTAINING AN As=N DOUBLE BOND

H. G. ANG* and F. K. LEE

Department of Chemistry, National University of Singapore, Kent Ridge Road, Singapore 0511, Republic of Singapore

(*Received* 13 *February* 1989; *accepted* 10 *March* 1989)

Abstract—$(CF_3)_2NON{=}AsH$ (**A**), the first example of a two-coordinate iminoarsine, was synthesized by a condensation reaction between $(CF_3)_2NONO$ and AsH_3. It underwent substitution reactions with the $(CF_3)_2NO$ radical to afford $(CF_3)_2NON{=}AsON(CF_3)_2$. Both the iminoarsines, $(CF_3)_2NON{=}AsR$ (where R = H and $ON(CF_3)_2$), underwent addition reactions with HI to give $(CF_3)_2NONHAsRI$.

Although unsaturated compounds containing N=M double bonds (where M = P, Si, and Ge in low coordination) have received increasing attention in recent years, the number of such compounds which are thermodynamically stable is still small.[1–10] The stability of these bonds has been attributed to the presence of bulky groups and also to mesomeric effects.[6,7,10] However, we have recently reported the synthesis of several stable iminophosphines, $(CF_3)_2NON{=}PR$ (where R = H and $ON(CF_3)_2$), whose substituents consist of electronegative groups.[9] We now report the first examples of iminoarsines, namely $(CF_3)_2NON{=}AsR$ (where R = H and $ON(CF_3)_2$), which contains two-coordinate arsenic and whose stability also appeared to be influenced by perfluoro substituents.

The reactions of O-nitrosobis(trifluoromethyl) hydroxylamine with arsine at room temperature in a 1:1 ratio in an evacuated glass ampoule, gave N-bis(trifluoromethyl)nitroxy-iminoarsine, $(CF_3)_2NON{=}AsH$ and water, according to the equation:

$$AsH_3 + (CF_3)_2NONO \longrightarrow (CF_3)_2NON{=}AsH + H_2O. \quad \textbf{(A)}$$

A dark brown intractable solid, which is hygroscopic, was also formed in the reaction ampoule.

The iminoarsine **A**, obtained in about 42% yield, was isolated at the −86°C trap as a white solid on trap-to-trap vacuum fractionation. Its IR spectrum shows the following absorption bands: 2238 cm^{-1} (νAs—H); 1322, 1273, 1245, 1186 cm^{-1} (νC—F); 1070 cm^{-1} (νN—O); 972 cm^{-1} (νC—N); 721 cm^{-1} (δC—F). The band located at 869 cm^{-1} can be attributed to the As=N stretching vibration. The EI MS (70 eV) of iminoarsine (**A**) does not exhibit the parent ion but gave other fragmentation ions at *m/z* 170 $[CF_2NONAsH]^{+\cdot}$, 154 $[CF_2N_2AsH]^{+\cdot}$, 119 $[AsNON]^{+\cdot}$ and 69 $[CF_3]^{+\cdot}$. The molecular weight determined by Regnault's method was 258 g mol^{-1} (compound **A** requires 258 g mol^{-1}).

The presence of the AsH moiety in **A** was chemically confirmed by its reactions with the bis (trifluoromethyl)nitroxy radical, which is a powerful hydrogen abstractor and a radical scavenger.[11] The reactions gave the bis(trifluoromethyl)nitroxy derivative $(CF_3)_2NON{=}AsON(CF_3)_2$ in 52% yield, together with a quantitative amount of bis(trifluoromethyl)hydroxylamine, as shown by the equation:

$$(CF_3)_2NON{=}AsH + 2(CF_3)_2NO \longrightarrow (CF_3)_2NON{=}AsON(CF_3)_2 + (CF_3)_2NOH. \quad \textbf{(B)}$$

* Author to whom correspondence should be addressed.

The iminoarsine **B**, shows typical IR absorptions due to the $(CF_3)_2NO$ group located at 1291, 1244, 1199, 1080, and 722 cm^{-1} and the As=N group at 869 cm^{-1}. Its mass spectrum shows fragmentation ions at *m/z* 344 $[C_2F_9N_3O_2As]^{+\cdot}$, 168 $[C_2F_6NO]^{+\cdot}$ and 75 $[As]^{+\cdot}$. Its molecular weight determined by Regnault's method was 425 g mol^{-1} (compound **B** requires 425 g mol^{-1}).

The presence of the As=N double bond in the $(CF_3)_2NO$-substituted iminoarsines, **A** and **B**, was chemically confirmed by its reactions with anhydrous hydrogen iodide to afford the addition products, according to the equation:

$$(CF_3)_2NON{=}AsR + HI \longrightarrow (CF_3)_2NO\underset{H}{N}\text{—}\underset{I}{As}R$$

(**C**): R = H
(**D**): R = $ON(CF_3)_2$.

Both products, **C** and **D**, were isolated by trap-to-trap vacuum fractionation at the −60°C trap, the former as a pale yellow solid in 75% yield and the latter as a pale yellow liquid in 85% yield. The IR spectra of the products, **C** and **D**, showed the N—H stretching vibrations at 3398 and 3415 cm^{-1}, respectively, suggesting that addition involves the migration of the hydrogen to the nitrogen atom and the iodine to the more electropositive arsenic atom. The IR spectra also showed the presence of the AsH group, **C**: 2271 cm^{-1}; and the $(CF_3)_2NO$ group(s), **C**: 1323, 1271, 1240, 1213, 1184, 1068, 972 and 717 cm^{-1}; **D**: 1312, 1269, 1226, 1046, 972 and 712 cm^{-1}. The EI MS (70 eV) of both products consist of the following fragmentation ions, **C**: *m/z* 218 $[HNAsHI]^{+\cdot}$, 217 $[NAsHI]^{+\cdot}$, 216 $[NAsI]^{+\cdot}$, 168 $[C_2F_6NO]^{+\cdot}$, 149 $[C_2F_5NO]^{+\cdot}$, 130 $[C_2F_4NO]^{+\cdot}$, 127 $[I]^{+\cdot}$ and 69 $[CF_3]^{+\cdot}$; **D**: 257 $[C_2F_6NONAs]^{+\cdot}$, 168 $[C_2F_6NO]^{+\cdot}$, 149 $[C_2F_5NO]^{+\cdot}$ and 69 $[CF_3]^{+\cdot}$. Analysis for iodine in the products **C** and **D** gave 33.02 and 22.07%, respectively; (Calc: **C**, 32.90%; **D**, 22.96%). ^1H NMR of product **C** consists of δNH, 6.13 ppm (multiplet) and δAsH, 0.40 ppm (multiplet) w.r.t TMS; and ^{19}F NMR of product **C** consists of δCF_3, 16.39 ppm (singlet) w.r.t. CF_3COOH.

A NEW RADIATION-CATALYTIC ROUTE TO HYDRAZINE AND AMMONIA

J. O. DZIĘGIELEWSKI

Department of Inorganic and Radiation Chemistry, Institute of Chemistry, Silesian University, Katowice, Szkolna 9 Street, Poland

(*Received* 7 *February* 1988; *accepted* 12 *December* 1988)

Abstract—In methanol solution, nitrogen was reduced to H_4N_2 and H_3N using the molybdenum(IV) complex with dppe and γ-radiation. Radiation-catalytic yields of hydrazine and ammonia were determined. These yields increase with increasing concentration of the molybdenum(IV) complex. $[Mo(N_2)_2(dppe)_2]$, H_4N_2 and H_3N were isolated and identified. Other intermediates of the reduction were also observed. The initial form of the catalyst was reproduced by oxidation of molybdenum(0) to molybdenum(IV) with the coordinated nitrogen. The solvent participated in the latter reaction. The process of N_2 fixation and reduction is a chain-reaction (see yields of H_4N_2 and H_3N in Table 1). The mechanism of the radiation-catalytic reduction of N_2 was suggested.

Many investigations on the molecular N_2 fixation and reduction using transition metal compounds have been carried out for over 20 years.[1,2] Molybdenum complexes play an important role in this process.[3–22] It is easy to fix N_2 by using metal ions in a low oxidation state. In most cases reduction of the coordinated N_2 with acids,[1,7,10,11,15,18,19] alcohol solutions[1,5,6,11,12] or other reagents,[1,6,8,9,13,14,16,17,20] was inefficient, which was connected with the oxidation of the central ion and destruction of the complex. The attempts to overcome these difficulties using the hydride complexes[11] were unsuccessful. Application of UV[23] or ionizing radiation,[24,25] in the case of dinitrogen complexes, led to the liberation of N_2. Significant progress was achieved by the use of catalytic systems[26–32] or electrocatalysis.[33,34] Amalgams of alkali metals are also used as reducers.[35] A report on the cyclic reduction of N_2 by electrocatalysis[36,37] and radiation-catalysis[38] has appeared recently.

Very recently, an attempt of N_2 fixation and reduction (to H_4N_2) by the UV irradiation of the hydride complexes of molybdenum and tungsten with phosphine compounds in N_2 saturated cyclohexane was made.[39] H_3N is a typical product of the reduction (sometimes together with H_4N_2). On the basis of our earlier radiation-spectroscopic investigations,[40–44] one can expect that a complex which exhibits a suitable symmetry and a proper spin state of the central ion with the free non-bonding acceptor orbitals localized on ligands, can be used for the N_2 fixation and reduction in the field of ionizing radiation. These conditions are met in the case of $[MoOCl(dppe)_2]Cl$[40,42] (dppe = $Ph_2PCH_2CH_2PPh_2$). The solvent type is also important in processes generated by ionizing radiation. Methanol is a suitable solvent because dppe contains low energetic acceptor orbitals and forms $(dppe)^-$ anions with e_s^-, which react with the $CH_3OH_2^+$ cations giving the neutral dppe molecules without decomposition.[45] Stability of the $Mo(dppe)_2$ group in the irradiated $[MoOCl(dppe)_2]^+$ complex, in methanol solutions, was shown earlier.[40,42]

The main purpose of this work was an attempt to fix and reduce molecular N_2 in the field of radiation by $[MoOCl(dppe)_2]^+$ in a methanol solution.

EXPERIMENTAL

The $[MoOCl(dppe)_2]Cl$ complex was prepared according to the literature.[46] Methanol was distilled after the removal of water. A solution of H_2SO_4 (0.05 mol dm^{-3}) or KOH (about 10^{-7}, 10^{-5} and 1 mol dm^{-3}) in methanol, was saturated for 30 min with N_2 (O_2 was removed with Cu) or with Ar. Then $[MoOCl(dppe)_2]Cl$ was dissolved and the solutions were saturated again (N_2 or Ar, 15 min). The concentration of N_2 was 6.83×10^{-3} mol dm^{-3}.[47] Next, the solutions of Mo^{IV} were irradiated in a Co γ-

source "Issledovatel". The dose rates were 3.97×10^{17} or 2.2×10^{4} eV cm^{-3} s^{-1} (recalculated for the methanol solutions). During the irradiation process, N_2 was bubbled through the solutions (earlier saturated with N_2) in a continuous or periodical way (10 min of saturation after each 30 min of irradiation). A system of methanol washers was used for N_2 or Ar saturation. The concentration of gases was kept constant to maintain the original concentrations of H_2SO_4, KOH and [MoOCl(dppe)$_2$]Cl. H_4N_2 was isolated quantitatively from irradiated alkaline ([KOH] $\approx 10^{-7}$ mol dm^{-3}) solution by adding $CuCl_2$ to a solution of Mo^{IV} before irradiation (see Table 1 for Cu^{II} concentration) or in a coordinated form with Mo and dppe ([KOH] $\approx 10^{-5}$ mol dm^{-3}). The Mo complexes with N_2 in the coordination sphere were isolated (not quantitatively) from the irradiated solutions at [KOH] = 1 mol dm^{-3}. Hydrazine was directly determined in the irradiated solutions or in the form of the Cu^{II} complex from the alkaline solutions by *p*-dimethylaminobenzoic aldehyde (following a previous dissolution in H_2SO_4).[48,49] Ammonia was determined by the indophenol test.[37,50]

The dose was determined with a Fricke dosimeter. The UV and visible spectra were recorded on a Beckman 5240 spectrometer, and IR spectra on a Specord IR 75 Carl Zeiss Jena spectrometer.

RESULTS AND DISCUSSION

Figures 1 and 2 show the numbers of $(N_2H_6)SO_4$ and $(NH_4)_2SO_4$ molecules as a function of dose and concentration of [MoOCl(dppe)$_2$]Cl, for the different rates of dose. Table 1 presents the radiation yields, calculated from Figs 1 and 2. From Figs 1 and 2, it is evident that the numbers of $(N_2H_6)SO_4$ molecules are the non-linear functions of dose and show the distinct maxima, and that the formation of ammonia and hydrazine are not simultaneous. In fact, after the binding of H_4N_2 as a form of the Cu^{II} complex and its removal from the methanol solution as a precipitate, there is no evidence of H_3N in the precipitate or in solution and the numbers of hydrazine molecules are the linear functions of dose (Fig. 3).

In the absence of $Cu^{II}Cl$ in the alkaline solution, formation of H_3N and H_4N_2 is similar to that shown in Figs 1 and 2. Table 2 presents the evaluated yield of H_4N_2 in the alkaline solutions. The shapes of the formation curves for H_4N_2 may originate not only from its conversion, but also from its decomposition.

Participation of Cu^{II} and Mo^{IV} in oxidation or

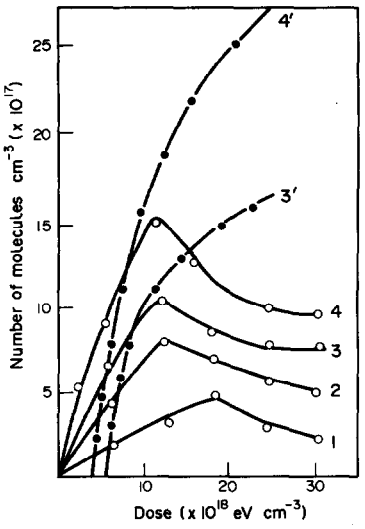

Fig. 1. Numbers of $N_2H_6^{2+}$ (curves 1–4) and NH_4^+ (curves 3′ and 4′) ions as a function of the dose and concentration of [MoOCl(dppe)$_2$]Cl: 1—5×10^{-3} mol dm^{-3}; 2—1×10^{-2} mol dm^{-3}; 3 and 3′—4×10^{-2} mol dm^{-3}; 4 and 4′—1×10^{-1} mol dm^{-3}.

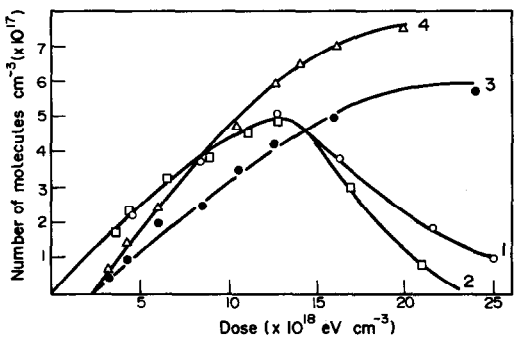

Fig. 2. Numbers of $N_2H_6^{2+}$ (curves 1 and 2) and NH_4^+ (curves 3 and 4) ions as a function of the dose and concentration of H_2SO_4 (concentration of [MoOCl(dppe)$_2$]$^+$ = 2×10^{-1} mol dm^{-3}): 1 and 3—2×10^{-5} mol dm^{-3}; 2 and 4—5×10^{-2} mol dm^{-3}.

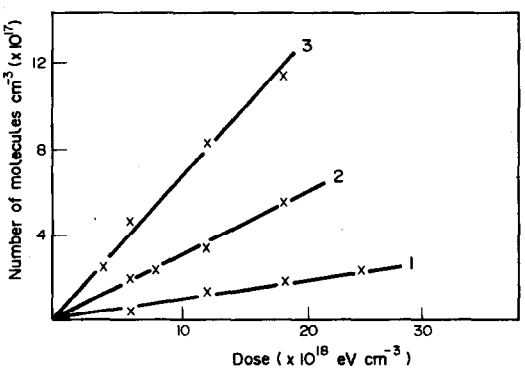

Fig. 3. Numbers of H_4N_2 molecules as function of the dose and concentration of [MoOCl(dppe)$_2$]Cl: 1—1.07×10^{-2} mol dm^{-3} ([$CuCl_2$] = 3.7×10^{-4} and [KOH] = 7.30×10^{-7} M); 2—2.70×10^{-2} mol dm^{-3} ([$CuCl_2$] = 3.7×10^{-4} and [KOH] = 7.40×10^{-7} M); 3—4.20×10^{-2} mol dm^{-3} ([$CuCl_2$] = 4.1×10^{-4} and [KOH] = 8.13×10^{-7} M).

Table 2. Radiation yields of hydrazine in alkalized methanol solutions. The dose rate was 3.97×10^{17} eV cm^{-3} s^{-1} and [KOH] ≈ $7\text{–}8 \times 10^{-7}$ mol dm^{-3}

Concentration of $[MoOCl(dppe)_2]^+$ (mol dm^{-3})	The radiation yield number of molecules per 100 eV solutions		Concentration of Cu^{II} ion (mol dm^{-3})
	Without Cu^{II} ions	With Cu^{II} ions	
1.07×10^{-2}	1.7	2.1	3.70×10^{-4}
2.14×10^{-2}	2.7	—	—
2.70×10^{-2}	—	3.7	3.75×10^{-4}
4.20×10^{-2}	5.0	7.6	4.10×10^{-4}

disproportionation of H_4N_2 was experimentally excluded (see Figs 5 and 6). Formation of H_3N due to disproportionation of H_4N_2 is also in disagreement with the data in Table 1.

Taking into account the values of the rate constants in the reaction of H_4N_2 with e_s^- ($k_{H_4N_2+e_s^-} = 3 \times 10^2$ dm^3 mol^{-1} s^{-1} [51]) and with H atoms ($k_{N_2H_5^++H} = 2.4 \times 10^4$ dm^3 mol^{-1} s^{-1} [52]), one should exclude this interaction with the unstable products of CH_3OH radiolysis. The presence of amines was also not proved and it excludes a reaction of H_4N_2 with (CH_2OH) radicals. Hence, according to the data presented above, the Mo with dppe complex in the field of radiation causes a binding (fixation) and reduction of N_2 to H_3N, and H_4N_2 is an intermediate product. The data in Table 1 indicate that the fixation and reduction of N_2 are chain processes, because the radiation yield of these processes is higher than a few molecules per 100 eV[53] ($G_{H_4N_2} + G_{H_3N} \cong 62$). Taking into account the fact that the value of the negative effective charge on N_β in Mo—N_α—N_β is higher than for N atoms in Mo—NH_2—NH_2, one can expect a greater influence of the H^+ ion concentration on H_3N yield compared to H_4N_2. Figure 2 meets these expectations, which proves the formation of H_3N via H_4N_2 reduction. A non-linear dependence of the number of H_4N_2 molecules as a function of the dose is caused by the hydrogenation of H_4N_2, and a higher rate of hydrogenation (a two-electron process; $G_{H_3N} > G_{H_4N_2}$) compared with the reduction of N_2 to H_4N_2 (a four-electron process) leads to a decreasing number of hydrazine molecules. The significant influence of the rate of dosage on the H_3N and H_4N_2 yields is due to the higher stationary concentration of the Mo^0 and Mo^{II} complexes with H_4N_2. All the processes caused by the irradiation of the methanol solutions of $[MoOCl(dppe)_2]Cl$ saturated with N_2, were followed by testing the changes in the coordination sphere of the central atom. Figure 4 shows a spectrum of a precipitate (dark brown) isolated from the irradiated complex of Mo^{II} in a 1 M methanol solution of KOH, saturated periodically with N_2.

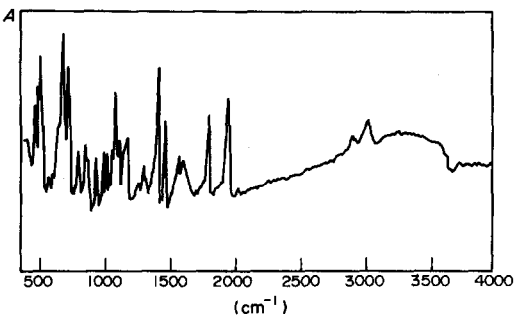

Fig. 4. IR spectrum of precipitate formed as a result of irradiation of $[MoOCl(dppe)_2]Cl$ (concentration = 10^{-2} mol dm^{-3}) in a 1 M methanol solution of KOH, periodically saturated with N_2. Dose = 2.48×10^{19} eV cm^{-3}.

According to Fig. 4, there is a valence vibration of N_2—Mo—N_2 (*trans*) at 1977 cm^{-1}. For the *cis* (C_{2v} symmetry) configuration of N_2 molecules, one can expect two ν_{Mo-N_2} vibrations (A_1 and B_1), while for C_{4v} symmetry  ν_{Mo-N_2} will occur at higher frequency if L is a stronger acceptor, or at lower frequency, if L is a weaker acceptor than N_2, during the formation of π-bonds.[3,54–57] The vibration at 1820 cm^{-1} can be assigned to $\nu_{Mo-CO-Mo}$ or ν_{Mo-CO}.[58] A band at 1820 cm^{-1} also occurs for a precipitate formed after irradiation of $[MoOCl(dppe)_2]Cl$ in a methanol solution of KOH (1 mol dm^{-3}), saturated with Ar. Carbon monoxide is a product of radiation decomposition of CH_3OH, particularly in an alkaline environment and in the presence of acceptors of the charge of the CH_2O^-

anion radicals[25] (see the proposed mechanism). A substance, whose spectrum is shown in Fig. 3, decomposes quickly.

In the light of the above data, one can assume that the unstable substance is a mixture of $[Mo(N_2)_2(dppe)_2]$, $[Mo(CO)(Cl)(dppe)_2]$ and $[MoOCl(dppe)_2]$. A substance with CO groups exchanges carbon monoxide for N_2 in the field of radiation, forming a bis-dinitrogen complex. A solution of $[MoOCl(dppe)_2]Cl$ irradiated in 1 M KOH in methanol, under constant saturation of N_2, forms a yellow–orange precipitate, and its IR spectrum is identical with the earlier interpreted one of $[Mo(N_2)_2(dppe)_2]$.[44] Hence we can assume the radiation route for the formation of the Mo^0 bis-dinitrogen complex.

In irradiated, alkaline ($[KOH] \geqslant 10^{-5}$ mol dm^{-3}) and constantly saturated with N_2 solutions of the Mo^{IV} complex, a chestnut substance is formed (Fig. 5 shows its IR spectrum). It is evident from Fig. 5 that the Mo complex contains dppe in its coordination sphere (ν_{C-H} at 3040 and 2900 cm^{-1}, ν_{P-C} at 1430 and 1480 cm^{-1} and aromatic deformation modes of C—C and C—H in the range 500–1350 cm^{-1}),[40,44] and also the Mo=O group ($\nu_{Mo=O}$ at 943 cm^{-1}). In the region of ν_{NH_2}, four bands at 3220, 3420, 3480 and 3550 cm^{-1} occur. Taking into account the intensities and their frequencies, one can assume that two of them are due to free NH_2 groups and the other two (at the lower frequencies) originate from Mo—NH_2 groups. Such a large number of ν_{NH_2} bands and the large differences in frequencies suggest the assignment of these vibrations to Mo—NH_2—NH_2 groups. An analysis of the deformation mode of NH_2 groups is not possible because of overlapping with dppe bands. A spectrum of the Mo complex does not change with time, indicating the stability of H_4N_2 within the coordination sphere of Mo.

The isolated product of N_2 reduction from an

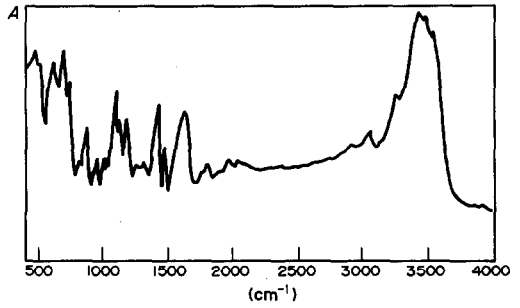

Fig. 5. IR spectrum of precipitate formed as a result of irradiation of $[MoOCl(dppe)_2]Cl$ (concentration = 10^{-2} mol dm^{-3}) in methanol in the presence of KOH ($\approx 10^{-5}$ mol dm^{-3}) saturated with N_2. Dose = 2×10^{21} eV cm^{-3}.

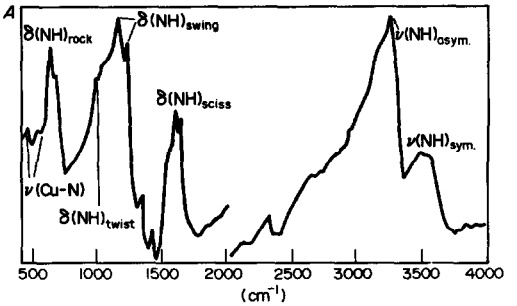

Fig. 6. IR spectrum of precipitate formed as a result of irradiation of $[MoOCl(dppe)_2]Cl$ (concentration = 10^{-2} mol dm^{-3}) in methanol ($[KOH] \approx 10^{-7}$ mol dm^{-3}, $[CuCl_2] = 4 \times 10^{-4}$ mol dm^{-3}) saturated with N_2. Dose = 7.15×10^{20} eV cm^{-3}.

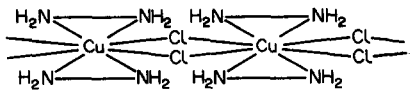
irradiated solution of $[MoOCl(dppe)_2]Cl$ in the presence of $Cu^{II}Cl$ is a dark blue precipitate and its spectrum is shown in Fig. 6. A similar precipitate, having an identical spectrum, is obtained during the reaction of $CuCl_2$ with H_4N_2 in alkaline CH_3OH ($[KOH] \approx 10^{-7}$ mol dm^{-3}). Similar spectra of Cu^{II} complexes with hydrazine and its derivatives (similar to Fig. 1) are known.[59,60] ν_{N-H} and δ_{N-H} present in Fig. 6 prove the reduction of N_2 to H_4N_2. A 2 : 1 molar ratio of H_4N_2 to $CuCl_2$ in the complex has been found. Taking into account the possible symmetries of Cu^{II} complexes[61] and with the aid of analysis of normal modes of NH_2 groups (seen in Fig. 6), one can come to the conclusion that the complex of Cu^{II} with H_4N_2 has a D_{2d} symmetry, because the number of normal vibrations active in the IR for the NH_2 group is six ($3B_2$ and $3E$). Complexes with D_{4h} or C_{2v} symmetry should have four (A_{1u}, $2E_u$ and B_{2u}) and 11 ($4A_1$, $4B_1$ and $3B_2$) vibrations active in the IR, respectively. In Fig. 6 two bands (among four : $2B_2$ and $2E$) were assigned to ν_{Cu-N}. δ_{Cu-N} vibrations occur at a lower frequency than those in Fig. 6. Hence, according to Fig. 6, the Cu^{II} with H_4N_2 complex is the $CuCl_2 \cdot 2H_4N_2$ compound and it is a chain type polymer:



This conclusion is confirmed by magnetochemical data ($\chi_g = 3.2 \times 10^{-6}$ erg G^{-2} g^{-1}, and μ_{eff} calculated for an elementary unit of the chain polymer for a dimer is 0.8 mB) and by stoichiometrical analysis: Cu 23.3% (calc. 32.03%); Cl 35.2% (calc. 35.7%). A spectrum of $CuCl_2 \cdot 2H_4N_2$ did not change.

According to all these facts, the proposed mechanism of radiation-catalytic fixation and reduction of N_2 is as follows:

(0) $CH_3OH \rightsquigarrow e_s^-, CH_3OH_2^+,$

$H, CH_2OH(CH_2O^-)$

(1) $[MoOCl(dppe)_2]Cl \xrightarrow[CH_2O^-]{e_s^-, H}$

$[MoCl_2(dppe)_2] + CO + H_2 + H_2O$

(2) $[MoCl_2(dppe)_2] \xrightarrow[2N_2]{e_s^-, H}$

$[Mo(N_2)_2(dppe)_2] + 2Cl^-(HCl)$

(3) $[Mo(N_2)_2(dppe)_2] \xrightarrow[H_2^+]{CH_3OH_2^+}$

$$\left[\begin{matrix} N{-}NH_2 \\ \| \\ Mo(CH_3O)(dppe)_2 \end{matrix}\right]^+ + N_2$$

(4) $$\left[\begin{matrix} N{-}NH_2 \\ \| \\ Mo(CH_3O)(dppe)_2 \end{matrix}\right]^+ \xrightarrow[CH_3OH_2^+]{e_s^-, H}$$

$$\left[\begin{matrix} N{-}NH_2 \\ \| \\ Mo(dppe)_2 \\ \| \\ O \end{matrix}\right]^+ + CH_4 + CH_3OH$$

(5) $$\left[\begin{matrix} N{-}NH_2 \\ \| \\ Mo(dppe)_2 \\ \| \\ O \end{matrix}\right]^+ \xrightarrow[CH_3OH_2^+, H_2^+]{e_s^-, H, 2Cl^-}$$

$2NH_3 + [MoOCl(dppe)_2]Cl + CH_3OH.$

The reduction of $[MoOCl(dppe)_2]Cl$ and other complexes of Mo by e_s^-, H and CH_2O^- was observed earlier,[40-42] and the formation of $[MoCl_2(dppe)_2]$ was shown.[40] Of course, e_s^- can play some role in non-acidic solutions, while CH_2O^- can only participate when in alkaline solutions. Reaction (2) is confirmed quite well by formation of the Mo^0 bis-dinitrogen complex which is protonated at the very moment of formation [reaction (3)]. Reaction (3) is usually generated by H^+ ions or by molecules of alcohol.[7,62-64] Hydrogen atoms react with N_2 molecules in the gaseous state.[65] Hence, it is likely that the reduction of the N_2 ligand and H_4N_2 by molecular H_2^+ ions [reactions (3) and (5)] formed in acidic methanol ($H^+ + H \rightarrow H_2^+$ [66]), occurs. H_2^+ ions are able to reduce gaseous N_2,[67] so the reduction of coordinated nitrogen should be even easier.

Reaction (4) presents the formation of Mo=O and H_4N_2 (see Fig. 5). A hydrazide (2−) ligand in the Mo^{IV} with dppe complex is not reduced effectively by the central ion.[5,62,68] The unstable products of radiolysis (e_s^-, H, CH_2O^-) reduce the central ions to lower oxidation state ($k_{Mo^V + e_s^-} > 10^9$ $dm^3\ mol^{-1}\ s^{-1}$,[43] $k_{CH_3OH + e_s^-} \approx 10^5$ $dm^3\ mol^{-1}\ s^{-1}$ [72]), the reduced central ion reduces a protonated hydrazide ligand to H_4N_2 and then to H_3N [reactions (4) and (5)]. The poor reducing power of Mo^{IV} was mentioned,[62] therefore protonation of *trans*-$[Mo(N_2)_2(dppe)_2]$ does not lead to H_4N_2 and H_3N.[5,7,62]

The diamagnetic complex of Mo^{IV} with dppe and with =N—NH_2, exhibits C_{4v} symmetry, hence by analogy with $[MoOCl(dppe)_2]^+$ its electron configuration is likely to be $(b_2)^2$. A low Mo^{IV} reduction potential in the hydrazide complex can be explained by the delocalization of $(b_2)^2$ electrons on phosphorus 3*d* orbitals (strong Mo—P bond). Monodentate phosphines form weaker Mo—P bonds, hence the delocalization of the Mo electrons is not so effective; that electrons can more easily reduce the protonated hydrazide group.

Reaction (5) is confirmed by the formation of H_3N and the presence of $[MoOCl(dppe)_2]Cl$ in a product obtained after several irradiations of a solution of the Mo^{IV} complex saturated with N_2. A solution saturated with Ar contains only $[MoCl_2(dppe)_2]$. Multiple irradiation of that same solution of the Mo^{IV} complex with dppe and saturated with N_2 leads to H_4N_2, H_3N and $[MoOCl(dppe)_2]Cl$ in all cases. Hence, the fixation and the reduction of N_2 by the use of the Mo^{IV} complex in the field of radiation are radiation-catalytic processes in which $[MoOCl(dppe)_2]^+$ undergoes the necessary modification to a form which is able to fix N_2, and following a reduction of coordinated nitrogen a reproduction of the original form of catalyst occurs. Due to gradual reduction of N_2 it is possible, in some conditions, to obtain H_3N or H_4N_2, or simultaneously both of these products.

Abstract—The tricarbonyl complexes [M(CO)$_3$(NN)(CH$_3$CN)] (M = Mo, W; NN = bipy, phen, en) react with the binuclear complexes [η^5-$C_5H_5Fe(CO)_2(HgX)$] (X = Cl, Br, I, SCN, N_3) to generate trinuclear products of the formula [η^5-$C_5H_5Fe(CO)_2HgM(CO)_3(NN)X$]. These complexes were characterized using IR and electronic spectroscopy. The results are interpreted as the insertion of M(CO)$_3$(NN) fragments into the Hg—X bonds to give the Fe—Hg—M—X arrays, with the metallic centre, M, being seven-coordinate. The general properties of the new compounds and their reactivity towards monodentate bases and mercury halide derivatives are discussed.

In previous work,[1] we established that the reaction of the M(CO)$_3$(NN) fragments [M = Mo, W; NN = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen)] with mercury halides, HgX_2 (X = Cl, Br, I), can be considered as the insertion of the former between the atoms of the Hg—X bonds to give either bimetallic or trimetallic complexes with X—Hg—M—X and X—M—Hg—M′—X (M′ = Mo, W) arrangements, respectively.

In an effort to gain further insight into the factors and conditions determining the insertion behaviour of the M(CO)$_3$(NN) fragments, we have now studied this reaction with the [CpFe(CO)$_2$(HgX)] complexes (Cp = η^5-C_5H_5; X = Cl, Br, I, N_3, SCN).[2] The results of this study show that, in all cases, new trimetallic compounds are obtained, using as the source of the insertion fragments the [*fac*-M(CO)$_3$(NN)(CH$_3$CN)] complexes.[1]

RESULTS AND DISCUSSION

Treatment of the [CpFe(CO)$_2$(HgX)] compounds (X = Cl, Br, I, SCN, N_3) with [M(CO)$_3$(NN)(CH$_3$CN)] (M = Mo, W; NN = bipy, phen, en) in methanol at room temperature, affords the heteronuclear trimetal complexes [CpFe(CO)$_2$HgM(CO)$_3$(NN)X], according to the reaction:

$$[CpFe(CO)_2(HgX)] + [M(CO)_3(NN)(CH_3CN)] \longrightarrow [CpFe(CO)_2HgM(CO)_3(NN)X] + CH_3CN. \quad (1)$$

The new compounds are air-stable, orange coloured microcrystalline solids. On exposure to sunlight they decompose producing mercury. They are soluble in organic solvents such as methylene chloride, chloroform and acetone; less soluble in alcohols and insoluble in light petroleum. Nevertheless, they are not at all stable in solution.

IR spectra

The IR spectra of the [CpFe(CO)$_2$HgM(CO)$_3$(NN)X] complexes in the CO stretching region (Fig. 1, Table 1) show the superimposition of the characteristic patterns of the CpFe(CO)$_2$Hg[2] and [HgM(CO)$_3$(NN)X] moieties. The last one has been characterized in the [M(CO)$_3$(NN)X]$_2$Hg[1] and [M(CO)$_3$(NN)(X)(HgX)] complexes.[1,3] This

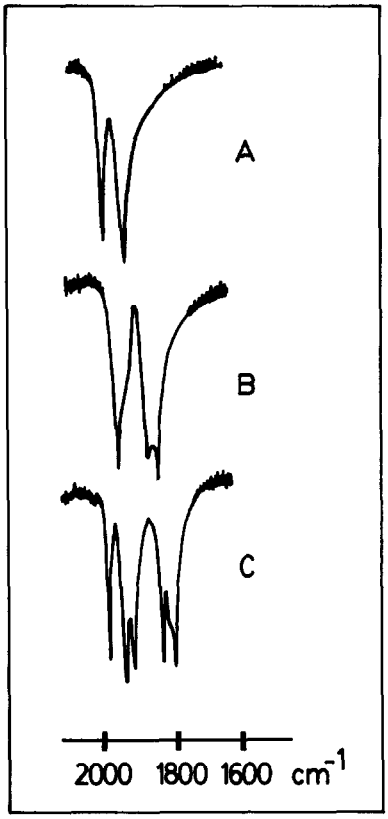

Fig. 1. IR spectra in the ν(CO) region of the complexes: (A) [CpFe(CO)$_2$(HgCl)]. (B) [Mo(CO)$_3$(bipy)(Cl)(HgCl)] and (C) [CpFe(CO)$_2$HgMo(CO)$_3$(bipy)Cl], measured using KBr discs.

fact is consistent with the M(CO)$_3$(NN) fragments having been inserted into the Hg—X bonds, giving rise to the Fe—Hg—M—X arrays.

The reaction products of the [CpFe(CO)$_2$HgSCN] complexes with [M(CO)$_3$(NN)(CH$_3$CN)] present the typical IR bands of the N-bonded thiocyanate ligands.[4] More specifically, the ν(CN) stretching vibrations appear near 2070 cm^{-1} and the patterns of the deformation vibrations, δ(NCS), are multiplets centred at *ca* 480 cm^{-1}. The products containing the azido group are characterized by the absorption ν(NN) at *ca* 2050 cm^{-1}. The other IR absorption regions show the presence of bands assignable to all other coordinated ligands.

Electronic absorption spectra in the visible region

The electronic spectra of the [CpFe(CO)$_2$HgM(CO)$_3$(NN)X] complexes in the visible region have been measured in dichloromethane solution. These consist of only one broad band in the 400–490 nm region when NN = bipy or phen, but it is absent if NN = en

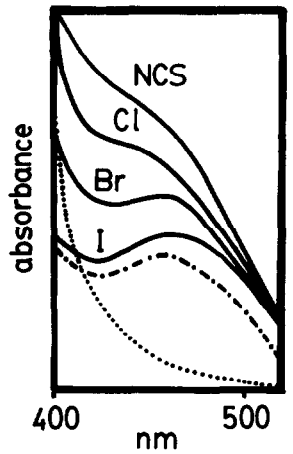

Fig. 2. Visible spectra of [CpFe(CO)$_2$HgMo(CO)$_3$(bipy)X] (——), [CpFe(CO)$_2$HgMo(CO)$_3$(en)Cl] (·····) and [Mo(CO)$_3$(bipy)(Cl)(HgCl)] (—·—·—·) complexes in dichloromethane solution.

(Table 1, Fig. 2). The intensity of this band is difficult to assess, as it generally appears on the tail of a much more intense absorption arising from the UV (Fig. 2). Nevertheless, in the [CpFe(CO)$_2$HgM(CO)$_3$(NN)] moiety, this absorption depends on X which is correlated with the spectrochemical series (Table 1), since it is shifted slightly towards the blue region in the sequence I < Br < Cl < NCS. Likewise, the related tricarbonyl complexes [M(CO)$_3$(NN)(X)(HgX)],[3] show comparable spectra (Fig. 2). For instance, their unique band in the visible ($\varepsilon > 3000$ M^{-1} cm^{-1}) is detected only when the π-delocalized bis-chelate ligands, bipy or phen, are present. These antecedents and the fact that the [CpFe(CO)$_2$(HgX)] complexes do not present absorption maxima in the visible, permit us to associate the band between 440 and 490 nm of the [CpFe(CO)$_2$HgM(CO)$_3$(NN)X] complexes with a NN(π^*) ← M($d\pi$) charge-transfer transition (MLCT).[5]

Reactivity of the [CpFe(CO)$_2$HgM(CO)$_3$(NN)X] *complexes with Lewis bases*

Dissolution of the [CpFe(CO)$_2$HgM(CO)$_3$(NN)X] complexes (M = Mo; NN = bipy, phen; X = Cl, Br, I) in donor solvents such as acetonitrile, produce slow colour changes of the solution from yellow to violet. The MLCT NN(π^*) ← M($d\pi$) absorption in the visible of the trimetallic complexes is displaced by that of the [Mo(CO)$_3$(NN)(CH$_3$CN)] complexes by *ca* 500 nm.[6] In addition, the UV region shows the superimposition of the bands of the [CpFe(CO)$_2$(HgX)] and [Mo(CO)$_3$(NN)(CH$_3$CN)] complexes. In methylene chloride and in the pres-

[d] Complex is too unstable in solution.

ence of an excess of monodentate base, such as triphenylphosphine or tetramethylthiourea, the trimetallic complexes react in a similar way to when they are in acetonitrile, giving solutions containing the $[CpFe(CO)_2(HgX)]$ and $[Mo(CO)_3(NN)L]$ complexes. These results suggest the existence of the equilibrium (L = donor solvent or monodentate bases):

$$[CpFe(CO)_2HgMo(CO)_3(NN)X] + L \longrightarrow [CpFe(CO)_2(HgX)] + [Mo(CO)_3(NN)L]. \quad (2)$$

The reaction rate of the $[CpFe(CO)_2HgMo(CO)_3(NN)X]$ complexes with acetonitrile was measured following the absorbance increase at 500 nm. The plots of $\ln(A - A_\infty)$ vs t yield straight lines indicating a first- or pseudo-first-order kinetic law. The rate constants depend on the electronegativity of the halide and increase in the sequence $Cl(k_{obs} = 0.1\ s^{-1}) < Br(k_{obs} = 1\ s^{-1}) < I(k_{obs}$ greater than $1\ s^{-1})$. When X = NCS or N_3 this reaction does not take place. Then, a plausible explanation for these results might be related mainly to the net electronic density upon the hepta-coordinate molybdenum atom.

The inert character of the $[CpFe(CO)_2M(CO)_3(NN)X]$ complexes (M = W) can probably be attributed to the softer character of the tungsten atom.

Exchange reactions with mercuric halides

The $[CpFe(CO)_2HgM(CO)_3(NN)Cl]$ complexes (M = Mo, W; NN = bipy, phen) react in acetone with $HgCl_2$. The characteristics of the reaction depend on the stoichiometric proportions of the reactants. If it is 1 : 1, the colour of the solution changes rapidly from orange to yellow, but if it is 2 : 1, then, besides the colour change, the symmetric trimetallic complexes $[M(CO)_3(NN)Cl]_2Hg$[1] are precipitated, while in solution the presence of the compound $[CpFe(CO)_2(HgCl)]$ is detected. These results suggest the occurrence of the following exchange reactions:

$$[CpFe(CO)_2HgM(CO)_3(NN)Cl] + HgCl_2 \longrightarrow [CpFe(CO)_2HgCl] + [M(CO)_3(NN)(HgCl)Cl] \quad (3)$$

$$[CpFe(CO)_2HgM(CO)_3(NN)Cl] + [M(CO)_3(NN)(HgCl)Cl] \longrightarrow [CpFe(CO)_2(HgCl)] + [M(CO)_3(NN)Cl]_2Hg. \quad (4)$$

In the first step, an exchange process involving the trimetallic complex $[CpFe(CO)_2HgM(CO)_3(NN)Cl]$ and mercuric chloride occurs, giving the soluble complexes $[CpFe(CO)_2(HgCl)]$ and $[M(CO)_3(NN)Cl(HgCl)Cl]$ [eq. (3)]. This last product, in its own time, exchanges with a second molecule of the initial complex yielding a solution containing the $[CpFe(CO)_2(HgCl)]$ complex and the insoluble compound $[M(CO)_3(NN)Cl]_2Hg$ [eq. (4)].

The verification of the above exchange reaction sequence was made by involving the $[CpFe(CO)_2HgM(CO)_3(NN)Cl]$ and $[M(CO)_3(NN)(HgCl)Cl]$ complexes in the reaction. The formation of the products indicated in eq. (4) was observed. Further evidence was gained when by this same process it was possible to isolate the asymmetric trimetallic complexes M′—Hg—M′[1] (M′ = Mo, W; NN = bipy, phen):

$$[CpFe(CO)_2HgM(CO)_3(NN)Cl] + [M'(CO)_3(NN')(HgCl)Cl] \longrightarrow [CpFe(CO)_2(HgCl)] + [Cl(NN)(CO)_3MHgM'(CO)_3(NN')Cl]. \quad (5)$$

The $[CpFe(CO)_2HgM(CO)_3(NN)Cl]$ complexes with NN = en, undergo the same reactions, but no noticeable colour changes of the solutions are observed due to the absence of the $NN(\pi^*) \leftarrow M(d\pi)$ band.

EXPERIMENTAL

The solvents were purified by standard methods and all operations were carried out under a nitrogen atmosphere. The starting materials, $M(CO)_4(NN)$,[7,8] $[M(CO)_3(NN)(CH_3CN)]$,[9] $[M(CO)_3(NN)(X)(HgX)]$[1,3] and $[CpFe(CO)_2(HgX)]$,[2] (M = Mo, W; NN = bipy, phen, en; X = Cl, Br, I), were prepared by similar methods to those described in the literature. The $[CpFe(CO)_2(HgX)]$ complexes ($X = N_3$, SCN) were precipitated by treating an acetonitrile solution of $[CpFe(CO)_2(HgCl)]$ with an excess of the NaX salt dissolved in water; the yellow crystals were filtered off and washed with water. The IR spectra were obtained by means of a Perkin–Elmer 577 spectrophotometer. The electronic spectra were recorded on a Carl–Zeiss DMR 22 instrument.

Synthesis of $[CpFe(CO)_2HgM(CO)_3(NN)X]$ ($Cp = \eta^5\text{-}C_5H_5$; M = Mo, W; NN = bipy, phen, en; X = Cl, Br, I, SCN, N_3)

These compounds were synthesized by reaction of the $[M(CO)_3(NN)(CH_3CN)]$ and $[CpFe(CO)_2(HgX)]$ complexes in methanol. All these substances were orange microcrystalline solids. The following preparation is described as a typical one.

$[CpFe(CO)_2HgMo(CO)_3(en)Cl]$. A mixture of 0.304 g (0.736 mmol) of $[CpFe(CO)_2(HgCl)]$ and 0.207 g (0.736 mmol) of freshly prepared $[Mo(CO)_3(en)(CH_3CN)]$ was vigorously stirred in 10 cm^3 of methanol in the dark for 0.5 h. The bright orange precipitate was filtered and washed 3–4 times with 3 cm^3 portions of methanol. 0.394 g (82% yield) of the microcrystalline compound were obtained. The elemental analyses of these compounds are given in Table 1.

COMPLEXES OF HYDROXAMATES—VII. EQUILIBRIA AND KINETICS OF IRON(III) REACTIONS WITH SALICYLHYDROXAMIC ACID

NADYAH M. SHUAIB,* MOHAMED S. EL-EZABY* and OMNIYA AL-HUSSAINI

Department of Chemistry, Faculty of Science, University of Kuwait, P.O. Box 5969, 13060 Safat, Kuwait

(*Received* 27 *September* 1988; *accepted after revision* 18 *January* 1989)

Abstract—The equilibria involved in the system iron(III)–salicylhydroxamic acid (SAX) has been studied at the ionic strength of 0.15 M Cl^- in the pH range 1.0–5.0, and at the ionic strength of 1.0 M Cl^- in the H^+ concentration range 0.01–1.0 M. Potentiometric as well as spectrophotometric methods have been used to determine the formation constants in aqueous solutions. Potentiometric methods yielded different equilibrium models to the spectrophotometric methods. The difference was rationalized on the basis that the iron(III) ions were easily hydrolysed to yield oligomeric forms when the ligand concentration was not in excess. The rate of the reaction of iron(III) with SAX has been also studied under pseudo-first-order conditions in the pH range 1.0–3.0 at 0.15 M Cl^- ionic strength, as well as in the H^+ concentration range 0.2–1.0 M at 1.0 M Cl^- ionic strength. A reaction mechanism is suggested and is discussed in the light of the spectrophotometric equilibrium results and compared with pertinent literature values.

Salicylhydroxamic acid (SAX) and its halogen derivatives have been reported to act as antitubercular, antifungal agents.[1] They showed strong hypoglycemic action and can lower blood serum cholesterol levels.[1] In addition, it was discovered to be effective against trypanosomiasis.[1]

Salicylhydroxamic acid forms stable complexes with iron(III) in acidic medium ($pH \leqslant 3.5$)[2] and the preparation of a tris-chelate solid has been reported.[3] However, a complete picture of iron(III) complexes with SAX over a wide range of pH has not been investigated. Furthermore, the kinetics of the interaction of iron(III) with SAX has not been studied.

The importance of such a study lies in the fact that simple monohydroxamic acids could be involved in the iron metabolic cycle for mammals. The successful prediction of biological activity for a given iron complex depends on our ability to relate the biological functions to the physicochemical properties of the complex measured *in vitro*. These properties are diverse and include solubility, toxicity, stability and lability under physiological conditions. Due to the tendency of iron(III) to undergo extensive hydrolysis and polymerization in aqueous solution, the prime concern is the selection of the ligand which stabilizes the metal ions at biological pH and secondly, is the lability of the formed complex. This work emphasizes these approaches.

EXPERIMENTAL

The stock solution of iron(III) chloride (Merck) was prepared in acidic media (1:1 at $pH < 1.0$). The concentration of iron(III) was checked by EDTA complexometric titration, as previously described.[5] SAX (Hundhill, 99%) stock solution (0.02 M; the maximum concentration in aqueous solution) was prepared by accurate weighing of the required amount of the solid (used as provided) and dissolving in doubly distilled water.

Measurements of pH were obtained using an Orion Research Ionalyser Model 901 provided with Orion glass (91-01) and calomel (91-02) electrodes, as well as a Radiometer Model PHM 84 Research pH-meter equipped with a Russell combined glass electrode (CNL). The Orion system was used in

* Authors to whom correspondence should be addressed.

the potentiometric titration, while the Radiometer system was used in the spectrophotometric study. The pH-meter was calibrated by using the appropriate Radiometer or Merck buffers (2.00, 4.00 and 6.87).

Kinetic measurements were carried out using the Union Giken Stopped-flow Reaction Analyser (RA-401) provided with an RA-451 data processor, RA-453 monitor scope and RA-452 x–y recorder. The recorded rates are the average of 5–10 replicate determinations. The data were processed using a program written for the Guggenheim kinetic method, followed by matching the calculated rate curves with the experimental curves.

Spectrophotometric measurements were obtained using a Shimadzu spectrophotometer Model 160 provided with thermostatted cuvettes.

The temperature was adjusted to $(25 \pm 0.1)^{\circ}C$ using Julabo and Grant thermostats. The ionic strength was kept at 0.15 M when the pH values were $\geqslant 1.0$ and at 1 M when they were in the H^+ concentration range 0.01–1.0 M.

The computation of formation constants was carried out using the potentiometric program SUPERQUAD (85)[6] and the spectrophotometric program SQUAD(II) (82).[7] The number of absorbing species was determined by making use of the TRIANG program.[8]

RESULTS AND DISCUSSION

Salicylhydroxamic acid interacted with iron(III) to produce different coloured solutions as the pH increased from ~ 1.0 to 7.5. Solution spectra are shown in Fig. 1. The maximum wavelengths are blue shifted as the pH increases. This is usually the case in most iron(III) complexation with chelating ligands. The change in absorbance with pH served as the basis for the determination of formation constants of the iron(III) complexes in solution. Although potentiometric methods are superior to spectrophotometric methods in the determination of the formation constants of the metal ion complexes in solutions, the latter approaches are favourable, in particular, in the case of iron(III) complexes where considerable hydrolysis and/or polymerization are known to occur in solution when an excess concentration of ligands was not used. In this work, the potentiometric method was used as a comparative method to emphasize the effect of variation in experimental conditions on the complex formation in solutions. The SQUAD II and SUPERQUAD programs have been used as previously described[5] to evaluate the formation constants given in Table 1. It was noticed that potentiometric methods yielded sets of constants different from those obtained by spectrophotometric methods. This may be due to the fact that in the latter case the concentration of ligand was at least 20 times that of iron(III), whereas, in the former case it was only three or four times. Higher concentrations of the ligand usually suppress the hydrolysis and/or polymerization of the metal ions in solution. In addition, lower concentrations of iron(III) [$(1.0–5.0) \times 10^{-5}$ M] were used in the spectrophotometric methods than in the potentiometric methods [$(0.05–1.0) \times 10^{-3}$ M].

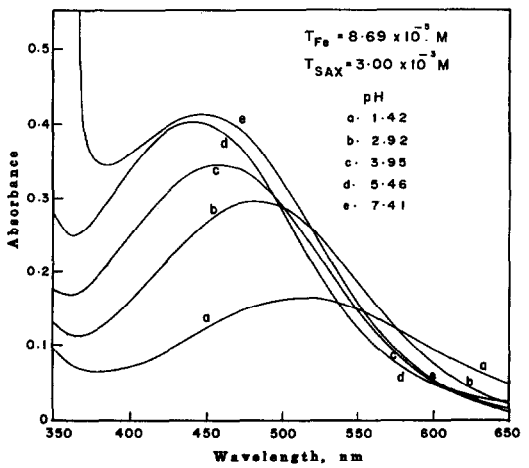

Fig. 1. The UV–vis spectra of iron(III)–SAX systems at different pHs.

Most of the formation constants obtained from the potentiometric results are for hydrolysed and polymerized species, while those obtained from spectrophotometry are mononuclear species with simple stoichiometry. We have not confirmed the presence of the previously reported[2] protonated species of the composition 1 : 1 : 2 (SAX^{-}–Fe^{3+}–H^{+}) at pH lower than 2.0. However, in a separate experiment, the spectra were taken in the H^+ concentration range 0.1–1.0 M at ionic strength 1.0 M Cl^-. One complex species was only determined with the stoichiometry 1 : 1 : 2, which is likely indicating the protonation of an —NH group. The mode of ligation cannot be simply decided from just the information obtained from potentiometric or spectrophotometric calculations. However, by analogy with other monohydroxamic and simple salicylic acids, one can predict the ligation sites involved in the complex formation. In the case of the protonated species 1 : 1 : 2, the ligation is through the oxygen atoms of the hydroxamate and carbonyl groups, and a five-membered chelate complex is probably formed with the protons located on the hydroxamate and phenoxy groups. This situation is usually encountered in most of the monohydroxamates. The chelation through the oxygen atom of the car-

bonyl group and the nitrogen atom of the hydroxamate is not possible since the less stable four-membered ring will be formed, in addition to the low affinity of iron(III) to the nitrogen atom.

In addition, there may be a possibility of ligation through the oxygen atom of the hydroxyl group and the oxygen atoms of either the carbonyl group or hydroxamate group to form either six- or seven-membered chelates, the latter being less probable. In this case the salicylhydroxamate will resemble the ligation property of salicylic acid (SAL) with iron(III).[11]

On the other hand, the ligation in the 1 : 1 : 1 species may be similar to the regular monohydroxamates where it is possibly through the oxygen atoms of the hydroxamate and carbonyl groups with the proton located on the phenoxy group ($pK_3 = 9.91$). The difference in the magnitudes of the formation constants of the 1 : 1 : 1 and 1 : 1 : 2 species is not significant (Table 1) and may be attributed to the difference in the ionic strength, which renders the value of the formation constant of 1 : 1 : 2 species less than that of the 1 : 1 : 1 species. This conclusion indicates that the 1 : 1 : 2 species is of lower stability than the 1 : 1 : 1 species and the deprotonation of the H_3SAX^+ is greatly facilitated in the presence of iron(III).

The other higher complex species occurs above

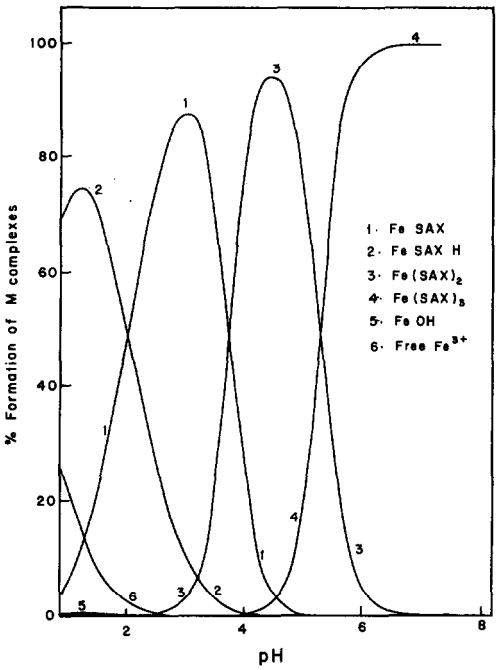

Fig. 2. SPECN program distribution diagram of different species as a function of pH, obtained from spectrophotometric measurements.

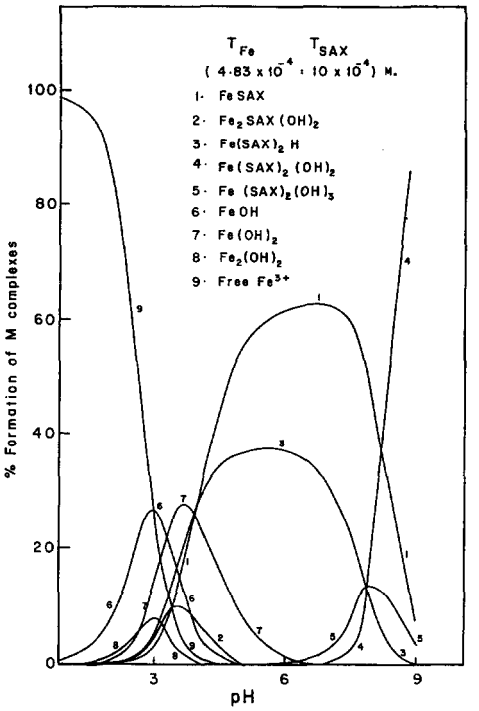

Fig. 3. SPECN program distribution diagram of different species as a function of pH, obtained from potentiometric measurements.

pH 3.0 and the mode of chelation is similar to the 1 : 1 species. The formation constants for all the complex species were obtained in the pH range 1.0–5.0. Figure 2 shows the dependence of the complex formation on pH as obtained from the program SPECN.[12] Unfortunately the spectral data above pH 5.0 did not yield an equilibrium model similar to that obtained from the potentiometric work, although they agree on the presence of three complex species (Table 1) but their formation constants are different.

The distribution of complex species as a function of pH obtained from the potentiometric study is shown in Fig. 3. The $1:1:-1$ or $2:1:-1$ species are just ternary complexes involving SAX and OH^- as ligands. The species involving more than one metal ion are mostly dimers where the OHs are probably acting as bridges between the metal ions.

It is worth mentioning that the complexes obtained from the spectrophotometric study have higher formation constants than those obtained from iron(III) with acetohydroxamic acid (AX),[12] which emphasizes the effect of the resonance of the aromatic ring on the stability of iron(III) complexes with hydroxamates.

The kinetics of the interaction of iron(III) *with* SAX

Two sets of kinetic experiments have been carried out at 0.15 and 1.00 M ionic strengths in the wavelength range 400–530 nm. The one at 0.15 M ionic strength was studied in the pH range 1.0–3.0, and the other at 1.0 M ionic strength was made in the H^+ concentration range 0.01–1.00 M. In both cases, pseudo-first-order conditions were preserved, in the first set the concentration of the ligand was at least 10 times that of iron(III) (T_{Fe} was kept constant) and in the second the concentration of iron(III) was at least 10 times that of the ligand (T_{SAX} was kept constant). Figure 4(a) shows the experimental dependence of k_{obs} on pH for the first set. The rate constants are monotonically increasing as the pH is increasing. A plot of the k_{obs} values as a function of T_{SAX} at interpolated pH values are linear, Fig. 4(b). These linear relations can be represented by the following equation:

$$k_{obs} = AT_{SAX}, \quad (1)$$

where A is a pH-dependent parameter. The mechanism of the reaction may be represented as in Scheme 1, where the aquated Fe^{3+}, $Fe(OH)_2^+$ are the only significant species in the iron(III) solution and H_2SAX is the only species in solution. The chloro complexes of iron(III) have been ignored due to their low formation constant values. The contributions of the iron(III) dimeric species to the mechanism have also been neglected under the experimental conditions used (pH = 1.0–3.0).

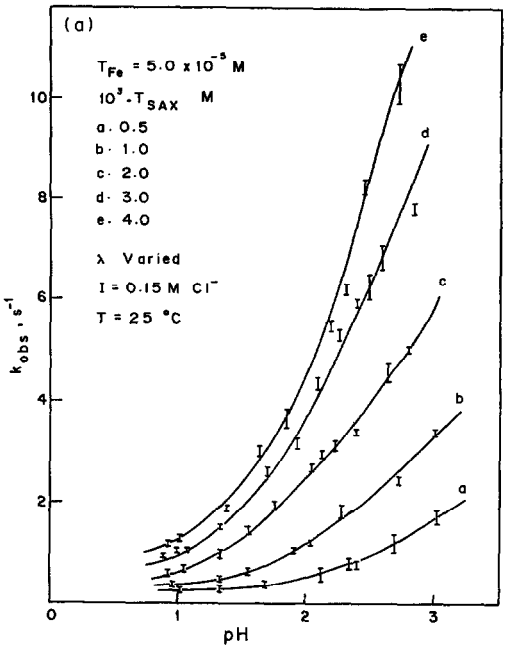

Fig. 4(a). The observed rate constants as a function of pH and T_{SAX}.

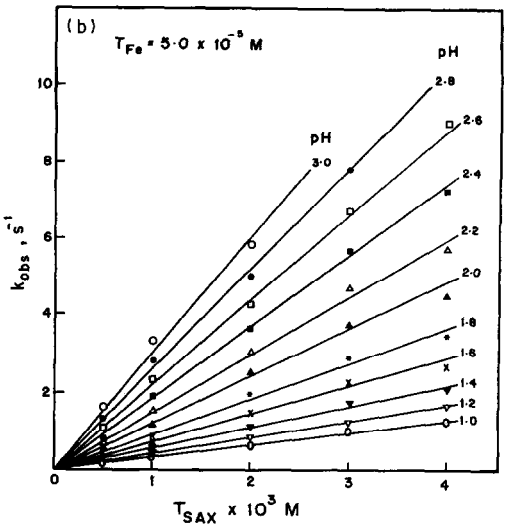

Fig. 4(b). The dependence of the observed rate constants, k, as a function of T_{SAX} at interpolated pH values obtained from Fig. 4(a).

One may ignore the contribution from the backward rate constants in the kinetic equation since the intercept at various values of pH are of negligible magnitudes ($\sim$ zeros), Fig. 4(b). The rate equation is expressed as follows:

$$d(C_1+C_2)/dt = Q_1\,dC_2/dt$$

$$= \alpha_{0SAX}T_{SAX}\left(\frac{T_{Fe-Q_1C_2}}{Q_2}\right)Q_3 \quad (2)$$

where,

$$C_1 = (FeHSAX^{2+}), \quad C_2 = (FeSAX^{+})$$

$$\alpha_{0SAX} = (H^+)^2/\{(H^+)^2+K_{1h}(H^+)+K_{1h}K_{2h}\},$$

where K_{1h} and K_{2h} are the first and the second deprotonation constants.

$$Q_1 = 1+(H^+)/K_{1CH}, \quad [K_{1CH} = (C_2)(H^+)/(C_1)],$$

$$Q_2 = 1+K_{10H}/(H^+)+K_{10H}K_{20H}/(H^+)^2,$$

$$K_{10H} = (FeOH)^{2+}(H^+)/(Fe^{3+}),$$

$$K_{10H}K_{20H} = Fe(OH)_2^+(H^+)^2/(Fe^{3+})$$

and

$$Q_3 = k_1+k_2+[K_{10H}/(H^+)](k_3+k_4)$$

$$+(K_{10H}K_{20H}/(H^+)^2)(k_5+k_6).$$

The integrated form of eq. (1) is:

$$k_{obs} = \frac{\alpha_{0SAX}Q_3}{Q_2}T_{SAX}. \quad (3)$$

On multiplying the slopes (Table 2) by Q_2 and by plotting as a function of $(H^+)^{-1}$, a straight line was obtained with an intercept equal

(a) $Fe_{aq}^{3+}+H_2SAX \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} FeHSAX^{2+}+H^+$

K_{1CH}

(b) $Fe_{aq}^{3+}+H_2SAX \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} FeSAX^{+}+2H^+$

(c) $Fe(OH)_{aq}^{2+}+H_2SAX \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} FeHSAX^{2+}+H_2O$

(d) $Fe(OH)_{2aq}^{+}+H_2SAX \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} FeSAX^{+}+H^+ +H_2O$

(e) $Fe(OH)_{2aq}^{+}+H_2SAX \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} FeHSAX^{2+}+H^+ +H_2O$

(f) $Fe(OH)_{2aq}^{+}+H_2SAX \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} FeSAX^{+}+2H_2O$

Scheme 1. k_i and k_{-i} are the forward and backward rate constants.

Table 2. The values of the parameter A at interpolated values of pH, and the calculated and observed values of AQ_2

pH	$10^{-2}\times A$	$10^{-3}\times(AQ_2)_{obs}$	$10^{-3}\times(AQ_2)_{calc}$
1.0	3.25	0.33	0.57
1.2	4.25	0.43	0.61
1.4	5.50	0.56	0.67
1.6	7.25	0.75	0.77
1.8	9.00	0.95	0.93
2.0	12.00	1.31	1.17
2.2	14.75	1.70	1.56
2.4	18.50	2.33	2.18
2.6	21.75	3.12	3.17
2.8	26.00	4.58	4.72
3.0	30.25	7.23	7.19

$AQ_2 = A(1+K_{10H}/(H^+)+K_{10H}K_{20H}/(H^+)^2)$ where A = slope of eq. (1).

to 4.67×10^2 ($=k_1+k_2$) and slope equal to 6.74 [$=K_{10H}(k_3+k_4)$]. This finding actually indicates that the reactions (a) → (d) in Scheme 1 are significant in the formation of the 1 : 1 metal complex species. There is, however, a slight variation between calculated and observed values of AQ_2 at lower pH values (Table 2). This may be explained as being due to the effect of the greater chloride complexing ability to iron(III) at higher acidity. The value of (k_1+k_2) is less than k_3+k_4 ($=7.56\times10^3$ $mol^{-1}\ dm^3\ s^{-1}$), indicating the higher reactivity of $FeOH^{2+}_{aq}$ over Fe^{3+}_{aq} species when interacting with SAX.

The observed rate constants, k'_{obs}, obtained at the ionic strength 1.0 M Cl^- have a peculiar dependence on the H^+ concentration. At a H^+ concentration lower than 0.2 M, a monotonic increase in k'_{obs} as the pH increased was observed, which is similar to the results obtained for the first set of experiments at 0.15 M ionic strength. However, at values greater than 0.2 M, there was an increase in the values of the k'_{obs} as the H^+ concentration was increased. There was a limited range of H^+ concentration where the k'_{obs} were not affected, Fig. 5(a). When the values of k'_{obs} were plotted as a function of T_{Fe}, at interpolated values of H^+ concentration, linear curves were obtained, Fig. 5(b). This behaviour can be expressed empirically as follows:

$$k'_{obs} = B+CT_{Fe}, \qquad (4)$$

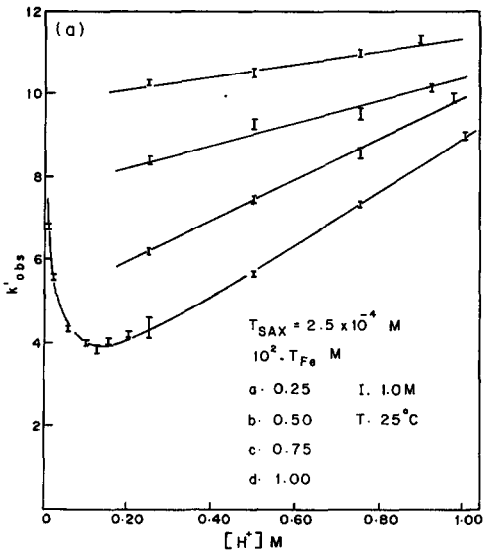

Fig. 5(a). The dependence of the observed rate constant, k', as a function of H^+ concentration at different T_{Fe} values.

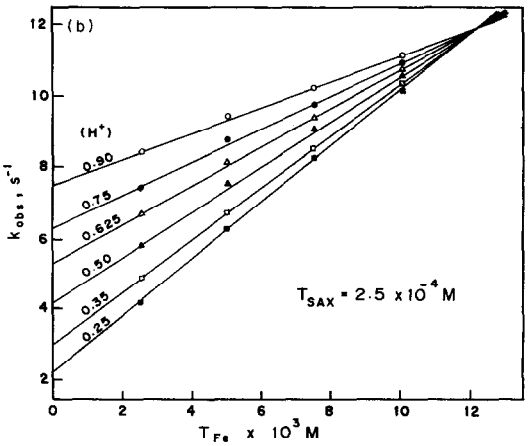

Fig. 5(b). The dependence of the observed rate constants, k', as a function of T_{Fe} at interpolated values of H^+ concentration.

where B and C are parameters which are dependent on H^+ concentration.

The rate data represented by eq. (4) can be described by the mechanism shown in Scheme 2.

The derived k'_{obs} is as follows:

$$k'_{obs} = Q_6+Q_5T_{Fe}/Q_2Q_4, \qquad (5)$$

$$Fe^{3+}_{aq}+H_3SAX^+ \rightleftharpoons FeH_2SAX^{3+}+H^+; \qquad k_1, k_{-1}$$

$$Fe(OH)^{2+}+H_3SAX^+ \rightleftharpoons FeH_2SAX^{3+}+H_2O; \qquad k_2, k_{-2}$$

Scheme 2.

Table 3. The values of the parameters B and C at interpolated values of H^+ concentration

$[H^+]$ (M)	B (s^{-1})	$10^{-2} \times C$ ($mol^{-1}\,dm^3\,s^{-1}$)	$10^{-2} \times (CQ_4Q_2)$
0.25	2.15	8.15	10.8
0.35	2.95	7.45	9.16
0.50	4.15	6.45	7.48
0.625	5.20	5.60	6.27
0.75	6.20	4.80	5.33
0.90	7.40	3.80	4.14

B and C are defined by eq. (4).

where H_3SAX^+ is the protonated species of H_2SAX ($pK_{1h} = 1.09$),

$$Q_4 = [(H^+) + K_{1h}]/(H^+),$$

$$(K_{1h} = [(H_2SAX)(H^+)/(H_3SAX^+)])$$

$$Q_5 = k_1 + k_2K_{10H}/(H^+)$$

and

$$Q_6 = k_{-2} + k_{-1}(H^+).$$

The plot of Q_6 ($= B$) (Table 3) vs (H^+) is linear in the H^+ concentration range $\sim$ 0.2–0.9, with values of the intercept and slope equal to 0.10 ($= k_{-2}$) and 8.11 ($= k_{-1}$), respectively. On the other hand, the plot of the quantity CQ_4Q_2 (Table 3) vs the reciprocal of H^+ concentration yielded a straight line, in the H^+ concentration range $\sim$ 0.3–0.9, with an intercept and slope equal to 0.7×10^2 ($= k_1$) and 3.43×10^2 ($= k_2K_{10H}$, i.e. $k_2 = 3.85 \times 10^5$). This reflects the importance of $Fe(OH)^{2+}$ species on the rate of the formation of FeH_2SAX. The mechanism shown in Scheme 2 has ignored the contribution from the chloro complexes of iron(III), $Fe(OH)_2^+$, and the iron(III) dimer, $[Fe_2(OH)_2]^{4+}$. However, the inclusion of the last two species did not successfully explain the rate data. Besides, the inclusion of the formation of the complex species, FeHSAX, in the mechanism did not interpret the dependence of the rate data on H^+ concentration.

CONCLUSION

The kinetic results of some structurally related systems are summarized in Table 4. It seems that the reactivity of $Fe(OH)^{2+}$ species towards different ligands are mostly similar except that a slight increase would be observed in the combination of the OH group with the hydroxamate group in the *ortho*-position. Although this similarity is clearly defined, the reactivity for Fe^{3+} is larger for ligands containing hydroxamate groups. This may indicate the ligand contribution to reactivity rather than that of the metal ion species. It is probably the first time a rate constant value $\sim$ 100 times greater than the regular value for the reactivity of $Fe(OH)^{2+}$, in the formation of FeH_2SAX species, has been reported. However, this may also indicate the more favourable reactivity of the chloro complexes of iron(III) towards these ligands, although these chloro complexes are not stable complexes.

Table 4. Summary of some SAX structurally related systems at 1.0 M ionic strength

Ligand	Rate constant Fe_{aq}^{3+} ($mol^{-1}\,dm^3\,s^{-1}$)	Rate constant $FeOH^{2+}$ ($mol^{-1}\,dm^3\,s^{-1}$)
Salicylic acid,[a] OHC_6H_4COOHS	$\leqslant 0.10 \times 10^2$	3.5×10^3

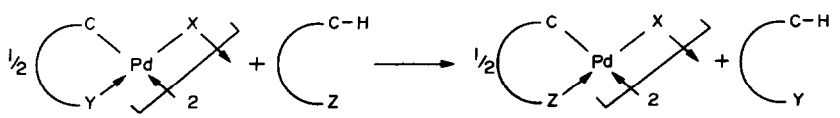
(*Received* 22 *December* 1988; *accepted* 24 *January* 1989)

Abstract—1-Diphenylphosphinomethyl-*o*-carborane, *o*-$HCB_{10}H_{10}CCH_2PPh_2$ (DPMC), reacts with Na_2PdCl_4 (methanol) or $PdCl_2(PhCN)_2$ (benzene) to give the "bis-adduct" *trans*-[$PdCl_2$(DPMC)$_2$], which on thermolysis in *n*-propanol transforms into the five-membered Pd—P—C—C—B palladacycle, di-μ-chlorobis[(1-diphenylphosphinomethyl-*o*-carboranyl-B,P)palladium(II)] (**IIa**), as a mixture of B(3) and B(4) metallated isomers according to ^{1}H and ^{31}P NMR. If the internal palladation is performed in the presence of LiBr or NaI, the corresponding bromo- or iodo-bridged dimers are obtained. Complex **IIa** can also be prepared via ligand exchange in carboxylic acid solvents. In particular, palladium(II) migrates from cyclopalladated chloro-bridged N,N-dimethylbenzylamine or 1C-diphenylphosphino-*o*-carborane, i.e. from complexes with C,N-five- and B,P-four-membered palladacycles, respectively, to 1-diphenylphosphinomethyl-*o*-carborane yielding **IIa**. Migration of palladium(II) is also observed from the compounds with great stability towards acetic acid, namely the [$PdCl(\eta^3$-allyl)]$_2$ dimers. No such processes except with this particular ligand were found in the case of palladium(II) allyls and other entering ligands (azobenzene, 2-phenylpyridine, α-methylstyrene). The exchange processes described clearly show that complex **IIa** is characterized by a remarkable thermodynamic stability in acetic acid which accounts for the course of many exchange reactions.

The σ-bond metathesis for C—H and related bonds in transition metal complexes is an intriguing problem.[1] In general, there are three key mechanisms of such metathetical transformations. The first, involving reductive C—H bond elimination, followed by oxidative addition, is typical, for example, of rhodium(I/III),[2] iridium(I/III),[3] and platinum(0/II)[4] couples; the second observed for scandium(III)[1] and thorium(IV)[5] complexes occurs via a concerted four-centred mechanism; finally, the third, realized in palladium(II) complexes,[6] is induced by the acid cleavage of the metal–carbon bond followed by subsequent metallation of the incoming ligand. The latter pathways were previously exemplified by the ligand exchange reactions of type (1), involving the starting cyclopalladated chloro- or acetato-bridged dimer and incoming ligand.[6]



(1)

In the present paper we report on several related reactions which involve not only the C—H bond metathesis but that of B—H and η^3-allyl bonds

* The key compounds used in this study are shown in Fig. 1.

as well and lead to cyclopalladated *o*-carboranes.[7] Some of the results presented here have been previously communicated.[8]

RESULTS

Interaction of P-*donor* o-*carboranes with simple palladium salts*

The reaction between DPMC, as well as DPMMC, and Na_2PdCl_4 in methanol or $PdCl_2(PhCN)_2$ in benzene, both at 20°C, cleanly affords the simple bis-adducts *trans*-$[PdCl_2(DPMC)_2]$ or *trans*-$[PdCl_2(DPMMC)_2]$ (Scheme 1). The geometry of the former is supported by a single strong IR band at 350 cm^{-1}.[9] As expected, the ligand is coordinated through phosphorus and only one isomer is present as judged from the corresponding $^{31}P\{^1H\}$ NMR singlet resonance of the complexed ligand at δ 10.9. (The free ligand resonates at δ −16.3.) Thermolysis of *trans*-$[PdCl_2(DPMC)_2]$ in different solvents induces the B—H bond palladation to afford a mixture of monomeric and dimeric complexes **Ia** and **IIa**, the relative amounts of which depend on the nature of solvent (Scheme 1). In particular, one obtains a 1 : 1 mixture in toluene, while only the dimer is formed in isopropanol. When thermolysed in isopropanol in the presence of a 10-fold excess of NaBr or NaI, *trans*-$[PdCl_2(DPMC)_2]$ transforms into the corresponding bromo- and iodo-bridged dimers **IIf** and **IIg**, in good yields. Two peaks of bridging chlorides in the IR spectrum are seen at 287 and 248 cm^{-1} and of bromides at 216 and 200 cm^{-1} (cf. with ref. 10). As usual, halide bridges can be cleaved by pyridine or 4-methylpyridine to afford monomers **III**, which are sufficiently soluble in common solvents, and, thus, useful for NMR structural investigations. The corresponding data for **III**, as well as for **I** and **II**, are summarized in Table 1. The formation of the five-membered palladacycle with a Pd—P—C—C—B chain makes the methylene CH_2 protons diastereotopic, giving in the ^1H NMR spectrum two quartet doublets with ^2J(HP) and ^2J(HH). Two sets of signals in **I**–**III** suggests that the complexes are a mixture of B(3) and B(4) palladated carboranes as shown in Fig. 2. The ^{31}P NMR spectra of **III** confirm this, since again two resonances are observed. It should be pointed out that the latter signals are doubled in the parent dimers **II** (Table 1). The reason is that every linkage isomer [B(3) or B(4)] is probably a mixture of *ab–hg* and *ab–gh* (*trans* and *cis*) isomers (see Scheme 1).

The nature of added metal halide has a remarkable effect on the rate of intramolecular metallation of *trans*-$[PdCl_2(DPMC)_2]$. The hot solution of the latter in *n*-propanol is yellow, and it becomes colourless when intramolecular palladation into **II** occurs. Thus, one can qualitatively estimate the relative rates in the presence of a 10-fold molar excess of MHal. At reflux, the fading occurs in a matter of 18–20, 10–15 and 5–7 min in the presence of LiCl, LiBr and NaI, respectively, the concentration of LiCl having negligible effect on the rate of internal metallation. Thus, the reactivity order Cl < Br < I suggests that this B—H bond palladation has a strong nucleophilic character. In accord with this is the relative amount of B(3) isomer formed (85%), which is independent of the nature of halide in the case of DPMC. In fact, the electron density is the lowest at B(3) of the *o*-carborane backbone,[11] and hence, the nucleophilic reagent would attack this position more readily. There is the same reactivity order in the case of DPMMC, but, contrary to DPMC, the relative amount of the B(4) isomer increases in the order Cl < Br < I (25, 35 and 70%, respectively), and this may reflect the steric effect of the methyl group at C(2), Fig. 2.

Direct palladation of DPC, DP2MC, and DPIC proceeds with such facility that the metallation occurs at 20°C giving four-membered palladacycles **Ic, IId** and **IIe**, respectively, in high yields (Table 2). Dimeric **IIc** is not formed under these conditions. The ratio of B(3) and B(4) isomers is the same as in the exchange reactions (see below). Only in the case of DP2MC is it strongly dependent on the solvent used. In particular, one obtains only the

B(4) isomer of **IId** in MeOH, while a mixture of B(3) and B(4) in a ratio of 1 : 4 and 3 : 2 is seen in $CHCl_3$–HOAc (1 : 1) and benzene, respectively.

Interaction of DAMC *with palladium salts*

The transformations of DAMC in the presence of simple palladium complexes (Scheme 2) are much the same as those of the related phosphorus ligands DPMC and DPMMC. Thermal cyclopalladation of *trans*-$[PdCl_2(DAMC)_2]$ in *n*-propanol again gives a 1 : 1 mixture of B(3) and B(4) isomers identical to those in Fig. 2, as judged from the two sets of diastereotopic methyls at As of equal intensity.

Cyclopalladation of DPMC *and related ligands via the exchange of cyclopalladated ligands*

Dimers **II** can be very easily prepared in high yields by the ligand exchange strategy, eq. (2), developed by us previously for C,N-palladacycles.[6] In particular, DPMC and DPMMC react readily with an equimolar amount of chloro-bridged cyclopalladated N,N-dimethylbenzylamine, [PdCl (damp)]$_2$, at 70°C in a HOAc–$CHCl_3$ mixture, to afford five-membered palladacycles, **IIa** and **IIb**, respectively, without detectable amounts of monomers **I**, Table 3. As above, complexes **II** are a mixture of B(3) and B(4) palladated species. The

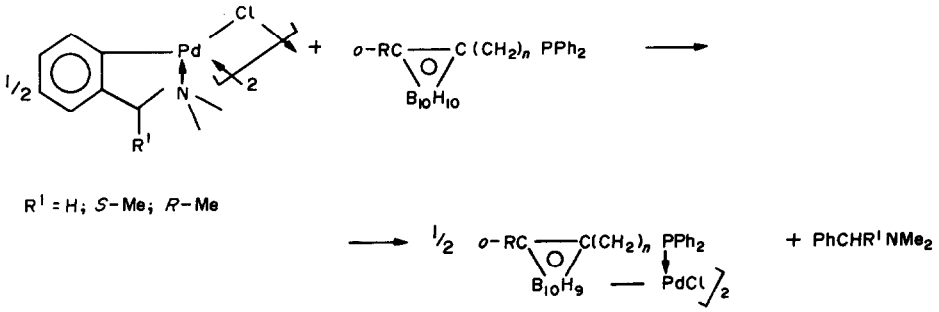
9	**IIe**	$HCB_{10}H_{10}CCH_2PPh_2$	60/6	**IIa**	65		

relative amounts of these according to ^{31}P NMR of the monomeric d_5-py derivatives, are shown in Table 3. It should be pointed out that the "carborane version" of the exchange reaction is limited by the ligands with phosphorus donor atoms. Ligands with N-donors, namely *o*-$HCB_{10}H_{10}CCH_2NEt_2$ and *o*-$HCB_{10}H_{10}CN{=}NPh$, reduce palladium(II) in acetic acid medium, as carboranes without donor centres do reacting with palladium(II) acetate.[12]

According to ^1H NMR, the interaction between $[PdCl(damp)]_2$ and DPMC begins with the cleavage of chloro-bridges of the palladium dimer by the phosphorus donor. (No such cleavage occurs during the formation of the four-membered palladacycles, see below.) Since mono-substituted *o*-carborane is prochiral,[13] the reaction with optically active cyclopalladated *R* and *S* α-methyl-N,N-dimethylbenzylamine, $[PdCl(daep)]_2$, could afford optically active palladated DPMC. The product **IIa** proved to be racemic, confirming the previous conclusion that the exchange of cyclopalladated ligands proceeds by the dissociative route, i.e. the palladation of C—H and B—H bonds follows the complete departure of the leaving ligand.[6c]

Five-membered palladacycles incorporating the As donor atom are also available via the ligand exchange. In particular, DAMC reacts with $[PdCl(damp)]_2$ to give **V** without **IV**, Scheme 2.

Four-membered cyclopalladated carboranes can also be prepared in the same way even under milder conditions, Table 3. In particular, DPIC and $[PdCl(damp)]_2$ react in a HOAc–$CHCl_3$ mixture at room temperature to give **IIe** in an isolated 40% yield. No pre-equilibrium bridge-cleavage by these incoming ligands takes place, obviously, due to their large cone angles. Remarkably, the ^{31}P NMR spectrum of dimeric **IIe** contains only two signals at δ 13.2 and 13.4 as expected for the mixture of *ab–hg* and *ab–gh* isomers. Addition of d_5-py, which monomerizes the dimer, transforms the two signals into one at δ 14.8, as expected for the one-linkage isomer. We believe that the palladacycle formed is the B(4) isomer, since the B(3) position is sterically hindered by the bulky isopropyl group, Fig. 2. Isopropyl C—H bonds are not metallated, and one can observe two doublets of diastereotopic methyls at δ 0.45 and 1.13 (J = 7 Hz) in the case of **IIIe**. Contrary to five-membered palladacycles **IIa,b,f,g**, the ^{11}B NMR spectroscopy of four-membered species **IIc–e,h** gives direct evidence for the presence of the Pd—B bond. In particular, the ^{11}B NMR spectrum of **IIe** contains a well separated signal shifted



(2)

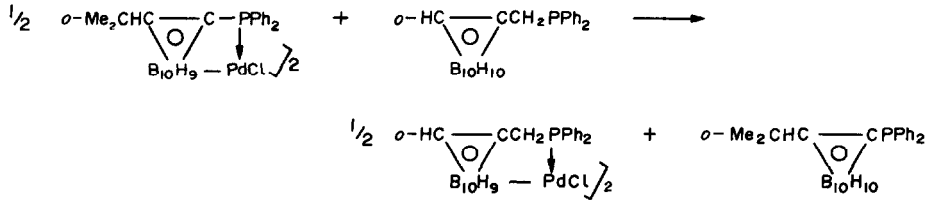
upfield at δ −19.3, the area under which corresponds to one boron. It should be pointed out that we never observed such separated ^{11}B signals in the related five-membered complexes.

DP2MC reacts with $[PdCl(damp)]_2$ like DPIC giving, however, a mixture of B(3) and B(4) palladated products. There are two corresponding signals both in the ^{31}P (δ −1.4 and 13.1) and ^{11}B (δ −16.6 and −18.9) NMR spectra of the monomeric complex obtained from **IId** and d_5-py. It is clear that the less sterically demanding methyl group allows the palladation of the B^3—H bond as well giving B(3) and B(4) products in a molar ratio of 1 : 4. Under the same conditions DPC also gives **IIc** in a low yield but without monomer **Ic**.

The ligand exchange in P-*donor* B-*palladated complexes*

In the previous section we considered the palladium(II) transfer from an N-donor ligand to a P-donor one. It was interesting to find out whether such an exchange from a P-donor ligand is possible. Reaction (3), between the four-membered cyclopalladated chloro-bridged dimer derived from DPIC (**IIe**) and free DPMC, shows that this is the case yielding the five-membered B-palladated chloro-bridged dimer **IIa** in 65% yield. It should be pointed out that the exchange takes place when only DPMC is the incoming ligand. No migration of palladium(II) from **IIe** was observed when $PhCH_2PPh_2$ or *o*-$PhCB_{10}H_{10}CN{=}NPh$ were tested as palladium(II) scavengers. At the same

time the reaction between $[PdCl(dmap)]_2$ and $PhCH_2PPh_2$ yields the cyclopalladated product $[PdCl(o\text{-}C_6H_4CH_2PPh_2)]_2$ in 21% yield (see Experimental). Note that palladation of $PhCH_2PPh_2$ by $Pd(OAc)_2$ gives the corresponding acetato palladacycle in 19% yield.[14] possibly indicating different mechanisms of the two rearrangements. By measuring the concentration of α-methylstyrene liberated, one could follow the reaction kinetics by GLC (Fig. 3). It is seen that the initial rate of dissociation is practically independent



(3)

Palladation of DPMC *by* η^3*-allyl palladium*(II) *dimers*

We have recently presented evidence[15] that $[PdCl(\eta^3\text{-allyl})]_2$ complexes are very resistant to protolytic cleavage, and the departure of the η^3-bonded allyl in acetic acid takes place in the monomeric phosphine complex $[PdCl(\eta^3\text{-}2\text{-}PhC_3H_4)(PPh_3)]$ when the latter is thermolysed at 80°C in the presence of lithium chloride:

$$[PdCl(\eta^3\text{-}2\text{-}PhC_3H_4)(PPh_3)] + HOAc + LiCl \longrightarrow \tfrac{1}{2}[PdCl_2(PPh_3)]_2 + H_2C{=}CMePh + LiOAc. \quad (4)$$

Wishing to carry out the reaction of type (4) with DPMC as a tertiary phosphine, we have found that the compound $[PdCl_2(DPMC)]_2$ does not form, but complex **IIa** is obtained instead [eq. (5)]. The reaction course is independent of whether the η^3-allyl dimer and DPMC or prepared before the monomer $[PdCl(\eta^3\text{-allyl})(DPMC)]$ has been introduced into the reaction (Table 4). The ratio of B(3) and B(4) isomers formed (Table 4) differed from that observed above in reaction (2) in acetic acid solvent, of the nature of added salt. We have also found that reaction (5) occurs even in the absence of added salts and the highest yield of **IIa** (75%) is achieved in this case. It is noteworthy that a palladacycle from the η^3-allylpalladium moiety was obtained by

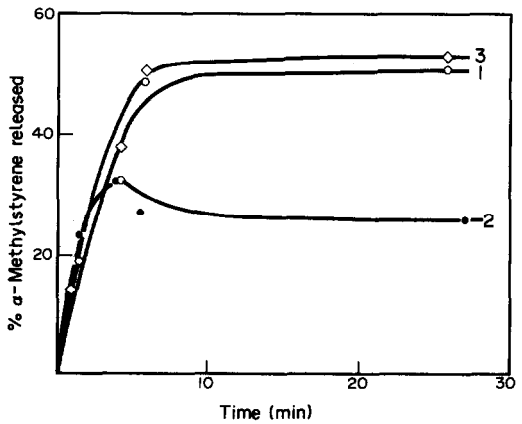


Fig. 3. Kinetic curves of reaction (5), as followed by measuring the liberation of α-methylstyrene from **VIb** by GLC: 1—LiCl, 2—LiBr and 3—LiI; 80°C, HOAc–$CHCl_3$.

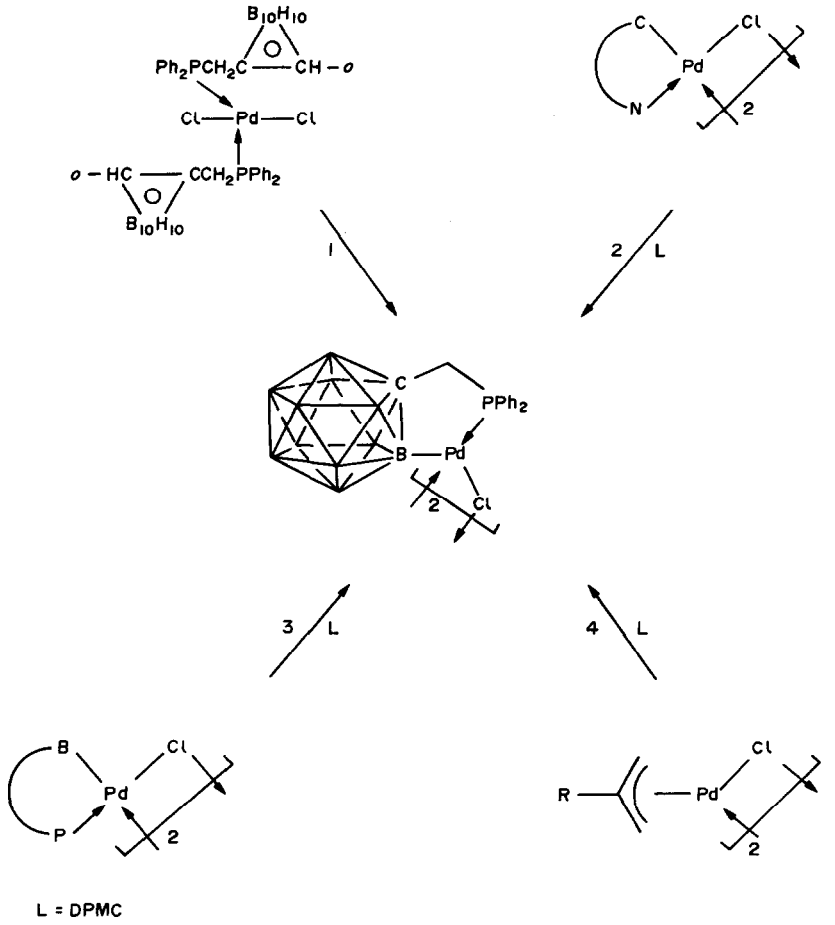
us only in the case of the carborane with a tertiary phosphine group in a side chain. No migration of palladium(II) from η^3-allyls to azobenzene, 2-phenylpyridine, N,N-dialkylbenzylamines as well as the exchange between dimeric η^3-allyls and corresponding allylic alkenes occurs.

VI [R = H (a), Ph (b)]

DISCUSSION

The cyclopalladated derivative of DPMC can be prepared in several ways as shown in Scheme 3. Of particular interest are pathways 2–3 which occur in acidic media. Our previous mechanistic investigation of the exchange of cyclopalladated C,N ligands[6c] revealed that at equilibrium, palladium(II) is preferably bound to a ligand which is the most resistant to the acidic cleavage, in particular, by acetic acid. The results of the present study clearly show that C,N-palladacycles are less protolytically stable than C,P, B,P and B,As ones; the four-membered B,P-carboranyl palladacycles are less stable than the corresponding five-membered ones. But the most surprising was the migration of palladium(II) from η^3-allyls which are very strongly bound to the central atom. It is clear that the lability of η^3-allyls is profoundly increased by the coordinated tertiary phosphines, since no exchange is observed in the case of 2-phenylpyridine, although the latter readily cleaves chloro-bridges of $[PdCl(\eta^3\text{-}2\text{-}PhC_3H_4)]_2$ to yield $[PdCl(\eta^3\text{-}2\text{-}PhC_3H_4)(2\text{-}Phpy)]$ with an equilibrium constant of 1.8×10^3 M^{-1} in $CHCl_3$ at 25°C. At the same time, one should assume that **IIa** itself must be very unreactive



Scheme 3.

towards acidic solvents. This was shown[6c] to be the driving force of the exchange of σ-bound ligands in palladium(II) complexes in protic solvents. Palladacycle **IIa** thus appears to be a deep "potential well" in acidic media, since the σ-bond metathesis leads to this particular compound in all cases studied.

EXPERIMENTAL

Instrumentation

IR spectra in the 400–4000 cm^{-1} region were recorded on a JASCO A-200 spectrophotometer with KBr pellets; those in the far-IR region were obtained on a Bruker JFS-113 instrument in Nujol mulls. ^1H NMR spectra were obtained using Tesla BS-467 (60 MHz) and Bruker WP-200 SY (200 MHz) spectrometers using TMS as internal standard. Chemical shifts are given in the δ scale and J are in Hertz throughout. ^{11}B and ^{31}P spectra were recorded on the Bruker instrument with BF_3–Et_2O and 85% H_3PO_4 as external standards, respectively.

Materials

Palladium(II) cyclopalladated complexes $[PdCl(damp)]_2$ and $[PdCl(daep)]_2$, were prepared as described in refs 16 and 17, respectively. $PhCH_2PPh_2$ was obtained according to ref. 18. Precursors of the four-membered B,P-palladacycles DPC, DPIC and DP2MC were prepared as described in ref. 19. Diphenylphosphinomethyl carborane derivatives and DAMC were synthesized according to the procedures of Zakharkin *et al.*,[19,20] respectively. Preparation of palladium(II) η^3-allyl complexes is described in detail elsewhere.[15]

General procedure for the synthesis of bis-adducts trans-$[PdCl_2L_2]$, *the precursors of five-membered palladacycles*

To a solution of DPMC, DPMMC or DAMC (1.6 mmol) in 5 cm^3 of benzene (or 10 cm^3 of methanol), 0.75 mmol of $PdCl_2(PhCN)_2$ in 10 cm^3 of benzene (or Na_2PdCl_4 in 10 cm^3 of methanol) was added and the mixture was stirred for 3 h at room temperature. The precipitate formed was filtered, washed with hexane and dried *in vacuo*. Yields and analytical data of the compounds formed are summarized in Table 2.

Cyclopalladation of trans-$[PdCl_2(DPMC)_2]$ *in toluene*

The bis-adduct (0.43 g, 0.46 mmol) was refluxed in 15 cm^3 of toluene. In a matter of 20 min the reaction mixture turned colourless from dark yellow; 20–25 cm^3 of heptane was added and the mixture cooled. The crystals formed were filtered, washed with hexane and dried to yield 100 mg (45%) of dimeric compound **IIa**. The mother liquor was evaporated *in vacuo* and the residue was crystallized from benzene–hexane to yield 178 mg (45%) of monomeric compound **Ia**. The corresponding characteristics are given in Tables 1 and 2.

Cyclopalladation of trans-$[PdCl_2(DAMC)_2]$ *in toluene*

This was performed as described above to yield 30 mg (13%) of **V** and 310 mg (82%) of **IV** from 0.40 g (0.57 mmol) of the starting material. For data see Tables 1 and 2.

General procedure for the cyclopalladation of trans-$[PdCl_2(DPMC)_2]$ *and* trans-$[PdCl_2(DPMMC)_2]$ *in* n-*propanol*

A mixture of 0.50 g of the complex and a 10-fold excess of lithium bromide or sodium iodide in 20 cm^3 of *n*-propanol was refluxed until the solution faded. The precipitate formed after cooling was filtered, washed consequently with water, methanol and hexane, and dried to yield **IIa,b**. For data see Tables 1 and 2.

Non-metathetical cyclopalladation of 1-*diphenylphosphino*-o-*carboranes*

To 1.0 mmol of DPC, DPIC or DP2MC dissolved in 5–10 cm^3 of the corresponding solvent (MeOH, C_6H_6), 0.5 mmol of the palladium(II) compound (Li_2PdCl_4, Na_2PdCl_4, $PdCl_2(PhCN)_2$), dissolved in 15–20 cm^3 of the same solvent, was added and the mixture was mixed at room temperature until it became colourless. The precipitate which formed was filtered, washed with hexane and recrystallized from benzene–hexane to yield either monomer **Ic** or dimers **IId,e**. The bromo-bridged dimer can be obtained by performing the reaction in methanol in a 10-fold excess of LiBr. For data see Tables 1 and 2.

Di-μ-chlorobis[(2-*diphenylphosphinomethylphenyl*-C^1,P)*palladium*(II)]

To a mixture of $[PdCl(damp)]_2$ (0.095 g, 0.17 mmol) and $PhCH_2PPh_2$ (0.096 g, 0.34 mmol) in 3 cm^3 of chloroform, acetic acid (3 cm^3) was added. The reaction solution was kept for 4 days at room temperature and then 20:20 cm^3 of $CHCl_3$–H_2O was added. The organic layer was separated, twice

washed with 10 cm^3 water and dried over $MgSO_4$. The solution was then concentrated *in vacuo* and column-chromatographed (SiO_2–$CHCl_3$). The first band was separated, the solvent removed, and the residue recrystallized from hexane–benzene to afford pale yellow crystals of [PdCl(*o*-$C_6H_4CH_2PPh_2$)]$_2$ (0.030 g, 21%). Found: C, 56.0; H, 4.2. Calc. for $C_{19}H_{16}ClPd \cdot 1/6C_6H_6$: C, 55.8; H, 4.0%. Spectral data were as reported in ref. 14.

Metathetical preparation of di-μ-chlorobis[(1-*diphenylphosphinomethyl- and -2-methyl-*o*-carboranyl*-B^{3,4},P)*palladium*(II)] (**IIa** *and* **IIb**)

(a) *From* [PdCl(damp)]$_2$ *or* [PdCl(daep)]$_2$. Acetic acid (4 cm^3) was added to a mixture of [PdCl(damp)]$_2$ (0.0975 g, 0.175 mmol) and DPMC (0.121 g, 0.35 mmol) dissolved in 4 cm^3 of chloroform. The solution was thermostatted at 70°C for 25 h. Cooling to room temperature afforded white scaly crystals which were washed subsequently with $CHCl_3$–HOAc (1:1), HOAc, HOAc–H_2O (1:1) and pure water. Product **IIa** was then dried *in vacuo* over NaOH. Yield 83% (0.142 g). **IIb** was obtained in 95% yield in a similar way.

(b) *From di-μ-chlorobis*[(1C-*diphenylphosphino*-2C-*isopropyl*-*o*-*carboranyl*-B^4,P)*palladium*(II)] (**IIe**). Acetic acid (2 cm^3) was added to a solution of **IIc** (0.078 g, 0.077 mmol) and DPMC (0.060 g, 0.176 mmol) in 2 cm^3 of chloroform. The mixture was thermostatted for 6 h at 60°C to produce fine white crystals of **IIa**. The mixture was cooled to −5°C and after 30 min the crystals were filtered and treated as above. Yield 65% (0.048 g).

(c) *From di-μ-chlorobis*[(η^3-*allyl*)*palladium*(II)]. Acetic acid (4 cm^3) was added to a mixture of [PdCl(η^3-C_3H_5)]$_2$ (0.143 g, 0.39 mmol) and DPMC (0.116 g, 0.34 mmol). The resulting solution was kept at 80°C for 24 h to produce white crystals of **IIa** which were treated as above. The runs with [PdCl(η^3-2-PhC_3H_4)]$_2$ in the absence and in the presence of lithium chloride, bromide and iodide were obtained in a similar way. Data are given in Table 4.

Metathetical preparation of di-μ-chlorobis[(1-*diphenylphosphino*-2-*isopropyl*-*o*-*carboranyl*-B,P)*palladium*(II)] (**IIe**) *from* [PdCl(damp)]$_2$

Acetic acid (9 cm^3) was added to a mixture of DPIC (0.260 g, 0.690 mmol) and [PdCl(damp)]$_2$ (0.190 g, 0.345 mmol). This mixture was kept for 60 h at room temperature and then 20:20 cm^3 $CHCl_3$–H_2O was added. The organic layer was separated, washed twice with water (10 cm^3) and dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue was crystallized from benzene–hexane. White crystals of **IIe** were filtered, washed with hexane and dried. Yield 40% (0.141 g). Data are given in Tables 1 and 2.

Metathetical preparation of di-μ-chlorobis[(1-*diphenylphosphino*-2-*methyl*-*o*-*carboranyl*-B,P)*palladium*(II)] (**IIf**)

A solution of [PdCl(damp)]$_2$ (0.263 g, 0.746 mmol) and DP2MC (0.212 g, 0.746 mmol) in 9 cm^3 of chloroform was mixed with 9 cm^3 of HOAc. The mixture was filtered and allowed to stand for 48 h at room temperature. White crystals which formed were filtered, washed consequently with HOAc–$CHCl_3$ (1:1), HOAc, HOAc–H_2O (1:1), H_2O and air-dried to yield 0.130 g of **IIf** (35%). An additional crop of less pure **IIf** (0.146 g) can be obtained by slow evaporation of chloroform from the initial filtrate, the total yield being 74%. Data are given in Tables 1 and 2.

REACTION OF ORGANOALUMINIUM SPECIES WITH BIDENTATE PHOSPHINE LIGANDS. SYNTHESIS AND MOLECULAR STRUCTURE OF $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2(CH_3)]$ AND $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$

SAMUEL A. SANGOKOYA, BAOSHENG LEE, MARK F. SELF, WILLIAM T. PENNINGTON and GREGORY H. ROBINSON*

Department of Chemistry, Clemson University, Clemson, SC 29634-1905, U.S.A.

(*Received* 30 *November* 1988; *accepted* 27 *January* 1989)

Abstract—Reaction of methylaluminium sesquichloride with bis(diphenylphosphino) methane and bis(diphenylphosphinoyl)methane affords $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2(CH_3)]$ (**I**) and $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (**II**), respectively. Compound **I** crystallizes in the triclinic space group $P\bar{1}$ with unit cell parameters $a = 10.009(3)$, $b = 10.748(4)$, $c = 14.806(5)$ Å, $\alpha = 90.38(3)$, $\beta = 103.36(2)$, $\gamma = 96.89(3)°$, $V = 1537.5$ Å^3 and $\rho = 1.36$ for $Z = 2$. Compound **II** crystallizes in the monoclinic space group $C2$ with unit cell parameters $a = 12.773(2)$, $b = 13.028(3)$, $c = 9.461(2)$ Å, $\beta = 104.43(2)°$, $V = 1524.60$ Å^3 and $\rho = 1.49$ for $Z = 2$. Full-matrix least-squares refinement based on 3034 observed reflections for **I** converged at $R = 0.047$ ($R_w = 0.066$); full-matrix least-squares refinement based on 1565 observed reflections for **II** converged at $R = 0.043$ ($R_w = 0.050$). Both products result from reaction of the disproportionation products of methylaluminium sesquichloride, $AlCl_3$ and $AlCl_2(CH_3)$.

Principally due to the fact that the close proximity of the two phosphorus atoms can often facilitate interesting behaviour in bimetallic complexes,[1–5] the bidentate phosphine ligand bis(diphenylphosphino)methane has proven to be quite popular in transition metal chemistry. Interestingly, the oxygen analogue of this ligand, bis(diphenylphosphinoyl)methane, has generated substantially less attention in transition metal chemistry. Although there has been sporadic interest in the organo main group chemistry, specifically organoaluminium chemistry, of bis(diphenylphosphino) methane,[6–11] the literature reveals only one study concerning the corresponding chemistry of bis(diphenylphosphinoyl)methane.[12] Herein, we report the synthesis and molecular structure of $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2(CH_3)]$ (**I**) and $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (**II**), isolated from reaction of methylalumium sesquichloride with bis(diphenylphosphino)methane and bis(diphenylphosphinoyl) methane, respectively.

EXPERIMENTAL

Synthesis

Standard Schlenk techniques were employed in conjunction with an inert atmosphere dry-box (Vacuum Atmospheres HE-43 Dri-Lab). Solvents were purified and degassed prior to use. Methylaluminium sesquichloride was purchased from Aldrich Chemical Company and used as received. Both phosphine ligands were prepared in our laboratory. Single crystal X-ray data were collected on a Nicolet R3m/V diffractometer with graphite-monochromated Mo-K_α radiation. ^{1}H NMR data were recorded on a JEOL-FX90Q NMR spectrometer. ^{31}P NMR data were recorded on an IBM 200-MHz NMR spectrometer.

(1) $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2(CH_3)]$ (I)

Inside the dry-box a reaction vessel was charged with bis(diphenylphosphino)methane (1.0 g, 2.8 mmol) and toluene (25 cm^3). Methylaluminium sesquichloride (1.0 cm^3, 3.0 mmol) was slowly added via syringe. Reaction was immediate and exothermic. The reaction vessel was subsequently removed

from the dry-box and heated in an oil bath for 6 h at 100°C. The solution was filtered and transferred to a 100 cm^3 Schlenk flask. The solution was concentrated and the flask was cooled to −15°C when colourless, extremely air-sensitive crystals were isolated; m.p. = 160–162°C. ^1H NMR (C_6D_6): δ −0.371 (s, 3H, Al(CH_3)), 3.72 (d of d, 2H, P—CH_2—P, $J_{P—CH}$ = 5.5 Hz), 7.36 (m, 20H, $2C_6H_5$). ^{31}P NMR (C_6D_6): δ −25.85 (d, 1P, *P*—Al($(CH_3)Cl_2$), 4.87 (d, 1P, *P*—$AlCl_3$, $J_{P—P}$ = 53.71 Hz).

(2) $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (II)

A reaction vessel was charged with bis(diphenylphosphinoyl)methane (0.50 g, 1.2 mmol) and methylaluminium sesquichloride (0.47 cm^3, 2.4 mmol) in a mixture of chlorobenzene–heptane (28 and 2 cm^3, respectively). The reaction vessel was removed from the dry-box and heated in an oil bath (120°C) for 24 h. Upon cooling to room temperature a multitude of small colourless, rectangular, extremely air-sensitive crystals were obtained in quantitative yield; m.p. = 177–179°C. ^1H NMR ($CDCl_3$): δ 3.5 (t, 2H, P—CH_2—P), 7.2 (m, 20H, C_6H_5). ^{31}P NMR ($CDCl_3$): δ 46.33 (s, 2P, *P*—$AlCl_3$).

X-ray structural solution and refinement

Single crystals of both compounds were mounted in thin-walled glass capillaries under an inert atmosphere of argon. Structures of both compounds were solved by direct methods using the SHELXTL[13] package of computer programs. Early in the refinement of **I** the thermal parameters of atoms Cl(5) and C(26) indicated that each of these two positions was occupied by both chloro and methyl groups, alternatively. The occupancy factors of these two atoms, both treated as chlorine, refined to values of 0.77 and 0.58, respectively. These values indicate that the position reported for the Cl(5) atom is occupied 55% by a chlorine atom and 45% by a methyl group, and that the position reported for the C(26) atom is occupied 55% by a methyl group and 45% by a chlorine atom. Hydrogen atoms of the methylene and phenyl groups for both compounds were located by standard difference Fourier techniques and were included in the structure factor calculations at idealized positions ($d_{C—H}$ = 0.95 Å); the methyl hydrogen atoms for compound **I** could not be located. An isotropic group thermal parameter was refined for the phenyl and methylene hydrogen atoms of each compound. As **II** crystallizes in an acentric space group,* refinement was carried out for both enantiomeric conformations of the molecule. Refinement of the model corresponding to the reported coordinates yielded residual values of $R = 0.043$, $R_w = 0.050$, and GOF = 1.15, while an identical refinement of the inverted model yielded final residuals of $R = 0.0436$, $R_w = 0.0502$, and GOF = 1.17. A summary of crystallographic data is given in Table 1.†

RESULTS AND DISCUSSION

For some time now this laboratory has been interested in the interactions of organoaluminium species with various sulphur-[14–16] and nitrogen-based[17–20] macrocyclic ligands. More recently our attention has shifted to the corresponding organoaluminium chemistry of multidentate open chain amines.[21–23] As a logical extension of this work we have endeavoured to examine the organoaluminium chemistry of multidentate phosphorus ligands. The versatile bidentate phosphine ligand bis(diphenylphosphino)methane was chosen to initiate these studies. We have recently reported interesting products resulting from reaction of organoaluminium species with bis(biphenylphosphino)methane,[6] its oxygen derivative,[12] and its sulphur derivative.[24] An interesting study concerning the organo main group chemistry of the bidentate phosphine ligand bis(diphenylphosphino)ethane has recently appeared.[25] Herein, we report the synthesis and molecular structure of $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2CH_3]$ (**I**) and $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (**II**).

In that methylaluminium sesquichloride, $(CH_3)_3Al_2Cl_3$, is usually regarded as a mixture of dimethylaluminium chloride and methylaluminium dichloride, it is interesting to note that **I** contains one $AlCl_2(CH_3)$ adduct and one $AlCl_3$ adduct, while **II** contains two $AlCl_3$ units. The presence of these species can be traced to Lewis acidity and basicity. Ziegler[26] reported nearly 30 years ago that an alkylaluminium halide dimer, in the presence of a sufficiently strong Lewis base, will readily disproportionate to favour the strongest available Lewis acid species. Necessarily, Ziegler suggested

* Space group *C*2 was verified as the correct choice by analysis of intensity distribution, packing considerations, and by the successful solution and refinement of the structure.

†Supplementary material available. Tables of crystal data, fractional coordinates, bond distances and angles, and calculated and observed structure factors have been deposited with the Cambridge Crystallographic Data Centre. Complete structural information is available from the Editor.

that this proceeds through the transient formation of a mixed alkyl–halo-bridged dimer (instead of the more commonly preferred di-halo-bridged dimer). Similarly, it is reasonable that the dimer of methylaluminium sesquichloride, capable of producing the reactive aluminium species in I and II, $AlCl_3$ and $AlCl_2(CH_3)$, proceeds through a mixed halo–alkyl- (chloro–methyl-) bridged species. Bridge cleavage of such a dimer would provide both $AlCl_3$ and $AlCl_2(CH_3)$. This situation for methylaluminium sesquichloride is illustrated in Fig. 1. Furthermore, of all the possible dimeric species of methylaluminium sesquichloride, only the mixed bridged species given in Fig. 1 can readily provide the reactive species [$AlCl_3$ and $AlCl_2(CH_3)$]. Indeed, we have recently observed a similar disproportionation of diethylaluminium chloride in its reaction with the nitrogen macrocycle cyclam.[17]

The X-ray crystal structure of $[AlCl_3][(Ph_2P)_2CH_2][AlCl_2(CH_3)]$ (I) is given in Fig. 2. The mean Al—Cl bond distance in I is 2.097(3) Å. The overall conformation of $(Ph_2P)_2CH_2$ in I is easily compared to that of the uncomplexed ligand.[27] The central methylene P—C—P bond angle in the uncomplexed ligand of 108.2(5)° is generally indicative of an atom in a tetrahedral environment. This P—C—P bond angle in I has increased to 122.4(2)°, resulting in C(13) being in a severely distorted tetrahedron. A comparison of I with the recently reported $[Al(CH_3)_3]_2[(Ph_2P)_2CH_2]$[6] complex is warranted. The P—C—P bond angle of 121.4(2)° in this complex is not as great as that observed in I. The Al—P bond distances of 2.585(2) and 2.521(2) Å in $[Al(CH_3)_3]_2[(Ph_2P)_2CH_2]$ compares to 2.451(2) and 2.497(2) Å for I.

While bis(diphenylphosphino)methane has been

examined in organoaluminium chemistry, the corresponding chemistry of the oxygen analogue, bis(diphenylphosphinoyl)methane, has remained largely unexplored. This ligand was allowed to react with methylaluminium sesquichloride; $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (II) was the only product isolated. The X-ray crystal structure of $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (II) is given in Fig. 3. Compound II resides about a crystallographic two-fold axis. The independent Al—O bond distance of 1.756(5) Å indicates a relatively strong aluminium–oxygen interaction. The P—O bond distance is 1.512(5) Å. Due to a relaxation of steric constraints, the P—C—P bond angle of 119.5(5)° in II is expectedly less than that observed in I. The mean Al—Cl distance is 2.107(4) Å.

Even though the presence of an oxygen atom on each phosphorus atom serves to sufficiently increase the acidity of the methylene hydrogen atoms so as to facilitate condensation in the presence of trimethylaluminium,[12] condensation is not observed in the present case where an alkylaluminium halide is concerned.

The fact that I contains one $AlCl_3$ adduct and one $AlCl_2(CH_3)$ adduct, while II has two $AlCl_3$ adducts is particularly noteworthy. It is reasonable that the central P—C—P fragment of the ligand plays a predominant role in the isolated reaction products. As mentioned earlier, the P—C—P bond angle in the uncomplexed ligand is 108.2(5)°. To accommodate one $AlCl_3$ and $AlCl_2(CH_3)$ unit, as in I, the P—C—P bond angle increased to 122.4(2)°. It is therefore conceivable that for bis(diphenylphosphino)methane to accept two of the slightly larger $AlCl_3$ units [rather than one of each $AlCl_3$ and $AlCl_2(CH_3)$], the P—C—P would have been forced to undergo still further distortion from its preferred tetrahedron. Thus, it was easier for the ligand to accept one slightly smaller $AlCl_2(CH_3)$ unit and one $AlCl_3$ unit than two $AlCl_3$ units. Conversely, in II the presence of an oxygen atom on either phosphorus atom serves to relieve some of

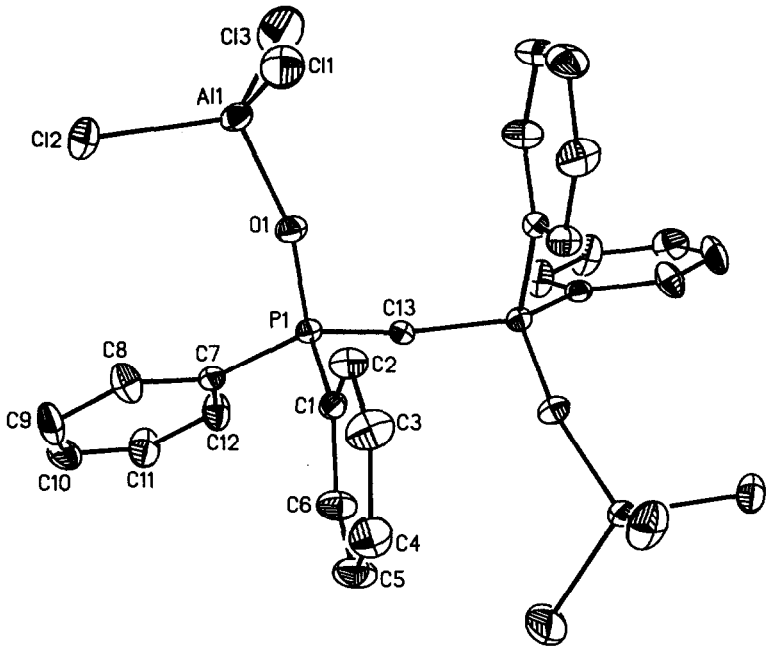

Fig. 3. A view of the $[AlCl_3]_2[(Ph_2P(O))_2CH_2]$ (II) molecule showing the atom labelling scheme. Thermal ellipsoids show 35% probability levels; hydrogen atoms have been omitted. the immediate steric strain about the P—C—P (P—C—P = 119.5(5)°) fragment and bis(diphenylphosphinoyl)methane was able to accept two $AlCl_3$ units.

We feel that this study is significant in that it provides further information on the dimeric species of alkylaluminium halides in the presence of strong Lewis bases.

(*Received* 29 *November* 1988; *accepted* 27 *January* 1989)

Abstract—$Fe(CO)_2[O_2CCH_2P(C_6H_5)_2]_2$ (I) was synthesized from $FeSO_4 \cdot 7H_2O$ and $Na[O_2CCH_2P(C_6H_5)_2]$ under CO pressure. The 18-electron compound has an octahedral coordination sphere around Fe^{2+}. Two diphenylphosphinoacetate ligands are bonded to the iron through the phosphorus atoms and one of the oxygen atoms of the carboxylato groups. Two carbonyl groups and two carboxylato oxygen atoms are in *cis* positions to each other, while the phosphorus atoms adopt *trans* positions. The unit cell contains both enantiomers of the chiral octahedral compound.

Due to the possibility of obtaining compounds with interesting structures and increased reactivity, the combination of hard and soft donor atoms in bidentate ligands has recently become more attractive,[1–4] especially since N—P and O—P type bidentate ligands have been used with success in homogeneous catalysis.[5,6] In continuation of our studies on iron(II) carbonyl complexes, prepared by the convenient method of CO absorption at atmospheric pressure,[7,8] we now report the synthesis and X-ray crystal structure of $Fe(CO)_2[O_2CCH_2P(C_6H_5)_2]_2$ (I), which to our knowledge, is the first mononuclear dicarboxylato iron carbonyl.

RESULTS AND DISCUSSION

Synthetic and spectroscopic results

Compound I was synthesized from $FeSO_4 \cdot 7H_2O$ and $Na[O_2CCH_2P(C_6H_5)_2]_2$ under CO pressure according to eq. (1):

$$Fe^{2+} + 2(C_6H_5)_2PCH_2CO_2^- \xrightarrow[MeOH,\ 100°C]{133\ bar\ CO} \underset{(I)}{Fe(CO)_2[O_2CCH_2P(C_6H_5)_2]_2}. \quad (1)$$

Under ambient conditions (1 bar CO, 25°C), there is no CO absorption. This result contrasts the synthesis of the isoelectronic and structurally similar compounds of formulae, $Fe(CO)_2(S—N)_2$ (S—N = *o*-$SC_6H_4NH_2$ or $SCH_2CH_2NH_2$)[7] and $Fe(CO)_2(DPPE)(SR)_2$ (DPPE = $Ph_2PCH_2CH_2PPh_2$; R = C_2H_5, $CH(CH_3)CH_2CH_3$, C_6H_5, etc.).[8] Compound I can also be prepared from $Fe(CO)_4I_2$ and $Na[O_2CCH_2P(C_6H_5)_2]$, but this route is less convenient and yields a less pure product.

The soft and nucleophilic character of the phosphorus atoms is probably one of the major contributors to the formation and thermal stability of I. While compounds of type $Fe(CO)_4(O_2CR)_2$ are not known and also other types of group VIII metal carbonyls containing M—O bonds are rather rare, in I the strong electron-withdrawing effect of the oxygen atoms is compensated by the two phosphorus atoms. Another factor contributing to the

† Authors to whom correspondence should be addressed.

stability of **I** is the special chelate effect of the ligand. For example, all our efforts to synthesize $Fe(CO)_2(PR_3)_2(O_2CR)_2$ type complexes with monodentate ligands, as well as experiments with P—P and O—O type diphos and dicarboxylato ligands were unsuccessful. In addition, the synthesis of the analogous complex $Fe(CO)_2[O_2CCH_2CH_2P(C_6H_5)_2]_2$ from $FeSO_4 \cdot 7H_2O$ and $Na[O_2CCH_2CH_2P(C_6H_5)_2]$ according to eq. (1) was unsuccessful; this result reflects the importance of the number of atoms in the chelating ligand.

In the solution IR spectrum of **I** (CH_2Cl_2), three well separated CO absorption bands were found. The band at 1660 cm^{-1} is assigned to the carboxylato C=O group, while the two bands of equal intensity in the metal carbonyl region (2048 and 1998 cm^{-1}) are characteristic of a *cis*-dicarbonyl structure. The latter two absorptions are at somewhat higher wave numbers ($\approx$ 20–25 cm^{-1}) than the ν(CO) bands of the $Fe(CO)_2(DPPE)(SR)_2$ complexes, which reflects the stronger electron-withdrawing capability of the carboxylato group as compared to the thiolate ligand.

The ^{31}P NMR ($CDCl_3$) spectrum of **I** shows a single absorption at δ 38.5 ppm due to the equivalent phosphorus nuclei. (The symmetry element is a C_2 axis.) The ^1H NMR spectrum ($CDCl_3$) displays multiplets of the phenyl protons in the range δ 7.4–7.9 ppm and two doublets of virtual triplets at δ 3.44 ppm, as well as 3.65 ppm. These latter resonances can be assigned to the diastereotopic methylene protons (H_AH_B) of the ligands which both couple with the phosphorus atoms ($H_AH_BP_XP_{X'}$ pattern, $^2J(H_AH_B) = 16.5$ Hz and $J(H_AP_XP_{X'}) = J(H_BP_XP_{X'}) = 11.0$ Hz). The following signals were found in the ^{13}C NMR spectrum (CD_2Cl_2): δ 34.8 (CH_2, t, $^1J(CP) = 28.2$ Hz), δ 127.7–134.1 (aromatic carbons), δ 177.2 (CO_2 groups, t, $^{2+3}J(CP) = 21.3$ Hz), δ 209.7 (CO groups, t, $^2J(CP) = 42$ Hz). The investigation of the reactions of **I** is the subject of further studies in the Veszprém laboratory.

X-ray structural results

A single crystal of the title compound, crystallized from CH_2Cl_2–*n*-hexane, was used for diffraction data collection. Data were collected at room temperature on a CAD-4 (Enraf–Nonius) with graphite-monochromated Mo-K_α radiation ($\lambda = 71.07$ pm). Parameters of data collection are summarized in Table 1. Lattice constants were obtained by a least-squares fit of 75 reflections in the range $37.07 \leqslant 2\theta \leqslant 58.8$.[10] Intensities of three standard reflections for decomposition and three orientation control reflections were measured every 60 min and every 200 reflections, respectively, during data collection. No decay or disorientation has been observed. Corrections for Lorentz and polarization effects were applied. No correction was applied on account of a negligible absorption coefficient ($\mu = 6.9\ cm^{-1}$). The structure was solved by direct methods (SHELX-86)[11] and refined by subsequent least-squares and difference Fourier techniques.[12] All hydrogen positional parameters could be obtained from difference Fourier maps and were refined with individual isotropic thermal parameters. All non-hydrogen atoms were refined using anisotropic thermal parameters. Scattering factors were taken from ref. 13, including anomalous scattering.[14] The refinement yielded final R values of $R = 0.047$ and $R_w = 0.035$, with all observed reflections ($I \geqslant 0.0$). With a maximum of 0.16 e $Å^{-3}$ and a minimum of -0.18 e $Å^{-3}$, final difference Fourier maps demonstrated no more significant electron density. All computations were carried out on a VAX 11/730 and a VAX 8200 with the Program System STRUX.[15]

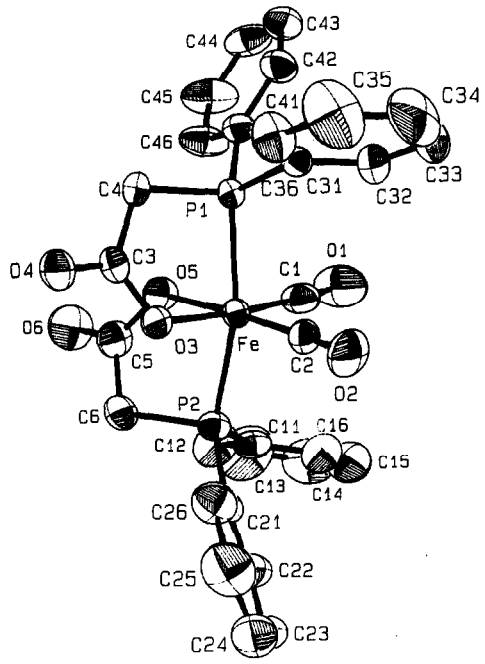

Fig. 1. ORTEP drawing[16] of $Fe(CO)_2[O_2CCH_2P(C_6H_5)_2]_2$, at 50% probability level, showing the labelling scheme. Hydrogen atoms are omitted for clarity.

The structure of the molecule can be best described as a distorted octahedron (see Fig. 1). Two phosphorus atoms (d(Fe—P) 225.24(3) pm and 226.18(3) pm) are in *trans* positions to each other. The remaining coordination sites are occupied by two carboxylato oxygen atoms in *cis* positions [d(Fe—O) 197.80(8) and 198.46(7) pm;

EXPERIMENTAL

$Na[O_2CCH_2P(C_6H_5)_2]$ was prepared according to ref. 15.

Synthesis of $Fe(CO)_2[O_2CCH_2P(C_6H_5)_2]_2$ (I)

A 100 cm^3 rocking autoclave was charged with 1.0 mmol of $FeSO_4 \cdot 7H_2O$ (278 mg), 2.0 mmol of $Na[O_2CCH_2P(C_6H_5)_2]$ (532 mg) and 55 cm^3 of methanol under an atmosphere of CO. Then the vessel was pressurized to 100 bar CO at 25°C and kept for 4 h at 100°C in a rocking autoclave heater. After 4 h the pressure was released, and the yellow solution as well as the solid was transferred under argon to a Schlenk tube. The solvent was pumped off. The residue was then first washed with a small amount of benzene–*n*-hexane mixture (1 : 2), then extracted with CH_2Cl_2. The CH_2Cl_2 solution was filtered under argon to remove Na_2SO_4. Addition of *n*-hexane and cooling to −20°C yielded yellow crystals of I. After recrystallization from the CH_2Cl_2–*n*-hexane (2 : 1) mixture, analytically pure I was obtained. Yield: 390 mg (65%). Single crystals suitable for X-ray diffractometry were grown by the slow diffusion method from CH_2Cl_2–*n*-hexane. Melting point, 210°C (dec.). Found: C, 60.1; H, 4.1; Fe, 9.5; P, 10.5. Calc. for $C_{30}H_{24}FeP_2O_6$: C, 60.2; H, 4.0; Fe, 9.3; P, 10.3%.

COBALT(II) AND COBALT(III) COMPLEXES WITH HEXADENTATE DIOXIME SCHIFF BASE LIGANDS

M. MOHAPATRA, V. CHAKRAVORTTY and K. C. DASH*

Department of Chemistry, Utkal University, Vani Vihar, Bhubaneswar—751004, India

(*Received* 5 *July* 1988; *accepted after revision* 27 *January* 1989)

Abstract—Cobalt(II) salts interact with the hexadentate dioxime Schiff base ligands derived from triethylenetetramine and isonitroso ethylmethyl ketone (H_2L') or isonitrosopropiophenone (H_2L''), to form two interesting types of complexes. With CoX_2 (X = Cl, NCS), binuclear, four-coordinated cobalt(II) complexes of the type $[Co_2(H_2L)X_2]X_2$ (L = L′, L″; X = Cl, NCS) are formed, which are paramagnetic with low magnetic moments (2.5–3.5 BM). In contrast, under identical conditions, CoX_2 (X = Br, I, NO_3, ClO_4) form mononuclear, six-coordinated and diamagnetic cobalt(III) complexes of the type $[Co(HL)]X_2$.

The vicinal dioximes e.g. dimethylglyoxime (DH_2), form cobalt(III) complexes containing the Co $(DH_2)^+$ group, which closely simulate the reactions of vitamin-B_{12} and are important in its model chemistry.[1–3] Imidazole is a versatile ligand for metal ions in many biologically important molecules.[4,5] Recent work from this laboratory has focussed attention on the interaction of imidazole with cobaloximes.[6–9] As a continuation of our work on cobaloximes[6–9] and with a view to gain more knowledge about the interaction of the dioxime-based Schiff base complexes, we have now synthesized a series of tetra-, penta- and hexadentate ligands in order to study their ligating behaviour with cobalt as such and in the presence of imidazole ligands.

This paper is concerned with the hexadentate dioxime-based Schiff base ligands, N,N′,N″,N‴-triethylenetetramine bis(isonitroso ethylmethylketoneimine) (H_2L') and N,N′,N″,N‴-triethylenetetramine bis(isonitroso propiophenoneimine (H_2L'') (**I**), synthesized by the condensation of triethylenetetramine with isonitroso ethylmethylketone (diacetylmonoxime) and isonitrosopropiophenone, respectively. The formation of $[Co(H_2L')](ClO_4)_3$, $[Co(H_2L')Br_3]\cdot 3H_2O$ and $[Co(L')](ClO_4)$ using the hexadentate ligand H_2L' has been reported.[10] With the same ligand, Chakravorty and co-workers[11] obtained Fe(L′), $[Fe(H_2L')](ClO_4)_2$, $[Ni(H_2L')](ClO_4)_2$ and $[Ni(L')](ClO_4)_2$ complexes, in addition to the above cobalt(III) complexes. Our investigation using a different synthetic approach and a series of coordinating and non-coordinating anions yield two different types of complexes—$[Co_2(H_2L)X_2]X_2$ (L = L′, L″; X = Cl, NCS) (**II**) and $[Co(HL)]X_2$ (L = L′, L″; X = Br, I, NO_3, ClO_4) (**III**). The former series of complexes are paramagnetic and binuclear, where the ligands seem to act as binucleating ligands forming two four-coordinate cobalt(II) centres, and in the latter, the six-coordinating sites of the mono-protonated hexadentate ligands, H_2L' and H_2L'', are bonded to one cobalt(III) centre, yielding diamagnetic, octahedral complexes. While all the complexes were synthesized from cobalt(II) salts, oxidation of cobalt(II) to cobalt(III) occurred in most cases (except for Cl^- and NCS^- salts) even in the absence of any external oxidizing agent.[12] With $CoCl_2$ and $Co(NCS)_2$, dimeric, paramagnetic cobalt(II) compounds were formed.

EXPERIMENTAL

Materials

Hydrated $CoCl_2$, $Co(NO_3)_2$ and $Co(ClO_4)_2$ were from BDH. $CoBr_2\cdot 6H_2O$ was prepared by the reaction of HBr with $CoCO_3$ in H_2O and recrystallization from H_2O. Ethanolic solutions of Co $(NCS)_2$ and CoI_2 were obtained by metathesis of $Co(NO_3)_2\cdot 6H_2O$ and KNCS or KI, respectively.

* Author to whom correspondence should be addressed.

The starting materials, diacetyl monoxime (isonitroso ethylmethylketone) was from Loba-Chemie and isonitrosopropiophenone was synthesized[13] from propiophenone.

The hexadentate Schiff base ligands N,N′,N″,N‴-triethylenetetramine bis(isonitroso ethylmethylketoneimine) (H_2L') and N,N′,N″,N‴-triethylenetetramine bis(isonitroso propiophenoneimine) (H_2L'') were prepared by condensing diacetyl monoxime or isonitrosopropiophenone with triethylenetetramine in Et_2O and *n*-hexane, respectively.

All the complexes were synthesized by a general method, detailed below. However, for $CoCl_2$ and $Co(NCS)_2$, green, dinuclear and four-coordinated cobalt(II) complexes were obtained, and for other cobalt(II) salts, CoX_2 (X = Br, I, NO_3, ClO_4), under identical conditions, orange, mononuclear and six-coordinated cobalt(III) complexes were obtained. The syntheses and analyses of each of these compounds were reproducible, establishing their authenticity.

Synthesis of cobalt perchlorate complex with N,N′,N″,N‴-*triethylenetetramine bis(isonitrosopropiophenoneimine)* $[Co(HL'')](ClO_4)_2$

To a warm solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1 mmol) in 10 cm^3 of EtOH, the prepared hexadentate ligand, H_2L'' (0.31 g, 1 mmol), was added slowly with constant stirring. Within about 10 min, an orange coloured compound formed and the mixture was stirred for a further 1 h to ensure completion of the reaction. The compound was then collected on a glass frit, washed three times with 3 cm^3 of Et_2O and dried *in vacuo*. Yield 0.36 g (66%).

Cobalt and halogen were determined by standard methods.[6–9] The microanalytical data for carbon, hydrogen and nitrogen were obtained from the Analytical Chemistry Department, Chemical Centre, University of Lund, Sweden.

The magnetic susceptibility, thermogravimetry, cyclic voltammetry, electrolytic conductivity, electronic spectra, mass spectra, and ^1H and ^{13}C NMR spectral measurements were carried out as reported earlier.[6–9] IR spectra in the 4000–400 cm^{-1} region were recorded as KBr pellets on a NICOLET 20 SXC FTIR spectrophotometer fitted with a data station. The diffuse reflectance spectra of complexes were obtained with a Hitachi-330 spectrometer.

RESULTS AND DISCUSSION

The hexadentate dioxime Schiff base ligands (I) derived from the condensation of triethylenetetramine and diacetylmonoxime (isonitroso ethylmethylketone) (H_2L') or isonitrosopropiophenone (H_2L'') interact with $CoCl_2$ and $Co(NCS)_2$ to form the binuclear, four-coordinated cobalt(II) complexes $[Co_2(H_2L)X_2]X_2$ (L = L′, L″; X = Cl, NCS), with a presumable structure **II**, where the neutral ligands, H_2L, seem to act as doubly tridentate. A similar behaviour of these ligands was observed earlier for certain copper(II) salts which formed complexes of the type $(CuX_2)_2 \cdot H_2L \cdot nH_2O$.[14] With CoX_2 (X = Br, I, NO_3 and ClO_4), however, mononuclear and six-coordinated complexes of the type $[Co(HL)]X_2$ (**III**) were obtained. All the complexes reported in this work are presented in Table 1. This difference in behaviour for the chloro and thiocyanato complexes, as compared to bromo, iodo, nitrato and perchlorato complexes, is adequately supported by our ESCA measurements,[15] which favour the binuclear structure for the former complexes. The molar conductivity values for all the complexes in DMF medium (*ca* 10^{-3} M) are in the range of 110–140 Ω^{-1} cm^2 mol^{-1}, suggesting them to be 1:2 electrolytes.[16] The conductance values for the cobalt(III) complexes of the type $[Co(HL)]X_2$ (**III**), were measured over a wide range of concentrations

using DMF as solvent. A plot of $\Lambda_\infty - \Lambda_e$ vs $\sqrt{C}$ gives a straight line, the slopes of which also indicate them to be 1 : 2 electrolytes.[17]

All the cobalt(III) complexes, $[Co(HL)]X_2$, are diamagnetic, coloured yellow or orange. However, the dimeric cobalt(II) complexes, $[Co_2(H_2L)X_2]X_2$ (X = Cl, NCS), are green and have magnetic moments in the range 2.5–3.5 BM, fairly close to the reported values for the spin-paired, square-planar cobalt(II) complexes.[18] The IR and TG studies do not show the presence of coordinated H_2O and these compounds seem to be dimeric and square-planar with the hexadentate ligand acting as a doubly tridentate ligand coordinating to two cobalt(II) centres, whose fourth position is occupied by either the Cl^- or NCS^-.

Formation of the ligands from the condensation of isonitrosoketones and triethylenetetramine was confirmed from the IR spectra which showed no typical absorption bands assignable to either C=O or NH_2 functions. The sharp bands of weak–medium intensity occurring in the 1600–1700 cm^{-1} region in the ligands, which shift to somewhat lower frequencies in the complexes, are appropriately assigned to coupled C⟷N and C⟷C stretching modes.[11] The ν(N—O) vibration of the complexes in the 1140–1190 cm^{-1} region suggests the oxime groups to be N-coordinated.[19] The ν(OH) vibrations of the ligands, H_2L' and H_2L'', appear at 2600 and 2800 cm^{-1}, respectively, and in the complexes they appear in the 3400 cm^{-1} region. The new bands of the complexes in the 520 cm^{-1} region is assigned to a ν(Co—N) vibration and at 1075 cm^{-1} to a ν'(NO) vibration.[20] The metal-sensitive strong as well as sharp bands occurring at 765–780 cm^{-1} may be attributed to the C=N—O deformation vibration mode. The metal-dependent strong and sharp bands at 990, 920 and 910 cm^{-1} can be ascribed to the deformation vibration modes of the ligand, analogous to the bands of metalloporphyrins.[21,22]

In the two cobalt(II) thiocyanato complexes, $[Co_2(H_2L)(NCS)_2](CNS)_2$ (L = L', L''), the bands at 2060–2080 cm^{-1} and 834–848 cm^{-1} are assigned to the ν(C≡N) and ν(C—S) vibrations of the N-coordinated isothiocyanate group.[23] The δ(NCS) signal is observed at 428 cm^{-1}. The vibration bands for the free thiocyanato groups in these complexes are also appropriately assigned. In the cobalt(III) complexes, $[Co(HL)]X_2$ (X = ClO_4, NO_3), the polyatomic anions are present in the outer-sphere. In the perchlorato complexes, the strong, unsplit absorptions in the 1100 and 620 cm^{-1} regions correspond to ν_3 and ν_4 absorption bands. The ν_1 and ν_2 bands for the uncoordinated ClO_4^- ion (both IR inactive) are not discernible and there is no tendency of ν_3 and ν_4 to split, which is good evidence in favour of non-coordination of the ClO_4^- group.[24] For the nitrato complexes, a strong and unsplit band around 1380 cm^{-1} (ν_3) and two IR active deformation bands at *ca* 830 cm^{-1} (ν_2) and at *ca* 700 cm^{-1} (ν_4) are observed. The absence of the ν_1 band as well as the appearance of the unsplit ν_3 band, suggest that the NO_3^- ion is not involved in covalent bonding to the cobalt(III) centre[25,26] (see Table 2).

The solid-state (diffuse reflectance) spectra and the spectra in DMF solution seem to be identical for the cobalt(III) complexes, with a peak of weak to moderate intensity at ~ 16,000 cm^{-1} assignable to a $^1A_{1g} \rightarrow {}^1E_g$ transition, typical of low-spin six-coordinated cobalt(III) complexes.[12] The more intense band in the 44,000–49,000 cm^{-1} region is attributable to the intra-ligand π–π^* transition of the coordinated oxime group. The band in the 26,000–30,000 cm^{-1} region may be due to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition,[12] while that at around 38,000 cm^{-1} may be due to the possible $d\pi(Co) \rightarrow \pi^*(HL)$ MLCT transition.[27] The low-spin, square-planar complexes of cobalt(II) invariably exhibit[28,29] a fairly broad but strong band at around 17,000–18,000 cm^{-1} as observed here.

The ^1H and ^{13}C NMR spectra of the hexadentate ligand, H_2L', and its cobalt(III) complexes $[Co(HL')]X_2$ (X = Br, I, NO_3, ClO_4), have been assigned (see Tables 3 and 4). In the ^1H NMR spectra, the two sharp singlet signals observed at 1.90 and 1.98 ppm for the ligand, H_2L', (**Ia**) are shifted downfield in the complexes to 2.40 and 2.48 ppm, respectively. These signals are due to the two magnetically non-equivalent —CH_3 groups. A virtual triplet in the 3.27–3.40 ppm region in the ligand, which shifts downfield to 3.87–4.05 ppm in the complexes, is assigned to the ethylene (—CH_2—CH_2—) protons in the ligand chain.[30] The —OH (oxime) proton of the ligand resonating at 8.31 ppm, undergoes considerable upfield shift on coodination and appears in the complexes in the vicinity of 6.0 ppm.

The ^{13}C NMR spectrum of the ligand and its complexes shows that the two non-equivalent —CH_3 groups give ^{13}C signals at 8.64 and 13.44 ppm in the ligand, which shift downfield in the complexes to *ca* 13.0 ppm and 17.5 ppm, respectively. The ethylene carbons (—CH_2—CH_2—) resonate at 48.96–51.84 ppm in the free ligand and appear as a symmetrical triplet. In the complexes, these signals shift downfield to 50.4–54.72 ppm and appear as a singlet and a doublet. The two other carbons (C^c and C^d) in the diacetylmonoxime skeleton resonate at 156.48 and 164.16 ppm, respectively, in the free ligand. On complexation the observed shift of C^c is either nil or slightly upfield,

(H_2L')

whereas the shift for C^d is substantially downfield (175.56–177.6 ppm).

The cyclic voltammograms of the samples were run in DMF using platinum as the working electrode and $(Et_4N)ClO_4$ (TEAP) as the supporting electrolyte. All voltammograms are usually characterized by three reductive waves at 0.81–0.92, 1.3 and 1.4–1.5 V corresponding to the reduction of $Co^{III} \rightarrow Co^{II} \rightarrow Co^{I} \rightarrow Co^{0}$, respectively. Often, the first peak, which is ill-defined, is accompanied by another similar peak in the 0.51–0.53 V region. The negative scan for $[Co(HL')](ClO_4)_2$ is shown in Fig. 1. In the positive scan for $[Co(HL')]X_2$ (X = ClO_4, NO_3), the experimental base line obtained indicates

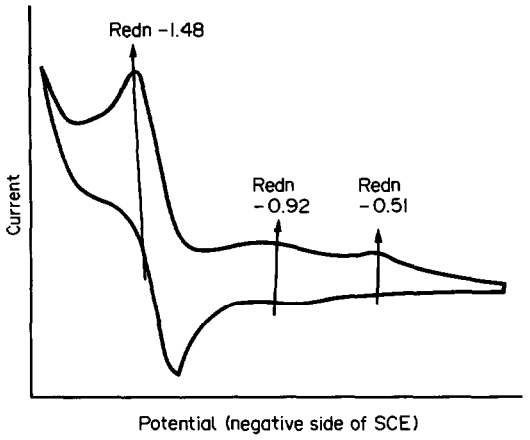

Fig. 1. Cyclic voltammogram of $[CoHL'](ClO_4)_2$ in DMF solution (negative side of SCE).

no effective chemical change. For the $[Co(HL')]Br_2$ complex, peaks at 0.67 and 0.75 V and for the $[Co(HL')]I_2$ complex, peaks at 0.57, 0.76 and 0.39 V are obtained. These are obviously not due to any effective oxidation of the metal[31] and may have arisen due to the oxidation of Br^- and I^- ions.

The mass spectra of the ligand, H_2L', and its complexes were investigated. For the ligand, the molecular ion peak at *m/z* 312, along with other prominent peaks due to the fragmentation products at 295, 254, 213, 185, 156, 142, 113, 99, 58 and 42, are obtained and appropriately assigned. However, for the complexes, no molecular ion peak nor any fragmentation product containing the metal were obtained. The thermogravimetric studies also show that the thermal stability of the complexes is quite high and with an increase in temperature the ligand is lost in steps giving polymeric intermediates, often forming Co_3O_4 as the stable end product at around 600°C.

(*Received* 27 *September* 1988; *accepted* 27 *January* 1989)

Abstract—The reaction of the sodium propargyloxide, $NaOCH_2C{\equiv}CH$, with hexachlorocyclotriphosphazene, $N_3P_3Cl_6$, led to a series of (propargyloxy)chlorocyclotriphosphazenes, $N_3P_3Cl_{6-n}(OCH_2C{\equiv}CH)_n$, ($n = 1$–6). All the compounds were characterized by a combination of elemental analysis, IR spectroscopy, mass spectrometry and NMR (^1H, ^{13}C, ^{31}P) spectroscopy. The results indicated that the substitution pattern of propargyloxylation was predominantly non-geminal with comparable amounts of the *cis* and *trans* isomers. However, a significant amount of geminal isomer was observed for the tris compounds from the ^{31}P spectrum. The mono- and bis-substituted derivatives have been converted to their phenoxy derivatives, $N_3P_3(OC_6H_5)_{6-n}(OCH_2C{\equiv}CH)_n$, ($n = 1$, 2), and the phenoxy derivative, $N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}CH)$, underwent an oxidative coupling reaction to produce a phosphazene-containing diacetylene, $[\text{-}N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}C\text{-})]_2$.

Since the phosphazene compounds received renewed attention in 1965,[1] hundreds of organophosphazenes and their polymer analogues have been synthesized.[2,3] Recently, Allen *et al.*[4–9] showed that the range of synthesis of new and useful phosphazene derivatives could be expanded by the incorporation of an organofunctional substituent on the phosphazene ring, and this substitutent could serve as the site for various synthetic transformations leading to new monomeric and polymeric phosphazene moieties. We were interested in preparing C≡C containing phosphazenes and chose propargyl alcohol as the substituent for the following reasons. Nucleophilic substitution on $N_3P_3Cl_6$ occurs via the hydroxy end of propargyl alcohol, leaving the terminal acetylene group. Through the terminal acetylenic unit the phosphazene may polymerize to yield substituted benzenoids or be oxidative coupled to form diacetylene derivatives. The pendant acetylenic units can also function as π-donors for transition metal units such as dicobalt hexacarbonyl residues, to form complexes which may function as catalysts.[10] Furthermore, the acetylene-terminated cyclotriphosphazene compounds may be used as the terminated monomers to co-polymerize with some organic oligomers to form phosphazene-containing acetylene-terminated co-polymers, which are able to be further cured through the terminated acetylene group like some acetylene-terminated organo polymers.[11–13]

Although C≡C containing organocyclotriphosphazenes have previously been prepared,[14–16] none of the particular series of (alkynyloxy)chlorocyclotriphosphazenes were reported in detail. In this paper, we describe the synthesis and the characterization of a series of (propargyloxy)chlorocyclotriphosphazenes, $N_3P_3Cl_{6-n}(OCH_2C{\equiv}CH)_n$ ($n = 1$–6). The preferred substitution pattern of the propargyloxide ions with hexachlorocyclotriphosphazene, $N_3P_3Cl_6$, compounds are discussed. It is anticipated that this information would be valuable for an initial analysis of the related reactions that take place in the high polymeric systems. In addition, a preliminary study concerning the potential of the terminal acetylene group on the phosphazene for synthetic work is also studied.

EXPERIMENTAL

Materials and methods

The hexachlorocyclotriphosphazene, $N_3P_3Cl_6$, was kindly supplied by the Nippon Fine Chemical Co., Japan and was used as received. Diethyl ether was distilled from sodium. Propargyl alcohol (Tokyo Chem.) was distilled before use. NMR spectra (in d-acetone) were recorded on a JEOL JNM-FX100 spectrometer. Tetramethylsilane, Me_4Si, was used as internal reference for ^1H and ^{13}C NMR measurements. For ^{31}P NMR, 85% H_3PO_4 was used as external reference. Chemical shifts upfield of the reference were assigned a negative sign. IR spectra were obtained as thin films (KBr discs) on a Perkin–Elmer 710 B spectrometer. Mass spectra were recorded on a JEOL JMS-D100 spectrometer. Elemental analyses were performed by the Instrument Centre of NSC at Tainan, Taiwan.

All reactions were carried out under anhydrous conditions in a three-necked round-bottomed flask fitted with a reflux condenser and a pressure-equalizing dropping funnel. The system was stirred magnetically and proceeded under nitrogen.

Preparation of $N_3P_3Cl_5(OCH_2C{\equiv}CH)$ (**1**) *and* $N_3P_3Cl_4(OCH_2C{\equiv}CH)_2$ (**2**)

A solution of sodium propargyloxide was prepared from sodium (1.40 g, 0.061 mol) and propargyl alcohol (2.52 g, 0.045 mol) in diethyl ether (100 cm^3). To this was slowly added a solution of hexachlorocyclotriphosphazene (10.0 g, 0.029 mol) in diethyl ether (75 cm^3). The solution was then stirred at reflux for 72 h and was then allowed to cool to room temperature. The salt was filtered off and the filtrate was washed with water and dried over anhydrous sodium sulphate. The solvent was removed at reduced pressure to yield 8.2 g of a pale yellow liquid. A 1.0 g sample of this liquid was purified by column chromatography with chloroform–hexane (1 : 9) as the eluant. The first product obtained was 0.18 g (16.8% of theory) of unreacted $N_3P_3Cl_6$. Continued elution from the column yielded 0.39 g (36.7% of theory) of a colourless liquid. Found: C, 71.7; H, 6.7; N, 10.4; *m/z* 365. Calc. for $C_3H_3Cl_5N_3OP_3$ (**1**): C, 71.1; H, 6.7; N, 10.4; *m/z* 365. IR(cm^{-1}): 3295 (s, ≡C—H str), 2130 (w, C≡C str), 1220 (s, PN str), 1040 (s, POC str), 990 (m, POC str), 885 (s, PCl), 760 (m, PCl).

The third compound obtained from the column yielded 0.20 g (17.9% of theory) of a colourless liquid. Found: C, 18.6; H, 1.6; N, 10.4; *m/z* 385. Calc. for $C_6H_6Cl_4N_3O_2P_3$ (**2**): C, 18.6; H, 1.6; N, 10.9; *m/z* 385. IR(cm^{-1}): 3300 (s, ≡C—H str), 2130 (m, C≡C str), 1220 (s, PN str), 1040 (s, POC str), 985 (m, POC str), 885 (s, PCl), 740 (m, PCl).

Preparation of $N_3P_3Cl_3(OCH_2C{\equiv}CH)_3$ (**3**)

The sodium propargyloxide (6.80 g, 0.087 mol) was prepared as above and diethyl ether (100 cm^3) was slowly added to a solution of $N_3P_3Cl_6$ (10.0 g, 0.029 mol) in diethyl ether (175 cm^3) at room temperature. The reaction mixture was stirred for 2 days and worked-up as before to give 6.9 g of a yellow liquid. A 1.0 g sample of this liquid was separated by using column chromatography with chloroform–hexane (2 : 3) as the eluant. The following compounds were obtained in succession: $N_3P_3Cl_5(OCH_2C{\equiv}CH)$ (**1**), 0.14 g (1.3%); $N_3P_3Cl_4(OCH_2C{\equiv}CH)_2$ (**2**), 0.23 g (20.6% of theory).

The third compound eluted was 0.29 g (24.7% of theory) of a colourless liquid. Found: C, 26.5; H, 2.2; N, 10.3; *m/z* 405. Calc. for $C_9H_9Cl_3N_3O_3P_3$ (**3**): C, 26.6; H, 2.2; N, 10.3; *m/z* 405. IR(cm^{-1}): 3300 (s, ≡CH str), 2130 (m, C≡C str), 1240 (s, PN str), 1030 (s, POC str), 985 (m, POC str), 900 (s, PCl), 800 (m, PCl). This compound was further isolated to obtain a small amount of the non-geminal isomer.

Preparation of $N_3P_3Cl_2(OCH_2C{\equiv}CH)_4$ (**4**)

Sodium propargyloxide (11.9 g, 0.15 mol) was prepared as above and diethyl ether (100 cm^3) was slowly added to a solution of $N_3P_3Cl_6$ (10.0 g, 0.029 mol) in diethyl ether (175 cm^3) at room temperature. The reaction mixture was stirred for 2 days and worked-up as before to give 7.30 g of a yellow liquid. A 1.0 g sample of this liquid was separated by column chromatography with hexane–diethyl ether (4 : 1) as the eluant. The following compounds were obtained in succession: $N_3P_3Cl_5(OCH_2C{\equiv}CH)$ (**1**), trace; $N_3P_3Cl_4(OCH_2C{\equiv}CH)_2$ (**2**), trace and $N_3P_3Cl_3(OCH_2C{\equiv}CH)_3$ (**3**), 0.12 g (10.2%).

The fourth compound eluted was 0.51 g (41.4% of theory) of a colourless liquid. Found: C, 33.1; H, 2.9; N, 9.6; *m/z* 425. Calc. for $C_{12}H_{12}Cl_2N_3O_4P_3$ (**4**): C, 33.1; H, 2.8; N, 9.7; *m/z* 425. IR (cm^{-1}): 3300 (s, ≡CH str), 2130 (m, C≡C str), 1230 (s, PN str), 1030 (s, POC str), 990 (s, POC str), 900 (s, PCl str), 790 (m, PCl).

Preparation of $N_3P_3Cl(OCH_2C{\equiv}CH)_5$ (**5**) *and* $N_3P_3(OCH_2C{\equiv}CH)_6$ (**6**)

The reaction of sodium propargyloxide (16.0 g, 0.220 mol) (prepared as above) and $N_3P_3Cl_6$ (10.0 g, 0.029 mol) in diethyl ether (200 cm^3) was carried

out as described above to yield 5.4 g of a pale yellow liquid. A 1.0 g sample of this liquid was separated by using column chromatograhy with chloroform–methanol (100 : 1) as the eluant. The first major product obtained was $N_3P_3Cl_4(OCH_2C{\equiv}CH)_2$ (**4**), 0.027 g (2.20% of theory) as a colourless liquid. The second major compound eluted was 0.19 g (14.7% of theory) of a colourless liquid. Found: C, 40.5; H, 3.4; N, 9.4; *m/z* 445. Calc. for $C_7H_6Cl_4N_3O_2P_3$ (**5**): C, 40.4; H, 3.4; N, 9.4; *m/z* 445. IR(cm^{-1}): 3300 (s, ≡CH str), 2130 (m, C≡C str), 1235 (s, PN str), 1030 (s, POC str), 990 (s, POC str), 900 (m, PCl), 770 (m, PCl).

The third major compound eluted was 0.33 g (24.5% of theory) of a colourless liquid which was solidified in refrigerator (m.p. = 29°C). Found: C, 46.5; H, 3.9; N, 8.9; *m/z* 465. Calc. for $C_{18}H_{18}N_3O_6P_3$ (**6**): C, 46.5; H, 3.9; N, 9.0; *m/z* 465. IR(cm^{-1}): 3300 (s, ≡CH str), 2130 (m, C≡C str), 1230 (s, PN str), 1030 (s, POC str), 995 (s, POC str). By using propargyl alcohol as solvent and reacting for 24 h, the yield of the major compound (**6**) was increased to 70%.

Reaction of $N_3P_3Cl_5(OCH_2C{\equiv}CH)$ (**1**) *and sodium phenoxide*

The reaction of $N_3P_3Cl_5(OCH_2C{\equiv}CH)$ (**1**) (4.8 g, 0.013 mol) with an excess of sodium phenoxide (9.0 g, 0.078 mol), prepared from sodium (1.8 g, 0.078 mol) and phenol (7.3 g, 0.078 mol) in THF (100 cm^3), was allowed to reflux for 2 days. The salt was filtered out. After removing the solvent, the oily residue was dissolved in diethyl ether, washed with water and dried over anhydrous sodium sulphate. The solvent was removed at reduced pressure to yield 8.2 g of a pale yellow syrup. A 1.0 g sample of this syrup was then purified by column chromatography, with dichloromethane–hexane (3 : 2) as the eluant, to produce 6.3 g (74% of theory) of a colourless liquid which was solidified in a refrigerator to a white solid (m.p. = 49°C), $N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}C)$ (**7**). Found: C, 60.5; H, 4.3; N, 6.4; *m/z* 655. Calc. for $C_{33}H_{28}N_3O_6P_3$ (**7**): C, 60.5; H, 4.3; N, 6.4; *m/z* 655. IR (cm^{-1}): 3300 (s, ≡C—H, str), 2120 (w, C≡C str), 1160–1220 (s, P—O—Ar str), 1220–1280 (s, PN str), 1050 (s, P—O—C str).

Reaction of $N_3P_3Cl_4(OCH_2C{\equiv}CH)_2$ (**2**) *and sodium phenoxide*

Sodium phenoxide (7.5 g, 0.065 mol) prepared as above in THF (50 cm^3) was added to a solution of compound **2** (5.0 g, 0.013 mol) in THF (50 cm^3). The reaction mixture was stirred and refluxed for 2 days. It was then worked-up as above for compound **7** to give a pale yellow syrup. The crude product was then purified by column chromatography with dichloromethane–hexane (3 : 2) as eluant. The yield of isolated product, $N_3P_3(OC_6H_5)_4(OCH_2C{\equiv}C)_2$ (**8**), was 5.61 g (70% of theory). Found: C, 58.5; H, 4.2; N, 6.9; *m/z* 617. Calc. for $C_{30}H_{26}N_3O_6P_3$ (**8**): C, 58.4; H, 4.2; N, 6.8; *m/z* 617. IR (cm^{-1}): 3300 (s, ≡C—H str), 2150 (m, C≡C str), 1595, 1495 (s, C=C arom. str), 1200–1280 (s, PN str), 1160–1200 (s, P—O—Ar str), 1050 (s, P—O—C str).

Oxidative coupling reaction of $N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}CH)$ (**7**)

Hay's catalyst was prepared by reaction of equal moles of CuCl and N,N,N′,N′-tetramethylethyl diamine in acetone with the inlet of oxygen. In the solution of the catalyst (0.1 g) in acetone (20 cm^3) with the inlet of oxygen, a solution of compound **7** (3.0 g, 4.9 mmol) in acetone (20 cm^3) was added dropwise and stirred for 4 h. After removing the acetone, the deep green mixture was washed several times with 20 cm^3 of an aqueous solution of hydrochloric acid (5% conc.) to obtain a thick green syrup. The crude product was then purified by column chromatography with chloroform–*n*-hexane (10 : 3) as eluant to obtain 2.3 g (78% of theory) of white solid (m.p. = 112.5°C)—the diacetylene $[-N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}C)-]_2$ (**9**). Found: C, 60.6; H, 4.1; N, 6.4. Calc. for $C_{66}H_{54}N_6O_{12}P_6$ (**9**): C, 60.3; H, 4.1; N, 6.3. IR(cm^{-1}): 2145 (w, C≡C str), 1595, 1495 (s, C=C arom. str), 1200–1270 (s, PN str), 1150–1200 (s, P—O—Ar str), 1050 (s, P—O—C str).

RESULTS AND DISCUSSION

Although there are two acidic protons on the propargyl alcohol, as expected, since the alcoholic proton is more acidic than the acetylenic proton, the alkoxide is quantitatively generated from the reaction of sodium and propargyl alcohol. The sodium alkoxide was then reacted with $N_3P_3Cl_6$ to obtain a series of (propargyloxy)chlorocyclotriphosphazenes, $N_3P_3Cl_{6-n}(OCH_2C{\equiv}CH)_n$ (n = 1–6), according to the ordinary nucleophilic substitution reactions.

Compounds **3**–**6** were only slightly soluble in hexane, pentane and petroleum ether, but the other compounds were soluble in most of the organic solvents but insoluble in water, and these compounds were all stable to air and atmospheric moisture.

[a] The data were measured in d-acetone, the chemical shifts are given in ppm relative to TMS and the coupling constants are in Hz.

[b] g: the atoms are in the $P(OR)_2$ environment. n: the atoms are in the $PCl(OCH_2C{\equiv}CH)$ environment.

displayed a parent ion with the characteristic Cl_n ($n = 1$–5) isotope patterns. The fragmentation pathway observed mainly involved the loss of alkynyloxy $-OCH_2C{\equiv}CH$ and alkynyl $-CH_2C{\equiv}CH$ groups as well as chlorine.

The IR spectra of all the compounds were similar and consistent with the proposed structures. In each case, an intense absorbance between 1200 and 1300 cm^{-1} was observed as a characteristic of the PN skeleton in cyclophosphazene compounds. The ≡C—H, C≡C and P—O—C absorbances were observed at 3300, 2100 and 1030 cm^{-1}, respectively.

As listed in Table 1, the ^{1}H and ^{13}C NMR spectra were all as expected and closely resembled one another. The chemical shifts of the atoms in the $P(OCH_2C{\equiv}CH)Cl$ environment were all slightly downfield from that in the $P(OCH_2C{\equiv}CH)_2$ environment.

Evidence for the occurrence of a trace amount of the geminal isomers was obtained for compound **2** from the ^{31}P NMR spectrum. It predominantly showed a second-order AB_2 system and a trace

[a] The data were measured in d-acetone, the chemical shifts are given in ppm (±0.5 ppm) relative to 85% H_3PO_4, and the coupling constants are in Hz.

[b] OR represents the $OCH_2C{\equiv}CH$ group and OΦ represents the OC_6H_5 group.

amount of the AX_2 system and implied the product isolated was predominantly non-geminal isomers. However, the chemical shifts for the *cis* and *trans* forms were so close to each other that only one set of the AB_2 pattern was found for the non-geminal isomers.

The ^{31}P NMR spectra of compound **3** also showed the existence of both geminal and non-geminal isomers. It was found that the estimated percentage of the geminal form might be as high as 35%. This was rationalized by the fact that in the substitution reaction, ignoring the steric effect, the nucleophile had equal opportunity to substitute the chlorine atom at the geminal position or the non-geminal position for the non-geminal bis isomers, therefore, a significant amount of the geminal tris compound was produced. A small amount of the non-geminal isomers was isolated by column chromatography, but attempts to isolate the geminal form were unsuccessful.

For compound **4**, although it was expected to have non-geminal and geminal isomers, the sample isolated was proved to be exclusively the non-geminal form from the ^{31}P NMR spectrum, showing that the substitution in this stage was almost all of the non-geminal pattern.

The data in Table 2 show that the ^{31}P chemical shifts are decreasing (more upfield) in the order of $PCl_2 > P(OCH_2C{\equiv}CH)Cl > P(OCH_2C{\equiv}CH)_2$, implying a more electron-withdrawing effect by the propargyloxy group than by the Cl atom. In addition, the coupling constants also increase with increasing numbers of the propargyloxy substituents.

In order to understand some of the chemical properties of the synthesized (propargyloxy)chlorocyclotriphosphazenes, two reactions were carried out as a preliminary study. One was the further substitution reaction with sodium phenoxide and the other was the oxidative coupling reaction.

The reactions of compounds **1** and **2** with sodium phenoxide proceeded smoothly to give the expected derivatives $N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}CH)$ (**7**) and $N_3P_3(OC_6H_5)_4(OCH_2C{\equiv}CH)_2$ (**8**) in good yields.

The elemental analysis, mass, IR and NMR (^1H, ^{13}C, ^{31}P) spectroscopic properties of compounds **7** and **8** were in accord with the assigned structures. Of particular interest was the ^{31}P NMR spectrum of compound **8**, which also showed the presence of the non-geminal isomers and a trace amount of the geminal isomer like its parent compound **2**. However, the two sets of AB_2 patterns of the *cis* and *trans* non-geminal isomers were separated by approximately 0.3 ppm. Comparison of their peak areas showed that the relative abundances of the two forms was roughly 35 : 65%. On consideration of the steric effect of the substituted groups on the ring, together with the examples studied by others,[6,17,18] it was suggested that the *trans* isomer was more abundant.

For simplicity, derivative **7**, containing only one acetylene group, was further used as an example to carry out the oxidative coupling reaction through the terminal actylene group. The reaction followed Hay's method[18] and is shown in the following scheme:

$$N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}CH) \xrightarrow{O_2,\text{catalyst}} [\text{-}N_3P_3(OC_6H_5)_5(OCH_2C{\equiv}C\text{-})]_2.$$

(9)

Product **9** was obtained as a colourless solid (m.p. = 112°C). The IR and ^1H NMR spectra showed the absence of the terminal proton (≡CH). A typical secondary AB_2 pattern was found in the ^{31}P NMR spectrum, as expected. The elemental analysis and the ^{13}C NMR spectrum confirmed unambiguously that the structure of compound **9** contained all the diacetylene group. This result showed that after all of the chlorine atoms were replaced by the OC_6H_5 groups, the PN skeleton was sufficiently stable to allow organic chemistry to be carried out on the side groups and it is possible to carry out various chemical reactions through the terminal acetylene groups.

CONCLUSIONS

From this study, it has been shown that the reaction of sodium propargyloxide with $N_3P_3Cl_6$ led to a series of compounds of the type $N_3P_3Cl_{6-n}(OCH_2C{\equiv}CH)_n$ (n = 1–6). The reaction was found to predominantly follow a non-geminal pathway, just like the majority of the reactions of alkoxides with hexachlorocyclotriphosphazene.[6,17,18] As observed in the reaction between sodium 2,2,2-trifluoroethoxide and hexachlorophosphazene[18] and that between sodium vinyloxide with hexachlorocyclotriphosphazene, a significant amount of the tris geminal isomer, which could be produced from both the geminal and the non-geminal bis compounds, was found in this study.

The fact that the (propargyloxy)chlorocyclotriphosphazenes (**1**) and (**2**) could be derivatized leaving the terminal acetylene group intact and that compound **7** could be further reacted through the acetylene group, demonstrates that one can prepare the analogous polyphosphazenes with a pendant acetylene group and carry out various synthetic transformations through the acetylene group on the (propargyloxy)chlorocyclotriphosphazenes syn-

thesized in this study. Work along this line, especially those compounds with $n = 1$ or 2, is currently in progress in our laboratory.

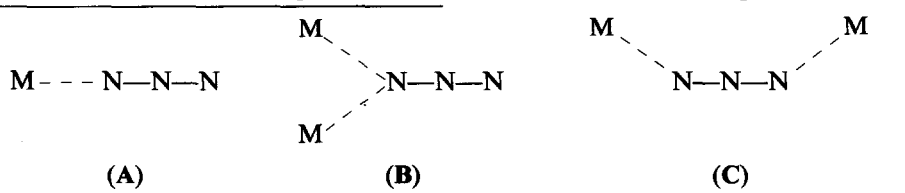
(*Received* 24 *October* 1988; *accepted after revision* 27 *January* 1989)

Abstract—The synthesis and characterization of thiocyanate and azide derivatives of mepirizole (4-methoxy-2-(5-methoxy-3-methyl-pyrazol-1-yl)-6-methylpyrimidine, hereinafter L) with manganese(II) and copper(II) is reported. The compounds were characterized by IR, electronic and EPR spectra and analytical data. Spectroscopic results suggest the existence of dimeric neutral entities $[L_2Cu_2(\mu\text{-}X)_2(X)_2]$ (X = NCS or N_3) with unsymmetrical end-to-end bridges and five-coordination geometry around the copper(II) ion. Magnetic susceptibility data show that in the azide derivative the copper atoms are antiferromagnetically coupled ($J = -18$ cm^{-1}), but no magnetic exchange interaction could be detected in the thiocyanate compound up to 4.2 K. With regard to manganese(II) complexes ($MnL_2(NCS)_2 \cdot 2H_2O$ and $MnL(N_3)_2$), an octahedral stereochemistry is proposed for the metal atom in both thiocyanate and azide derivatives, thus implying a polymeric structure in the second one.

In recent years considerable attention has been paid to pyrazoles, pyrimidines and related N-containing heterocyclic derivatives due to the significant role played by this kind of system in several biological processes, often related to their coordinating ability for a trace metal ion.[1–4] We have focussed on the study of pyrimidino–pyrazoles from the coordination chemistry point of view. In our earlier work[5–7] we reported the study of the interaction of several metal ions with mepirizole (4-methoxy-2-(5-methoxy-3-methyl-pyrazol-1-yl)-6-methylpyrimidine, hereinafter L), a biologically active pyrimidino–pyrazole derivative used as an anti-inflammatory agent.[8] In previous structural studies[9–11] we have shown that the mepirizole acts as a bidentate ligand through two nitrogen atoms (which are asterisked in Fig. 1) with significant steric hindrance to the formation of metallic complexes.

The azide ligand has various modes of binding. So, terminal (**A**), μ-1,1 (or end-on) bridging (**B**) and μ-1,3 (or end-to-end) bridging (**C**) are known in azido coordination compounds:[12]



(A) (B) (C)

Because of the importance of azide coordination in protein studies, several authors have examined its coordination properties in relevant model systems.[13] On the other hand, all three coordination modes

* Author to whom correspondence should be addressed.

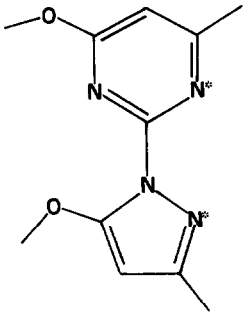


Fig. 1. Schematic view of the mepirizole ligand.

are also exhibited by the thiocyanate group. Moreover, the NCS anion can function as a unidentate ligand (as N_3 in A) in two ways depending on whether the nitrogen atom or the sulphur atom is bonded to the metal.

In this paper we report the synthesis and characterization of azide and thiocyanate derivatives of complexes of mepirizole with manganese(II) and copper(II). The insight gained into the nature and properties of these compounds may be a good basis for studies in related, more complex chelating systems.

EXPERIMENTAL

Preparation of the complexes

A solution of mepirizole (2 mmol for the MLX_2 complexes or 4 mmol for the $MnL_2(NCS)_2 \cdot 2H_2O$ compound) in ethanol (25 cm^3) was added with stirring to an aqueous solution of the metallic nitrate (2 mmol in 25 cm^3). Then a solution of the respective potassium or sodium pseudohalide salt (4 mmol) in H_2O (25 cm^3) was added. The powders which appeared in each case were separated by filtration, washed with a water–ethanol mixture and dried in a desiccator over silica gel.

Analysis

Carbon, hydrogen and nitrogen contents were determined by elemental analysis. Metals were determined by atomic absorption. Analytical data are given in Table 1.

Physical measurements

IR spectra (KBr pellets) were recorded on a Pye–Unicam SP 2000 spectrophotometer. Electronic spectra (diffuse reflectance) were registered using a Perkin-Elmer Lambda 9 UV/VIS/IR spectrophotometer. Polycrystalline powder and frozen solution EPR spectra were obtained on a Bruker ER 200 X-band spectrometer equipped with a variable temperature device. Variable temperature (4.2–298 K) magnetic susceptibility data were obtained on polycrystalline samples with a Faraday-type magnetometer equipped with a continuous flow Oxford Instruments cryostat. $Hg(SCN)_4Co$ was used as the susceptibility standard. Diamagnetic corrections were applied using Pascal's constants.[14] The molar conductances in solution were measured using a Radiometer CDC 304 electrode (cell constant 1.0 cm) in conjunction with a Radiometer CDM 83 conductivity bridge.

RESULTS AND DISCUSSION

As shown in Table 1, the analytical data correspond with the assigned molecular formulae. Attempts to isolate the $MnL(NCS)_2$ compound were unsuccessful, as occurs with the analogous cobalt(II) and nickel(II) complexes.[15]

Assignments of the more relevant IR spectral bands in the complexes are listed in Table 2. Bands due to the mepirizole ligand are not included. As can be expected, characteristic bands of the pyrimidine and pyrazole rings of the free ligand are shifted to lower wavenumbers upon complexation, indicating coordination of the heterocycle N-atoms.[6]

Manganese(II) *complexes*

The molar conductance value of the thiocyanate derivative (Table 1) is lower than expected for a 1 : 1 electrolyte in nitromethane,[16] indicating the non-ionic character of the complex. The positions of the bands assignable to NCS group vibrations suggest that it acts as a monodentate terminal N-bonded ligand.[17–19] On the other hand, the well-defined splitting of the ν(CN) band may be interpreted as evidence for a *cis*-octahedral arrangement,[20] as could be expected from the steric hindrance imposed by the methyl groups of the mepirizole. A broad band centred at *ca* 3400 cm^{-1} is observed in the IR spectrum, consistent with the existence of water of crystallization.[21] The IR spectrum of the $MnL(N_3)_2$ compound is compatible with the presence of a mono-coordinated and/or bridging μ-1,1 azide.[17,19] This assignment is only tentative since the best defined feature of this spectrum, the absorption centred at *ca* 2070 cm^{-1} (ν_{as}), cannot be used as diagnostic for the coordination mode of the azide group.

The electronic spectra of both manganese compounds display three weak bands at *ca* 18,500, 21,000 and 23,500 cm^{-1} and are assigned[22] to $^6A_{1g} \rightarrow {}^4T_{1g}$, $^6A_{1g} \rightarrow {}^4T_{2g}$ and $^6A_{1g} \rightarrow {}^4B_g, {}^4A_{1g}$ transitions, respectively. The other expected transitions which must occur at higher energies than 25,000 cm^{-1} are masked by a charge-transfer band. The position of the observed *d–d* transition bands are very similar to those reported for MnN_6 chromophores.[23,24] In the spectrum of the thiocyanate derivative, a well-defined splitting of the $^4T_{2g}$ band ($\Delta\nu = 1300$ cm^{-1}) is observed. This fact may be interpreted in terms of a tetragonal splitting of the $^4T_{2g}(^4G)$ state, as has been reported for some *cis*-MnL_4L_2 chromophores,[25] being consistent with the IR and EPR (see below) interpretation. On the other hand, the room temperature magnetic moments (5.91 and 6.12 BM for the $MnL_2(NCS)_2 \cdot 2H_2O$ and $MnL(N_3)_2$ compounds, respectively) are consistent with a d^5 high-spin configuration. Unfortunately, no conclusive information about the manganese stereochemistry can be obtained from these spectral and magnetic data.

The polycrystalline powder, room temperature EPR spectrum of $MnL_2(NCS)_2 \cdot 2H_2O$ shows one very strong line centred at $g = 2.00$. In addition, there are several shoulders both at lower and higher field [Fig. 2(a)], which suggest a low value of the zero-field splitting parameter D. By using the Dowsing and Gibson diagrams[26] it can be estimated that $0.05 \leqslant D \leqslant 0.10$ cm^{-1}. The λ ($= E/D$) parameter cannot be accurately determined, but it might be assumed to be less than 0.1. The small value of both D and λ parameters may be indicative of a *cis*-octahedral arrangement[27] in line with the spectral data. The frozen solution (nitromethane, 100 K) EPR spectrum is analogous to that obtained on a polycrystalline sample, indicating a similar geometry around the manganese(II) ion in both cases. Moreover, in the frozen solution EPR spectrum, the hyperfine coupling with the manganese nucleus ($I = 5/2$), with an averaged value of $|A| = 90 \times 10^{-4}$ cm^{-1}, can be observed. In manganese(II) complexes the ionic character of the metal–ligand bond is proportional to the magnitude of A, with an estimated value of 100×10^{-4} cm^{-1} for a "full-ionic" bond.[28] The value obtained for the compound under consideration falls in the range observed for other MnN_6 chromophores,[23,24] indicating a similar covalent character in the Mn—N bonds.

The EPR spectrum of the $MnL(N_3)_2$ compound shows only an isotropic signal at $g = 2.01$ without any appreciable shoulder either at lower or higher field [Fig. 2(b)]. This suggests a D value close

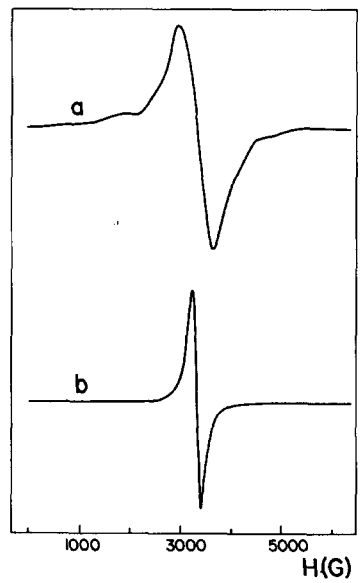

Fig. 2. X-band EPR spectra of polycrystalline samples of (a) $MnL_2(NCS)_2 \cdot 2H_2O$ and (b) $MnL(N_3)_2$.

to zero, but it is not possible to estimate the λ value. Hence, on the basis of the EPR results it cannot be established what the geometry of the metallic environment is. As in the analogous azide derivatives of cobalt(II) and nickel(II),[15] the very poor solubility of the compound in common solvents suggests a polymeric structure for this derivative.

Copper compounds

The IR data of the $CuL(NCS)_2$ compound suggest an end-to-end bridging coordination mode for the NCS^- group. In fact, non-observance of ν(CS) and the shifting of ν(CN) to higher wavenumbers argues in favour of simultaneous coordination of both N and S ends of the thiocyanate to give Cu—NCS—Cu bridged entities.[17,19] On the other hand, from the IR data of the copper(II) azide derivative no conclusive information can be obtained about the azide coordination mode, as has been previously discussed.

The electronic spectra of both compounds exhibit a very broad unresolved band in the visible region (Table 3). The position of the band intensity maximum suggests for the two complexes, a pentacoordinated copper(II) chromophore with an intermediate geometry between the ideal square pyramidal and trigonal bipyramidal,[22,29] although a distorted tetrahedral environment cannot be ruled out.[9] Apart from the *d–d* band, both spectra display a more intense band centred at *ca* 20,000 cm^{-1} assigned to a metal–ligand ($t_{2g} \Rightarrow \pi^*$) charge-transfer band.[30]

The X-band EPR spectrum of a polycrystalline sample of $CuL(NCS)_2$ shows an axial-type signal [Fig. 3(a)] which remains unchanged from room temperature down 90 K. The resulting g and A values (Table 3) are in good agreement with a mainly $d_{x^2-y^2}$ copper(II) ground state.[29,31] The spectrum also shows a weak intensity feature at *ca* 1620 G. This can be assigned to a $\Delta M_s = 2$ forbidden transition, thus suggesting a magnetic coupling interaction between two copper atoms. The G parameter, defined as $G = g_\parallel - 2/g_\perp - 2$ (which is indicative of exchange interactions between copper centres in polycrystalline solids), is close to four, indicating that exchange interactions are weak.[32]

The observed magnetic behaviour of the copper

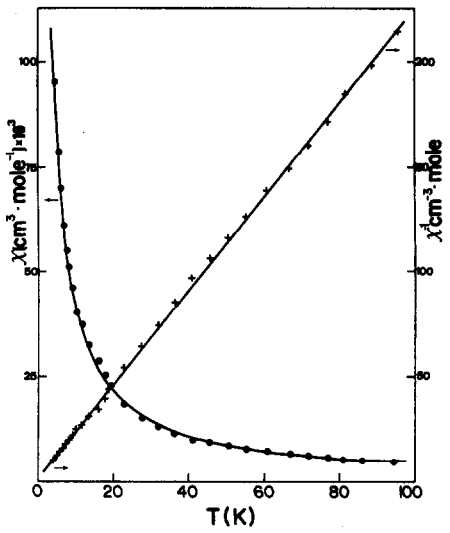

Fig. 4. Temperature dependence of the molar magnetic susceptibility X_M and the inverse susceptibility of $CuL(NCS)_2$. The solid lines were obtained by fitting to the Curie–Weiss formulae (see text).

thiocyanate derivative agrees with the EPR interpretation. In fact, the good fit of the inverse susceptibility to a straight line with temperature in the range 4.2–100 K, adhering closely to the Curie law (Fig. 4), indicates a very small singlet–triplet splitting. The whole susceptibility data were fitted to the Curie–Weiss expression $X = C/(T-\theta)$ affording $C = 0.443\ cm^3\ mol^{-1}\ K$ and $\theta = -0.6\ K$. The small absolute value of the Weiss correction, less than 1 K, reflects a very weak antiferromagnetic coupling ($|J| < 0.5\ cm^{-1}$), which would only be detected unambiguously at temperatures below 4.2 K. From the Curie constant $C = N\beta^2g^2S(S+1)/3k$ with $S = 1/2$, a g value of 2.17 can be obtained, in good agreement with the EPR data. This result indicates that the two copper ions in a pair of $CuL(NCS)_2$ moieties may be considered as essentially magnetically non-coupled. At the present time, all spectroscopic and magnetic data suggest a dimeric structure with a copper(II) ion environment geometry close to square pyramidal with end-to-end asymmetric Cu—NCS---Cu bridges (Fig. 5).

Dealing with the $CuL(N_3)_2$ compound, the EPR

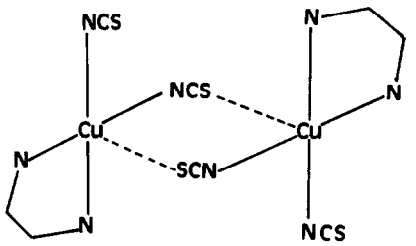

Fig. 5. Schematic view of the proposed approximate geometry for dimeric $[L_2Cu_2(\mu\text{-}NCS)_2(NCS)_2]$ species.

room temperature polycrystalline powder spectrum consists of an extremely broad feature (2200 G peak-to-peak) centred at *ca* 3200 G. Cooling down to 4.2 K does not improve this broad feature, although its intensity decreases and a weak axial signal ($g_\parallel = 2.28$, $g_\perp = 2.06$) due to monomeric impurities, becomes more intense as the temperature is lowered. Even though the poor resolution of this spectrum precludes any qualitative interpretation, it apparently arises from unresolved transitions in a triplet state. In fact, the magnetic behaviour at low temperatures supports this argument. A representation of the magnetic susceptibility vs temperature is shown in Fig. 6. Upon cooling down, the magnetic susceptibility increases until a maximum is reached at *ca* 19 K, after which the susceptibility decreases. The magnetic moment (per Cu^{2+} ion) varies from 1.87 BM at 281 K to 0.28 BM at 4.7 K, being typical of an antiferromagnetic interaction. The experimental data were fitted to the Bleaney–Bowers equation modified according to Khan and co-workers[33] to take into account some paramagnetic impurity (ρ):

$$X = (2N\beta^2g^2)[3+\exp(-J/kT)]^{-1}(1-\rho)/kT + 2N\beta^2g^2\cdot\rho/2kT+2N\alpha,$$

where J (singlet–triplet energy gap), g and ρ were taken as adjustable parameters. The temperature independent paramagnetism was assumed as $N\alpha = 6\times10^{-5}\ cm^3\ mol^{-1}$ of copper(II) ions. The least-squares fitting procedure led to $J = -18\ cm^{-1}$, $g = 2.16$ and $\rho = 0.036$. The agreement factor between the observed and calculated data, defined

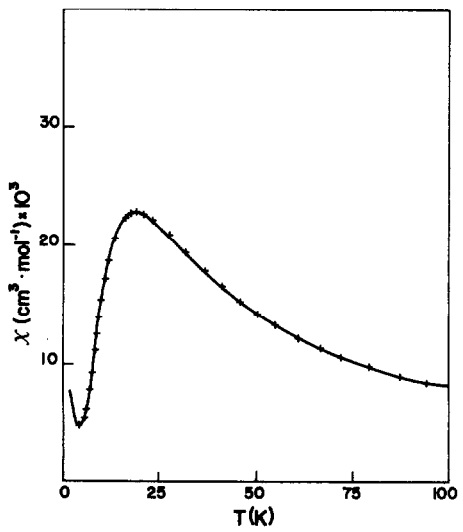

Fig. 6. Experimental (+) and theoretical (—) temperature dependences of the molar magnetic susceptibility of $CuL(N_3)_2$.

as $R = \Sigma(X_{M_{theory}} - X_{M_{exp}})^2/\Sigma X_{M_{theory}}$, is then equal to 1.53×10^{-4}.

The magnetic behaviour of μ-azido copper(II) binuclear complexes has been the subject of several studies in recent years.[34-37] The interaction between two copper(II) ions is ferromagnetic when they are bridged by an azido group in a μ-1,1 fashion or strongly antiferromagnetic in a symmetrical μ-1,3 fashion. On the other hand, when two N_3 groups bridge in an unsymmetrical μ-1,3 fashion (with a short Cu—N bond and a long Cu—N bond) the dimeric copper(II) compound exhibits either negligible interaction when the geometry around the metal atom is square pyramidal or weak antiferromagnetic interaction when this geometry tends toward trigonal bipyrimidal.[36] In the light of the results obtained, the existence of unsymmetrical end-to-end azido bridges, similar to those pointed out for the copper thiocyanate derivative, may be stated, implying dimeric $[Cu_2L_2(\mu\text{-}N_3)_2(N_3)_2]$ entities in the compound. In this sense, the different magnetic behaviour of both $CuL(NCS)_2$ and $CuL(N_3)_2$ compounds could be understood on the basis of: (1) a greater distortion of the copper(II) environment toward the TBP geometry in the azide derivative (supported by the electronic spectral data), with a significant contribution of the d_{z^2}-type orbital to the magnetic orbital and (2) probably, a greater unsymmetrical character in the NCS bridges, as has been argued for the interpretation of the magnetic behaviour in related azido bridged dimers.[34]

Finally, for both copper compounds the electronic spectral and EPR data indicate the non-preservation of the proposed dimeric entities in a non-coordinating solvent such as chloroform. In this solvent, the $CuL(NCS)_2$ and $CuL(N_3)_2$ complexes show an isotropic hyperfine EPR spectra at room temperature. In frozen solution at 100 K, X-band EPR spectra show very similar axial signals for two complexes [the corresponding $CuL(NCS)_2$ compound is shown as the representative in Fig. 3(b)], and do not exhibit any sign of coupling apart from the copper hyperfine structure. The resulting EPR parameters are listed in Table 3, together with those corresponding to the chloride derivative for comparison. The A value has been estimated from the relation $A_0 = (A_\parallel + 2A_\perp)/3$, where the A_0 values were obtained from the room-temperature spectra, assuming that dA/dT is negligible.[38] The whole of the EPR results suggest a flattened tetrahedral copper environment (CuN_4 chromophore) with a d_{xy} ground state,[31,39] being similar to those previously reported[9,10,40] for the $CuL_2(ClO_4)_2$ and $CuLCl_2$ compounds, where the copper atom exhibits a flattened tetrahedral stereochemistry (indeed, the CuN_4 and CuN_2Cl_2 chromophores have formally D_{2d} and C_{2v} symmetry, respectively). With regard to the electronic spectral data, by using the position of the d–d band intensity maximum (Table 3) as criterion for the distortion of the proposed CuN_4 chromophore,[9] the parameter ϕ may be estimated, defined as the dihedral angle between N_L—Cu—N_L and N_x—Cu—N_x planes ($\phi = 0$ for D_{4h} symmetry and $\phi = 90°$ for Td symmetry), affording $\phi = 55°$ for $CuL(N_3)_2$ and $\phi = 62°$ for $CuL(NCS)_2$. These values are consistent with the obtained R factor (Table 3) for both compounds, also related with the ϕ parameter.[39]

In short, the EPR and electronic spectral data, besides the low conductivity of the solutions (Table 1) indicating the non-electrolyte character,[16] support the existence in $CHCl_3$ solution of neutral $[CuL(X)_2]$ species, with a flattened tetrahedral stereochemistry for the copper atoms.

Acknowledgement—We thank Dr J. P. Tuchagues for his assistance with susceptibility measurements.

BIMETALLIC HEXANUCLEAR COMPOUNDS CONTAINING UNUSUAL COPPER–LANTHANIDE ARRAYS: THE CRYSTAL STRUCTURES OF $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2$ (Ln = Dy OR Gd; LH = 2-(1H)-PYRIDONE, C_5H_5NO)

DAVID M. L. GOODGAME,* DAVID J. WILLIAMS* and RICHARD E. P. WINPENNY

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 3 *November* 1988; *accepted* 3 *February* 1989)

Abstract—Reaction of copper hydroxide, 2-(1H)-pyridone (= LH), and dysprosium (or gadolinium) nitrate in methanol results in the formation of the unusual hexanuclear complexes, $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2$ [Ln = Dy(**1**) and Gd(**2**)], which have been characterized by X-ray diffraction. The compounds are isostructural and in each case four copper and two lanthanide ions are bridged by trinucleating 2-pyridone anions to form an essentially octahedral Cu_4Ln_2 core. The lanthanide atoms are each nine-coordinate and the copper atoms five-coordinate. The core is surrounded by an exterior of largely hydrophobic ligand units.

The recent, rapid developments in the synthesis of high-temperature superconductors of the mixed-metal oxide type have been mainly focussed on systems containing combinations of copper and yttrium or lanthanide (= Ln) ions. Attention is also increasingly being paid to the techniques of sample preparation, both in terms of the experimental method[1] and choice of precursor chemicals.[2] Precursors comprising Cu/Ln heterometallic complexes of organic ligands are of potential value in this context because they contain well-defined Cu_x/Ln_y combinations for conversion to oxides by thermal methods. We have extended our recent studies on heterometallic compounds involving lanthanide ions[3] to include Cu/Ln systems. During this work we have obtained two unusual, new hexanuclear complexes: $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2$ (Ln = Dy(**1**) and Gd(**2**) and LH = 2-pyridone) and we report here the structures of these compounds.

EXPERIMENTAL

Preparation

Reaction of copper hydroxide (1 mmol), 2-pyridone (6 mmol) and the appropriate hydrated lanthanide nitrate (2 mmol) in refluxing methanol (100 cm^3) resulted in a dark green solution, which on evaporation at room temperature for 6 weeks with regular filtrations, gave crystals suitable for single-crystal X-ray diffraction analysis.

X-ray study

Crystals of **1** and **2** formed as dark green cubes from methanol. They contained solvent methanol and required coating with epoxy resin to prevent solvent loss and consequent crystal decomposition, during data collection. Despite these precautions, three separate crystals were required for **2**. The crystal data are: $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2 \cdot 3CH_3OH$ (**1**): $C_{63}H_{70}Cu_4Dy_2N_{16}O_{31}$, orthorhombic, $a = 16.751(6)$, $b = 21.463(6)$, $c = 23.471(6)$ Å, $V = 8439$ Å^3, space group *Pbnn*, $Z = 4$ (the complex has crystallographic C_2 sym-

metry), $M_r = 2126.6$, $D_c = 1.67$ g cm^{-3}, μ(Cu-K_α) = 104 cm^{-1}; $Cu_4Ln_2L_8(LH)_4(OH)_2(NO_3)_4(H_2O)_2 \cdot 2CH_3OH$ (**2**): $C_{62}H_{66}Cu_4Gd_2N_{16}O_{30}$, orthorhombic, $a = 16.774(16)$, $b = 21.344(11)$, $c = 23.441(16)$ Å, $V = 8392$ Å^3, space group *Pbnn*, $Z = 4$ (the complex has crystallographic C_2 symmetry), $M_r = 2084.0$, $D_c = 1.65$ g cm^{-3}, μ(Cu-K_α) = 125 cm^{-1}.

Refined unit cell parameters for crystals of approximate dimensions, **1**: 0.6 × 0.3 × 0.34 mm, **2**: 0.5 × 0.3 × 0.32 mm, were obtained by centring 18 reflections on a Nicolet R3m diffractometer. For **1**, 5842 independent reflections were measured ($\theta \leqslant 58°$) with graphite monochromated Cu-K_α radiation using ω-scan measurement routine. Of these, 3899 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. For **2**, 5946 independent reflections were measured on three crystals (844 on the first, 826 on the second and 4276 on the third; data were collected until the sample had decomposed by ≈ 25%). Of these, 2866 were considered observed. The data were corrected for Lorentz and polarization factors. For **1**, an empirical absorption correction, based upon 398 azimuthal measurements, was applied.

The structure of **2** was solved by the heavy-atom method, which revealed the position of the gadolinium. The remaining non-hydrogen atoms were located from subsequent ΔF maps and were refined anisotropically. Two methanol solvent fragments, each of site occupancy 50%, were also located from ΔF maps and were refined isotropically. The pyridone rings were idealized and refined as rigid bodies. The positions of the hydrogen atoms of the pyridones were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinement was by block-cascade, full-matrix least-squares to $R = 0.115$, $R_w = 0.107$ [$w^{-1} = \sigma^2(F)$

$+0.001F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 1.54 and -1.17 e Å^{-3}, respectively.

The structure of **1** was solved by refining the coordinates of **2** using the data for **1** and with dysoprosium replacing gadolinium. Refinement was as for **2**, but ΔF maps showed two methanol fragments, one of site occupancy 50%, the other of full weight, but with two 50% occupancy sites for the oxygen atoms. Refinement was to $R = 0.099$, $R_w = 0.096$ [$w^{-1} = \sigma^2(F) + 0.001F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 2.59 and -2.18 e Å^{-3}, respectively.

In both structures, although the atoms of the central metal core do not exhibit significant thermal anisotropy, as one moves further out the anisotropic vibrations become very pronounced—particularly in the pyridone and nitrate groups. This, coupled with the difficulty in correcting for the absorption effects of an irregular, partially split crystal (hence higher than average ESDs in the cell parameters) coated in epoxy resin, probably explains the high final value of R.

Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[4] Scattering factors were taken from ref. 5. Important bond lengths and angles are listed in Tables 1 and 2.

RESULTS AND DISCUSSION

The X-ray structural analyses show **1** and **2** to be isostructural. The lanthanide ions are coordinated to nine oxygen atoms (Fig. 1). Four of these oxygens are from deprotonated 2-pyridone units, two from neutral pyridone ligands, two from a bidentate nitrate anion and one from a water molecule. The

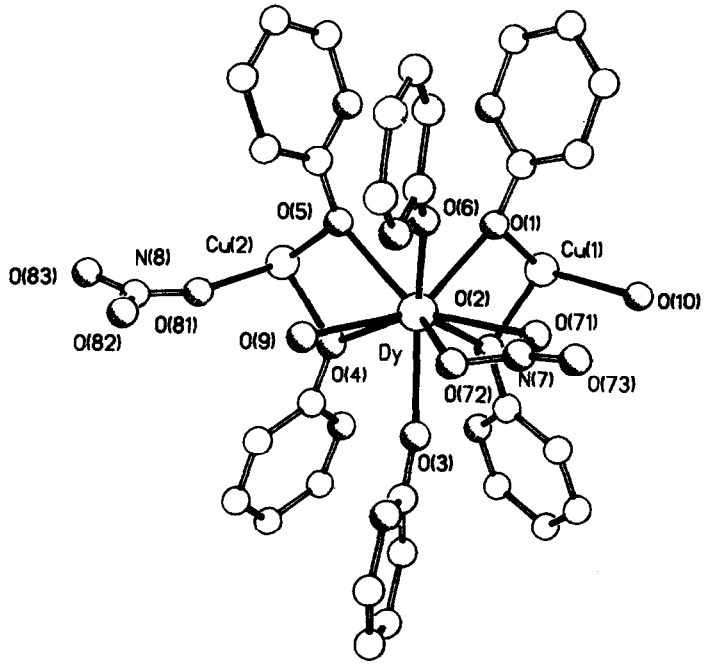

Fig. 1. The lanthanide coordination environment in **1**, showing the numbering scheme.

lanthanide–oxygen bond lengths (Tables 1 and 2) are unexceptional. The coordination geometry in each case is best described as face-capped square antiprismatic. The degree of distortion is small; the angle between the mean planes of the square faces is 1.0° for **1** and 1.3° for **2**. The two faces are rotated out of register by 46° for both compounds. The capping oxygen atom is contributed by one of the oxygen atoms of the bidentate nitrate group. This oxygen atom is at a significantly longer distance (Ln—O $\approx$ 2.68 Å).

There are two types of copper site in the structure. In both, the copper ion is five-coordinate with square-pyramidal geometry (Fig. 2). The principal difference between the two copper sites is the source of the apical oxygen atom. For Cu(1) and Cu(1′) the oxygen is derived from an hydroxide anion, whilst for Cu(2) and Cu(2′) it is from a nitrate anion. In all cases the basal atoms are two pyridone oxygen atoms and two nitrogen atoms in a *cis*-arrangement. The oxygen atoms are shared with the lanthanide ion, and the two nitrogen atoms are derived from different pyridone ligands. The copper–donor atom bond lengths are normal, for the base *ca* 1.97 Å, and for the apical oxygen considerably longer, *ca* 2.35 Å. As might be expected, the copper(II) ions are raised slightly (0.09–0.14 Å) above the basal plane of the pyramid.

Each deprotonated 2-pyridone unit is tri-nucleating, the exocyclic oxygen atom bridging between the lanthanide ion and one copper, and the nitrogen bound to another copper. This appears to be the first example of 2-pyridone binding in this way, although we have recently shown that a related ligand 2-pyrrolidone binds three metal atoms in $[Hg Ag(C_4H_6NO)_2(NO_3)]_2$.[6] The $CuLnO_2$ rings formed in **1** and **2** are nearly planar in all cases. The di-

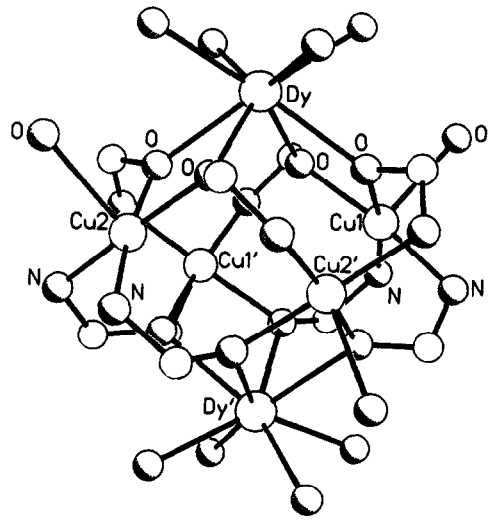

Fig. 2. The ligand-bridged metallic core of **1**, also showing the copper(II) coordination environments. (Atoms not involved in metal atom bridging have been omitted for clarity.)

hedral angles between the LnO_2 and CuO_2 planes within each four-membered ring are within the range 176–178°, and the largest deviation from planarity is for Cu(2) in **1**, which is 0.03 Å out of the plane. The angles at the oxygen atoms are also very similar for all oxygens involved [range 108.0(6)–109.8(6)°].

The result of these several interactions is an unusual spheroidal molecule with four copper and two lanthanide atoms comprising an essentially octahedral core, in which the copper atoms occupy the equatorial region while the lanthanide atoms occupy *trans*-positions (Fig. 3); metal–metal distances in both compounds are within the range 3.57–3.78 Å. This octahedron of metal ions is surrounded by a largely hydrophobic exterior presented by the organic ligands. The exceptions to this are two orthogonal, non-intersecting, hemi-circumferal seams extending from equatorial copper to equatorial copper via a lanthanide atom (Fig. 4). These hydrophilic seams comprise two nitrate anions, one hydroxide anion and a water molecule.

Both structures contain included methanol molecules which are involved in hydrogen bonding interactions with the main molecule. One fragment binds weakly to the hydroxide anion on Cu(1) (O(10)—O(11) = 2.77 Å in **1**, 2.92 Å in **2**) and the other to the water molecule on the lanthanide atom (O(9)—O(21) = 2.73 Å in **1**, 2.68 Å in **2**). This water

molecule, in turn, forms a second intramolecular hydrogen bond to the nitrate group attached to Cu(2) (O(9)—O(81) = 2.80 Å in **1**, 2.85 Å in **2**). There are also intramolecular hydrogen bonds between the protonated 2-pyridone ligands and the nitrate anions, in **1** N(3)—O(72) = 3.04, N(6)—O(72) = 2.79 Å, in **2** N(3)—O(72) = 3.12, N(6)—O(72) = 2.97 Å.

Although 2-pyridone and its derivatives have previously been employed to form homobimetallic compounds,[7,8] as far as we are aware they have not, prior to this work, been used to bridge heterometals. That 2-pyridone will do so suggests that a large range of mixed-metal compounds involving this type of organic ligand could be synthesized. The ready availability of many, varied, substituted derivatives of this basic ligand also leads to the possibility of fine tuning such polymetallic systems, not only by choice of metal combinations but also by choice of ligand.

BRIDGING RATHER THAN CHELATION IN THE SUBSTITUTION CHEMISTRY OF THE OSMIUM(I) COMPLEX $[Os_2(MeCO_2)_2(CO)_6]$ WITH POTENTIALLY CHELATING PHOSPHINES AND ARSINES

ANTONY J. DEEMING,* DIDIER NUEL, NEIL P. RANDLE and CAROLINE WHITTAKER

(*Received* 18 *January* 1989; *accepted* 3 *February* 1989)

Abstract—Substitution of the osmium(I) dimer $[Os_2(MeCO_2)_2(CO)_6]$ with monophosphines has been previously shown to give mono- and disubstituted products with the introduced ligands exclusively *trans* to the Os—Os bond. This has allowed the preparation of the complexes, $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1\text{-L})]$ and $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-L})_2]$, in which the ligands L are $Ph_2PCH_2PPh_2$ (dppm), $Ph_2PCH_2CH_2PPh_2$ (dppe) or $1,2\text{-}C_6H_4(AsMe_2)_2$ (diars). These ligands are normally found to be chelating or bridging but here are coordinated through a single heteroatom, but these complexes show no tendency to lose CO ligands *cis* to the metal–metal bonds to allow the ligands L either to chelate or bridge. There is, however, a strong tendency to form oligomers with bridging diphosphine ligands linking separate Os_2 groups, but the designed synthesis of chains of Os_2 units has failed because of slow redistribution reactions involving cleavage of the Os—L—Os bridges.

It is very easy to substitute the axial CO ligands (those *trans* to the Os—Os bond) of the osmium(I) dimer $[Os_2(MeCO_2)_2(CO)_6]$ (**1**), to give the complexes $[Os_2(MeCO_2)_2(CO)_4L_2]$ (L = PPh_3, PMe_2Ph, py, MeCN, MeNC).[1–3] We have been unable to substitute the CO ligands *cis* to the Os—Os bond.[3] This large difference in lability between the different CO sites has allowed us to label the axial CO sites selectively and to observe very slow intramolecular scrambling between axial and equatorial ligands ($t_{1/2}$, *ca* 6 days at 20°C). It is difficult to synthesize anything but the disubstituted species by direct substitution, but the monosubstituted compounds $[Os_2(MeCO_2)_2(CO)_5L]$ may be prepared by using the ligand L under mild conditions to displace the coordinated THF ligand from $[Os_2(MeCO_2)_2(CO)_5(THF)]$ prepared from **1** in refluxing THF.[3]

We report here our attempts to establish how difficult it really is to substitute more than two CO ligands per dimer by introducing readily chelating or bridging bidentate ligands into the axial positions. We have found no evidence that monodentate diphosphine or diarsine ligands, L, in the complexes $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-L})_2]$, compound **2** (L = $Ph_2PCH_2PPh_2$, dppm), compound **3** (L = $Ph_2PCH_2CH_2PPh_2$, dppe) and compound **4** (L = $1,2\text{-}(Me_2As)_2C_6H_4$, diars), can become bidentate by displacing an adjacent CO ligand even under rather forcing conditions. In none of our work have we been able to displace the CO *trans* to acetate. However, we have been able to use this property to build compounds with Os_2 units linked by dppm and dppe bridges, and have attempted to construct chain and rings of Os_2 units linked in this way. Although we have evidence for catenation and ring formation in this system, controlled synthesis of such compounds is impaired by slow Os—P bond cleavage leading to mixed products. Ruthenium analogues of some of the osmium compounds reported in this paper have been described recently, in particular $[Ru_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})_2]$ and the polymer $[Ru_2(MeCO_2)_2(CO)_4(\mu\text{-dppm})]_n$.[4]

RESULTS AND DISCUSSION

Synthesis and studies on η^1-diphosphine and η^1-diarsine compounds

Reaction of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) with a three-fold excess of the diars ligand in refluxing chloroform gave a 58% yield of the compound $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-diars})_2]$ (**2**) (Scheme 1). The IR ν(CO) spectrum is very similar to that of $[Os_2(MeCO_2)_2(CO)_4(PMe_2Ph)_2]$;[3] ν(CO)($CHCl_3$) 2006vs, 1976m, 1925vs and 1907sh cm^{-1} for **2**, compared with 2011vs, 1969m, 1938vs and 1907w cm^{-1} for the PMe_2Ph complex (Table 1). We have been able to use spectra of this characteristic kind to identify di-axially substituted tetracarbonyl Os_2 complexes. On its own this evidence would require each diars ligand to be axially coordinated through one arsenic atom and corroboration of this comes from the ^1H NMR spectrum. Three methyl singlets in the ratio 12 : 12 : 6 are assigned to the coordinated and free $AsMe_2$ groups and the $MeCO_2$ ligands, respectively (Table 1). Compound **2** is rapidly formed in refluxing chloroform, but even in refluxing toluene over 48 h there is no further CO substitution even though the η^1-diars is ideally positioned to chelate. In none of our work on this system have we been able to displace the CO *trans* to acetate.

Likewise, reactions of **1** with an excess of dppm or dppe give the complexes $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-L})_2]$ (**3**) (L = dppm) and (**4**) (L = dppe) (Scheme 1), whose IR and NMR spectra are totally consistent with the η^1-modes of coordination of the diphosphines. The clearest evidence for this comes from $^{31}P\{^1H\}$ NMR spectra. For example, free dppm gives a singlet at δ −22.2, whereas **3** gives an AA′XX′ spectrum with the multiplets centred at δ −26.8 and 17.2 for free and coordinated PPh_2 groups, respectively (Table 1 and Fig. 1). The occurrence of an AA′XX′ rather than an AX spectrum results from there being a substantial spin–spin coupling between the dppm ligands across the Os_2 unit. Simulation of this spectrum for **3** gave $^3J_{AA}$ = 60 Hz for the P—Os—Os—P coupling constant, which is close to the corresponding value of 59.3 Hz for $[Os_2(MeCO_2)_2(CO)_4(PMe_2Ph)(PPh_3)]$,[3] but lower than the value of 115 Hz for $[Ru_2(MeCO_2)_2(CO)_4(\mu^1\text{-dppm})_2]$.[4]

As with the η^1-diars compound (**2**), compounds **3** and **4** show no tendency to lose CO ligands. We have not been able to prepare $[Os_2(MeCO_2)_2(CO)_5(\eta^1\text{-dppm})]$ by the direct action of dppm (1 mol/mol dimer), since the first and second substitution reactions have similar rates and this compound reacts further with itself to form chains (see later). To synthesize compounds with one η^1-diphosphine ligand we reacted $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$ with the diphosphine. Since the pentacarbonyl compounds cannot be formed directly from **1**, compound **1** was heated in refluxing tetrahydrofuran until $[Os_2(MeCO_2)_2(CO)_5(THF)]$ was formed quantitatively. Subsequent treatment of this with PPh_3 yields the corresponding pentacarbonyl compound. Reactions of this PPh_3 complex with the appropriate diphosphine yields the compounds $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1\text{-L})]$ (**5**) (L = dppm) and (**7**) (L = dppe). When 1 mol of dppm per mol of $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$ is used, compound (**5**) is only a minor product (20%); the major product is the dppe-bridged compound $[\{Os_2(MeCO_2)_2(CO)_4(PPh_3)\}_2(\mu\text{-dppm})]$ (**6**) (70%). Likewise, the μ-dppe compound (**8**) is formed in the reaction with dppe (Scheme 2). Even when a two-fold excess of dppe is used, a 21% yield of **8** accompanies the formation of **7** (51%). This implies that the uncoordinated PPh_2 groups of compounds **5** and **7** compete very effectively with the free dppm or dppe for substitution of the starting material $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$. Compounds **5** and **7** are thermally stable in refluxing xylene over 48 h; again no further CO substitution occurs.

These results led us to explore the possibility of building chains of Os_2 units linked by dppm ligands.

Synthesis of dppm-*bridged compounds*

The reaction of **1** with dppm (0.5 mol/mol Os_2) does not lead specifically to $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu\text{-dppm})]$ (**9**) but to a complex mixture. This was expected because our earlier work had

indicated that substitution of the second CO of **1** is at least as fast as the first, so that monosubstituted species are not formed specifically. However, compound **9** can be formed in a pure state by reaction of dppm with a 10-fold excess of compound **1**, from which it is easily separated by TLC at the end of the reaction. We were able to synthesize the dppm compound (**9**) and the dppe analogue (**10**) in this way (Scheme 3). These compounds are easy to characterize since they each show a single $^{31}P\{^1H\}$ NMR resonance in the region expected for coordinated ligand and the ν(CO) spectrum is characteristic of a pentacarbonyl compound; ν(CO) for **9** in chloroform; 2071vs, 2003vs, 1978vs and 1925m cm^{-1}, compared with 2072vs, 2001vs, 1978s, and 1922m cm^{-1} for $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$. Thus the pentacarbonyl and tetracarbonyl Os_2 units can be easily distinguished by their IR spectra.

This synthetic method can then be applied to making three Os_2 units linked by two μ-dppm ligands. Using the compound $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})_2]$ (**3**) as the starting "diphosphine ligand", reaction with a large excess of **1** gave a mixture of **1** and the compound $[Os_2(MeCO_2)_2(CO)_5(\mu\text{-dppm})Os_2(MeCO_2)_2(CO)_4(\mu\text{-dppm})Os_2(MeCO_2)_2(CO)_5]$ (**11**), more simply formulated as $[Os_6(MeCO_2)_6(CO)_{14}(dppm)_2]$. The formation of **11** was followed by $^{31}P\{^1H\}$ NMR spectra which demonstrated that this method led to **11**, but over a period, redistribution of the ligands led to its breakdown. Thus a solution of **3** and **1** (1 : 10 mol ratio) in d^6-benzene was prepared and the spectrum recorded immediately and then periodically over 10 days. After 30 min at room temperature the spectrum of **3** had disappeared to be replaced by signals in a 3 : 1 ratio for coordinated and free PPh_2 groups, respectively. The signal at δ −27 is like that

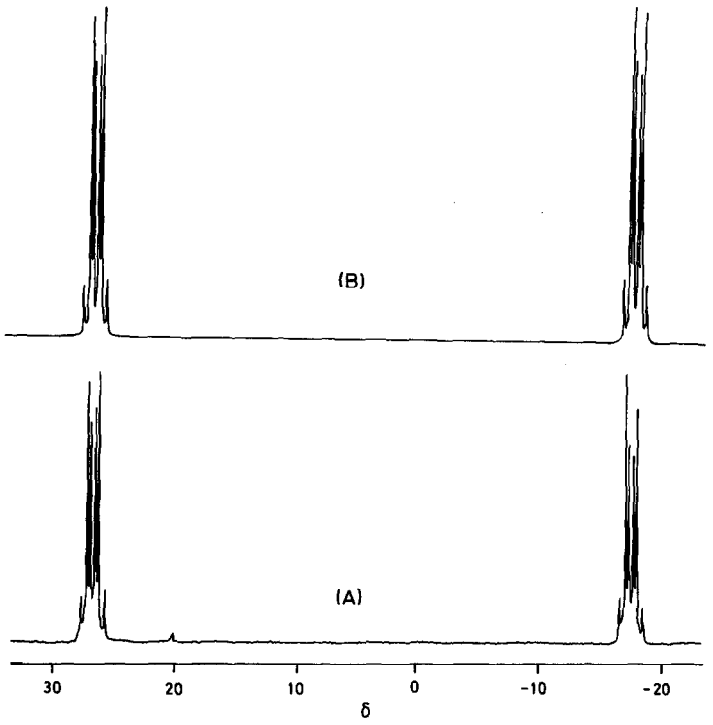

Fig. 1. $^{31}P\{^{1}H\}$ NMR spectra: (A) a $CDCl_3$ solution of $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})_2]$ (3) and (B) the simulated spectrum using $J(PCP) = 70$ Hz and $J(POs_2P) = 60$ Hz.

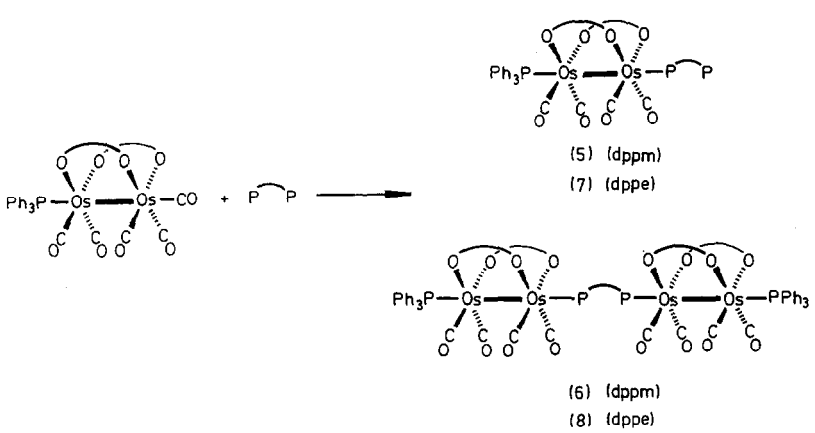
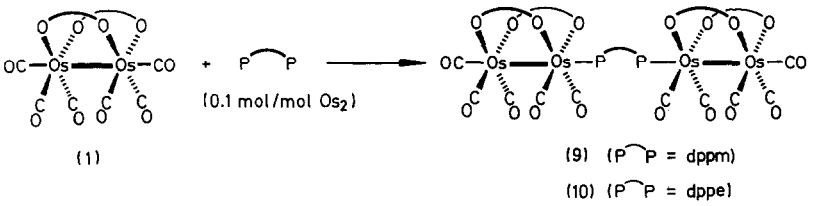
for free PPh_2 in **3**, but the other signal centred at δ +16 is a complex multiplet (at least 24 lines) consistent with overlapping multiplets of a second-order spectrum and with the formation of $[Os_2(MeCO_2)_2(CO)_5(\mu\text{-dppm})Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})]$, the species one would expect to be the initial product. After 4 h the spectrum had simplified and was dominated by an AA'BB' pattern (δ 19.0 and 15.8) which we assign to $[Os_6(MeCO_2)_6(CO)_{14}(dppm)_2]$ (**11**) with the complete loss of signals for free PPh_2 around δ −27. (The same spectrum was obtained immediately on mixing the complexes **3** and $[Os_2(MeCO_2)_2(CO)_5(THF)]$ in 1 : 10 mol ratio in C_6H_6. Clearly the THF ligand is more rapidly displaced than CO, but the THF compound in excess is unstable and the solution becomes dark brown in 1 h.) Analysis of the AA'BB' spectrum gave the values $J(POs_2P) = 42$ Hz and $J(PCH_2P) = 32$ Hz, both values smaller than the corresponding values for compound **3**. Bridging will open the PCP angle which is expected to lower the value of $J(PCH_2P)$.



Scheme 2.

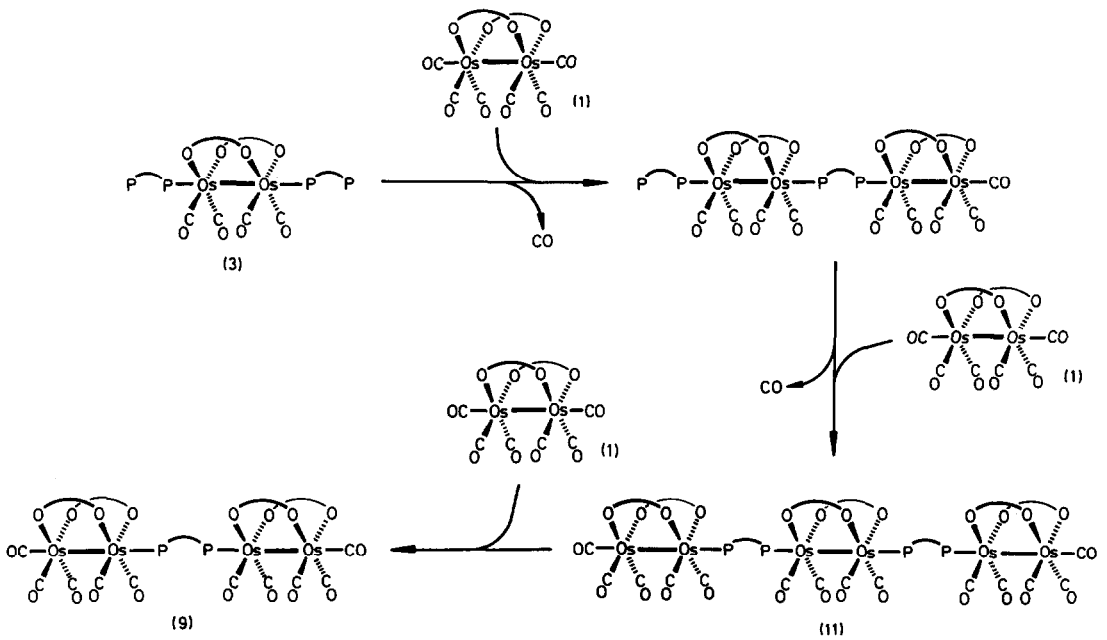


Scheme 3.

If the Os—P bonds were completely inert at room temperature, no further reaction of compound **11** with **1** could occur, but over the next few hours and days the spectrum changed. After 24 h a singlet at δ 18.7 had grown to about the same intensity as that of the AA'BB' signals of **11** and after 10 days the singlet predominated with **11** only in trace amounts. The final product is $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu\text{-dppm})]$ (**9**). This is the expected product if cleavage of Os—P bonds of **11** occurred to give transient η^1-dppm compounds, which then reacted with the excess of complex **1** to reform a μ-dppm ligand. Under the conditions of an excess of **1** we would predict that all the dppm ligand would be incorporated into compound **9**. The reaction of **11** with **1** to give two molecules of **9** is stoichiometrically precise and the vacant coordination site created by the cleavage of an Os—P must be filled by the CO subsequently displaced when **1** reacts with the η^1-dppm intermediate. Thus the conversion can only be quantitative if no CO is lost from solution. Attempts to isolate compound **11** by separating the reaction mixture (TLC) when **11** predominated in solution gave only impure samples. We also monitored the reaction by IR. In the early stages absorptions of tetracarbonyl, pentacarbonyl and hexacarbonyl species were apparent but only pentacarbonyl and hexacarbonyl after 10 days, that is compounds **9** and **1**, respectively. These reactions are summarized in Scheme 4.

Further evidence for the cleavage of Os—P bonds in this system came from the reaction of $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu\text{-dppm})]$ (**9**) with an excess of dppm, in an attempt to synthesize a complex with two Os_2 units bridged by dppm and with terminal uncoordinated PPh_2 groups. Instead, complete conversion to $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})_2]$ (**3**) occurred. Thus in this Os_2/dppm system, an excess of dppm will always lead to **3** and a deficiency of dppm, that is an excess of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**), will lead to **9**, however the particular components are introduced.

A simple direct way to grow chains of Os_2 units bridged by dppm might be to react precisely equi-



Scheme 4.

molar amounts of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) and dppm. An accurately equimolar solution of these compounds in $CDCl_3$ was monitored by its $^{31}P\{^1H\}$ NMR spectrum. Changes occur smoothly over 72 h at room temperature, by which time all traces of any signal for uncoordinated PPh_2 had disappeared and the IR spectrum contained only absorptions for a tetracarbonyl species (ν(CO)($CHCl_3$): 2009vs, 1967m, 1933vs and 1907w cm^{-1}). Therefore we assign the product the formula $[Os_2(MeCO_2)_2(CO)_4(\mu\text{-dppm})]_n$. If the compound is a linear chain, it must contain > 50 Os_2 units since $> 2\%$ of chain termini would have been detected spectroscopically. That is the molar mass must be $> 50{,}000$ and yet the compound is still slightly soluble in chloroform. However, the compound is not in a single form since four singlets of non-integral intensities are observed in the $^{31}P\{^1H\}$ NMR spectrum in the coordinated PPh_2 region (δ 17.2, 16.8, 16.3 and 15.5) (Fig. 2), indicating the presence of various forms. TLC gave several broad ill-defined bands; one band of which gave just two phosphorus signals at δ 17.2 and 15.5. Attempts to grow crystals for an X-ray structure determination gave only microcrystals. The compound may be a high molar mass linear polymer since $[Ru_2(MeCO_2)_2(CO)_4(\mu\text{-MeSCH}_2\text{SMe})]$ has been shown to be such a polymer with two crystallographically different Ru_2 units alternating along the chain.[4] The different NMR signals might therefore be for non-equivalent links in the polymer chain. However, because of the significant solubility of **12** we believe that at least one form of the compound might be cyclic. Even though the dppm ligands are coordinated axially there is sufficient flexibility in the system to get cyclic oligomers. In the absence of more information the nature of this material remains uncertain.

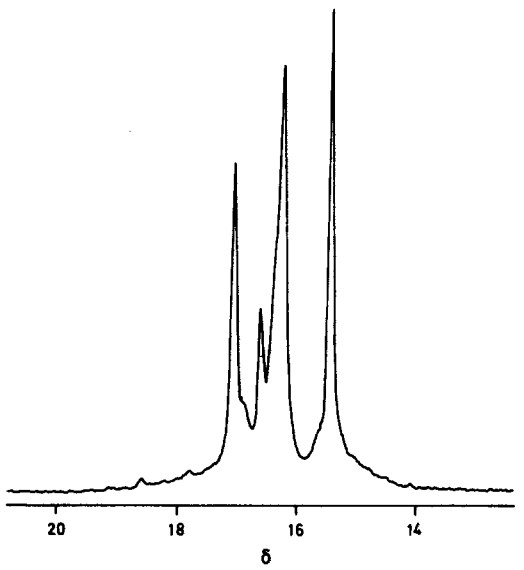


Fig. 2. $^{31}P\{^1H\}$ NMR spectrum of $[Os_2(MeCO_2)_2(CO)_4(\mu\text{-dppm})]_n$ formed from an equimolar mixture of **1** and dppm in $CDCl_3$ over 70 h at room temperature.

EXPERIMENTAL

The compound $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) was prepared from $[Os_3(CO)_{12}]$ and acetic acid[1] and its derivative $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$[3] from the hexacarbonyl as reported. The ligands dppm and dppe were obtained from Aldrich plc and diars was synthesized by known methods. Reactions but not work-up procedures were carried out under nitrogen. TLC was carried out with Keiselgel HF 254 (Merck) and the petroleum ether used as eluant mixtures had b.p. 30–40°C. NMR spectra were recorded on a Varian XL200 and IR spectra on a Perkin–Elmer PE983 spectrometer.

Substitution of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) *with an excess of* diars

A lemon-yellow solution of compound **1** (0.050 g) and diars (0.065 cm^3, *ca* 3 mol/mol Os_2) in chloroform (20 cm^3) was refluxed for 1 h. Removal of the solvent gave a yellow oil, which was washed several times with pentane to remove excess of ligand and to leave a residual lemon-yellow solid, which was recrystallized from dichloromethane–hexane mixtures to give $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-diars})_2]$ (**2**) as yellow crystals (0.035 g, 58%) (Found: C, 28.9; H, 3.4. $C_{28}H_{38}As_4O_8Os_2$ requires: C, 28.4; H, 3.2%).

Substitution of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) *with an excess of* dppm

A solution of dppm (0.290 g, 10 mol/mol Os_2) and compound **1** (0.050 g) in benzene (25 cm^3) was refluxed for 1 h. The solvent was removed under reduced pressure and the pale yellow residue separated by TLC (eluant: petroleum ether–CH_2Cl_2, 2:3 v/v). The top, colourless band gave unreacted dppm and the very pale yellow band below it gave $[Os_2(MeCO_2)_2(CO)_4(\eta^1\text{-dppm})_2]\cdot 0.5CH_2Cl_2$ (**3**) as pale yellow crystals (Found: C, 49.1; H, 3.6; Cl, 2.4; P, 9.3. $C_{58.5}H_{51}ClO_8Os_2P_4$ requires: C, 49.4; H, 3.6; Cl, 2.5; P, 8.7%).

Substitution of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) *with an excess of* dppe

This reaction was carried out similarly, from **1** (0.050 g) and dppe (0.300 g) to give $[Os_2(Me$

$CO_2)_2(CO)_4(\eta^1$-dppe$)_2]$ (**4**) as pale yellow crystals (0.068 g, 64%) (Found: C, 51.6; H, 3.7; P, 8.7. $C_{60}H_{54}O_8Os_2P_4$ requires: C, 51.2; H, 3.8; P, 8.8%).

Reaction of $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$ *with* dppm

A solution of the PPh_3 compound (0.050 g) and dppm (0.018 g, 1 mol/mol Os_2) in chloroform (20 cm^3) was refluxed for 20 min. Removal of the solvent and TLC work-up (eluant: CH_2Cl_2–petroleum ether–diethyl ether, 13:6:1 v/v/v) gave two pale yellow bands which were extracted with dichloromethane to give two products. Recrystallization of these from CH_2Cl_2–hexane mixtures gave $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1$-dppm$)]$ (**5**) (0.018 g, 20%) (Found: C, 48.1; H, 3.3; P, 7.15. $C_{51}H_{43}O_8Os_2P_3$ requires: C, 48.7; H, 3.4; P, 7.4%) and $[\{Os_2(MeCO_2)_2(CO)_4(PPh_3)\}_2(\mu$-dppm$)]$ (**6**) (0.042 g, 70%) (Found: C, 43.6; H, 3.1; P, 5.7. $C_{77}H_{64}O_{16}Os_4P_4$ requires: C, 43.4; H, 3.0; P, 5.8%), each as creamy-yellow crystals.

Reaction of $[Os_2(MeCO_2)_2(CO)_5(PPh_3)]$ *with* dppe

A similar reaction to that above using the PPh_3 complex (0.100 g) and dppe (0.090 g, 2 mol/mol Os_2) gave, after TLC separation (eluant: petroleum ether–CH_2Cl_2, 1:1 v/v), bands yielding two products each as pale yellow–green crystals from CH_2Cl_2–methanol mixtures: $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1$-dppe$)]$ (**7**) (0.063 g, 52%) (Found: C, 48.7; H, 3.4; P, 7.1. $C_{52}H_{45}O_8Os_2P_3$ requires; C, 49.1; H, 3.5; P, 7.3%) and $[\{Os_2(MeCO_2)_2(CO)_4(PPh_3)\}_2(\mu$-dppe$)]$ (**8**) (0.025 g, 21%) (Found: C, 43.6; H, 3.1; P, 6.1. $C_{78}H_{66}O_{16}Os_4P_4$ requires: C, 43.7; H, 3.1; P, 5.8%).

Thermolysis of η^1-dppm, η^1-dppe *and* η^1-diars *complexes*

(a) $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1$-dppm$)]$ (**5**). A solution of this complex in xylene was heated under reflux for 48 h. Removal of the solvent and TLC work-up (eluant: petroleum ether–CH_2Cl_2, 1:1 v/v) gave the starting material (85–90%) as the only observed carbonyl compound.

(b) $[Os_2(MeCO_2)_2(CO)_4(PPh_3)(\eta^1$-dppe$)]$ (**7**). A similar treatment gave a 90% recovery of compound **7**.

(c) $[Os_2(MeCO_2)_2(CO)_4(\eta^1$-diars$)_2]$ (**2**). The IR spectrum of a solution of this complex in refluxing toluene over 48 h showed no change and chromatographic work-up gave **2** (90%) as the only observed metal carbonyl compound.

Substitution of $[Os_2(MeCO_2)_2(CO)_6]$ (**1**) *with a deficiency of* dppm

A solution of dppm (0.015 g, 0.1 mol/mol Os_2) in benzene (10 cm^3) was added dropwise to a refluxing solution of **1** (0.130 g) in benzene (15 cm^3) over 30 min, and the reflux was continued for a further 30 min to give a lemon-yellow solution. Removal of the solvent under reduced pressure and TLC work-up (eluant: petroleum ether–CH_2Cl_2, 2:3 v/v) gave two main bands yielding compounds **1** and $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu$-dppm$)]\cdot 0.5CH_2Cl_2$ (**9**) (0.036 g, 55% based on dppm) (Found: C, 30.7; H, 2.1; Cl, 2.5; P, 3.7. $C_{43.5}H_{35}ClO_{18}Os_4P_2$ requires: C, 30.65; H, 2.0; Cl, 2.1; P, 3.6%).

Substitution of $[Os_2(MeCO_2)_2(CO)_6]$ *with a deficiency of* dppe

This reaction was carried out similarly with dppe (0.010 g) and **1** (0.165 g) to give $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu$-dppe$)]$ (**10**) as orange microcrystals (0.022 g, 52% based on dppe) (Found: C, 32.0; H, 2.1; P, 4.0. $C_{44}H_{36}O_{18}Os_4P_2$ requires: C, 31.5; H, 2.1; P, 3.7%).

Reaction of $[Os_2(MeCO_2)_2(CO)_4(\eta^1$-dppm$)_2]$ (**3**) *with a large excess of* **1** *attempting to synthesize* $[Os_6(MeCO_2)_6(CO)_{14}(dppm)_2]$ (**11**)

A mixture of **1** (0.3750 g) and **3** (0.0788 g, 0.1 mol/mol of **1**) in C_6D_6 (3 cm^3) was prepared in a 10 mm diameter NMR tube. Initially not all of **1** dissolved. The $^{31}P\{^1H\}$ NMR spectrum was recorded immediately and then periodically over 24 h and again after 10 days. The spectra showed that after 4 h 90% of the dppm was in the form of compound **11**, but after 10 days this had converted (> 95%) into $[\{Os_2(MeCO_2)_2(CO)_5\}_2(\mu$-dppm$)]$ (**9**), which could be isolated by TLC.

Reaction of **1** *with an equimolar amount of* dppm

$[Os_2(MeCO_2)_2(CO)_6]$ (0.0500 g) and dppm (0.0288 g, 1.00 mol/mol Os_2) were accurately weighed into a 10 mm diameter NMR tube and dissolved in $CDCl_3$ (2.5 cm^3). The tube was kept at about 15°C and the $^{31}P\{^1H\}$ NMR spectrum recorded over 70 h, by which time there was no detectable signal for uncoordinated PPh_2 groups. The solvent was removed under reduced pressure and the residue separated by TLC (eluant: petroleum ether–CH_2Cl_2, 2:3 v/v) to give several very broad, ill-defined bands of which the strongest was extracted with CH_2Cl_2 to give a pale yellow solid (Found: C, 40.0; H, 2.7; Cl, 0.15; P, 6.0.

$C_{33}H_{28}O_8Os_2P_2$ requires: C, 39.8; H, 2.8; Cl, 0.0; P, 6.2%). The low chlorine content indicates a little CH_2Cl_2 in the crystals; $[Os_2(MeCO_2)_2(CO)_4(dppm)]_{50}(CH_2Cl_2)$ requires: C, 39.8; H, 2.85; Cl, 0.14; P, 6.2%. Recrystallization from CH_2Cl_2–methanol mixtures gave yellow–cream microcrystals, none being suitable for a single-crystal X-ray structure determination.

POLYMERIC COORDINATION OF 4,4′-DITHIODIPYRIDINE WITH COBALT(II), NICKEL(II) AND COPPER(II) HALIDES

J. GUILLERMO CONTRERAS* and HERNÁN CORTÉS

Departamento de Química, Universidad de Concepción, Casilla 3-C, Concepción, Chile

(*Received* 8 *November* 1988; *accepted* 3 *February* 1989)

Abstract—A series of complexes of the type MX_2(4,4′-DTDP)$_2$ (**A**) and MX_2(4,4′-DTDP) (**B**), where M = Co^{II}, Ni^{II} or Cu^{II}, X = Cl, Br or I and 4,4-DTDP is 4,4′-dithiodipyridine, have been prepared and spectroscopically characterized. The chloride and bromide complexes are of type **A** and possess a polymeric octahedral structure, whereas the iodide derivatives are polymeric tetrahedral type **B** species. The copper(II) chloride complex is also type **B**, whereas the bromide derivative can be formulated as Cu_2Br_4(4,4′-DTDP) in which the organic ligand is in a *cis* conformation and bridging two copper atoms. The copper atoms are also bridged by bromide ligands in such a way that each metal atom is tetrahedrally coordinated. Although, a structure consisting of a polymer dimer with each ligand molecule bridging two Cu_2Br_4 units is also possible.

In a previous paper we reported the preparation and characterization of a series of complexes of 4,4′-dithiodipyridine (4,4′-DTDP) with group IIB metal halides.[1] The IR spectra showed that the uncoordinated ligand adopts a *trans* conformation and that both pyridine residues are chemically equivalent. In the coordination compounds, the ligand is bridging two metal halide units to produce a polymeric pseudotetrahedral structure.

Ferraro *et al.*[2] have reported the preparation and characterization of $CoCl_2$(4,4′-DTDP)$_2$ and $CoBr_2$(4,4′-DTDP)$_2$ and found that they possess a polymeric octahedral structure, based on some four IR bands.

Since the N,S- or N,N-coordination are precluded for this ligand unless it adopts a *cis* or *gauche* conformation to accommodate the various stereochemical requirements imposed by the metal ions, it seems clear that even in these cases considerable angular strain needs to be introduced. However, a pure S-coordination cannot be completely ruled out. In an attempt to know more about the coordination capability of this ligand we have prepared and characterized complexes of cobalt(II), nickel(II) and copper(II) halides of the type MX_2(4,4′-DTDP)$_2$ or MX_2(4,4′-DTDP). In order to study the influence of the halogen we have also prepared the cobalt(II) and nickel(II) iodide complexes of the title ligand.

EXPERIMENTAL

The coordination compounds of 4,4′-DTDP were prepared by a general method. To a hot ethanolic solution of the ligand the stoichiometric amount of the appropriate metal halide dissolved in the same solvent, was added. The complexes precipitated out and were filtered off, washed with ethanol and dried. All compounds are insoluble in most common solvents precluding conductivity measurements. Table 1 gives the analytical and magnetic data for the compounds reported here.

The IR and Raman spectra were obtained as described previously.[3,4] The electronic spectra were obtained in Nujol mulls in the range of 200–2500 nm and recorded on a Zeiss PMQ II spectrophotometer. The magnetic measurements were carried out at room temperature (20°C) on a Cahn electrobalance coupled to a digital millivoltmeter and to a permanent magnet of *ca* 8000 *g*.

RESULTS AND DISCUSSION

The free 4,4′-DTDP shows four bands in the region 1400–1650 cm^{-1} that are due to the C=C

Table 1. Analytical and magnetic data for the 4,4′-DTDP complexes of cobalt(II), nickel(II) and copper(II) halides

	Complex[a]	C (%)	H (%)	X (%)	M (%)	μ_{eff}(BM)
I	$NiCl_2$(4,4′-DTDP)$_2$	42.0 (42.1)	2.9 (2.8)	12.1 (12.4)	10.9 (10.3)	3.40
II	$NiBr_2$(4,4′-DTDP)$_2$	36.1 (36.4)	2.8 (2.4)	24.4 (24.3)	8.7 (8.9)	3.44
III	NiI_2(4,4′-DTDP)	22.7 (22.5)	1.3 (1.5)	47.3 (47.6)	10.3 (11.0)	3.15
IV	$CoBr_2$(4,4′-DTDP)$_2$	12.6 (12.2)	1.4 (1.2)	24.3 (25.0)	8.7 (8.4)	5.20
V	CoI_2(4,4′-DTDP)	22.8 (22.5)	1.8 (1.5)	47.6 (48.2)	11.4 (11.1)	4.54
VI	$CuCl_2$(4,4′-DTDP)	33.1 (33.8)	1.8 (2.2)	20.1 (20.0)	18.1 (17.9)	2.10
VII	Cu_2Br_4(4,4′-DTDP)	18.5 (18.0)	1.4 (1.2)	47.9 (47.9)	19.1 (19.1)	1.04

[a] 4,4′-DTDP = $C_{10}H_8N_2S_2$; Calculated values are given in parentheses.

and C=N stretching modes of the pyridine rings.[5] At 990 cm^{-1}, the A_1 breathing mode occurs and the bands detected at 803, 725 and 698 cm^{-1} can be assigned to the out-of-plane C—H and C—C deformation modes.[6] The band at 414 cm^{-1} corresponds to a ϕ(C—C) out-of-plane deformation mode.[6,7]

In the coordination compounds of cobalt(II), nickel(II) and copper(II) we have also observed four bands in the 1400–1650 cm^{-1} region, implying that the pyridine residues are equivalent[8] and hence the free and coordinated pyridine groups adopt a *trans* conformation about the S—S bond.

Band I (1562 cm^{-1} in free ligand) shifts by *ca* 15–30 cm^{-1} upon coordination, whereas band IV (1402 cm^{-1} in free ligand) moves to higher frequencies by *ca* 5–20 cm^{-1}. Bands II and III remain unchanged or shift slightly (*ca* 5 cm^{-1}) to higher frequencies.

The free ligand shows a weak feature at 1452 cm^{-1} that is absent in the coordination compounds.

Sinha[9] has shown that a shift greater than 10 cm^{-1} of the ring breathing mode is also an indication of pyridine coodination. As in the 2,2′-DTDP ligand, the γ(C—H) mode observed at 803 cm^{-1} in the free ligand, is shifted slightly in the coordination compounds or disappears to be replaced by two or three bands located at variable frequencies. The ϕ(C—C) mode detected at 698 cm^{-1} shifts by *ca* 15–25 cm^{-1}, appearing as a single band. The same situation is observed for the band at 414 cm^{-1}.

It is worth noting that if one pyridine residue was bonded to the metal and the other uncoordinated, two bands due to this mode should be observed. The lower frequency band would be shifted by *ca* 3–6 cm^{-1} with respect to the free ligand. Since in our case a single band is detected (except for compound **VII**), we can conclude that both pyridine groups are coordinated[5,6,10] to produce a polymeric structure. The complex ($CuBr_2$)$_2$(4,4′-DTDP) deserves special mention, in which the band at 445 cm^{-1} is rather broad, presumably containing two components. In fact, it is likely that in this case the ligand is in a *cis* conformation with the two pyridine groups not being fully equivalent. This effect has been observed in [Cu(OAc)$_2$]$_2$LE where LE is the 1,2-bis(2′-pyridyl)ethane.[11] At room temperature a single broad band located at 417 cm^{-1} suggests a *trans* conformation of the ligand, however at low temperature the band splits into two bands lying at 421 cm^{-1}.

The Raman spectra of all the complexes reported here show the metal–halogen, metal–nitrogen and sulphur–sulphur stretching bands. A very intense emission at *ca* 340 cm^{-1} has also been observed in all cases. Table 2 lists some selected Raman bands for these species. The metal–ligand stretching vibrations were assigned by comparison with previously reported data.[12,13] The metal–halogen stretching bands of compounds **I**, **II** and **IV** correspond to typical values for terminal metal–halogen stretching modes in octahedral complexes, whereas for compounds **III**, **V** and **VI** the frequency values of these modes agree well with those observed for tetrahedral species.

Compound **VII** presents terminal copper–bromide (211 and 201 cm^{-1}) as well as bridging copper–bromide (184 and 188 cm^{-1}) stretching bands, confirming the structure proposed above.

The metal–nitrogen stretching bands have weak intensities and hence their assignments must be taken as only tentative. The ν(S—S) is also weak, though in the complexes of zinc(II), cadmium(II) and mercury(II) shows up with "normal" intensities.[1] An interesting feature appears at 340 cm^{-1}. In all complexes a very strong band at *ca* 340 cm^{-1} is observed. This band must be associated with the C—S bond since it is detected in the pyridine-2-thiol and bis(tolyl)disulphide. It cannot be associated

Table 2. Raman bands for the 4,4′-DTDP complexes of nickel(II), cobalt(II) and copper(II)

Complex[a]	ν(M—X)	ν(M—N)	ν(S—S)	Band at *ca* 340 cm^{-1}

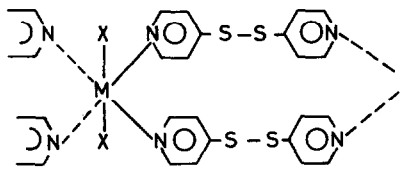
[a] Numbering of the compounds according to Table 1.

with a ring vibration since it is not observed in the pyridine, but detected in tetramethylthiuram disulphide, i.e. a compound that contains a S—S bridge linked to two non-aromatic substituents.[1]

An interesting effect has been observed for this very strong emission. In the octahedral species it shows up split into two or more components, whereas in the tetrahedral ones a single band is observed. A single band was also detected for all tetrahedral species of zinc(II), cadmium(II) and mercury(II). In this sense this band seems to be very sensitive to stereochemistry, though no theoretical explanation could be found. Additional work on this effect for some complexes of other dithiodipyridine is being carried out in our laboratory.

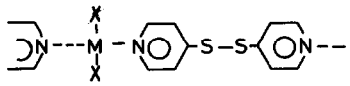
The magnetic moments of all complexes are in the range of high spin values for octahedral and tetrahedral structures. The departure of the corresponding spin-only values must be certainly due to some orbital contribution. Unfortunately, magnetic measurement of a single temperature allows only limited discussion of the stereochemistry of complexes, however the fact is known that tetrahedral cobalt(II) complexes show smaller magnetic moments than the corresponding octahedral ones. The nickel(II) complexes (I) and (II) have moments of 3.40 and 3.44 BM, respectively; these values are in agreement with an octahedral structure.[14] The magnetic moments of freshly prepared samples of compounds I and II consistently gave the same values. These values along with the IR data suggest a polymeric structure of type A (see below).



(A)

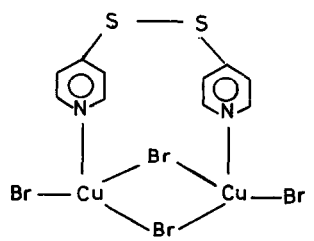
A similar situation is observed for the $CoBr_2$(4,4′-DTDP)$_2$ (IV) species, for which a magnetic moment of 5.20 BM is observed and hence its A type structure is in agreement with the one proposed by Ferraro and co-workers.[2]

The magnetic moments of complexes III, V and VI are characteristic of a tetrahedral structure.[15] The magnetic moment and the IR data allow us to postulate a polymeric tetrahedral structure for these species:



The compound Cu_2Br_4(4,4′-DTDP) (VII) deserves special discussion since its magnetic moment is very low (1.04 BM per copper atom). The IR data suggest that both pyridine residues are coordinated and that the ligand adopts a *cis* configuration. Therefore the structure of this compound is likely to be of type C (see below). Molecular models for this species show that both pyridine groups must be in a face–face configuration and that they are not completely equivalent. The pyridine residues are slightly twisted and not parallel to one another. The angles at the sulphur atoms must be larger than 90°. Alternatively, the structure can consist of a polymer of dimers with each ligand molecule bridging two Cu_2Br_4 units.

The low magnetic moment is probably due to a super-exchange mechanism operating through the bridging bromides and magnetic measurements at several low temperatures are obviously called for.



(C)

The electronic spectra of all these species in Nujol mulls show a number of weak absorptions which

are not always easy to assign. Thus, the octahedral nickel(II) complexes show the following bands: 5.26, 9.76, 11.1, 16.3 and 28.6 kK for compound **I** and 4.26, 5.90, 13.5, 16.4 and 22.2 kK for compound **II**. Compound **IV** shows bands at 8.70, 19.7 and 29.4 kK, whereas the tetrahedral complex **V** shows bands at 5.80 and 13.6 kK only. No attempts to assign these bands were made.

SYNTHESIS AND METAL-COMPLEXING ABILITY OF *m*-XYLYLENEBIS(β-DIKETONES)

ANDREW W. MAVERICK* and DANIEL P. MARTONE

Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803, U.S.A.

and

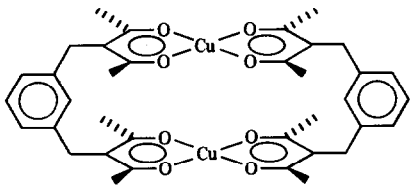
JULIE R. BRADBURY and JANET E. NELSON

Department of Chemistry, Washington University, St. Louis, MO 63130, U.S.A.

(*Received* 14 *September* 1988; *accepted after revision* 13 *February* 1989)

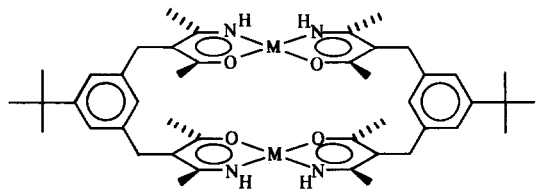
Abstract—The preparation of the bis(β-diketone) $XBAH_2$ (3,3′-[1,3-phenylenebis(methylene)bis(2,4-pentanedione)]) and five of its derivatives, and a study of their complexation reactions with Cu^{2+}, is reported. Of these ligands (LH_2), only sterically unhindered derivatives of acetylacetone readily yield binuclear copper(II) complexes, Cu_2L_2. The introduction of bulkier groups (Ph, *t*-Bu) into the 2,4-pentanedione portions of the ligands inhibits the complex-forming reaction, resulting in lower yields ($XBBH_2$; see ligand abbreviations in Fig. 1), no reaction ($XBPH_2$) or decomposition ($XBDH_2$). The copper complex of Cl_4XBAH_2 appears to be polymeric; this is probably due to the steric effects of the bulky chlorine atom in the two-position.

We have been interested in the use of new cofacial binuclear transition metal complexes as catalysts for multi-electron redox reactions. The cofacial geometry is attractive in these systems because of the possibility of intramolecular binding and activation of small redox-active substrates. We have concentrated on bis(β-diketones) as ligands for these complexes, because β-diketones form planar complexes with a variety of metal ions and also because the synthetic versatility of the bis(β-diketones) should make the cofacial binuclear complexes accessible for a variety of bridging groups. Our initial report concerned the synthesis of $Cu_2(XBA)_2$ (**1**) (see drawing below; all ligands discussed herein are *meta* isomers),[1] and its structural and spectroscopic properties.



1

More recently we have shown that larger bis(β-diketone) species can undergo selective intramolecular complexation reactions,[2] and we have observed multi-electron redox activity in the bis(β-ketoenamine) complexes, $M_2(BBI)_2$ (**2**), shown below.[3]



2

We have also been interested in the influence of other substituents in the bis(β-diketone) ligands on the complexation reactions and on the stereochemistry and reactivity of the resulting complexes. Therefore, we have prepared several new *m*-xylylenebis(β-diketones) (**3**) (see Fig. 1); syntheses of these ligands, and a discussion of their ability to form metal complexes, are reported herein.

EXPERIMENTAL

Materials and procedures

The ligand syntheses were carried out under N_2; this led to improved purity of the bis(β-diketone) products. *t*-Butyl alcohol (Mallinckrodt) was purified by treatment with potassium metal and subsequent distillation. Methyl 3,5-bis(bromomethyl)benzoate[4] and 1,3-bis(bromomethyl)-2,4,5,6-tetrachlorobenzene[5] were prepared by literature procedures. Other chemicals and solvents were reagent or spectrophotometric grade and were used as received. Melting points (uncorrected) were measured by using an Electrothermal apparatus. ^{1}H and ^{13}C NMR spectra were recorded on Varian XL300 or Bruker AC100 or AC200 instruments. Microanalyses were performed by Desert Analytics (Tucson, Arizona) or Midwest Laboratories (Indianapolis, Indiana).

*Bis(β-diketones)**

(a) *By nucleophilic substitution*

The general method of Martin and co-workers[6] was used for all six ligands. The appropriate β-

*Abbreviations for β-diketones: acacH = acetylacetone (2,4-pentanedione); bzacH = benzoylacetone (1-phenyl-1,3-butanedione); dbmH = dibenzoylmethane (1,3-diphenyl-1,3-propanedione); dpmH = dipivaloylmethane (2,2,6,6-tetramethyl-3,5-heptanedione); bzacacH = 3-benzylacetylacetone; Cl$_5$bzacacH = 3-(pentachlorobenzyl)acetylacetone. Abbreviations for the new ligands **3** are given in Fig. 1.

[b] Two different crystal modifications; see Experimental.

diketone (3 mol) was added slowly to a refluxing solution of potassium *t*-butoxide (2 mol) in *t*-butyl alcohol. After 30 min of further refluxing, the appropriate 1,3-bis(bromomethyl)benzene derivative (1 mol) was added in small portions; approximately 1 h later, KI (*ca* 0.25 mol) was added. Variations in reaction time and proportion of solvent are noted in Table 1. After the reaction mixture became acidic to moist litmus, three-fourths of the *t*-butyl alcohol was removed by distillation at atmospheric pressure, and further work-up proceeded as follows.

For $XBAH_2$ (**3a**), $EBAH_2$ (**3b**) and Cl_4XBAH_2 (**3c**), the residue was extracted with H_2O and CH_2Cl_2 and the CH_2Cl_2 layer removed, dried with Na_2SO_4 and evaporated to dryness. Excess acetylacetone was removed from the product under dynamic vacuum at room temperature (24–48 h). $XBAH_2$ (**3a**), when prepared by this method, was obtained as an oil; this material sometimes solidified partially over a period of weeks, and pure solid $XBAH_2$ (m.p. 89–92°C; entirely in the enol form) could be isolated from the mixture by trituration with methanol. $EBAH_2$ (**3b**) was obtained only as an oil; it was further characterized by its mass spectrum (parent ion, *m/e* 360,361) and by NMR (see Tables 2 and 3). Cl_4XBAH_2 (**3c**) was crystallized from toluene.

For $XBBH_2$ (**3d**), the *t*-butyl alcohol was removed completely. Excess benzoylacetone was then removed by dissolving the residue in CH_2Cl_2, extracting with a six-fold excess of 0.4 M

NaOH(aq)* and then with $NaHCO_3$(aq) and H_2O, drying with Na_2SO_4 and evaporating to dryness. The amber oily residue was placed in a refrigerator and, when it had largely solidified (several weeks), it was triturated with methanol, collected by filtration, washed with methanol, and air-dried to yield a white powder.

For $XBDH_2$ (**3e**) and $XBPH_2$ (**3f**) the residue was washed with hot water, taken up in benzene, precipitated by addition of hexane, and recrystallized from benzene–hexane.

(b) *Preparation of* $XBAH_2$ (**3a**) *from isophthalaldehyde*

(i) XBE (**4**) (3,3′-[1,3-*phenylenebis*(*methylidene*)]*bis*(2,4-*pentanedione*)). Isophthalaldehyde (13.4 g, 0.1 mol), acetylacetone (20.0 g, 0.2 mol), benzoic acid (12.2 g, 0.1 mol) and triethylamine (10.1 g, 0.1 mol) were dissolved in benzene (100 cm^3) and the solution was brought to reflux, using a Dean–Stark trap to collect the water formed in the condensation. After *ca* 34 h the expected quantity of water had collected and the solvent was removed. The residue was dissolved in CH_2Cl_2 and the solution extracted successively with 5% $NaHCO_3$(aq), H_2O, 5% HCl(aq) and H_2O, dried with $MgSO_4$ and evaporated to dryness. The resulting dark red oil was extracted several times with boiling diethyl ether and the yellow ether extracts were concentrated and cooled to *ca* −15°C to give a pale yellow product (total yield 10–20%).

(ii) $XBAH_2$. XBE (2.70 g, 9.05 mmol) was dissolved in methanol (150 cm^3) and 10% Pd/C (*ca* 0.10 g) added. Catalytic hydrogenation (2–3 atm, RT) required 3–5 h. Filtration and removal of the solvent gave partially solid, colourless $XBAH_2$ in almost quantitative yield. Analytically pure crystalline material was obtained from methanol by slow cooling. The melting point of this product (105°C) was noticeably higher than that for $XBAH_2$ prepared by method (a) above. NMR spectra for solutions of this higher-melting material show that both keto and enol tautomers are present, in contrast to the material prepared by method (a), which is entirely in the keto form. Martin *et al.* observed multiple crystal forms in other bis(β-diketones);[6] we have also shown in a closely related bis(β-diketone)[3] that the ratio of keto and enol tautomers depends on the solvent of crystallization.

Copper(II) *complexes*

(a) *Two-phase method*

A solution of bis(β-diketone) (0.05–0.2 M) in CH_2Cl_2 or $CHCl_3$ was extracted with a 10-fold

* A pH > 13 is probably required for efficient extraction of benzoylacetone into water, as judged from its pK_a [8.7: J. R. Jones, *Ionization of Carbon Acids*. Academic Press, London (1973)] and from its partition coefficient, which strongly favours solution in CH_2Cl_2 (Y. Yoshimura and N. Suzuki, *Anal. Chim. Acta* 1976, **85**, 383). A similar pK_a is expected for $XBBH_2$, but its partition coefficient is likely to favour solution in CH_2Cl_2 much more strongly than that for benzoylacetone.

excess of $Cu(NH_3)_4^{2+}$(aq). The organic layer was dried over Na_2SO_4, filtered and evaporated to dryness. The residue was purified by washing with benzene; alternatively, the complex was crystallized over a period of several days by dissolving the residue in CH_2Cl_2 or $CHCl_3$ and layering the solution with CH_3CN, isopropyl alcohol or diethyl ether.

(b) *One-phase method*

Bis(β-diketone) (1 mmol) was added to a stirred solution of (i) $Cu(NO_3)_2 \cdot 3H_2O$ (0.23 g, 1 mmol) and Et_3N (0.22 g, 2.2 mmol) in *N*,*N*-dimethylformamide (40 cm^3); or (ii) $Cu_2(OAc)_4 \cdot 2H_2O$ (0.20 g, 0.5 mmol) in pyridine (50 cm^3). Formation of a complex was indicated by the appearance of a precipitate ($Cu_2(XBA)_2$, $[Cu(Cl_4XBA)]_n$) or a dark olive-green solution ($Cu_2(XBB)_2$) after 6–8 h. $Cu_2(XBB)_2$ was precipitated by pouring the solution into a large excess of vigorously stirred dil. NaCl(aq).

The crude solid products were collected, washed with fresh solvent where appropriate, and air-dried; some of the complexes could be crystallized from CH_2Cl_2 or $CHCl_3$ as outlined in (a) above. In cases where the complexes could be prepared by more than one method (e.g. $Cu_2(XBA)_2$), the products were identical, as judged by electronic absorption spectra. The binuclear copper complexes are generally soluble only in chlorinated hydrocarbon solvents. Analytical data for the ligands and new copper(II) complexes are presented in Table 4; ^1H and ^{13}C NMR spectral data for the ligands appear in Tables 2 and 3.

Recovery of ligands from copper(II) complexes

A solution of the complex in CH_2Cl_2 or $CHCl_3$ was extracted with excess 0.1 M HCl, which decolorized the CH_2Cl_2 layer; when large amounts of the copper complex were used, the pale blue colour of $Cu(H_2O)_6^{2+}$ could be observed in the aqueous layer. The CH_2Cl_2 layer was then washed with water, dried over Na_2SO_4, filtered and evaporated to dryness. The residue was characterized by its ^1H NMR spectrum in $CDCl_3$ or CD_2Cl_2.

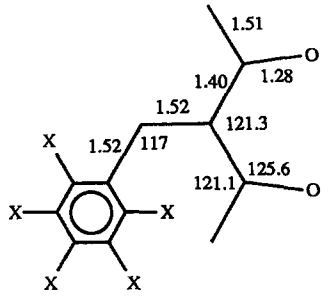

Fig. 2. Geometry utilized in SYBYL[9] molecular-mechanics calculations for 3-benzylacetylacetonato (X = H) and 3-(pentachlorobenzyl)acetylacetonato (X = Cl) metal complexes. Distances (Å) and angles (°) are average values based on crystal structure investigations of $Cu_2(XBA)_2$[1] and $Cu_2(NBA)_2 \cdot 2CHCl_3$.[2]

Molecular-mechanics calculations

For these calculations, the SYBYL program set[7] was utilized. The geometry assumed in the calculations, which was intended to approximate that of the complexes (rather than the free ligands) as closely as possible, is illustrated in Fig. 2. Bond lengths and angles used in the acac and CH_2 moieties were average values from the X-ray crystal structures of $Cu_2(XBA)_2$[1] and $Cu_2(NBA)_2 \cdot 2CHCl_3$;[2] idealized C—H distances and phenyl-ring geometries were assumed. In generating the potential-energy contour diagrams in Figs 2 and 3, only the torsion angles about the acac–CH_2 and CH_2–arene bonds (α and β, respectively) were allowed to vary; therefore, the results reflect only changes in torsional and van der Waals interactions.

RESULTS AND DISCUSSION

Ligand synthesis

All of the bis(β-diketone) ligands could be prepared in satisfactory yield by modifications of the nucleophilic-substitution procedure described by Shamma and co-workers[6] for *p*-$XBAH_2$ (3,3′-[1,4-phenylenebis(methylene)bis(2,4-pentanedione]). Our initial attempts to prepare the *meta*-substituted isomer, $XBAH_2$ (**3a**), by this method led to oily products that were difficult to purify. As an alternative

approach, therefore, we explored Knoevenagel condensation of isophthalaldehyde with acetylacetone to produce the unsaturated tetraketone XBE (**4**), followed by catalytic hydrogenation. (Similar condensations of isophthalaldehyde with diethyl malonate[8] and terephthalaldehyde with acetylacetone[9] have been reported.) Although the yields of $XBAH_2$ were much lower by this method, the product was an analytically pure crystalline solid.

The ligands $XBAH_2$ (**3a**) and $EBAH_2$ (**3b**) show evidence for both keto and enol tautomers in their ^1H and ^{13}C NMR spectra (see Tables 2 and 3) in $CDCl_3$; the other four bis(β-diketones) exist entirely in the keto form.

Copper complexes

Since the copper(II) complexes we have studied previously are easily prepared and purified,[1-3] we investigated the reactions of copper(II) with the new ligands as well. Only the unhindered acetylacetone derivatives $XBAH_2$ (**3a**) and $EBAH_2$ (**3b**) produced copper(II) complexes in good yield. With $XBBH_2$ (**3d**) the copper(II) product, which is probably also binuclear, could be obtained only in low yield by the single-phase method in DMF. Although $Cu_2(XBB)_2$ prepared by this method was not analytically pure, unchanged $XBBH_2$ (identified by ^1H NMR) could be regenerated from it by extraction of a $CHCl_3$ solution with dilute acid. Also, its relatively high solubility in CH_2Cl_2 and $CHCl_3$, and its EPR spectrum,* indicate that it is likely to be a discrete binuclear complex. Cl_4XBAH_2 (**3c**) also reacted with Cu^{2+} only in the single-phase attempts, but the product in this case was a grey powder that was insoluble in common organic solvents. Based on the low solubility of the material, and on a conformational study of Cl_4XBA^{2-} complexes (see below), we believe the complex is polymeric.

No reaction occurred under these conditions between copper(II) and $XBDH_2$ (**3e**) or $XBPH_2$ (**3f**). More vigorous conditions, such as heating the pure ligands with $Cu(acac)_2$, $Cu_2(OAc)_4 \cdot 2H_2O$ or CuO either under vacuum or in high-boiling solvents (e.g. DMF, mesitylene), also gave no binuclear complexes with the latter two ligands. Small amounts of a crystalline olive-green solid were obtained from $XBDH_2$ in some of these reactions, but this was shown to be $Cu(dbm)_2$.† (Partial hydrolysis of $XBDH_2$ is the most likely source of dibenzoylmethane in these reaction mixtures: the ligand is analytically pure and shows no evidence of inhomogeneity.)

Steric congestion in ligands and complexes

Although the bis(β-diketones) derived from benzoylacetone, dibenzoylmethane and dipivaloylmethane ($XBBH_2$, $XBDH_2$, and $XBPH_2$, respectively) are somewhat easier to purify than $XBAH_2$, their bulky substituents inhibit the formation of metal complexes. Of these three ligands, only $XBBH_2$ could be converted to a copper(II) complex. The increasing difficulty in complex formation along this series can be attributed to the large steric bulk of the phenyl and *t*-butyl substituents. Mononuclear complexes with these substituents, $M(bzac)_2$, $M(dbm)_2$ and $M(dpm)_2$, are well known. However, the metal-containing planes in a binuclear complex such as $Cu_2(XBA)_2$ are sufficiently close together (the distance between the two $Cu(acac)_2$ moieties in **1** is *ca* 5.0 Å) that substantial interference can be anticipated between groups attached to adjacent metal atoms. Therefore, even XBB^{2-} can probably form a discrete binuclear complex such as $Cu_2(XBB)_2$ only if the arrangement of Ph and CH_3 groups is *anti* (as shown for $XBBH_2$ in Fig. 1). This geometric restriction may be responsible for the experimental difficulties we experience in preparing $Cu_2(XBB)_2$ We expect that complexes such as $M_2(XBD)_2$ and $M_2(XBP)_2$ will be much more difficult to prepare.

Conformational analysis of XBA^{2-} *and* Cl_4XBA^{2-} *complexes*

Although Cl_4XBAH_2 yields a copper complex on treatment with Cu^{2+} in DMF, the product is insoluble in all common solvents and is therefore likely to be polymeric. In order to examine the role of steric interactions in this behaviour, and to compare it with the facile formation of $Cu_2(XBA)_2$, we undertook a molecular-mechanics study. Since the relative conformational energies of XBA^{2-} and Cl_4XBA^{2-} are likely to be influenced most strongly by adjacent groups on the aromatic rings and not by longer-range interactions between the acac moieties, we utilized the model compounds 3-benzylacetylacetone (bzacacH; see Fig. 2, with X = H) and its pentachloro derivative (Cl_5bzacacH;

* A. W. Maverick and D. F. Church, work in progress. EPR spectra for $Cu_2(XBA)_2$, $Cu_2(EBA)_2$, and $Cu_2(XBB)_2$ in chloroform or trichloroethylene solution are similar, reflecting weak coupling between the two copper atoms; all are substantially more complex than those for mononuclear copper(II) β-diketone complexes.

† Shown by X-ray crystallography; our results were essentially identical to those previously reported for $Cu(dbm)_2$: M. Blackstone, J. Van Thuijl and C. Romers, *Rec. Trav. Chim. Pays-Bas* 1966, **85**, 557.

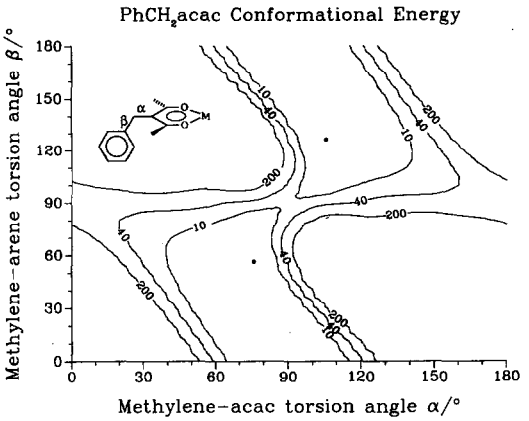

Fig. 3. Calculated potential-energy contour diagram for a 3-benzylacetylacetonato metal complex, based on the geometry in Fig. 2, as a function of torsion angles α and β (see inset structure). Filled circles represent lowest-energy conformations (α = 75, β = 55; α = 105, β = 125°).

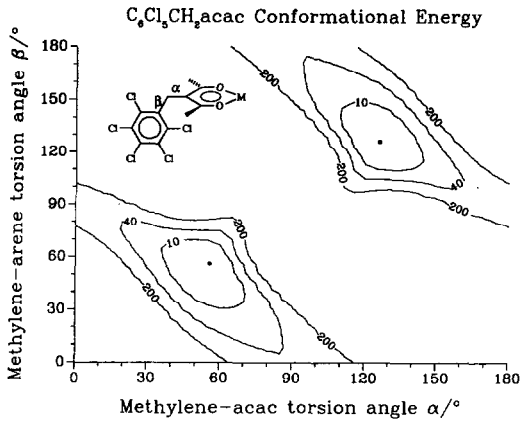

Fig. 4. Calculated potential-energy contour diagram for a 3-(pentachlorobenzyl)acetylacetonato metal complex, based on geometry in Fig. 2, as a function of torsion angles α and β (see inset structure). Filled circles represent lowest-energy conformations (α = β = 55; α = β = 125°).

X = Cl). The bond distances and angles for both of these molecules were taken in part from our previous crystallographic investigations,[1,2] so as to model as closely as possible the interactions that would occur in metal complexes of these ligands.

The geometric features in our ligands that are most important in governing the assembly of binuclear complexes are the torsion angles α and β about the acac–CH_2 and CH_2–arene bonds, respectively. The most symmetrical geometry, with the $M(acac)_2$ and *m*-xylylene moieties perpendicular, is achieved when α = 90° and β = 0°. Experimental values of α and β in the structures of $Cu_2(XBA)_2$ (87.5–88.9° and 2.8–4.3°)[1] and $Cu_2(NBA)_2 \cdot 2CHCl_3$ (81.6–88.4° and 0.3–4.5°, respectively)[2] are close to these ideal values.

Calculated potential-energy contour diagrams are shown in Fig. 3 (for a $bzacac^-$ complex) and Fig. 4 ($Cl_5bzacac^-$). Complexes of benzylacetylacetone show considerable conformational flexibility; we estimate that the conformation corresponding to our assembled binuclear complexes (α ≈ 90°; β ≈ 0°) is no more than 1 kJ mol^{-1} higher in energy than the most stable conformation. In contrast, the set of readily accessible conformations for a $Cl_5bzacac^-$ complex is much smaller; and the barrier for formation of the α = 90°, β = 0° conformation is *ca* 42 kJ mol^{-1}. This unfavourable energy is primarily due to repulsion between the chlorine atom in the two-position and the central carbon atom in the acac moiety. In a hypothetical binuclear $Cu_2(Cl_4XBA)_2$ complex, this repulsion would occur twice in each ligand; therefore, the barrier to formation of a discrete binuclear complex $Cu_2(Cl_4XBA)_2$ may be as high as 160 kJ mol^{-1}.

The strong C---Cl repulsion that accompanies the α = 90°, β = 0° conformation in $Cl_5bzacac^-$ and Cl_4XBA^{2-} could be relieved somewhat by increasing the arene–CH_2–acac bond angle. Even though this distortion introduces additional strain into the molecule, it results in some overall stabilization: calculations suggest that the best compromise is achieved for a bond angle of *ca* 126°. However, this conformation is still *ca* 15 kJ mol^{-1} higher in energy than the optimum conformation in Fig. 4; this would correspond to a 60 kJ mol^{-1} barrier for formation of $Cu_2(Cl_4XBA)_2$. Furthermore, an arene–CH_2–acac bond angle greater than 120° will introduce additional destabilization in a binuclear metal complex (see above) by distorting the metal coordination environment. The proposed polymeric structure, on the other hand, places few restrictions on the conformation of the ligands; in this arrangement, α and β for individual ligands are likely to be close to the minimum-energy values suggested by Fig. 4.

CONCLUSIONS

We have prepared a variety of *m*-xylylenebis(β-diketones). Their capacity for forming cofacial binuclear copper complexes is strongly dependent on steric properties of the substituents, especially those in the β-diketone moieties or in the 2-position of the *m*-xylylene bridge. In general, the binuclear complexes are accessible for a more limited range of substituents than the correspond-

ing mononuclear systems. The hindered ligand Cl_4XBAH_2 (**3c**) is prevented from adopting a conformation suitable for a binuclear complex by unfavourable steric interactions, but a polymeric species is relatively stable. Our experience so far indicates that copper(II) complexes are among the easiest to prepare with these bis(β-diketone) ligands. Therefore, we expect that the steric restrictions outlined here will apply to other metals as well. Work currently in progress in our laboratory includes the conversion of the less hindered new ligands to the corresponding bis(β-ketoenamines) and their complexes, as well as the adaptation of functionalized bis(β-diketones) such as $EBAH_2$ (**3b**) for improving the solubility of the binuclear complexes in more polar solvents.

THE MOLECULAR STRUCTURE OF BIPYRIDINIUM TRIS(BIPYRIDINE)CHROMIUM(III) PERCHLORATE

KYU-WANG LEE and PATRICK E. HOGGARD*

Department of Chemistry, North Dakota State University, Fargo, ND 58105, U.S.A.

(*Received* 17 *January* 1989; *accepted* 15 *February* 1989)

Abstract—$[Cr(bpy)_3](ClO_4)_3$ (bpy = 2,2′-bipyridine) cocrystallizes with bipyridinium perchlorate in the triclinic space group $P\bar{1}$ (No. 2), with $a = 13.532(2)$, $b = 16.596(3)$, $c = 10.324(1)$ Å, $\alpha = 92.16(1)$, $\beta = 100.92(1)$, $\gamma = 102.76(1)°$, $V = 2212.7$ Å^3 and $Z = 2$. The structure was refined to $R = 0.073$ and $R_w = 0.098$. The cocrystallized $HbpyClO_4$ may also have been present in earlier preparations, but could have escaped detection because of the similarity in carbon, hydrogen, nitrogen and chlorine percentages, with and without the cocrystallite.

Hauser *et al.* recently published the crystal structure and low temperature polarized sharp-line absorption spectra for $[Cr(bpy)_3](PF_6)_3$.[1] The space group was reported to be $R32$, in which by necessity the enantiomers must occupy non-equivalent positions. The differences between the two sites, however, appeared extreme. The N—Cr—N bite angle, for example, was reported as 74.8° in one site (equal by symmetry for all three rings) and 84.7° in the other. Large differences in other bond lengths and bond angles were also manifest. If this structure is correct it is unique among transition metal chelate complexes.

Because the geometry of the tris(bipyridine) chromium(III) complex is important to the ligand field analysis of the electronic spectra,[2] we attempted to repeat the solution of the crystal structure of $[Cr(bpy)_3](PF_6)_3$, but failed due to an apparent twinning of the crystals.[3]

We therefore chose another salt, the perchlorate, for crystallographic work. It has been the most commonly used salt of $[Cr(bpy)_3]^{3+}$ for photochemical and spectroscopic studies. A problem surfaced in the course of the elemental analyses of this compound. The carbon, hydrogen and nitrogen analyses were as expected, and in one case so was the chromium analysis. However, another sample from the same batch sent to a different firm produced a chromium percentage about 25% lower than expected. The latter analysis turned out to be correct, however, since refinement of the crystallographic data revealed the presence of cocrystallized bipyridinium perchlorate. This does, however, raise the question of what compound was actually used by previous investigators.

RESULTS AND DISCUSSION

Solution of the X-ray crystal structure showed there to be one chromium complex per asymmetric unit and revealed the presence of the cocrystallized $HbpyClO_4$. The enantiomeric complex is related by inversion symmetry in the $P\bar{1}$ space group. One enantiomer is shown in an ORTEP diagram in Fig. 1. Table 1 contains an abbreviated list of bond lengths and angles.

Table 1 also includes a comparison with the data of Hauser *et al.* for the hexafluorophosphate salt.[1] Although the two sites in the latter compound are characterized by several disparate bond lengths and angles, when they are averaged they agree fairly well with an average of the same quantities from the three rings in the perchlorate salt. For example, the bipyridine bite angle (N—Cr—N) is 79.6, 79.7 and 80.4° in the three rings of $[Cr(bpy)_3](ClO_4)_3 \cdot HbpyClO_4$, as opposed to the 74.8 and 84.7° angles mentioned above for the two sites in the $[Cr(bpy)_3](PF_6)_3$ structure. The inter-ring C—C distance, an important measure of the extent of delocalization, is between 1.46 and 1.49 Å in the perchlorate salt, but stated by Hauser to be 1.39

and 1.56 Å in the two sites of the PF_6^- salt. The most likely explanation for the overlarge site differences is that the crystallographic data were refined in the wrong space group.

There are numerous references in the literature to $[Cr(bpy)_3](ClO_4)_3$, and it is impossible to tell which of them are actually cocrystallized with bipyridinium perchlorate. The carbon, hydrogen, nitrogen and chlorine percentages are very similar in $[Cr(bpy)_3](ClO_4)_3$ and $[Cr(bpy)_3](ClO_4)_3 \cdot HbpyClO_4$. There are many reports of the synthesis of $[Cr(bpy)_3](ClO_4)_3$ without the inclusion of analytical data.[4-7] In some cases, one-half of a water of crystallization is included in the formula, either with a (C, H, N, Cl) analysis[8] or without.[9] In one instance, two waters of crystallization are reported,[10] but the supporting analyses were not published. The optimum coincidence in analytical percentages occurs with no additional water molecules, so it may be inferred that bipyridinium perchlorate has not cocrystallized when any water of crystallization is reported.

The bipyridinium ion probably becomes available for cocrystallization through displacement of coordinated bipyridine by water in $[Cr(bpy)_3]^{2+}$. This in turn should be facilitated by higher acid concentrations, and it is likely that the perchloric acid concentration during oxidation is the critical factor in determining whether or not bipyridinium perchlorate is incorporated in the crystal. Porter and Van Houten have also discussed the method and order of addition during the oxidation procedure and how they affect the yield.[6] They found that when $[Cr(bpy)_3]^{2+}$ was first dissolved in acid and then slowly oxidized, the yield was reduced through displacement of bipyridine.

[a] As reported in ref. 1.

In the procedure we followed,[11] oxidation was not as rapid as in the method advised by Porter and Van Houten. Our "dilute" perchloric acid was approximately 1 M, whereas other workers have often used solutions 10–100 times more dilute. It thus seems that two different products may be formed depending on the perchloric acid concentration and/or the speed of oxidation. The solution characteristics would of course be identical. But without appropriate elemental analyses it is unclear how many of the literature references to this compound do and do not contain cocrystallized $HbpyClO_4$.

COMPLEXATION OF LANTHANIDES(III) WITH MACROCYCLIC 18-CROWN-6 IN METHANOL UTILIZING A COLORIMETRIC COMPLEXANT BY SPECTROPHOTOMETRY

EMIKO OHYOSHI* and SUSUMU KOHATA

Yatsushiro National College of Technology, Hirayamashinmachi 2627, Yatsushiro, Kumamoto 866, Japan

(*Received* 27 *June* 1988; *accepted* 15 *February* 1989)

Abstract—A spectrophotometric procedure using a colorimetric complexant has been developed for the study of the complexation between several lanthanides(III) (Ln^{III}) and 18-crown-6 (18C6, A) in methanol. 2-(2-Thiazolylazo)-4-methylphenol (TAC, L) was used as a colorimetric complexant because of its simple structure with which no protonated complexes may be formed. The absorption spectra of the species in the Ln–TAC–18C6 system at various concentrations of 18C6 showed no formation of the ternary complex, LnLA. The conditional stability constants of the Ln(TAC) complexes at constant acidity in the absence ($K_{LnL'}$) and the presence ($K_{Ln'L'}$) of 18C6 were determined by monitoring the absorbance due to the Ln(TAC) complexes. The competition between TAC and 18C6 for the metal ion resulted in a decrease in $K_{Ln'L'}$ with increasing 18C6 concentration. From the dependence of $1/K_{Ln'L'}$ on the concentration of 18C6, the stability constants of the Ln(18C6) complexes could be determined. The stability constants of these complexes were found to decrease with increasing atomic number. The results are compared with those reported previously. On the basis of the complexation trend observed, 18C6 was used as a competitive ligand to increase the selectivity of chelating agents.

Macrocyclic polyethers of the 18-crown-6 type are unique ligands because of their lower complexing-ability with the small lanthanides, despite their higher charge density.[1,2] This trend in the lanthanides is very interesting because a reverse order has been always noted for most chelating agents. It suggests, therefore, that the ligands of the 18C6 type might be used competitively so as to increase the selectivity of the chelating agent. Since 18C6 is soluble both in aprotic and protic (methanol) solvents, it should be suitable for this purpose. Izatt *et al.*[1] studied the lanthanide complexation of 18C6 in methanol by calorimetric titrations and showed no formation of 18C6 complexes with any post-Gd^{III}. However, Almasio *et al.*[3] reported that 18C6 formed very stable complexes with Dy^{III} ($\log K = 7.90$), Er^{III} ($\log K = 7.67$) and Yb^{III} ($\log K = 7.50$) in anhydrous propylene carbonate (aprotic solvent). It thus seemed that further investigations should be made in methanol. Recently, spectrophotometric procedures[4–7] involving the competition of the two ligands have successfully been applied to the study of many complexes.

In the present work, we have developed a similar spectrophotometric procedure to study the complexation of several lanthanides with 18C6 in methanol, and have compared the results with those reported by Izatt *et al.* Also, the competitive effect of 18C6 on the selectivity of chelating agents has been explored.

EXPERIMENTAL

Reagents

All chemicals used were of GR grade. The ligands, TAC (Dojindo Chemical Co.) and 18C6 (Aldrich Chemical Co.) were dissolved in methanol (spectroscopic grade) to prepare 1.0×10^{-3} M and 0.20 M stock solutions, respectively. Seven types of $LnCl_3 \cdot nH_2O$ [Ln = La, Ce, Pr ($n = 7$); Ln = Nd,

* Author to whom correspondence should be addressed.

Eu, Dy, Yb ($n = 6$)] were dissolved in methanol to give concentrations of $5–20 \times 10^{-3}$ M, which were standardized by EDTA titration. Perchloric acid and tetraethylammonium perchlorate were used to adjust the acidity and to control the ionic strength, respectively.

Procedure

(a) The metal solution was added in small steps, 25×10^{-3} cm^3 each time, using a microliter pipet, to 5.0 cm^3 of a methanol solution containing TAC (2.0×10^{-5} M), at a constant acidity and ionic strength, to give concentrations of $2.5–40 \times 10^{-5}$ M. (b) To the same solution, prepared by procedure (a), 18C6 solution was further added in small steps to give concentrations of $1.0–12 \times 10^{-3}$ M. After each addition of the metal and 18C6 solution, the absorbance due to the Ln(TAC) complex (570 nm) was measured using a Shimadzu UV-260 spectrophotometer.

RESULTS AND DISCUSSION

Absorption spectra

Figure 1 shows the variation in absorption spectra of the TAC(L) solutions with varying Yb concentration, C_{Yb}, at $[HClO_4] = 4 \times 10^{-4}$ M and [18C6] = 0 (procedure (a), solid lines 1–4), or varying the 18C6(A) concentration, C_A, at $[HClO_4] = 4 \times 10^{-4}$ M and $C_{Yb} = 1.0 \times 10^{-4}$ M (procedure (b), dotted lines 5–10). In each procedure, (a) or (b), the Yb(TAC) complex formation ($\lambda_{max} = 572$ nm) or its dissociation occurs, respectively. It is seen that the solid and dotted curves have the same isosbestic point (488 nm). Moreover, the two curves, 2 and 8, are identical. These facts indicate that the dissociation of the YbL complex only takes place in procedure (b), i.e. there is no formation of ternary complex, YbLA. Similar results were obtained for other systems of Ln–L and Ln–L–A studied.

Determination of the conditional stability constants of Ln–TAC *complexes*

The absorbance D due to the Ln–TAC complex was used to determine the conditional stability constant at a given acidity, $K_{LnL'}$: D was measured at a constant acidity and various Ln concentrations in the binary Ln–TAC(L) system [procedure (a)]. The constant defined as $K_{LnL'} = [LnL]/([Ln][L'])$, where $[L'] = [L]+[HL]$ (the charges are omitted for simplicity), was determined by the method of Lang[8] [eq. (1)]:

$$C_{Ln}C_L/D = \{C_{Ln}+C_L-(D/\varepsilon_{LnL})\}(1/\varepsilon_{LnL}) + \{1/(K_{LnL'}\varepsilon_{LnL})\}, \quad (1)$$

where C_{Ln} and C_L are the total concentrations of Ln and L, and ε_{LnL} is the molar absorptivity of LnL. Plots of $C_{Ln}C_L/D$ vs $C_{Ln}+C_L-(D/\varepsilon_{LnL})$, where ε_{LnL} is assumed to be D_{max}/C_L (D_{max} is the maximum absorbance), were almost linear and show that only the 1 : 1 complex is formed. The reciprocal of the slope of the line yielded the corrected value of ε_{LnL} which was utilized to replot the above relation. The slope/intercept ratio of the resulting plot gave the $K_{LnL'}$ value. The results obtained for different lanthanides are listed in Table 1. From the values obtained at different acidity for La^{III}, Ce^{III} and Yb^{III}, it is found that $K_{LnL'}$ decreases due to the side reaction, H + L = HL occurring.

In the ternary Ln–TAC(L)–18C6(A) system [procedure (b)], D was observed to decrease with increasing concentration of 18C6 (C_A) (see

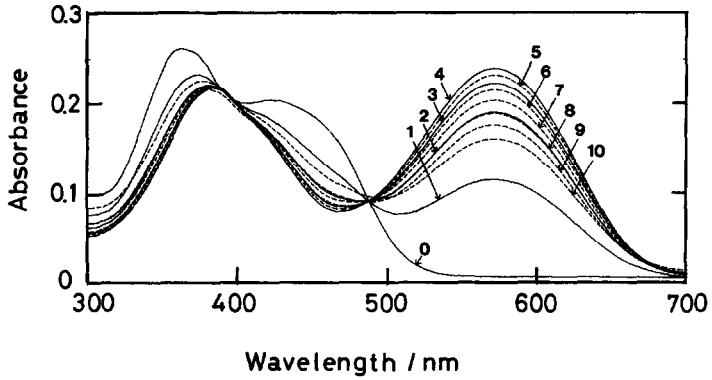

Fig. 1. Spectral changes of Yb–TAC (——) and Yb–TAC–18C6 (– – –) in a 4×10^{-4} M $HClO_4$–methanol solution at $\mu = 0.025$. TAC only: 0, 2.1×10^{-5} M. C_{Yb} in procedure (a): 1, 0.25; 2, 0.5; 3, 0.75; 4, 1.0×10^{-4} M. C_A in procedure (b): 5, 0.2; 6, 0.6; 7, 1.0; 8, 1.4; 9, 1.8; 10, 2.6×10^{-2} M.

curves 5–10 in Fig. 1). The conditional stability constant at a given C_A and at the same acidity as that in the binary system, $K_{Ln'L'}$, which is defined as $K_{Ln'L'} = [LnL]/([Ln'][L'])$, where $[Ln'] = [Ln]+[LnA]+[LnA_2] = C_{Ln}-[LnL]$ and $[L'] = [L]+[HL] = C_L-[LnL]$, was obtained by eq. (2):

$$K_{Ln'L'} = D/[(\varepsilon_{LnL}C_L - D)\{C_{Ln}-(D/\varepsilon_{LnL})\}]. \quad (2)$$

The $K_{Ln'L'}$ values decreased with increasing C_A.

Determination of the stability constants of Ln–18C6 *complexes*

$K_{Ln'L'}$ values obtained at constant acidity and various C_A can be related to the stability constants of the 1:1 and 1:2 Ln–18C6 complexes, K_{LnA} and K_{LnA_2}, where $K_{LnA} = [LnA]/([Ln][A])$ and $K_{LnA_2} = [LnA_2]/([Ln][A]^2)$, as follows:

$$K_{Ln'L'} = [LnL]/([Ln'][L'])$$
$$= [LnL]/\{[Ln](1+K_{LnA}[A]+K_{LnA_2}[A]^2)[L']\}$$
$$= K_{LnL'}/(1+K_{LnA}[A]+K_{LnA_2}[A]^2) \quad (3)$$

$$1/K_{Ln'L'} = (1/K_{LnL'})(1+K_{LnA}[A]+K_{LnA_2}[A]^2), \quad (4)$$

where $[A] = C_A$ since C_A is usually in sufficient excess compared with C_{Ln}. According to eq. (4), a plot of $1/K_{Ln'L'}$ vs [A] (A:18C6) at relatively low values of [A] and constant acidity yields a straight line, and K_{LnA} as the slope/intercept ratio. When formation of LnA_2 occurs with increasing [A], K_{LnA_2} can also be obtained from the slope of the plot according to eq. (5), obtained by rearrangement of eq. (4):

$$\{(1/K_{Ln'L'})-(1/K_{LnL'})\}/[A]$$
$$= (1/K_{LnL'})(K_{LnA}+K_{LnA_2}[A]). \quad (5)$$

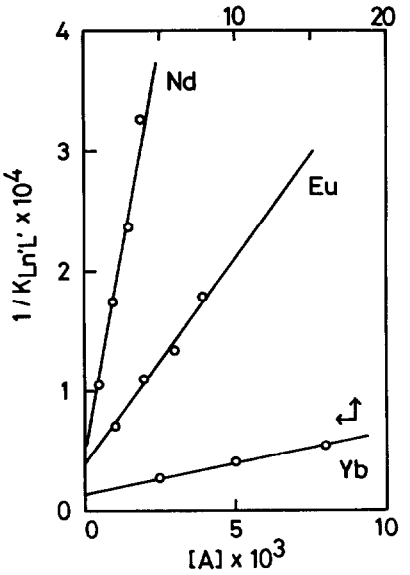

Fig. 2. Plots of the reciprocal conditional stability constants $1/K_{Ln'L'}$ vs [18C6].

Figure 2 shows the results of the plots of eq. (4) for the Ln–TAC–18C6 systems (Ln = Nd^{III}, Eu^{III} and Yb^{III}) at $[HClO_4] = 4\times10^{-4}$ M. Similar linear plots were obtained for Ce^{III}, Pr^{III} and Dy^{III}. However, the acidity was too high for La^{III} to obtain reliable values of $K_{Ln'L'}$. A lower acidity, $[HClO_4] = 2\times10^{-4}$ M, was thus used for La^{III}, and the linear plot of eq. (4) was obtained. At higher acidity, $[HClO_4] = 8\times10^{-4}$ M used for Yb^{III}, or a lower one, $[HClO_4] = 2\times10^{-4}$ M used for Ce^{III}, the plots of eq. (4) were also found to be linear. The facts indicate that these lanthanides only form the 1:1 complex with 18C6 in the range of [18C6] used. The $K_{LnL'}$ values given by the reciprocal intercept of the plots generally agreed with the corresponding values obtained in the binary system (Table 1), but were less accurate than the latter. Thus, we used the latter value for calculation of K_{LnA} which corresponds to the product of the slope and $K_{LnL'}$. The results for different lanthanides are listed in Table 2. By varying the acidity, the K_{LnA} values for Ce^{III} and Yb^{III} remain unchanged, indicating no effect of the hydrogen ion on complexation between Ln and 18C6.

Dependence of the stability of Ln(18C6) *on the atomic number of the lanthanides*

Figure 3 shows the variation in stability constants of Ln–18C6 complexes (K_{LnA}) with atomic number, together with the values reported by Izatt *et al.*,[1] which were obtained by calorimetric titrations

Table 2. Stability constants of Ln(18C6) complexes in methanol at 25°C and $\mu = 0.025$

Ln	Ln–TAC–18C6 $\log K_{LnA}$ ([$HClO_4$]) $(2\times10^{-4}$ M)	$(4\times10^{-4}$ M)	$(8\times10^{-4}$ M)
La	3.89(8)		
Ce	3.67(5)	3.72(6)	
Pr		3.60(8)	
Nd		3.40(6)

The numbers in parentheses are uncertainties of the last decimal place.

under identical experimental conditions to this work except for the ionic strength. As is expected, the stability constants of the LnA complexes decrease through the lanthanides series despite the increase in charge density.

It is noted that the values of La^{III} to Gd^{III} reported by Izatt *et al.*[1] are about one order of magnitude smaller than ours, and those after Tb^{III} decrease to zero. This difference may arise from the difference in the ionic strength of the solution. The electrolyte $(C_2H_5)_4NClO_4$ (TEAP) was used to adjust the ionic strength to 0.025 in our study, while they performed at $\mu = 0.005$, suggesting no supporting electrolyte being used. As Massaux *et al.*[2] pointed out, the presence of protic solvents such as water or methanol gives rise to a significant reduction of the stability of metal–macrocycle complexes because of solvation effects. It thus seems that the electrolyte TEAP, existing in solution, released the solvent molecules H_2O and/or CH_3OH coordinated to the Ln^{3+} ion and favoured to react the Ln^{3+} ion with 18C6. This effect was confirmed by the fact that the stability of Eu(18C6) increases by increasing the ionic strength, i.e. $\log K_{EuA} = 2.54$, 2.85 and 3.04 at $\mu = 0.013$, 0.025 and 0.05, respectively.

Effect of another ligand on the selectivity of a chelating agent

From eq. (4) simplified by neglecting the last term, the ratio of the conditional stability constants of the chelates for the two lanthanides (Ln_1 and Ln_2), Ln_1L and Ln_2L, at a particular [A] is given by

$$K_{Ln'_1L'}/K_{Ln'_2L'} = K_{Ln_1L'}(1+K_{Ln_2A}[A])/\{K_{Ln_2L'}(1+K_{Ln_1A}[A])\}. \quad (6)$$

It is evident from eq. (6) that when the stability order of LnL for Ln_1 and Ln_2 is opposite to that of LnA, the ratio, $K_{Ln'_1L'}/K_{Ln'_2L'}$, becomes larger than $K_{Ln_1L'}/K_{Ln_2L'}$. This is the case for the present system, L = TAC and A = 18C6. However, the former is smaller than the latter if the stability of LnL and LnA for the two lanthanides varies in the same order.

To make sure of the effect of A on the selectivity of L, we plotted the conditional stability constants of Ln–TAC complexes at $[HClO_4] = 4\times10^{-4}$ M in the absence ($K_{LnL'}$) and in the presence ($K_{Ln'L'}$) of 18C6 ($C_A = 1.0\times10^{-3}$ M) vs atomic number (Fig. 4). The stability of Ln–TAC complexes, either in the absence or presence of 18C6, increases with charge density on the cation, as is characteristic of

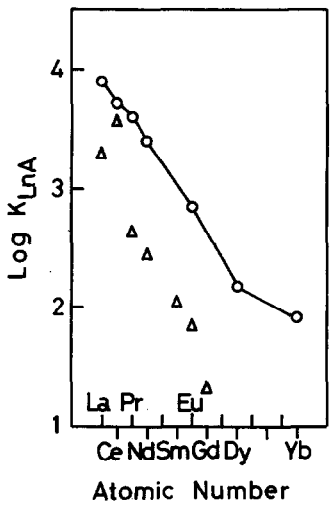

Fig. 3. Plots of stability constants $\log K_{LnA}$ vs the atomic number of lanthanides: this work (○) and ref. 1 (△).

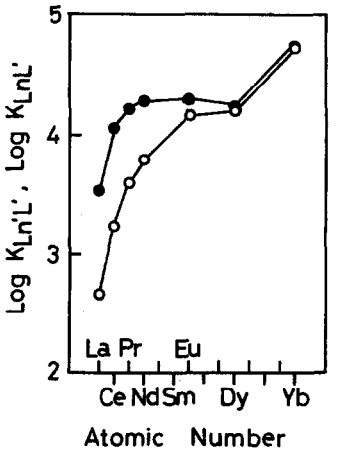

Fig. 4. Plots of conditional stability constants $\log K_{LnL'}$ and $\log K_{Ln'L'}$ vs the atomic number of lanthanides. Ln–TAC (●) and Ln–TAC–18C6(A) ($C_A = 1\times10^{-3}$ M) (○).

usual chelates. However, a comparison of the two curves shows a greater slope in the ternary system than in the binary system. Consequently it is evident that 18C6 reacts competitively with the Ln^{3+} ion to increase the selectivity of TAC. Hence, in order to increase the separation factor of the two lanthanide chelates it is important to choose another ligand which shows an opposite coordinating trend toward lanthanides. This discussion is based on the assumption that no ternary complex, LnLA, is formed.

SYNTHESIS AND STRUCTURAL CHARACTERIZATION OF SOLID SOLUTIONS $Cd_xHg_{1-x}B_4O_7$ ($x = 1$, 0.75, 0.5, 0.25, 0)

(*Received* 20 *July* 1988; *accepted after revision* 15 *February* 1989)

Abstract—Solid solutions, $Cd_xHg_{1-x}B_4O_7$, were obtained from $Cd(OH)_2$, HgO and $B(OH)_3$ in appropriate stoichiometric amounts, at low temperatures ranging between 523 and 623 K and 10^{-4}–10^{-5} Hg mm. These materials were characterized by X-ray powder diffraction, giving orthorhombic symmetry (space group *Pbca*, No. 61) and the lattice parameters (in Å) are: $a = 8.704$, $b = 14.176$, $c = 8.229$ (for $x = 1$), $a = 8.729$, $b = 14.168$, $c = 8.242$ (for $x = 0.75$), $a = 8.758$, $b = 14.162$, $c = 8.303$ (for $x = 0.5$), $a = 8.769$, $b = 14.147$, $c = 8.348$ (for $x = 0.25$) and $a = 8.792$, $b = 14.107$, $c = 8.382$ (for $x = 0$). IR spectra and TG are discussed on the basis of the stereochemistry of the boron atoms in these structures. The results seem to indicate that this method of synthesis can be applied to the isolation of related metal borates at temperatures that are several hundred degrees below those cited in the literature.

The binary systems MO–B_2O_3 (M = Zn, Cd) have been studied by several workers using calcinated samples.[1–7] The previous literature concerning the HgO–B_2O_3 system is quite limited,[8,9] probably due to the low thermal stability of mercury compounds.

In view of the technical applications of metallic borates and the potential uses of the CdO–B_2O_3 system for recovering materials in devices for nuclear reactors, due to the important cross sections of both elements for slow neutron capture (^{10}B, 3836 and ^{113}Cd, 2000 Barn), we have explored new methods of synthesis in order to obtain solid phases of definite stoichiometry, avoiding the usual ceramic temperature ranges. The experimental conditions are useful to synthesize various metal borates whose characterization is in progress.[10]

The aim of the present paper is to describe the preparation and structural characterization of solid solutions, $Cd_xHg_{1-x}B_4O_7$ with $x = 1, 0.75, 0.5, 0.25$ and 0.

EXPERIMENTAL

Microcrystalline solid solutions were prepared from mixtures of analytical grade $B(OH)_3$ (Merck, F.R.G.), $Cd(OH)_2$ (isolated by hydrolysis of cadmium acetate[2]) and HgO (Merck, F.R.G.), in stoichiometric amounts under a static initial vacuum of 10^{-4}–10^{-5} Hg mm at temperatures between 600 and 673 K over 24 h. An improved crystallinity of the products was obtained when cooling was performed at a rate of 0.5 K h^{-1}. The *d*-spacing measurements were made using a Siemens Kristalloflex D500 powder diffractometer, at a scanning rate of 0.1° 2θ min^{-1}, using Cu-K_α radiation and W ($a = 3.16524$ Å) as internal standard. The unit cell parameters were refined from the 2θ values of the last 14 reflections.[11] X-ray diffraction intensities I'_o were collected by step-scanning from 10 to 120° 2θ with increments of 0.02° 2θ and a counting time of 3 s for each step; the goniometer being controlled by a DACO-MPV2 computer, which carried out the integration of the diffraction peaks and the background correction. The intensities were calculated with the program RIETVELD,[12,13] assuming a unique network $B_4O_7^{2-}$ and statistical distribution of metallic ions in the general positions of the structure (space group, *Pbca*). The discrepancy factors, $R = \Sigma|I_o^{1/2} - I_c^{1/2}|/\Sigma I_o^{1/2}$, between observed and calculated intensities were computed making $I_o = KI'_o$ and $K = \Sigma I_c/\Sigma I'_o$.

Densities were determined by a picnometric method, using CCl_4 as the immersion liquid.

Thermal analyses were carried out on a Mettler TG 50 thermobalance and in a DSC 30 cell attached to a Mettler TA 3000 controller. Sample weights were about 10 mg and thermal runs were performed in air at a rate of 10 K min^{-1}.

IR absorption spectra were recorded on a Perkin–Elmer 1320 spectrophotometer in the range 4000–200 cm^{-1} using KBr pellets.

The boron content was determined by titration with NaOH in the presence of mannitol.[14] Cadmium and mercury contents were measured by complexometric titration with 0.1 M EDTA using eriochrome black T as indicator,[15] and the oxygen content was assigned by difference.

RESULTS AND DISCUSSION

Chemical analyses confirm the stoichiometry $Cd_xHg_{1-x}B_4O_7$ for all the phases ($x = 1$, 0.75, 0.5, 0.25, 0) obtained.

Crystallographic data for these materials are shown in Tables 1 and 2. The discrepancy factors between observed and calculated intensities for the different reflections are in good accordance with the structural data.

The basic structures of CdB_4O_7 ($a = 8.704$, $b = 14.176$, $c = 8.229$ Å) and HgB_4O_7 ($a = 8.79$, $b = 14.10$, $c = 8.39$ Å), which are isomorphous, have been previously determined by other

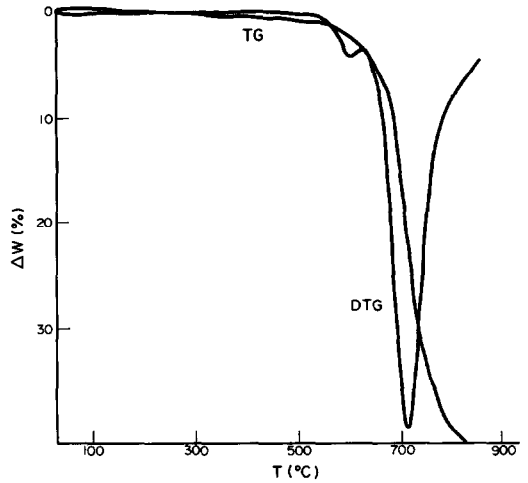

Fig. 3. Thermogravimetric curves for $Cd_{0.5}Hg_{0.5}B_4O_7$.

workers,[5-7] and our crystallographic data are in agreement with those.

Both structures consist of two infinite three-dimensional networks of B—O linkages, connected by two-fold screw axes. The network may be described as composed of borate units containing four boron atoms (two of which are tetrahedrally coordinated and two triangularly coordinated) and five oxygen atoms within the unit, as well as four oxygen atoms shared with four adjacent units. The two tetrahedra and two triangles form a $B_4O_7^{2-}$ unit as shown in Fig. 1, and which is repeated throughout the structure. The cadmium and mercury atoms are surrounded by four close oxygen atoms, arranged in a distorted tetrahedron. These atoms in the solid solutions are randomly distributed in these positions. The metal atoms therefore seems to be mainly covalent tetrahedrally bonded.

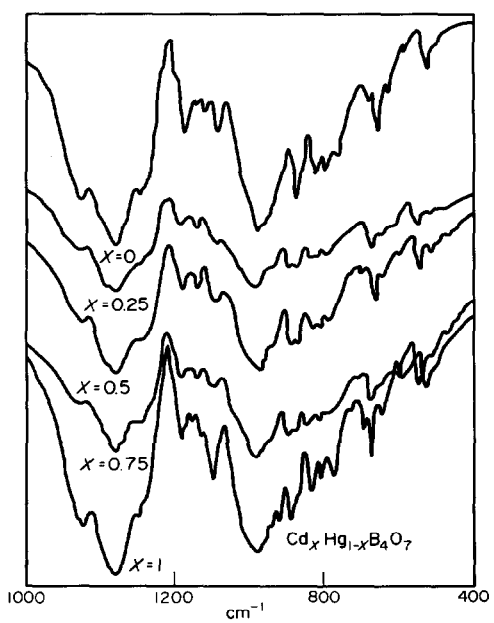

Fig. 2. IR absorption spectra of the solid solutions, $Cd_xHg_{1-x}B_4O_7$.

In Fig. 2 the IR spectra of the synthesized materials are presented. Three well-differentiated zones can be observed:[16] in the 1100–800 cm^{-1} range, strong bands that can be assigned to $\nu(BO_4)$ appear; in the 1500–1100 cm^{-1} region, the observed strong absorptions correspond to $\nu(BO_3)$; the bands in the 700–600 cm^{-1} range can be assigned to the three-fold and four-fold coordinated boron. On the other hand, the frequencies of these vibrations diminish with an increase of the mercury content in the obtained borates.

CdB_4O_7 showed no significant weight loss in this temperature interval. An X-ray diffraction pattern of the residue was identical to the one of the starting material.

TG curves of solid solutions showed weight losses which can be assigned to the mercury elimination according to the process:

$$Cd_xHg_{1-x}B_4O_7 \longrightarrow xCdB_4O_7 + (1-x)Hg + (2-2x)B_2O_3 + 1-x/2O_2.$$

The decomposition residues were characterized by X-ray diffraction and showed the characteristic spacings of CdB_4O_7, broadened as a consequence of the presence of vitreous B_2O_3. Figure 3 shows the thermogravimetric curve for $x = 0.5$.

For $x = 0$ (HgB_4O_7), the decomposition process led to a vitreous residue amorphous to the X-ray. The observed weight loss (59.9%) is concordant with the complete sublimation of mercury and the formation of B_2O_3 (calc. 60.88%).

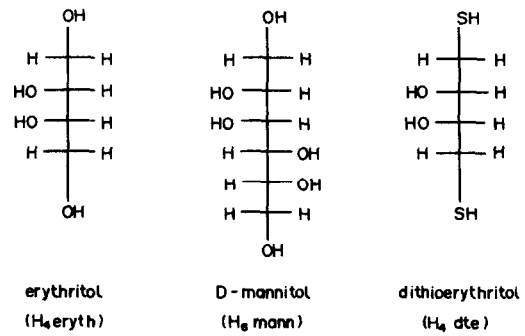
Abstract—The reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ with *meso*-erythritol in methanol yields $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5(eryth)]\cdot 0.5C_4H_{10}O_4\cdot H_2O$ (**I**), a complex having the $[Mo_2O_5]^{2+}$ core bound to a single erythritolate tetraanion. Reaction of **I** with chloroacetic acid in methanol results in a single protonation of the coordinated erythritolate ligand to give $[(n\text{-}C_4H_9)_4N][Mo_2O_5(Heryth)]$ (**II**). Crystal data: $C_{40}H_{85}N_2O_{12}Mo_2$ (**I**): orthorhombic, space group *Pbca*, $a = 16.651(3)$, $b = 24.043(5)$, $c = 24.935(5)$ Å, $V = 9982.5(12)$ Å^3, $Z = 8$, $D_{calc} = 1.30$ g cm^{-3}; 3625 reflections to give $R = 0.0522$. $C_{20}H_{43}NO_9Mo_2$ (**II**): monoclinic, space group $P2_1/n$, $a = 21.827(4)$, $b = 18.638(3)$, $c = 29.188(4)$ Å, $\beta = 108.3(1)°$, $V = 11269.9(15)$ Å^3, $Z = 16$, $D_{calc} = 1.49$ g cm^{-3}; 5911 reflections to give $R = 0.0687$.

Coordination complexes of polyoxomolybdates with alkoxy ligands[1–3] have been discussed as models for surface-bound intermediates in heterogeneous catalysis employing solid molybdenum oxides.[4–8] We recently reported the synthesis and structure of $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_8H_{13}O_5)]\cdot 0.5(C_2H_5)_2O$,[9] a complex containing the $[Mo_2O_5]^{2+}$ core ligated to a tetradentate ligand derived from 2,3,4,5-tetrahydroxy-2,3,4,5-tetramethylfuran, a structure closely related to those of the lyxose dimolybdate, $(NH_4)[Mo_2O_5(C_4H_5O_5)]$,[10] and of the mannitolate derivative $[(n\text{-}C_4H_9)_4N][Mo_2O_5(C_6H_{10}O_6)]$.[11] In the course of our investigations of polyoxomolybdate–polyalkoxide interactions, we have examined the chemistry of *meso*-erythritol with molybdate and have isolated both the tetraanionic and trianionic ligated derivatives, $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5(eryth)]\cdot 0.5C_4H_{10}O_4\cdot H_2O$ (**I**) and $[(n\text{-}C_4H_9)_4N][Mo_2O_5(Heryth)]$ (**II**), respectively. The conformation of the tetradentate ligand



* Author to whom correspondence should be addressed.

is relevant to discussions of dimolybdate binding by dithiothreitol and dithioerythritol, a required component in the synthesis of Fe—Mo cubane clusters by rhodanese.[1,2] Furthermore, the dimolybdate core is shown to be sufficiently flexible in its coordination requirements to accommodate both the $(eryth)^{4-}$ and $(Heryth)^{3-}$ forms of the ligand.

Reaction of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_7]$ with an equimolar amount of *meso*-erythritol in methanol, followed by addition of ether, gives colourless transparent blocks of a mixture of $[(n\text{-}C_4H_9)_4N]_2[Mo_2O_5(eryth)]\cdot 0.5C_4H_{10}O_4\cdot H_2O$ **(I)** and $[(n\text{-}C_4H_9)_4N][Mo_2O_5(Heryth)]$ **(II)** in 60% yield.* Recrystallization of a portion of the product from methanol–ether, to which triethylamine has been added, yields **I** in pure form, while recrystallization of the remaining portion of the product from methanol, to which several drops of chloroacetic acid have been added, gives **II**. The IR spectrum of **I** is characterized by strong bands at 920 and 905 cm^{-1} associated with $\nu_s(Mo{=}O)$ and $\nu_{as}(Mo{=}O)$, respectively, and a number of features in the 650–900 cm^{-1} range associated with ν(Mo—O—Mo) and ν(Mo—O—alkoxy). Complex **II** exhibits similar IR characteristics with the bands attributed to $\nu_s(Mo{=}O)$ and $\nu_{as}(Mo{=}O)$ appearing at 935 and 905 cm^{-1}, respectively, and a strong, broad absorption at 3410 cm^{-1}, associated with ν(O—H) for the protonated trianionic ligand. The complexes are readily interconverted by the addition of acid or base:

$$\underset{\textbf{(I)}}{[Mo_2O_5(eryth)]^{2-}} \underset{-H^-}{\overset{+H^+}{\rightleftharpoons}} \underset{\textbf{(II)}}{[Mo_2O_5(Heryth)]^-}.$$

Complex **I** crystallizes in the orthorhombic space group *Pcab* with $a = 16.651(3)$, $b = 24.043(5)$, $c = 24.935(5)$ Å, $V = 9982.5(12)$ Å^3, $Z = 8$, $D_{calc} = 1.30$ g cm^{-3}. Structure solution and refinement based on 3625 reflections with $F_o \geq 6\sigma(F_o)$ (Mo-K_α, $\lambda = 0.71073$ Å) converged at $R = 0.0522$. Complex **II** is monoclinic, $P2_1/n$ with $a = 21.827(4)$, $b = 18.638(3)$, $c = 29.188(4)$ Å, $\beta = 108.3(1)°$, $V = 11269.9(15)$ Å^3, $Z = 16$, $D_{calc} = 1.49$ g cm^{-3}. Structure solution and refinement were based on 5911 reflections (conditions as for **I**) and converged at $R = 0.0687$.

The structure of the dinegative anion of **I**, $[Mo_2O_5(eryth)]^{2-}$, is illustrated in Fig. 1, with selected bond lengths and angles presented in the caption. The structure consists of the *syn*-$[Mo_2O_5]^{2+}$ core, bridged and chelated by a single tetradentate tetraanionic erythritolate ligand. The ligand configuration is such that alternate hydroxylate groups bridge the molybdenum centres. This chelation mode requires that the Mo—O_b—Mo angle decreases from the usual range of 112–115° to 104.4(3)°. The Mo—O(bridging alkoxy) distances are inequivalent, such that Mo—O(6) is 2.280(10) Å (av) while Mo—O(8) is 2.203(11) Å (av).†

The structure of one of the four crystallographically-independent monoanions of **II**, $[Mo_2O_5(Heryth)]^-$, shown in Fig. 2, is seen to consist of the same tetradentate ligand configuration about the $[Mo_2O_5]^{2+}$ core as that exhibited by **I**. The most significant structural consequence of pro-

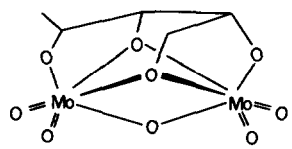
O(3)—Mo(2)—O(9)	143.2(5)
Mo(1)—O(3)—Mo(2)	109.5(6)
Mo(1)—O(6)—Mo(2)	77.2(4)
Mo(1)—O(8)—Mo(2)	94.1(5)

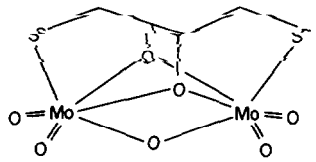
tonation of the alkoxy group O(6) is the lengthening of the Mo—O(6) bond distances to 2.52(2) Å (av), an unusually long distance when compared to the range of 2.10–2.30 Å, characteristic for bridging alkoxide groups.

The coordination of the $[Mo_2O_5]^{2+}$ core to the tetradentate ligands $(eryth)^{4-}$ and $(Heryth)^{3-}$ in **I** and **II**, respectively, through four consecutive hydroxylate groups with alternate oxygen donors bridging the Mo centres, is also characteristic of the structures of $[Mo_2O_5(C_8H_{13}O_5)]^-$,[9] $[Mo_2O_5(C_4H_5O_5)]^-$[10] and $[Mo_2O_5(mannitolate)]^-$.[11] It is noteworthy that the dithiothreitol structure, $[Mo_2O_5(dtt)]^{2-}$, exhibits bridging through the adjacent alkoxy oxygen donors with the thiolate groups terminal, to provide the only structurally characterized example of binding mode **IV** for such tetradentate ligand types.[12] Although the analogous dithioerythritolate complex, $[Mo_2O_5(dte)]^{2-}$, has not been structurally characterized, it may be argued that the correlation between the configurations of the chelating portion of D-mannitol and *meso*-



(III)

erythritol to *meso*-dithioerythritol suggests binding mode **III**. The difficulties encountered in the purification and crystallization of the dithioerythritolate complex may reflect the presence of several complex forms as a consequence of variable ligand protonations, $[Mo_2O_5(H_xdte)]^{(2-x)-}$.



(IV)

The characterization of both $[Mo_2O_5(eryth)]^{2-}$ (**I**) and $[Mo_2O_5(Heryth)]^-$ (**II**) and their ready interconversion, suggest that variations in the degree of ligand deprotonation may be characteristic of complexes containing polyalkoxide and polyalkoxide–thiolate ligands. We are currently investigating the chelation modes of various polyalkoxides and polythiolates with molybdenum–oxo species.

METAL PROMOTED REARRANGEMENT OF $Ph_2PO_2CCH{=}CH_2$; CRYSTAL AND MOLECULAR STRUCTURE OF $[RhCl(Ph_2POPPh_2)(PPh_3)]\cdot THF$, TETRAPHENYLDIPHOSPHOXANE-TRIPHENYLPHOSPHINE CHLORORHODIUM(I) (TETRAHYDROFURAN) 1:1

(*Received* 30 *January* 1989; *accepted* 15 *March* 1989)

Abstract—Reaction of $[RhCl(PPh_3)_3]$ with two mole equivalents of $Ph_2PO_2CCH{=}CH_2$ produces $[RhCl(Ph_2POPPh_2)(PPh_3)]$, involving a major rearrangement of the ligand to tetraphenyldiphosphoxane, a bidentate diphenyl phosphinous acid anhydride exhibiting a very short P—P separation (2.457 Å).

Ligands of the general form $Ph_2PO_2CCR{=}CR'R''$ are of interest since they promote the binding of highly functionalized alkenes to transition metals and allow such alkenes to take part in catalytic reactions.[1,2] The mechanisms of these reactions are believed to involve both metal and phosphorus centred steps.[2] These complexes also promote regioselective reactions, for example hydrogenation centred on the C(2) double bond of hexa-2,4-dienoic acid.[2]

During studies of the coordination chemistry of this form of ligand, bonding is observed through (i) the phosphorus alone as in $[RhCl(PPh_3)_2(Ph_2PO_2CCH{=}CMe_2)]$, (ii) phosphorus and oxygen, as in $[Rh(PPh_3)_2(Ph_2PO_2CCH{=}CMe_2)][SbF_6]$[3] and (iii) phosphorus and the double bond as in $[RhCl(Ph_2PO_2CCH{=}CMe_2)]_2$.[1] We now report studies of reactions of $Ph_2PO_2CCH{=}CH_2$, which show that disruption of the ligand can occur, producing a rare example of a complex containing tetraphenylphosphoxane, a diphenylphosphinous acid anhydride.

Reaction of $[RhCl(PPh_3)_3]$ with 2 mol equivalents of $Ph_2PO_2CCH{=}CH_2$ prepared from Ph_2PCl, propenoic acid and triethylamine, but not isolated, in tetrahydrofuran (THF) at 3°C produces an orange solution, from which yellow crystals separate on standing at 3°C for several days. The spectroscopic†

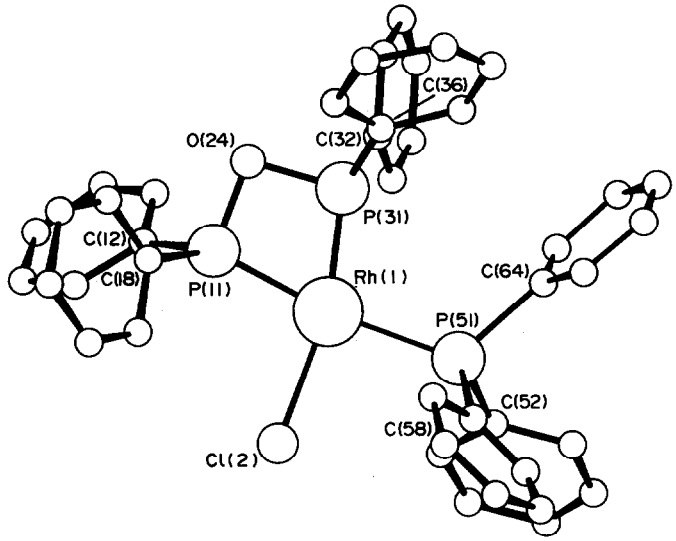

Fig. 1. X-ray structure and numbering scheme for $[RhCl(PPh_3)(Ph_2POPPh_2)]\cdot THF$ (the THF molecule is omitted from the figure).

properties and X-ray crystal* structure show that the compound is $[RhCl(PPh_3)(Ph_2POPPh_2)]\cdot THF$, indicating that a major rearrangement of the $Ph_2PO_2CCH{=}CH_2$ ligand had occurred. Under similar conditions (standing at 3°C for a day), $Ph_2PO_2CCH{=}CH_2$ is stable, with only slight decomposition occurring to give tetraphenyldiphosphine monoxide.[4] The bidentate binding of Ph_2POPPh_2 has only previously been observed in carbonyl complexes of group 6 metals.[5] $[RhCl(PPh_3)(Ph_2POPPh_2)]$ has also been obtained from reaction of 1 mol equivalent of isolated $Ph_2PO_2CCH{=}CHMe$ with isolated $[RhCl(PPh_3)(Ph_2PO_2CCH{=}CHMe)]$, as well as from $[RhCl(PPh_3)_3]$ and isolated $Ph_2PO_2CCH{=}CH{-}CH{=}CHMe$, although in the last case $[RhCl(PPh_3)_2L]$ ($n = 1$ or 2) are also products.[3]

In an attempt to discover the mechanism of the metal promoted rearrangement, we have carried out *in situ* ^{31}P NMR studies. Addition of 1 mol equivalent of $Ph_2PO_2CCH{=}CH_2$ to $[RhCl(PPh_3)_3]$, immediately gives what is thought to be $[RhCl(PPh_3)(Ph_2PO_2CCH{=}CH_2)]$ with *trans* phosphorus atoms and binding of the mixed anhydride through the phosphorus and the double bond.† This compound is stable in solution during the time-scale of the experiment at low temperature, but on addition of a further equivalent of $Ph_2PO_2CCH{=}CH_2$ immediately gives another, as yet unidentified, compound which slowly rearranges to the final product. The observation of $[RhCl(PPh_3)(Ph_2PO_2CCH{=}CH_2)]$ as an intermediate and the failure to produce $[RhCl(PPh_3)(Ph_2POPPh_2)]$ from reaction of $[RhCl(PPh_3)_3]$ with preformed tetraphenyldiphosphine monoxide confirm that the rearrangement to Ph_2POPPh_2 is metal promoted. These reactions are summarized in Scheme 1.

The X-ray structure of $[RhCl(Ph_2POPPh_2)(PPh_3)]$ is shown in Fig. 1, together with important bond lengths and angles in Table 1. The most important are those of the RhPOP ring. The ring angles are all much smaller than the strain free values, most markedly the tight angles at rhodium (68.39°) and oxygen (95.40°), which result in the close approach of the two ring phosphorus atoms (2.457 Å separation). The distance is much less than the sum of the van der Waals radii of phosphorus (3.2 Å), but longer than the largest found P—P single bond distances (2.35 Å in P_4S_7). The usual bonded distances are in the region of 2.10–2.20 Å.

* Crystallographic data: Formula $C_{42}H_{35}ClOP_3Rh\cdot C_4H_8O$, $M = 786.50$, triclinic, space group $P\bar{1}$ $a = 11.294(4)$, $b = 11.475(6)$, $c = 17.144(9)$ Å, $\alpha = 102.31(4)$, $\beta = 102.71(4)$, $\gamma = 74.11(4)°$, $V = 2056.68$ Å^3, $Z = 2$, $D_x = 1.270$ g cm^{-3}, λ (Mo-K_α) = 0.71069 Å, $\mu = 5.60$ cm^{-1}, $F(000) = 878.00$, $T = 293$ K, $R = 0.0718$ for 2329 reflections. Final refinement (minimizing $w||F_o|-|F_c||^2$), 486 refined parameters, $wR = 0.0746$, $w = 1.9641/(\sigma^2(F)+0.000618F^2)$, mean shift/ESD = 0.008, max. shift/ESD = 0.050, max. diff. peak = 0.873, max. neg. peak = 1.427 e Å^{-3}. 		P(11)—O(24)—P(31)	95.4(11)

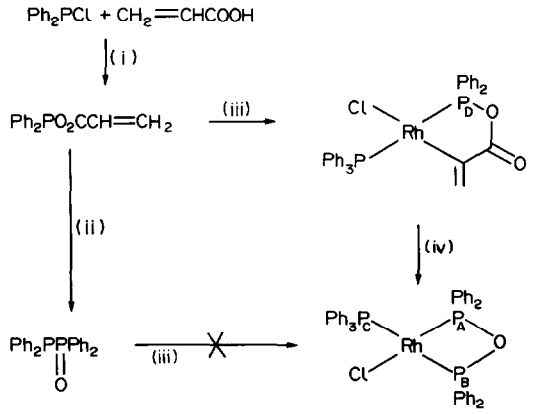
Table 2. Intra-ring angles for known complexes of Ph_2POPPh_2 with bidentate coordination

	Angles (°)				
Metal	$M—P_1—O$	$M—P_2—O$	P—O—P	P—M—P	Reference
Mo	96.9(1)	96.0(1)	103.3(1)	63.82(3)	5
Cr	97.0(1)	96.1(1)	100.2(1)	66.76(4)	5
Rh	98.8(4)	97.3(4)	95.4(5)	68.4(2)	This work

The P···P distance is less than that in the related $[M(CO)_4(Ph_2POPPh_2)]$ complexes, M = Mo (2.608 Å) or Cr (2.533 Å),[4] and also less than those usually observed in bidentate $Ph_2PCH_2PPh_2$ complexes.[6] MNDO calculations do not indicate any significant P—P bonding.[7] A comparison of the various ring angles in the complexes of Cr, Mo and Rh (Table 2) show that the M—P—O angles are $97.5 \pm 1.5°$ in all cases, suggesting that it is the rigidity of these angles that predetermine the overall ring geometry. Unfortunately, the crystal structure of the isoelectronic $[RhCl(Ph_2PCH_2PPh_2)(PPh_3)]$ has not been reported, although a similar value for $J_{P—P}$ between the $Ph_2PCH_2PPh_2$ phosphorus atoms and that for Ph_2POPPh_2 suggests that it may have similar P—P interactions.[6]



Scheme 1. Preparation and rearrangement of $Ph_2PO_2CCH{=}CH_2$ in the presence or absence of a metal centre: (i) NEt_3, THF, 3°C; (ii) THF, 3°C, 7 days; (iii) $[RhCl(PPh_3)_3]$, 1 : 1, THF, 3°C, 10 min; (iv) $Ph_2PO_2CCH{=}CH_2$, 1 mol equiv, THF, 3°C, 3 days.

The structure, which is distorted square-planar abour rhodium, has an almost planar Rh—P—O—P ring, the oxygen being 0.083 Å out of the P—Rh—P plane. This may be due to the slight difference in angles between the left and right side of the structure, resulting from one ring phosphorus being *trans* to the chlorine atom and the second *trans* to the much bulkier triphenylphosphine group. Hence, the ring geometry is altered slightly to relieve the strain.

Acknowledgements—We thank BP Research International and the SERC for a studentship (D.J.I.), Dr A. Howie (University of Aberdeen) for collection of the X-ray data set and Johnson Matthey plc for generous loans of rhodium salts. The high field NMR machine was purchased mainly with a grant from the SERC.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF A HOMOLEPTIC BISMUTH AMIDE

WILLIAM CLEGG, NEVILLE A. COMPTON, R. JOHN ERRINGTON,* NICHOLAS C. NORMAN* and NEIL WISHART

Department of Chemistry, The University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 27 *February* 1989; *accepted* 16 *March* 1989)

Abstract—The reaction between $BiCl_3$ and 3 equivalents of $Li[NPh_2]$ in THF solution affords the bismuth amide complex, $[Bi(NPh_2)_3]$, which has been characterized by X-ray crystallography.

Current interest in the chemistry of bismuth containing compounds is, in part, due to their importance as heterogeneous catalysts[1] and more recently, as superconducting materials with high critical temperatures.[2] Whilst many synthetic routes to such materials are available, any solution based methods are potentially hampered by the apparent lack of suitable precursors reported in the literature. This is particularly evident in the case of bismuth amides and alkoxides, very few reports of which exist. With regard to the former, the only accounts dealing with homoleptic complexes, of which we are aware, describe the syntheses of $[Bi(NR_2)_3]$ (R = Me, Et, *n*-Pr),[3] $[Bi\{N(SiMe_3)_2\}_3]$[4] and $[Bi\{N(Me)SiMe_3\}_3]$,[5] with other examples of molecules containing bismuth bound amides being $[Bi(Me)_2\{N(Me)SiMe_3\}]$,[6] $[BiCl_2(NEt_2)]$,[7] $[BiBr_2(NMe_2)]$,[8] $[BiI(NHR)_2]$ (R = *n*-Pr, *n*-Bu)[9] and $[BiMe_x\{N(Me)SiMe_3\}_y]$ ($x = 1$, $y = 2$; $x = 2$, $y = 1$).[5] As part of a study of bismuth chemistry in general, we have become interested in bismuth amides and report herein some preliminary results including the first crystal structure determination of this class of compound.

A solution of $Li[NPh_2]$ in THF (20 cm^3) was prepared from $HNPh_2$ (1.25 g, 7.42 mmol) and Bu^{n}Li (2.9 cm^3 of a 2.5 M hexane solution, 7.42 mmol) at 0°C. After stirring for 30 min, the solution containing $Li[NPh_2]$ was added to a solution of $BiCl_3$ (0.779 g, 2.47 mmol) in THF (25 cm^3) and the resulting mixture was stirred for 3 h at room temperature. Removal of all volatiles, followed by extraction with toluene (3 × 15 cm^3) and subsequent filtration, afforded an orange solution of $[Bi(NPh_2)_3]$ (**1**), from which an orange solid was obtained upon removal of the toluene under reduced pressure.

Analytically pure crystals of **1** were obtained by solvent diffusion from CH_2Cl_2 (5 cm^3)–hexane (25 cm^3) at −30°C over a period of days (0.53 g, 30%), these being suitable for X-ray diffraction.

Compound **1** is soluble in toluene, THF and CH_2Cl_2, and is very sensitive to traces of moisture.

molecules in the asymmetric unit (one of which is shown in Fig. 1), although the overall molecular geometries of each do not differ significantly and there are no short intermolecular contacts. Each bismuth centre adopts a trigonal pyramidal coordination geometry (sum of angles at Bi(1) = 296°, at Bi(2) = 297°), being bonded to three NPh_2 groups (av. Bi(1)—N = 2.20 Å, Bi(2)—N = 2.20 Å). The amido fragments contain a trigonal planar nitrogen atom with the phenyl groups twisted from coplanarity, the overall spatial arrangement being such as to endow the molecule with approximate C_3 symmetry.

We have also investigated the silylamide complex, $[Bi\{N(SiMe_3)_2\}_3]$ (**2**)[4] which is readily prepared by treatment of $BiCl_3$ with 3 equivalents of $Li[N(SiMe_3)_2]$. Compound **2** can be isolated as a pale yellow powder in good yield by extraction of the crude reaction mixture with hexane followed by filtration and removal of all volatiles. Spectroscopic data* indicate hindered rotation about the Bi—N bonds at low temperature, a feature which would also appear to exist in **1** at room temperature judging by the complexity of the ^1H and ^{13}C NMR spectra when compared with those of $HNPh_2$.

Finally we note that attempted preparations of $[Bi(NPr^i_2)_3]$ and $[Bi\{\overline{NC(Me_2)(CH_2)_3C(Me_2)}\}_3]$, while resulting in transient yellow solutions, have been hindered by the apparent photosensitivity of the Bi—N bonds resulting in facile decomposition.

Further studies are in progress to synthesize a wider range of bismuth amides and to explore their reaction chemistry.

FOREWORD

This issue contains the papers and posters submitted to the International Conference on the Chemistry of the Early Transition Metals held by the Dalton Division of the Royal Society of Chemistry at the University of Sussex, 10–14 July 1989.

A simple glance through the contents list will reveal the breadth of interests involved in this meeting, with contributions ranging from the solid state properties of refractory materials to studies on metalloproteins.

I have enjoyed reading all of the contributions, and must thank my co-editors Ray Richards and John Dilworth for all their hard work in preparing this issue, which must have been an unpardonable burden to put on top of the conference organization.

HYDRIDE TO CARBENE MIGRATIONS

MARK J. WINTER

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

Abstract—Hydrido carbene complexes of the type $CpMH(CO)_2\{=CR^1R^2\}$ (M = Mo, W) are available by the consecutive treatment of $CpMI(CO)_2\{=CR^1R^2\}$ with $NaC_{10}H_8$ and acid. Some of these hydridometal complexes are isolable and fully characterized, while others are too labile to isolate. Most of these compounds [for example, $CpMoH(CO)_2\{=\overline{C(CH_2)_3NMe}\}$ and $CpMH(CO)_2\{=C(NHEt)Ph\}$ (M = Mo, W)] undergo hydride to carbene migration reactions during which an intramolecular source of ligand (a nitrogen donor atom for instance) binds to the metal in order to maintain the 18-electron count. In some cases, the hydride appears to migrate so fast as to prevent its identification. In other cases, the products of hydride to carbene migration rearrange to further products such as η^3-benzyls.

The migration of alkyl to carbonyl to form an acyl group is well known. It is a central process in a number of important catalytic cycles. There are considerably less data, particularly mechanistic, on another fundamental process, the migration of a group R to carbene:

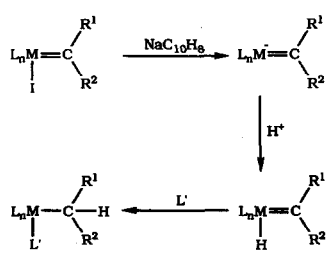
(1)

It is likely that migrations to carbene are central in a number of processes involving carbene complexes, but their facility renders their direct observation infrequent. There are, however, some examples in the literature of very clear hydride,[1,2] alkyl[3] and aryl[4] to carbene migrations. Our interest in this area continues since our first observation of a hydride to carbene migration 3 years ago.[2] This article addresses some of our work on hydride to carbene migrations but we are also working on the migrations of alkyl, aryl and acyl groups to coordinated carbene.

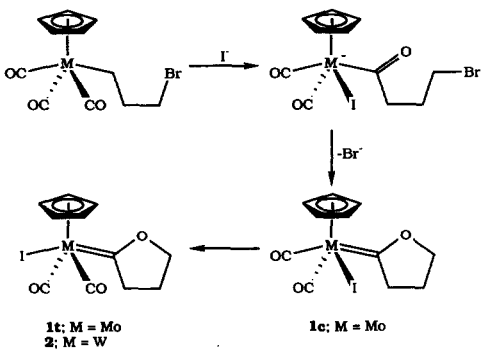
In order to study migrations of a group R to a carbene $\{=CR^1R^2\}$, one needs a source of $L_nM(R)\{=CR^1R^2\}$ complexes. The basic strategy we are currently using to make such complexes is very simple and illustrated in Scheme 1 for the case of hydride. It requires a source of carbene complexes $L_nM(X)(=CR^1R^2)$, where X is a group such as iodide. The next stage is the reduction of the metal halide bond with a reducing agent such as $NaC_{10}H_8$ to form anionic carbene complexes $[L_nM(=CR^1R^2)]^-$. We expected the reaction of acids with these anions to proceed at the metal to form neutral derivatives, $L_nM(H)(=CR^1R^2)$, and that such compounds should be suitable vehicles for studying migrations of hydride to carbene. This turns out to be the case.

SYNTHESIS OF CARBENE COMPLEXES $L_nM(X)(=CR^1R^2)$ (X = HALIDE)

There are many carbene complexes of the general class $L_nM(X)(=CR^1R^2)$ in the literature, but here I shall restrict discussion to the two principle strategies that we use in our laboratories to make carbene complexes of the type $LM(X)(carbene)(CO)_2$ (M = Mo, W; L = Cp or Cp derivative). The first complex we synthesized was the molybdenum complex, **1**[5] (Scheme 2). Addition of $X(CH_2)_3X$ (X = Br or I) to $[CpMo(CO)_3]^-$ results in a straightforward nucleophilic replacement of halide to form $CpMo\{(CH_2)_3X\}(CO)_3$. This undergoes migration of the



Scheme 1.



1t; M = Mo
2; M = W

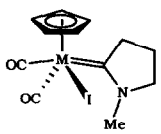
1c; M = Mo

Scheme 2.

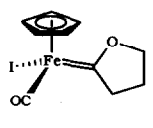
$(CH_2)_3X$ (X = Br, I) group to an adjacent carbonyl and coordination of iodide (added as I^- in the case of X = Br) at molybdenum. Ring closure of the resulting acyl anion results in the carbene complex, **1t**, probably by way of the *cis* isomer, **1c**.

The corresponding tungsten reaction also works well to form **2t**, but more forcing conditions are necessary to promote the insertion step. To date, we have not made the analogous chromium compounds.[6] This basic reaction is very adaptable. The most obvious extension is to the corresponding Cp* (η-C_5Me_5)[7] and Ind (η^5-C_9H_7, indenyl) derivatives, and these compounds are known.

As a rule, alkyl groups migrate more readily to isonitrile than carbonyl, even to the extent of multiple migrations being known.[8] This leads to a further extension of the basic synthetic route of Scheme 2. Addition of $I(CH_2)_3I$ to $[LM(CNMe)(CO)_2]^-$ (M = Mo or W; L = Cp, Cp*) results in a one-pot synthesis of the molybdenum and tungsten carbenes, *cis*-$LMI\{=\overline{C(CH_2)_3NMe}\}(CO)_2$ (**3**) and (**4**), from $LMBr(CNMe)(CO)_2$.[9] The fact that these complexes are *cis* whereas the corresponding $\{=\overline{C(CH_2)_3O}\}$ derivatives are *trans* is interesting. We are still examining in detail these differences in structure.



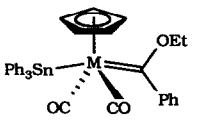
3; M = Mo
4; M = W



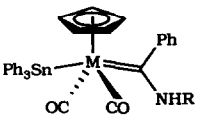
5

The same basic strategy of Scheme 2 also extends to iron. The reaction of $[CpFe(CO)_2]^-$ with $Br(CH_2)_3Br$ followed by I^- results in the new iron carbene complex $CpFeI\{=\overline{C(CH_2)_3O}\}(CO)$ (**5**).[10]

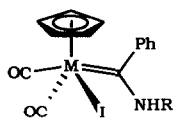
The second main route that we use to make carbene complexes, $L_nM(X)(=CR^1R^2)$, relies upon standard approaches to Fischer-type carbenes. The consecutive additions of PhLi and Et_3O^+ to $CpM(SnPh_3)(CO)_3$ (M = Mo or W) result in the carbenes $CpM(SnPh_3)\{=C(OEt)Ph\}(CO)_2$ (**6**) and (**7**).[11] Under slightly different reaction conditions



6; M = Mo
7; M = W



8; M = Mo, R = Me
9; M = W, R = Me
10; M = Mo, R = Et
11; M = W, R = Et

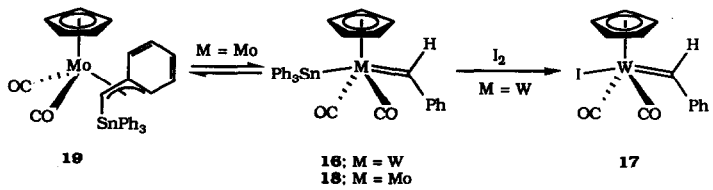


12; M = Mo, R = Me
13; M = W, R = Me
14; M = Mo, R = Et
15; M = W, R = Et

to those published, these reactions proceed in near quantitative yields. The analogous Cp* and Ind derivatives also form in closely related reactions.[12] Aminolysis of these ethoxy carbenes leads to amino carbenes such as $CpM(SnPh_3)\{=C(NHR)Ph\}(CO)_2$ (**8**)–(**11**), in high yield.[11] Again, the Cp* and Ind derivatives are accessible in high yield in analogous reactions.[12]

These M—$SnPh_3$ carbene compounds all react with iodine. In most cases the result is high yield metal–tin bond cleavage to form products such as **12**–**15**, but some of the ethoxy carbene reactions are more complex and the required products are not isolable or are difficult to isolate.[12]

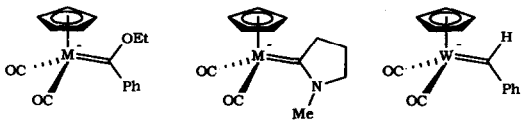
Complexes of non-heteroatom stabilized carbenes are available from these Fischer-type carbenes by application of standard methods. As examples, the reaction of $LiBEt_3H$ with complex **7** followed by protonolysis results in the complex $CpW(SnPh_3)\{=C(H)Ph\}(CO)_2$ (**16**) (Scheme 3); in turn complex **16** reacts with iodine to form the iodotungsten carbene,**17**. Other cases show unexpected behaviour which interfere with these orderly syntheses of halometal carbene complexes, but perhaps it is worth it in some cases. For example, the molybdenum complex, **18**, exists in equilibrium with the η^3-benzyl, **19**, in a remarkable process which involves a $SnPh_3$ to carbene migration. Coordination of the Ph group forming the η^3-benzyl ensures the 18-electron count of the molybdenum atom is maintained.[13]



Scheme 3.

FORMATION OF ANIONIC CARBENE COMPLEXES

It is clear that there are many complexes of the type $L_nMI(=CR^1R^2)$ available. Since sodium reduction of halide complexes such as $CpMoI(CO)_3$ results in formation of the anion $[CpMo(CO)_3]^-$, one expects that reduction of $L_nMI(=CR^1R^2)$ complexes would form the anions $[L_nM(=CR^1R^2)]^-$. In our hands, the reagent of choice for reducing these halide complexes is $NaC_{10}H_8$, a common reducing agent for organic chemistry that also finds favour in organotransition metal chemistry. This reduction proves successful in all the molybdenum and tungsten cases that we have examined to date. A small selection of the available anionic metal carbene complexes is shown below.[14]

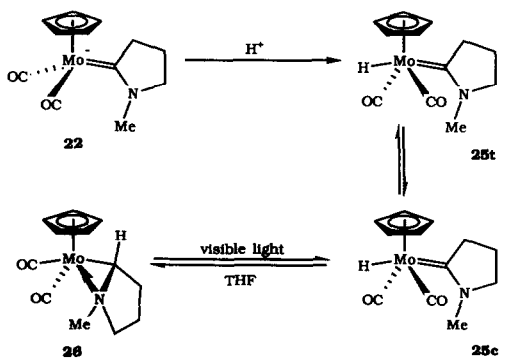


The carbene anions thus produced are a new class of anionic carbene complex. We are aware of one other anion in this class that has been reported by another group.[15] These anions are quite distinct from complexes of the type $L_nM\{=CR^1(CR^2_2Li)\}$[16] which react with electrophiles at the α-carbon atom. This new class of compound is characterized by its reactivity with electrophiles at the metal atom. Most are thermally rather unstable and have to be handled at low temperatures, but are sufficiently stable for their IR spectra to be acquired at ambient temperature, provided this is done reasonably quickly. They show two low frequency ν(CO) bands typically around 1780 and 1660 cm^{-1}. Addition of 15-crown-5 to solutions of a representative example, **22**,[14] results in changes in the IR spectrum, which are about the same in terms of frequency changes as those seen on adding 15-crown-5 to solutions of $[CpMo(CO)_2\{P(OPh)_3\}]^-$.[17] This suggests that the carbene anions exist in solution as tight ion pairs with sodium cations. By way of a chemical derivatization, all the anions made so far react with Ph_3SnCl to form $CpM(SnPh_3)(=CR^1R^2)(CO)_2$; these are all highly crystalline, air-stable materials whose isolation is straightforward.[10]

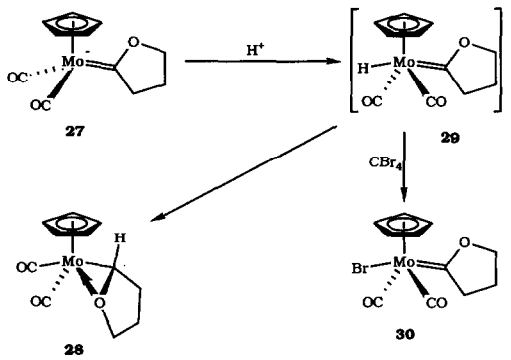
HYDRIDE TO CARBENE MIGRATIONS

Protonation of solutions of the anion **22** results in formation of the hydride $CpMoH(CO)_2\{=\overline{C(CH_2)_3NMe}\}$ (**25**) (Scheme 4), which exists as a mixture of *cis* (**25c**) and *trans* (**25t**) isomers.[2] The two isomers interconvert quite rapidly on the NMR time scale, with the hydride, Cp and methyl signals coalescing around ambient temperature in the ^1H NMR spectrum. Stirring solutions of the hydride at ambient temperature for several hours results in the new *cis* dicarbonyl $CpMo(CO)_2\{\eta^2\text{-}\overline{CH(CH_2)_3NMe}\}$ (**26**).[2] Compound **26** is also formed in the reaction between $LiBEt_3H$ and *cis*-$CpMoI(CO)_2\{=\overline{C(CH_2)_3NMe}\}$ (**3**).[9]

Early kinetic studies show this hydride to carbene migration is a unimolecular process with an Arrhenius activation barrier of 98 kJ mol^{-1}. The nitrogen atom binds at the metal in order to maintain an 18-electron count. Remarkably, this migration is *reversible* on visible light irradiation.[18] The corresponding tungsten hydride shows no sign of any such hydride to carbene migration. It also exists only as its *trans* isomer. The lack of a *cis* isomer may contribute to its failure to undergo migration, since that is likely to be the isomer which



Scheme 4.



Scheme 5.

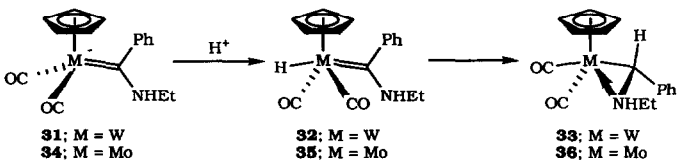
undergoes migration, but the strength of the W—H bond is also undoubtedly important.[2]

Protonation of the related anion [CpMo(CO)$_2${=C(CH$_2$)$_3$O}]$^-$ (**27**), results in the rapid formation of CpMo(CO)$_2${η^2-CH(CH$_2$)$_3$O} (**28**) (Scheme 5). This compound is also formed in the reaction of CpMoI(CO)$_2${=C(CH$_2$)$_3$O} (**1t**) with LiBEt$_3$H.[19] Although the hydride, CpMoH(CO)$_2${=C(CH$_2$)$_3$O} (**29**), is not detected at ambient temperature, its existence is implied at low temperatures, since low temperature protonation followed immediately by addition of CBr_4 results in CpMoBr(CO)$_2${=C(CH$_2$)$_3$O} (**30**).[20] This type of reaction is often taken as indicative of the existence of a reactive hydride complex.

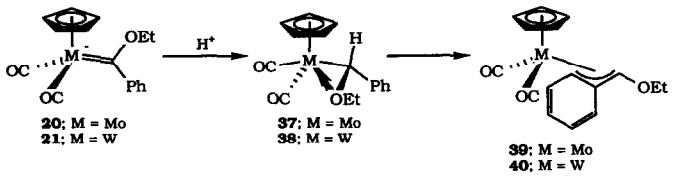
Protonation of the anion [CpW(CO)$_2${=C(NHEt)Ph}]$^-$ (**31**) results in the isolable, air-sensitive oil CpWH(CO)$_2${=C(NHEt)Ph} (**32**). This interconverts into the fluxional complex CpW(CO)$_2${η^2-CHPh(NHEt)} (**33**) over 2–3 days by a hydride to carbene migration (Scheme 6). The molybdenum anion, [CpMoH{=C(NHEt)Ph}]$^-$ (**34**), also protonates to form its corresponding hydride, CpMoH(CO)$_2${=C(NHEt)Ph} (**35**). However, although detectable by IR spectroscopy, compound **35** is not isolable since it undergoes a rapid hydride to carbene migration (about 5 min at ambient temperature) to form the complex CpMo(CO)$_2${η^2-CHPh(NHEt)} (**36**). This last migration is complete within a few minutes at ambient temperature.[21]

The corresponding migration reactions of the {=C(OEt)Ph} carbene appear to be very rapid. Protonation of the anions [CpM(CO)$_2${=C(OEt)Ph}]$^-$ (**20**) and (**21**) (Scheme 7) clearly occurs very rapidly, but the corresponding hydrides, CpMH(CO)$_2${=C(OEt)Ph}, are not detectable by IR spectroscopy at ambient temperature. If one assumes that the initial products are these hydrides, then one expects them to undergo hydride to carbene migration to form the compounds CpM(CO)$_2${η^2-CHPh(OEt)} (**37**) and (**38**). These are certainly detectable by IR spectroscopy, but they are too sensitive to isolate and because they also undergo facile isomerizations into the η^3-benzyl derivatives CpM(CO)$_2${η^3-CH(OEt)(C$_6$H$_5$)} (**39**) and (**40**). Both these compounds are fully characterized. This isomerization is driven by the tendency to form the stable η^3-benzyl interaction at the expense of the weak O→M donor bond. The formation of the tungsten derivative is reversible to some extent. Photolysis of a solution of **40** in THF contained in an NMR tube results in a build-up of a small concentration of **38**, detectable by ^{1}H spectroscopy. This soon disappears as it reverts to the η^3-benzyl, **40**.[21]

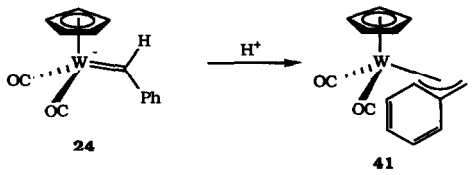
We have started to examine the corresponding chemistry of non-heteroatom stabilized carbenes. As an example, protonation of anion **24** results in the known η^3-benzyl, **41** (Scheme 8). In this case, there is no sign of any intermediate hydridotungsten complex, nor have we been able to derivatize such an intermediate by reaction with CBr_4 or similar reagents. However, the migration of hydride from



Scheme 6.



Scheme 7.



Scheme 8.

such an intermediate hydride and coordination of the phenyl ring would explain the formation of **41** quite neatly.[22] However, we have still to determine in this last example whether protonation occurs at the metal or at the carbene.

What we see from the above survey of results is the gradual emergence of some trends, even though we have yet to quantify them. Clearly hydridotungsten carbene complexes undergo hydride to carbene migration more slowly than the corresponding molybdenum derivatives. Clearly complexes of the carbenes $\{=\overline{C(CH_2)_3NMe}\}$, undergo migration more slowly than the corresponding carbenes $\{=\overline{C(CH_2)_3O}\}$, complexes of carbenes $\{=\overline{C(CH_2)_3NMe}\}$, undergo migration more slowly than the corresponding carbenes {=C(NHEt)Ph}, and complexes of carbenes $\{=\overline{C(CH_2)_3O}\}$, undergo migration more slowly than the corresponding carbenes {=C(OEt)Ph}. In some cases the migrations are sufficiently fast that the intermediate hydrides are not detected. This has to be remedied. Other factors under examination include variation of the metals, ancillary ligands, solvent effects, as well as an examination of a role for external nucleophiles other than the solvent.

FORMATION OF METAL–ELEMENT DOUBLE BONDS BY CHLOROSILANE ELIMINATION

ULRICH SCHUBERT,* UWE KIRCHGÄSSNER, JÜRGEN GRÖNEN and HERMANN PIANA

Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-8700 Würzburg, F.R.G.

Abstract—Transition metal complexes, capable of chlorosilane elimination to give metal–element double bonds, are generated as transient species by two novel methods. The first one involves reaction of anionic silyl complexes with geminal dihalides and is exemplified by reactions of $[MeCp(CO)_2Mn\text{-}SiR_3]^-$ with dihalides of carbon and main-group V elements. Formation of carbene complexes and phosphinidene-bridged complexes, $[MeCp(CO)_2Mn]_2PR$, proves that the anionic silyl complex can be used as an equivalent for $[MeCp(CO)_2Mn]^{2-}$ in the synthesis. The second method proceeds by oxidative addition of the C—Cl bond of (α-chlorovinyl)silanes to electronically unsaturated transition-metal complex moieties to give vinylidene complexes, e.g. $(\eta^6\text{-}C_6R'_6)(CO)_2Cr{=}C{=}CR_2$ or $MeCp(CO)(L)Mn{=}C{=}CR_2$. With an excess of (α-chlorovinyl)silane, butatriene complexes are formed instead.

During recent years a large number of reliable preparative methods have been developed to generate metal–element multiple bonds, particularly metal–carbon multiple bonds. Among them, chlorosilane eliminations and related reactions are conspicuously absent, despite their very successful applications in main-group chemistry. One of the reasons is the lack of suitable precursor complexes. In Scheme 1, three routes are shown by which, in principle, formation of metal–element double bonds could be achieved via the intermediates **A** or **B**, which differ by the relative position of the groups R_3Si and X.

In this article, efforts towards the realization of these reactions are described. Discussion is restricted to group VI and VII transition metal compounds. Preliminary results show that the methods can also be applied to earlier or later transition metal compounds.

Anionic silyl (germyl, stannyl) complexes exhibit the typical properties common to negatively-charged metal complexes, like ion pairing or substitution reactions with monohalides,[1,2] but render possible additional preparative applications due to the presence of the silyl ligand, which is not necessarily an innocent bystander in certain reactions.[2] Combination of the substitution chemistry of anionic metal complexes and the reactivity of silyl ligands is a promising onset for reactions according to route (a) in Scheme 1.

Anionic silyl (germyl, stannyl) complexes can be synthesized by several routes, the most versatile one being the deprotonation of hydrido silyl (germyl, stannyl) complexes. The latter complexes are commonly prepared by oxidative addition of $HSiR_3$ to electronically unsaturated metal complexes. Typical representatives involving group VI and VII transition metals are compounds of the type $(\eta^6\text{-}C_6R'_6)(CO)_2Cr(H)SiR_3$ or $(\eta^5\text{-}C_5R'_5)L_2M(H)SiR_3$ (M = Mn, Re), the chemistry of which has recently been reviewed.[3] Addition of $HSiR_3$ to photochemically generated $Cr(CO)_5$ does not result in stable products, but we recently succeeded in preparing phosphine-substituted derivatives **1**, analogously (eq. (1), dppe = $Ph_2PCH_2CH_2PPh_2$), for $SiR_3 = SiCl_3$ or $SiCl_2R$:

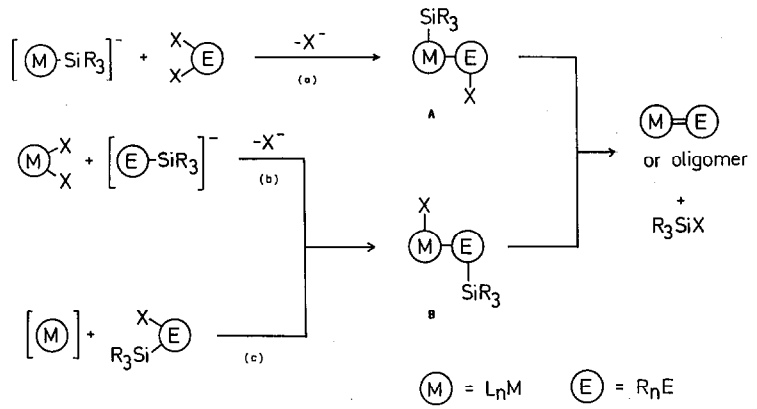
$$(dppe)M(CO)_4 + HSiR_3 \xrightarrow[+10°C]{h\nu/\text{toluene}} (dppe)(CO)_3M(H)SiR_3 + CO \quad (1)$$

(M = Cr, Mo, W)

(1) (two isomers)

Two isomers are formed, only one of them having

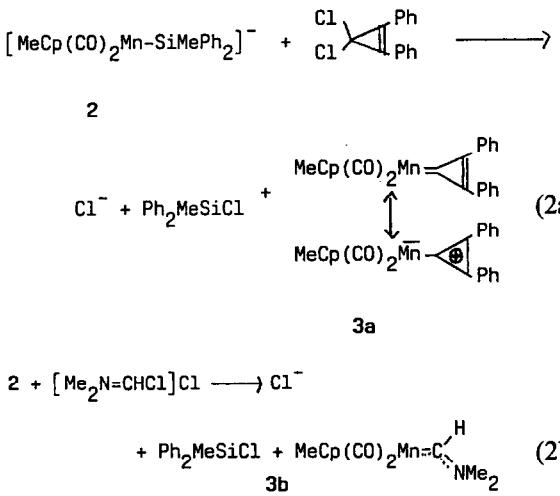
* Author to whom correspondence should be addressed.



Scheme 1.

a symmetric structure (chemically equivalent phosphorus atoms). The ratio between both isomers (the structures of which still have to be elucidated) depends on the metal, the SiR_3 group and the reaction conditions.[4]

Deprotonation of hydrido silyl complexes was extensively studied for complexes of the type (η^5-C_5R_5)$L_2M(H)SiR_3$ (M = Mn, Re), particularly MeCp- or $Cp(CO)_2Mn(H)SiR_3$ (MeCp = η^5-MeC_5H_4, Cp = η^5-C_5H_5),[5] their acidity strongly depending on the substituents at silicon and the ligands at the metal. Dicarbonyl derivatives are easily deprotonated by a variety of bases, the most convenient being NaH or KH[5b] (as long as there are no substituents at silicon which can be replaced by a hydride ion). The anionic compounds, $[Cp(CO)_2M\text{-}ER_3]^-$ (E = Ge, Sn), were also prepared by displacing a CO ligand of $CpM(CO)_3$ by ER_3^-.[5c,6] There are no reports on attempts to similarly deprotonate hydrido silyl complexes of chromium, molybdenum or tungsten. While preparation of $[(CO)_5M\text{-}SiR_3]^-$ from $[(CO)_5M]^{2-}$ (M = Cr, Mo, W)[7] is not efficient in respect to the formation of metal-element double bonds (*vide infra*), reaction of $[(CO)_5MCl]^-$ with SiR_3^- provides a preparatively interesting access to these particular anionic silyl complexes.[8] Among early transition metal compounds, $[MeCp(CO)_2Mn\text{-}SiR_3]^-$ (**2**) is the only anionic silyl compound which was used to generate metal–element double bonds according to Scheme 1 [route (a)]. Its reactions with geminal dihalides therefore set examples. Reaction with 3,3-dichloro-1,2-diphenylcyclopropene does indeed yield the anticipated carbene complex **3a** [eq. (2a)].[9] Complex **3a** is also obtained by reaction of the corresponding Ph_3Ge- or Ph_3Sn-substituted compounds. We propose that the reaction proceeds by substitution of one chlorine atom to give an intermediate of type **A**, followed by chlorosilane elimination. Similar results were obtained with $[Me_2N{=}CHCl]Cl$ as a dihalide [eq. (2b)]:[10]

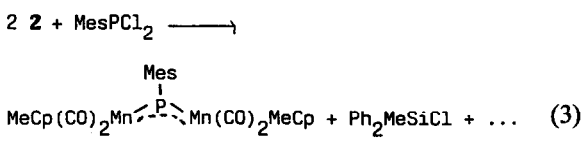


(2a)

(2b)

Complex **2** instantaneously reacts with Ph_3SbBr_2, Ph_3AsCl_2, or R_2TeCl_2 to give $MeCp(CO)_2MnEPh_3$ (E = As, Sb) or $MeCp(CO)_2MnTeR_2$, respectively.[11] Although these complexes are more conveniently prepared by the usual methods, starting from EPh_3 or TeR_2, the outcome of these reactions proves that the substitution/chlorosilane elimination route is more general and not restricted to the formation of carbene complexes. This is corroborated by the formation of the dinuclear, phosphinidene-bridged complex **4**, in the reaction of **2** with $MesPCl_2$ (Mes = 2,4,6-$C_6H_2Me_3$) [eq. (3)].[11] Analogous complexes are also obtained with other dihalides, REX_2 (E = P, As, Sb). Complexes of this type have already been synthesized by other methods and thoroughly investigated by Huttner and co-workers.[12] The question, whether in the reaction of **2** with $MesPCl_2$ a terminal phosphinidene complex is originally formed, as has been postulated for other preparative approaches to these complexes,[12]

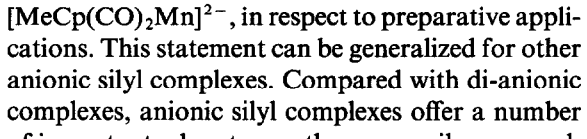
remains open.



$$2\ \mathbf{2} + MesPCl_2 \longrightarrow MeCp(CO)_2Mn\text{–}P(Mes)\text{–}Mn(CO)_2MeCp + Ph_2MeSiCl + \ldots \quad (3)$$

The same products would be expected if the same geminal dihalides were reacted with the di-anionic complex, $[MeCp(CO)_2Mn]^{2-}$. While this prediction has not yet been verified for $[MeCp(CO)_2Mn]^{2-}$, which was prepared for the first time only very recently,[13] similar reactions of $[(CO)_5Cr]^{2-}$ are known and clearly show the proposed analogy: reactions of $[(CO)_5Cr]^{2-}$ with 3,3-dichloro-1,2-diphenylcyclopropene or $[Me_2N{=}CH_2]^+$ give the corresponding $(CO)_5Cr$(carbene) complexes,[14,15] and complexes of the type $[(CO)_5Cr]_2ER$, *inter alia*, can be synthesized by reaction of $Na_2Cr_2(CO)_{10}$ with REX_2.[12] The anionic silyl compound **2** (and analogously the corresponding germyl and stannyl complex) therefore is an equivalent to $[MeCp(CO)_2Mn]^{2-}$, in respect to preparative applications. This statement can be generalized for other anionic silyl complexes. Compared with di-anionic complexes, anionic silyl complexes offer a number of important advantages: they are easily prepared, they can be handled without particular precautions, and they can be accessed for a greater number of metals in a greater variety of ligand environments. Use of anionic silyl complexes therefore is an interesting preparative alternative to di-anionic complexes, particularly if the latter are inaccessible or difficult to handle.

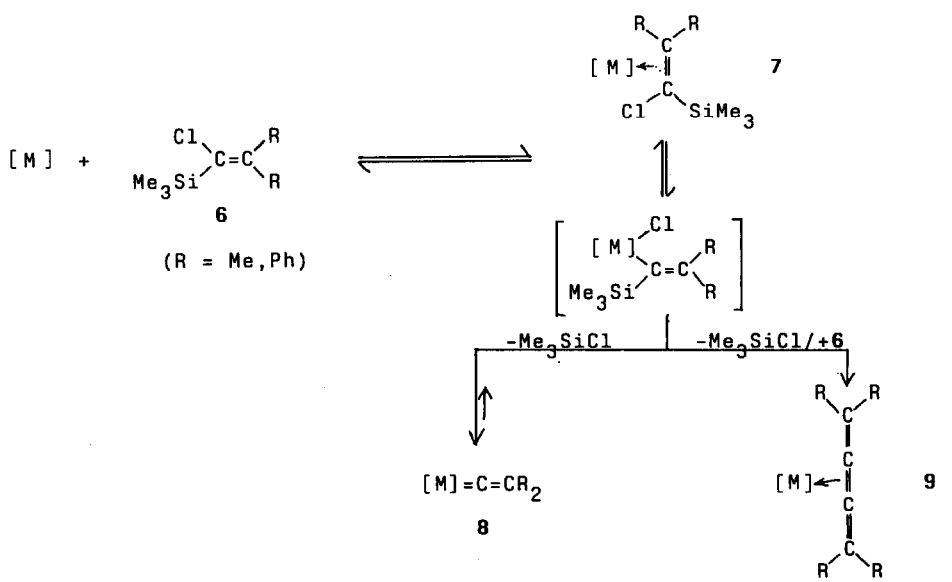
By reversal of the substitution pattern of the starting compounds, i.e. reaction of transition metal complexes bearing two halogeno ligands with α-silyl-substituted anionic compounds (route (b) in Scheme 1), intermediates of type **B** should be accessible, which would also be suitable precursors for metal–element double bonds. Only very few experiments towards a realization of this approach are known. When Cp_2WCl_2 is reacted with $LiSi(SiMe_3)_3$, the only product is the metal dihydride **5** [eq. (4)], even if an equimolar ratio of the compounds is employed.[16] Mechanistic studies indicate that substitution of a chloro ligand by SiR_3^- is indeed the primary step in this reaction. However, the intermediate complex, $Cp_2W(Cl)Si(SiMe_3)_3$, rearranges instead of eliminating Me_3SiCl.[16b] Reaction of Cp_2MCl_2 (M = Zr, Hf) with $LiSi(SiMe_3)_3$ yields $Cp_2M(Cl)Si(SiMe_3)_3$ as stable compounds.[17]



$$Cp_2WCl_2 + 2LiSi(SiMe_3)_3 \longrightarrow 2LiCl + [C_5H_4Si(SiMe_3)_3]_2WH_2 \quad (4)$$

(5)

Reacting the analogous phosphorus compound $LiP(Ar)SiMe_3$ (Ar = 2,4,6-$Bu^t_3C_6H_2$) with Cp_2ZrCl_2 again only gives the substitution product $Cp_2Zr(Cl)P(Ar)SiMe_3$, but two isomers of com-



7-9a [M] = MeCp(CO)LMn (L = CO, $P(OPh)_3$, $PMePh_2$)

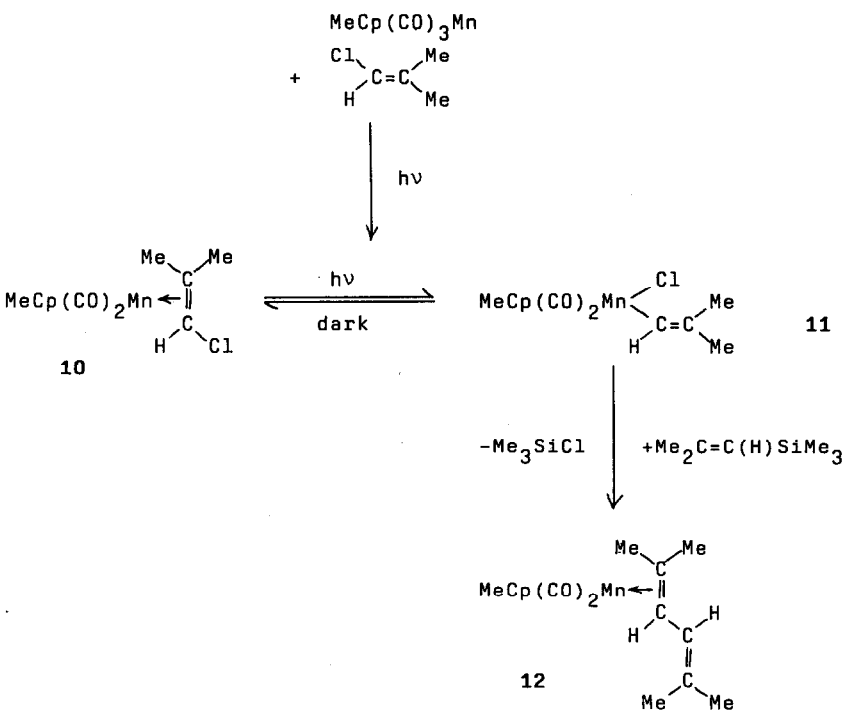
7-9b: [M] = (π-Ar)$(CO)_2Cr$ (Ar = C_6H_6, C_6Me_6, 1,3,5-$C_6H_3Me_3$)

Scheme 2.

position $MeCpWH[\eta^5\text{-}C_5H_3Me(PAr)]$ are formed with $(MeCp)_2WCl_2$.[18] The isomers are believed to be formed via the anticipated terminal phosphinidene complex; in the light of eq. (4) other mechanisms appear possible.

An alternative approach to type **B** compounds is oxidative addition of a silyl derivative $R_3Si(X)ER'_n$ to a coordinatively unsaturated metal complex (route (c) in Scheme 1). Based on this idea we developed a new method to prepare vinylidene complexes (ER'_n being a vinylidene moiety) using (α-halogenovinyl)silanes (**6**) as precursors. Photochemical reaction of **6** with an equimolar amount of $MeCp(CO)_2LMn$ (L = CO, $P(OPh)_3$, $PMePh_2$ or (π-arene)$(CO)_3Cr$) most likely proceeds by initial oxidative addition of the C—Cl bond to the transition metal fragment, followed by Me_3SiCl elimination to give the vinylidene complexes **8** (Scheme 2).[19] The scope of this new reaction appears to be rather general; it is particularly useful for the synthesis of β-disubstituted vinylidene complexes, which are not so easily prepared by other routes.[20] In the photochemical reaction of the metal carbonyl derivatives with (α-halogenovinyl)silanes, π-olefin complexes, **7**, are sometimes observed as by-products, and in some cases can even be isolated. In the case of $MeCp(CO)_2Mn(\pi\text{-}Me_2C{=}C(Br)SiMe_3)$, we observed slow conversion of the isolated, oily complex to the vinylidene complex $MeCp(CO)_2Mn{=}C{=}CMe_2$.[19b] Presently we are unable to decide whether the π-olefin complexes, **7**, are reversibly formed by-products or precursors to the oxidative addition products.

In the presence of an excess of **6**, the butatriene complexes, **9**, are formed instead of the vinylidene complexes, **8**, but both types of complexes originate from the same precursor, which is the oxidative addition product.[19] To elucidate the mechanism of the butatriene formation, the model reaction shown in Scheme 3 was carried out. Photochemical reaction of $MeCp(CO)_3Mn$ with $Me_2C{=}CHCl$ gives a complex which from spectroscopic data is believed to be the oxidative addition product, **11**. Complex **11** is only stable during irradiation and (reversibly!) converts to the π-olefin complex, **10**, in the dark (Scheme 3). Since elimination of HCl from **11** is less favourable than that of Me_3SiCl in the corresponding reaction of (α-chlorovinyl)silanes, no vinylidene complex is formed. However, the reaction channel leading to a C—C coupled organic ligand is still open. To enable this reaction, $Me_2C{=}C(H)SiMe_3$ is added to a solution of **11**. Formation of the buta*diene* complex, **12**, probably proceeds via a bis-vinyl complex, which reductively eliminates the butadiene.[19b] By extrapolation of the results shown in Scheme 3 one can be certain that the butatriene ligands in **9** do not originate from vinylidene units, but from substituted butadiene ligands ($R_2C{=}C(SiMe_3){-}C(Cl){=}CR_2$), which are formed by coupling of two vinyl units of the (α-



Scheme 3.

chlorovinyl)silanes and then elimination of another Me_3SiCl molecule to give the butatriene unit.

ELECTROPHILIC β-ADDITION TO ISOCYANIDE, CYANIDE AND ALKYNE-DERIVED LIGANDS

ARMANDO J. L. POMBEIRO

Centro de Química Estrutural, Complexo I, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal

Abstract—When binding an electron-rich group VI (Mo or W) or VII (Re) metal site (M), such as $\{M(dppe)_2\}$ (M = Mo or W, dppe = $Ph_2PCH_2CH_2PPh_2$) or $\{ReCl(dppe)_2\}$, isocyanides (M—C≡NR), cyanides (M—N≡CR) or alkyne-derived allene [$M(\eta^2$-H_2C—C=CHR)], vinylidene (M=C=CHR) or alkynyl (M—C≡CR) ligands undergo β-electrophilic attack (commonly by H^+) to give ligating aminocarbyne (M≡C···NHR), methyleneamido (M···N=CHR), η^2-vinyl [M=C(CH_2R)CH_2] or carbyne (M≡C—CH_2R) species, respectively; electronic factors driving the β-electrophilic addition are also discussed.

A number of pathways have been reported[1] for the synthesis of complexes with metal–carbon multiple bonds and usually they are initiated by, or involve, a nucleophilic attack, an α-abstraction process or a scission, elimination or rearrangement reaction at a suitable organic ligand.

Another route, which consists of a *β-electrophilic attack* at an unsaturated C-bonded ligand, is discussed herein and shown to be particularly effective in the case of molecules with unsaturated C—N or C—C bonds when activated by a mononuclear electron-rich metal site with a high π-electron releasing ability, presenting a heavier member of a central transition metal group (Mo, W or Re). Such unsaturated species are well represented by isocyanides and alkyne-derived allene, vinylidene and alkynyl ligands.

Cyanides, at such a type of metal centre, appear to be susceptibile to a similar electrolphilic β-addition reaction.

ELECTROPHILIC β-ADDITION TO ISOCYANIDES AND CYANIDES

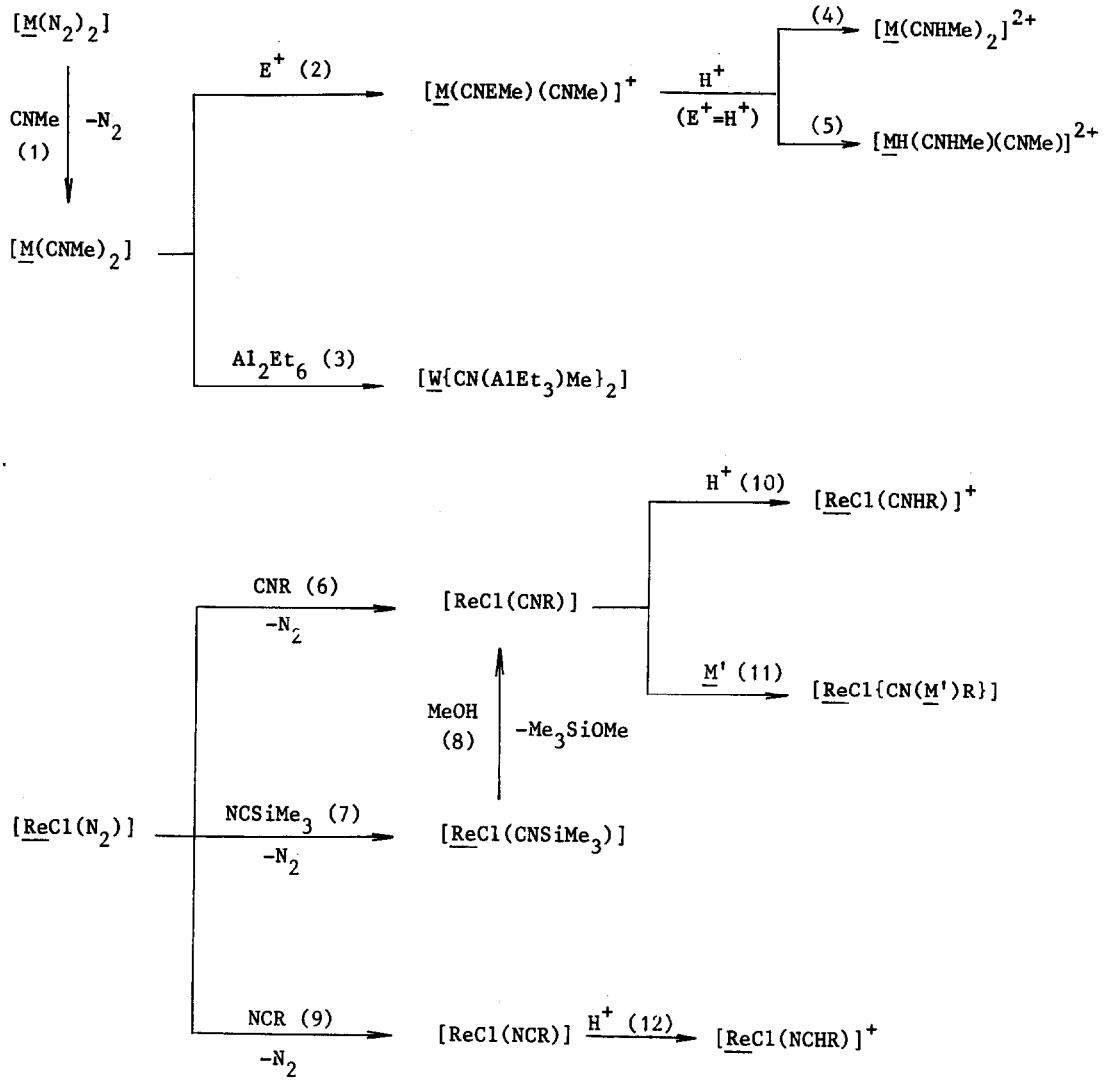
Typical isocyanide and cyanide complexes with the above-mentioned electron-rich metal centres are conveniently prepared from parent dinitrogen compounds or, in the case of rhenium, also from benzoyldiazenido precursors. Examples are given in Schemes 1 and 2 which include the preparation of *trans*-$[M(CNR)_2(dppe)_2]$ [M = Mo or W; R = alkyl or aryl; dppe = $Ph_2PCH_2CH_2PPh_2$) [eq. (1)],[2] $[M(CNR)_x(PMe_2Ph)_{6-x}]$ (x = 2 or 3) [eq. (13)],[3] *trans*-$[ReCl(CNR)(dppe)_2]$ {R = H [eqs (7) and (8)],[4] alkyl or aryl [eq. (6)][5]}, *trans*-[ReCl(NCR)$(dppe)_2$] (R = aklyl or aryl) [eq. (9)][6] and $[ReCl(N_2)(CNR)\{P(OMe)_3\}_3]$ [eq. (15)].[7]

These complexes exhibit short metal–carbon (or metal–nitrogen for the cyanide complexes)[6] bond lengths,[7–9] and, in their IR spectra, ν(C≡N) [or ν(N≡C)] occurs at low wavenumbers; a bending of the isocyanide ligand may also occur.[8] These observations are rationalized by some VB considerations, simplified π-MO schemes[10] and theoretical studies,[11] and are in agreement with an extensive π-electron donor character of the metal centres towards the isocyanide or the cyanide ligands; therefore, they are activated to electrophilic attack which was shown to occur at the β-position (relative to the metal) (Schemes 1 and 2).

Hence, *trans*-$[M(CNMe)_2(dppe)_2]$ (M = Mo or W)[12,13] or *trans*-$[ReCl(CNR)(dppe)_2]$ (R = H,[4] alkyl[14] or aryl[14]) react with protic acid to give the aminocarbyne complexes *trans*-$[M(CNHMe)(CNMe)(dppe)_2]^+$ or *trans*-$[ReCl(CNHR)(dppe)_2]^+$ [eqs (2) and (10)], respectively. The molecular structures of the latter (for R = H[4] or Me[14]) have been authenticated by single-crystal X-ray diffraction analyses, which indicate that the aminocarbyne complex should be represented as a hybrid of the following VB forms:

$$\overset{+}{Re}\equiv C-\ddot{N}HR \longleftrightarrow Re=C=\overset{+}{N}HR.$$

Electrophilic β-addition also results from the



Scheme 1. Syntheses and electrophilic β-addition to electron-rich isocyanide and cyanide complexes with *non*-labile co-ligands. M = *trans*-{M(dppe)$_2$} (M = Mo or W). Re = *trans*-{ReCl(dppe)$_2$}. Equation (2)—$E^+ = H^+$, Me^+ or Et^+. Equation (6)—R = alkyl or aryl. Equation (7)—$NCSiMe_3$ in equilibrium with a small percentage of the isocyanide isomer. Equation (8)—R = H.

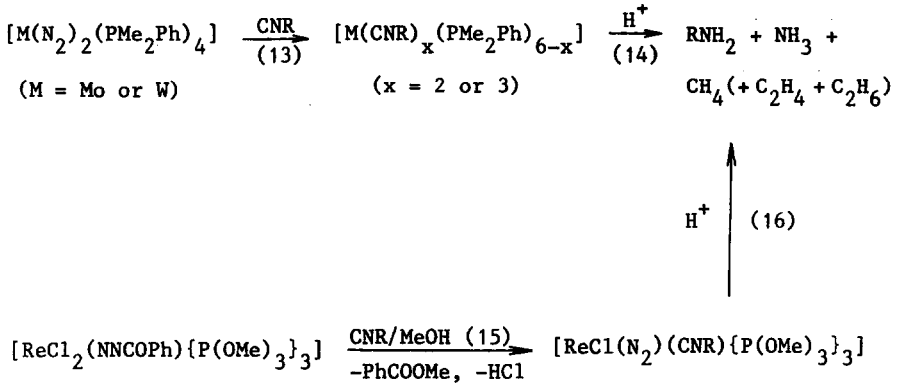
reactions of those isocyanide complexes with other electrophiles, particularly a carbocation[15]—from $MeFSO_3$, Me_2SO_4, $[Me_3O][BF_4]$ or $[Et_3O][BF_4]$—or a Lewis acid, such as Al_2Et_6[12] or an unsaturated transition-metal centre (M′) derived, for example, from $CoCl_2(THF)_{1.5}$ or $[ReOCl_3(PPh_3)_2]$.[16]

As products of these reactions, the following types of aminocarbyne complexes have been obtained: $[M(CNEMe)(CNMe)(dppe)_2]^+$ (M = Mo or W, $E^+ = Me^+$ or Et^+) [eq. (2)],[15] $[W\{CN(AlEt_3)_2Me\}_2(dppe)_2]$ [eq. (3)][2] or $[ReCl\{CN(M')R\}(dppe)_2]$ [R = Me or Bu^t, M′ = $CoCl_2(THF)$ or $ReOCl_3(PPh_3)$] [eq. (11)].[16]

The β-electrophilic attack at ligating isocyanide is in agreement with extended Hückel calculations[11] which indicate, e.g. that the nitrogen atom in *trans*-$[ReCl(CNR)(dppe)_2]$ bears a negative charge, whereas both the ligating carbon and the metal exhibit positive net atomic charges.

Cyanides at {ReCl(dppe)$_2$} also appear to be activated towards β-protonation to give methyleneamido species NCHR, as in the formation of $[ReCl\{NC(H)C_6H_4OMe\text{-}4\}(dppe)_2]^+$ by reaction of $[ReCl(NCC_6H_4OMe\text{-}4)(dppe)_2]$ with acid [eq. (12)].[6]

Although the mixed aminocarbyne–isocyanide complexes *trans*-$[M(CNHMe)(CNMe)(dppe)_2]^+$ can undergo protonation which occurs either at the metal or at the isocyanide ligand to give $[MH(CNHMe)(CNMe)(dppe)_2]^{2+}$ [eq. (5)],[13,17]



Scheme 2. Syntheses and extensive β-protonation at electron-rich isocyanide complexes with labile co-ligands.

$[M(CNHMe)_2(dppe)_2]^{2+}$ [eq. (4)][12,13] or the unstable species $[M(CNH_2Me)(CNHMe)(dppe)_2]^{3+}$ (which undergoes ready deprotonation),[13] no further electrophilic attack is observed beyond the carbyne stage in these compounds with chelating phosphine ligands.

However, when activated by an electron-rich metal centre with *labile* co-ligands, as in $[M(CNR)_x(PMe_2Ph)_{6-x}]$ (M = Mo or W, $x = 2$ or 3)[18] or in $[ReCl(N_2)(CNR)\{P(OMe)_3\}_3]$,[7] isocyanides can undergo a more extensive protonation with complete reductive cleavage of the unsaturated CN bond (Scheme 2) to give mainly amines (RNH_2) and ammonia apart from hydrocarbons (predominantly methane) in lower yields. The metal behaves as a reducing agent and the facile replacement, during the reaction, of the labile phosphine or phosphite ligand by a stronger electron donor (e.g. the anion from the protic acid or methoxide from the solvent methanol) enhances the π-electron releasing ability of the oxidized metal centre and thus promotes further protonation at intermediate aminocarbyne stages.

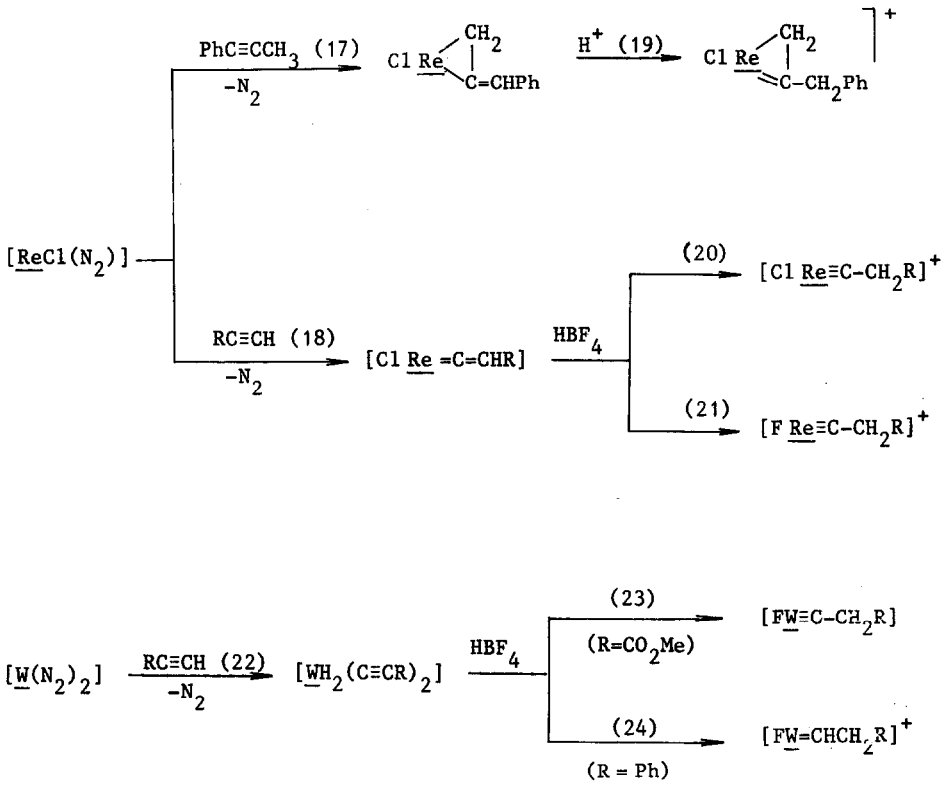
ELECTROPHILIC β-ADDITION TO ALKYNE-DERIVED SPECIES

Phenylpropyne ($PhC{\equiv}CCH_3$) and 1-alkynes ($RC{\equiv}CH$) undergo shift reactions with *trans*-$[ReCl(N_2)(dppe)_2]$ or *trans*-$[M(N_2)_2(dppe)_2]$ (M = Mo or W) (Scheme 3): 1,3- and 1,2-hydrogen migrations along the carbon framework of the alkyne occur in the rhenium systems to give the allene and the vinylidene complexes *trans*-$[ReCl(\eta^2\text{-}H_2C{-}C{=}CHPh)(dppe)_2]$ [eq. (17)][19] and *trans*-$[ReCl(=C{=}CHR)(dppe)_2]$ [eq. (18)],[20] respectively, whereas, for the more readily oxidizable molybdenum or tungsten centres, hydrogen shift to the metal is observed to afford for example the alkynyl–hydrido $[MH_2(C{\equiv}CR)_2(dppe)_2]$ [eq. (22)][21] or the derived dialkynyl complexes $[M(C{\equiv}CR)_2(dppe)_2]$.[21,22] The molecular structures of these products have been determined by X-ray analyses.

The metal-centred alkyne rearrangements at the unstable intermediate alkyne complexes have been interpreted[19,20] by considering the destabilizing repulsive interaction between the filled $\pi_\perp$ orbital of the alkyne and a filled d_π orbital of the electron-rich d^6 metal centre.

As observed for isocyanides and cyanides, all those alkyne-derived ligands can undergo β-protonation (Scheme 3). Hence, the η^2-vinyl (metallacyclopropene) complex, *trans*-$[Re\{{=}C(CH_2Ph)CH_2\}(dppe)_2][BF_4]$, whose molecular structure has been determined by an X-ray analysis, is obtained by reaction of the allene compound, *trans*-$[ReCl(\eta^2\text{-}H_2C{-}C{=}CHPh)(dppe)_2]$, with HBF_4 [eq. (19)],[23] and the site of protonation is in agreement with extended Hückel calculations,[23] which indicate that the HOMO of the latter complex has a substantial contribution (36%) to the p_y orbital of the allene carbon in the β-position (relative to rhenium), whereas the α-carbon contributes only 10%. Although the HOMO is mainly metal *d*-centred (54%), protonation occurs at the β-carbon, which offers a highly directional *p* orbital, rather than at the metal with a diffuse electronic density and which is coordinatively saturated.[23]

The vinylidene and the alkynyl species are also protonated at the β-position and e.g. the carbyne complexes *trans*-$[ReCl(\equiv CCH_2R)(dppe)_2][BF_4]$ (R = Bu^t, Ph, etc.) [eq. (20)],[24] *trans*-$[ReF(\equiv CCH_2Bu^t)(dppe)_2][BF_4]$ [eq. (21)][24] (whose molecular structure has been confirmed by X-rays)[24] and $[WF(\equiv CCH_2CO_2Me)(dppe)_2]$ [eq. (23)],[21] as well as the carbene compound $[WF(=CHCH_2Ph)$



Scheme 3. Syntheses and β-protonation of alkyne-derived electron-rich complexes.

$(dppe)_2][BF_4]$ [eq. (24)],[21] are obtained by reaction of HBF_4 with the appropriate *trans*-[ReCl(=C=CHR)$(dppe)_2$] or [$WH_2(C{\equiv}CR)_2(dppe)_2$] complex, respectively. In these reactions, BF_4^- may behave as a metal fluorinating agent.

The site (β-carbon) of the electrophilic addition to the vinylidene and alkynyl ligands in the complexes mentioned above, is in accord with molecular orbital calculations carried out on other complexes with such substrates (as well as with ligating vinyl);[25] moreover, in the latter systems, the β-electrophilic attack was shown to be charge controlled, whereas the nucleophilic addition, which occurred at the α-carbon, was frontier orbital controlled.[25]

FINAL REMARKS

Electron-rich metal centres with heavier transition metals of central groups (typically Mo-, W- or Re-phosphinic sites), present a high π-electron releasing ability and promote electrophilic attack at unsaturated organic ligands, particularly isocyanides, cyanides and alkyne-derived allene, vinylidene and alkynyl species. Such electrophilic addition appears to be regioselective, occurring at the atom of the substrate in the β-position (relative to the metal), and this has been rationalized by extended Hückel calculations.

This pattern of reactivity contrasts with that commonly observed for isocyanides when ligating an electron-poor metal site; they are then susceptible to activation towards attack by nucleophiles which occurs at the α-position (the ligating atom).[26] This dichotomy of β-electrophilic and α-nucleophilic additions has also been recognized for other related unsaturated species, such as thiocarbonyl,[27] alkynyl,[28] vinylidene[28] and dinitrogen,[29] and has been investigated by MO studies;[30] however, cyanides do not follow this type of regioselectivity and either the electrophilic (mentioned in this work) or the nucleophilic[31] attack occurs at the β-position.

The electrophilic β-additions discussed in this account corresponded to novel types of reactions of isocyanide, organocyanide and allene ligands, and provided novel routes for a variety of species, such as ligating aminocarbynes, methyleneamido or η^2-vinyl ligands; they also allowed the synthesis of novel species, particularly the simplest aminocarbyne group, CNH_2.

As a result of the β-electrophilic addition to isocyanide or to any of the above-mentioned alkyne-derived ligands, a weakening of the unsaturated bond with a concomitant strengthening of the

metal–carbon bond occurs to give species which are stabilized by multiple bond coordination, in accord with a high tendency of the metal (commonly assisted by an electron donor halide ligand) to form multiple bonds to carbon.

As demonstrated by electrochemical studies,[32] these metal–carbon multiple bonded species behave as very strong net electron acceptors (even stronger than carbonyl or isocyanides), according to the following order: carbynes > η^2-vinyl > aminocarbynes.

Although the chemistry of the products of the electrophilic β-additions of this study still remains to be fully explored, they are expected to represent fundamental types of intermediate states in the conversion of isocyanides, cyanides, alkynes and allenes into a variety of organic or organonitrogenated products, namely those formed[33] in their enzymatic reduction.

Abstract—The synthesis of 11 organozirconium compounds is described, together with their characterization. Nine of them are zirconocene(IV) derivatives bearing cyclopentadienyl (Cp) or related ligands [Cp′ = η-$\bar{C}_5H_5SiMe_3$, $\bar{C}p''$ = η-$\bar{C}_5H_3(SiMe_3)_2$-1,3 or $\bar{C}p'''$ = η-$\bar{C}_5H_2(SiMe_3)_3$-1,2,4]. The remaining two compounds are [$ZrCp''_2$(DMPE)] (**8**) and [$Zr(CH_2Mes)_2Cl_2$]·$2Et_2O$ [DMPE = $(Me_2PCH_2)_2$ and Mes = $C_6H_2Me_3$-2,4,6]. X-ray structural data are presented for seven of these complexes: [$ZrCp_2$(Cl)(OAr)], [$ZrCp_2\{\eta^2$-C(NMe)CHPh$_2\}$(Me)], [$ZrCp_2(NMe_2)$(OAr′)], [$ZrCp'_2(CH_2C_6Me_5)$(Cl)], [$ZrCp''_2(\eta^2$-$BH_4)$(Cl)], (**8**) and [$ZrCp'''(NMe_2)_3$] (Ar = $C_6H_2Bu^t_2$-2,6-Me-4, Ar′ = $C_6H_3Bu^t_2$-2,6). Cyclic voltammetric results are presented for the zirconocene halides of formula [$ZrCp''_2X_2$] (X = F, Cl, or Br) and on some related compounds. The zirconocene(II) complex, **8**, undergoes reversible one-electron oxidation and ESR data are provided on the zirconium(III) product. Some variable temperature NMR results are described on the aryloxides and tetrahydridoborates.

For some years we have been actively pursuing aspects of organozirconium chemistry.[1,2] Among the compounds which we have studied in detail are the metallocene halides [$ZrCp_2Hal_2$] (Cp = η-C_5H_5; Hal = F, Cl, Br, or I). We have recently reported on the synthesis and X-ray structures of [$ZrCp''_2Hal_2$] [Cp″ = η-$C_5H_3(SiMe_3)_2$-1,3].[1] The effect of introducing an alkyl or trimethylsilyl substituent into the cyclopentadienyl ligand on the properties of zirconocene(II, III, or IV) complexes has received some attention.[1–3] The ligand $\bar{C}p''$ was originally introduced into 4*f* element chemistry; *inter alia* we synthesized complexes of formula [{$LnCp''_2(\mu$-Cl)}$_2$] for the early lanthanide metals (Ln = La, Ce, Pr, or Nd);[4] these are not accessible for the $\bar{C}p$ analogues (if formed they disproportionate yielding 2/3$LnCp_3$ + 1/3$LnCl_3$).

A feature of the $\bar{C}p'$ (≡ η-$\bar{C}_5H_4SiMe_3$) and $\bar{C}p''$ ligands is that with increasing trimethylsilyl substitution they generally confer on their metal complexes, increasing lipophilicity and volatility. Furthermore, as a result of their bulk, steric effects may come into play to yield unusual chemistry.

The objectives of this paper are to present some new results on zirconocene derivatives, including a good deal of crystallographic information. Some comparisons will also be made relating to cyclic voltammetry data on the metallocene halides, illustrating the role of (a) trimethylsilyl substituents in the cyclopentadienyl group of [$Zr(\eta$-$C_5H_3RR')_2Cl_2$] (R and R′ = H or $SiMe_3$) and (b) Hal in [$ZrCp''_2Hal_2$]. Because of the bulk of the $\bar{C}p''$ ligand, steric effects may be manifested in various ways. For the tetrahydridoborates this will be shown by the mode of bonding between that ligand and the metal, and for an aryloxide by restriction to rotation about the O—C(Ar) bond; variable temperature

12	29%, white crystals, m.p. 136–138°C; ^{1}H NMR (C_6D_6, 300 K): δ 1.03t (CH_2CH_3), 1.83s (CH_2Mes), 2.54s (*p*-Me), 2.65s (*o*-Me), 3.36q (CH_2CH_3), 6.96s [CH (aromatic)]

NMR data have provided the means of monitoring these effects. Another aspect of ZrCp chemistry relates to steric effects and their influence on thermal stability; this will be demonstrated by reference to the stable compounds [$ZrCp_2\{\eta^2$-C(NMe)$CHPh_2\}$(Me)], [$ZrCp''_2$(DMPE)] and [$ZrCp'''(NMe_2)_3$]. Finally, we draw attention to two new ligands: $\bar{C}H_2$Mes and $\bar{C}H_2C_6Me_5$ (Mes = $C_6H_2Me_3$-2,4,6) which have been developed in the context of zirconium(IV) chemistry.

RESULTS AND DISCUSSION

We report on 11 organozirconium compounds, **1**–**11**, as illustrated in Scheme 1; the synthesis of the aryloxide [$ZrCp_2$(Cl)(OAr)] (Ar = $C_6H_2Bu^t_2$-2,6-Me) (**1**) has already been described,[5] and compounds **2** and **3** have previously been briefly mentioned.[6] Each of the complexes **1**–**8**, **10** and **11** has been obtained in crystalline form and has been fully characterized by microanalytical, IR, and ^{1}H and ^{13}C NMR data. Yields and some spectroscopic information are shown in Table 1. Additionally, single-crystal X-ray crystallographic results are available for complexes **1**, **3**, **4**, **5**, **6**, **8** and **10**, as summarized briefly in Figs 1–7, respectively.

Cyclic voltammetric information has been obtained on a series of zirconocene halides [$ZrCp''_2Hal_2$] (Hal = F, Cl, or Br), as shown in Table 2, which also includes data on related compounds. From Table 2, it is clear that ease of reduction falls

Table 2. Cyclic voltammetry parameters for a range of group 4 metallocene(IV) halides[a]

Compound	E^0(V)[b]	ΔE_{pp}(V)[c]	$i^r : i^f$[d]

Whereas these results deal with the reduction of zirconium(IV) to zirconium(III), data are also available on the oxidation process zirconium(II) to zirconium(III) in which the substrate was $[ZrCp''_2(DMPE)]$ [DMPE = $(Me_2PCH_2)_2$] (**8**). Thus, there was a reversible one-electron oxidation of $Zr^{II} \rightarrow Zr^{III}$, with $E^{ox} = -0.6$ V followed by an irreversible one-electron $Zr^{III} \rightarrow Zr^{IV}$ oxidation at

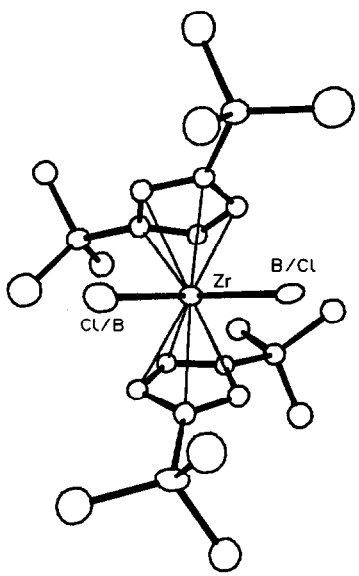

Fig. 5. The X-ray structure of $[ZrCp''_2(\eta^2\text{-}BH_4)(Cl)]$ (**6**). Important bond distances and angles: Zr—B 2.44(1), Zr—Cl 2.410(9), Zr—Cen 2.217 Å; Cl—Zr—B 98.9(4), Cen—Zr—Cen′ 131.9, Cen—Zr—Cl 106.1°.

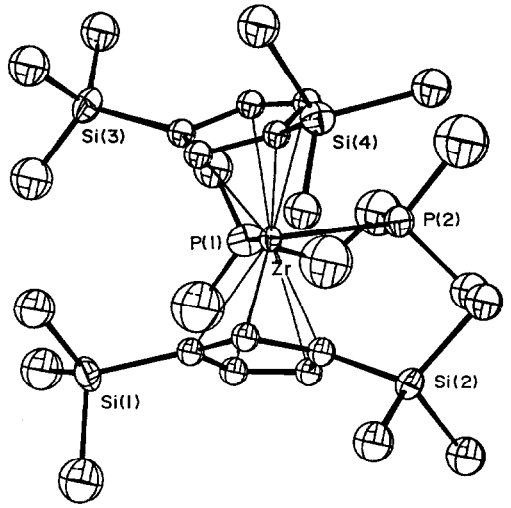

Fig. 6. The X-ray structure of $[ZrCp''_2(DMPE)]$ (**8**). Important bond distances and angles: Zr—P 2.678(3); P(1)—Zr—P(2) 73.7(1), Zr—P—CH_3 126.6(9) and 123.9(5), Zr—P—CH_2 110.7(9)°.

0.49 V (the cell conditions were those of Table 2). The chemical oxidation of complex **8** by $Ag[BF_4]$ (1 mol) in THF, or electrochemically at a potential of −0.6 V, generated a green d^1 complex, showing a triplet ESR signal, $g_{av} = 1.9871$, $a(^{31}P) = 26.7$ G, which decomposed over *ca* 6 h at 20°C to yield the diamagnetic colourless $[ZrCp''_2F_2]$.

The IR spectra of the zirconium(IV) tetrahydridoborato complexes, **6** and **7**, revealed them to have the $Zr(\mu\text{-}H)_2BH_2$ structure, as had been noted for $[ZrCp_2(\eta^2\text{-}BH_4)_2]$.[8] In the prochiral $[ZrCp''_2(Cl)(\eta^2\text{-}BH_4)]$ (**6**), the ^1H NMR signals due to the ring proton H(2) and $SiMe_3$ were each split into doublets. The BH_4 protons were observed as a featureless singlet at 300 K, but this was resolved into a broad 1 : 1 : 1 : 1 quartet at 338 K. Similarly, the ^{11}B NMR spectrum showed fast exchange (a binomial quintet) at 360 K, but a slowing down of the bridge–terminal exchange at lower temperatures, Fig 8; by contrast in $[ZrCp_2(\eta^2\text{-}BH_4)_2]$, this exchange is rapid even at ambient temperature.[8]

As (a) the $\eta\text{-}\bar{C}_5Me_5$ ligand has powerfully extended cyclopentadienylmetal chemistry, and (b) $\bar{C}H_2Ph$ has an important role in zirconium(IV) chemistry,[2] it was considered to be of interest to examine the new ligands $\bar{C}H_2C_6Me_5$ or $\bar{C}H_2C_6H_2Me_3$-2,4,6 (= $\bar{C}H_2Mes$). There was some difficulty in preparing $C_6Me_5CH_2MgCl$ (and attempts to prepare the corresponding lithium benzyl failed), but this was eventually accomplished by using THF as solvent in high dilution (<0.1 mol dm^{-3}), activating the magnesium dust immediately prior to use $[(BrCH_2)_2]$, and slow addition of $C_6Me_5CH_2Cl$. Addition of a 10-fold excess of *p*-dioxane to a THF solution of $C_6Me_5CH_2MgCl$ slowly (several hours at *ca* 25°C) yielded a precipitate of $MgCl_2(THF)_2$ and, from the filtrate, $Mg(CH_2C_6Me_5)_2(p\text{-dioxane})_n$. No doubt due to the bulk of $\bar{C}H_2C_6Me_5$ only one $\bar{C}l$ ligand of $[ZrCp'_2Cl_2]$ was displaced to yield $[ZrCp'_2(CH_2C_6Me_5)(Cl)]$ (**5**) (the Cp analogue and

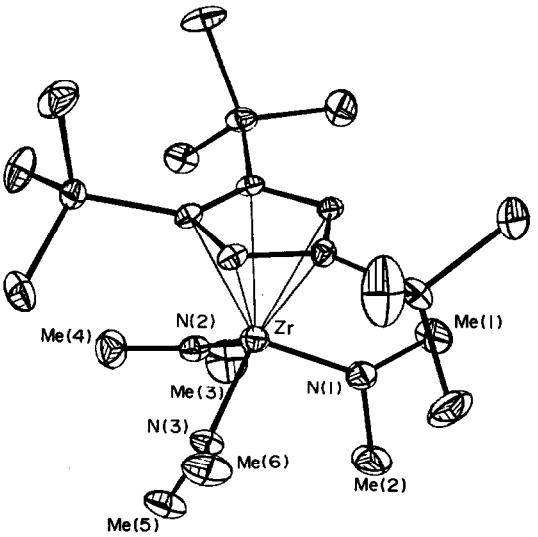

Fig. 7. The X-ray structure of $[ZrCp'''(NMe_2)_3]$ (**10**). Important bond distances and angles: Zr—N(1) 2.051(5), Zr—N(2) 2.047(5), Zr—N(3) 2.067(4) Å; N(1)—Zr—N(2) 97.3(2), N(1)—Zr—N(3) 105.9(2), N(2)—Zr—N(3) 99.5(2)°.

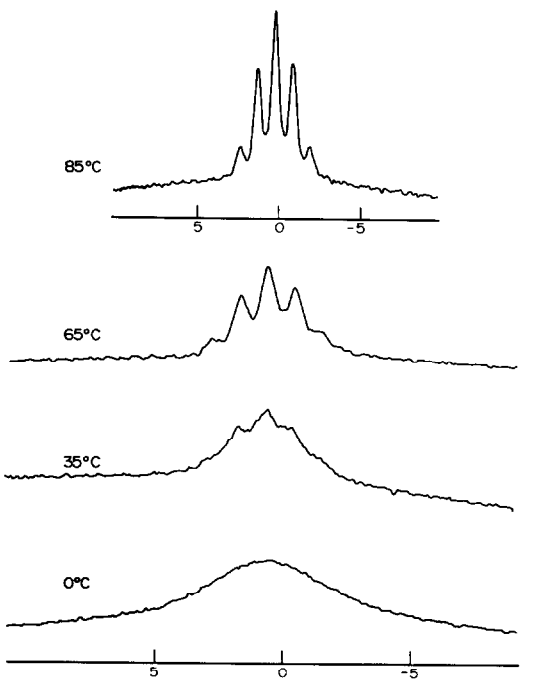

Fig. 8. Variable temperature ^{11}B NMR spectra of $[ZrCp''_2(\eta^2\text{-}BH_4)(Cl)]$ (**6**) in toluene-d_8.

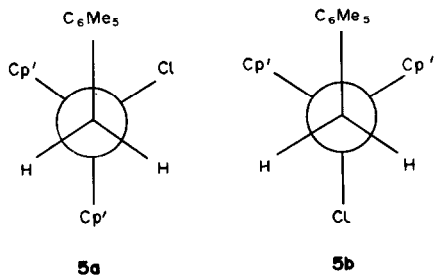
the corresponding Hf complex were also prepared and characterized). The low temperature ^{1}H NMR spectrum of **5** was consistent with the conformation **5a** rather than **5b**, as also evident in the crystal (Fig. 4). From the NMR and the X-ray data, we conclude that the steric demands of the $\bar{C}H_2C_6Me_5$ ligand are not as stringent as those of $\bar{C}H(SiMe_3)_2$ ($\equiv \bar{R}$), cf. corresponding data for [ZrCp$'_2$(R)(Cl)].[9]



5a **5b**

In the ^{1}H NMR spectrum of [ZrCp$_2$(NMe$_2$)(OAr')] (Ar = C$_6$H$_3$Bu$^t_2$-2,6) (**4**) the 2- and 6-Bu^t groups are distinct and different under ambient conditions, the coalescence temperature (T_c) being 324 K, corresponding to $\Delta G^{\ddagger}_{324K} = 70$ kJ mol^{-1}; as the cyclopentadienyl protons remain equivalent, the effect is attributed to restricted rotation about the O—C(Ar) rather than the Zr—O bond. The T_C value for some analogues [ZrCp$_2$(OAr')(X)] was >343 K for X = OMe (prepared from **4**+MeOH) and >333 K for X = OC(O)NMe$_2$ (prepared from **4**+CO$_2$). The Zr—O bond length and Zr—O—C(Ar) bond angle in **4** (Fig. 3), [ZrCp$_2$(Cl)(OAr')] (**1**) (Fig. 1), and [Zr{η^2-C(NBu^t)CH$_2$Ph}$_2$(OAr)$_2$] (**13**) [2.027(2) Å and 172.7(2)°][10] are available for comparison.

The Zr—CH$_3$ bond length in [ZrCp$_2${η^2-C(NMe)CHPh$_2$}Me] (**3**) (Fig. 2) is remarkably long, cf. 2.287(5) Å in [ZrCp$_2$Me$_2$].[2] There are significant differences in bond lengths relating to the iminoacyl fragment of **13**: Zr—N, 2.221(3); Zr—η^2-C, 2.228(3); C—N, 1.286(4) Å.[10]

The monomeric nature of the monocyclopentadienylzirconium(IV) complex, [ZrCp'''(NMe$_2$)$_3$] [Cp''' = C$_5$H$_2$(SiMe$_3$)$_3$-1,2,4] (**10**), is noteworthy. The steric crowding is evident from the low temperature ^{1}H NMR spectrum (Table 1), which reveals three distinct methyl environments for the NMe$_2$ protons.

THE METALLATION AND HYDROGENATION OF ARYL RINGS IN EARLY TRANSITION METAL ARYLOXIDE SYSTEMS

ROBERT W. CHESNUT, BRYAN D. STEFFEY and IAN P. ROTHWELL*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

Abstract—The mixed chloro-aryloxide compounds of stoichiometry $M(OAr\text{-}2,6Ph_2)_2Cl_3$ and $[M(OAr\text{-}2,6Ph_2)_3Cl_2]$ (M = Nb, Ta; $OAr\text{-}2,6Ph_2$ = 2,6-diphenylphenoxide) serve as useful substrates for the synthesis of a series of corresponding tris- and bis-alkyl derivatives. Thermolysis of these alkyl compounds in hydrocarbon solvents leads to the formation of cyclometallated compounds of the type $M(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)(R)_2$ and $M(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(R)$ (R = CH_3, $CH_2\text{-}C_6H_4\text{-}4Me$). Reduction of the dichlorides $M(OAr\text{–}2,6Ph_2)_3Cl_2$ with sodium amalgam in toluene solution does not yield the corresponding tris-aryloxides. Instead the bis-cyclometallated compounds $M(OC_6H_3Ph\text{-}C_6H_4)_2(OAr\text{-}2,6Ph_2)$ (M = Nb, Ta) are produced in high yield along with H_2. However, in the presence of one atmosphere of H_2 the niobium compound undergoes reduction to produce $Nb(OC_6H_3Ph\text{-}\eta^4\text{-}C_6H_7)(OAr\text{-}2,6Ph_2)_2$. Spectroscopic and structural studies of this latter compound show it to contain an η^4-bound cyclohexadiene ring formed by hydrogenation of an *ortho*-phenyl substituent of an aryloxide ligand. Treatment of the niobium cyclohexadiene complex with H_2 (1000 psi, 25°C) leads to the hydrogenation of the original 2,6-diphenylphenoxide ligands to produce, after hydrolysis, high yields of 2,6-dicyclohexylphenol. The selective side chain hydrogenation of 2,6-diphenylphoxide ligands can also be achieved by reacting alkyl compounds such as $Nb(OAr\text{-}2,6Ph_2)_3Me_2$ with H_2. In this latter case a mono-hydride of stoichiometry $Nb(H)(OAr\text{-}2,6cy_2)_4$ was isolated and structurally characterized.

The high valent early *d*-block, lanthanide and actinide metal–hydride and metal–alkyl bonds have been shown over the last few years to be extremely important functional groups, being implicated in a wide range of stoichiometric and catalytic reactivity.[1–4] Besides their ability to carry out the reduction of unsaturated small molecules and functionalities, a recently demonstrated reactivity of these metal hydrides and alkyls has been their propensity for activating a range of carbon–hydrocarbon bonds both intra- and intermolecularly.[5–8] An intriguing dual reactivity is demonstrated by their reactivity towards olefins.[1,5–7] By careful choice of the metal system and olefin substrate, both migratory insertion into metal–hydride or metal– alkyl bonds can be achieved: reactions of synthetic utility and relevance to catalytic processes. However, it is also possible to obtain metal σ-vinyl products resulting from activation of sp^2-CH bonds and elimination of either alkane or dihydrogen.[5–7] In the case of the related aromatic hydrocarbon substrates, either no reaction is observed or else ring metallation and formation of σ-aryl compounds is found to take place.[5–8] There is little evidence for arene hydrogenation occurring.[9–12] During our studies of the early transition metal chemistry associated with sterically demanding aryloxide ligation[8] we have investigated the behaviour of 2,6-diphenylphenoxide ($OAr\text{-}2,6Ph_2$) as ancillary ligation for supporting organometallic chemistry.[13,14] This work, which is outlined here, has demonstrated that it is possible not only to induce intramolecular metallation of this ligand,[13,14] but that intramolecular hydrogenation of the side chain aryl groups by metal–hydride ligands can also be a directly competing reactivity.[15]

The chloride compounds $M(OAr\text{-}2,6Ph_2)_2Cl_3$ and $M(OAr\text{-}2,6Ph_2)_3Cl_2$ (M = Nb, Ta) prove to be useful substrates for the synthesis of simple alkyl derivatives containing 2,6-diphenylphenoxide ancillary ligation (Scheme 1).[13,14] However, the

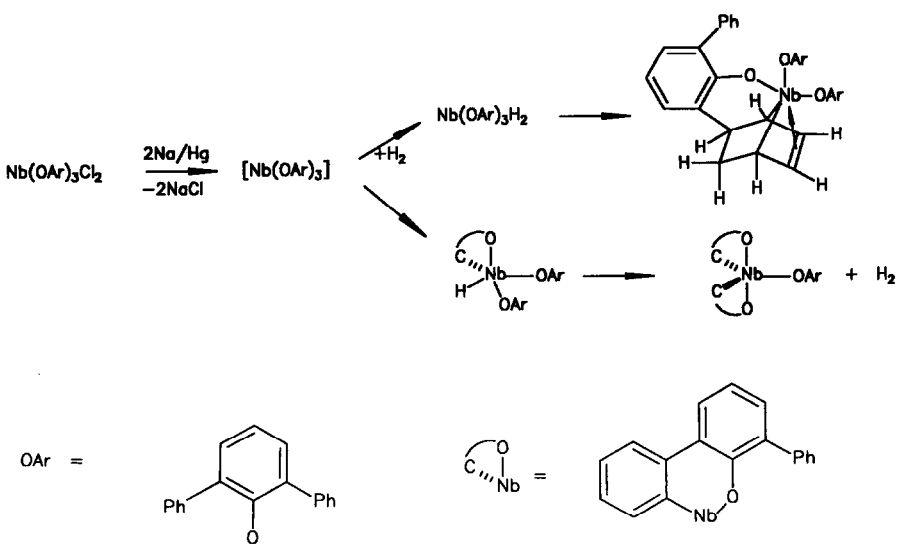
Scheme 1.

simple methyl and 4-methylbenzyl derivatives are thermally unstable and undergo elimination of methane and *p*-xylene, respectively, to generate cyclometallated compounds. Structural studies[14] confirm the presence of six-membered metallacycle rings formed by the metallation of one of the side chain phenyl groups.[8] The use of labelled compounds such as $Ta(OAr\text{-}2,6Ph_2)_3(CD_3)_2$ clearly shows that the reaction proceeds by loss of CD_3H, indicating the absence of methylidene intermediates.[8] The use of 2,4,6-tri-aryl phenoxides that contain differing substituents attached to the 2- and 6-aryl ring shows that there is only a minor substituent effect on the rate of cyclometallation.[16]

Attempts to form low valent aryloxide compounds of niobium and tantalum by sodium amalgam reduction of $M(OAr\text{-}2,6Ph_2)_3Cl_2$ (M = Nb, Ta) also leads to cyclometallated compounds. In this case, bis-cyclometallated compounds are obtained along with H_2 (Scheme 1).[14,17] A minor component was also observed in the reduction of the niobium compound. It is possible to generate this material in essentially quantitative yields by running the reduction under one atmosphere of H_2. Spectroscopic and structural studies show this compound to be $Nb(OC_6H_3Ph\text{-}\eta^4\text{-}C_6H_7)(OAr\text{-}2,6Ph_2)_2$ in which one of the side chain aryloxide phenyl groups has undergone 1,2-hydrogenation (Scheme 2).[15] The resulting cyclohexadiene ring is then bound to the niobium in an η^4-fashion.[18] Hydrolysis of this material yields two equivalents of $HOAr\text{-}2,6Ph_2$, along with one equivalent of 2-(cyclohex-2-enyl)6-phenylphenol. A combination of 1D and 2D NMR experiments, as well as the use of deuterium labels, conclusively show that the two hydrogen atoms are added in a mutually *cis*-fashion. However, due to the unfavourable stereochemistry at the initial *ipso*-carbon the niobium metal centre has to bind to the *opposite* face of the cyclohexadiene unit to which the hydrogenation took place.[18]

Treatment of toluene solutions of the compound $Nb(OC_6H_3Ph\text{-}\eta^4\text{-}C_6H_7)(OAr\text{-}2,6Ph_2)_2$ with H_2 (1000 psi, 25°C, 6 days or 400 psi, 80°C, 6 h) results in the complete hydrogenation of all of the side chain phenyl rings. Hydrolysis allows the isolation of 2,6-dicyclohexylphenol in 85% isolated yield based on initial 2,6-diphenylphenoxide ligands. Partial hydrogenation followed by hydrolysis yields a mixture of 2,6-diphenylphenol; 2-cyclohexyl-6-phenylphenol and 2,6-dicyclohexylphenol. Com-



Scheme 2.

plete hydrogenation of the substituent phenyl rings can also be achieved by treating the dimethyl substrate, Nb(OAr-2,6Ph$_2$)$_3$Me$_2$, or the bis-cyclometallated compound, Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)$_2$(OAr-2,6Ph$_2$), with H_2. Presumably initial formation of a dihydride intermediate (Scheme 2) takes place by hydrogenolysis of the Nb—C bonds. Analysis of the final reaction mixture by ^{1}H NMR spectroscopy indicates the presence of Nb—*H* functionalities as broad resonances in the δ −10–12 region. In the case of the hydrogenation of Nb(OAr-2,6Ph$_2$)$_3$Me$_2$, large orange blocks of stoichiometry Nb(H)(OAr-2,6cy$_2$)$_4$ (OAr-2,6cy$_2$ = 2,6-dicyclohexylphenoxide) were obtained and structurally characterized (Fig. 1).*

The use of 2,4,6-triphenylphenoxide ligation results in the formation of 2,6-dicyclohexyl-4-phenylphenol, with no evidence for hydrogenation of either the 4-phenyl substituent or the phenoxy ring. The use of deuterium as the reagent gas, as well as the use of asymmetric 2,6-di-arylphenoxide ligation, gives considerable mechanistic insight into these arene hydrogenation processes.

HIGHLY REDUCED CARBONYLS OF THE EARLY TRANSITION METALS

JOHN E. ELLIS

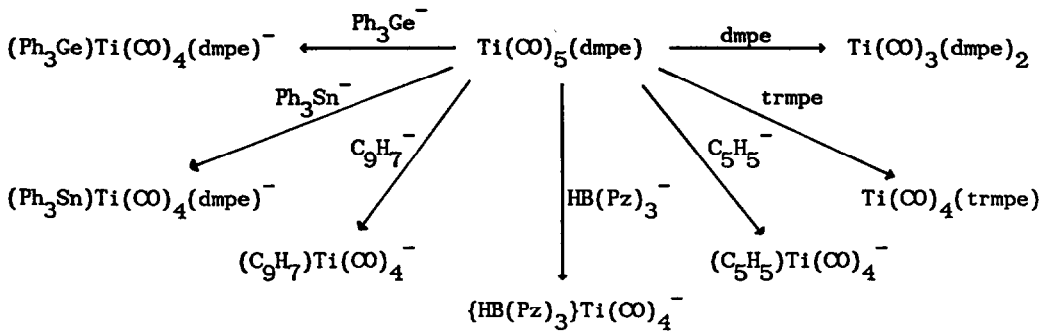
Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, U.S.A.

Abstract—Pioneering ventures in low valent carbonyl and related chemistry of titanium, zirconium, hafnium and other early transition elements have been undertaken to discover new classes of organometallic and inorganic materials. Useful synthetic methodology—involving a two step reductive carbonylation of a variety of group 4 halides by alkali metal naphthalenides at low temperatures—has been developed recently in our laboratory. By this procedure the first carbocyclic and anionic derivatives of the unknown $Ti(CO)_7$, $Zr(CO)_7$ and $Hf(CO)_7$ have been obtained. Also, this method provides the first general route to organophosphine carbonyls of zerovalent titanium, zirconium and hafnium. Very recently the initial stabilized "pure" carbonyl complexes of these elements have been obtained in the form of the hexacarbonylmetallate(2−) ions, $M(CO)_6^{2-}$.

For the past decade most of the research in this laboratory has involved the synthesis, isolation, characterization and study of the general reactivity patterns of novel highly reduced metal carbonyls. These contain *d*-block transition elements in their lowest known formal oxidation states and provide fundamentally new units for chemical synthesis. Examples of these "super-reduced" species include $Na_3[Co(CO)_3]$,[1] $Na_3[Mn(CO)_4]$,[2] $Na_4[Cr(CO)_4]$,[3] $Na_3[V(CO)_5]$[4] and the very recently synthesized $[K(15\text{-Crown-}5)_2]_2[Ti(CO)_6]$[5] of the first row transition elements. Analogous compounds have also been prepared for many of the corresponding second and third row transition metals. Of particular importance in the characterization of $V(CO)_5^{3-}$ and $Ti(CO)_6^{2-}$ were ^{51}V and ^{49}Ti NMR spectra of the 99% ^{13}CO enriched anions.[5,6] These spectra along with the corresponding ^{13}C NMR data provided unequivocal proof for the existence of these anions in solution.

A more recent objective of this research programme has been to examine the reduction of early transition metal halides and related substances by aromatic radical anions at low temperatures as a possible alternative or complement to metal atom vapour syntheses. Chatt, Watson and Davidson were the first to establish the utility of aromatic radical anions (especially of naphthalene) in the synthesis of low valent metal complexes,[7] including $Ru(dmpe)_2(C_{10}H_8)$ where dmpe = $Me_2PCH_2CH_2PMe_2$, and its naphthyl hydride tautomer.[8] Later, in important variations on this theme, Timms'[9] and Wreford's groups[10] employed naphthalenide salts to obtain the first isolated examples of naphthalene and substituted naphthalene complexes of early transition metals directly from their respective halides. Previously, such materials were available only from the interaction of transition metal atoms with naphthalenes.[11,12] Kündig and Timms' pioneering demonstration of the ease with which coordinated naphthalene in $Cr(C_{10}H_8)_2$ and $Mo(C_{10}H_8)_2$ was displaced by carbon monoxide and other small ligands, emphasized the great utility of labile naphthalene complexes in the syntheses of unusual organometallics.[11,13] On the basis of these prior studies, we developed the first useful atmospheric pressure reductive carbonylation synthesis of both $Nb(CO)_6^-$ and $Ta(CO)_6^-$.[14,15] These materials were previously available by only high pressure reactions.[16] It was then proposed that low valent, group 4 carbonyls might be available by similar procedures.[14] At this time we were unaware that the group of Jonas was actively investigating the properties of early transition metal naphthalene complexes obtained via alkali metal naphthalenides.[17] More recently, other groups have appreciated the importance of naphthalenides in the synthesis of unusual early transition metal compounds.[18]

Although early attempts to obtain the previously unknown hexacarbonylmetallates(2−) of titanium, zirconium and hafnium by the same basic procedures used for the niobium and tantalum analogues were totally unsuccessful, in 1984 we were



Scheme 1. Reactions of $Ti(CO)_5(dmpe)$ with various main group nucleophiles.

able to obtain zerovalent titanium carbonyls for the first time by this method.[19] For example, reduction of $(C_5Me_5)MCl_3$ (M = Ti, Zr, Hf) by 4 equivalents of $NaC_{10}H_8$ provided brightly coloured reactive intermediates which function as weakly solvated $(C_5Me_5)M^-$ units. Although the actual structure(s) of these and related intermediates are not yet known, we have spectroscopic and other evidence that strongly suggests the presence of coordinated naphthalene in these materials. They readily absorbed carbon monoxide at low temperature and on warming at atmospheric pressure, to provide moderate to excellent yields of $(C_5Me_5)M(CO)_4^-$, the first class of carbonyl anions known for all three groups 4 elements.[19,20] It is especially noteworthy that prior to this work, all hafnium(0) complexes (a grand total of four!) were prepared from atomic hafnium which was generated in a metal atom reactor.[21,22] Studies on the reactions of these intermediates with a variety of small molecules other than carbon monoxide are presently underway in this laboratory and should help to define their general utility in chemical synthesis.

Neutral phosphine carbonyls of group 4 elements have also been obtained in moderate to good yields by similar procedures. Perhaps the most useful of these is $Ti(CO)_5(dmpe)$, the closest "living relative" of the hypothetical $Ti(CO)_7$. This dmpe complex is an extremely valuable precursor to other zerovalent titanium carbonyls, by virtue of its facile reaction with nucleophiles.[23] Some of the reactions of $Ti(CO)_5(dmpe)$ examined are shown in Scheme 1. Due to the thermal instability of $Ti(CO)_5(dmpe)$, this fluxional, seven-coordinate substance was characterized in solution by ^{31}P and ^{13}C NMR spectra of the 99% enriched ^{13}CO derivative (Figs 1 and 2).

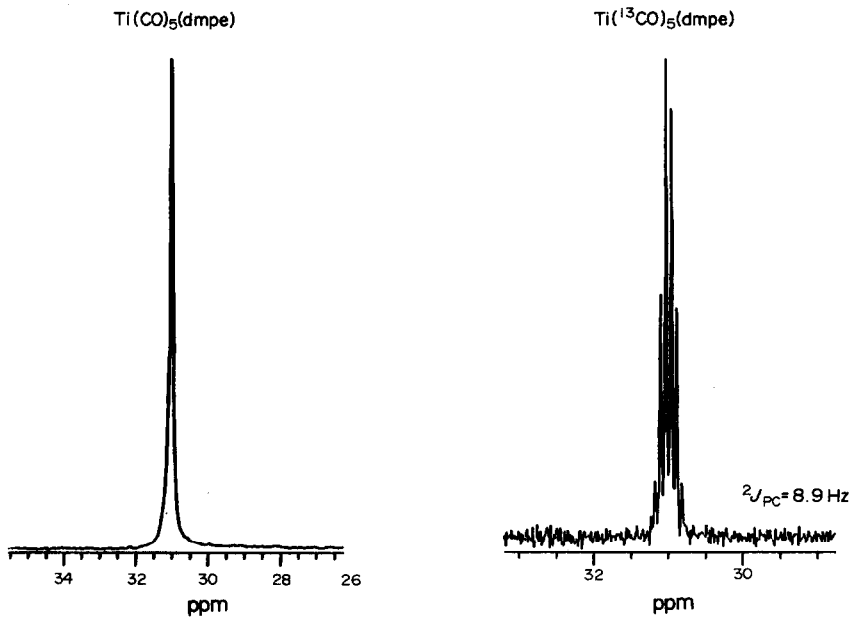


Fig. 1. $^{31}P\{^1H\}$ NMR spectra of $Ti(CO)_5(dmpe)$ and 99% ^{13}C enriched $Ti(^{13}CO)_5(dmpe)$ in THF at room temperature.

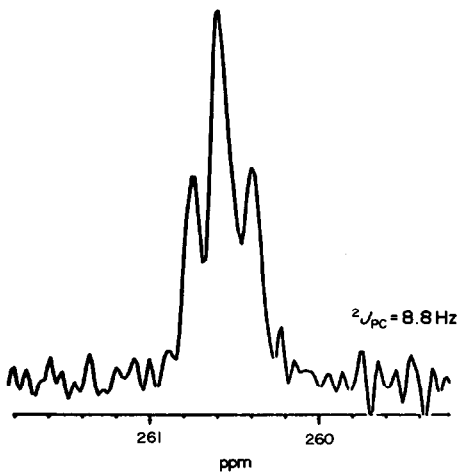

Fig. 2. The $^{31}C\{^1H\}$ NMR spectra of 99% ^{13}C enriched $Ti(^{13}CO)_5(dmpe)$ in THF at room temperature.

While zirconium and hafnium analogues of $Ti(CO)_3(dmpe)_2$ or $Ti(CO)_5(dmpe)$ have not been obtained by this route, phosphine derivatives of the composition $M(CO)_4(trmpe)$, where trmpe is the tripodal ligand 1,1,1-tris(dimethylphosphinomethyl)ethane, have also been prepared by direct reduction of the tetrachlorides of titanium, zirconium and hafnium in the presence of trmpe. These thermally robust materials presently represent the only class of neutral zerovalent metal carbonyls known for all three group 4 elements. Confirmation of the nature of $Zr(CO)_4(trmpe)$ has been provided by an X-ray analysis, the first reported for any Zr(0) carbonyl.[24] The hafnium complex is of particular interest in that is the sole precursor to $Hf(CO)_6^{2-}$ presently known (*vide infra*).

Related research has involved the synthesis and characterization of other new classes of zerovalent titanium carbonyls. For example, seven-coordinate zerovalent titanium carbonyls containing only unidentate ligands, $Ti(CO)_5(EPh_3)_2^{2-}$ (E = Ge, Sn, structurally characterized for Sn), and organoarsine and arylphosphine ligands, $Ti(CO)_3[o\text{-}C_6H_4(AsMe_2)_2]_2$ and $Ti(CO)_4[MeC(CH_2PPh_2)_3]$, respectively, have been prepared for the first time from highly reactive and quite thermally unstable, low valent titanium intermediates, one of which has been characterized as $Ti(CO)_5(PMe_3)_2$ on the basis of ^{13}C and ^{31}P NMR spectra.[25] In other studies, eight-coordinate and formally divalent zirconium and hafnium complexes of the type $M(CO)_4(SnPh_3)_4^{2-}$, $M(CO)_2(dmpe)_2I_2$[26] and $(C_5Me_5)M(CO)_2(dmpe)Cl$ (M = Zr, Hf)[27] have been obtained, where the latter substances are related to $(C_5H_5)Ti(CO)_2(dmpe)H$, the first structurally characterized carbonyl hydride of titanium.[28]

Perhaps, the most significant development in this research on early transition metal carbonyls, however, has been the recent synthesis, isolation and characterization of salts containing $Ti(CO)_6^{2-}$, $Zr(CO)_6^{2-}$ and $Hf(CO)_6^{2-}$.[5,26,29] Noteworthy is the fact that the previously known binary carbonyl dianions of first row transition metals, $Cr(CO)_5^{2-}$ and $Fe(CO)_4^{2-}$, were first prepared over 30 years ago.[30] While no other binary carbonyl of zirconium or hafnium has been reported, the titanium compound may be regarded as a saturated and dianionic derivative of the extremely unstable neutral $Ti(CO)_6$ (dec > −200°C). The latter was prepared by Ozin and co-workers from titanium atoms and observed by matrix isolation spectroscopy.[31] Of crucial importance for the synthesis and isolation of these materials is the the requirement that strong alkali metal ion complexants, such as crown ethers or cryptands, be present during their formation. Weakly solvated alkali metal cations promote decomposition of these dianions to presently uncharacterized substances. By comparison, the isoelectronic anions, $V(CO)_6^-$, $Nb(CO)_6^-$ and $Ta(CO)_6^-$, are thermally stable as unsolvated alkali metal salts at room temperature. Very recently, single crystal, X-ray studies have confirmed the presence of discrete and essentially unperturbed octahedral $Ti(CO)_6^{2-}$, $Zr(CO)_6^{2-}$ and $Hf(CO)_6^{2-}$ units in the $K(cryptand\ 2.2.2)^+$ salts of these materials.[26]

Extensions of this research to the group 3 transition metals, for which no carbonyls are presently known, as well as a general study of the reactivity patterns of these weakly solvated atoms and anions with a variety of small molecules such as dinitrogen, dihydrogen and unsaturated organic species, promises to be a grand adventure. It is also possible that the synthetic methodology developed recently in this group for the synthesis of highly reduced organometallics of the group 4 elements will be of use in the stabilization of unusual materials containing low valent *f*-block elements, an emerging area of chemistry.[32]

Acknowledgements—I wish to express my gratitude and appreciation to all of my co-workers who are listed as joint authors in the references and to the Petroleum Research Fund, administered by the American Chemical Society, and the National Science Foundation for continuing generous support of this research on highly reduced organometallics.

GAS SENSORS BASED ON OXIDES OF EARLY TRANSITION METALS

P. T. MOSELEY* and D. E. WILLIAMS

Materials Development Division, Harwell Laboratory, Didcot, Oxon OX11 0RA, U.K.

Abstract—The conductivities of semiconducting oxides are generally influenced by the chemical reactions of any gas molecules that have access to their surfaces. This phenomenon is exploited in the development of gas sensitive resistors that offer a simple route to the monitoring of atmospheric composition. Material properties may be optimized for this application by adjustment of the stoichiometry of the semiconducting oxide. Oxides of early transition metals are particularly useful in this "tuning" process. Examples are given of the development of two oxides with useful gas response characteristics—one for the monitoring of oxygen, the other for ammonia.

There are widespread requirements for gas sensors that are simple and reliable. Two important categories are the monitoring of oxygen partial pressure in a range of background atmospheres and the detection of small concentrations of reducing gases in a background of air.

The special demand in both cases is usually for *specificity*. The oxygen sensor should respond only to changes in p_{O_2} and not to changes in other parameters (e.g. temperature). The reducing gas sensor is required to respond to the presence of one gas and not to others. Sensors based on the measurement of the atmosphere-dependent resistance of a semiconducting oxide ceramics element are of potential interest for both types of application. Specificity is achieved by engineering an optimum stoichiometry within a stable crystal structure.

This paper describes a group of perovskite-structure materials that, when optimally constituted, offer suitable characteristics for oxygen monitoring and a mixed chromium–titanium oxide that responds selectively to the presence of ammonia in air.

OXYGEN SENSING

Processes affecting the bulk conductivity of semiconducting oxides

The resistance of semiconducting oxides is affected by changes in temperature and by changes in stoichiometry. The conductivity of TiO_{2-x} at high temperature follows the prevailing oxygen partial pressure and this has been proposed as the basis of an oxygen sensor,[1] but there is a significant temperature dependence and this is a serious disadvantage.

Temperature. The generation of charge carriers is a thermally-activated process so that, in general, whether a semiconductor is *n*-type or *p*-type, conductivity, σ, increases exponentially with temperature:

$$\sigma = \sigma_0 \exp -E_A/RT, \qquad (1)$$

where E_A is an activation energy.

Stoichiometry. Oxides of transition metals vary in conductivity according to the oxygen partial pressure with which they are in equilibrium.

Generally at the low extreme of the oxygen partial pressure range (left-hand branch of Fig. 1) the material is *n*-type (σ decreasing with increasing p_{O_2}). Above a transition level of oxygen partial pressure that is strongly influenced by the presence of impurities,[2] the material becomes *p*-type (right-hand branch of Fig. 1).

The slopes of the plot in the *n*-type and *p*-type regions reflect the types of crystal defects that are involved in accommodating the change in stoichiometry. For example, if the principal defect is a doubly charged oxygen vacancy, $V_O^{\cdot\cdot}$, replacing an occupied oxygen site, O^x, then the equilibrium can be written

$$O^x \rightleftarrows V_O^{\cdot\cdot} + \tfrac{1}{2}O_2 + 2e^-, \qquad (2)$$

* Author to whom correspondence should be addressed.

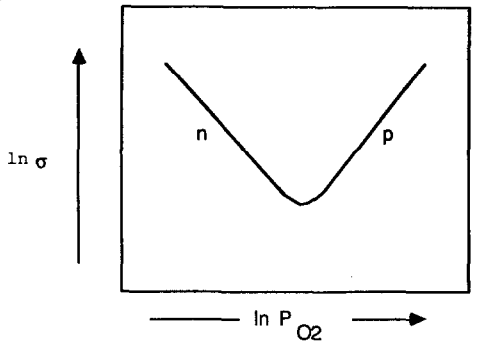

Fig. 1. Isothermal variation of conductivity with oxygen partial pressure for semiconducting oxide.

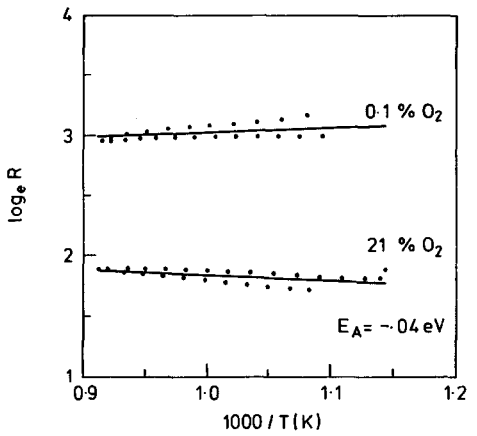

Fig. 2. Conductivity dependence of $BaFe_{0.8}Ta_{0.2}O_3$ on temperature and oxygen partial pressure.

so that the equilibrium constant,

$$K = [V_o^{\cdot\cdot}][e]^2[p_{O_2}]^{1/2}, \quad (3)$$

where [e] is the concentration of electrons.

Now for charge balance $[V_o^{\cdot\cdot}] = 2[e]$, so that eq. (2) becomes

$$K = [2e][e]^2[p_{O_2}]^{1/2} \quad (4)$$

and hence $[e] \propto p_{O_2}^{-1/6}$, defining the slope of the *n*-type part.

Thus the full expression for the conductivity of a transition metal oxide is

$$\sigma = \sigma_o \exp(-E_A/RT)p_{O_2}^{1/N}, \quad (5)$$

where the value of N is -6 for the case of doubly charged oxygen vacancies. Other types of defect lead to other values of slope.[3]

Now in general, as the temperature is raised at a fixed oxygen partial pressure then oxides of transition metals lose oxygen and, if they are *p*-type, their conductivity will tend to decrease. This effect is opposite to the thermal promotion of charge carriers and the possibility arises of doping the transition metal oxide so that the two effects may cancel and the effect of temperature changes will be to leave conductivity unchaged.

Two points should be made. First, if such a balance of thermal effects is achieved it need not alter the effect of changes in oxygen partial pressure at a fixed temperature. Second, such a balance is only possible for *p*-type oxides, where the thermal activation of charge carriers and the stoichiometry effect are opposed.

The combination of an apparent activation energy for conduction of near zero with a significant oxygen partial pressure dependence has been achieved in a group of oxides with the perovskite crystal structure. The materials, which were discovered during a programme of development of vehicle exhaust sensors funded by Lucas Industries plc, are based on barium (or strontium) ferrate doped with certain early transition metals.[4]

Figure 2 clearly shows how the conductivity of $BaFe_{0.8}Ta_{0.2}O_3$ is strongly dependent on oxygen partial pressures but is almost invariant with temperature. The magnitude of the oxygen response and the observed activation energy both vary with the fraction of substitution of tantalum for iron, as shown in Table 1.

The transition to a regime of significant activation energy is not sharp but occurs as the composition moves towards a regime where iron(IV) is no longer required, based on a complete oxygen stoichiometry in the structure.

Very low activation energies are sustained to higher values of x where the ferrate is doped with four-valent ions (Hf^{4+}, Zr^{4+} or Ti^{4+}) rather than tantalum.

REDUCING GASES

Processes affecting the surface conductivity of semiconducting oxides

The oxygen sensitive resistor based on doped barium or strontium ferrates functions due to a

Table 1. Activation energy in air and oxygen sensitivity as a function of composition (the value of x in $BaFe_{1-x}Ta_xO_3$)

	Value of x			
	0.1	0.2	0.3	0.4
Activation energy, E_A[a]	−0.4	−0.4	0.03	0.13
Oxygen sensitivity, N[a]	5.0	5.0	5.9	0.1

[a] Refer to eq. (5).

full equilibration of the stoichiometry of the oxide with the prevailing oxygen partial pressure. This requires an operating temperature in the region of 700–800°C in order to achieve useful response times.

At temperatures of 500°C and below, atmosphere-dependent conductivity changes can be measured that depend solely on surface reactions. The density of charge carriers in the near-surface region of the oxide can be influenced by either direct chemisorption of the target gas or by the interaction of molecules of the target gas with a chemisorbed species (usually an oxygen ion) that is already in place, e.g.

$$2CO + O_2^- \rightarrow 2CO_2 + e^-,$$

where the electron is released by the reaction to return to the conduction band.

Such processes provide a means for detecting reducing gases in air with great sensitivity. The first generation of sensors of this type, based on tin dioxide, can detect methane, carbon monoxide and several other oxidizable gases at concentrations of a few parts per million in air. A disadvantage, however, is that such sensors are inherently non-specific.

In fact, many semiconducting oxides exhibit the facility to catalyse gas reactions at their surfaces and very few of them show the same generality of response to different gases that characterizes the resistance dependence of tin dioxide. Doping of robust crystal structures with suitable cations can often provide the route to an interesting pattern of gas responses by altering electronic and catalytic properties.

Titanium dioxide, like tin dioxide, behaves as an *n*-type semiconductor, offering resistance decreases when reducing gases are introduced to an air ambient. The incorporation of 10% of chromium, which is readily accommodated by the formation of crystallographic shear planes,[5] alters the gas response to that of a *p*-type material. As shown in Fig. 3, $Ti_{0.9}Cr_{0.1}O_{2-x}$ increases in resistance when exposed to small concentrations of carbon monoxide, hydrogen, ethane and ammonia, but does not respond to methane.

A more specific response results from the introduction of 10% of titanium into the robust rhombohedral structure of Cr_2O_3. Figure 4 shows that, when exposed to a sequence of different reducing gases at low concentrations in air, $Cr_{1.8}Ti_{0.2}O_{3-x}$ responds significantly only to ammonia.[6]

Doubtless, further work with other semiconducting oxides will reveal many more materials with specific responses for other gases, and thus we may expect that, in future, the powerful simplicity of the gas sensitive resistor will be exploited far more than it has been with tin dioxide devices.

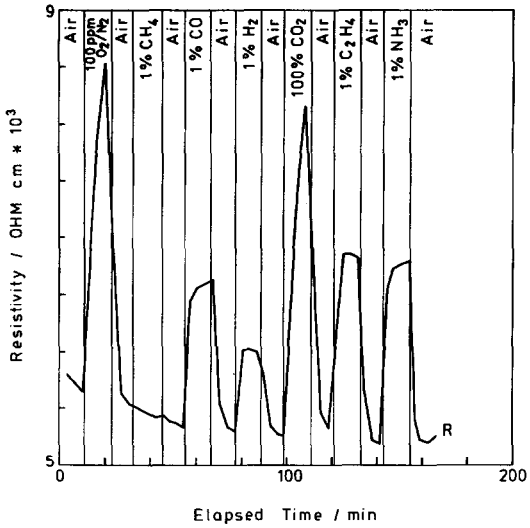

Fig. 3. Resistance responses of $Ti_{0.9}Cr_{0.1}O_{2-x}$ exposed to a sequence of reducing atmospheres and low concentrations of reducing gases in air. An air purge separated the exposures of the material to the different test atmospheres. The resistance increases in the test gases are characteristic of a *p*-type material.

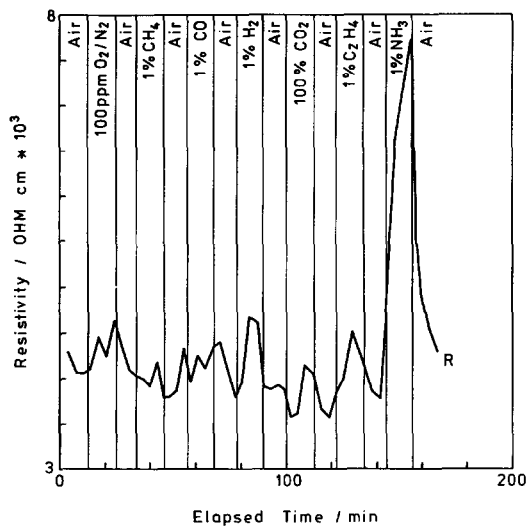

Fig. 4. Resistance responses of $Cr_{1.8}Ti_{0.2}O_{3+x}$ exposed to the same sequence of atmospheres as in the experiment described by Fig. 3.

SUMMARY

We may conclude that adjusting the stoichiometry of semiconducting oxides provides the route to materials with a wide variety of catalytic and electronic properties that will be extremely valuable in the development of specific gas sensors.

Further, the similarity between the mode of operation of such sensors and the mechanisms of heterogeneous catalysis may result in a far wider application of "tailor-made" oxide surfaces.

STRUCTURE AND BONDING IN THE CHALCOGENIDES OF THE EARLY TRANSITION METALS

D. W. BULLETT

School of Physics, University of Bath, Claverton Down, Bath BA2 7AY, U.K.

Abstract—Results of electronic structure calculations are reported for a wide range of chalcogenide compounds of the early transition elements, concentrating on those features relevant to metal–metal bonding and low dimensionality.

In the last 20 years, our knowledge and understanding of the electronic structure and properties of the chalcogenides of transition metals have advanced enormously,[1–3] and any survey of band structure calculations would now require a substantial monograph to do the subject justice. There are a great variety of compositions and structures, even within the binary family of compounds. In order to restrict the discussion here, we will concentrate our considerations on a few examples which display two related phenomena that recur in many of these materials: low-dimensional behaviour and metal–metal bonding.

(1) MX COMPOUNDS

The stoichiometric monochalcogenides exhibit metallic properties and occur most commonly in the two structure types, NaCl (e.g. ScS, YS, LaS and all rare-earth monosulphides, ZrS), or NiAs/MnP (e.g. TiS, Vs, NbS). Excluding MnP, the MX structure types consist of different sequences of alternating metal and non-metal close packed layers: ABCABC . . . for the NaCl type, ABACABAC . . . for the NiAs type (with the metal in the A positions), or ABAB . . . for the WC-type structure of HfS. The occurrence of the NiAs sequence demonstrates the significance of metal–metal interactions between layers: while each X is trigonal-prismatically coordinated by six M atoms, each M is octahedrally coordinated by six X atoms, with an additional pair of M atoms above and below. For example, in TiS the six metal–metal distances within the layer are 3.30 Å, and the two out-of-layer distances are 3.19 Å. Comparing these with the atomic separation in the pure metal (2.95 Å), it is clear that there must be a substantial degree of metal–metal bonding.

In the first column of transition metals the *d*-level lies high relative to the chalcogen *p*-level, ionic contributions predominate, and the Madelung sum favours the rocksalt structure. For more electron-rich transition metals, the competing demands of metal *d*–metal *d* and metal *d*–non-metal *p* covalent interactions act to stabilize some variant of the NiAs structure. The signature of the M—M interactions in the electronic structure near the Fermi level may be seen in band structure calculations reported elsewhere.[4–6] It is perhaps not too surprising that electronic effects drive nearly all "NiAs-type" compounds (even including NiAs itself) into more complicated superstructures as the temperature is lowered, nor that the details of the transition should depend sensitively on composition, especially when this moves off stoichiometry; motion of the metal substructure distorts the lattice of M atoms into a network of criss-crossing zigzag chains, such as those that typify MnP. For higher *d* occupations rocksalt-type structures are again more stable (e.g. the d^5 compounds MnS and MnSe, but not MnTe which prefers a high-spin ground state and the NiAs structure).

(2) MX_2 COMPOUNDS

The dichalcogenides of the early transition elements form a fairly coherent family of quasi-two-dimensional materials. Again the underlying structure is of a sequence of hexagonally-close-packed layers of either metal (M) or non-metal (X) atoms, but now the layer sequence is XMX XMX . . . , and the large separation between the outer X layers of adjacent sandwiches leads to strongly anisotropic properties. A rich variety of stacking sequences occurs in different compounds of the family, and for a detailed survey we refer the

reader to Wilson and Yoffe.[7] Within a single MX_2 sandwich, the coordination of ligands about the central metal atom may be either octahedral (e.g. TiS_2) or trigonal prismatic (e.g. MoS_2). Madelung terms favour the octahedral arrangement, since this avoids anion positions falling one above another, and the more ionic compounds such as the group IV family all occur in this coordination. Figure 1 illustrates the calculated band structure and density of states[8] that typify two of these materials, TiS_2

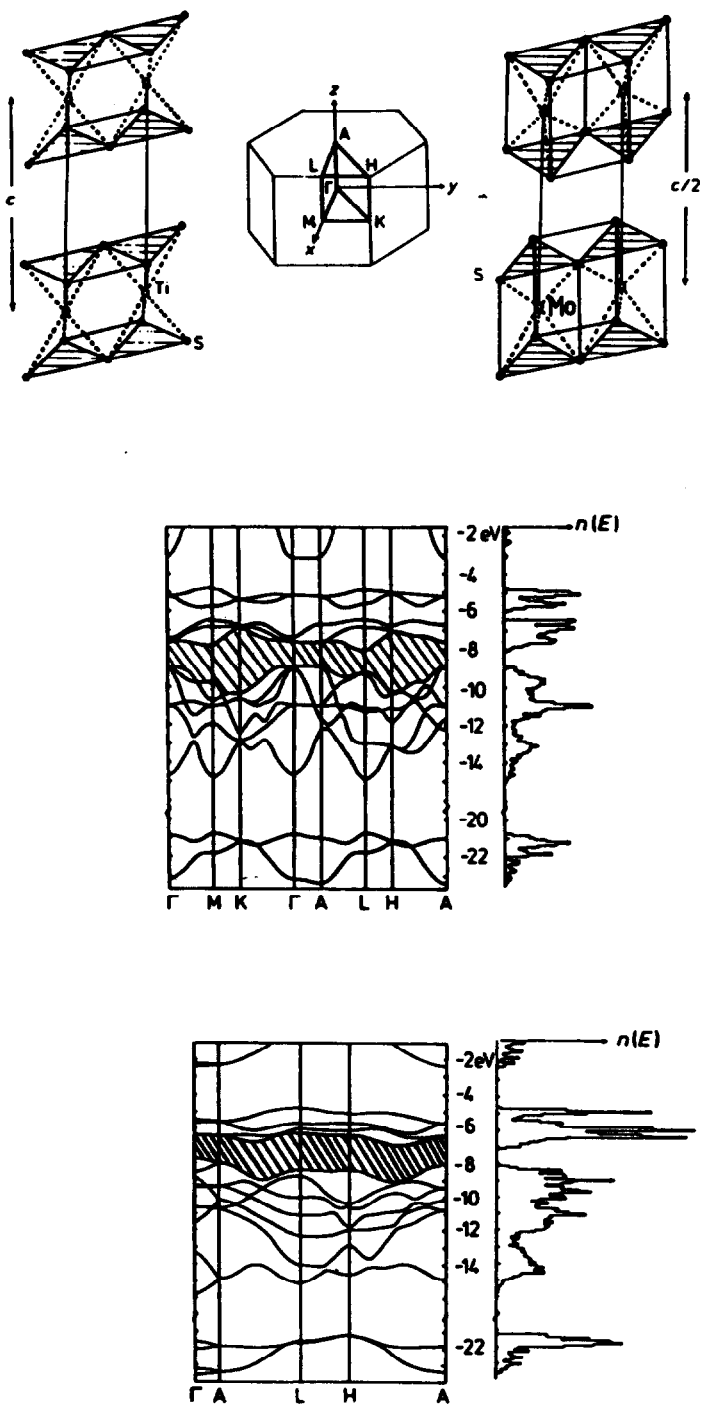

Fig. 1. Coordination of chalcogens around metal atoms in the IT—TiS_2 and 2H—MoS_2 structures, and the resulting electronic structure[8] calculated for these semiconducting compounds. The standard notation for Brillouin zone symmetry points is also shown.

and MoS_2. In TiS_2, as might be anticipated, a semiconducting *p–d* gap separates the six "sulphur *p*-bands" from the five "metal *d*-bands", which themselves split in the octahedral ligand field into t_{2g} and e_g sub-bands; formally these group IV dichalcogenides are d^0 filled *p*-band structures, although because of overlap between *p*- and *d*-bands not all are semiconductors (e.g. $TiTe_2$, $TiSe_2$, $HfTe_2$). The group VI (d^2) dichalcogenides (with the exception of WTe_2 and β-$MoTe_2$) adopt the trigonal prismatic coordination, since in this environment the t_{2g} triplet splits further into a lower singlet (sometimes labelled the "d_{z^2}" band) and upper doublet; complete occupation of the lower band stabilizes the trigonal prismatic coordination in d^2 compounds such as MoS_2 (Fig. 1). Electronic structure investigations of edges and defects in the structure may be particularly significant from the point of view of understanding the active sites for hydrogenation catalysis over MoS_2 and WS_2.

Bridging the two columns of the periodic table, the d^1 dichalcogenides of the group V elements display both coordinations, and some individual members (e.g. TaS_2, $TaSe_2$) can occur in either arrangement, even in successive layers of the same crystal structure. Successive sandwiches are separated by wide van der Waals gaps, and the subtle balance between different contributions to the weak inter-layer interactions lead to a rich variety of different stacking sequences; in some dichalcogenides the repeat distances along the *c*-axis can be many layers. In addition to their interest for the strongly anisotropic elastic, optical, and electrical properties common to all the layer structure dichalcogenides, the group V compounds have been very extensively investigated because of the phase transitions which result from their quasi-two-dimensional metallic nature. Detailed discussions of the subtle features in the electronic structure which drive these charge–density–wave/periodic lattice distortions may be found elsewhere.

Many kinds of atoms and molecules have been inserted into the van der Waals gaps between the MX_2 layers, and this type of intercalation provides an interesting tool for varying structural, magnetic and transport properties. Yamasaki *et al.*[9,10] recently reported some self-consistent (but non-magnetic) band structure calculations for intercalated iron and chromium atoms in TiS_2.

The group VI ditellurides show deviations from the simplest band model, which predicts semiconducting behaviour due to trigonal prismatic crystal-field splitting of the filled non-bonded d_{z^2} orbital, and a detailed interpretation of their electronic structure and crystallography has recently been reported.[11] For WTe_2 and one form of $MoTe_2$, the metal atom is displaced from the centre of an *octahedron* of tellurium atoms, and metal–metal chains with bond lengths only slightly longer than the elemental metals run along the layers. The enhanced Madelung term for this configuration compensates for loss of the lone d_{z^2} band, and results in semi-metallic properties.

(3) MX_3 COMPOUNDS

The crystal structures of the trichalcogenides of groups IV and V transition elements can again be viewed in terms of linked MX_6 trigonal prisms, but this time instead of sharing rectangular side-faces to form two-dimensional layers as in MoS_2, they are linked by sharing triangular end-faces to form MX_3 chains (Fig. 2). Interactions between the chains are weaker in one direction than the other, so that in their properties these compounds display aspects of both one- and two-dimensional behaviour. In all cases there is strong X—X pairing along one side of each triangular face of the prism. This causes the group IV compounds (with the exception of $ZrTe_3$, where there is slight semi-metallic *p–d* band overlap) to be semiconductors: bands formed from antibonding combinations of the paired X σ *p*-orbitals are forced up into the same unoccupied energy range as the metal *d*-bands, giving a formal valence configuration $M^{4+}X^{2-}(X_2)^{2-}$. The group IV trichalcogenides form an isostructural family, from TiS_3 right through to $ThTe_3$, with the slight complication that two variants exist (often denoted **A** and **B**) in the relative orientation of the chains. Their electronic structure,[3,12] and associated optical, electrical transport and vibrational properties have been studied in detail, along with their intercalation reactions with alkali metals such as lithium in connection with applications as solid-state cathodes.

The extra *d*-electron in the group V trichalcogenides, and the consequent tendency for metal–metal pair bonding, causes a variety of structural distortions and phase transitions. The simplest case is NbS_3, where complete metal pairing takes place along the chain axis, to give a doubling of the intrachain lattice parameter.[13] Axial displacements of 0.16 Å from the centres of the coordination prisms give Nb—Nb bonding distances of 3.04 Å. The bridging triangle of sulphur atoms is pushed outwards at one end of the prism and drawn in at the other, in an attempt to conserve M—S bond lengths; anion pairs are fully retained in the structure, with S—S distances of 2.05 Å in NbS_3, compared to 2.09 Å in ZrS_3. As in the group IV structure, unpaired sulphur atoms on neighbouring chains cap two of the rectangular faces of each

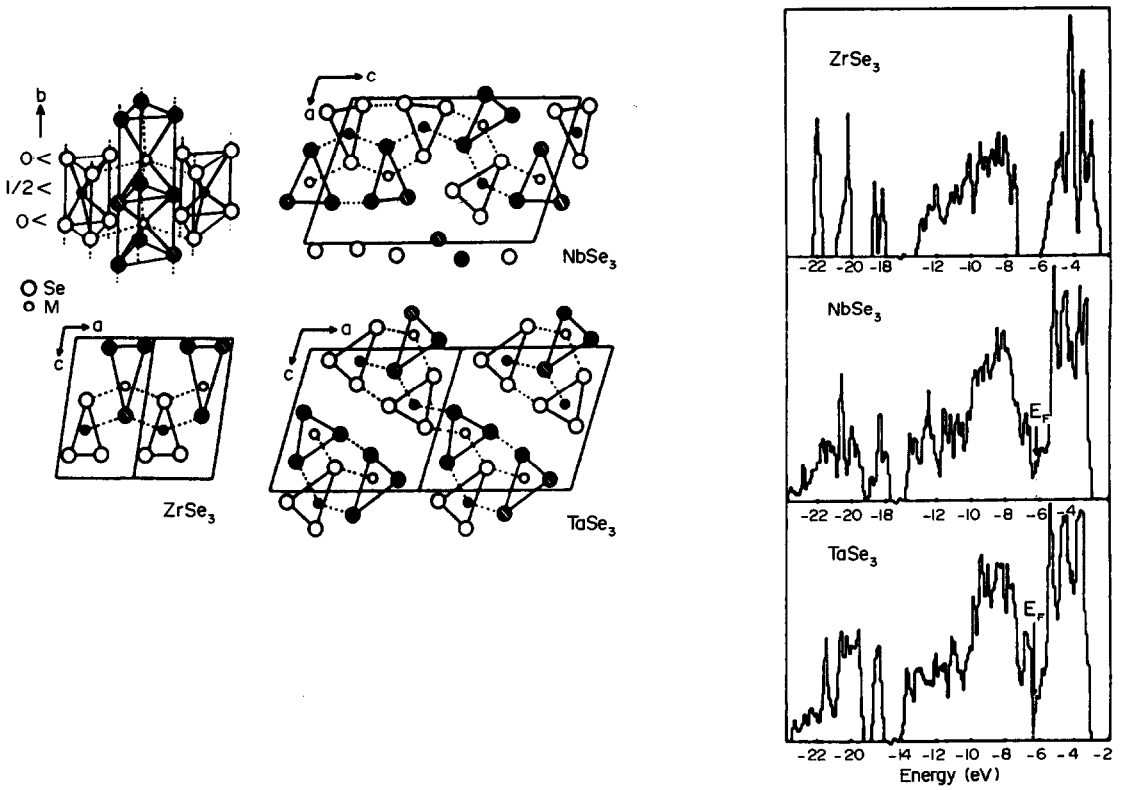

Fig. 2. Atomic arrangements and calculated electron densities of states[15] in some transition metal triselenides MSe_3, showing the stacking of MSe_6 prisms along the b-axis (open atoms at 0, shaded atoms at $\frac{1}{2}b$).

prism to provide a weak bonding of the chains into two-dimensional layers, and overall eight-fold coordination of each metal atom. Figure 3 illustrates the crystal structure and associated density of electron states,[14] with many features reminiscent of $ZrSe_3$, plus the added feature of well-defined Nb—Nb bonding states forming the highest occupied states. The sulphur s-bands again split roughly into three sub-bands—the bonding and anti-bonding s-states of the S_2 pairs, separated by the non-bonding s-state of the third atom in the S_3 triangle—but because of the lower crystal symmetry the distinction is less precise than in $ZrSe_3$, and the non-bonding and antibonding sub-bands of NbS_3 overlap. Eight p-bands per formula unit again form the main valence band, now followed in order of increasing energy by the metal–metal bonding states. A calculated energy gap of 0.5 eV separates

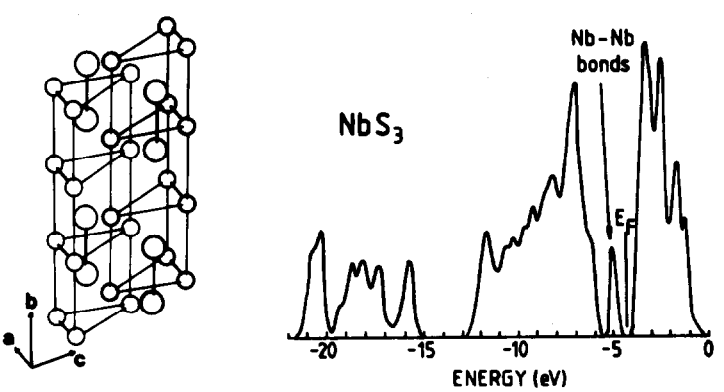

Fig. 3. The NbS_3 structure and the calculated density of states,[14] showing how Nb—Nb pairing along the b-axis leads to metal–metal d-bonding states just below the Fermi level.

these from the unoccupied *d*- and *po**-conduction states; thus the calculated distribution of states accounts naturally for the diamagnetic semiconducting properties and black needle-like appearance of NbS_3 crystals.

In other group V trichalcogenides (and at enhanced pressures and temperatures even in NbS_3), there are different degrees of coupling between the one-dimensional chains and different types of chain within each unit cell. Typical examples are provided by $TaSe_3$ and $NbSe_3$. $TaSe_3$ contains four chains per unit cell, two with strong (2.58 Å) and two with weak (2.90 Å) Se—Se pairing; the weaker Se—Se bonding is compensated by interchain Se—Se distances of only 2.65 Å. The calculated electron density of states for this arrangement of chains[15] shows an energy overlap between *p*- and *d*-bands, with the Fermi energy EF lying in a deep, but non-zero, minimum in the density of states: in $TaSe_3$ some of the states which would otherwise have been Se—Se antibonds within a chain become Se—Se or Ta—Se bonding states between chains, providing the required total of 17 valence bands per pair of MX_3 units (compared to the eight valence *p*-bands per MX_3 unit in $ZrSe_3$). The band structure shows little reason to expect incipient M—M pairing along the chains, nor is there any experimental evidence for a phase transition between 4 and 700 K at atmospheric pressure.

The $NbSe_3$ structure contains six chains per unit cell, in an arrangement most easily recognized as the $TaSe_3$-type blocks of four chains, now interconnected through pairs of tight $ZrSe_3$-type chains. $NbSe_3$ is thus left with two spare electrons per unit cell (six MX_3 units) to place in the bottom of the conduction *d*-band. These lowest *d*-bands rise very rapidly as **k** moves away from the origin along the chain direction (because of a strong d_{z^2} component along this *b*-axis), but are almost dispersionless in directions normal to the chain axis.[15,16] The result is a highly anisotropic metal, showing incommensurate phase transitions and extraordinary non-linear transport properties because of the very weak pinning of these structural distortions to the underlying lattice.[17] At 144 and 59 K, periodic lattice distortions eliminate large properties of the free carriers and the resistivity increases sharply, but even very modest electric fields allow these distortions to slide through the lattice and the resistivity to drop back to its former value. There also exist ternary compounds, such as $FeNb_3Se_{10}$, with a similar kind of one-dimensional metallic band structure but less extreme properties, because the periodic distortions along the chain are now pinned by effects of disorder.

(4) $NbTe_4$, $ZrTe_5$

Further examples of quasi-one-dimensional materials are provided by the group IV transition metal pentatellurides, $ZrTe_5$ and $HfTe_5$, and the group V tetratellurides, $NbTe_4$ and $TaTe_4$, though in none of these materials are the transport properties as spectacularly anomalous as in $NbSe_3$ and TaS_3. The pentatelluride structure preserves the MX_3 trigonal columns characteristic of $ZrSe_3$, but instead of being linked directly into pairs, and then layers, of columns as in the trichalcogenides, the MX_3 columns are now linked through intermediate "Te_2" chains (Fig. 4). This arrangement retains the coordination of eight tellurium atoms around each metal atom: six tellurium neighbours lie at the corners of the triangular prism and two lie outside the rectangular faces. Te—Te pairings are slightly stronger within prisms (2.76 Å) than in the intervening zigzag chains (2.91 Å), the two distances

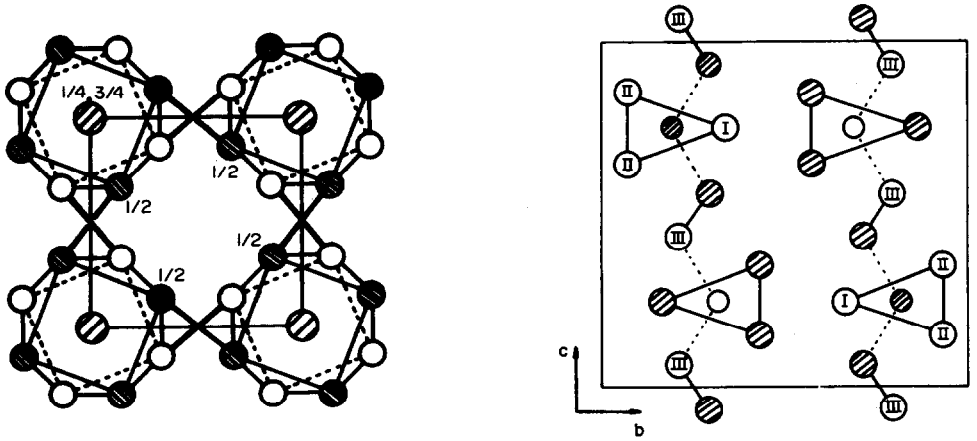

Fig. 4. The MTe_4 and MTe_5 crystal structures.

falling either side of the corresponding single bond distance in elemental tellurium (2.835 Å). Interlayer Te—Te contacts exceeding 4 Å illustrate that interactions between layers are of only the weak van der Waals type. Superficially we might have expected $ZrTe_5$ to be an anisotropic diamagnetic semiconductor: each zirconium donates two electrons to each Te—Te pair and two to each lone tellurium atom, while the zigzag chains of tellurium atoms (bond angle close to 90°) retain the normal p^4 configuration of elemental tellurium. In fact electronic structure calculations[18,19] confirm a semiconducting gap, 1 eV separating the highest occupied from lowest unoccupied bands over most of the Brillouin zone, but interlayer coupling produces a semi-metallic band crossing one edge of the Brillouin zone. In this case there is no intrinsic electron excess, the bands at the Fermi level are not one-dimensional in the sense of $NbSe_3$, and there is much less reason to expect any kind of charge–density–wave instability.

Such instabilities probably do occur in $NbTe_4$ and $TaTe_4$, however. Here again the transition metal atoms lie in one-dimensional columns, but now the repeat units are distorted-square-antiprisms, MX_8. All the telluriums are paired, but the pairing occurs between columns rather than within columns. Thus these are formally d^1 compounds analogous to NbS_3, and one might have expected some form of M—M pairing along the chains, perhaps leading to semiconducting properties. In fact the calculations show that the three-dimensional coupling between MTe_4 columns is too strong to allow an energy gap to open.[20] The superlattice spots seen in X-ray and electron diffraction are probably correctly interpreted in terms of charge–density–wave instabilities, which are unusual in existing even at room temperature.

Space restrictions prevent any more than the briefest mention of other families of metal–metal bonded chalcogenides of the early transition metals. Perhaps the most extensive group that we have omitted are those structures based on the M_6X_8 octahedral unit: the Chevrel series of (primarily ternary) compounds, with their unusual superconducting properties and electronic structures that depend sensitively on the distortions of the Mo_6X_8 unit brought about by the presence of a third component in the lattice and by deviations from stoichiometry.[21,22] Full valence satisfaction of the isolated M_6X_8 cluster would require 42 electrons to be supplied by the six metal atoms (16 are required to fill the chalcogen p-shells, and a further 24 to form M–M bonding states along the 12 edges of the octahedron), and most of the Chevrel compounds conduct only as a result of their intrinsic electron deficit.

The unusual rhenium telluride structure provides an appealing example[23] of a semiconducting compound composed of a quasi-rocksalt array of $[Re_6Te_8]^{2+}$ and $[Te_7]^{2-}$ composite ions, while in $TlMo_3Se_3$ the same Mo_6S_8 octahedral units condense by sharing opposite Mo_3 triangular faces into a one-dimensional metal.[24,25]

Abstract—Inorganic syntheses starting with the tetrathiometallates of molybdenum, tungsten, vanadium and rhenium produce new homonuclear transition metal sulphide (TMS) complexes and clusters by utilizing internal redox processes. The resultant molecular structures often contain features or fragments that resemble those in TMS solids. The homonuclear complexes serve synthetically as excellent ligands, particularly to low-valent organometallic metals. The resulting heteronuclear TMS clusters serve as precursors to TMS solids that are active hydrodesulphurization catalysts. Moreover, the same reactions that lead to the heteronuclear TMS clusters allow decoration of the edges of preformed MoS_2 catalysts, leading to active catalytic materials.

Transition metal sulphide (TMS) solids have remarkable structural and electronic structural characteristics. These are manifested in such interesting phenomena as metallic conductivity,[1] superconductivity,[2] semiconductivity,[3] battery electrode behaviour,[4] photoelectric effects,[5] intercalation reactions,[6] lubrication properties[7] and catalysis.[8–11] Attempts to understand and control these properties have led to significant technological advances. In particular, many studies have shown that variation in synthesis and the resultant structural subtlety of particular TMS systems exerts a profound influence on physical and chemical properties. For catalytic function, significant control of activity and specificity can be achieved by the controlled synthesis of TMS solids. In this paper we discuss how molecular systems, TMS complexes and clusters, can lead either directly as precursors or indirectly through novel methodology, to new TMS solid catalysts.

We first discuss the synthesis of homo- and heteronuclear complexes and clusters and the systematization of methodology for their planned assembly. Many of the TMS complexes and clusters display structural features that resemble those of related solid-state systems. Moreover, these complexes/clusters decompose thermally into active Mo—S and Co—Mo—S catalyst systems. Furthermore, since the molecular reactivity may resemble that of the solid surfaces, reactions of clusters may be used as models for reactions at surfaces of TMS solids. Such reactions lead to interesting new catalytic materials.

MOLECULAR SYNTHESIS AND STRUCTURE

The tetrathiometallate anions have proven to be useful starting points for the preparation of more complex molecular TMS systems.[12–18] We illustrate the reactivity of MoS_4^{2-} in Scheme 1. The reaction of MoS_4^{2-} with RSSR is instructive as it involves the reduction of molybdenum(VI) to molybdenum(V) induced by the external oxidant RSSR.[15,16] Internal redox processes involving electron transfer from sulphur to molybdenum are responsible for this synthetically useful mode of reactivity and illustrate the closeness of sulphur and molybdenum orbital energy levels.

WS_4^{2-} reacts in a similar manner to MoS_4^{2-} but, as tungsten is more difficult than molybdenum to reduce, the internal redox processes are less common and the chemistry to date is less extensive.[17] Although VS_4^{3-} and ReS_4^- have been less investigated than the group VI tetrathiometallates, their chemistry promises to be extensive. When VS_4^{3-} reacts with the organic disulphide of a dithio-

Scheme 1. Reactions in the Mo—S system.

carbamate ligand, e.g. the thiuram disulphide, $(^tBu)_2NC(S)S_2(S)CN(^tBu)_2$, the novel structure shown in Fig. 1 occurs.[18] The $V_2(\mu\text{-}S_2)_2^{4+}$ core has dimensions virtually identical to those in the vanadium mineral patronite, VS_4. The reaction of ReS_4^- with thiuram disulphide gives the dinuclear complex $Re_2S_2(dtc)_4$, which in the *meso* stereoisomer has a layered structure with a bis(sulphido)-bridged bioctahedral structure, as shown in Fig. 2. The structure contains a strong Re—Re bond and is reminiscent of the layered distorted octahedral structure of ReS_2.

The ions $Mo_2S_{12}^{2-}$ [19] and $Mo_3S_{13}^{2-}$ [19] have also proven to be useful starting materials (Scheme 1). The trinuclear cluster, $Mo_3S_4(edt)_3^{2-}$ (formed from $Mo_3S(\mu_2\text{-}S_2)_3(S_2)_3^{2-}$) has the layered S—Mo—S structure[20] shown in Fig. 3, which is reminiscent of the layered structure of MoS_2. Clearly, some of the molecular species have *core* structures that are reminiscent of the structures known to be present in TMS solids. A recent spectacular example of this occurrence is the synthesis of the $Mo_6S_8^{4-}$ core structure of the Chevrel phases.[21]

In addition to the structural similarity between the clusters and solids, there may be analogous behaviour in reactivity as well. For example, many layered TMS structures such as MoS_2 can be stoichiometrically inexact, with MoS_{2-x} and MoS_{2+x}

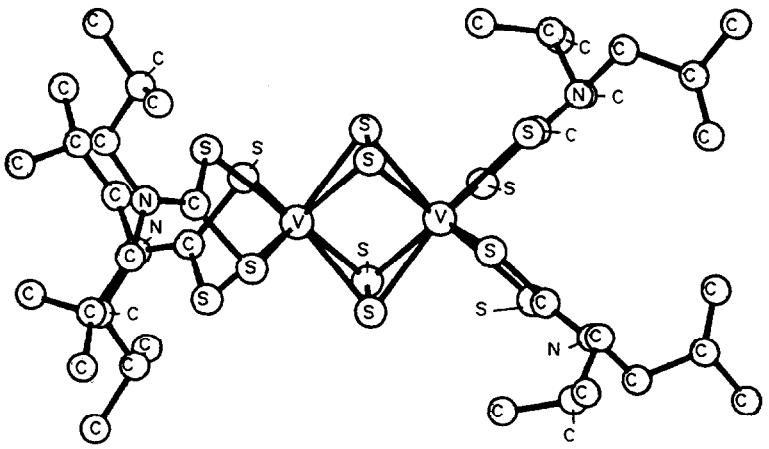

Fig. 1. The structure of $V_2(\mu\text{-}S_2)_2[S_2CN(^tC_4H_9)_2]_4$.

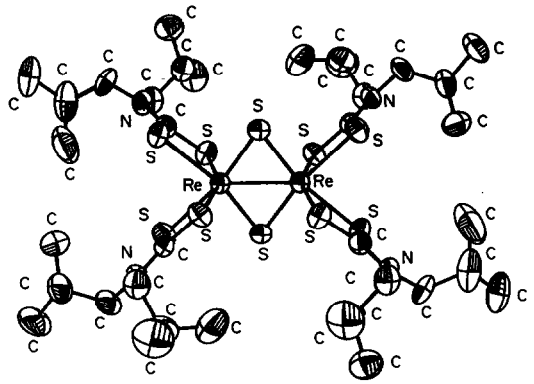

Fig. 2. The structure of $Re_2S_2[S_2CN(^iC_4H_9)_2]_4$.

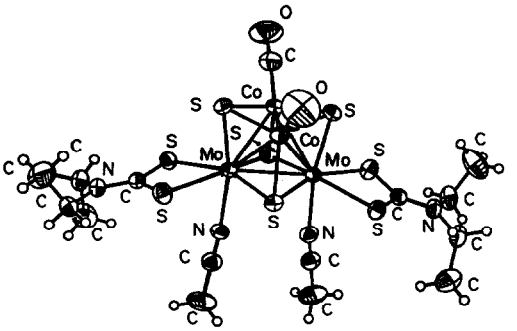

Fig. 4. The structure of $Mo_2Co_2(\mu_3\text{-}S)_4[S_2CN(C_2H_5)_2]_2(CO)_2(CH_3CN)_2$.

stoichiometries both being possible depending upon the mode of preparation and treatment. $Mo_3S_4(edt)_3^{2-}$ displays related behaviour, being easily and reversibly converted to sulphur-rich $Mo_3S_7(edt)_3^{2-}$ by treatment with elemental sulphur.[20] The $Mo_3S_7(edt)_3^{2-}$ species can be converted back to $Mo_3S_4(edt)_3^{2-}$ by sulphur-atom extracting reagents such as CN^- or $P(C_6H_5)_3$.[20] The $Mo_3S_4^+$ core structure can be thought of as sulphur poor, while the $Mo_3S_7^{4+}$ core structure can be viewed as a sulphur-rich analogue of an MoS_2 surface site. The presence of bridging disulphide ligands in the $Mo_3S_7^{4+}$ core suggests that such ligands should be considered as candidate surface species on the edges of MoS_2.

The homonuclear mono-, di- and trinuclear clusters serve as building blocks for the synthesis of heteronuclear clusters. Molecular orbital studies reveal that MoS_4^{2-} and the $Mo_2S_4^{2+}$ core structure should each serve as donor–acceptor ligands, bonding most strongly to low-valent metals.[22,23] MoS_4^{2-} is a versatile bidentate ligand which binds to many transition metals[23] including low valent cobalt where the ion $Co(MoS_4)_2^{3-}$ is formed.[24,25] The $Mo_2Co_2S_4^{2+}$ core cluster, which contains the fully metal–metal bonded thiocubane structure shown in Fig. 4, is formed by reaction of the $Mo_2S_4^{2+}$ core with $Co_2(CO)_8$.[26] This type of reactivity can be exploited in the reactions of solids.

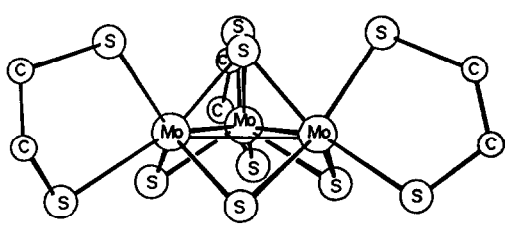

Fig. 3. The structure of $Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3(S_2C_2H_4)_3^{2-}$ in its tetraethyl ammonium salt.

FROM PRECURSORS TO SOLID CATALYSTS

MoS_2 is the TMS phase most closely involved in hydrotreating catalysis, including the industrially important hydrodesulphurization of petroleum feedstocks. In commercial practice, MoS_2 is usually supported on alumina and promoted by nickel or cobalt.[8,9] It has been shown that the properties of MoS_2 formed thermally are dependent on its mode of preparation.[27] Moreover, it is known that incorporation of the usual promotor metals, cobalt or nickel, into the precursor leads to the formation of active catalysts.[28,29]

Discussion of the mechanism of TMS catalysis and of the specific mechanism for promotion is beyond the scope of this article. Suffice it to say that an intimate contact between Mo—S and either Ni—S or Co—S functionalities seem to be implicated. In particular, a so-called Co—Mo—S phase has been suggested as being responsible for the promotion of HDS activity.[30] Mechanistically, this promotion effect could be due to a bridging sulphur in a Co—S—Mo unit, which has a binding energy intermediate between that in Mo—S—Mo and Co—S—Co.[31] This intermediate binding energy for sulphur in the Co—S—Mo structure may be necessary to allow effective binding and facile release of sulphur, thereby maximizing catalytic ability.

Since intimate connection of the promotor metal and molybdenum may be required for optimal catalysis, it seemed appropriate to attempt the use of molecular precursors in which the cobalt and molybdenum are covalently bound in the same precursor molecule. In particular, various salts of $Co(MoS_4)_2^{3-}$ and $Ni(MoS_4)_2^{2-}$ are found to be effective precursors of highly active hydrodesulphurization catalysts.[28,29] Likewise, the $Co_2Mo_2S_4^{2+}$ thiocubane cluster, upon thermal decomposition, forms an active hydrotreating

catalyst.[32] Related clusters have been placed on supports where they show interesting catalytic properties.[33,34]

MOLECULAR APPROACHES TO SURFACE CONTROL

The "surface" of MoS_2 that is important in catalysis is the "edge", rather than the close-packed sulphide basal plane. Unfortunately, the detailed structural nature of the edge is likely complex and is as yet unknown at atomic resolution. Therefore, any rendition of the surface is imprecise and necessarily speculative. A structure showing some of the possible surface species is given in Fig. 5. The presence of terminal or bridging sulphide, disulphide and polysulphide ligands is included to define some of the possibilities. Structures containing S—H or Mo—H links, possible under hydrogenating conditions, are omitted from consideration.

The hypothesized presence of surface terminal and bridging sulphido groups suggests that the surface could react in a manner similar to molecular species containing such units. This appears to be the case. For example, reaction of MoS_2 with $Co_2(CO)_8$ leads to rapid CO evolution and "decoration" of the edge of the layered MoS_2 structure. The use of low-valent, organometallic complexes is suggested by the reactivity of similar low-valent organometallics with molecular complexes containing terminal sulphido ligands.

The "low-valent promotion" (LVP) technique leads to edge-decorated MoS_2 particles, as shown by element specific microscopy. The resultant derivatized surfaces, upon sulphiding with H_2/H_2S, are found to be active in hydrodesulphurization, albeit relatively inactive in hydrodenitrogenation, i.e. selectivity appears to be enhanced by the LVP process.

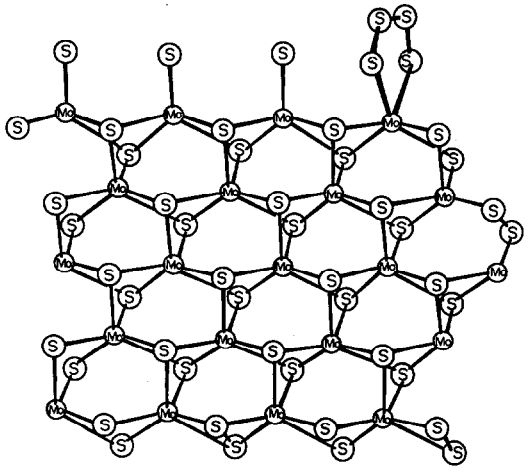

Fig. 5. Possible structures on the edge sites of MoS_2.

The use of LVP, an approach based on analogy with molecular systems, allows the preparation of solid structures wherein the surface species are added on to a pre-existing bulk phase. Such molecular-based grafting approaches carried out at low temperatures offer a distinct alternative to the more conventional thermal methods of catalyst preparation.

THE ELECTROCHROMIC BEHAVIOUR OF ZIRCONIUM DIPHTHALOCYANINE AND MOLYBDENUM PHTHALOCYANINE OXIDE

J. SILVER,* P. J. LUKES, P. K. HEY and J. M. O'CONNOR

Department of Chemistry and Biological Chemistry, University of Essex, Wivenhoe Park, Colchester CO4 3SQ, U.K.

Abstract—The electrochromic behaviour of sublimed, thin films of zirconium and molybdenum phthalocyanines is presented. The electrochromic properties of these M^{IV} phthalocyanines are compared to those of the lanthanide diphthalocyanines. An explanation of the observed electrochromic phenomena in which the reduction and oxidation take place on the phthalocyanine ring rather than on the metals is presented.

The possible applications of electrochromic technology[1] in the areas of "smart" windows and visual display systems has stimulated research interest in a wide range of inorganic,[2,3] organometallic,[4–9] organic[10–11] and graphite insertion compounds.[12] Of these, the lanthanide diphthalocyanines have been shown to possess a wide range of colours, good reversibility and be usable over a reasonable temperature range, 0–90°C. We and others have shown the lanthanide diphthalocyanines can be cycled (colours switched) more than 10^7 times.[8,13]

An electrochromic material is one which shows reversible colour changes under the influence of an applied electric current and/or electric field. The lanthanide diphthalocyanines ($L(pc)_2$) (where L = lanthanide ion, pc = phthalocyanine dianion) possess both ionic and electronic conduction.[14] Such materials can be sublimed as thin green-coloured films onto transparent or non-transparent electrodes.[4b,8,15] The film coated electrode can be placed in a cell containing an electrolyte (e.g. a solution of 5% NaCl) and a counter electrode. Then, when a voltage of around ± 1.5 V is applied, the lanthanide diphthalocyanine layer changes colour. The initial green colour changes as follows for $Lu(pc)_2$ (Lu = Lutetium) and other heavy $L(pc)_2$ materials:[4b,8]

$$\underset{+1.0\text{ V}}{\text{Red}} \longleftarrow \underset{0.0\text{ V}}{\text{Green}} \longrightarrow \underset{-0.8\text{ V}}{\text{Blue}} \longrightarrow \underset{-1.20\text{ V}}{\text{Purple}}$$

(with reference to SCE).

The true formulation of the electrochromic $L(pc)_2$ films has been the subject of much debate in the literature, though we and others favour [L(pc)(p$\dot{c}$)] (where p$\dot{c}$ = the radical monoanion anion of pc) for the green species.[14,16,17]

We have demonstrated that mixed rare-earth element diphthalocyanine material devices exhibit broader absorption bands and enhanced (more pleasing) colours than single element devices. In addition, they display longer lifetimes and the cost of the starting mixed rare-earth element materials (partialy refined ores) is substantially less than that of pure rare-earth elements.[8]

$Sn(pc)_2$ has been found to have a similar structure[18] to the [L(pc)(p$\dot{c}$)] materials,[19,20] although it contains the metal in the IV and not the III oxidation state. It has been shown that turquoise $Sn(pc)_2$ undergoes colour changes through green to red on oxidation, and to blue and purple on reduction.[14] These colours are similar to those of the [L(pc)(p$\dot{c}$)] complexes and like those colours of the latter materials, are said to be due to oxidation and reduction of the pc rings.[14] In the light of these findings we turned our attention to other metal IV phthalocyanines to establish their electrochromic behaviour and structure. We chose zirconium and molybdenum phthalocyanines for this purpose, to compare any electrochromic properties with those of the $L(pc)_2$ materials. We report the results of these studies here.

EXPERIMENTAL

Zirconium diphthalocyanine $[Zr(pc)_2]$[21] (identified from crystal structure) (see Fig. 1) was

* Author to whom correspondence should be addressed.

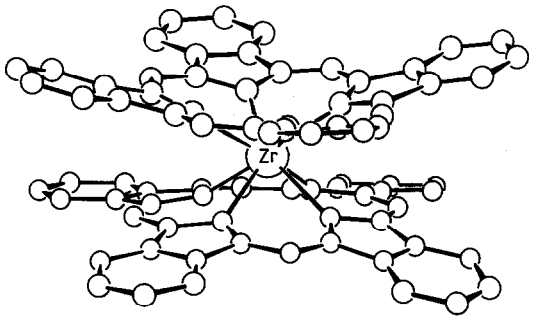

Fig. 1. The structure of $[Zr(pc)_2]$.

prepared by refluxing diaminoisoindoline with $ZrCl_4$ (ratio 8 : 1) in quinoline under an N_2 atmosphere for 2 h. The reaction mixture was filtered hot to avoid the precipitation of tarry by-products. The purple crystalline powder obtained was washed with benzene, methanol and acetone to remove any unreacted starting materials, and then sublimed under vacuum. The product was then resublimed several times under a slow flow of N_2 in a tube furnace until cyan needle-like crystals appeared. The crystals were shown by X-ray diffraction crystal structure analysis to be $[Zr(pc)_2]$.[21]

Molybdenum phthalocyanine oxide [MoO(pc)]

The established procedure to prepare this complex is by the melt reaction of 1,2-dicyanobenzene with ammoniummolybdate.[22] [MoO(pc)] is produced in high yield. This material is cyan–blue in colour, and was identified by its electronic absorption and IR spectra.[22]

Physical measurements

Electronic absorption spectra of the thin films on indium-doped tin oxide covered glass (ITO) (both as sublimed layers and in cell devices) were recorded in a Perkin–Elmer Lambda 5 spectrophotometer.

Thin films on ITO glass were prepared by vacuum sublimation of the powdered metal phthalocyanines using an Edwards E306 vacuum depositing unit. The glass slides were 3 cm × 0.9 cm and had a resistance of 5–20 ohms/□. For cycling tests and for electronic absorption spectroscopy the devices were used as electrodes in 1 cm path length cuvettes, using a platinum wire as a counter electrode. The cuvettes contained approximately 2.5 cm^3 of a 5% NaCl–water solution as electrolyte. A BBC computer interfaced via DAC (digital to analogue converter) was used to change the voltages and cycle the devices in the cuvettes, using a program written in these laboratories.[23] The voltage range used was between +1.2 and −1 V.

RESULTS AND DISCUSSION

$[Zr(pc)_2]$

Examination of the visible spectra of a neutral, sublimed film of $[Zr(pc)_2]$ (Fig. 2) reveals a strong resemblance to that of $[Sn(pc)_2]$.[23] The Q band splits into two with maxima at 702 and 637 nm.

The spectral behaviour on reducing the $[Zr(pc)_2]$ film is shown in Fig. 3. There is a 50% reduction in the Q band intensity, but only a slight change in the position of the main Q bands. However, new bands are seen to develop at 535 and 580 nm and also around 850 nm (close to the limit of the spectrometer). In addition, the Soret band around 350 nm gains in intensity. The absorption at 850 nm in the reduced form is stronger than was seen in $[Sn(pc)_2]$,[23] but otherwise, the two reduced forms are very similar. During the reduction a cyan (neutral colour) to purple–red colour change was observed, though the colour was less intense than that seen for reduced species in the [L(pc)(pc)] complexes.[8] Assuming that the material which sublimed from the $[Zr(pc)_2]$ crystals retained the same stoichiometry as the crystal structure, then the electronic absorption spectra in Figs 2–4 are representative of this material. The reduced form is probably the single-electron reduction product

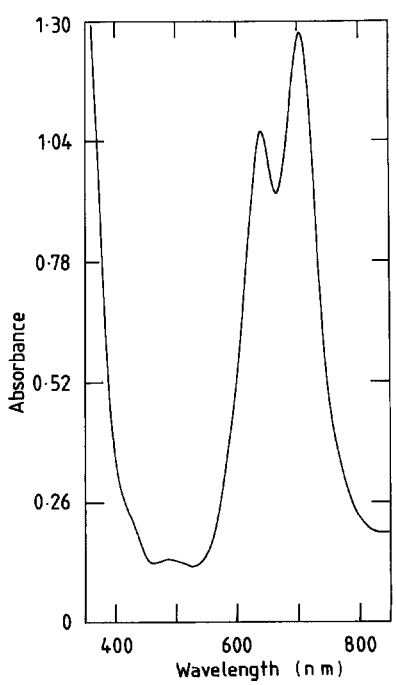

Fig. 2. The electronic absorption spectrum of a neutral sublimed film of $[Zr(pc)_2]$ on an ITO glass slide.

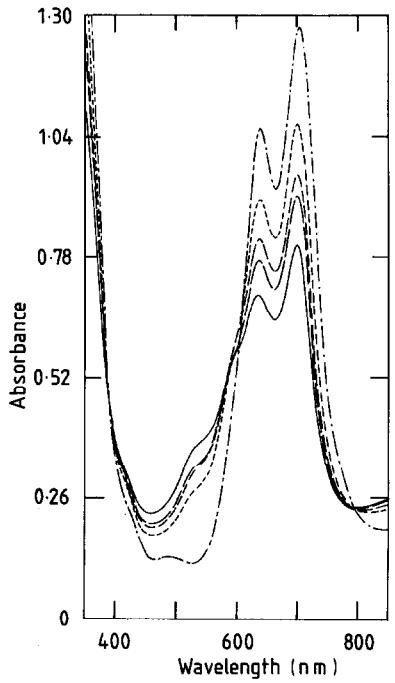

Fig. 3. The electronic absorption spectra of the neutral sublimed film of $[Zr(pc)_2]$ on an ITO glass slide, showing new peaks emerging on reduction at 534.8, 582 and above 850 nm. The successive runs at voltages between 0 and −1.1 V show a decrease in the main absorption bands.

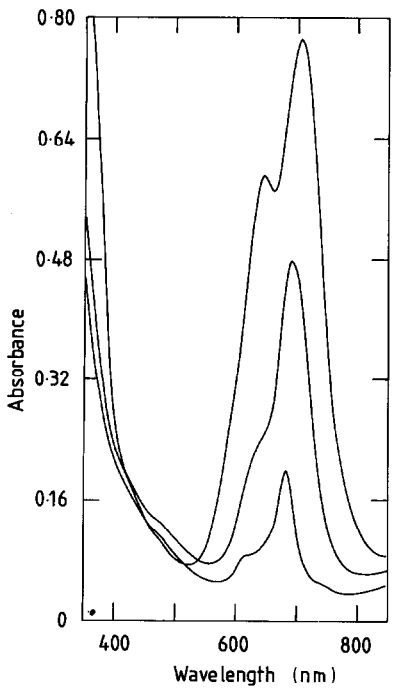

Fig. 4. The electronic absorption spectrum of the neutral sublimed film of $[Zr(pc)_2]$ on an ITO glass slide. Successive runs show both movement and loss of intensity when voltages of +0.5 to +0.1 V are applied. Eventually the slide loses all colour of the $[Zr(pc)_2]$ complex.

from the reaction:

$$[Zr(pc)_2] + e^- \longrightarrow [Zr(pc)_2]^-.$$
cyan purple–red

An explanation of this spectrum could be that the Q band absorption of the neutral phthalocyanine ring is perturbed whilst the second ring (the reduced ring) gives rise to the new bands in the spectra (Fig. 3). The spectral changes on reduction were reversible, and up to 10^3 colour cycles were achieved between the neutral and reduced states, the voltage necessary for reduction was around −1.1 V.

Oxidation of $[Zr(pc)_2]$ films gave rise to an irreversible loss of colour of the film in contrast to the results of others on a gold electrode.[24] The spectra of the oxidized films (Fig. 4) show both an initial movement of the Q bands and a simultaneous loss of intensity. Then a successive spectrum shows further movement and loss of intensity. This change from cyan to colourless was not reversible.

The failure to observe a colour change upon oxidation of the film is surprising, as the [L(pc)(pc)] material series all show colour changes upon oxidation. We found similar difficulties in obtaining an oxidized form for $[Sn(pc)_2]$[25] in contrast to other workers.[14]

[MoO(pc)]

The visible spectrum of a neutral sublimed film of [MoO(pc)] is presented in Fig. 5. A very strong

I = relative intensity normalized on strongest band of the original neutral film.

absorption is present in the 600–850 nm region, but no structure has yet been reported for this material. On the basis of evidence from the similarity of the visible spectra to that of [VO(pc)], it probably resembles the latter material. The data summarizing the electrochromic reduction of [MoO(pc)] are presented in Table 1. The reduction was accompanied by a colour change from cyan–blue (neutral) to purple–violet, in agreement with the results of Collins and Schiffrin.[14]

We suggest that the reduction may be represented as

$$[MoO(pc)] + e^- \longrightarrow [MoO(pc)]^-$$

and that it is pc based, as found in the [L(pc)(pc)] materials and in $[Zr(pc)_2]$, not metal based as suggested by others.[14] This hypothesis is based on the changes in the absorption in the visible region that result from the electronic levels on the pc rings. A change in the metal oxidation state should be expected to move these bands, but not to generate new additional bands.

The reduced to neutral colour change was successfully cycled in several devices 10^4 times. Breakdown of devices was through peeling, possibly caused by films swelling, or induced by mechanical stress, caused by anion incorporation in the lattice.[14] It was noticed that partially peeled devices were still colour cycling on all the peeled film, if they still were in contact with the ITO surface at some point in their periphery. This fact suggests both good conduction properties in the films themselves, and also that the layers are mechanically breaking down, not chemically breaking down.

CONCLUSIONS

$[Zr(pc)_2]$ and [MoO(pc)] both show electrochromic changes, however, neither of these compounds show either the reversibility or the range of colours found in the [L(pc)(pc)] complexes. They are therefore less attractive as potential materials for commercial device applications.

The fact that $[Zr(pc)_2]$ has a similar structure to [L(pc)(pc)] complexes is of great interest as its electrochromic properties are very different. These differences and those of the $[Sn(pc)_2]$ complex[25] must be due to the presence of an M^{IV} species in the complex.

The systems are compared (L = Lanthanide element) and the various identified species listed under their similar colours in Table 2.

It can be seen from this work that the $[Zr(pc)_2]^+$ complex is chemically unstable and degrades, losing its colour. This must mean the the pc rings are chemically broken down (opened) on oxidation. We

Table 2.

Metal oxidation state	Colour of species			
	Red	Green	Blue	Purple
III	$[L(pc)(pc)]^+$	$[L(pc)(pc)]^0$	$[L(pc)_2]^-$	$[L(pc)_2]^{2-}$
IV		$\boxed{[Zr(pc)_2]^+}$	$[Zr(pc)_2]^0$	$[Zr(pc)_2]^-$
IV			$[Sn(pc)_2]^0$	$[Sn(pc)_2]^-$

found that the $[Sn(pc)_2]$ complex behaves similarly. This must be due to the greater polarizing power of the M^{IV} ions destabilizing the oxidized rings. In addition, it can be appreciated that the total electron count is the same in all the blue complexes and in all the purple complexes. It therefore appears that the same number of electrons on the rings cause similar colours in the metal diphthalocyanine complexes irrespective of the charge on the metal, providing the species are chemically stable. This finding is in agreement with the oxidations and reductions being pc ring based.

The [MoO(pc)] material is not a diphthalocyanine and shows a very different spectrum on reduction, with new bands appearing in the visible region. This material turns yellow–grey on oxidation, a colour not found in the metal diphthalocyanines. The fact that the molybdenum(IV) does not form a diphthalocyanine under the conditions tried in this work shows that the stability of the $[MoO]^{2+}$ ion dominates its chemistry. The $[MoO]^{2+}$ ion is able to bind to a single pc ring, presumably the resulting structure is similar to that of [VO(pc)],[26] and the molybdenum atoms sit above the pc plane.

INFRARED SPECTROSCOPY FROM MEGASECONDS TO PICOSECONDS

JAMES J. TURNER* and MARTYN POLIAKOFF

Department of Chemistry, University of Nottingham, Nottingham NG7 2RD, U.K.

Abstract—The study of the structure and dynamics of chemical intermediates is an important part of the unravelling of reaction mechanisms. Time-resolved UV–vis and resonance Raman spectroscopy play an important role in these investigations. Here we concentrate on the application of IR techniques, including very recent developments, and give examples from organometallic chemistry.

Infrared (IR) spectroscopy is much less "fashionable" than NMR or X-ray crystallography in inorganic or organometallic chemistry. However, IR becomes particularly valuable in probing the structure and dynamics of unstable species where X-ray or NMR are hard to apply. Over the last few years there have been dramatic advances in IR technology which have greatly increased the scope of measurements which can be made. It is the purpose of this paper to illustrate the organometallic possibilities of "state of the art" IR spectroscopy. We show how one can now monitor processes which occur on timescales from 10^6 to 10^{-12} seconds. Our examples include the photochemistry of dinuclear compounds, reaction intermediates, fast reactions in solution and intramolecular rotation.

MEGASECOND IR SPECTROSCOPY

Since we are concerned with unstable species, this title clearly refers to methods of extending the lifetime of such species so that the IR spectra can be obtained at leisure. This implies the technique of matrix isolation which has been applied to a very wide range of organometallics.[1] The most common experimental method is to start by isolating a stable parent molecule at high dilution in a large excess of an inert matrix. The matrix is usually either a frozen rare gas such as argon—in which case the parent must be volatile under high vacuum—or a glass, or cast polymer film. The parent is then photolysed with UV light and the resulting photofragments are trapped in the rigid matrix. In a rare gas matrix at 10 K, there is essentially no limit to the lifetime of the fragments, since reactions at such a low temperature have near zero rate constants: we have in fact kept such species for weeks (1 Ms = 11.57 days!). Particularly when combined with isotopic substitution, the use of IR spectroscopy for structural determination is well known. What is less appreciated is the subtlety of the photochemistry that can be probed with the use of either (or both of) wavelength variation and polarized photolysis/spectroscopy. A recent example[2] that illustrates the former is the photochemistry of $Re_2(CO)_{10}$:

$$Re_2(CO)_{10} \underset{546\,nm}{\overset{313\,nm}{\rightleftharpoons}} eq\text{-}Re_2(CO)_9 \underset{313\,nm}{\overset{546\,nm}{\rightleftharpoons}} ax\text{-}Re_2(CO)_9,$$

where *eq*-$Re_2(CO)_9$ and *ax*-$Re_2(CO)_9$ refer to two different structures of the unbridged $Re_2(CO)_9$ species with empty coordination sites along and perpendicular to the Re—Re axis, respectively.

The second technique[3] depends on the fact that, usually, molecules are held orientationally fixed in the matrix. The UV–vis photolysis is performed with plane-polarized light, and the subsequent IR (and UV–vis) spectroscopy is carried out with light which is plane-polarized in a direction either parallel to, or perpendicular to, the photolysis light. This technique was first used in organometallic chemistry[4] to unravel the primary processes in the photochemistry of $Cr(CO)_6$, a study which has been crucial in understanding very recent IR experi-

* Author to whom correspondence should be addressed.

ments[5] on the picosecond timescale (see later):

$$Cr(CO)_6 \xrightarrow{h\nu} [Cr(CO)_6]^* \longrightarrow \underset{\text{square-pyramidal}}{[Cr(CO)_5]^*}(+CO)$$

$$\longrightarrow \underset{\text{trigonal-bipyramidal}}{[Cr(CO)_5]} \longrightarrow \underset{\text{square-pyramidal}}{[Cr(CO)_5]}.$$

A powerful application of the polarized technique is to dinuclear metal species,[6] where there is a clear distinction between the directions parallel and perpendicular to the metal–metal axis. For instance, it can be shown that the intermediates $Mn_2(CO)_9$[7] and $Cp_2Pt_2(\mu\text{-}CO)$[8] have bridging CO groups at 45 and 90°, respectively, to the M—M axis. Warming up the matrix leads to softening which often allows the trapped fragments to react, with corresponding changes in the IR spectrum. This method has been particularly valuable with frozen hydrocarbon glasses where such changes can be followed right up to room temperature.[9]

"MONOSECOND" IR SPECTROSCOPY

Monosecond simply refers to reactions where the half-life of the important intermediate in solution is of the order of seconds. It is usually possible to increase the lifetime by lowering the temperature. The problem is the solvent; we have shown that liquid rare gases—particularly liquid xenon and krypton—provide an ideal solvent environment for the study of relatively unstable species.[10] For instance, photolysis of the appropriate parent metal carbonyl in liquid xenon under a pressure of hydrogen generates a whole range of "non-classical" H_2 complexes. The nature of the bonding is demonstrated by observation of the appropriate ν(H—H) stretching vibration.[11] It is then possible to use Fourier transform IR to follow changes in the spectrum with photolysis and temperature. This has been a very valuable technique for establishing the mechanism of the $M(CO)_6$ photocatalysed hydrogenation of dienes.[12]

Liquid xenon becomes supercritical at 16.9°C. Chemistry in the supercritical phase is a largely unexplored area. With specially designed cells it is proving possible to use IR spectroscopy to monitor photochemically induced chemical changes; for instance, previously unknown dihydrogen complexes such as (toluene)$Cr(CO)_2(H_2)$ can be observed in supercritical xenon at temperatures up to 80°C.[13]

With a high concentration of compound and large IR extinction coefficients, the time-resolution is limited by the scan time of the FTIR instrument; modern instruments have very short scan times, so that in principle a time resolution of tens of milliseconds with spectral resolution of 8 cm^{-1} can be achieved. With a low concentration it is necessary to generate the species repetitively. Conventional grating spectrometers have much slower scan rates. However their advantage is that the change of intensity at a single wavelength is easily monitored, and this is particularly valuable for kinetic studies.

It must however be noted that most "interesting" kinetics do not occur on such a convenient time scale. Over typical concentration ranges, bimolecular reactions have half-lives from milliseconds to nanoseconds. If we are probing solvent interactions or very fast unimolecular rearrangements, even shorter time resolution will be needed. We consider the techniques in these two stages.

MILLISECOND TO NANOSECOND IR SPECTROSCOPY

There have been spectacular technical advances[14a] in rapid IR spectroscopy since Pimentel's original experiments.[15] Applied to organometallic chemistry, much the most common method is to do "point-by-point" experiments. Here the transient is generated repetitively—invariably these days by a UV laser—and the changing intensity monitored at a series of data points in either the frequency or interferometric domain.

The simplest technique is to utilize a conventional IR dispersive instrument at a series of fixed frequencies, with the slits set wide to make up for the weak IR source, and with a fast IR detector replacing the conventional detector. First used by Siebert,[16] this technique was successfully applied to the organometallic species $M(CO)_6$ (M = Cr, Mo and W) by the Muelheim group.[17] A sophisticated development, employing a combination of a high repetition rate Nd : YAG laser with fast gated detection, has allowed the IR spectrum of the triplet exciton of phthalocyanine to be obtained.[18] The limitation of these experiments is, as implied, the inherent low intensity of the IR source.

Several groups[14] have used a CO laser as source, and examined organometallic transients in both gas phase and solution. A CO laser, operating in the continuous mode, has tunable output between 1600 and 2050 cm^{-1}, a range particularly useful for the detection of ν(C—O) bands of organometallic species. The output consists of a series of very narrow lines approximately 4 cm^{-1} apart; the laser is tuned from one line to the next by rotating a diffraction grating which forms one end of the laser cavity. A CO laser is a much brighter IR source than a globar and, hence, much higher signal/noise is possible.

For instance, using such apparatus recent experiments have followed the recombination kinetics[19] of myoglobin with CO and the reactions[20] of $CpMn(CO)_2$ generated from $CpMn(CO)_3$. The time resolution is limited by a combination of laser power, detector sensitivity/response time, and speed of data handling. However, with appropriate combinations of detectors and digitisers, times over the range of many milliseconds to about 100 nanoseconds can be examined.

Time-resolved IR with a CO laser is limited in its wavenumber range and in its resolution, because the laser lines are 4 cm^{-1} apart. With the increasing reliability of tunable IR diode lasers, both drawbacks can be overcome, in principle at least. These diodes, although much less intense than the CO laser and more difficult to operate, are likely to be applied increasingly to inorganic systems.

In principle, the "point-by-point" technique can also be applied in the interferometric domain by combining fast repetitive transient generation with repetitive scanning of an FTIR instrument. Indeed manufacturers have developed software for re-sorting the data points collected in this way. Thus, following Fourier transformation, it is possible to obtain a set of IR spectra each corresponding to a specific time after the photolytic flash. Although this technique is awash with difficulties,[21] it has proved possible to follow the stretching of polymer films and liquid crystals[22] and, rather more relevant here, the reactions[23] of the intermediate $CpFe(\mu\text{-}CO)_3FeCp$, generated on photolysis of $[CpFe(CO)_2]_2$.

A better way of combining flash photolysis of transients with FTIR is to use "step-scan" rather than "continuous-scan" interferometry. This was originally demonstrated by Murphy *et al.*[24] Very recently, equipment has been developed by Siebert working in association with Bruecker; this has been applied to the photoprocesses of bacteriorhodopsin and very promising preliminary results have been obtained.[25] This is likely to be a significant advance for the study of organometallic intermediates.

PICOSECOND IR SPECTROSCOPY

IR detectors have a time resolution limited to about 100 nanoseconds. Thus to obtain IR spectra in the picosecond range one cannot use the techniques described above. There are broadly speaking two methods of doing it: one is to "cheat" and, via laser mixing techniques, to monitor IR changes in the UV–vis region where much faster detectors are available; the other is to measure the changes in IR bandwidths with temperature.

Laser mixing methods

There have very recently been two interesting applications to metal species. Moore *at al.*[26] have monitored the initial photodissociation step in the myoglobin/CO complex and by using polarized light have even been able to determine the Fe/CO angle! The second application is perhaps more relevant to this meeting. As mentioned above, matrix isolation/polarized photochemistry[4] suggested a particular mechanism for the photolysis of $Cr(CO)_6$. It was long thought, partly on the basis of experiments using picosecond UV–vis detection,[27] that the only important reaction on this time scale, is that between the ground state square-pyramidal $Cr(CO)_5$ fragment and the solvent (e.g. cyclohexane) to give $Cr(CO)_5 \cdots S$. Spears and colleagues,[5] employing picosecond IR detection, have now produced evidence that $Cr(CO)_5$ intermediates with both square-pyramidal and trigonal-bipyramidal structures can be detected in solution and their reactivity towards the solvent is substantially different.

Band width studies

The broadening and coalescence of NMR bands has played a very important role in mechanistic organometallic chemistry.[28] It is frequently said that the IR time scale is much too fast to provide information about kinetics. However there are several examples in the literature where the broadening of IR bands has been correlated with dynamic effects;[29] a simple example[30] is the internal rotation of CH_2ClCH_2Cl. Recently Grevels and colleagues[31] have observed a very striking example in organometallic chemistry. In (diene)$Fe(CO)_3$ complexes where the diene is symmetrical (e.g. norbornadiene), the low temperature solution IR ν(C—O) spectrum shows the three bands expected for C_s symmetry. On warming the solution, however, the two lower frequency bands coalesce into a single band and the overall spectrum is then appropriate to a molecule with three-fold symmetry. Grevels associates this observation with interconversion of the CO groups on a picosecond timescale and applies a modified Bloch equation to estimate the barrier height. In contrast to flash photolysis studies where systems are far from equilibrium, such band coalescence involves a dynamic equilibria on a picosecond timescale.

There is considerable discussion[29a] about the detailed interpretation of such phenomena and in particular whether the modified Bloch equations can be applied. In collaboration with Grevels, we have carefully examined the IR band profiles in liquid rare gas solvents of ^{13}CO substituted diene

molecules and obtained clear evidence of picosecond behaviour.[32] It is possible, particularly when the equations are cast in density matrix form, to draw close analogies between the IR and NMR behaviour. It is our view that careful temperature-dependent IR band analysis, combined with appropriate theoretical analysis, will provide subtle information on very fast dynamics of interest to many transition metal systems. Moreover the experiments are much cheaper than those involving sophisticated laser mixing!

BIS(η-ARENE) COMPLEXES OF THE EARLY TRANSITION METALS DERIVED FROM THE 1,3,5-TRI-*t*-BUTYLBENZENE LIGAND

F. GEOFFREY N. CLOKE,* KERRY A. E. COURTNEY, AUSAMA A. SAMEH and ANTHONY C. SWAIN

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

Abstract—Co-condensation of yttrium, titanium, zirconium, hafnium, niobium, chromium, molybdenum or tungsten atoms with the bulky arene 1,3,5-tri-*t*-butylbenzene, affords the homoleptic sandwich compounds $[M(\eta\text{-}^tBu_3C_6H_3)_2]$, where M = Y, Ti, Zr, Hf, Nb, Cr, or W; in the case of chromium, the reaction also yields the triple-decker sandwich compound $[Cr_2(\eta\text{-}^tBu_3C_6H_3)_2(\mu\text{-}\eta:\eta\text{-}^tBu_3C_6H_3)]$. $[Hf(\eta\text{-}^tBu_3C_6H_3)_2]$ reacts irreversibly with carbon monoxide to give the stable 18-electron carbonyl adduct $[Hf(\eta\text{-}^tBu_3C_6H_3)_2(CO)]$, whereas $[Zr(\eta\text{-}^tBu_3C_6H_3)_2(CO)]$ is unstable in the absence of excess carbon monoxide. Oxidation of $[Nb(\eta\text{-}^tBu_3C_6H_3)_2]$ with silver tetrafluoroborate affords the stable 16-electron cation $[\{Nb(\eta\text{-}^tBu_3C_6H_3)_2\}\{BF_4\}]$.

Starting with its application for the preparation of bis(η-arene)chromium complexes,[1] metal vapour synthesis has developed into a powerful technique for the synthesis of a wide range of homoleptic bis(η-arene)metal complexes, particularly those of the early transition metals where conventional methods have thus far been unsuccessful (Ti, Nb, Ta) or not proved synthetically useful (W).[2] To date however, the homoleptic 16-electron bis(η-arene) complexes of zirconium and hafnium, assumed to be present at low temperature during the co-condensation experiment, have only been isolated as their 18-electron trimethylphosphine adducts $[M(\eta\text{-arene})_2(PMe_3)]$ (M = Zr, Hf),[3] and there has been no definitive evidence for the existence of the analogous 15-electron bis(η-arene)yttrium complex. We were interested to see whether it would be possible to stabilize the electron deficient homoleptic bis(η-arene) complexes of yttrium, zirconium and hafnium by the use of an appropriately bulky arene ligand. Such a strategy has considerable precedent in the use of sterically demanding pentamethylcyclopentadienyl[4,5] and tertiary phosphine[6,7] ligands to stabilize coordinatively unsaturated complexes. We chose 1,3,5-tri-*t*-butylbenzene as the arene ligand because of its high symmetry and size, but also because the combined inductive effect of the *t*-butyl substituents was anticipated to lead to an increase in the metal–arene bond strength. We also felt it possible that such an arene ligand might lead to unusual modifications in the chemistry of other η-arene complexes. Parts of this work have been briefly communicated.[8,9]

EXPERIMENTAL

All manipulations were carried out on a conventional vacuum line using standard Schlenk techniques or in a dry box, under an atmosphere of argon or dinitrogen, and all glassware was flame-dried under vacuum before use. Celite 545 filter aid was dried under vacuum at 300°C. The general design of the metal vapour synthesis apparatus has been described elsewhere.[2] Solvents were dried and purified by prolonged reflux over a suitable drying agent followed by distillation under an atmosphere of dinitrogen. NMR solvents were stored in ampoules containing a freshly prepared potassium mirror under an atmosphere of dinitrogen. Nujol for FAB–mass spectrometry was thoroughly deoxygenated and dried over activated molecular sieves (4 Å). Carbon monoxide was purified by passage through a column containing BASF catalyst and activated molecular sieves (4 Å). Metal samples were vacuum melted in a separate operation prior to their use in the co-condensation experiments

(except for chomium, which sublimes under vacuum). 1,3,5-Tri-*t*-butylbenzene was prepared by the literature procedure.[10] NMR spectra were recorded on Bruker WM360 or WP 80 instruments at probe temperature unless otherwise stated, and calibrated by reference to the residual proton chemical shift of the deuterated solvent. ESR spectra were recorded on a Bruker ESP 300 instrument at York and solid-state magnetic susceptibility measurements were made on a SHE905 SQUID magnetometer at Berkeley. IR spectra were recorded on a Perkin–Elmer 1720 FT instrument. Mass spectra were obtaind using the fast atom bombardment (FAB–MS) technique on an MS80RF instrument equipped with a dedicated Kratos ion source and Ion Tech atom gun, using a Nujol matrix, and xenon as the bombarding gas. Microanalyses were performed by Butterworth Laboratories Ltd, London.

Preparation of bis(η-1,3,5-tri-t-butylbenzene)yttrium (1)

Electron beam vapourized yttrium (0.90 g, 10 mmol; power input 400 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (25 g, 100 mmol) at 77 K over a 2 h period. After warm-up to room temperature under dinitrogen, the product was extracted from the reactor with *n*-hexane (750 cm^3) and the resultant deep purple solution filtered through a bed of Celite on a frit. The solvent was removed under reduced pressure and excess 1,3,5-tri-*t*-butylbenzene removed by sublimation at 60°C/10^{-4} mbar. The residue was extracted with *n*-pentane (150 cm^3) and the resultant solution again filtered through Celite. Concentration of the solution under reduced pressure and cooling to −30°C afforded deep purple crystals of $[Y(\eta\text{-}^tBu_3C_6H_3)_2]$, which were collected, washed with *n*-pentane (2 × 10 cm^3) at −80°C and dried *in vacuo*. Yield: *ca* 40% based on yttrium (Microanalysis (%) Found: C, 74.41; H, 10.58. Required: C, 74.32; H, 10.40. Mass spectrum: *M/e* 581 [P^+]).

Preparation of bis(η-1,3,5-tri-t-butylbenzene) titanium (2)

Electron beam vapourized titanium (0.35 g, 7 mmol; power input 500 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (25 g, 100 mmol) at 77 K over a 2 h period. Identical work-up to **1** above afforded deep red crystals of $[Ti(\eta\text{-}^tBu_3C_6H_3)_2]$ in *ca* 50% yield based on titanium (Microanalysis (%) Found: C, 79.80; H, 10.96. Required: C, 79.90; H, 11.18). ^1H NMR (C_6D_6): δ 5.04 [6H, s, $^tBu_3C_6H_3$], 1.48 [54H, s, $^tBu_3C_6H_3$]. $^{13}C\{^1H\}$ (C_6D_6): δ 111.14 [*ring C*], 7.76 [*ring* CH], 36.27 [$C(CH_3)_3$], 33.07 [$C(CH_3)_3$].

Preparation of bis(η-1,3,5-tri-t-butylbenzene) zirconium (3)

Electron beam vapourized zirconium (0.36 g, 4 mmol; power input 1800 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (30 g, 120 mmol) at 77 K over a 3 h period. Identical work-up to **1** above afforded deep green crystals of $[Zr(\eta\text{-}^tBu_3C_6H_3)_2]$ in *ca* 40% yield based on zirconium (Microanalysis (%) Found: C, 74.02; H, 10.32. Required: C, 74.03; H, 10.35. Mass spectrum: *M/e* 582 [P^+]). ^1H NMR (C_6D_6): δ 5.34 [6H, s, $^tBu_3C_6H_3$], 1.33 [54H, s, $^tBu_3C_6H_3$]. $^{13}C\{^1H\}$ (C_6D_6): δ 111.19 [*ring C*], 80.28 [*ring* CH], 35.16 [$C(CH_3)_3$], 32.79 [$C(CH_3)_3$].

Preparation of bis(η-1,3,5-tri-t-butylbenzene) hafnium (4)

Electron beam vapourized hafnium (4.56 g, 25 mmol; power input 2200 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (80 g, 325 mmol) at 77 K over a 3 h period. Identical work-up to **1** above afforded purple crystals of $[Hf(\eta\text{-}^tBu_3C_6H_3)_2]$ in *ca* 40% yield based on hafnium (Microanalysis (%) Found: C, 64.15; H, 9.28. Required: C, 64.40; H, 9.00. Mass spectrum: *M/e* 672 [P^+]). ^1H NMR (C_6D_6): δ 5.15 [6H, s, $^tBu_3C_6H_3$], 1.34 [54H, s, $^tBu_3C_6H_3$]. $^{13}C\{^1H\}$ (C_6D_6): δ 107.49 [*ring C*], 76.80 [*ring* CH], 35.57 [$C(CH_3)_3$], 33.39 [$C(CH_3)_3$].

Preparation of bis(η-1,3,5-tri-t-butylbenzene) hafnium(carbonyl) (5)

A solution of $[Hf(\eta\text{-}^tBu_3C_6H_3)_2]$ (200 mg, 0.25 mmol) in *n*-pentane (50 cm^3) was exposed to 1 atm of carbon monoxide for 5 min. The solution was filtered, and concentration under reduced pressure and cooling to −30°C afforded deep green crystals of $[Hf(\eta\text{-}^tBu_3C_6H_3)_2(CO)]$ which were collected, washed with *n*-pentane (2 × 10 cm^3) at −80°C and dried *in vacuo*. Yield: *ca* 80% (Microanalysis (%) Found: C, 62.92; H, 8.55. Required: C, 63.54; H, 8.65). IR (Nujol mull, NaCl plates): 1870 cm^{-1}, strong ν(CO). An identical procedure using ^{13}CO (90% ^{13}C enriched) afforded the ^{13}C labelled carbonyl complex. ^1H NMR (C_6D_6): δ 5.25 [6H, d, $^tBu_3C_6H_3$, J_{CH} 0.98 Hz], 1.47 [54H, s, $^tBu_3C_6H_3$]. $^{13}C\{^1H\}$ (C_6D_6): δ 239.91 [*CO*], 118.62 [*ring C*], 82.90 [*ring* CH], 35.46, [$C(CH_3)_3$], 31.89 [$C(CH_3)_3$]. ^{13}C (gated) (C_6D_6): 239.91 [m, *CO*, J_{CH} 0.98 Hz].

Characterization of bis(η-1,3,5-tri-t-butylbenzene) zirconium (carbonyl) (**6**)

To a 10 mm NMR tube equipped with a greaseless stopcock, was added a solution of [Zr(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] (35 mg, 0.05 mmol) in d_8-toluene. Carbon monoxide (90% ^{13}C enriched) was added via a Toepler pump to a pressure of 1 atm at 77 K. The resultant green solution was allowed to warm to room temperature; ^{13}C{^{1}H} (C_7D_8): δ 234.00 [*C*O], 85.95 [*ring C*H], 31.97 [C(*C*H$_3$)$_3$]. The ^{1}H NMR spectrum was obtained similarly, employing a 5 mm NMR tube and natural abundance carbon monoxide; ^{1}H NMR (C_7D_8): δ 4.88 [6H, s, ^{t}Bu$_3$C$_6$*H*$_3$], 1.37 [54H, s, ^{t}*Bu*$_3$C$_6$H$_3$]. A solution of [Zr(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] in *n*-pentane was exposed to 1 atm of natural abundance carbon monoxide at room temperature, and the resultant solution rapidly transferred to a solution IR cell (1 mm path, NaCl windows) under a carbon monoxide atmosphere; 1890 cm^{-1}, strong, ν(CO).

Preparation of bis(η-1,3,5-tri-t-butylbenzene) niobium (**7**)

Electron beam vapourized niobium (0.87 g, 10 mmol; power input 2000 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (80 g, 325 mmol) at 77 K over a 3 h period. Identical work-up to **1** above afforded purple–red crystals of [Nb(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] in *ca* 40% yield based on niobium (Microanalysis (%) Found: C, 72.61; H, 10.49. Required: C, 73.81; H, 10.32. Mass spectrum: *M*/*e* 585 [P$^+$]). ESR (toluene, 25°C): g_{iso} 1.985, decet, A_{iso} 1.7 mT.

Preparation of bis(η-1,3,5-tri-t-butylbenzene) niobium tetrafluoroborate (**8**)

To a stirred solution of [Nb(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] (180 mg, 0.30 mmol) in toluene (30 cm^3), was added a solution of [AgBF$_4$] (60 mg, 0.30 mmol) in toluene (50 cm^3) dropwise at −78°C. A metallic mirror rapidly appeared, and the reaction mixture was allowed to warm to room temperature over 30 min. The resultant red–brown precipitate was collected on a frit, washed with toluene and dried *in vacuo*. The solid on the frit was then extraced with dichloromethane and toluene was carefully layered on the resultant deep orange solution to afford golden orange crystals of [{Nb(η-^{t}Bu$_3$C$_6$H$_3$)$_2$}{BF$_4$}]. The crystals were collected, washed with *n*-pentane (2 × 10 cm^3) and dried under an argon stream. Yield: 80% (Microanalysis (%) Found: C, 62.68; H, 8.31. Required: C, 64.30; H, 8.99).

Reaction of chromium atoms with 1,3,5-tri-t-butylbenzene; preparation of bis(η-1,3,5-tri-t-butylbenzene)chromium (**9**) *and bis(η-1,3,5-tri-t-butylbenzene)(μ-η:η-1,3,5-tri-t-butylbenzene)dichromium* (**10**)

Electron beam vapourized chromium (3.0 g, 50 mmol; power input 400 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (80 g, 325 mmol) at 77 K over a 3 h period. Identical work-up to **1** above afforded an orange–green, crystalline product, an approximately equimolar mixture of [Cr(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] and [Cr$_2$(η-^{t}Bu$_3$C$_6$H$_3$)$_2$(μ-η:η-^{t}Bu$_3$C$_6$H$_3$)] in a total *ca* 30% yield based on chromium (Mass spectrum: *M*/*e* 544 [P$^+$] for **9**, 596 [P − 246$^+$] for **10**). Compound **9**, ^{1}H NMR (C_6D_6): δ 4.65 [6H, s, ^{t}Bu$_3$C$_6$*H*$_3$], 1.43 [54H, s, ^{t}Bu$_3$C$_6$H$_3$]; ^{13}C{^{1}H} (C_6D_6): δ 102.20 [*ring C*], 69.13 [*ring C*H], 34.84 [*C*(CH$_3$)$_3$], 33.08 [C(*C*H$_3$)$_3$]. Compound **10**, ^{1}H NMR (C_6D_6): δ 4.71 [3H, s, ^{t}Bu$_3$C$_6$*H*$_3$], 4.43 [6H, s, ^{t}Bu$_3$C$_6$*H*$_3$], 1.29 [27H, s, ^{t}*Bu*$_3$C$_6$H$_3$], 1.26 [54H, s, ^{t}*Bu*$_3$C$_6$H$_3$]; ^{13}C{^{1}H} (C_6D_6): δ 73.43 [outer *ring* C*H*], 70.60 [inner *ring* C*H*], 32.49 and 32.08 [C(*C*H$_3$)$_3$].

Chromatography of a mixture of **9** and **10** on deactivated alumina (4% w/w H_2O, *n*-hexane eluant) yielded a single red band which afforded orange crystals of pure **9** on removal of the solvent *in vacuo*.

Preparation of bis(η-1,3,5-tri-t-butylbenzene) molybdenum (**11**)

Electron beam vapourized molybdenum (0.46 g, 5 mmol; power input 800 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (30 g, 120 mmol) at 77 K over a 2½ h period. Identical work-up to **1** above afforded deep green–brown crystals of [Mo(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] in *ca* 30% yield based on molybdenum (Mass spectrum: *M*/*e* 590 [P$^+$]). ^{1}H NMR (C_6D_6): δ 4.87 [6H, s, ^{t}Bu$_3$C$_6$*H*$_3$], 1.34 [54H, s, ^{t}*Bu*$_3$C$_6$H$_3$]. ^{13}C{^{1}H} (C_6D_6): δ 105.56 [*ring C*], 72.88 [*ring C*H], 34.65 [*C*(CH$_3$)$_3$], 32.87 [C(*C*H$_3$)$_3$].

Preparation of bis(η-1,3,5-tri-t-butylbenzene) tungsten (**12**)

Electron beam vapourized tungsten (0.54 g, 3 mmol; power input 1600 W) was co-condensed with an excess of 1,3,5-tri-*t*-butylbenzene (30 g, 120 mmol) at 77 K over a 2½ h period. The work-up was identical to **1** above up to the stage at which all the excess ligand had been removed. Chromatography on deactivated alumina (4% w/w H_2O, *n*-hexane eluant) yielded a single orange band, which on removal of the solvent *in vacuo* afforded orange

crystals of $[W(\eta\text{-}^t Bu_3C_6H_3)_2]$ in *ca* 20% yield based on tungsten (Mass spectrum: *M/e* 676 [P^+]). ^1H NMR (C_6D_6): δ 5.18 [6H, s, $^tBu_3C_6H_3$], 1.33 [54H, s, $^tBu_3C_6H_3$].

RESULTS AND DISCUSSION

The known organometallic chemistry of yttrium is confined to the +3 oxidation state, there being no reported examples of stable unambiguous lower oxidation state complexes of this element. Recently we reported the synthesis of the *formally* yttrium(0) complex [Y('Bu—DAB)$_3$][11] ('Bu—DAB = 'Bu—N=CH—CH=N—'Bu), although the absence of coupling to yttrium (^{89}Y, 100%, $I = \frac{1}{2}$) in the ESR spectrum of the latter strongly suggests that the bulk of the electron density lies in ligand based orbitals. 'Bu—DAB is known to form the stable radical anion 'Bu—DAB$^-$, so that this compound might be best realistically classified as a complex of yttrium(III).

The co-condensation of yttrium atoms with toluene or mesitylene results in deep purple matrices at 77 K, but the colour (presumably due to the formation of a bis(η-arene) complex) is rapidly discharged on warm-up.[12] However, the reaction between yttrium atoms and the bulky 1,3,5-tri-*t*-butylbenzene ligand afforded a thermally stable product, and work-up yielded deep purple crystals of $[Y(\eta\text{-}^t Bu_3C_6H_3)_2]$ (**1**). Compound **1** is highly soluble in hydrocarbon solvents, thermally stable up to 100°C and may be sublimed at 80°C/10^{-4} mbar with partial decomposition. Both the solutions and the solid are highly air-sensitive and must be handled with rigorous exclusion of oxygen and, in particular, water, but may be stored indefinitely under an argon atmosphere.

Compound **1** is paramagnetic with a value for μ_{eff} of 1.74 BM at room temperature in the solid state, but displays no ESR spectrum at room temperature in methylcyclohexane solution. However, cooling the solution to 77 K results in an ESR signal exhibiting coupling to ^{89}Y: $g_\parallel = 2.085$, doublet, $A = 3.0$ mT; $g_\perp = 2.005$. This is consistent with a 15-electron bis(η-arene) complex, predicted to have a ^2E (e_{2g}^3) ground state, in which the large g-value anisotropy would be expected to make an ESR signal hard to detect. The spin-only value for the magnetic moment arising from an unpaired electron in the e_{2g} orbitals presumably results from quenching of any orbital contribution to the magnetic moment by the ligand field. The previously reported X-ray crystallographic results[9] confirm that the molecule possesses the parallel-ring sandwich structure, so that **1** represents the first authentic example of an yttrium(0) complex.

The reaction between titanium atoms and 1,3,5-tri-*t*-butylbenzene gave good yields of deep red $[Ti(\eta\text{-}^t Bu_3C_6H_3)_2]$ (**2**). Compound **2** has similar spectroscopic (see Experimental) and physical properties to previously reported bis(η-arene) titanium complexes,[13] although is somewhat more thermally stable. Of more interest was the potential synthesis of the zirconium and hafnium analogues of **2**: the 16-electron homoleptic bis(η-arene) zirconium and -hafnium complexes are highly thermally unstable for simple arenes such as toluene, but may be trapped as their 18-electron trimethylphosphine adducts $[M(\eta\text{-}MeC_6H_5)_2(PMe_3)]$ (M = Zr, Hf).[3] In the latter, the trimethylphosphine ligand presumably serves not only to give the complex an 18-electron configuration, but also to sterically saturate the metal centre. It therefore was anticipated that the steric bulk and electronic properties of the 1,3,5-tri-*t*-butylbenzene ligand might stabilize the 16-electron bis(η-arene) complexes of these elements.

Co-condensation of zirconium or hafnium atoms with 1,3,5-tri-*t*-butylbenzene afforded deep green $[Zr(\eta\text{-}^t Bu_3C_6H_3)_2]$ (**3**) and purple $[Hf(\eta\text{-}^t Bu_3C_6H_3)_3]$ (**4**), respectively. Compounds **3** and **4** are diamagnetic, thermally stable up to 120°C, and highly air- and water-sensitive. NMR and other characterizing data are given in the Experimental.

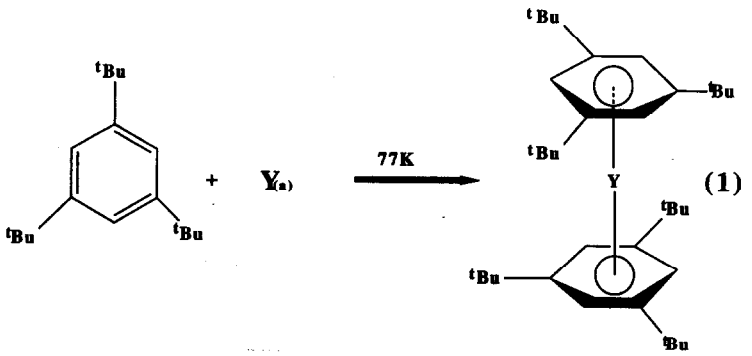
It was of interest to see if the 16-electron compounds, **3** and **4**, would undergo simple ligand addition reactions to give 18-electron adducts, despite the bulk of the 1,3,5-tri-*t*-butylbenzene ligands. Treatment with trimethylphosphine gave no observable reaction by ^{31}P NMR (presumably for steric reasons), and reaction with trifluorophosphine led to rapid decomposition. However, exposure of a pentane solution of **4** to carbon monoxide resulted in a rapid irreversible colour change from purple to green, and deep green crystals of $[Hf(\eta\text{-}^t Bu_3C_6H_3)_2(CO)]$ (**5**) could be isolated from the solution in high yield. The carbonyl ligand in **5** is characterized by a low carbonyl stretch at 1870 cm^{-1}, associated with the high electron density on the hafnium(0) centre, and by a ^{13}C NMR resonance (in a sample prepared using ^{13}CO) at δ 240, which is a partially resolved septet in the gated spectrum due to coupling with the ring protons of the two $\eta\text{-}^t Bu_3C_6H_3$ ligands. In contrast, the reaction between CO and the zirconium analogue, **3**, was found to be reversible, so that green $[Zr(\eta\text{-}^t Bu_3C_6H_3)_2(CO)]$ (**6**) could only be characterized spectroscopically in solution in the presence of excess CO; *in vacuo*, the starting bis(η-arene) zirconium complex, **3**, was regenerated quantitatively. The carbonyl ligand in **6** is spectroscopically very similar to that in **5**, showing a

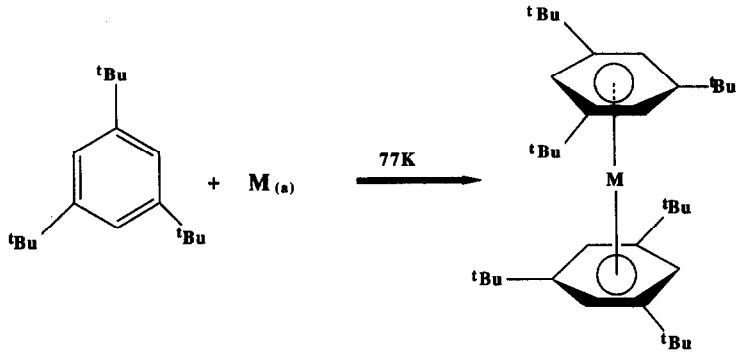
strong carbonyl stretch at 1890 cm^{-1} and a ^{13}C resonance at δ 234, although coupling to the ring protons in the latter was not resolved. The origin of the disparities in the colours of the homoleptic bis(η-arene) complexes, **3** and **4**, and in the relative stabilities of the carbonyl adducts, **5** and **6**, is not clear, but similar differences in the organometallic chemistry of zirconium and hafnium have been previously observed.[14]

Recently we reported on the oxidation of 17-electron bis(η-toluene)niobium: one-electron oxidation of the latter in the presence of a tertiary phosphine gives the stable 18-electron cation $[\{Nb(\eta\text{-}MeC_6H_5)_2(PR_3)\}^+]$, whereas in the absence of the tertiary phosphine the 16-electron $[\{Nb(\eta\text{-}MeC_6H_5)_2\}^+]$ cation is unisolable.[15] This parallels the chemistry of the isoelectronic, neutral $[Zr(\eta\text{-}MeC_6H_5)_2]$, which is also highly unstable, as discussed earlier. Given the stability of the 1,3,5-tri-*t*-butylbenzene derivative $[Zr(\eta\text{-}^tBu_3C_6H_3)_2]$ (**3**), we were encouraged to examine the oxidation of the niobium analogue of **3** in the absence of any additional two-electron ligands.

Red–purple $[Nb(\eta\text{-}^tBu_3C_6H_3)_2]$ (**7**) was obtained in good yield by the co-condensation of niobium atoms with 1,3,5-tri-*t*-butylbenzene. Compound **7** has similar spectroscopic (see Experimental) and physical properties to the bis(η-arene)niobium complexes derived from other arenes (i.e. benzene, toluene and mesitylene) which we reported previously.[16] Oxidation of **7** with one equivalent of silver tetrafluoroborate in toluene solvent at −78°C resulted in the rapid formation of a silver mirror, and orange, crystalline $[\{Nb(\eta\text{-}^tBu_3C_6H_3)_2\}\{BF_4\}]$ (**8**) could be isolated in high yield from dichloromethane–toluene. Compound **8** is very air-sensitive, but stable in dichloromethane solution; tetrahydrofuran (THF) solutions, however, rapidly decompose to regenerate the neutral bis(η-arene) compound, **7** and unidentified by-products (possibly due to ring opening of the THF). Compound **8** is paramagnetic with $\mu_{eff} = 2.2$ BM in solution (Evans' method[17]) at 0°C, but is ESR silent at room temperature; this is in accord with a 16-electron $[Nb(\eta\text{-}^tBu_3C_6H_3)_2]^+$ cation having two unpaired electrons and hence a triplet ground state. This is in marked contrast to the neutral isoelectronic 16-electron zirconium analogue, **3**, which is diamagnetic. Presumably, the positive charge on the niobium centre changes the orbital energies such that the $e_{2g}^3a_{1g}^1$ configuration in the cationic niobium complex is more stable than the e_{2g}^4 configuration in the neutral zirconium compound.

A wide range of bis(η-arene)chromium complexes have been prepared via metal vapour synthesis,[1] and the triple-decker sandwich compound bis(η-mesitylene)(μ-η:η-mesitylene)dichromium can also be obtained in low (2%) yield from the co-condensation of chromium atoms and mesitylene with high metal-to-ligand ratios.[18] The reaction between chromium atoms and 1,3,5-tri-*t*-butylbenzene afforded a green–orange crystalline product after work-up, which ^1H and ^{13}C NMR showed to be an approximately equimolar mixture of the simple sandwich compound $[Cr(\eta\text{-}^tBu_3C_6H_3)_2]$ (**9**), and the triple-decker complex $[Cr_2(\eta\text{-}^tBu_3C_6H_3)_2(\mu\text{-}\eta:\eta\text{-}^tBu_3C_6H_3)]$ (**10**). The ^{13}C NMR spectrum exhibits the characteristic upfield shift for the ring carbons of the bridging arene ligand in **10**, relative to those of the terminal arene ligands (see Experimental);[18] however, the ^1H NMR spectrum shows a corresponding *downfield* shift for the ring *protons*. The origin of this anomaly is not obvious, but may be due to the influence of the substituents—the *t*-butyl groups on the adjacent rings in **10** are almost certainly staggered (see Scheme 1), even in solution, and hence the ring protons of the bridging arene ligand are effectively sandwiched between them. The mass spectrum of the mixture showed strong patterns (with the appropriate chromium isotope distributions) centred at *M/e* 544 for the molecular ion of **9**, and





M = Ti, (2); Zr, (3); Hf, (4)

Scheme 1 (*contd*).

at *M/e* 596, the latter ion corresponding to the loss of one arene ring from **10**. Attempts to separate **9** and **10** were unsuccessful; column chromatography on either Sephadex or deactivated alumina resulted in the decomposition of **10**, and only **9** could be eluted from the column; the similar solubilities and volatilities of **9** and **10** also precluded separation by fractional crystallization or sublimation.

The relatively high yield of the triple decker compound, **10**, may be a reflection of the ability of the 1,3,5-tri-*t*-butylbenzene ligand to effectively stabilize the mono(η-arene) fragment [Cr(η-^{t}Bu$_3$C$_6$H$_3$)], which is presumably an intermediate in the formation of **10**. Accordingly, we were encouraged to investigate the reactions of molybdenum and tungsten atoms with 1,3,5-tri-*t*-butylbenzene, there being no known examples of η-arene triple decker complexes of these elements.

The reaction of molybdenum atoms with 1,3,5-tri-*t*-butylbenzene yielded deep green–brown [Mo(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] (**11**) after work-up, there being no evidence for any other (η-arene)molybdenum species by NMR. However, the mass spectrum of the product showed, in addition to the molecular ion of **11**, a very weak pattern corresponding to the ion [Mo$_2$(^{t}Bu$_3$C$_6$H$_3$)$_2^+$]. The latter may arise from trace amounts of the molybdenum analogue of **10**, although its presence as a result of ion recombination reactions in the mass spectrometer cannot be ruled out. The reaction between tungsten atoms and 1,3,5-tri-*t*-butylbenzene gave orange [W(η-^{t}Bu$_3$C$_6$H$_3$)$_2$] (**12**) as the sole product, both by NMR and mass spectrometry. Whether the failure to isolate either molybdenum or tungsten analogues of **10** is due to their intrinsic kinetic/thermodynamic instability and consequent decomposition during matrix warm-up or work-up, or that such species are not formed at all during the co-condensation experiment is not clear, but the former seems more likely.

The results described here (and summarized in Scheme 1) demonstrate the unique ability of the 1,3,5-tri-*t*-butylbenzene ligand to electronically stabilize unsaturated bis(η-arene) complexes of the electropositive early transition metals, and further studies in this area are in progress.

Acknowledgements—We thank SERC for equipment support and a studentship (to A.C.S.), and the Iraqi government for a scholarship (to A.A.S.). We are grateful to Dr R. N. Perutz (York) for recording the ESR spectra, and Dr N. Edelstein (Berkeley) for the solid-state magnetic moment determination. We wish also to thank Dr G. A. Lawless for experimental assistance, and Professor M. F. Lappert for useful discussions.

Abstract—Metal K-edge EXAFS studies have provided the only structural evidence so far available for the molybdenum and vanadium centres in enzymes. This paper describes the results of vanadium and iron K-edge EXAFS on the iron–molybdenum and iron–vanadium cofactors of the nitrogenase enzymes for *Klebsiella pneumoniae* and *Azotobacter chroococcum*, respectively, and the vanadium K-edge EXAFS of the bromoperoxidase from *Ascophyllum nodosum*. These and other results suggest that molybdenum and vanadium sites in enzymes may be classified in a similar manner: (a) as part of an Fe_3MS_4 (M = Mo, V) cubane-like cluster which forms a sub-unit of the cofactor of the nitrogenases; (b) bound to one (or more) oxo groups plus sulphur (in the case of molybdenum) or oxygen/nitrogen (in the case of vanadium) ligands to form a catalytic centre for oxygen atom transfer.

Both molybdenum and vanadium are clearly recognized as being essential for the activity of particular enzymes.[1–8] The classification of molybdenum-containing enzymes is clear, to the extent that the nitrogenases are distinct from the oxomolybdo enzymes, not least in respect of the chemical environment of the molybdenum. Thus, the MoFe-protein of the nitrogenases contains an iron–molybdenum cofactor (FeMoco), of approximate composition[9] $MoFe_6S_8$, and oxomolybdo enzymes (such as xanthine oxidase, aldehyde oxidase, sulphite oxidase and nitrate reductase) contain a common molybdenum cofactor (Moco), in which molybdenum is complexed by an organic component known as the molybdopterin (**1**).[10] There is much evidence to support the view that the molybdenum-containing cofactor constitutes the catalytic centre of the corresponding enzyme.

Vanadium is now clearly recognized as an essen-

1

tial element for two classes of enzymes. EPR and MCD studies[11] on the VFe-proteins of vanadium nitrogenases indicate that these proteins contain similar redox centres to those of the MoFe-proteins of the molybdenum nitrogenases and a vanadium- and iron-containing cofactor (FeVaco), corresponding to FeMoco, has been extracted from the VFe-protein of *Azotobacter chroococcum*.[12] Also, bromoperoxidases from some marine algae, such as *Ascophyllum nodosum* have been shown to involve vanadium at the catalytically active site.[6-8]

X-ray absorption spectroscopy (XAS), and especially the extended X-ray absorption fine structure (EXAFS) associated with metal absorption edges, has proved to be a powerful and versatile probe of metal centres in proteins.[13] This technique has been widely applied to characterize the molybdenum centres in enzymes and has served to provide chemical details concerning these centres.[2] This paper describes results of XAS studies of vanadium in both nitrogenase and bromoperoxidase, and compares the information obtained to that provided by corresponding studies for molybdenum centres in enzymes.

EXPERIMENTAL

Samples of thionine-oxidized, super-reduced (during enzyme turnover) and dithionite-reduced forms of the VFe-protein of nitrogenase from *A. chroococcum* were prepared and manipulated as described elsewhere.[14,15] Vanadium K-edge XAS were recorded in the fluorescence mode on station 7C at the Photon Factory (Tsukuba-gun, Japan) operating at 2.5 GeV and an average current of 200 mA; *ca* 10 scans were recorded and averaged for each sample. A sagittal focusing, double crystal silicon(111) monochromator was used together with a 200 mm long fused quartz mirror placed at an angle of *ca* 8 mrad to reduce harmonic contamination. Samples were maintained at *ca* 80 K during investigation.

Samples of reduced and native bromoperoxidase from *A. nodosum*, purified as described previously,[7] were studied as the native enzyme, the native enzyme in the presence of hydrogen peroxide, and potassium bromide, and sodium dithionite.[16] XAS were recorded in the fluorescence mode on station 8.1 at the Daresbury Synchrotron Radiation Source operating at 2 GeV and an average current of 130 mA. A slit-less double crystal silicon(111) monochromator was employed, thus minimizing harmonic contamination. Crystal glitches limited the data range to approximately 400 eV beyond the edge. Samples were maintained at *ca* 80 K during data collection. For each bromoperoxidase sample *ca* 15 scans were averaged.

Vanadium K-edge XAS were also collected for a number of compounds considered relevant to these enzyme environments. These data were collected at room temperature in the transmission mode and a single scan was considered sufficient.

Data analysis was accomplished via the curved-wave method for EXAFS calculation and phase-shifts derived from *ab initio* calculations.[17]

RESULTS AND DISCUSSION

The vanadium K-edge XAS studies accomplished for the VFe-protein of *A. chroococcum* nitrogenase and in the bromoperoxidase of *A. nodosum* clearly demonstrate that the vanadium is in a distinctly different chemical environment in the two systems. The difference is clearly apparent from a comparison of Figs 1 and 2, which show the profile of the vanadium K-absorption edge and XANES for the thionine-oxidized and dithionite-reduced VFe-protein, and dithionite-reduced and native bromoperoxidase. This spectral region is very sensitive to the oxidation state of vanadium and its chemical environment.[18]

For the VFe-protein, the vanadium centre changes little as the oxidation level of the protein

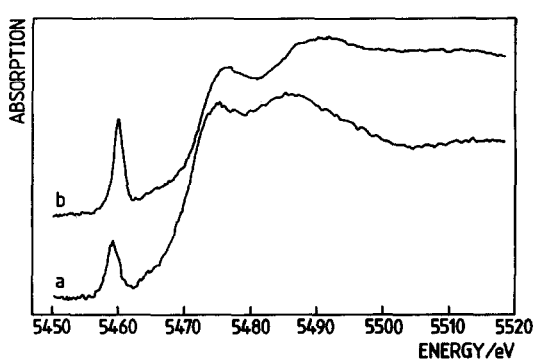

Fig. 1. Vanadium K-edge and XANES of (a) dithionite-reduced and (b) native bromoperoxidase of *Ascophyllum nodosum*.

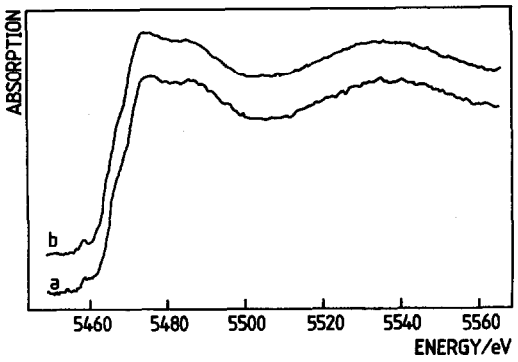

Fig. 2. Vanadium K-edge and XANES of (a) thionine-oxidized and (b) dithionite-reduced VFe-protein of *Azotobacter chroococcum*.

is altered, even when the comparison in Fig. 2 is extended to indicate the super-reduced form of the VFe-protein. The positions of the pre-edge feature (5459 eV) and the edge (5466 eV) indicate an oxidation state of between vanadium(II) and vanadium(IV), and the very weak pre-edge feature implies "octahedral" coordination at the vanadium. Both of these conclusions are consistent with the great similarity of the profiles in Fig. 2 to that recorded[14] for vanadium in $[NMe_4][VFe_3S_4Cl_3(DMF)_3]$.[19]

The comparison provided by Fig. 1 shows that the vanadium environment changes between the dithionite-reduced and native forms of bromoperoxidase, however, in each case the distinct pre-edge feature is typical of compounds with an oxo-vanadium (VO) group. EPR studies[7,20] clearly indicate the presence of vanadium(IV) in dithionite-reduced bromoperoxidase and ^{51}V NMR studies[21] are consistent with the presence of vanadium(V) in the native enzyme. The respective positions of the pre-edge feature (5459 and 5460 eV) and the edge (5469 and 5472 eV) of Fig. 1 are consistent with the assignment of oxidation states by magnetic resonance. Our XAS studies suggest very little change in the vanadium environment upon addition of bromide or peroxide to the native enzyme.

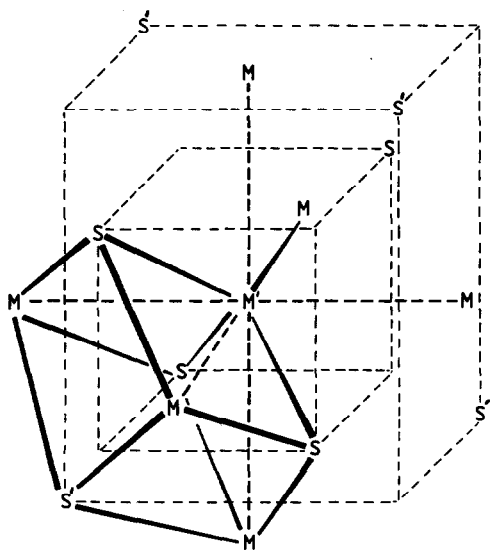

Fig. 3. Metal–sulphur framework, of composition $M'M_6S_8$, proposed for FeMoco and FeVaco, emphasizing one M_4S_4 cubane-like sub-unit.

EXAFS data are readily interpreted to provide the nature, number and distances of atoms immediately adjacent to the primary absorber of the X-rays.[13] The EXAFS associated with the vanadium K-edge for the VFe-protein of nitrogenase is consistent with the vanadium being part of a V—Fe—S cluster,[14,15,22] with 3 ± 1 sulphur atoms at 2.31(3) Å and 3 ± 1 iron atoms at 2.75(3) Å; also, there is evidence for *ca* three light atoms (oxygen, nitrogen) at 2.15(3) Å. These details are consistent with vanadium being octahedrally coordinated in a similar environment to that in the cubane-like cluster anion $[VFe_3S_4Cl_3(DMF)_3]^-$.[19] This situation parallels that for molybdenum in nitrogenase where XAS data[2] are consistent with this element being present in an $MoFe_3S_4$ cubane-like cluster. Iron K-edge EXAFS data recorded for FeMoco[23] and FeVaco show clear evidence for the presence of FeS_2M (M = Mo, V, Fe) rhombs, with Fe---Fe separations of *ca* 2.61 Å, *plus a longer range* Fe---Fe *separation at ca* 3.65 Å. This latter distance has special significance in at least two respects. Firstly, the observation of this relatively long separation implies that the metal–sulphur framework of the cofactors is highly ordered, i.e. the Fe---Fe back-scattered contributions are coherent. Secondly, a geometric relationship appears to exist between the longer and the shorter Fe---Fe separations, viz. $\sqrt{2}\times2.61$ approximates to 3.65. These results are consistent with the structure proposal for FeMoco and FeVaco in Fig. 3. The central M′ is surrounded by an octahedron of six metal atoms (M) and is tetrahedrally coordinated to four sulphur atoms; each of the other four sulphur atoms are also tetrahedrally disposed about M′ and each caps one face of the M_6 octahedron. Molybdenum (or vanadium) is suggested to occupy one M site, thus (Fig. 3) constituting one vertex of an $M_3M'S_4$ cubane-like cluster. Iron atoms are suggested as occupying the M′ and five of the M sites. In this model each M atom is coordinated by *four* sulphur atoms (two S and two S′); for molybdenum (or vanadium), this would permit "octahedral" coordination to be achieved by two ligands external to the cluster, for iron, this is consistent with the iron

EXAFS data[23] which detect only sulphur as the nearest neighbour of this metal in FeMoco.

The EXAFS data for native bromoperoxidase are consistent with the presence of an oxo group (V—O, 1.61(3) Å), together with additional coordination by other light atoms, *ca* three at 1.72(3) Å and *ca* two at 2.11(3) Å. Vanadium in reduced bromoperoxidase is also suggested to be present bound to an oxo group (V—O, 1.63(3) Å) and ligated by similar groups to those found for the native enzyme, *ca* three light atoms at 1.91(3) Å and *ca* two at 2.11(3) Å. The 2.11(3) Å distance is suggested to correspond to coordination by the imidazole group of histidine in each case, the outer carbon and nitrogen shells being clearly apparent for the reduced enzyme. The other ligands are suggested to be the phenols of tyrosines, since the significant reduction in the V—O distance from 1.91(3) to 1.72(3) Å upon oxidation clearly parallels known vanadium chemistry and would correspond to an increase in π-donation from the phenolic oxygen to vanadium upon oxidation.

CONCLUSION

Thus the vanadium centres of the two classes of enzymes presently known to require this metal for catalytic activity are clearly distinguished by XAS. In nitrogenases, vanadium is present as a cubane-like cluster which is part of the larger metal–sulphur cluster cofactor, FeVaco; in bromoperoxidase, vanadium is bound to an oxo group with imidazole and tyrosine suggested as other ligands. This distinction resembles that proposed for molybdenum centres in enzymes.

ELECTROCHEMISTRY OF LIGANDS MULTIPLY BONDED TO MOLYBDENUM AND TUNGSTEN

D. L. HUGHES, D. J. LOWE, M. Y. MOHAMMED, C. J. MacDONALD and C. J. PICKETT*

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—This paper describes some new electrochemically driven reactions of ligands which are multiply bonded to molybdenum or tungsten.

We describe some new electrochemical reactions of ligands which are multiply bonded to molybdenum and tungsten. Our interest was initially focused on the electrochemistry of imide ligands for the following reasons.

First, electron-transfer reactions involving MoNH or WNH groups are plausible steps in electrochemical[1] and biochemical[2] nitrogen fixation pathways, as outlined in Scheme 1 (Box).[3]

Secondly, oxidation reactions involving imide or alkylimide groups might provide a means of diversifying the nitrogen products which can be made from molecular nitrogen, via chemistry at the square-planar $\{M(dppe)_2\}$ assembly (M = Mo or W; dppe = $Ph_2PCH_2CH_2PPh_2$).[4]

However, work with imides has led us to explore the electrochemistry of oxide, methyleneamide, cyanide and aminocarbyne ligating molybdenum or tungsten and has provided some new ligand-centred chemistry.

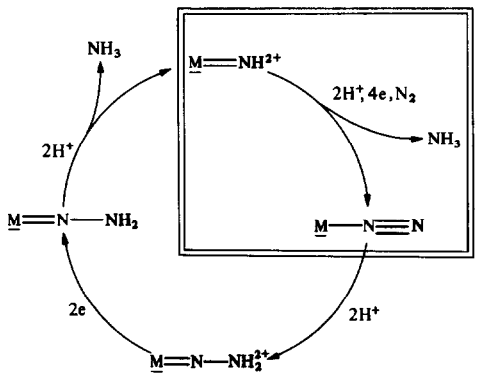
IMIDE AND OXIDE REDUCTION

Simple imide complexes such as *trans*-$[Mo(NH)Cl(dppe)_2]^+$ are reduced under molecular nitrogen to dinitrogen complexes and ammonia,[3] and this provides some support for a role of the {MNH} group in both electrochemical and biological fixation pathways, Scheme 2.

However, it is also possible to obtain ammonia by hydrolysis of an imide which produces an oxide via a prototropic rearrangement, Scheme 3.[5]

What is rather interesting here is that the primary reversible reduction of the oxides, *trans*-$[MOCl(dppe)_2]^+$, occurs at potentials more than 300 mV positive of those of their imido analogues. Moreover, in the presence of a source of protons, the reduction of the oxide becomes irreversible and, under molecular nitrogen, *trans*-$[M(N_2)_2(dppe)_2]$ is produced in an overall 4F mol^{-1} process. The effect of molecular nitrogen on the voltammetry of the molybdenum oxide is illustrated in Fig. 1; the intermediate detected as peak (i) in the voltammogram is the hydroxide intermediate, *trans*-[Mo(OH)Cl $(dppe)_2$], and that labelled (ii) is of the product, *trans*-$[M(N_2)_2(dppe)_2]$, Scheme 4.[5,6]

The relative ease of the multi-electron reduction of the Mo=O group, compared to that of



Scheme 1. In this scheme and Scheme 5, M represents a metal centre and conserved co-ligands. Elsewhere it represents the specific assemblies *trans*-{Mo or $W(dppe)_2$}.

$$Cl—\underline{Mo}{=}NH^{+} \xrightarrow{2e,H^{+}} Cl—\underline{Mo}—NH_2 \xrightarrow[2N_2,\,-Cl^{-}]{2e,H^{+}} N_2—\underline{Mo}—N_2 + NH_3$$

Scheme 2.

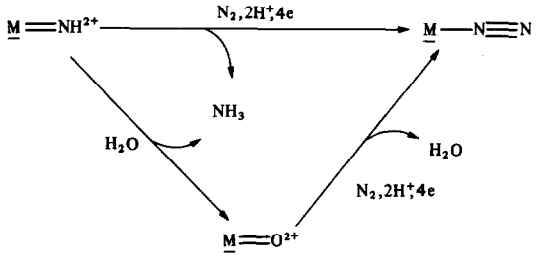
$$MeO—\underline{W}{=}NH^{+} \xrightarrow[-MeOH]{H^{+},H_2O} H_2O—\underline{W}{=}NH^{2+} \longrightarrow O{=}\underline{W}—NH_3^{2+} \xrightarrow{Cl^{-}} O{=}\underline{W}—Cl^{+} + NH_3$$

Prototropic rearrangement

Scheme 3.

$$Cl—\underline{M}{=}O^{+} \xrightarrow{2e,H^{+}} Cl—\underline{M}—OH \xrightarrow[2N_2,\,-Cl^{-}]{2e,H^{+}} N_2—\underline{M}—N_2 + H_2O$$

Scheme 4.



Scheme 5.

Mo=NH, suggests that a sequence involving hydrolysis and oxide reduction might be more favourable in an enzymic nitrogen fixation pathway than direct imide reduction, Scheme 5.[3,5]

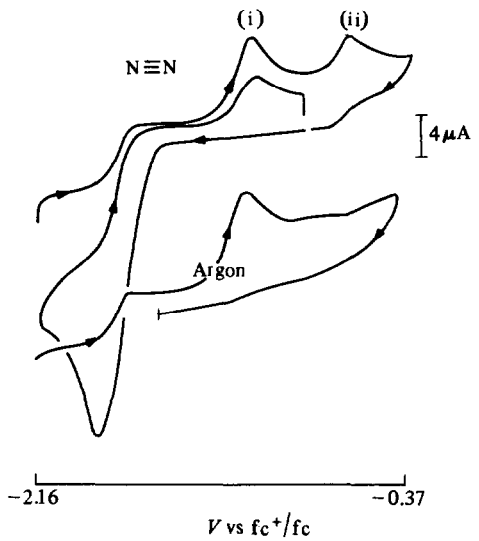


Fig. 1. Clamp voltammograms of *trans*-[MoOCl(dppe)$_2$]$^+$, in a tetrahydrofuran electrolyte containing phenol, showing the detection of the hydroxide (i) and the product (ii), *trans*-[Mo(N$_2$)$_2$(dppe)$_2$]. Potentials are relative to ferrocinium/ferrocene, fc$^+$/fc, here and in Scheme 7. For details see ref. 3.

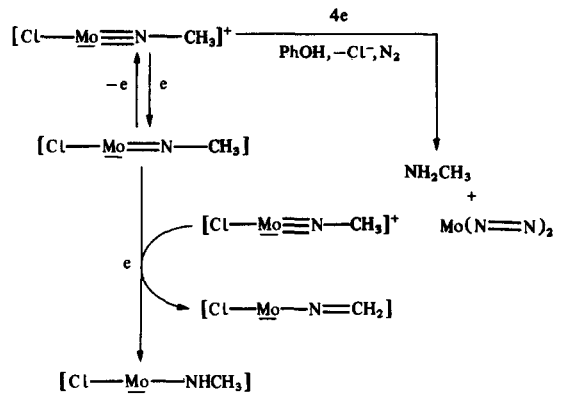
METHYLIMIDE REDUCTION: GENERATION OF A STRONG BASE

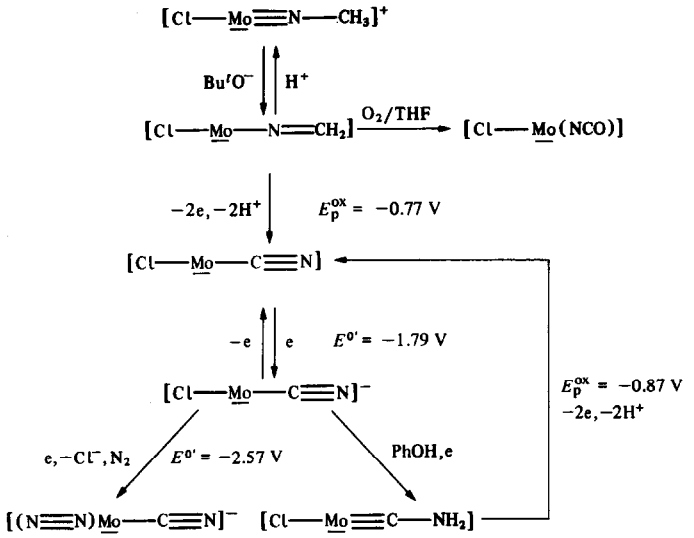
In detail, the electrochemical reduction of *trans*-[Mo(NH)Cl(dppe)$_2$]$^+$ is an irreversible process which initially produces two products viz. the unstable amide, *trans*-[Mo(NH$_2$)Cl(dppe)$_2$], and the nitride, *trans*-[Mo(N)Cl(dppe)$_2$].[2,3] This occurs as an apparent one-electron process, because the primary reduction product removes a proton from the reactant to give the nitride and a cation, the latter is then rapidly reduced to the neutral amide, Scheme 2.[3]

That the primary reduction step involves a single electron-transfer step is suggested by the behaviour of the methylimide analogue, *trans*-[Mo(NMe)Cl(dppe)$_2$]$^+$, which at low temperature displays an electrochemically reversible one-electron reduction, Scheme 6.

We might expect that the reactant, *trans*-[Mo(NMe)Cl(dppe)$_2$]$^+$, would be incapable of furnishing a proton to the neutral one-electron intermediate, but this is not the case. At ambient tem-



Scheme 6. Oxidation of methylimide and methyleneamide ligands: a radical di-cation and a cyanide.



Scheme 7.

peratures, the reduction becomes less reversible and we detect *trans*-[Mo(NHMe)Cl(dppe)$_2$] and the methyleneamide species, *trans*-[Mo(NCH$_2$)Cl(dppe)$_2$], Scheme 6.

Deprotonation of the methylimide by K[OBu^t] affords the methyleneamide by an independent route, and the complex has been isolated and fully characterized.[7] Its formation during electro-reduction is circumvented when phenol is present as a source of protons; a clean four-electron reduction to the amine and *trans*-[Mo(N$_2$)$_2$(dppe)$_2$] is possible on a preparative scale using a mercury cathode and a THF electrolyte, Scheme 6.

Whether the "19-e" primary intermediate adopts a "17-e" bent MoNC configuration remains a matter of speculation, the important message is that we generate a metallo-nitrogen base that is capable of deprotonating the parent carbon acid, the methylimide. Such "father–son" reactions appear to be a common feature of the electrochemistry of imide, alkylimide, hydrazide and diazoalkane cations.[1,3]

Cyclic voltammetry showed that *trans*-[Mo(NMe)Cl(dppe)$_2$]$^+$ undergoes a partially reversible one-electron oxidation in common non-aqueous electrolytes, but our attempts to electrosynthesize clean products in such solvents were unsuccessful.

However, in trifluoroacetic acid containing 0.2 M [NBu$_4$][BF$_4$] and trifluoroacetic anhydride, a medium of low nucleophilicity, the radical di-cation *trans*-[Mo(NMe)Cl(dppe)$_2$]$^{2+}$ is reasonably stable and can be prepared as a solution species by either electro-oxidation at platinum, or by chemical oxidation with [NO][PF$_6$]. We have characterized the di-cation, certain of its isotopically substituted derivatives and a minor co-product, by EPR and ENDOR spectroscopy. This has enabled us to establish that the radical retains the essential structure of the 18-electron parent.[8]

As a means of transforming a methylimide ligand, direct electro-oxidation appeared unpromising, we therefore looked at the oxidation of the de-protonated species, the methyleneamide, *trans*-[Mo(NCH$_2$)Cl(dppe)$_2$].

Electrochemical or iodine oxidation of this complex afforded the cyanide *trans*-[Mo(CN)Cl(dppe)$_2$], which was characterized by an X-ray crystallographic analysis of green prisms isolated in low yield from an anolyte.[7] Labelling studies suggest that the rearrangement of the MoNC framework to MoCN is an intramolecular process, Scheme 7.[7]

THE REDUCTION OF A MOLYBDENUM CYANIDE TO AN AMINOCARBYNE AND TO A DINITROGEN COMPLEX

Cyclic voltammetry shows that *trans*-(Mo(CN)Cl(dppe)$_2$] undergoes two successive one-electron reduction steps in a dry THF electrolyte at a vitreous carbon electrode. The first of these is reversible, the second leads to the irreversible loss of Cl$^-$ and to the formation of the known anionic dinitrogen complex *trans*-[Mo(N$_2$)(CN)(dppe)$_2$]$^-$, Scheme 7. The cyanide also undergoes a reversible one-electron oxidation.

In the presence of a proton source, phenol, the primary reduction of the cyanide becomes an irreversible two-electron process and at a mercury pool cathode the aminocarbyne *trans*-[Mo(CNH$_2$)Cl(dppe)$_2$] is formed in good yield. As far as we

are aware, this is the first example of the partial reduction of a cyanide ligand to aminocarbyne; the complex has an isostructural rhenium analogue, the hitherto unique *trans*-$[Re(CNH_2)Cl(dppe)_2]^+$.[9] In formal terms, the 16-electron Mo^{II}–cyanide is "reduced" to an 18-electron Mo^{IV} product, a process which is chemically reversible, Scheme 7.[7]

The reduction of the cyanide to a molybdo–aminocarbyne provides a chemical precedent for a plausible step in enzymic reduction of CN^- by molybdenum nitrogenase.[10]

CONCLUSIONS

We summarize our conclusions as follows:

(1) In the presence of a proton source, cathode reactions can provide a means of releasing multiply-bonded ligands from $\{M(dppe)_2\}$ assemblies and of exposing a site at which dinitrogen (and other π-acid ligands) can then bind. This is important in the construction of nitrogen fixing pathways and also bears upon possible mechanisms of enzymic fixation.

(2) In the *absence* of a proton source, the primary products of electron-transfer to closed-shell hydrazides, imides or alkylimides can be sufficiently basic to remove a proton from the parent cation. Indeed metallo–nitrogen bases can be electrogenerated which are capable of deprotonating a methylimide ligand.

(3) Electro-oxidation of the methyleneamide to a cyanide and reduction of this cyanide to an aminocarbyne provides a pathway for the isomerization of the $\{MoNCH_2\}$ group to $\{MoCNH_2\}$.

(4) The partial reduction of CN^- at a simple mononuclear molybdenum to a bound aminocarbyne suggests that the generation of a $\{MoCNH_2\}$ group is a plausible stage in cyanide metabolism by molybdenum nitrogenase.

NMR SPECTROSCOPY OF THE EARLY TRANSITION METALS

JOAN MASON

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

Abstract—Many early transition metal nuclei have good NMR properties, and the chemical shifts are sensitive to small structural changes. A key role is played in nuclear magnetic shielding, as in electronic spectroscopy, by the ability of transition metals and ligands to split the ligand field and to expand the *d* shell, in coordination complexes and organometallic compounds. Strong periodic trends can be discerned; thus earlier (compared with later) transition metals show the influence of low-lying *d* levels (smaller nephelauxetic influences) in their chemical shifts. The metal shifts correlate with those of ligating atoms, and with substituent effects on the ligands. Quadrupolar linewidths reflect the symmetry of the coordination sphere (as well as the size and mobility of the complex); and spin–spin coupling constants contribute information on bond type and connectivity. The database of NMR spectroscopic information is growing fast as technical problems are solved for less favourable nuclei, and for solid state studies.

With modern NMR instrumentation the chemist can "dial" almost any nucleus and communicate with it in a matter of minutes, according to Laszlo;[1] indeed, the majority of the early transition metals have magnetic nuclei that can yield reasonable spectra by direct observation of many of their (mainly) diamagnetic compounds, with spectrometers that are now standard.[2,3] In favourable cases NMR spectra have also been measured in the solid-state. Connectivity in extended systems, both organometallic and inorganic (notably in polyoxometallates), can be elucidated by 2-D NMR, e.g. COSY for more abundant nuclei (such as ^{51}V), or special pulse sequences such as INADEQUATE for rarer nuclei (such as ^{183}W).[4,5]

Spectroscopy of the metal nucleus has some advantages over work with ligand nuclei (^{1}H, ^{13}C, ^{31}P etc.). Metal nucleus spectra are simpler and easier to interpret, and the chemical shifts (also the relaxation times and coupling constants) probe the coordination sphere directly, and are sensitive to quite small structural changes (as in diastereomers, for example). Because of the recent expansion of this field, mainly key references, and some illustrative ones, will be given. NMR reviews have dealt with the early transition metals,[6] the *d* block as a whole,[7–11] the first transition series only,[12] various selected transition metals,[13–15] organometallic compounds,[16–18] and particular metals (vanadium[19]) or groups (chromium, molybdenum and tungsten[20]). Useful accounts of work carried out with quadrupolar transition metal nuclei are included in reviews of quadrupolar nuclei,[21] and of electrolyte solutions.[22,23] Reviews of NMR results are updated annually.[24]

NMR PROPERTIES OF THE EARLY TRANSITION METALS

Table 1 gives relevant nuclear properties and their definitions.[3] For reasonable accessibility the nucleus must have a large enough receptivity R^C, that is, a large enough natural abundance and magnetogyric ratio (γ). Low-γ nuclei have the further disadvantage of lower working frequencies ($\nu = \gamma B_0/2\pi$), with associated technical problems such as probe ringing, which transforms as a rolling baseline. All of the group 3 and group 5 nuclei in Table 1 have natural abundances in the region of 100%, as compared to 5.5–18.5% in groups 4 and 6. Quadrupolar nuclei ($I > 1/2$) must have, in addition, a sufficiently small (line) width factor WF, and this is uncomfortably large only for ^{177}Hf and ^{181}Ta. A measure of the favourability of a nucleus is the volume of the NMR literature, or database, to date.[6–24]

The most favourable of the early transition metal nuclei is ^{51}V, which has a large receptivity (2170 times that of ^{13}C) and small width factor (0.37). ^{93}Nb has even larger receptivity (2770) but gives broader lines (width factor 7.65), while ^{181}Ta gives very broad lines. ^{95}Mo, also, is well-studied. ^{53}Cr,

I is the spin quantum number, γ the magnetogyric ratio, and R^C the receptivity (relative to that of ^{13}C in natural abundance, N.A.), which depends on γ^3, I^2, and N.A. Ξ is the resonance frequency of the standard substance in a field of 2.3488 T, at which TMS protons resonate at 100 MHz. WF is a (line)width factor for quadrupolar nuclei which depends on Q^2 and I^{-2} (also called the nuclear IQ).

however, is insensitive and few types of compounds have been measured so far. ^{183}W is a high-resolution nucleus (spin 1/2) but of rather low receptivity, so that indirect methods of detection are often preferable.[5] ^{55}Mn and the radionuclide ^{99}Tc are good NMR nuclei, but ^{189,187}Re give very broad lines.

^{45}Sc, ^{89}Y and ^{139}La have received considerable study, ^{49}Ti and ^{91}Zr rather less, and ^{177}Hf none as yet because of its combination of a low receptivity with a large width factor. ^{49}Ti spectra are complicated by the presence of resonances due to ^{47}Ti, which has rather similar NMR frequency and natural abundance, but gives broader lines (Table 1). ^{175}Lu has not been studied as yet by chemists because of its large width factor (1630), although the receptivity (173) is quite good and its compounds are diamagnetic. One very broad signal has been reported for ^{235}U,[25] which has very low receptivity (0.0054) and large width factor (2820).

NMR TECHNIQUES

Some early transition metal nuclei are sufficiently NMR-receptive that not even a superconducting magnet is needed, as for many vanadium or molybdenum compounds. For less receptive nuclei, sensitivity may be increased by the use of a widebore spectrometer for larger sample volumes, or by higher field working, which increases NMR sensitivity and shift dispersion. Isotopic enrichment was needed to raise a ^{235}U signal,[25] and would be advantageous in bioinorganic studies with ^{95}Mo, for example, since a 6.4-fold enrichment yields a 40-fold advantage in spectrometer time. Multiple resonance or special pulse techniques for sensitivity enhancement (polarization transfer) are of use for spin-1/2 nuclei when there is a resolvable coupling to a high-sensitivity nucleus, usually the proton.[4,5]

Many of the technical problems that arise are related to unfavourable relaxation rates.[4,5] Relax-

ation may be uncomfortably slow, leading to problems of detection or of spectrometer time, for spin-1/2 nuclei with small magnetic moments, such as ^{183}W or ^{89}Y. Depending on the chemical system, relaxation reagents such as $[Cr(pd)_3]$ may be added, or dipole–dipole relaxation may be enhanced by slowing the molecular motions (by cooling the sample, or by use of higher-viscosity solvents). Additional relaxation mechanisms are sometimes advantageous, such as shielding anisotropy (favoured by higher fields) for organometallic compounds of tungsten,[5c] or the spin-rotation mechanism (favoured at higher temperatures).

For quadrupolar nuclei ($I > 1/2$) with large quadrupole moments (Q) relaxation may be uncomfortably fast and lead to (uncertainty) broadening of the lines; although relatively fast quadrupolar relaxation has the advantage that the pulsing can be faster. The linewidth at half-height ($W_{1/2}$) for mobile molecular fluids ($\omega_o\tau_c \ll I$) is given by:[26]

$$W_{1/2} = 1/T_q = \frac{3}{40}\frac{(2I+3)}{I^2(2I-1)}\left\{\frac{e^2qQ}{\hbar}\right\}^2\left\{1+\frac{a^2}{3}\right\}\tau_c, \quad (1)$$

where $T_q(= T_2 = T_1)$ is the relaxation time, e^2qQ the nuclear quadrupole coupling constant (nqcc) as measured by NQR spectroscopy, eq the largest component of the electric field gradient (efg) at the nucleus, with asymmetry parameter a; τ_c is an effective correlation time for the molecular tumbling. On the Stokes–Einstein–Debye frictional model, τ_c is equal to $\eta V/6kT$, where V is the molecular volume, η the viscosity, 1/6 a microviscosity factor as observed for pure liquids, and kT the Boltzmann factor.

Quadrupolar broadening, therefore, is less the smaller the molecule, and the higher the local electronic symmetry (that is, the lower the electric field gradient with which the nuclear electric quadrupole couples). For some transition metal nuclei with large quadrupole moments the main species for which an NMR signal has been reported are relatively small complexes with cubic symmetry, such as tetraoxo, hexafluoro or hexacarbonyl species. An example of the value of a low-viscosity solvent (acetone) is recent pioneer work in ^{53}Cr resonance (with a purpose-built probe), with linewidths ranging from 2–3 Hz for $[Cr(CO)_6]$ to over 3500 Hz for some $[Cr(CO)_5(carbene)]$ compounds.[27] Higher temperatures are often used in ^{95}Mo studies,[20] cf. also the measurement of UF_6 at 380 K (to give a signal 20 kHz wide).[25]

The linewidth can be a useful indicator of the symmetry of the coordination shell, as in studies of the solvation of group 3 ions,[21,22] or of seven- and eight-coordinate complexes formed by lanthanum with small ligands.[28]

In "free" metal ions there may be no permanent efg, if coordination by the solvent is symmetrical, but thermal motions, the buffeting by other ions and dipoles in solution, and fluctuating hydrogen bonds, produce fluctuating efgs, which relax the nuclear electric quadrupole and therefore the nuclear spin.[21–23] These efgs are amplified by distortion of the core electron shells, depending on the Sternheimer antishielding factor γ_∞. This appears as the square in the expression for the linewidth, and increases sharply for heavier ions (cf. the values of ca -40 for Sr^{2+} and -120 for Ba^{2+}).[29]

Fast-relaxing quadrupolar nuclei, also, raise the problem of rolling baselines, arising from contamination of the very short free induction decay by probe ringing. This can be reduced by special pulse sequences (and instrumentation) as the RIDE (Ring-Down Elimination) technique.[30] For heavier elements a degree of quadrupolar broadening is tolerable because of the large shift range.

TRANSITION METAL NUCLEUS SHIELDING

Chemical shifts are given by the paramagnetic term σ_p of Ramsey's perturbation theory,[31–33] which has been reformulated for the transition metals.[34–40] The shift, δ, and nuclear magnetic shielding, σ, are defined with opposite sign, so that increase in δ is given by increase in the absolute magnitude of σ_p. The paramagnetic term is balanced by a diamagnetic term that is comparable in magnitude (each being measured relative to the bare nucleus), but variations in σ_d are small compared with those in σ_p for transition metal nuclei, and can usually be neglected.[33]

For open-shell transition metal compounds the major contribution arises from the mixing into the ground state by the magnetic field of d–d excited states, as these are magnetic dipole allowed (involving circulation of charge). We can therefore visualize circulations of valence d electrons, using ligand field LUMOs (usually $d\pi \rightarrow d\sigma^*$ or $d\sigma \rightarrow d\pi^*$) which reinforce the applied field, deshielding the nucleus. The shielding of main-group nuclei is similarly mediated by $p\sigma \leftrightarrow p\pi$ circulations.[33]

A simple ligand field formulation for a transition metal nucleus in a d^6 octahedral complex is[34]

$$-\sigma_p \approx \left(\frac{\mu_o}{4\pi}\right)\left(\frac{e^2}{m^2}\right)\frac{\langle r^{-3}\rangle_{nd}\langle 0|L^2|0\rangle}{\Delta E}, \quad (2)$$

where μ_o is the permeability of free space, e and m the electronic charge and mass, $\langle r_{nd}\rangle$ the valence

d electron radius, and ΔE the (virtual) excitation energy associated with the angular momentum operator L, with the origin at the metal nucleus. A formulation for main-group or transition elements is[35]

$$-\sigma_p \approx \left(\frac{2\mu_o}{3\pi}\right)(\mu_B^2)\frac{[\langle r^{-3}\rangle_p P_i + \langle r^{-3}\rangle_d D_i]}{\Delta E} \quad (3)$$

where P_i and D_i express the imbalance of charge in the valence p- and d-shells. Fuller expressions sum over the (magnetically allowed) excited states, with appropriate modifications for other symmetries.[35-37] Theoretical studies of nuclear magnetic shielding are reviewed annually.[42]

Most articulations of the theory have centred on cobalt, although studies of earlier transition metal nuclei are increasing. The theory was applied[38] to a range of octahedral cobalt(III) complexes by use of an optical parameter $(h_1/\beta)^{-1}$, where h_1 is the energy of the first spin-allowed absorption band ($^1A_{1g} \rightarrow T_{1g}$) and β the nephelauxetic ratio, discussed below. Deviations were observed for chelate complexes with en, ox (etc.) ligands; more complex optical parameters are required for non-orthoaxial complexes (in which the ligands are not symmetrically disposed on Cartesian axes). Anisotropic nephelauxetism can be used for lower symmetries.[43] The radial term may be modified from the free-atom value by use of an orbital angular momentum reduction factor k, as $k^2\langle r^{-3}\rangle_{nd}$,[43] or as $C_M^2\langle r^{-3}\rangle_{nd}$, where C_M is the coefficient of the d(M) orbital in the LCAO description of the MO;[44] or $\langle r^{-3}\rangle_{nd}$ may be reduced in proportion to a calculated reduction of the central charge by L → M charge-transfer (as in metalate ions)[37] and so on.

Although closed shells make no contribution to the paramagnetic term, the ligand field theory applies also to d^0 and d^{10} complexes because of σ,π-electron delocalization and metal d, s, p orbital mixing. Thus in d^0 complexes ground state nd orbitals may be populated by covalent bonding (including L → M π-bonding).[37,41] In d^{10} compounds back-donation to the ligand (M → L) produces holes in d orbitals, allowing d–d circulations, while L → M donation populates the metal p orbitals.[40] Such effects have been demonstrated by *ab initio* calculations (which are difficult for transition metal nuclei, because of the computing power required).[39,40] In $[Mn(CO)_5L]$ complexes the ^{55}Mn shielding decreases in the sequence H > CN > CH_3 > Cl of the L ligand, as it becomes more π-donating, and also harder, reducing its interaction with the soft acid $Mn(CO)_5^+$.[39] (The deshielding thus correlates with reduction in ΔE, with raising of the $d\pi$ homo and lowering of the $d\sigma^*$ lumo.) In d^{10} complexes of copper, zinc, silver, cadmium, the ^{63}Cu shielding decreases in the sequence CN > NH_3 > Cl of the ligand, as its π-acceptor ability increases, increasing the hole in the d shell. The ^{67}Zn and ^{113}Cd shielding decreases with decrease in ligand electronegativity (with increase in p-contribution to the metal) but in the silver complexes the p and d mechanisms are comparable.[40]

In transition metal nucleus NMR there is usually no *overall* correlation of the chemical shift with the oxidation number of the metal. Thus in Table 2 the more highly shielded complexes of molybdenum and tungsten have (formal) d-electron configurations d^0, d^2, d^4 and d^6. (What they have in common is that all are complexes of strong ligands.) Lower oxidation numbers and negative charges commonly correlate with higher shielding, but the highest ^{95}Mo shielding has been observed[45] for the hydride $[MoCp_2H_3]^+$, in which the metal is formally molybdenum(VI), d^0 (and the complex is positively charged), cf. also the high ^{183}W shielding in $[WCp_2H_2]$.[46] Overall, increase in oxidation number of the metal tends to increase both the energy term (Δ) and the radial factor $\langle r^{-3}\rangle_{nd}$ and these act in opposition, according to eq. (2). There are, however, important regularities.

SHIELDING OF THE EARLY TRANSITION METAL NUCLEI

Table 2 gives approximate ranges of chemical shifts observed for the early transition metals. For the main-group elements the range (or dispersion) of chemical shifts tends to vary periodically, increasing across the row and down the group, reflecting the variation of the radial factor $\langle r^{-3}\rangle_{nd}$,[7,32,35] as seen in the values calculated for the free atoms.[47] Shift ranges are much larger for d block than for main-group elements of similar quantum number (despite smaller $\langle r^{-3}\rangle_d$ than $\langle r^{-3}\rangle_p$ values later in the row). This is attributable in part to the larger range of $\langle 0|L^2|0\rangle$ values [eq. (2)] for d than p orbitals. In eq. (3) the P_i parameter increases (from 0 for spherical symmetry) to 2, for two p orbitals filled and one empty, or vice versa. The D_i parameter, however, can take values up to 12, for three d orbitals filled and two empty (as in low-spin d^6 octahedral complexes), or vice versa (as for d^4 tetrahedral complexes).

For transition elements, also, the energy term may play a larger role. The metal contribution to the ligand field splitting (Δ) increases across the series (with decrease in atomic radius), and increases markedly down the group, by about 50%

from the first series to the second, and 10–25% from the second to the third, with increase in covalent bonding. Very large ranges are observed towards the end of the first transition series (^{59}Co shifts span 19,000 ppm). These can be explained by a large range of ΔE values, and of the angular momentum term; also by relatively large values of the radial terms in the first transition series (as in the second row of the Periodic Table) because of the relatively small number of inner electrons.[7]

In Table 2, the ranges for ^{53}Cr and ^{181}Ta are truncated by the difficulties of observation, due to the low sensitivity and the large quadrupole moment, respectively. For ^{45}Sc and ^{89}Y the small ranges reflect the rather limited chemistry of these elements as well as the relatively small values of $\langle r^{-3}\rangle_{nd}$. The ranges for vanadium, niobium and tantalum are extended by the inclusion of semiconductors[37] (with very small ΔE), and those for molybdenum and tungsten by the quadruply bonded compounds $[M_2(O_2CCF_3)_4]$.[45,48] Metallic solids are not included.

For isostructural compounds, the metal shifts may be scaled, approximately, in proportion to the free atom $\langle r^{-3}\rangle_{nd}$ values. Thus the shift ranges for ^{183}W and ^{181}Ta are in the ratio 1.3, as against 1.2 for the ratio of the free atom $\langle r^{-3}\rangle_{nd}$ values; the corresponding values for the ^{95}Mo/^{93}Nb comparison, are 1.4 and 1.25, respectively. Disparities may be greater in comparisons with heavier elements; thus plotting ^{183}W against ^{95}Mo shifts in corresponding compounds gives lines of slope *ca* 1.7,[49] whereas the ratio of the (free atom) radial terms is two, and the excitation energies are probably similar for the molybdenum and tungsten compounds.[50] Relativistic effects will be identified for heavy atom shifts, but the theory is as yet undeveloped.

THE VARIATION OF METAL NUCLEUS SHIFTS ACCORDING TO THE NATURE OF THE LIGANDS

As shown by eq. (2), the shift (δ) is the greater the closer is the paramagnetic circulation to the resonant nucleus (r small), the smaller its excitation energy (ΔE), and the larger the orbital angular momentum ("unquenched" by the magnetic field) which depends on the imbalance of charge in the $d\pi$ and $d\sigma^*$ (or $d\sigma$ and $d\pi^*$) orbitals. Since ΔE is effectively the ligand field splitting, Δ (or a weighted mean of the splittings for lower symmetries), the shielding tends to increase from weak to strong ligands, following the spectrochemical series. It also increases with increase in d-electron delocalization, or nephelauxetism (cloud expansion), decreasing the radial term $\langle r^{-3}\rangle_{nd}$ from its free-atom value.

INFLUENCE OF THE ENERGY TERM: THE SPECTROCHEMICAL SERIES

Beginning with ^{59}Co shifts,[34] there have been very many δ/λ correlations of transition metal nucleus shifts with the wavelength λ of the long-wavelength UV–vis absorption, according to eqs (2) and (3). In principle, the correlation should be with (spin-allowed) *d–d* excitation energies, but the (relatively weak) bands are often obscured by stronger charge-transfer bands, which may vary in the same sense.[51] Thus ^{53}Cr shifts in carbene complexes $[Cr(CO)_5(CXY)]$ are found to increase as the long-wavelength LMCT (ligand-to-metal charge-transfer) bands go to lower energies.[27] A corresponding relationship is of chemical shifts with the inverse of the binding energies measured by XPES (ESCA), as in ^{49}Ti studies of titanocene dihalides.[52]

If the energy term, ΔE, is dominant, the metal nucleus shielding may be expected to decrease with decrease in the ligand field splitting Δ, following the spectrochemical series in optical spectroscopy. This depends largely on the ligating atom, and may be written as H > C > N > O > F > S > Cl > Br > I, from strong to weak field (an order of decreasing bond strength).[53] Synergic ($\sigma+\pi$) bonding increases Δ, so that O > S > Se > Te, though N > P $\approx$ As.

These regularities are very evident in Table 2. Complexes of strong ligands (H, Cp, CO, RNC, phosphines) show high metal shielding. Low shielding for an M^0 complex (δ ^{95}Mo = 1500) is shown by [Mo(2-PAP)$_3$], with six ligating nitrogens; 2-PAP is 2-(phenylazopyridine).[54] Very low vanadium, niobium and tantalum shielding is observed for the sulvanite type semiconductors A_3BC_4 (with A = Cu, Tl; B = V, Nb, Ta, and C = S, Se, Te).[37] In these the V, Nb, Ta shift increases greatly down the group of the ligand, as S < Se $\ll$ Te, and also as Cu $\ll$ Tl. It is a general observation that very large shifts may be observed when ΔE values are small, since relatively small differences in ΔE bulk large.

The "spectrochemical" pattern is seen also in the vanadates, molybdates and tungstates (O < S < Se). There are usually regular increments in the shift for a given replacement as also in halide and other complexes. In these compounds the metal shielding decreases as the low-energy electronic absorption moves to longer wavelengths, and this was noted also for the ^{17}O shielding, which is

[b] Crystallographically non-equivalent positions.

mediated by the same excitations of oxygen σ- and π-bonding electrons to low-lying d orbitals.[41,51] The chemical shifts of ligating atoms are often found to correlate with those of the metal nucleus, because of the paramagnetic circulations that they have in common.

Dominance of the energy term is evident also in the shifts for halide complexes of Ti, V, Zr, La, Ta, and W. For titanium, the whole shielding range is spanned by the halides, with δ increasing in the sequence F < Cl < Br < I.[12] Other (d^0) complexes of molybdenum and tungsten (containing oxo, nitrido or imido ligands) follow this pattern,[20] as do d^0 arylimido complexes of vanadium, in which the vanadium shift increases with increase in the wavelength of the visible absorption, and with decrease in substituent electronegativity and p-donor ability.[55]

Very low shielding is observed also for the quadruply-bonded carboxylate dimers of molybdenum and tungsten, with low-lying δ orbitals (and considerable electronic asymmetry in the coordination sphere).[45,48] The addition of two axial pyridine ligands to the molybdenum trifluoroacetate dimer lengthens the quadrupole bond, red-shifts the low-energy absorption, and further decreases the ^{95}Mo shielding.[45]

The high metal shielding observed for the cyclopentadienyl compounds, and particularly the hydrides, is clearly related to the strong ligand field, and probably also to nephelauxetism (linked with the back-bonding). The effect of protonation of $[MoCp_2H_2]$ is striking, since it increases the metal shielding by 450 ppm[45] a similar protonation of ferrocene increases the ^{57}Fe shielding by more than twice as much. Such increase (observed also on alkylation) is linked with removal of a relatively low-energy d–d circulation as the d-electron lone pair is stabilized by bonding to hydrogen. An analogue in main-group chemistry is the increase in nitrogen shielding, by 100 ppm or more, with protonation of nitrogen in a delocalized system, pyridine for example.[45]

It is observed for all metal nuclei that alkylation of a polyhapto ligand (as from Cp to Cp′ to Cp″) deshields the metal nucleus, usually incrementally (per alkyl group). This has been attributed to the positive inductive effect of the alkyl groups, and confirmation of this has now been achieved in the XPES measurements on titanocene dihalides, $[TiCp_2X_2]$, $[TiCp''_2X_2]$, etc., since the Ti($2p_{3/2}$) binding energies decrease with methylation of the ligand and deshielding of ^{49}Ti.[52]

^{95}Mo shifts in sandwich complexes with a range of C_5, C_6, and C_7 ring types can be interpreted in terms of the ligand field splittings, with evidence from the (PES) orbital ionization energies. The shielding increases with forward- and back-bonding, and so decreases with an increase in ring size, and from closed to open systems (decreasing, therefore, with increase in reactivity, as observed in other transition metal sandwich complexes).[56]

Bulky substituents are found to deshield a metal (or other) nucleus, usually because of bond-weakening or angle distortion, as may be confirmed by IR spectroscopic or X-ray crystallographic measurements.[27] Deshielding is observed also for a metal nucleus in a four-membered chelate ring, whereas in a five-membered ring the shielding is increased relative to a larger ring or to comparable non-chelating ligands.[49]

In the transition series as a whole (and in main-group compounds) spectrochemical ligand dependence is less common than the nephelauxetic pattern, and is always linked with low-energy magnetically active excitations. Early in the transition series these involve low-lying d orbitals, and often tetrahedral species, in which the ligand field splitting is 4/9 of that for analogous octahedral coordination (and the nephelauxetic effect is smaller for four ligands than for six).

DECREASE IN METAL SHIELDING WITH INCREASE IN METAL–METAL BOND ORDER

In carbon (or nitrogen) resonance, as is well known, higher shielding is observed for triple than double bonds; the carbon shifts are 6, 123 and 72 ppm, respectively, for ethane, ethene and ethyne. In transition metal–metal bonds, however, it is likely that the shielding decreases monotonically with increase in bond order, as observed in ^{95}Mo resonance.[45] This result is not surprising, in view of the decrease in overlap from s to p to d orbitals, and the decrease in electronic symmetry (and increase in quadrupolar broadening) with increase in multiplicity of the M—M bond. It is the high alkyne shielding that is anomalous: the linearity of the bonds at carbon allow free diamagnetic circulation about the bond axis, which is prevented by the higher coordination number in transition metal complexes.[45]

INFLUENCE OF THE RADIAL TERM; THE NEPHELAUXETIC SERIES

The shielding pattern for titanium contrasts dramatically with those observed later in the transition series. For platinum the whole shielding range is spanned by the $[PtX_6]^{2-}$ hexahalides, with δ increasing as I < Br < Cl < I. This nephelauxetic pattern is observed when changes in the radial term

are larger than changes in Δ. For platinum(IV), the Δ and $\langle r^{-3}\rangle_{nd}$ values are both large, at the end of the series. Among the early transition metals, this pattern is evident in d^6 compounds of molybdenum and tungsten, such as $[M(CO)_5X]^-$ or $[Mo(phos)_5X]^-$ halide complexes, in which, again, the Δ and $\langle r^{-3}\rangle_{nd}$ values are large.

The nephelauxetic term, β, obtained from optical spectra,[53] is the ratio of the value of the Racah (interelectron repulsion) parameter B in the complex to that in the gaseous metal ion. The sequence of increase in $(1-\beta)$ and in the d-electron radius is given[53] as $F^- < H_2O <$ urea $< NH_3 <$ en $\approx ox^{2-} < NCS^- < CN^- \approx Cl^- < Br^- < I^- <$ S-ligands < Se-ligands (from hard to soft). For a given metal ion, therefore, the nephelauxetic effect tends to decrease across the row of the table (as C > N > O > F, etc.), but to increase down the group (as F < Cl < Br < I, etc.). The dependence on the ligating atom is weaker in the nephelauxetic compared to the spectrochemical series, and there may be a greater sensitivity to the nature of the metal (strong π-acceptors interacting more strongly with electron-rich metals).

The nephelauxetic effect thus increases with decrease in electronegativity of the ligand, as its reducing power and polarizability increase, also with increase in covalency of the M—L bond. Clearly, there is a difference in periodicity for the spectrochemical and nephelauxetic effects. They reinforce for ligating atoms from the same row, as was found in the early work on cobalt complexes, when linear δ/λ correlations were observed. Down the group of the ligating atom, however, spectrochemical and nephelauxetic effects are usually opposed (with an exception from nitrogen to phosphorus). This explains the multiplicity of δ/λ correlation lines when ligands from different rows of the Periodic Table are compared.[7]

The nephelauxetic pattern has been called "normal ligand (or halogen) dependence" and the spectrochemical pattern, "inverse ligand (or halogen) dependence".[10] The nephelauxetic pattern is normally observed in complexes of the later transition metals, such as cobalt or platinum (which were studied before the early transition metals), and in organic compounds; thus carbon shielding is maximal in CI_4, whereas titanium shielding is minimal in TiI_4.

Curiously, in the quadruply-bonded molybdenum compounds $[Mo_2X_4(PMe_3)_4]$, the metal shift decreases (though rather little) in the sequence Cl > Br > I of the X ligand. This appears to be a relativistic influence of the heavier halogens, since much of the decrease occurs from the bromide to the iodide.[45]

SOLID STATE NMR SPECTROSCOPY OF THE EARLY TRANSITION METAL NUCLEI

With the development of MAS (magic angle sample spinning) NMR instrumentation, solid state spectra are beginning to appear for the early transition metals (many for fairly symmetric species); some solid state shifts are included in Table 2. Spectra and chemical shifts, and some nqcc values, have been reported for ^{45}Sc, ^{89}Y and ^{139}La in inorganic solids,[58] ^{89}Y in aluminate and silicate phases[59] and in bismuth oxide solid solutions,[60] ^{51}V in V_2O_5–Al_2O_3 phases[61] and in vanadyl esters and chlorides,[62] ^{95}Mo in molybdates,[63] and ^{183}W in various tungstates.[64] These include a Keggin compound in which 12 equivalent tungstens, each octahedrally coordinated by oxygen, form a cage with an interstitial phosphorus. The tungsten spinning sidebands give the tensor elements which show an anisotropy of 1357 ppm for the tungsten.[64a] Clearly, the shielding anisotropy relaxation mechanism is likely to be important for ^{183}W compounds, not only polyoxotungstates.[5b,c]

POLYOXOMETALATES

There is a large and important literature of NMR studies of polyoxometalate systems, in resonance of ^{51}V, ^{93}Nb, ^{95}Mo, ^{183}W and many other nuclei (^{31}P, ^{17}O, etc.), as described in the reviews.[64b] Heterocomponents, including paramagnetic substitutions, are usefully studied by NMR.[5b]

BIOINORGANIC STUDIES

Transition metal nucleus NMR is beginning to be used in biological studies, as in recent ^{51}V work on metal ion binding in metalloproteins,[65] and on a vanadate-dependent peroxidase.[66] There have been several studies of the interaction of early transition metals with amino acids, hydroxy acids, etc. and some with polypeptides.

SPIN–SPIN COUPLING TO EARLY TRANSITION METAL NUCLEI

Like metal nucleus chemical shifts, spin–spin coupling constants J(ML) between a metal and a ligand nucleus contain information about the coordination sphere.[67,68] A large number of coupling constants are known from work with the other nucleus: couplings to ^{183}W, for example, from satellites in ^1H, ^{13}C, ^{19}F or ^{31}P spectra. Since J values are proportional to the magnetogyric ratios (γ) of the coupled nuclei, comparisons are made in terms

of the reduced coupling constant K (where J is in Hz and K in N A^{-2} m^{-3}):

$$K(\mathrm{ML}) = \frac{4\pi^2 J(\mathrm{ML})}{h\gamma_{\mathrm{M}}\gamma_{\mathrm{L}}}. \quad (4)$$

Metal nucleus coupling is dominated by the Fermi contact term (J^{Fc}) of Ramsey's second-order perturbation theory.[69] The nuclei interact by way of the s electrons in the bonds between them (since s but not $p, d, \ldots$ electrons can contact the nucleus). Like σ_{p}, J^{Fc} involves a sum over excited states, but can be approximated by use of an effective excitation energy. This now refers to a triplet state ($^3\Delta E$), as the electron spins must be uncoupled. A simple expression is[70]

$$K^{\mathrm{Fc}}(\mathrm{ML}) = \left(\frac{2}{3}\mu_o\mu_B\right)^2 \frac{s_{\mathrm{M}}^2(0)s_{\mathrm{L}}^2(0)P^2}{(^3\Delta E)}, \quad (5)$$

where the $s^2(0)$ terms represent the electron densities at the M and L nuclei, and P is the bond order given by the valence s-orbital coefficients in the MO. Alternatively,[71]

$$K^{\mathrm{Fc}}(\mathrm{ML}) = (\tfrac{2}{3}\mu_o\mu_B)^2 s_{\mathrm{M}}^2(0)s_{\mathrm{L}}^2(0)\pi_{\mathrm{ML}}, \quad (6)$$

where π_{ML} is the mutual polarizability of the orbitals on M and L, involving a sum over excited states. ^1J(VP) values in [VCp(CO)$_3$(PZ$_3$)] complexes have been found to correlate with isotropic ^{31}P hyperfine coupling constants in the ESR spectra of the isoelectronic complexes [FeBr(NO)$_2$(PZ$_3$)],[72] since both couplings are mediated by the Fermi contact.

The $s^2(0)$ terms are strongly periodic, increasing across the row and down the group, so K values vary in this manner.[67] Thus ^1K(WP) parallels ^1K(MoP) in corresponding compounds, with a ratio of 2.76, attributed to the increased electron density at the heavier nucleus.[49] There are strong relativistic increases for heavier elements.[68] Although not allowed for in the simpler theory,[69–71] spin–spin coupling is particularly susceptible to relativistic effects, which involve contraction of s (and p) shells and the consequent expansion of d and f shells, and the spin–orbit splitting of $p, d, \ldots$ shells.[57] These effects become sizeable after the lanthanide series, as for example for tungsten.

Coupling constants commonly decrease in magnitude as $^1K \gg {}^3K > {}^2K > {}^4K$, with alternations of sign. When there are multiple paths for the coupling, as in chelate or other rings, ^1K is the algebraic sum of the contributions. Thus a ^2J(ML) value in a five-membered ring is small (compared with the value for corresponding open-chain ligands) since the ^3J coupling contributes also, and is normally opposite in sign; but a ^2J value in a six-membered ring is increased by the ^4J contribution, for which the sign is the same. One-bond couplings ^1K are usually positive, tending to become negative to the right of the Periodic Table and lower down the groups;[67] a lone pair on a coupled nucleus gives a negative contribution to K^{Fc}. Two-bond couplings ^2K usually correlate with ^1K. ^1K decreases (algebraically) with increase in oxidation number of M. It increases in magnitude (regardless of sign) with increase in electronegativity of substituents on either nucleus (since the bonds to the more electronegative substituents have more p character). Ligands on the metal are less influential than substituents on the ligating atom. Thus the largest ^1J(WP) value observed, 485 Hz, is that for the PF_3 ligand in [W(CO)$_5$(PF$_3$)];[73] and ^1J(VP) values in [VCp(CO)$_3$(PZ$_3$)]$^-$ complexes correlate with the electronegativity (or Taft σ constant) of the substituent Z (e.g. as F > Ph > OMe > $NNMe_2$ > Me).[74]

^1K decreases with increase in coordination number (with decrease in the number of bonds over which the s orbital is distributed). Similarly, magnitudes of ^1K are smaller for bridging than terminal ligands, if monatomic or diatomic (H, N_2, CN etc.). Decrease in a coupling constant in a free ligand is used as a test of complexation (particularly since a negative contribution is lost when a lone pair forms a bond). ^1K increases also with the multiple bonding (with increase in the s component of the σ bond); ^1J(WC) is 80, 120, and 210 Hz, respectively, for W—C, W=C and W≡C bonds in the same complex.[75]

The stereospecificity of coupling constants is well known. ^1K(ML) is greater for equatorial than for axial ligands in trigonal bipyramidal molecules (as the axial bonds are longer, with more p, d character); and greater for ligands which are *trans* to a ligand with a smaller *trans* influence (the tendency to lengthen and weaken a bond *trans* to itself).

In conclusion: many NMR parameters which are measured for analytical purposes have a greater chemical significance than is generally supposed. This may be truer for the transition metal nuclei than for main-group nuclei, for which NMR parameters have been measured for many decades, and for which the theory is better known. The new opportunities provided by the developments in instrumentation ensure that NMR study of the transition metal nuclei, particularly those of the earlier members of the series (^{53}Cr for example) which have only recently come into the spectroscopist's net, offers considerable promise.

REDOX, PHOTOCHEMICAL AND OPTICAL ACTIVITY IN MOLYBDENUM CHEMISTRY: TOWARDS MOLECULAR ELECTRONICS

J. A. McCLEVERTY

School of Chemistry, University of Birmingham, P.O. Box 363,
Birmingham B15 2TT, U.K.

Abstract—Compounds containing the $[Mo(NO)]^{3+}$ group are redox-active. Incorporation into tris(3,5-dimethylpyrazolyl)borato (L*) systems, e.g. [MoL*(NO)XY] where X, Y = halide, alkoxide, aryloxide, amide, anilide, thiolate, etc. affords a variety of species which undergo one-electron reduction. The factors influencing this behaviour are described. Attachment of the molybdenum redox centre to macrocyclic polyethers and the effect of added cation is discussed. The group {MoL*(NO)X} can be attached to the periphery of tetra-aryl porphyrins, and the electrochemistry and photochemistry of the extra-ring metallated species is reported. A series of ferrocenyl compounds, $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)C_6H_4E\{ML^*(NO)X\}]$ and *trans*-$[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)C_6H_4Z{=}ZC_6H_4E\{ML^*(NO)X\}]$ (where Z = CH or H, E = O or NH, M = Mo or W, X = Cl or I) have been prepared, their electrochemistry investigated and several compounds identified as having non-linear optical (Secondary Harmonic Generation) properties.

In general, compounds containing the $[Mo(NO)]^4$ or $[Mo(NO)]^{3+}$ groups are redox-active, readily undergoing one-electron reduction to $[Mo(NO)]^5$ or $[Mo(NO)]^{2+}$ species. This is true of the tris(3,5-dimethylpyrazolyl)borato nitrosyl complexes of molybdenum [MoL*(NO)XY], where X, Y = halide, or pseudo-halide, alkoxide, aryloxide, alkyl- or aryl-amide, alkane or arene thiolate, hydrazide or related species. The most carefully studied of this group of compounds have been the halides, where Y = Cl and I.[1] The dichloride, $[MoL^*(NO)Cl_2]$, is readily reduced electrochemically to the monoanion $[MoL^*(NO)Cl_2]^-$, which is stable in solution and can be isolated by chemical reduction of the neutral precursor using trifluoroethylhydrazine and triethylamine. The diiodide, in contrast, exhibits much more complex behaviour. In scrupulously dry THF, $[MoL^*(NO)I_2]$ is reversibly reduced to the corresponding monoanion at a relatively anodic potential. The ESR spectrum of this species ($\langle g \rangle = 2.027$) is characteristic and consistent with a paramagnetic $[Mo(NO)]^5$ system in which the unique electron is in an orbital predominantly located on the metal. However, if moisture is allowed to enter the system, or if the neutral diodide is exposed to water even in the absence of formally reducing conditions, reduction to $[MoL^*(NO)I_2]^-$ is rapidly superseded by formation of a new reduced species, identified as $[MoL^*(NO)I(solvent)_n]$, resulting from dissociation of I^- from $[MoL^*(NO)I_2]^-$. Iodide ion was readily detected in "wet" solutions of $[MoL^*(NO)I_2]$.

The ESR spectrum of $[MoL^*(NO)I(solvent)_n]$ ($\langle g \rangle = 1.988$) was significantly different to that of $[MoL^*(NO)I_2]^-$ and the two species could be readily identified by this technique. Attempts to isolate $[MoL^*(NO)I_2]^-$ or $[MoL^*(NO)I(solvent)_n]$ were not very successful, although $[MoL^*(NO)I_2Li(OEt_2)_2]$ was obtained on treatment of $[MoL^*(NO)I_2]$ with tolyl lithium in ether. This compound could be regarded either as $[MoL^*(NO)I_2]^-$ stabilized by $[Li(OEt_2)_2]^+$, or as $[MoL^*(NO)I]$ "solvated" by $LiI(OEt_2)_2$. ESR and IR spectral data were most consistent with the former model. Analogues of $[MoL^*(NO)I(solvent)_n]$, where the "solvent" is amine, viz. $[MoL^*(NO)X(NHC_nH_{2n})]$ (X = Cl or I; $n = 4$ or 5) have, however, been isolated and characterized.[2] They too are paramagnetic ($\langle g \rangle = 1.999$) and were very readily oxidized to the diamagnetic $[MoL^*(NO)I(NC_nH_{2n})]$. The electrochemical behaviour was irreversible as expected ($E_p^c = -1.04 \rightarrow 1.68$ V in CH_2Cl_2 vs SCE, depending on X and n).

The compounds [ML*(NO)XQ] (Q = OR, OAr,

NHR, NHAr, SR, SAr), like their dihalide analogues, undergo one-electron reductions, and it is not surprising that when X = Cl, the reduced species are stable to dissociation, whereas [MoL*(NO)IQ]$^-$ readily dissociates with I^- loss. This property can be very important not only for the electrochemical behaviour of this class of molybdenum and related tungsten nitrosyl complexes, but also for the synthetic chemistry of this system.

Substitution of halide in [ML*(NO)X_2] (M = Mo, X = Cl, I; M = W, X = Cl) is facile. Thus, in general, mono-alkoxides and aryloxides are obtained by heating the dihalide with the alcohol or phenol, or by addition of triethylamine or sodium carbonate under milder conditions in the presence of substrate.[3] An alternative is to convert the dihalide to a halide acetate, e.g. [MoL*(NO)X(OCOMe)]; treatment of this with ROH affords the alkoxide with elimination of acetic acid demonstrating neatly the power of acetate as a most effective leaving group.[4] The mono-amido compounds are prepared even more easily by reaction, in many cases at room temperature, of the dihalide with 2 mole equivalents of diluted amine.[3] Formation of [ML*(NO)$(NHR)_2$], however, requires more vigorous conditions.[5] It is also possible to prepare mixed ligand species of the types [ML*(NO)(OR)(NHR)], [ML*(NO)(OR)(SR)] etc.

The structures of representative members of the series [MoL*(NO)XQ] have been determined crystallographically.[6] In all of them, the protective nature of the tris(3,5-dimethylpyrazolyl)borate ligand is evident, the 5-methyl groups hanging down over the metal atom, effectively enforcing six-coordination of these species which normally prefer seven- or eight-coordination. In addition, the bond distances between the metal and the hetero atom of the Q group are short, indicating a substantial amount of p_π–d_π or d_π–d_π bonding between O, N or S and Mo. These factors undoubtedly contribute to the high stability of this class of compounds towards oxidative decomposition and to the facility with which they may be reduced.

The $E_{1/2}$ values of the reduction potentials of [ML*(NO)XQ] are strongly influenced by the nature of M, X and Q.[7] In general, potentials of tungsten compounds are usually between 300 and 500 mV more cathodic than those of their molybdenum analogues. There are insufficient data to state precisely how X influences the redox potential in these species, other than that the $E_{1/2}$ values of iodo complexes are usually significantly more anodic than those of their chloro analogues. However, the value of redox potential is substantially affected by the hetero atom in Q, and by the substituents attached to them. In general, for molybdenum complexes $E_{1/2}$ values fall in the ranges $-0.50 \rightarrow 0.65$ V when Q = OR, $-0.10 \rightarrow -0.42$ V when Q = OAr, $-1.10 \rightarrow -1.22$ V when Q = NHR and $-0.60 \rightarrow -1.10$ V when Q = NHAr. Further fine-tuning of the redox potential can be achieved by using *para-* or *meta*-substitution of aryl rings in species of the type [MoL*(NO)X(ZC_6H_4Y)], where Z = O or NH and Y = H, NH_2, OMe, F, CN, etc., in the *meta* or *para* positions.[8] Thus, in the series [MoL*(NO)I$(NCH_6H_4Z$-*p*)] (Z = NH_2, OH, OMe, H, F, Br, Cl, I, SO_2Ph, N_2Ph) the $E_{1/2}$ value ranged from *ca* -0.5 to -1.0 V and can be correlated very well with Hammett σ constants for these substituents.

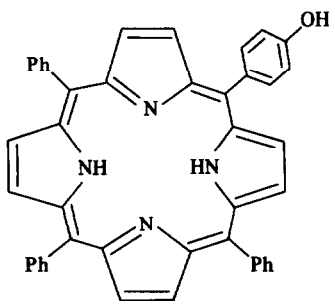
MIXED VALENCE SYSTEMS BASED ON MOLYBDENUM AND TUNGSTEN BIMETALLIC COMPLEXES

The facility with which phenolato and anilido complexes could be prepared presented an opportunity to synthesize bimetallic species bridged by $OC_6H_4O^{2-}$, $NHC_6H_4NH^{2-}$ and related groups. A series of compounds, both *meta-* and *para-*, of the type [{ML*(NO)X}$_2$$ZC_6H_4Z$] (Z = O, NH) and [{ML*(NO)X}$_2${$ZC_6H_4EC_6H_4Z$}] (M = Mo or W, X = Cl or I; Z = O or NH, E = nothing, O, S, SO_2, CH_2, CH_2CH_2, CO) were examined electrochemically. All underwent two reduction processes, and the electrochemical behaviour was interpreted in terms of interaction between the two metal centres as follows:[9] (a) very strong where the ligands were *p*-$ZC_6H_4Z^{2-}$; (b) intermediate where the ligands were *m*-$ZC_6H_4Z^{2-}$, $NHC_6H_4OC_6H_4NH^{2-}$ or $OC_6H_4COC_6H_4O^{2-}$; and (c) very weak or negligible where the ligands were $NHC_6H_4QC_6H_4NH^{2-}$ or CH_2CH_2. The extent of coupling was estimated by the separation, ΔE, between the two reduction waves exhibited by the bimetallic species. Systems having ΔE between 500 and 1000 mV revealed strong interaction, those in the range 100–400 mV were regarded as intermediate, whereas those where ΔE was less than 100 mV hardly interacted at all. A careful analysis of the electrochemical data, and comparison with those obtained from "simple" monometallic phenolates and anilides, suggested that interaction between the two redox centres owed much to transmission through the σ-bonding system. Our view was strengthened by the discovery that a number of bimetallic species bridged by *saturated* ligands, e.g. [{MoL*(NO)Cl}$_2${$N(CH_2CH_2)_2N$}], in which the piperidine (2−) ligand is known to adopt the chair configuration, undergo two distinct one-electron reductions (ΔE in this case is 560 mV). Reduction of diamagnetic [{MoL*(NO)Cl}$_2$$(OC_6H_4O$-*p*)] electrochemically

and by cobaltocene afforded the paramagnetic ($S = 1/2$) monoanion.[11] ESR spectral examination of this species at room temperature revealed that the unique electron is hopping between the two metal centres, but that at liquid N_2 temperatures, it is localized on one metal. Similar treatment of the *meta*-isomer revealed that the monoanion exhibits valence-trapped behaviour at room temperature.

PHOTOCHEMICALLY-ACTIVE REDOX SYSTEMS

As a development of our interest in the electrochemical and electronic properties of bimetallic redox systems, we have attempted to prepare biredox centres containing a metal and an organic electron-transfer centre. Porphyrins are well-established redox systems in their own right, and we have succeeded in modifying the periphery of tetraphenylporphyrin to create mono- and tetraphenolic functionality, **IV**.



Treatment of $[MoL^*(NO)X_2]$ (X = Cl, I, OH, NHCMePh) with $(HOC_6H_4)Ph_3PorphH_2$ afforded the extra-ring metallated species $[MoL^*(NO)X\{(OC_6H_4)Ph_3PorphH_2\}]$.[12] These species are electrochemically rich, a total of five electron-transfer processes being detected by cyclic voltammetry and differential pulse techniques. However, from the accumulated data, it is quite clear that there is very little interaction between the porphyrin and molybdenum redox centres in the ground state. Thus, the unmetallated porphyrin (i.e. $(HOC_6H_4)Ph_3PorphH_2$) exhibits two oxidation and two reduction processes, all one-electron transfers, and the potentials are virtually unaffected by the nature of the molybdenum species when they are attached. The $E_{1/2}$ values of the molybdenum moiety are influenced only by the nature of X in $[MoL^*(NO)X\{(OC_6H_4)Ph_3PorphH_2\}]$. Similar results have been obtained from related metallophorphyrins, $[MoL^*(NO)X\{(OC_6H_4)Ph_3PorphM'\}]$ (M′ = Zn, Ni, Pt, FeCl).

However, it was noticed that the normal fluorescence of the tetra-arylporphyrins was quenched on attachment of the $\{OMoL^*(NO)X\}$ fragment. Thus the emission at 645 nm (caused by excitation at 510 nm) of $[MoL^*(NO)Cl\{(OC_6H_4)Ph_3PorphH_2\}]$ is reduced to 7% of that in $Ph_4PorphH_2$ and that in the species where X = OH and NHCHMePh to 15 and 25%, respectively. That the observed quenching process is apparently intramolecular has been demonstrated by dilution studies. There is a broad correlation between the efficiency of quenching and the $E_{1/2}$ values for the reduction of the molybdenum fragment in the porphyrin species (X = Cl, $E_{1/2} = -0.29$ V; X = OH, $E_{1/2} = 0.81$ V; X = NHCMePh, $E_{1/2} = -1.12$ V). The energy of the first excited state in the porphyrin fragment is 0.85 eV, and this is sufficient to effect reduction of the molybdenum fragment, at least when X = Cl, and OH. A possible explanation for the quenching effect is that, on photo-excitation of the porphyrin centre, electron-transfer occurs from the macrocycle's first excited state to the LUMO of the $\{MoL^*(NO)X\}$ moiety, thereby preventing normal relaxation processes in the porphyrin which lead to fluorescence. Such behaviour in porphyrins to which quinonoidal groups are attached (the so-called diad, triad and tetrad centres) is well-established and is central to biological photosynthesis.[13]

The extra-ring metallated porphyrins are diamagnetic, at least in the ground state, and thus are ESR "silent". On irradiation (visible light) of dichloromethane–toluene (75:25 v/v) glasses of $[MoL^*(NO)Cl\{(OC_6H_4)Ph_3PorphH_2\}]$, the system is still ESR "silent".[14] It was hoped that signals due to the porphyrin radical cation and $\{OMoL^*(NO)Cl\}^-$ centres would be observed. Reduction of $[MoL^*(NO)Cl\{(OC_6H_4)Ph_3PorphH_2\}]$ with cobaltocene did indeed afford a paramagnetic ($S = 1/2$) species whose ESR spectrum is entirely consistent with a reduced molybdenum phenoxide centre to which a virtually unperturbed porphyrin ring was attached. Interestingly, this system also exhibits extremely efficient fluoroscence quenching.[12]

The behaviour of this system has been further complicated by the observation of apparent photochemically-stimulated intermolecular electron-transfer between $(HOC_6H_4)Ph_3PorphH_2$ and $[MoL^*(NO)Cl_2]$, or species closely related to this dichloride. Solutions of $[MoL^*(NO)Cl_2]$ show weak ESR signals associated with a paramagnetic $\{MoL^*(NO)Cl\}$ ($S = 1/2$) centre. It is not clear whether this is $[MoL^*(NO)Cl_2]^-$, or a closely related species, or a decomposition product. However, when dichloromethane–toluene glasses containing a mixture of $(HOC_6H_4)Ph_3PorphH_2$ and this $[MoL^*(NO)Cl_2]$ are irradiated by visible light,

the weak ESR signal is significantly enhanced. In our view, photo-electron transfer must be occurring between the excited porphyrin and a molybdenum-based acceptor.

TOWARDS MOLECULAR ELECTRONICS: NON-LINEAR OPTICAL PROPERTIES AND SECONDARY HARMONIC GENERATION IN FERROCENYL MOLYBDENUM NITROSYL COMPOUNDS

There is currently great interest in the general field of "molecular electronics". This has stimulated a search for new liquid crystalline compounds, for "organic" metals and semiconductors, for materials exhibiting non-linear optical, photochromic or electrochromic properties and for molecular species exhibiting bulk piezo- or pyro-electric phenomena.

Non-linear optical properties are extremely important in optical information processing, viz. in the switching, amplification and modulation of optical signals. According to the Pockels effect, the refractive index of a material varies with an applied electric field, and this permits the switching or modulation of light signals which are passing through that material in response to the applied field. To a first approximation, the polarization, P, of a material (i.e. the induced dipole per unit volume) is proportional to an applied electric field (produced by the oscillating electric (E) of the radiation) and the linear electrical susceptibility (χ).

However, a more exact description of this relationship includes higher powers of E:

$$\chi = \varepsilon_0(\chi_1 E+\chi_2 E^2+\chi_3 E^3+\chi_4 E^4+\cdots),$$

where χ_2, χ_3, χ_4 are higher order electric susceptibilities and ε_0 is a universal constant. It should be noted that for materials which crystallize in centrosymmetric space groups (which includes the majority of non-chiral coordination and organometallic compounds), the even terms, χ_2 and χ_4, must be zero. In linear optics, the refractive index, η, of a substance is related to the electric susceptibility by the relationship $\eta^2 = 1+\chi_1$. In non-linear optics, if terms beyond second order are ignored, $P = \varepsilon_0(\chi_1 E+\chi_2 E^2)$ which can be simplified to $P = \varepsilon_0\chi_{\text{eff}}E$ where $\chi_{\text{eff}} = (\chi_1+\chi_2 E)$. Thus

$$\eta^2 = 1+\chi_{\text{eff}}.$$

Since χ_{eff} is dependent on the field E, the refractive index is also field dependent. Having established these relationships for materials exhibiting non-linear optical behaviour, similar considerations are needed for molecular species. The molecular dipole moment, μ, which is induced by an applied electric field, E, obeys a relationship very similar to that in solids, viz:

$$\mu = \alpha E+\beta E^2+\gamma E^3+\cdots,$$

where α is the molecular polarizability, and β and γ are the first and second hyperpolarizabilities. To obtain large values for χ_2, large values of β are needed.

The necessary requirements to obtain large values of β in molecules are that they must have (a) excited states close in energy to the ground state, (b) large oscillator strengths for electronic transitions from ground to excited states, and (c) a large difference between ground and excited state dipole moments. This means, in effect, that suitable molecules must be dipolar and highly polarizable. If the molecule as a solid material is to have NLO properties, however, it must crystallize in a non-centrosymmetric space group. This may be achieved adventitiously, but can be guaranteed if a chiral species is isolated as a pure enantiomer or diastereomer. Demonstration of potentially interesting β values is obtained by the Kurtz powder test in which Secondary Harmonic Generation (SHG) is measured by irradiating a powdered or microcrystalline sample with a laser frequency, ν (typically 1907 or 1064 nm), and observation of emission at 2ν. The efficiency of the material as a Secondary Harmonic Generator is referred to that of urea, taken as unity ($\Xi = 1$).

In constructing compounds with potentially non-linear optical properties, design usually requires a powerful donor and separate strong acceptor functions connected by a polarizable bridge. Typical donor groups are NMe_2, OMe or 4-pyridyl and acceptors can be NO_2, CO_2R or 4-pyridinium salts. The bridging group may be a benzene ring or *trans*-$C_6H_4Z{=}ZC_6H_4$—, where Z = CH or N. Some simple organic materials which exhibit SHG are 3-nitroaniline ($\Xi = 8$) and 2-methyl-4-nitroaniline ($\Xi = 22$),[15] and certain types of polyacetylenic compounds have Ξ values in the hundreds. Coordination and organometallic species can have donor or acceptor properties at least as powerful as amines or the cyano group, and the ability of organometallics to exhibit non-linear optical properties was elegantly demonstrated by the ferrocenyl species *trans*-$[(\eta^5\text{-}C_5H_5)Fe\{(\eta^5\text{-}C_5H_4)CH{=}CHC_6H_4NO_2\text{-}p\}]$[16] where the SHG efficiency, Ξ, was 62 (excitation at 1907 nm).

Recognizing that {MoL*(NO)X} is extremely electron-withdrawing (electron "deficient" metal, electronegative X and powerful π-acceptor NO), compounds incorporating this functionality and ferrocenyl residues have been prepared.[17] Three basic types of complex have been prepared: (i) $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)C_6H_4E\{ML^*(NO)X\}]$,

(ii) $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)C_6H_4N{=}NC_6H_3RE\{ML^*(NO)X\}]$ and (iii) $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)C_6H_4CH{=}CHC_6H_4E\{ML^*(NO)X\}]$, where E = O or NH, M = Mo or W, X = Cl or I and R = H or Me. In species (ii) and (iii) the alkene diazo bridges adopt the *trans*-configuration, but as yet no crystallographic data are available. These compounds are, or course, electroactive and the ferrocenyl moiety undergoes a reversible one-electron oxidation at $E_{1/2}$ values in the region of +0.58 V. The oxidation potential is very little influenced by the nature of the attached groups, in contrast to the behaviour of the chelating dithioferrocenyl species $[\{\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_3)S_2\{MoL^*(NO)X\}]$ where there is close contact between the iron and the nitrosyl group on the molybdenum, and $E_{1/2}$ (ferrocenyl) is shifted cathodically by 90 mV relative to dithioferrocene.[18] In a comparable way, the reduction potentials of the {MoL*(NO)X} fragment in the ferrocene-containing systems is little influenced by the metallocene, but follows the normal trends as influenced by M, X and E. In testing these materials for SHG behaviour, we have found that iodides are readily decomposed by laser light at 1064 nm, but this is not too surprising in view of the facile reductive elimination of I^- in solution, referred to above. Many of the compounds investigated exhibit negligible or very low values of Ξ, but a number have been found which give rise to Ξ values up to 125.

In attempting to design compounds' NLO properties, we have resolved the chiral species [ML*(NO)X(OR)] and [ML*(NO)X(HNR)].[19] These species are enantiomeric and resolution was effected by forming alkoxides with optically pure monosaccharides and with resolved $NH_2CHMePh$. It appears that the prochiral $[ML^*(NO)X_2]$ reacts with (+)-sugar or (+)- or (−)-$NH_2CHMePh$ to form two diastereomers, one of which rapidly converts into the thermodynamically stable form. A crystal structure of one diastereomer, $[MoL^*(NO)I(C_{12}H_{19}O_6)]$, where $C_{12}H_{19}O_6H$ is 1,2,5,6-di-O-isopropylidene-D-glucofuranose, has established that the absolute configuration at the metal is *S*. The conformations of all related compounds were then established by CD measurements. The iodoglucofuranose does not exhibit SHG and, so far, incorporation of enantiomerically pure {MoL*(NO)X} fragments into other simnple systems has not yielded compounds with significant Ξ values.

CONCLUSION

The effectiveness and versatility of the redox centres based on {ML*(NO)} has been demonstrated. That these have useful and applicable properties is clear, and the design of molecules which have unusual and even specific electronic properties is already possible. The creation of liquid crystalline species and polymers containing {ML*(NO)} is in progress.

Acknowledgements—I am very grateful to my close colleagues Drs C. J. Jones and P. D. Beer who have provided much of the energy and day-to-day guidance essential to the prosecution of several key developments in the work described above. Those who achieved the results described are mentioned in the references, and to our skilled, dedicated and persevering post-doctoral and post-graduate colleagues must go my particular thanks. We are grateful to Professor M. B. Hursthouse and Drs A. J. Edwards and T. A. Hamor for specific assistance with crystallographic studies, to Professor D. Bloor for carrying out SHG measurements, to Drs F. H. Mabbs and D. Collinson for valuable help with ESR measurements, and to Professor R. D. Gillard and Dr P. Williams for help with CD spectroscopy. Finally, I wish to specially acknowledge the contributions of our Polish colleagues, Drs A. Wlodarczyk and S. S. Kurek, who have reminded us of the value and benefit of a rigorous classical laboratory training. The work described above was generously supported by the SERC and by the University of Birmingham.

and

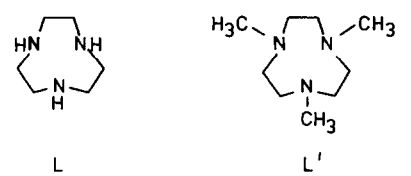
BERNHARD NUBER and JOHANNES WEISS

Anorganisch-Chemisches Institut der Universität, D-6900 Heidelberg, F.R.G.

Abstract—This paper reviews recent work from our laboratory on the nucleophilic behaviour of monomeric complexes of the type LWO_3 and $L'WO_3$ (L = 1,4,7-triazacyclononane and L′ = N,N′,N″-trimethyl-1,4,7-triazacyclononane) which contain a *cis*-trioxometal(VI) unit. The chemistry of oxotungsten(VI) species has received far less attention in the past than the corresponding chemistry of oxomolybdenum(VI) complexes. Crystal structures of $LWO_3 \cdot 3H_2O$, $[L'WO_2(OH)]Br$, $[LWO_2Br]Br$, $[L_2W_2O_5](S_2O_6) \cdot 4H_2O$, $[(LWO_3)_2BPh_2][BPh_4]$, $[LWO_2(\mu\text{-}O)W(O_2)_2O(H_2O)]$, $[(L'MoO_3)_4Co][BPh_4]_2 \cdot C_2H_5OH$ and $[(L'MoO_3)_4Fe^{III}][BPh_4]_3 \cdot Na[BPh_4]$ have been determined and the results are presented here. From this study it is clearly established that the terminal oxo-groups in *cis*-trioxometal(VI) complexes display nucleophilic character. They react readily with electrophiles (H^+, Co^{2+}, Fe^{3+}) or oxophiles, such as the BPh_4^- anion, forming a variety of novel complexes.

A number of oxotungsten(VI) complexes have been characterized by X-ray crystallography in the past.[1] Monomeric compounds containing one or two terminal oxo-groups are quite abundant, whereas the chemistry of the corresponding *cis*-trioxotungsten(VI) complexes has only recently been investigated in more detail. No such complex has been characterized by X-ray crystallography to date;[2] the only example appears to be $(dien)WO_3$ where dien represents diethylenetriamine.[3] This complex is labile in aqueous solution affording uncoordinated amine and WO_4^{2-}. The reaction of WO_3 with oxalate has been reported to give $[WO_3(C_2O_4)]^{2-}$ and $[W_2O_5(C_2O_4)_3]^{4-}$, but again no structural data are available.[4]

We have recently reported the facile synthesis of two *cis*-trioxotungsten(VI) complexes and their molybdenum analogues containing the tridentate macrocycles 1,4,7-triazacyclononane (L) and N,N′,N″-trimethyl-1,4,7-triazacyclononane (L′)



L L′

via exhaustive oxidative decarbonylation of $LM(CO)_3$ species (M = W, Mo) with H_2O_2 in tetrahydrofuran (THF), or via reaction of MO_3 with L and L′ in water according to eqs (1) and (2).[5–7] It was shown that these species are relatively stable in aqueous or alcoholic solutions; they are therefore suited for investigations of the reactivity of the *cis*-trioxotungsten(VI) moiety.

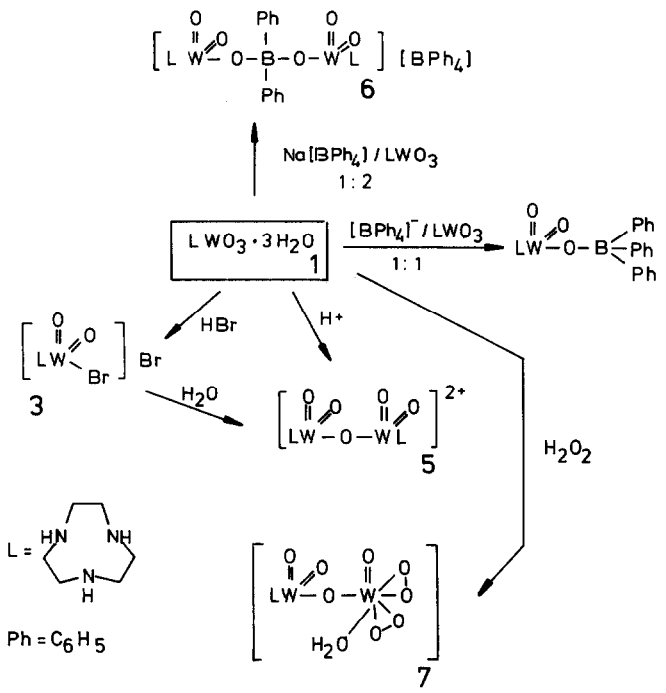

Scheme 1.

From ^{17}O NMR studies of these complexes it was concluded that the terminal oxo-groups of the *cis*-MO_3 unit are quite basic[7] and, consequently, should be susceptible to electrophilic attack by oxophilic reagents such as transition metal cations, protons or suitable silicon and boron compounds. Indeed, we have shown that $Co(ClO_4)_2 \cdot 6H_2O$ reacts in dry methanol with $L'MO_3$ species (M = Mo, W) affording deep blue cations of $[(L'MO_3)_4Co^{II}]^{2+}$ which contain a tetrahedral $Co^{II}O_4$ core. The $L'MO_3$ moieties function as monodentate ligands. A similar species, $[(L'MoO_3)_4Fe^{III}](ClO_4)_3$, with unknown structure, has also been obtained (an $Fe^{III}O_8$ polyhedron has been proposed incorrectly on the basis of IR spectroscopic data).[7] At that time no single crystals suitable for X-ray crystallography were available.

In this report we will review the chemistry of the LWO_3 and $L'WO_3$ species and present crystallographic results of a variety of products. Full details of these investigations will be published subsequently elsewhere.[8]

SYNTHESES

Scheme 1 summarizes the reactions of $LWO_3 \cdot 3H_2O$ investigated. Compounds $LWO_3 \cdot 3H_2O$ (**1**) and $L'WO_3 \cdot 3H_2O$ (**2**) are readily protonated in acidic aqueous solution. Three products have been isolated as colourless, crystalline materials, eqs (3)–(5), depending on the exact reaction conditions:

$$\mathbf{1} + HBr \longrightarrow \underset{(\mathbf{3})}{[LWO_2Br]Br} \quad (3)$$

$$\mathbf{2} + HBr \longrightarrow \underset{(\mathbf{4})}{[L'WO_2(OH)]Br} \quad (4)$$

$$2\,\mathbf{1} + 2H^+ \rightleftharpoons \underset{(\mathbf{5})}{[LWO_2{-}O{-}WO_2L]^{2+}} + H_2O. \quad (5)$$

One terminal oxo-group in **1** or **2** is converted into a coordinated hydroxide generating **4**, which may then undergo substitution reactions with nucleophiles such as Br^- forming **3**. In the absence of coordinating anions, using $HClO_4$ or CH_3SO_3H as the source for protons, **1** dimerizes to produce the μ-oxo-bridged species $[L_2W_2O_5]^{2+}$ (**5**).[9] The corresponding binuclear species, $[L'_2W_2O_5]^{2+}$, has been obtained previously by the reaction of $L'W(CO)_3$ with concentrated nitric acid.[10]

The reaction of **1** with H_2O_2 in aqueous solution affords colourless crystals of an unsymmetrical binuclear complex $[LWO_2(\mu\text{-}O)WO(O_2)_2(H_2O)]$ (**7**), which contains a bis(peroxo)oxoaquatungsten(VI) unit. This reaction demonstrates that the coordinated ligands L and L′ may be cleaved off in solution.

Compounds **1** and **2** were found to react with $[B(C_6H_5)_4]^-$ in acidic aqueous solution. Thus, by using a ratio tungsten–boron of 1 : 1 the neutral

complexes $LWO_3B(C_6H_5)_3$ and $L'WO_3B(C_5H_5)_3$, respectively, precipitated, which contain the W—O—$B(C_6H_5)_3$ structural unit. Goedken and co-workers have recently reported a similar reaction of a vanadyl(IV) complex with $[BPh_4]$.[11] When the tungsten–boron ratio was raised to 2:1 the binuclear complex, $[LO_2W—O—B(C_6H_5)_2—O—WO_2L][B(C_6H_5)_4]$ (**6**), precipitated. These reactions demonstrate convincingly, that the oxo-ligands of the *cis*-trioxotungsten(VI) moiety in **1** and **2** react smoothly with oxophiles; they are good nucleophiles.

The reaction of $L'WO_3$ (or $L'MoO_3$), in weakly coordinating solvents (methanol), with $Co(ClO_4)_2 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot 6H_2O$ affords deep blue $[(L'MO_3)_4Co](ClO_4)_2$ and pale yellow $[(L'MO_3)Fe](ClO_4)_3$ (M = Mo, W), respectively.[7] Single crystals suitable for X-ray crystallography have now been obtained with $[BPh_4]^-$ counter-anions: $[(L'MoO_3)_4Co][BPh_4]_2$ (**8**) and $[(L'MoO_3)_4Fe][BPh_4]_3 \cdot Na[BPh_4]$ (**9**).

CRYSTAL STRUCTURES

The structure of the monomeric *cis*-trioxo-molybdenum(VI) complex, (dien)MoO_3, has been reported.[12] Compound **1** represents the first such structurally characterized species of tungsten(VI) (Fig. 1). Surprisingly, there are two significantly different W=O_t bonds in the solid state (Table 1): two short bonds of 1.77(1) Å and one longer W(1)—O(3) bond of 1.851(8) Å. This is in contrast to the structures of (dien)MoO_3,[12] $[LReO_3]Cl$[13] and $[(MoO_3)_2(EDTA)]^{4-}$,[14] where three equivalent short M—O bonds have been found. In **1** each terminal oxo-group is bound via hydrogen bonding to two water molecules of crystallization. The O—W—O bond angles are obtuse (av. 107°). The

[a] The second column gives distances and angles in the molecule which are related to the first column assuming a non-crystallographic symmetry.

average W—N distance is 2.31(1) Å; the N—W—N bond angles are acute (av. 72.2°) due to the steric constraints of the cyclic triamine.

The structures of the cations in **3** and **4** (Fig. 1) are quite similar, they consist of the *cis*-dioxotungsten(VI) group, a monodentate anion (Br^- or OH), and a tridentate amine ligand. The average $W{=}O_t$ bond length is 1.77 Å and the O=W=O angle is again obtuse in both complexes. Interestingly, the W—N bonds in the *trans* position with

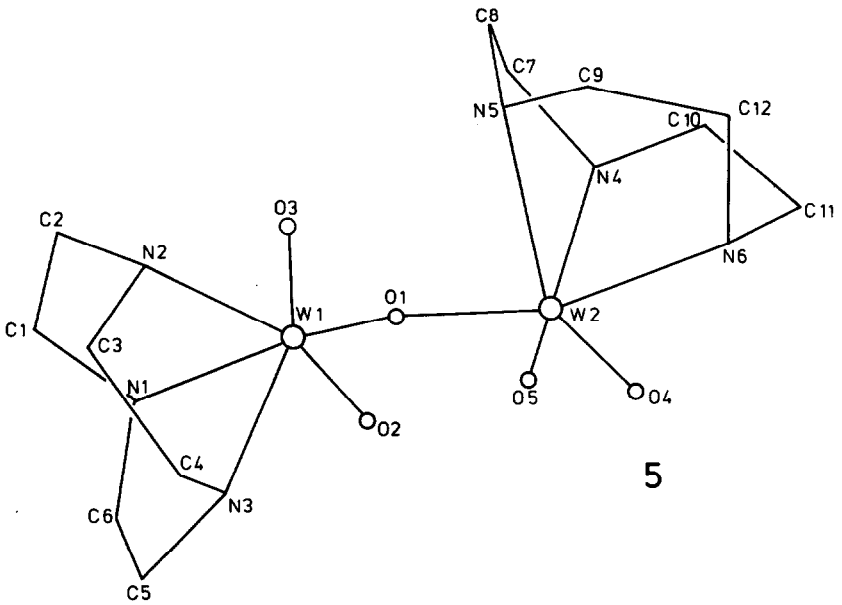

Fig. 2. Perspective view of the dication in $[L_2W_2O_5](S_2O_6) \cdot 4H_2O$ (**5**).

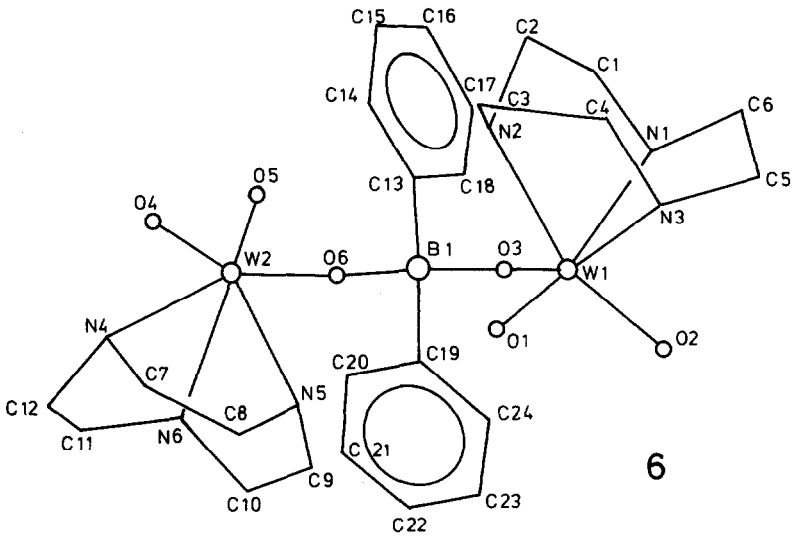

Fig. 3. Perspective view of the cation in $[(LWO_3)_2BPh_2][BPh_4]$ (**6**).

respect to the bromo and hydroxo ligands, are significantly shorter than the corresponding W—N bonds *trans* to the terminal oxo-groups. This reflects a strong structural *trans*-influence of the π-donating oxo-groups. The μ-oxo-bis[*cis*-dioxomolybdenum(VI)]$^{2+}$ unit is known,[1,15] but corresponding complexes of tungsten(VI) have not been structurally characterized previously.[2] $[L_2W_2O_5](S_2O_6)\cdot 4H_2O$ (**5**) has now been characterized by X-ray crystallography (Fig. 2). The overall structure of the dication is very similar to its $[L'_2Mo_2O_5](Br_3)_2$ analogue,[15] except that the μ-oxo bridge is *not* linear (W—O—W 157.6(9)°) as it is in the $[Mo_2O_5]^{2+}$ unit. The terminal W=O_t groups exert again a *trans*-influence on the *trans*-W—N bond lengths (Table 1). The structure of the cation in **6** is shown in Fig. 3. It consists of two LWO_3 units which are connected by a BPh_2-fragment which is bound to one oxo-group of each LWO_3 unit. The boron centre is pseudo-tetrahedrally surrounded by two oxygen and two carbon atoms. The two W—O—B bond angles are obtuse and not equivalent (152.4(4) and 175.7(4)°).

Compound **7** consists of LWO_3 and $WO(O_2)_2(H_2O)$ units connected by an unsymmetrical μ-oxo bridge (Fig. 4). The dimensions of the

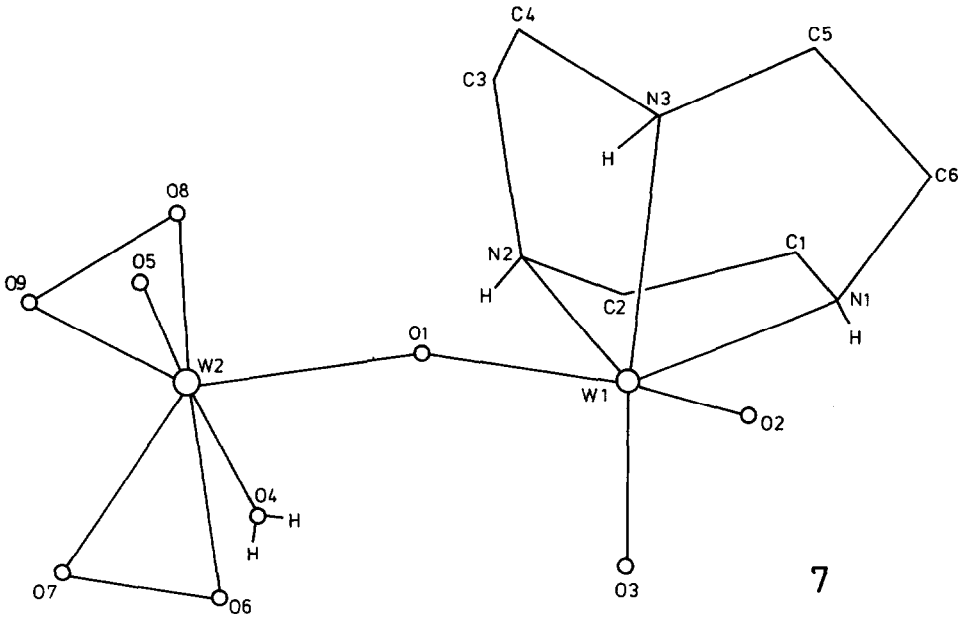

Fig. 4. Perspective view of the molecule in crystals of $[L'WO_2(\mu\text{-}O)WO(O_2)_2(H_2O)]$ (**7**).

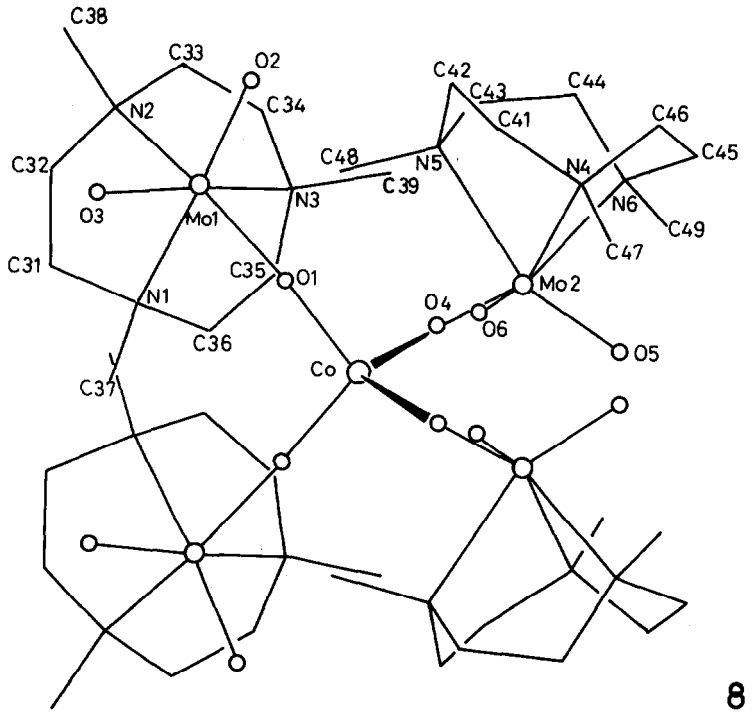

Fig. 5. Perspective view of the dication in $[(L'MoO_3)_4Co][BPh_4]_2 \cdot C_2H_5OH$ (**8**).

$WO(O_2)_2(H_2O)$ unit are very similar to those observed in the binuclear diperoxotungsten(VI) complex, $K_2[\{WO(O_2)_2(H_2O)\}_2O] \cdot 4H_2O$.[16] The LWO_3 unit in **7** is, within experimental error, identical to those in **5**. The W—O—W bridge is again not linear (W—O—W 152.2(2)°).

Figures 5 and 6 show the structures of the cations in **8** and **9**. The cobalt(II) ion in **8** is surrounded

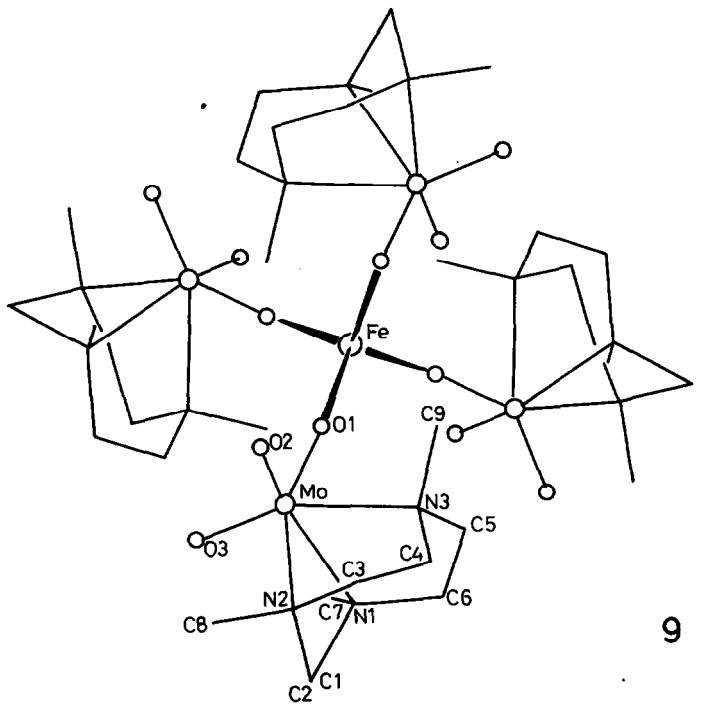

Fig. 6. Perspective view of the trication in $[(L'MoO_3)_4Fe][BPh_4]_3 \cdot Na[BPh_4]$ (**9**).

by four monodentate $L'MoO_3$ ligands forming a slightly distorted tetrahedral CoO_4 central core. Molecular analogues of **8** are $[Co(Me_3PO)_4]^{2+}$ and $[Co(Ph_3PO)_4]^{2+}$ which have not been characterized by X-ray crystallography.[17] The effective magnetic moment of **8** (at 298 K) of 4.2 μ_B is quite typical for tetrahedral cobalt(II).[7] The Co—O bond distance of 1.92 Å is identical to the one found in a heteropolytungstate, $[Co^{II}Mo_{12}O_{40}]^{6-}$.[18] The high-spin iron(III) centre (5.9 μ_B at 298 K) in **9** is in an exact tetrahedral environment of four monodentate $L'MoO_3$ units. Similar $Fe^{III}O_4$ cores have been identified in the compounds $[Fe^{III}W_{12}O_{40}]^{5-}$[19] and $Na_{14}[Fe^{III}_6O_{16}]$.[20]

THE COORDINATION CHEMISTRY OF TECHNETIUM IN ITS INTERMEDIATE OXIDATION STATES

ULDERICO MAZZI

Dipartimento di Scienze Farmaceutiche, Universita di Padova, via Marzolo 5, 35131 Padova, Italy

Abstract—The coordination behaviour of technetium is reviewed with an emphasis placed upon the chemical rather than pharmaceutical properties.

Among the early transition elements technetium is the most recently discovered, but, owing to its considerable use in nuclear medicine as a radiotracer, studies of its chemistry are expanding and its chemical properties are now beginning to be understood.

All technetium coordination chemistry studies to date have been directed towards the synthesis of Tc-99m labelled radiopharmaceuticals. This means that the ligands have been specifically designed to attain this goal, and the range of complexes[1] is limited by the rather special requirements of nuclear medicine. Thus, it is preferred to use only one type of ligand per complex, and from the kinetic point of view, first-order synthetic reactions are preferred. Other possible limitations include the necessary use of pertechnetate as starting material, which may in turn require the use of an external reducing agent if the coordinating ligand is not a suitable reductant for pertechnetate. Finally the reactions must proceed in physiologically relevant solutions. Despite these limitations some important chemical information has been derived and also some pseudo-theoretical studies have been made on the chemical behaviour of technetium.

The electronic configuration of technetium in the ground state is $[Kr]4d^65s^2$ and the element can show formal oxidation states from $+7$ to -1 in its compounds. Technetium complexes can be classified according to the oxidation state of the central metal into two large classes: technetium complexes in intermediate oxidation states and technetium complexes in low oxidation states.

TECHNETIUM(VII), (VI)

Technetium(VII) is exclusively represented by the pertechnetate anion (TcO_4^-). Technetium(VI) usually disproportionates to V and VII, but recently many complexes containing mainly the $Tc{=}N^{3+}$ core have been synthesized and show good stability. Interesting EPR studies on these d^1 systems were performed by Abram *et al.*[3,4]

TECHNETIUM(V)

Technetium(V) complexes can be considered as derived from a two-electron reduction of pertechnetate with the partial elimination of oxygen atoms. Technetium(V) has a d^2 electronic configuration and is diamagnetic or slightly paramagnetic. The magnetic properties arise from the orbital distortion induced by the polar Tc—X group (X = O, N or S), as reported by Chatt *et al.*[5] for rhenium analogues. The presence of at least one oxo group around technetium is a characteristic of technetium(V) cores, while the geometries of the complexes depend on the nature of the ligands. TcO^{3+}, *trans*-TcO_2^+ and $Tc_3O_3^{4+}$ cores are very common in five-, six- or seven-coordinated compounds.

A large group of ligands, mostly symmetrical or unsymmetrical, bidentate, tridentate, tetradentate or pentadentate, can stabilize oxotechnetium(V) and can have O, N, S, As, or P donor atoms. Many complexes have been completely characterized and

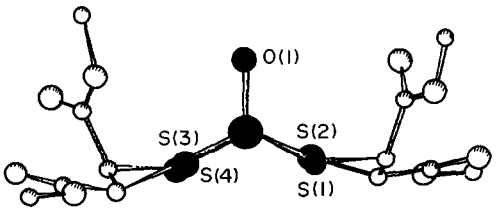

Fig. 1. Structure of (1,2(dicarbomethoxy)ethane-1,2-dithiolato)oxotechnetate(V).[7] An example of the $[TcO(SS)_2]$ configuration.

it is possible to deduce some rules to predict how the type of complex formed depends on the properties of the ligands.

Ligands with exclusively sulphur donor atoms tend to lead to five-coordinate complexes with $Tc{=}O^{3+}$ cores. A general characteristic of these complexes is the "reversed umbrella" shape with the technetium atom displaced above the equatorial plane of the four sulphur atoms[6] (Fig. 1).

Analogous behaviour occurs with OS (e.g. mercaptoethanol)[8] or OO (e.g. ethyleneglycol)[9] donor ligands, where again five-coordination with a $Tc{=}O^{3+}$ core is observed. Occasionally a sixth ligand, *trans* to Tc=O is bound and is preferably a phenolic,[10] alcoholic or hydroxy oxygen,[11] and, sometimes, a halogen or a μ-oxo group bridging two technetium centres.[12] This sixth group is normally weakly bonded if it is a monodentate ligand, whereas it is relatively stable when it is part of a polydentate ligand (Fig. 2).

In all the technetium(V) oxo complexes, the stretching vibration of the Tc=O bond in the IR spectrum is considered a good indicator of its presence. The value ranges from 890 to 1020 cm^{-1}, and the value is related to the electron affinity of the ligands in the equatorial plane and the nature of any sixth ligand *trans* to Tc=O. The Tc=O distance lies in the range 1.61–1.68 Å and correlates in the same way, showing longer distances for six-coordination compared to five-coordinated species with the same type of ligands.[15]

Proceeding towards complexes containing N-donor ligands such as monodentate nitrogen ligands (pyridine, imidazole), diamine (ethylenediamine, 1,2-diaminopropane), cyclam or even diarsine and diphosphine, two *trans*-oxo groups remain in the complex giving the TcO_2^+ core.[6] As a second oxygen is now *trans* to Tc=O, the Tc=O stretching vibration is at 790–834 cm^{-1} for TcO_2^+ complexes and also the Tc—O distance is longer, averaging 1.75 Å for these complexes.

It is possible to conclude that oxygen plays an important role in stabilizing the V oxidation state of technetium. One oxygen is indispensable to alleviate the electron deficiency of the technetium atom and to neutralize its charge. Another oxygen must be located *trans* to Tc=O when the ligands in the equatorial plane do not donate enough electron density to the technetium centre.

The reactivity of the oxotechnetium(V) complexes has also been well studied because it gives information on the kinetic stability of the complexes once injected "*in vivo*". From this point of view, the most stable complexes were with polydentate ligands and with coordinative saturation. In the case of the PnAO complex[16] [PnAO = 3,3′ - (1,3 - propanediyldiimino)bis(3 - methyl - 2 - butanone oximato)], the stabilization is achieved by means of cyclization due to the formation of a hydrogen bridge. Good stabilization was also attained in [TcO(DADS)] (DADS = diaminodisulphur ligand),[17] in which a tetradenate ligand containing a NSSN coordination set forms the square base of the pyramid and the oxo-oxygen is apical (see Fig. 3).

Few detailed studies have been made on the redox properties of technetium(V) owing to the non-reversible nature of the electrode processes. The only study to date deals with the electrochemical behaviour of oxotechnetium complexes containing Schiff's base or 8-quinolinol ligands. The reduction of technetium(V) to technetium(IV) and then to technetium(III) shows the relative stability, or at least the existence of, TcO^{2+} and TcO^+ cores.[18]

Under certain conditions the oxo-oxygen can be replaced by nitrogen or sulphur atoms. Thus, reduction of pertechnetate with hydrazine or substituted hydrazines in the presence of an appropriate ligand, leads to the formation of technetium nitrido complexes (see Fig. 4). $Tc{\equiv}N^{2+}$ is a very stable core and when the first complexes were prepared by Baldas *et al.*[19] it was suggested that its chemistry was less versatile than that of the $Tc{=}O^{3+}$ core. Indeed only five-coordinated products with soft donor atoms in the equatorial plane were initially isolated and characterized.[20] In recent years it has been demonstrated that the $Tc{\equiv}N^{2+}$ core also occurs in a range of six-coordinated complexes with a large variety of ligands,[21,22] including amines, phosphines, cyclam or aminophosphines.

Once formed, the Tc≡N ligand is relatively inert and is not at all readily replaced by oxygen or sulphur. The main characteristic physico-chemical properties of this group reported in the literature are the IR stretching vibration (1050–1070 cm^{-1}) and the Tc—N distance (1.58–1.63 Å). The structures, where available, generally exhibit square-pyramidal configurations with a high displacement of the technetium atom above the equatorial plane

for five-coordinated species and pseudo-octahedral geometries for six-coordinated complexes.

The technetium(V) nitrido complexes exhibit diamagnetic character for analogous reasons to the oxo-compounds. Their reactivity is not yet well studied; but the possibility of their oxidation to technetium(VI) has to be considered because the $Tc{\equiv}N^{3+}$ core is now known to be stabilized by particular ligands such as "salen".[23]

The $Tc{=}S^{3+}$ core is less common and, to date, only one example is known: $[TcS(HBPz_3)Cl_2]$ ($HBPz_3$ = hydrotris(1-pyrazolyl)borato) prepared starting from the known oxo analogue by reaction with B_2S_3.[24] In this complex sulphur is replaced in solution by oxygen from air.

A general theory can rationalize the behaviour of all the technetium(V) complexes reported to date. Duatti *et al.*[25] correlated the Tc=X bond distance (X = O or N) with the magnitude of the displacement of the technetium atom above the equatorial plane in the five- and six-coordinated complexes. The data have been discussed in terms of the basicity of the ligands in the equatorial plane. Soft ligands such as those containing sulphur groups,

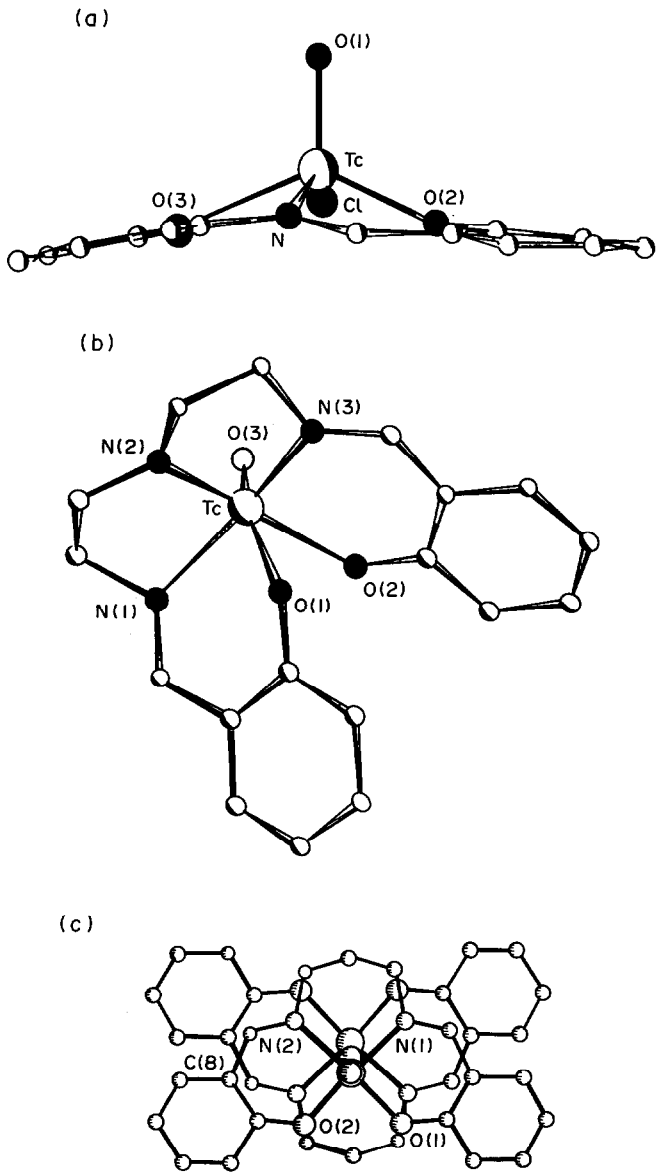

Fig. 2. Examples of structures of technetium(V) complexes with mixed O and N donor atom sets: (a) chloro(N-(2-oxidophenyl)salicylideneiminato)oxotechnetium(V);[13] (b) N,N′-(3-diethyleneaminato)-1,2-diylbis(salicylideneiminato)oxotechnetium(V);[14] (c) oxo-bis(oxo(N,N′-propylenebis(salicylideneiminato)))oxotechnetate(V).[12]

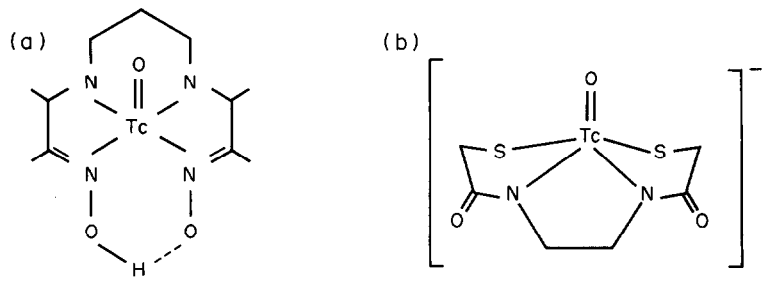

Fig. 3. Structures of (a) [TcO(PnAO)] and (b) [TcO(DADS)].

create high displacement and long Tc—X distances. On decreasing the ligand donating power, the displacement is lower and the Tc=X distance also decreases. The five-coordinate complexes, $[TcXCl_4]^-$, have the lowest displacement and the shortest Tc=X distances. Hard ligands with low basicity stabilize the Tc=X group only by means of a sixth *trans* group. The displacement above the equatorial plane is also related to the basicity of the group *trans* to Tc=X. A pseudo-octahedral geometry is attained only with TcO_2^+ cores.

TECHNETIUM(IV)

The first technetium(IV) product discovered was the very insoluble oxide TcO_2 and this product must be avoided when technetium complexes are prepared. In strong haloacid media, TcO_2 is converted to the hexahalogeno complexes $[Tc^{IV}X_6]^{2-}$.[26] $[TcX_4P_2]$ (X = Cl, Br or I and P = tertiary phosphine) are the first phosphine complexes of technetium synthesized by Fergusson *et al.*[28] and can be produced starting directly from pertechnetate in hydrohalogen acid media (see Fig. 5 for structures).[29] The reactions of these $[TcCl_4P_2]$ complexes with acetylacetone produced complexes of both Tc^{IV} and Tc^{III}[31] revealing the easy interconversion of Tc^{IV} and Tc^{III}.

Relatively few technetium(IV) complexes have been used as radiopharmaceuticals and these include some polymeric phosphate and phosphonate species,[32] and some EDTA complexes such

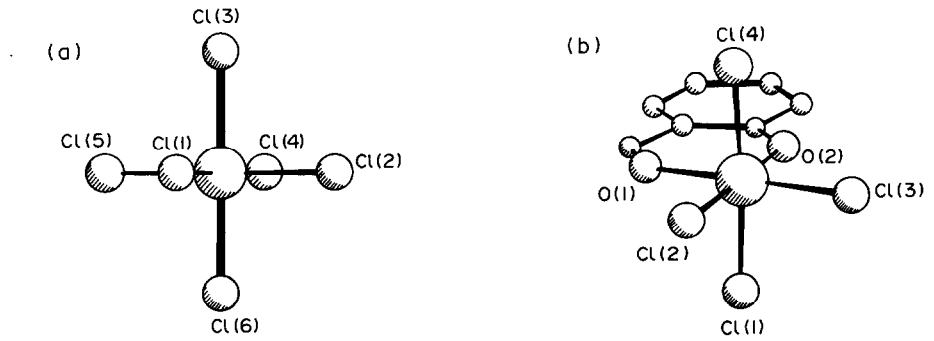

Fig. 5. Examples of technetium(IV) complexes. Structure of: (a) $[TcCl_6]^{2-}$ and (b) $[TcCl_4(sal)]^-$.[30]

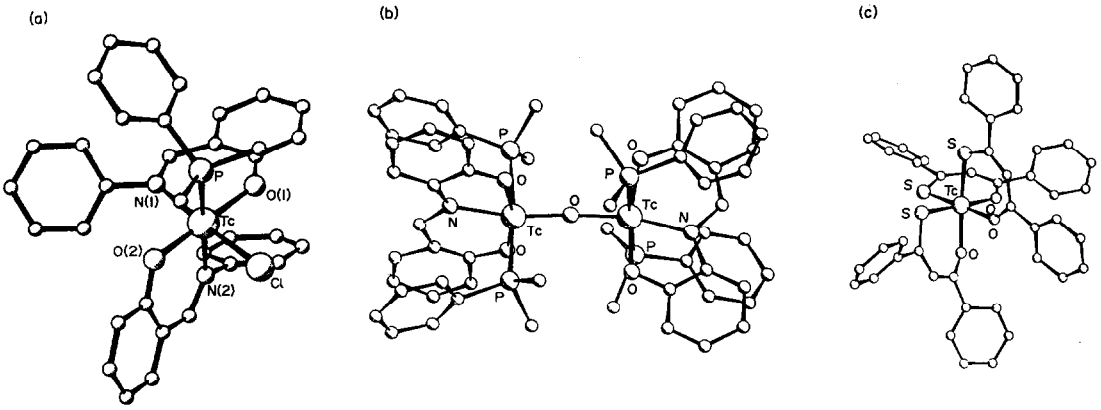

Fig. 6. Examples of technetium(III) complexes: (a) $[TcCl(PMe_2Ph)(Phsal)_2]$; (b) $[\mu\text{-}O(Tc(PMe_2Ph)_2(OPhsal))_2]$;[36] (c) $[Tc(SC(Ph)CHC(Ph)O_3]$.

as $[(H_2EDTA)Tc(\mu\text{-}O)_2Tc(H_2EDTA)]\cdot 5H_2O$.[33] Technetium(IV) is an intermediate oxidation state and is less studied because generally it undergoes kinetically fast reactions so that this oxidation state is by-passed. Thus technetium(V) is reduced by a bielectronic process to technetium(III), and technetium(IV) can be obtained only by oxidation of technetium(III). This bielectronic process could involve the loss of the oxo-oxygen from $Tc{=}O^{3+}$ in the presence of bielectronic reducing agents such as Sn^{II}/Sn^{IV}, P^{III}/P^{V} etc. The Tc^{IV}/Tc^{III} couple is electrochemically reversible and some systems have been studied in detail.[34] Technetium(IV) has a d^3 electronic configuration and usually displays six-coordination. The three unpaired electrons generally lead to high paramagnetic character for the complexes.

TECHNETIUM(III)

The d^4 electronic configuration of technetium(III) provides an electron density high enough to require ligands with back donation capabilities to produce stable complexes. Thus, arsines, carbonyls, acetylacetonate, thiourea, aminopolycarboxylates (EDTA, DTPA, HIDA)[6] or Shiff's base ligands[35–38] will also stabilize technetium(III) (Fig. 6).

Technetium(III) coordination chemistry is not particularly complicated and only six coordination complexes are known which show a two unpaired electron paramagnetism.[6] Favourable complex formation, together with low reactivity, are found when the ligands exhibit π-back bonding capabilities. Interesting examples are $[Tc(NCS)_6]^{3-}$,[39] $Tc(thiourea)_6Cl_3\cdot 4H_2O$[40] and $[Tc(monothiodibenzoylmethanato)_3]$.[41] Also, seven-coordinated technetium(III) complexes are becoming more common following an early report of $[TcCl_3(CO)(PMe_2Ph)_3]$ (Fig. 7).[42] The complex $[TcCl(DMG)_3]$[43] (DMG = dimethylglyoximate) and its derivatives have recently been studied.

Obviously, seven-coordination is only attained easily when the ligands are small enough. However in this situation the seventh possible site has to be occupied in order to prevent nucleophilic destabilizing reactions. The formal charge of technetium(III) complexes is very variable going from 3− in $[Tc(NCS)_6]^{3-}$ to 3+ in $[Tc(thiourea)_6]^{3+}$. Many complexes are monocations e.g. $[TcX_2(DPPE)_2]^{+}$,[44] some are neutral, and some can be monoanionic as in $[Tc(HIDA)_2]^{-}$.[45]

In addition to studies of the chemical reactivity of these complexes, it is important to determine the stability of the technetium complexes. In fact, even though ligand substitution reactions may in general

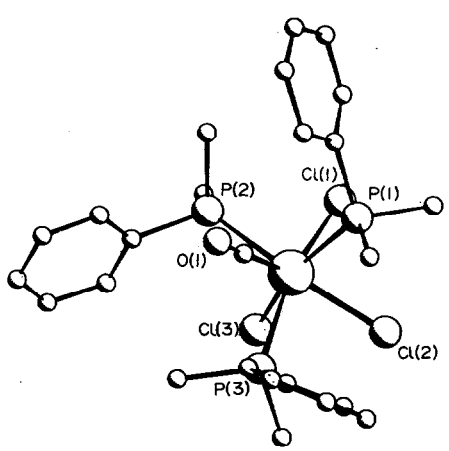

Fig. 7. Heptacoordinated technetium(III) complex: $[TcCl_3(CO)(PMe_2Ph)_3]$.

be slow, the overall charge of the complexes profoundly affects the accessibility or otherwise of redox processes. The properties and stability of the oxidized and reduced forms of the compounds will be different. The redox properties of the technetium(III) complexes $[TcCl_3(PMe_2Ph)_3]$ have been studied in detail,[46] as well as complexes of the type $[TcD_2X_2]^+$ (D = bidentate phosphine).[47]. The Tc^{III}/Tc^{II} couple was found to be electrochemically reversible in several instances, and the reduction potentials are a very useful index of the stability of the complexes *in vivo*.[1]

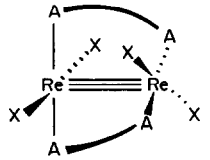
THE TRIPLY-BONDED COMPLEX TETRACHLOROBIS[BIS(DIPHENYLPHOSPHINO)METHANE] DIRHENIUM(II) AND RELATED SPECIES, AND THEIR USE AS REAGENTS IN DIRHENIUM CHEMISTRY

RICHARD A. WALTON

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

Abstract—The complex $Re_2Cl_4(\mu\text{-dppm})_2$ (dppm = $Ph_2PCH_2PPh_2$) and its bromide analogue serve as important precursors to many other dirhenium complexes because of the ability of the bridging dppm ligands to stabilize the dimetal unit. Reactions of these complexes with π-acceptors such as CO and RNC lead to the incorporation of up to three of these ligands, as exemplified by the conversion of $Re_2Cl_4(dppm)_2$ to $Re_2Cl_4(dppm)_2(CO)$, then $Re_2Cl_4(dppm)_2(CO)_2$, and finally $[Re_2Cl_3(dppm)_2(CO)_3]^+$. The redox activity of $Re_2X_4(\mu\text{-dppm})_2$ (X = Cl or Br) has been utilized in the reductive coupling of nitrile ligands (RCN) to give $[Re_2X_3(\mu\text{-}HN_2C_2R_2)(\mu\text{-dppm})_2(NCR)]PF_6$. When a non-bridging phosphine ligand is used, then the reaction course can be quite different. Thus, $\alpha\text{-}Re_2Cl_4(dppbe)_2$ (dppbe = 1,2-bis(diphenylphosphino)benzene) reacts with EtCN in the presence of conc. HCl to give the rhenium(V) imido complex, $Re(NCH_2Et)Cl_3(dppbe)$, in good yield. A different aspect of the redox activity of $Re_2Cl_4(\mu\text{-dppm})_2$ is encountered in its reactions with $LiAlH_4$ in THF to give $Re_2(\mu\text{-H})_2H_6(\mu\text{-dppm})_2$.

The complex $Re_2Cl_4(dppm)_2$ (dppm = bis(diphenylphosphino)methane) is the prototype of an important class of triply-bonded dirhenium complexes of stoichiometry $Re_2X_4[\mu\text{-}R_2A\text{—}X\text{—}AR_2]_2$ which contain a pair of *trans*-bridging $R_2A\text{—}X\text{—}AR_2$ ligands and a staggered rotational geometry (Structure 1). These complexes, which are known in the case of X = Cl or Br for $R_2A\text{—}X\text{—}AR_2$ = dppm,[1–3] $Ph_2AsCH_2AsPh_2$ (dpam)[4,5] or $Ph_2PNHPPh_2$ (dppa),[5] and X = I when $R_2A\text{—}X\text{—}AR_2$ = dppm,[3] are in turn members (or close cousins) of a much more extensive series of multiply-bonded dimetal complexes of stoichiometry $M_2X_4[\mu\text{-}R_2P(CH_2)_nPR_2]_2$, which exist for M = Mo, W or Re, X = Cl, Br or I and n = 1 or 2.[6] X-ray crystal structure determinations of $Re_2Cl_4(dppm)_2$[7] and $Re_2Cl_4(dppa)_2$[5] have confirmed the structure to be as shown in Structure 1.



Structure 1.

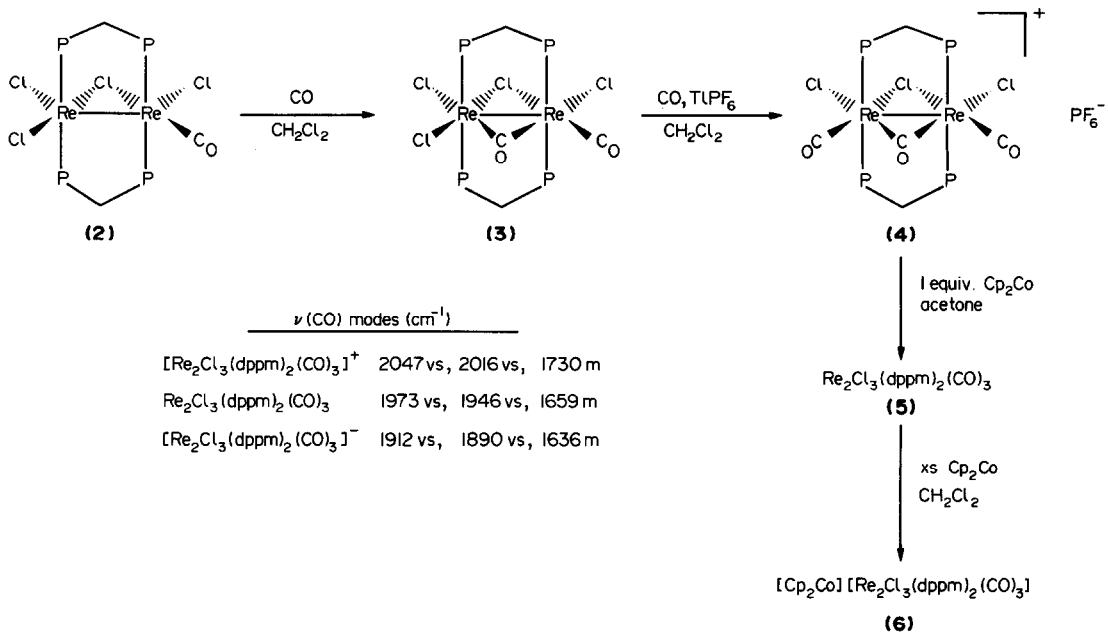
An important characteristic of $Re_2Cl_4(dppm)_2$, and the other complexes of this type that contain a Re≡Re bond and a $\sigma^2\pi^4\delta^2\delta^{*2}$ ground state electronic configuration,[8,9] is the accessibility of two one-electron oxidations. These correspond to oxidations to $[Re_2Cl_4(dppm)_2]^+$ and $[Re_2Cl_4(dppm)_2]^{2+}$, species which possess Re—Re bond orders of 3.5 ($\sigma^2\pi^4\delta^2\delta^{*1}$ configuration) and 4.0 ($\sigma^2\pi^4\delta^2\delta^{*0}$ configuration), respectively. Cyclic voltammetry on solutions of these complexes in 0.1 M $n\text{-}Bu_4NPF_6$–CH_2Cl_2 show these oxidations to be reversible; oxidation with $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ in acetone has been used to prepare the paramagnetic, ESR-active salts $[Re_2X_4(dppm)_2]PF_6$ (X = Cl or Br) and $[Re_2Cl_4(dppa)_2]PF_6$.[5]

The redox activity of $Re_2Cl_4(dppm)_2$ has been used in a sequence of one-electron electrochemical oxidations and coupled chemical reactions which lead to its conversion to $Re_2(\mu\text{-Cl})_2Cl_4(\mu\text{-dppm})_2$, via $Re_2Cl_5(\mu\text{-dppm})_2$, viz.:[2]

$$Re_2Cl_4(dppm)_2 \xrightarrow[+0.6\ V]{CH_2Cl_2} [Re_2Cl_4(dppm)_2]^+$$

$$\xrightarrow[Cl^-]{CH_2Cl_2} Re_2Cl_5(dppm)_2 \xrightarrow[+0.6\ V]{CH_2Cl_2}$$

$$[Re_2Cl_5(dppm)_2]^+ \xrightarrow[Cl^-]{CH_2Cl_2} Re_2Cl_6(dppm)_2.$$

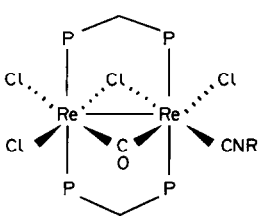


Scheme 1.

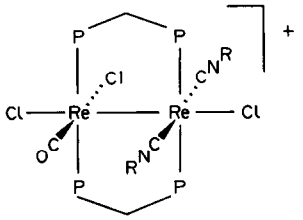
This transformation represents a change from a M_2L_8 structure to an edge-sharing bioctahedral M_2L_{10} geometry, with accompanying reduction in the metal–metal bond order from 3.0 ($\sigma^2\pi^4\delta^2\delta^{*2}$ configuration) to 2.0 ($\sigma^2\pi^2\delta^{*2}\delta^2$ configuration).[2] Within the series $Re_2Cl_4(dppm)_2$, $Re_2Cl_5(dppm)_2$ and $Re_2Cl_6(dppm)_2$, the Re—Re distances increase from 2.234(3) to 2.263(1) to 2.616(1) Å.[2,7,10]

In a formal sense, the reaction of $Re_2Cl_4(dppm)_2$ with CO can also be regarded as giving rise to a net two-electron oxidation of the Re_2^{4+} core. The A-frame-like monocarbonyl adduct, **2**, is formed first, and then reacts further to form the carbonyl complexes, **3** and **4** (see Scheme 1), both of which contain a bridging carbonyl ligand.[11–13] Similar complexes have been obtained from $Re_2Br_4(dppm)_2$.[12,13] The structures of all three chloride complexes have been determined by X-ray crystallography,[11–13] and these are represented in Scheme 1. Complex **4** has two reversible one-electron reductions, both of which can be accessed chemically with the use of $(\eta^5\text{-}C_5H_5)_2Co$ as the reducing agent,[13] to give complexes **5** and **6**. The Re—Re distance in **2** (2.338(1) Å)[12] is much shorter than the comparable distances in the edge-shared bioctahedral complexes **3** and **4**, which are 2.584(1)[11] and 2.582(1) Å,[13] respectively. While complex **2** can be regarded as still possessing a Re—Re bond of order three,[14] the distances in **3** and **4** are close to that in $Re_2(\mu\text{-}Cl)_2Cl_4(dppm)_2$,[2] a complex that contains a Re—Re double bond. Formally, a double bond formulation for **3** and **4** arises if we treat the μ-CO ligand as a divalent bridge; this accords with a d^4–d^4 dimetal entity and a $\sigma^2\pi^2\delta^{*2}\delta^2$ configuration, just as in $Re_2(\mu\text{-}Cl)_2Cl_4(dppm)_2$.[2]

A variety of other dirhenium complexes that contain a μ-CO bridge and mixed carbonyl–isocyanide and carbonyl–nitrile ligand sets have also been prepared from $Re_2Cl_4(dppm)_2$.[6,12,15–17] An interesting example is the mixed carbonyl–isocyanide complex $Re_2Cl_4(dppm)_2(CO)(CNxylyl)$ (**7**), which has a structure similar to that of $Re_2Cl_4(dppm)_2(CO)_2$ (**3**), with a bridging CO ligand and a terminal xylyl–NC ligand *cis* to it.[12] In contrast, the *t*-BuNC analogue, $Re_2Cl_4(dppm)_2(CO)(CN\text{-}t\text{-}Bu)$ (**8**), has a structure in which there are no bridging ligands other than the dppm bridges. This conclusion is based upon the X-ray crystal structure determination of $[Re_2Cl_3(dppm)_2(CO)(CN\text{-}t\text{-}Bu)_2]PF_6$ (**9**), a derivative of **8**.[17] A comparison between the structure of **7** and **9** is shown below. The Re—Re



(7)



(9)

distances in **7** and **9** are 2.581(1) and 2.379(1) Å, respectively. In view of the close chemical and structural relationships between **8** and **9**, the Re—Re distance in **8** can be expected to be close to 2.38 Å. Since **7** and **8** are both prepared from $Re_2Cl_4(dppm)_2$ by essentially identical procedures,[12] it does not seem reasonable to consider **7** as a derivative of the Re_2^{6+} core (on the assumption of a *divalent* CO bridge), while at the same time maintaining that **8** is a derivative of the triply-bonded Re_2^{4+} core. We would not expect a two-electron redox change to be triggered simply by this switch in isocyanide ligand. Accordingly, any simple bond length/bond order/core charge correlation must be treated with caution since the notion of a Re_2^{6+} core being present in **7** is clearly suspect.

The preceding chemistry, which involves the reactions of $Re_2Cl_4(dppm)_2$ with CO and isocyanide ligands, can be modified to include σ-donors such as PMe_3. Thus, the reactions of $Re_2Cl_4(dppm)_2(CO)$ and $Re_2Cl_4(dppm)_2(CO)_2$ with PMe_3 in CH_2Cl_2 in the presence of $TlPF_6$, yield the complexes $[Re_2Cl_3(dppm)_2(CO)(PMe_3)_2]PF_6$ (**10**) and $[Re_2Cl_3(dppm)_2(CO)_2(PMe_3)]PF_6$ (**11**), respectively, in which the CO and PMe_3 ligands occupy mutually *cis* arrangements in edge-sharing bioctahedral structures.[18] The structure of the cation in **11** is given in Fig. 1 and shows the presence of a semi-bridging CO ligand. The associated Re—C distances are 2.16(1) and 1.96(1) Å; the shorter distance involves the more electron-rich metal centre which contains the PMe_3 ligand. A similar structure is found in the case of the $P(OEt)_3$ analogue of **11**. For both complexes, the Re—Re distances are very similar, being 2.593(1) Å in the case of **11**. The bis(trimethylphosphine) complex, **10**, possesses a symmetric carbonyl bridge and a Re—Re distance (2.602(1) Å) which is similar to that in **11**.[18]

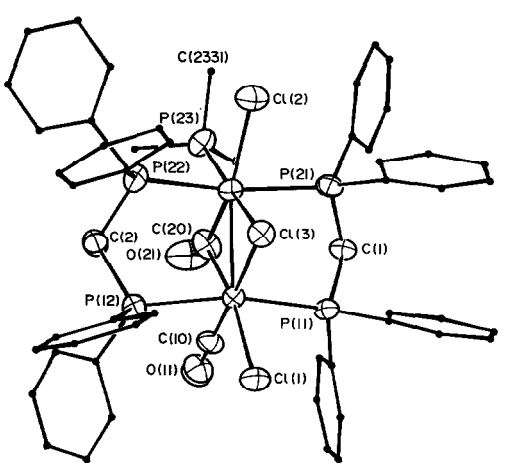


Fig. 1. ORTEP representation of the structure of the $[Re_2Cl_3(dppm)_2(CO)_2(PMe_3)]^+$ cation of **11**.[18] Thermal ellipsoids are drawn at the 50% probability level, except for the carbon atoms of the phenyl rings and PMe_3 ligands where they are shown as circles of arbitrary radius.

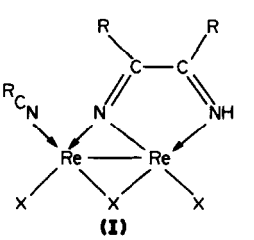
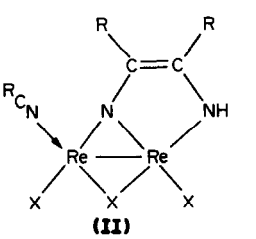
An interesting feature in the structure of the carbonyl complex $[Re_2Cl_3(dppm)_2(CO)_3]PF_6$ (**4**), is the surprisingly close C···C contacts between the CO ligands (2.38 Å).[13] However, in spite of the well-defined redox reactivity of the dirhenium unit in **4** (see Scheme 1), we have not yet been able to induce the reductive coupling of the CO ligands in this complex. Accordingly, we suspect that this "steric crowding" of the CO ligands is more a consequence of the non-bonded repulsions between the *all-cis* chloride ligands on the other side of the equatorial plane, rather than an indication of putative C—C bonding. Nonetheless, we have encountered an interesting instance where the redox activity of the complexes $Re_2X_4(dppm)_2$ (X = Cl or Br) can induce the reductive coupling of organic molecules. This involves the reductive coupling of nitriles, in which the dimetal unit is retained and the coupled nitrile ligands exhibit a novel μ_2-η^2 bonding mode.

The reactions of $Re_2X_4(dppm)_2$ with nitriles initially give the bis(nitrile) complexes $[Re_2X_3(\mu\text{-}dppm)_2(NCR)_2]PF_6$.[19] Reaction of these derivatives with further nitrile under reflux conditions affords the green, paramagnetic complexes $[Re_2X_3(\mu\text{-}HN_2C_2R_2)(\mu\text{-}dppm)_2(NCR)]PF_6$ (**12**, X = Cl or Br; R = Me, Et, *i*-Pr, *t*-Bu or Ph). The lability of the nitrile ligands (RCN) in **12** has been demonstrated by carrying out nitrile exchange reactions. The structural identity of these complexes has been confirmed by an X-ray structure analysis of a salt of the $[Re_2Br_3(\mu\text{-}HN_2C_2Me_2)(\mu\text{-}dppm)(NCMe)]^+$ cation.[19,20] The Re—Re distance in this complex is 2.666(1) Å. The geometry is that of an edge-sharing bioctahedron, with *trans*-bridging dppm ligands and three bromide ligands occupying mutually *cis* positions on one side of the equatorial plane. Distances within the five-membered metallacycle ring, formed from the coupled nitrile ligands, can best be rationalized in terms of contributions from a singly deprotonated diimine ligand (as represented in **I**), and a triply deprotonated ene-diamine ligand (as in **II**). Experiments



(I)



(II)

in which CD_3CN is used in place of CH_3CN in the reaction with $[Re_2Cl_3(dppm)_2(NCMe)_2]PF_6$, have shown that the source of the unique hydrogen in the $HN_2C_2Me_2$ ligand is the acetonitrile ligand itself.[20,21] The treatment of **12** with either $[(\eta^5\text{-}C_5H_5)_2Fe]PF_6$ in acetone, or $NOPF_6$ in CH_2Cl_2, leads to oxidation and the formation of the red, diamagnetic salts $[Re_2X_3(\mu\text{-}HN_2C_2R_2)(\mu\text{-dppm})_2(NCR)](PF_6)_2$ (**13**).[20,21]

These reductive coupling reactions may proceed by the type of carbonyl–carbyne and isocyanide–aminocarbyne coupling mechanism that Lippard and co-workers[22] have provided evidence for in their studies on the reductive coupling of carbonyl and isocyanide ligands. If so, this could involve a nitrile–alkylimido coupling step. Unfortunately, the reactions of $Re_2X_4(dppm)_2$ with nitriles to give **12** require quite forcing conditions, and have not yielded any characterizable reaction intermediates. Accordingly, they do not appear to be ideal from the standpoint of further mechanistic studies. However, we have independent evidence that imido complexes are formed quite readily from the reactions of nitriles with other dirhenium complexes, as shown by our studies of the reactions between $(n\text{-}Bu_4N)_2Re_2X_8$ (X = Cl or Br) and an excess of 1,2-bis(diphenylphosphino)benzene (dppbe) with an alkyl nitrile (RCN) as solvent. Under reflux conditions, and in the presence of a few drops of conc. HX, these reactions afford the mononuclear rhenium(V) imido complexes, $Re(NCH_2R)X_3(dppbe)$.[23,24] The reactions probably proceed via the corresponding dirhenium(II) complex, $\alpha\text{-}Re_2X_4(dppbe)_2$. We have isolated this complex in the case of X = Cl, and find that when it is reacted with EtCN in the presence of conc. HCl, the imido species $Re(NCH_2Et)Cl_3(dppbe)$ can be isolated in 47% yield.[24] One plausible explanation is that the Re_2^{4+} core of $\alpha\text{-}Re_2Cl_4(dppbe)_2$ undergoes disproportionation to rhenium(I) and rhenium(III), and that it is the former mononuclear species which provides the four-electrons necessary to reduce the nitrile.

A different aspect of the redox activity of the dirhenium core of $Re_2Cl_4(dppm)_2$ is encountered in its conversion to the dirhenium octahydride complex, $Re_2H_8(dppm)_2$ (**14**). This octahydride complex is prepared through the reaction of $Re_2Cl_4(dppm)_2$ with $LiAlH_4$ in THF at room temperature, followed by hydrolysis of the reaction mixture. This procedure is adaptable to the synthesis of other octahydride complexes of the type $Re_2H_8(PR_3)_4$ starting from $Re_2Cl_4(PR_3)_4$ (PR_3 = PMe_3, PEt_3, P—*n*-Pr_3, PMe_2Ph, PEt_2Ph, $PMePh_2$ or $Ph_2PCH_2CH_2PPh_2$).[25] The crystal structure and NMR spectral properties of the dppm derivative are consistent with the structue $Re_2(\mu\text{-}H)_2H_6(\mu\text{-dppm})_2$, rather than $Re_2(\mu\text{-}H)_4H_4(\mu\text{-dppm})_2$. The structure of the $Re_2(\mu\text{-dppm})_2$ unit of **14** is shown in Fig. 2. While the tetra-μ-hydrido-bridged structure is preferred in the case of the octahydride complexes with monodentate phosphines,[26] the different structure of **14** is probably a consequence of the constraints imposed by the bridging dppm ligands. This leads to an opening up of the P—Re—P angles (to 164°) and a lengthening of the Re—Re bond (to 2.934(1) Å) compared to the situation in the structurally characterized complex $Re_2(\mu\text{-}H)_4H_4(PEt_2Ph)_4$, where P—Re—P = 102.7(2)° and Re—Re = 2.538(4) Å.[26]

The non-redox substitution chemistry of $Re_2X_4(dppm)_2$ (X = Cl or Br) with carboxylate ligands provides a convenient route to the complexes $Re_2(\mu\text{-}O_2CR)_2X_2(\mu\text{-dppm})_2$; these exist as the *trans* and *cis* isomers, **15** and **16**, respectively.[27] This is a very rare instance where metal–metal bonded dimetal complexes that contain two bridging dppm ligands exist in *trans and cis* isomeric forms. The reactions of $Re_2Cl_4(dppm)_2$ with $(PPN)O_2CR$ (PPN = $[(Ph_3P)_2N]^+$; R = Me, Et or Ph) in CH_2Cl_2 at room temperature for 5 min, afford *trans*-$Re_2(O_2CR)_2X_2(dppm)_2$ in yields of

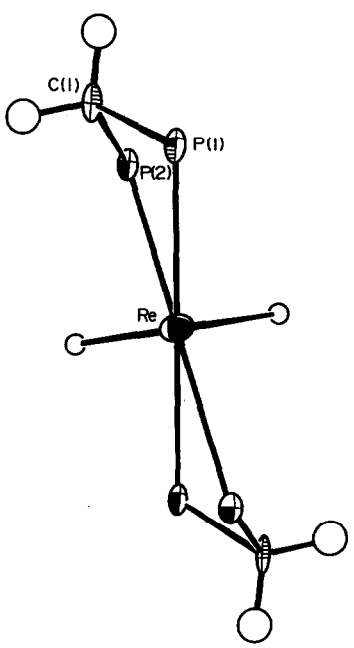


Fig. 2. ORTEP representation of the $Re_2(\mu\text{-}H)_2P_4$ core of $Re_2(\mu\text{-}H)_2H_6(\mu\text{-dppm})_2$ (**14**), as viewed down the Re—Re axis to show the non-zero P_1—Re—Re—P_2 torsional angle (χ = 15.9(1)°).[25] The probable positions of the bridging hydrido ligands are shown as circles of arbitrary radius. Phenyl rings have been omitted but the CH_2 bridgehead groups are included. Thermal ellipsoids for the rhenium, carbon and phosphorus atoms are drawn at the 50% probability level. This structure has $\bar{1}$ symmetry.

(16)

70% or more. When these *trans* isomers are heated in ethanol for approximately 3 h, they convert to the corresponding *cis* isomers.[27] The *cis* and *trans* isomers are readily oxidized to their corresponding monocationic forms as in the salts *cis*-/*trans*-$[Re_2(\mu\text{-}O_2CR)_2X_2(\mu\text{-dppm})_2]PF_6$; these paramagnetic complexes contain Re—Re bond orders of 3.5 and have structures very similar to those of their parent, neutral dirhenium(II) precursors.[3,27]

THE VANADIUM NITROGENASE OF *AZOTOBACTER*

ROBERT R. EADY

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory,
University of Sussex, Brighton BN1 9RQ, U.K.

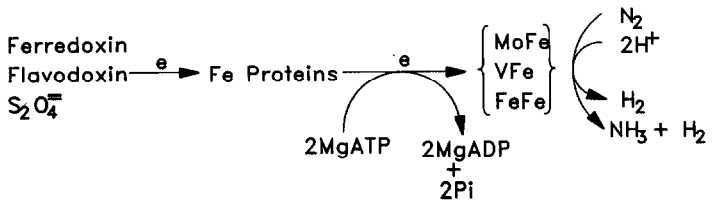
Abstract—The properties of the recently characterized vanadium-dependent nitrogenase system of *Azotobacter* are reviewed and compared with the better characterized Mo–nitrogenases. Vanadium is present in V–nitrogenase in a vanadium- and iron-containing protein (VFe protein), analogous in structure and function to the MoFe protein of Mo–nitrogenase. The VFe protein contains vanadium in a polynuclear cluster in an environment with iron, sulphur and oxygen (or nitrogen or carbon) as nearest neighbour atoms, very similar to the environment of molybdenum in the iron and molybdenum cofactor (FeMoco) centre of the MoFe proteins. A vanadium-containing cluster can be extracted from the VFe protein by treatment with N-methylformamide (NMF). The NMF extract contains vanadium, iron and sulphur in a 1:6:5 ratio and activates the inactive MoFe protein synthesized by some mutant organisms unable to synthesize FeMoco. This hybrid protein has the characteristic substrate reduction pattern of a VFe protein, in forming some C_2H_6 from C_2H_2. These data are consistent with the NMF extract containing an iron and vanadium cofactor FeVaco, analogous to FeMoco. Although the hybrid protein is active in nitrogenase assays with H^+ or C_2H_2 as reducible substrates, N_2 is not reduced, suggesting that specific interactions of the cofactor centre with a polypeptide ligand are lacking. Pre-steady-state kinetics of the ATP-dependent electron-transfer from the Fe protein of V–nitrogenase to a VFe protein are very similar to those of Mo–nitrogenase components, consistent with a common mechanism of substrate reduction. However, at low temperatures N_2 is a more effective substrate for V–nitrogenase compared with Mo–nitrogenase.

The role of molybdenum in stimulating biological nitrogen fixation has been known for 50 years,[1] but only in the last 4 years has it been unequivocally established that biological routes for nitrogen fixation exist which do not involve molybdenum.[2–4] The soil bacterium *Azotobacter chroococcum* has a molybdenum-containing nitrogenase,[5] similar to those found in many other organisms, but also has a vanadium-containing nitrogenase which functions under conditions of molybdenum deficiency.[2] A closely-related species, *Azotobacter vinelandii*, has in addition to Mo–nitrogenase and V–nitrogenase,[3] a third nitrogenase system which functions under conditions where both molybdenum and vanadium are deficient.[4,6] When purified, the third system contains only very low levels of molybdenum or vanadium.[4]

All three types of nitrogenase have similar requirements for activity—a low potential electron donor, MgATP and anoxic conditions. They can also be separated into two component proteins. All have a distinctive Fe protein, which together with a MoFe protein or a VFe protein, or a protein which contains neither molybdenum or vanadium, make up the active enzyme. The separate existence of molybdenum-independent nitrogenases was shown by using recombinant DNA techniques to construct strains of *Azotobacter* which lacked the structural genes of the Mo–nitrogenase protein.[6–8] The demonstration of N_2-dependent growth of such strains vindicated the suggestion of Bishop and colleagues that molybdenum-independent routes of N_2 fixation existed in *Azotobacter*.[9,10]

BIOCHEMISTRY OF V–NITROGENASE

Vanadium nitrogenases of *A. chroococcum*[2,11,12] and *A. vinelandii*[3,13] have been purified and characterized, and shown to have very similar properties. Attention has naturally focussed on the role of vanadium in this system, and only an overview of the Fe protein is given here. A schematic view of nitrogenase function is shown in Scheme 1.



Scheme 1. Function of nitrogenase.

Substrate reduction by V-*nitrogenase*

In addition to N_2, both Mo- and V-nitrogenases will reduce H^+ or C_2H_2 as alternative substrates. A feature of substrate reduction by V-nitrogenase when assayed at 30°C is the decreased effectiveness with which N_2 or C_2H_2 compete with H^+ as a reducible substrate, when compared with Mo-nitrogenase (Table 1). For Mo-nitrogenase functioning under conditions of optimum electron flux, the limiting stoichiometry for N_2 reduction is:

$$N_2 + 8e + 8H^+ + 16MgATP \rightarrow 2NH_3 + H_2 + 16MgADP + 16Pi. \quad (1)$$

The overall reaction requires the sequential MgATP-dependent transfer of eight electrons from the Fe protein to the MoFe protein, and the rate-limiting step is the dissociation of the two proteins following electron transfer (see ref. 14). H_2 evolution concomitant with N_2 reduction, a reaction which utilizes 25% of the electron flux through nitrogenase, has been proposed to arise from a requirement for a reduced site for the binding of N_2, which results in the displacement of H_2. Under conditions where the rate of electron flux is restricted (e.g. by limiting Fe protein or MgATP concentrations), the proportion of electron flux resulting in H_2 evolution increases as partially-reduced MoFe protein species relax to more oxidized forms as H_2 is evolved.[14]

In the case of V-nitrogenase, even when functioning under optimum conditions of electron flux and saturating N_2 levels, approximately half the electron flux results in H_2 evolution. This reaction appears to occur *in vivo*, since cultures of *Azotobacter* evolve considerably more H_2 when fixation occurs by V- rather than Mo-nitrogenase. A study of the kinetics of electron-transfer from the Fe protein to VFe protein by stopped-flow spectrophotometry,[15] has shown that association of the two proteins and the MgATP-dependent electron-transfer occur at rates very similar to those of Mo-nitrogenase and are too fast to be rate-limiting in turnover. The difference in reactivity towards N_2 and H^+ was proposed to reside in the substrate-binding cofactor centre of the VFe protein.

A recent study of the effect of temperature on the reduction of N_2 has shown that as the temperature was decreased from 30°C (the usual assay temperature *in vivo* and *in vitro*) to 5°C, N_2 remained an effective substrate for V-nitrogenase but not Mo-nitrogenase.[16] Over this temperature range, the specific activity for N_2 reduction by Mo-nitrogenase decreased 10-fold more than V-nitrogenase. The lower activity of Mo-nitrogenase at 5°C did not equal that of V-nitrogenase, even under conditions of high electron flux occurring at a 12-fold molar excess of Fe protein. This behaviour which, surprisingly is conferred by the Fe protein of V-nitrogenase, may explain why this apparently less effective nitrogenase has persisted in nature.

Mo-nitrogenase reduces C_2H_2 to give exclusively the two-electron reduced product, C_2H_4. A distinctive difference between Mo- and V-nitrogenase is the formation of C_2H_6 as a minor ($\sim 5\%$) product of C_2H_2 reduction by V-nitrogenase.[17,18] This specificity is conferred by the VFe protein and as discussed below, provided supportive evidence that this protein contains an iron and vanadium cofactor centre at the substrate-binding site.

THE Fe PROTEIN OF V-NITROGENASE

The physicochemical properties of the Fe proteins of V-nitrogenases of *A. chroococcum* and *A. vinelandii* are very similar to those of the Fe protein of Mo-nitrogenase. The four Fe and four acid-labile sulphur atoms that these proteins contain are probably arranged in a single [4Fe–4S] cluster which bridges the two identical subunits.[31] The dithionite-reduced proteins exhibit EPR signals at $g_{av} = 1.95$ and $g = 4$–5, consistent with the presence of both

[a] R. R. Eady and B. E. Smith, unpublished results.

Note that in the presence of N_2 or C_2H_2 the reduction of H^+ to H_2 is not as effectively suppressed with V–nitrogenase as compared with Mo–nitrogenase.

$S = 1/2$ and $S = 3/2$ spin states which together integrate to 1 spin mol. During electron transfer the [4Fe–4S] cluster functions as a 1e donor between the +1 and +2 oxidation levels. MgATP binds to Fe proteins and results in a conformational change which enhances the accessibility of iron in the cluster to chelation by α,α'-bipyridyl, causing the EPR signal at 1.94 to become more axial and lowers the mid-point potential by ~ 100 mV.

In the case of the Fe proteins of V– and Mo–nitrogenases of *A. chroococcum*, the MgADP-bound forms have similar redox mid-point potentials of −463 and −450 mV respectively, and the oxidized proteins are reduced by SO_2^- at very similar rates.[19] The structural genes encoding these proteins have been sequenced and at the amino acid level these proteins show 89% conservation of sequence, including the five invariant cysteine residues which are conserved in all known Fe proteins. A reflection of this high degree of conservation of structure is the ability of both these proteins to form active hybrid nitrogenases with either MoFe or VFe proteins. The Fe proteins associated with V–nitrogenase are clearly typical of the class of Fe proteins associated with Mo–nitrogenases.

THE VFe PROTEIN OF V–NITROGENASE

The overall properties of VFe proteins show strong similarities with MoFe proteins except that vanadium replaces molybdenum (Table 1). This similarity extends to the ability to form active hybrid nitrogenases with the Fe protein from either system. Fully active MoFe proteins are considered to contain two FeMoco centres, the probable site of substrate binding and reduction, and four "P" clusters, Fe/S centres with unusual spectroscopic properties which can be extruded as [4Fe–4S] clusters (see refs 20 and 21). All MoFe proteins have an $\alpha_2\beta_2$ subunit structure and homologous subunits are present in VFe proteins.[2,3] The structural genes encoding these subunits of the VFe protein of *A. chroococcum* have been sequenced,[22] and when compared with the sequences of a number of MoFe proteins, as a group the derived amino acid sequences of VFe protein subunits show only 15–18% conservation with those of MoFe proteins. However, the conserved regions contain five cysteinyl residues in the α subunits, and three in the β subunit, which are conserved in all MoFe protein sequences and are likely candidates for cluster lig-

ation. The VFe of the *A. chroococcum* protein also has an additional small (M_r 13000) subunit and therefore an $\alpha_2\beta_2\delta_2$ subunit structure,[22] and it is probable that the protein of *A. vinelandii* has a similar structure. Despite these differences, together with the probability that the metal content of preparations of the VFe protein so far obtained are not maximal, EPR, MCD and X-ray absorption spectroscopies, together with extrusion experiments, are consistent with the same types of redox centres being present in MoFe and VFe proteins.

EPR spectroscopy

Dithionite-reduced MoFe proteins exhibit an EPR signal with $g = 4.3$, 3.7 and 2.01 arising from the $S = 3/2$ spin system of the FeMoco centre. The EPR spectra of VFe proteins are more complex, since they contain an additional EPR centre. The dithionite-reduced VFe protein of *A. vinelandii*[23] has an EPR spectrum with g values at 5.8, 5.4, 4.34, 2.04 and 1.93. The signals at 5.8 and 5.4 have been assigned to a $S = 3/2$ spin system which integrates to 0.89 spin per vanadium atom. The $g = 4.34$ feature was attributed to adventitious high-spin Fe^{3+} and those at $g = 2.04$ and 1.93 to an $S = 1/2$ spin system associated with a reduced Fe–S centre of low potential. The latter spin integrates to 0.2 spin per vanadium atom.

The EPR spectrum of the VFe protein from *A. chroococcum*[11] has signals at $g = 5.6$, 4.35, 3.77 and 1.94. The first three are consistent with an $S = 3/2$ ground state spin system with the $M_zS = 1/2$ Kramer's doublet being thermally accessible (D. J. Lowe, personal communication). The $g = 1.94$ signal, as with the *A. vinelandii* protein, has been assigned to an $S = 1/2$ spin system associated with a reduced Fe–S centre. The major difference between these proteins is the presence of the feature at $g = 3.77$ in the spectrum of the *A. chroococcum* VFe protein and may reflect differences in the environment of the cofactor centre with a $S = 3/2$ spin state that these spectra suggest is present.

Magnetic circular dichroism spectroscopy

Low temperature MCD spectroscopy has been used to probe the nature of the redox centres of MoFe proteins, since although the room temperature spectra resemble those of [4Fe–4S] clusters, at low temperature the contribution from paramagnetic species predominate and MoFe proteins exhibit distinctive spectra (see ref. 20). A study of the VFe protein of *A. vinelandii*[24] showed the dithionite-reduced protein to have spectra very similar to those shown by the $S = 3/2$ paramagnetic centre of MoFe proteins, with only a small additional contribution from the $S = 1/2$ paramagnetic species. Although VFe protein temperature-dependent MCD transition were consistent with an $S = 3/2$ spin system, it has different electronic and magnetic properties to the cluster in the MoFe protein. By analogy with the MoFe protein, this study provided further spectroscopic data suggesting the presence of a V–Fe–S cluster in VFe proteins.

In the dye-oxidized state, the MCD and magnetization characteristics, although not identical witho those of the "P" clusters of MoFe proteins, are sufficiently similar to be assigned to an $S = 5/2$ spin system associated with clusters analogous to "P" clusters.

X-ray spectroscopic studies

Vanadium–K edge X-ray absorption spectroscopy has been used to provide information about the chemical environment of vanadium in the VFe proteins from both *A. chroococcum*[25,26] (and also Garner *et al. Polyhedron* 1989, **8**, 1649) and *A. vinelandii*.[27] The data for the dithionite-reduced proteins are in good agreement and the absorption edge shows a weak pre-edge feature and an edge inflection. The intensity of the pre-edge feature implies distorted octahedral coordination around the vanadium atom, and the position of these features indicates an oxidation state between vanadium(II) and vanadium(IV). The data closely resemble those for the octahedral VFe_3S_4 complex in $[NMe_3][VFe_3S_4(DMF)_3]^-$ and are different from the complex $[VS_4(FeCl_2)_2][Et_4N]_3$ where vanadium is tetrahedrally complexed to sulphur. These spectral features show no significant change on dye-oxidation of the protein, or under enzyme turnover when the protein is "super-reduced".

The extended X-ray absorption fine structure (EXAFS) spectra have provided information about the distance, type and number of nearest neighbour atoms to the vanadium atom. Fourier transform analysis of the EXAFS region is consistent with vanadium, like molybdenum in MoFe proteins, having iron, sulphur and oxygen (or nitrogen or carbon) atoms as nearest neighbours and at very similar distances (Table 2). No significant changes occur in the EXAFS spectra on dye-oxidation. This insensitivity of the vanadium environment to the oxidation level of the protein is analogous to molybdenum in MoFe proteins, and has been attributed to the unpaired spin being delocalized onto the iron atoms. These data provide strong spectroscopic evidence for the presence of an iron- and

vanadium-containing cofactor centre in these VFe proteins.

The iron- and vanadium-containing cofactor

Under the appropriate conditions the molybdenum of the MoFe protein can be extracted by treatment of the protein with N-methyl formamide[28] (NMF). The NMF extract contains FeMoco, which can be assayed by its ability to activate MoFe proteins isolated from mutants unable to synthesize FeMoco. Extraction of the acid-precipitated VFe protein of *A. chroococcum* with NMF[29] resulted in a brown solution containing vanadium, iron and S^{2-} in the ratio 1 : 6 : 5, which exhibited a weak EPR spectrum with g values near 4.5, 3.6 and 2.0, characteristic of a $S = 3/2$ spin system. The NMF extract activated purified FeMoco-less-MoFe protein when recombined with Fe protein in a nitrogenase assay system. The active hybrid protein catalysed the reduction of H^+ to H_2, and the reduction of C_2H_2 to C_2H_4 and C_2H_6. The formation of C_2H_6 from C_2H_2 is a product characteristic of the VFe protein but not the MoFe protein. These data, together with the X-ray absorption data indicate that VFe proteins contain an iron–vanadium cofactor (FeVaco) analogous to FeMoco of the MoFe proteins. The hybrid FeVaco–MoFe protein did not reduce N_2, suggesting that a specific interaction of the polypeptide and cofactor centre is necessary for the reduction of N_2 but not other substrates.

Acknowledgements—I thank the many co-workers who have made significant contributions to the work on V-nitrogenase of *A. chroococcum* discussed above, in particular Professors Barry Smith and Mike Dilworth and Drs David Lowe, Roger Thorneley, Dick Miller, Richard Pau and Rob Robson. I also thank Beryl Scutt for typing.

Abstract—The known methods of preparation of the title complexes are reviewed. The preparation, structure and reactions of new monohydride complexes containing bulky thiolate ligands are then described: $[MH(SR)_3(PMe_2Ph)_2]$ (I) and $[MoH(SR)_3(PR'Ph_2)]$ (II) (M = Mo or W; R = $C_6H_2Me_3$-2,4,6 or $C_6H_2{}^iPr_3$-2,4,6; R′ = Me or Et). Complexes I have an unusual structure with the hydride capping a face of a distorted trigonal bipyramid defined by equatorial thiolates and axial phosphines. A significant discovery is that the hydrides of these complexes of molybdenum(IV) (II) and tungsten(IV) (I and II) undergo $^1H/^2H$ exchange with $^2H_2$. Complexes I react with ligands L = py or $P(OR')_3$ to give $[MH(SR)_3(PMe_2Ph)(L)]$, and with CO to give $[M(SR)_2(CO)_2(PMe_2Ph)_2]$.

Molybdenum compounds coordinated predominantly by sulphur ligands catalyse the transfer of hydrogen to or from a variety of substrates. Catalytic processes include hydrogen transfer to organosulphur compounds by molybdenum disulphide in hydrodesulphurization reactions,[1] and reduction of dinitrogen to ammonia by nitrogenase.[2] Molybdenum hydride intermediates have been suspected but never observed in these reactions.

We have been preparing and studying some simple hydride complexes of molybdenum and tungsten of this type to learn about their reactivity patterns. A significant discovery is that hydrogen gas reacts with our hydride complexes of molybdenum(IV) and tungsten(IV).

ROUTES TO HYDRIDE COMPLEXES OF MOLYBDENUM AND TUNGSTEN IN A SULPHUR ENVIRONMENT

There are only a few reports of hydride complexes of molybdenum with thiolate or other sulphur donor co-ligands e.g. $[MoH(SR)(dppe)_2]$, [dppe = $Ph_2PCH_2CH_2PPh_2$, RS = ^{i}PrS, ^{t}BuS, 2,4,6-$C_6H_2Me_3$ (tmt) or 2,4,6-$C_6H_2(^iPr)_3$ (tipt)],[3] $[MoH_2(C_6H_4S_2)(PMePh_2)_3]$[4,5] and $[MoH(C_6H_4S_2)_3]$.[3–6] Some tungsten hydride complex containing bridging thioethers[7] (Table 1) were the only tungsten complexes of this type before our work [see reactions (4) and (5)]. These four types of complexes were prepared by use of four distinctive sources of hydride (see Table 1). The hydride complexes are reducing as indicated by their reactions listed in the table, but none of the complexes react with dihydrogen.

No syntheses of such molybdenum or tungsten hydrides directly from dihydrogen have been reported. In cases where reaction has been observed, the hydrides result in being bonded to sulphur as in the work of Rakowski-Dubois[8] [reaction (1)]:

$$[Mo(C_5H_4Me)(S)_2]_2 + H_2 \longrightarrow [Mo(C_5H_4Me)(\mu\text{-}SH)(\mu\text{-}S)]_2. \quad (1)$$

Our attempt to react the new complex, *cis*-$[Mo(S_2C_6H_4)_2(PMePh_2)_2]$, with H_2 failed.[5]

* Authors to whom correspondence should be addressed.

Table 1. Group VI metal hydride/sulphur donor complexes

Complex	Source of hydrogen in its preparation	δ(MH) (ppm)	Hydride reacts with:	to give:
$[Cl_3W(\mu\text{-}H)(\mu\text{-}SMe_2)_2WCl_2(SMe_2)]$	Et_3SiH	+3.76	EtSSEt	HSEt
$[Mo(H)(C_6H_4S_2)_3]^{3-}$	BuLi	−10.4	MeOH	H_2
cis-$[Mo(H)(SR)(dppe)_2]$	$HSR/Mo(N_2)_2L_2$	−4 to 5	HSR	H_2
$[Mo(H)_2(S_2C_6H_4)(PMePh_2)_3]$	$[MoH_4L_4]$	−2.3	HSR	H_2

However, this complex does react reversibly with CO (1 atm, 20°C) to give *cis*-$[Mo(S_2C_6H_4)_2(CO)(PMePh_2)]$. The reaction can be driven to the right by use of MeI[5] [reaction (2)]:

$$cis\text{-}[Mo(S_2C_6H_4)_2(PMePh_2)_2]+CO+MeI \longrightarrow cis\text{-}[Mo(S_2C_6H_4)_2(CO)(PMePh_2)]+[PMe_2Ph_2]I. \quad (2)$$

The lack of reaction with H_2 is not surprising considering that the high stretching frequency for the carbonyl complex, 1970 cm^{-1}, signals a very unstable interaction of η^2-H_2 with the d^2-metal binding site of $[Mo(S_2C_6H_4)_2(PMePh_2)]$ (stable η^2-H_2 complexes on d^6-metals are expected when $1840 < \nu(CO) < 1970\ cm^{-1}$).[9]

PREPARATION OF MONOHYDRIDE COMPLEXES OF MOLYBDENUM AND TUNGSTEN CONTAINING BULKY THIOLATE LIGANDS

A route via hydrazido(2−) complexes to some very interesting monohydride complexes of molybdenum and tungsten with the bulky SR^- ligands, 2,4,6-trimethyl or 2,4,6-triisopropylthiophenolate (tmt and tipt, respectively), was recently reported[10] [reactions (3) and (4)]:

$$[M(N_2)_2(PMe_2Ph)_4]+2HBr \longrightarrow [M(NNH_2)(Br)(PMe_2Ph)_3]Br+PMe_2Ph+N_2 \quad (3)$$

$$[M(NNH_2)(Br)(PMe_2Ph)_3]Br+3RSH+2NEt_3 \longrightarrow [M(H)(SR)_3(PMe_2Ph)_2]+N_2+H_2+PMe_2Ph+2HNEt_3Br. \quad (4)$$

The polyhydride route [reaction (5)] is preferred for the synthesis of the analogous tungsten complexes (*ca* 50% yield):[11]

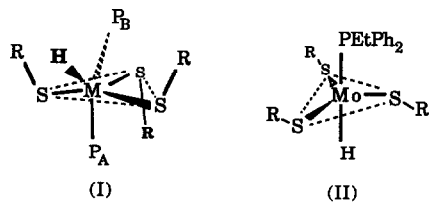
$$[WH_6(PMe_2Ph)_3]+3HSR \longrightarrow [W(H)(SR)_3(PMe_2Ph)_2]. \quad (5)$$

It is the unique route to an unusual 12-electron molybdenum monohydride complex in 40% yield (SR = tipt):[5]

$$[MoH_4(PEtPh_2)_4]+3HSR \longrightarrow [Mo(H)(SR)_3(PEt_2Ph)]+3H_2. \quad (6)$$

STRUCTURES OF THE MONOHYDRIDE COMPLEXES

Preliminary X-ray diffraction work on deep-green crystals of $[M(H)(tipt)_3(PMe_2Ph)_2]$, (M = Mo,[12] W[13]) suggests that they have very similar structures. The stereochemistry can be regarded as capped trigonal bipyramidal with the three bulky thiolates being equatorial, the phosphines being approximately axial and the hydride (not located) capping a PS_2 face (Fig. 1, **I**). The FAB mass spectra of these complexes verify that one hydride is present. Spectroscopic studies show that it is coordinated to the metal and not to a sulphur (e.g. ν(MoH) = 1740 cm^{-1}). This unusual geometry for a six-coordinate complex is explained by a combination of steric and electronic factors. Three large thiolate ligands are always equatorial in complexes like $[Mo(NNPh)(tipt)_3(MeCN)]$[14] and $[Mo(tipt)_3(CO)_2]^-$[15] to minimize inter-ligand repulsions, with one large arene substituent pointing up and two substituents pointing down. Distortion from octahedral geometry gives a favourable diamagnetic, d^2 electronic configuration at the metal.



(I) (II)

Fig. 1. The structures of the complexes $[M(H)(SR)_3(PMe_2Ph)_2]$ (**I**) (M = Mo, W; SR = tipt, tmt; P_A and P_B = PMe_2Ph), and $[Mo(H)(tipt)_3(PEtPh_2)]$ (**II**).

The coupling patterns in the ^1H and ^{31}P NMR spectra of the complexes strongly suggest that the capped bipyramidal geometry, structure **I**, is retained in solution. The hydride resonance in the ^1H NMR spectrum of $[W(H)(tipt)_3(PMe_2Ph)_2]$ at δ +9.1 for tungsten shows a large, pseudo-*trans* coupling of 100 Hz to one phosphorus (P_A, Fig. 1) and a small, *cis* coupling of 8 Hz to the other. The resonance has the coupling $^1J(^1H, ^{183}W)$ of 20 Hz expected for a hydrogen bonded to tungsten ($[WH(C_5H_5)(CO)_3]$ has $^1J = 38$ Hz; $[WH_6(PMe_2Ph)_3]$ has $^1J = 37$ Hz) but not to sulphur. A chemical shift of +2 ppm is inferred for the corresponding molybdenum complex by comparison with the ^2H NMR spectrum of the deuterated analogue $[Mo(^2H)(tipt)_3(PMe_2Ph)_2]$ [see reaction (7)]. The hydride chemical shifts are the most positive of those observed so far for chromium group hydrides in a sulphur environment (see Table 1). The $^{31}P\{^1H\}$ NMR spectra indicate that there are two inequivalent phosphorus nuclei with a large coupling constant of 109 Hz for molybdenum and 101 Hz for tungsten, again consistent with a pseudo-*trans* relationship. The ^1H coupled ^{31}P NMR spectra show large $^2J(H, P_A)$ couplings of 100 Hz, as expected.

Related tmt complexes give very similar spectra. Variable temperature ^1H NMR studies indicate that $[W(H)(tmt)_3(PMe_2Ph)_2]$ has more mobile substituents on sulphur than the tipt complex, in keeping with the smaller size of the tmt ligands. Changes in resonances due to the methyl groups on tmt as a function of temperature, indicate that the exchange of arene conformations between the "two up" and "one down" sites is observable, as well as rotation about the S—C bonds.

The FAB mass spectrum and NMR and IR spectra of the green complex $[Mo(H)(tipt)_3(PEtPh_2)]$ [as obtained from reaction (6)] are all consistent with structure **II** of Fig. 1. The hydride has an unusual chemical shift of δ +3.3 and has the large coupling constant, $^2J(H,P)$ 87 Hz, required for a *trans*-disposed phosphine. The IR absorption at 1858 cm^{-1} is in the region expected for ν(MoH). This hydride complex has one of the lowest formal electron counts (12) known for a hydride complex.

REACTIONS OF THE MONOHYDRIDE COMPLEXES

A most interesting property of the complexes **I** (M = W) and **II** is that their hydride ligand undergoes complete H/^2H exchange with 1 atm $^2H_2$ (benzene solution, 20°C, less than 15 h). For example, treatment of a benzene solution of the unsaturated complex **II** with 1 atm $^2H_2$, 22°C, gives 50% conversion to $[Mo(^2H)(tipt)_3(PEtPh_2)]$ in 1.5 h:

$$[MH(SR)_3L_n] + {}^2H_2 \longrightarrow [M{}^2H(SR)_3L_n] + H{}^2H. \quad (7)$$

Presumably, the formation of $[Mo(^2H)(tipt)_3(PEtPh_2)]$ involves the addition of $^2H_2$ to the unsaturated molybdenum, followed by elimination of H^{2}H under the conditions of excess $^2H_2$. There is therefore the possibility of a trihydride, $(\eta^2\text{-}H_2)(H)$,[16,17] or $(H)_2(HSR)$ complex intermediate in these reactions which we have not yet detected. This is to our knowledge the first example of an interaction of molybdenum(IV) with H_2 ($^2H_2$), although reactions with tungsten(IV) are known.[18] Complexes **I** (M = W, SR = tipt) and **II** do not react with $^2HSC_6H_2{}^iPr_3$-2,4,6 (^{2}Htipt) in benzene at 20°C under argon for 48 h and 16 h, respectively; this rules out a mechanism of H_2 interaction which would involve reductive elimination of Htipt from the hydride complex prior to addition of $^2H_2$ (or ^{2}Htipt). There is the possibility that there are $Mo(\eta^2\text{-}H_2)$ or MoH functionalities at the active site of nitrogenase. These would explain why H_2 is released when N_2 reacts, and why there is H^{2}H formation during nitrogen fixation under $^2H_2$ gas. Molybdenum hydrides in the HDS catalyst could explain the hydrogenation of C=C bonds and possibly the hydrogenolysis of S—C bonds.

Despite the positive chemical shift of the hydride, the tungsten complexes are reducing. They react with $CHCl_3$ to give CH_2Cl_2 and unidentified decomposition products.

The molybdenum and tungsten complexes react with pyridine to give $[MH(SR)_3(py)(PMe_2Ph)]$ where P_B in Fig. 1 has been substituted. Complex **I** (W) reacts with $P(OR')_3$ (R' = Me, Et) to give $[MH(SR)_3(P(OMe)_3)(PMe_2Ph)]$, where P_A in Fig. 1 has been replaced. The complexes reductively eliminate RSH under a CO atmosphere to give dicarbonyls $[M(SR)_2(CO)_2(PMe_2Ph)_2]$, which have been shown by X-ray diffraction to have a trigonal prismatic structure.[12]

CONCLUSIONS

Hydrides in a sulphur environment are still fairly rare. We have reported here some new monohydride complexes with several novel features: the chemical shifts of the hydrides are to unusually low field; the geometry and electron count of the complexes is unusual (14-electron, 6-coordinate, but not octahedral for the complexes $[MH(SR)_3(PMe_2Ph)_2]$ and 12-electron, 5-coordinate, trigonal bipyramidal for $[MoH(SR)_3(PEtPh_2)]$). The fact

that these complexes of (formally) molybdenum(IV) and tungsten(IV) react with deuterium is very unusual and significant. As pointed out, the reactivity of these complexes may be of relevance to the hydrodesulphurization reaction and the action of nitrogenase.

AN INORGANIC FUNCTIONAL GROUP APPROACH TO THE SYSTEMATIC SYNTHESIS AND REACTIVITY STUDIES OF BINUCLEAR Mo/S AND Mo/S/O COMPLEXES

D. COUCOUVANIS,* A. TOUPADAKIS, SANG-MAN KOO and A. HADJIKYRIACOU

Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109, U.S.A.

Abstract—A number of general reactions, based on molybdenum-coordinated sulphido or polysulphido ligands, can account for the synthesis of many members of the $[Mo_2^V(S)_n(S_2)_{6-n}]^{2-}$, $[Mo_2^V(O)(S)_n(S_2)_{5-n}]^{2-}$ and $[Mo_2^V(O)_2(S)_n(S_2)_{4-n}]^{2-}$ homologous series. These reactions include: (a) sulphur addition and sulphur abstraction reactions; (b) oxidative removal of the S_x^{2-} ligands and their replacement by substitutionally labile ligands; (c) oxidation of coodinated RS^- ligands by S_x^0 fragments, and *in situ* generation of S_x^{2-} ligands; (d) oxidative dimerization reactions of molybdenum(IV) complexes; and (e) reductive elimination of S_x^0 fragments. The synthesis of the new $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_4]^-$ and $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_2]^-$ anions has alowed the use of ^1H NMR spectroscopy to monitor the solution behaviour and reactivity of the $Mo^V(O)S_2$ group. The existence of the $Mo^V(O)S_2+S_2 \rightleftarrows Mo^V(O)S_4$ equilibrium has been unequivocally established. The $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_2]^-$ complex gives a vinyl disulphide derivative by insertion of dicarbomethoxyacetylene, DMA, into the Mo-η^2-S_2 group. Upon prolonged heating to 70°C the vinyl disulphide ligand is converted quantitatively to a dithiolene ligand. The same conversion takes place swiftly at ambient temperatures when catalytic amounts of S_8 are present in the reaction medium. Reaction pathways for both the thermal and catalytic conversions have been suggested by ^1H NMR studies. Preliminary studies of the utility of the $(Et_4N)[Mo_2O_2S_8Cl]$, $[Ni(DMF)_6][Mo_2O_2S_8Cl]_2$, $(Et_4N)_2[Mo_4O_4S_{18}]$ and $(Ph_4P)_2[Mo_2S_6]$ complexes as catalysts for the hydrodesulphurization of thiophene are reported. The Ni/Mo catalyst obtained from $[Ni(DMF)_6][Mo_2O_2S_8Cl]_2$ is at least 10 times more effective than a commercial Co/Mo catalyst.

The binary, Mo/S, or tertiary, Mo/S/O, thiomolybdate complexes[1–4] are characterized by a remarkable complexity in structure and by interesting reactivity characteristics. The vast majority of these complexes are anionic species and can be described in terms of various combinations of the O^{2-}, S^{2-}, S_2^{2-} and S_4^{2-} ligands coordinated to molybdenum(IV), -(V) or -(VI) ions.

At times, the deceivingly simple procedures that are used in the synthesis of some of these compounds result in products with unexpected formal oxidation states for the molybdenum atoms and the appearance of sulphur ligands in various degrees of catenation. The latter phenomena have their origin in facile intramolecular electron transfer processes that derive from a close matching of the S 3*p* and Mo 4*d* orbital energies.† An example of intramolecular electron transfer can be found in the synthesis of the $[(S_4)_2Mo^{IV}{=}S]^{2-}$ and $[(S_4)_2Mo^{IV}{=}O]^{2-}$ anions[6] (Figs 1 and 2). These anions are obtained by the reaction of S_8 with $[Mo^{VI}S_4]^{2-}$ or $[Mo^{VI}S_xO_{4-x}]^{2-}$ under oxidizing conditions! Intramolecular electron transfer also accounts for an apparent diversity in structural isomerism for certain molybdothioanions, where S—S bonds break or form as molybdenum atoms are oxidized or reduced.[2]

Our exploration of the reactivities of the coor-

† For the neutral free atoms, a compilation of Roothaan–Hartree–Fock atomic wavefunctions[5] show the sulphur 3*p* orbitals with an energy of −0.43694 a.u. and the molybdenum $4d(s^1d^5)$ with an energy of 0.34811 a.u. The localization of partial positive charge on the molybdenum and partial negative charge on the sulphur is expected to bring these energies even closer together.

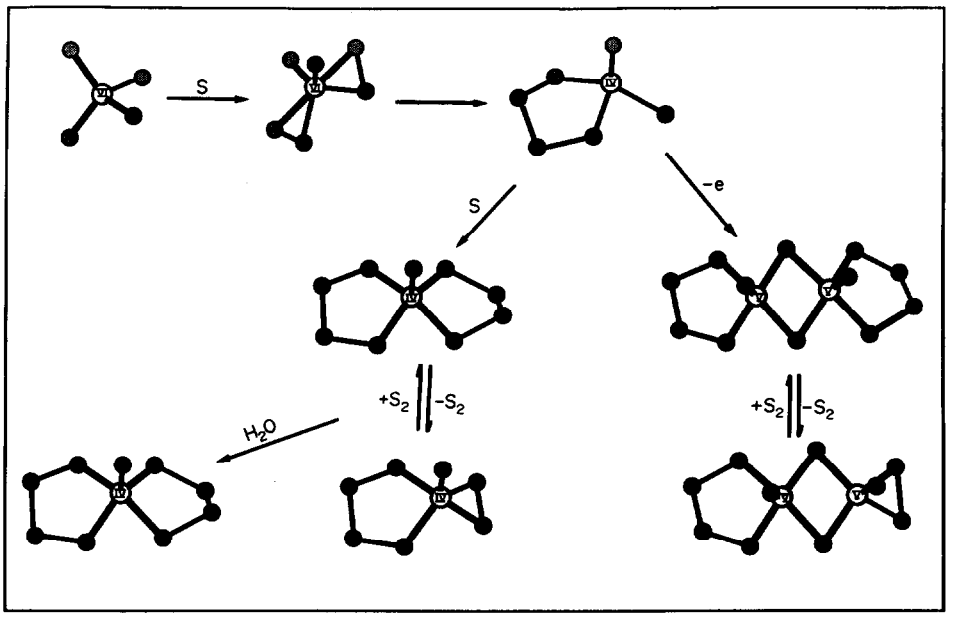

Fig. 1. Possible reaction pathways for the syntheses of the $[(S_4)_2Mo^{IV}{=}S]^{2-}$ and $[(S_4)Mo^{V}{=}S(\mu\text{-}S)]_2^{2-}$ complexes by the reaction of S_8 with the $[MoS_4]^{2-}$ anion.

dinated S^{2-}, S_2^{2-} and S_4^{2-} ligands has revealed a number of reliable general reactions that can be used for the systematic synthesis of certain thiomolybdates. Furthermore, these studies have made it apparent that neighbouring ligands, and the molybdenum oxidation state, have profound influence on reactivity.

In this paper we report on general reactivity patterns of the molybdenum-coordinated S^{2-}, S_2^{2-} and S_4^{2-} ligands. These first attempts in the development of "functional group" chemistry in the Mo/S and Mo/S/O complexes have led to rational syntheses of homologous series of complexes such as $[Mo_2^{V}(S)_n(S_2)_{6-n}]^{2-}$ [2] and $[Mo_2^{V}(O)(S)_n(S_2)_{5-n}]^{2-}$ [7] and a better understanding of the reactions of these complexes with activated alkynes and CS_2.

The synthesis of homologous series of Mo/S and Mo/S/O binary and tertiary complex anions makes it possible to systematically evaluate their activity, and the activity of their Ni^{2+} or Co^{2+} "salts" in the hydrodesulphurization (HDS) reaction of thiophene. In this paper we also report preliminary results on the catalytic properties of certain γ-Al_2O_3 supported, thiomolybdate complexes.

DISCUSSION

Synthesis of molybdothioanions

A number of general reactions, based on molybdenum-coordinated sulphido or polysulphido ligands, can account for the synthesis of many members of the $[Mo^{V}_{2}(S)_{n}(S_2)_{6-n}]^{2-}$ [2], $[Mo^{V}_{2}(O)(S)_{n}(S_2)_{5-n}]^{2-}$ [7] and $[Mo^{V}_{2}(O)_2(S)_{n}(S_2)_{4-n}]^{2-}$ [8,9] homologous series. Furthermore, these reactions make it possible to design procedures for the synthesis of new thiomolybdate complexes. In the discussion that follows, a detailed account is offered for the synthesis and reactivities of the molybdenum-coordinated sulphido and persulphido functional groups.

The molybdenum-coordinated S^{2-} *ligands*

The reactions of oxomolybdates $[(Mo^{VI}O_4)^{2-}$ or $(Mo^{VI}_{7}O_{24})^{6-}]$ with H_2S or $(NH_4)_2S_x$ under basic conditions give thiomolybdate products that, depending on reaction times or conditions, contain Mo—S_x and Mo=O units in various combinations. The simplest among the S^{2-}_{x} ligands is the S^{2-} ligand that exists mainly as: (a) a terminal ligand in thiomolybdenyl units[1-3] (Mo^{n+}=S, n = IV, V, VI), (b) a μ_2-bridging unit in cores such as $(Mo_2S_2)^{6+}$ [1-4] and (c) a μ_3-bridging unit in $[Mo_3S_{13}]^{2-}$ [10] and in the Mo_4S_4 cores of the $[(L_3Mo)_2S_4]$ complexes[11,12] and in $[Mo_7S_8(H_2O)_{18}]^{8+}$.[13] The nucleophilicity that dominates the chemistry of the S^{2-} ligands depends on the coordination mode [(a), (b) or (c) above] and appears to be stronger for the terminal Mo=S sulphido ligands. In this paper we will direct our attention to the chemistry of the S^{2-} terminal ligands.

The addition of sulphur to terminal sulphido ligands is very likely the end result of electrophilic attack on the Mo^{n+}=S sulphur by the $^{+}S(S)_xS^{-}$ products of heterolytically cleaved S_8 molecules. This general reaction occurs readily with various Mo^{n+}=S groups (n = IV, V, VI) and is encouraged in the synthesis of the $[(S_4)_2Mo^{IV}{=}E]^{2-}$ anions[6] (E = S, O; Fig. 1) and various members of the $[Mo^{V}_{2}(S)_{n}(S_2)_{6-n}]^{2-}$ [2] (Fig. 3) and $[Mo^{V}_{2}(O)(S)_{n}(S_2)_{5-n}]^{2-}$ [7] series. Addition of sulphur atoms to the Mo=S units gives stable Mo-η^2-S_2 units that on occasion may undergo subsequent intramolecular electron transfer on their way to more stable, electron redistribution isomers (Figs 1 and 2). Electrophilic attack on the Mo^{n+}=S sulphur very likely also occurs in the reactions of various thiomolybdates with CS_2[14] and activated alkynes, RC≡CR,[1,15] (*vide infra*).

With transition metal ions, the thiomolybdenyl groups can serve as either electron pair donors, or as a source of sulphide ions for the eventual formation of highly insoluble, thermodynamically stable, transition metal sulphides. The former course of reactivity is aptly represented in the multitude of heterometallic complexes where the MoS_4^{2-} anion serves as a ligand for transition metal ions.[16] The irreversible removal of sulphide ions from Mo=S units by the formation of insoluble transition metal sulphides allows for the introduction of non-sulphur terminal ligands in the thiomolybdate ions by metathetical reactions. An example of this reaction is available in the synthesis of the $[Mo_2O_2S_8X]^{-}$ anions[17] from the reaction

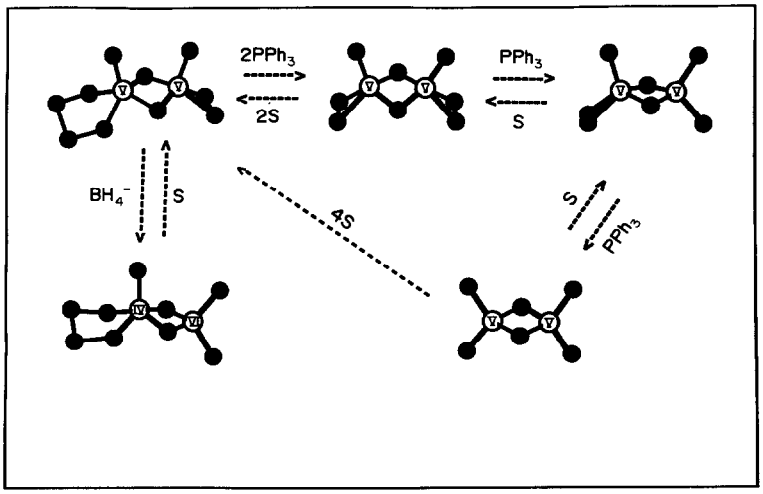

Fig. 3. The syntheses of members in the $[Mo^{V}_{2}(S)_{n}(S_2)_{6-n}]^{2-}$ series by sulphur addition and sulphur-abstraction reactions.

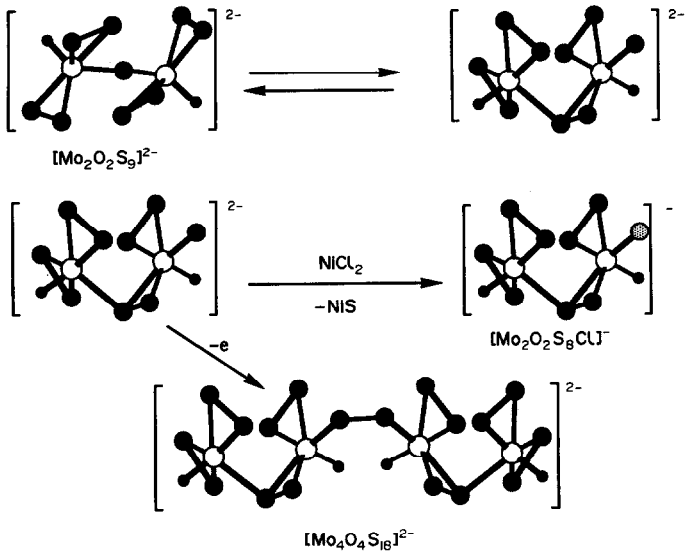

Fig. 4. Reactions and derivatives of the $[[(S_2)_2Mo^{VI}{=}O]_2(S)]^{2-}$ anion.

of NiX_2 (X = Cl, I) with an isomeric form of the $[Mo_2^{VI}O_2S_9]^{2-}$ anion[18] (Fig. 4). The latter is obtained readily by oxidation of the $[(S_4)_2Mo^{IV}{=}O]^{2-}$ anion (Fig. 2).

The oxidation of the thiomolybdenyl group by various oxidizing agents depends on the formal oxidation state of the molybdenum atom and the nature of the neighbouring ligands in the coordination sphere of the molybdenum atom. The dimerization of Mo^V, $4d^1$ complexes to diamagnetic dimeric complexes with a formal Mo—Mo single bond is well documented. Not surprisingly, the one-electron oxidations of $(L)_nMo^{IV}{=}S$ complexes invariably lead to dimerization with formation of the very stable di-μ-sulphido $[(L)_nMo^VS]_2$ products.

Examples of this oxidative dimerization include the formation of $[(S_4)SMo^V{=}E]_2^{2-}$ from the air-oxidation of $[(S_4)_2Mo^{IV}{=}E]^{2-}$ [7] (Figs 1 and 2), and the formation of the $[(L)_2Mo^V{=}S]_2^{2-}$ dimer[1] apparently from the oxidation of an unstable $[(L)_2Mo^{IV}{=}S]^{2-}$ intermediate (L = 1,2-dicarboethoxyethylene-1,2-diethiolate). An unusual oxidation is evident in the reaction of the $[(S_4)_2Mo^{IV}{=}O]^{2-}$ complex with $[(C_5H_5)_2Fe]^+$, and formation of the $[(S_2)_2(O)Mo^{VI}{-}S{-}S{-}Mo^{VI}(O)(S_2)_2]^{2-}$ dimer[17] (Fig. 2). This oxidation may involve the $[(S_2)_2(O)Mo^{VI}{=}S]^{2-}$ intermediate complex that forms as a result of intramolecular electron transfer. The $[(S_2)_2(O)Mo^{VI}(\mu\text{-}S_2)Mo^{VI}(O)(S_2)_2]^{2-}$ dimer (Fig. 2) readily dissociates sulphur to give the apparently more stable $[(S_2)_2(O)Mo^{VI}{-}S{-}Mo^{VI}(O)(S_2)_2]^{2-}$ complex.

The molybdenum-coordinated S_2^{2-} ligands

As discussed previously, the $Mo^{n+}{-}\eta^2\text{-}S_2$ units are obtained by sulphur addition to the $Mo^{n+}{=}S$ units (n = IV, V, VI). The same units also can be obtained by the oxidation of molybdenum-coordinated PhS^- ligands with the dibenzyltrisulphide reagent. This general reaction generates S_x^{2-} ligands *in situ*, from the reduction of S_x^0 fragments by PhS^- ligands, and has been used previously[19] in the synthesis of $[M(S_x)_2]^{2-}$ complexes from the $[M(SPh)_4]^{2-}$ anions. The oxidative removal of the coordinated PhS^- ligands from the $[OMo^V(SPh)_2MoS_4]^{2-}$ derivative[7] of the $[OMo^V(SPh)_4]^-$ complex,[20] with the concomitant introduction of the $\eta^2\text{-}S_2$ ligand, is shown in Fig. 5. This reaction and subsequent sulphur-addition or sulphur-abstraction reactions have made possible the rational synthesis of the new $[Mo_2^V(O)(S)_n(S_2)_{5-n}]^{2-}$ anions (n = 3,4) and derivatives[8] (Figs 5 and 6) based on predictable functional group chemistry.

The $Mo{-}\eta^2\text{-}S_2$ functional groups in the $L_x(S)Mo{-}\eta^2\text{-}S_2$ complexes react with both electrophilic and nucleophilic reagents. Nucleophilic attack by triphenylphosphine, presumably on a highly polarized S_2^{2-} ligand, occurs readily and the ligand undergoes desulphurization with generation of $L_x(S)Mo{=}S$ units. This general sulphur-abstraction reaction has been used effectively for the synthesis of various members of the $[Mo_2^V(S)_n(S_2)_{6-n}]^{2-}$,[2] and $[Mo_2^V(O)(S)_n(S_2)_{5-n}]^{2-}$ [7] series (Figs 3, 5 and 6) from "sulphur-rich" precursors.

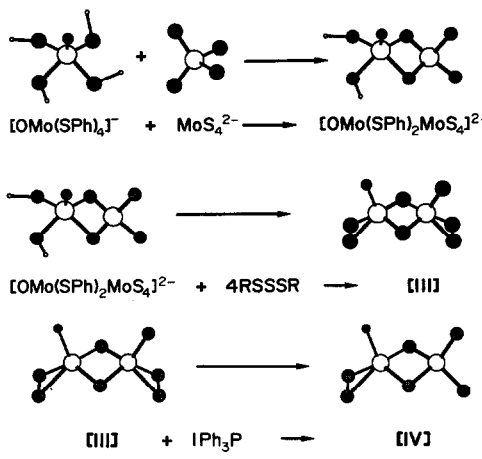

Fig. 5. Syntheses of members of the $[Mo_2^V(O)(S)_n(S_2)_{5-n}]^{2-}$ series ($n = 3, 4$) from $[(PhS)_2Mo^V(O)(Mo^{VI}S_4)]^-$.

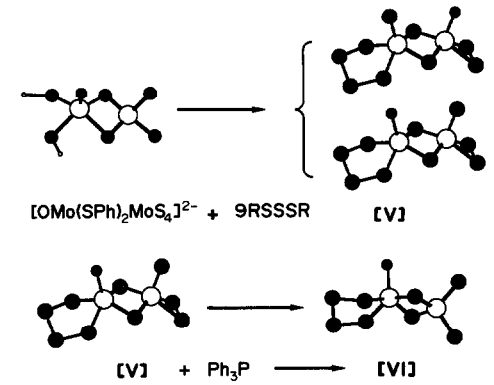

Fig. 6. Synthesis of electron redistribution isomers of the $[Mo_2^V(O)(S)_n(S_2)_{5-n}]^{2-}$ series ($n = 1, 2$) from $[(PhS)_2Mo^V(O)(Mo^{VI}S_4)]^-$.

The reaction of Ph_3P with the $L_x(O)Mo^V$—η^2-S_2 complexes probably proceeds with formation of $L_x(O)Mo^V$=S units that readily dimerize to the $[L_x(O)Mo^V{=}S]_2$ complexes (Fig. 2). The greater tendency of the $L_x(O)Mo^V$=S units to dimerize, by comparison to $L_x(S)Mo^V$=S units, could be attributed in part to steric effects. The molybdenum(V) ions in the four-coordinate $L_x(O)Mo^V$=S units are not only coordinatively unsaturated but considerably less crowded than the molybdenum(V) ions in the $L_x(S)Mo^V$=S units. The importance of this type of steric effect also is apparent in the synthesis of the $[(S_4)Mo^{IV}(O)(Mo^{VI}S_4)]^{2-}$ complex.[7] This anion (but not the isomeric $[(S_4)Mo^{IV}(S)(Mo^{VI}S_3O)]^{2-}$) is obtained exclusively in the reaction of a 50:50 mixture of the $[(S_4)Mo^V(O)(\mu\text{-}S)_2Mo^V(S)(S_2)]^{2-}$ and $[(S_4)Mo^V(S)(\mu\text{-}S)_2Mo^V(O)(S_2)]^{2-}$ isomers with Ph_3P (Fig. 6). A similar preferential sulphur abstraction from a $Mo(S)(\eta^2\text{-}S_2)$ functional group is also apparent in the exclusive synthesis of the $[(S_2)Mo^{IV}(O)(Mo^{VI}S_4)]^{2-}$ anion[7] from $[(S_2)Mo^V(O)(\mu\text{-}S)_2(S)Mo^V(S_2)]^{2-}$ (Fig. 5).

In DMF solution, I_2 oxidation of η^2-S_2^{2-} ligands gives polymeric thiomolybdates when neighbouring terminal S^{2-} ligands are also present on the same molybdenum atom. If instead of S^{2-} a neighbouring O^{2-} ligand is present on the molybdenum atom, the S_2^{2-} ligands are oxidatively removed (as S_8) and are replaced by DMF ligands[8] (Fig. 7). The neutral $[(S_2)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(DMF)_3]$ complex, and the I^- salt of the $[(DMF)_3Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(DMF)_3]^{2+}$ cation have been obtained in excellent yields in crystalline form.[8] These complexes have made it possible to synthesize a wide

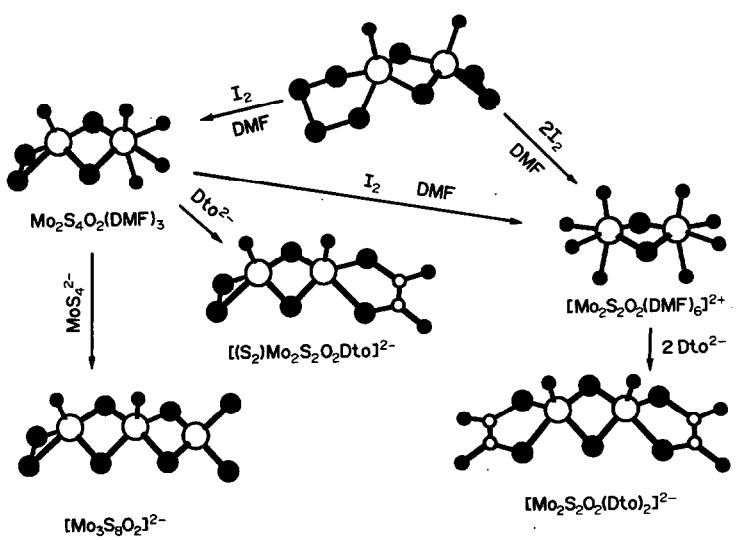

Fig. 7. Iodine oxidation of the S_x^{2-} ligands in the $[(S_4)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(S_2)]^{2-}$ complex. Synthesis and derivatives of the $[(DMF)_3Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(S_2)]$ and $[(DMF)_3Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(DMF)_3]^{2+}$ complexes.

variety of complexes containing the $[Mo_2^V(O)_2(\mu\text{-}S)_2]^{2+}$ core by replacement of the labile DMF ligands (Fig. 7).

The molybdenum-coordinated S_4^{2-} ligands

Addition of elemental sulphur to the Mo—η^2-S_2 functional group results in the formation of the Mo—η^2-S_4 unit, in a reaction that could be visualized as an insertion of a polarized $^{\delta+}$S—S$^{\delta-}$ species into the Mo—S_2 bond. This insertion is reversible and in solution the Mo—η^2-S_4 group exists in equilibrium with Mo—η^2-S_2 and elemental sulphur.

This equilibrium has been established unequivocally by an ^{1}H NMR study of mixtures of the $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_4]^-$ and $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_2]^-$ anions in CH_3CN solution (Fig. 8). Such a mixture, that contains the $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_4]^-$ anion as the major component (84%), is obtained[21] in the reaction between $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(DMF)_3]^+$ and an excess of $(NH_4)_2S_x$. The $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)(DMF)_3]^+$ cation is obtained by I_2 oxidation of the $[(Cp)Mo^V(O)(\mu\text{-}S)_2Mo^V(O)S_2]^-$ complex in DMF solution. It is now apparent that the chemistry of the Mo—η^2-S_4 group is dominated by the presence of the Mo—η^2-S_2 groups. The ready dissociation of S_2 from the coordinated S_4^{2-} ligand is due to a weakening of the S—S bonds proximal to the molybdenum atom. This weakening has been attributed previously to Mo—S $d\pi$–$p\pi$ bonding[1,19,*] and is reflected in unusually long S—S bond lengths in the coordinated ligand.

* See footnote † on p. 1705.

Reactivity of the molybdenum-coordinated S_x^{2-} ligands toward unsaturated electrophilic molecules

The reaction chemistry of the molybdenum thioanions with electrophiles such as CS_2[1,14] and dicarboalcoxyacetylenes[1,15] has been investigated in considerable detail. It appears that both the Mo—η^2-S_x and Mo=S groups are sufficiently nucleophilic to attack by dicarbomethoxyacetylene (DMA). This is clearly established for thiomolybdates that contain both Mo=S and Mo(η^2-S_x) groups. The reactions of the $[(S_4)_2Mo^{IV}{=}S]^{2-}$ and $[(S_4)(S)Mo^{V}(\mu\text{-}S)_2Mo^{V}(S)(S_2)]^{2-}$ complexes with DMA (Fig. 9) proceed until all S_x^{2-} sulphido ligands (with the exception of the μ-S^{2-} ligands) are converted into the dithiolene (DMAD) ligands. The type of DMAD complex obained depends on the synthetic conditions. Thus, the $[(S_4)_2Mo^{IV}{=}S]^{2-}$ complex under anaerobic conditions reacts with DMA to give the $[Mo^{IV}(DMAD)_3]^{2-}$ complex.[15] Under aerobic conditions the same reaction affords the dimeric $[(DMAD)_2Mo^{V}(\mu\text{-}S)_2Mo^{V}(DMAD)_2]^{2-}$.[1] The latter is also obtained from reactions of DMA with either the $[(S_4)(S)Mo^{V}(\mu\text{-}S)_2Mo^{V}(S)(S_2)]^{2-}$ or the $[(S_2)(S)Mo^{V}(\mu\text{-}S)_2Mo^{V}(S)(S_2)]^{2-}$ complex anions. Possible reaction pathways are shown in Fig. 9. The formation of the DMAD ligands in these complexes can be ex-

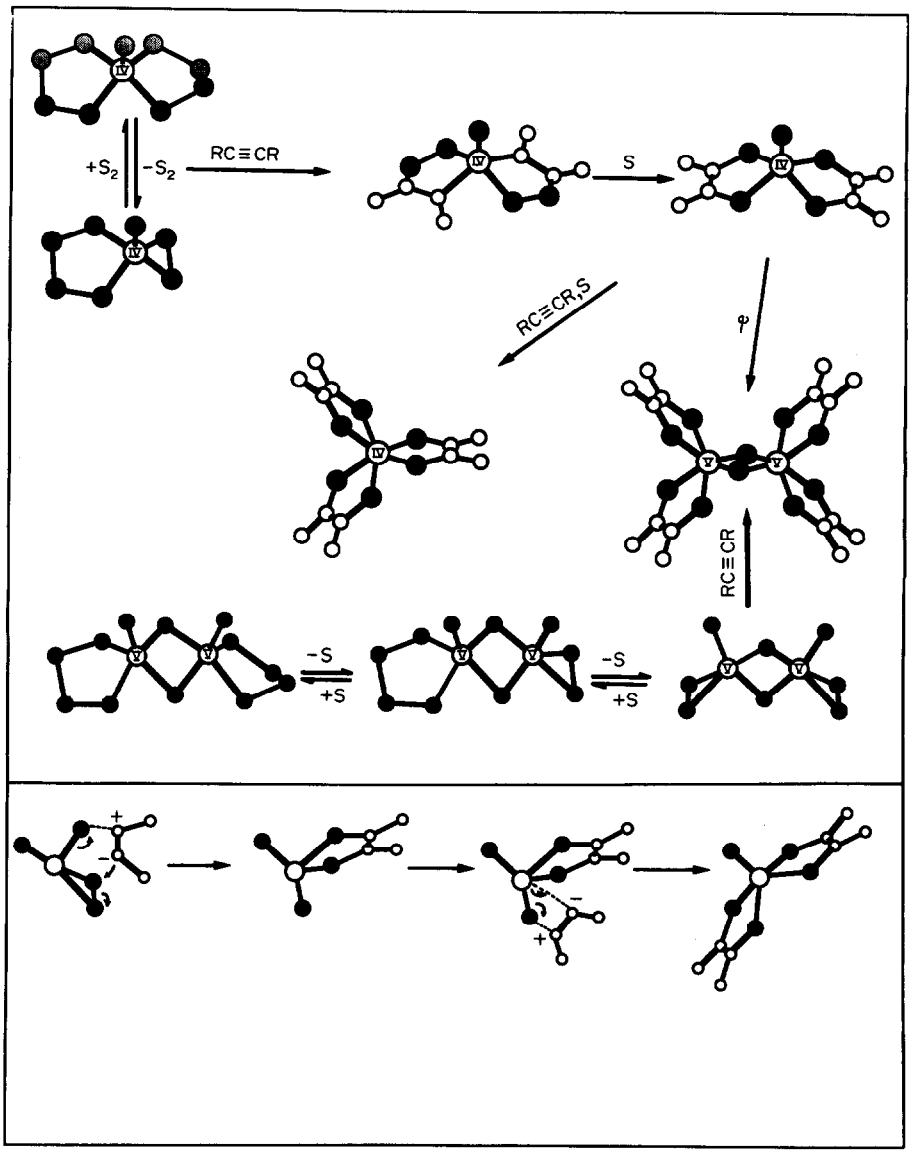

Fig. 9. Reactions of dicarbomethoxyacetylene, DMA, with the $[(S_4)_2Mo^{IV}{=}S]^{2-}$ and $[(S_4)Mo^{V}(S)(\mu\text{-}S)_2Mo^{V}(S)(S_2)]^{2-}$ complexes, under aerobic and anaerobic conditions.

plained in terms of electrophilic attack by DMA on either the Mo=S or the Mo—η^2-S_2 functional groups. The initial step in these reactions is difficult to ascertain, but it could be electrophilic attack by DMA followed by insertion into either the Mo=S or Mo—η^2-S_2 bonds. These insertions lead to the formation of reactive vinyl sulphide or vinyl disulphide ligands, that eventually transform to dithiolenes. This transformation could occur for the vinal sulphide by insertion of sulphur into the Mo—C bond, and for the vinyl disulphide by a thermal or sulphur-catalysed isomerization reaction. Other possible schemes suggested previously[15] for the addition of an alkyne into the Mo—S—S unit include: (a) direct formation of the DMAD dithiolene ligand, by electrophilic attack of DMA on the η^2-S_2 ligand, followed by insertion into the S—S bond and (b) a 4+2 Diels–Alder cycloaddition reaction.

The reactions of oxothiomolybdates with DMA (Fig. 10) have been quite useful from a mechanistic point of view. Replacement of the Mo=S groups by the apparently unreactive Mo=O groups, in otherwise isostructural complexes, simplifies the reactivity patterns and eliminates some of the ambiguities inherent in the reactions of totaly "sulphided" thiomolybdates.

The initial report[22] on the synthesis of the vinyl disulphide complex, $[(L)(O)Mo^{V}(\mu\text{-}S)_2Mo^{V}(O)(L)]^{2-}$ (L = [—(R)C=C(R)—S—S—]^2), from the reaction of DMA with the $[(S_2)(O)Mo^{V}(\mu\text{-}S)_2Mo^{V}(O)(S_2)]^{2-}$ anion, revealed unequivocally that in the $(O)Mo(S_2)$ structural subunits of the thiomolybdate anions, insertion into the Mo—S bond is prevalent. Subsequently, we have observed that the vinyl disulphide complex thermally isomerizes to the $[(DMAD)(O)Mo^{V}(\mu\text{-}S)_2Mo^{V}(O)(DMAD)]^{2-}$ dithiolene complex. The latter and also the $[(DMAD)_2Mo^{IV}{=}O]^{2-}$ complex are obtained directly from the reactions of the $[(S_4)(O)Mo^{V}(\mu\text{-}S)_2Mo^{V}(O)(S_2)]^{2-}$ and $[(S_4)_2Mo^{IV}{=}O]^{2-}$ anions, respectively, with DMA[1] (Fig. 10). Isomerization of vinyl disulphide ligands to dithiolenes also has been reported to proceed via a first-order reaction in the $(Cp)_2Ti$(vinyl disulphide) complex.[23]

The S_4^{2-} ligands play an indirect but important role in promoting the formation of dithiolenes, by supplying dissociated "S_2" that catalyses the vinyl disulphide to dithiolene conversion.

Convincing evidence for the catalytic effects of sulphur in this interconversion has been obtained from ^{1}H NMR studies of the DMA derivatives of the $[(Cp)Mo^{V}(O)(\mu\text{-}S)_2Mo^{V}(O)S_2]^{-}$ complex.[24] This complex initially reacts with DMA to give a vinyl disulphide derivative by insertion of DMA into the Mo—η^2-S_2 group. Upon prolonged heating to 70°C the vinyldisulphide ligand in this complex is converted quantiatively to a dithiolene ligand. The same conversion takes place swiftly at the same temperature when catalytic amounts of S_8 are added to CH_3CN solutions of the vinyl disulphide complex. A plausible reaction pathway for the *thermal*, vinyl disulphide–dithiolene conversion initially

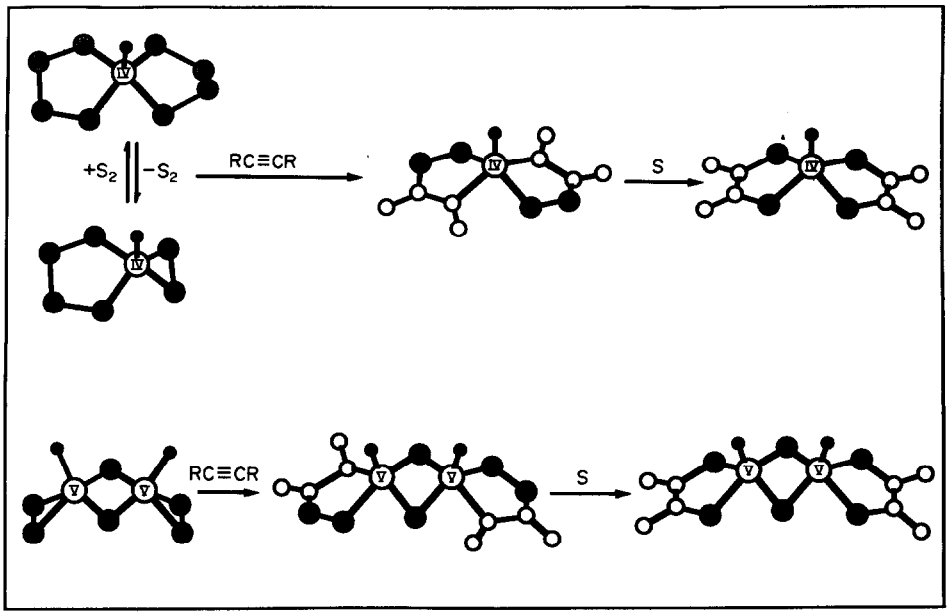

Fig. 10. Reactions of DMA with the $[(S_4)_2Mo^{IV}{=}O]^{2-}$ and $[(S_4)Mo^{V}(O)(\mu\text{-}S)_2Mo^{V}(O)(S_2)]^{2-}$ complexes.

may involve dissociation of a sulphur atom (the one adjacent to the olefinic bond) from the vinyl disulphide complex. The resulting vinyl sulphide complex is expected to be quite reactive and should readily undergo sulphur insertion reactions into the Mo—C bond to give a dithiolene complex. Preliminary results support this proposed sequence of reactions. Thus in the reaction of the $[(Cp)Mo^{V}(O)(\mu\text{-}S)_2Mo^{V}(O)((R)C{=}C(R){-}S{-}S)]^-$ vinyl disulphide complex, with one equivalent of Ph_3P, the two CH_3 resonances of the vinyl disulphide ligand are replaced completely and cleanly by two new resonances that we attribute to the vinyl sulphide complex (Fig. 11). Addition of sulphur to this solution of the vinyl sulphide complex gives a 2 : 1 dithiolene–vinyl disulphide mixture. This experiment suggests that the assumed coordinated vinyl sulphide ligand can undergo sulphur insertion at either the Mo—S or the Mo—C bonds, and that insertion into the Mo—C bond is a more facile process.

The sulphur-catalysed, vinyl disulphide–dithiolene conversion is proposed to proceed via formation of catalytic amounts of the "sulphur-rich" dithiolene complex by sulphur insertion into the Mo—C bond of the vinyl disulphide complex (Fig. 12). Precedence for the insertion of sulphur into a M—C bond exists in the reaction of the $[(\eta^5\text{-}Cp)W(NO)(CH_2SiMe_3)_2]$ complex with S_8 to give $[(\eta^5\text{-}Cp)W(NO)(SCH_2SiMe_3)_2]$.[25] Once formed, the "sulphur-rich" dithiolene complex is expected to undergo nucleophilic attack by the molybdenum-bound carbon atom of the vinyl disulphide ligand. This attack should occur at the electrophilic sulphur atom adjacent to the ethylenic double bond in the "sulphur-rich" dithiolene and will result in sulphur abstraction, formation of dithiolene and regeneration of a sulphur-rich dithiolene that will repeat the cycle. In the scheme shown in Fig. 12 a large excess of sulphur is expected to quench the formation of dithiolene by conversion of most of the vinyl disulphide complex to the "sulphur-rich" dithiolene complex. The latter should be stable in the absence of nucleophilic "sulphur-acceptor" molecules. Indeed, we have observed (by ^1H NMR) a retardation in the rate of formation of dithiolene as larger than catalytic amounts of sulphur are added to the reaction medium.

The importance of alkyne insertion into Mo—S bonds and the formation of vinyl disulphide complexes preceding the formation of dithiolenes, still

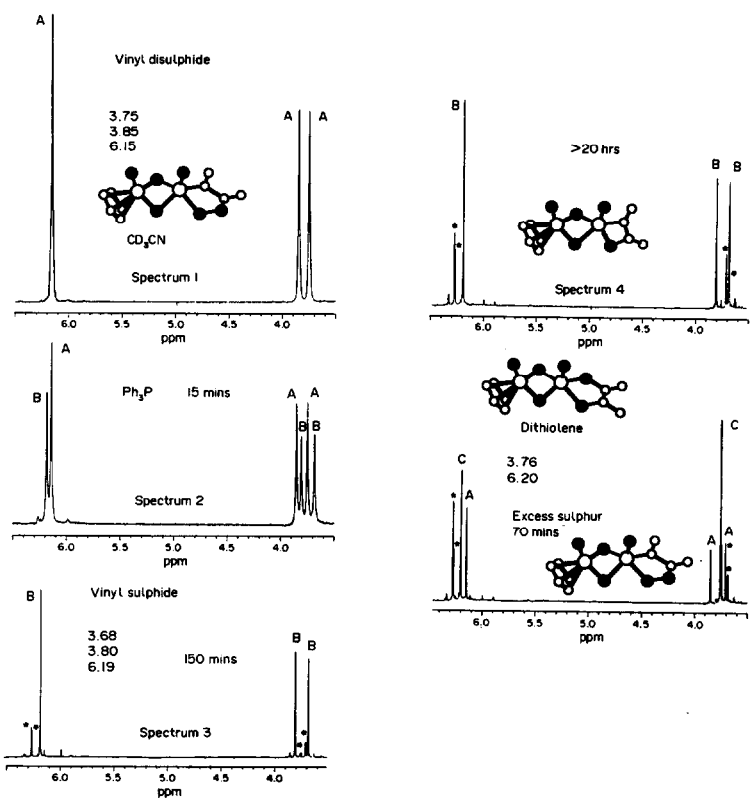

Fig. 11. Addition of triphenyl phosphine to a CH_3CN solution of the $[(Cp)Mo^{V}(O)(\mu\text{-}S)_2Mo^{V}(O)((R)C{=}C(R){-}S{-}S)]^-$ vinyl disulphide complex (**A**) and the proposed generation of a vinyl sulphide analogue (**B**). Addition of elemental sulphur to this solution with the subsequent formation of the vinyl disulphide (**A**) and dithiolene (**C**) complexes.

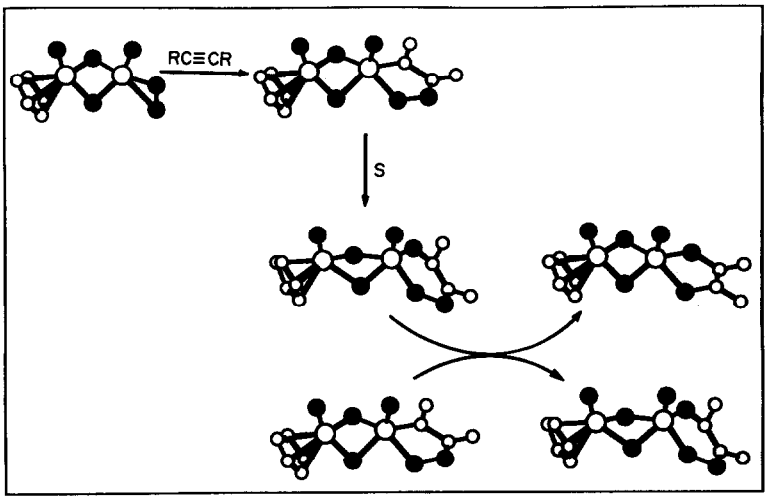

Fig. 12. A proposed reaction pathway, suggested by ^{1}H NMR spectroscopy, for the *sulphur-catalysed transformation* of the vinyl disulphide ligand in the $[(Cp)Mo^{V}(O)(\mu\text{-}S)_2Mo^{V}(O)((R)C{=}C(R)\text{—}S\text{—}S)]^-$ complex to a dithiolene ligand.

remain to be established for certain systems. This is particularly true for the synthesis of diothiolene complexes by the reaction of completely sulphided thiomolybdates with DMA (Fig. 9). To date we have been unable to detect evidence for the formation of a vinyl disulphide ligand in the reactions of DMA with any of the $[Mo_2^{V}(S)_n(S_2)_{6-n}]^{2-}$ complexes. It is entirely conceivable that the nucleophilic Mo—S sulphur atoms in the latter, first react with electrophiles that insert into the Mo=S bond to give short lived vinyl sulphide species. Subsequent intramolecular sulphur transfer from the proximal η^2-S_x^{2-} ligand rapidly results in the formation of dithiolenes.

The importance of the Mo=S group is evident in the relative reactivities of the $[(S_4)_2Mo^{IV}{=}O]^{2-}$ and $[(S_4)_2Mo^{IV}{=}S]^{2-}$ complexes toward CS_2. The latter readily reacts with CS_2 to give both *cis*- and *trans*-$[(CS_4)_2Mo^{IV}{=}S]^{2-}$ complexes.[26] By comparison, the $[(S_4)_2Mo^{IV}{=}O]^{2-}$ complex is totally unreactive toward CS_2. An exception to the facile oxidative dimerization of the $[(L)_2MoS]^{2-}$ complexes is found with the $[(Cs_4)_2Mo^{IV}{=}S]^{2-}$ complex. This anion is quite stable and does not air-oxidize to the $[(CS_4)_2Mo^{V}{=}S]_2^{2-}$ product, at least under mild reaction conditions.

A remarkable characteristic of the Mo—η^2-CS_4 groups is their ability to reversibly release CS_2 (Fig. 13) and revert to Mo—η^2-S_2. On the basis of this observation, we have suggested previously[1] that

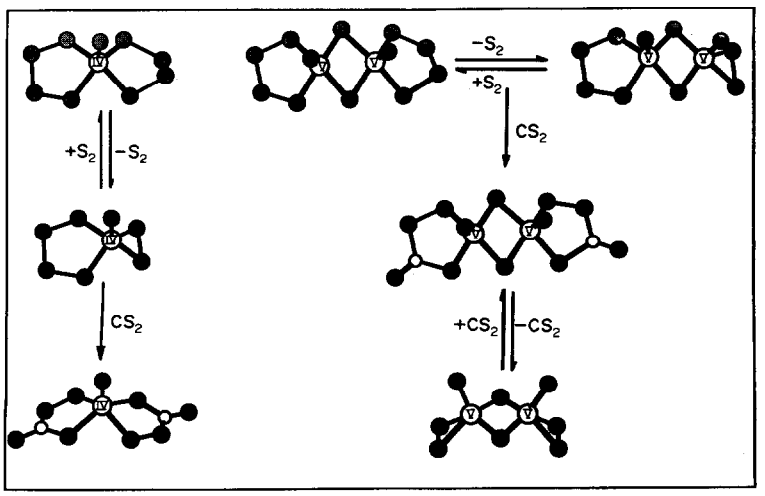

Fig. 13. Reversible addition of CS_2 to the thiomolybdate complexes.

Table 1. Comparison of the thiophene HDS activity[a] over alumina-supported catalysts obtained from thiomolybdate precursors

Catalyst precursor	Per cent molybdenum loading	TOF[b] C_4 (s^{-1})	Per cent conversion,[b,c] C_4
$(Ni(DMF)_6)[Mo_2O_2S_8Cl]_2$	1.7	0.0021–0.0019	54.3–47.5
$(Et_4N)[Mo_2O_2S_8Cl]$	2	0.00028–0.00024	4.2–3.5
$(Et_4N)_2[Mo_4O_4S_{18}]$	2	0.00013–0.00014	1.9–2.1
$(Ph_4P)_2[Mo_2S_6]$	3.2	0.00015–0.00009	8.3–5.2
Commercial Co—Mo—S "Catalco"	[d]	0.0011–0.0009	29.6–25.3

[a] Vapour pressure of thiophene = 20 torr, stream of hydrogen = 20 cm^3 min^{-1}.

[b] The figure of merit "TOF" is defined as the number of moles of desulphurized thiophene, per second, per mole of molybdenum. The first entry gives the TOF number within 30 min of thiophene conversion. The second value gives the TOF number after *ca* 3 h of thiophene conversion.

[c] The major products of thiophene conversion are C_4 hydrocarbons. The ratio of *trans*-/*cis*-butene typically is ~ 1.8; C_3 and C_2 hydrocarbons are minor components.

[d] The commercial catalyst used as reference has a higher per cent metal loading: 12–16% MoO_3 + 2–5% CoO.

under certain conditions the Mo—η^2-S_2 functional group may be directly involved in the activation of C—S bonds in saturated or unsaturated sulphur-containing organic molecules, in the catalysis of the hydrodesulphurization, HDS, reaction.

Supported thiomolybdate complexes as catalysts for the hydrodesulphurization reaction

The removal of sulphur from organosulphur compounds, present in crude petroleum, is carried out catalytically by the HDS reaction[27] [eq. (1)]:

$$RSH + H_2 \longrightarrow H_2S + RH. \qquad (1)$$

The catalyst used industrially consists of "sulphided" molybdates supported on γ-Al_2O_3, although many second- and third-row transition metal sulphides are active catalysts for the HDS reaction, with Ru, Os, Rh and Ir sulphides showing the highest activity.[28] Among the first-row transition metal ions, Ni^{2+} and Co^{2+} ions serve as promoters in the MoS_2 HDS catalysis.[27]

Certain heteromtallic complexes have been used as precursors for the preparation of HDS catalysts. Among them are included: $[(WS_4)_2Ni]^{2-}$[29] and $(MeCp)_2Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)(CO)_4$.[30] In a preliminary study the thiomolybdate salts $(Et_4N)_2[(S_4)_2Mo^{IV}{=}O]$ and $(Et_4N)_2[(S_4)_2Mo^{IV}{=}S]$ were used as precursors for alumina supported HDS catalysts in the absence of promoter ions.[26] At 205°C, the catalyst obtained from $(Et_4N)_2[(S_4)_2Mo^{IV}{=}O]$ (3.1% loading) approached the activity shown by commercial Co—Mo catalysts, at the same temperature, and showed superior thiophene HDS activity then a similar "catalyst" obtained from $(Et_4N)_2[(S_4)_2Mo^{IV}{=}S]$. These results suggested that the Mo=O groups may be important in HDS catalysis and prompted us to examine other thiomolybdate complex anions. The thiophene–HDS catalytic activities of the $(Et_4N)[Mo_2O_2S_8Cl]$,[31] $[Ni(DMF)_6][Mo_2O_2S_8Cl]_2$,[32] $(Et_4N)_2[Mo_4O_4S_{18}]$[17] and $(Ph_4P)_2[Mo_2S_6]$[2] have been examined* (Table 1).

The $(Et_4N)^+$ cation in $(Et_4N)[Mo_2O_2S_8Cl]$[31] (Fig. 4) can be exchanged conveniently in the reaction of this compound with $NiCl_2 \cdot 6H_2O$ in DMF solution. The black–red $[Ni(DMF)_6][Mo_2O_2S_8Cl]_2$ salt has been isolated in ~ 50% yield.[33] The corresponding iodo complex, $[Ni(DMF)_6][Mo_2O_2S_8I]_2$, has also been obtained by a similar reaction using $NiI_2 \cdot 6H_2O$.[32] The crystal and molecular structure of the latter was determined by X-ray crystallography[32] and the structure of the anion is virtually identical to that of the $[Mo_2O_2S_8Cl]^-$ anion[31] (Fig. 4). An examination of the preliminary results* reported in Table 1 shows that the

* A detailed study of the catalytic properties of the thiomolybdate complexes is currently underway, in collaboration with Professor J. Schwank and Mr J. Lindner in the Department of Chemical Engineering, The University of Michigan. The results of this study will be published in detail elsewhere.

Ni/Mo catalyst obtained from $[Ni(DMF)_6][Mo_2O_2S_8Cl]_2$ is nearly 10 times more effective than a commercial Co/Mo catalyst, on the basis of relative figure of merit values.* At present we are conducting detailed systematic studies of the HDS catalytic properties of the thiomolybdate anions and of the Ni^{2+}, Co^{2+} and Fe^{2+} "salts" of these complexes.

EARLY TRANSITION METAL–SCHIFF BASE COMPLEXES: FROM STRUCTURE TO REACTIVITY

CARLO FLORIANI

Institut de Chimie Minérale et Analytique, Université de Lausanne, Place du Château 3, CH-1005 Lausanne, Switzerland

Abstract—A review is given of the chemistry of early transition metal–Schiff base complexes. The emphasis is on the synthetic routes, the structural properties of these complexes, their transformation into organometallic derivatives, and their use for storing and releasing electrons.

The versatile chemistry of late transition metal complexes derived from the use of Schiff base ligands[1a] does not have a counterpart in early transition metals.[1b] Our recent contribution to this area will be reviewed with special emphasis on:

(a) Synthetic methods for functionalizable complexes;
(b) How Schiff base ligands provide new and interesting environments for M—C< functionalities;
(c) Redox reactions which do not involve changes in the oxidation state of the metal.

SYNTHETIC METHODS AND STRUCTURAL PROPERTIES

Schiff base ligands assure a constant coordination geometry and an electronically flexible environment to the metal.

The relative arrangement of the two vacant or functionalizable coordination sites is of a crucial importance for reactivity, but is almost exclusively dependent on the ionic radius of the metal ion. The very versatile method for the synthesis of all these compounds is shown in eqs (1)–(3):[2]

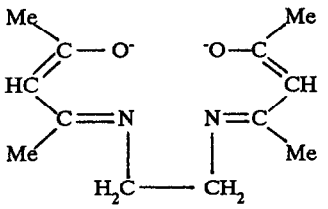
$$MCl_4(THF)_2 + L_4Na_2 \xrightarrow{-NaCl} ML_4Cl_2 \quad (1)$$

$$MCl_4(THF)_2 + 2L'_2Na \xrightarrow{-NaCl} M(L'_2)_2Cl_2 \quad (2)$$

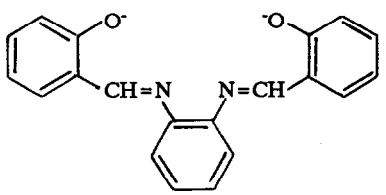
$$M'Cl_3(THF)_3 + L_4Na_2 \xrightarrow{-NaCl} M'L_4(Cl) \quad (3)$$

(M = Ti, Zr, Hf, V, Nb, Mo; M′ = Ti, V).

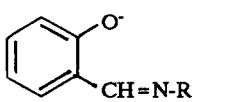
Reactions (1)–(3) are usually carried out in tetrahydrofuran (THF). A significantly different method is used in case of vanadium(IV) and vanadium(III) derivatives. The availability of oxovanadium(IV) derivatives prompted us to use



acen = N,N'-ethylenebis-(acetylacetoneiminato) dianion, L_4.



salophen = N,N'-o-phenylenebis-(salicylideneiminato) dianion, L_4.



salN-R = N-alkyl-(salicylideneiminato) anion, L'_2.

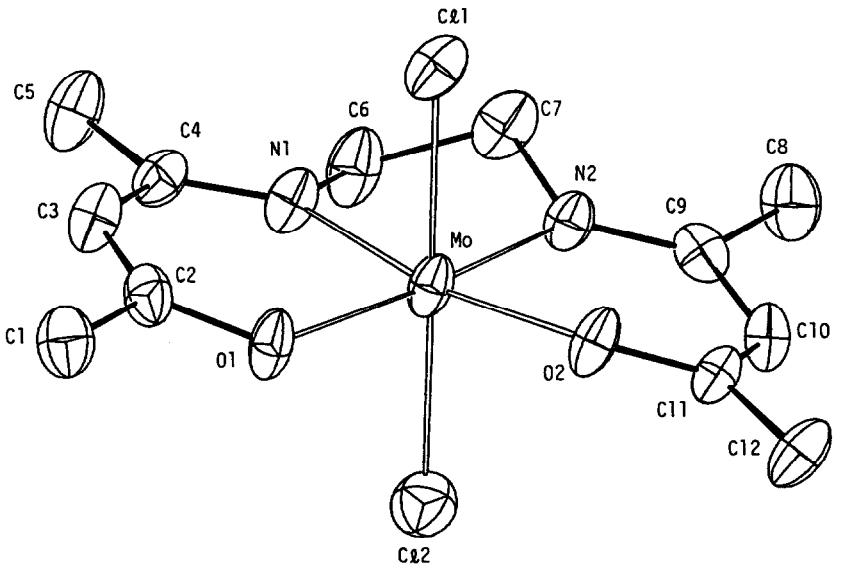


Fig. 1. [Mo(acen)Cl_2]. Bond lengths (Å): Mo—Cl_{av}, 2.394(4); Mo—O_{av}, 2.074(6); Mo—N_{av}, 2.074(6). Bond angles (°): Cl(2)—Mo—Cl(1), 177.9(1); O(1)—Mo—O(2), 103.9(1).

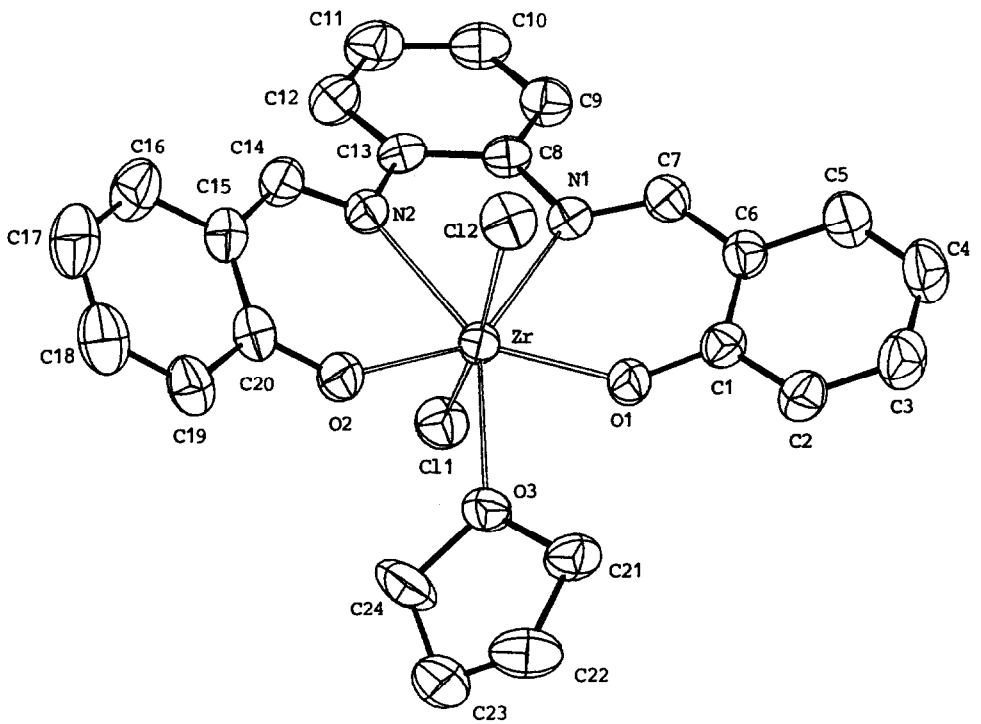

Fig. 2. [Zr(salophen)Cl_2(THF)]. Bond lengths (Å): Zr—Cl(1), 2.447(1); Zr—Cl(2), 2.447(1); Zr—O(1), 2.015(2); Zr—O(2), 2.051(3); Zr—O(3), 2.338(2). Bond angles (°): Cl(1)—Zr—Cl(2), 165.2(1); O(1)—Zr—O(2), 137.6(1).

them as starting materials [see eqs (4) and (5)]:

$$L_4V{=}O + SOCl_2 \xrightarrow[\text{benzene}]{-SO_2} \textit{trans}\text{-}[V(L_4)Cl_2] \quad (4)$$

$$L_4V{=}O + TiCl_3 \xrightarrow[THF]{-TiOCl_2} \textit{trans}\text{-}[V(L_4)(Cl)(THF)]. \quad (5)$$

Structural information is available on the most significant complexes.[2d] Complexes of Ti, V, Nb, Mo containing either a tetradentate or a bidentate Schiff base have a *trans* arrangement of the free or functionalizable coordination sites, as exemplified in Fig. 1 for $[Mo(acen)Cl_2]$ (**1**).[2d] Zirconium and hafnium derivatives are unique complexes showing a *cis–trans* isomerism, the *cis* isomer being the most stable one.[2d] Zirconium complexes containing bidentate ligands have a *cis* configuration, i.e. *cis*-$[Zr(salNMe)_2Cl_2]$ (**2**). In the presence of very rigid tetradentate ligands, the two chlorine atoms are forced to be *trans*, i.e. in $[Zr(salophen)Cl_2(THF)]$ (**3**) (see Fig. 2).[2d] For less rigid tetradentate ligands, i.e. acen, both the *cis*- (**4**) and *trans*- (**5**) isomers have been observed, depending on the ligating ability of the solvent.

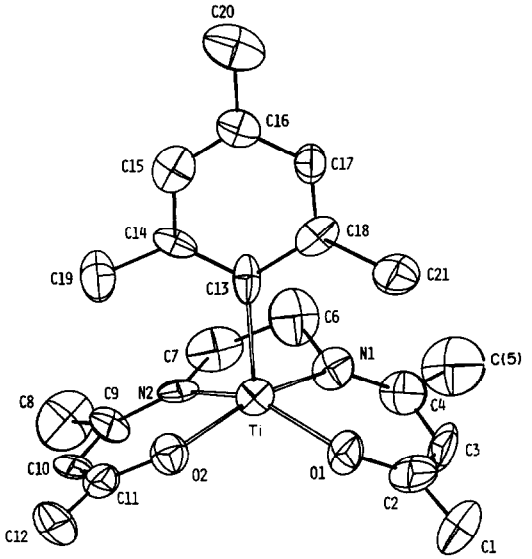

Fig. 3. [Ti(acen)(Mes)]. Bond lengths (Å): Ti—O(1), 1.928(15); Ti—O(2), 1.926(12); Ti—N(1), 2.103(16); Ti—N(2), 2.138(17); Ti—C(13), 2.216(20).

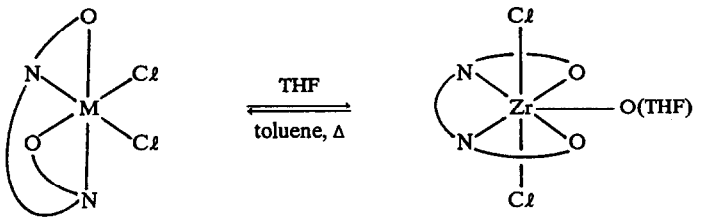


(6)

(4), *cis*-$[Zr(acen)Cℓ_2]$ (5), *trans*-$[Zr(acen)Cℓ_2(THF)]$

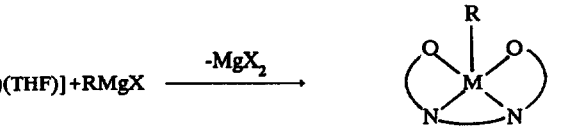
Complexes **4** and **5** have been characterized in the solid state by an X-ray analysis, and they maintain their structure in solution, as proven by ^1H NMR spectra in non-coordinating solvents.[2d]

ORGANOMETALLIC DERIVATIVES

The major factor affecting the alkylation reactions of products from reactions (1)–(3) is the oxidation state of the metal. Alkylation and arylation of [M(acen)(Cl)(THF)] ($M = Ti^{III}$, V^{III}) is an extremely clean reaction leading to the corresponding alkyl and aryl derivatives in good yields:[2d,3]

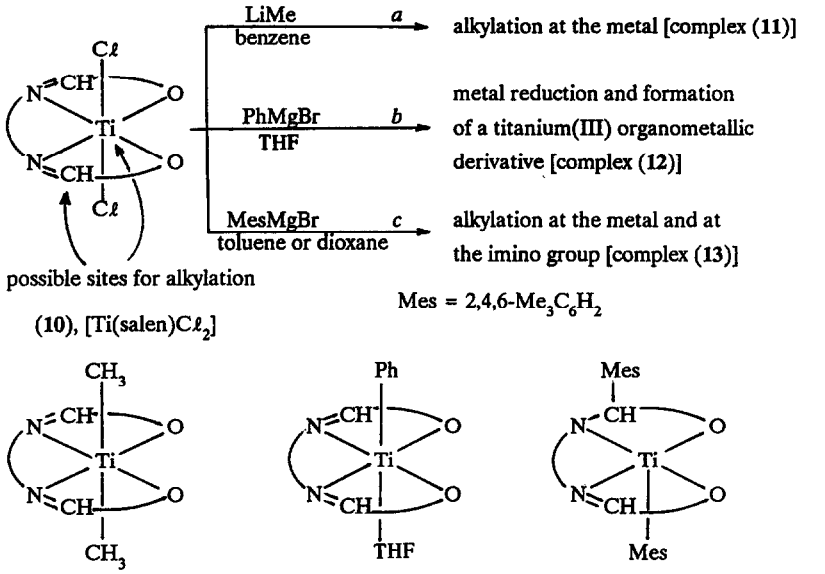
Complexes **7** are isolated in the solid state as monomeric species, usually containing a five-coordinated metal, or in a dimeric form (M = V; R = Me, $PhCH_2$),[3a] with two units sharing an oxygen atom. The structure of the monomeric [Ti(acen)(Mes)] is shown in Fig. 3,[2d] while the structure of the dimer, $[V(acen)(CH_2Ph)]_2$, was reported years ago.[3a]

An interesting synthetic method is the reductive alkylation of oxovanadium(IV) complexes leading to the same vanadium(III) alkyl derivatives shown



(6) (7), [M(acen)R] (7)

M = Ti, V; R = Me, CH_2Ph, Ph, 2,4,6-$Me_3C_6H_2$.



Scheme 1.

in reaction (7). Reaction (8) has to be carried out in THF with an excess of the Grignard reagent:[2d]

$$\underset{\textbf{(8)}}{[VO(salophen)]} \xrightarrow{PhMgBr} \underset{\textbf{(9)},\ M = V;\ R = Ph.}{[V(salophen)(Ph)]} \qquad (8)$$

The alkylation and arylation of compounds in reactions (1)–(3) containing the metal in the IV oxidation state were much more complex than expected because of the presence of electrophilic sites in the ligand,[4] as exemplified by the reactivity of $[Ti(salen)Cl_2]$ (**10**).[5] Depending on the nucleophile and the solvent, the reaction can follow three different pathways (*a*–*c*) (Scheme 1) to form complexes **11**–**13**.[5] The reaction is influenced by a considerable number of variables, of which the polarity of the solvent is probably the major factor determining the reaction pathway.

Among the most plausible mechanisms for explaining the formation of compounds **11**–**13**, we can invoke the intramolecular alkyl migration from the metal to the imino groups of the ligand. The existence, though very thermally labile, of a remarkable *trans*-dimethyltitanium compound should be emphasized. Such a compound is extremely reactive as a consequence of the autolabilization effect of the two methyl groups. Its structure was recently reported and is shown in Fig. 4.[5] The migration of the methyl groups to the ligand was easily followed by ^1H NMR. In order to show that the significant difference in the chemical reactivity of the M—C bond is dependent on the chemical environment, we mention the reaction of [M(acen)(R)] (M = Ti, V) with carbon monoxide.[2d]

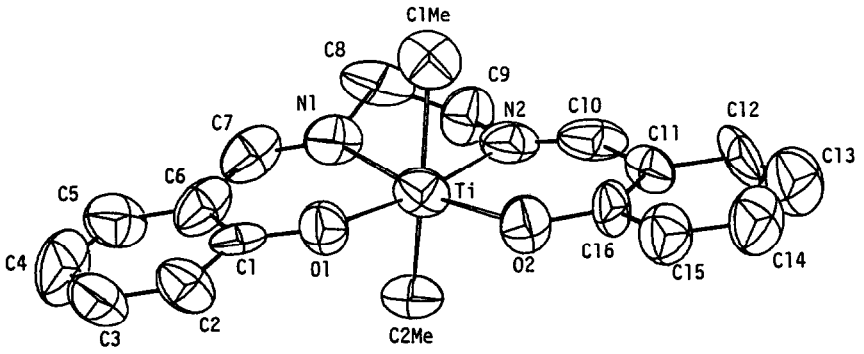


Fig. 4. $[Ti(salen)Me_2]$. Bond lengths (Å): Ti—O(1), 1.83(1); Ti—O(2), 1.86(1); Ti—N(1), 2.14(1); Ti—N(2), 2.15(1); Ti—C(1)Me, 2.15(2); Ti—C(2)Me, 2.15(1). Bond angles (°): O(1)—Ti—O(2), 110.9(4); N(1)—Ti—N(2), 76.5(6); N(1)—Ti—O(1), 86.5(5); N(2)—Ti—O(2), 86.1(5); N(1)—Ti—O(2), 162.6(5); N(2)—Ti—O(1), 162.8(5); C(1)Me—Ti—C(2)Me, 154.9(6).

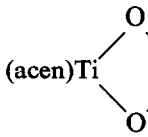
$2[Ti(acen)(R)] + 2CO \longrightarrow$
(7), R = Mes, CH_2Ph, Me.



$$(acen)Ti \quad Ti(acen) + \text{organic products} \qquad (9)$$

(13)

$[V(acen)(R)] + CO \longrightarrow$
(7), R = Mes, CH_2Ph, Me.

$$[(acen)V{=}O] + \text{organic products.} \qquad (10)$$

(14)

The probable preliminary insertion of carbon monoxide is followed by the deoxygenation of the resulting acyl, a result very different from that known in cyclopentadienyl chemistry.

REDOX PROPERTIES

Reduction of early transition metals bonded to Schiff base ligands may be rather complex chemistry. The factors affecting the reaction are the nature of the metal, its oxidation state and the nature of the ligand. Reduction of titanium(IV), vanadium(IV) and molybdenum(IV) to titanium(III),[6] vanadium(III) and molybdenum(II)[7] is a rather common and easy reaction. Generation of radical anions at the ligand is quite general in such chemistry,[8] but we found some rare cases in which such a reduction led to the reductive coupling of two imino groups belonging to two different molecules.[9]

Significant examples can be found for different metals, i.e. vanadium(III)[2d] and zirconium(IV),[2d] while the use of the ligand is strictly limited to the rigid and planar "salophen".

The reduction does not affect the degree of oxidation of the metal and the resulting compounds are still vanadium(III) and zirconium(IV) derivatives. In addition to this, these complexes are reducing agents by two and four electrons, respectively. A number of substrates, O_2, I_2, CO_2 and organic functionalities are reduced under very mild conditions.[2d] Reduction occurs with the cleavage of the C—C bond and the restoration of the original imino functionality. The C—C unit is never involved in the interaction with the substrate. Such systems provide a unique example of a molecular rechargeable battery, which is not based on variations of the oxidation state of metals.[2d] The peculiarity of such molecule systems will be discussed in forthcoming papers.

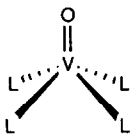
RECENT DEVELOPMENTS IN VANADIUM SULPHUR AND OXYGEN CHEMISTRY

G. CHRISTOU,* D. HEINRICH, J. K. MONEY, J. R. RAMBO, J. C. HUFFMAN and K. FOLTING

Department of Chemistry and the Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—We survey recent results from our efforts in vanadium sulphur and oxygen chemistry. A unifying theme for most of the discussion is the reactivity characteristics of vanadyl (VO^{2+}) complexes, and it is shown how such complexes are capable of a variety of transformations leading to products with oxidation states in the range III–V and nuclearities in the range 1–5. Also described are mononuclear non-oxo vanadium sulphur complexes, including the structural characterization of both $V(SBu^t)_4$ and $V(SBu^t)_4^-$. The relevance of this work to our understanding of the fate of crude oil vanadyl impurities during hydrotreating processes is discussed.

This paper will survey some of our recent results in vanadium chemistry and will concentrate primarily on the reactivity characteristics of vanadyl ($V{=}O^{2+}$)-containing materials. Our interest in this



area stems from the presence of large amounts of vanadium impurities in crude oils (as both vanadyl porphyrins and non-porphyrins) and their conversion via currently unknown mechanisms into vanadium(III) sulphides under reducing and sulphide-rich hydrotreating conditions.[1–4] These sulphides contribute to the deactivation of hydrotreating catalysts and thus represent a serious problem in processing the heavy crudes characteristic of the western hemisphere. Our programme is directed towards achieving a greater understanding of the various pathways by which vanadyl impurities are reduced/aggregated/sulphided to vanadium sulphides, an objective which entails the systematic exploration of the reactivity characteristics of model vanadyl complexes. Although such complexes have been prepared in great numbers over many decades, the reactivity chemistry of these very stable materials has been poorly investigated.[5–7] We herein describe the products from the reaction of vanadyl complexes under a variety of conditions.

(1) PRODUCTS CONTAINING ONLY VANADIUM(IV)

A variety of procedures have now been developed that lead to products involving no change in metal oxidation state. These involve both attack at the terminal oxide and attack at the basal ligands. Treatment of $VO(edt)_2^{2-}$ (**1**; edt = ethane-1,2-dithiolate) with $(Me_3Si)_2S$ in MeCN, leads to clean conversion to $VS(edt)_2^{2-}$ (**2**).[8] By rapid addition of a large excess of Et_2O, an intermediate in this transformation can be isolated, viz $V(OSiMe_3)(edt)_2^-$ (**3**),[9] indicating the probable mechanism to be as shown in eq. (1):

$$VO(edt)_2^{2-} + (Me_3Si)_2S \rightarrow V(OSiMe_3)(edt)_2^- + Me_3SiS^- \leftrightarrows V(SSiMe_3)(edt)_2^- + Me_3SiO^- \rightarrow VS(edt)_2^{2-} + (Me_3Si)_2O. \quad (1)$$

Complex **2** may more conveniently be prepared[10] in large quantities by the direct reaction of VCl_3, S and Na_2edt [eq. (2)]:

$$VCL_3 + E + 2.5Na_2edt \rightarrow [VE(edt)_2]^{2-} + 3NaCl + 2Na^+ + \tfrac{1}{2}\text{“}(edt)_2\text{”}. \quad (2)$$

(E = S, Se)

Advantage of this direct synthesis procedure was subsequently taken to prepare an extremely rare

* Author to whom correspondence should be addressed.

example of a selenovanadyl (VSe^{2-}) unit in the complex $VSe(edt)_2^{2-}$ (**4**), which allowed the first structural characterization of this moiety.[10]

In contrast to $(Me_3Si)_2S$, treatment of **1** with equimolar Me_3SiCl leads to attack at the basal edt^{2-} ligands and the formation of dinuclear $V_2O_2(edt)_3^{2-}$ (**5**), shown in Fig. 1.[11] Its formation is rationalized in eq. (3), the aggregation triggered by lowering of the edt–V ratio:

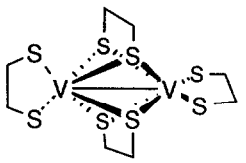
$$2VO(edt)_2^{2-} + 2Me_3SiCl \rightarrow V_2O_2(edt)_3^{2-} + 2Cl^- + Me_3SiSCH_2CH_2SSiMe_3. \quad (3)$$

The VO^{2+} units adopt a *syn*-arrangement. Interestingly, although complex **1** exhibits only irreversible electrochemical processes, the cyclic voltammogram of **5** exhibits a *reversible* one-electron oxidation at −0.83 V vs ferrocene in MeCN; coulometry confirmed the one-electron nature of this process. Reactions employing higher Me_3SiCl–V ratios could lead to a greater degree of aggregation, and such reactions have been under investigation.[11,12]

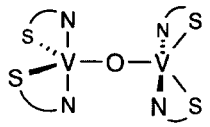
(2) REACTIONS INVOLVING OXIDATION STATE CHANGES

(a) *Reduction*

To model the reducing conditions that the crude oil vanadyl impurities experience during hydroprocessing, we have treated several model vanadyl complexes with an electron source in the presence of protons; this combination is designed as a low-temperature substitute for hydrogen gas employed at high temperature, and also allows homogeneous single-phase reactions. The electron source chosen is the organic radical anion acenaphthylenide (ACN^-). Treatment of **1** with NaACN in the presence of $HNEt_3Cl$, leads to formation of the V^{III} anion, $V_2(edt)_4^{2-}$ (**6**).[13] In contrast, a similar reaction employing $VO(aet)_2$ (aet = 2-aminoethanethiolate) leads to $V_2O(aet)_4$ (**7**) containing the linear $[V—O—V]^{4+}$ unit.[13] Both **6** and **7** are also



6



7

available by direct synthesis from VCl_3 and have been structurally characterized.[14,15] In both these transformations, initial reduction of V^{IV} to V^{III} destabilizes the VO multiply-bonded terminal unit and leads to aggregation with either partial or complete loss of the oxide ions, the latter facilitated by H^+. The basic reaction is summarized in eqs (4) and (5):

$$2VO(edt)_2^{2-} + 2e^- + 4H^+ \rightarrow V_2(edt)_4^{2-} + 2H_2O \quad (4)$$

$$2VO(aet)_2 + 2e^- + 4H^+ \rightarrow V_2O(aet)_4 + H_2O + 2H^+. \quad (5)$$

The actual identity of the product (i.e. remaining content of O^{2-}) must be governed by the identity of the basal ligands, since in both reactions sufficient protons were available for complete loss of oxygen as H_2O. That complex **7** is indeed the thermodynamically-preferred product with this ligand is supported by its direct synthesis from VCl_3, Na(aet) and advantitious oxygen (probably H_2O), with no evidence for a non-oxo product.[13]

More recently, we have extended use of this "reductive activation" of the VO^{2+} unit to access additional V^{III} species from simple VO^{2+} complexes. Using $VOCl_4^{2-}$, a convenient source of the VO^{2+} unit, we have investigated reactions with just NaACN or with NaACN/VCl_3; the latter have been investigated in greater detail to date and one example is described here. Reaction of $VOCl_4^{2-}$ with VCl_3 and NaACN in CH_2Cl_2 in the presence of excess pyridine leads to reductive coupling of the VO^{2+} unit with the V^{3+} centre and the formation

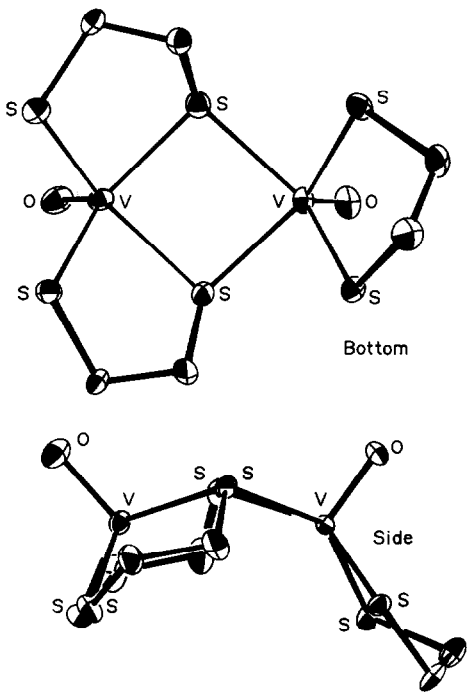


Fig. 1. Two views of the structure of complex **5**, $V_2O_2(edt)_3^{2-}$.

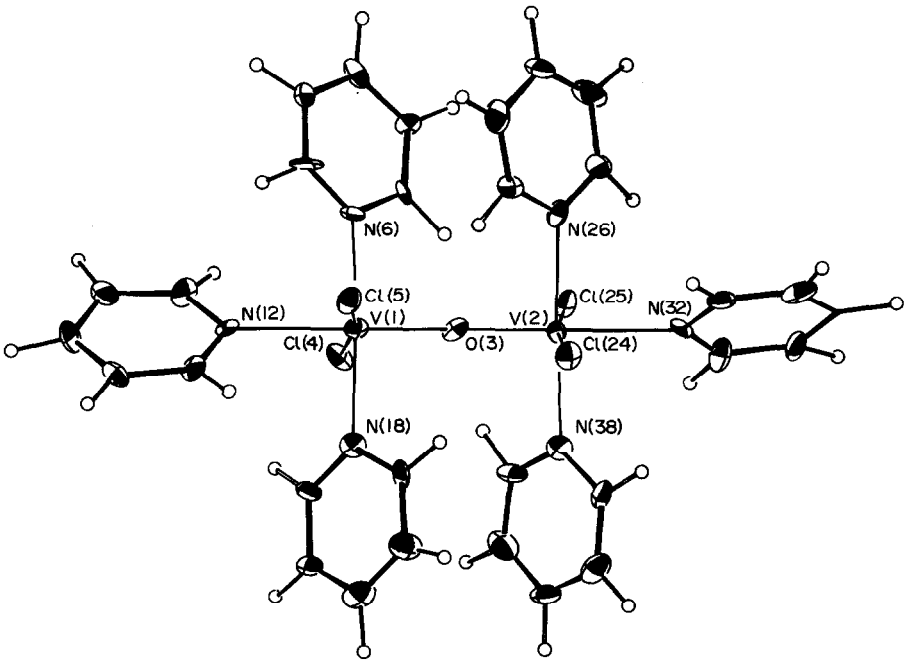

Fig. 2. The structure of complex **8**, $V_2OCl_4(py)_6$.

of $V_2OCl_4(py)_6$ (**8**) (Fig. 2),[12] as summarized in eq. (6):

$$VOCl_4^{2-} + VCl_3 + e^- \xrightarrow{py} V_2OCl_4(py)_6 + 3Cl^- . \quad (6)$$

The complex possesses the same linear $[V—O—V]^{4+}$ unit as **7** but the metals are now six- rather than five-coordinate.

(b) *Oxidation*

An additional ligand type we have been employing is carboxylates, since they have been detected in crude oils and may therefore be involved in metal binding.[1,2,4] Treatment of $VOCl_4^{2-}$ with sodium thiophene-2-carboxylate (Natca) under aerobic conditions leads to formation of deep green $V_5O_9(\mu_4\text{-}Cl)(\mu\text{-tca})_4^{2-}$ (**9**), containing 4 V^{IV}, V^V; its structure is shown in Fig. 3.[16] If the reaction is carried out in the presence of $AgNO_3$ to sequester all available Cl^-, the resulting product is $V_4O_8(tca)_4(NO_3)^{2-}$ (**10**), possessing V^{IV}, 3 V^V. The structure is similar to complex **9** except that the apical VO is absent, leaving a square of four vanadium atoms. In addition, the μ_4-Cl^- is now replaced by a η^1-μ_4-NO_3^-, a single NO_3^- oxygen bridging all four metals. There is no evidence for OH^- instead of O^{2-} in any position of either **9** or **10**. The oxidation state assignments are being confirmed as part of a detailed magnetochemical investigation; results

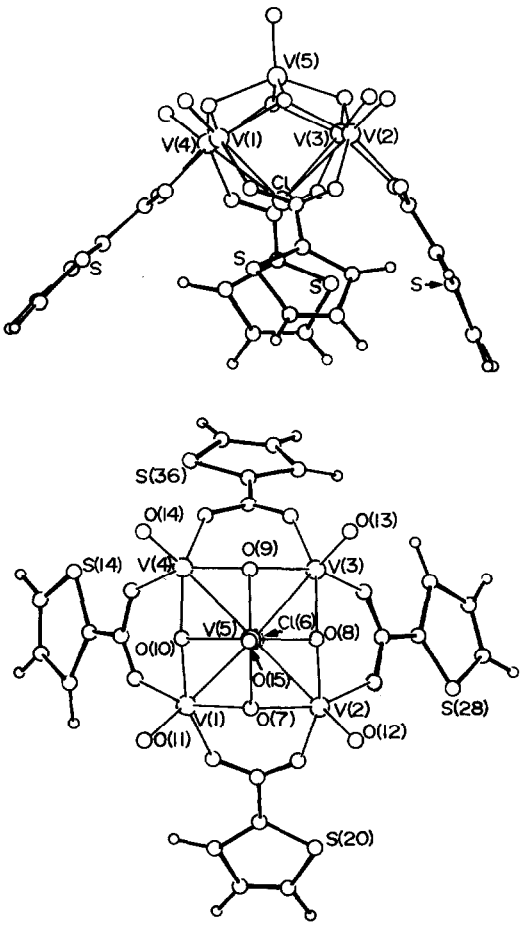

Fig. 3. Two views of the structure of complex **9**, $V_5O_9Cl(tca)_4^{2-}$.

available at the time of writing conclusively establish the V^{IV}, 3 V^{V} nature of **10**, a temperature-independent magnetic moment corresponding to a single unpaired electron per V_4 being observed.

Complexes **9** and **10** can be considered to possess V_xO_y units representing fragments of known iso- or heteropolyvanadates, examples of which include $PV_{14}O_{42}^{9-}$ and $V_{18}O_{42}^{12-}$. The function of the carboxylates is thus to stabilize these "fragments", preventing higher aggregation; it can readily be seen how the RCO_2^- moiety can substitute for an $O_2VO_2^{3-}$ group and terminate higher oligomer formation.

(3) NON-OXO VANADIUM THIOLATE COMPLEXES

We conclude with some recent results in vanadium chemistry not derived from vanadyl starting materials and not possessing any oxygen. Treatment of VCl_3 with 2 NaSBu^t and Bu^{t}SSBu^t leads to formation of V(SBu^t)$_4$ (**11**), whose structure is shown in Fig. 4.[16] This molecule joins the few other known examples of neutral tetrahedral $M(SR)_4$ species, including Ti(SBu^t)$_4$,[17] W(SBu^t)$_4$[19] and Mo(SBu^t)$_4$.[20] The synthetic procedure is summarized in eq. (7):

$$2\,VCl_3 + 6\,NaSBu^t + Bu^tSSBu^t \rightarrow 2\,V(SBu^t)_4 + 6\,NaCl. \quad (7)$$

In the absence of an oxidizing agent, a black intractable solid is obtained, which we believe to be $NaV(SBu^t)_4$ or polymeric $[V(SBu^t)_3]_n$. In a subsequent reaction carried out in the presence of bipy, we hoped to form soluble V(SBu^t)$_3$(bipy), and analytical data on the resulting product certainly supported this formulation:

$$2\,VCl_3 + 6\,NaSBu^t + 2\,bipy \rightarrow [V(SBu^t)_2(bipy)_2][V(SBu^t)_4]. \quad (8)$$

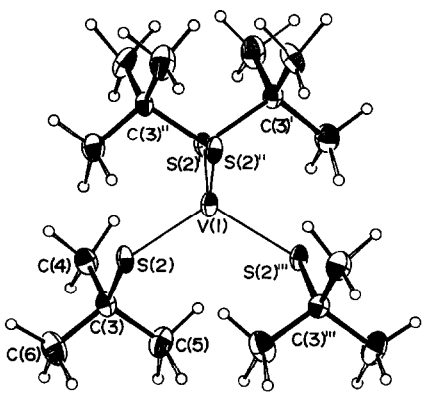

Fig. 4. The structure of complex **11**, V(SBu^t)$_4$.

However, a crystal structure determination showed a ligand redistribution had occurred, for the product was in reality $[V(SBu^t)_2(bipy)_2]^+[V(SBu^t)_4]^-$ (**12**); this would of course yield the analytical formulation "V(SBu^t)$_3$(bipy)". The cation of **12** has an octahedrally-coordinated vanadium and *cis*-Bu^{t}S$^-$ groups, while the anion is essentially identical to the V^{IV} complex, **11**, in Fig. 4, except for the expected slight lenghthening of V—S bond distances.[16]

CONCLUDING COMMENTS

In an attempt to ascertain the possible fate of crude oil vanadyl impurities under reducing and sulphur-rich conditions, we have investigated a variety of reactivity characteristics of model VO^{2+} complexes. Conversion to VS^{2+}, aggregation to $[VO^{2+}]_2$ and reductive coupling to oxo or non-oxo V^{III} aggregates have all been shown to be possible in the initial stages of hydroprocessing, and probably all occur. Interestingly, the complexity of the observed vanadyl carboxylates suggests not all vanadium impurities may be mononuclear if bound to such functionalities; the behaviour of these synthetic clusters under reducing conditions will be interesting to determine.

Continued reaction under reducing and sulphur-rich conditions is known to yield vanadium products with only sulphur ligation which aggregate and deposit on the molybdenum catalyst. To model these species, we have synthesized a variety of V/S species including $V(SBu^t)_4^{0,+}$, $V_2(edt)_4^{2-}$, $V_3S_4(edt)_3^{3-}$ and $V_4S_2(edt)_6^{2-}$ (the latter two from work not described here[15,20]). This kind of progressive build-up of V/S nuclearity may correspond to that occurring for the crude oil vanadium that ultimately leads to $(V/S)_\infty$ polymer formation. The interaction of such synthetic V/S species with synthetic Mo/S species now provides a model system for the initial stages of V/S deposition on the MoS_2 catalyst, which initiates the contribution by the former to the deactivation of the latter. Such investigations are currently in progress.

METALLAHETEROCYCLES—PRECURSORS FOR INORGANIC POLYMERS

HERBERT W. ROESKY

Institut für Anorganische Chemie der Universität Göttingen, Tammannstrasse 4, D-3400 Göttingen, F.R.G.

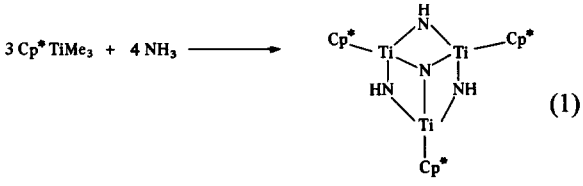
Abstract—Several synthetic routes are described to generate metal-containing heterocycles. Ring systems with one, two or three metal atoms within the skeleton were obtained. At elevated temperatures the heterocycles are converted to polymers via ring opening reactions. The polymers are soluble in organic solvents and were characterized by elemental analysis and molecular weight determinations. Furthermore the synthesis of eight- and nine-membered rings is described.

TITANIUM–NITROGEN COMPOUNDS

Titanium nitride is formed by direct reaction between the elements at 1000–1400°C, by treatment of $TiCl_4$ and ammonia at elevated temperatures, or by the reaction of $TiCl_4$ and nitrogen in the presence of hydrogen. The nitride is a yellow–brown powder, which is isomorphous with TiC and thus has the NaCl structure. The character of bonding within TiN is considered to be more ionic than in TiC. It has many metallic properties, including high melting point (2950°C), high electrical conductance and great hardness. It is unaffected by hot mineral acids but it liberates ammonia with alkalis. Other possible nitrides are TiN_3 and Ti_2N.[1] The properties of the corresponding compounds ZrN and HfN are similar.

Preparation of the first imido and nitrido compounds of titanium

The metallic nitrides of titanium are a challenge to generate new precursors for their preparation which might be soluble or volatile. A synthetic approach is the reaction of organometallic derivatives with ammonia. Treatment of Cp^*TiMe_3 ($Cp^* = C_5Me_5$) with ammonia results in the formation of $[Cp^*Ti(NH)]_3N$ (**1**),[2] eq. (1):



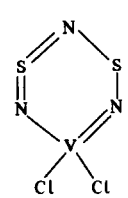
(1)

(1)

Compound **1** is a red, crystalline material. It is soluble in *n*-hexane or pentane. Suitable crystals for an X-ray structural investigation have been obtained from *n*-hexane. The molecule exhibits a six-membered $(TiNH)_3$ ring in a chair form, with tetrahedral coordinated titanium atoms. All three titanium atoms are bridged by a fourth nitrogen atom located on top of the ring. The Ti—N bond lengths (av. 192.4 pm) observed are between those in $CpTiCl_2NPPh_2$ (177.5(13) pm)[3] and $Ph(CNSiMe_3)_2]_2TiCl_2$ (206.6 and 210.1 pm).[4] Compounds of this type might be interesting precursors for the generation of thin films of TiN at low temperatures.

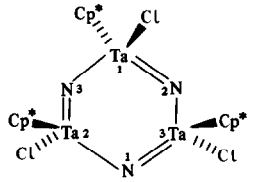
TRIAZATRIMETALLABENZENES—A NEW CLASS OF INORGANIC HETEROCYCLES

In 1983 we reported for the first time[5] the synthesis and structure of $(Cl_2VN_3S_2)_x$, an unsaturated six-membered ring (see Structure 1). This compound has semiconducting properties. We have not been able to generate acyclic polymers from this heterocycle by thermolytic ring opening reactions.



Structure 1.

The reaction of Cp^*TaCl_4 and tris(trimethylstannyl)amine leads to a six-membered ring of composition $[Cp^*TaN(Cl)]_3$ (**2**).[6] The ^1H NMR



(2)

spectrum indicates two non-equivalent pentamethyl cyclopentadienyl groups ($\delta = 2.08$, 2.12) in a ratio of 1 : 2. From mass spectroscopic investigations we have found the molecular ion (m/z 1905), together with small amounts of the tetramer $[Cp^*TaN(Cl)]_4$. The X-ray structure analysis reveals not a completely planar six-membered ring in the solid state, but instead it exists in a kind of boat conformation, with the atoms Ta(2), N(3), Ta(3) and N(2) lying in the same plane. Ta(1) lies 13 pm and N(1) 39 pm from this plane. The puckered conformation is probably due to steric hindrance. The Ta—N bond lengths (av. 188(2) pm) lie between the values for Ta=NR (175–178 pm) and $TaNR_2$ (195–203 pm) compounds.[7]

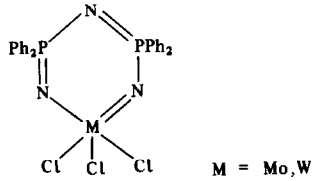
TANTALUM–NITROGEN POLYMERS

Thermal ring opening of $[Cp^*TaN(Cl)]_3$ leads to the linear chain polymer, $[Cp^*TaN(Cl)]_n$ (**3**).[8] This polymer is soluble in THF or xylene. The molecular weights of **3** have been determined by viscosity and GPC measurements, with reference to polystyrene standards. GPC measurements supplied molecular masses of about 129, 800, 67,000, 35,800, 11,300 and 3000. From viscosity measurements we have estimated, in reference to the polystyrene calibration curve, the average molecular mass to be 40,000. So far we have not been able to replace the chlorine atoms in the polymer by organic substituents.

POLYMETALLAPHOSPHAZENES

In 1986 we described $[Cl_3MN_3(PPh_2)_2]$ (**4**) (M = Mo, W), the first cyclophosphazenes[9] in which a ring phosphorus atom is replaced by a transition metal in its maximum oxidation state.

Polymetallaphosphazenes have been obtained via a ring-opening reaction upon heating **4** in xylene.



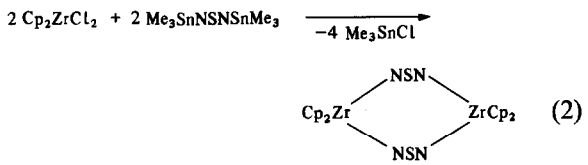
M = Mo,W

(4)

Elemental analyses show that no eliminations occur as side reactions. The molecular weights of the fractions soluble in THF have been determined by HPLC, viscosimetry and GPC measurements. Based on GPC measurements of the THF soluble fractions, we have obtained molecular weights of 35,800, 11,300 and 3500 for the tungsten polymer. The limiting viscosities obtained from the soluble fractions of the molybdenum and tungsten polymer from the viscosity measurements have been compared with those of the polystyrene calibration standards. The results show mean molecular weights of 24,000 (Mo) and 37,000 (W). The different physical methods for the determination of the molecular weights gave comparable results.

EIGHT-MEMBERED METALLACYCLES WITH A $M(NSN)_2M$-FRAME[10] (M = Zr, Hf)

The reactions of Cp_2ZrCl_2, $CpCp^*ZrCl_2$ and $CpCp^*HfCl_2$ with $Me_3SnNSNSnMe_3$ yielded $Cp_2Zr(NSN)_2ZrCp_2$, $CpCp^*Zr(NSN)_2ZrCpCp^*$ and $CpCp^*Hf(NSN)_2HfCpCp^*$:

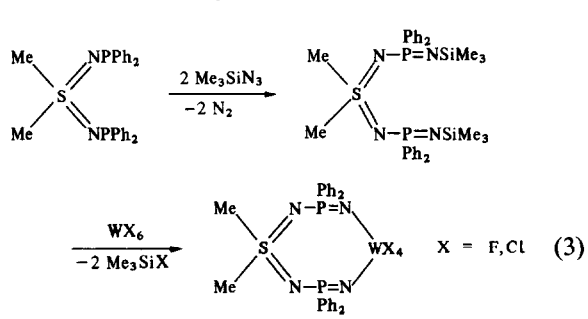


(2)

The compounds are thermally- and air-stable, yellow solids. With Cp and Cp* substituents we observed *cis*- and *trans*-isomers in the product based on ^1H NMR investigations.

HETEROCYCLES CONTAINING TUNGSTEN, PHOSPHORUS, SULPHUR AND NITROGEN IN THE RING SKELETON[11]

Eight-membered rings with tungsten, phosphorus, sulphur and nitrogen atoms as building units for the ring skeleton have been obtained from the new ligand $Me_2S(NPPh_2NSiMe_3)_2$ and WF_6 or WCl_6, respectively, eq. (3):

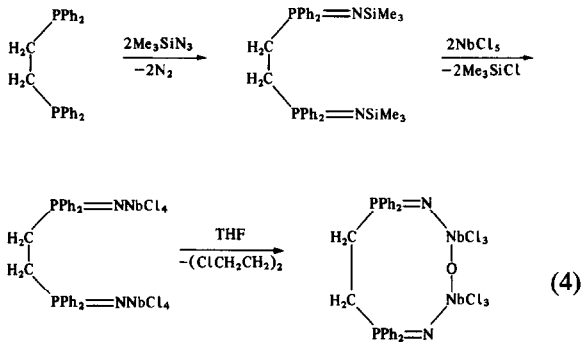


(3)

The X-ray single crystal structure analysis exhibits a puckered eight-membered ring with alternating short and long bond lengths. This is especially characteristic for the P(2)—N(2) and P(1)—N(1) bonds (P(2)—N(2), 165.9(14); P(1)—N(1), 155.4(10) pm).

PREPARATION AND STRUCTURE OF A NINE-MEMBERED NIOBIUM-CONTAINING RING WITH OXYGEN AND NITROGEN ATOMS AS BUILDING BLOCKS

The nine-membered ring, **5**, has been prepared according to the following reaction:



(4)

(5)

Compound **5** crystallizes from acetonitrile with four molecules of solvent. The molecular structure deduced from a single-crystal X-ray study shows a non-planar nine-membered ring with octahedrally coordinated niobium atoms. The sixth coordination site of the metal is occupied by a solvent molecule. The Nb—O—Nb angle is close to linear (176.7(2)°), comparable to that found in $[Nb_2Cl_9O]_2^{2-}$ (174.1(3)°). However, in contrast to $[Nb_2Cl_4O]_2^{2-}$, the Nb—O bond lengths (189.5(1) pm) are equal.

THE REACTION OF $[Bu^n_4N]_2[Re_2Cl_8]$ WITH DIPHENYLARSINOETHANE (dpae); EVIDENCE FOR THE FORMATION OF $(dpae)Re_2Cl_6$

JOSEPH FERRY, JOHN GALLAGHER, DESMOND CUNNINGHAM and PATRICK McARDLE*

Department of Chemistry, University College, Galway, Ireland

Abstract—The reaction of dpae with $[Bu^n_4N]_2[Re_2Cl_8]$ yields $[(dpae)_2ReCl]_2[Re_2Cl_8]$ and $(dpae)_2Re_2Cl_4$. The crystal structures of both of these compounds have been determined and the latter contains $(dpae)Re_2Cl_6$ as a minor component.

There have been no successful attempts to synthesize complexes of rhenium(III) which contain a possible quadruple bond and an M—M bridging ligand.[1] The only complex reported to contain an Re—Re quadruple bond and a bidentate ligand, albeit without chelation, was formulated as $(dpae)_2Re_2Cl_6$.[2] This complex was prepared by reaction of dpae with $[Bu^n_4N]_2[Re_2Cl_8]$. This reaction has been re-examined. Using the reaction conditions previously used, refluxing butanol, green and red crystals were isolated. The crystal structures of both of these products have been determined.

The green crystals have the formula $[(dpae)_2ReCl]_2[Re_2Cl_8]\cdot 2BuOH$ (**1**). The crystal data for this compound are given in Table 1 and the structure of the cation is shown in Fig. 1. Final difference maps show what appears to be a coordinated dinitrogen in the vacant coordination site. Dinitrogen coordination is often found in related systems.[3] However, elemental analysis indicated that the nitrogen content was less than measurable, $< 0.5\%$ and $[(dpae)_2Re(N_2)Cl]_2[Re_2Cl_8]$ contains 1.7% of nitrogen. Attempts to refine the apparent N_2 molecule led to N—N and M—N bonds, which were unrealistically long and short, respectively.

The red crystals were formulated as $(dpae)_2Re_2Cl_4$ (**2**), the crystal data are given in Table 1 and the structure is shown in Fig. 2, with the phenyl rings omitted. The Re_2 unit was two-fold disordered within the approximate square antiprism defined by the ligating atoms. The ratio of the major and minor orientations was 0.86:0.14 and only the major orientation is shown in Fig. 2. Two-fold disorder of this type has been observed in all $(L—L)_2Re_2Cl_4$ systems that have been reported.[4] The minor Re_2 configuration, however, did not adopt the expected configuration. In all other cases of two-fold disorder involving $(L—L)_2Re_2Cl_4$ systems the centroids of the M—M bonds of the major and minor components coincide and the bonds are approximately orthogonal. In the present case, the M—M bond centroids are 0.32 Å apart and the M—M bonds deviate from orthogonality (Table 2). The major Re_2 unit, Re(1)—Re(2), shows reasonable bonding

distances to all ligating atoms (Table 2). The minor Re_2 unit, Re(3)—Re(4), is at a bonding distance to only two of the four arsenic atoms (Table 2 and Fig. 3). The most reasonable interpretation of this result is that the minor component is $(dpae)Re^{III}_2Cl_6$ which has co-crystallized with $(dpae)_2Re^{II}_2Cl_4$. Difference maps showed peaks due to the extra chloride ligands in the former, but these were very weak and were not included in the refinement.

Attempts to prepare pure samples of several $(L—L)Re_2Cl_6$ complexes are currently in progress.

BIFUNCTIONAL PHOSPHAZENES—PRECURSORS FOR THE SYNTHESIS OF CYCLIC AND ACYCLIC METALLAPHOSPHAZENES

M. WITT and H. W. ROESKY*

Institut für Anorganische Chemie der Universität Göttingen, Tammannstraße, D-3400 Göttingen, F.R.G.

Abstract—Several pathways for the synthesis of six-membered metallacyclophosphazenes $Cl_x\overline{MNPR_2NPR_2N}$ with different substituents on phosphorus are reported. Acyclic intermediates are discussed. The reaction of a persilylated aminophosphazene, **7**, with $VOCl_3$ affords the eight-membered ring $(Cl_2VNPPh_2N—)_2$ (**6b**), WCl_6 yields an acyclic compound, **8**, and group IV tetrachlorides lead to the formation of four-membered rings, **9**, with a $\overline{NPNM}$-skeleton. $Me_3SiOPPh_2NSiMe_3$ (**10**) and $TiCl_4$ form an eight-membered ring $(Cl_2TiNPPh_2O—)_2$ (**11**) with the shortest Ti—N bond found so far. The X-ray structures of each type of metallacyclophosphazenes are discussed.

Depending on the nature of the ligands, metal chelates have been found useful catalysts in various aspects of organic chemistry.[1] Thus, we were interested in synthesizing metallaphosphazenes to test their applicability in catalysis. Furthermore, another crucial aspect of our work is the vast area of phosphazene chemistry, namely poly-[2] and cyclophosphazenes.[2,3] Incorporating metal centres in phosphazenes might afford materials with unusual properties depending on the metal atom and the substituents on both the metal and phosphorus centres. In this paper we summarize our present results in building up novel ring systems and open-chain compounds, as well as in attaching new organic groups on phosphorus.

RESULTS AND DISCUSSION

Recently, we have reported the synthesis of metallatriazadiphosphorines, **2a–e**, from the reactions of $[H_2NPPh_2NPPh_2NH_2]^+Cl^-$ (**1a**) with metal halides or metal nitride halides in their highest oxidation state, or by passing chlorine through solutions containing lower metal halides [eq. (1)]:[4]

Starting from the *p*-chlorophenyl-, **1b**, and methyl-substituted, **1c**, precursors, the metallacycles **2f–j** have been synthesized according to method (ii).

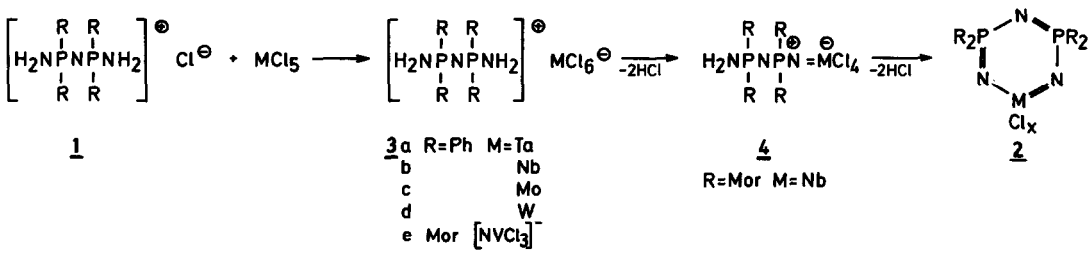
* Author to whom correspondence should be addressed.

The phenoxy-substituted phosphazenium salt failed to form the expected rings.[5]

Since aminophosphazenes are known to be affected by both elemental chlorine and hydrogen chloride,[2] these conditions had to be avoided in the reactions of the amino-substituted phosphazenium chlorides, **1d**, **e**. The metallaphosphazenes **2k–n** are accessible only to methods (iii) and (iv).[6]

Monitoring the progress of the reactions by ^{31}P NMR spectroscopy showed the mechanism to be rather complex. The first intermediates identified or isolated were the hexachlorometallates **3**, which on heating, e.g. in $CHCl_3$, subsequently yield two sets of pairs of doublets, indicating unsymmetric acyclic compounds disappearing with the growth of the singlets of **2**.

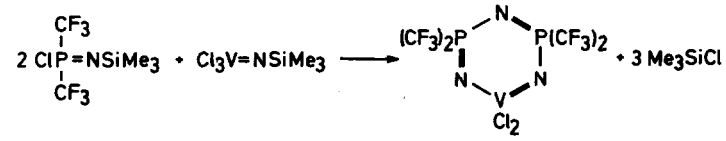
A second method to avoid acidic conditions, besides the use of metal nitrides, is the reaction in the presence of a tertiary base, e.g. pyridine. While with **1a** and $NbCl_5$, **2b** is formed, $TaCl_5$ yields an inseparable mixture of the hexachlorotantalate, **3a**, and two compounds showing two pairs of doublets in the ^{31}P NMR spectrum.[7] In the reaction of **1e** with $NbCl_5$ and pyridine an open chain compound, **4**, has been isolated as the sole product as shown by ^{31}P NMR, IR and elemental analyses.[6] These facts give rise to the reaction sequence depicted in eq. (2):



1 2 4

(2)

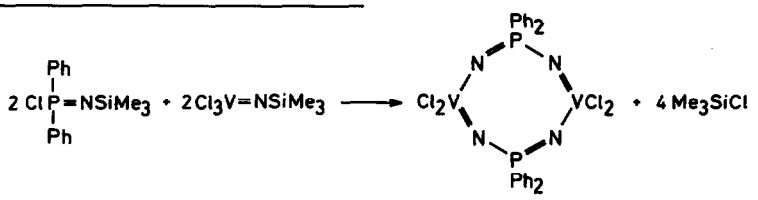
A somewhat surprising product has been found in the reaction of the CF_3-substituted P-chlorophosphazene, **5a**, and $Cl_3V{=}NSiMe_3$: instead of the expected eight-membered ring system, **6** (*vide infra*), the CF_3-substituted derivative, **2o**, was isolated in low yields as a volatile solid, melting with decomposition at 22.5°C:[8]



5a 2o

(3)

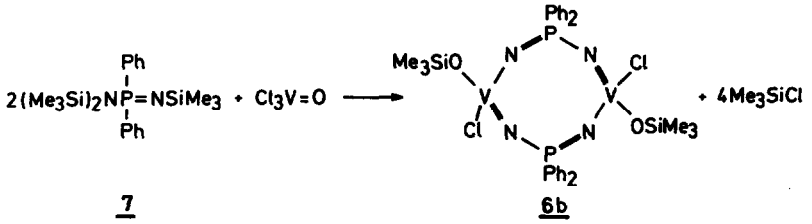
The expected tetrazadiphosphadivanadocine, **6a**, has been isolated in high yields as a brick-red microcrystalline solid from the reaction according to eq. (4):[9]



5b 6a

(4)

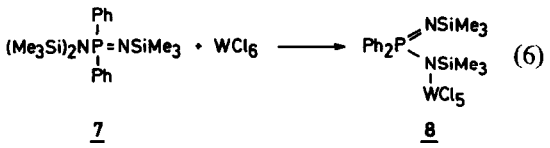
A derivative, **6b**, is accessible via silyl migration from aminoiminophosphorane, **7**, and $VOCl_3$ in 80% yield, which after recrystallization from CH_2Cl_2–CH_3CN forms translucent brick-red rhombs:[9]



7 6b

(5)

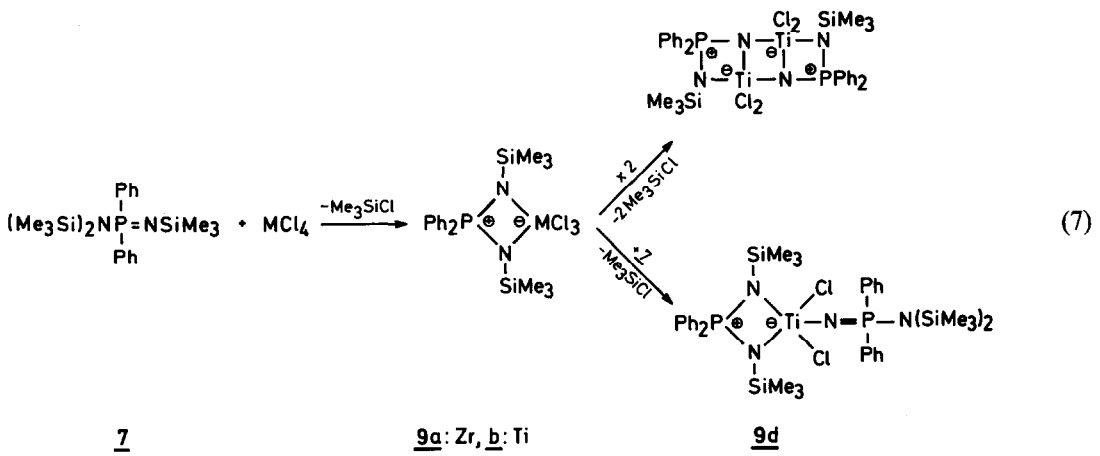
Up until now, attempts to extend this synthetic pathway to other tetrazadiphosphadimetallocines have been unsuccessful. The reaction of **7** with WCl_6 yields an acyclic metal-substituted phosphazene, **8**, characterized by elemental analysis and NMR spectroscopy [eq. (6)]:[6]



(6)

7 **8**

Since multiple bonds to group IV metals are rather unfavourable, the reactions of **7** with $TiCl_4$[10] and $ZrCl_4$[6] proceed in a different way [eq. (7)]:



(7)

7 **9a**: Zr, **b**: Ti **9d**

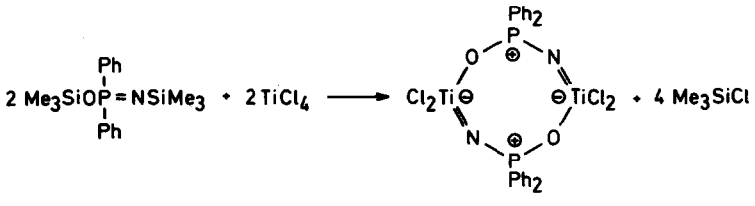
While the reaction of **7** with $ZrCl_4$ proceeds unequivocally, $TiCl_4$ yields a mixture of different products, **9b–d**. By varying the reaction conditions (see Experimental) the yields of the respective compounds could be optimized, the products have been isolated by fractional crystallization from CH_3CN.

The analogous reaction of silyloxyphosphazene, **10**, with $TiCl_4$ leads to the unexpected formation of the eight-membered ring system, **11**, besides several silicon-containing species which have not yet been identified:[11]

Spectroscopical and X-ray investigations

Mass spectroscopical measurements (EI, FI and FD techniques) show the parent ion or $M^+ - Cl$ as the peaks with the highest masses for most of the six-membered rings, **2**. Of the eight-membered rings, only tetrazadiphosphadivanadocine, **6a**, gave the molecular ion, as well as the trichlorosubstituted four-membered rings, **9a**, **b**. The other metallaphosphazenes showed fragmentation and rearrangement patterns, e.g. in the EI mass spectrum of **6b**, $M^+ - Cl$ for **2a** had been detected.[6] Interestingly, the open-chain intermediates $[H_2N(PPh_2N)_2H_2]^+ MCl_6^-$ (**3b–d**) failed to show the signal for the cation. Instead, FI mass spectra consisted of the parent ions of the corresponding six-membered rings, **2b–d**.[6] This is in contrast to the homologous compounds $[H_2N(PPh_2N)_3H_2]^+MC_6^-$, where the cation peak, together with the parent ions of the tetrazatriphosphametallocines with intensities between 0 and 30%, have been observed.[12]

^{31}P NMR studies show downfield shifts for all metallaheterocycles compared to their acyclic phosphazene precursors. The chemical shifts of the six-membered rings, **2**, have been found 20–30 ppm downfield of the corresponding bis(amino-



(8)

10 **11**

phosphoranylidene)immonium precursors, **1**.[4,5,8] While the ^{31}P signal of the open-chain compound, **8**, is shifted downfield *ca* 50 ppm, compared to **7**, an upfield shift of 17 ppm and line broadening has been observed for the phosphorus atom in **4** bearing the —N=$NbCl_4$ unit. The other phosphorus atom shows a signal at 14 ppm as does the precursor **2e**.[6] Interestingly, the ^{31}P signals of the vanadium heterocycles **2l**, **2o**, **6a** and **6b** have half-widths of *ca* 1000 c.p.s., which is not due to paramagnetic influence.[13]

X-ray crystallographic work on the four-membered rings, **9a–d**,[10,11] on the six-membered rings, **2c**,[4b] **2d**[4a] and **2o**,[8] and on the eight-membered rings, **6b**,[9] and **11**,[11] has been done. All structures except that of **11** show the ring skeletons to be essentially planar. While donor solvents such as CH_3CN are attached to the metals in the crystal state in **2c**, **d**, **9a–c** and **11** resulting in a distorted octahedral environment, the vanadium compounds, **2o** and **6b**, as well as the titanium heterocycle, **9d**, contain no solvent in the crystals, thus resulting in distorted tetrahedral and trigonal-bipyramidal geometries, respectively. Compounds **9c**, **6b** and **11** are centrosymmetric and **2o** contains a C_2 axis through vanadium and the opposite nitrogen, causing pairwise equal bond lengths and angles. *Trans*-effects due to the CH_3CN and Cl bond in the ring planes of **2c**, **d** make the ring bonds and angles differ slightly. Due to steric effects a somewhat greater deviation from equality is found in the four-membered rings **9a**, **b**, **d**. While bond lengths and angles in the P—N sections of the ring systems do not differ significantly from those of these non-metallated analogues, some unusual features have been found around the metal atoms. While the Ti—N and Zr—N bond lengths in the PN_2M moiety in **9a–d** can be regarded close to single bonds, the Ti—N bonds in the central Ti_2N_2 ring of **9c** are 189.0 pm, in the exocyclic Ti—N—$PPh_2N(SiMe_3)_2$ moiety of **9d** are 179.2 pm, and in **11** are 173.9 pm, which are definitively shorter than single bonds, **11** having the shortest Ti—N distances found so far. The Ti—N—P angles in **9d** (exocyclic) are 170.3° and in **11** are 175.9° and are almost linear. The angles at the ring nitrogen atoms adjacent to the metal atoms are also increased from 158.4° in **6b** to 129.0° in **2o**. The M—N separations in the fully unsaturated rings, **2** and **6b**, have to be regarded as double bonds, the bond angles at the four coordinated vanadium atoms are close to the tetrahedral angle (104.2° in **2o** and 110.8° in **6b**), while the octahedral angles in **2c**, **d** are slightly bigger than 90° and around 75° in the four-membered rings, **9a–d**. The exocyclic Si—O—V angles in **6b** are almost linear.

EXPERIMENTAL

General methods

All manipulations were carried out under an atmosphere of dry argon or nitrogen or *in vacuo*. Solvents were dried and degassed by conventional methods and stored over molecular sieves. If not otherwise noted, solvents and volatile starting materials were transferred into the reaction vessel *in vacuo* at −190°C and the reaction mixtures slowly warmed up to ambient temperatures, solids transferred to the flask in a dry box (prior to condensation) and liquids injected with a syringe. Metal halides and $VOCl_3$ were commercial products, $Cl_3VNSiMe_3$, Cl_3MN (N = Mo, W), and the phosphazene precursors were prepared as described in the papers referred to in this article and the original papers cited therein. The syntheses of the six-membered rings, **2a–e**, have been described elsewhere,[4] the syntheses of **2f–j**[5] closely follow these procedures and are therefore omitted in this article. As a fully characterized example of an amino-substituted metallacyclophosphazene, the synthesis of **2l** together with the CF_3-substituted **2o** are given.

Synthesis of 2,2,4,4-*tetramorpholino*-1,3,5,2λ^5,4λ^5,6λ^6-*triazadiphosphatungstenine*·THF (**21**)[6]

4.9 g (10 mmol) of **1e** and 3.1 g (10 mmol) of $NWCl_3$ were refluxed in 100 cm^3 of $CHCl_3$ for 5 h. The solvent was evaporated and the remainder extracted with hot THF. **2l·THF** precipitates as a microcrystalline, yellow solid in 26% (2.1 g) yield. Found for **2l·THF**: C, 28.9; H, 5.1; Cl, 13.4; N, 11.9. $C_{20}H_{10}Cl_3N_7O_5P_2W$ requires: C, 29.63; H, 4.97; Cl, 13.12; N, 12.09%.

Synthesis of 2,2,4,4-*tetrakis*(*trifluoromethyl*)-1,3,5,2λ^5,4λ^5,6λ^5-*triazadiphosphavanadinine* (**2o**)[8]

2.4 g (10 mmol) of Cl_3V=$NSiMe_3$ and 60 cm^3 of CH_2Cl_2 were cooled to −190°C and 5.8 g (20 mmol) of **5a** were added. After warming up to room temperature the mixture was stirred for 5 h. Volatiles were removed at −10°C *in vacuo* and the crude product was sublimed twice in a cold finger held at −10°C. Compound **2o** was isolated as translucent yellow crystals, which melt at 22.5°C with decomposition, in 28% (1.4 g) yield. Found for **2o**: C, 9.7; Cl, 14.4; N, 8.4. $C_4Cl_2F_{12}N_3P_2V$ requires: C, 9.57; Cl, 14.13; N, 8.37%.

Synthesis of the bis(*aminodiphenylphosphoranylidene*)*immoniumhexachlorometallates* (**3a–d**)[6]

Of the intermediates, **3**, only hexachlorotungstate, **3d**, has been fully characterized.

Equimolar amounts of **1a** and WCl_6 were stirred in CH_2Cl_2 at room temperature for 1 h. Cl_2 evolution was observed. After removal of the solvent, **3d** was recrystallized from CH_3CN. It forms brown blocks melting at 239°C with decomposition. The yield (before recrystallization) was virtually quantitative. Found for **3d**: C, 34.8; H, 3.0; Cl, 27.2; N, 4.7. $C_{24}H_{24}Cl_6N_3P_2W$ requires: C, 35.46; H, 2.98; Cl, 26.16; N, 5.17%.

Synthesis of [(*aminodimorpholinophosphoranylideneimino*) *aminodimorpholinophosphoranylideneimino*] *aminoniobiumtetrachloride* · C_5H_5N (**4**)[6]

4.9 g (10 mmol) of **1e** and 2.35 g (10 mmol) of $NbCl_5$ were refluxed in a mixture of 100 cm^3 of CH_2Cl_2 and 10 cm^3 of pyridine for 6 h. After cooling, pyridine hydrochloride was filtered off, the solution evaporated and the residue extracted with CH_2Cl_2. The compound was isolated as yellow crystals in 15% (1.2 g) yield by slow diffusion of the solvent in an evacuated two legged Schlenk vessel from 21 to 18°C. Found for **4** · C_5H_5N: C, 34.1; H, 5.4; Cl, 19.2; N, 15.1. $C_{21}H_{39}C_{14}N_8NbO_4P_2$ requires: C, 33.0; H, 5.14; Cl, 18.56; N, 14.66%.

Synthesis of 2,2,6,6-*tetraphenyl*-4,4,8,8-*tetrachloro*-1,3,5,7,2λ^5,6λ^5,4λ^5,8λ^5 - *tetrazadiphosphadivanadocine* (**6a**)[9]

2.4 g (10 mmol) of $Cl_3V{=}NSiMe_3$ and 3.1 g (10 mmol) of **5b** in 120 cm^3 CH_3CN were heated for 4 h at 40°C. The solid was filtered off, washed with a little CH_3CN and dried *in vacuo*. The brick-red microcrystalline powder, melting at 225°C with decomposition, was isolated analytically pure in 75% (5 g) yield. Found for **6a**: C, 42.2; H, 3.2; Cl, 21.3; N, 8.4. $C_{24}H_{20}Cl_4N_4P_2N_2$ requires: C, 43.02; H, 3.01; Cl, 21.16; N, 8.36%.

Synthesis of 2,2,6,6-*tetraphenyl*-trans-4,8-*dichloro*-4,8 - *bis*(*trimethylsilyloxy*) - 1,3,5,7,2λ^5,6λ^5,4λ^5,8λ^5-*tetrazadiphosphadivanadocine* (**6b**)[9]

1.7 g (10 mmol) of $VOCl_3$ and 4.3 g (10 mmol) of **7** in 120 cm^3 of CH_3CN were stirred at room temperature for 24 h. The residue was filtered off, washed with a little CH_3CN, and then redissolved in CH_2Cl_2 and a little CH_3CN. At −30°C **6b** crystallizes in brick-red rhombs of m.p. 206°C with decomposition. The yield of crude **6b** was 80% (6.2 g). Found for **6b**: C, 46.1; H, 4.9; Cl, 9.3; N, 7.3. $C_{30}H_{38}C_{12}N_4O_2P_2Si_2V_2$ requires: C, 46.34; H, 4.93; Cl, 9.12; N, 7.4%.

Synthesis of N,N′-*bis*(*trimethylsilyl*)-N-*pentachlorotungstenamino* - P - *diphenyliminophosphorane* (**8**)[6]

7.9 g (20 mmol) of WCl_6 and 8.6 g (20 mmol) of **7** were stirred for 10 h in 150 cm^3 of CH_2Cl_2 at room temperature. The volatiles were evaporated and the tarry dark-brown residue extracted several times with hot PCl_3. An olive–yellow microcrystalline solid residue remained, which was dried thoroughly *in vacuo*. Elemental analysis showed this material to be analytically pure **8** in 55% (8.1 g) yield. Found for **8**: C, 31.3; H, 4.4; Cl, 25.0; N, 3.8. $C_{18}H_{30}C_{15}N_2PSi_2W$ requires: C, 29.92; H, 4.18; Cl, 24.53; N, 3.88%.

Synthesis of 1,3-*bis*(*trimethylsilyl*)-2,2-*diphenyl*-4,4,4 - *trichloro* - 1,3,2λ^5,4λ^4 - *diazaphosphazirconetidine* · CH_3CN (**9a**) *and* -*titanetidine* · CH_3CN (**9b**)[10]

2.4 g (10 mmol) of $ZrCl_4$ or 1.9 g (10 mmol) of $TiCl_4$, respectively, and 4.3 g (10 mmol) of **7** were stirred at 0°C in 100 cm^3 of CH_2Cl_2 for 2 h. Insoluble material was filtered off, volatiles were evaporated and 80 cm^3 of CH_3CN added. After several days at −25°C the products started to crystallize. Additional material has been obtained by partial removal of the solvent. The yields of **9a** (colourless needles melting at 135°C with decomposition) and **9b** (orange cubes melting at 105°C with decomposition) were 48% (2.9 g) and 42% (2.3 g), respectively. Found for **9a** · **CH_3CN**: C, 40.3; H, 5.6; Cl, 17.7; N, 7.1. $C_{20}H_{31}Cl_3N_3PSi_2Zr$ requires: C, 40.17; H, 5.22; Cl, 17.78; N, 7.02%. Found for **9b** · **CH_3CN**: C, 43.8; H, 5.7; Cl, 19.2; N, 7.1. $C_{20}H_{31}Cl_3N_3PSi_2Ti$ requires: C, 43.29; H, 5.63; Cl, 19.17; N, 7.57%.

Synthesis of 3,7-*bis*(*trimethylsilyl*)-2,2,6,6-*tetraphenyl* - 4,4,8,8 - *tetrachloro* - 1,3,5,7,2λ^5,6λ^5,4λ^4,8λ^4-*tetrazadiphosphadititanatricyclo*[2, 2, 0, 0]*octane* · 2CH_3CN (**9c**)[10]

1.1 g (2 mmol) of **9b** · **CH_3CN** were dissolved in 50 cm^3 of CH_3CN and heated to 60°C for 3 h. After several days at −25°C a mixture of crystals of **9b** and **9c** precipitated, which after filtration were separated manually, but were not pure enough for elemental analysis.

Synthesis of 1,3-*bis*(*trimethylsilyl*)-2,2-*diphenyl*-4,4-*dichloro* - 4 - [N,N - *bis*(*trimethylsilyl*)*aminodiphenylphosphoranylideneimino*] - N′ - *amino* - 1,3,2λ^5,4λ^4 - *diazaphosphatitanetidine* · CH_3CN (**9d**)[11]

8.6 g (20 mmol) of **7** and 1.9 g (10 mmol) of $TiCl_4$ were stirred at room temperature for 12 h.

Subsequently all volatiles were evaporated and the solid residue redissolved in 50 cm^3 of CH_3CN. After cooling, **9d · CH_3CN** crystallized in dark yellow blocks melting at 135°C. This was slightly contaminated with **9b · CH_3CN** to give insufficient elemental analyses.

Synthesis of 2,2,6,6-*tetraphenyl*-4,4,8,8-*tetrachloro*-1,5,3,7,2λ^5,6λ^5,4λ^4,8λ^4 - *dioxadiazadiphosphadititanocine* · 4CH_3CN (**11**)[11]

3.8 g (20 mmol) of $TiCl_4$ and 7.2 g (20 mmol) of **10** were stirred in 120 cm^3 of CH_3CN at room temperature for 12 h. Insoluble material was filtered off and volatiles were evaporated. The residue was redissolved in a minimum amount of CH_3CN and kept at −25°C for crystallization. Found for **11 · 4CH_3CN**: C, 46.4; H, 4.2; Cl, 16.2; N, 9.0. $C_{32}H_{22}Cl_4N_6O_2P_2Ti_2$ requires: C, 46.19; H, 3.88; Cl, 17.04; N, 10.10%.

STRUCTURE AND REACTIVITY OF TRANSITION METAL COMPLEXES: A STEREOCHEMICAL APPROACH

ALISON RODGER

and

BRIAN F. G. JOHNSON*

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Abstract—A novel approach to describing the structure and reactivity of metal complexes, in which steric repulsions and attractive forces are reassessed, is reported.

The structure and reactivity of transition metal complexes have been one of the most intensively pursued areas of inorganic chemistry.[1] X-ray crystallography enables the (solid state) structure of most transition metal complexes to be determined experimentally. Experimental studies of reactivity are, however, of necessity, less direct. For high symmetry systems, symmetry rules for reactants, products and proposed transition states have proved useful complements to experiment, for example see refs 2–6. For lower symmetry systems one can often proceed by analogy with a high symmetry system using a "corresponding" principle.[7] Symmetry analyses have the advantage of giving strict yes/no answers which can be transferred between systems. Their major drawback is that they give no information of the magnitude of an effect for a "yes", nor how much distortion of the system is required to convert a "no" into a "yes, but small". The other theoretical extreme is a detailed calculation of some kind which gives precise information for the system being studied,[8] but usually provides no transferable information to help solve similar problems in other systems.

The stereochemical approach we have developed[7,9] aims to combat the problems inherent in the two types of approach, by coupling symmetry results with a chemically-based electrostatic approximation to the energy of a molecular system, which enables relative stabilities to be determined. When applied to equilibrium structures it enables ground-state geometries to be determined and when applied to proposed transition state geometries it enables the most favourable reaction pathways to be identified. The symmetry results used are those summarized in the classical symmetry selection rule procedure of ref. 3. The energetics follow from partitioning the total energy of a molecule ML_n into three contributions: that due to M—L bonding, that due to L—L interactions and that due to the non-bonding electron density:

$$E_{tot} = \sum M\text{—}L + \sum L\text{—}L + \sum e.$$

The geometry a molecule adopts is then determined by minimizing E_{tot}. The most significant *stabilizing* factor is the M—L bonding interaction. With only a few exceptions,[9] Σ M—L is approximately independent of the orientation of the ligands, as long as the M—L bond length remains the same. Comparison with a wide range of experimental data[8] indicated that Σ L—L is generally dominant over Σe (in contrast to valence-shell electron-pair repulsion theory which assumes a dominant role for the formation of lone *pairs* of spatially localized electrons). Thus, subject to M—L bond length constraints, the geometry adopted by ML_n is determined by L—L interactions. At very short L—L

* Author to whom correspondence should be addressed.

distances, repulsion due to the overlapping of L electron clouds is dominant, at intermediate distances, an attractive r^{-6} dispersion interaction is dominant and at longer range, an r^{-1} repulsive charge–charge interaction is dominant. The short range L—L repulsion is semi-quantitatively accounted for by a hard sphere radius for L. The intermediate range attraction then favours a geometry where L hard spheres are in contact. For uncharged ligands, whose net charges come from polarities of bonds, the r^{-1} repulsion is not important for determining the positions of ligand atoms about a metal. It is, however, crucial for determining the most stable orientations of the next "sphere" of atoms in e.g. $M(OH_2)$. We illustrate this discussion by application to tris-chelate complexes.

GEOMETRY OF TRIS-CHELATE COMPLEXES

The simplest and most successful rationalization of the geometries of a wide range of tris-chelate transition metal complexes is the ligand–ligand repulsion model of Keppert.[10] The previous discussion enables us to understand why this model has been so successful and also to predict where it is likely to be inapplicable and what deviations can be expected.

Let us consider a tris-chelate complex whose ligating atoms are so large that the short range L—L repulsions (most easily viewed as hard sphere repulsions) force M—L bonds to be stretched in order to accommodate three chelates. Keppert's model, where the geometry adopted is that which minimizes repulsion, will then agree with the observed structure. Examples of this are $[Cr(en)_3]^{3+}$ and $Co(S_2COEt)_3$. For complexes with a chelate bite (the distance between ligating atoms of a chelate in units where the M—L bond length is one), b, less than $\sqrt{2}$, the geometry adopted is twisted from octahedral towards a trigonal prism, and conversely for b being greater than $\sqrt{2}$.

The situation is both more complex and more interesting for complexes with smaller ligands, since attractive forces come into play. The short range repulsive forces are still important, since an ML_6 system is crowded, but now the modifying effect of the attractive forces must be taken into account. We consider the attractive force as a perturbation which modifies the repulsion determined geometry. A twist in either direction from the repulsion determined twist angle of Ω_{rep} stabilizes the complex; the question is which direction is more favourable and how much of a twist is expected? The direction and amount of twist depends on b and the L hard sphere radius. The rapid fall off of r^{-6} with distance ensures that the shortest L—L distance is approximately twice the hard sphere radius. Thus, we compare the two twist angles, Ω_+ and Ω_-, at which, respectively, two L not related by a three-fold rotation are closest and two L related by a three-fold rotation are closest. When the energies are calculated it turns out that for larger b, the geometry with the smaller twist angle (i.e. closer to a trigonal prism) is always adopted. The situation is the other way round for small values of b. The change from one type of behaviour to the other occurs for b values of about 1.2. It should, however, be noted that when the energy difference between the two angles is small, other factors such as crystal packing forces can be expected to influence the angle adopted in a crystal. Thus $[Co(en)_3]^{3+}$, for example, is sometimes Ω_+ and sometimes Ω_-.

REARRANGEMENTS OF TRIS-CHELATE COMPLEXES

The only two concerted symmetry allowed mechanisms for a tris-chelate complex are the Ray Dutt and Bailar twist mechanisms. These two mechanisms are usually viewed as quite different, but they are in fact very similar: the Bailar twist involves a totally symmetric twist about the three-fold axis of the complex via a trigonal prismatic transition state, and the Ray Dutt twist is the same twist but about an axis which is a three-fold axis in the octahedral template of the complex, but not in the D_{3h} chelated complex. In order to accommodate the ligating atoms in the trigonal prism, the M—L bonds must stretch during these twists. The most stable transition state will be that with the least M—L bond stretching. It can then be shown that the Bailar twist is more favourable than the Ray Dutt twist if $b > \sqrt{2}$, and conversely though, for $b \approx \sqrt{2}$ the difference is very small. In addition, the smaller the value of b, the less the energy required for a twist mechanism to operate. So as b is usually less than $\sqrt{2}$, a tris-chelate complex will rearrange more readily via a twist mechanism than its octahedral counterpart. Since tris-chelate complexes are usually the more stable, we can conclude that bond breaking mechanisms are usually favoured for tris-chelate mechanisms.

THE SYSTEMS L-CYSTEINE AND D-PENICILLAMINE + OXOVANADIUM(IV); A POTENTIOMETRIC AND SPECTROSCOPIC STUDY

J. COSTA PESSOA and L. F. VILAS BOAS

Centro de Química Estrutural, Complexo I, Instituto Superior Técnico, 1096 Lisboa, Portugal

and

R. D. GILLARD*

Department of Chemistry, University of Wales, P.O. Box 912, Cardiff CF1 3TB, Wales, U.K.

Abstract—The equilibria in the systems L-cysteine (and D-penicillamine) + VO^{2+} in aqueous solution for $1.5 \lesssim pH \lesssim 12$ have been studied by a combination of pH-potentiometric and spectroscopic methods (EPR, visible absorption and circular dichroism). For pH > 4, high ligand-to-metal ratios were used. The results of the various methods are made self-consistent, then rationalized assuming an equilibrium model including species MXH_2, MXH, MX_2H_4, MX_2H_3, MX_2H_2, MX_2H, MX_2, M_2X_2 (where H_2X denotes L-cysteine or D-penicillamine, and M denotes VO^{2+}), and several hydrolysis products; their formation constants and individual electronic spectra (isotropic and circular dichroism) are given. Plausible isomeric structures for each of the stoichiometries are discussed.

Although knowledge of the complex equilibria of VO^{2+} in the presence of amino acids is relevant in understanding its possible interaction with likely biological ligands, few reliable data exist.[1–4]

This work involves the study of the L-cysteine and D-penicillamine + VO^{2+} systems in aqueous solution for $1.5 < pH < 12$, by combining the results of potentiometric and spectroscopic techniques [EPR, visible absorption and circular dichroism (CD)].

In the EPR spectra recorded with frozen "solutions" containing VO^{2+} and D-Pen at 77 K with high ligand-to-metal ratios (e.g. 25), the several species that may be detected in the pH range 1.5–4 are of the same type as those found in the pH range 1.5–6 in the L-Ala,[2] L-Ser and L-Thr[3] + VO^{2+} systems. This is also consistent with the visible and CD spectra recorded.

For $pH \gtrsim 4$ ($\gtrsim 4.5$ for L-Cys) all spectroscopic results for the D-Pen (and L-Cys) + VO^{2+} system differ from those found in the other systems. The EPR spectra clearly show that one R—S^- group coordinates for $pH \gtrsim 4$ ($\gtrsim 4.8$ for L-Cys) and two R—S^- groups for $pH \gtrsim 5.5$ ($\gtrsim 6.3$ for L-Cys). In the pH range 7.1–11 only one species is detected in the EPR spectra, corresponding to a N_2S_2 coordination in the equatorial plane.

In Fig. 1 we include some of the CD spectra recorded. In the pH range 8.3–10.3 the CD (and

Table 1. Composition and formation constants of the species in the D-Pen (and L-Cys) + VO^{2+} systems at 25°C and 2.25 M $NaNO_3$. Values for $\log \beta_{xyz}$ of eq. (1) are given

Species	L-Cys + VO^{2+}	D-Pen + VP^{2+}

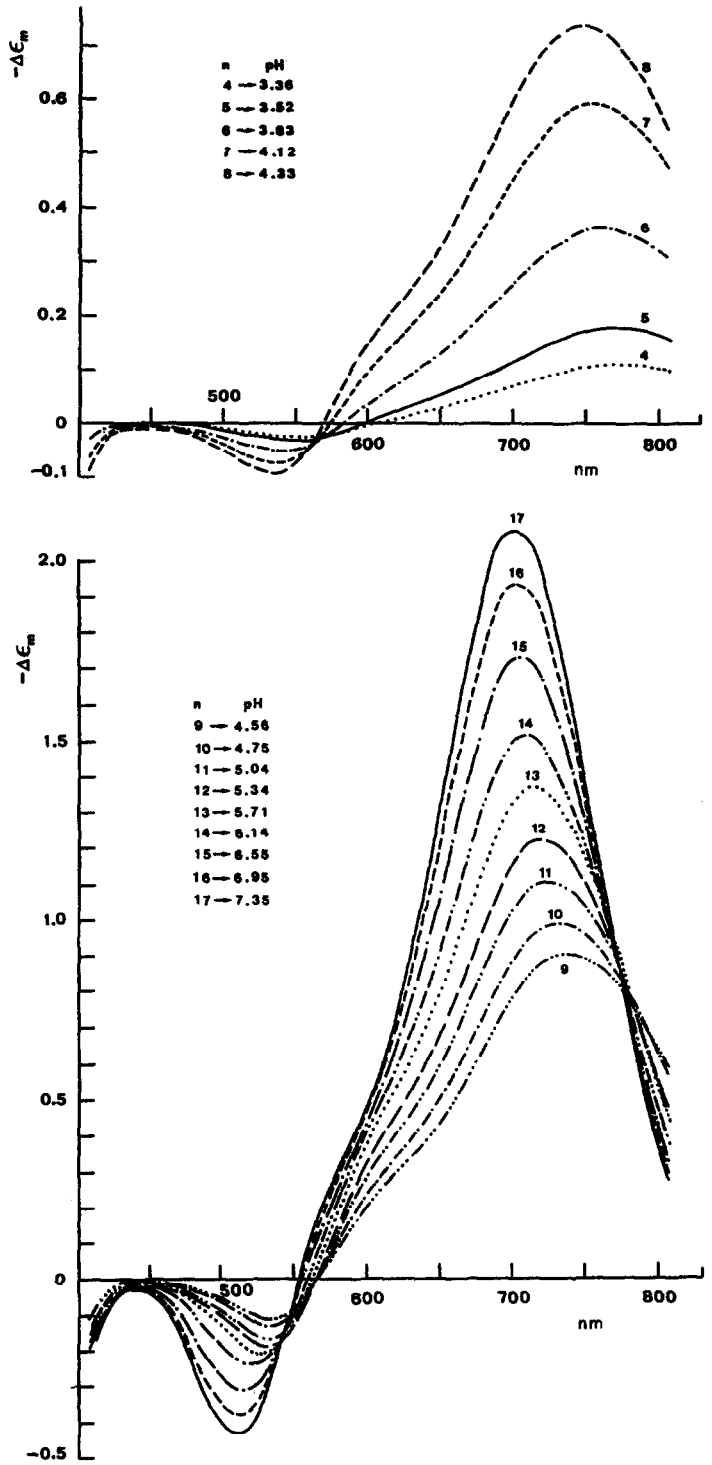

Fig. 1. Circular dichroism spectra of solutions containing L-cys+VO^{2+} with $C_{VO} = 0.01$ M and a ligand-to-metal ratio of 23.7.

visible) spectra practically coincide and are of the same type as those recorded in the system L-cysteine ethyl ester+VO^{2+} for $6 \lesssim pH \lesssim 9$.

The formation constants were calculated using the MINIQUAD,[5] SUPERQUAD[6] and SQUAD[7] programs (the SQUAD program was also used to calculate the individual electronic spectra—isotropic and CD). The calculated $\log \beta_{xyz}$ are summarized in Table 1 and correspond to the general equation:

$$xVO^{2+} + yL^{2-} + zH^{+} \rightleftharpoons (VO)_x(L)_y(H)_z. \quad (1)$$

For each of the log β_{xyz} values, plausible ranges are also given, established by a critical examination of all the calculations.

ELECTRON SPIN RESONANCE SPECTRAL STUDIES OF VANADYL COMPLEXES WITH SOME SCHIFF BASES

S. S. DODWAD,* R. S. DHAMNASKAR and P. S. PRABHU

Chemistry Department, The Institute of Science, 15 Madam Cama Road, Fort, Bombay 400 032, India

Abstract—Vanadyl complexes with Schiff bases of 2-hydroxy-1-naphthalidene and aryl amines were prepared. The ESR spectra of all the complexes were recorded at room temperature and at liquid nitrogen temperature (177 K), by the method of Kneubuhl, Sands and German. A small polycrystalline sample of the tetracyanoethylene (TCNE) free radical was used as a "g" marker. The spectra were again analysed by the method of Kneubuhl, Sands and Garman. The values $|g|$, $g_{\parallel}$ (parallel), $g_{\perp}$ (perpendicular), $|A|$, $A_{\parallel}$, $A_{\perp}$ were obtained. The expression $h\nu = g\beta H$ was used for evaluating the "g" values. Due to rapid tumbling of the molecules in solution at room temperature the anisotropy is not observed, but it is clearly visible at 177 K. "g" is a function indicating covalency and therefore an order of covalency in the vanadyl complexes has been reported.

The ESR spectra of metal complexes have been studied by various workers.[1-6] Such studies give information regarding the stereochemistry of metal ions in their complexes and the nature of metal–ligand bonding. Detailed ESR studies of metal–oxygen, metal–nitrogen and metal–sulphur bonding have been reported.[7,8] The spectra of vanadyl complexes have been reported by a few authors. The ESR spectra of vanadyl complexes with some Schiff bases have been studied and interpreted by the authors.

EXPERIMENTAL

The vanadyl complexes with Schiff bases of 2-hydroxy-1-naphthalidene-anil and some substituted 2-hydroxy-1-naphthalidene-anils were prepared by refluxing vanadyl sulphate and the corresponding Schiff base in a 1 : 2 ratio in ethanol for 2 h. The complexes were characterized by their electronic and IR spectra, magnetic studies and by conductivity measurements in solution. These properties suggest a square-pyramidal structure for the complexes. The ESR spectra of the vanadyl complexes were recorded on a Varian E-112 spectrometer (X-band) at room temperature (R.T.) and at 177 K in chloroform. A minute polycrystalline sample of the TCNE free radical was used as a "g" marker. All these spectra were run at RSIC, I.I.T., Powai, Bombay. The spectra are represented in Figs 1 and 2.

RESULTS AND DISCUSSION

The ESR spectra were analysed by the method of Kneubuhl,[9] Sands[10] and German *et al.*[11] The "g" values from ESR spectra obtained at R.T. are presented in Table 1. The hyperfine coupling (A) and "g" values at 177 K are presented in Table 2. The ESR spectra (Figs 1 and 2) of the complexes indicate square-pyramidal symmetry. These facts support the observation made on the basis of magnetic and spectral studies. Kivelson and Neiman[3] showed that $g_{\parallel}$ is a moderately sensitive function for indicating covalency. In view of this covalency of the metal–ligand bond in the

Table 2. Liquid nitrogen temperature "g" values and "A" values of vanadyl complexes

Vanadyl complexes of	$g_\parallel$	$g_\perp$	$\|g\|$	$A_\parallel$	$A_\perp$	$\|A\|$
HNA	1.969	2.005	1.993	158.57	64.28	95.71
HNPCA	1.962	1.991	1.981	171.42	57.85	95.70
HNOCA	1.966	1.993	1.984	171.42	58.57	96.18
HNMCA	1.960	2.005	1.990	174.28	57.14	96.18

present vanadyl complexes the following order is suggested: 2-hydroxy-1-naphthalidene-anil (HNA) > 2-hydroxy-1-naphthalidene-4′-chloro-anil (HNPCA) > 2-hydroxy-1-naphthalidene-2′-chloro-anil (HNOCA) > 2-hydroxy-1-naphthalidene-3′-chloro-anil (HNMCA).

Values for all of the complexes in the polycrystalline state are nearly the same as in chloroform. Therefore it is quite probable that the arrangement of the vanadyl ion in the polycrystalline state and in chloroform may be the same.[8]

There are eight lines in all the spectra taken at room temperature. This is due to hyperfine splitting of ^{51}V whose nuclear spin number $I = 7/2$. This shows that a single vanadium is present in the molecule, i.e. it is a monomer. Since there is rapid tumbling of molecules in solution at room temperature, the anisotropy is not observed and single $|g|$ and $|A|$ values are obtained (Table 1).

The anisotropy is clearly visible in the spectra recorded at 177 K in chloroform. Eight bands each due to $g_\parallel$ and $g_\perp$ are observed separately, the former being fully resolved. $g_\parallel$, $g_\perp$, $A_\parallel$, $A_\perp$, values were measured from the spectra. The values are normal for a square-pyramidal structure.[12–14] From these values, $|A|$ and $|g|$ were calculated using the expressions:

$$|g| = 1/3(g_\parallel + 2g_\perp) \text{ and } |A| = 1/3(A_\parallel + 2A_\perp).$$

The values thus evaluated are shown in Table 2. The values of $|g|$ and $|A|$ calculated from these formulae agree closely with the values measured from room temperature spectra, thus confirming the accuracy of the calculations. The "g" values are all very close to the spin-only value (the free electron value) of 2.0023, suggesting little spin-orbit coupling. The spin Hamiltonian is simple and can be written in terms of "g" and "A" only, as follows:

$$\mathcal{H} = g_\parallel \beta H\zeta S\zeta + g_\perp \beta(HxSx + HySy) + A_\parallel S\zeta I\zeta + A_\perp(SxIx + SyIy).$$

The solution spectra thus agree with the square-pyramidal structure for the vanadyl complexes under study.

REACTIONS OF ALLYLIC COMPOUNDS WITH PHOTO-ACTIVATED MOLYBDENUM HYDRIDE

TAKASHI ITO,* TETSUAKI MATSUBARA, KAZUAKI HAMAMOTO, YOICHIRO YAMASHITA and SUSUMU KURISHIMA

Department of Materials Chemistry, Faculty of Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240, Japan

Abstract—$[MoH_4(dppe)_2]$ (**1**) (dppe = $Ph_2PCH_2CH_2PPh_2$) reacted photochemically with allylic esters and carbonates, $RCO_2CH_2CH{=}CH_2$, to give seven-coordinate hydrido-carboxylato complexes, $[MoH(O_2CR)(dppe)_2]$ (**2**), together with H_2 and propene. When the esters with bulky R or carbonates were employed, the yield of propene increased significantly, while that of H_2 remained unchanged. The photoreactions of **1** with N-substituted succinic imides were also investigated.

Transition metal-assisted selective activation of the C—O bond in the unsaturated carboxylic esters and carbonates has been studied in depth for the group 8 transition elements,[1] with reference to their utilization to organic syntheses such as catalytic allyl substitution reactions.[2] In contrast, there have been few such studies with group 6 transition metals,[3] in spite of the recent finding by Trost *et al.* of the metal-dependent chemoselectivity of allylic alkylation.[4]

A yellow suspension of the molybdenum tetrahydride, $[MoH_4(dppe)_2]$ (**1**) (dppe = $Ph_2PCH_2CH_2PPh_2$), in an excess of allyl acetate and benzene as solvent, changed to a deep red solution after irradiation with a 100 W high-pressure mercury lamp *in vacuo* at room temperature. Orange crystals of $[MoH(O_2CCH_3)(dppe)_2]$ (**2**)† were isolated from the solution (yield 45%) and the accompanying formation of H_2 and propene, each in amount corresponding to the yield of **2**, was confirmed by GLC. The reactions of **1** with other allylic esters and carbonates proceeded similarly, affording the corresponding carboxylato and carbonato complexes, respectively [eq. (1)]. The formato complex, **2** (R = H), has been prepared via a different route starting from **1** and carbon dioxide.[5]

$$[MoH_4(dppe)_2] + RCO_2CH_2CH{=}CH_2 \xrightarrow{h\nu} \underset{(1)}{} \underset{(2)}{[MoH(O_2CR)(dppe_2]} + H_2 + CH_3CH{=}CH_2 \quad (1)$$

(R = H, Me, Et, Pr^n, Bu^t, $CH_2{=}C(Me)$, Ph, MeO, EtO).

With the increased bulkiness of R, the yield of propene in the reaction increased significantly, whereas that of H_2 remained unchanged. Thus, when R = Bu^t, 1.01 mol/mol of **1** of propene was evolved together with 0.67 mol of H_2.

The C=C double bond of an allyl group was found to affect the allyl–O bond cleavage, since the C—O bond cleavage did not take place when propyl acetate was employed as the substrate. Considering that **1** has been known to photochemically generate the coordinatively unsaturated intermediate $[MoH_2(dppe)_2]$ (**A** in Scheme 1),[6] we can assume that allyl acetate may coordinate to **A** through its C=C bond to give **B**. Reactions of 1-methylprop-2-enyl acetate and but-2-enyl acetate with **1** under similar conditions, afforded 1-butene and *trans*-2-butene, respectively, as major C_4 products. Absence of the isomerized butenes suggests that the release of olefins occurs directly from the hydrido-σ-allyl intermediate, **C**, without an intervening π-allyl intermediate. The reductive elimination of alkene from **C** yields **2** *via* a monodentate carboxylate, **D**. The less stable carboxylate, **2**, with bulkier R

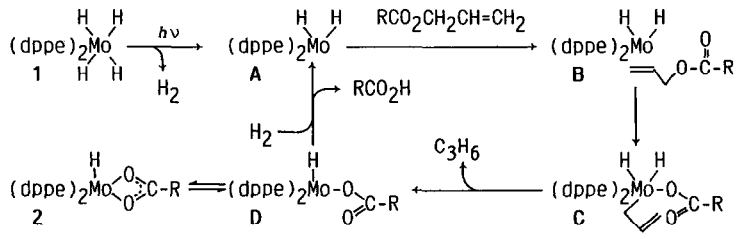
† All new compounds including this complex which were isolated in this study showed satisfactory results in elementary analyses.



Scheme 1.

groups, may be attacked by H_2 present in the system to regenerate **A**, making the reaction catalytic with respect to the C—O cleavage. The proposed mechanism was supported by the fact that bubbling of H_2 into the reaction system of **1** and allyl pivalate raised the yield of propene to 2.67 mol/mol of **1**, suggesting the possible catalytic hydrogenolysis of allylic esters.

Carboxylato and carbonato complexes, **2**, were moderately air-stable in the solid state and were readily soluble in aromatic hydrocarbons to give reddish-brown air-sensitive solutions. The IR of **2** (R = Me) showed the ν(Mo—H) band at 1870 cm^{-1} and $\nu(CO_2)$ of the bidentate carboxylato ligand at 1540 and 1450 cm^{-1}. The ^1H NMR spectra of **2** (R = Me) in benzene-d_6 at room temperature exhibited a Mo—H signal at δ −6.23 ppm as triplets of triplets (A_2M_2X pattern), suggesting coupling of the hydride with two pairs of magnetically inequivalent ^{31}P nuclei, each consisting of two equivalent ^{31}P (^2J(HP) = 64.8 and 30.7 Hz, respectively). The $^{31}P\{^1H\}$ NMR spectrum of **2** (R = Me) in xylene at room temperature, which showed a pair of triplets at δ 75.4 and 101.0 ppm (with reference to external PPh_3; ^2J(PP) = 17.7 Hz), was consistent with the ^1H NMR results. The spectral characteristics of the other carboxylato and carbonato complexes were very similar to those found for the acetato complex and suggest the pentagonal bipyramidal coordination geometry of the seven-coordinate complex, **2**, at room temperature, which is fluxional in the solution as revealed by the temperature ^1H and $^{31}P\{^1H\}$ NMR spectra.

The preliminary X-ray molecular structural analysis of the single crystal of the carbonato complex, **2** (R = OEt), shows that it possess essentially the same geometry as in solution, although it is considerably distorted from the pentagonal bipyramidal framework.

Reaction of **1** with N-allyloxysuccinic imide in benzene under irradiation resulted in the allyl–O bond cleavage to give a hydrido–oxyimido complex, **3**, together with propene and H_2 [eq. (2)]. Treatment of **3** with CO released N-hydoroxysuccinic imide with the accompanying formation of known $Mo(CO)_2(dppe)_2$:

$$[MoH_4(dppe)_2] \quad \textbf{(1)}$$

$$+\overline{C(O)CH_2CH_2C(O)NO}CH_2CH{=}CH_2 \xrightarrow{h\nu}$$

$$[MoH\{\overline{ONC(O)CH_2CH_2C(O)}\}(dppe)_2] \quad \textbf{(3)}$$

$$+H_2+CH_3CH{=}CH_2. \quad (2)$$

and

T. HIGGINS

School of Chemical Sciences, Regional Technical College, Galway, Ireland

Abstract—Vanadyl salicylaldimine complexes are capable of forming 1 : 1 adducts with tin Lewis acids, both as a result of ligand oxygen and vanadyl donation to tin; examples of the latter were established by X-ray crystallographic studies.

Despite the very extensive and diverse investigations of vanadyl chemistry, few have addressed one of the fundamental properties of the vanadyl group, viz. its Lewis basicity. Its basic character manifests itself in polymeric structures in which stacking of vanadyl units occurs. Furthermore, there are several reports of vanadyl forming donor bonds to divalent metal ions in heterobimetallic transients, and to ruthenium in a stable vanadium–ruthenium complex, but in no case has this been totally authenticated.[1] This communication describes adduct formation between vanadyl salicylaldimines and tin Lewis acids, in some instances as a result of a ligand oxygen donation, while in others as a result of vanadyl donation to tin; crystallographic studies confirm the latter mode of bonding.

Typical adducts, along with relevant IR data, are in Table 1. Adducts **1**, **5**, **6** and **7** have vanadyl frequencies greater than those of the parent vanadyl complexes, thus consistent with electron drain from vanadium and consequent strengthening of the vanadyl double bond. This observation, coupled with the marked increase of the phenolic C—O stretching frequencies, strongly suggests phenolic oxygen donation to tin.[2] On the other hand, the

marked lowering of the vanadyl frequencies (compared to those of the parent vanadyl complexes) coupled with the relatively unperturbed phenolic C—O frequencies for the other adducts of Table 1, suggest vanadyl donation to tin. This was confirmed by X-ray studies for **2** and **9**. Preliminary crystallographic details are shown in Figs 1 and 2, and in Table 2.

There is substantial donation to tin (as indicated by the Sn—O bond lengths[3]) in both adducts,

donation being greater in **9** as a result of the *trans* water donation to vanadium. The vanadyl bond lengths are considerably longer than those for either VO(salen) or its sodium adduct (average values 1.588 and 1.584 Å, respectively[4,5]), and there is evidence for a longer V=O bond length in **9** than in **2**; these observations are consistent with the ν(V=O) data of Table 1. Vanadium is 0.6 Å removed from the mean plane defined by the salicylaldimine donor atoms in the case of **2**, and this is essentially as in VO(salen). However, in the case of **9**, vanadium is only 0.334 Å from this plane, a fact which probably reflects the influence of the coordinated water. A most interesting feature of both structures is the close to linear V—O—Sn system which indicates essentially *sp* hybridized oxygen. By contrast, M=O donor moieties, where M is P, As, S, Se, C and N, give M—O—Sn bond angles which are consistent with essentially sp^2 hybridized oxygen.[3]

REACTIONS OF MONODINITROGEN COMPLEXES OF MOLYBDENUM. ISOLATION AND CHARACTERIZATION OF HYDRAZIDO(2−) AND MONO- AND DIHYDRIDE COMPLEXES

T. ADRIAN GEORGE* and ROBERT C. TISDALE

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, U.S.A.

Abstract—The mono-N_2 complex *fac*-Mo(N_2)(triphos)(L_2) (**1**), where triphos = $PhP(CH_2CH_2PPh_2)_2$ and L = PMe_2Ph, reacts with HX (X = Br, Cl) to give the hydrazido(2−) complex, [Mo(NNH_2)(η^2-triphos)(PMe_2Ph)$_2$]X (**2**), in which triphos is bidentate. Complex **1** reacts with HBr (1 mol) to give an almost quantitative yield of MoHBr(triphos)(PMe_2Ph) (**3**). With HBr (1 mol), **3** produces MoH_2Br(triphos)(PMe_2Ph).

The bis-N_2 complexes of molybdenum and tungsten occupy a unique position among the N_2 complexes of the transition metal elements, because of their reactivity with (i) acids to afford high yields of ammonia and (ii) alkyl halides to produce organonitrogen ligands.[1-3] Some of these reactions have shown encouraging catalytic behaviour.[4,5] It has been stated that one reason for the unique reactivity behaviour of these complexes is the fact that they contain two rather than the single N_2 ligand found in other metal complexes. Recently we synthesized a series of mono-N_2 complexes of molybdenum and demonstrated that they generate ammonia and hydrazine in an analogous fashion to the bis-N_2 complexes.[6] We now report the isolation and characterization of species formed in the early part of the reactions of acids with *fac*-Mo(N_2)(triphos)(L_2) (**1**).

The reaction of **1** with either 2 mol of HX (X = Br, Cl) in toluene or excess (*ca* 20 mol) of HX in the absence of solvent, afforded a pinkish-yellow hydrazido(2−) complex in moderate yield (eq. 1; X = Br, Cl). Addition of THF to the solid (X = Cl) produced a solution from which **2** (X = Cl) was isolated by the addition of pentane.

$$Mo(N_2)(triphos)(PMe_2Ph)_2 \xrightarrow{HX} [MoX(NNH_2)(\eta^2\text{-triphos})(PMe_2Ph)_2]X \quad (1)$$
(**2**)

Evidence for the formation of a hydrazido(2−) ligand comes from (i) the IR spectrum: ν(NH) 2800–2500 cm^{-1}; 3350 (w) and 3250 (m) cm^{-1} in the BPh_4 salt; (ii) the ^{15}N NMR data: δ −63.34 (m, 1, N_α), −212.30 (m, 1, N_β) which agrees with published data;[7] and (iii) the ^1H NMR spectrum; $\delta(NNH_2)$ 10.6 ppm broad; 5.2 and 5.4 ppm in the BPh_4 and PF_6 salts, respectively.

The ^{31}P NMR spectrum shows the presence of four coordinated phosphorus atoms and with a fifth appearing as a doublet at δ −17.19 ppm, very near to the position for the terminal phosphorus atoms of free triphos. The data suggest that triphos is behaving as a bidentate ligand with P_a and P_b coordinated, and P_c pendant. Therefore, the reaction of **1** is formally analogous to that of the bis-N_2 complexes; a hydrazido(2−) ligand is formed *trans* to the conjugate base of the acid used.[3a,8]

Complex **2** (X = Br) was similarly obtained in greater than 90% yield by thorough extraction of the solid prepared by the reaction of **1** with HBr.

Heating either **6** or **7** in toluene solution resulted in the loss of one PMe_2Ph per mol of complex and the re-coordination of P_c to form *mer*-[MoX(NNH_2)(triphos)(PMe_2Ph)]X.

The reaction of **1** with 1 mol of HBr in benzene at room temperature, rapidly (0.25 h) produced an equimolar mixture of **1** and **2** (X = Br). When the orange solution was allowed to stir for 15 h, a dark green hydride *mer*-Mo(H)Br(triphos)(PMe_2Ph) (**3**) was isolated in quantitative yield. The corresponding chloride, **4**, was obtained in lower yield. Each 16-electron complex exhibited ν(MoH) in the IR spec-

* Author to whom correspondence should be addressed.

trum at 1876 (**3**) and 1874 (**4**) cm^{-1}. The hydride resonance appeared as a split doublet of triplets in the ^1H NMR spectrum at δ −3.60 (**3**) and −3.82 (**4**) ppm, respectively. The ^{31}P NMR spectrum of each complex was interpreted as arising from a coplanar arrangement of *mer*-triphos and PMe_2Ph. Free PMe_2Ph was identified in the ^{31}P NMR spectrum of the reaction mixture and 0.9 mol of N_2 were evolved. The reaction of **3** with HBr (1 mol) resulted in the very rapid formation of the orange eight-coordinate dihydride MoH_2Br_2(triphos)(PMe_2Ph) (**5**). In the IR spectrum ν(MoH) appears at 1878 cm^{-1} and in the ^1H NMR spectrum the hydride resonance occurs as a multiplet at δ −5.90 ppm.

ZIRCONIUM(III) CHEMISTRY: INFLUENCE OF OLEFINS IN THERMOLYTIC BEHAVIOUR OF $(Cp_2ZrHX)_n$ (X = Cl, CH_2PPh_2)

R. CHOUKROUN,* D. GERVAIS and Y. RAOULT

Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse, France

Abstract—Thermolysis of $(Cp_2ZrHCl)_n$ at 80°C for several weeks results in the formation of the diamagnetic fulvalenide dinuclear zirconium(IV) derivative, $(CpZrCl)_2(C_5H_4—C_5H_4)$, via the intermediate formation of $[CpZrCl(\mu\text{-}\eta^5\text{-}\eta^1\text{-}C_5H_4)]_2$. In the presence of 1,5-COD (COD = cyclooctadiene) the same reaction occurs at room temperature. Under similar conditions, $[Cp_2ZrH(CH_2PPh_2)]_n$ yields paramagnetic zirconium(III) species, $Cp_2Zr(CH_2PPh_2)$; with 1-hexene, at room temperature a labile intermediate, $Cp_2Zr(CH_2PPh_2)$(Hexyl), was observed. These results will be discussed and related to the catalytic activity of both systems for hydrogenation of alkenes.

Improved catalytic performances of $[Cp_2ZrH(CH_2PPh_2)]_n$[1] for hydrogenation of olefins, when compared to the poor result obtained with $(Cp_2ZrHCl)_n$[2] (**1**) under similar experimental conditions (80°C, 40b H_2), led us to study the thermolytic behaviour of both systems in the presence or absence of a substrate.

Thermolysis of $(Cp_2ZrHCl)_n$ (**1**)[1] at 80°C in a sealed tube was followed by ^1H and ^{13}C NMR spectroscopy. The general pathway is reported in Scheme 1. After weeks, the diamagnetic fulvalenide dinuclear zirconium(IV) derivative, $(Cp_2ZrCl)_2(C_5H_4—C_5H_4)$ (**4**),[3] is formed via the intermediate formation of diamagnetic $[CpZrCl(\mu\text{-}\eta^5\text{-}\eta^1\text{-}C_5H_4)]_2$ (**5**). In parallel, diamagnetic $(Cp_2ZrCl)_2$ (**3**)[4] is formed. The same complexes are obtained similarly when thermolytic experiments were carried out in the presence of a stoichiometric amount of $(Cp_2ZrHCl)_n$ and cyclohexene, or starting directly from isolated Cp_2ZrCl (cyclohexyl) (**2b**). In the latter case, evolution of the system occurred after 27 h at 80°C: **2b**: 10%; **3**: 20%; **5**: 50%; **4**: 20%, together with 80% cyclohexane.

In the presence of 1,5-COD, **1** is thermally decomposed at room temperature: **5** is detected after 1 day and is progressively transformed into **4** (quantitatively after 4 weeks). Detection of *ca* 20% of 1,3-COD by C.P.V. (together with cyclooctene, the main organic product of the reaction) may be interpreted by the formation of a labile π-allyl derivative, $Cp_2Zr(\eta^3\text{-}C_8H_{13})Cl$. EPR spectra, registered periodically, show that low intensity signals at the beginning of the reaction become EPR silent after *ca* 1 h of thermolysis.

On the other hand, $[(Cp_2ZrH(CH_2PPh_2)]_n$ (**6**) was previously reported to give rise to zirconium(III) species, Cp_2ZrH and $Cp_2\dot{Z}r(CH_2\dot{P}Ph_2)$,[5] at 80°C (Fig. 1). In the presence of the cyclic

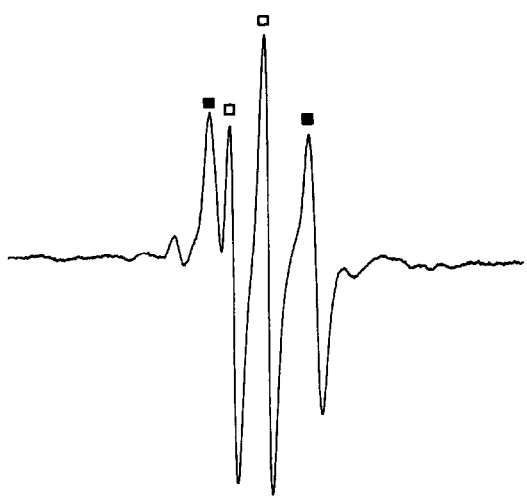

Fig. 1. X band EPR spectrum of $Cp_2ZrH(CH_2\dot{P}Ph_2)$ (**6**) in THF solutions at room temperature, after thermolysis at 80°C: □: Cp_2ZrH (g = 1.987, $a(^1H)$ = 8 G); ■: $Cp_2\dot{Z}r(CH_2\dot{P}Ph_2)$ (g = 1.985, $a(^{31}P)$ = 19.5 G).

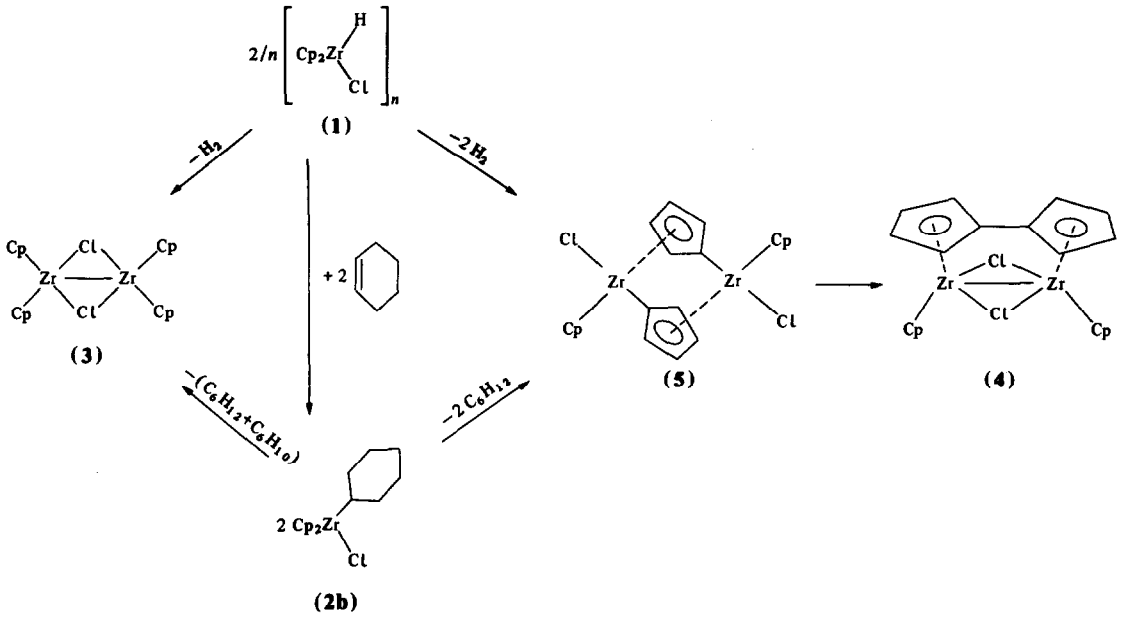

Scheme 1. Pathway of thermolysis of $(Cp_2ZrHCl)_n$ (1).

diene, 1,5-COD, thermolytic decomposition occurs at room temperature to give an intense EPR signal of the chelated zirconium(III) complex, $Cp_2\dot{Z}r(CH_2\dot{P}Ph_2)$,[5,6] and unexploitable ^1H NMR. In the presence of 1-hexene, at room temperature, the course of the reaction, monitored by ^1H and ^{31}P NMR, shows the formation of the zirconium(IV) complex, by insertion of the olefin into the Zr—H bond, which slowly decomposes to give the paramagnetic species, $Cp_2\dot{Z}r(CH_2\dot{P}Ph_2)$, as observed by EPR spectroscopy. At 80°C, the same reaction immediately gives $Cp_2\dot{Z}r(CH_2\dot{P}Ph_2)$.

In summary, thermolytic experiments on **1** give diamagnetic complexes involving C—H activation in the cyclopentadienyl group, whereas **6** gives paramagnetic species stabilized by chelation of the phosphinomethyl group. This may be interpreted as the important role of a paramagnetic zirconium(III) complex in the selective catalytic hydrogenation of cyclodienes.

BIMETALLIC COMPLEXES [Zr, Rh]: $Cp'_2Zr(CH_2PPh_2)_2[Rh(\mu\text{-}S\text{-}^tBu)(CO)]_2$ AND $Cp'_2Zr(CH_2PPh_2)_2[Rh(COD)]BPh_4$ ($Cp' = C_5H_4CMe_3$) AND THEIR CATALYTIC BEHAVIOUR AS HYDROFORMYLATION CATALYSTS

R. CHOUKROUN,* D. GERVAIS and C. RIFAÏ

Laboratoire de Chimie de Coordination du CNRS, 205 Route de Narbonne, 31077 Toulouse, France

Abstract—In our strategy, introduction of a substituent into a cyclopentadienyl group could allow new reactivity in the bimetallic system [Zr, Rh], compared with non-substituted cyclopentadienyl analogues [Zr, Rh]. A first step was reached by synthesizing $(C_5H_4CMe_3)_2Zr(CH_2PPh_2)_2$ as a new zirconium-containing diphosphine. The title compounds were isolated and their structural aspects, as well as their catalytic hydroformylation performances, will be presented and compared to previous regular cyclopentadienyl [Zr, Rh] complexes.

The bimetallic d^0–d^8 [Zr, Rh] compounds associating the zirconium-containing diphosphine $Cp_2Zr(CH_2PPh_2)_2$ and various rhodium complexes, present improvements of the catalytic activity for the hydroformylation reaction.[1–3]

In our strategy, introduction of a R substituent in the cyclopentadienyl groups bonded to zirconium in $(C_5H_4R)_2Zr(CH_2PPh_2)_2$ could allow new reactivity and catalytic activity and selectivity of the bimetallic systems [Zr, Rh], compared to the non-substituted cyclopentadienyl analogues. A first step was reached by synthesizing $(C_5H_4CMe_3)_2Zr(CH_2PPh_2)_2$ (**I**) as a new zirconium-containing diphosphine.

Treatment of the binuclear rhodium moiety $[Rh_2(S\text{-}^tBu)_2(CO)_4]$ (**II**) with **I** led to the heterobimetallic complex, **III**, according to the equation:

$$\mathbf{I} + \mathbf{II} \xrightarrow{-2CO} (C_5H_4CMe_3)_2Zr(CH_2PPh_2)_2[Rh_2(S\text{-}^tBu)_2(CO)_2],$$
(III)

which was fully characterized by NMR spectroscopy (^1H, ^{31}P, ^{13}C) and by X-ray structural determination (Fig. 1).

The solid state structure of **III** shows a classical pseudo-tetrahedral arrangement around zirconium (C(11)ZrC(12) = 97.0°) and a classical square-planar coordination geometry around the rhodium atoms, with d(Rh—Rh) = 3.043 Å. This is to be opposed to the analogous system previously reported, $(C_5H_5)_2Zr(CH_2PPh_2)_2[Rh_2(S\text{-}^tBu)_2(CO)_2]$ (**III'**),[4] where the zirconium atom was pentacoordinated (C(11)ZrC(12) = 134.3°) due to interaction with the lone pair of one of the sulphur atoms (Fig. 2).

The catalytic activity in the hydroformylation of 1-hexene of both **III** and **III'** systems has been examined under identical experimental conditions

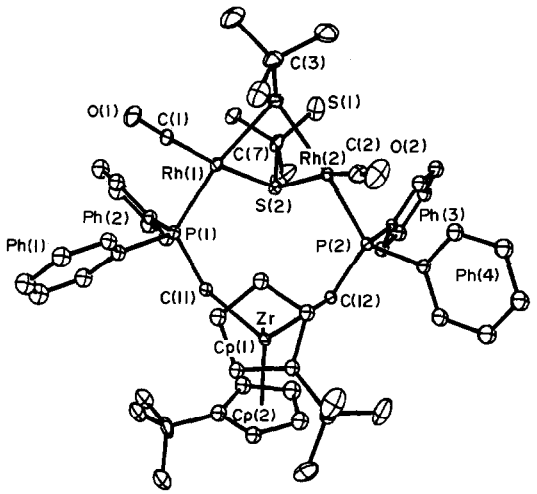

Fig. 1. An ORTEP drawing of $(C_5H_4CMe_3)_2Zr(CH_2PPh_2)_2[Rh_2(CO)_2(S\text{-}^tBu)_2]$ (**III**).

* Author to whom correspondence should be addressed.

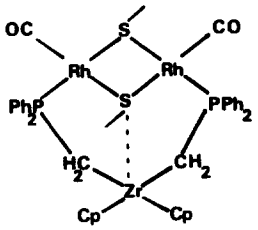

Fig. 2.

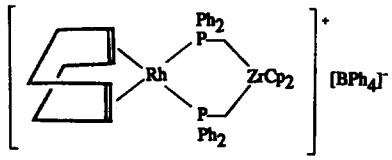

Fig. 4.

(Fig. 3). The catalytic performances are similar (conversion of 1-hexene is nearly quantitative within 2 h and ratio = [heptanal]/[methylhexanal] = 1.9). This may suggest that the donating 'Bu substituent on the cyclopentadienyl groups in **III** counterbalances the donating effect of the sulphur atom on the zirconium centre in **III'** which finally gives the same catalytic results.

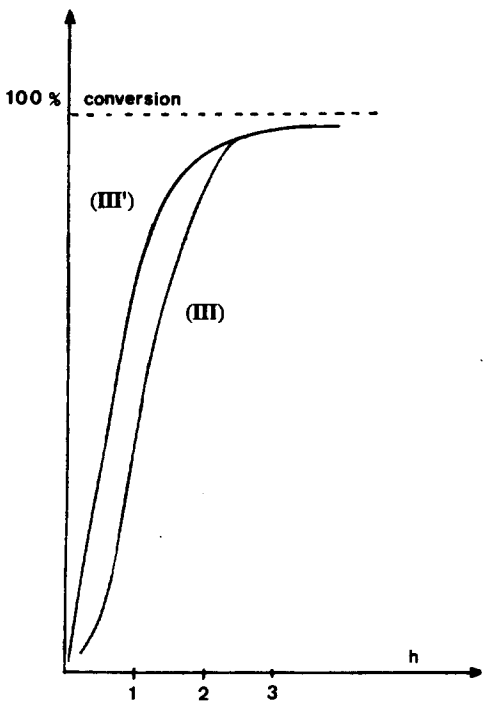

Fig. 3. Hydroformylation of 1-hexene using **III** and **III'** vs time. Conditions: *T*, 80°C; *P*, 20 Bar (1:1 H_2–CO mixture); [1-Hexene]/[Catalyst] = 400; solvent, THF.

Treatment of $Rh(COD)(PPh_3)_2BPh_4$ (**IV**) with **I** led to the crystalline heterobimetallic complex $[(C_5H_4CMe_3)_2Zr(CH_2PPh_2)_2Rh(COD)]^+$ (**V**), fully characterized by NMR spectroscopy (^1H, ^{31}P, ^{13}C). The *cis* position of COD on the rhodium centre forced the *cis* chelation in **V** (Fig. 4) as in **V'**, the homologous complex with regular cyclopentadienyl.[5]

In these cationic systems, in contrast with the non-ionic species previously studied, no improvement of the catalytic performances in the hydroformylation reaction is noted when a zirconium-containing phosphine is added on the rhodium complex.

NEW APPROACHES TO PREPARING HETEROBINUCLEAR μ-SULPHIDO COMPLEXES: MODELS FOR STEPS IN HYDRODESULPHURIZATION PROCESSES

P. M. BOORMAN,* J. F. FAIT and G. K. W. FREEMAN

Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4

Abstract—In an attempt to mimic the possible reactions of M—H groups with organosulphur molecules on the surface of hydrodesulphurization catalysts, early transition metal hydrido complexes have been shown to react with thiolato complexes of molybdenum(IV) to eliminate an alkane. The reaction of Cp_2NbH_3 with $Mo(^tBuS)_4$, for example, produces isobutane and a mixture of sulphido-bridged heterobimetallic complexes. The crystal structure of one of these, $Cp_2Nb(\mu\text{-}S)_2Mo(\mu\text{-}S)_2NbCp_2$, confirms that the above type of reaction can generate new cluster molecules.

Reactions in which transition metal centres activate carbon–sulphur bonds are of relevance to the catalytic hydrodesulphurization of fossil fuels.[1] The activation of hydrogen on the surface of the metal sulphide catalysts is now believed to occur via the heterolytic cleavage of the H_2 bond, yielding two types of hydrogen species on the surface, namely protonic —SH and hydridic M—H groups. The activity of the —SH groups has received considerable attention, but the role of the M—H groups has been less studied.[2]

We have been studying systems in which the elimination of an alkane from hydrido(thiolato) or hydrido(thioether) complexes might occur from either one or two metal centres, as per the following equations:

$$H—M—SR \longrightarrow M{=}S + RH \qquad (1a)$$

$$H—M—SR_2 \longrightarrow M—SR + RH \qquad (1b)$$

$$M'—H + M—SR \longrightarrow M{=}S + RH + [M'] \longrightarrow M—S—M' \qquad (2a)$$

$$M'—H + M—SR_2 \longrightarrow M—SR + RH + [M'] \longrightarrow M—(SR)—M'. \qquad (2b)$$

In an earlier paper[3] we reported reactions of type (1b) and we have subsequently turned our attention to the hydride/thiolate reactions. The difficulty of preparing hydrido(thiolato) complexes is well documented,[4] and reactions of type (1a) have been difficult to observe. The twin objectives of activating the C—S bond and having a hydridic M—H group on the same metal centre are, in practice, incompatible and hence we have begun a programme to study heterobimetallic systems which could allow distinct sites for hydride generation and C—S bond activation.[5]

The reaction between the early transition metal hydride Cp_2ZrH_2[6] and $Mo(S^tBu)_4$[7] proceeds via the desired pathway, yielding ^tBuH (isobutane) and an insoluble material containing sulphide ligands. Definitive proof of the hydride's involvement in the production of the isobutane was obtained by using Cp_2ZrD_2, which produced ^tBuD upon reaction with $Mo(^tBuS)_4$. The reaction of Cp_2NbH_3[8] with $Mo(S^tBu)_4$ yields similar results, generating isobutane and an unstable bimetallic species whose ^1H NMR spectrum is consistent with that expected for the compound $Cp_2Nb(\mu\text{-}S)_3Mo(S^tBu)$. Although this species has not been isolated in a crystalline form, from the reaction solution we obtained crystals of the new trinuclear complex, $Cp_2Nb(\mu\text{-}S)_2Mo(\mu\text{-}S)_2NbCp_2$ (**1**). This compound is obtained in relatively low yield and another, polymeric, sulphido-bridged species is also produced. The precise decomposition pathway by which **1** arises from the initial reaction product is not yet known. The structure of **1** is shown in Fig. 1. The (formally) niobium(III) centres might be expected to form metal–metal bonds to the molybdenum(VI) atom. The observed Nb—Mo distances (2.995(9) Å) and the angles subtended at the bridging sulphurs (av. = 79.0(2)°) suggest a weak metal–metal interaction.[9] This compound is intrinsically interesting

in its own right, but more important in the present context, it confirms that the synthetic objective of this work has been realized. The interaction between a strongly hydridic metal hydride and the activated carbon–sulphur bond of a coordinated thiolate has been demonstrated to proceed with C—S bond cleavage, thus illustrating one of the fundamental steps in the HDS process.[1]

The availability of suitable terminal metal thiolate complexes is very limited and hence we proceeded to examine another of the Otsuka[10] molybdenum thiolates, *cis*-$Mo(S^tBu)_2(^tBuNC)_4$. This complex was expected to give more soluble binuclear products, should its thiolates be sufficiently activated to react with hydrido complexes. The following, slow, reaction was observed over a 72 h period:

$$Cp_2NbH_3 + \textit{cis}\text{-}Mo(S^tBu)_2(^tBuNC)_4 \longrightarrow Cp_2Nb(H)(\mu\text{-}S)_2Mo(^tBuNC)_4 + 2\,^tBuH.$$

The possible synthetic value of this type of reaction for making polynuclear sulphido complexes is an obvious secondary benefit of this work. To date, however, we have been unsuccessful in promoting the cleavage of any aryl–sulphur bonds. The additional strength of the C—S bonds in these systems has been noted previously to lead to different reactivity in metal thiolate complexes.[11]

The choice of the metal, as well as its oxidation state, is critically important for both the hydride and the thiolate complex. Thus, for example, the nickel(II) complexes such as [Ni(diphos)(SCH_2CH_2S)] are unreactive towards Cp_2ZrH_2. Similarly, late transition metal hydrides have not been observed to effect cleavage of the S—C bonds in $Mo(S^tBu)_4$. These observations support our earlier hypothesis about factors which control the reactivity of metal thiolates.

EXPERIMENTAL

(1) *Reaction between* Cp_2ZrH_2 *and* $Mo(S^tBu)_4$

A benzene solution of $Mo(S^tBu)_4$ was added to a stirred suspension of the Cp_2ZrH_2 (or Cp_2ZrD_2) in benzene (approx. 1 : 1 molar ratio). Immediate darkening of the solution occurred, accompanied by precipitation of a fine brown precipitate. The insolubility of the precipitate precluded its recrystallization or complete spectroscopic characterization. By carrying out the same reaction in C_6D_6 in

a sealed NMR tube, we were able to confirm the production of isobutane (^{t}BuH and ^{t}BuD), indicating the successful demonstration of the feasibility of the target reaction. ^{1}H NMR, (C_6D_6)^{t}BuH, 0.907 ppm (d, $J = 6.61$ Hz); ^{t}BuD, 0.90 ppm (t, $J = 1.92$ Hz).

(2) *Reaction between* Cp_2NbH_3 *and* $Mo(S^tBu)_4$

The Cp_2NbH_3 reagent has the advantage of being soluble in benzene, hence reaction control and product separation were expected to be easier than for Cp_2ZrH_2, which is polymeric. A 1:1 reaction between Cp_2NbH_3 and $MO(S^tBu)_4$ in benzene appeared to be complete within 1 h, yielding a red–brown precipitate and a dark brown solution. Collection of the precipitate followed by extraction with $CHCl_3$ gave a green–brown solution, from which crystals of $[(Cp_2Nb)_2MoS_4]$ (**1**) were obtained. The residue, after this extraction was completed, was analysed for carbon and hydrogen, and from the *ca* 1:1 ratio obtained appeared to contain only Cp as the organic fragment. Its total insolubility suggested a polymeric sulphido-bridged species.

The dark brown supernatant reaction solution yielded a solid product when treated with hexane, whose elemental analyses and ^{1}H NMR spectrum were consistent with its formulation as $Cp_2Nb(\mu\text{-}S)_3Mo(S^tBu)$. Found: C, 32.70; H, 3.87. Calc: C, 33.33; H, 3.80%. ^{1}H NMR ($CDCl_3$): 1.54 (s, 9H), 5.50 ppm (s, 10H). The instability of this compound in solution suggests that it is the precursor to the μ-sulphido species which precipitate out of solution over a period of time.

(3) *Reaction between* Cp_2NbH_3 *and* $Mo(S^tBuNC)_4$

A benzene solution of Cp_2NbH_3 was added to solution of *cis*-$Mo(S^tBu)_2(^t BuNC)_4$ in the same solvent (1:1). A slow colour change from green to red–brown over *ca* 72 h was accompanied by the precipitation of a red crystalline product. This product is believed to be $Cp_2Nb(H)(\mu\text{-}S)_2Mo(^t BuNC)_4$, the hydride being implied by three inequivalent resonances for coordinated ^{t}BuNC ligands. ^{1}H NMR ($CDCl_3$): 5.68 (s, 10H), 1.64 (s, 9H), 1.63 (s, 9H), 1.38 ppm (s, 18H). Isobutane was observed to be produced in this reaction, as before.

(4) *Crystal structure of* $[(Cp_2Nb)_2MoS_4]\cdot CHCl_3$ (**1**)

A crystal of **1** was mounted on a glass fibre and coated with epoxy resin. Crystal data: $C_{21}H_{21}Cl_3S_4MoNb_2$, $M = 789.75$, orthorhombic, space group $P2_12_12_1$, $a = 11.895(2)$, $b = 12.002(2)$, $c = 18.855(4)$ Å, $V = 2695.614$ Å^3, $D_{calc} = 1.946$ g cm^{-3}, $Z = 4$, λ(Mo-K_α radiation, graphite monochromator) = 0.71069 Å, $2\theta_{max} = 60°$, total number of reflections measured = 8348, number of unique reflections, $[I > 2\sigma(I)] = 4020$, number of variables = 280, $R = 0.043$, $R_w = 0.035$.

SOLID SOLUTION FORMATION IN ALUMINA–CHROME REFRACTORIES

T. J. DAVIES,* H. G. EMBLEM, C. S. NWOBODO, A. A. OGWU and V. TSANTZALOU

Manchester Materials Science Centre, University of Manchester/UMIST, Manchester, U.K.

Abstract—Preparative procedures, densification, grain growth and change in corundum lattice dimensions in sintered compacts made from chromium(III)oxide/aluminium(III) oxide mixtures were evaluated in a study of alumina–chrome refractories. High energy milling using A-17 "reactive" alumina gave densification at low temperature and the most rapid grain growth, also (by Weibull analysis) the least variability in modulus of rupture, 7% W/W chromium(III)oxide giving minimum strength. XRD confirmed solid solution formation, the corundum lattice dimensions contracting with 7% W/W chromium(III)oxide, other compositions giving lattice expansion. The modulus of rupture at 1150°C for a series of ethyl–silicate-bonded alumina refractories containing 5–12% W/W chromium(III)oxide and fired at 1700°C was also a minimum at 7% W/W chromium(III)oxide.

Resistance to thermal shock and reduction of slag attack can both be achieved by incorporating chromium(III)oxide in alumina or mullite bodies. Examples are the addition of fine chrome to coarse alumina or mullite to reduce slag attack[1] and mullite–chrome systems[2] in which an iron–chromite ore is the source of chrome. Incorporating fine chromium(III)oxide into ethyl–silicate-bonded refractories[3] reduces slag attack and improves resistance to thermal shock. In the present work, preparative procedures, densification, grain growth and change of corundum lattice dimensions in sintered compacts, made from chromium(III)oxide/aluminium(III)oxide mixtures, were evaluated in a study of alumina–chrome refractories.[4–6]

The aluminium(III)oxide materials were MA95 (BA Chemicals Ltd, average particle size 4 μ angular) and A17 "reactive" alumina (Alcoa, average particle size 2μ, round). The chromium(III)oxide (British Chrome and Chemicals Ltd) had an average particle size of 0.4 μ. Materials containing 3, 7 or 14 wt% chromium(III)oxide were prepared by ball-milling, high energy milling, or grinding in a tungsten carbide mill. These mixtures were compacted at 97.5, 120 or 310 MPa and sintered for various times at 1600, 1650 or 1700°C. XRD measurements were used to evaluate changes in the corundum lattice dimensions.

For both aluminium(III)oxide materials, better blending was obtained with increasing chromium(III)oxide content, the highest "green" density being observed with 14 wt% chromium(III) oxide, because the fine chromium(III)oxide particles fill the spaces between the aluminium(III) oxide particles. As expected, high compaction pressure gave high green density. The microstructure observed in the sintered compact depends on (i) composition, (ii) the milling process, (iii) sintering temperature and (iv) sintering time. At a short sintering time, the method of mixing is not important. High energy milling using A17 "reactive" material gave densification at low temperatures and the most rapid grain growth during sintering. For MA95 material the milling process is important, probably because this material has a larger primary particle size. In general, this material gives sintered compacts with lower density.

XRD studies of compacts prepared from A17 "reactive" material with 14 wt% chromium(III) oxide, sintered at 1600°C for 0.5 h, show them to contain free chromium(III)oxide. Other sintered compacts do not contain free chromium(III)oxide. The corundum peak width increases as the chromium(III)oxide content increases. The corundum lattice parameters, a and c, for sintered compacts

* Author to whom correspondence should be addressed.

containing 3 or 14 wt% chromium(III)oxide, increase by 0.02–0.45%, depending on the sintering temperature and the sintering time. However, for sintered compacts containing 7 wt% chromium (III)oxide the parameters decrease, especially in compacts fired at 1650°C, where the *a* parameter decreases by 2.13%. Compacts prepared from MA95 material behave similarly. The results confirm the formation of a chromium(III)oxide/aluminium(III)oxide solid solution. Compacts prepared with MA95 material lose chromium on sintering at high temperature for long periods, suggesting that chromium volatilization is faster than solid solution formation, which would be expected because of the large primary particle size of the MA95 material.

The modulus of rupture of sintered compacts was determined at ambient temperature (three point loading; Instron testing machine). Weibull analysis[7] showed that compacts prepared from high energy milled materials had the highest Weibull modulus (*ca* 17), hence the least variability in strength. Weibull modulus values of 5–20 are common for ceramic materials,[8] the higher values indicating less strength variability. A typical value for the modulus of rupture of a compact prepared from material high energy milled and sintered at 1650°C for 5 h would be 205 MPa.

The modulus of rupture of a series of ethyl–silicate-bonded alumina refractories prepared[9] from coarse alumina grain, and a "fines" fraction comprising fine aluminium(III)oxide plus fine chromium(III)oxide, was determined at 1150°C. The refractories contained from 5 to 12 wt% chromium(III)oxide and were fired at 1700°C prior to determining the modulus of rupture, which was a minimum at 7 wt% chromium(III)oxide. The occurrence of the minimum strength at this level of chromium(III)oxide coincides with the change in aluminium(III)oxide lattice parameters found in aluminium(III)oxide/chromium(III)oxide compositions containing 7 wt% chromium(III)oxide. This change would alter the elasticity of the refractory body, which could reduce the modulus of rupture.

NEW EARLY TRANSITION METAL COMPLEXES STABILIZED BY TERDENTATE ANIONIC P-BLOCK DONOR LIGANDS

A. A. DANOPOULOS, P. G. EDWARDS,* J. S. PARRY and A. R. WILLS

School of Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, Wales, U.K.

Abstract—A wide range of new classes of early transition metal and actinide compounds have been isolated with the new amido and phosphido ligands $^{-}E(CH_2CH_2E'R_2)_2$ (where R = alkyl; E = N, E′ = N, P, As and E = P, E′ = P). Structural and chemical properties of metal derivatives are seen to be sensitive to variations in the ligands. Dependent on the nature of the donors, monomeric complexes with pendant bases may be obtained. These may be used as precursors for the preparation of homo- and heterobimetallic compounds.

Our recent studies[1] of complexes with chelating terdentate amido ligands {of the type $HE(CH_2CH_2E'R_2)_2$ (**1**), where E = N, E′ = N, R = Et, **1** = NNN} have shown the potential of these systems to stabilize unusual ternary amido–halide and organometallic compounds. Since partial substitution of halide ligands on metal centres is possible with this amine, without the common event of redistribution to binary amido complexes[2] that occurs with other amido• ligands, we now have potential access to classes of tractable derivatives previously rare or unattainable. In view of this we have exended our study to applications of new terdentate amidophosphine (**1** = PNP, E = N, E′ = P, R = Me, Et, ^{i}Pr) and amidoarsine (**1** = ANA, E = N, E′ = As, R = Me, Et) ligands. To our knowledge, the only similar ligand system that has been used for the stabilization of transition metal amido complexes (for metals in groups IV and VII) is the series $(R_2PCH_2Si(Me)_2)_2NH$ (R = alkyl or aryl).[3]

With PNP ligands, vanadium(III) appears to behave as it does with NNN ligands. Interaction of $Cl_3V \cdot 3THF$ with $LiN(CH_2CH_2PMe_2)_2$ in THF enables the isolation of the purple crystalline $Cl_2VN(CH_2CH_2PMe_2)_2$ (**2**). An identical material may be isolated from $VCl_3(NMe_3)_2$ by a similar procedure. Attempts to obtain crystals suitable for X-ray crystallography have so far been unsuccessful. It is likely, however, that the stereochemistry about vanadium is similar to that in the analogous amine complex $Cl_2VN(CH_2CH_2NEt_2)_2$,[1a] where the three anionic donors occupy the equatorial sites of a distorted trigonal bipyramid, with the neutral donors in the apical positions.

Compound **2** may be readily converted to organometallic derivatives by the action of organolithium reagents. Thus with methyl lithium, an oil, $Me_2VN(CH_2CH_2PMe_2)_2$ (**3**), may be obtained from petroleum ether. The compound decomposes upon attempted distillation and is very soluble in apolar solvents. With aryl lithium reagents, **2** provides the similar diarylvanadium amides, $Ar_2VN(CH_2CH_2PMe_2)_2$ [Ar = Ph (**4**), 2-$CH_3C_6H_4$ (**5**)]. Compounds **4** and **5** are both readily prepared from **2** in THF and both may be obtained as emerald green crystals in good yield from petroleum ether. Attempts to obtain X-ray crystallographic data have so far failed. The compounds are very air-sensitive, especially in solution, becoming brown and eventually yellowish, presumably due to oxidation to vanadium(V) species. As well as by analytical data,† **4** and **5** are additionally identified by IR spectra that show characteristic aryl absorbancies.

For zirconium(IV), the behaviour with PNP ligands differs from that with NNN ligands. For the latter, the only well-characterized amido halide is $(NNN)ZrCl_3$,[1] whereas with the PNP phosphines (**1**, R = Me, Et and ^{i}Pr), compounds formulated as

* Author to whom correspondence should be addressed.

† All new complexes reported here provide satisfactory elemental analyses.

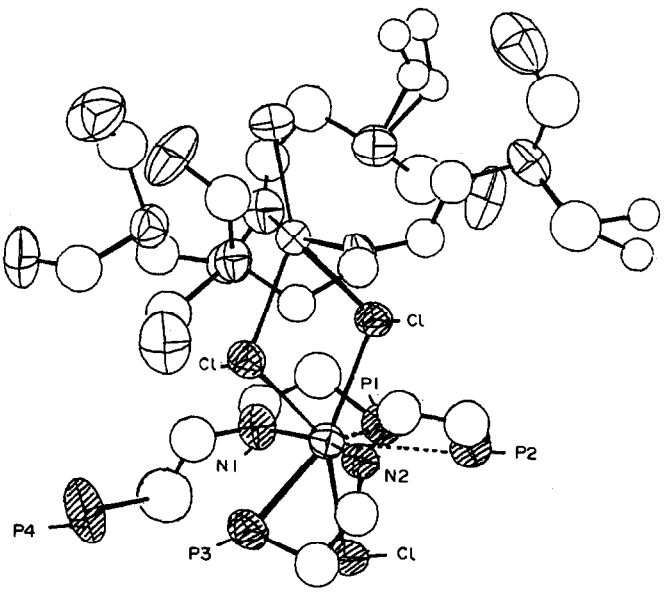

Fig. 1. The structure of $\{[(Et_2PCH_2CH_2)_2N]_2UCl_2\}_2$.

$(PNP)_2ZrCl_2$ (**6**) are the only isolable species. In each case these complexes contain pendant tertiary phosphine donors (by variable temperature ^{31}P NMR). Exchange between free and coordinated phosphine is rapid at room temperature for compounds **5**, where R = Me, Et, and is slow for **6**, where R = ^{i}Pr. With uranium(IV), the compound $[(PNP)_2UCl_2]$ (**7**, R = Et) shows similar behaviour (labile phosphines) and the X-ray crystal structure[4] (Fig. 1) confirms the presence of pendant phosphines in the solid state.

To date we have only a preliminary insight into the properties of ANA ligands. In general with vanadium(III), titanium(III) and zirconium(IV), the products are difficult to isolate. An exception is the well-characterized niobium(IV) dimer, $(ANANbCl_3)_2$ (**8**). This diamagnetic orange crystalline material is far more stable than any other derivatives of this ligand, has magnetically equivalent ligands (NMR) and preliminary X-ray crystallographic studies[5] (Fig. 2) reveal a symmetrical arrangement for the ligands with bridging nitrogen atoms. With NNN ligands under the same conditions, the monomeric, paramagnetic (d^1) $(NNN)_2NbCl_2$[1] is obtained; there is no evidence of a binuclear compound under any conditions.

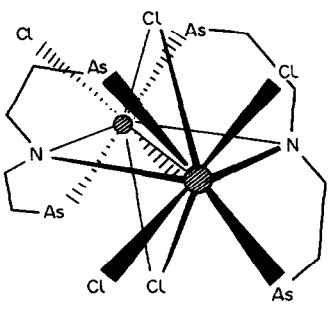

Fig. 2. The structure of $[(Me_2AsCH_2CH_2)_2NNbCl_3]_2$. For clarity, methyl groups have been omitted and ⌒ = —CH_2CH_2—.

As these studies have demonstrated that these ligands may provide compounds with pendant donors, potentially available for coordinating further metal ions and that they may support bimetallic compounds, we have extended this study to the phosphidophosphine ligands (**1** = PPP, E = P, E′ = P, R = Me, Et). As we know that zirconium provides PNP complexes with pendant phosphines, we have attempted the preparation of zirconium PPP complexes. Whereas NNN enables the isolation of only the "mono" ligand derivative and PNP provides only the "bis" ligand derivative despite variations in the stoichiometry of reagents, with PPP both yellow $(PPPZrCl_3)_2$ (**9**) and red $(PPP)_2ZrCl_2$ (**10**) may be prepared by control of stoichiometry and isolated as crystalline solids. The former compound **9** is a dimer (cryoscopy), has magnetically equivalent ligands with bridging phosphido atoms (^{31}P NMR) and is far more stable than **10**. The "bis" ligand derivative (**10**) has pendant phosphines (^{31}P NMR) and reacts with MCl_4 (M = Zr, Hf) and AlX_3 (X = Cl, Br) to give high yields of the 1:1 adducts, each of which contains bridging phosphides (^{31}P NMR).

COORDINATION OF THE MACROCYCLIC THIOETHER 1,4,7-TRITHIACYCLONONANE (TTCN) TO CHROMIUM(3+) AND TO DIMOLYBDENUM(2+) DI-ACETATO BRIDGED MOLECULES

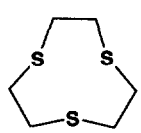
HEINZ-JOSEF KÜPPERS* and KARL WIEGHARDT

Ruhr-Universität Bochum, D4630 Bochum, F.R.G.

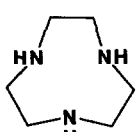
Abstract—Although chromium(III) is a hard acid and the macrocyclic thioether 1,4,7-trithiacyclonone (TTCN) a soft base, the following compounds could be synthesized: $[Cr(TTCN)Cl_3]$, $[Cr(TTCN)(SO_3CF_3)_3]$ and $[Cr(TTCN)_2]^{3+}$ (a rare example of a $Cr^{III}(thioether)_6$ coordination sphere). Comparison with the analogous 1,4,7-triazacyclononane (TACN) complexes shows that the bonding is relatively weak and the ligand-field splitting small. This is in contrast to the bonding properties of these ligands in "late" transition metals and results from the lack of π-donor capability of the Cr^{3+} centre. TTCN forms several dimeric di-acetato bridged complexes with the $(Mo_2)^{4+}$ unit. The unique interaction of steric and electronic effects of TTCN causes the unusual coordination of a tridentate ligand to the $[Mo_2(\mu\text{-}OAc)_2]^{2+}$ unit.

The coordination chemistry of the crown thioether 1,4,7-trithiacyclononane (TTCN) has been intensively investigated in the last few years. Although TTCN forms stable complexes with nearly every transition metal,[1] only a few examples of the coordination to early transition metals are known.[2]

We report here the reaction of TTCN with chromium(III) and with the $[Mo_2(\mu\text{-}OAc)_2]^{2+}$ unit.



TTCN



TACN

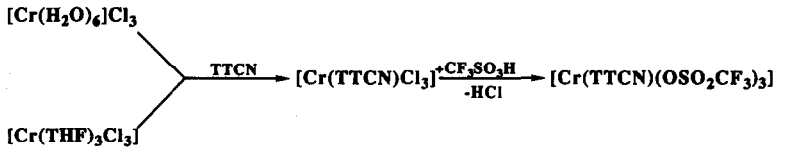
The strong coordination of TTCN to the "late" transition metals comes from both its steric (*endo*-conformation) and electronic properties (π-acceptor capability). The question arises, whether this soft base can coordinate to a hard acid such as Cr^{3+} (class A metal).

The reaction of $[Cr(H_2O)_6]Cl_3$ (in MeCN) or $[Cr(THF)_3Cl_3]$ (in dioxane) with TTCN yields $[Cr(TTCN)Cl_3]$. This blue–violet complex is inert and sparingly soluble in common solvents. Stirring in trifluoromethanesulphonic acid for some hours, at room temperature, results in the substitution of chloride by triflate to form blue–green $[Cr(TTCN)(SO_3CF_3)_3]$. The IR spectrum confirms monodentate coordination of triflate. In solution, solvent molecules such as CH_3CN, $(CH_3)_2CO$, DMF, THF replace the labile triflate ligands.

All attempts to synthesize the bis-TTCN—Cr^{3+} complex by the reaction of excess TTCN with Cr^{III} salts of $Cr(TTCN)X_3$ ($X = Cl^-$; $CF_3SO_3^-$; solvent) in solution, under various conditions, failed. Only the heating of a mixture of solid $[Cr(H_2O)_6](ClO_4)_3$ and solid TTCN results in the pink, very explosive $[Cr(TTCN)_2](ClO_4)_3$, which decomposes in a few seconds in solution. All compounds gave suitable elemental analyses and IR spectra. The magnetic moments of $\mu_{eff} = 4.1$ BM ($[Cr(TTCN)Cl_3]$) and $\mu_{eff} = 3.9$ BM ($[Cr(TTCN)(SO_3CF_3)_3]$) are in the normal range of octahedral Cr^{3+} compounds.

The electronic spectra allow the discussion of the binding properties in these compounds. For octahedral chromium(III) complexes one expects three bands which correspond to the transitions $^4A_{2g} \rightarrow {}^4T_{2g}(\nu_1)$, $^4A_{2g} \rightarrow {}^4T_{1g}(F)(\nu_2)$ and $^4A_{2g} \rightarrow {}^4T_{1g}(P)(\nu_3)$. In most cases ν_3 is obscured by charge-transfer bands. From the spectra the ligand-field splitting, $10Dq$, can be calculated. The data for the Cr—TTCN complexes and some other Cr^{3+} compounds are summarized in Table 1.

* Author to whom correspondence should be addressed.



Scheme 1.

Substitution of three Cl^- by TTCN increases $10Dq$ only slightly. Further substitution of Cl^- by a second TTCN molecule does not affect $10Dq$. This can be explained by the loss of charge neutralization, which leads to an increasing positive charge at the chromium centre. This in turn, effects a contraction of the chromium *d*-orbitals and, therefore, decreases their interaction with the ligand orbitals.[8]

The value of $10Dq$ also does not change if one TTCN is replaced by three dimethylsulphide or tetrahydrothiophene ligands. In addition, the open chain ligand $S(CH_2)_3SCH_3$ causes a larger ligand-field splitting than TTCN. Accordingly, the macrocyclic nature of TTCN does not enhance the apparent ligand-field strength (cf. $[Ni(TTCN)_2]^{2+}$). The ring size and the rigidity of the TTCN-macrocycle obviously does not allow optimal interaction between the thioether donor atoms and the relatively large Cr^{3+} centre.

The two pairs, $[Cr(TTCN)_2]^{3+}/[Cr(TACN)_2]^{3+}$ and $[Cr(TTCN)(SO_3CF_3)_3]/[Cr(TACN)(SO_3CF_3)_3]$ (which was synthesized by the reaction of $[Cr(TACN)(Br)_3]$[9] with trifluoromethanesulphonic acid), allow a comparison of the different effect of TTCN and TACN (TACN = 1,4,7-triazacyclononane). Therefore TTCN generates a smaller ligand-field splitting than does TACN for Cr^{3+}; for Fe^{2+}, Co^{3+} or Ni^{2+} the opposite is true.[1a]

The data can be summarized in the following spectrochemical series: $Cl^- < S(CH_3)_2$, TTCN, THT, THF $< H_2O < NH_3 <$ TACN.

In case of Cr^{3+} coordination, TTCN binds weakly. Although the ring size and the rigidity do not allow optimal interaction between the Cr^{3+} and the ligand orbitals, $[Cr(TTCN)_2]^{3+}$ is a rare case of $Cr^{III}(thioether)_6$ coordination. The great difference in the bonding properties of TTCN of chromium(III) and "late" transition metals seems to be the lacking of *p*-donor capability of the metal centre.

Another interesting reaction of TTCN with an early transition metal is the reaction of TTCN with the dimeric molybdenum(II) unit, $[Mo_2(\mu\text{-}OAc)_2]^{2+}$. The chemistry of $(Mo_2)^{4+}$ has been intensively studied in the last 25 years. However, only a few compounds with tridentate coordinated ligand are known.[10] Is TTCN with its unique characteristics[1,2] able to form such a class of coordination compounds?

In 1986, Garner and Clegg described the synthesis of $[(CH_3CN)_3Mo(\mu\text{-}OAc)_2Mo(CH_3CN)_3](BF_4)_2$ (**1**) [see Fig. 1(a)] from $[Mo_2(\mu\text{-}OAc)_4]$ with Me_3OBF_4.[11] This compound proved to be an ideal starting material for the synthesis of several dimeric Mo^{II}—TTCN complexes.

Stirring of **1** with excess TTCN for 12 h at room temperature, in MeCN, leads to the red–violet

THT: tetrahydrothiophene.

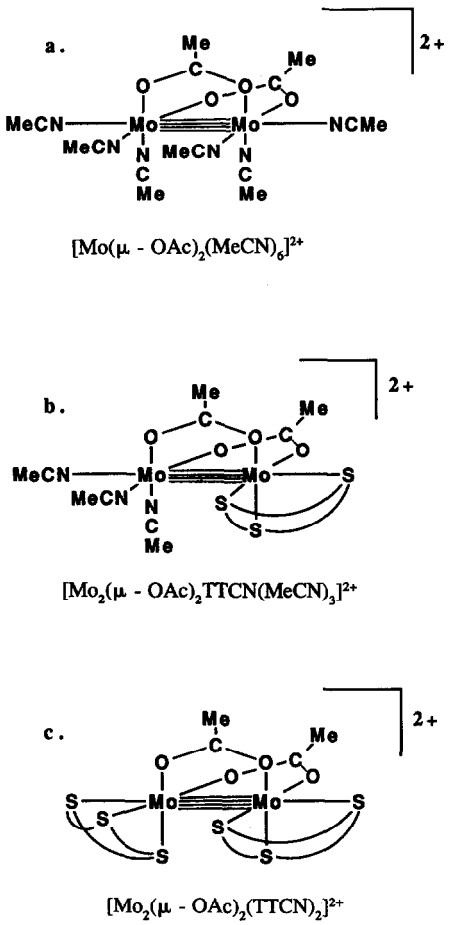

Fig. 1. The structures (b) and (c) are proposed, while (a) has been proved by X-ray analysis.[11]

$[(TTCN)Mo(\mu\text{-}OAc)_2Mo(CH_3CN)_3](BF_4)_2$ (**2**) [see Fig. 1(b)]. Substitution of the last MeCN ligands requires refluxing of **2** in CH_2CCl_2 with excess TTCN. This procedure forms the blue–violet $[(TTCN)Mo(\mu\text{-}OAc)_2Mo(TTCN)](BF_4)_2$ (**3**) [see Fig. 1(c)]. Compound **2** reacts in aqueous solution with KX to form the blue $[(TTCN)Mo(\mu\text{-}OAc)_2Mo(X)_2]$ ($X = Cl^-, Br^-, SCN^-, OCN^-$) (**4**), (**5**), (**6**), (**7**), respectively. The IR spectra of these compounds prove the retention of the bridging $[Mo_2(\mu\text{-}OAc)_2]$ unit. Also, the elemental analyses and the electronic spectra further support this structural suggestion.

In electronic spectra a band at about 500 nm, corresponding to the transition $\delta \rightarrow \delta^*$ in $(Mo_2)^{4+}$ compounds, is expected. The data of these absorption bands are listed in Table 2.

A comparison of the absorption bands of $[Mo_2(\mu\text{-}OAc)_2(CH_3CN_3)_4]^{2+}$ and $[Mo_2(\mu\text{-}OAc)_2(CH_3CN_3)_6]^{2+}$ shows a shift to lower energy. The reason for this is probably the weakening of the metal–metal bond by the coordination of axial MeCN ligands. The bonding of a ligand *trans* to the Mo—Mo axis weakens the metal–metal σ-bonding and therefore increases the metal–metal distance, which causes a smaller overlapping of the π- and δ-orbitals. Substitution of the MeCN ligands by TTCN in **2** and **3** further weakens the metal–metal bonding because of the larger π-acceptor capability of the thioether donor atoms compared to the N-atoms of MeCN. Coordination of ligands with even larger π-acceptor capability, e.g. CO and NO, cleaves the metal–metal bond.[10]

In the solid state the compounds **2**–**7** are stable in air for several weeks. Dissolved in non-coordinating solvents, however, **3**, **6** and **7** rapidly react with air.

The $[Mo_2(\mu\text{-}OAc)_2(TTCN)]$ compounds are an example of the coordination of tridentate ligands to the $[Mo_2(\mu\text{-}OAc)_2]$ unit. This unusual coordination sphere further exemplifies the unique chelating ability of TTCN caused by the interaction of its steric and electronic properties.

Acknowledgements—One of us (H.J.K.) would like to thank Dr S. R. Cooper for helpful discussions and S. Stötzel for synthesizing compounds **4** and **7**.

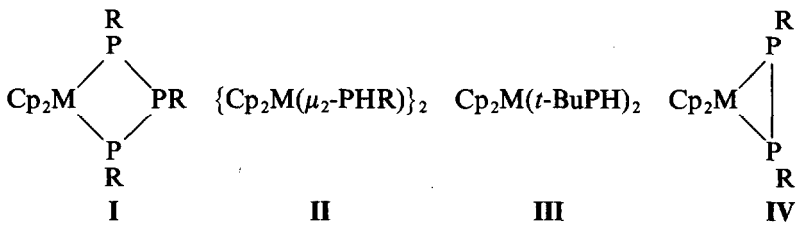
TRIPHOSPHANATO ($R_3P_3^{2-}$), PRIMARY PHOSPHIDO (RPH^-) AND DIPHOSPHANATO (DIPHOSPHENE) ($R_2P_2^{2-}$) COMPLEXES OF ZIRCONIUM AND HAFNIUM METALLOCENES

BRIAN L. BENAC and RICHARD A. JONES†

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712-1167, U.S.A.

Abstract—A variety of triphosphanato ($R_3P_3^{2-}$), primary phosphido (RPH^-) and diphosphanato (diphosphene) ($R_2P_2^{2-}$) derivatives of zirconium and hafnium (**I–IV**) have been prepared via reactions of primary phosphides LiPH(R) (R = Ph, *t*-Bu) with Cp_2MCl_2 (Cp = η^5-C_5H_5, C_5Me_5, $C_5H_3(SiMe_3)_2$). The products depend on the steric bulk of the P—R group and the Cp (or substituted Cp) group. When Cp = C_5H_5 or C_5Me_5 and R = Ph, triphosphanato complexes of type **I** are produced (E. Hey, S. G. Bott and J. L. Atwood, *Chem. Ber.* 1988, **121**, 561). When R = *t*-Bu, types **II** and **III** are also formed. For Cp = $C_5H_3(SiMe_3)_2$ diphosphanato complexes **IV** and the diphosphides **III** are formed.



There are several classes of diorganophosphide (R_2P^-) and related complexes of the group 4 metals. Homoleptic complexes such as [Li(DME)][Hf(PCy_2)$_5$] (Cy = *c*-C_6H_{11}) were reported by Baker *et al.*[1] In addition, Bercaw and co-workers have described complexes of mono-pentamethylcyclopentadienyl (Cp*) hafnium such as Cp*HfCl{P(CMe_3)$_2$}$_2$.[2] The largest class of group 4 metal phosphides is comprised of dicyclopentadienyl derivatives of the type $Cp_2M(PRR')_2$ (Cp = C_5H_5; M = Zr, Hf; R, R′ = alkyl, aryl, $SiMe_3$).[3]

The $Cp_2M(PR_2)_2$ compounds have been used primarily as diphosphine ligands in heterobimetallic complexes such as $Cp_2Hf(\mu\text{-}PEt_2)_2Ni(CO)_2$,[4] $Cp_2Zr(\mu\text{-}PEt_2)_2Rh(\eta\text{-indenyl})$[5] and $Cp_2Zr(\mu\text{-}P(C_6H_5)_2)_2Pt\{P(C_6H_5)_3\}$.[6] The heterobimetallics, $Cp_2M(\mu\text{-}PR_2)_2Mo(CO)_4$ (M = Ti, Zr), had been previously prepared by Johannsen and Stelzer[7] and were studied further by others.[8] The only reported primary phosphides of the group 4 metals are the heterobimetallics, $Cp_2M\{\mu\text{-}PH(C_6H_5)\}_2Mo(CO)_4$, made by Johannsen and Stelzer by treating Cp_2MCl_2 (M = Ti, Zr) with *cis*-$Mo(CO)_4(PhPHLi)_2$.[7] We chose to investigate the chemistry of primary phosphido (RPH^-) ligands, since these should possess an additional site of reactivity in the P—H bond which could lead to unusual new phosphinidene (RP^{2-}) complexes.

It has been known for some time that the reaction of Cp_2MCl_2 (Cp = C_5H_5; M = Zr, Hf) with LiPH(Ph) gives the triphosphanato metallocycles $Cp_2M[P(Ph)]_3$ (**Ia**: M = Zr; **Ib**: M = Hf).[9] Even treatment of $Cp_2Zr(CH_3)_2$ and $Cp_2Zr(CH_3)Cl$ with $PhPH_2$ gives only $Cp_2Zr[P(Ph)]_3$ (**Ia**) and no primary phosphido zirconium complexes.[9] These types of compounds **I** were previously made by the reaction of Cp_2MCl_2 with $K_2(PR)_n$ (M = Ti, Zr, Hf).[10]

In our hands, the reaction of Cp_2MCl_2 with LiPH(C_6H_5) also gives the triphosphanato complexes, **Ia** (Cp = C_5H_5; M = Zr; R = C_6H_5) and **Ib** (Cp = C_5H_5; M = Hf; R = C_6H_5). However,

the reaction of Cp_2ZrCl_2 with 2 equivalents of the bulkier primary phosphide, LiPH(*t*-Bu), in toluene–ether (70 : 30) at −78°C, results in formation not only of the previously characterized[10b] triphosphanato complex **Ic** (Cp = C_5H_5; M = Zr; R = *t*-Bu) in 15% yield, but also the reduced complex **II** (Cp = C_5H_5; M = Zr; R = *t*-Bu). Compound **II** may be isolated as red crystals in 50% yield after recrystallization from hexane and is very air-sensitive† in the solid-state and in solution. Compound **II** is diamagnetic like other Zr^{III} complexes[12] and NMR data are obtainable. (^{1}H and ^{31}P NMR data for **II** and all other new compounds reported are given in Tables 1 and 2 respectively.) The corresponding reaction of Cp_2HfCl_2[12] with 2

† Since most of all the new complexes were very air-sensitive, all manipulations were performed using either standard Schlenk line or dry-box techniques.

[a] C_6D_6 solutions, 30°C, 121.51 MHz. Referenced to external 85% H_3PO_4 ($\delta = 0.0$) with high field increasingly negative.

equivalents of LiPH(*t*-Bu) in toluene–THF (60 : 40) also yields the previously characterized[10b] triphosphanato complex **Id** (Cp = C_5H_5; M = Hf; R = *t*-Bu) in 15% yield and the new diphosphido complex **IIIa** (Cp = C_5H_5; M = Hf). Complex **IIIa** can be isolated in 60% yield as red, hexane-soluble, air-sensitive crystals from toluene at −30°C.

Utilizing the bis-pentamethylcyclopentadienyl metal dichlorides, $Cp^*_2ZrCl_2$[13] and $Cp^*_2HfCl_2$,[14] it was hoped that the steric effect of the pentamethylcyclopentadienyl groups would help to stabilize other primary phosphido compounds of zirconium and hafnium. However, reaction of the $Cp^*_2ZrCl_2$ with LiPH(Ph) in toluene–THF (60 : 40) at −78°C, yields upon crystallization from toluene at −30°C, the triphosphanato complex $Cp^*_2Zr\{P(C_6H_5)\}_3$ **(Ie)** in 27% yield. Similarly, for the reaction of $Cp^*_2HfCl_2$ with LiPH(Ph) in THF at room temperature, $Cp^*_2Hf\{P(C_6H_5)\}_3$ **(If)** is isolated in 19% yield from the reaction mixture after recrystallization from toluene at −30°C.

Both compounds **Ie** and **If** are red in solution and the ^1H NMR spectra for both complexes exhibit two distinctly different Cp* resonances. This is due to the orientation of the triphosphanato unit with respect to the Cp* groups. This type of inequivalence of the Cp groups has been extensively studied by Köpf and Voigtländer for the analogous Cp (Cp = C_5H_5) compound.[10b] Table 3 compares the ^{31}P data for the compounds **Ia**, **Ie**, **Ib** and **If**. The ^{31}P resonances for the phosphorus nuclei directly attached to the metal (P_A) for compounds **Ie** and **If** are at higher field than in the normal cyclopentadienyl analogues, compounds **Ia** and **Ib**. This shift to higher field is indicative of less phosphorus lone pair donation to the empty $1a_1$ orbital[15] at the metal centres. Also noticeable is that the resonances for the apical phosphorus nuclei (P_B) shift downfield by ~55 ppm. The other interesting fact from Table 3 is the reduced coupling constant between the phosphorus nuclei (P_A and P_B) in compounds **Ie** and **If** when compared to compounds **Ia** and **Ib**. Nonetheless, despite the steric effect of the pentamethylcyclopentadienyl groups, the driving force of the reaction is the formation of the triphosphanato metallocycle.†

Reaction of $CP^*_2ZrCl_2$ with 2 equivalents of LiPH(*t*-Bu) in toluene–ether (70 : 30) at room temperature for 4 h, affords purple $Cp^*_2Zr(t\text{-BuPH})_2$ **(IIIb)**. Complex **IIIb** can be isolated in 71% yield as purple blocks by crystallization from hexane at −30°C. Similarly, reaction of $Cp^*_2HfCl_2$ with 2 equivalents of LiPH(*t*-Bu) in THF for 2 days affords, after the appropriate work-up, red, crystalline $Cp^*_2Hf(t\text{-BuPH})_2$ **(IIIc)** in 63% yield. Both compounds **IIIb** and **IIIc** are highly air-sensitive in solution and the solid state. In addition, both of these compounds reductively eliminate the diphosphine, (*t*-Bu)PHPH(*t*-Bu), when treated with CO (3 atm) at room temperature in toluene solution, to form the dicarbonyls, $Cp^*_2M(CO)_2$.[17] This reaction demonstrates the weakness of the metal–phosphorus bonds in these complexes and the ease with which the metal centres are reduced.

The reaction of Cp''_2MCl_2[18] (Cp″ = $C_5H_3(SiMe_3)_2$) with 2 equivalents of LiPH(Ph) in toluene–THF (60 : 40) for 2 h, produces the orange crystalline $Cp''_2Zr[P(Ph)]_2$ **(IVa)** and green crystalline $Cp''_2Hf[P(Ph)]_2$ **(IVb)** diphosphanato (diphosphene) complexes in good yield (60–70%), after recrystallization from toluene at −30°C. The ^1H NMR signals at 25°C for **IVa** and **IVb** are very broad and make the assignment and integration of the resonances difficult. The $^{31}P\{^1H\}$ NMR signals for **IVa** and **IVb** are also very broad (**IVa**, $\Delta w_{1/2} = 37$ Hz; **IVb**, $\Delta w_{1/2} = 40$ Hz) at 25°C and indicate that there is some fluctionality of the diphosphanato metallocycle. In contrast to the triphosphanato metallocycles (**I**), complexes **IVa** and **IVb** are easily hydrolysed to $Cp''_2M(OH)_2$ and the *meso* and D,L isomers of diphenyldiphosphine.[19]

Reaction of Cp''_2ZrCl_2 with 2 equivalents of LiPH(*t*-Bu) in toluene at room temperature for 2 days yields, after work-up and crystallization from hexane at −30°C, the red microcrystalline diphos-

† The mechanisms for the formation of the triphosphanato metallacycle are not clear. Professor G. L. Hillhouse and co-workers have synthesized $Cp^*_2HfH(PHPh)$ from the reaction of $Cp^*_2HfH_2$ with $PhPH_2$ and $Cp^*_2Hf(I)(PHPh)$ from the reaction of $Cp^*_2HfI_2$ with LiPH(Ph).[16]

Table 3. ^{31}P data for $(C_5R_5)_2M[P(C_6H_5)]_3$ complexes[a]

Complex	R	M	P_A	P_B	J_{AB} (Hz)

phido compound $Cp''_2Zr(t\text{-BuPH})_2$ (**IIId**) in 11% yield and the red–orange diphosphanato complex $Cp''_2Zr[P(t\text{-Bu})]_2$ (**IVc**) in 48% yield. The $^{31}P\{^1H\}$ NMR resonance for **IVc** at δ 270.56 is much sharper ($\Delta w_{1/2} = 3$ Hz) than in the phenyl analogue **IVa**. The ^1H NMR for **IVc** is also sharper than for **IVa** and **IVb**, and hydrolysis of complex **IVc** yields mainly the D,L isomer of the diphosphine, (*t*-Bu)PHPH(*t*Bu), in addition to $Cp''_2Zr(OH)_2$. In contrast, reaction of Cp''_2HfCl_2 with 2 equivalents of LiPH(*t*-Bu) does not give a diphosphanato complex, but instead only the red diphosphido complex, $Cp''_2Hf(t\text{-BuPH})_2$ (**IIIe**), which is isolated in 55% yield after crystallization from hexane.

From these studies it is evident that the distribution of products depends upon three factors: (1) the metal used and the reducibility of that metal; (2) the steric and electronic nature of the cyclopentadienyl group utilized in stabilizing the complexes and (3) the bulk of the aryl or alkyl group on the phosphorus. In conclusion, primary phosphido complexes of the group 4 metallocenes can be stabilized given the correct conditions and these new complexes should provide a wealth of new and interesting chemistry. Further studies of these and related compounds are in progress.

DIAZENIDO, DINITROGEN AND TRIISOCYANIDE COMPLEXES OF RHENIUM(I) WITH PHOSPHITE OR PHOSPHONITE CO-LIGANDS

M. FERNANDA, N. N. CARVALHO and ARMANDO J. L. POMBEIRO*

Centro de Química Estrutural, Complexo I, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal

Abstract—Treatment of $[ReCl_2(NNCOPh)(PPh_3)_2]$ with $P(OMe)_3$, $PPh(OEt)_2$ or $PPh(OMe)_2$, in benzene and in the presence of hot methanol, leads to the formation of $[ReCl(N_2)(PPh_3)L_3]$ [L = $P(OMe)_3$ or $PPh(OEt)_2$] or $[ReCl(N_2)\{PPh(OMe)_2\}_4]$, whereas, without hot methanol, intermediate benzoyldiazenido species are obtained. The dinitrogen complexes react with isocyanides to afford $[ReCl(CNR)_3L_2]$ [R = Me, L = $PPh(OMe)_2$; R = C_6H_4Me-4, L = $P(OMe)_3$].

In contrast with the well-documented chemistry of rhenium phosphine complexes, that of phosphite or phosphonite compounds of this metal is relatively underdeveloped and, therefore, is explored in this study.

The chelating benzoyldiazenido complex, $[ReCl_2(NNCOPh)(PPh_3)_2]$, is a known suitable starting material for dinitrogen and benzoyldiazenido complexes of rhenium, commonly with phosphines as co-ligands, such as *trans*-$[ReCl(N_2)L_4]$ [L = PR_3 or $P(OMe)_3$],[1] *mer*-$[Re(\eta^2\text{-}S_2PPh_2)(N_2)(PMe_2Ph)_3]$[2] or $[ReCl_2(NNCOPh)L_3]$,[1–4] from which mono- and diisocyanide complexes, particularly *trans*-$[ReCl(CNR)L_4]$,[5] $[ReCl(N_2)(CNR)L_3]$ or $[Re(\eta^1\text{-}S_2PPh_2)(N_2)(CNR)_2(PMe_2Ph)_2]$,[6] are derived.

We extend now these studies to novel phosphite or phosphonite complexes with dinitrogen, diazenido or isocyanide ligands.

RESULTS AND DISCUSSION

$[ReCl_2(NNCOPh)(PPh_3)_2]$ reacts with a phosphite, $P(OMe)_3$, or a phosphonite, $PPh(OEt)_2$ or $PPh(OMe)_2$, in refluxing benzene, followed by addition of hot methanol, to give the dinitrogen complexes $[ReCl(N_2)(PPh_3)L_3]$ [L = $P(OMe)_3$ or $PPh(OEt)_2$] or $[ReCl(N_2)\{PPh(OMe)_2\}_4]$ (eqs (1) and (2), Scheme 1), isolated as yellow or light brown solids.

However, if the use of hot methanol is avoided, intermediate benzoyldiazenido complexes may be isolated, such as $[ReCl_2(NNCOPh)(PPh_3)_2\{PPh(OMe)_2\}]$ obtained from the reaction of that chelate with $PPh(OMe)_2$. These complexes can undergo NN—C bond cleavage upon nucleophilic attack by methanol, with heating, to give the final dinitrogen compounds, a step which is also involved in the above mentioned and more convenient single-pot synthesis of the dinitrogen complexes.

The IR spectra of the dinitrogen compounds exhibit $\nu(N_2)$ at values (2010–1985 cm^{-1} range) which, by comparison with those known for related compounds, appear to indicate that a phosphonite behaves as a considerably stronger net electron-donor than a related phosphite ligand.

In those complexes, the N_2 and the Cl ligands are believed to be *trans* to each other, thus corresponding to an arrangement which favours the stabilization of the Re—N_2 bond.

They react with isocyanides (added in excess), in THF and at room temperature, to give the triisocyanide complexes $[ReCl(CNR)_3L_2]$ {R = C_6H_4Me-4, L = $P(OMe)_3$ [eq. (3)]; R = Me, L = $PPh(OMe)_2$ [eq. (4)]}, isolated as reddish-brown or brown solids, possibly formed via intermediate mixed dinitrogen–isocyanide compounds of known types,[6] where the Re—N_2 bond (which is usually quite strong in neutral Re^I—N_2 complexes)[5] is labilized by the strong π-electron withdrawing ability of the CNR co-ligand.

Hence, the convenient application of dinitrogen compounds of rhenium to the syntheses of low-valent mono- and diisocyanide complexes with this metal has been extended to triisocyanide species.

SYNTHESIS OF $[Co(\eta^5\text{-}C_5H_5)_2][M(\eta^5\text{-}C_5H_5)Cl_3]$ SALTS (M = Ti OR V): CRYSTAL STRUCTURE OF $[Co(\eta^5\text{-}C_5H_5)_2][Ti(\eta^5\text{-}C_5H_5)Cl_3]$

D. L. HUGHES, M. JIMENEZ-TENORIO and G. J. LEIGH*

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—The salts, $[Co(\eta^5\text{-}C_5H_5)_2][M(\eta^5\text{-}C_5H_5)Cl_3]$ (M = Ti or V), are readily prepared from the reaction between $[Co(\eta^5\text{-}C_5H_5)_2]$ and $[M(\eta^5\text{-}C_5H_5)Cl_3]$ in dichloromethane. The crystal structure of $[Co(\eta^5\text{-}C_5H_5)_2][Ti(\eta^5\text{-}C_5H_5)Cl_3]$ shows well-defined $[Co(\eta^5\text{-}C_5H_5)_2]^+$ and $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$ moieties, despite the fact that the anion has been claimed to be unstable above 77 K. IR, NMR and EPR spectroscopic data are also discussed.

The literature suggests that $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$ is an unstable species which can be generated by ^{60}Co-γ irradiation of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$ in methyltetrahydrofuran. It was claimed to be only stable at 77 K, and upon annealing at some higher temperature it produces $[Ti(\eta^5\text{-}C_5H_5)Cl_2]$. Apparently, $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$ rapidly loses chloride to give dinuclear or solvated species.[1] Following a report[2] that $[Co(\eta^5\text{-}C_5H_5)_2]$ can reduce $[Ti(\eta^5\text{-}C_5H_4Me)Cl_3]$ to yield a stable paramagnetic product, characterized as $[Ti(\eta^5\text{-}C_5H_4Me)Cl_3]^-$, we have shown that $[M(\eta^5\text{-}C_5H_5)Cl_3]$ (M = Ti or V) and $[Co(\eta^5\text{-}C_5H_5)_2]$ react to give the corresponding salts, $[Co(\eta^5\text{-}C_5H_5)_2][M(\eta^5\text{-}C_5H_5)Cl_3]$. The vanadium salt is diamagnetic, but the titanium one is paramagnetic, giving an axial EPR spectrum with $g_\parallel = 1.743$ and $g_\perp = 1.973$, in good agreement with the reported data for the methylcyclopentadienyl derivatives, although at variance with the earlier report on the existence of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$.[1]

We find that, contrary to the earlier report, $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$ is very stable thermally both in the solid state and in solution. Dark green, single crystals of $[Co(\eta^5\text{-}C_5H_5)_2][Ti(\eta^5\text{-}C_5H_5)Cl_3]$ (monoclinic, space group $P2_1/a$, $a = 14.404(1)$, $b = 10.365(1)$, $c = 11.591(1)$ Å, $\beta = 108.256(7)°$ and $Z = 4$) were studied by X-ray crystallography. The structure contains discrete $Ti(\eta^5\text{-}C_5H_5)Cl_3$ and $Co(\eta^5\text{-}C_5H_5)_2$ moieties, separated by van der Waals contacts. The cobalt atom is sandwiched between parallel eclipsed cyclopentadienyl rings, with an average distance (Co—C_5H_5 ring) of 1.631(4) Å,

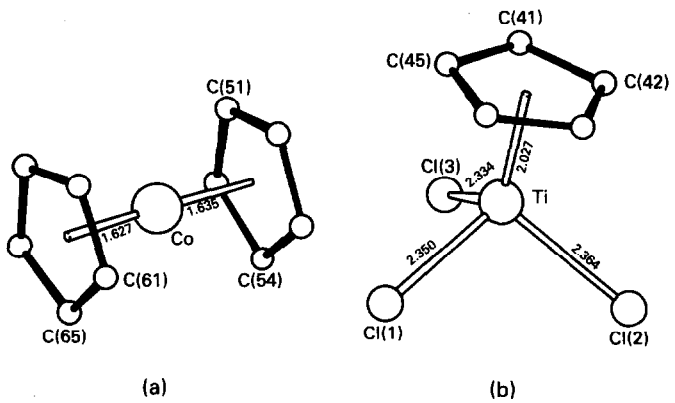

Fig. 1. Diagrammatic representation of the molecular structure of $[Co(C_5H_5)_2]^+$ (a) and $[Ti(C_5H_5)Cl_3]^-$ (b), showing selected bond lengths and atomic numbering.

shorter than the corresponding distance in cobaltocene, 1.726 Å, supporting the formulation as $[Co(\eta^5\text{-}C_5H_5)_2]^+$ rather than the neutral species. The $Ti(\eta^5\text{-}C_5H_5)Cl_3$ moiety has a three-legged piano-stool arrangement, as found for $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$, although all the bond distances are longer than in the titanium(IV) molecule, and fully consistent with our formulation as $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$.

The stability in solution of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]^-$ was checked by ^1H NMR spectroscopy. The spectrum of a 1 : 1 mixture of $[Co(C_5H_5)_2]$ and $[Ti(C_5H_5)Cl_3]$ shows a sharp singlet, intensity 10 H, for the cobaltacinium protons and a very broad signal centred at about 27.5 ppm, width of about 4 ppm, of the correct intensity for $[Ti(C_5H_5)Cl_3]^-$.

PREPARATION AND REACTIONS OF A BIS(PHENYLHYDRAZINE) COMPOUND OF VANADIUM(III)

G. JEFFERY LEIGH* and J. ROGER SANDERS

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—Complexes $[VX_2(salen)]$ (X = Cl, Br) are reduced by hydrazines to give either [VX(salen)(ROH)]ROH (R = Me, Et) or $[\{VX(salen)\}_2]$, depending on the solvent. Treatment of [VO(salen)] with I_2 in acetonitrile gives I_5^- or I_7^- salts of the $[\{V(salen)\}_2(\mu\text{-}O)]^+$ cation, which are reduced by diethylaluminium ethoxide in the presence of phenylhydrazine, to give $[V(PhNHNH_2)_2(salen)]I$.

Following the discoveries that vanadium can replace molybdenum in nitrogen-fixing enzymes[1] and that vanadium complexes can reduce dinitrogen to hydrazine in homogeneous protic media,[2] we have been attempting to make vanadium compounds containing partially reduced nitrogen species such as hydrazine. This report describes attempts to use tetradentate Schiff base ligands to bind to four sites on a penta- or hexa-coordinate vanadium atom, leaving sites free for hydrazine or similar ligands; accordingly, the starting materials were $[VX_2(salen)]$ (X = Cl or Br) [salen = N,N′-bis(salicylidene)ethylenediaminate(2−)] and $[VX_2(salophen)]$ [salophen = N,N′-bis(salicylidene) *o*-phenylenediaminate(2−)].

$[VX_2(salen)]$ complexes give [VX(salen)(ROH)] ROH (R = Me or Et) when treated with hydrazines in alcohols. Analyses do not distinguish between this structure and a vanadium(IV) structure containing an alkoxide ligand, but the magnetic moments and EPR spectra of these complexes show them to contain vanadium(III). Treatment of $[VX_2(salen)]$ with hydrazine, phenylhydrazine or silyl-substituted hydrazines in non-protic solvents gives $[\{VX(salen)\}_2]$. These compounds are halide-bridged dimers; the chloride has been prepared[3] from $[VCl_3(THF)]$ (THF = tetrahydrofuran) and Na_2salen. Salophen analogues of all the compounds described above have been made and characterized.

Unlike $[VCl_2(salen)]$ and [VBr(salen)], $[VI_2(salen)]$ is unknown. Treatment of [VO(salen)] with PPh_3I_2 (analogous to the bromide preparation) gives $[VI(OPPh_3)(salen)]I$. Treatment of [VO(salen)] with I_2 in acetonitrile gives dark blue needles, whose composition varies with the relative quantities of starting materials used. Equimolar quantities of [VO(salen)] and I_2 give $[\{V(salen)\}_2(\mu\text{-}O)](I_5)$ with an unsymmetrical oxo-bridged divanadium cation. The colour, elemental analysis, X-ray crystal analysis, magnetic moment and EPR spectrum of this compound are consistent with this structure; in its IR spectrum the band assigned to $\nu_{V=O}$ occurs at 880 cm^{-1} rather than 990 cm^{-1} as in [VO(salen)]. Use of an excess of I_2 in the preparation gives a product whose elemental analysis shows it to be $[\{V(salen)\}_2(\mu\text{-}O)](I_7)$. We have been unable to prepare salophen analogues.

Treatment of $[\{V(salen)\}_2(\mu\text{-}O)]^+$ salts with phenylhydrazine gives [VI(salen)(MeOH)]MeOH or $[\{VI(salen)\}_2]$, depending on the solvent; however, treatment of a suspension of $[\{V(salen)\}_2(\mu\text{-}O)]I_5$ in acetonitrile at 10°C, first with diethylaluminium ethoxide in toluene and then with phenylhydrazine gives $[V(PhNHNH_2)_2(salen)]I$ in good yield. Its magnetic moment and EPR spectrum are normal for a monomeric vanadium(III) compound, and a crystal structure shows that the cation has an octahedral geometry with the phenylhydrazine ligands bound *trans* to one another through the terminal nitrogen atoms (V—N distances, 21.7 nm, V—N—N angles, 111°).

Treatment of the dark blue V^{III}—V^{IV} dimer with trimethylsilyl(trimethyl)hydrazine in acetonitrile, gives $[V(NMeNMe_2)(salen)]I$; attempts to grow X-ray quality crystals of this compound have so far been unsuccessful.

THE INTERACTION OF NIOBIUM AND VANADIUM CYCLOPENTADIENYL COMPLEXES WITH SUBSTITUTED HYDRAZINES

M. JIMENEZ-TENORIO and G. J. LEIGH*

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—The hydrazido(1−) complexes $[V(\eta^5\text{-}C_5H_5)Cl_2(NRNR_2)]$ and $[Nb(\eta^5\text{-}C_5H_5)Cl_3(NRNR_2)]$ ($NRNR_2$ = $NMeNMe_2$ or $NPhNH_2$) were synthesized by reaction of $[V(\eta^5\text{-}C_5H_5)Cl_3]$ or $[Nb(\eta^5\text{-}C_5H_5)Cl_4]$ with either the lithium- or trimethylsilyl-substituted hydrazine. The interaction of $[V(\eta^5\text{-}C_5H_5)Cl_3]$ with diphos (diphos = dppe or dmpe) in Et_2O yields the adducts $[V(\eta^5\text{-}C_5H_5)Cl_3(diphos)]$. Complexes such as $[Nb(C_5H_5)(diphos)_2]$ and $[V(C_5H_5)Cl(diphos)]$ are the reaction products of the reduction under N_2 of $[Nb(\eta^5\text{-}C_5H_5)Cl_4]$ and $[V(\eta^5\text{-}C_5H_5)Cl_3]$, either with Na(Hg) or Mg in the presence of phosphines or diphosphines. No stable dinitrogen complexes were isolated.

The reaction of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$ with trimethylsilyl-substituted hydrazines allows the isolation of hydrazido(1−) complexes, $[Ti(\eta^5\text{-}C_5H_5)Cl_2(NRNR_2)]$ ($NRNR_2$ = $NMeNMe_2$, NH_2NPh, $NHNMe_2$, etc.), which exhibit side-on coordination of the hydrazine fragment.[1,2] We also prepared complexes containing ligands such as RNN^- or R_2NN^{2-}, which correspond to putative intermediates in the process of conversion of dinitrogen to ammonia and/or hydrazine.

The recent discovery of a vanadium-containing nitrogenase[3] prompted us to extend this work to vanadium, and also to niobium.

The starting material, $[V(\eta^5\text{-}C_5H_5)Cl_3]$, is not as easily accessible as $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$.[4] We eventually optimized a three step synthesis pattern for the preparation of $[V(\eta^5\text{-}C_5H_5)Cl_3]$ in reasonable yields.

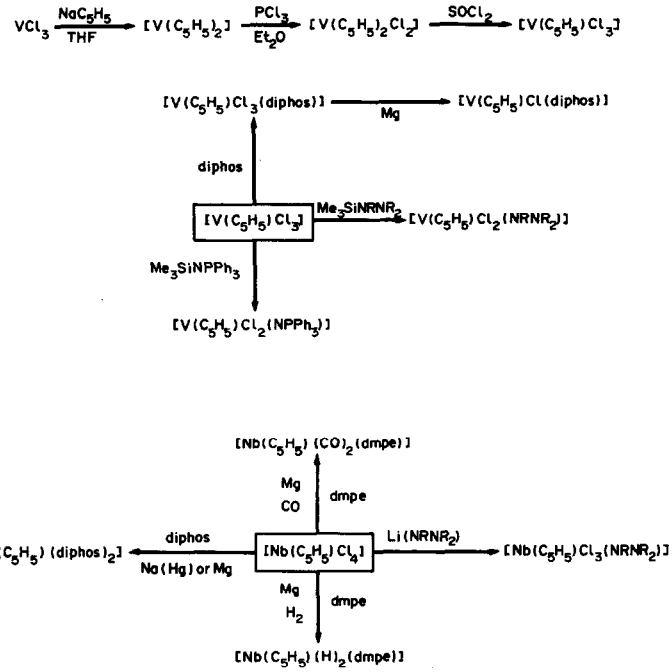
$[V(\eta^5\text{-}C_5H_5)Cl_3]$ reacts with trimethylsilyl-substituted hydrazines to give the hydrazido(1−) complexes $[V(C_5H_5)Cl_2(NRNR_2)]$, which have been characterized by IR and EPR spectroscopy, and by analyses. The phosphineiminate complex, $[V(C_5H_5)Cl_2(NPPh_3)]$, can be prepared in an analogous fashion from $[V(C_5H_5)Cl_3]$ and Me_3Si $NPPh_3$. Side-on coordination is expected in the hydrazide(1−) complexes, as occurs with titanium compounds, but end-on coordination is likely for $[V(\eta^5\text{-}C_5H_5)Cl_2(NPPh_3)]$, due to the bulk of the $NPPh_3^-$ ligand.

$[Nb(\eta^5\text{-}C_5H_5)Cl_4]$, prepared as described in literature from $NbCl_5$ and $Sn(C_5H_5)Bu^n_3$ in dichloromethane,[5] reacts with $Li(NRNR_2)$ in THF yielding diamagnetic $[Nb(\eta^5\text{-}C_5H_5)Cl_3(NRNR_2)]$ ($NRNR_2$ = $NMeNMe_2$ or $NPhNH_2$). $[Nb(\eta^5\text{-}C_5H_5)Cl_3(NMeNMe_2)]$ is stable in solution, as inferred from its NMR spectrum. However, $[Nb(C_5H_5)Cl_3(NPhNH_2)]$ behaves in a different way, and seems to lose the cyclopentadienyl ligand on standing in THF solution at room temperature.

We also have studied the reactions of $[V(C_5H_5)Cl_3]$ with phosphines and diphosphines. The complexes $[V(C_5H_5)Cl_3(diphos)]$ (diphos = dppe or dmpe) can be prepared in high yields from $[V(C_5H_5)Cl_3]$ and the diphosphine in ether. However, the reaction with PMe_3 is accompanied by decomposition. Presumably reduction of vanadium(IV) to lower oxidation states occurs, and no stable adduct is isolated. The EPR spectra of the $[V(C_5H_5)Cl_3(diphos)]$ complexes show well-defined eight-line patterns with lines broadened due to coupling with phosphorus.

The synthesis of new vanadium and niobium dinitrogen complexes was pursued. Reductions of $[V(C_5H_5)Cl_3]$ and $[Nb(C_5H_5)Cl_4]$ under different conditions yielded no dinitrogen complexes, but

* Author to whom correspondence should be addressed.



Scheme of reactions.

other low oxidation-state complexes of vanadium and niobium were readily isolated. For example, the reduction of $[V(C_5H_5)Cl_3(dppe)]$ with Mg under N_2, leads to the complex $[V(C_5H_5)Cl(dppe)]$.[6] $[Nb(C_5H_5)Cl_4]$ is reduced either with Na(Hg) or Mg in the presence of a diphosphine yielding $[Nb(C_5H_5)(diphos)_2]$. The reduction of $[Nb(C_5H_5)Cl_4]$ with Mg under CO in the presence of dmpe produces $[Nb(C_5H_5)(CO)_2(dmpe)]$. Reduction under H_2 affords red crystals analysing as $[Nb(C_5H_5)(H)_2(dmpe)]$, which are not yet fully characterized.

REACTIVITY OF SEVEN-COORDINATE MOLYBDENUM(II) AND TUNGSTEN(II) ISOCYANIDE COMPLEXES: THE CRYSTAL STRUCTURE OF $[MoCl(CNBu^t)_4(PMe_3)_2]Cl$

M. J. FERNANDEZ-TRUJILLO, M. JIMENEZ-TENORIO and M. C. PUERTA

Departamento de Quimica Inorganica, Facultad de Ciencias, Universidad de Cadiz, Puerto Real, Cadiz, Spain

and

D. L. HUGHES*

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—The seven-coordinate isocyanide complexes $[MCl_2(CNBu^t)_3(PMe_3)_2]$ (M = Mo or W), react with additional $CNBu^t$ yielding the derivatives $[MCl(CNBu^t)_4(PMe_3)_2]Cl$. The crystal structure of the $[MoCl(CNBu^t)_4(PMe_3)_2]Cl$ complex shows an almost perfect two-fold symmetry for the cation $[MoCl(CNBu^t)_4(PMe_3)_2]^+$ along the Mo—Cl bond, and two different possible orientations for the *t*-butyl groups. The reaction of $[MCl_2(CNBu^t)_3(PMe_3)_2]$ (M = Mo or W) with anhydrous $SnCl_2$ yields complexes containing the $SnCl_3^-$ ligand, derived from the insertion of $SnCl_2$ into the metal–halide bond.

We have been studying the reactivity of 16-electron six-coordinate molybdenum(II) and tungsten(II) species towards organic isocyanides, which allowed us to isolate $[MCl_2(CNBu^t)_3(PMe_3)_2]$ (M = Mo or W).[1] Spectroscopic data for these complexes supported a capped-octahedral structure, with *trans*-phosphines for the molybdenum complex and *cis*-for the tungsten derivative, although fluxional behaviour was also observed.

These complexes react with additional $CNBu^t$ to give $[MCl(CNBu^t)_4(PMe_3)_2]Cl$. Spectroscopic data for these derivatives suggest a capped trigonal prismatic structure, with the chloride ligand in the capping position, as was found for the parent derivatives $[MX(CNR)_6]X$.[2] This has been confirmed by an X-ray structure analysis for the $[MoCl(CNBu^t)_4(PMe_3)_2]Cl$ complex, which crystallizes as $[MoCl(CNBu^t)_4(PMe_3)_2]Cl \cdot 2Me_2CO$ in the monoclinic system, space group $P2_1$, with a = 11.563(6), b = 18.722(2), c = 11.202(2) Å, β = 103.67(1)° and Z = 2.

The crystal is composed of a lattice of molybdenum-complex cations and chloride anions. There are also large regions which, at the time of crystallization, contain acetone(solvent) molecules. There are two distinct solvent sites, each occupied by an acetone molecule, but these solvent molecules do not appear to have any well-defined positions or orientations in these regions.

The molybdenum complex cation $[MoCl(CNBu^t)_4(PMe_3)_2]^+$ has seven-fold coordination in a capped trigonal prismatic pattern. The chloro ligand is the capping atom on the rectangular face formed by two *trans*-phosphines and two *trans*-isocyanides. The opposite edge of the prism has the two remaining isocyanides at its ends. The cation has an almost perfect two-fold symmetry axis along the Mo—Cl bond. As is quite common in related $Mo(CNBu^t)_n$ complexes, there are two possible orientations for each of the *t*-butyl groups, although only one is shown in the figure for clarity.

The reaction of $[MCl_2(CNBu^t)_3(PMe_3)_2]$ with an excess of $SnCl_2$ allows the isolation of yellow–orange $[M(SnCl_3)(CNBu^t)_3(PMe_3)_3](SnCl_3)$ (M = Mo or W). These compounds are formally

* Author to whom correspondence should be addressed.

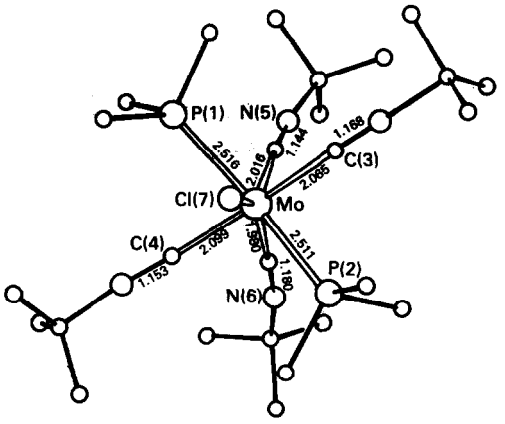

Fig. 1. Diagrammatic representation of the molecular structure of the cation $[MoCl(CNBu^t)_4(PMe_3)_2]^+$, showing selected bond lengths.

derived from the insertion of $SnCl_2$ into the metal–halide bond. ^{119}Sn NMR spectroscopy shows a quartet for coordinated $SnCl_3^-$ coupled with three phosphorus atoms, and a singlet for $SnCl_3^-$ in the external coordination sphere. This, together with ^1H and $^{31}P\{^1H\}$ NMR data, supports a capped-octahedral structure, with $SnCl_3^-$ as the capping ligand, and *fac*-arrangement of phosphines and isocyanides.

POLYTUNGSTATE SELF-ASSEMBLY: STRUCTURES OF THE NEW OXOANIONS, $[W_4(NBu^t)_4O_4Cl_{10}]^{2-}$ AND $[W_6O_{14}Cl_{10}]^{2-}$

WILLIAM CLEGG, R. JOHN ERRINGTON,* DAVID C. R. HOCKLESS and CARL REDSHAW

Department of Chemistry, The University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, U.K.

Abstract—The tetratungstate $[W_4(NBu^t)_4O_4Cl_{10}]^{2-}$ and the hexametalate $[W_6O_{14}Cl_{10}]^{2-}$, isolated from reactions generating organoimidooxo species in solution, have been structurally characterized by X-ray crystallography.

The spontaneous self-assembly of inorganic or metalloorganic fragments in solution to give certain stable, recurring structures has been noted in a variety of systems.[1] During the course of our work with organoimido tungsten compounds, we found that the binuclear complex $[W_2(NBu^t)_2(\mu\text{-}NPh)_2Cl_4(NH_2Bu^t)_2]$,[2] can be converted to the tritungstate $[W_3(NBu^t)_3(\mu\text{-}NPh)_3Cl_7]^-$ (**1**), by treatment with chloride ion [eq. (1)]:[3]

$$3[W_2(NBu^t)_2(NPh)_2Cl_4(NH_2Bu^t)_2] + 2Q^+Cl^- \longrightarrow 2Q[W_3(NBu^t)_3(NPh)_3Cl_7] + 6Bu^tNH_2. \quad (1)$$

The analogy between the structure of the tritungstate (**1**) (Fig. 1) and that of the W_3O_{13} fragment, which is the basic structural unit of many polyoxotungstates,[4] stimulated our interest in polyoxometalate chemistry and we have proceeded to investigate routes to analogous oxo complexes.

Treatment of binuclear $[W_2(NC_6H_4Me\text{-}4)_2Cl_8]$ with $Me_3SiOSiMe_3$ gives the organoimidooxo compound $[W(NC_6H_4Me\text{-}4)(O)Cl_2]$† which, on the basis of its IR spectrum (no terminal W=O stretch and bands at 820 and 720 cm^{-1} due to W—O—W), appears to be polymeric with bridging oxides. Unfortunately, our attempts to break down the polymeric structure to form a trimetalate analogous to **1** have so far been unsuccessful. However, in a reaction designed to produce a *t*-butylimidooxo analogue of **1**, i.e. $[W_3(NBu^t)_3(\mu\text{-}O)_3Cl_7]^-$, we treated $WOCl_4N^+$ with Bu^tNH_2 in the presence of Q^+Cl^- ($Q^+ = Et_4N^+$, $Bu^n_4N^+$, or $Ph_3(PhCH_2)P^+$) and after work-up obtained yellow crystals of the tetrametalate $Q_2[W_4(NBu^t)_4(\mu\text{-}O)_4Cl_{10}]$ (**2**) in high yield.‡ The X-ray crystal structure of the $Ph_3(PhCH_2)P^+$ salt has been determined§ and the anion is shown in Fig. 2 with methyl groups omitted for clarity. The distorted tetrahedron of four tungsten atoms is bridged across two opposite edges by chlorine atoms and across the remaining edges by

* Author to whom correspondence should be addressed.

† Satisfactory microanalytical data have been obtained.

‡ Spectroscopic data for $[W_4(NBu^t)_4O_4Cl_{10}]^{2-}$: δ_H (200 MHz; CD_2Cl_2) 1.34 (s, N*Bu*^{t}). δ_C (50.3 MHz; CD_2Cl_2) 31.98 [C(*C*H_3)$_3$], 71.88 [*C*(CH$_3$)$_3$]. ν(W—O) 900, 840 cm^{-1}; ν(W—Cl) 360, 349, 335 cm^{-1}.

§ Crystal data for $[Ph_3(PhCH_2)P](W_4(NBu^t)_4O_4Cl_{10}]\cdot 2CH_2Cl_2$: $C_{68}H_{84}N_4O_4P_2Cl_{14}W_4$, $M = 4460.4$, triclinic, $a = 12.639(2)$, $b = 12.839(2)$, $c = 27.463(4)$ Å, $\alpha = 79.79(1)$, $\beta = 7997(1)$, $\gamma = 85.67(1)°$, $V = 4314.3$ Å^3, $Z = 2$, space group $P\bar{1}$; $R = 0.061$, $R_w = 0.051$ from 9714 unique observed reflections with $3 < 2\theta < 45°$ measured with Mo-K_α radiation ($\lambda = 0.71073$ Å) and corrected for absorption. Anisotropic thermal parameters were refined for tungsten, phosphorus and chlorine atoms, isotropic for others; hydrogen atoms were included in calculated positions, and phenyl rings were refined as rigid ideal hexagons.

Crystal data for $(Bu^n_4N)_2[W_6O_{14}Cl_{10}]$: $C_{32}H_{72}N_2O_{14}Cl_{10}W_6$, $M = 2166.6$, monoclinic, $a = 18.164(4)$, $b = 19.506(4)$, $c = 18.085(4)$ Å, $\beta = 109.90(2)°$, $V = 6025.0$ Å^3, $Z = 4$, space group $C2/c$; $R = 0.061$, $R_w = 0.049$ from 3243 unique observed reflections with $3 < 2\theta < 50°$ measured with Mo-K_α radiation ($\lambda = 0.71073$ Å) and corrected for absorption. Cations are probably disordered, and were refined with restrained bond lengths and angles, and with isotropic thermal parameters for carbon atoms, and without hydrogen atoms. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited as supplementary data with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

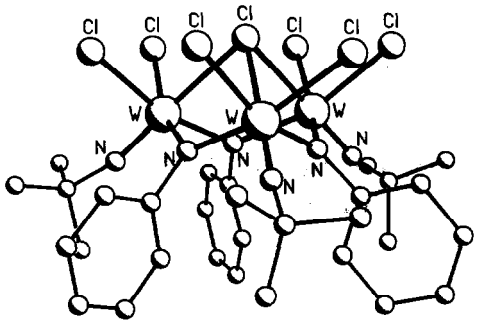

Fig. 1. The molecular structure of **1**.

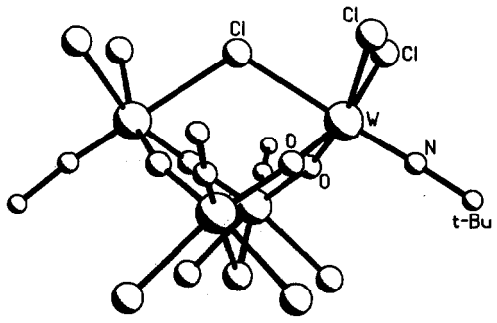

Fig. 2. The molecular structure of **2** without methyl groups. Important mean bond lengths and angles include W—N, 1.697; W—O, 1.879; W—Cl(terminal), 2.407; W—Cl(bridging), 2.657 Å; W—O—W, 159.6; W—Cl—W, 115.6; W—N—C, 174.5°.

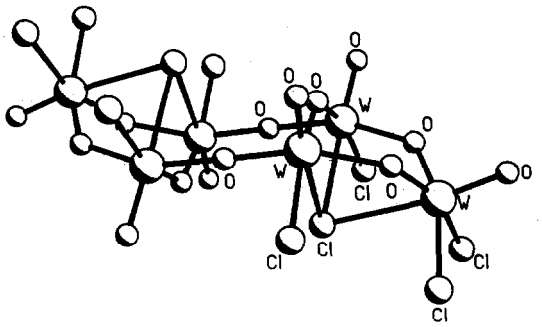

Fig. 3. The molecular structure of **3**. Important mean bond lengths and angles include W—Cl(terminal), 2.311; W—Cl(bridging), 2.803; W—O(terminal), 1.684; W—O(bridging), 1.897 Å; W—Cl—W, 76.8; W—O—W (within W_3 units), 132.4; W—O—W (between W_3 units), 177.9°.

oxygen atoms to give the molecule approximate D_{2d} symmetry. As expected, the stronger π-donor ligands, O and NBu^t, occupy mutually *cis* positions at each tungsten centre. The oxygen bridges are approximately symmetrical with large W—O—W angles (160° av.).

From the reaction between the binuclear tungsten(V) compound $(Bu^n_4N)[W_2O_2Cl_7]$[3] and *p*-tolylazide, designed to introduce a *p*-tolylimido group, we isolated the hexametalate, $[W_6O_{14}Cl_{10}]^{2-}$ (**3**), which has been characterized by X-ray crystallography.* The structure is shown in Fig. 3 and consists of two trinuclear $W_3O_3(\mu\text{-}O)_3Cl_4(\mu_3\text{-}Cl)$ fragments joined by two linear W—O—W linkages about a centre of symmetry. The bent W—O—W bridges are slightly asymmetric with an average angle of 132°. Organomido/oxo exchange is evidently occurring in this reaction and the product which is subsequently isolated depends upon the cation present in solution, since treatment of $[Ph_3(PhCH_2)P][W_2O_2Cl_7]$ with *p*-tolylazide yielded $[Ph_3(PhCH_2)P][W(NC_6H_4Me\text{-}4)Cl_5]$[5] on crystallization. We have observed similar organoimido/oxo exchange during the reaction between tetrametalate (**2**) and 2,2′-bipyridyl in toluene under reflux, which produces $[W(NBu^t)_2Cl_2(bipy)]$, whereas the room-temperature reaction yields the expected product, $[W(NBu^t)(O)Cl_2(bipy)]$. These reactions and other studies of the reactivity of **2** will be discussed in greater detail in a full paper.

Acknowledgement—We thank SERC for a grant (W.C.) and an earmarked studentship (C.R.).

X-RAY CRYSTALLOGRAPHIC STUDIES OF SOME VANADYL COMPLEXES OF SCHIFF BASES

S. S. DODWAD*

Institute of Science, 15 Madam Cama Road, Fort, Bombay—400 032, India

and

D. K. KULKARNI

Institute of Science, Nagpur, India

Abstract—Some vanadyl complexes containing nitrogen and oxygen donors have been synthesized and characterized. They have the general formulae $[VO(C_xH_yNO)_2]$ or $[VO(C_xH_yCl_zNO)_2]$. The molecular structure of these complexes has been reported elsewhere. The present investigation reports the crystal structure determined by the X-ray powder method. All the observed reflections for every sample indicate a single phase with similar crystalline structures. The observed reflections are indexed and the unit cell dimensions are determined within an accuracy of 0.02 Å.

X-ray diffractometry of some metal complexes has been greatly studied and provided information about their crystallization and unit cell dimensions etc. The authors have also studied the vanadyl complexes by X-ray diffractometry.

EXPERIMENTAL AND DISCUSSION

The authors have prepared four vanadyl complexes of Schiff bases by refluxing vanadyl sulphate and the corresponding Schiff base in an ethanolic medium in a 1:2 ratio for 2 h. Their molecular structures are characterized[1] by studying their physical properties. In the present investigation, X-ray studies of these complexes were undertaken. X-ray diffractograms were measured[2] on a PW-1010 Philips diffractometer. The patterns obtained show a concentration of reflection with an abrupt decrease in intensities at higher angles. Similar observations have been reported by Brown and Bngaall.[3] All the observed reflections were indexed by the method described by Henry *et al.*[4] All the complexes crystallized in a primitive tetragonal unit cell with dimensions ranging from 14 to 18 Å. The crystallographic results, e.g. "*d*" in A (calculated and observed) and the "*c*/*a*" ratio, are reported in Tables 1 and 2. The observed "*c*/*a*" ratio is closer to 1.0 on both sides. The calculated and observed "*d*" values agree extremely well with each other, implying that all the reported complexes have similar crystal structures.

THE PHOTODECOMPOSITION OF THE EARLIER 3*d* METAL–OXALATO COMPLEXES

M. W. ROPHAEL

The National Research Centre, Dokki, Giza, Egypt

and

M. A. MALATI*

Mid-Kent College of Higher and Further Education, Chatham ME5 9UQ, U.K.

Abstract—Under nitrogen, an acidified solution of $[TiO(C_2O_4)_2]^{2-}$ or $[V(C_2O_4)_3]^{3-}$ is photolysed by 254 nm radiation, giving the lower-valent cation and CO_2, trapped as $BaCO_3$. Quantum yields were determined by uranyl–oxalate actinometry, combined with Ti^{3+} titration against iron(III) and vanadium(II) determination by MnO_4^- titration and spectrophotometrically. Values of $\phi_{Ti^{III}}$ and $\phi_{V^{II}}$ in 0.148 M H_2SO_4 were 0.06_8 and 0.04_0, respectively. Both increased with increasing $[H_2SO_4]$. $\phi_{Ti^{III}}$ decreased on reducing the light intensity and was lower than ϕ_{ox}. The results are compared with the published works on the photolysis of the oxalato complexes of chromium(III) and manganese(III).

The photolysis of $[Mn(C_2O_4)_3]^{3-}$ has been extensively studied.[1] We have investigated the photodecomposition of solutions of the oxalato complexes of chromium(III), using a vacuum system[2] and quantum yields were calculated from results of volumetric gas analysis. Recently we reported the photolysis of $[TiO(C_2O_4)_2]^{2-}$ and $[V(C_2O_4)_3]^{3-}$ solutions under a nitrogen atmosphere.[3] In all cases, the metal ion is reduced to a lower oxidation state and oxalate is oxidized to carbon dioxide.

EXPERIMENTAL

$K_3[V(C_2O_4)_3]3H_2O$ was prepared by reducing vanadate(V) by $N_2H_4H_2O$ and CH_3CO_2H, and complexing with oxalate.[4] Titrimetry and gravimetry gave %$(V+C_2O_4)$, 63.5 (calc. 64.8) and %H_2O, 10.8 (calc. 11.1). $K_2[TiO(C_2O_4)_2]\cdot 2H_2O$ (B.D.H.A.R., 98.5% pure) was used as supplied. The absorption spectrum of a solution of the vanadium complex exhibited LMCT at $\lambda < 260$ nm. The corresponding band for the titanium complex had λ_{max} at 210 nm. The spectra agreed with the published data.[5,6]

A solution of either complex (70 cm^3), usually in sulphuric acid, was magnetically stirred and irradiated, under nitrogen, in a cylindrical vessel surrounding the quartz thimble of a Hanovia low pressure mercury lamp (4 W). Carbon dioxide, resulting from the photo-oxidation of oxalate, was trapped in $Ba(OH)_2$/NaOH solution. The titanium(III)–oxalate complex produced was determined by titration with iron(III).[7] Titrations with permanganate before and after irradiation gave the amount of oxalate decomposed. The vanadium(II)–oxalate complex formed on irradiation was estimated from permanganate titrations before and after irradiation, which were repeated after precipitating and filtering off vanadium hydroxides. All titrations were carried out under nitrogen. The effect of light intensity on the photolysis of the titanyl complex was studied by repeating irradiations after surrounding the lamp thimble with a coarse or a fine copper gauze. In one run, a known amount of $TiCl_3$ was added prior to photolysis and two known quantities of oxalate were introduced into the solution, in two experiments, before irradiation. The yield of vanadium(II) was also estimated by measuring the absorbance of the vanadium complex before and after irradiation at the wavelengths of maximum absorption of the original solution and of $[V(C_2O_4)_2(H_2O)_2]^{2-}$, which is believed to be predominant in vanadium(II)–oxalate solutions. The photolysed solution was

* Author to whom correspondence should be addressed.

transferred under nitrogen to a vacuum spectrophotometer cell. For actinometry, a uranyl oxalate solution replaced the photolysed solution. Details of the measurements and quantum yield were as described previously.

RESULTS AND DISCUSSION

Similar to other tris-oxalate complexes of trivalent ions, the following mechanism is suggested for the vanadium complex:

$$[V(C_2O_4)_3]^{3-} \xrightarrow{h\nu} [V(C_2O_4)_2]^{2-} + C_2O_4^-$$

$$[V(C_2O_4)_3]^{3-} + C_2O_4^- \longrightarrow C_2O_4^{2-} + 2CO_2 + [V(C_2O_4)_2]^{2-}.$$

The increase in $\phi_{V^{II}}$ with increasing acid concentration, shown in Table 1, may be ascribed to the higher yield of photolysis of $[V(C_2O_4)(H_2O)_4]^+$, which is believed to predominate at pH < 1. The titration results were in good agreement with the results of spectrophotometry.

The increase in $\phi_{Ti^{III}}$ with increasing acid concentration, indicated in Table 1, suggests that $[TiO(C_2O_4)]$, known to be present at pH < 1,[10] is more readily photolysed than the bis-oxalato ion. This explanation is in agreement with the decrease in the rate of titanium(III) formation from $3.2_0 \times 10^{-3}$ to $1.9_1 \times 10^{-3}$ or $1.6_1 \times 10^{-3}$ mol in the absence or presence of $8.7_5 \times 10^{-2}$ or $1.7_5 \times 10^{-2}$ mol oxalate, respectively. The latter would shift the equilibrium to the left.

$$[TiO(C_2O_4)_2]^{2-} \rightleftharpoons [TiO(C_2O_4)] + C_2O_4^{2-}.$$

At the same acid concentration, the quantum yield of oxalate oxidation, 0.23, was appreciably higher than the yield of titanium(III) formation, 0.06_8. This may be ascribed to photosensitized decomposition of oxalate. Adding titanium(III) to the photolysed titanyl complex had an insignificant effect on the photolysis rate. The amount of photo-produced titanium(III) varied linearly with the irradiation time, as expected.

Table 1. Quantum yields of formation of titanium(III) from titanyl(IV) oxalate and of formation of vanadium(II) from tris-oxalatovanadate(III)

Complex concentration (mol dm^{-3})	[HSO] (mol dm^{-3})	Light intensity quanta ($s^{-1} \times 10^{17}$)	Quantum yield
0.050	0.078	2.06	0.03_8
0.050	0.111	2.06	0.04_2
0.050	0.148	2.06	0.06_8
0.050	0.148	0.94	0.03_9
0.050	0.148	0.71	0.03_4
0.032	None	2.06	0.00_8
0.032	0.148	2.06	0.04_0
0.032	0.295	2.06	0.04_5

The top 5 lines show the yields of titanium(III) and the bottom 3 lines show the yields of vanadium(II).

The higher quantum yield of titanium(III) compared to vanadium(II) can be explained by the apparently lower electron-transfer energy of the titanyl complex compared to the vanadium(III) complex.

The quantum yields of the photolysis of $[Mn(C_2O_4)_3]^{3-}$ are much higher than either of the complexes studied and are appreciable in the visible region. This behaviour is apparently due to the stability of the manganese(II) produced by photolysis. On the other hand, ϕ_{gas} determined for the chromium tris-oxalato ion was lower than that of the titanyl complex, presumably because of the relative instability of chromium(II) compared to the stable chromium(III). The results of the photolysis of the chromium(III) complexes in water and heavy water and at different pH values and temperatures, have been published elsewhere. The interesting feature observed was the production of hydrogen, as well as carbon dioxide, when a solution of *cis*-$[Cr(C_2O_4)_2(H_2O)_2]^-$ was photolysed.

LOW TEMPERATURE PYROLYSIS PRODUCTS OF CHROMIUM, MOLYBDENUM AND TUNGSTEN HEXACARBONYLS

I. M. WATSON and J. A. CONNOR*

University of Kent, Canterbury, Kent, U.K.

and

R. WHYMAN

ICI Chemicals and Polymers Group, Runcorn, Cheshire, U.K.

Abstract—The Group 6 metal hexacarbonyls have often been investigated as precursors in chemical vapour deposition processes. The solid products, obtained by thermal decomposition of the vapours of the compounds below 300°C, have been re-examined. Under these conditions, all three carbonyls produce a metallic phase with a face-centred cubic structure, distinct from the body-centred cubic structure of the pure metals. Microanalysis shows that the materials contain roughly equimolar amounts of carbon and oxygen. Pyrolysis of ^{18}O-labelled $Mo(CO)_6$ has demonstrated that the oxygen derives from the CO ligand of the precursors. Evidence that the pyrolysis products are insterstial oxycarbides is presented; their response to annealing treatment is described.

The importance of thin films of chromium, molybdenum and tungsten in microelectronics and other technologies has motivated many investigations of chemical vapour deposition processes using the metal carbonyls, $M(CO)_6$, as precursor compounds. In the first such study,[1] it was found that face-centred cubic (fcc) materials formed when $Mo(CO)_6$ and $W(CO)_6$ were pyrolysed below 500°C. Higher temperatures and other precautions were necessary to obtain the body-centred cubic pure metals. The fcc materials were originally formulated as carbides, but chemical analyses carried out on the pyrolysis products of $Mo(CO)_6$[2] and $W(CO)_6$[3] showed the materials contained oxygen. Recently, a similar fcc phase has been prepared by the decomposition of $Cr(CO)_6$ in a corona discharge.[4] The fcc materials, obtained by pyrolysis of the three $M(CO)_6$ complexes below 300°C, have been re-investigated. A fuller appraisal of their chemical nature and probable mechanism of formation than in previous work has been possible.

The pyrolysis products were prepared by subliming the carbonyl up a Pyrex tube under dynamic vacuum, and allowing pyrolysis to occur in a heated portion of the tube. The tubes were 3 mm internal diameter and sealed at their lower end. The carbonyls (Aldrich) were sublimed before use. Each pyrolysis run used roughly 20–30 mg of carbonyl, which was initially placed in the bottom of the tube. The samples of $Cr(CO)_6$ and $Mo(CO)_6$ were held at 50°C, and $W(CO)_6$ at 60°C. The pyrolysis zone was heated by a tubular resistance furnace, 75 mm long. In all cases, the temperature at the centre of the furnace was 300°C. Heavy deposition of solid material from $Cr(CO)_6$ and $Mo(CO)_6$ onto the tube wall began at ~ 150°C, and at ~ 230°C in the case of $W(CO)_6$. The dark, metallic deposits were poorly adherent, and all analyses were performed on loose flakes of material detached from the tubes. The equilibrium vapour pressures of the carbonyls under the conditions used[5] are much higher than the ultimate vacuum of ~ 0.05 torr obtainable in the pyrolysis apparatus. Allowing for the production of CO on decomposition, it is apparent that the pyrolysis products formed under a flux of CO sufficient to eliminate the possibility of oxidation by residual oxygen in the apparatus. The actual CO pressure during pyrolysis was at least 0.2–0.3 torr.

Qualitative analyses of the pyrolysis products

* Author to whom correspondence should be addressed.

were obtained by laser ionization mass analysis (LIMA) using a Cambridge LIMA 2A system. Positive ion LIMA spectra of the pyrolysis products all showed strong M^+, C^+ and O^+ peaks. No polyatomic ions such as CO^+ were detected. These results provided initial evidence that the materials were oxycarbides. Confirmation of the origin of the oxygen was sought by pyrolysing a sample of 50% ^{18}O-labelled $Mo(CO)_6$. This was prepared by reacting cycloheptatriene molybdenum tricarbonyl[6] with $C^{18}O$ (Alfa) in 1,2-dichloroethane solution. LIMA showed that the $^{16}O/^{18}O$ ratio in the pyrolysis product was 1.1 ± 0.1, confirming that 91–100% of the oxygen in the material originated from the CO ligand of the precursor. The mechanism of incorporation of carbon and oxygen into the pyrolysis products will be considered below.

Quantitative analyses were made by conventional chemical methods, and the results are summarized in Table 1. Carbon analyses were performed by combustion with an iron oxide additive in a Carlo Erba 1130 instrument. Samples of Cr_3C_2 (Johnson Matthey), Mo_2C and WC (both Alfa) were used as standards. Oxygen analyses were made by Pascher Laboratories, Remagen, using a Balzers Exhalograph EAO-202 instrument. The results indicated approximately equimolar amounts of oxygen and carbon in each of the pyrolysis products. Very similar analytical data were obtained by Vogt[3] for the low temperature pyrolysis products of $W(CO)_6$.

Scanning electron microscopy (SEM) was used to confirm that the materials had dense, locally uniform microstructures, consisting of grains 50–200 nm in size. These observations helped support the supposition that the products were chemically homogeneous, with bulk compositions reflecting the analytical data.

X-ray powder diffraction patterns were recorded using Cu-K_α radiation. The materials each consisted of a single fcc phase, with the approximate lattice parameters listed in Table 1. Diffuse diffraction peaks, consistent with the particle size broadening expected from 25 nm particles,[7] were observed. Since the actual grain sizes observed by SEM were somewhat larger, disorder in the materials was probably responsible. Pure molybdenum and tungsten have been claimed to crystallize in the fcc structure, but only in the form of extremely thin films, below the thicknesses encountered here.[8] In view of the analytical data, it is likely the pyrolysis products are non-stoichiometric interstitial phases, with the carbon and oxygen atoms occupying octahedral interstices in an fcc lattice of metal atoms, presumably in a random fashion. This suggestion has been made previously,[1,2] but will be briefly reviewed.

Table 1. Analytical data for the pyrolysis products

Precursor	Element weight (%) C	O	Deduced composition	Lattice parameter (Å)
$Cr(CO)_6$	9.55	12.0	$CrC_{0.52}O_{0.49}$	4.14
$Mo(CO)_6$	4.33	5.47	$MoC_{0.38}O_{0.36}$	4.19
$W(CO)_6$	2.44	2.93	$WC_{0.39}O_{0.36}$	4.17

To investigate their thermal stability, samples of the oxycarbides were annealed in evacuated silica ampoules at 600°C for 24 h, and examined by X-ray powder diffraction. The fcc material obtained from $Cr(CO)_6$ was entirely transformed into Cr_3C_2, Cr_2O_3 and an unidentified phase. The $Mo(CO)_6$ pyrolysis product was partially converted into α-Mo_2C, MoO_2 and molybdenum metal, while the $W(CO)_6$ pyrolysis product remained unchanged.

The B1(NaCl) structure described above is one of the types adopted by the so-called Hägg phases, discussed by Toth.[9] The molybdenum and tungsten carbides, α-MoC_{1-x} and α-WC_{1-x}, have this structure. The atomic radius of chromium is slightly too small to allow interstitial carbides to form, and phases such as Cr_3C_2 have more complicated structures. In formulating the pyrolysis products as interstitial phases of this sort, a further novel feature is their relatively large oxygen content. The composition of the $Cr(CO)_6$ pyrolysis product is very close to the idealized composition, $CrC_{0.50}O_{0.50}$, expected for full occupation of the octahedral interstices. In the other two oxycarbides, vacancies must be present. The metal lattices in these materials are rather dilated, particularly in the $Cr(CO)_6$ pyrolysis product. Here, the distance between neighbouring metal atoms is 2.93 Å, which is considerably more than twice the normal radius of a 12-coordinate chromium atom, 1.267 Å.[9] It might be anticipated that the fcc phase would possess limited stability, as shown by the annealing experiments.

In the discussion above, it has been assumed that the pyrolysis products are oxycarbides, containing no undissociated CO. The distance between the carbon and oxygen atoms on adjacent interstitial sites will be ~ 2.95 Å, much too far to allow any direct bonding to be retained. The best evidence that the materials contain no undissociated CO is the lack of any CO^+ or CO^- peaks in their LIMA spectra. Furthermore, their IR spectra, recorded in KBr discs, showed no ν(CO) absorptions. Vogt obtained X-ray photoelectron spectra for the fcc tungsten oxycarbide,[3] but definite conclusions could not be reached about the chemical state of the constituent

atoms. It is known, however, that in the β-state of chemisorbed CO on molybdenum and tungsten surfaces, the C—O bond is greatly weakened, with both atoms involved in bonding to the surface.[10] Desorption of β-CO from tungsten occurs only above $\sim$ 700°C.[11] A recent study of the adsorption of CO on a chromium (110) surface showed that at -150°C CO preferentially bonded in a "side-on" fashion, with ν(CO) appearing in the 1150–1330 cm^{-1} range, and dissociation occurred above -100°C.[12] These findings provide some precedent for the surface dissociation of CO which must occur during synthesis of the oxycarbides. The deposition of carbon in the material could also be accompanied by the production of CO_2, as considered by Kaplan and d'Heurle.[13] This process is clearly not very important here, and it is uncertain whether the slight excess of carbon over oxygen observed in the materials is significant. A study of the gaseous thermal decomposition products of $Mo(CO)_6$ and $W(CO)_6$ by mass spectrometry showed that the CO^+/CO_2^+ ratio was always above 50.[14]

It is likely that the pyrolysis products described closely resemble those obtained in previous work, under somewhat different sets of conditions. Their compositions were not always investigated in great detail, particularly when film deposition rates and electrical properties were of principal interest.[13,15,16] The presence of hydrogen as a background gas clearly did not prevent the incorporation of carbon and oxygen into the pyrolysis products.[2,3] Auger electron spectroscopy (AES) indicated that films produced by the photo-assisted decomposition of $Mo(CO)_6$ had a composition close to the pyrolysis products discussed here.[16] Electron diffraction and AES also showed that similar materials can be obtained by the decomposition of $Cr(CO)_6$[4] and $Mo(CO)_6$[17] in a corona discharge. Hence, the results described are likely to be relevant to a range of low temperature chemical vapour deposition techniques.

Acknowledgements—I.M.W. gratefully acknowledges support from the SERC and ICI Chemical and Polymers, who provided the analyses. Dr M. M. Lee is particularly thanked for her careful LIMA work.

PREPARATION AND REACTIONS OF NIOBIUM(V) SULPHIDE COMPLEXES

J. L. SEELA, J. C. HUFFMAN and G. CHRISTOU*

Department of Chemistry and the Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—An improved synthetic procedure to $(PPh_4)[NbSCl_4]$ (**1**) is described involving the reaction of $NbCl_5$ with two equivalents of $NaSBu^t$. Complex **1** reacts with NaSPh to yield $(PPh_4)[NbS(SPh)_4]$ (**2**), the crystal structure of which confirms a square-pyramidal geometry at the metal with a multiply-bonded sulphur at the apex (Nb—S = 2.171(2) Å).

The sulphur-based chemistry of the group 6 metals, molybdenum and tungsten, has been the subject of intense investigation over many years. In contrast, the corresponding chemistry of the group 5 metals is still only poorly explored. We have a program directed towards the development of group 5 metal–sulphur chemistry and most of our efforts to date have been concentrated in vanadium. However, we herein describe some recent results with niobium involving the +5 oxidation level.

The anion $[NbSCl_4]^-$ was considered an attractive starting point for the synthesis of M—S—SR complexes by metathesis. However, available procedures to this material are less than optimal with respect to yield, purity or convenience of preparation,[1] and we have therefore sought a facile, one-step, high-yield procedure from readily-available starting materials. Given the tendency of Bu^tS^- to act as a sulphide (S^{2-}) source via C—S bond cleavage [eq. (1)]:

$$Bu^tS^- \longrightarrow Bu^{t+} + S^{2-} \qquad (1)$$

the reaction between $NbCl_5$ and equimolar amounts of $NaSBu^t$ in CH_2Cl_2 was investigated. Addition of PPh_4Cl to the reaction mixture led to isolation of approximately equal amounts of green $(PPh_4)[NbSCl_4]$ (**1**) and yellow $(PPh_4)[NbCl_6]$. The formation of two products was rationalized according to eq. (2):

$$2NbCl_5 + 2Bu^tS^- \longrightarrow NbSCl_4^- + NbCl_6^- + Bu^t_2S; \qquad (2)$$

thus, it was suspected that incomplete conversion of $NbCl_5$ to $NbSCl_4^-$ was due to reaction of generated Bu^{t+} with remaining Bu^tS^- [eq. (3)]:

$$Bu^{t+} + Bu^tS^- \longrightarrow Bu^tSBu^t. \qquad (3)$$

If this were really the case, then additional Bu^tS^- should result in clean formation of $NbSCl_4^-$. Treatment of $NbCl_5$ with 2 equivalents of $NaSBu^t$ does indeed produce only $NbSCl_4^-$ [eq. (4)], and isolated yields of pure crystalline $(PPh_4)[NbSCl_4]$ are routinely ~ 60%. The NEt_4^+ salt can be prepared in a similar fashion.

$$NbCl_5 + 2Bu^tS^- \longrightarrow NbSCl_4^- + Bu^t_2S + Cl^-. \qquad (4)$$

Treatment of complex **1** in MeCN with 4 equivalents of NaSPh leads to a rapid colour change from light green to intense red. Removal of solvent and recrystallization from THF–hexanes yields essentially black crystals of $(PPh_4)[NbS(SPh)_4]\cdot$THF (**2**) [eq. (5)]:

$$NbSCl_4^- + 4NaSPh \longrightarrow NbS(SPh)_4^- + 4NaCl. \qquad (5)$$

The structure† of the anion is shown in Fig. 1; the niobium possesses square-pyramidal geometry with a multiply-bonded sulphur atom S(2) at the apex and four terminally-coordinated sulphur atoms from the PhS^- groups in the basal plane. The

[d] Site *trans* to Nb=S occupied.
[e] Not reported.

important bond lengths and angles are collected in Table 1. It can readily be seen that the NbS_5 core possesses almost perfect C_{4v} symmetry, with the basal Nb—S bonds and S(2)—Nb(1)—S(3,10,17,24) angles lying in the very narrow ranges of 2.440–2.443 Å and 108.2–110.9°, respectively. Of interest is the apical Nb=S distance of 2.171(2) Å, which is at the longer end of the observed Nb=S values; inspection of Table 2 shows a range of 2.085–2.196 Å. We have noted elsewhere in our investigations of V—S chemistry that basal RS^- ligands result in noticeably longer apical $V{=}O^{2+}$ and $V{=}S^{2+}$ distances;[9] we have rationalized this as due to the excellent electron-releasing properties of thiolate ligands. Note that the anionic nature of the PhS^- ligands cannot be the sole explanation, because $NbSCl_4^-$ has the *shortest* distance yet observed. Note also that the distance observed for complex **2** is even longer than those observed for some complexes possessing a sixth ligands *trans* to the sulphide.

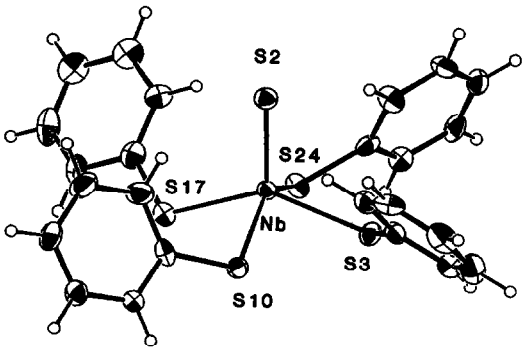

Fig. 1. ORTEP representation of complex **2** at the 50% probability level.

The reactivity characteristics of complex **2** are under investigation. With excess PhCOCl, clean conversion back to complex **1** is observed [eq. (6)]:

$$NbS(SPh)_4^- + 4PhCOCl \longrightarrow NbSCl_4^- + 4PhCOSPh. \quad (6)$$

The products from the reaction of **2** under a variety of other conditions (e.g. reduction, heating, treatment with MeI or I_2, etc.) are currently being investigated.

VANADIUM(V) PROTONATION AND CONDENSATION EQUILIBRIA IN THE pH RANGE 7–10 (NaCl MEDIUM, 25°C); A POTENTIOMETRIC AND SPECTROPHOTOMETRIC STUDY

J. J. CRUYWAGEN,* J. B. B. HEYNS and J. L. VISAGIE

Department of Chemistry, University of Stellenbosch, Stellenbosch, R.S.A.

Abstract—Investigations into the speciation in the vanadium(V)–aqua system are described.

Previous investigations of this system by various methods[1] have shown that several species occur in simultaneous overlapping equilibria in the pH range 7–10. The equilibria can be represented by the following general equation:

$$pH^+ + qHVO_4^{2-} \rightleftharpoons H_p^+(HVO_4^{2-})_q.$$

For brevity, species with overall formation constants $\beta_{p,q}$ are denoted by the coefficients p and q which define their stoichiometry, e.g. (1,1) and (0,2) for $H_2VO_4^-$ and $V_2O_7^{2-}$. The most recent investigations show that the existence of the following ions (−1,0), (0,1), (1,1), (0,2), (1,2), (2,2), (4,4) and (5,5) are fairly well established, but that not all authors agree about the existence of some minor polyanions, e.g. the (2,4), (3,4), (1,3) and (2,3) species.[2–6]

What is now much needed for this system is information about the thermodynamic quantities, ΔH and ΔS, for the various reactions. Such information ought to give a better understanding of the relative stabilities of the different species in terms of the driving forces for the reactions and thereby also provide indirect evidence for the formulation of some of the polyions. The correct interpretation of calorimetric data not only depends on the reaction model chosen, but also relies heavily on the values of the formation constants of the species. With this in mind, we have first conducted a potentiometric investigation supplemented by extensive spectrophotometric measurements in the UV region.

EXPERIMENTAL

Potentiometric measurements were carried out either by a manual titration procedure, as described elsewhere,[7] using a Radiometer PHM 64 Research pH meter and Ross (Orion) electrode, or with a Metrohm 636 Titroprocessor fitted with glass and calomel electrodes. Solutions examined were 0.004000, 0.007985, 0.01500, 0.02823, 0.05853 M in vanadium(V) [all 0.6 M in NaCl], and 0.004000, 0.007998, 0.02992, 0.04250, 0.06000 M in vanadium(V) [all 1.0 M in NaCl]. Spectrophotometric measurements were likewise carried out by a previously reported titration procedure,[7] using a Varian Cary 210 spectrophotometer and Apple II computer for data collection. A total of 62 spectra were collected at 2 nm intervals in the range 220–334 nm, for the following vanadium(V) concentrations: 0.03, 0.015, 0.008, 0.002 and 0.0005 M [all 0.6 M in NaCl]. A flow-through cuvette of variable pathlength[8] was used to facilitate measurements at relatively high concentrations.

RESULTS AND DISCUSSION

The potentiometric data were analysed with the computer program SUPERQUAD.[9] Extensive model testing with the data for 0.6 M NaCl showed that a model (A), comprising the following species, resulted in the lowest s value (1.00): (−1,1), (1,1), (0,2), (1,2), (2,2), (1,3), (2,3), (4,4), (5,5). An alternative model (B) which includes the tetramers (2,4) and (3,4) instead of the trimers (1,3) and (2,3), gave a somewhat higher s value (1.07). In fact, if all four of these species are included the tetramers are rejected and model A is again obtained. On assigning fixed values to the formation constants of the (2,4) and (3,4) species to retain them (in addition to the trimers) in the model (C), a lower s value (1.02) than for model B is obtained, but it is still a little higher than that for model A. Exactly the same pattern of results is obtained using the data for a 1.0 M NaCl medium.

[a] Models based on potentiometric data.
[b] Spectrophotometric data.
[c] Reported values are inconsistent.

The spectrophotometric data were analysed with the program SPECFIT.[10] Because of the great number of unknowns (constants and molar absorptivities), simultaneous calculation of all spectra and equilibrium constants was not possible. Only the spectrum of the (−1,1) species could be determined experimentally, and was fixed in the calculations. No more than two β-values, in addition to all remaining spectra, could be calculated at one time.

Thus different combinations of two β's were taken in turn as unknowns, after initially assigning their potentiometric values. By following this "iterative" procedure for all species included in the model (C), the model of best fit could be determined. Significantly, only model B, which included the tetramers, yielded acceptable results, while models including trimers yielded either negative molar absorptivities for trimers, or very large uncertainties in their theoretical spectra.

The agreement between the $\log \beta$ values calculated from the potentiometric and spectrophotometric data (model B) and those reported by Pettersson for the same medium, NaCl = 0.6 M, is excellent (Table 1). However, because of the practical limitations on the maximum concentration that can be measured spectrophotometrically, the minor species occurred in relatively low concentrations. The spectrophotometric evidence supporting model B should therefore be accepted with some caution at this stage. The potentiometric measurements are now being extended to still higher concentrations in an attempt to characterize the minor species more conclusively.

An enthalpimetric study of the system has, at the time of writing, been almost completed. Treatment of the data in terms of the above models has just been started. Although it is not expected that the results of the calculations will facilitate a choice between models, the enthalpy and entropy changes should give a clear indication of the driving force responsible for the formation of the major species.

SOME NEW CYANO AND ISONITRILE COMPLEXES OF $Mo(\eta^5\text{-}C_5H_5)_2$

M. J. CALHORDA,* A. R. DIAS, A. M. MARTINS and C. C. ROMÃO

Centro de Química Estrutural, Instituto Superior Técnico, 1096 Lisboa Codex, Portugal

Abstract—New cyano and isonitrile complexes of molybdenocene, $[MoCp_2(CN)X]$ (X = CN, H, Cl), $[MoCp_2(CNCH_3)X]I$ (X = H, I, CH_3), $[MoCp_2(CNCH_3)_2]I_2$ and $[MoCp_2(CNCH_3)]$, were prepared and characterized. The molybdenocene adduct, $[MoCp_2(CNCH_3)]$, was prepared by reduction of $[MoCp_2Cl_2]$ with Na/Hg or from $[MoCp_2(CNCH_3)H]I$ with NaH. The other complexes were obtained from reaction of $[MoCp_2IX]$ (X = H, I) with the appropriate ligand.

Following our studies on the activation of coordinated nitriles bound to $M(\eta^5\text{-}C_5H_5)_2$ fragments (M = Mo, W; $\eta^5\text{-}C_5H_5$ = Cp),[1] we became interested in studying their isonitrile analogues, as well as their possible cyanide precursors. Although a very large number of molybdenocene derivatives are known for a wide variety of ligands, cyano and isonitrile complexes have not been reported, with the exception of $W(Cp)_2(OR)(CN)$.[2]

Reaction of $Mo(Cp)_2XI$ (X = H, I) with NaCN in acetonitrile, led to the new compounds $Mo(Cp)_2H(CN)$ and $Mo(Cp)_2(CN)_2$, quantitatively, after substitution of iodide by cyanide. The hydride complex reacts with CCl_4 in acetonitrile to give $Mo(Cp)_2Cl(CN)$. The two monocyano derivatives were characterized by elemental analysis, IR spectroscopy (ν(C≡N) at 2080 and 2110 cm^{-1}, for the hydride and the chloride derivatives, respectively) and ^1H NMR spectroscopy (δ_{Cp} = 5.01, δ_H = −9.07 for $Mo(Cp)_2H(CN)$ in d^3-acetonitrile; δ_{Cp} = 5.58 for $Mo(Cp)_2Cl(CN)$ in d^6-acetone). The bis-cyanide complex shows a C≡N stretching frequency at 2100 cm^{-1}, while the chemical shift of the Cp protons is δ 5.49 (D_2O). $Mo(Cp)_2(CN)_2$ can act as a ligand. Reaction with $Cu(BF_4)_2$, for instance, leads to the trinuclear species, $[\{Mo(Cp)_2(CN)_2\}_2Cu][BF_4]$.

Complexes of the neutral CNMe ligand can be obtained in a similar way by reaction of $Mo(Cp)_2XI$ (X = H, I) with the isonitrile in THF or acetonitrile, respectively. $[Mo(Cp)_2H(CNMe)]I$, $[Mo(Cp)_2I(CNMe)]I$ and $[Mo(Cp)_2(CNMe)_2]I_2$ were thus prepared and characterized by elemental analysis and spectroscopy. The C≡N stretching bands are observed at 2190, 2205 cm^{-1}, and 2220, 2240 cm^{-1}, respectively, in the IR spectrum. ^1H NMR spectroscopy gives the following chemical shifts (δ): 5.49 (Cp), 3.60 (Me), −8.84 (H) for the hydride derivative in d^6-acetone; 5.75 (Cp), 3.65 (Me) for the iodide derivative in d^3-acetonitrile; 5.98 (Cp), 3.60 (Me) for the bis-isonitrile complex in d^3-acetonitrile.

The $[Mo(Cp)_2H(CN)]I$ complex reacts with NaH in THF to afford the new molybdenocene derivative $Mo(Cp)_2(CNMe)$. This complex can also be prepared by reduction of $Mo(Cp)_2X_2$ (X = Cl, Br) with Na/Hg in methyl isocyanide. Both elemental analysis (Calc. for $C_{12}H_{16}NMo$: C, 53.54; H, 5.62; N, 5.20. Found: C, 52.86; H, 5.62; N, 4.50%) and ^1H NMR spectroscopy (δ_{Cp} = 4.35, δ_{Me} = 2.76 in d^6-benzene, integrating 10:3) indicate coordination of only one isonitrile ligand, while the bands in the IR spectrum suggest an end-on coordination for this ligand.

Extended Hückel molecular orbital calculations[3] show a preference for this type of coordination, the energy being *ca* 1.5 eV lower than that of a complex containing a bent, side-on coordinated isonitrile. A molecular orbital diagram comparing the two bonding modes is shown in Fig. 1.

The energy of the isonitrile orbitals changes with bending, as studied before.[4] The weaker bonding observed for the side-on coordination mode can be primarily assigned to a smaller overlap between the ligand HOMO and $2a_1$, leading to a less stable bonding molecular orbital.

It is interesting to notice that for the related nitrile complex, $Mo(Cp)_2(NCMe)$,[5] where the nitrile

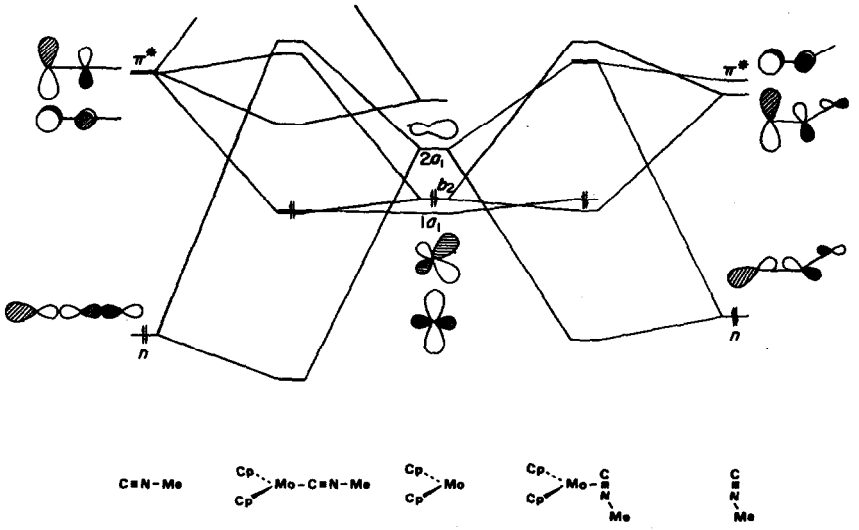

Fig. 1. Interaction between a $MoCp_2$ fragment and end-on (left) or side-on (right) isonitrile.

ligand is known to bind side-on to the molybdenum atom, our calculations give comparable energies for the two coordination geometries.

Reactions between the dication, $[Mo(Cp)_2(CNMe)_2]^{2+}$, and several nucleophiles were studied, but the products have not yet been fully characterized.

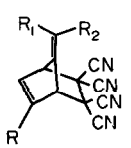
Abstract—Synthesis of two substituted cyclopentadienes, 1,3-bis(1-methylcyclohexyl) cyclopentadiene, Cp′H and [2-methyl-2-(2-pyridyl)ethyl]cyclopentadiene, Cp″H from fulvene intermediates is reported. These are readily converted to their early transition metal complexes $Cp'W(CO)_3Me$, $Cp''Mo(CO)_3Me$, $Cp''W(CO)_3Me$ and $[Cp''Ti(O)Cl \cdot CH_2Cl_2]_2$. The X-ray crystal structure of the titanium compound shows that the nitrogen of the pyridine cyclopentadienyl substituent is coordinated to the titanium.

The search for synthetic routes to 1,3-cyclopentadienes with a variety of substitution patterns is an area of great current interest. We report here on the synthesis of some novel substituted 1,3-cyclopentadienes (as mixtures of double bond isomers) and their early transition metal complexes.

Regioselective routes to isomeric 1,3-dialkylcyclopentadienes are limited but we have recently developed high yield regioselective syntheses using fulvene intermediates.[1] For example, 1,3-bis(1-methylcyclohexyl)cyclopentadiene (**I**, Cp′H) may be obtained via (1-methylcyclohexyl)-6,6-pentamethylenefulvene (**III**) (Fig. 1). The regio selectivity of the synthesis of **III** is confirmed by isolation of its Diels–Alder adduct with tetracyanoethylene, which yields only **IV**, which is identified by its ^1H NMR spectrum.



(IV)

The cyclopentadiene, Cp′H, can readily be converted into its transition metal complexes, e.g. $[Cp'W(CO)_3Me]$ (**V**) (Fig. 1). The solution IR spectrum of this compound is solvent dependent. In hexane, for example, it shows three stretches at 2010, 1925 and 1890 cm^{-1}, whereas in chloroform it shows four stretches at 2005, 1920, 1870 and 1820 cm^{-1}. This may be due to varying proportions of rotomers in different solvents, perhaps indicating that the steric bulk of the 1-methylcyclohexyl substituents causes an appreciable barrier to rotation. Similar effects have been observed with other cyclopentadienyl complexes.[2,4] Further studies are underway.

1,3-Cyclopentadienes with substituents containing potential chelating donor atoms should provide organometallic complexes with interesting properties. As an example, [2-methyl-2-(2-pyridyl)ethyl] cyclopentadiene (**VII**, Cp″H) can be obtained in 52% yield from 6-methyl-6-(2-pyridyl)-fulvene (**VI**) eq. (1):

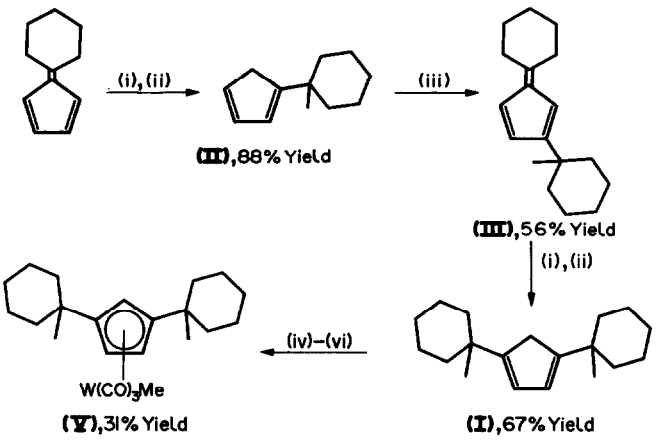

Fig. 1. Synthesis of [1,3-bis(1-methylcyclohexyl)ethylcyclohexyl)cyclopentadienyl]tricarbonylmethyltungsten (V). Reaction conditions (i) MeLi; (ii) H_2O, H^+; (iii) cyclohexanone, pyrrolidine, methanol; (iv) BuLi; (v) $(C_2H_5CN)_3W(CO)_3$; (vi) MeI.

The cyclopentadiene, Cp″H, can be converted to the metal complexes [Cp″M(CO)$_3$Me] (**VIII**, M = Mo; **IX**, M = W). The carbonyl stretches of those complexes are similar to those of the unsubstituted cyclopentadienyl complexes [**VIII**, (CO) 2020, 1940 cm^{-1} (hexane), **IX** (CO) 2020, 1920 cm^{-1} ($CHCl_3$)], indicating no coordination of the nitrogen, as this would be expected to give stretches at lower wavenumbers. Neither thermolysis in refluxing octane or UV irradiation caused changes in the spectra that could be interpreted as chelation of the pyridine moiety or as insertion of carbon monoxide into the metal methyl bond.

However, chelation of the pyridine nitrogen did occur in the [2-methyl-2-(2-pyridyl)ethylcyclopentadienyl]chlorotitanoxane dimer (**X**). This compound was prepared from the reaction between 1,1′-bis(2-methyl-2-(2-pyridyl)ethyl)magnesocene and titanium tetrachloride, followed by recrystallization with wet dichloromethane [eq. (2)].

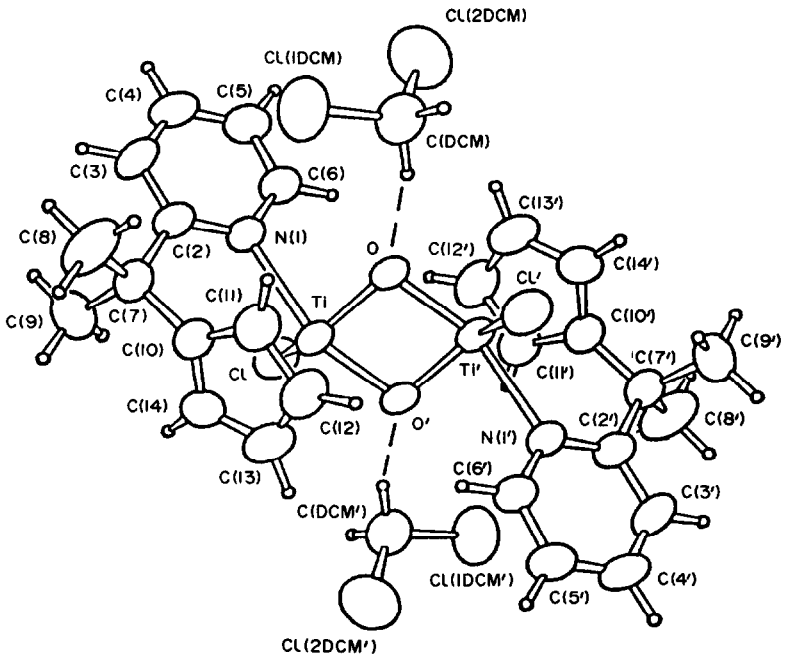

Fig. 2. Structure, solid-state conformation and atom-numbering scheme for **X**: small circles denote hydrogen atoms. Selected bond distances (Å): Ti—N, 2.297(3); Ti—O, 1.791(3); Ti—O′, 1.910(2); Ti—Ti′, 2.801(1).

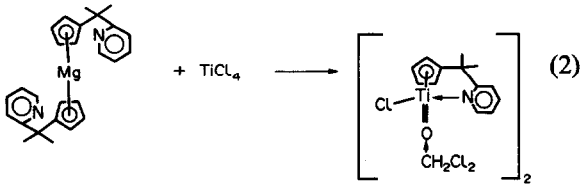

(2)

The X-ray crystal structure confirmed **X** as the product. The crystal structure and ORTEP diagram are shown (Fig. 2).* The titanium centre is coordinated to both the cyclopentadienyl ring, as well as the nitrogen atom, with a Ti—N bond distance of 2.297 Å.

Polytitanoxanes are known,[5] however, this is the first example of a dimeric product. Previous complexes exist as trimers and tetramers. This change in structure is presumed to be due to the internal chelation of the nitrogen atom occupying the coordination site normally used in forming a Ti—O bond in trimeric and tetrameric complexes. The high oxidation state of titanium and electronegative oxygen atoms aid in the internal coordination of the nitrogen atoms in this complex.

*Crystal data of **X**: $[C_{12}H_{11}ClNOTi \cdot CH_2Cl_2]_2$, $M = 737.10$, triclinic space group $P\bar{1}(C_i^1)$, $a = 10.188(3)$, $b = 10.385(2)$, $c = 8.410(3)$ Å, $\alpha = 101.78(2)$, $\beta = 92.76(2)$, $\gamma = 68.51(2)°$, $V = 810.16$ Å^3, $Z = 1$, $D_c = 1.511$ g cm^{-3}, μ(Cu-K_α) = 91.4 cm^{-1}, 2884 non-equivalent reflections, 2014 retained [$I > 3.0\sigma(I)$], $R = 0.046$, $R_w = 0.054$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Abstract—Thermolysis of $[W_2(CO)_4\{\mu\text{-}(CO_2Me)C_2CO_2Me\}(\eta\text{-}C_5H_5)_2]$ with PPh_2Cl gives $[W_2Cl_2(\mu\text{-}Ph_2PC{\equiv}CHCO_2Me)(\mu\text{-}PPh_2)(\eta\text{-}C_5H_5)_2]$, $[W_2(CO)_2(\mu\text{-}Cl)\{\mu\text{-}Ph_2PC(CO_2Me){=}CCO_2Me\}(\eta\text{-}C_5H_5)_2]$ and $[W_2(CO)C\{\mu\text{-}(CO_2Me)C_2CO_2Me\}(\mu\text{-}PPh_2)(\eta\text{-}C_5H_5)_2]$; further reactions involving these products give $[W_2(CO)O\{\mu\text{-}C(CO_2Me){=}CHCO_2Me\}(\mu\text{-}PPh_2)(\mu\text{-}C_5H_5)_2]$ and the paramagnetic complex $[W_2(CO)Cl(\mu\text{-}Cl)\{M\text{-}Ph_2PC(CO_2Me){=}CCO_2Me\}(\eta\text{-}C_5H_5)_2]$, which has been characterized by an X-ray diffraction study.

We have previously shown that the reaction of $[Mo_2(CO)_4(\mu\text{-}R^1C_2R^2)(\mu\text{-}C_5H_5)_2]$ (R^1,R^2 = H, alkyl or aryl) with PPh_2Cl proceeds via P—Cl bond cleavage and coupling of the diphenylphosphido group with the alkyne in one of three different ways, depending on the nature of R^1 and R^2.[1] In this communication we describe corresponding reactions of ditungsten alkyne complexes. Although these reactions are similar in many respects to those of the dimolybdenum species, additional products are obtained in the ditungsten system, perhaps because of the longer reaction times and higher temperatures (refluxing xylene instead of refluxing toluene) which are needed to induce the reaction to take place.

Prolonged thermolysis (2.5 days) of a xylene solution of $[W_2(CO)_4\{\mu\text{-}(CO_2Me)C_2CO_2Me\}(\eta\text{-}C_5H_5)_2]$ (**1**)[2] with excess PPh_2Cl affords, after chromatographic separation on silica (in order of elution), brown, crystalline $[W_2Cl_2(\mu\text{-}Ph_2PC{=}CHCO_2Me)(\mu\text{-}PPh_2)(\eta\text{-}C_5H_5)_2]$ (**2**)† (CH_2Cl_2–acetone 98:2) (7%), an uncharacterized brown compound, red, crystalline $[W_2(CO)_2(\mu\text{-}Cl)\{\mu\text{-}Ph_2PC(CO_2Me){=}CCO_2Me\}(\eta\text{-}C_5H_5)_2]$ (**3**)† (CH_2Cl_2–acetone 95:5) (42%) and green, crystalline $[W_2(CO)Cl\{\mu\text{-}(CO_2Me)C_2CO_2Me\}(\mu\text{-}PPh_2)(\eta\text{-}C_5H_5)_2]$ (**4**)† (CH_2Cl_2–acetone 92:8) (6%).

The proposed structures of **2**, **3** and **4** (Fig. 1) are based on spectroscopic data and on the results of X-ray diffraction studies of related dimolybdenum complexes.[1] The C—C bond scission involved in the formation of **2** from **1** is, however, a process which was not observed in the dimolybdenum system.

Thermolysis of **3** in xylene for 3.5 days gives **4** and unreacted **3** in approximately equal yields. The phosphorus–carbon bond cleavage necessary for the conversion of **3** to **4** was also not observed in our previous study.[2]

When **4** is absorbed on silica and left to stand

TETRAPHENYLCYCLOPENTADIENONE COMPLEXES OF MOLYBDENUM: X-RAY CRYSTAL STRUCTURE OF $[Mo(CO)_3(C_4Ph_4CO)]_2$

ROY L. BEDDOES, ELIZABETH S. COOK and MICHAEL J. MORRIS*

Department of Chemistry, University of Manchester, Manchester M13 9PL, U.K.

Abstract—The new complex $[Mo(CO)_3(C_4Ph_4CO)]_2$ has been prepared from $[Mo(CO)_6]$ and tetracyclone, and structurally characterized by X-ray diffraction. A high yield synthesis of $[Mo(CO)_2(C_4Ph_4CO)_2]$ is also described; one of the diene ligands of this complex is readily displaced by phosphines or alkynes.

We have recently reported[1] the synthesis and structural characterization of tetraphenylcyclopentadienoneruthenium dicarbonyl dimer (**1**). This complex functions as an effective catalyst precurser for hydrogenation and dehydrogenation reactions, owing to its facile dissociation in solution into two 16e⁻ $Ru(CO)_2(C_4Ph_4CO)$ units, which are thought to be the catalytically active species.[1,2] Since only one other dimer of this type, $[Fe(CO)_2(C_4H_4CO)]_2$, is known,[3] we were interested in preparing further examples. In this communication we report our preliminary studies of molybdenum cyclopentadienone chemistry, including the crystal structure of the dimer $[Mo(CO)_3(C_4Ph_4CO)]_2$.

Overnight reaction of $[Mo(CO)_6]$ with 2 equivalents of tetracyclone in refluxing toluene affords a 95% yield of bright yellow $[Mo(CO)_2(C_4Ph_4CO)_2]$ (**2**), isolated by column chromatography and characterized spectroscopically.† This complex was first prepared in low yield by Weiss and Hübel,[4] and presumably has a structure similar to that of the bis-cyclobutadiene complex, $[Mo(CO)_2(C_4Ph_4)_2]$.[5]

If 1 equivalent of tetracyclone is used with toluene as solvent, the yield of **2** becomes very low and the major product is a brown complex, which as yet we have been unable to characterize, as it decomposes to tetracyclone and insoluble material. However, its IR spectrum shows no peaks due to metal-bound carbonyls, and it therefore seems likely that it contains toluene as a ligand. In support of this view, when a 1:1 mixture of $[Mo(CO)_6]$ and C_4Ph_4CO was refluxed overnight in heptane, the brown material was not obtained; instead a precipitate was deposited consisting of a mixture of the new complex $[Mo(CO)_3(C_4Ph_4CO)]_2$ (**3**) (30% yield following chromatographic separation) and **2** (32% yield).

The nature of complex **3** was suggested by the presence of a peak at 1543 cm^{-1} in its IR spectrum in KBr (cf. 1535 cm^{-1} for **1**), indicative of the ketonic ring carbonyl bonding to a second metal atom; the NMR spectroscopic data† were also consistent with the proposed dimeric formulation, and

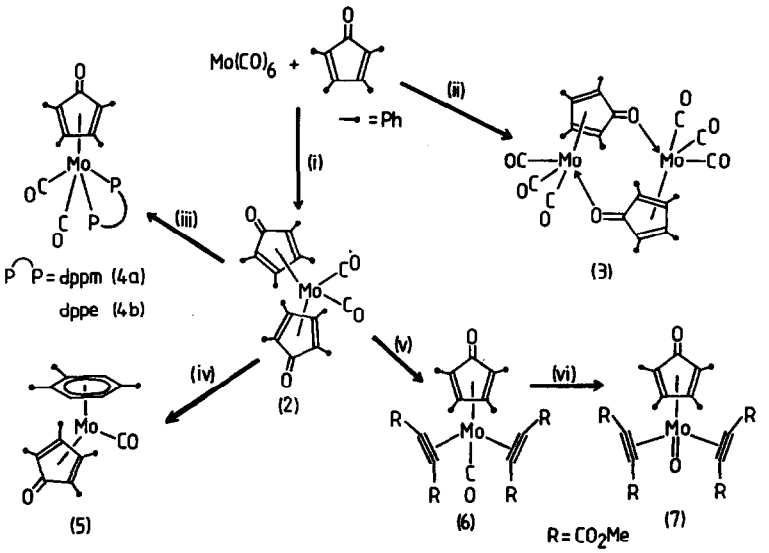
Satisfactory analytical data were obtained for all new complexes.



Scheme 1. Reagents and conditions: (i) 1:2 ratio, refluxing toluene, 17 h; (ii) 1:1 ratio, refluxing heptane, 17 h; (iii) dppm or dppe, refluxing toluene, 8 h; (iv) PhC≡CH (5 equivalents), refluxing toluene, 17 h; (v) $C_2(CO_2Me)_2$ (5 equivalents), refluxing toluene, 17 h; (vi) air, or aged THF.

it was confirmed by an X-ray diffraction study.* The structure, shown in Fig. 1, consists of centrosymmetric dimers in which each molybdenum bears three terminal carbonyl ligands and an η^4-bonded tetracyclone ring, the ketonic carbonyl of which is joined to the second molybdenum atom. This carbonyl group is bent back from the diene plane at an angle of 9.6°, in common with other η^4-cyclopentadienone complexes,[1,6] and the C(3)—O(2) bond length of 1.271(8) Å (cf. 1.270 Å in **1**) indicates that this bond is still essentially double in character. These features may be contrasted with those in $[Mo_2(CO)_3(\mu\text{-}C_2Ph_2)(\eta\text{-}C_4Ph_4)(\mu\text{-}C_4Ph_4CO)]$,[7] where the five carbon atoms of the bridging tetracyclone are all coplanar, and the C—O bond length is considerably longer (1.38(2) Å), indicating an η^5-bonded ring.

Preliminary investigations into the reactivity of **2** and **3** indicate that **2** provides a convenient entry into further chemistry. For example, in refluxing toluene one of the tetracyclone ligands is readily replaced by chelating phosphines to give $[Mo(CO)_2(\widehat{P\ P})(C_4Ph_4CO)]$ (**4a**: $\widehat{P\ P}$ = dppm, 92%; **4b**, $\widehat{P\ P}$ = dppe, 90%); further substitution to give the known complexes $[Mo(CO)_2(\widehat{P\ P})_2]$ does not occur. Moreover, under similar conditions, **2** is reactive towards alkynes: thus phenylacetylene gives a red–brown complex, to which we assign the structure $[Mo(CO)(1,2,4\text{-}C_6H_3Ph_3)(C_4Ph_4CO)]$ (**5**) (54%), free 1,2,4-triphenylbenzene, 1,3,5-triphenylbenzene, and pentaphenylbenzene (formed through Diels–Alder condensation of phenylacetylene with the liberated tetracyclone). With dimethyl acetylenedicarboxylate, the sole organometallic product is the green bis-alkyne complex $[Mo(CO)(MeO_2CC{\equiv}CCO_2Me)_2(C_4Ph_4CO)]$ (**6**) (45%), which on standing in the solid state (or immediately on dissolution in THF containing peroxides) undergoes oxidation to the oxo–alkyne species $[MoO(MeO_2CC{\equiv}CCO_2Me)_2(C_4Ph_4CO)]$ (**7**); a strong peak in the IR spectrum at 937 cm^{-1} is assigned to the Mo=O group. These reactions are summarized in Scheme 1.

Further investigations into the reactivity of these complexes are in progress.

Crystal data for **3**: $C_{32}H_{20}O_4Mo$, M = 564.4 (for monomer), triclinic, space group $P\bar{1}$ (No. 2), a = 8.980(3), b = 11.332(4), c = 13.516(5) Å; α = 77.55(3), β = 71.94(3), γ = 81.02(3)°, U = 1271 Å^3, D_c = 1.47 g cm^{-3} for Z = 2 (monomer units), $F(000)$ = 636, absorption. coefficient = 6.0 cm^{-1} (λ = 0.71069 Å, Mo-K_α). Final R = 0.0535% for 2194 unique, observed [$F > 3\sigma(F)$] intensity data, collected on an Enraf–Nonius CAD4 diffractometer to a maximum θ of 22°. As $\mu R < 0.11$, no absorption correction was applied, but a linear drift correction for a total intensity drop of 12% was used. The structure was solved by direct methods using the MULTAN 80 program, and eventually refined with anisotropic thermal parameters for all non-hydrogen atoms. A non-unit weighting scheme was used.

Abstract—Small MoS_2 slabs, which are the active component of hydrotreating catalysts, have been modelled by molecular graphics and molecular mechanics. Active sites at molybdenum are created by removing edge sulphur atoms. The structures and energies of slabs having molybdenum atoms with different degrees of coordinative unsaturation have been investigated. Structures where two molybdenum atoms are *not* linked by at least one sulphur atom are unstable owing to repulsion between the molybdenum atoms. They distort to increase the distance between the molybdenum atoms. Fully saturated slabs (those which terminate with SH groups) are also strained because of repulsions between the SH groups.

We are using computer modelling to investigate fundamental problems of heterogeneous catalysis. Recent work in our laboratory has been concerned with developing molecular graphics and energy calculations to investigate molybdenum disulphide-based catalysts.[1] These catalysts are used for hydrotreating oil feedstocks.[2] A slab model of the active phase of these catalysts has been devised based on the layered structure of MoS_2[3] and on experimental evidence, from transmission electron microscopy, for small single MoS_2 slabs in a hydrodesulphurization catalyst.[4,5] The slab model allows us to consider one slab as representative of the catalytically active phase and is particularly suitable for computer modelling.

In previous work we investigated the interaction of a simple molecule, isoprene, with catalytic sites on the edges of a MoS_2 slab, by molecular graphics and molecular mechanics.[1] In the present work, we consider the process of site generation and investigate the structural and energetic consequences of introducing vacancies at slab edges.

Computer modelling was carried out on an IBM PC–AT with the PC–Chemmod system.[6] The atomic coordinates of MoS_2 were retrieved from the SERC crystallographic database.[7] Molecular mechanics was used to calculate the energies of our structures.[8,9] We start from an ideal model structure and optimize the geometry by minimizing the total steric energy, E, which is approximated by a sum of energy contributions:

$$E = E_s + E_b + E_t + E_{nb},$$

where E_s is the bond stretching energy, E_b, the angle bending energy, E_t, the torsional energy due to rotation about bonds and E_{nb}, the energy of interactions between non-bonded atoms (van der Waals interactions).

The active phase of an alumina-supported molybdenum disulphide catalyst comprises small isolated slabs of MoS_2. In our computer graphics modelling we make a regular MoS_2 single slab by cutting a MoS_2 layer along two different crystallographic edge planes, (10−10) and (−1010).[10,11] We made a series of hexagonal slabs containing from seven up to 61 molybdenum atoms. The 61-atom hexagon is shown in Fig. 1.

The catalytic sites of molybdenum disulphide are edge plane molybdenum atoms exposed by remov-

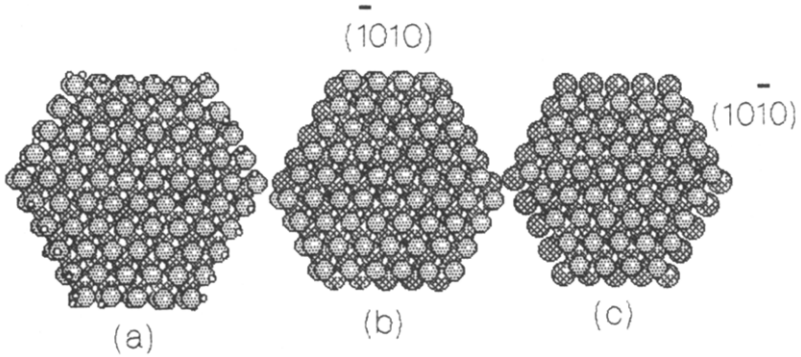

Fig. 1. Computer-drawn representations of hexagonal 61-Mo atom slabs, viewed with their basal plane in the plane of the diagram: (a) fully saturated slab terminated by SH groups; (b) partly unsaturated slab, singly bound SH groups removed from (10−10); (c) fully unsaturated slab, bridging S removed from (−1010). The edge planes are labelled. Note that in our computer graphics representation, the relative atomic sizes are according to their atomic radii: bigger, cross-hatched spheres are molybdenum atoms, small dotted spheres are sulphur atoms. The very small spheres in (a) are hydrogen atoms.

ing edge sulphur atoms.[1,2] The two types of peripheral sulphur atoms are apparent in Fig. 1: the terminal sulphur atoms in the (10−10) edge plane, designated S_I, and the bridging sulphur atoms in the (−1010) edge plane, S_{II}. In recent work the catalytic chemistry of MoS_2 has been associated with the S_{II} edge plane.[12] Various structures can be generated on this plane by removing sulphur atoms from around a pair of adjacent molybdenum atoms. This pair of molybdenum atoms constitutes an elementary ensemble.[13,14]

Molecular mechanics calculations have been carried out on various types of slab, see Fig. 1: (a) saturated, (b) partly unsaturated, singly bound sulphur atoms (S_I) removed, (c) fully unsaturated slabs, bridging sulphur atoms (S_{II}) removed. The saturated slabs are terminated by SH groups, which are necessary for electroneutrality. For the 61-molybdenum atom hexagonal slab, three sides each contain eight S_{II}; therefore, 24 S_{II} can be removed. Successive removal of S_{II} bridging sulphur atoms creates two types of molybdenum ensemble sites: (a) three-fold coordinately-unsaturated molybdenum atoms (designated 3-cus), those linked by one sulphur bridging atom; (b) 4-cus molybdenum atoms, those without bridging sulphur. Up to 12 S_{II} can be removed before 4-cus sites are formed. Our main observations, which refer to the structures *after minimization*, are as follows (final energy, E (kcal mol^{-1}); Mo···Mo nearest neighbour distance, r (Å) in the (−1010) and (10−10) edges):

(a) High energy (or strained) slabs are the ones fully saturated with SH groups [see Fig. 1(a)] (E, 62.9; r, 3.24, 3.48) and the fully unsaturated slab [Fig. 1(c)] (E, 116; r, 4.42, 2.96). The high energies are due to repulsions between the SH groups and pairs of unsaturated molybdenum atoms, respectively. Note how the repulsions open up the Mo···Mo distances (3.18 Å before minimization) along the strained edge [(10−10) in Fig. 1(a) and (−1010) in Fig. 1(c)].

(b) The high strain in the fully saturated slab is consistent with the presence of a type of easily removed sulphur in MoS_2 catalysts,[15] now considered to be the terminal sulphur in the (10−10) edge plane.[12]

(c) The partly unsaturated slab with molybdenum linked by two sulphur atoms is more stable [Fig. 1(b)] (E, 3.55; r, 3.28, 3.25). Unsaturated molybdenum atoms in the (−1010) edge plane are generated by the gradual removal of S_{II} atoms from the 61-Mo slab. The energy of the slab hardly changes as we remove up to 12 S_{II}, four from each S_{II}-type side, provided the molybdenum atoms are kept linked always by one sulphur (after removing 12 S_{II}: E, −2.90; r, 3.35, 3.23). However, successive removal of the last six sulphur atoms leads to large increases in energy because of the strong non-bonded repulsions which then arise between pairs of adjacent unsaturated molybdenum atoms (e.g. after removing three more S_{II}: E, 22.4; r, 4.31, 3.10).

Our calculations clearly show that structures where the two molybdenum atoms are *not* linked by at least one sulphur atom have high energy and are deformed relative to the normal structure. This conclusion is illustrated in Fig. 2. We see that after minimization the distance between the molybdenum atoms has increased; the cavity has opened up. Therefore, in discussing substrate binding at an active site created in the way we have

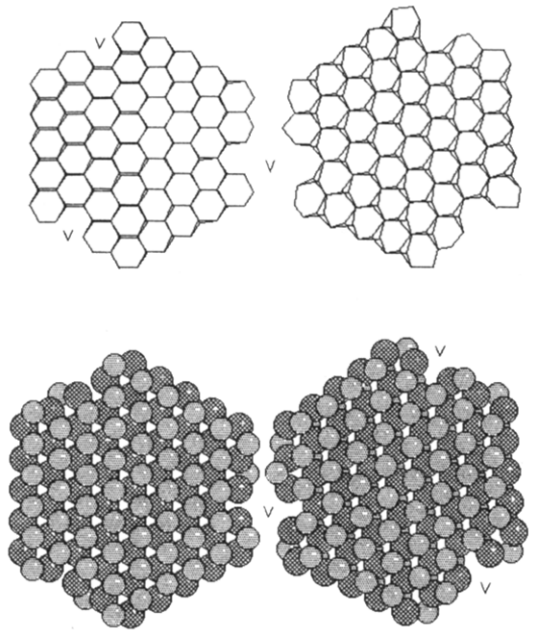

Fig. 2. Vacancies (labelled v) along (−1010), four-fold unsaturated molybdenum atoms, before and after energy minimization showing the expansion of the cavity due to Mo···Mo repulsion.

described we need to consider the final, distorted site. Experimentally, we may relate the deformation to the curved structure of the MoS_2 layers in bulk molybdenum disulphide, which may explain the rag structure of MoS_2.[16]

The active site cavity shown in Fig. 2 is reminiscent of the active centre of an enzyme; moreover, the coordination centre is strained analogously to the entatic-state description of a metalloenzyme.[17] In future work we shall investigate geometric factors in the accommodation and exclusion of a substrate molecule at the site, and electronic factors in binding and activation of the molecule. We shall also be concerned with how the strained site may be stabilized, for example by adsorption of sulphur or a reactant species such as hydrogen or a substrate molecule.

AN EXPERIMENTAL AND COMPUTATIONAL APPROACH TO MODELLING MOLYBDOENZYMES

M. G. B. DREW,* N. J. JUTSON, P. C. H. MITCHELL and S. A. WASS

Department of Chemistry, The University, Whiteknights, Reading RG6 2AD, U.K.

Abstract—Molybdoenzymes such as xanthine oxidase and nitrate reductase have at their active centre a molybdenum atom coordinated by oxide and sulphur ligands. In these enzymes molybdenum is monomeric; the protein apparently stops the molybdenum from dimerizing. As a first step towards constructing an inorganic analogue of a molybdoenzyme, we have synthesized molybdenum–sulphur complexes in zeolite cages of different sizes. The presence of a monomeric molybdenum(V) complex in the Linde A supercage is shown by its electron spin resonance spectrum. Using our molecular graphics computer system we have constructed accurate models of molybdenum–sulphur complexes in various zeolite cages. We have modelled the minimum energy configuration of the system via molecular mechanics and investigated possible modes of reaction. Our theoretical modelling results account well for our experimental data, and, in particular, suggest that dimerization of the molybdenum complexes cannot occur within the Linde A cage, in agreement with experiment.

Enzymes are remarkable catalysts. They catalyse, under ambient conditions, reactions which over heterogeneous catalysts require elevated temperatures and pressures. They are highly selective. There is an obvious technical interest in exploiting the catalytic chemistry of enzymes.[1]

The key feature of enzyme catalysis which we are modelling is the ability of an enzyme to create a reaction space where the active enzyme groups and the substrate molecule are organized, in order to provide the optimum configuration for the catalysis.[1] The zeolites, as potential biomimetic catalysts, are our particular interest. There are similarities between cavities in the zeolite and those in the protein tertiary structure.[2,3] Also, they can be tailored for shape selectivity and acid/base functionality. Our reaction–space model is a molybdenum centre in a zeolite cage.

Samples of molybdenum dithiocarbamate in the Linde A zeolite were prepared as follows. The zeolite was stirred with an aqueous solution of sodium molybdate for *ca* 3 h; water was removed in a vacuum rotary evaporator; and the molybdenum–zeolite (denoted MoZ) was oven-dried. The reactions of MoZ with sodium diethyldithiocarbamate, $Na[Et_2NCS_2]$ (abbreviated Nadtc), were carried out according to procedures for the preparation of the complexes $MoO_2(dtc)_2$ and $Mo_2O_3(dtc)_4$.[4] For example, MoZ was added to an aqueous solution of sodium diethyldithiocarbamate acidified with dilute hydrochloric acid. The samples were washed with carbon tetrachloride to remove molybdenum dithiocarbamates from the external surface of the zeolite. The products, ModtcZ, with 5 and 10% molybdenum were blue solids. Their strong paramagnetism (ESR, g 1.977) is consistent with the presence of a monomeric molybdenum(V) species. In the absence of the zeolite the molybdenum(V) product was the diamagnetic dimer, $Mo_2O_3(dtc)_4$. Clearly the zeolite stabilizes monomeric molybdenum(V).

Using our molecular graphics computer system we have constructed accurate models of molybdenum dithiocarbamato complexes in various zeolite cages. We report here our calculations with Linde A. Computer modelling was carried out on an IBM PC-AT with the PC-Chemmod system.[5] The atomic coordinates of the zeolites and molybdenum dithiocarbamato complexes were retrieved from the SERC crystallographic database.[6] Molecular mechanics were used to calculate the energies of our structures.[7,8] We start from an ideal model structure and optimize the geometry by

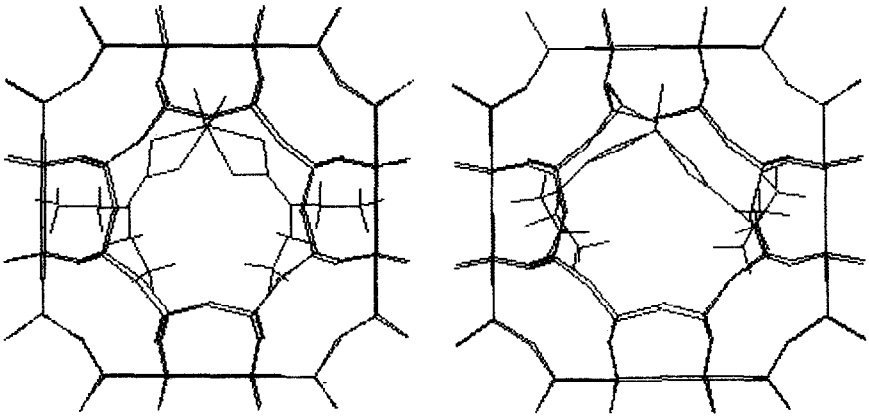

Fig. 1. The molybdenum dithiocarbamato complexes, $MoO_2(dtc)_2$ and $MoO(dtc)_2$, encapsulated in a Linde A cage: computer-drawn representations of the lowest energy structures.

minimizing the total steric energy, E, which is approximated by a sum of energy contributions:

$$E = E_s + E_b + E_t + E_{nb},$$

where E_s is the bond stretching energy, E_b, the angle bending energy, E_t, the torsional energy due to rotation about bonds and E_{nb}, the energy of interactions between non-bonded atoms (van der Waals interactions). The final energies after minimization for molybdenum dithiocarbamates in a Linde A cage were: $MoO_2(dtc)_2$, -17.1; $MoO(dtc)_2$, 50.1; $Mo_2O_3(dtc)_4$, 558 kcal mol^{-1}. The dimer is obviously very strained. The two monomers can, however, fit into the cage; computer-drawn representations of the final structures are shown in Fig. 1. Surprisingly, the monoxo compound, $MoO(dtc)_2$, is more strained than the bigger dioxo compound. The strain is caused by bending of the dithiocarbamates to achieve the best fit in the cage. The observation of a strained coordination centre is of great interest in analogy to the enzyme chemistry, evoking the entatic-state description of a metalloenzyme.[9] Further experimental and computational studies are underway.

SYNTHESIS, X-RAY STRUCTURE AND REACTIVITY OF THE HALF-SANDWICH IMIDO COMPLEX (η-C_5H_5)$NbCl_2(NCH_3)$

VERNON C. GIBSON† and DAVID N. WILLIAMS

Department of Chemistry, University Science Laboratories, South Road, Durham DH1 3LE, U.K.

and

WILLIAM CLEGG and DAVID C. R. HOCKLESS

Department of Chemistry, The University, Newcastle upon Tyne NE1 7RU, U.K.

Abstract—Room temperature treatment of (η-C_5H_5)$NbCl_4$ with a stoichiometric amount of $(Me_3Si)_2NMe$ in acetonitrile, gives (η-C_5H_5)$NbCl_2(NCH_3)$ in 87% yield. The X-ray structure reveals a three-legged piano stool geometry with a Nb—N bond length of 1.752(2) Å and a Nb—N—C angle of 163.4(3)°.

The reactivity of metal-bound oxygen and nitrogen atoms is of considerable interest due to their role in a variety of important industrial processes.[1] Half-sandwich metal oxides have been the focus of much recent attention[2] due to the stabilizing and solubilizing properties of ancillary C_5R_5 [R = H(Cp), Me(Cp*)] ligands. However, analogous compounds containing the iso-electronic alkylimido ligand (NR) remain rare. For the group 5 metals, we are aware of only two: $CpVCl_2(Ntol)$,[3] which has been prepared from the reaction of $V(Ntol)Cl_3$ with $Me_3SiC_5H_5$, and compounds of the type $Cp^*TaMe_2(NR)$[4] (R = Me, CMe_3, CH_2CMe_3) which are formed upon treatment of Cp^*TaMe_3Cl with LiNHR.

Here, we describe a convenient entry into half-sandwich niobium–imido chemistry through the treatment of $CpNbCl_4$ with heptamethyldisilazane, $(Me_3Si)_2NMe$, according to eq. (1).

$$CpNbCl_4 + (Me_3Si)_2NMe \longrightarrow CpNbCl_2(NMe) + 2Me_3SiCl. \quad (1)$$

(1)

In a typical reaction, $(Me_3Si)_2NMe$ (2.93 g, 16.7 mmol) in acetonitrile (30 cm^3) was added dropwise, with stirring, to a suspension of $CpNbCl_4$ (5.0 g, 16.7 mmol) in acetonitrile (100 cm^3) at room temperature. The red suspension was consumed over a period of 2 h to give a yellow–orange solution, which was stirred for a further 6 h. Removal of the volatile components, followed by washing with light petroleum ether (2×25 cm^3) and drying *in vacuo* gave a yellow powder, which can be recrystallized from toluene to give **1** (3.74 g, 87%) in the form of large orange crystals. Compound **1** has been characterized by ^1H NMR and IR spectroscopies, mass spectrometry and gives satisfactory elemental analyses. The ^1H NMR spectrum (C_6D_6, 250 MHz) reveals singlet resonances at δ 5.72 and 3.21 (ratio 5:3) attributable to equivalent ring hydrogens and the methyl hydrogens of the imido ligand, respectively. Also, a parent ion is observed at m/z 258 (^{35}Cl) in the mass spectrum.

The molecular structure‡ of **1** is shown in Fig. 1, and important bond distances and angles are included in the figure caption. The molecule possesses a three-legged piano stool geometry, with a crystallographic mirror plane which bisects the Cl—Nb—Cl angle and contains the niobium, nitro-

‡ Crystal data for **1**: $C_6H_8Cl_2NNb$, $M = 258.0$, monoclinic, $a = 7.1778(6)$, $b = 9.8969(10)$, $c = 7.1994(6)$ Å, $\beta = 118.04(6)°$, $U = 451.41$ Å^3, $Z = 2$, space group $P2_1/m$; $R = 0.016$, $R_w = 0.016$ from 827 unique observed reflections with $2\theta < 50°$, measured with Mo-K_α radiation ($\lambda = 0.71073$ Å) and corrected for absorption. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited as supplementery data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

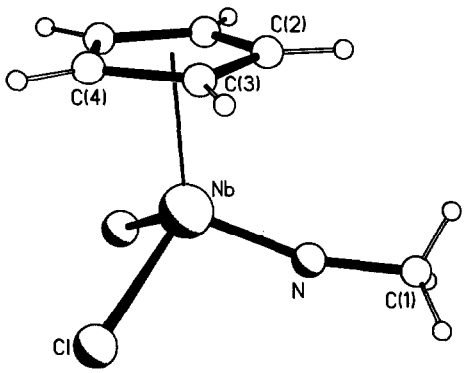

Fig. 1. The molecular structure of **1**. The molecule has crystallographic mirror symmetry. Selected bond lengths and angles are: Nb—Cl, 2.335(1); Nb—N, 1.752(2); Nb—C, 2.380(4), 2.404(3), 2.500(3); N—C(1), 1.432(3) Å. Cl—Nb—Cl, 104.7(1); Cl—Nb—N, 103.3(1); Nb—N—C(1), 163.4(3)°.

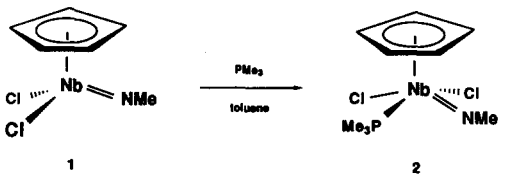
gen and carbon atoms C(1) and C(2). The niobium–nitrogen distance of 1.752(2) Å lies within the range expected for a metal–nitrogen triple bond (typically 1.73–1.79 Å for niobium–imido compounds[5–7]), arising by donation of the nitrogen lone pair. The Nb—N—C angle of 163.4(3)° lies at the low end of the range (161–180°)[1] typically observed for a terminal imido ligand containing a *sp*-hybridized nitrogen.

The methyl substituent is bent towards the cyclopentadienyl ring suggesting that the primary interaction of the nitrogen lone pair-containing *p* orbital is with a lobe of a vacant metal orbital projecting *trans* to the Cp ring. Although **1** is formally a 16-electron species (including donation of the lone pair from the imido nitrogen), it does not bind acetonitrile, the reaction solvent. However, it readily reacts with highly basic trimethylphosphine to give colourless, crystalline **2** [eq. (2)] for which a preliminary structural investigation shows a four-legged piano stool geometry, with the trimethylphosphine ligand lying *trans* to one chloro group and *cis* to the methylimido and remaining chloride ligand [as illustrated in eq. (2)]:



(2)

Further derivatization of **1** may be achieved by exchange of the halide ligands. The compounds $CpNb(OAr)_2(NMe)$ (Ar = 2,6-$Me_2C_6H_3$) and $CpNbMe_2(NMe)$ have been obtained by treatment of **1** with 2 equivalents of LiOAr and MeMgI, respectively. These, and related studies will be described in detail in a future report.

Abstract—The chromium(II) complex $[CrI_2(depe)_2]$, where depe is 1,2-bis(diethylphosphino)ethane, is unusual in that it is high spin at room temperature, but on cooling undergoes a sharp transition to the low spin form at *ca* 170 K. Other complexes of chromium(II) halides and depe or 1,2-bis(dimethylphosphino)ethene (dmpe) are low spin. The structure of the high spin form of $[CrI_2(depe)_2]$ has been determined.

There are many examples of spin state transitions in complexes with the d^5, d^6 and d^7 configurations,[1] but hardly any with the d^4 configuration. Chromium(II) is an example of a metal ion with the $3d^4$ configuration and it forms many octahedral, high spin complexes, e.g. $[Cr(en)_3]Cl_2$, where en is 1,2-diaminoethane, which have temperature-independent magnetic moments close to the spin-only value for four unpaired electrons ($\mu_{S.O.} = 4.90$ BM, $S = 2$). Complexes containing strong field ligands, e.g. $[Cr(bipy)_3]Cl_2$, where bipy is 2,2′-bipyridyl, are low spin with essentially temperature-independent moments somewhat above the spin-only value for two unpaired electrons ($\mu_{S.O.} = 2.83$ BM, $S = 1$).[2]

The chromium(II) complexes $[CrX_2(depe)_2]$, where X = Cl, Br or I, depe = 1,2-bis(diethylphosphino)ethane, and $[CrX_2(dmpe)_2]$, where X = Br or I, dmpe = 1,2-bis(dimethylphosphine)ethane, have been prepared by the addition of the diphosphine to a solution of the hydrated chromium(II) halide in methanol. The known complex $[CrCl_2(dmpe)_2]$ is low spin in toluene at room temperature ($\mu_{eff} = 2.8$ BM).[3] Magnetic measurements on the solids show that all complexes except $[CrI_2(depe)_2]$ are low spin, with little variation of magnetic moment with temperature. The magnetic behaviour of one low spin complex $[CrI_2(dmpe)_2]$, is depicted in Fig. 1. Rather surprisingly, $[CrI_2(depe)_2]$ is high spin at room temperature, but there is a sharp spin crossover to the low spin form at approximately 170 K (Fig. 2). In accordance with the essentially constant moments of each spin state, the reciprocal susceptibility (χ_{Cr}^{-1}) vs temperature plot follows the Curie law on either side of the discontinuity.

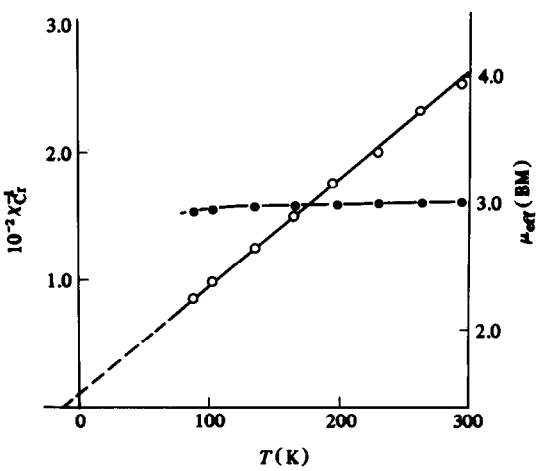

Fig. 1. Variation with temperature of reciprocal molar susceptibility χ_{Cr}^{-1} (○) and effective magnetic moment μ_{eff} (●) of $[CrI_2(dmpe)_2]$.

*Author to whom correspondence should be addressed.

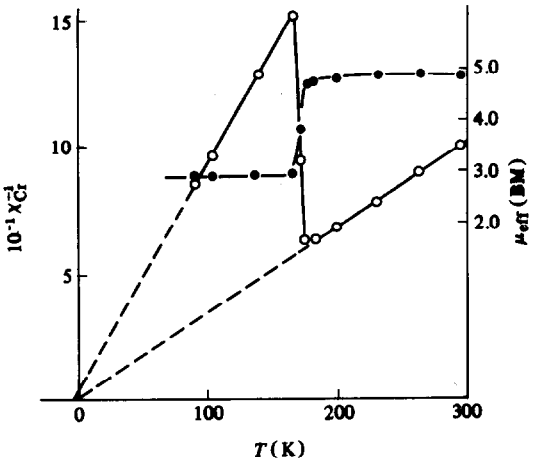

Fig. 2. Variation with temperature of reciprocal molar susceptibility χ_{Cr}^{-1} (○) and effective magnetic moment μ_{eff} (●) of $[CrI_2(depe)_2]$.

The molecular structure of $[CrI_2(depe)_2]$ has been determined at room temperature. It is a *trans* complex; the Cr—P distances are 2.503(1) and 2.533(1) Å, and the Cr—I distance, 3.068(0) Å. Further investigations are in progress.

Abstract—The hydrated vanadium(II) compounds $[VCl_2(H_2O)_4]$, $[V(H_2O)_6]Br_2$, $[V(H_2O)_6](BF_4)_2$ and $[V(H_2O)_6](CF_3SO_3)_2$ have been isolated from vanadium and the aqueous acid. From reactions of the hydrogen halide and vanadium immersed in glacial acetic acid, $[VCl_2(CH_3COOH)_4]$ and $[V(CH_3COOH)_6]Br_2$ have been obtained. The structures of $[V(H_2O)_6](CF_3SO_3)_2$, $[VCl_2(CH_3COOH)_4]$ and $[V(CH_3COOH)_6]Br_2$, which are new complexes, have been determined.

Previously, hydrated vanadium(II) salts, e.g. $[V(H_2O)_6]Br_2$, were prepared by electrolytic reduction. There is a brief report[1] that $[V(H_2O)_6]Br_2$ and other hydrates can be prepared from the acid and vanadium, hitherto considered too unreactive towards non-oxidizing acids. We have confirmed this report with the synthesis of $[VCl_2(H_2O)_4]$, $[V(H_2O)_6]Br_2$ and $[V(H_2O)_6](BF_4)_2$, and the new salt $[V(H_2O)_6](CF_3SO_3)_2$ (Scheme 1). Also, the novel complexes $[VCl_2(CH_3COOH)_4]$ and $[V(CH_3COOH)_6]Br_2$ have been prepared from vanadium and glacial acetic acid saturated with HX (X = Cl or Br) (Scheme 2). Satisfactory analytical data have been obtained.

Structure of $[V(H_2O)_6](CF_3SO_3)_2$

In $[V(H_2O)_6](CF_3SO_3)_2$, the VO_6 octahedron has equal V—O distances as expected for a $3d^3$ complex. The mean value of 2.119(1) Å agrees closely with that found for the V—OH_2 distances in $[V(H_2O)_6]SO_4$,[2] (2.131 Å). The triflate anions are extensively hydrogen-bonded to the coordinated water molecules. Eight anions form a cage around each $[V(H_2O)_6]$ octahedron, and the framework of 12 hydrogen bonds consists of two independent contacts from each of the four O(4) water molecules to different triflate anions (O(4)—O(1) = 2.839 Å and O(4)—O(2) = 2.814 Å) and two symmetrical contacts between each water molecule O(3) and the O(2) atoms of two anions (O(3)—O(2) = 2.785 Å). The hydrogen bonding clearly contributes to the stability of the lattice.

Structures of $[VCl_2(CH_3COOH)_4]$ *and* $[V(CH_3COOH)_6]Br_2$

Structural analyses show that these two complexes contain acetic acid coordinated via the carbonyl oxygen, and they also show that in each case the vanadium atom is octahedrally coordinated. In the VCl_2O_4 coordination sphere of $[VCl_2(CH_3COOH)_4]$ the average V—Cl distance is 2.500 Å and the average V—O distance is 2.125 Å (range 2.09–2.15 Å). A bond scan around each chlorine atom shows that six oxygen atoms cluster in a hemisphere around each chlorine atom, with distances of 3.01–3.34 Å, suggesting a weak intramolecular hydrogen bond interaction.

In $[V(CH_3COOH)_6]Br_2$, the VO_6 octahedron is symmetrical with an average V—O distance of 2.11 Å, which is similar to those for the chloro complex

Scheme 2. Compounds isolated from acetic acid.

and the hydrates above. Each bromide ion is surrounded by three hydroxyl groups with Br—O distances of 3.13–3.19 Å, suggesting that the hydroxyl hydrogen is intermolecularly hydrogen-bonded to the bromide ions. This also occurs in the analogous nickel(II) complex, $[Ni(CH_3COOH)_6](BF_4)_2$.[3]

Vanadium metal is thus a convenient source of vanadium(II) compounds.

NEW STRUCTURAL TYPES FOR CHROMIUM(II)

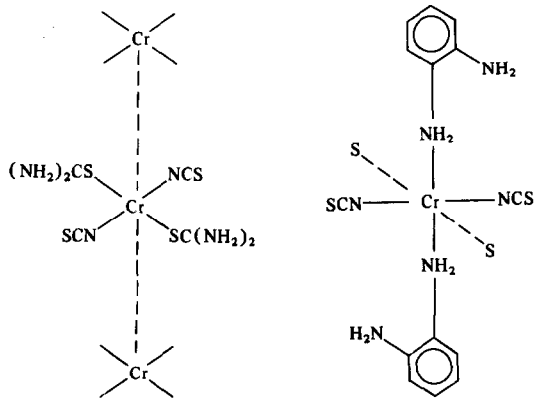
JAYNE JUBB, LESLIE F. LARKWORTHY,* DAVID C. POVEY and GLEN W. SMITH

Department of Chemistry, University of Surrey, Guildford GU2 5XH, U.K.

Abstract—The new compound $Cr(thiourea)_2(NCS)_2$ contains *trans*-planar units stacked along the *a*-axis of the unit cell so that the chromium ions lie in infinite chains. In this first example of chains of directly interacting paramagnetic metal ions, the Cr—Cr separation is 3.97 Å which leads to weak antiferromagnetism but does not provide a conducting pathway. In contrast, the molecules in $Cr(OPD)_2(NCS)_2$, where OPD is *o*-phenylenediamine, prepared during investigations aimed at producing planar Cr^{2+} complexes by template reactions, do not stack and contain thiocyanate bridges. The new complexes $Cr(OPD)Cl_2$ and $[Cr(OPD)_6]Cl_2$ have been prepared. The latter has been used in reactions with acetylacetone aimed at producing planar chromium(II)–tetra-azamacrocyclic complexes, but a new metal-free octa-azamacrocycle has been obtained.

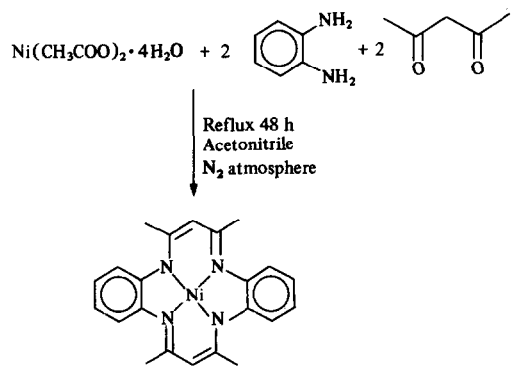
High-spin chromium(II) can exist as tetragonally distorted six-coordinate and planar four-coordinate complexes.[1] The structure of $Cr(thiourea)_2(CNS)_2$ (**A**) revealed *trans*-planar units stacked along the *a*-axis of the unit cell. The chromium ions lie in infinite parallel chains so that the metal ions can directly interact. This suggested that square-planar complexes of chromium(II) could stack and a conducting pathway could arise. In **A** however, the Cr—Cr separation was found to be too large (3.97 Å) and the complex was non-conducting.[2]

An analogous complex, **B**, was prepared using *o*-phenylenediamine (OPD) instead of thiourea. Magnetic measurements showed antiferromagnetic behaviour ($\mu_{eff}^{293} = 4.19$ BM, $\mu_{eff}^{87} = 3.20$ BM) and the structure of **B** revealed a non-stacking system containing thiocyanate bridges.



A **B**

Investigations aimed at producing planar chromium(II)–tetra-aza macrocycles were based on the nickel(II) template reactions used by Goedken and Weiss:[3]



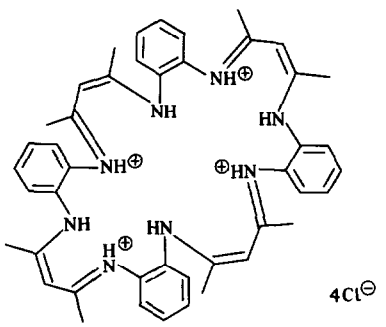
There was no reaction using $Cr_2(CH_3COO)_4 \cdot (H_2O)_2$ due to the thermal stability resulting from its dimeric nature. Since the above route proceeds via the formation of an intermediate OPD complex of nickel(II) which then condenses with acacH, it was decided to synthesis OPD complexes of chromium(II).

Compound **B** was refluxed under nitrogen with acacH in acetonitrile for 48 h. There was no reaction. However, the structure of **B** had shown the presence of monodentate OPD, and the formation of the nickel(II) macrocycle is dependent on the acacH being able to condense with the coordinated $-NH_2$ groups. This possibly requires bidentate OPD.

Efforts were switched to the preparation of a

* Author to whom correspondence should be addressed.

chloride containing an OPD salt of chromium(II), and $[Cr(OPD)_6]Cl_2$ and a polymeric, chloride-bridged compound, $Cr(OPD)Cl_2$, were isolated. In solution, at room temperature, the hexakis(amine) undergoes a series of rapid stepwise equilibria ending with $Cr(OPD)Cl_2$. No $Cr(OPD)_2Cl_2$ could be isolated from this. However, reaction of $[Cr(OPD)_6]Cl_2$ with acacH yielded a highly crystalline, purple–black product, which was believed to be the desired chromium(II) macrocycle. Further characterization, however, revealed it to be the macrocyclic product, **C**.



C

Presumably, **C** forms when $[Cr(OPD)_6]Cl_2$ loses two axial ligands, readily in solution, through Jahn–Teller distortion, leaving a square-planar arrangement which condenses with four acacH. The macrocycle is now too bulky to stay coordinated to the chromium ion, so it "relaxes" and the chromium(II) ion is ejected into solution. Other hexakis OPD compounds of nickel(II)[4] and iron(II)[5] have been reported. We repeated the preparation of $[Ni(OPD)_6]Cl_2$ using the method of Marks *et al.*,[4] but this did not undergo the analogous reaction for the formation of **C**.

SYNTHESIS AND CHARACTERIZATION OF SOME MIXED LIGAND OXOVANADIUM(IV) COMPLEXES: THE $[LVO]^+$ CHROMOPHORE, WHERE L = HYDROTRIS(3,5-DIMETHYLPYRAZOLYL)BORATE

DAVID COLLISON,* FRANK E. MABBS, MOHAMMAD ALI PASSAND and KEITH RIGBY

Chemistry Department, University of Manchester, Manchester M13 9PL, U.K.

and

WALT E. CLELAND, JR

Chemistry Department, University of Mississippi, MS 38677, U.S.A.

Abstract—The characterization of compounds LVOB, where B = β-diketonate or N,N-diethyldithiocarbamate, is reported. A comparison of their electronic absorption and ESR spectra with those of the corresponding VOB_2 complexes is made. The electronic structures of LVOB are closest to that of a trigonally-distorted octahedron, whilst VOB_2 are closest to that of a square-based pyramid.

We are interested in establishing the relationship between the geometric and electronic structures of oxovanadium(IV) and oxomolybdenum(V) compounds,[1–3] especially when particular constraints are imposed by the ligands. The stabilization of early transition metal oxo compounds by the sterically demanding hydrotris(3,5-dimethylpyrazolyl) borate anion (= L), which has been extensively demonstrated for molybdenum,[3] has now been extended to vanadium(IV) in the form of complexes of formula LVOB, where $B = O^-$ or S-donor uninegative, bidentate ligand. The compounds are most conveniently prepared under non-aqueous conditions according to eq. (1):

$$VOB_2 + KL \xrightarrow[\text{solvent}]{ca\ 50–60°C} LVOB + KB. \quad (1)$$

The complexes show parent-ion peaks for electron impact mass spectrometry. For LVOB, the values of ν(B—H) fall in the range 2510–2539 cm^{-1}, which are comparable with those in a number of LMo(oxy) compounds.[3,4] When B = β-diketonate, the values of ν(V=O) fall in the narrow range 959–967 cm^{-1}, indicative of little variation in the bonding in the V=O fragment. The β-diketonate complexes all exhibit quasi-reversible one-electron oxidations in methyl cyanide as assessed by cyclic voltammetry (e.g. for LVO(acac), acac = 2,4-pentanedionato, $E = 1.45$ V, $\Delta E_p = 80$ mV, $i_{pa}/i_{pc} = 1.04$). There is a small dependence of the potential, E, on the substituents of the β-diketonate ligand.

It is the electronic structure of the LVO (β-diketonate) complexes which are most noteworthy. The electronic absorption spectra of these compounds in toluene solution generally exhibit *four* bands in the range 13,000–26,000 cm^{-1}, which can be assigned to *d–d* transitions based on their extinction coefficients. The energies and extinction coefficients of these bands show only small changes in different solvents, ranging from non-coordinating toluene through dichloromethane to potentially coordinating methyl cyanide. In contrast, the corresponding VO(β-diketonate)$_2$ compounds in non-coordinating solvents usually exhibit only *three d–d* bands[5] [e.g. the band maxima × 10^{-3} cm^{-1} (molar extinction coefficient) are VO(acac)$_2$: 15.44(60), 16.88(67), 25.81(128); LVO(acac): 13.11(54), 17.62(11), 24.22(50), 25.11(50)].

In the VOB_2 compounds, it is generally assumed that the $[VO]^{2+}$ moiety dominates the electronic structure, and hence the *d*-orbital splitting pattern

* Author to whom correspondence should be addressed.

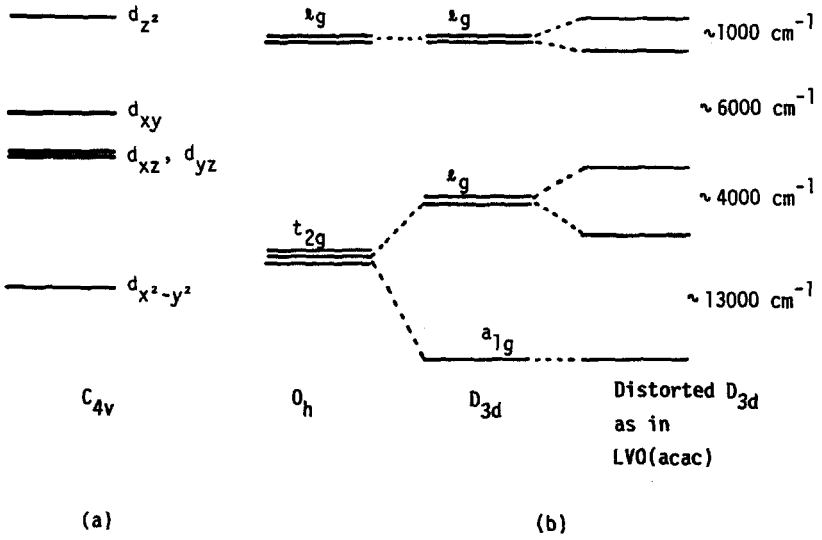

Fig. 1. *d*-Orbital splitting diagram for (a) C_{4v} point symmetry; (b) an octahedron with a predominantly trigonal distortion.

approximates to that expected for a square-based pyramid (C_{4v} point symmetry), see Fig. 1(a). This confines the unpaired electron to an orbital which is perpendicular to V=O. However, in LVOB we propose that the $[VO]^{2+}$ moiety is not so dominant, although it still exerts a *trans*-lengthening effect (V—N(11) = 2.434 Å, V—N(21) = 2.113 Å, V—N(31) = 2.105 Å), and that the tridentate ligand L alters the electronic structure so that it is better regarded as a distorted octahedral complex with the predominant distortion along the three-fold axis of the octahedron. This would lead to an energy level diagram as in Fig. 1(b). This view is reinforced by our single crystal ESR studies on LVO(dtc), where dtc = N,N-diethyldithiocarbamato, diluted in the isomorphous LMoO(dtc).[6] Here, we find that the direction of one principal g and one principal A value approximates to a pseudo-three-fold axis in the complex, see Fig. 2. There are no principal g or A values particularly close to any metal–ligand directions. In contrast to this, compounds which approximate to square-pyramidal geometry have one g and one A tensor axis coincident, or almost coincident, with the V=O direction.[1] Note that it is not possible to obtain the orientations of the g and A tensor axes from frozen solution spectra. However, we must point out that it is not obligatory for the tridentate ligand to impose a three-fold distortion on a compound, since we did not observe it in $LMoOCl_2$.[7]

The principal g and A values for LVO(β-diketonate), obtained from fluid and frozen solution, fall in the range $\bar{g} = 1.970 \pm 0.002$, $\bar{A} = -92.0 \pm 0.9 \times 10^{-4}$ cm^{-1}, $g_1 = 1.948 \pm 0.001$, $g_2 =$

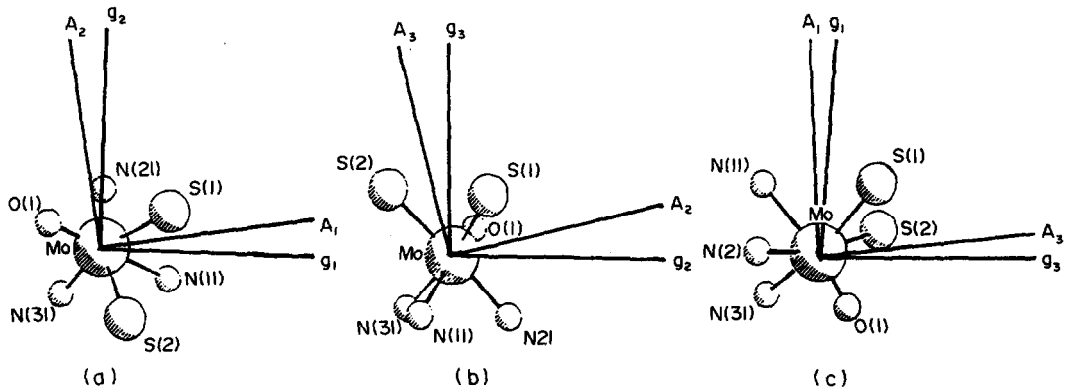

Fig. 2. The relationship of the principal axes of the g and A tensors to the first coordination sphere in LVO(dtc). Views are down: (a) $g_3 = 1.986$ ($A_3 = 50.4 \times 10^{-4}$ cm^{-1}); (b) $g_1 = 1.958$ ($A_1 = -151.7 \times 10^{-4}$ cm^{-1}); (c) $g_2 = 1.983$ ($A_2 = -53.9 \times 10^{-4}$ cm^{-1}).

1.979 ± 0.001, $g_3 = 1.980 \pm 0.002$, $A_1 = -162.3 \pm 1.1 \times 10^{-4}$ cm^{-1}, $A_2 = -57.7 \pm 1.2 \times 10^{-4}$ cm^{-1}, $A_3 = -55.5 \pm 0.9 \times 10^{-4}$ cm^{-1}. From these values (and the appearance of the spectra) alone it would be impossible to deduce that there is any significant difference between the electronic (and hence geometric) structures of LVOB and VOB_2 compounds. The only significant observation from the fluid and frozen ESR spectra is the anticipated increase in the g values and a decrease in the A values as we change from oxygen- to sulphur-donor ligands.

THE ELECTRONIC STRUCTURES OF "NON-AXIAL" MONO-OXO COMPLEXES OF THE EARLY TRANSITION ELEMENTS

DAVID COLLISON,† FRANK E. MABBS and KEITH RIGBY

Department of Chemistry, University of Manchester, Manchester M13 9PL, U.K.

Abstract—A comparison of the ESR parameters of oxometal complexes of the early transition metals is made. The compounds studied are divided into two groups: (i) those in which the $[MO]^{n+}$ moiety defines the molecular z-direction and constrains the unpaired electron to be in an orbital in the plane perpendicular to M=O and (ii) those in which the $[MO]^{n+}$ moiety does not define the molecular z-direction, necessitating an alternative description for the location of the unpaired electron compared to (i).

The description of the electronic structure of a d-transition metal complex is best determined with recourse to the molecular point symmetry. In the case of the mono-oxo complexes of the early transition metals, the method of descent in symmetry from O_h to C_{4v}, for $[MOX_{4/5}]^{n+}$, has been followed successfully since the early work of Jorgensen,[1] and of Ballhausen and Gray.[2] By using single crystal spectroscopic methods the polarization characteristics of electronic absorption bands or the tensorial relationships of electron spin resonance (ESR) parameters, each with respect to the molecular geometry, have provided the experimental evidence for the electronic description as an axial distortion. It has been demonstrated that the oxo (O^{2-}) group dominates the ligand field and in C_{4v} symmetry the unique elements of the g- and metal A-tensors are coincident and are aligned along the metal–oxo vector.[3a] Similarly, the electronic absorption bands show characteristic parallel and perpendicular polarizations carrying the appropriate vibrational fine structure.[3] For example, in the case of $[Ph_4As][CrOCl_4]$, which crystallizes in the $P_{4/n}$ space group with the anion possessing local C_{4v} symmetry, the ESR parameters are $g_\parallel = 2.006$, $g_\perp = 1.979$; $A_\parallel = 35.1 \times 10^{-4}$ cm^{-1}; $A_\perp = 9.6 \times 10^{-4}$ cm^{-1}, where the parallel direction is found along the Cr—O vector. In the polarized single crystal electronic absorption spectrum three bands are found, centred on 13,000, 18,500 and 22,500 cm^{-1}, carrying vibrational fine structure consistent with ν(Cr—O), ν(Cr—Cl) and ν(Cr—O), respectively. The bands are all more intense in perpendicular than parallel polarization and are assigned as one-electron promotions from $3d^*_{xy}$ to $3d^*_{xz,yz}$, $3d^*_{x^2-y^2}$ and $3d^*_{z^2}$ in order of increasing energy.

In the case of mixed ligand mono-oxo complexes the dominance of the oxo group on the electron structure has previously been demonstrated, or presumed, to be maintained. For the particular examples in oxovanadium(IV) chemistry we select $[VOCl_2(tmu)_2]$,[5] $[VO(mnt)_2]^{2-}$,[6] [VO(salen)][7] and $[VO(meox)_2]$,[8] where tmu = N,N,N′,N′-tetramethylurea, mnt = maleonitriledithiolate, salen = N,N′-bis(salicylidene)ethylenediimine and meox = 2-methylquinolin-8-olate. The relationship between the site symmetry, molecular geometry and "unique" ESR parameters, as obtained from single crystal studies, are given in Table 1 for each of the above complexes. In a similar manner, information for the complexes $[MoOCl_3(hmpa)_2]$,[9] $[LVO(R_2dtc)]$[10] and $[LMoOCl_2]$,[10] where hmpa = hexamethylphosphoramide, L = tris(3,5-dimethylpyrazolyl)hydridoborate and R_2dtc = dialkyldithiocarbamate, are also presented in Table 1.

The information in the table reveals a number of interesting aspects. The symmetry-determined nature of the orientation of the g- and metal A-tensors is demonstrated for those complexes possessing strict C_{4v} or C_2 point symmetry. For the complexes $[VO(mnt)_2]^{2-}$, [VOsalen] and $[MoOCl_3(hmpa)_2]$, the distortion from the highest appropriate symmetry does not require coincidence of a g- and A-tensor element along the metal–oxo

direction, but for each case at least one of these elements is so defined and therefore behaves as an "axial" complex by comparison with high symmetry. However, when the complexes $[LVO(R_2dtc)]$ (for R = Et or Pr^n) and $[LMoOCl_2]$ are considered, none of the principal axes of the ESR parameters lies along the so-called "unique" molecular direction and so these complexes are classified as "non-axial". An empirical view of these results reveals that the "non-axial" nature of some of these complexes correlates with six-coordination at the metal centre (it should be remembered that six-coordinate, high symmetry complexes, e.g. $[MoOCl_4(H_2O)]^-$, would still be required to have principal ESR parameters coincident with the metal–oxo direction). However, since the ambiguous possibilities for $[MoOCl_3(hmpa)_2]$ both place a principal A-value along the Mo—O vector, then the twist away from the Mo—O direction in the remaining complexes may be a consequence of the strong trigonal field exerted by the facially demanding N-donor ligand, L. The electronic absorption spectra of the complexes labelled "high symmetry" and "axial" in the table all show the expected form, viz. the five-coordinate complexes give three d–d bands (cf. $[CrOCl_4]^-$), which on six-coordination results in the (presumed) shift of the $d^*_{xy} \rightarrow d^*_{z^2}$ transition to higher energy. Whilst the six-coordinate $[LMoOCl_2]$ only shows two broad band envelopes of low extinction coefficient before the onset of charge-transfer transitions, $[LVO(R_2dtc)]$ shows three d–d bands and the related [LVO(acac)] (where acac = acetylacetonate) displays four such bands at 13,110, 17,620, 24,220 and 25,110 cm^{-1}.

CONCLUSIONS

The preliminary data presented for the novel tris(3,5-dimethylpyrazolyl)hydridoborate oxo complexes of molybdenum and vanadium when compared with similar established data has shown some unexpected ESR and optical properties. The currently accepted description for the electronic ground state and electronic properties of d^1-mono-oxo complexes, as depicted in Fig. 1(a), places the unpaired electron in an orbital located in a plane predominantly normal to the metal–oxo vector, and for the principal g- and metal A-values being oriented as indicated by the axis framework. The discovery of vanadium–oxo complexes in which these

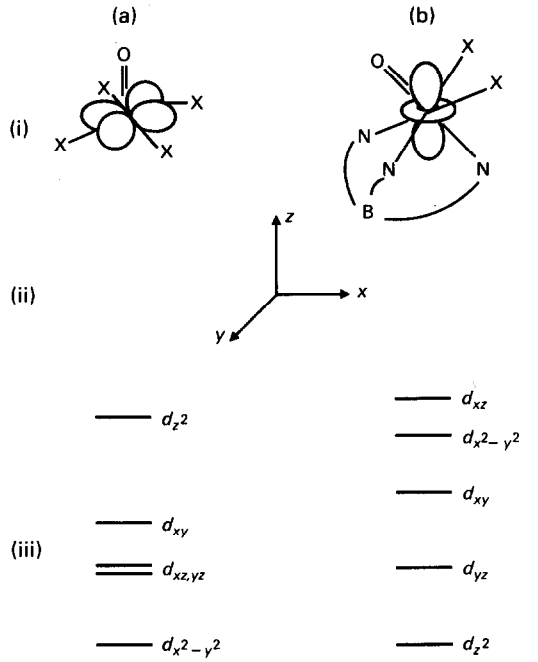

Fig. 1. Description of a metal–oxo complex viewed as (a) axial and (b) trigonal distortions from octahedral symmetry. The predominant ground state orbital (i), molecular and ESR axis framework (ii), and idealized orbital stacking diagram (iii) are shown.

principal directions align near to a pseudo-three-fold axis of an octahedron now implies that a more suitable starting point for the description of the electronic structure of these complexes may be that shown in Fig. 1(b). It should be remembered that the symmetry-determined description of the ground state may intermix the *d*-orbitals. For example,[11] assuming C_s point symmetry we would have

$$\psi_{g.s.} = a_1 d_{x^2-y^2} + b_1 d_{xz} + c_1 d_{z^2}.$$

We are currently investigating the circumstances under which a metal–oxo complex has unusual electronic properties. These effects may also have a profound implication for the reactivity of metal–oxo complexes, especially where the kinetic model requires substrate binding to cause an increase in the coordination number and/or affords a substantial change in the ligand field strength.

Abstract—The results of a single crystal ESR study of $LMoOCl_2$ diluted in the isostructural host $LSnCl_3$ are reported. These results confirm the monoclinic ESR symmetry deduced previously from frozen solution measurements giving the rotation angle between the tensor axes as 35° compared with 33° in previous study. The single crystal data show that none of the principal g- or A-tensor axes coincide with metal–ligand directions.

Whilst many monomeric oxomolybdenum(V) compounds are known, relatively few detailed single crystal ESR studies have been performed because of the lack of suitable diamagnetic host lattices. In particular, we have been interested in the effects on the spin-Hamiltonian parameters of the ligand hydridotris(3,5-dimethylpyrazolyl)borate (= L), and on systematic changes in the ligands X and Y in molybdenum(V) compounds of formulation LMoOXY.[1] To date we have had to rely on obtaining these parameters from frozen solution spectra, because the chemistry of the preferred diamagnetic isostructural compounds LNbOXY or LMoNXY is not sufficiently well-developed to provide the wide range of required compounds.

Following our successful use[2] of the pseudo-isostructural relationship $[VO]^{2+} \equiv [GaCl]^{2+}$, we now report the use of a similar relationship, viz. $[LMoO]^{2+} \equiv [LSnCl]^{2+}$. We have recently determined the single crystal structure of $LSnCl_3$, and shown it to consist of monomeric six coordinate molecules which have a geometry very similar to that of $LMoOCl_2$. We have grown single crystals of $[LSnCl(MoO)Cl_2]$ containing *ca* 5% molybdenum. An ESR study of these crystals is compatible with the $LMoOCl_2$ molecule occupying the $LSnCl_3$ sites and has yielded values of the metal g- and A-tensors in close agreement with those determined by spectrum simulation of frozen toluene solutions of $[LMoOCl_2]$,[3,4] see Table 1. The simulations assumed monoclinic ESR symmetry, consistent with a mirror plane in $[LMoOCl_2]$. An angle, α, for the rotation of the g- and A-tensor axes in the plane perpendicular to the necessarily coincident g- and A-tensor elements is required in the simulation. The angle α is a variable used in the simulation of the spectra, and its value can only be obtained by systematic variation. The three principal g and A values must also be varied until satisfactory fits of the spectra are obtained at at least two different microwave frequencies (in our case X and Q band). There are no other means of assessing the correctness of values of α or the principal A values from the frozen solution spectra. However, a single crystal study yields the required tensors, and furthermore it provides the orientation of these tensors with respect to the atomic framework. This latter information cannot be obtained from frozen solution spectra. The relationship between the g- and A-tensors and the first coordination sphere is shown in Fig. 1.

The data in Table 1 show that the relative rotation of the g- and A-tensors, derived from the single crystal study, confirm that deduced from simulation of the frozen solution spectra. We have

Frozen toluene	1.941	1.971	1.934	18.1 (20)	71.4 (78)	38.1 (42)	33
$LSnCl_3$ single crystal	1.939[c]	1.969[c]	1.931[c]	33.4 (36.9)	72.2 (78.6)	33.7 (37.4)	35

[a] Values in parentheses are in Gauss.

[b] Lower case letters are used for the principal axes of the g-tensor and upper case letters for those of the A-tensor.

[c] These are the principal values of the g-tensor which become $g_{yy} = 1.939$, $g_{zz} = 1.945$, $g_{xx} = 1.947$ when expressed in the A-tensor axis system ($g_{xz} = 0.017$).

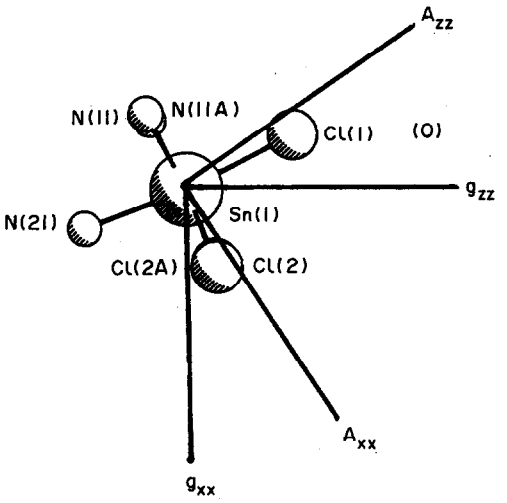

Fig. 1. The orientation of the principal g- and metal A-tensor axes with respect to the first coordination sphere. The view is down the direction perpendicular to the mirror plane in the molecule (g_{YY} and A_{YY} are coincident with this direction and N(21)—Sn(Mo)—C(11)(O) are in the mirror plane).

previously[3,4] assumed that the largest A-tensor element (A_{ZZ}) will be either coincident with or very close to Mo=O. This present single crystal study, whilst in near agreement with this, giving the angle between A_{ZZ} and $SnCl_2$ (Mo=O) as 8°, nevertheless demonstrates the genuine deviation of any principal ESR value away from the metal–oxo direction. However, such a close correspondence between a principal A-tensor element and a metal–oxo direction cannot generally be assumed as we have demonstrated for LVO(dtc).[5]

The single crystal study confirms the monoclinic ESR symmetry previously assumed for $LMoOCl_2$. Recognition of this symmetry has important consequences when trying to relate the ESR parameters to molecular geometry. If we did not know that the ESR symmetry is monoclinic, and merely attempted to interpret the numerical values of the principal g- and A-tensors, we would be tempted to approximate the molecule to be nearly axial, with the implication that the molecular geometry is also nearly axial. Clearly this cannot be true as the only symmetry element that the $LSnCl_3$ molecule has in the crystal structure, and the only one probable for $LMoOCl_2$, is a mirror plane.

IMIDAZOLE AND RELATED HETEROCYCLIC LIGAND COMPLEXES OF OXOVANADIUM(IV)—POTENTIAL MODELS FOR THE REDUCED VANADIUM SITE OF THE SEAWEED BROMOPEROXIDASES

LOUISE J. CALVIOU, DAVID COLLISON,* C. DAVID GARNER, FRANK E. MABBS, MOHAMMAD A. PASSAND and MICHAEL PEARSON

Department of Chemistry, University of Manchester, Manchester M13 9PL, U.K.

Abstract—We have used the model compound approach to comment on the structural hypotheses that in reduced bromoperoxidase (BPO) the vanadium is coordinated by at least one imidazole-type nitrogen donor and possibly a phenolate-type oxygen donor. We report here the synthesis and spectroscopic characterization of representative examples of three classes of oxovanadium(IV)–imidazole complexes

(i) $[VO(acac)_2(imid)]$, where acac = 2,4-pentanedionate and imid = N- or 2-substituted imidazole.
(ii) $[VO(imid)_4Cl]^+$, which is stabilized in solution in the presence of excess imid.
(iii) $[VO(O—N)_2]$, where (O—N) =  , $n = 0$ or 1, and E = O, S, NH, NMe.

It is the complexes of type (iii) above which most closely resemble the non-axial nature of ESR spectrum of the reduced BPO enzymes.

Vanadium is a trace element, essential for the normal development and growth of plants and animals. In halogen metabolism vanadium finds a role in the marine brown algae *Ascophyllum nodosum* and *Laminaria saccharina* as a component of a bromoperoxidase (BPO)† enzyme.[1] The enzyme appears to operate in nature exclusively with the metal in the +5 oxidation state,[1b,2] and in concert with hydrogen peroxide produces the brominating species tentatively assigned as HOBr.[3] Reduction of the enzyme with sodium dithionite produces an inactive form of BPO, with vanadium now present in the +4 oxidation state.[4] The accessibility of both diamagnetic and paramagnetic levels for this enzyme has meant that a variety of spectroscopic techniques has been applied to elucidate the nature of the metal site, e.g. ^{51}V NMR, EST, EXAFS,[6] ESEEM[7] and FTIR.[8] In particular, the results of X-ray absorption spectroscopy and paramagnetic resonance techniques have suggested that histidine is coordinated to the metal in a distorted electronic environment. There is additional evidence for short V—O interactions to anionic oxygen donor groups, such as those supplied by tyrosine or glutamate residues. We report, here, representative results from the model compound approach to assess the validity of various oxovanadium(IV) imidazole complexes in reproducing the ESR characteristics of the reduced BPO enzymes.

* Author to whom correspondence should be addressed.

† The following abbreviations have been used in this paper: BPO—bromoperoxidase; NMR—nuclear magnetic resonance; ESR—electron spin resonance; EXAFS—extended X-ray absorption fine structure; ESEEM—electron spin echo envelope modulation; FTIR—Fourier transform IR; acac—acetylacetonate; meox—2-methylquinolin-8-olate; imid—imidazole or substituted imidazole; O—M—uninegative bidentate ligand depicted in the abstract.

SYNTHESES OF OXOVANADIUM(IV) IMIDAZOLE COMPLEXES

(i) $[VO(acac)_2(imid)]$ were prepared after the method of Nath and Dash,[9] by treating $[VO(acac)_2]$ with 1 equivalent of imid in diethyl ether. The complexes separated as green powders.

(ii) $[VO(imid)_4Cl]Cl$ were prepared by treating $[VOCl_2(MeCN)_2(H_2O)]$[10] with 5 equivalents of imid in methyl cyanide solution. For N-substituted imidazoles the products formed as purple microcrystals directly from solution.

(iii) $[VO(O—N)_2]$ were prepared from either $VOSO_4 \cdot 5H_2O$ in water by adding a slight stoichiometric excess of the ligand[11] as a solution in ethanol or from $[VO(acac)_2]$ by refluxing in methyl cyanide. The complex where E = O separated as a yellow powder in both cases.

Complexes of each class, (i)–(iii), had satisfactory elemental analyses, consistent with their formulation, for C, H, N, V and Cl, and have characteristic values of $\nu(V{=}O)$ in the IR and Raman spectra. In addition, for class (ii) where imid = 1-vinylimidazole, the complex has been studied by single crystal X-ray diffraction methods. Figure 1 shows a schematic representation of the probable structures about the vanadium atom for each class.

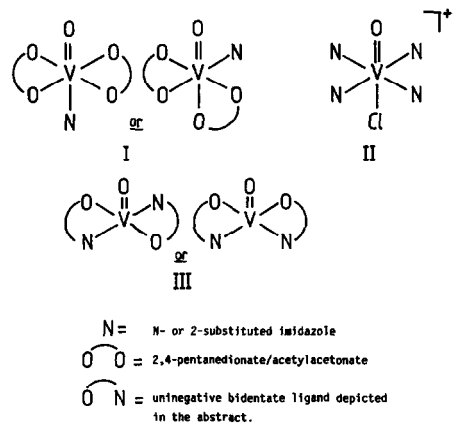

Fig. 1. Schematic representation of oxovanadium(IV) imidazole complexes.

ESR STUDIES

The ESR spectra of the reduced BPO enzyme under a variety of conditions have already been reported[4] and one of these is reproduced in Fig. 2 for comparative purposes. It was deduced from the form of a wide range of enzyme spectra that there is considerable interaction of the unpaired electron with ^1H and ^{17}O nuclei (and with ^{14}N as detected by ESEEM measurements). Thus the optimal resolution obtained in D_2O demonstrates the considerable rhombicity of the ESR parameters, where $g_2 - g_3$ is estimated to be 0.01. This may be compared with the values of $g_2 - g_3$ found for $[VO(meox)_2]$[12] and $[VO(acac)_2]$[13] of 0.005 and 0.004, respectively. Such large distortions away from apparent axial symmetry for oxovanadium(IV) complexes are usually interpreted to be the result of (i) mixed ligand coordination and/or (ii) geometric distortion produced by chelation. There is usually no diagnostic effect in ESR spectroscopy allowing the distinction between five and six coordination in complexes of this type. Visual inspection of Fig. 2 shows the relative extents of rhombicity in the ESR spectra of various model compounds. Class (ii) appears axial, as expected, as does class (i). It is the example from the class (iii) series, in common with $[VO(meox)_2]$, which shows considerable rhombicity; the $g_2 - g_3$ value for the former complex being estimated as 0.012. There is no splitting of the "$g_\perp$" features for class (ii) when spectra are obtained at Q band frequency.

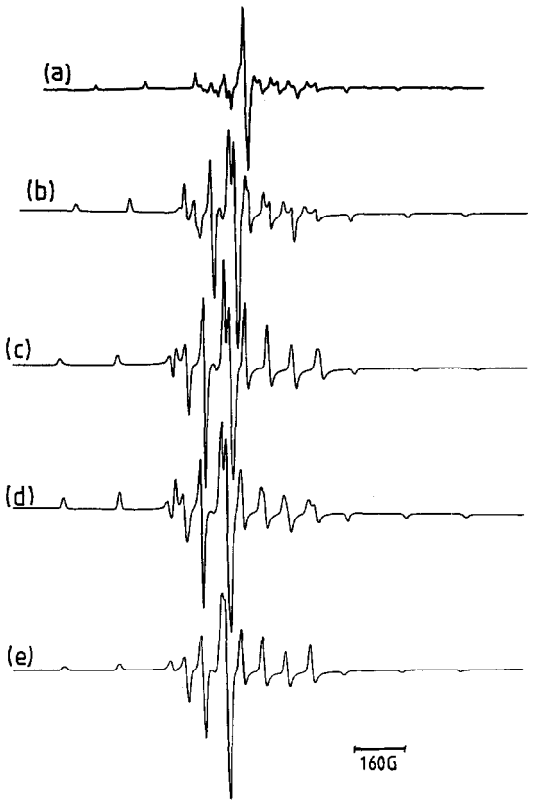

Fig. 2. Frozen solution ESR spectra at X band frequency of BPO and some oxovanadium(IV) complexes. (a) BPO in D_2O; (b) $[VO(meox)_2]$; (c) $[VO(acac)_2(imid)]$; (d) $[V(C—N)_2]$; (e) $[VO(imid)_4Cl]^+$.

CONCLUSIONS

On the basis of the model compound approach to the study of the reduced form of vanadium-containing bromoperoxidase enzymes, the nature of the coordination environment at the metal site may be suggested. The results of EXAFS, ESEEM and now ESR spectroscopy, are consistent with a mono-oxo vanadium(IV) ion coordinated by imidazole-type nitrogen atoms (from histidine), phenolate oxygen (from tyrosine) and weakly bound water in a distorted/strained geometry.

SYNTHESIS OF CATIONIC ALKYL BIS(CYCLOPENTADIENYL)TITANIUM COMPLEXES BY ONE-ELECTRON OXIDATION OF TITANIUM(III) ALKYLS. THE STRUCTURE OF $[Cp^*_2TiMe(THF)]BPh_4$ AND $[Cp^*_2Ti(OH)(H_2O)]BPh_4 \cdot 2THF$†

MANFRED BOCHMANN,‡ ANDREW J. JAGGAR and LADISLAV M. WILSON

School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

and

MICHAEL B. HURSTHOUSE‡ and MAJID MOTEVALLI

Department of Chemistry, Queen Mary College, London E1 4NS, U.K.

Abstract—The reaction of Cp^*_2TiMe ($Cp^* = C_5Me_5$) with $AgBPh_4$ in THF gives $[Cp^*_2TiMe(THF)]BPh_4$ (**1**). The sterically congested complex contains a labile THF ligand which is easily displaced by donor molecules. Compound **1** reacts with traces of moisture to give the hydroxo complex $[Cp^*_2Ti(OH)(H_2O)]BPh_4 \cdot 2THF$ (**2**). The structures of both complexes have been determined by X-ray diffraction. The THF ligand in **1** is oriented parallel to the Me—Ti—O plane; the Ti—O (THF) distance is 0.95 Å longer than the titanium–methyl bond. By contrast, the short Ti—OH distance in **2** (1.853 Å) indicates substantial Ti—O double bond character. The more weakly bound water ligand is associated with two THF molecules through strong hydrogen bonds.

The chemistry of cationic alkylbis(cyclopentadienyl) complexes of group IV metals has attracted interest recently because of their possible involvement as intermediates in olefin polymerizations catalysed by homogeneous Cp_2MCl_2/AlR_3 systems.[1–3] Although cationic titanium complexes $[Cp_2TiMe(L)]^+$ ($Cp = \eta^5\text{-}C_5H_5$) are readily accessible, for example by halide displacement from $Cp_2TiMeCl$, in which L is a nitrogen or phosphorus donor ligand,[2] this method does not allow the incorporation of weakly coordinated ligands such as tetrahydrofuran (THF). We report here the synthesis and structure of a THF complex obtained by the oxidation of a titanium(III) alkyl precursor under mild conditions.

EXPERIMENTAL

All operations were carried out under dried argon using standard vacuum-line techniques. Solvents were distilled under nitrogen from sodium benzophenone (THF, diethyl ether, petrol), sodium (toluene) or calcium hydride (dichloromethane). Perkin–Elmer 684 and 1720X (IR) and Jeol PMX-60 spectrometers were used. Cp^*_2TiMe was prepared from Cp^*_2TiCl and LiMe.[4] $AgBPh_4$ was obtained from aqueous $AgNO_3$ and $NaBPh_4$ and dried for several hours at 60°C/10^{-2} mm Hg.

Preparation of $[Cp^*_2TiMe(THF)]BPh_4$ (1)

To a cold (−78°C) solution of Cp^*_2TiMe (0.6 g, 1.8 mmol) in 10 cm^3 of THF was added $AgBPh_4$ (0.77 g, 1.8 mmol) in small portions. The stirred mixture was allowed to warm to room temperature. The colour changed from deep green to brown. Metallic silver was removed by filtration. The filtrate was concentrated *in vacuo* and the residue washed twice with petrol, followed by recrystallization from THF. The addition of a small amount of ether aids crystallization. Compound **1** was obtained as dark red–brown plates (0.8 g, 1.1 mmol, 61%). IR (Nujol mull, cm^{-1}): 3060 (w), 3035 (w), 1580 (m), 1265 (m), 1180 (w), 1143 (m), 1125 (w), 1065 (w), 1030 (w), 1005 (m), 840 (s), 742 (m),

† Dedicated to Professor Sir Geoffrey Wilkinson on the occasion of his retirement from the Sir Edward Frankland Chair of Inorganic Chemistry.

‡ Authors to whom correspondence should be addressed.

730 (s), 703 (s), 625 (w), 615 (m), 605 (m), 490 (w), 465 (w). ^{1}H NMR (pyridine-d_5): 8.05 (m, broad, 8H), 7.45–7.09 (m, 12H, BPh_4^-), 3.65 (m, 4H, THF), 1.71 and 1.65 (34H, THF and Cp* overlapping), 0.61 (s, 3H, Ti—Me). Found: C, 80.7; H, 8.6. Calc. for $C_{49}H_{61}BOTi$: C, 81.2; H, 8.5.

Preparation of $[Cp_2^*Ti(OH)(H_2O)]BPh_4 \cdot 2THF$ (2)

A solution of **1** (0.5 g) in 20 cm^3 of THF was treated with undried CO gas for 1 h. The solution was concentrated and left to crystallize at −15°C. Red–brown rhombic crystals of **2** were recovered in low yield. An identical product was obtained when Cp_2^*TiMe was oxidized with insufficiently dry $AgBPh_4$ in THF. IR (Nujol mull, cm^{-1}): 3620 (s, sharp), 3100–2900 (broad), 3060 (m), 3040 (m), 1670 (w), 1580 (m, BPh_4^-), 1460 (s), 1425 (m), 1265 (m), 1140 (m), 1065 (sh), 1043 (s), 1030 (m), 918 (m), 885 (m), 845 (s), 730 (s), 705 (s), 610 (s), 468 (w), 425 (m). Found: C, 76.1; H. 8.7. Calc. for $C_{52}H_{69}BO_4Ti$: C, 76.5; H, 8.5.

X-ray crystallography

All measurements were made on crystals sealed under argon in glass capillaries, using a CAD4 diffractometer and graphite monochromated Mo-K_α radiation (λ = 0.071069 Å). Unit cell and intensity data were obtained following standard procedures as previously described.[4] In both cases, crystal quality was poor, with variable mosaic spread and low scattering power.

The structures were solved using the heavy-atom procedure and refined via full-matrix least-squares methods. Non-hydrogen atoms were refined anisotropically, hydrogens with idealized positions and group U_{iso} values for all but those on the OH and OH_2 groups in compound **2** which were freely refined isotropically. In the final cycles, a weighting scheme of the type $w = [\sigma^2(F_o) + g(F_o)^2]^{-1}$ was used, with g varied to give flat agreement analogues. Experimental details are as follows:

Crystal data. (a) **1**, $C_{49}H_{61}BOTi$, M_r = 724.73, monoclinic, a = 20.920(6), b = 11.811(2), c = 17.299(7) Å, β = 106.93(4)°, V = 4089.1 Å^3, Z = 4, D_{calc} = 1.18 g cm^{-3}, $F(000)$ = 1560, μ(Mo-K_α) = 2.393 cm^{-1}, space group $P2_1/c$. 8138 intensities measured ($1.5 \leqslant \theta \leqslant 25.0°$), 7171 unique, 3350 observed [$F_o > 3\sigma(F_o)$], corrected for absorption via azimuthal scan data. 577 parameters in least-squares, R = 0.073, R_w = 0.072, g = 0.00023.

(b) **2**, $C_{52}H_{63}BO_4Ti$, M_r = 816.83, triclinic, a = 10.362(5), b = 14.871(6), c = 16.097(5) Å, α = 86.92(2), β = 72.69(3), γ = 85.44(4)°, V = 2359.4 Å^3, Z = 2, $D_{calc.}$ = 1.15 g cm^{-3}, $F(000)$ = 880, μ(Mo-K_α) = 2.18 cm^{-1}, space group $P\bar{1}$. 9090 intensities measured ($1.5 \leqslant \theta \leqslant 25.0°$), 8288 unique, 4920 observed [$F_o > 3\sigma(F_o)$], corrected for absorption via azimuthal scan data. 590 parameters in least-squares, R = 0.071, R_w = 0.067, g = 0.00014.

Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c lists have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Titanium(III) alkyls of the general composition Cp_2^*TiR ($Cp^* = C_5Me_5$) are readily prepared by reacting solutions of Cp_2^*TiCl[5] with lithium alkyls in diethyl ether, followed by crystallization of the dark green, paramagnetic complexes at low temperature. Treatment of a THF solution of Cp_2^*TiMe with solid $AgBPh_4$ in the dark, results in an immediate colour change to deep red–brown and a precipitation of metallic silver. Filtration and crystallization at −15°C yields air- and moisture-sensitive $[Cp_2^*TiMe(THF)]BPh_4$ (**1**) as brown crystalline plates [eq. (1)]:[6]

$$Cp_2^*TiMe + AgBPh_4 \xrightarrow{THF,\ RT} [Cp_2^*TiMe(THF)]BPh_4 + Ag^0. \quad (1)$$

(1)

The structure of **1** has been determined by X-ray crystallography. A diagram of the cation is shown in Fig. 1, selected bond lengths and angles are given in Table 1. The titanium centre has pseudo-tetra-

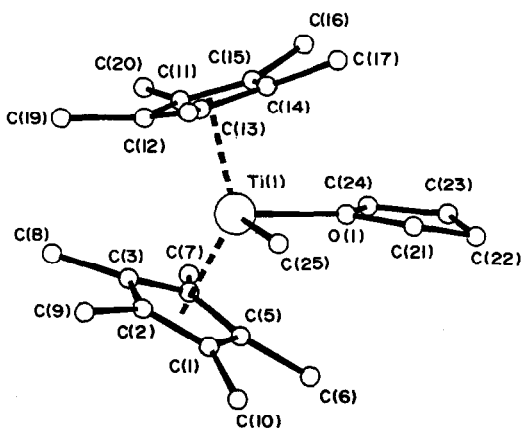

Fig. 1. The structure of $[Cp_2^*TiMe(THF)]^+$, showing the atomic numbering scheme. Ellipsoids correspond to 50% probability.

hedral coordination. The coordinated THF ligand is oriented parallel to the O(1)—Ti—C(25) plane, and the Ti—O distance (2.165 Å) is 0.095 Å longer than the Ti—CH_3 bond. The orientation of the THF ligand and the bond length distribution provide an interesting contrast to the sterically less congested zirconium complex, $[Cp_2ZrMe(THF)]BPh_4$;[7] here, the THF ligand is perpendicular to the O—Zr—CH_3 plane and the Zr—O bond is 0.13 Å shorter than the Zr—CH_3 bond, indicating an effective p_π–d_π interaction between an oxygen lone electron pair and zirconium. In **1**, repulsive interactions between the bulky Cp* ligands and THF override such an electronic stabilization.

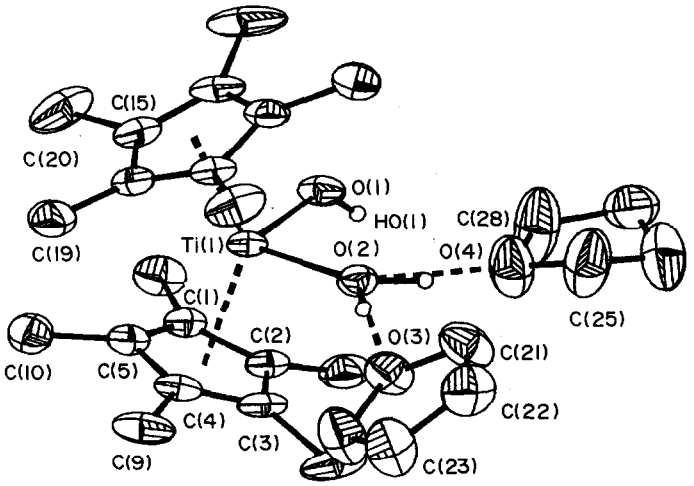

Fig. 2. The structure of $[Cp^*_2Ti(OH)(H_2O)]^+ \cdot 2THF$, including the atomic numbering scheme.

A similar "in-plane" orientation of THF is found in the neutral complexes $Cp_2YbMe(THF)$[8] and $Cp^*_2YbMe(THF)$.[9]

Under ambient conditions, **1** does not polymerize ethylene. It decomposes slowly in non-coordinating solvents such as dichloromethane. Although the THF ligand is labile and easily displaced by donor molecules such as nitriles, isocyanides or pyridine,[10] **1** is less reactive than C_5H_5 and indenyl analogues. For example, whereas $[Cp_2TiMe(MeCN)]^+$ reacts with Bu^{t}NC instantaneously under insertion to give an iminoacyl complex,[2b] the addition of Bu^{t}NC to cold solutions of **1** allows the spectroscopic observation of a relatively stable adduct (ν_{CN} 2202 cm^{-1}; presumably $[Cp^*_2TiMe(Bu^tNC)]^+$), which is converted to the corresponding iminoacyl complex on attempted isolation.

If the oxidation of Cp^*_2TiMe is carried out with $AgBPh_4$ containing traces of moisture, or if a THF solution of **1** is stirred under an atmosphere of CO which has not been rigorously dried, red–brown crystals of the aquo complex, $[Cp^*_2Ti(OH)(H_2O)]BPh_4 \cdot 2THF$ (**3**), are isolated in low yield. The IR spectrum of the complex shows a distinct and very sharp band at 3620 cm^{-1}, typical for an OH ligand free of hydrogen bonding,[7] and a very broad feature at *ca* 3300–2800 cm^{-1}, indicative of hydrogen-bonded OH.

The existence of both OH bonding modes was confirmed by X-ray crystallography. The structure of the complex cation of **3** is shown in Fig. 2, selected bond lengths and angles are given in Table 2. A noticeable feature is the short Ti—OH bond (1.866 Å) which is 0.23 Å shorter than the Ti—OH_2 bond. Similarly short metal–oxygen distances indicative of metal–oxygen double bond character have previously been observed in $Cp^*_2Zr(OH)_2$ and $Cp^*_2Zr(OH)Cl$.[11] The OH ligand does not interact with any of the solvent molecules. The O—H bond is oriented out of the O(1)—Ti—O(2) plane, with a Ti—O(1)—H angle of 125.7°. By contrast, each hydrogen of the H_2O ligand is closely associated with a THF molecule. The strength of this hydrogen bonding is confirmed by the short O—O distances between the H_2O and THF oxygens of 2.55 and 2.70 Å.

While this work was in progress, the independent preparation of trifluoromethylsulphonate complexes, $[Cp^*_2Ti(OH)(H_2O)]CF_3SO_3 \cdot nH_2O$ ($n = 1$, 2), has been reported.[12] The structures of the cations in these complexes strongly resemble that found in **2**; differences arise, however, in the pattern of hydrogen bonding which, in the case of the trifluoromethylsulphonates, includes interactions with the anion and the water of crystallization, and involves both the water and the hydroxo ligand.

Abstract—The synthesis of 31 complexes of the type $Cp_2Ti(OCOPhX)_2$ (X = substituent, Cp = η-C_5H_5) is reported together with their mass, ^{1}H NMR, ^{13}C NMR, mid- and far-IR spectra. The data are consistent with a model in which the Ti—OOC bond strength—weaker than Ti—Cp and Ti—Hal—is stabilized by electron-withdrawing groups, X, on the phenyl ring. The influence of the electronic properties of X also extends into the cyclopentadienyl rings.

In recent years, much research has been devoted to titanium(IV) complexes of the type $Cp_2Ti(OCOR)_2$, which may be attributed to their unique structures[1–4] and to their anticancer activity.[5,6] In the present communication, we are concerned with those complexes where R is a (substituted) phenyl ring or furan ring.

All complexes were obtained by reaction of Cp_2TiCl_2 with the sodium salt of the appropriately substituted benzoic acid, except for two nitro substituted complexes which were made from Cp_2TiCl_2 and nitrobenzoic acid in THF in the presence of triethylamine. Thus, 31 complexes were prepared, which included 13 *para*- (NH_2, OMe, OEt, Me, Et, *t*-Bu, Ph, F, Cl, Br, I, CN, NO_2), eight *meta*- (OMe, Me, F, Cl, Br, I, CN, NO_2), six *ortho*- (Me, Ph, F, Cl, I, CH_3COO^-), two bis- (2,4-Cl, Cl, 3,4-Cl, Cl) and one unsubstituted (H) benzoato complex, as well as one 2-furyl carboxylato complex. They were characterized by MS, ^{1}H NMR, ^{13}C NMR, mid- and far-IR spectra.

EIMS spectra show the ligands L (L = $ArCO_2$) and Cp_2Ti moieties, as well as structurally informative ions, e.g. $(Cp_2TiL)^+$, $(CpTiL)^+$, $(CpTiL—CO_2)^+$, $(Cp_2Ti)^+$ and $(CpTi)^+$. Further numerous ions characteristic of the ligands occur, including the molecular ion of the free substituted benzoic acid, HL. We observe the preferred loss of a benzoic acid ligand, L, over the loss of Cp from the title complexes. This suggests a greater strength of the Ti—Cp bond compared to the Ti—OOC bond. Exceptions are observed in the 4-NO_2 and 3-NO_2 complexes, where the intensity of the $(Cp_2TiL)^+$ ion is low (~ 5%) and that of the $(CpTiL_2)^+$ ion is high (~ 100%), suggesting a strengthening of the Ti—OOC bond due to a decreasing influence of resonance hybrid **b** in Fig. 1. We also note the preferential loss of CO_2 from $(CpTiLi)^+$ and rearrangement processes to $CpTiX^+$ ions when X = hal, with fluorine showing the strongest tendency to coordinate titanium.

NMR SPECTRA

Signals of the phenyl protons and carbons are easily assigned by applying standard corrections of substituents[7] to the known chemical shifts of the unsubstituted complex.[2] The 10 protons of the two Cp rings absorb in the range 6.57–6.76 ppm (singlet) and the 10 carbons between 118.25 and 119.22 ppm (singlet). The chemical shifts can be correlated with the electronic properties of the substituents on the phenyl rings. As expected, electron-donating groups cause an upfield shift, while electron-withdrawing groups cause a downfield shift. On the other hand, the carboxylate carbons, resonating between 166.92 and 174.84 ppm, show the opposite trend. It may reflect the greater impact of resonance hybrid **a** (Fig. 1) with an electron-withdrawing substituent and of hybrid **b** with a donating one. A quantitative correlation between chemical shifts and substituent parameters is currently under way.

IR SPECTRA

Strong bands are observed near 1640 and 1330 cm^{-1} which are ascribed to the asymmetric COO stretch and the symmetric COO stretch, respectively. The difference $\Delta\nu(\nu_{asym}(COO)-\nu_{sym}(COO))$ is in the range of 300–370 cm^{-1} in all cases. It is clear evidence of monodentate coordination of the benzoate ligand in the complexes. A qualitative IR analysis for all the complexes indicates an increase of $\Delta\nu$ with electron-withdrawing properties of substituents as measured by Hammett $\sigma m/\sigma p$ values. In the far-IR region (500–50 cm^{-1}) tentative assignments include titanium–cyclopentadienyl (420 ± 10 cm^{-1}, 370–335 cm^{-1} and ~ 300 cm^{-1}), titanium–oxygen (~ 400 cm^{-1}), cyclopentadienyl–titanium–cyclopentadienyl (~ 240 cm^{-1}), oxygen–titanium–oxygen (140–110 cm^{-1}) and ligand (500–400 cm^{-1}) vibrations.

PREPARATION AND REACTIONS OF SOME TITANIUM(IV) CARBOXYLATE SPECIES

N. W. ALCOCK, D. A. BROWN, T. F. ILLSON, S. M. ROE and M. G. H. WALLBRIDGE*

Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K.

Abstract—A series of compounds of general formula $TiCl_x(RCO_2)_{4-x}$ have been prepared and structurally characterized.

Prior to work carried out here, there were few halo titanium carboxylate compounds known.[1,2] No definitive structural evidence exists in the literature on these compounds. A series of compounds of type $TiCl_x(RCO_2)_{4-x}$ ($x = 2, 3$), have therefore been prepared and fully characterized.

In previous studies[1] a series of trischloromonocarboxylates have been obtained at room temperature by reaction of titanium tetrachloride with carboxylic acids, RCO_2H ($R = CH_3CH_2CH_2$, $(CH_3)_3C$, CH_2Cl, $CHCl_2$, CCl_3) [eq. (1)]:

$$TiCl_4 + RCO_2H \longrightarrow TiCl_3(RCO_2) + HCl \quad (1)$$

$$TiCl_4 + 2RCO_2H \longrightarrow TiCl_2(RCO_2)_2 + 2HCl. \quad (2)$$

The corresponding biscarboxylates were also prepared [eq. (2)]. The biscarboxylate, $TiCl_2(CH_3CH_2CO_2)_2$, was shown by X-ray powder diffraction[3] to exist in two forms. We have extended the range of trischloromonocarboxylates prepared. Thus, in eq. (1), $R = C_6H_5$, $CH_3C(C_6H_5)_2$, $(CH_3)_2CH$, $(CH_3)_3C$, *o*-$CH_3C_6H_4$, *p*-$CH_3C_6H_4$, $C_6H_2(CH_3)_3$, $CH_3CH{=}CH$, $C_6H_5CH{=}CH$. The trichloro-monopivalate derivative, $TiCl_3[(CH_3)_3CCO_2]$, has been structurally characterized by X-ray diffraction study, which shows that the compound is trimeric in the solid state (Fig. 1).

The titanium atoms form an approximate isosceles triangle and are joined by chlorine and carboxylate bridges, an interesting feature is the triply bridging chlorine atom (Cl_3) which bonds to the three titanium atoms. This chlorine atom is located 0.961 Å above the Ti_3 plane. Its bond to Ti(3) is long (2.839 Å) and its bonds to Ti(1) and Ti(2) (2.577, 2.565 Å) show some lengthening relative to the Ti—Cl bonds of the bridging chlorine Cl(2) (2.49, 2.476 Å). The Ti—Cl bridge has elongated (Ti—Cl—Ti angle > 90°), and the angle between the terminal chlorines has opened up from the ideal 90°. The carboxylate O—C—O angles are all between 121 and 123°.

All the compounds prepared were air- and moisture-sensitive. However, some surprisingly stable intermediates in the hydrolysis reaction of titanium(IV) carboxylates, $TiCl_x(RCO_2)_{4-x}$ (R = Me, Ph, $x = 3$; R = Me, $x = 2$) in the solvents, ethylacetate and tetrahydrofuran (EtOAc, THF), have been isolated.[4] The yellow crystalline binuclear complexes, $Ti_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2Cl_4 \cdot 2L$ (L = EtOAc, THF), were obtained in high yield (~ 80%) by the addition of 1 molar equivalent of water to $TiCl_x(RCO_2)_{4-x}$ (R = Me, Ph, $x = 3$; R = Me, $x = 2$) in a solution of the appropriate ligand. It is noteworthy that the μ-oxo species are formed by the hydrolysis of a Ti—Cl bond in

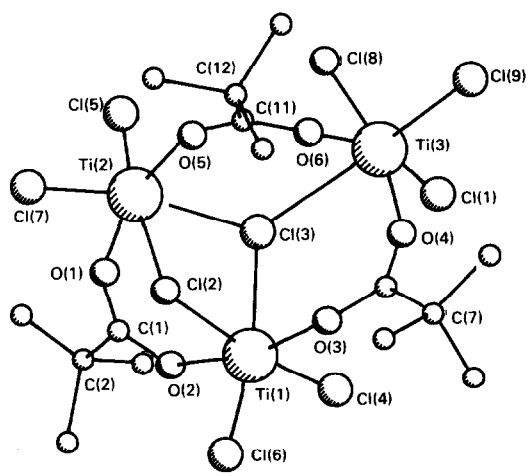

Fig. 1. Structure of $TiCl_3((CH_3)_3CCO_2)$.

* Author to whom correspondence should be addressed.

$TiCl_3(RCO_2)$ (R = Me, Ph), or by hydrolysis of a titanium-carboxylate bond in $TiCl_2(RCO_2)_2$ (R = Me), indicating the stability of the μ-oxo-carboxylate unit formed. The X-ray structure of the adducts (Fig. 2, R = Ph), show near octahedral coordination of the metal atoms, with the ligand *trans* to the bridging oxygen.

The presence of the two carboxylate bridges causes a deviation in the Ti—O—Ti angle (137.4°) from the ideal 180°. The μ-oxo atom arises from water added, since when $H_2{}^{17}O$ is used for the hydrolysis, the ^{17}O NMR of the crystalline product shows a sharp singlet at +810 ppm (relative to H_2O), which is in the region expected for μ-oxo bridges with octahedrally coordinated metal centres.

Preliminary evidence has been obtained for a further product of hydrolysis, namely, $Ti_2Cl_7(CH_3CHCHCO_2)(CH_3CHCHCO_2H)$. This compound forms as yellow–green brick-shaped crystals and X-ray diffraction studies show (Fig. 3) that the compound is dimeric with the two titanium centres linked by two bridging chlorine atoms and one bridging carboxylate group.

The titanium atoms are in pseudo-octahedral environments. The Ti—$Cl_{(bridge)}$ distance (average 2.5 Å) is very similar to the average distance reported for Ti—$Cl_{(bridge)}$ in $TiCl_4$ adducts of 2.49 Å. The Ti—$O_{(carboxylate)}$ distances of 1.896 and 2.008 Å may be compared with the Ti—O distance of 1.966 Å in $TiMgCl_5(ClCH_2CO_2)Cl$ $CH_2COOC_2H_5$),[5] of 2.029 Å in $[TiCl_4MeCO_2Et]_2$,[5] and of 2.014 Å in $[Ti_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2Cl_4\cdot 2L]$; the distance in the latter compound being the Ti—$O_{(carboxylate)}$ distance. Compared with the above, the Ti(1)—O(1) distance of 1.896 Å seems rather short. The C(21)—O(3) bond length of 1.222 Å compared with the C(21)—O(4) bond length of 1.334 Å indicates the presence of a proton on O(4).

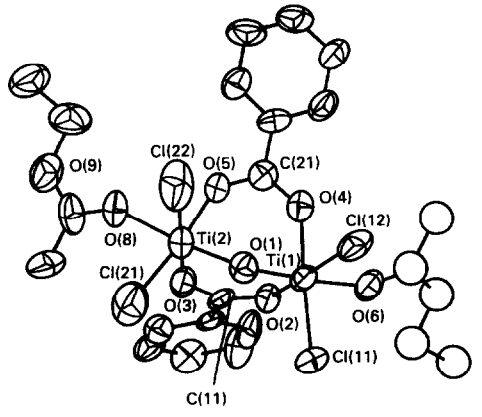

Fig. 2. Structure of $Ti_2(\mu\text{-}O)(\mu\text{-}O_2CPh)_2Cl_4\cdot 2EtOAc$.

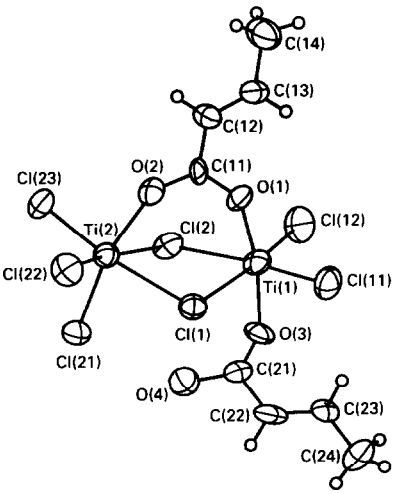

Fig. 3. Molecular structure of $Ti_2Cl_7(CH_3CHCHCO_2)(CH_3CHCHCO_2H)$.

The presence of small amounts of water in the solvents used for recrystallization would have caused the formation of oxo species and liberated HCl. The HCl is then proposed to react with a $Ti_2Cl_6(CH_3CHCHCO_2)_2$ fragment as in eq. (3):

$$Ti_2Cl_6(CCH_3CHCHCO_2)_2 + HCl \longrightarrow Ti_2Cl_7(CH_3CHCHCO_2)(CH_3CHCHCO_2H). \quad (3)$$

The $Ti_2Cl_6(CH_3CHCHCO_2)_2$ species may form by dissociation of the hypothetical trimeric species (cf. Fig. 1) in solution. Attempts to prepare $Ti_2Cl_7(CH_3CHCHCO_2)(CH_3CHCHCO_2H)$ on a large scale are currently in progress.

SYNTHESIS OF BIS-SILYLATED CYCLOPENTADIENYL NIOBIUM(IV) AND (V) NEUTRAL AND CATIONIC COMPLEXES

A. ANTIÑOLO, M. FAJARDO, F. A. JALÓN, A. OTERO* and M. C. PUERTA

Departamento de Química Inorgánica, Campus Universitario,
Universidad de Alcalá de Henares, Spain

and

Y. MUGNIER

Laboratoire de Synthèse et d'Electrosynthèse Organométalliques, Faculté des Sciences,
6 bd Gabriel, 21000 Dijon, France

Abstract—New niobium(IV) complexes, $Nb(\eta\text{-}C_5H_3RR')_2X_2$, R = H, R′ = $SiMe_3$, X = Br (**1**), X = I (**3**); R = R′ = $SiMe_3$, X = Br (**2**), X = I (**4**), have been isolated in high yields from the reactions of $Nb(\eta\text{-}C_5H_3RR')_2H_3$ and $Nb(\eta\text{-}C_5H_3RR')_2X$ with EtBr and MeI. Both chemical and electrochemical oxidation processes of these niobium(IV) complexes produce the cationic niobium(V) compounds, $[Nb(\eta\text{-}C_5H_4SiMe_3)_2X_2]^+$, X = Cl (**5**), Br (**6**), I (**7**), which exhibit an acidic character towards nucleophilic reagents, such as Me_2SiOR, to give new niobium(V) alkoxo complexes, $[Nb(\eta\text{-}C_5H_4SiMe_3)_2Cl(OR)]^+$, R = CH_3 (**8**), CH_2CH_3 (**9**), $CH(CH_3)_2$ (**10**). Spectroscopic IR, ESR and NMR data are available for these compounds.

During our studies of the electronic and steric influence of trimethylsilyl substituted cyclopentadienyl ligands on the properties of niobocene complexes, we have found that the reactions [eq. (1)] of complexes $Nb(\eta\text{-}C_5H_3RR')_2H_3$ and $Nb(\eta\text{-}C_5H_3RR')_2X$ with an excess of EtBr and MeI represent a new and easy method to isolate quantitatively niobium(IV) complexes, $Nb(\eta\text{-}C_5H_3RR')_2X_2$:

$$Nb(\eta\text{-}C_5H_3RR')_2X + R''\text{—}X \longrightarrow Nb(\eta\text{-}C_5H_3RR')_2X_2. \quad (1)$$

In the case of the trihydride complexes the reaction takes place with the initial formation of $Nb(\eta\text{-}C_5H_3RR')_2X$ and H_2.[1]

A GLC analysis of the gaseous phase allows us to obtain information on the reaction mechanisms and it rules out a pathway via radicals, because C—C coupling has never been observed.

The ESR spectra of d^1 paramagnetic complexes, **1**, **2**, **3** and **4**, were run. (The g_{av} values ranged over 2.0018–2.0806, in keeping with reported data on related compounds.[2])

Complexes $Nb(\eta\text{-}C_5H_4SiMe_3)_2X_2$ can be oxidized both chemically[3] [eq. (2)] and electrochemically to give niobocene d^0 cationic complexes:

$$Nb(\eta\text{-}C_5H_4SiMe_3)_2X_2 + Fc^+PF_6^- \longrightarrow Nb(\eta\text{-}C_5H_4SiMe_3)_2X_2^+ + Fc. \quad (2)$$

Fc = ferrocene

The new air stable d^0 niobium complexes were isolated in high yield as red crystals, X = Cl (**5**), Br (**6**), I (**7**), which have been spectroscopically characterized.†

These complexes can be easily obtained by one-electron oxidation of niobium(IV) complexes in dichloromethane, but when the solvent was THF or DMF the results by cyclic voltammetry show the existence of some interaction between the solvent and the resultant $[Nb(\eta\text{-}C_5H_4SiMe_3)_2X_2]^+$ complex obtained in the electrochemical oxidation process, which was unstable. Thus, when the solvent was THF the oxidation of $Nb(\eta\text{-}C_5H_4SiMe_3)_2Cl_2$ consumed more than one fluorine. Work to identify all of these resultant cationic species is in progress.

* Author to whom correspondence should be addressed.

† ^1H NMR data (solvent $CDCl_3$, δ in ppm relative to TMS) **5**: $C_5H_4SiMe_3$: 6.90 (m; 4); $C_5H_4SiMe_3$: 0.33 (s; 9). **6**: $C_5H_4(SiMe_3$: 7.10 (m; 4); $C_5H_4SiMe_3$: 0.34 (s; 9).

Complex **5** reacts with several nucleophilic reagents, such as H_2O, ROH, Me_3SiOR [eq. (3)]:

$$Nb(\eta\text{-}C_5H_4SiMe_3)_2Cl_2^+PF_6^- + Me_3SiOR \longrightarrow [Nb(\eta\text{-}C_5H_4SiMe_3)_2ClOR]^+PF_6^- + Me_3SiCl. \quad (3)$$

While it has been possible to isolate the corresponding organoalkoxo niobium(V) complexes, R = CH_3 (**8**), CH_2CH_3 (**9**), $CH(CH_3)_2$ (**10**), with Me_3SiOR as yellow crystalline solids which have been spectroscopically characterized,* the reactions with ROH give solutions which probably contain the corresponding adducts, but all attempts to isolate these compounds as solids were unsuccessful and the starting complexes were obtained. Now we are trying to isolate the reaction products using a basic medium and we have also started the electrochemical synthesis of the related compounds.

Finally, preliminary studies show the oxidizing character of the d^0 cationic species. For example [eq. (4)], they may be involved in the catalytic electrochemical oxidation of phosphines:

$$Nb(\eta\text{-}C_5H_4SiMe_3)_2I_2^+ + PR_3 + H_2O \longrightarrow Nb(\eta\text{-}C_5H_4SiMe_3)_2I_2 + OPPh_3 + 2H^+ + e^-. \quad (4)$$

We are now investigating the reactivity of cationic d^0 complexes, through both chemical and electrochemical ways, towards other organic substrates.

* ^1H NMR data (solvent $CDCl_3$, δ in ppm relative to TMS) **8**: $C_5H_4SiMe_3$: 7.01 (m; 6); 7.43 (m; 2); $C_5H_4SiMe_3$: 0.40 (s; 18); OR: 4.61 (s; 3). **9**: $C_5H_4SiMe_3$: 7.11 (m; 6); 7.45 (m; 2); $C_5H_4SiMe_3$: 0.55 (s; 18); OR: 1.55 (t; 3) J_{H-H} = 6.9 Hz, 4.96 (q; 2) J_{H-H} = 6.9 Hz. **10**: $C_5H_4SiMe_3$: 7.10 (m; 4); 7.36 (m; 2); 7.44 (m; 2); $C_5H_4SiMe_3$: 0.61 (s; 18); OR: 1.60 (d; 6) J_{H-H} = 5.5 Hz, 5.26 (m; 1) J_{H-H} = 5.5 Hz.

MONOCYCLOPENTADIENYL LANTHANIDE CHEMISTRY: TOWARDS THE LIMITS OF STERIC UNSATURATION

COLIN J. SCHAVERIEN* and HARRY VAN DER HEIJDEN

Koninklijke/Shell-Laboratorium Amsterdam (Shell Research B.V.), Postbus 3003, 1003 AA Amsterdam, The Netherlands

and

A. GUY ORPEN

Department of Inorganic Chemistry, University of Bristol, Bristol BS8 1TS, U.K.

Abstract—The synthesis and single-crystal X-ray structure determinations of salt- and solvent-free $La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2$, and of its THF precursor, are described. These complexes contain unusual agostic Si—Me bonds that facilitate stabilization of the unsaturated lanthanum centre. The first neutral "mixed" dialkyl organolanthanide complex, $Lu(\eta^5\text{-}C_5Me_5)(CH_2SiMe_3)[CH(SiMe_3)_2](THF)$, has been prepared.

The recent growth in organolanthanide chemistry has produced a wealth of fascinating reactions including propylene oligomerization,[1] methane transmetallation[2] and β-methyl elimination[3] by $Lu(\eta^5\text{-}C_5Me_5)_2Me$. Furthermore, $[M(\eta^5\text{-}C_5Me_5)_2H]_2$ (M = La, Nd, Lu) have been shown to be excellent olefin hydrogenation and ethylene oligomerization catalysts.[4]

Despite this recent increase of interest in organolanthanide chemistry, few mono-ligand supported lanthanide complexes have been prepared. Limitations to the potential scope of bis(pentamethylcylopentadienyl)lanthanide species may exist, however, in that they possess only one reactive metal–carbon or metal–hydride bond. In seeking new catalytic hydrocarbon and alkene transformations we rationalized that neutral, salt- and solvent-free organolanthanide alkyl complexes containing only *one* supporting cyclopentadienyl ligand would allow greater flexibility in this reactivity.

Reaction of $LuCl_3(THF)_3$ with NaC_5Me_5 (1 equiv.) in refluxing THF, under homogeneous conditions, afforded the useful precursor $[Na(THF\cdot OEt_2)]Lu(\eta^5\text{-}C_5Me_5)Cl_3$ (**1**)† in 70% yield:

$$LuCl_3(THF)_3 + NaC_5Me_5 \longrightarrow [Na(THF\cdot OEt_2)]Lu(\eta^5\text{-}C_5Me_5)Cl_3. \quad (1)$$

Compound **1** reacts cleanly with $LiCH(SiMe_3)_2$ in diethyl ether, in the presence of THF (5 equiv.), to afford the monoalkyl complex $[Li(THF)_2]Lu(\eta^5\text{-}C_5Me_5)CH(SiMe_3)_2Cl_2$ (**2**), which after treatment with tetramethylethylenediamine (TMEDA) affords $[Li(TMEDA)]Lu(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]Cl_2$ (**3**).

A LiCl-free, mixed alkyl, complex **5**, can be prepared from reaction of **2** with $LiCH_2SiMe_3$ to give a mixture of $[Li(THF)_3]Lu(\eta^5\text{-}C_5Me_5)(CH_2SiMe_3)[CH(SiMe_3)_2]Cl$ (**4**) and $Lu(\eta^5\text{-}C_5Me_5)(CH_2SiMe_3)[CH(SiMe_3)_2](THF)$ (**5**). Compound **4** loses LiCl on dissolution in non-coordinating solvents, thus recrystallization of this mixture (once) from hexane gave neutral, LiCl-free **5**. This represents the first reported neutral "mixed" alkyl organolanthanide complex.

* Author to whom correspondence should be addressed.

† All compounds have been fully characterized and satisfactory analytical data obtained.

$$[Li(THF)_2]Lu(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]Cl_2 + LiCH_2SiMe_3 \longrightarrow$$
(2)

$$[Li(THF)_3]Lu(\eta^5\text{-}C_5Me_5)(CH_2SiMe_3)[CH(SiMe_3)_2]Cl$$
(4)

Hexane

$$Lu(\eta^5\text{-}C_5Me_5)(CH_2SiMe_3)[CH(SiMe_3)_2](THF).$$
(5)

Complexes **3** and **4** have been structurally characterized.[5]

Attempts at stabilizing the sterically unsaturated lutetium centre with two bis(trimethylsilyl)methyl groups were unsuccessful, presumably due to steric limitations.

Salt-free **5**, especially, has limited thermal stability, with rapid decomposition in solution above 40°C. Use of the 1,3-diphenyl-2,4,5-trimethylcyclopentadienyl ligand gave greater thermal stability to the lutetium alkyl complexes, $[K(OEt_2)]Lu(\eta^5\text{-}C_5Me_3Ph_2)\{CH(SiMe_3)_2\}Cl_2$ (**6**) and $Lu(\eta^5\text{-}C_5Me_3Ph_2)(CH_2SiMe_3)_2(THF)$ (**7**).

Investigation of this chemistry was severely hampered by salt coordination and the poor thermal stability of the salt-free compounds, so we decided to explore similar goals with lanthanum.

Reaction of $La(\eta^5\text{-}C_5Me_5)I_2(THF)_3$[6] (**8**) with two equivalents of $LiCH(SiMe_3)_2$ in hexane–diethyl ether affords thermally unstable, salt-free $La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2(THF)$ (**9**):

$$La(\eta^5\text{-}C_5Me_5)I_2(THF)_3 + 2LiCH(SiMe_3)_2 \longrightarrow$$
(8)

$$La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2(THF).$$
(9)

The removal of coordinated THF is achieved by a novel and potentially general, yet simple chemical method which leaves the highly reactive, electrophilic organolanthanide complex intact. Trimethylsilyl iodide is known to ring-open cyclic ethers such as THF to afford trimethylsilyl ethers. We postulated that this would provide a simple method to *cleanly* remove coordinated THF from highly reactive and sensitive **9**. To our knowledge, this method of THF removal has never been utilized in organometallic chemistry. Treatment of **9** with Me_3SiI affords salt- and solvent-free $La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2$ (**10**), with concomitant formation of $Me_3SiO(CH_2)_4I$. Because of the inherent instability of **9** (half life is *ca* 2 h at 25°C and 40 mM concentration), a more practically useful synthetic approach was needed and discovered. Reaction of **8** with Me_3SiI afforded THF-free $[La(\eta^5\text{-}C_5Me_5)I_2]_n$ (**11**). Treatment of isolated **11** with $KCH(SiMe_3)_2$ (2 equiv.), in ether, gave $La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2$ (**10**) directly in 75% yield.

The X-ray crystal structures of compounds **9** and **10** (Fig. 1) have been determined and reported by us.[7] They show unique β-Si—Me agostic interactions with the lanthanum centre, as opposed to the C—H—M interactions previously observed

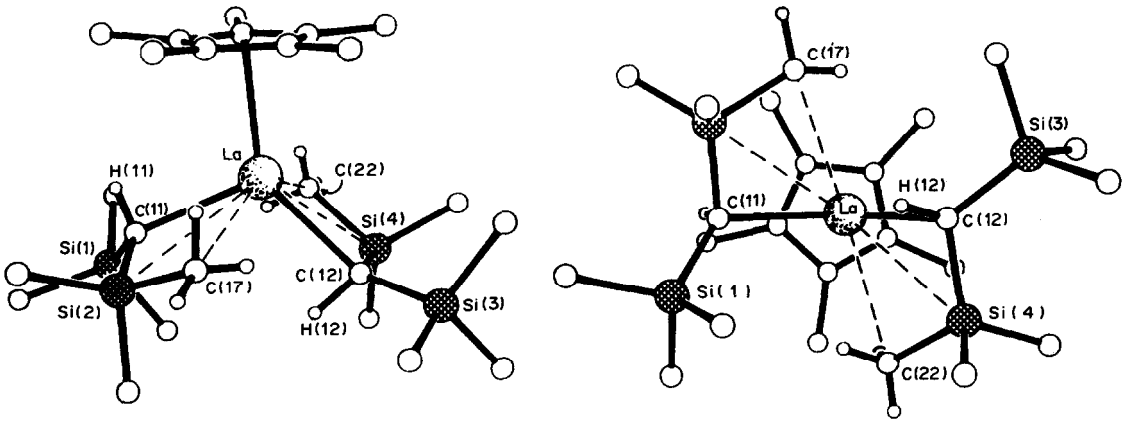

Fig. 1. Alternative views of the molecular structure of $La(\eta^5\text{-}C_5Me_5)[CH(SiMe_3)_2]_2$ (**10**). Methyl group hydrogens have been omitted except for those on C(17) and C(22).

La···C(17)	2.988(6)	La···Si(2)	3,353(2)	La···H(11)	2.64(5)
La···C(22)	3.353(2)	La···Si(4)	3.400(2)	La···H(12)	2.75(5)

La—C(11)—Si(1)	126.4(4)	La—C(12)—Si(3)	129.6(3)
La—C(11)—Si(2)	99.6(3)	La—C(12)—Si(4)	98.8(3)

with the $CH(SiMe_3)_2$ ligand. There appears to be only a marginal lengthening of the interacting Si—Me bond compared to the other Si—Me bonds in the same molecule. Although we were able to locate the hydrogen atoms on the interacting carbon in **10**, and they are not pointing towards the lanthanum, we are in the process of carrying out a single-crystal neutron structure determination on **10** to elucidate exactly the nature of this interaction. Furthermore, variable temperature solid state ^{13}C studies are in progress, and will be reported elsewhere, to determine the dynamic processes available to these rather flexible alkyl groups.

The near-planarity of the La—C—Si—Me system is reminiscent of the planar four-centre intermediates postulated and observed[8] in β-hydride elimination. These species may be viewed as models for the early stages of the β-methyl elimination reaction,[9] analogous to β-C—H agostic species which model the β-hydride elimination reaction.

NEW NITROGEN BASE ADDUCTS OF MANGANESE(II) DIALKYLDITHIOPHOSPHATES AND THE X-RAY STRUCTURE OF $[Mn(phen)_3]^{2+}[S_2P(OC_2H_5)_2^-]_2$

MICHAEL G. B. DREW, MASIHUL HASAN* and YANN HELLO†

Department of Chemistry, The University, Whiteknights, Reading RG6 2AD, U.K.

Abstract—A number of manganese(II) complexes with $[(RO)_2PS_2]^-$ ligands have been prepared and structurally characterized.

A review of the literature[1,2] shows that the chemistry of $Mn^{II}[Rdtp]_2$ ($Rdtp = S_2P(OR)_2^-$) and its adducts with N-bases has been neglected. There are however two papers which refer to $Mn^{I}[Rdtp(CO)_4]$ ($R = C_6H_5$,[3] CH_3[4]) and their substituted adducts with N-bases and Lewis bases, but these were published over 20 years ago.

Here we report the characterization for a range of complexes of the type $Mn[Rdtp]_2 \cdot L$, [$R = C_2H_5$, i-C_3H_7, n-C_4H_9; L = bipy (2,2′-bipyridyl), phen (1,10-phenanthroline), dmphen (2,9-dimethyl,1,10-phenanthroline)] and $[Mn(phen)_3]^{2+}$ $[Rdtp^-]_2$ ($R = C_2H_5$, i-C_3H_7). It is surprising that although the $[Mn(phen)_3]^{2+}$ cation has long been known to possess anti-fungal[5] and more recently anti-venereal and contraceptive properties,[6] its single crystal X-ray structure has not been reported,[2] and so we have carried out such a study on $[Mn(phen)_3]^{2+}[Rdtp^-]_2$ ($R = C_2H_5$), and this is described below.

The $Mn[Rdtp]_2 \cdot L$ complexes were prepared by mixing solutions of $[NH_4][Rdtp]$ in H_2O and the appropriate N-base in ethyl alcohol with aqueous $Mn(NO_3)_2 \cdot 6H_2O$ in a stoichiometric ratio. All the complexes described here have been characterized by elemental analysis and IR spectra. Yields are generally in excess of 60%.

The nature of the products [shown in eqs (1)–(3)] is dependent upon L, substituent R and the solvent. When the ratio of metal salt–Rdtp–phen is 1:2:1, then $Mn(Rdtp)_2 \cdot L$ is precipitated in H_2O for $R = C_2H_5$ and n-C_4H_9, but not when $R = i$-C_3H_7. On increasing the relative ratio of phen from 1 to 3, no change in product was observed. When L = bipy, only when $R = n$-C_4H_9 is the compound $Mn[Rdtp]_2 \cdot L$ formed. But on extraction with CH_2Cl_2 from a mixture of solutions of Mn^{II}, $Rdtp^-$ and L in the ratio 1:2:1, a larger range of complexes of this type are obtaind ($R = C_2H_5$, i-C_3H_7; L = phen, bipy, dmphen; and $R = n$-C_4H_9, L = dmphen). In the case of $R = C_2H_5$, L = phen, the major product was yellow crystals of $Mn[Rdtp]_2$(phen). However, small traces of red crystals were also observed, which were separated by repeated recrystallization and characterized as $[Mn(phen)_3]^{2+}[Rdtp^-]_2$.

On the other hand, treatment of $Mn(Rdtp)_2 \cdot L$ ($R = C_2H_5$; L = phen) with 2 mol equivalent of phen gave a yellow complex in quantitative yield, which was identified as $[Mn(phen)_3]^{2+}[Rdtp^-]_2$. This is in marked contrast to the reaction with bipy, where $Mn(Rdtp)_2 \cdot L$ undergoes oxidation to give MnO_2, the disulphide[7] $[(RO)_2P(S)S^-]_2$ (^{31}P NMR, 83.7 ppm) and bipy. Holah and Murphy isolated $[Mn(phen)_3]^{2+}$ with a similar ligand, e.g. $S_2COC_2H_5^-$, by mixing Mn^{II}, $S_2COC_2H_5^-$, and phen (1:2:3) in water, but found that with bipy,

$$Mn^{II} + 2Rdtp^- + L \xrightarrow[H_2O]{} Mn[Rdtp]_2 \cdot L \quad (1)$$

$$Mn[Rdtp]_2 \cdot L + 2L \xrightarrow[C_2H_5OH]{} \begin{cases} \rightarrow [MnL_3]^{2+}[Rdtp^-]_2 \\ \quad (R = C_2H_5,\ L = \text{phen})\ 90\%\ \text{yield} \end{cases} \quad (2)$$

$$\rightarrow MnO_2 + L + \{(RO)_2P(S)S^-\}_2 \quad (R = C_2H_5,\ L = \text{bipy}) \quad (3)$$

† Permanent address: Institut des Sciences de l'Ingénieur en Thermique–Enérgetique et Matériaux (ISITEM), Nantes, France.

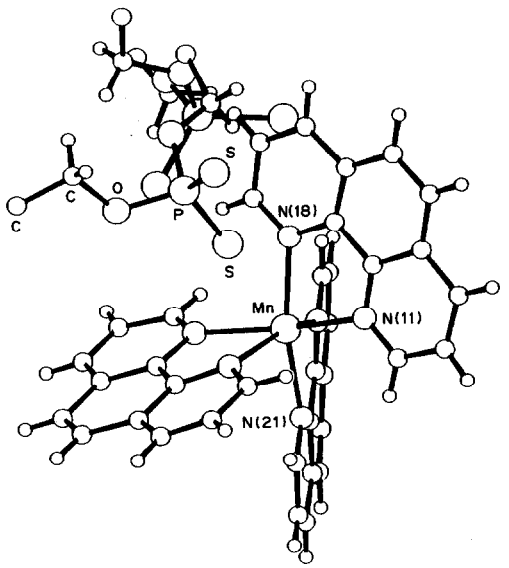

Fig. 1

intractable oils were obtained which could not be characterized.[8]

The above results are not unexpected since complexes of phen with other transition metals are generally more stable[9] than with bipy.

A crystal structure determination was carried out on the yellow crystals of $[Mn(phen)_3]^{2+}[Rdtp^-]_2$ ($R = C_2H_5$).* Preliminary investigations show that the red crystals isolated from the preparation of $Mn[dtp]_2(phen)$ are isomorphous, so we have no immediate explanation for the variation in the colour. Spectral measurements on the two compounds are similar.

The structure is shown in Fig. 1; there are only van der Waals contacts between the ions. In the cation the independent Mn—N distances are 2.224(18), 2.285(13) and 2.263(12) Å. The geometry of the metal atom coordination sphere can be described as distorted octahedral. The main features of the distortion arise from the N—Mn—N chelate angle, for which the mean value is 73.4°. It is noteworthy that of the three *trans* N—Mn—N angles, one at 153.4(5)°, is significantly shorter than the other two [163.6(5)°]. Dimensions in the $Rdtp^-$ anion are compatible with previous studies.[7] Further X-ray and spectroscopic studies on compounds in this series are in progress.

* Crystal data: $[Mn(phen)_3]^{2+}[Rdtp^-]_2$ (**1**), $C_{44}H_{44}N_6S_4O_4P_2Mn$, $M = 965.47$, monoclinic, $a = 16.55(1)$, $b = 17.50(1)$, $c = 17.46(1)$, $\beta = 93.0(1)$, $U = 4680.0$ Å^3, $F(000) = 2004$, $d_m = 1.37(2)$ g cm^{-3}, $d_c = 1.37$ g cm^{-3}, $Z = 4$, $F(000) = 506$, Mo-K_α radiation, $I = 0.7107$ Å, $\mu = 5.85$ cm^{-1}, space group $I2/c$ (No. 15). The structure was determined by statistical methods. The structure consists of $[Mn(phen)_3]^{2+}$ cations with crystallographically imposed C_2 symmetry and discrete $dedtp^-$ anions in general positions. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions, although the methyl hydrogen atoms were refined as rigid groups. The final R was 0.098 ($R_w = 0.097$) for 1565 independent data with $I > 2\sigma(I)$. Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Abstract—Novel $Mn_2(CO)_{10-n}L_n$ complexes have been investigated as hydrogenation catalysts and a representative member has been structurally characterized.

We are investigating the behaviour of carbonyl clusters, and in particular that of phosphine-substituted and phosphido-bridged derivatives as homogeneous hydrogenation catalysis.[1] We have studied the behaviour of $Mn_2(CO)_{10}$ (**1**), $Mn_2(CO)_9(PPh_2H)$ (**2**), $Mn_2(\mu\text{-}H)(\mu\text{-}PPhH)(CO)_8$ (**3**), $Mn_2(\mu\text{-}H)(\mu\text{-}PPh_2)(CO)$ (**4**) and $Mn_2(\mu\text{-}PPh_2)_2(CO)_8$ (**5**) in the hydrogenation of diphenylacetylene.

Phosphine-substituted dimanganese derivatives are generally obtained by thermal or photochemical activation of the CO's, generally in non-selective processes; indeed it is believed that Mn—Mn bond cleavage occurs and that the phosphine-substituted fragments recombine in a random fashion.[3]

We have attempted the synthesis of $Mn_2(CO)_{10-n}L_n$ derivatives by labilization of CO's with Me_3NO[4] in relatively mild conditions (L = PPh_3, PPh_2H, $PPh_2CH{=}CH_2$, $PPh_2PC{\equiv}CPPh_2$). Heating $Mn_2(CO)_{10}$ with a 1–5 molar excess of ligand in hexane or heptane, in the presence of dry Me_3NO for 2 min, leads to mixtures containing 30–40% of $Mn_2(CO)_9L$, about 5–10% of $Mn_2(CO)_8L_2$ (one or two isomers) and about 50% of unreacted carbonyl (which was re-used).

The complexes were identified by spectroscopy and, in particular, by ^{31}P NMR; for **2** a sharp singlet at δ 51.12 was observed. However, for the other monosubstituted complexes sharp singlets centred at δ 50–60 and a broad peak at δ 20–30 was found (but for PPh_3, a sharp singlet at δ 29.52, a broad peak at δ 74.62 ppm). This should indicate

1	1–27	5.0–12.5	24.0–22.4	76.0–77.6	3.2–3.5
2	1–48	5.1–11.9	15.7–21.0	84.3–79.0	5.4–3.8
3	1–76	14.2–21.3	28.9–27.2	71.1–72.8	2.5–2.7
4[c]	48	50.4	20.2	79.8	3.9
5	1–48	5.8–15.4	25.9–27.3	74.1–72.7	2.9–2.7

[a] Minimum and maximum value; 1 atm H_2.
[b] Initial and final valuc.
[c] Under 34 atm pressure of H_2.

that mostly equatorial, monosubstituted complexes are obtained.

Thus, apparently, the use of Me_3NO gives, in most cases, stereospecific substitution of one equatorial CO, a statistically favoured process. In order to confirm the structure of **2**, a suitable crystal of **2** was selected for an X-ray diffraction study. Crystal data: $C_{21}H_{11}Mn_2O_9P$, $M = 548.16$, monoclinic space group, $C2/c$, $a = 24.038(8)$, $b = 14.645(6)$, $c = 16.328(6)$ Å, $\beta = 125.58(2)°$, $Z = 8$, $d_{calc} = 1.559$ g cm^{-3}, μ(Mo-K_α) = 11.50 cm^{-1}. Of 4409 reflections collected on an Enraf–Nonius CAD-4 diffractometer (Mo-K_α) ($3 < \theta < 24°$), 1548, having $I > 2\sigma(I)$, were used in the refinement. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were clearly located and refined isotropically. Final R and R_w values were 0.0363 and 0.0436, respectively. Atomic coordinates have been deposited with the Director, Cambridge Crystallographic Data Centre. The structure of **2** is shown in Fig. 1. The Mn—Mn distance of 2.910(2) Å, is practically identical to that found in $Mn_2(CO)_{10}$.[5]

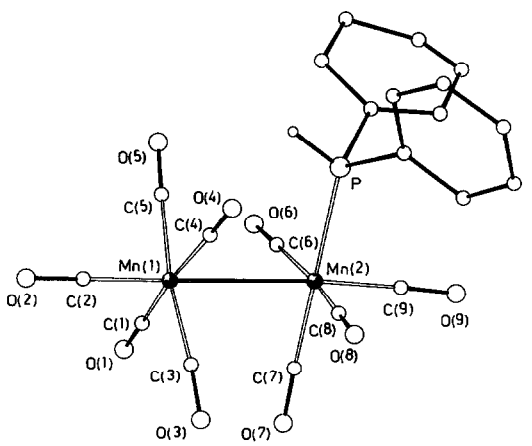

Fig. 1. View of the molecular structure of $Mn_2(CO)_9(PPh_2H)$.

Monosubstituted derivatives, characterized as axial, were obtained with PPh_3, PBu_3, $P(OPh)_3$, $AsPh_3$, $PPhMe_2$ (X-ray structure),[6] $AsPhMe_2$, PPh_2Me and PF_3; only with PH_3 was an equatorial derivative observed.[7] A few X-ray structures for axial,[6] diaxial[8] and diequatorial[8] complexes have been reported; thus **2** is the first confirmed example of equatorial substitution.

Some preliminary results in homogeneous hydrogenation of diphenylacetylene are given in Table 1.

Worthy of note are the high *trans–cis* stilbene ratios observed; identification of the organometallic species in the hydrogenation solutions is in progress in order to gain better insight into the reaction mechanisms.

THE INTERACTION OF ORGANOTRANSITION METAL FRAGMENTS WITH OXAAZAMACROCYCLES. SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $Mo(CO)_3$[O-en-N-pyn-H_4]·CH_2Cl_2

HARRY ADAMS, NEIL A. BAILEY,* DAVID E. FENTON,* PAUL D. HEMPSTEAD, BRIAN A. HEWES, SIMON J. KITCHEN and MARK J. WINTER*

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

Abstract—The reaction of *fac*-$Mo(NCMe)_3(CO)_3$ with [O-en-N-pyn-H_4] in CH_2Cl_2 gives *fac*-$Mo(CO)_3$[O-en-N-pyn-H_4]·CH_2Cl_2, whose X-ray crystal structure is monoclinic, $a = 10.448(20)$, $b = 14.975(23)$, $c = 16.598(27)$ Å, $\beta = 100.57(14)°$. The macrocycle is bonded confacially to a trigonally elongated octahedral molybdenum through one pyridinyl nitrogen, one amino nitrogen and one oxygen donor.

There is small but burgeoning literature concerning chemistry at the interface between macrocyclic coordination chemistry and organotransition metal chemistry. Much of this work concerns macrocycles bearing homodonor sets (polyaza-, polythia, etc.)[1–7] with relatively little concerning ligands with mixed donor sets (oxaaza-,[8] azathia,[9] etc).[10,11] A constraining factor is the ability to synthesize the free macrocycle in adequate yields. We recently devised a useful route to oxaazamacrocycles based on the template cyclocondensation of the diamino and dicarbonyl containing precursors, followed by reductive demetallation of the macrocyclic Schiff base metal complex so formed.[12] Using this approach, a wide range of macrocycles is accessible and it is of interest to examine their comparative complexing capabilities. We therefore report on the reaction between the macrocycle [O-en-N-pyn-H_4]† with *fac*-$Mo(NCMe)_3(CO)_3$, a source of the $Mo(CO)_3$ fragment.[14]

Addition of a CH_2Cl_2 solution of [O-en-N-pyn-H_4] to a suspension of *fac*-$Mo(NCMe)_3(CO)_3$ in CH_2Cl_2 immediately resulted in a green solution that deposited small brown crystals of complex **1** on standing.‡ The mass spectrum (positive ion FAB) shows a molecular ion [m/z 529; (^{98}Mo)], successive losses of three carbonyl groups from that ion, and the free macrocycle ion (m/z 348; $[M+H]^+$). The compound is insoluble in most common organic solvents and dissolution in donor solvents such as MeCN, pyridine, acetone, etc, results in ligand decomplexation. This phenomenon precludes NMR studies and solution IR studies, but the solid phase IR spectrum shows carbonyl stretches (ν_{CO}(KBr); 1910s, 1775s, and 1740s cm^{-1}) consistent with an asymmetric *fac*-$Mo(CO)_3(L_3)$ structure.

* Authors to whom correspondence should be addressed.

† The nomenclature adopted is that of Lindoy (ref. 13); e.g. the macrocycle named as [O-en-N-pyn-H_4] with O-en defining the ethylenic bridge between the two oxygen atoms, N-pyn defining the pyridyl bridge between the two amino nitrogen atoms, and -H_4 indicating that the system is fully reduced. The Chemical Abstracts name is 5,6,12,13,19,20-hexahydro-7,11-nitrilo-7H-dibenzo [e,p]-[1,4,7,15]di-oxadiazacycloheptadecane.

‡ Crystal data for $(C_{21}H_{21}O_2N_3)Mo(CO)_3 \cdot CH_2Cl_2$ (**1**); $C_{25}H_{23}Cl_2MoN_3O_5$; $M = 612.28$; crystallizes from dichloromethane as small yellow needles; monoclinic, $a = 10.448(20)$, $b = 14.975(23)$, $c = 16.598(27)$ Å, $\beta = 100.57(16)°$, $U = 2553(8)$ Å^3; $D_c = 1.594$ g cm^{-3}, $Z = 4$; space group $P2_1/n$ (a non-standard setting of $P2_1/c$, C_5^{2h}, No. 14); Mo-K_α radiation ($\lambda = 0.71069$ Å), μ(Mo-K_α) = 7.51 cm^{-1}, $F(000) = 1239.67$. R converged to 0.097.

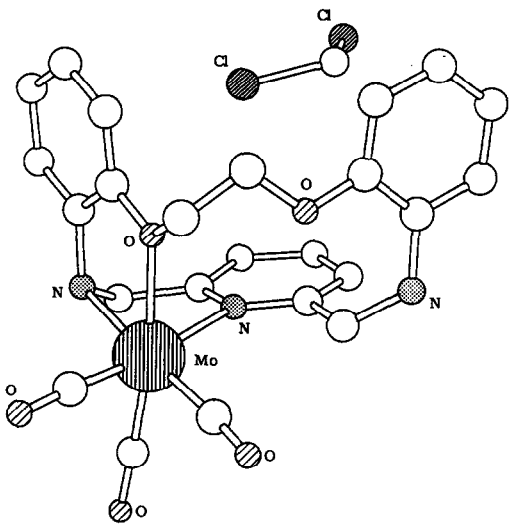

Fig. 1. Molecular structure of $Mo(CO)_3[O\text{-en-}N\text{-pyn-}H_4]\cdot CH_2Cl_2$.

The molecular structure of **1** is illustrated in Fig. 1. The macrocycle adopts a "boat" conformation. The donor set is particularly interesting in that the $Mo(CO)_3$ fragment binds to the pyridinyl nitrogen, one amino nitrogen and one oxygen atom. The angles within the tricarbonyl donor set and the macrocycle donor set are all less than 90°, and so the coordination geometry at the molybdenum atom is a trigonally elongated octahedron. Facial bonding of the N_3 donor set from the macrocycle appears to be sterically disallowed. A feature of the N_2O donor set is that the macrocycle, or its derivatives, might bridge appropriate bimetallic fragments.

Acknowledgements—We thank the SERC and the Royal Society for support.

Abstract—The methoxy alkyls, $CpM\{CHMe(OMe)\}(CO)_2(PPh_3)$ (M = Mo, W), undergo proton catalysed MeOH loss to give the vinyl, $CpW(\eta^2\text{-}CH{=}CH_2)(CO)_2(PPh_3)$ (for M = W) and the η^3-propenoyl, $CpMo(CO)(PPh_3)(\eta^3\text{-}CH_2CH{=}O)$ (for M = Mo); the formation of the latter is interpreted by a mechanism involving a vinyl to carbonyl migration.

Examples of vinyl to carbonyl migrations are rare.[1–3] We describe here, proton induced MeOH loss from methoxy alkyl derivatives $CpM\{CHMe(OMe)\}(CO)_2(PPh_3)$ (M = Mo, W), a process which results in a molybdenum η^3-propenoyl complex. We suggest this is best rationalized as proceeding by a mechanism involving a vinyl to carbonyl migration.

Additions of $LiBEt_3H$ to suspensions of the cationic carbenes **1**[4] or **2** result in attack at the carbene by H^- and formation of the methoxy alkyl derivatives, **3**[5] and **4**, respectively. The tungsten compound, **4**, undergoes MeOH loss on treatment with traces of HCl dissolved in $CHCl_3$, resulting in the vinyl, **5**. The molybdenum species, **3**, also undergoes proton induced loss of MeOH, but in this case the product is the η^3-propenoyl, **6**. Compound **6** is fluxional by a process not yet fully elucidated, but probably related to the known fluxionality of the η^3-allyls, $CpM(CO)_2(\eta^3\text{-}C_3H_5)$.[6]

* Author to whom correspondence should be addressed.

Deuterium labelled complexes M{CDMe(OMe)}$(CO)_2(PPh_3)(\eta$-$C_5H_4R)$ (**3**-D_1) (R = H) and (**4**-D_1) (R = Me) are accessible by treatment of **1** or **2** with $LiBDEt_3$. Treatment of **3**-D_1 and **4**-D_1 with traces of HCl gives $CpMo(\eta^3$-$CH_2CDC{=}O)(CO)(PPh_3)$ (**6**-D_1) and $Cp'W(\eta^2$-$CD{=}CH_2)(CO)_2(PPh_3)$ (**5**-D_1), respectively. The labelled methyl CpMo$(CD_3)(CO)_3$ is a good precursor for CpM{CH(CD_3)(OMe)}$(CO)_2(PPh_3)$ (**1**-D_3). Treatment of **1**-D_3 with $LiBEt_3H$ followed by acid, results in the sequential formation of CpMo{CH(CD_3)(OMe)}$(CO)_2(PPh_3)$ (**3**-D_3) and $CpMo(\eta^3$-$CD_2CHC{=}O)(CO)(PPh_3)$ (**6**-D_2). In all cases, these isotopomers are exclusive products within the limits of NMR detection.

These results are best interpreted as follows. Protons attack the OMe groups within **3** or **4** causing MeOH loss, resulting in the non-heteroatom stabilized carbene (alkylidene) intermediates, **7** or **8**, respectively. The related cations $[CpM(CO)_2(CHR)(PPh_3)]^+$ (M = Mo or W, R = H; M = W, R = Ph) have a brief existence at low temperatures.[7] Proton loss from the methyl group of **8** gives the tungsten vinyl, **5**. A similar proton loss from the methyl group of the molybdenum intermediate, **7**, would give the currently undetected vinyl, **9**. The formation of **6** from **9** then proceeds by a rapid vinyl to carbonyl migration and double bond coordination. The isotope labelling studies are consistent with these interpretations. In particular, the formation of **6**-D_2 confirms the loss of protons from the methyl group of the intermediate, **7**.

We consider an alternative mechanism in which the alkylidene =CHMe group of **7** links with a carbonyl ligand to form an intermediate ketene complex, from which protons are subsequently lost, as less likely. The rearrangements of the related alkylidenes, $[CpMo(CO)_2(=CHR)(L)]^+$ (L = CO, R = Me; L = PPh_3, R = H), show no sign of comparable coupling reactions;[7,8] indeed, such couplings generally involve direct addition of external CO and require more forcing conditions than those employed here.[9]

The vinyls, $CpFe(\eta^1$-$CH{=}CH_2)(CO)(L)$ (L = CO, PPh_3), $CpW(\eta^1$-$CH{=}CH_2)(CO)_3$, and complex **9** appear not to undergo facile vinyl to carbonyl migrations.[10] The related dicarbonyls, $CpM\{\eta^1$-C$(NR^1_2){=}CHR^2\}(CO)_2\{P(OMe)_3\}$ (R^1 = Et, R^2 = Me; M = Mo, W), convert into η^2-keteneimmonium complexes, but the corresponding tricarbonyls display complex behaviour depending on the metal, R^1 and R^2, to form products including η^3-propenoyl complexes.[2]

That compound **9** undergoes vinyl to carbonyl migration, whereas **5** and $CpFe(\eta^1$-$CH{=}CH_2)(CO)(PPh_3)$ do not, parallels the sluggish tendencies of many iron and tungsten compounds to undergo alkyl to carbonyl migrations relative to those of molybdenum.[11]

SYNTHESES AND REACTIONS OF $LM(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ ($L = C_5Me_5$ OR η^5-C_9H_7; M = Mo OR W)

GARY W. BENTLEY, GORDON HOUGH, MARK J. WINTER† and SIMON WOODWARD

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

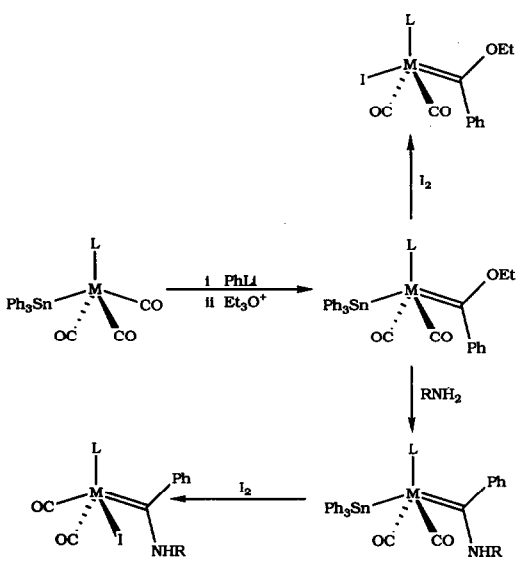
Abstract—Successive treatment of $LM(SnPh_3)(CO)_3$ (M = Mo or W; L = Cp(η-C_5H_5), Cp*(η-C_5Me_5), or Ind(η^5-C_9H_7), indenyl) with PhLi and Et_3O^+ results in the carbene complexes *trans*-$LM(SnPh_3)(CO)_2\{=C(OEt)Ph\}$. These undergo aminolysis with RNH_2 (R = Me, Et) to form the carbenes, *trans*-$LM(SnPh_3)(CO)_2\{=C(NHR)Ph\}$. Most of these compounds react with I_2 to form the new carbenes $LMI(CO)_2\{=C(X)Ph\}$ (X = OEt, NHMe, or NHEt) that exist in *cis*, *trans* or *cis* + *trans* conformations.

We are interested in systems $L_nMR\{=CR^1R^2\}$ that undergo migrations of a ligand R such as hydride, alkyl, acyl and aryl to the coordinated carbene to form new C—H and C—C bonds.[1] The synthetic strategy to form $L_nMR\{=CR^1R^2\}$ complexes relies on $NaC_{10}H_8$ reduction of compounds $L_nMI\{=CR^1R^2\}$, followed by protonation or alkylation. These reactions proceed through the intermediacy of anionic carbene complexes[2] $[L_nM\{=CR^1R^2\}]^-$. We are therefore interested in general syntheses of complexes of the type $L_nMI\{=CR^1R^2\}$ as precursor molecules to further study such migrations. We therefore report syntheses of Cp* (Cp* = η^5-C_5Me_5) and Ind (Ind = η^5-C_9H_7, indenyl) molybdenum and tungsten carbene complexes.

One might expect that Fischer type carbenes, $LMI(CO)_2\{=C(OR)Ph\}$ (M = Mo, W; L = Cp, Cp*, Ind), would arise by treatment of $LMI(CO)_3$ with PhLi followed by alkylation. In fact, this approach fails. For example, the reaction of $CpMI(CO)_3$ with PhLi results in $[CpM(CO)_3]^-$ rather than $[CpMI(COPh)(CO)_2]^-$. It is therefore necessary to synthesize the iodides by an indirect route.

It is already known that consecutive treatment of $CpM(SnPh_3)(CO)_3$ (M = Mo or W) with PhLi in THF and Et_3O^+ in water results in the carbene complexes $CpM(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ in moderate yields.[3] We find these yields increase to nearly quantitative in some cases if the first step is executed in Et_2O. We further find that the related compounds $Cp^*M(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ and $IndM(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ are formed in good yields starting from $Cp^*M(SnPh_3)(CO)_3$ or $IndM(SnPh_3)(CO)_3$ (M = Mo or W), respectively (Scheme 1).

All these compounds are fully characterized. The spectroscopic properties of all are, not unexpectedly, closely related and all are *trans* dicarbonyls. The cyclopentadienyl[3] and indenyl complexes $LM(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ (L = Cp, Ind) are interesting in that their IR spectra show four bands



Scheme 1. M = Mo or W; L = Cp, Cp*, or Ind; R = Me, Et.

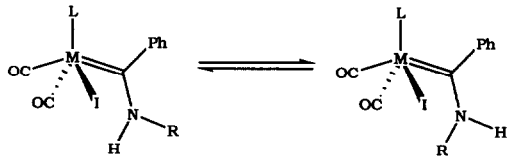
† Author to whom correspondence should be addressed.

(for instance, $IndMo(SnPh_3)(CO)_2\{=C(OEt)Ph\}$: $\nu_{CO}(Et_2O)$; 1943m, 1929m, 1877s, and 1863s cm^{-1}) rather than the anticipated two. This multiplicity was ascribed earlier[3] to carbene rotamers in the Cp case. Clearly the same phenomenon which produces the four IR bands in the Cp base will account for the band multiplicity in the indenyl case. Notably the Cp* complexes show only two bands in their IR spectrum, a manifestation of the steric influence of the Cp* ligand which is still under investigation.

In common with many other Fischer type carbenes, reactions with aqueous solutions of amines RNH_2 (R = Me, Et) results in aminolysis to form carbenes such as $LM(SnPh_3)(CO)_2\{=C(NHR)Ph\}$ (M = Mo or W; L = Cp or Cp*, Ind; R = Me or Et). These compounds are all *trans* dicarbonyls.

Iodine cleaves the M—$SnPh_3$ bond of all the aminocarbenes cleanly to form the corresponding iodides $LMI(CO)_2\{=C(NHR)Ph\}$ (L = Cp, Cp*, Ind; R = Me, Et) and $SnIPh_3$. The corresponding reactions of the alkoxy carbenes are sometimes less successful. For instance, while iodine reacts with $Cp^*Mo(SnPh_3)(CO)_2\{=C(OEt)Ph\}$ to form $Cp^*MoI(CO)_2\{=C(OEt)Ph\}$ (IR evidence only), the product is not isolable since it undergoes facile loss of EtI to form the η^1-phenyl $Cp^*MoPh(CO)_3$. This is interesting because the corresponding $CpMoPh(CO)_3$ appears to be unstable.[4] On the other hand, formation of $CpWI(CO)_2\{=C(OEt)Ph\}$ is clean and the product isolable in good yield.

Some of these iodometal complexes show interesting isomerism. For instance, the IR spectrum of the tungsten complex $CpWI(CO)_2\{=C(OEt)Ph\}$ in cyclohexane shows eight bands corresponding to three *trans* isomers and one *cis* isomer while the molybdenum analogue just shows two *trans* isomers together with one *cis* isomer in the same solvent. In both cases, the *trans* components of the mixture predominate. The proportions of the isomers are solvent dependent and the NMR spectra show these



Scheme 2. M = Mo or W; L = Cp, Cp*, or Ind; R = Me, Et.

compounds are fluxional. The multiplicity of the IR bands is a consequence of carbene rotations (but in this case both M=C and C—OEt rotations are involved) and also *cis–trans* isomerism.

The complexes $LMI(CO)_2\{=C(NHR)Ph\}$ exist purely in the *cis* form, but here also these is isomerism since the NMR spectra show that there are two isomers of each complex. We ascribe the presence of two sets of signals to rotamers related by rotation about the carbene-N bond (Scheme 2).

VISIBLE LIGHT PHOTOCHEMICAL REVERSAL OF HYDRIDE TO CARBENE MIGRATION

CARIN E. DAVEY, ROBIN DEVONSHIRE and MARK J. WINTER*

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

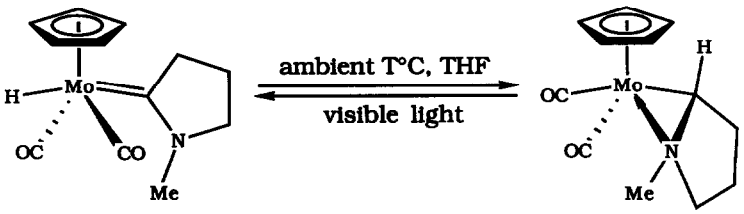
Abstract—Visible light photolysis of the complex $CpMo(CO)_2\{\eta^2\text{-}CH(CH_2)_3NMe\}$, which is made by utilizing a hydride to carbene migration within the complex $CpMoH(CO)_2\{=C(CH_2)_3NMe\}$, results in reversal of the hydride to carbene migration to reform $CpMoH(CO)_2\{=C(CH_2)_3NMe\}$.

Migrations of hydride to carbene are important in the context of C—H bond forming reactions at metal centres and in the sense that they are a fundamental reaction step.[1] While frequently postulated in reaction sequences involving carbenes, there are comparatively few well-defined direct observations[2,3] and little mechanistic information on this process. The reverse of hydride to carbene migration is α-elimination.[4] In eq. (1) it is assumed the metal is one whose electron count must be maintained, hence the incoming L′ two electron ligand:

We recently established that the hydride, $CpMoH(CO)_2\{=C(CH_2)_3NMe\}$ (**1**), which exists as a mixture of *cis* and *trans* isomers, undergoes a hydride to carbene migration reaction in forming $CpMo(CO)_2\{\eta^2\text{-}CH(CH_2)_3NMe\}$ (**2**) (Scheme 1). The 18 electron count at the metal is maintained through coordination of the nitrogen atom (an intramolecular source of L′). The conversion of **1** into **2** is a first-order reaction and takes place over several hours at ambient temperature in THF. The Arrhenius activation energy is 98 kJ mol^{-1} in THF.

We report, here, the observation that irradiation by bright, Sheffield, February sunlight (or by light from a fluorescent tube) of solutions containing $CpMo(CO)_2\{\eta^2\text{-}CH(CH_2)_3NMe\}$ (**2**) in THF, or at a slower rate in toluene, results in the reformation of the hydride $CpMoH(CO)_2\{=C(CH_2)_3NMe\}$ (**1**). In effect, this is a light induced α-elimination.

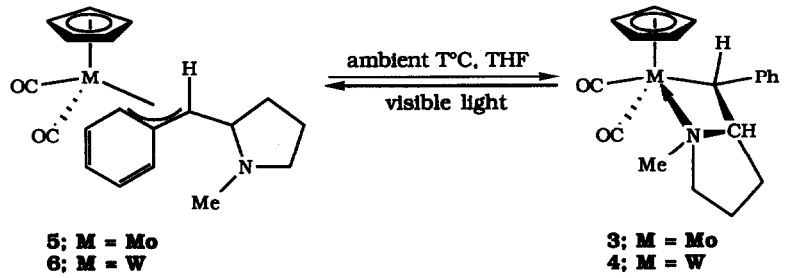
This photoreaction is apparently linked to a UV absorption maximum at 412 nm. Comparison with some related molecules such as $Mo(CO)_4(Ph_2PCH_2CH_2NEt_2)$[5] suggests this is associated with the N → Mo bond. The measured quantum



1 **2**

Scheme 1.

*Author to whom correspondence should be addressed.



Scheme 2.

yields for the reaction are 0.07 and 0.09 molecules photon^{-1} at 436 and 405 nm in THF, but 0.03 and 0.05 molecules photon^{-1} in toluene. The system shows no sign of phosphorescence or fluorescence.

We currently envisage that irradiation cleaves the N → Mo bond of **2** to leave a vacant coordination site, which in principle can be stabilized by the solvent. From here, the intermediate can revert to starting material or proceed to the hydride, **1**.

We also observe related N → M cleavage in visible light photoreactions of complexes **3** and **4**.[6] In these cases, the α-hydrogen does not migrate to the metal, rather, the phenyl ring enters into the metal coordination sphere producing the fully characterized η^3-benzyl complexes, **5** and **6** (Scheme 2).

We plan to investigate the mechanism of these and related photoreactions using time resolved UV–vis and Raman spectroscopies.

THE BINDING OF A $MoFe_3S_4$ DOUBLE-CUBANE CLUSTER BY CYSTEINE ETHYL ESTER

D. J. EVANS,* G. J. LEIGH and J. B. PARRA-SOTO

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—The $MoFe_3S_4$ double-cubane cluster, $[Mo_2Fe_7S_8(\mu\text{-SEt})_6(SEt)_6]^{3-}$ (**1**), is shown by ^1H NMR spectroscopy to react with cysteine ethyl ester hydrochloride, initially to form the terminal chloride substituted cluster $[Mo_2Fe_7S_8(\mu\text{-SEt})_6Cl_6]^{3-}$ (**2**) and this then reacts further to form a novel terminal cysteinate substituted cluster, **3**. The temperature-dependence of the isotropically shifted ^1H NMR signals of **3** is reported.

Cysteinyl residues in proteins are the principal ligands to iron–sulphur clusters in biological systems, as in ferredoxins.[1] The residues which bind ferredoxin and rubredoxin cores to the protein backbone are cysteines, generally in the sequence cys—X—X—cys—X—X—cys, where X is some other non-binding amino acid residue. We have recently demonstrated that a range of other amino acids, including serine and tyrosine, are capable of binding to the model cluster core $\{Fe_4S_4\}^{2+}$.[2,3] Here we describe the first reported interaction between cysteine and a heterometallic double-cubane complex as observed by ^1H NMR spectroscopy.

RESULTS AND DISCUSSION

The iron–sulphur cluster $[Fe_4S_4(SBu^t)_4]^{2-}$ has been shown to react with a range of amino acid ester hydrochlorides, AAHCl, to form $[Fe_4S_4(AAH)_4]^{2+}$.[2,3] The initial reaction produces $[Fe_4S_4Cl_4]^{2-}$, which then reacts further to form the amino acid derivative. The chloride cluster can be prepared independently by reaction of $[Fe_4S_4(SBu^t)_4]^{2-}$ with acetyl chloride[4] or with butyl-2-amine hydrochloride,[3] the liberated amine and thiol being removed from solution by pumping.

We have now extended our studies to the interaction of amino acid esters with $MoFe_3S_4$ double-cubane clusters. We first confirmed that 6 equivalents of acetyl chloride convert the double-cubane cluster, $[NEt_4]_3[Mo_2Fe_7S_8(\mu\text{-SEt})_6(SEt)_6]$ (**1**), in acetonitrile to the terminal chloride substituted cluster, $[NEt_4]_3[Mo_2Fe_7S_8(\mu\text{-SEt})_6Cl_6]$ (**2**),[5,6] and have characterized this product in solution by ^1H NMR spectroscopy (Table 1). The same cluster can be prepared by addition of 6 equivalents of butyl-2-amine hydrochloride to **1**. The terminally coordinated thiolate groups are labile. This behaviour parallels that of the single cluster $[Fe_4S_4(SBu^t)_4]^{2-}$.[3]

Addition of 6 molar equivalents of cysteine ethyl ester hydrochloride to **1** (2×10^{-3} mol dm^{-3}, CD_3CN, ambient temperature) initially generates **2**. Over a period of 3 h the isotropically shifted signals characteristic of the chloride substituted cluster are lost and signals generated by a new species appear (Table 1). The signals at 27.1 and 13.5 ppm are typical of bridging thiolate methylene groups, and that at −1.9 ppm is assigned to the bridging thiolate methyl group. These shifts are similar to those found for a range of $MoFe_3S_4$ double-cubane complexes.[5,6] The signal at low field, 81.8 ppm, is assigned to the β-CH_2 of terminally bound ethyl cysteinate. The relative shifts of the signals arising from terminally coordinated groups and from bridging groups are consistent with other literature data. Addition of 9 or 12 molar equivalents of cysteine ethyl ester hydrochloride to **1** showed the same reactions, except that they were completed quicker. There is no evidence for bridge cleavage, even when a large excess of amino acid ester hydrochloride is employed. Replacement of all six chloro ligands should require 6 equivalents of cysteine ethyl ester hydrochloride, and when only 3 were employed a complex spectrum was obtained, probably resulting from mixed ligand clusters. By analogy with previously reported $[Mo_2Fe_7S_8(\mu\text{-SEt})_6(SR)_6]^{3-}$

clusters,[5,6] we propose that in solution the novel $[Mo_2Fe_7S_8(\mu\text{-SEt})_6(\text{cysteinate})_6]^{3-}$ (3) cluster is generated.

Variable-temperature ^1H NMR data for 3 are listed in Table 2. As the temperature decreases the isotropically shifted bridging methylene groups move to higher field. This change is in the opposite sense, but has similar degree to that observed in the parent cluster. However, the bridging methyl signal moves away from the diamagnetic on decreasing the temperature. The terminal cysteinate β-CH_2 also moves away from the diamagnetic with decrease in temperature. The magnitude of change in shift is large, being 25 ppm over a 105°C range, consistent with binding at an iron site on the cluster. These observations are not consistent with a simple contact shift mechanism.

We are currently investigating the metathesis reaction between 2 and cysteine ethyl ester hydrochloride, cysteine ethyl ester and sodium cysteinate ethyl ester. Also attempts are being made to isolate the novel cluster 3, in order to characterize it definitively.

Abstract—The study of replication effects in propylene polymerization by $TiCl_3$ Ziegler–Natta catalysts is made by comparison of optical microscope (OM) and scanning electron microscope (SEM) pictures of the catalyst and the polymer, obtained either in standard conditions or in absence of hydrogen, with corresponding values of "calculated" replication factor (Rc) and "found" replication factor (Rf). It has been shown that under given conditions replication is evident both in structure and substructure details; it is not influenced noticeably by polymerization pressure, but may depend on the time of polymerization in a way dependent on the architecture of the catalyst.

Recent studies have shown that the morphology of polyolefin particles is determined by the size, shape and porosity of the particles of the applied Ziegler–Natta catalyst.[1–5] For the evaluation of replication effects two experimental criteria have been proposed: the found replication factor which represents the ratio of average particles sizes (APS), $Rf = APS_{pol}/APS_{cat}$ and the calculated replication factor which is a function of isotactic polymer yield (Y) and catalyst and polymer densities (δ), $Rc = (Y\delta_{cat}/\delta_{pol})^{1/3}$. Both criteria are based on macroscopic properties closely related to the structure of particles. Detailed study of replication mechanisms including their dependence on polymerization conditions is of interest for remote control of polymerization processes.

Such an approach represents the comparison of microscopic properties of the polymer and the catalyst connected with the analysis of parameters included in Rc and Rf definitions.

EXPERIMENTAL

Propylene polymerization was performed on a laboratory scale at 70°C, 0.6 and 0.9 MPa, in standard conditions and in the absence of hydrogen. A slurry reactor (3 dm^3) was used, with industrial heptane (1.5 dm^3) containing 0.33 g of $TiCl_3$ catalyst and 1.65 g of $Al(C_5H_5)_2Cl$. Commercial catalysts were A and B of irregular shape and C microspherical. Ti–Al ratios were 0.187, 0.173 and 0.0178, respectively. Average particle sizes were determined by sieving and by optical microscopy. OM and SEM were performed by OM Carl Zeiss Lab 2 and SEM JEOL JSM-35.

RESULTS AND DISCUSSION

Data given in Table 1 confirm that under standard testing conditions all three catalysts are able to control the replica phenomena; shape regularity and size distribution of polymer particles correspond to the catalyst used. This similarity of macroscopic properties means that their structures and substructures should coincide.

As has been shown,[2] the structure of $TiCl_3$

Ziegler–Natta catalyst consists of primary particles, 2–12 nm, which are responsible for catalytic activity and are combined in globules, 15–200 nm, which determine the porosity of the catalyst and are built into coarser particles.

Figure 1 shows the OM and SEM pictures of catalyst samples and of polymers (PP) obtained when hydrogen effects were excluded. Conspicuous analogy in structures and substructures illustrates the mechanism of replication. The data given in Table 2 show that the changes of polymerization pressure do not seem to influence replication to a high extent. The time of polymerization might be of importance when an irregularly shaped catalyst is used, particularly in the first period of polymerization. This method of catalyst particle disintegration unavoidably modifies replication. It can be seen (Table 2) that when a microspherical catalyst is used, Rf and Rc values are very similar during the whole observed period of polymerization. However, with irregularly shaped catalysts, Rf and Rc values differ until a stationary polymerization rate is reached. In such a case, APS_{pol} values experimentally determined at a given yield of isotactic polypropylene will be about 15% higher than those suggested by Rf values.

THE PROTONATION OF METAL HYDRIDES

DAVID DAWSON, RICHARD A. HENDERSON,* ADRIAN HILLS and DAVID L. HUGHES

AFRC Institute of Plant Science Research, Nitrogen Fixation Laboratory, University of Sussex, Brighton BN1 9RQ, U.K.

Abstract—The rôle of acids in the rapid binding (and sometimes transformation) of small molecules at a metal–hydride site is discussed for the systems, $[MoH_4(Ph_2PCH_2CH_2PPh_2)_2]$ and $[WH_6(PMe_2Ph)_3]$.

Although much is known about the binding of small molecules at a metal–hydride site by displacement of dihydrogen, relatively little is known about how such reactions are augmented by the presence of an acid. That such reactions may involve dihydrogen complexes[1–3] as intermediates is a distinct possibility and mechanistic studies on such reactions may elucidate the chemistry of this species, both in simple metal complexes and in biological processes such as nitrogen fixation and hydrogenase activity.[4,5]

We have aleady shown[6] that in the presence of $HBF_4 \cdot OEt_2$, a variety of small molecules can be bound (and sometimes transformed) by $[MoH_4(dppe)_2]$ (dppe = $Ph_2PCH_2CH_2PPh_2$), as illustrated by the selected examples in Fig. 1.

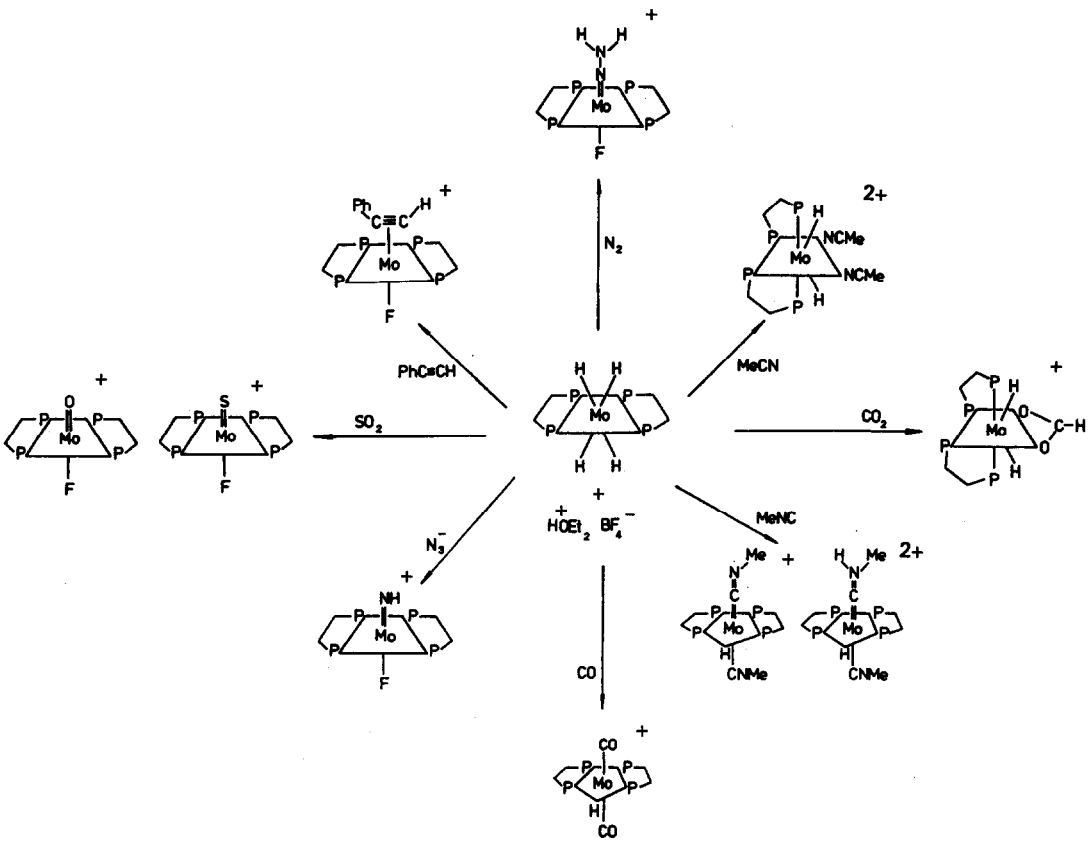

Fig. 1.

* Author to whom correspondence should be addressed.

Fig. 2.

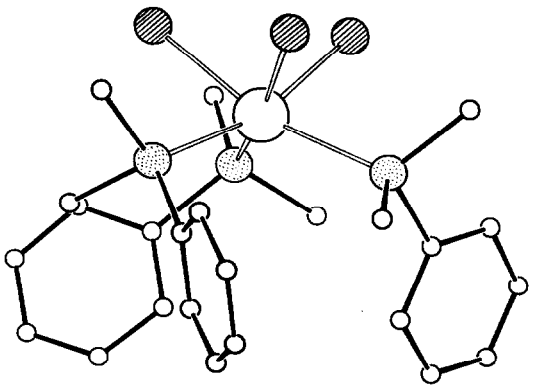

Fig. 3.

Probably the most important feature of this diverse range of reactions is their rapidity: all the reactions are complete within a few seconds under ambient conditions. The mechanism of all these reactions[5] involves the initial rapid diprotonation of the parent tetrahydride, to generate the spectrophotometrically detected $[MoH_4(\eta^2\text{-}H_2)(dppe)_2]^{2+}$. Subsequent rate-limiting loss of dihydrogen generates a coordinatively-unsaturated species capable of binding the substrate, as shown in Fig. 2.

In order to establish whether or not the reactivity pattern shown in Fig. 2 can be generalized, the reactions of other polyhydrido complexes with acids are being studied. In particular, we are investigating the protonation of $[WH_6(PMe_2Ph)_3]$; a system in which direct protonation at the tungsten(VI) centre is precluded since the metal is in its highest formal oxidation state. This system is not so versatile in its reactions with small molecules such as $[MoH_4(dppe)_2]$ in part, at least, because of competitive phosphine loss. However, we have isolated the complexes $[WH_3X_3(PMe_2Ph)_3]$ (X = Cl or Br), $[WH_2(CO)_2(PMe_2Ph)_3](BF_4)_2$ and $[WH_2(NCMe)_3(PMe_2Ph)_3](BF_4)_2$.[7] The structure of the chloro complex has been determined (except for the positions of the hydrides) by X-ray crystallography, as shown in Fig. 3.

Detailed kinetic studies are currently being pursued to establish the mechanism of the rapid protonation of $[WH_6(PMe_2Ph)_3]$.

PREPARATION AND PROPERTIES OF THE NITRILE COMPLEXES *TRANS*-[ReCl(NCR)(dppe)$_2$] (R = ALKYL OR ARYL)

ARMANDO J. L. POMBEIRO* and M. FÁTIMA C. G. SILVA

Centro de Química Estrutural, Complexo I, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal

and

DAVID L. HUGHES and RAYMOND L. RICHARDS

AFRC Nitrogen Fixation Laboratory, University of Sussex, Falmer, Brighton BN1 9RQ, U.K.

Abstract—The series of nitrile complexes *trans*-[ReCl(NCR)(dppe)$_2$] (R = methyl, phenyl or *p*-substituted phenyl; dppe = $Ph_2PCH_2CH_2PPh_2$) has been prepared by reaction of *trans*-[ReCl(N_2)(dppe)$_2$] with the appropriate nitrile, in toluene or tetrahydrofuran under tungsten-filament irradiation. IR properties of these complexes are reported, as well as the molecular structure of *trans*-[ReCl(NCMe)(dppe)$_2$], which presents an unusually short Re—N bond (1.978(5) Å).

Within our interest on the study of the activation of nitrogenase substrates[1] by electron-rich transition metal centres, we have prepared series of isocyanide and alkyne-derived complexes with the rhenium(I) site {ReCl(dppe)$_2$} (dppe = $Ph_2PCH_2CH_2PPh_2$), by reaction of the appropriate substrate with the dinitrogen compound *trans*-[ReCl(N_2)(dppe)$_2$].

The isocyanide complexes *trans*-[ReCl(CNR)(dppe)$_2$] (R = alkyl or aryl)[2] and the vinylidene compounds *trans*-[ReCl(=C=CHR)(dppe)$_2$],[3] as well as the phenylallene species *trans*-[ReCl(H_2C—C=CHPh)(dppe)$_2$],[4] have been obtained by such a route, from the corresponding isocyanides, 1-alkynes (RC≡CH) or phenylpropyne (PhC≡CCH_3), respectively.

We now report our preliminary studies on the reactions of nitriles (which constitute another type of nitrogenase substrates) with *trans*-[ReCl(N_2)(dppe)$_2$].

RESULTS AND DISCUSSION

Treatment of a THF or toluene solution of *trans*-[ReCl(N_2)(dppe)$_2$] by an organonitrile, under tungsten-filament irradiation, affords the corresponding nitrile complexes *trans*-[ReCl(NCR)(dppe)$_2$] [**1**, R = Me or C_6H_4X-4 (X = H, OMe, Me, Cl or F)] [eq. (1)]:

$$\textit{trans}\text{-}[ReCl(N_2)(dppe)_2] + NCR \xrightarrow{h\nu} \textit{trans}\text{-}[ReCl(NCR)(dppe)_2] + N_2 \quad (1)$$

The molecular structure (Fig. 1) of the acetonitrile complex has been authenticated by a single-crystal X-ray diffraction analysis, which indicates an unusually short Re—N bond (1.978(5) Å) as a result of the high π-electron releasing ability of the rhenium centre.

This is consistent with the IR spectra of these complexes which exhibit ν(NC) at values which lie below those observed for the corresponding free nitrile molecules.

However, nitriles are expected to behave as weaker π-acceptors than dinitrogen or isocyanides and, in complexes **1**, the nitrile ligand (for R = alkyl) is rather labile, in contrast with the strong

* Author to whom correspondence should be addressed.

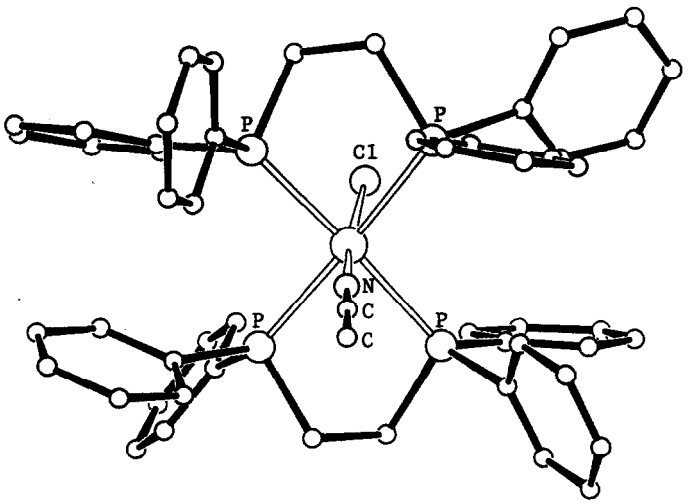

Fig. 1. Molecular structure of *trans*-[ReCl(NCMe)(dppe)$_2$].

coordination[2] of N_2 and CNR to the electron-rich {ReCl(dppe)$_2$} centre.

In agreement with this interpretation, the aryl cyanide complexes are commonly more stable than the alkyl ones. Moreover, for the aromatic series, an inverse correlation appears to be observed between ν(NC) and the Hammett's σ_p constant for the substituent (X) of the aromatic ring: an increase in the electron-withdrawing ability of the latter promotes the net electron acceptor character of the ligand and thus leads to a decrease of ν(NC). A similar trend has been reported[5] for [Mo(N_2)(NCR)(dppe)$_2$].

As a result of the strong π-electron donor character of the metal centre in this study, nitrile ligands appear to be susceptible to activation towards protonation to give ligating methyleneamido-type species, such as NC(H)C_6H_4OMe-4.[6]

OXIDATIONS BY MANGANESE(III)—II. OXIDATION OF CHROMIUM(III)

M. A. MALATI* and A. SEAR

Mid-Kent College of Higher and Further Education, Chatham ME5 9UQ, U.K.

Abstract—The oxidation of chromium(III) by manganese(III) in sulphuric acid solution was followed by extracting aliquots of the quenched reaction mixture with a dibutyl phosphate–xylene solution. The absorbance of the manganese(III) dibutyl phosphate complex gave the concentration of manganese(III) as the reaction proceeded. The reaction followed second-order kinetics. Applying the Eyring equation to the rate constants at different temperatures, gave an activation enthalpy of 129 kJ mol^{-1} and entropy of 140 J K^{-1} mol^{-1}. The suggested mechanism includes a bimolecular slow oxidation of chromium(III) to chromium(IV) by manganese(III), followed by faster oxidations of chromium(IV) and chromium(V) by manganese(III), which is reduced in each stage to manganese(II). Spectral examination proved that $Cr_2O_7^{2-}$ ions are ultimately produced.

Qualitatively, the oxidation of acidified chromium(III) solutions to dichromate by manganese(III) has been reported earlier. An investigation of the oxidation of chromium(III) by various manganese oxides indicated that manganese(III) ions from the solid oxides may be responsible for the oxidation. Later, kinetic studies of the reaction between manganese(III) and chromium(III) showed that it followed second-order kinetics. However, the spectrophotometric technique used encountered a problem of overlapping of the spectra of the reactants and products. A suggested procedure for the separation of manganese(III), based on its extraction with dibutyl phosphate solution, has been developed in the present investigation. The coloured compound extracted was found to be the dibutyl phosphate of manganese(III).

EXPERIMENTAL

Manganese(III) sulphate solutions were freshly prepared by the oxidation of manganese(II) sulphate, in sulphuric acid, by potassium permanganate solutions. The resulting solution was standardized against standard iron(II) or ascorbic acid solution, prepared using boiled-out distilled water. Measured volumes of A.R. chrome alum solution in sulphuric acid were heated in the flash of a reaction vessel at a temperature above that planned for the kinetic run, and then thoroughly mixed with the manganese(III) solution kept at room temperature. A constant ionic strength was maintained by adding sodium sulphate to the reaction mixture. The reaction mixture was placed in a thermostat and aliquots were withdrawn at intervals into bulbs cooled in salt and ice. A quenched aliquot was extracted with an equal volume of Fluka dibutyl phosphate in A.R. xylene (1 : 5 by volume). The absorbance of the organic layer, dried with anhydrous sodium sulphate, was measured at the maximum wavelength of absorption (537 nm). Beer's law was found to be applicable to the coloured solutions. This was established by extracting standardized manganese(III) solutions and measuring the absorbance of the organic layer at the above wavelength.

RESULTS AND DISCUSSION

Figure 1 depicts the results of duplicate runs in which equal concentrations of reactants were mixed at four different temperatures. The reciprocal of the manganese(III) concentration is plotted against time. The rate constants, k_r, calculated from the plots, were used to calculate the activation enthalpy $\Delta H^{\ddagger}$ and entropy $\Delta S^{\ddagger}$ using the Eyring equation:

$$\ln (k_r h/KT) = \Delta H^{\ddagger}/RT + \Delta S^{\ddagger}/R.$$

* Author to whom correspondence should be addressed.

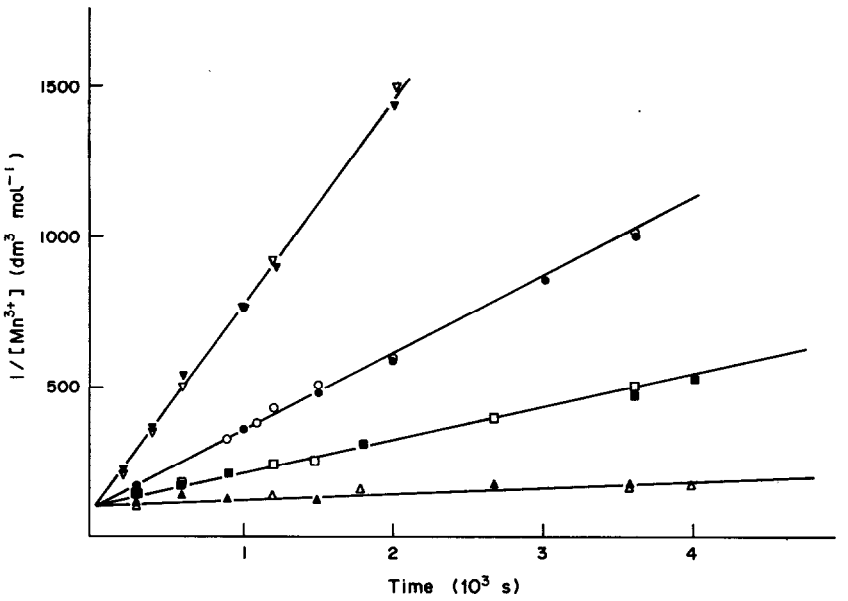

Fig. 1. Variation of the reciprocal of the concentration of manganese(III) with the reaction time at 36°C (△, ▲), 44°C (□, ■), 50°C (○, ●) and 58°C (▽, ▼).

The activation enthalpy estimated from the slope of the plot in Fig. 2 was 129 kJ mol^{-1} and the activation entropy was 140 J K^{-1} mol^{-1}. The mechanism suggested is:

$$Cr^{3+} + Mn^{3+} \xrightarrow{k_1} Cr^{IV} + Mn^{2+}$$

$$Cr^{IV} + Mn^{3+} \xrightarrow{k_2} Cr^{V} + Mn^{2+}$$

$$Cr^{V} + Mn^{3+} \xrightarrow{k_3} Cr^{IV} + Mn^{2+}.$$

If $k_1 \ll k_2$ and k_3, the bimolecular reaction becomes rate-determining. Both chromium(IV) and chromium(V) have been postulated in the reactions involving oxidations by dichromate. The latter ions were identified in the spectra of reaction mixtures near the end of the reaction.

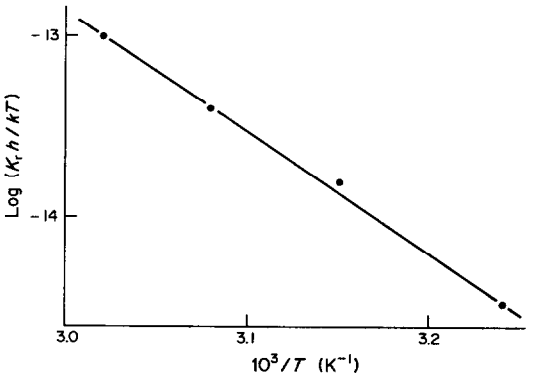

Fig. 2. Variation of $\log(k_r h/kT)$ with the reciprocal of the thermodynamic temperature.

BIMETALLIC COMPLEXES OF MOLYBDENUM AND TUNGSTEN WITH FUNCTIONALIZED DIPHOSPHINES: X-RAY CRYSTAL STRUCTURE OF [{W(CO)$_3$}(μ-mtppe)]

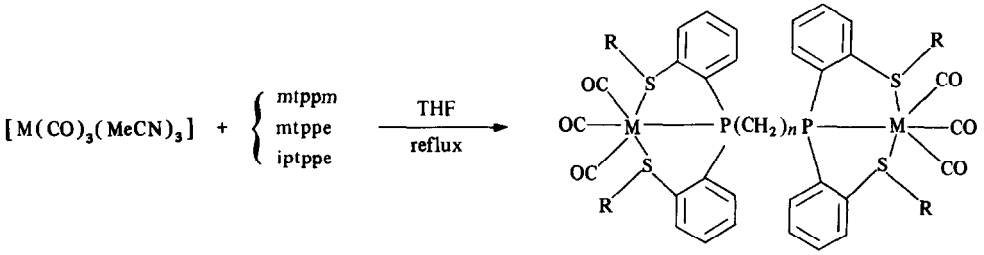
MOHAMMED F. M. AL-DULAYMMI, PETER B. HITCHCOCK and RAYMOND L. RICHARDS*

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

Abstract—The binuclear complexes [{M(CO)$_3$}$_2$(μ-diphos)] (M = Mo or W; diphos = mtppm, mtppe or iptppe) (X-ray structure for M = W, diphos = mtppe), [{M(CO)$_4$}$_2$(μ-dppmpe)] and [{MBr$_2$(CO)$_2$}$_2$(μ-mtppe)], and the mononuclear compounds [M(CO)$_4$(dbtpe)] and [MoBr$_2$(CO)$_2$(mtppe)] have been prepared.

We have recently reported the preparation of diphosphines substituted at phosphorus by potentially ligating groups and we have described some of their complexes with rhodium.[1] Here, we describe the preparation of new binuclear complexes of molybdenum and tungsten with mtppm (**Ia**), mtppe (**Ib**), iptppe (**Ic**), dppmpe (**II**) and mononuclear complexes with dbtpe (**III**). (See Fig. 1 for phosphine nomenclature.)

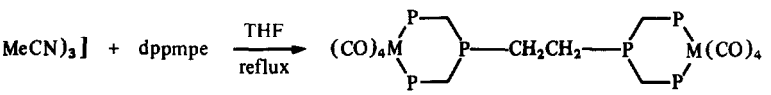
The reaction of mtppm, mtppe and iptppe with [M(CO)$_3$(MeCN)$_3$] (M = Mo or W) in a 1:2 molar ratio in refluxing THF, produced yellow, crystalline bimetallic complexes of general formula [{M(CO)$_3$}$_2$(μ-diphos)] (diphos = mtppm, mtppe or iptppe) [eq. (1)]:



All complexes show a singlet in their ^{31}P{H} NMR spectra, and characteristic (CO) bands in their IR spectra, as expected for tricarbonyl complexes.[2,3]

The X-ray structure of [{W(CO)$_3$}$_2$(μ-mtppe)] (Fig. 2) confirms the above formulation and shows it to be binuclear, with the mtppe ligand coordinated to each metal through one phosphorus and two sulphur atoms in an almost octahedral environment.

In a similar way, dppmpe reacted with [M(CO)$_3$(MeCN)$_3$] (M = Mo or W) to form pale yellow bimetallic tetracarbonyl complexes [eq. (2)]:



Their structure has been assigned on the basis of elemental analysis and spectroscopic measurements. The mechanism of formation of the tetracarbonyl species is unclear, but presumably they are formed to avoid the highly strained four-membered ring which coordination of the third phosphorus atom would produce. Reactions of the products of eq. (2) with [PdCl$_2$(COD)] (COD = cyclooctadiene) and [{RhCl(CO)$_2$}$_2$] appear to form trinuclear complexes.

The dbtpe ligand reacted with [M(CO)$_3$(MeCN)$_3$] as an ordinary diphosphine, without involvement of the functional groups, to give mononuclear, tetracarbonyl complexes [M(CO)$_4$(dbtpe)].

Two seven-coordinated complexes have been sep-

Abstract—The optimal nuclear characteristics of technetium make it an ideal radionuclide for diagnostic medical imaging. However, the development of new imaging agents requires the prior development of technetium coordination chemistry to generate appropriate new complexes and their precursors. Here we report the synthesis of some new technetium complexes containing metal–nitrogen bonds and their coordination chemistry.

TECHNETIUM NITRIDO COMPLEXES

Deutsch *et al.* have synthesized cationic complexes of the type $[TcX_2(dmpe)_2]^+$ (X = halide, dmpe = $Me_2PCH_2CH_2PMe_2$) and showed that their ^{99m}Tc analogues exhibited promise as myocardial imaging agents in rats.[1,2] However, in humans, there was significant "washout" from the heart which was attributed to facile reduction to the neutral $[TcX_2(dmpe)_2]$ species. Earlier we had synthesized $[ReNCl(dppe)_2]^+$ and showed that this required a reduction potential of -1.8 V vs SCE to be reduced irreversibly. We therefore anticipated that complexes of the type $[TcNX(dmpe)_2]^+$ should be significantly harder to reduce than the technetium(III) species $[TcCl_2(dmpe)_2]^+$.

We here report that the nitride precursor $[TcNCl_4]^-$[3] reacts with excess dmpe in methanol under reflux to give orange $[TcNCl(dmpe)_2]^+$ in good yield, isolated as the tetraphenylborate salt. The structure of the complex is shown in Fig. 1. The Tc—N bond length is considerably longer at 1.854(6) Å than in other nitrides such as $[TcNCl_4]^-$ (1.581(5) Å).[3] Such lengthening has been observed before and attributed to steric interactions between the nitride nitrogen and the four co-planar phosphorus atoms.[4]

The ^{99m}Tc analogue of $[TcNCl(dmpe)_2]^+$ was synthesized in high RCP and its biodistribution

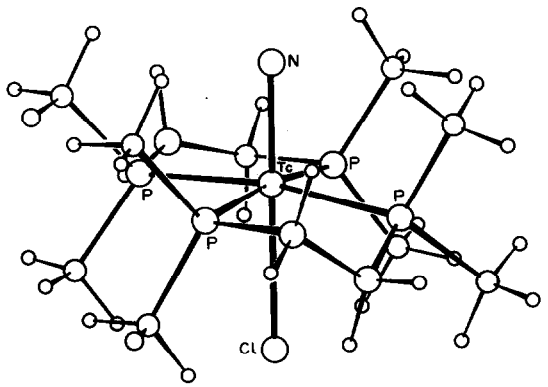

Fig. 1. Structure of $[TcCl(N)(dmpe)_2]^+$.

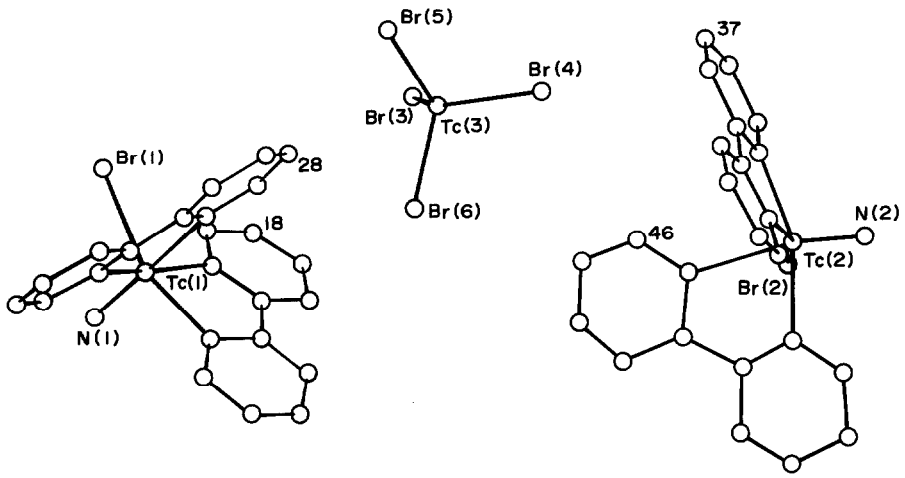

Fig. 2. Structure of $[TcBr(N)(bipy)_2]_2[TcBr_4]$ showing both cation and anion.

studied. Significant heart uptake was observed but there was rapid "washout" of ^{99m}Tc, suggesting reduction to the technetium(IV) species. Cyclic voltammetry was consistent with this, with a reversible reduction process occurring at −0.02 V vs SCE. The unexpected ease of reduction is ascribed to the rapid formation of $[TcN(dmpe)_2]^{2+}$ in solution by loss of the *trans*-chloride ligand labilized by the *trans*-effect.

By contrast, the analogous reaction of $[TcNBr_4]^-$ with 2,2′-dipyridyl in ethanol gives the complex *cis*-$[TcBr(N)(dipy)_2]_2[TcBr_4]$ (see Fig. 2), containing the novel technetium(II) tetrabromotechnetate anion. This represents the first reported example of a tetrahalidometallate complex of a second row transition metal. In contrast to $[TcCl(N)(dmpe)_2]^+$, the nitride and chloride ions are *cis* in $[TcBr(N)(bipy)_2]^+$. This reflects the steric difficulties imposed by arranging the two bipyridyl ligands in a plane and their relatively small bite angle.

Access to technetium(III) chemistry has in the past been restricted by a lack of suitable precursors. We have now synthesized the technetium analogue of $[ReCl_3(MeCN)(PPh_3)_2]$[4] by reduction of $[TcCl_4(PPh_3)_2]$ with zinc in dichloromethane–acetonitrile. The complex is an air-stable, readily soluble, orange, crystalline material which reacts rapidly with a wide range of ligands. Thus, reaction of $[TcCl_3(MeCN)(PPh_3)_2]$ with excess dipyridyl in refluxing methanol gives $[Tc(bipy)_3]^{2+}$ rather than the expected $[TcCl_2(bipy)_2]^+$. The structure of the dication is shown in Fig. 3. The overall geometry about the technetium is, as expected, distorted octahedral and general bond distances and angles are similar to those found in $[Ru(bipy)_3]^{2+}$.[5] Reaction of $[TcCl_3(MeCN)(PPh_3)_2]$ with 2 equivalents of tridentate ligand L^1 gives the purple cationic technetium(III) complex $[TcL^1_2]^+$, whereas the more reducing phosphine ligand L^2 gives, under analogous conditions, the red neutral technetium(II) complex, $[TcL^2_2]$.

ASPECTS OF THE CHEMISTRY OF A BULKY ZIRCONOCENE(III) CHLORIDE

ANTONIO ANTIÑOLO, MICHAEL F. LAPPERT,* GERARD A. LAWLESS and HELÉNE OLIVIER

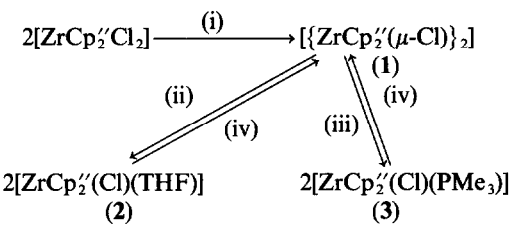
School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

We report the synthesis of the zirconium(III) complex $[\{ZrCp''_2(\mu\text{-}Cl)\}_2]$ [Cp'' = η-$C_5H_3(SiMe_3)_2$-1,3] (**1**) and of the 1:1 adduct of its monomeric equivalent with THF (**2**) or PMe_3 (**3**), as shown in Scheme 1. The adducts **2** and **3** are indefinitely stable in solution under ambient conditions, as evident from their ESR spectra.

The NMR spectra of the zirconocene(III) complex, **1**, demonstrates that the compound is essentially diamagnetic (although it showed a weak ESR signal), consistent with the structure shown in Scheme 1; the slight paramagnetism in PhMe is attributed to a small equilibrium concentration of monomer in solution. Support for this formulation also comes from the analogy with the corresponding compound $[\{ZrCp_2(\mu\text{-}Cl)\}_2]$ (Zr, Zr) which has been crystallographically characterized and which shows no ESR signal in solution.[1]

Details of the ESR solution spectra of complexes **2** and **3** are shown in Scheme 1. Both the g_{av} and the $a(^{91}Zr)$ values are consistent with a metal-centred d^1 complex.[2]

Each of the complexes **2** and **3** readily loses the neutral ligand when the volatiles are removed from the solution at 10^{-1} torr. It is clear, therefore, that the donor–acceptor bond in these complexes is quite weak. Nevertheless, the stability of complexes **2** and **3** in solution is directly attributed to the steric effect of the trimethylsilyl substituents in cyclopentadienyl rings.



Scheme 1. *Reaction conditions* (25°C): (i) Na–Hg (1 mol), PhMe; (ii) THF; (iii) PMe_3 (1 mol), PhMe; (iv) 25°C at 10^{-1} torr. *Characterization of compounds*: **1**, very pale blue–green crystals, m.p. 137°C; **2**, red solution, g_{av} = 1.9775, $a(^{91}Zr)$ = 23 G; **3**, red solution in PhMe, g_{av} = 1.9780; $a(^{91}Zr)$ = 6 G, $a(^{31}P)$ = 14.5 G.

We are investigating various reactions of complex **1**, including nucleophilic displacement of the $\bar{Cl}$ ligand. Attempts are also being made to obtain X-ray data on crystalline materials.

Acknowledgement—We thank the E.E.C. (Stimulation Contract: ST2000335) for support.

SYNTHESIS OF SOME LOW OXIDATION STATE ORGANOTITANIUM COMPOUNDS

MICHAEL F. LAPPERT* and WING-POR LEUNG

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

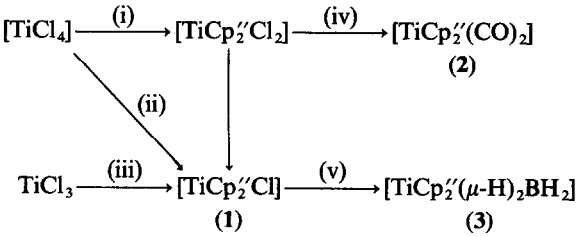
and

RUTH A. BARTLETT and PHILIP P. POWER

Department of Chemistry, University of California, Davis, CA 95616, U.S.A.

We have used the ligand $^{-}Cp''$ ($= \eta\text{-}^{-}C_5H_3(SiMe_3)_2\text{-}1,3$) to examine a number of organotitanium compounds in oxidation state +3. The starting materials were either $[TiCl_4]$ or $TiCl_3$; details of the reactions are shown in Scheme 1.

Each of the crystalline compounds $[TiCp''_2Cl]$ (**1**), $[TiCp''_2(CO)_2]$ (**2**) and $[TiCp''_2(\mu\text{-}H)_2BH_2]$ (**3**) has been characterized by microanalytical and spectroscopic data. The paramagnetic compound **1**, like $[Ti(\eta\text{-}C_5Me_5)_2Cl]$,[1] is unusual in being a monomer even in the crystalline state; by contrast, the corresponding unsubstituted cyclopentadienyl is a metal–metal-bonded antiferromagnetic dimer $[\{TiCp_2(\mu\text{-}Cl)\}_2]$.[2] Some important bond lengths and angles for complex **1** are as follows: ($Cp'' = \eta\text{-}C_5H_3(SiMe_3)_2\text{-}1,3$), Ti—Cl 2.346(2), ⟨Ti—C⟩ 2.368 Å (ranging from 2.349(6) to 2.403(5) Å); Cl—Ti—C [Cp''(1)]: 107.6(2), 82.2(2), 92.1(3), 126.9(2), 139.4(2)°; Cl—Ti—C [Cp''(2)]: 110.0(2), 82.5(2), 89.0(2), 122.7(2), 139.9(2)°. The corresponding tetrahydridoborate **3**, like $[TiCp_2(\mu\text{-}H)_2BH_2]$,[3] is also a monomer and on the basis of IR data is formulated as being η^2-bonded.



Scheme 1. *Reaction conditions*: (i) LiCp'', C_6H_6, 30°C; (ii) LiCp'', THF, −78°C; (iii) $MgCp''_2$, THF, 30°C; (iv) Na/Hg, CO/1 atm, THF, −78°C; (v) $Na[BH_4]$, THF, 30°C.

SYNTHETIC AND STRUCTURAL STUDIES ON SOME BIS(CYCLOPENTADIENYL)MOLYBDENUM AND -TUNGSTEN COMPLEXES CONTAINING DOUBLY BONDED TIN OR PHOSPHORUS

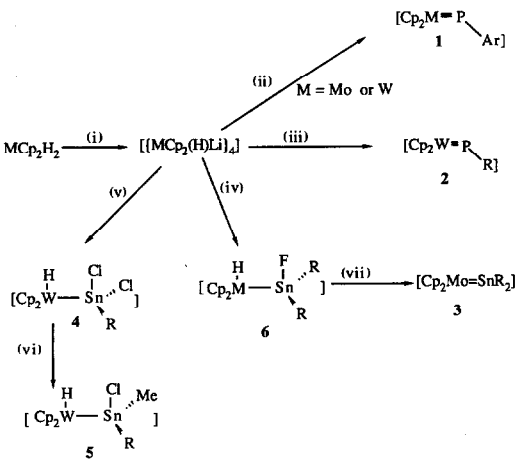
RAKESH BOHRA, PETER B. HITCHCOCK, MICHAEL F. LAPPERT* and WING-POR LEUNG

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

We have recently shown that the phosphorus equivalents of arylimides are accessible for certain derivatives of molybdenum and tungsten, as shown in **1** and **2** of Scheme 1.[1]

The X-ray structure of one of the compounds, **1** (M = Mo, Ar = $C_6H_2Bu^t_3$-2,4,6), has been published.[1] We now have the corresponding data on the isomorphous tungsten analogue; some important bond lengths and angles are: W—P 2.349(5), P—C 1.84(2), W—Cen(1) 1.98, W—Cen(2) 1.93 Å; W—P—C(Ar) 114.8(5), P—W—Cen(1) 113.4, P—W—Cen(2) 102.7, Cen(1)—W—Cen(2) 143.7°.

Scheme 1 also reveals some related reactions which were designed to yield analogues in which molybdenum or tungsten bonded to tin rather than phosphorus. We believe that such a tin compound has been isolated, [Mo(Cp_2(SnR$_2$)] (**3**) (R = CH(SiMe$_3$)$_2$). However, along the reaction pathway some further compounds, **4**–**6**, have been identified, for one of which, [WCp$_2$(H){Sn(R)Cl$_2$}] (**4**), there is an X-ray structure. Some important bond lengths and angles in **4** are: W—Sn 2.706(1), W—Cen(1) 1.948, W—Cen(2) 1.938, Sn—Cl 2.442(3) and 2.405(3), Sn—C 2.180(8) Å; W—Sn—C 123.7(2),



Scheme 1. *Reagents*: (i) LiBu^n, PhMe; (ii) ArPCl$_2$; (iii) RPCl$_2$; (iv) R$_2$SnX$_2$, X = Cl or F; (v) RSnCl$_3$; (vi) LiMe; (vii) LiBu^t, C_6H_{14}.

W—Sn—Cl 117.6 and 109.1, Cen—W—Cen 144.7°.

CLUSTER SYNTHESIS—XXIII. THE SYNTHESIS, STRUCTURE AND BONDING OF $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$

RICHARD D. ADAMS,* JAMES E. BABIN, JAVIER ESTRADA and JIN-GUU WANG

Departments of Chemistry and Physics, University of South Carolina, Columbia, SC 29208, U.S.A.

and

MICHAEL B. HALL* and ARTHUR A. LOW

Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 15 *December* 1988; *accepted* 13 *February* 1989)

Abstract—The compound $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (**1**) was synthesized in 38% yield by the UV induced decarbonylation of $Fe(CO)_5$ in the presence of $Fe_3(CO)_9(\mu_3\text{-}S)_2$. Compound **1** was characterized by a single-crystal X-ray diffraction analysis. Space group: *Pccn*, $a = 6.603(1)$, $b = 15.429(3)$, $c = 17.292(4)$ Å, $Z = 4$. The structure was solved by direct methods and was refined (807 reflections) to the final values of the residuals $R = 0.043$ and $R_w = 0.054$. The molecule consists of a planar array of four iron atoms with a quadruply bridging sulphido ligand on each side of the plane. The shortest metal–metal bond, 2.489(3) Å, contains a bridging carbonyl ligand. Semi-bridging carbonyl ligands bridge the two adjacent metal–metal bonds, 2.532(2) Å. The longest metal–metal bond, 2.605(2) Å, has no carbonyl bridge. Compound **1** is unsaturated (by EAN rule) by the amount of two electrons. The two semi-bridged carbonyl–metal bonds in **1** are significantly shorter than those in the saturated cluster $Fe_2Co_2(CO)_{11}(\mu_4\text{-}S)_2$. A molecular orbital description which explains the differences in bonding between the two compounds is proposed.

Recently, we have demonstrated the value of $Ru(CO)_5$ and $Os(CO)_5$ as reagents for the enlargement of metal carbonyl clusters of ruthenium and osmium that contain sulphido ligands.[1–5] We have now begun investigations into the iron system. This report describes the synthesis and structural characterization of the new iron cluster, $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (**1**). The structure of compound **1** was compared with that of $Fe_2Co_2(CO)_{10}(\mu\text{-}CO)(\mu\text{-}S)_2$ (**2**), which has an analogous structure, but has two additional valence electrons.[6] A molecular orbital description that explains differences in the metal–metal bonding of the two structures is proposed.

EXPERIMENTAL

General procedures

Compound **1** is slightly air-sensitive. Thus, all reactions were performed under a dry nitrogen atmosphere. Reagent grade solvents were dried over molecular sieves and were deoxygenated by purging with nitrogen prior to use. $Fe(CO)_5$ was purchased from Alfa. $Fe_3(CO)_9(\mu_3\text{-}S)_2$ was prepared as previously reported.[7] IR spectra were recorded on a Nicolet 5-DXB FT-IR spectrometer. Elemental analysis was performed by Desert Analytics, Tucson, Arizona.

Synthesis of $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (**1**)

$Fe_3(CO)_9(\mu_3\text{-}S)_2$ (50 mg, 0.103 mmol) and $Fe(CO)_5$ (0.136 cm^3, 1.03 mmol) were dissolved in 50 cm^3

* Authors to whom correspondence should be addressed.

of cyclohexane solvent in a Pyrex flask. The solution was irradiated (UV external) in the presence of a continuous nitrogen purge for 4.5 h. The solvent was removed *in vacuo* and the residue was chromatographed by TLC on silica gel with hexane solvent. This yielded the following compounds in order of elution: yellow $Fe_2(CO)_6(S)_2$, 3 mg; red $Fe_3(CO)_9(\mu_3\text{-}S)_2$, 21.8 mg, and green **1**, 13.1 mg (38% based on the amount of $Fe_3(CO)_9(\mu_3\text{-}S)_2$ consumed). Found: C, 21.57. Calc: C, 22.18%. IR(νCO in hexane): 2063(w), 2044(s), 2022(m), 2011(m), 1856(w).

Reaction of **1** *with carbon monoxide*

15 mg of **1** were dissolved in 30 cm^3 of hexane. The solution was refluxed under a slow purge of carbon monoxide for 18 h. During this time the green solution turned to a greenish-red colour. The solvent was then removed *in vacuo*, and the residue was chromatographed by TLC. This yielded (in order of elution): yellow $Fe_2(CO)_6(\mu\text{-}S_2)$ (0.5 mg), red $Fe_3(CO)_9(\mu_3\text{-}S)_2$ (6.5 mg) and unreacted **1** (6.4 mg).

Molecular orbital calculations

Fenske–Hall molecular orbital calculations[8] were performed on a VAX 11/780 computer. The iron basis functions were taken from Richardson *et al.*[9] The carbon, oxygen and sulphur functions were taken from the double-ζ functions of Clementi[10] and reduced to a single-ζ function,[11] except for the *p*-valence functions which were retained as the double-ζ function. The atomic functions were made orthogonal by the Schmidt procedure. The Mulliken population analysis[12] was used to determine both the individual atomic charges and the atomic orbital populations.

Calculations were performed on **1** in its crystal structure geometry. Additional calculations were performed on **2** in its crystal structure geometry[6]* and the 2^+ cation of **2** (hereafter designated as **2a**), in order to compare the effect of adding two electrons to the fixed cluster framework. The calculations were performed with 3*d*-orbitals included on the capping sulphur atoms (exponents equal to that of the best atom single-ζ 3*p*-function).

Crystallographic analyses

Very dark green crystals of **1** suitable for X-ray diffraction measurements were grown by slow evaporation of solvent from solutions in a CH_2Cl_2–C_6H_{14} solvent mixture at 5°C. The data crystal was mounted in a thin-walled glass capillary. Diffraction measurements were made on a Rigaku AFC6 fully automated four-circle diffractometer, using graphite monochromatized Mo-K_α radiation. The unit cell was determined and refined from 25 randomly selected reflections obtained by using the diffractometer automatic search, centre, index and least-squares routines. Crystal data and results of the analysis are listed in Table 1. All data processing was performed on a Digital Equipment Corporation MICROVAX II computer by using the TEXSAN structure solving program library obtained from the Molecular Structure Corporation, College Station, Texas. Neutral atom scattering factors were calculated by the standard procedures.[13a] Anomalous dispersion corrections were applied to all non-hydrogen atoms.[13b] Full-matrix least-squares refinements minimized the function

$$\sum_{hkl} w(|F_{obs}| - |F_{calc}|)^2$$

where

$$w = 1/\sigma(F)^2, \quad \sigma(F) = \sigma(F_{obs}^2)/2F_{obs}$$

and

$$\sigma(F_{obs}^2) = [\sigma(I_{raw})^2 + (PF_{obs}^2)^2]^{1/2}/Lp.$$

All non-hydrogen atoms were refined anisotropically. The unit cell and systematic absences indicated that the crystals belonged to the orthorhombic crystal system and the space group, *Pccn*. The structure was solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses.

RESULTS AND DISCUSSION

When purged with nitrogen, solutions of $Fe_3(CO)_9(\mu_3\text{-}S)_2$ and $Fe(CO)_5$ exposed to UV irradiation yield the new compound $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (**1**) (38% yield based on the amount of $Fe_3(CO)_9(\mu_3\text{-}S)_2$ consumed in the reaction). When treated with carbon monoxide (1 atm) in refluxing hexane solvent (18 h), compound **1** was converted back to $Fe_3(CO)_9(\mu_3\text{-}S)_2$ (53% yield) by removal of one iron grouping, presumably as $Fe(CO)_5$. Compound **1** was characterized by a single-crystal X-ray diffraction analysis. An ORTEP diagram of the molecular structure of **1** is shown in Fig. 1. Intramolecular bond distances and angles are listed in Tables 2 and 3. The molecule contains a C_2 rotation axis that is crystallographically imposed. The bridging ligand C(11)—O(11) lies on this axis. The cluster consists of a trapezoidal arrangement of four iron

* Additional details concerning the structure of **2** were provided by Professor H. Vahrenkamp.

atoms which is bridged on each side by a quadruply bridging sulphido ligand. It is structurally very similar to $Fe_2Co_2(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (**2**),[6*] and the structures of both compounds will be compared and contrasted. The shortest metal–metal bond in **1** contains a bridging carbonyl ligand, Fe(1)—Fe(1′) = 2.489(3) Å. The corresponding bond in **2** is the cobalt–cobalt bond, which is essentially equal in length, 2.495(2) Å. Fe(2)—Fe(2′) is the longest metal–metal bond in **1**, 2.605(2) Å, and compares favourably with the corresponding Fe—Fe bond in **2**, 2.604(2) Å. The sides of the trapezoid in **1**, Fe(1)—Fe(2), are equal in length, 2.532(2) Å, but are significantly shorter, 0.045–

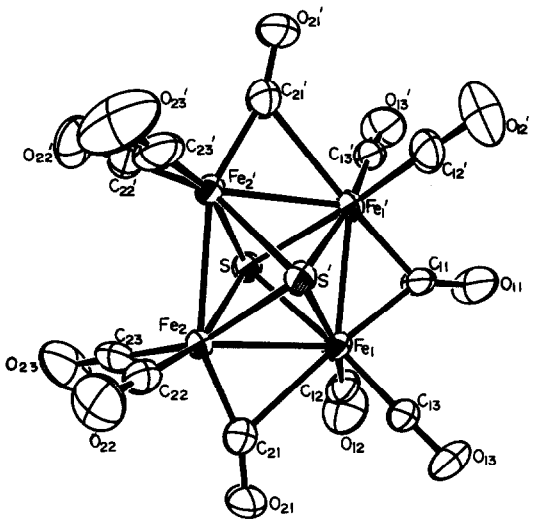

Fig. 1. An ORTEP diagram of $Fe_4(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2$ (1) showing 50% probability thermal ellipsoids.

0.048 Å, than the corresponding bonds in **2**, Fe—Co, 2.580(2) and 2.577(2) Å.[9] In both **1** and **2**, these metal–metal bonds contain semi-bridging carbonyl ligands, but the semi-bridging effect is slightly stronger in **1**, Fe(2)—C(21)—O(21) = 161.2(8)°, than in **2**, Fe—C—O = 167(1) and 169(1)°. The metal–sulphur bonds in **1** and **2** are very similar, Fe(1)—S = 2.332(2) Å, Fe(1′)—S = 2.347(2) Å, Fe(2)—S = 2.278(2) Å and Fe(2′)—S = 2.294(2) Å in **1**, and Fe—S = 2.262(3)–2.277(2) Å and Co—S = 2.303(2)–2.329(2) Å in **2**. The non-bonding S···S′ distance in **1** is 2.911(4) Å.

One of the products obtained from the reaction of $Ru(CO)_5$ with $Ru_3(CO)_9(\mu_3\text{-}S)_2$ was $Ru_4(CO)_9(\mu\text{-}CO)_2(\mu_4\text{-}S)_2$.[4] The structure of this compound was determined in the form of the bis-phosphine substituted derivative, $Ru_4(CO)_7(PMe_2Ph)_2(\mu\text{-}CO)_2(\mu_4\text{-}S)_2$ (**3**). The cluster of **3** is similar to that of **1** and **2**, but **3** contains two bridging carbonyl ligands. The Ru—Ru bonds associated with the bridging carbonyl ligands are significantly shorter than the unbridged Ru—Ru bonds.

Compound **1** contains a total of 62 valence electrons. According to the Effective Atomic Number (EAN) rule, it is electron deficient by two electrons, although it does obey the Skeletal Electron Pair (SEP) theory.[14] Compound **2** on the other hand, contains 64 valence electrons and obeys the EAN rule. It was of interest to examine the possibility that the comparative shortness of the Fe(1)—Fe(2) bonds in **1** could be related to its intrinsic unsaturation. These results are described in the following section and are compared with those of Halet *et al.*, who investigated the cluster bonding in the molecules $M_4(CO)_n(\mu_4\text{-}L)_2$ (n = 11, 12) by the extended Hückel method.[15]

In Fig. 2 is shown the coordinate systems used in the calculations. In the coordinate systems about the iron atoms, the z-axis points towards the centre of the Fe_4 trapezoid, the y-axis is tangential to the trapezoid and the x-axis is perpendicular to the Fe_4 plane. The HOMO of compound **1** is primarily of Fe x^2-y^2 character of all four iron atoms with the major portion on the unbridged Fe(2) and Fe(4) atoms (13.5% Fe(2) and Fe(4) x^2-y^2 vs 2.8% Fe(1) and Fe(3) x^2-y^2). It possesses a node through the semi-bridged Fe(1)—Fe(2) and Fe(3)—Fe(4) bonds. The LUMO, 1.88 eV above the HOMO, is very similar to the HOMO of b_u symmetry in Halet's calculations on the cluster $Fe_4(CO)_{12}(\mu\text{-}PH)_2$ (**4**), which contains two more electrons.[15] This orbital is mainly of Fe xz character on all the iron atoms and is antibonding around the Fe_4 ring. It contains slightly more xz character on the bridged Fe(1) and Fe(3) atoms than on the unbridged Fe(2) and Fe(4) atoms (12.3 vs 7.5%). In his calculations on **4**, Halet[15] noted that the HOMO would be stabilized

in the calculations by the addition of *d*-orbitals on the capping phosphorus atom and indeed this is the case for **1**. Our LUMO contains a substantial amount of sulphur *xy* character (7.5%) from each capping sulphur atom.

The calculation on compounds **2** and **2a** (the 2^+ cation of **2**) gave similar orbitals for the HOMO and LUMO of **2a** and the SHOMO and HOMO of **2**, respectively. The HOMO–LUMO gap has shrunk considerably to 0.13 eV for **2a**. Comparing the overlap population between the metal atoms for the three types of metal–metal bonds in the cluster, one can observe the effect of adding two electrons to the M_4 framework. The overlap populations are shown in Table 4. As two electrons are added to **2a** to form **2**, the overlap populations for all three types of metal–metal bonds decrease in value. This is not too surprising since the LUMO of **2a** is antibonding along each metal–metal bond axis. However, the total overlap goes from bonding to antibonding for the semi-bridged Fe—Co bond and the bridged Co—Co bond. The largest decrease in overlap population (0.038) occurs for the bridged Co—Co bond. However, *the metal atoms could be restrained from moving further apart by the bridging carbonyl ligand.* The semi-bridged Fe—Co bonds show a decrease in overlap of 0.026 upon the addition of two electrons. Since semi-bridging ligands are presumably not as supportive as a full bridge, the Fe—Co bonds might be lengthened as a result. The

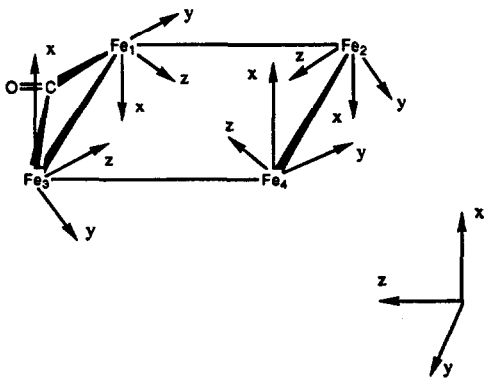

Fig. 2. Molecular and local coordinate systems used in Fenske–Hall calculations on compound **1**.

Table 4. Mulliken overlap populations along the metal–metal bonds of $[Fe_2M_2(CO)_{10}(\mu\text{-}CO)(\mu_4\text{-}S)_2]$ (M = Fe or Co)

Compound	Fe—Fe unbridged	Fe—M semi-bridged	M—M bridged
1 (M = Fe)	0.036	0.016	0.018
2 (M = Co)	0.026	0.017	0.013
2a (M = Co)	0.016	−0.009	−0.025

unbridged Fe—Fe bond shows the smallest decrease in overlap population (0.010) and the overlap is positive for **1**, **2** and **2a**. Thus, bond lengthening effects might remain small on the Fe—Fe bond. We expect that the structural differences between **1** and **2** would be similar to those between **2a** and **2**. This is fully consistent with our observations.

(*Received* 1 *September* 1988; *accepted after revision* 20 *February* 1989)

Abstract—The direct condensation between metal oxide powders (Zn^{II}, In^{III}, Sb^{III} and Bi^{III}) and dithiocarbamic acids, prepared by the reaction of ethanolamine or 1,3-propanolamine with CS_2, gave corresponding metal dithiocarbamate complexes in good yields. Although antimony and bismuth dithiocarbamates decomposed up to 80°C to give elimination products such as oxazolidine-2-thione, thiazolidine-2-thione or bis(3-hydroxypropyl)thiourea, the zinc and indium derivatives were recovered after heating in benzene at 80°C for 6 h. In the reactions of organometallic oxides such as Bu_2SnO, $BuSnO_2H$ and Ph_3SbO with the dithiocarbamic acids, the elimination products were directly obtained even at 20°C.

Metal dithiocarbamate complexes are an important class of compounds, especially in analytical and coordination chemistry, and the dithiocarbamates are generally prepared by metathesis or insertion reactions.[1,2] Recently, some newer methods of preparation using metal powders,[3] rods or foils[4] instead of metal salts have been developed. However, these routes, together with the conventional methods, are still limited to the preparation of simple dialkyldithiocarbamates.

Recently, we have proposed a facile synthesis of antimony dithiocarbamate complexes.[5–7] The reaction consisted of direct condensation between the metal oxide and dithiocarbamic acids, without the use of alkaline and/or acidic conditions. Thus, dithiocarbamates which have labile functional groups can now be prepared. In this paper, we describe attempts to extend the direct condensation method to metal derivatives other than antimony, especially for the hydroxyl-substituted dithiocarbamate complexes of main group elements.

EXPERIMENTAL

General

Melting points are uncorrected. IR and NMR spectra were recorded on a Hitachi 260-30 spectrophotometer and a Hitachi R90H FT spectrometer, respectively. Metal oxides (ZnO, In_2O_3, SnO, SnO_2, $(Bu_3Sn)_2O$, Bu_2SnO, $BuSnO_2H$, Sb_2O_3, Bi_2O_3 and TeO_2) were from commercial sources and used without further purification. Amorphous triphenylstibine oxide was prepared by means of the H_2O_2 oxidation method[8] (m.p. 285°C, ref. 9 285–290°C).

Reaction of metal oxides with (ω-hydroxyalkyl) dithiocarbamic acids

Into a suspension of metal oxides (5 mmol) in methanol (20 cm^3), prescribed amounts of aminoalcohols and CS_2 were added dropwise in this order at 0°C. The mixture was then stirred for 5 h at room temperature, filtered off and the filtrate was evaporated *in vacuo* to dryness. The residue was dissolved in MeOH–acetonitrile and the metal dithiocarbamates were crystallized by cooling. Certain metal oxides as well as organometallic oxides directly gave elimination products such as 1,3-thiazolidine-2-thiones (**I**), 1,3-oxazolidine-2-thiones (**II**), or 1,3-bis(3-hydroxypropyl)thiourea (**III**) (Scheme 1).

1,3-*Thiazolidine*-2-*thione* (**Ia**)

Recrystallized from chloroform. Melting point 104.5–106°C (ref. 10 105.5–107°C). ^{13}C NMR

($CDCl_3$): δ 33.6(t, SCH_2), 51.3 (t, NCH_2), 201.5 (s, C=S).

1,3-*Oxazolidine-2-thione* (**IIa**)

Recrystallized from chloroform. Melting point 97.5–98.9°C (ref. 11 97–99°C). ^{13}C NMR (DMSO-d_6): δ 43.7 (t, NCH_2), 69.7 (t, OCH_2), 188.4 (s, C=S).

3-*Methyl*-1,3-*thiazolidine*-2-*thione* (**IIb**)

Recrystallized from EtOH–hexane.[5] Melting point 66–68°C (ref. 12 69.5–70.5°C).

3-*Methyl*-1,3-*oxazolidine*-2-*thione* (**IIb**)

Recrystallized from benzene–hexane.[5] Melting point 29–30°C (ref. 13 27–28.5°C).

1,3-*Bis*(3-*hydroxypropyl*)*thiourea* (**III**)

Recrystallized from MeOH–ethyl acetate. Melting point 94–94.5°C (ref. 14 90.4–91°C). ^{13}C NMR (CD_3OD): δ 33.0 (qn, $CH_2CH_2CH_2$), 42.2 (t, CH_2N), 60.3 (t, CH_2OH), 182.6 (S, C=S).

Thermal decompositions

Dithiocarbamates (10 mmol) and methanol (20 cm^3) were placed in a 20 cm^3 glass tube which was set into a 30 cm^3 stainless steel autoclave (SUS 304, Taiatsu Garasu Kogyo Co., Tokyo, TVS-1 type). The reactor was then heated at 80°C for 6 h. After cooling, the mixtures were filtered off. The filtrates were evaporated and chromatographed on silica gel (Wako C-200, eluted by chloroform). Metal sulphide residues were washed several times with MeOH and benzene and dried *in vacuo*.

RESULTS AND DISCUSSION

First of all, we investigated the direct condensation using dithiocarbamic acids prepared from N-methylethanolamine and CS_2, and the results obtained are summarized in Table 1. Thus, it was found that N-hydroxyethyl-N-methyldithiocarbamate could be obtained from the oxides of zinc, indium, antimony and bismuth, and two organotin oxides, similarly to dialkyldithiocarbamates.[6] However, tin(II and IV) and tellurium oxides did not react with the dithiocarbamic acids and they were quantitatively recovered. Melting points and analytical and selected spectral data of the isolated dithiocarbamates are shown in Table 2. It should be pointed out that melting points of these hydroxy-substituted dithiocarbamate complexes were lower than those of dialkyl derivatives. For example, melting points of diethyldithiocarbamates of zinc(II), antimony(III) and bismuth(III) are reported as follows: 181.5–182.0,[15] 133–135[6] and 193–195°C,[16] respectively.

The introduction of a β-hydroxyl group could form weak hydrogen bonding with the CS_2 moiety and greatly affect the ν(C—N) and $\delta(N^{13}CS_2)$ as reported previously.[7] Namely, $\delta(N^{13}CS_2)$ of these hydroxyl-substituted dithiocarbamates lie at lower fields than those of diethyl derivatives by 1–5 ppm. In addition, their ν(C—N) bands split into a doublet or showed a slightly higher wave number shift.

[b] Values of ν(C—N) and $\delta(N^{13}CS_2)$ for ammonium dithiocarbamates were as follows: EA (1490, 213.3), MEA (1460, 212.0), PA (1480, 213.0); (cm^{-1}, ppm).

[c] In Me_2SO-d_6 unless otherwise noted, concentration, *ca* 10 wt%.

[d] Not detected.

[e] In $CDCl_3$.

These phenomena could be explained by an increase of unequivalency in the two C—S bonds, in other words, an increase in the anisobidenticity.[17]

Generally, it is known that monoalkyldithiocarbamate complexes of heavy metals are thermally labile and are frequently converted into the corresponding alkyl isothiocyanates and metal sulphides *in situ*.[18,19] In our preliminary investigations, the reactions of metal oxides (Zn, In, Sn, Sb, Bi, and Te) with dithiocarbamic acids prepared from monoalkylamines such as ethyl- and butylamine, gave isothiocyanate as the sole product even at −15 to −10°C and no dithiocarbamate was obtained. However, the introduction of a hydroxyl group at the end of the alkyl chains stabilizes such labile mono-substituted dithiocarbamate complexes and they could be isolated from several metal oxides such as zinc, indium, antimony and bismuth in moderate to good yields. Their yields and physical properties are also shown in Tables 1 and 2. In our consideration, the success of isolation of the monosubstituted dithiocarbamate complexes was due to hydrogen bonding between the NCS_2 fragment and the hydroxyl group at the β- or γ-positions.

$$Mt^nO_{n/2} + nHS_2CNHR \longrightarrow Mt(S_2CNHR)_n + n/2H_2O$$

$$R = CH_2CH_2OH,\ CH_2CH_2CH_2OH.$$

The mono-substituted dithiocarbamates obtained were characterized by their ν(C—N) and $\delta(N^{13}CS_2)$ values, which were slightly higher than 1500 cm^{-1} and 200 ppm, respectively. Based on the empirical correlation between δ and ν applied to the NCS_2 fragment reported by van der Linden *et al.*,[17] the high values of δ could be explained by an increase of π-bond order in the whole NCS_2 fragment. Namely, an interaction between the end hydroxyl and one of two sulphur atoms in the CS_2 moiety promoted the delocalization of the unshared electron pair in the nitrogen atoms without a decrease in the anisobidenticity of the CS_2 moiety; namely a slight decrease of their chelation abilities. Then ν(C—N) and $\delta(N^{13}CS_2)$ values appeared at higher positions. Thus, hydrogen bonding by a hydroxyl group can be said to stabilize the NCS_2 fragment. If the intramolecular hydrogen bonding was absent, intermolecular hydrogen bonding using N—H might accelerate the elimination of isothiocyanates.[1]

The effect of chelation was also justified by the observation of ^{119}Sn NMR spectra of two organotin dithiocarbamates as shown in Table 3. In general, it is well known that δ^{119}Sn can be used to estimate the coordination number of the tin atoms. Namely, the δ^{119}Sn value lies at higher fields with an increase of coordination number. For example, δ^{119}Sn lies between −125 and −515 ppm for six-coordinated complexes[20] and between −340 and −790 ppm for seven-coordinated ones.[21] Thus, it could be found that $Bu_2Sn(S_2CN(CH_3)CH_2CH_2OH)_2$ (δ^{119}Sn = −333.6) and $BuSn(S_2CN(CH_3)CH_2CH_2OH)_3$ (δ^{119}Sn = −767.7) existed as six- and seven-coordinated complexes, respectively, like their dialkyl dithiocarbamate analogues.[20-22] However, the values of their δ^{119}Sn were slightly smaller than those of dialkyldithiocarbamates, in the range of 6 and 19 ppm, respectively. These shifts were considered to result from a decrease in the coordination number around the tin atoms to a small extent by the interaction from the end hydroxyl moieties.

Dithiocarbamates as a precursor for heterocycles

The heterocycles containing thione groups such as oxazolidinethiones and oxazinethiones are useful as pharmaceutics and their synthetic precursors.[23-25] Usually, they are prepared from aminoalcohols and CS_2, however, it is known that strong basic and/or reflux conditions are necessary.[26-28] Some modifications were made by using

organotin aminoalkoxides[12,13] or thiophosgene[29] in place of aminoalcohols and CS_2, respectively.

Organometallic oxides such as Bu_2SnO, $BuSnO_2H$ and Ph_3SbO and tellurium oxide, selectively gave **IIa** in the reactions of ethanolamine and CS_2 under mild conditions, in spite of the formation of corresponding thiazolidine ring. Thus, it can be said that these metallic oxides are useful accelerators for the ring closure into **IIa**. The cyclization was considered to occur through the formation of the dithiocarbamates and successive elimination of **IIa** *in situ*.

In contrast, the isolated dithiocarbamate complexes seemed to be stable. Although thermal decomposition of them in methanol solution at 80°C was carried out, the breakdown of the dithiocarbamate linkage did not occur in the zinc and indium dithiocarbamates. The antimony and bismuth derivatives decomposed but gave complex mixtures of products. The pyrolysates isolated are summarized in Table 4.

In general, dithiocarbamates of primary amines are known to be easily converted into isothiocyanates and are sometimes unable to be isolated.[18,19] However, in these cyclizations, no isothiocyanate was detected by NMR, IR and GLC analyses of the reaction mixture. Thus, we considered that the cyclization proceeded via nucleophilic attack of the end hydroxyl group at the centre carbon of CS_2 moieties, by a concerted mechanism with elimination. Thus, it can be said that these dithiocarbamates should resist the elimination of hydroxyethyl isothiocyanate. In contrast, the reaction of propanolamine gave the symmetrical thiourea. Although it is reported that the formation of hydroxypropyl isothiocyanate must be followed by the cyclization into tetrahydro-1,3-oxazine-2-thione,[14] the formation of thiourea in our reactions preceded by the elimination of the corresponding 3-hydroxypropyl isothiocyanate, because similar formation of a symmetrical thiourea via aryl isothiocyanates was reported in the pyrolysis of the organometallic aryldithiocarbamates.[30]

In conclusion, attributable to the stabilization of the labile $HNCS_2$ fragment by the hydrogen bonding from β- or γ-hydroxyl, dithiocarbamate complexes possessing the NH moiety could be isolated. The chelation also significantly affected the course of succeeding eliminations from the dithiocarbamate complexes. Thus, chelation of the hydroxyl at the β-position was preferable to cyclization–elimination, while chelation of the γ-hydroxyl disturbed the cyclization and promoted the formation of the isothiocyanate.

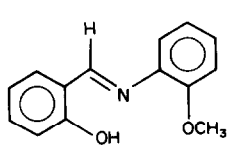
(*Received* 14 *December* 1988; *accepted* 20 *February* 1989)

Abstract—Triphenyltin isothiocyanate and 1-(salicylideneimino)-2-methoxybenzene (L) form a pseudo-complex of formula $L_2Ph_3SnNCS \cdot HNCS$. The crystal and molecular structures of this compound are reported. The crystals are monoclinic, space group $I2/a$, $a = 10.9050(10)$, $b = 24.6527(16)$, $c = 16.2251(10)$ Å, $\beta = 95.208(7)°$, $V = 4343.91$ Å^3, $Z = 4$, $D_{calc} = 1.409$ Mg m^{-3}, $\mu = 0.70$ mm^{-1}, $F(000) = 1172$, final $R = 0.041$ for 2858 unique observed reflections. The X-ray crystal structure shows the compound to consist of protonated ligand pairs $[L_2H]^+$ co-crystallizing with a five-coordinate organotin moiety of formula $[Ph_3Sn(NCS)_2]^-$. The ligand dimers are held together by hydrogen bonds. The organotin anion is trigonal bipyramidal, with the phenyl groups arranged equatorially and the thiocyanato groups occupying the axial positions.

In our studies of the triorganotin complexes of some potentially bidentate Schiff bases, we have recently published[1,2] the structures of complexes having stoichiometric ratios of ligand–triorganotin of 1 : 1 and 3 : 2.

We now wish to report the crystal and molecular structure of the triphenyltin isothiocyanate complex of 1-(salicylideneimino)-2-methoxybenzene (L) (see Structure 1) in which the ligand–triphenyltin ratio is 2 : 1.



Structure 1. 1-(Salicylideneimino)-2-methoxybenzene (L).

EXPERIMENTAL

The reagents triphenyltin chloride, salicylaldehyde and 2-methoxyaniline were obtained commercially and used without further purification. Triphenyltin isothiocyanate (m.p. 168–170°C) was prepared by the literature method[3] and recrystallized from benzene before use. The Schiff base was prepared by the condensation of salicylaldehyde and 2-methoxyaniline in refluxing benzene, the water formed being removed azeotropically. The ligand was purified by recrystallization from 95% ethanol. The complex was prepared by refluxing the calculated amount (for 2 : 1 complex formation) of ligand and triphenyltin isothiocyanate in 95% ethanol for 30 min. The complex crystallized when the solution was cooled in a freezer overnight. It was filtered off and recrystallized from ethanol (m.p. 170–172°C).

X-ray studies

A summary of the crystal data for $[L_2H]^+[Ph_3Sn(NCS)_2]^-$ is given in Table 1. Intensity data were collected at 295 K using graphite monochromatized Mo-K_α radiation on an automated Picker 4-circle diffractometer using the θ–2θ scanning mode with profile analysis[4] at a scan speed of 4° min^{-1}. Three standards were measured after every 100 reflections and no significant decay was detected. The intensity data showed systematic absences consistent with the space groups *Ia* and *I2/a*. The structure was solved and refined successfully in the centrosymmetric space group *I2/a*. The unit cell parameters listed in Table 1 were obtained by a least-squares refinement of the setting angles for 44 reflections ($25° \leqslant 2\theta \leqslant 35°$). The intensity data were corrected for Lorentz and polarization factors, but not for absorption.

The structure was solved with MULTAN[5] plus a difference Fourier map and refined by full-matrix least-squares with the weighting scheme: $w^{-1} = o(F_o)^2 + (0.0002(F_o)^2$.

All heavier atoms were refined anisotropically and hydrogen atoms isotropically. All calculations were performed with the NRCVAX crystal structure programs.[6] Scattering factors were taken from the *International Tables for X-ray crystallography*.[7] The bond lengths and angles are given in Table 2.

RESULTS AND DISCUSSION

It appears to be extremely difficult to coax the triorganotin halides and pseudo-halides to take up six-coordinate configurations on complex formation, regardless of the nature of the ligand involved. The 1 : 1 complexes are trigonal bipyramidal, even with potentially bi- and tridentate ligands, as a result of the adoption of some fascinating stereochemical alternatives.[1,8–12] The recently-reported isolation of a 3 : 2 triorganotin complex with a

potentially bidentate ligand held promise of an increase in the coordination number of the tin, but the structure[2] showed that this complex too, was five-coordinate, with the ligand behaving as unidentate and the excess ligand co-crystallizing with the complex in the ratio of one free ligand molecule to every two of the organotin complex units. The isolation of the title compound, which has a 2:1 (ligand–triphenyltin) ratio, led us to hope that this time the coordination around the tin might be different. In fact, in a previous report[13] of some 2:1 (ligand–triphenyltin pseudo-halide) complexes, it has indeed been suggested that the tin atom displays an octahedral geometry. However, in the present instance, the results of the X-ray study show that the tin atom once again adopts a five-coordinate

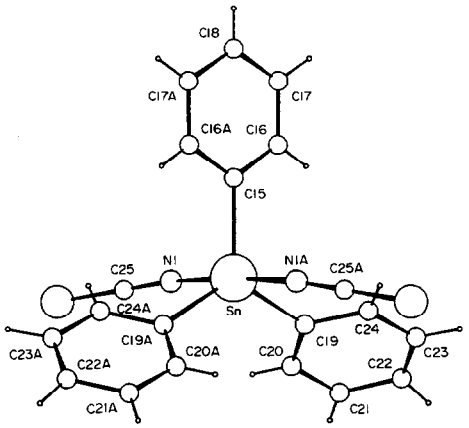

Fig. 1. The five-coordinate organotin anion.

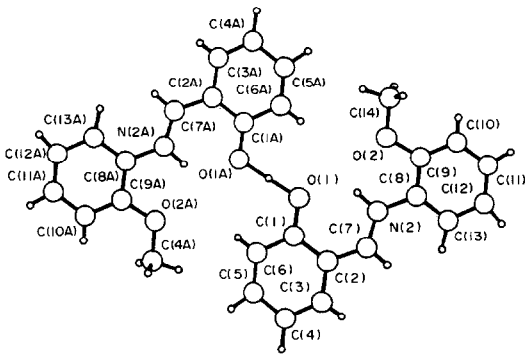

Fig. 2. Cationic ligand dimer.

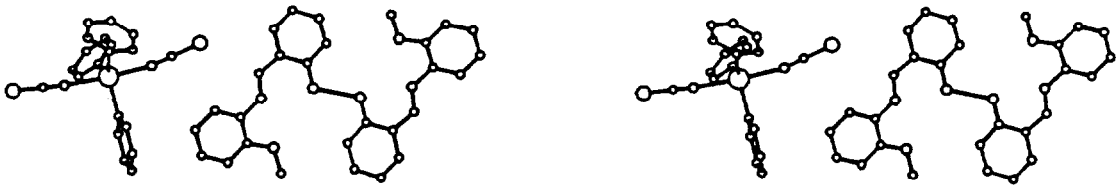

Fig. 3. Stereo pair showing the alignment of the organotin anion and the cationic ligand dimer.

configuration, but with an unusual ionic structure for the complex, consisting of cationic protonated ligand pairs $[L_2H]^+$ co-crystallizing with five-coordinate organotin anions with formula $[Ph_3Sn(NCS)_2]^-$. The ligand dimers are held together by hydrogen bonds between the phenolic oxygen atoms. The organotin anion is trigonal bipyramidal, with the phenyl groups arranged equatorially and the thiocyanato groups occupying the axial positions. The atomic numbering scheme and the structures of the organotin anion and the cationic ligand pair are shown in Figs 1 and 2, respectively. Figure 3 shows the relative alignment of the organotin and ligand-pair species.

In the five-coordinate organotin anion, there is a two-fold symmetry axis passing through Sn, C(15), C(18) and H(18). In this anion, the C—Sn—C angles between the three phenyl rings are 117.9, 117.9 and 124.3°, while the N—Sn—N angle is 176.8°, showing only very slight deviation from trigonal bipyramidal geometry around the tin atom. The average Sn—C(Ph) distance of 2.12 Å is within the range of Sn—C(Ph) distances (2.105–2.16 Å) reported in the literature.[14] The C—C bond lengths in the phenyl groups are all normal. The NCS groups are virtually linear, with NCS angles of 179.7°. The Sn—N distances of 2.307 Å, the C—S bond lengths of 1.606 Å and the N—C bond lengths of 1.137 Å are all similar to those found in isothiocyanatotriphenyl(pyridinium-2-carboxylato)-tin(IV) monohydrate[15] and other metal isothiocyanato complexes.[16–18]

The Schiff base molecules dimerize to form cationic ligand pairs, with an effectively planar structure. In these dimers, which contain one extra proton, both imine nitrogen atoms are protonated. The additional hydrogen atom is situated between the two phenolic oxygen atoms, where the very short O(1)—O(1′) distance of 2.444(9) Å indicates the presence of a hydrogen bond.[19]

This most unusual structure once again demonstrates the reluctance of triorganotin isothiocyanato complexes to adopt a six-coordinate configuration.*

(*Received* 12 *December* 1988; *accepted* 21 *February* 1989)

Abstract—*Apical*(H,Cl)-*anti-mer*-{IrHCl(Cyttp)(μ-H)[AuPPh$_3$]}BF$_4$, where Cyttp = $C_6H_5P(CH_2CH_2CH_2P(C_6H_{11})_2)_2$, was prepared in THF solution by mixing equimolar quantities of *cis-anti-mer*-[IrH$_2$Cl(Cyttp)] and [AuCl(PPh$_3$)] in the presence of TlBF$_4$. The ^{1}H NMR spectrum (acetone-d$_6$) showed resonances of an apical terminal hydrido proton at −19.68 ppm and a meridional bridging hydrido proton at −5.45 ppm. The assignment of meridional stereochemistry to the bridging hydride indicates that the [Au(THF)PPh$_3$]$^+$ cation attacked the diastereotopic proton that was located *trans* to the higher *trans*-influence ligand in the starting complex. Nuclear Overhauser Effect experiments confirm the apical assignment for the terminal hydride and show that it is spatially close to the *ortho*-protons of the phenyl group (i.e. an anti-configuration diastereomer in which phenyl and chlorine are located on opposite sides of the meridional reference place). Geminal heteronuclear $^2J_{AuP—(\mu\text{-}H)}$ coupling constants for the spin–spin interactions between the μ-hydrido proton and the Cyttp internal phosphorus atom (65.9(3) Hz) or the phosphorus atom bonded to gold (71.1(3) Hz) indicate *trans* linear-type P—Ir—(μ-H) and (μ-H)—Au—P relationships.

Numerous reports on the characterization and preparation of gold-containing mixed-metal complexes and clusters have recently appeared in the literature.[1–11] The structures of some of these mixed-metal compounds illustrate the isolobal analogy between the hydrido ligand and the AuPR$_3$ moiety.[1,5,6,10,11]

Hydrido complexes of gold are relatively rare and those few that have been isolated and unambiguously characterized have bridging hydrido ligands between gold and another transition metal atom in an M—(μ-H)—Au—PR$_3$ sequence.[2,3] These complexes include {M(CO)$_5$(μ-H)[AuPPh$_3$]}BF$_4$ where M = Cr, Mo and W;[2] *mer*-[IrH$_2$(PPh$_3$)$_3$(μ-H)[AuPR$_3$]}BF$_4$ where R = Ph, Et;[3] and *trans*-{Pt(C$_6$Cl$_5$)(PPh$_3$)(μ-H)[AuPPh$_3$]}BF$_4$,[3] {Ru(dppm)$_2$(μ-H)$_2$[AuPPh$_3$]$_2$}(NO$_3$)$_2$ [dppm = bis(1,2-(diphenylphosphino)methane)][6e] and {Ru(dppm)$_2$(μ-H)$_2$[AuPPh$_3$]}PF$_6$.[6i] In the case of {Ir(μ-H)$_2$(bipy)(PPh$_3$)$_2$[AuPPh$_3$]}(BF$_4$)$_2$,[6e] the hydrido ligands were not located by X-ray crystallography, but the X-ray structure and NMR data are consistent with bridging hydrides. However, it is noted that a terminal hydride for {IrH(PPh$_3$)$_3$[AuPPh$_3$]}$^+$ and {IrH(CO)(PPh$_3$)$_3$[AuPPh$_3$]}PF$_6$

* R.G. and S.M.S. dedicate this paper to the memory of their teacher, colleague and friend, Professor Devon W. Meek (died 7 December 1988).

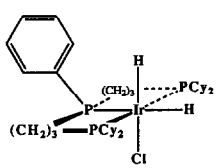
have been assigned based on NMR and IR spectroscopic evidence.[6e] Transition metal–gold clusters $\{IrH(PPh_3)_2(NO_3)[AuPPh_3]_2\}BF_4$,[6b] $\{IrH_2(PPh_3)_2[AuPPh_3]_4\}BF_4$,[6d] $\{ReH_4(PPh_3)_2[AuPPh_3]_5\}(PF_6)_2$,[6f] $\{RhH(CO)(PPh_3)_2[AuPPh_3]_3\}PF_6$[6f] and $\{ReH_4[P(p\text{-tol})_3]_2[AuPPh_3]_4\}BPh_4$[6h] have been isolated and partially characterized by NMR spectroscopy and X-ray diffraction analysis. An unambiguous assignment regarding bridging versus terminal hydrido ligands in these clusters was not possible, and in the case of $\{IrH(PPh_3)_2(NO_3)[AuPPh_3]_2\}BF_4$, a terminal Ir—H assignment was most consistent with the NMR data. In addition to the stable binuclear complexes noted above, three unstable intermediates (*trans*-phosphine complexes: $\{Ir(PPh_3)_2(acetone)(\mu\text{-}H)_2[AuPPh_3]\}^{2+}$; $\{Ir(NO_3)(PPh_3)_2(\mu\text{-}H)_2[AuPPh_3]\}^{+}$; and $\{IrH(NO_3)(PPh_3)_2(\mu\text{-}H)[AuPPh_3]\}^{+}$) show M—($\mu$-H)—Au—$PPh_3$ moieties according to NMR spectroscopy.[6b]

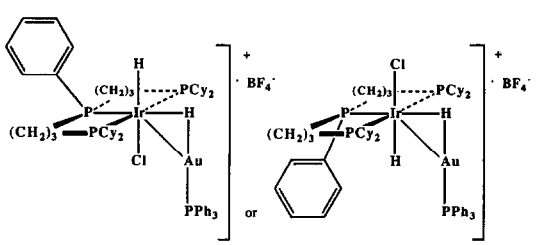
Earlier, we[12] reported on the syntheses, reactivities and stereochemistries of six coordinate iridium(III) dihydrido $[IrH_2Z(Cyttp)]^{(0\text{ or }1+)}$ complexes containing the chelating tritertiary phosphine ligand Cyttp[13] [Cyttp = bis((3-dicyclohexylphosphino) propyl)phenylphosphine, $C_6H_5P(CH_2CH_2CH_2P(C_6H_{11})_2)_2$]. This paper reports the preparation and NMR spectroscopy of a stable iridium–gold complex containing a bridging hydrido ligand and the chelating Cyttp ligand.

RESULTS AND DISCUSSION

Cis-anti-mer-$[IrH_2Cl(Cyttp)]$ (**1**) was mixed with $[AuCl(PPh_3)]$ in a 1 : 1 mole ratio in THF, and then an equimolar quantity of $TlBF_4 \cdot 6H_2O$ was added to yield *apical*(H,Cl)-*anti-mer*-$\{IrHCl(Cyttp)(\mu\text{-}H)[AuPPh_3]\}BF_4$ (**2**).



1



2(a) or 2(b)

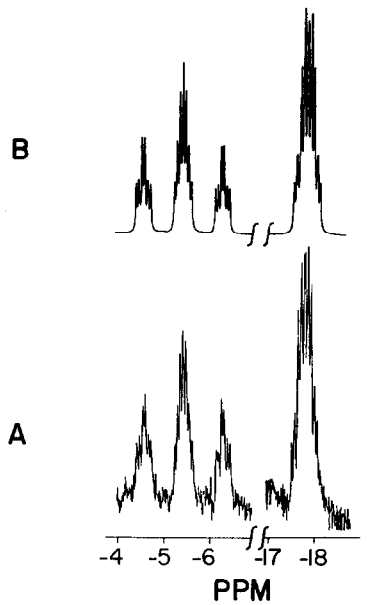


Fig. 1. (A) Hydrido region of the ^1H NMR spectrum (80 MHz, acetone-d_6, 298°K) of *apical*(H,Cl)-*anti-mer*-$\{IrHCl(\mu\text{-}H)(Cyttp)[Au(PPh_3)]\}BF_4$(**2**); (B) hydrido region of the simulated spectrum.

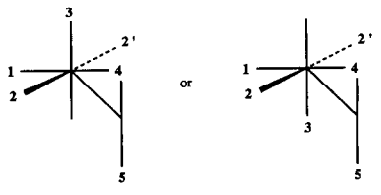
In the preparation of the previously described *mer*-$\{IrH_2(PPh_3)_3(\mu\text{-}H)[AuPPh_3]\}BF_4$ complex, the solvated cation $[Au(THF)PPh_3]^+$ was first prepared (via reaction of $[AuCl(PPh_3)]$ with $AgBF_4$ in THF), and then added to a THF solution of *mer*-$[IrH_3(PPh_3)_3]$.[3]

^1H *NMR spectroscopic studies*

Analysis. The six-spin system for **2** is shown in structures **3(a,b)**. The ^1H NMR partial spectrum (80 MHz, acetone-d_6, 298 K) of **2** in the hydride region is shown in Fig. 1. Two hydrido absorbances were found: a 19-line pattern for H(4) (−5.45 ppm) (three subgroups with relative intensities of 1 : 1 : 2 : 2 : 1 : 1, 1 : 2 : 3 : 4 : 3 : 2 : 1 and 1 : 1 : 2 : 2 : 1 : 1) and a 10-line pattern for H(3) (−17.68 ppm) with relative intensities of 1 : 2 : 4 : 6 : 3 : 3 : 6 : 4 : 2 : 1. These relative intensities show that each proton exhibits 32 transitions as expected for a six-spin system (five coupling constants are involved).



3(a) 3(b)

Mer-H(4) *absorbance*: the multiplicity of 1:1:2:2:1:1 seen for the first and last eight H(4) transitions arises from three coupling constants, of which two are of similar magnitude (homonuclear $^2J_{H(3)—H(4)}$ 4.5(3) Hz and two heteronuclear $^2J_{P(2)—H(4)}/^2J_{P(2')—H(4)}$ both 9.9(3) Hz). The observation of two equal magnitude coupling constants indicate that the enantiotopic symmetry equivalence of the terminal Cyttp phosphorus nuclei in $[IrH_2Cl(Cyttp)]$ (**1**) is also preserved in the binuclear cationic product **2**. Enantiotopic symmetry equivalence for a six-spin system results in the 32 transitions of each nucleus being arranged in a 24-line pattern. Our observation of a 19-line pattern is explicable in terms of five sets of overlapping transitions which result from the fact that $^2J_{P(5)—H(4)} \approx (^2J_{H(3)—H(4)} + {}^2J_{P(1)—H(4)})$ (i.e. 71.1 Hz $\approx$ 4.5(3)+65.9(3) Hz). This explains the intensities of 1:2:3:4:3:2:1 found for the middle subgroups of seven lines. Selective heteronuclear decoupling experiments $\{\underline{P}Ph_3\}$ and $\{P_{internal}$ of Cyttp$\}$ provided the assignment of the respective $^2J_{P(1)—H(4)}$ and $^2J_{P(5)—H(4)}$ coupling constants.

Apical-H(3) *absorbance*: the relative intensities of the 10 lines observed for this absorbance are in the ratio of *ca* 1:2:4:6:3:3:6:4:2:1. The frequency differences between these lines point to a "quartet of triplets" pattern involving two similar magnitude smaller coupling constants (mean value of 5.6(3) Hz) and three similar magnitude larger coupling constants (mean value of 11.7(3) Hz) whose magnitude is approximately twice that of the smaller counterparts. The terminal lines of the H(3) nucleus absorbance are observed as having one unit-transition intensity, while the second and penultimate lines are each two unit-transition intensities. Since the average value of the three larger coupling constants is about double that of the two smaller ones, there is an overlap between each of the smaller triplet patterns and the corresponding adjacent larger triplet pattern, so that the relative intensities are actually 1:2:[1+3]:6:3:3:6:[3+1]:2:1. The very small frequency difference between the two middle three-unit intensity lines of the multiplet, results in their appearance at approximately equal height relative to their six-unit intensity neighbours. The values of the five coupling constants were hand calculated from the spectrum and then refined by iteration calculations and spectrum simulation using the "PANIC"[14] program. The simulated hydrido multiplets are shown in Fig. 1. From the *mer*-H(4) multiplet one can measure the value of the homonuclear $^2J_{H(3)—H(4)}$ coupling constant (4.5(3) Hz) common to both hydride multiplets. Thus, the 5.6(3) Hz value for the two smaller coupling constants represents an average value for $^2J_{H(3)—H(4)}$ and one of the heteronuclear coupling constants assigned as $J_{P(5)—H(3)}$. The signs of the coupling constants have not been determined. The summation of the five H(3) coupling constants is 45.2(3) Hz compared to the observed frequency difference between the terminal lines of 45.4 Hz.

Stereochemical interpretation

^1H and ^{31}P NMR spectral parameters for **2** are listed in Table 1. Hydride H(3) shows two het-

Table 1. ^1H and $^{31}P\{^1H\}$ NMR spectral parameters for *apical*(H,Cl)-*anti-mer*-$\{IrHCl(\mu\text{-}H)(Cyttp)[Au(PPh_3)]\}BF_4$ (**2**)

X	δ_X[a]	X—X	$J_{X—X}$[b]
P(1) (Cyttp internal-P)	−19.18	P(1)—P(2)	27
P(2) (Cyttp terminal-P)	−12.81	P(1)—H(3)	11.7(3)
H(3) (*apical*-H)	−17.68	P(1)—H(4)	65.9(3)
H(4) (*mer*-μ-H)	−5.45	P(1)—P(5)	35
P(5)	46.21	P(2)—H(3)	11.7(3)
		P(2)—H(4)	9.9(3)
		P(2)—P(5)	[c]
		H(3)—H(4)	4.5(3)
		H(3)—P(5)	5.6(3)
		H(4)—P(5)	71.1

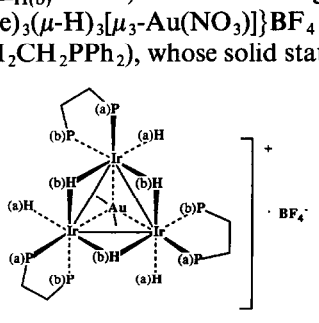
[a] ^1H NMR (acetone-d_6) and $^{31}P\{^1H\}$ NMR (THF) δ-values in ppm relative to tetrahydrosilane and 85% H_3PO_4, respectively. Negative values are upfield from the reference standard.

[b] Hz, standard deviation given in parentheses.

[c] Not observed.

eronuclear geminal coupling constants ($^2J_{P(1)—H(3)}$ and $^2J_{P(2)—H(3)}$) each with 11.7(3) Hz magnitudes typical of that expected for a *cis* $^2J_{PH}$ coupling constant in an octahedral complex.[15] The magnitude of the geminal homonuclear 4.5(3) Hz $^2J_{H(3)—H(4)}$ coupling constant is also consistent with a *cis* orientation of the diastereotopic protons.[12] In complex **1** this value is 6 Hz.[12] These three *cis* coupling constants characterize the H(3) proton as one that is apical to the meridional reference plane of the three Cyttp phosphorus atoms. The 5.6(3) Hz magnitude of the heteronuclear $J_{P(5)—H(3)}$ coupling constant is consistent with a terminal hydride which undergoes a longer range splitting interaction with a phosphorus atom ligated to gold. A Nuclear Overhauser Effect experiment (NOE) was performed in which *ortho*-protons of the Cyttp phenyl ring were irradiated, and an intensity enhancement for the H(3) signal was observed. This result simultaneously confirmed the apical assignment for H(3) and enabled the anti configuration of the product to be determined. (The phenyl and Cl are on opposite sides of the three Cyttp phosphorus atom reference plane.) An NOE for H(3) upon $\{H_{phenyl(ortho)}\}$ testifies to a close spatial relationship between these two moieties. Such a close spatial relationship was also found for the analogous case in the starting complex **1**.[12] A similar NOE enhancement of the apical hydride was also observed for compound **1**, whose structure is known from X-ray studies.[12] A single crystal X-ray diffraction analysis of *cis-anti-mer*-[IrH_2Cl(Cyttp)] (**1**), showed that the apical hydrido proton and one of the phenyl *ortho*-protons to have a non-bonded distance of 2.25 Å (within the range of distances commensurate with NOE phenomena).[16]

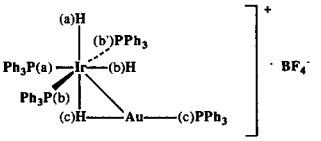
Hydrido proton H(4) shows two heteronuclear geminal constants $^2J_{P(1)—H(4)}$ and $^2J_{P(5)—H(4)}$ of similar magnitude (65.9(3) and 71.1(3) Hz, respectively). The magnitude of the $^2J_{P(1)—H(4)}$ coupling constant is reduced from the 130 Hz value observed for the analogous coupling in compound **1**. This reduction is similar to that found for the bridging hydrido proton H(b) *trans* to an iridium-bound phosphorus atom ($J_{P(b)—H(b)}$ 72 Hz) in the iridium–gold cluster $\{Ir_3H_3(dppe)_3(\mu\text{-}H)_3[\mu_3\text{-}Au(NO_3)]\}BF_4$ (**4**) (dppe = $Ph_2PCH_2CH_2PPh_2$), whose solid state structure



4

was determined by single crystal X-ray crystallography.[6a]

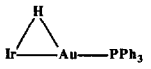
The 71.1(3) Hz magnitude of $^2J_{P(5)—H(4)}$ in **2** is consistent with a linear (μ-H)—Au—P disposition. This stereochemical arrangement is noted in the solid state structure of *mer*-$\{IrH_2(PPh_3)_3(\mu\text{-}H)[AuPPh_3]\}BF_4$ (**5**), and the corresponding coupling constant between the bridging hydrido proton and the phosphorus atom ligated to gold is 79.4 Hz.[3]



5

The remaining heteronuclear 9.9(3) Hz coupling constant for $^2J_{P(2)—H(4)}$ is reasonable for a hydride *cis* to an iridium-bound phosphorus atom. Thus, the four heteronuclear geminal coupling constants $^2J_{P(1)—H(4)}$, $^2J_{P(2)—H(4)}$, $^2J_{P(2')—H(4)}$ and $^2J_{P(5)—H(4)}$ indicate that H(4) is a bridging hydride close to or in the meridional plane, and having a linear (μ-H)—Au—P orientation to both P(1,5).

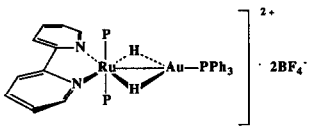
While there is literature precedent for the *trans*-(μ-H)—Au—P linear arrangement postulated for **2** on the basis of the 71.1 Hz $^2J_{AuP—(\mu\text{-}H)}$ coupling constant, this does not imply that other angular relationships for this moiety have not been found. NMR evidence has recently been presented which suggested a linear Ir—Au—P relationship (and concomitant reduced (μ-H)—Au—P angle) in some transition metal–[$AuPPh_3$] hydrido complexes, see structure **6**.[6b,e] Based on $^2J_{AuP—(\mu\text{-}H)}$ coupling con-



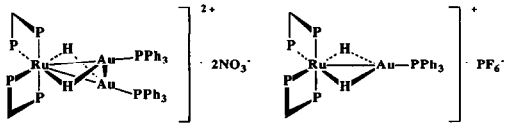
6

stants of *ca* 30 Hz, the M—(μ-H)—[$AuPPh_3$] moiety and a linear Ir—Au—P relationship was proposed for three unstable intermediates having *trans*-$\underline{P}Ph_3$—Ir—$\underline{P}Ph_3$ geometry: $\{Ir(PPh_3)_2$(acetone)$(\mu\text{-}H)_2[AuPPh_3]\}^{2+}$; $\{Ir(NO_3)(PPh_3)_2(\mu\text{-}H)_2[AuPPh_3]\}^{+}$; and $\{IrH(NO_3)(PPh_3)_2(\mu\text{-}H)[AuPPh_3]\}^{+}$.[6b] Subsequent single crystal X-ray crystallography of $\{Ir(\mu\text{-}H)_2$(bipy)$(PPh_3)_2[AuPPh_3]\}(BF_4)_2$ (**7**) proved an approximately linear Ir—Au—P relationship.[6e] Although the hydrido ligands in **7** were not located in the X-ray analysis, the solid-state structure was consistent with a bridging hydrido ligand located *trans* to each nitrogen.[6e] The 31 Hz $^2J_{AuP—(\mu\text{-}H)}$ coupling constant suggested that the above-mentioned stereochemistry for crystalline **7** was maintained in solution.[6e]

In solid state $\{Ru(dppm)_2(\mu\text{-}H)_2[AuPPh_3]_2\}(NO_3)_2$ (**8**) and $\{Ru(dppm)_2(\mu\text{-}H)_2[AuPPh_3]\}PF_6$ (**9**), the positions of the bridging hydrido ligands were now located by single crystal X-ray crystallography.[6e,i] These complexes showed approximately linear Ir—Au—P relationships.[6e,i] However, the observation of a 74.8 Hz $^1J_{AuP-(\mu\text{-}H)}$ coupling constant for **8** has been interpreted as showing a change to *trans*-(μ-H)—Au—PPh_3 stereochemistry in solution.[6e] A change from the solid-state geometry has also been indicated for solutions of **9**.[6i] The 54.0 Hz $^2J_{AuP-(\mu\text{-}H)}$ coupling constant has been interpreted as pointing to a rapid equilibrium between *trans*- and *cis*-(μ-H)—Au—PPh_3 stereochemistries.[6i] For these reasons we believe that the 65.9 Hz $^2J_{P(1)-H(4)}$ and 71.1 Hz $^2J_{P(5)-H(4)}$ coupling constants for **2** indicate *trans* dispositions for the relevant (μ-H)—M—P moieties.



7



8 9

It is noted that the *mer*-bridging hydride proton H(4) in **2** is *trans* to the stronger *trans*-influence phosphorus (as opposed to being an apical bridging hydride which would have placed it *trans* to the weaker chloro ligand). From the structure of complex **5**, it appears that the cationic $[Au(THF)PPh_3]^+$ species has also attacked the hydrido ligand that is *trans* to a hydride in *mer*-$[IrH_3(PPh_3)_3]$ (as opposed to a proton *trans* to the relatively weaker *trans*-influence phosphorus ligand).

Finally, the position of the putative iridium–gold bond in **2** (postulated by analogy to the solid state structures of **5**, $\{Ir(H)(PPh_3)_2(NO_3)[AuPPh_3]_2\}BF_4$, $\{Ir(H)_2(PPh_3)_2[AuPPh_3]_4\}BF_4$)[3,6b,d] can not be determined from the NMR spectroscopic data without equivocation. Two models [**2(a)** or **2(b)**] are possible, and differ in the orientation of the gold atom *vis-a-vis* the apical hydrido or the apical chloro ligands. The *syn*-periplanar relationship between H(3) and P(5) in model **2(b)** is very similar to that found between H(b) and H(c) in the binuclear complex **5**. Note that $J_{P(c)-H(b)}$ (13 Hz) in **5** is greater than $J_{P(5)-H(3)}$ (5.6(3) Hz) in **2**, although this by itself does not disprove one model over the other. On the other hand, there is a *syn*-periplanar homonuclear P(1)—P(5) relationship in **2** versus an *anti*-periplanar P(a)—P(c) relationship in **5**, and the $^{31}P\{^1H\}$ NMR *syn*-periplanar $J_{P(1)-P(5)}$ (35 Hz) in **2** is markedly larger than the corresponding *anti*-periplanar $J_{P(a)-P(c)}$ (19.5 Hz)[3] coupling constant in **5**. Since models **2(a)** and **2(b)** differ primarily in the *syn*- or *anti*-periplanar H(3)—P(5) relationship, the finding that $J_{P(5)-H(3)} < J_{P(c)-H(b)}$ is a point in favour of model **2(a)**. Unfortunately, several efforts to prepare suitable crystals of **2** for single crystal X-ray diffraction analysis have so far proven unsuccessful.

EXPERIMENTAL

Elemental analysis was performed by MHW Laboratories, Phoenix, Arizona. IR spectra were recorded on a Perkin–Elmer 283B spectrophotometer. ^1H NMR spectra (1.9 T) were recorded in acetone-d_6 solution at 80 MHz on an IBM NR-80 Fourier transform spectrometer. The $^1H\{^{31}P\}$ selective decoupling experiments were performed at 300 MHz on a Bruker WM-300 Fourier transform spectrometer (equipped with an Aspect 3000 data system). Nuclear Overhauser Effect experiments were performed at 500 MHz on a Bruker AM-500 Fourier transform spectrometer (equipped with an Aspect 3000 data system) at The Ohio State University Chemical Instrument Center. Deuterated solvents were used as an internal lock, and the residual protio absorbances were used as internal secondary references (relative to TMS). $^{31}P\{^1H\}$ NMR spectra (2.1 T) were recorded in THF solution at 36.43 MHz on a Bruker HX-90 Fourier transform spectrometer. For ^{31}P NMR spectra, an acetone-d_6 solution of trimethyl phosphate $[(CH_3O)_3P{=}O]$ in a co-axial insert tube was used as an external lock and an external secondary reference (1.594 ppm relative to 85% H_3PO_4), respectively. For all NMR spectra, negative chemical shifts are upfield from the respective reference standards. Protons were decoupled from the phosphorus nuclei by broad-band irradiation. Iteration calculations and simulated NMR spectra were calculated with the use of the "PANIC"[14] program on a Bruker WP-200-SY Fourier transform spectrometer. "PANIC" is a microcomputer version of the "LAOCOON"[17] program.

All reactions were carried out under an atmosphere of high purity nitrogen by using standard Schlenck techniques. Solutions of air-sensitive reagents were transferred between reaction vessels with syringes flushed with nitrogen, stainless steel needles, or a glass transfer tube with a Teflon stopcock.

Cis-anti-mer-$[IrH_2Cl(Cyttp)]$[12] and $[AuCl(PPh_3)]$[18] were prepared by literature methods.

Apical(H,Cl) - *anti* - *mer* - {IrHCl(μ - H)(Cyttp)[Au(PPh_3)]}BF_4 (**2**)

To a solution of *cis-anti-mer*-[IrH_2Cl(Cyttp)] (**1**) (300 mg, 0.37 mmol) and [$AuCl(PPh_3)$] (170 mg, 0.37 mmol) in THF (25 cm^3) was added $TlBF_4 \cdot 6H_2O$ (137 mg, 0.37 mmol). The mixture was stirred for 4 h during which time TlCl precipitated. The solvent was removed under reduced pressure after which the product was extracted with acetone. After removing the acetone solvent, the product was washed with water, and then benzene and recrystallized (acetone–ether) to yield 310 mg (62%) of the title compound **2**. Product **2** was stable indefinitely in the solid state, but decomposes in solution within hours, if not protected from the atmosphere. IR (KBr) cm^{-1}: 2239 [$\nu_{Ir—H(apical)}$].

Found: C, 47.45; H, 5.84; P, 9.31. Calc. for $C_{54}H_{78}AuBClF_4IrP_4$: C, 47.60; H, 5.77; P, 9.09%.

Acknowledgements—Thanks are expressed to Dr Charles Cottrell of The Ohio State University Campus Chemical Instrument Center for performing the NOE experiment. Gratitude is also expressed to the Kreitman Family Endowment Fund, Ben Gurion University of the Negev, for the purchase of a Bruker WP-200-SY FT-NMR spectrometer.

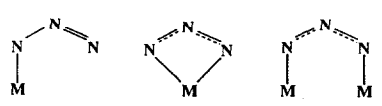
(*Received* 26 *January* 1989; *accepted* 21 *February* 1989)

Abstract—The reaction of $AlMe_3$ with 1,3-diphenyltriazene [Hdpt] in toluene gives $Al(dpt)_3$, even when $AlMe_3$ is in large excess. The monomeric structure has been established by X-ray diffraction. Crystals of $Al(dpt)_3$ are monoclinic, space group $C2/c$ with $a = 20.587(3)$, $b = 16.005(3)$, $c = 13.236(3)$ Å and $\beta = 119.172(12)°$, $Z = 4$, $R = 0.067$ and $R_w = 0.083$. The aluminium(III) is coordinated by three chelating triazenido ligands to give a trigonally distorted octahedral geometry. The gallium and indium analogues are also reported.

The triazenide anion, RN=N—NR^-, might be expected to display a variety of coordination modes. Transition metal complexes containing monodentate (**1**), chelate (**2**) and bridging (**3**) triazenide ligands have been reported,[1] suggesting a formal analogy to the carboxylate anion, O=C(R)—O^-. Despite this analogy and the wide range of Group III carboxylates reported in the literature,[2] the only examples of Group III triazenides are $Tl(dpt)_3$ (Hdpt = 1,3-diphenyltriazene) and $Tl(ppt)_3$ (Hppt = 1-phenyl-3-(2′-pyridyl)triazene), which were characterized as tris-chelate complexes by IR spectroscopy,[3] and the dimeric $[Tl(dpt)]_2$ whose structure was determined by X-ray crystallography.[4]



(1) (2) (3)

We now report the synthesis and characterization of the tris(1,3-diphenyltriazenido)aluminium(III), gallium(III) and indium(III) complexes.

RESULTS AND DISCUSSION

The complex $Al(dpt)_3$ (Hdpt = 1,3-diphenyltriazene) was first obtained in low yield from the reaction of $AlCl_3$ with Li(dpt). An improved procedure, however, is the direct reaction of Hdpt with $AlMe_3$ in toluene.

The compound $Al(dpt)_3$ has been fully characterized by elemental analysis and spectral data. The ^1H NMR spectrum, in $CDCl_3$, shows an A_2B_2C pattern for the monosubstituted phenyl groups, indicating that the triazenides are either fluxional on an NMR time scale, or in a symmetrical environment. The ^{27}Al NMR spectrum consists of a broad peak whose shift ($\delta = 25$ ppm) is indicative of a six-coordinate aluminium centre,[5] but is extremely broad ($w_{1/2} = 1160$ Hz), possibly exacerbated by coupling to the quadrupolar ^{14}N nuclei. The IR

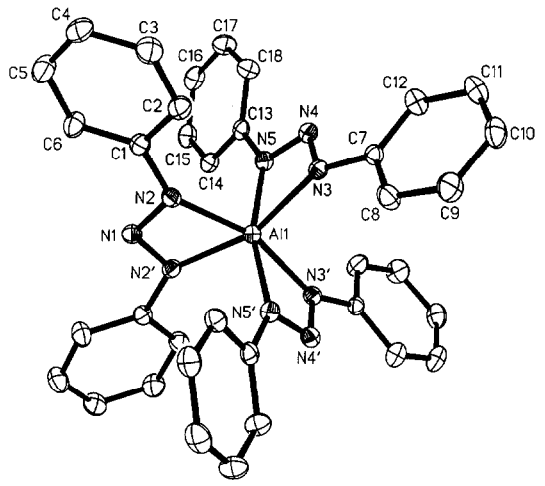

Fig. 1. Molecular structure of $Al(dpt)_3$ showing the atom numbering; hydrogen atoms are omitted for clarity.

spectrum shows bands at 1320 and 1295 cm^{-1}, which are characteristic of chelating triazenide groups.[1] The chelating coordination mode has been confirmed by X-ray crystallography.

The structure of $Al(dpt)_3$ is shown in Fig. 1; selected bond lengths and angles are given in Table 1. One disordered molecule of toluene per $Al(dpt)_3$ is present in the lattice as a solvent of crystallization (see Experimental). The molecule of $Al(dpt)_3$ has a two-fold crystallographic axis passing through Al(1) and N(1). The aluminium is in a trigonally distorted octahedral environment, which is consistent with the ^{27}Al NMR spectrum.

The average Al—N distance (1.972(5) Å) is within the range previously observed for Al—N bonds (1.88–2.09 Å),[6] however, the small N—Al—N angles (64.1(2)-64.2(2)°) suggest that the chelate ring is under considerable strain. The simi-

larity between the N—N distances within each ligand implies a delocalization of the π-electron in the N_3 portion of the ligand. As with the cobalt analogue, $Co(dpt)_3$,[7] the delocalization could, however, extend to the phenyl rings because the average N—C distance (1.410(6) Å) is significantly shorter than the N—C single bond length of 1.472 Å.[8]

It is interesting to note that $Al(dpt)_3$ is the only product to be isolated from the reaction of Hdpt and $AlMe_3$, even when a large excess of $AlMe_3$ is employed. This suggests that the tris-chelate complex is thermodynamically favoured over $AlMe_2(dpt)$ and $AlMe(dpt)_2$.

The gallium and indium analogues can be obtained in a similar manner to the aluminium complex, and are spectroscopically equivalent (see Experimental). All three complexes are bright yellow–orange crystalline solids with only limited solubility in non-polar organic solvents, are stable under dry nitrogen at room temperature, but decompose slowly in air, both in solution and the solid state.

EXPERIMENTAL

Microanalyses were obtained by Oneida Research Services Inc., Whitesboro, New York. Melting points were determined in sealed capillaries and are uncorrected. IR spectra were recorded in the 4000–600 cm^{-1} region on a Perkin–Elmer 137 grating spectrometer in Nujol mulls. NMR spectra were recorded (in $CDCl_3$) on Bruker AM-250 (^1H) and WM-300 (^{27}Al) spectrometers [δ in ppm relative to $SiMe_4$ (^1H) and external $Al(H_2O)_6^{3+}$ (^{27}Al)]. 1,3-Diphenyltriazene was prepared according to published procedures.[1] All manipulations were carried out under nitrogen. Solvents were distilled and degassed before use.

(1) *Tris*(1,3-*diphenyltriazenido*)*aluminium*(III)

To a solution of Hdpt (5.0 g, 25.0 mmol) in toluene (100 cm^3) at room temperature, was added $AlMe_3$ (4.15 cm^3, 2 M solution in hexane, 8.3 mmol). Immediately following addition, gas was evolved and the solution changed from yellow to orange. After refluxing for 12 h the solvent was reduced in volume and cooled to give orange crystals. The crystals contained toluene of solvation, which was eliminated by dissolving in pentane and removing the volatiles under vacuum. Yield: 4.04 g, 79%. Melting point: 263° dec. Found: C, 69.3; H, 4.14; N, 20.1. Calc. for $Al(dpt)_3$: C, 70.2; H, 4.91; N, 20.4%.

^1H NMR: 7.49 [2H, d, J(H—H) = 9.9 Hz, *o*-H], 7.34 [2H, "t", J(H—H) = 9.3 Hz, *m*-H], 7.19 [1H, t, J(H—H) = 8.6 Hz, *p*-H]. ^{27}Al-{^1H} NMR: +25 (br s, $W_{1/2}$ = 1160 Hz). IR: 1590s, 1480s, 1320m, 1295s, 1275s, 1205s, 1170w, 1070w, 900w, 845w, 755s, 680s, 670s.

(2) *Tris*(1,3-*diphenyltriazenido*)*gallium*(III)

This complex was prepared as for $Al(dpt)_3$ but using $GaMe_3$ to give a yellow solid. Yield: 45%. Melting point: 243°C dec. Found: C, 65.2; H, 4.42; N, 18.7. Calc. for $Ga(dpt)_3$: C, 65.6; H, 4.59; N, 19.1%.

^1H NMR: [2H, d, J(H—H) = 8.9 Hz, *o*-H], 7.35 [2H, "t", J(H—H) = 9.1 Hz, *m*-H], 7.21 [1H, t, J(H—H) = 8.6 Hz, *p*-H]. IR: 1590m, 1480m, 1330sh, 1300s, 1280s, 1205m, 1155m, 1070m, 1020m, 900w, 795w, 755m, 685w, 660w.

(3) *Tris*(1,3-*diphenyltriazenido*)*indium*(III)

This complex was prepared as for $Al(dpt)_3$ but using $InMe_3$ to give an orange solid. Yield: 62%. Melting point: 244–246°C dec. Found: C, 61.5; H, 4.42; N, 17.8. Calc. for $In(dpt)_3$: C, 61.4; H, 4.31; N, 17.9%.

^1H NMR: 7.51 [2H, d, J(H—H) = 10.3 Hz, *o*-H], 7.37 [2H, "t", J(H—H) = 9.2 Hz, *m*-H], 7.22 [1H, t, J(H—H) = 8.4 Hz, *p*-H]. IR: 1590m, 1480s, 1325s, 1310s, 1280s, 1210w, 1070w, 900w, 765m, 690m, 660m.

X-ray crystallography

Collection of X-ray diffraction data. A light orange crystal of approximate dimensions 0.10 × 0.23 × 0.47 mm was immersed in Paratone-N (lube oil additive), mounted on a glass fiber and transferred to the Syntex $P2_1$ diffractometer, which was equipped with a modified LT-1 apparatus. Subsequent set-up operations (determination of accurate unit cell dimensions and orientation matrix) and collection of low temperature (213 K) intensity data were carried out using standard techniques similar to those of Churchill *et al.*[9] Details are given in Table 2.

All 2587 data were corrected for Lorentz and polarization effects and placed on an approximately absolute scale by means of a Wilson plot. A careful survey of a preliminary data set revealed the systematic extinctions hkl for $h-k = 2n+1$ and $h0l$ for $l = 2n+1$; the diffraction symmetry was $2/m$. Possible space groups are the non-centrosymmetric Cc [C_s^4: No. 9] or the centrosymmetric $C2/c$ [C_{2h}^6; No. 15]. Successful solution and refinement of the structure using the centrosymmetric monoclinic space group $C2/c$ later proved it to be the correct choice.

Table 2. Experimental data for the X-ray diffraction study

Formula: $C_{36}H_{30}N_9Al \cdot C_7H_8$
Fw: 707.8
Crystal system: Monoclinic
Space group: $C2/c$
$a = 20.587(3)$ Å
$b = 16.005(3)$ Å
$c = 13.236(3)$ Å
$\beta = 119.172(12)°$
$V = 3808.1(11)$ Å^3
$Z = 4$
$D_{calc.}$ (Mg m^{-3}) = 1.235
Diffractometer: Syntex $P2_1$
Radiation: Mo-K_α ($\lambda = 0.710730$ Å)
Monochromator: Highly oriented graphite
Data collected: $+h$, $+k$, $\pm l$
Scan type: 2θ–θ
Scan width: 1.10° plus K-separation
Scan speed: 2.5° min^{-1} (in ω)
$2\theta_{max}$ (°): 45.0
μ(Mo-K_α) (mm^{-1}) = 0.092
Reflections collected: 2587
Reflections with $\|F_o\| > 3.0\sigma(\|F_o\|)$: 2020
Number of variables: 298
$R_F = 6.7\%$
$R_{wF} = 8.3\%$
Goodness-of-Fit: 2.37

Solution and refinement of the crystal structure. All crystallographic calculations were carried out using either our locally modified version of the UCLA Crystallographic Computing Package[10] or the SHELXTL PLUS program set.[11] The analysis,[12a] both the real ($\Delta f'$) and imaginary ($i\Delta f''$) components of anomalous dispersion[12b] were included. The quantity minimized during least-squares analysis was $\Sigma w(|F_o|-|F_c|)^2$ where $w^{-1} = \sigma^2(|F_o|)+0.00046(|F_o|)^2$.

The structure was solved by direct methods (SHELXTL PLUS); and refined by full-matrix least-squares techniques. Hydrogen atom contributions from the disordered toluene molecule were not included. Refinement of positional and thermal parameters (isotropic for hydrogen atoms and for the carbon atoms of the disordered toluene) led to convergence with $R_F = 6.7\%$, $R_{wF} = 8.3\%$ and G-O-F = 2.37 for 298 variables refined against those 2020 data with $|F_o| > 3.0\sigma(|F_o|)$. A final difference-Fourier map was "clean", ρ(max) = 1.01 e Å^{-3}. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

Acknowledgements—Funds for the purchase of the Nicolet R3m/V diffractometer system were made available from the National Science Foundation under Grant CHE-85-14495. J.T.L. is a Joshiah Parsons Cooke Fellow, 1988–1989.

Abstract—Reaction of bis(2-pyrrolidonato)mercury(II) (**1**) with zinc nitrate, cadmium nitrate, or mercury(II) chloride in methanol, yields the compounds $[Hg_3Zn_2(C_4H_6NO)_6(NO_3)_{3.33}(CH_3O)_{0.67}]_n$ (**2**), $[Hg_3Cd(C_4H_6NO)_6(NO_3)_2]_n$ (**3**), and $[Hg_2(C_4H_6NO)_2Cl_2]_n$ (**4**), respectively. Compound **2** is cubic $P4_132$ with $a = 16.370(5)$ Å, $Z = 4$. The structure was refined on 565 reflections to $R = 0.060$. The compound forms a three-dimensional polymer made up of interleaving macrobicyclic units, each macrocycle being 80-membered and containing 10 mercury, 10 zinc, 20 carbon, 20 nitrogen and 20 oxygen atoms. One-third of the zinc atoms are tetrahedrally coordinated by three pyrrolidone oxygen atoms and a methoxide ion; the methoxide groups are replaced by bidentate nitrates on the other zinc atoms. A further nitrate ion symmetrically links a triad of mercury atoms lying within each macrobicycle. Compound **4** is monoclinic $P2_1/c$ with $a = 8.563(2)$, $b = 15.887(2)$, $c = 10.533(2)$ Å, $\beta = 113.55(1)°$, $Z = 4$. The structure was refined on 1513 reflections to $R = 0.051$. The compound forms a loosely linked chain polymer in which units of **1** chelate via the oxygen atoms to the mercury atoms of $HgCl_2$ molecules, with a resultant bending (*ca* 167°) of the Cl—Hg—Cl angle. X-ray powder diffraction photographs show that compound **3** is isostructural with its previously reported cobalt(II) analogue and further information about the cadmium site in **3** was obtained from the EPR spectra of manganese(II)-doped samples.

We have recently demonstrated that bis(2-pyrrolidonato)mercury(II) (**1**) obtained[1] by reaction of 2-pyrrolidone with mercuric acetate, functions as a very versatile ligand system towards other metal ions capable of binding to the oxygen atoms of the pyrrolidone units. The resulting heterometallic, Hg/M, polymeric complexes display a diversity of structural types. Chain polymers involving 16-membered macrocycles were formed when the nitrates of cobalt,[1] lanthanides[2] or thorium[3] were used as the source of the heterometal ions, layer polymers containing contiguous 32-membered macrocycles were obtained[4] with CuX_2 (X = NO_3, ClO_4 or ReO_4). With silver(I) nitrate, however, a simpler, dimeric complex $[HgAg(C_4H_6NO)_2(NO_3)]_2$ was obtained,[5] in which 2-pyrrolidone functions as a trinucleating ligand.

In all these compounds, an important factor influencing the nature of the resulting structure appears to be the preferred coordination number and geometry of the heterometal ion binding to the oxygen atoms of the $Hg(C_4H_6NO)_2$ unit, supplemented by the ability of the two oxygen atoms of that unit to adopt a range of different conformational modes by ligand rotation about the N—Hg—N bonds. These considerations have led us to explore the reactions of **1** with the Group IIB

(12) metal ions, Zn^{2+}, Cd^{2+} and Hg^{2+}. These metal ions commonly present a variety of coordination geometries, including, for zinc and mercury(II), the distinct possibility of tetrahedral coordination—a geometry not so far observed in the heterometallic complexes formed by **1**. During these studies we have isolated the compounds $[Hg_3Zn_2(C_4H_6NO)_6(NO_3)_{3.33}(CH_3O)_{0.67}]_n$ (**2**), $\{[Hg_3Cd(C_4H_6NO)_6](NO_3)_2\}_n$ (**3**) and $[Hg_2(C_4H_6NO)_2X_2]_n$ where X = Cl (**4**) or Br (**5**). We report here the results of single crystal X-ray diffraction studies on **2** and **4**, and characterization of **3** by powder diffraction and spectroscopic measurements.

EXPERIMENTAL

Preparations

Compound **2**, $[Hg_3Zn_2(C_4H_6NO)_6(NO_3)_{3.33}(CH_3O)_{0.67}]_n$. Zinc nitrate (1 mmol) in methanol (5 cm^3) was added to a methanolic solution of **1** (2 mmol in 20 cm^3), prepared as described previously.[1] The resulting colourless solution was allowed to evaporate at 3°C. After 2 days, colourless, multi-faceted crystals of suitable quality for X-ray analysis were obtained, and were collected, washed with cold methanol (2×5 cm^3) and dried at the pump. Yield: 64%. Found: C, 20.0; H, 2.7; N, 8.8. Calc. for **2**: C, 20.2; H, 2.6; N, 8.9%.

Compound **3**, $\{[Hg_3Cd(C_4H_5NO)_6](NO_3)_2\}_n$. This was obtained by the method described previously[1] for the cobalt(II) analogue. Yield: 84%. Found: C, 21.9; H, 2.7; N, 8.4. Calc. for **3**: C, 21.5; H, 2.7; N, 8.4%.

The compound could not be obtained in suitable crystalline quality for single crystal X-ray analysis. The manganese(II)-doped samples were obtained using solutions of cadmium nitrate mixed with 1% manganese(II) nitrate.

Compounds **4**, $[Hg_2(C_4H_6NO)_2Cl_2]_n$ *and* **5**, $[Hg_2(C_4H_6NO)_2Br_2]_n$. These were obtained as for **2** but using the appropriate mercury(II) halide in place of zinc nitrate and with evaporation at room temperature.

For **4**, white needles of X-ray quality formed after a day. Yield: 66%. Found: C, 15.0; H, 1.7; N, 4.2. Calc. for **4**: C, 15.0; H, 1.9; N, 4.2%. Raman: ν_1 (Hg—Cl) 300 cm^{-1}. IR: ν_3 (Hg—Cl) 351 cm^{-1}.

For **5**, a cream powder formed after 2 days. Yield: 34%. Found: C, 12.7; H, 1.6; N, 3.3. Calc. for **5**: C, 13.2; H, 1.7; N, 3.8%. Raman: ν_1 (Hg—Br) 187 cm^{-1}. IR: ν_3 (Hg—Br) 249 cm^{-1}.

Attempts to make analogous compounds with mercury(II) iodide, cyanide, or thiocyanate were unsuccessful.

X-ray studies

A summary of the crystal data and of the data collection and refinement parameters for compounds **2** and **4** is given in Table 1. Intensity data were measured with graphite monochromated Cu-K_α radiation using ω-scans on a Nicolet R3m/Eclipse S140 diffractometer system. The data were

corrected for Lorentz, polarization and absorption factors.

Both structures were solved by the heavy-atom method and their non-hydrogen atoms refined anisotropically, except for atoms O(5), C(6), N(4), O(7), O(6), O(3), N(3) and O(4) in **2**, which had partial site occupancies and were refined isotropically. The hydrogen atom positions were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2\ U_{eq}(C)$ and allowed to ride on their parent carbon atoms. Due to high thermal anisotropy, the methyl protons in **2** were not included in the refinement process. Refinements were by block-cascade, full-matrix least-squares. The chirality and space group of **2** were established by an *R* factor test. Computations were carried out using the SHELXTL program system.[6]

Tables 2 and 3 list selected bond lengths and angles.

Spectroscopy

IR spectra were recorded on a Perkin–Elmer 1720 FTIR spectrometer as Nujol mulls (CsI). Raman spectra of compounds **4** and **5** were obtained on solid samples using a Spex Ramalog V instrument with a Coherent model 52 Krypton ion laser (514.5 nm line), and data collection with a Spex Datamate computer controller. EPR spectra were obtained for polycrystalline samples at room temperature using Varian E12 X-band (*ca* 9.5 GHz) and Bruker ER200 Q-band (*ca* 34 GHz) spectrometers. The Q-band results were used to determine the zero-field splitting parameters *D* and *E* in the Spin Hamiltonian:

$$\mathcal{H} = g\beta B \cdot S + D(S_z^2 - 35/12) + E(S_x^2 - S_y^2).$$

These values were then used to calculate resonance fields using the ESRS program.[7]

RESULTS

We shall first consider compounds **2** and **4**, for which single crystal X-ray structural information is available.

$Hg_3Zn_2(C_4H_6NO)_6(NO_3)_{3.33}(CH_3O)_{0.67}$ (**2**)

The X-ray analysis shows that **2** has the stoichiometry shown above, in which there is partial replacement of the nitrate ions, derived from the zinc nitrate, by methoxide ions from an incomplete solvolysis reaction with the methanol used as solvent. The compound has a complex, polymeric structure with some disorder.

In discussing the details of the structure it is convenient first to consider the coordination environment at the zinc sites (Fig. 1). The zinc atoms are on three-fold rotation axes. The crystal structure represents the average of two superimposed coordination environments, **A** and **B**. In two-thirds of the zinc sites (the **A** sites) the metal ions are coor-

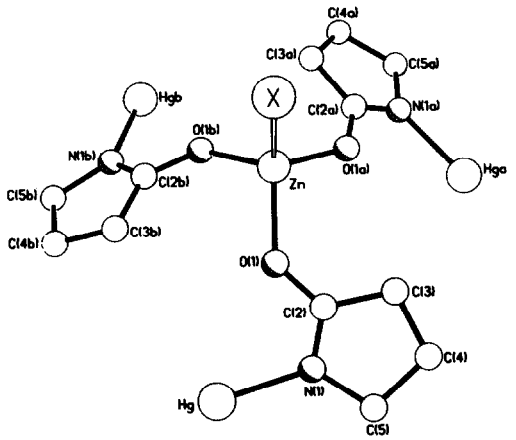

Fig. 1. The zinc environment in **2** showing the crystallographic numbering scheme. X represents the position occupied by the bidentate nitrate, N(4), O(6), O(6a), O(7) (**A** sites), or by the methoxide group, O(5), C(6) (**B** sites).

dinated to five oxygen atoms derived from three symmetry-related 2-pyrrolidone ligands and one bidentate nitrate. The nitrate group is disordered as a consequence of satisfying the crystallographic three-fold site symmetry requirements. In the remaining one-third of the zinc sites (the **B** sites) the nitrate group is replaced by a methoxide ion. If one regards the bidentate nitrate groups in the **A** sites as occupying one coordination position, then the coordination geometry about zinc is best described as distorted tetrahedral in both cases. The distortions are not severe; the angles between the Zn—O(pyrrolidone) bonds are slightly compressed [104.2(6)°] and there is a concomitant increase in the angles to the nitrate/methoxide site [114.3(16)°]. Bond lengths (Table 2) are unexceptional.

The mercury atoms are on two-fold rotation axes and are bound to the nitrogen atoms of two symmetry-related 2-pyrrolidone ligands [Hg—N(1) 2.03(2) Å]. The N—Hg—N unit is slightly distorted from linearity [N(1)—Hg—N(1a) 171(1)°] by interaction of the mercury with oxygen atoms from the second nitrate anion in the asymmetric unit: [Hg—O(2) 2.79(2) Å].

The combination of these zinc and mercury coordination environments leads to the formation of a three-dimensional polymer. A major feature of this array is the presence of a series of 80-membered macrocycles containing 10 mercury, 10 zinc, 20 carbon, 20 nitrogen and 20 oxygen atoms. These intersect at zinc atoms to form three-fold symmetric, interleaving, macrobicyclic units (Fig. 2). The zinc atom at the apex of each such unit is linked by three molecular strands, each spiralling through 120°, to the zinc atom at the base. The base–apex Zn—Zn separation is 18.6 Å.

Each macrobicycle is "waisted" at the intersection of the crystallographic three-fold and two-fold axes, coincident with the position of one of the nitrate ions which lies at the centre of each macrobicycle. By adopting such a position these nitrates serve weakly to link a mercury atom from each of the three strands (Fig. 3). The gross structural arrangement is illustrated schematically in Fig. 4. As far as we are aware, the symmetrical bridging role of the nitrate ion to these three metal ions is unique, though a similar, but asymmetric, linking of three copper atoms has been reported.[8]

The 80-membered macrocyclic rings in this compound are by far the largest we have observed for the heterometallic compounds formed by 2-pyrrolidone. Previously the largest was 32-membered.[4]

There are three independent nitrate anions in the structure; the first is coordinated to the zinc atoms; the second is loosely bound to the mercury atoms; the third is uncoordinated and disordered.

$Hg_2(C_4H_6NO)_2X_2$ [X = Cl (**4**), Br (**5**)]

Crystals suitable for single crystal X-ray study were obtaind for **4** but not for **5**. Compound **4** has a loosely linked polymeric structure, the repeat unit of which is shown in Fig. 5. Each such unit contains two chemically distinct mercury atoms. One of them, Hg(1), is bound to two chloride ions [Hg(1)—Cl(1) 2.320(5), Hg(1)—Cl(2) 2.314(5) Å] and also to two pyrrolidone oxygen atoms [Hg(1)—O(1) 2.56(2), Hg(1)—O(2) 2.58(1) Å]. In compounds containing the $HgCl_2O_2$ unit a wide range of O—Hg—O angles is observed, though with retention of an approximately linear Cl—Hg—Cl moiety. In bis(imidazolidinone)dichloromercury(II)[9] the geometry is square-planar, whilst in bis(testosterone)dichloromercury(II)[10] the O—Hg—O and Cl—Hg—Cl angles are 87 and 164°, respectively. In **4**, O(1)—Hg—O(2) = 104.0(5)° and Cl(1)—Hg—Cl(2) = 166.8(2)°.

The second mercury atom, Hg(2), is strongly bound to two pyrrolidone nitrogen atoms [Hg(2)—N(1) 2.04(2), Hg(2)—N(2) 2.00(2) Å] in an essentially linear fashion [N(1)—Hg(2)—N(2) 173.3(6)°]. The observed distortion from linearity may be ascribed to an Hg(2) interaction with an oxygen atom, O(2′), from a 2-pyrrolidone ligand in the next asymmetric unit [Hg(2)—O(2′) 2.62(1) Å]. This linking of adjacent units results in polymeric strands propagated along the *c*-direction (Fig. 6).

Chelation by **1** results in the formation of an eight-membered ring comprising two mercury, two carbon, two nitrogen and two oxygen atoms. The

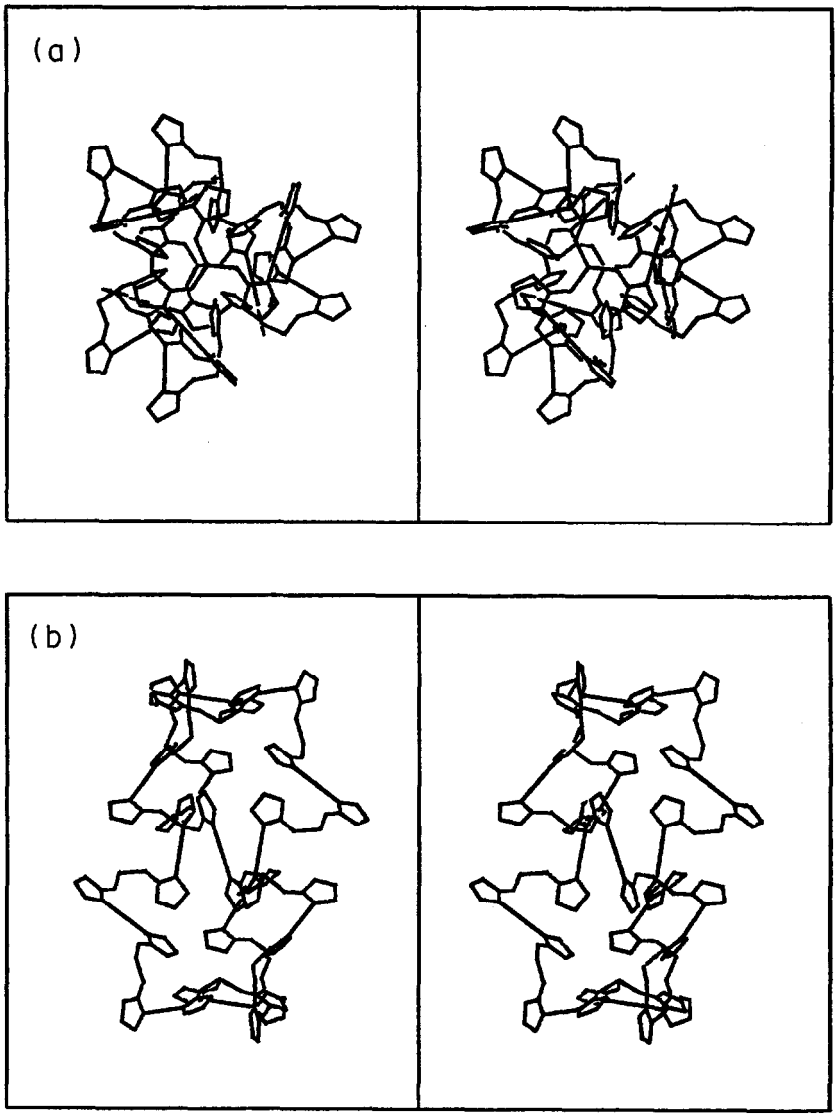

Fig. 2. Stereoscopic view of the packing in **2** showing the macrobicyclic units: (a) plan (viewed down three-fold axis); (b) elevation (viewed down two-fold axis). The anions have been omitted for clarity.
