
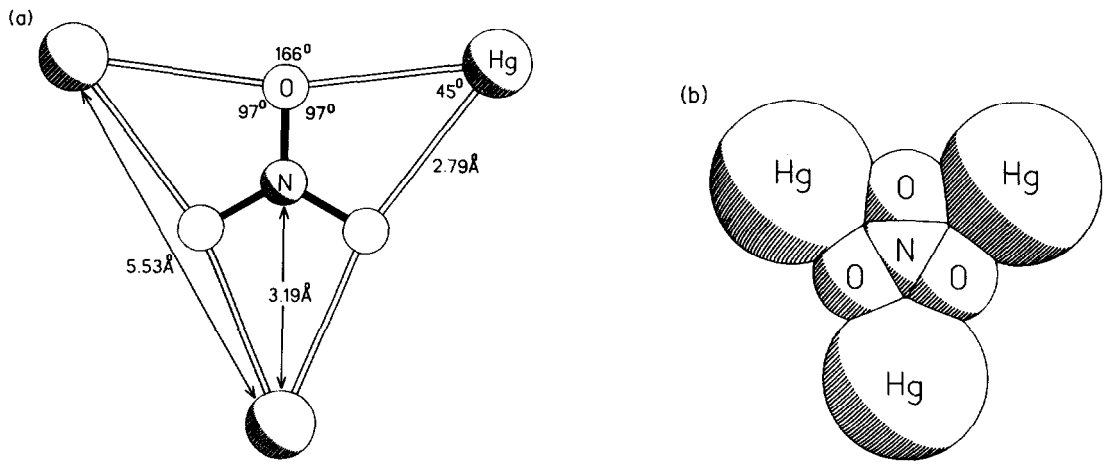

Fig. 3. (a) Skeletal and (b) space-filling representations of the central nitrate environment in **2**.

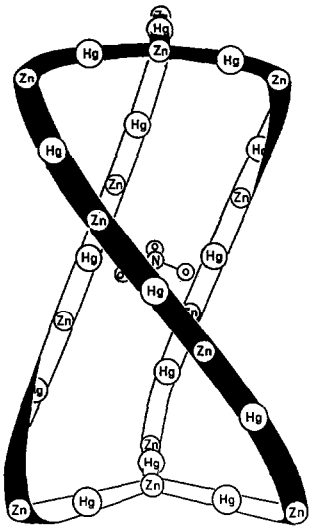

Fig. 4. Schematic representation of the twisted 80-membered macrobicyclic, heterometallic arrays in **2**, also showing the central nitrate ion linking the mercury atoms of each strand.

ring is essentially planar, with the only major deviation from planarity being Hg(1) which lies 0.6 Å below the ring plane, a very similar situation to that in the related Hg/Ag complex.[5] The transannular Hg—Hg distance (3.53 Å) is too long to be considered bonding. This is also true for the Hg(2)—Cl(2) contact (3.33 Å).

In view of the distortion from linearity of the Cl—Hg—Cl unit in **4**, we have studied the effect this has on the metal–halogen stretching bands in the vibrational spectra. For **4** we observed ν_1 (Hg—Cl) at 300 cm^{-1} and ν_3 (Hg—Cl) at 351 cm^{-1}, which are lower than the values reported[11] for linear $HgCl_2$ (ν_1 348, ν_3 405 cm^{-1}). As the analogous bromide, **5**, shows a similar decrease in ν(Hg—Br): ν_1 187, ν_3 249 cm^{-1} (cf. 219 and 294 cm^{-1}, respectively for $HgBr_2$[11]), the Br—Hg—Br unit in **5** is probably also non-linear.

$Hg_3Cd(C_4H_6NO)_6(NO_3)_2$ (3)

Elemental analysis of **3** showed that it had an analogous stoichiometry to the complex $[Hg_3Co(C_4H_6NO)_6(NO_3)_2]_n$ (**6**). Although suitable single crystals of **3** could not be obtained, X-ray powder diffraction photographs confirmed that **3** and **6** are isostructural.

The cobalt atom in **6** is known[1] to be in a slightly *trans*-compressed octahedral CoO_6 coordination geometry (four Co—O bonds of 2.12 Å and two of 2.05 Å). In order to obtain some information about any distortion of the analogous CdO_6 unit, we have used manganese(II) ions as probes for the cobalt and cadmium sites in **3** and **6**, by examining the zero-field splitting (ZFS) in the X- and Q-band EPR spectra of manganese(II) ions doped into these lattices (e.g. Fig. 7). From the Q-band spectrum of **3** the ZFS parameters were calculated to be: $D = -0.037\ cm^{-1}$ and $\lambda (= E/D) = 0.18$. A similar analysis of the spectrum of manganese-doped **6** yielded: $D = -0.034\ cm^{-1}$ and $\lambda = 0.25$. For the latter compound the small value of D and its negative sign (determined as in ref. 12), are in very good agreement with the small axial compression

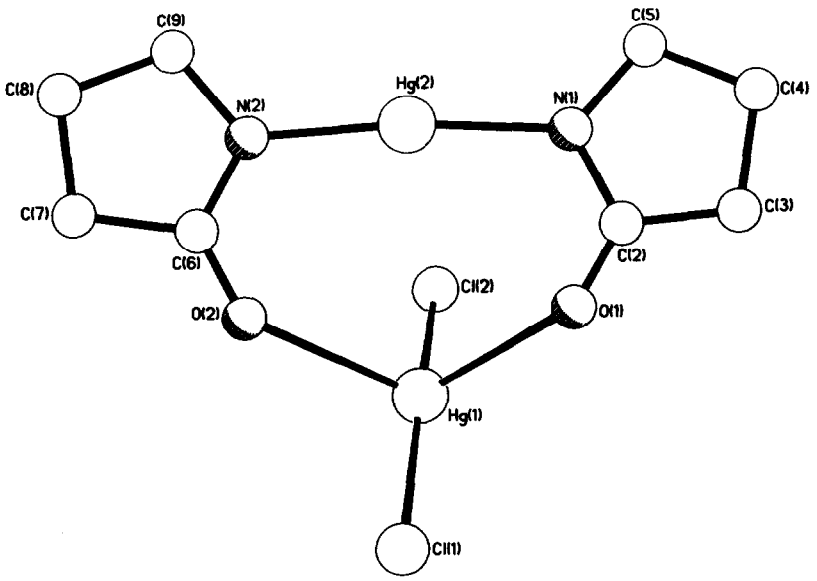

Fig. 5. The molecular structure of **4** showing the crystallographic numbering scheme.

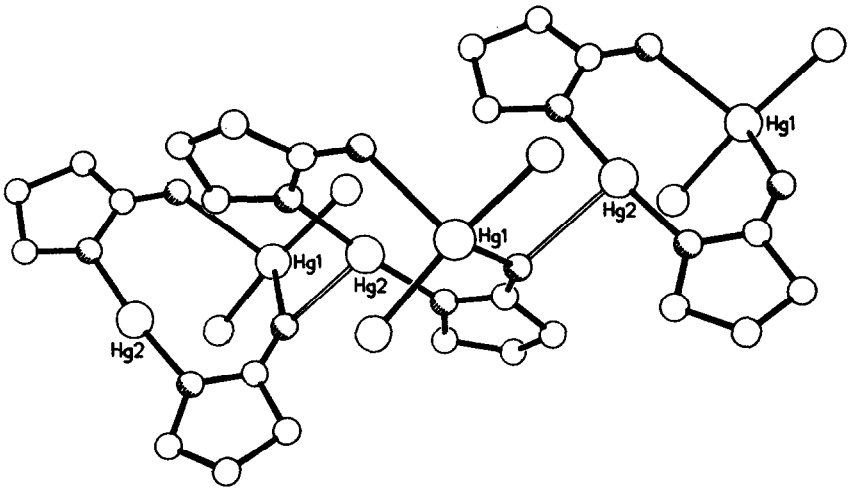

Fig. 6. Part of the polymeric strands in **4**.

observed for the cobalt site in the host lattice. The close similarity of the *D* value found for manganese-doped **3**, both in magnitude and sign, suggests that the cadmium site is also close to octahedral geometry, but with a small axial compression.

DISCUSSION

The two new structural types reported here for compounds **2** and **4** add yet further examples to the novel polymeric heterometallic structures generated by use of **1** as a ligand system. As in the other M/Hg heterometallic compounds formed by **1**, the actual structures adopted, though complex, can be understood by considering both the adoption of a "normal", or near normal, coordination geometry by the metal, M, and the various possible arrangements of **1** as a ligand. The diversity of the ligand behaviour of **1** merits discussion.

The first point to be made is that, from all the structural results we have obtained so far, there is little or no flexibility arising from bending of the N—Hg—N unit. The largest departure from N—Hg—N linearity is 9° in **2**.

That limitation is more than offset by two other factors: (a) the free rotation of the pyrrolidone rings

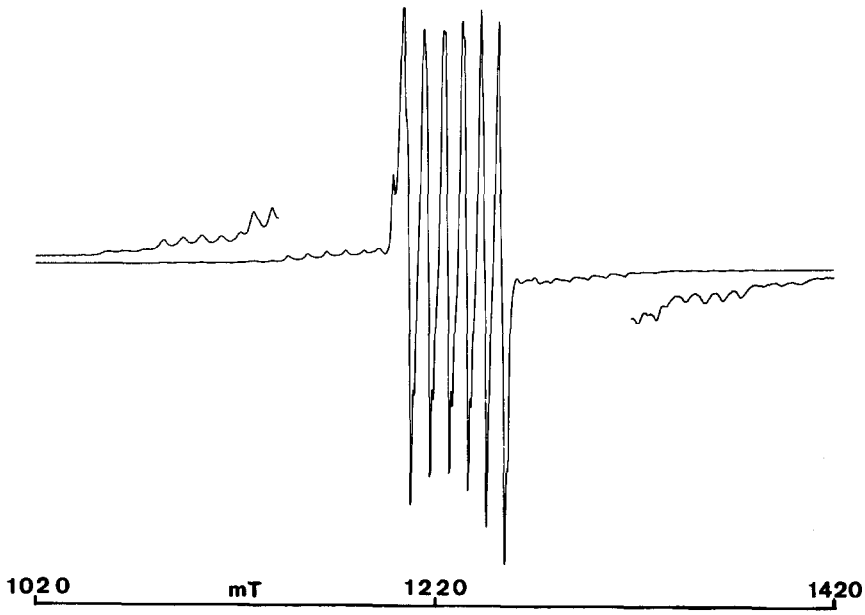

Fig. 7. Q-band EPR spectrum of a manganese(II)-doped sample of **3**.

Table 4. Angle between the mean planes of the pyrrolidone rings in HgL_2 ($L = C_4H_6NO$) in various heterometallic complexes

Complex	Mercury atom	Angle (°)[a]	Reference
$[Hg_2L_2Cl_2]$	Hg(2)	7.0	This work
$[HgAgL_2(NO_3)_2]$	Hg(1)	15.0	5
	Hg(2)	16.9	
$[Hg_3CoL_6(NO_3)_2]_n$	Hg(1)	52.4	1
	Hg(2)	180.0	
$[Hg_3Zn_2L_6(NO_3)_{3.33}(CH_3O)_{0.67}]_n$	Hg	55.7	This work
$[Hg_2EuL_4(NO_3)_3]_n$	Hg(2)	70.8	2
	Hg(1)	107.4

	Hg(1)	133.3	
$[Hg_2CuL_4(ClO_4)_2]_n$	Hg	82.8	4
$[Hg_2CuL_4(NO_3)_2]_n$	Hg	86.1	4
$[Hg_3Tb_2L_6(NO_3)_6]_n$	Hg(1)	110.8	2
	Hg(2)	180.0	

[a] 0° represents *cis*-coplanar, 180° represents *trans*-coplanar.

about the Hg—N bonds and (b) the directionality of the oxygen atom lone pairs of electrons, permitting coordination to other metals in *syn*- or *anti*-dispositions with respect to the mercury atom.

As may be seen from the data collected in Table 4, the mutual free rotation of the pyrrolidone rings about the Hg—N bonds results in a wide range of observed conformations for the HgL_2 unit (where $L = C_4H_6NO$). At the extremes of ring co-planarity, or near co-planarity, the oxygen atoms may be *cis*-disposed (I), O—N—N—O torsion angle *ca* 0° (as in Hg(2) of $Hg_2L_2Cl_2$; torsion angle of 7°) or *trans*-disposed (II), O—N—N—O torsion angle 180° (as in Hg(2) of $[Hg_3CoL_6(NO_3)_2]_n$[1]), but there is also a wide range of intermediate conformations.

Various possible *syn*- and/or *anti*-arrangements for one or two metal ions, M, to bind to **1** are shown in III–VIII (in which, for simplicity, only the NCO fragments of the pyrrolidone rings are shown). Binding modes III and IV are found[5] in $[HgAgL_2(NO_3)]_2$, III is also found in **4**, VI in $[Hg_3CoL_6(NO_3)_2]_n$[1] and VII in $[Hg_3Tb_2L_6(NO_3)_6]_n$.[2] The remaining compounds listed in Table 4 have binding modes related to either V or VII. Clearly it is this capacity of the oxygen atoms to bind in any of these several ways, combined with the possible

VI VII VIII

rotation of the two pyrrolidone rings about the mercury atom, which accounts for the versatility of the system.

(*Received* 4 *January* 1989; *accepted* 21 *February* 1989)

Abstract—Two novel six-nitrogen-donor macrocyclic complex cations of yttrium(III) were obtained from the metal-templated Schiff-base condensation of 1,2-diaminoethane with either 2,6-diacetylpyridine or 2,6-diformylpyridine. The complex cations were isolated as salts of coordinating as well as non-coordinating anions. Single crystal X-ray analysis was carried out for the mixed acetate perchlorate salt of composition $Y(C_{22}H_{26}N_6)(CH_3COO)_2(H_2O)_{0.5}ClO_4$, which crystallized in the triclinic system, space group $P\bar{1}$ with $Z = 2$, in a unit cell having $a = 13.052(2)$, $b = 11.362(2)$, $c = 11.426(2)$ Å, $\alpha = 108.87(4)$, $\beta = 104.73(4)$ and $\gamma = 100.26(4)°$. The structure was characterized by the presence of two slightly different coordination entities, statistically distributed in the crystal lattice in a 1 : 1 ratio. Both entities contained a yttrium(III) ion linked to the six-nitrogen-donor atoms of the macrocycle, which was slightly folded into a butterfly configuration. A bidentate chelating acetate on the convex side of the macrocycle and either a monodentate acetate or a molecular of water on the opposite side, completed the coordination sphere, resulting in coordination number nine. Ionic acetate and perchlorate balanced the residual charges of the complex cations. The yttrium(III) macrocyclic cations remained undissociated in solution, as shown by the chemical behaviour and NMR spectra.

The complexes of the lanthanide(III) ions with six-donor monomacrocyclic ligands have been extensively studied in regard to synthesis, structure and solution properties. The complexes of crown ethers were the first to be obtained and studied;[1] more recently, a number of six-nitrogen as well as mixed nitrogen–oxygen and nitrogen–sulphur six-donor systems have been reported.[2–18] In contrast, very little is so far known on the macrocyclic chemistry of yttrium(III), despite its close similarity to the lanthanide(III) ions in both size and chemical behaviour. A potentially useful series of lanthanide macrocycles is that containing the six-nitrogen cations L_I and L_{II} (Fig. 1), obtained from the metal-templated cyclic Schiff-base condensation of 1,2-

diaminoethane with either 2,6-diacetylpyridine (L_I) or 2,6-diformylpyridine (L_{II}). The salts of these macrocyclic cations with appropriate counterions are unique among the lanthanide complexes in that they are very soluble in water as well as in a variety of organic solvents: furthermore, they are inert towards metal release in solution, even in the presence of acids, bases or competing ligands. We were interested in developing a parallel series of macrocyclic complexes of yttrium(III), in the anticipation that these might similarly exhibit a high degree of kinetic stabilization and thus offer a viable alternative to the use of functionalized aminocarboxylic acids[19] for the attachment of the ^{89}Y isotope to biological substrates.

EXPERIMENTAL

Starting materials and procedures

Yttrium salts, 2,6-diacetylpyridine, 2,6-diformylpyridine and the acids (benzoic, 4-hydroxybenzoic, 4-aminobenzoic, 2-furancarboxylic) were purchased from Aldrich Chemical Co. A solution of 1,2- diaminoethane in anhydrous methanol (0.40 M) was prepared as described.[9] All solvents were reagent grade and anhydrous unless specified otherwise. Microanalysis (C, H, N) were performed by Atlantic Microlab, Atlanta, Georgia and Galbraith Laboratories, Knoxville, Tennessee. IR absorption spectra were obtained with a Perkin–Elmer 283 spectrophotometer (4000–200 cm^{-1}) using both KBr pellets and a combination of Nujol and hexachlorobutadiene mulls.

Template synthesis of $YL_I(CH_3COO)_2Cl \cdot 4H_2O$ ($L_I = C_{22}H_{26}N_6$)

Hydrated yttrium(III) acetate and 2,6-diacetylpyridine were dissolved separately in methanol and mixed with a methanol solution of 1,2-diaminoethane (1:2:2 mole ratio) to produce an approximately 2×10^{-2} M solution with respect to yttrium(III). (Best results were obtained with a freshly prepared solution of 1,2-diaminoethane.) The mixture was heated to reflux for 4 h, during which time the colour changed from bright yellow to light amber. After evaporation of the solution to dryness under reduced pressure, the amber-coloured pasty residue was worked up several times with diethyl ether and the resulting solid was filtered and dissolved in the minimum volume of chloroform. The turbid chloroform solution was clarified with charcoal, filtered and evaporated again to dryness under reduced pressure. The residue was crystallized several times from methanol–diethyl ether, affording small off-white crystals which were dried at room temperature over Drierite (yields: 60–70%). Found: C, 44.6; H, 5.6; N, 11.4. Calc. for $YC_{22}H_{26}N_6(CH_3COO)_2Cl \cdot CH_3OH \cdot 4H_2O$: C, 45.0; H, 6.1; N, 11.7%. The compound gradually lost the methanol when exposed to the atmosphere.

The compound was very soluble in water (*ca* 35 mg cm^3) as well as in most organic solvents, except low boiling ethers and aliphatic hydrocarbons. An intense purple colour developed when benzene–chloroform solutions of the complex were heated to boiling for several minutes; the colour faded gradually when the solution cooled down to room temperature in the presence of air.

The IR spectrum of the complex showed the typical pattern of the macrocycle (see below for bromide complex), together with a very strong, broad absorption centred at 3440–3200 cm^{-1} (ν_{OH}). The major carboxylate absorptions appeared as two very strong and rather narrow bands at 1550 cm^{-1} ($\nu_{COO_{asym}}$) and 1440 cm^{-1} ($\nu_{COO_{sym}}$), and a strong sharp band at 655 cm^{-1} [δ(OCO)].

^1H NMR chemical shifts at 89.56 MHz (δ, ppm relative to TMS): 8.31, 6H, py; 3.95, 8H, CH_2; 3.36, 8H, H_2O; 2.53, 12H, CH_3 of macrocycle; 1.35, 6H, CH_3 of acetate.

Metathesis reactions of the bis-acetate-chloride complex of the yttrium(III)–L_I *cation*

(1) Exchange of all anions of the diacetate–chloride with bromide was achieved by warming a methanol solution of the original complex with a two-fold molar excess of conc. hydrobromic acid diluted in methanol at 40°C for 1 h. The resulting solution was chilled at 0°C and diluted with diethyl ether; the nearly colourless crystals that formed (yield: 55%) were filtered, washed with methanol–ether (1:10) and dried over Drierite. Found: C, 33.4; H,

4.6; N, 10.5. Calc. for $Y(C_{22}H_{26}N_6)Br_3 \cdot 5H_2O$: C, 33.3; H, 4.6; N, 10.6%.

The IR spectrum showed the following absorptions (cm^{-1}): 3500–3000 vs, vbr (ν_{OH}), 1660 and 1605, vs, sharp ($\nu_{C=N}$), 1430 m, 1385 vs, 1330 vw, 1303 w, 1268 s, 1230 sh, 1190 s, 1155 vw, 1125 vw, 1065 vw, 1003 m, 975 vw, 930 vw, 880 vw, 808 s, 735 m, 710 vs, 640 vw, 600–400 w,vbr, with peak at 580 m (ρ_{H_2O}). Except for the presence of the water absorptions, this spectrum may serve as an identifying fingerprint for the $C_{22}H_{26}N_6$ macrocycle free of interference from anion absorptions.

(2) Partial exchange of the acetates by chloride was accomplished by dissolving the diacetate–chloride complex in a small volume of methanol, adding conc. hydrochloric acid diluted with methanol (HCl–complex mole ratio, approximately 5:1), and warming the mixture for 1 h at 40°C. Dilution of the resulting chilled solution with diethyl ether gave nearly colourless microcrystals that were filtered, washed with methanol–ether (1:10) and dried over Drierite (yields: 60%). Found: C, 41.1; H, 5.5; N, 12.5. Calc. for $Y(C_{22}H_{26}N_6)(CH_3COO)_{0.5}Cl_{2.5} \cdot 5H_2O$: C, 41.1; H, 5.6; N, 12.5%. The IR spectrum showed the typical macrocycle pattern (see bromide complex) as well as water and acetate absorptions: 1530 cm^{-1} ($\nu_{COO_{asym}}$) and 1460 cm^{-1} ($\nu_{COO_{sym}}$).

(3) Exchange of chloride by perchlorate was accomplished by dissolving the diacetate–chloride complex in a small volume of methanol, adding a five-fold molar excess of solid $LiClO_4$, filtering the resulting cloudy solution and allowing it to stand loosely covered for 1 week at room temperature. The transparent, light amber crystals that formed became cloudy and crumbled upon exposure to the atmosphere; those used for X-ray analysis were stored and handled in their mother liquor.

(4) Reaction of the diacetate–chloride complex with a two-fold excess of $LiBF_4$ in methanol gave nearly colourless microcrystals of the tris-tetrafluoroborate (yield: 75%). Found: C, 29.1; H, 5.7; N, 11.3. Calc. for $Y(C_{22}H_{26}N_6)(BF_4)_3 \cdot 2H_2O$: C, 29.0; H, 5.7; N, 11.3%. The IR spectrum showed, in addition to the typical macrocycle absorptions, a band centred at 1050 cm^{-1} (vs,br) and one at 510 cm^{-1} (m) arising from the ν_3 and ν_4 modes of ionic BF_4^-.

(5) Exchange of the acetates by other carboxylates (benzoate, 4-hydroxybenzoate, 4-aminobenzoate, 2-furancarboxylate) was accomplished by mixing methanol solutions of the diacetate–chloride complex and of the substituent acid (mole ratio, 1:2), warming the mixture at 40°C for 1 h and cooling for 1–2 days in a refrigerator. The nearly colourless crystalline solids that formed were filtered, washed with a small volume of methanol and dried *in vacuo* over Drierite (yields ranged from 50 to 85%). Found: C, 49.7; H, 5.3; N, 10.1. Calc. for $Y(C_{22}H_{26}N_6)(C_6H_4COO)_2Cl \cdot 4H_2O$. C, 49.7; H, 5.2; N, 10.1%. Found: C, 50.6; H, 5.3; N, 10.3. Calc. for $Y(C_{22}H_{26}N_6)(OHC_6H_4(COO)_{1.75}Cl_{1.25} \cdot 4H_2O$: C, 50.2; H, 5.3; N, 10.3%. Found: C, 51.1; H, 5.4; N, 13.2. Calc. for $Y(C_{22}H_{26}N_6)(NH_2C_6H_4COO)_2Cl \cdot 4H_2O$: C, 51.3; H, 5.7; N, 13.3%. Found: C, 46.8; H, 5.3; N, 10.2. Calc. for $Y(C_{22}H_{26}N_6)(C_4H_3OCOO)_2Cl \cdot 5.5H_2O$: C, 46.9; H, 5.3; N, 10.3%. The IR spectra of all these complexes showed the pattern of the macrocycle together with the absorptions of water and of the respective carboxylate.

Template synthesis of $YL_{II}(CH_3COO)_2Cl \cdot 4H_2O$ ($L_{II} = C_{18}H_{18}N_6$)

This compound was obtained from hydrated yttrium(III) acetate, 2,6-diformylpyridine and 1,2-diaminoethane as described for the 2,6-diacetylpyridine analogue, except that the handling of the aldehyde precursor and the template synthesis were carried out in a nitrogen atmosphere. The product (off-white crystals) was obtained in *ca* 70% yields after two recrystallizations from methanol–diethyl ether. Found: C, 41.7; H, 4.9. Calc. for $Y(C_{18}H_{18}N_6)(CH_3COO)_2Cl \cdot 4H_2O$: C, 41.8; H, 5.1%. IR absorptions (cm^{-1}): 3480–3200 vs, vbr (ν_{OH}), 3068 vw, 2922 vw, 2862 vw, 1662 and 1594 vs, sharp ($\nu_{C=N}$), 1540 vs ($\nu_{COO_{asym}}$), 1456 ($\nu_{COO_{sym}}$), 1424 sh, 1385 w, 1338 w, 1277 m, 1253 sh, 1162 m, 1103 w, 1077w, 1045 m–s, 1006 m–s, 983 vw, 956 vw, 936 vw, 824 m, 810 m, 748 w, 680 s (δ_{OCO}), 645 w, 617 vw, 602 vw.

Thermogravimetric measurements

A computer driven Perkin–Elmer TGS System 4 Thermogravimetric Analyser was used, with a dry helium flow of 60 cm^3 min^{-1}. It was observed that some samples underwent a variable-rate mass loss at room temperature when placed under the helium flow; exposure to the atmosphere immediately regenerated the original mass, thus ruling out the possibility that some of the sample had been blown off the balance pan. For this reason, heating of the samples was started after the mass had reached an approximately constant value under helium flow at 25°C. All experiments gave the same general pattern: a first mass loss (4–10%) occurred in either one or two steps at a temperature lower than 120°C, a second mass loss occurred above 180°C and gradual decomposition set in at about 250°C. Samples heated up to 250°C rehydrated instantly upon

cooling and exposure to the atmosphere; their masses and IR spectra were than identical to those of the original samples. Samples heated above 250°C had a slightly charred appearance and less sharp IR spectra. It was observed that samples heated in a helium atmosphere or *in vacuo* above 150°C changed from colourless to deep blue–purple; the colour faded rapidly upon cooling in air but persisted for hours *in vacuo* at room temperature. Representative thermogravimetric results follow: $Y(C_{22}H_{26}N_6)Br_3 \cdot 5H_2O$: mass loss of 9.3% in a step centred at *ca* 110°C (calc. for four H_2O, 9.35%); 2.1% loss between 200 and 250°C (calc. for one H_2O, 2.3%). $Y(C_{22}H_{26}N_6)(C_4H_3COO)_2Cl \cdot 5.5H_2O$: mass loss of 4.49% in a step centred at *ca* 35°C and 1.42% in a step centred at *ca* 105°C, corresponding respectively to two H_2O (calc. 4.39%) and less than one H_2O (calc. for one H_2O, 2.20%). Partial loss of water occurred during equilibration in dry helium flow.

X-ray measurements and structure determination of the yttrium(III)–L_I diacetate perchlorate complex

A transparent, pale yellow, prismatic single crystal of dimensions 0.16 × 0.20 × 0.30 mm was centred on a four-circle Philips PW 1100 diffractometer with graphite-monochromated Mo-K_α radiation. A total of 4771 reflections ($2\theta_{max} = 50°$) were measured, which when merged gave 2959 unique reflections with $I \geqslant 3\sigma(I)$. The intensity data were corrected for Lorentz polarization effects and for absorption, following the method of North *et al.*[20] The structure was solved using three-dimensional Patterson and Fourier techniques and refined with full-matrix least-squares. Hydrogen atoms were introduced at calculated positions and were allowed to ride on associated carbon atoms during the least-squares refinement ($d_{C-H} = 0.98$ Å and $U_{iso} = 0.07$ Å^2). Atomic scattering factors were taken from ref. 21. Data processing and computations were carried out by using the SHELX 76 program package.[22]

In the last stages of refinement, difficulties were encountered in identifying either the species in the ninth coordination position or the positions of the counter ions. While the O(41) position was well identified, the final difference Fourier map showed electron density residuals of the order of 3 e Å^{-3}. These could be best interpreted by considering the O(41) position to be occupied by the oxygen atom of either a water molecule or a monodentate acetate, each with 50% occupancy. Other residuals were accounted for by a statistical distribution of the ionic acetates [0.5 mol/yttrium(III)], together with the disordered perchlorate, as required for complete charge balance. Another minor residual, 0.8 e Å^{-3}, suggested that an even more complicated statistical distribution of the anions might occur; the presence of traces of methanol and water molecules could not be excluded. The best refinement was achieved for the molecular composition $[YL_I(CH_3COO)(H_2O)_{0.5}(CH_3COO)_{0.5}](CH_3COO)_{0.5}(ClO_4)$, which is consistent with IR spectral properties.

Crystal data

$C_{26}H_{33}N_6O_{8.5}ClY$, $M = 689.94$, triclinic space groups $P1$ or $P\bar{1}$ ($P\bar{1}$ was confirmed after structure solution). $a = 13.052(2)$, $b = 11.362(2)$, $c = 11.426(2)$ Å, $\alpha = 108.87(4)$, $\beta = 104.73(4)$, $\gamma = 100.26(4)°$, $U = 1486.60$ Å^3, $Z = 2$, $D_c = 1.54$ Mg m^{-3}, $F(000) = 710$, μ(Mo-K_α) = 20.50 cm^{-1}. Supplementary material (tables of atomic coordinates, atomic vibrations and calculated structure amplitudes) have been deposited with the Editor. Atomic coordinates have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and spectral properties

The metal-templated synthesis and general properties of the yttrium(III) six-nitrogen macrocyclic complexes, L_I and L_{II}, closely resembled those of the previously reported corresponding complexes of the lanthanide(III) ions.[2,7,9,12] The yttrium(III) macrocyclic entitites had a very high thermal stability, as shown by their thermogravimetric behaviour. In the example of $YL_IBr_3 \cdot 5H_2O$, four of the water molecules were lost below 120°C but the yttrium(III) macrocyclic cation remained essentially undecomposed up to 250°C, this was confirmed by the IR spectrum of samples isolated after the thermobalance experiment. The yttrium(III) macrocycles were also inert with respect to metal release in solution. Their very simple NMR spectra were consistent with the highly symmetrical structures shown in Fig. 1,[10] and no change was observed over a period of time, even in a strongly coordinating solvent such as dimethylsulphoxide.

Treatment with a variety of coordinating and non-coordinating counterions, as well as with strong acids, resulted in anion metathesis without disruption of the macrocyclic entities. Thus, reaction with the stoichiometric quantity of aromatic monocarboxylic acids resulted in exchange of the acet-

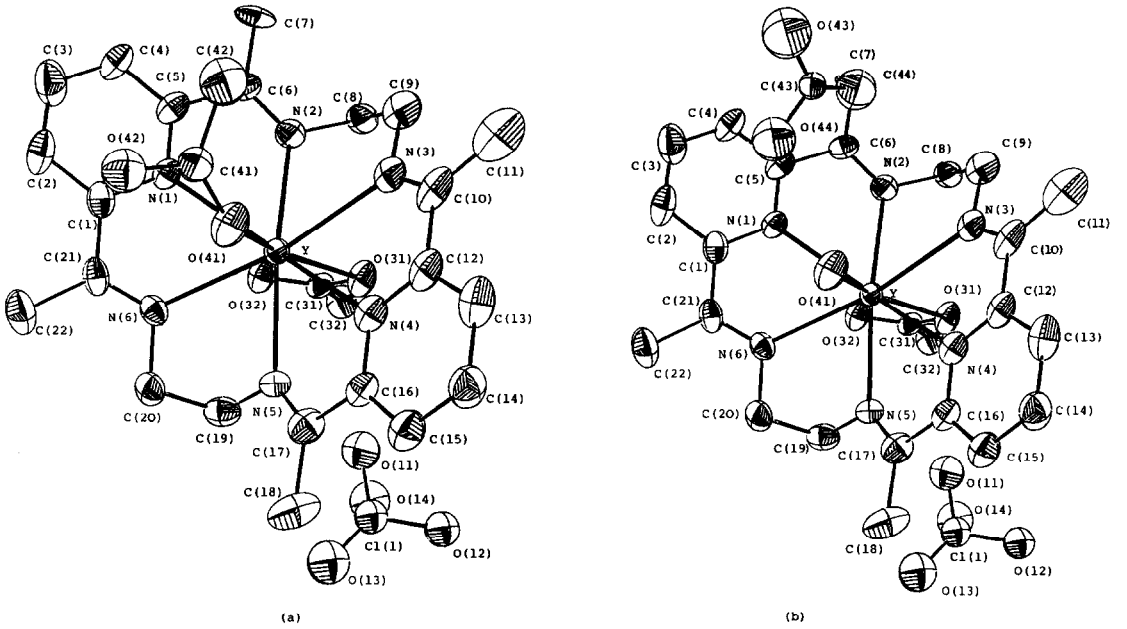

Fig. 2. ORTEP perspective views: (a) $[YL(CH_3COO)_2](ClO_4)$; (b) $[YL(H_2O)(CH_3COO)](CH_3COO)(ClO_4)$. The thermal ellipsoids are at 40% probability.

ates by other monocarboxylates and formation of complexes with the general formula $YL_IX_2Cl \cdot nH_2O$ (X = benzoate, 2-furancarboxylate, 2-hydroxobenzoate, 2-aminobenzoate). Treatment of the diacetate chloride with an excess of $LiClO_4$ resulted in exchange of chloride by perchlorate, yielding a complex of stoichiometry $YL_I(CH_3COO)_2ClO_4 \cdot 0.5H_2O$, the structure of which is discussed in the following section. Finally, substitution of both acetates and chloride was obtained by treatment with a two-fold excess of concentrated hydrobromic or a five-fold excess of $LiBF_4$, resulting in complexes of the formula $YL_IX_3 \cdot nH_2O$ ($X = Br^-$ or BF_4^-).

The IR spectrum of the tribromide complex, being free from anion absorptions, provided a useful "fingerprint" pattern for the identification of the absorptions of the macrocyclic moiety as well as of the anions in other complexes. Especially characteristic were the two intense and sharp absorptions near 1650 and 1600 cm^{-1}, arising from the C=N stretching vibrations. A comparison of the spectrum of the diacetate chloride of the Y—L_I complex with that of the tribromide allowed the unambiguous identification of the carboxylate stretching absorptions as the two very strong and relatively narrow bands at 1550 and 1460 cm^{-1}. The frequency difference between the two bands, $\Delta\nu = 90$ cm^{-1}, suggests that the two acetates present in this complex are both coordinated as bidentate chelating ligands.[23]

Crystal structure of the YL_I *diacetate perchlorate complex*

This compound contains two different complex cations, $[YL_I(CH_3COO)_2]^+$ and $[YL_I(H_2O)(CH_3COO)]^{2+}$, present in a 1:1 ratio in the crystal lattice. The charge of the 1+ cation is balanced by a disordered ionic perchlorate, that of the 2+ cation is balanced by a disordered ionic perchlorate and an ionic acetate. The bonding and conformation of the two Y—L_I complex cations are illustrated in Fig. 2, which also shows the atomic numbering scheme. In each case, the yttrium(III) is nine-coordinate and is bonded to the six nitrogen atoms of the macrocycle, which is slightly folded in a butterfly configuration. In addition, the yttrium(III) is bonded to the two oxygen atoms of a bidentate acetate on the convex side of the macrocycle, and to either a monodentate acetate [Fig. 2(a)] or a water molecule [Fig. 2(b)] on the opposite side. The coordination geometry is the same for both complex cations and is best described, despite the distortion imposed by the presence of a short-span bidentate acetate, as a monocapped square antiprism in which the two bases are defined by [N(1), N(2), O(32), N(6)] and [N(3), O(31), N(5), O(41)], respectively, and the capping position is occupied by N(4).

The bond distances and angles for the two complex cations (a) and (b) are reported in Table 1; significant torsion angles are given in Table 2. The

macrocyclic moieties, identical in (a) and (b), consist of two nearly planar sections, C(8)—N(2)···N(6)—C(20) and C(19)—N(5)···N(3)—C(9), with deviations from their best mean planes ranging from −0.17 to 0.20 Å. The macrocycle is folded in the direction of a singly coordinated ligand (water or acetate), with a dihedral angle of 115.7(1)°; the torsion angles N(2)—C(6)—C(9)—N(3) and N(5)—C(19)—C(20)—N(6) are 54(1) and 55(1)°, respectively. The metal coordination sphere is characterized by three slightly different pairs of yttrium–nitrogen bond lengths, the bonds of each pair being *trans* to each other. The Y—N$_{py}$ distance is 2.582 Å (averaged value), the Y—N$_{imine}$ distance for the Y—N(3) and Y—N(6) pair is 2.610 Å, and that for the Y—N(2) and Y—N(5) pair is 2.524 Å. In the organic part of the macrocycle, the average bond distances and angles have the expected values: C=N = 1.27 Å, C—N$_{py}$ = 1.35 Å and C—C$_{py}$ = 1.37 Å.

The presence of two complex species of different stoichiometries statistically distributed in the crystal lattice and accompanied by disordered solvent molecules and disordered anions is unusual but

not unique. A somewhat similar situation has been reported for a complex of lanthanium(III) chloride with a bicyclic polyether,[24] in which the presence of (often disordered) solvent molecules promotes crystallization, most likely through the formation of hydrogen bonds. An even closer similarity exists with the lutetium(III) complex of the L_I macrocycle having the formula $[LuL_I(CH_3COO)(H_2O\ 50\%, CH_3OH\ 50\%)](CH_3COO)(ClO_4)(H_2O)_{0.5}$.[10] The structure of this lutetium(III) complex is actually very similar to that of the yttrium(III) complex described in the present work. In both compounds the metal ion is nine-coordinate and bound to the six nitrogen atoms of the macrocyclic ligand, to a bidentate acetate on one side of the macrocycle and to a single O-donor ligand on the other side. In both compounds the macrocycle is hinged at the flexible ethylenediamine segments, resulting in a "butterfly" configuration that relieves steric strain and allows the metal ion to best fit into the ligand cavity. The yttrium(III) and lutetium(III) complexes thus differ only in the identity of the single ligands [50% monodentate acetate and 50% water for yttrium(III), 50% methanol and 50% water for lutetium(III)] that occupy the axial coordination position on the concave side of the macrocycle. This facile interchange of neutral as well as anionic axial ligands within the crystal structure is consistent with the high lability of the exocyclic ligands observed in solution. It should be pointed out that the lutetium(III) and yttrium(III) complexes, even though not strictly isostructural, have very similar cell parameters; also, bond lengths and angles follow a parallel trend, differing in magnitude only to the extent expected from the different sizes of the metal ions.[25] These similarities are illustrated by the representative values reported in Table 3. It is instructive to further compare the structure of the Y—L_I macrocycle with that of the complex cation $[YCl(H_2O)_2(18\text{-crown-}6)]^{2+}$, present in the complex of formula $[Y(H_2O)_7(CH_3OH)][YCl(H_2O)_2(18\text{-crown-}6)]Cl_7 \cdot 2H_2O$.[26] In the 18-crown-6 complex the yttrium(III) is again nine-coordinate and the crown ether ligand is folded in the direction of the single chlorine ligand, with the two water molecules bound on the opposite side. The resulting coordination geometry is described as a tricapped trigonal prism distorted towards a capped square antiprism, and thus approaches that observed in the Y—L_I cation. In the crown complex, the Y—O_{crown} bond distances average 2.44(5) Å vs an average value of 2.572(8) Å for the Y—N_{cycle} bonds of the Y—L_I complex. Conversely, the average of the Y—O_{water} bonds (2.36(3) Å) in the crown complex is shorter than the Y—$O_{water\ or\ monodentate\ acetate}$ (2.274 Å) in the Y—L_I complex. These variations are consistent with the usual trends in M—O and M—N bond lengths for neutral and anionic ligands.

CONCLUSIONS

The results reported here show that yttrium(III) acetate is an effective template for the cyclic Schiff-base condensation of suitable diamine and dicar-

bonyl precursors, producing complex cations in which the yttrium(III) ion is linked to the six-nitrogen-donor atoms of an 18-atom macrocyclic cavity and to the O-donor atoms of exocyclic ligands (anions or solvent molecules). In solution, the exocyclic ligands are labile and easily undergo metathesis, whereas the macrocyclic cations are inert and retain their identity even in very dilute aqueous solution and in the presence of acids and competing ligands. Coupling of these macrocyclic complexes to a substrate via a functional group present in the periphery of the organic moiety should, therefore, result in attachment of the yttrium(III) to a substrate, in a manner unaffected by dilution and pH changes. Work is in progress to achieve peripheral functionalization of the yttrium macrocycles and their coupling to representative substrates.

(*Received* 19 *October* 1988; *accepted* 10 *March* 1989)

Abstract—We show how geometrical selection rules (such as those due to McIvor and Stanton) may be applied to cluster rearrangements to provide further insight into the types of process which may occur. We also demonstrate how a second-order Jahn–Teller vibrational analysis fits in with the orbital symmetry selection rules for diamond–square–diamond processes.

The theoretical study of rearrangements in cluster compounds has recently been elegantly analysed using Stone's Tensor Surface Harmonic (TSH) theory.[1,2] The new approach, discussed in Parts I and II in this series, enables some cluster rearrangement processes which have an orbital crossing, and are therefore "forbidden" in the Woodward–Hoffmann sense,[3] to be identified very simply. In Part I we also explained, in terms of TSH theory, why Lipscomb's diamond–square–diamond (DSD) process[4] (illustrated in Fig. 1) should generally be energetically favourable.

The conclusion of Part I was that transition states between *closo* boranes or carboranes with a single atom on a principal rotation axis of order three or more will generally have an orbital crossing, and hence be high energy processes. The effect of lower symmetry environments, for example, when there is a single atom on a two-fold axis, was also considered. In Part II this result was extended to show that an orbital crossing will generally result if a mirror plane through the critical face is retained throughout the process. If a C_2 axis is retained, however, then there is an avoided crossing and the process is "allowed".

Using the above rules, and the additional criterion that multiple DSD processes are likely to be less favourable than the single DSD process, it is possible to rationalize the whole range of rearrangement rates of the *closo* boranes and carboranes. In Part II we also discussed the application of the rules to rearrangements of transition metal clusters, and suggested some new mechanisms for these species.

Recently, Rodger and Johnson have considered the geometrical symmetry selection rules for the rearrangement of transition metal clusters with between five and 12 atoms.[5] This approach is not concerned with the conservation of *orbital* symmetry, but with the fact that any reaction mechanism must follow a vibrational normal mode of the cluster at every point. These authors consider single edge-cleavage processes only, on the grounds that these are expected to be most favourable. Some of these mechanisms correspond to the diamond–square–diamond processes considered previously,[1] except that they are considered to be stepwise if more than one edge must be broken. In fact all of the processes considered in Part I are geometrically allowed because they all follow normal modes. The purpose of this paper is to eliminate some candidate

* For Parts I and II, see refs 1 and 2, respectively.

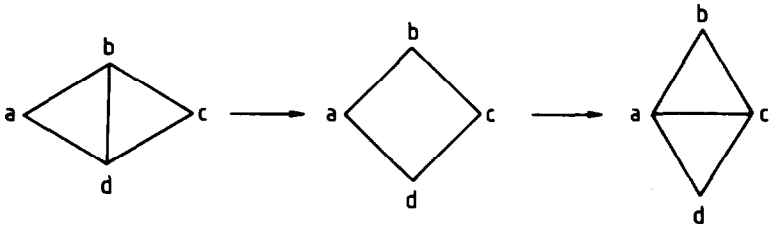

Fig. 1. The diamond–square–diamond process.

structures as transition states using the McIvor–Stanton theorems[6] or the classical selection rules as formulated by Rodger and Schipper.[7] Furthermore, considering the symmetry properties of the transition vector for the DSD process in the point groups C_s and C_2 shows that the orbital symmetry rules developed in Parts I and II are consistent with a vibrational symmetry analysis.

GEOMETRICAL SELECTION RULES

Murrell and Laidler[8] first emphasized the requirement that a true transition state must have precisely one negative "force constant"; that is one normal mode with an associated imaginary frequency. This follows from a straightforward consideration of the multidimensional potential energy surface; if there were two normal modes with negative force constants then the "transition state" would be a hill rather than a saddle point, and there would be a lower energy pathway connecting reactants and products. McIvor and Stanton extended this group theoretical analysis and derived several theorems concerning the transformation of the transition vector and the effect of transition state symmetry operations on the reactants and products.

Their method may be applied as follows. First we assume that the transition state has some specific geometry and find its point group. Then we sketch the displacements of the atoms to their equilibrium positions in the products and reactants. These unlabelled displacement vectors can be regarded as the objects acted upon by the symmetry operations of the transition state point group. If it happens that a symmetry operation of the putative transition state converts the product displacements into reactant displacements, then the transition vector must be antisymmetric under this operation. (The transition vector lies in the direction of the critical normal mode with the negative force constant.) There are various other restrictions on the transformation properties of the transition vector which apply if a symmetry operation maps a reactant onto an equivalent structure.[6] Furthermore, the transition vector must belong to a non-degenerate irreducible representation of the transition state point group by the Murrell–Laidler theorem.

For our purposes the most important result of Stanton and McIvor's work is the antisymmetric nature of the transition vector under operations which interconvert reactant and product displacements. This has an important corollary that a transition state cannot have an odd degree symmetry element linking the product and reactant displacements.[6] (A symmetry element has odd degree if it must be repeated an odd number of times to achieve the identity operation.) The most important examples in this paper will involve structures with a C_3 symmetry axis. Note, however, that this method can only rule out a candidate structure as a transition state for a particular process. It cannot determine whether the structure may be a true transition state for a different reaction, or indeed an intermediate with no negative force constants.

In Rodger and Schipper's approach, the stationary permutation–inversion operations of the product and reactant molecules are considered.[7] With the assumption that all the common stationary operations are preserved throughout the reaction path, it is possible to deduce the symmetry of the transition state, if there is one, for concerted processes which involve only permutations of identical atoms (homoconversions). In fact we can summarize their results for such cases as follows: a transition state for a concerted homoconversion along a maximal symmetry path must have an even-order operation which is not present in the product or reactant. This is a necessary but not a sufficient condition because the operation in question must also be a product generator operation.[7] However, it provides a simple first criterion for examining possible transition state geometries.

For heteroconversions, in which the product is not simply related to the reactant by a permutation of identical nuclei, the geometrical selection rules for concerted processes are much less restrictive. Rodger and Schipper have tabulated the vibrational modes which relate particular point groups, and the presence or absence of modes of the required type is

now the determining factor. In fact their tabulation shows that there is very often a mode (usually E-type) which breaks all the symmetry, and this may help to explain why so many transition states are calculated to have C_1 symmetry.[9] Exceptions arise for point groups with no E modes such as C_{2v}.

APPLICATION TO CLUSTER REARRANGEMENTS

We will consider three specific examples using the McIver–Stanton approach. In each case two DSD processes result in a permutation of the vertices of the starting geometry. First consider the single DSD process leading from the pentagonal bipyramid to the capped octahedron (Fig. 2). The capped octahedron has C_{3v} symmetry and the reactant displacements are clearly mapped onto the product displacement by a C_3 rotation. Since this operation has odd degree, we conclude that the capped octahedron cannot be a transition state for the stepwise double DSD process. It is easy to see that it would be impossible to find a transition vector antisymmetric to this operation: such a species would also have to be antisymmetric under C_3^3, which is the identity operation. This does not preclude the possibility that this structure may be a metastable intermediate, although orbital symmetry considerations suggest that this mechanism probably represents a high-energy process.[2]

The second example is the single DSD process for the bicapped square antiprism (Fig. 3). Again this

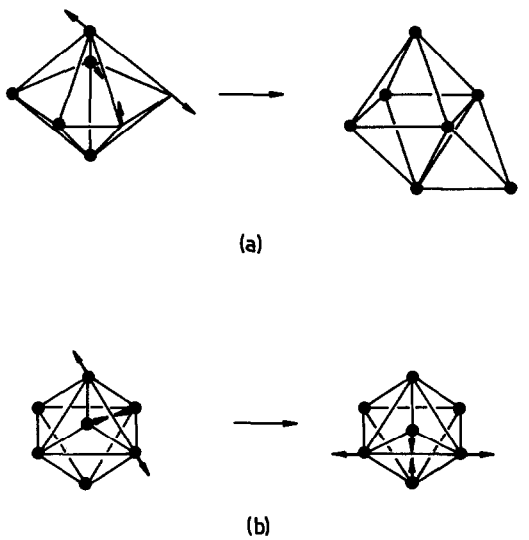

Fig. 2. (a) The single DSD process leading from the pentagonal bipyramid to the capped octahedron, for which (b) the reactant and product displacements are related by a C_3 rotation.

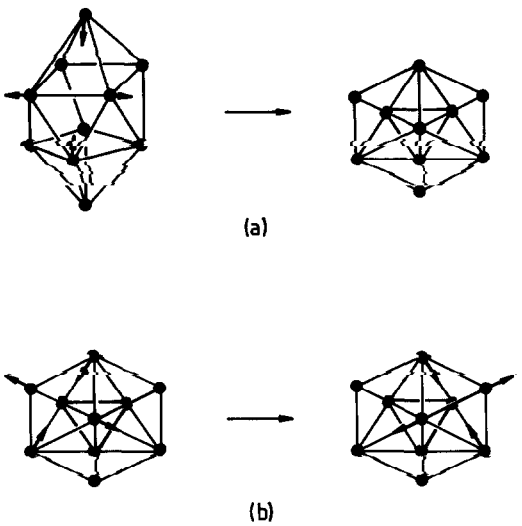

Fig. 3. (a) A single DSD process leading from the bicapped square antiprism to the C_{3v} deltahedron for which (b) the reactant and product displacements are related by a C_3 rotation of the transition state point group.

leads to a C_{3v} intermediate structure for which the reactant and product displacements are related by a C_3 rotation. Hence, we can again conclude that this geometry cannot be a true transition state for the non-concerted double DSD process. There is no such prohibition on the concerted double DSD, however. Furthermore, in this and the previous example a mirror plane through the critical face is considered during each single DSD process. However, this does not necessarily lead to an orbital crossing because the steps do not lead back immediately to the starting geometry. Instead, each intermediate structure has a non-bonding e pair of orbitals at the HOMO–LUMO level, arising from the single atom on the three-fold rotation axis.[1] There is bound to be a significant rise in the total orbital energy for this open shell configuration because the doubly occupied e pair is non-bonding. We conclude that these structures cannot be true transition states and furthermore that they entail significant rises in the electronic energy.

In contrast, consider the single DSD process illustrated in Fig. 4 for the tricapped trigonal prism which leads to a C_{2v} symmetry deltahedron. In this case the point group of the possible transition state contains no odd-order operations. The reactant and product displacements are related by a C_2 operation and one of the reflections, while both sets of displacements are mapped onto themselves under reflection in the other mirror plane. Hence, the transition vector must be antisymmetric under the former operations and symmetric under the

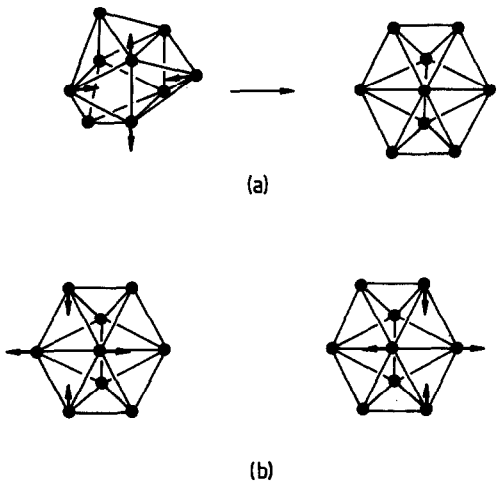

Fig. 4. (a) A single DSD process leading from the tricapped trigonal prism to a C_{2v} symmetry deltahedron and (b) the reactant and product displacements.

latter. It must therefore transform as either B_1 or B_2, depending upon the choice of axes.

The reader may verify that the same conclusions can be reached using the general principle for concerted maximal symmetry homoconversions deduced from Rodger and Schipper's results at the end of the previous section.

THE SECOND-ORDER JAHN–TELLER EFFECT

In this section we will examine the DSD mechanism using the symmetry properties of the terms arising in a perturbation theory analysis of the energy of a distorted molecule.[10] Consider distortion along a normal mode of symmetry species S_i. Using first- and second-order perturbation theory the energy of the distorted system may be written as[10]

$$E(S_i) = E_0 + S_i \int \psi_0 \hat{H}_i \psi_0 \, d\tau + \tfrac{1}{2} S_i^2 \left[\int \psi_0 \hat{H}_{ii} \psi_0 \, d\tau - 2 \sum_m{}' \frac{|\int \psi_0 \hat{H}_i \psi_m \, d\tau|^2}{\Delta E_{m0}} \right].$$

Where ψ_0 is the ground-state wavefunction of the undistorted geometry, ΔE_{m0} is the zeroth-order energy separation between the states ψ_0 and ψ_m of the undistorted geometry, $\hat{H}_i = (\partial \hat{H}/\partial S_i)_0$ and $\hat{H}_{ii} = (\partial^2 \hat{H}/\partial S_i^2)_0$. E_0 is the unperturbed energy of the system and $S_i \int \psi_0 \hat{H}_i \psi_0 \, d\tau$ is the first-order Jahn–Teller term which is not important for non-degenerate electronic states because it vanishes. The term in square brackets can be identified with the "force constant" for distortion along the normal mode in question and can be divided into two parts. The first part, involving the second derivative, represents the nuclear motion in a fixed electron distribution, while the second term represents the "relaxation" of the electron distribution in respect to the nuclear displacement. If this "force constant" is negative then the energy of the system is lowered on distortion and we have a second-order Jahn–Teller effect.

It is often productive to proceed in a non-rigorous manner and consider only the contribution of the HOMO–LUMO mixing to the second part of this term.[10] In this case one simply seeks a normal mode whose symmetry species is contained in the direct product of the symmetry species of the HOMO and the LUMO (and recall that the term $(\partial \hat{H}/\partial S_i)_0$ transforms like S_i). Distortion along such a mode results in the HOMO and LUMO splitting further apart through their mutual admixture, and we will now consider when this occurs for possible single DSD "transition states" of different symmetry.

Consider the product and reactant displacements for the single DSD process sketched in Fig. 5. If the cluster has C_{4v} symmetry it follows from the McIvor–Stanton rules[6] that the transition vector must be antisymmetric under C_4, C_4^3 and σ_d, i.e. it must transform like x^2-y^2. This, in fact, simply corresponds to the displacements as sketched. Now consider descent in symmetry to the point group C_2. The HOMO and the LUMO of the hypothetical *nido* cluster both transform as B in this point group,[2] and the DSD transition vector transforms as A. Since $B \otimes B = A$, we conclude that the contribution of the particular energy term considered above would be non-zero and therefore negative. In C_s, on the other hand, when a diagonal mirror plane is retained, the DSD transition vector transforms as A', while the HOMO and LUMO transform as A' and A''. Since $A' \times A'' = A''$, the DSD mode cannot lead to mixing of the HOMO and LUMO in this case. This fundamental difference between the C_s and C_2 point groups results from the properties of the Tensor Surface Harmonic theory parity operator, $\hat{P}$, which relates L^π and $\bar{L}^\pi$ cluster orbitals.[2] $\hat{P}$ is symmetric to rotations and antisymmetric to reflections, and hence in C_2 the parity

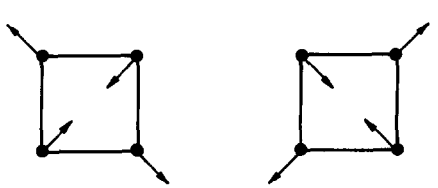

Fig. 5. Displacements to products and reactants in the DSD process. Only the critical face is sketched for clarity.

related HOMO and LUMO belong to the same irreducible representation. In fact, the critical matrix element will have a non-zero component (and lead to a lowering of the energy) for vibrations which transform in the same way as $\hat{P}$. The DSD vibration clearly does transform in this way in C_2, but not in C_s, and this kind of argument could also be applied to predict "mode-softening" in an equilibrium geometry.

This analysis fits in perfectly with the alternative approach of Part II,[2] where we show that a crossing occurs if a mirror plane is retained throughout, and an avoided crossing if a C_2 axis is conserved. Furthermore, if C_{2v} symmetry is conserved throughout a McIvor–Stanton analysis, this leads to the conclusion that the only possible symmetry species for the transition vector is A_1, which does not allow HOMO–LUMO mixing. This analysis, which pertains to the single DSD process in an icosahedron, is again in agreement with the orbital symmetry conclusion, because two mirror planes are retained throughout.

CONCLUSIONS

In this paper we have illustrated how geometrical selection rules may be used to disqualify structures as transition states for skeletal rearrangements in clusters. As examples, we have demonstrated that the stepwise double DSD processes for the pentagonal bipyramid and the bicapped square antiprism have intermediate structures which cannot be true transition states for this mechanism. This does not exclude the possibility that they could be transition states for some other process, or indeed metastable intermediates with no negative force constants. For concerted homoconversions, in which only identical atoms are permuted, the most restrictive conditions are found for paths of maximal symmetry.[7] It is interesting to note that the appearance of a new even-order operation in the "transition state" will lead to an orbital crossing if the symmetry element in question is a C_4 or higher even-order rotation axis.[1]

We have also considered a second-order Jahn–Teller analysis of the diamond–square–diamond mechanism. This alternative approach results in the same conclusion as the orbital symmetry analyses of Parts I and II: single DSD processes, in which a mirror plane is conserved throughout, are expected to be less favourable than those in which a C_2 rotation axis is retained. This is reassuring, since the orbital symmetry arguments generally appear to be the most powerful means for determining the favourability of a proposed reaction path. However, the geometrical rules can be applied to, say, argon clusters just as well as to borohydrides, and the orbital symmetry rules obviously cannot. In fact there is an interesting relation between the single DSD mechanism for $B_8H_8^{2-}$ and a similar process for the Ar_7 skew structure.[11] *Ab initio* calculations for the former structure reveal that the potential energy surface around the transition state is rather flat,[12] and that the barrier to rearrangement is small, in agreement with experiment. A geometrical analysis reveals that the single DSD process, in which a C_2 axis is preserved, is allowed for the Ar_7 skew structure,[12] yet Berry *et al.* could not locate the corresponding saddle point.[12] We conjecture that this region of the Ar_7 potential energy surface is also very flat, making the saddle point difficult to locate. Geometrical analyses of possible "transition states" for the homoconversions of the other Ar_7 geometries which correspond to local minima are in good agreement with the calculations.

Bürgi and Dunitz[13] have demonstrated that reaction pathways can sometimes be traced using X-ray crystallographic analysis of a range of compounds whose distortions from idealized geometries appear to follow a "reaction coordinate". This can lead to a mistaken impression that if a structure is observed in the solid-state it is a good candidate for a transition state. The geometrical selection rules clearly indicate the limitations of this thinking and show how some high symmetry geometries are forbidden as transition states. In the context of the present work, although a capped octahedral geometry has been observed for $Os_7(CO)_{21}$, this structure is forbidden as a transition state for the non-concerted double DSD rearrangement of a pentagonal bipyramid.

(*Received* 6 *December* 1988; *accepted* 10 *March* 1989)

Abstract—$CpCo(C_2H_4)_2$ (**1a**) and $Cp'Co(C_2H_4)_2$ (**1b**) (Cp′ = methylcyclopentadienyl) react with dihydrogen to give mixtures of μ_3-alkylidyne clusters, namely $(CpCo)_3(CCH_3)_2$ (**2a**), $(Cp'Co)_3(CCH_3)_2$ (**2b**), $H(CpCo)_4(CCH_3)$ (**3a**), $H(Cp'Co)_4(CCH_3)$ (**3b**), $(CpCo)_4(CCH_3)_2$ (**4a**) and $H(CpCo)_5(CCH_3)$ (**5a**). Compounds **2a**, **3a** and **3b** were separated, and **2a** and **3a** were structurally characterized by single-crystal X-ray crystallography. In solution, **3a** and **3b** show temperature dependent hydride fluxionality.

Stepwise replacement of BH in the (unknown) series of *n*-vertex *closo*-boranes $(BH)_nH_2$ by the isolobal[1] CpCo moiety, formally leads to the metallaboranes $(CpCo)_k(BH)_{n-k}H_2$ and finally to the series of cobalt hydrido clusters, $(CpCo)_kH_2$. Likewise, starting from the *closo*-carboranes, $(BH)_{n-m}(CR)_mH_{2-m}$ ($m = 1$, 2), the metallacarboranes, $(CpCo)_k(BH)_{n-m-k}(CR)_mH_{2-m}$ and cobalt alkylidyne clusters, $(CpCo)_k(CR)_mH_{2-m}$, are obtained. There are numerous examples of cobaltaboranes and cobaltacarboranes, e.g. $(CpCo)_4(BH)_2H_2$,[2] $(CpCo)_3(BH)_3H_2$[3] and $(CpCo)_2(BH)_3(CH)_2$,[4] to name just a few of the more metal-rich examples.[5,6]

The tetranuclear $(CpCo)_4H_4$ (although electron precise, as a tetrahedral molecule it does not comply with the general formula given above) has been prepared by $LiAlH_4$ reduction of $[CpCo(NO)]_2$.[7a] Tricobalt bis(alkylidyne) clusters, $(CpCo)_3(CR)_2$, are formed via cleavage of alkynes with $CpCo(CO)_2$ or $CpCo(C_2H_4)_2$ (**1a**).[8] Thermal decomposition of **1a** and Cp* $Co(C_2H_4)_2$ (**1c**) (Cp* = pentamethylcyclopentadienyl) was reported to yield as the only products, tetrametallic $H(CpCo)_4(CCH_3)$ (**3a**)[9] and trimetallic $(Cp^*Co)_3(CCH_3)_2$ (**2c**),[10] respectively.

RESULTS AND DISCUSSION

We have been looking for a general route into the series of cluster hydrides $(CpM)_kH_2$ (M = Co, Rh). Hydrogenation of unsaturated ligands in metal complexes has opened low energy pathways to polynuclear hydrides. Examples include $[Co(CO)_2(PR_3)]_3H$ from $(\eta^3$-allyl$)Co(CO)_2(PR_3)$ and H_2,[11] and a series of hydrides $[(R_3P)Pt]_xH_y$ ($x = 3$, $y = 6$, R = ^{t}Bu; $x = 4$, $y = 8$, $R_3 = {}^iPr_2Ph$; $x = 5$, $y = 8$, $R_3 = {}^tBu_2Ph$) from $(R_3P)Pt(C_2H_4)_2$ and H_2.[12] In the latter, the steric requirements of the phosphine ligands appear crucial in dictating the cluster nuclearity.[12] Indeed, reaction of **1a** with 1 bar of H_2 in ether or alkane solvents smoothly proceeds, even below room temperature, to yield a dark brown solution. However, analysis by field desorption mass spectroscopy (FD–MS) indicated the presence of the CpCo(alkylidyne) clusters $(CpCo)_3(CCH_3)_2$ (**2a**) (*m/z* 426), $H(CpCo)_4(CCH_3)$ (**3a**) (*m/z* 524), $(CpCo)_4(CCH_3)_2$ (**4a**) (*m/z* 550) and $H(CpCo)_5(CCH_3)$ (**5a**) (*m/z* 648) in appreciable quantities. No traces of $(CpCo)_4H_4$[7] or its higher homologues $(CpCo)_kH_2$ were found in the spectra. Under identical conditions, but in the absence of H_2, pure **1a** proved to be stable in solution for several weeks. Careful low temperature chromatography of the products resulted in the isolation of red **2a** (18% yield) and dark brown **3a** (47% yield). The hexanuclear clusters **4a** and **5a** could not be completely separated from residual **3a**.

By increasing the steric bulk of the Cp ligands we hoped to increase the relative yield of some of the clusters, presumably those with lower nuclearity. Low temperature chromatography of the mixture

obtained from hydrogenation (room temperature, 1 bar H_2) of $Cp'Co(C_2H_4)_2$ (**1b**) indeed indicated a higher yield of the trimetallic $(Cp'Co)_3(CCH_3)_2$ (**2b**), compared to the tetrametallic $H(Cp'Co)_4(CCH_3)$ (**3b**). Clusters with higher nuclearity could not be detected in the reaction mixture by FD–MS. However, only **3b** was obtained as a pure solid (11% yield); separation of **2b** from **3b** and other impurities was not possible either by chromatography or crystallization.

In contrast to **1**, a solution of $CpRh(C_2H_4)_2$ was stable under 1 bar of H_2 at room temperature for several days. Addition of a small amount of palladium on charcoal to this solution resulted in the quantitative precipitation of a rhodium mirror.

We have determined the crystal structures of **2a** and **3a**. Compound **2a** has the expected trigonal bipyramidal geometry, with the cobalt atoms occupying equatorial sites and both faces of the Co_3 triangle capped by ethylidyne groups (Fig. 1). The 1,4-C_2Co_3 core has very nearly D_{3h} symmetry. The planes of the Cp rings intersect the Co_3 triangle at dihedral angles close to 90°. Both CoCo and CoC(1/3) bond lengths (Table 1) are similar to the mean values found in $(CpCo)_3(\mu_3\text{-}CSiMe_3)(\mu_3\text{-}CC_2SiMe_3)$ (d(Co—Co) = 2.38 Å, d(Co—C) = 1.873 Å).[8a] The corresponding values for **2c** and **3a** are d(Co—Co) = 2.369 Å, d(Co—C) = 1.94 Å[10] and $d(\text{Co—Co})_{\text{mean}}$ = 2.415 Å, $d(\text{Co—C})_{\text{mean}}$ = 1.85 Å, respectively.

Compound **3a** has a trigonal bipyramidal (or monocapped tetrahedral) Co_4C core (Fig. 2). Since the structure of **3a** was published by others[9] while our work was under way, we shall discuss it here in less detail. Our findings (obtained from two different crystals) are in reasonable accord with those of ref. 9. Although the hydride could not be located in the X-ray diffraction studies, for geometric reasons we believe it to occupy a μ_3-(Co_3) face-bridging position in the solid state. This proposal is substantiated by semi-quantitative potential energy calculations,[13] which give much higher potential energies for all possible μ_2-bridging sites. Application of a modified† topological electron book-keeping treatment[14] gives balanced equations for both poss-

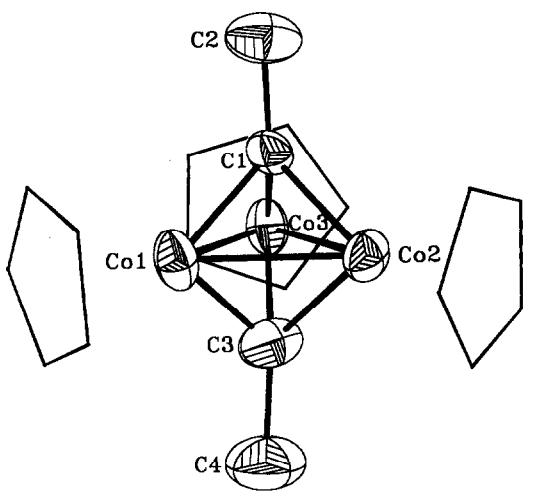

Fig. 1. Molecular structure of complex **2a**.

† To account for the CR groups, the original equations of balance[14] were extended as follows: for $\{(ML_3)_{p-1}(CR)_1H_q\}^{(z+1)+}$ (ML_3 = $Fe(CO)_3$, CoCp), $x = q-s$, $t = (3-n)p+z-q-x$, $2y = (np-z)-q-2t$ (where n, s, t, x, y are defined in analogy to ref. [15]). Hence, $(CpCo)_4(CCH_3)H$ gives $(styx) = (0231)$ [μ_3-H] and (1320) [μ_2-H].

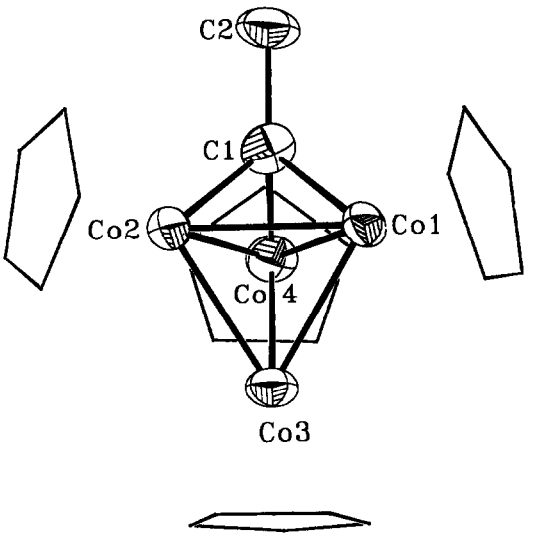

Fig. 2. Molecular structure of complex **3a**.

ible isomers (μ_2-H and μ_3-H). It is tempting to compare these findings with the available data for the closely related isoelectronic $H[Fe(CO)_3]_4(CCH_3)$,[15] which has the same polyhedral structure as **3a**. In the X-ray crystallographic study[15] the hydride was assumed to bridge an equatorial to axial iron–iron edge, based on the lengthening of this bond by 1.5% and the coordination geometry of the adjacent CO groups. Since the CpCo group is a lot more rigid than its isoelectronic and isolobal $Fe(CO)_3$ equivalent, and since the ligand environment in **3a** as a whole is much more crowded, the edge-bridging site is not available to the hydride in the latter molecule.

Table 2. NMR data for complex **2a** (δ in $[D_6]$-benzene)

	^1H	$^{13}C\{^1H\}$
CH_3	4.83 (s, 6H)	50.86
Cp	4.30 (s, 15H)	83.83

In the ^1H NMR spectra of **2a**, **3a** and **3b** (Tables 2 and 3), the ethylidyne groups appear as singlets in the range δ 4.8–5.0. Likewise, the resonances due to the ethylidyne methyl carbons are shifted to low field (δ 50–55) (Tables 2 and 4). Owing to relaxation effects of the quadrupolar ^{59}Co nuclei, no resonances were observed for the carbon atoms capping the Co_3 faces. The hydride resonances appear at δ −19.6 and −19.23 for **3a** and **3b**, respectively, strongly suggesting bridging (either μ_2 or μ_3) sites.[16]

In solution, **3a** and **3b** show dynamic behaviour. In the ^1H NMR spectra of **3a** at room temperature, only resonances for two sets of equivalent cyclopentadienyl protons are observed (intensity ratio 3 : 1) (Table 3). On lowering the temperature, the signal at δ 4.56 (intensity 3) collapses and eventually splits into two singlets (intensity 2 : 1) at 190 K. The spectra can be explained in terms of a dynamic process which involves rapid migration of the hydride across the three "open" Co_3 faces of the Co_4C bipyramid at the higher temperatures, effectively equilibrating the resonances of the two sets of "equatorial" CpCo groups. At low temperature, the structure is static on the NMR time scale, with the hydride most likely capping one of the triangular Co_3 faces. The same dynamic process operates in the methylcyclopentadienyl derivative, **3b**. However, due to the inherently lower symmetry, the low temperature spectra are more complicated (Table 3). Assuming free rotation of the Cp′ ligands, the molecular symmetry of a structure with the hydride localized on a Co_3 face (Fig. 3) approximates to C_s on the NMR timescale. Rings **A** and **A′** are related by symmetry; rings **B** and **C** are effectively bisected by the mirror plane. Therefore the methyl groups of the four Cp′ ligands appear as three signals with an intensity ratio of 2(**A**+**A′**) : 1(**B**) : 1(**C**). All four CH protons in ring **A** (and, by symmetry, also ring **A′**) are non-equivalent, giving a total of four sets of two CH protons each. Each of the rings, **B** and **C**, give rise to two sets of two CH protons, making a total of eight CH multiplets in the spectrum (two of which coincidentally overlap).

Cyclic voltammetry reveals reversible one-electron reduction and oxidation waves for both **2a** and **3a** (Table 5). As expected, reduction and oxidation of the clusters become easier going from the tricobalt Co_3C_2 polyhedron, **2a**, to the tetrametallic Co_4C polyhedron, **3a**. Further electrochemically irreversible one-electron oxidation of the monocations occurs at $E_0 = +1.17$ V (vs SCE) (**2a**) and $E_0 = +0.52$ V (**3a**). A stable monocation and a monoanion of $(CpCo)_3(CPh)_2$ have been prepared in solution.[17] Electrochemical data were given only for the 0/+1 couple; the value of $E_0 = 0.34$ V[17] compares well with $E_0 = 0.23$ V for **2a**.

Both **2a** and **3a** proved to be thermally and chemically very stable. Both compounds can be sublimed *in vacuo* at temperatures above 140°C without decomposition. Attempts to expand the Co_4C polyhedron of **3a** with either $Fe_2(CO)_9$, $Fe_3(CO)_{12}$ or $Co_2(CO)_8$, were not successful. Space filling models show the hydride in **3a** to be completely buried inside the ligand shell of the cluster. Consequently, no sign of deprotonation was apparent after prolonged contact with strong bases like NaH and $Na(HBEt_3)$.

[b] In acetonitrile.

In conclusion, we were able to show that a whole range of CpCo-containing clusters is formed via hydrogenation of $CpCo(C_2H_4)_2$ (**1a**) and $Cp'Co(C_2H_4)_2$ (**1b**) under very mild conditions. Under our reaction conditions (that is, under low pressure of H_2 and consequently with a relatively low concentration of H_2 in the solution), one or more ethylene molecules are always incorporated into the new formed clusters as μ_3-alkylidyne moieties. From our experiments we cannot tell whether the hydride ligands in **3** and **5** originate from gaseous H_2 or from coordinated ethylene. At higher temperatures, and in the absence of dihydrogen, the latter was shown to be the case.[9,10] Conversion of surface bound ethylene to μ_3-ethylidyne is a process which is quite common on metal surfaces,[18] but much less so in molecular systems. Most significantly, a layer of alkylidyne fragments is present on certain metal surfaces during and after the catalytic hydrogenation of ethylene and plays an active role in the catalytic cycle.[19] Hence, the formation and stability of molecular alkylidyne clusters in the hydrogenation reaction of olefin complexes serves as yet another example of the conceptual similarity of molecular and surface organometallic chemistry.[20]

EXPERIMENTAL

All operations were performed under purified N_2. Solvents were dried by conventional methods and stored under N_2. The alumina used for chromatographic separations was Brockmann activity II.

Compound **1a** (1.56 g, 8.7 mmol) in 150 cm^3 of light petroleum was shaken in an atmosphere of H_2 (1 bar) for 48 h. The resulting brown suspension was chromatographed on an alumina column at −30°C. Elution with light petroleum afforded a red solution of $(CpCo)_3(CCH_3)_2$ (**2a**). Further elution with toluene resulted in a brown eluate. Removal of solvent *in vacuo*, followed by crystallization of the residue from a large volume of light petroleum, gave dark brown crystals of $H(CpCo)_4(CCH_3)$ (**3a**) (530 mg, 47%). With ethanol, a mixture (290 mg) of **3a**, $(CpCo)_4(CCH_3)_2$ (**4a**) and $H(CpCo)_5(CCH_3)$ (**5a**) could be obtained from the alumina column. The red solution of **2a** was re-chromatographed with light petroleum on alumina. The solvent was removed from the first red fraction and the residue recrystallized from light petroleum at −78°C to give deep red platelets of **2a** (220 mg, 18%).

Compound **2a**: EI–MS *m/z*(%) 426 (100, M^+), 370 (85, $\{(CpCo)_3-2H\}^+$), 247 (38, $\{(CpCo)_2-H\}^+$), 189 (84, $\{Cp_2Co\}^+$), 124 (20, $\{CpCo\}^+$), 59 (7, Co^+). Compound **3a**: EI—MS *m/z*(%) 524 (67, M^+), 456 (79, $\{M-Cp-3H\}^+$), 370 (34, $\{(CpCo)_3-2H\}^+$), 247 (25, $\{(CpCo)_2-H\}^+$), 189 (69, $\{Cp_2Co\}^+$), 124 (13, $\{CpCo\}^+$).

In a similar way, 250 mg (11%) of pure $H(Cp'Co)_4(CCH_3)$ (**3b**) was obtained from 3.00 g (15.5 mmol) of **1b**. Compound **3b**: FD–MS *m/z*(%) 580 (100, M^+).

X-ray crystallographic data

Red crystals of **2a** were grown from light petrol by slow evaporation of solvent over a period of several weeks. Diffraction data were collected on a two-circle STOE STADI2 diffractometer at ambient temperature. Of the 2621 intensities measured (ω-scans, Mo-K_α X-radiation, $\lambda = 0.71069$ Å, graphite monochromator), 1797 unique reflections had $I \geqslant \sigma(I)$ and only these were used in the solution and refinement of the structure. Intensity data were corrected for Lorentz, polarization and X-ray absorption effects.

Crystal data for **2a**. $C_{19}H_{21}Co_3$, $M = 426.2$, orthorhombic, space group $Pbn2_1$, $a = 9.185(8)$, $b = 13.94(1)$, $c = 13.96(1)$ Å, $V = 1787$ Å^3, $Z = 4$, $D_c = 1.58$ g cm^{-3}, $F(000) = 864$, μ(Mo-K_α) = 26.4 cm^{-1}.

Systematic absences indicated space group *Pbnm* or $Pbn2_1$. The structure was solved, and all non-hydrogen atoms were located by conventional heavy-atom and difference Fourier methods. Hydrogen atoms were included in calculated positions. All remaining atoms were given anisotropic thermal parameters. Refinement by full-matrix least-squares was carried out in both possible space groups. In the centrosymmetric *Pbnm* (crystallographic molecular symmetry *m*) some carbon atoms showed very large anisotropic temperature factors perpendicular to the mirror plane. Therefore refinement was completed in the non-centrosymmetric $Pbn2_1$ with the Cp rings as rigid groups, and converged at $R = 0.057$ ($R_w = 0.043$, with a weighting scheme of the form $w^{-1} = [\sigma^2(F)]$). Scattering factors were taken from ref. 21. All calculations were carried out with the SHELX-76 system of programs.[22]

SYNTHESIS AND SPECTROSCOPIC CHARACTERIZATION OF A NOVEL IRIDIUM POLYHYDRIDE $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$; dippe = 1,2 BIS(DIISOPROPYLPHOSPHINO)ETHANE

(*Received* 23 *January* 1989; *accepted* 10 *March* 1989)

Abstract—Treatment of $[Ir(cod)(dippe)]PF_6$ (**1**) (dippe = 1,2 bis(diisopropylphosphino) ethane, $PPr^i_2(CH_2)_2PPr^i_2$) with molecular hydrogen at room temperature, in benzene and in the presence of 10 equivalents of NEt_3, affords the binuclear polyhydride complex $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**) and not $[IrH_5(dippe)]$. The complex $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**) is shown to be fluxional in solution, whereby the hydrides and the phosphorus ligands exchange rapidly at room temperature with respect to the NMR time scale.

Polyhydrides of the type $[Ir_2(\mu\text{-}H)_3H_2L_4]PF_6$ (L = PPh_3, PPh_2Me) can be conveniently prepared by hydrogenation of the respective complexes, $[Ir(cod)L_2]PF_6$ (L = PPh_3, PPh_2Me).[1-3] However, a second method, concerning the hydrogenation of $[Ir(cod)LL']PF_6$, (L = L′ = PPh_3) (L = PPr^i_3, Pcy_3; L′ = Py) but in the presence of an excess of NEt_3, yields the mononuclear pentahydride complexes of the type IrH_5L_2. The latter compounds are well known, particularly due to their use as precursors in the mild catalytic activation of C—H bonds of saturated hydrocarbons.[4] A notable example is the complex $[IrH_5(PPr^i_3)_2]$.[5] Nevertheless, these monodendate phosphine derivatives tend to be rather labile in solution.[6] Hence we were interested in preparing the hypothetical bidendate species $IrH_5(dippe)$ from $[Ir(cod)(dippe)]PF_6$ (**1**), thus following the second procedure. However, the new polyhydride dimer $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**) is formed under these conditions and in this paper we describe its detailed synthesis and fluxional behaviour in solution at ambient temperature.

RESULTS AND DISCUSSION

Previous studies carried out by Crabtree *et al.* have shown that hydrogenation of $[Ir(cod)LL']PF_6$ (L = L′ = PPh_3) (L = PPr^i_3, Pcy_3; L′ = Py) in the presence of Lewis base NEt_3 and excess of L, affords the pentahydride complexes IrH_5L_2 [eq. (1)][2]

$$[Ir(cod)LL']PF_6 + 5H_2 \xrightarrow[NEt_3, L]{CH_2Cl_2} IrH_5L_2 + NEt_3HPF_6 + \text{Cyclo-octane} \quad (1)$$

(L = Pcy_3, PPr^i_3).

Following the same procedure, using $[Ir(cod)(dippe)]PF_6$ (**1**) as starting material, we isolated and characterized the polyhydride complex, $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**). The complex $[Ir(cod)(dippe)]PF_6$ (**1**) was prepared by treatment of $[Ir(cod)(py)_2]PF_6$[7] with one equivalent of dippe in dichloromethane. The $^{31}P\{^1H\}/CDCl_3$ shows a singlet at 66 ppm (2P), indicating that in solution two equivalent phosphorus nuclei are coordinated to iridium(I). In addition, a septet centred at −140 ppm (1P) corresponding to free PF_6^- was observed. The ^1H NMR/$CDCl_3$ shows by integration, the presence of one equivalent of dippe to that of cod (cod = 1.5-cyclo-octadiene). Satisfactory microanalyses were obtained for carbon, hydrogen and phosphorus. Hydrogenation of a suspension of $[Ir(cod)(dippe)]PF_6$ (**1**) in benzene using one atmosphere of molecular hydrogen at room temperature

and in the presence or absence of NEt_3, yielded the complex $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**).

The IR spectrum of complex **2** prepared in Nujol, exhibits a strong band at 830 cm^{-1} assigned to ν(P—F) of free PF_6^- and a medium band at 2200 cm^{-1} assigned to the terminal hydrides ν(Ir—H), which is similar to that observed for the analogous compound, $[Ir_2(\mu\text{-}H)_3H_2(PPh_3)_4]PF_6$.[2] The $^{31}P\{^1H\}$ NMR spectrum of complex **2** recorded at 185 K in CD_2Cl_2, shows a doublet of doublets with some likely second-order contribution corresponding to $(P_a+P_{a'})$ and $(P_b+P_{b'})$ centred at 87 and 89.2 ppm, respectively, with $^2J(P_a—P_b) = {}^2J(P_{a'}—P_{b'}) = 15$ Hz. This suggests two non-equivalent phosphorus atoms P_a (or $P_{a'}$), P_b (or $P_{b'}$) of dippe chelating to iridium(III) (see Fig. 1). However, the coupling value reported for the $[Ir_2(\mu\text{-}H)_3H_2(PPh_3)_4]PF_6$ complex is $^2J(P_a—P_b) = 95$ Hz.[1] This difference is probably due to the chelating effect in complex **2** which forces the two phosphorus atoms P_a, P_b, of dippe to remain in a *cis* geometry. In addition, the $^{31}P\{^1H\}$ NMR of compound **2** shows a septet at −140 ppm, corresponding to free PF_6^- (0.9P) $^1J(P—F) = 712$ Hz. The ^1H NMR of this complex recorded at 180 K in CD_2Cl_2 shows three sets of hydrides at high field: a doublet centred at −8.16 ppm ($^2J(P_a—H_a) = {}^2J(P_{a'}—H_{a'}) = 73$ Hz) corresponding to $(H_a+H_{a'})$ bridging hydrides, where each hydride H_a (or $H_{a'}$) is *trans* to one phosphorus nucleus P_a (or $P_{a'}$); a multiplet centred at −8.35 ppm corresponding to one bridging hydride H_b which is *trans* to P_b and $P_{b'}$ and *cis* to P_a and $P_{a'}$ with the coupling constants ($^2J(P_b—H_b) = {}^2J(P_{b'}—H_b) = 122$ Hz, $^2J(P_a—H_b) = {}^2J(P_{a'}—H_b) = 62$ Hz); and finally a doublet of doublets centred at −21.9 ppm ($^2J(P_a—H_c) = {}^2J(P_{a'}—H_{c'}) = 16$ Hz, $^2J(P_b—H_c) = {}^2J(P_{b'}—H_{c'}) = 20$ Hz) corresponding to $(H_c+H_{c'})$ terminal hydrides, where each H_c (or $H_{c'}$) is *cis* to two phosphorus nuclei P_a (or $P_{a'}$), P_b (or $P_{b'}$). The ^1H NMR of the $[Ir_2(\mu\text{-}H)_3H_2(PPh_3)_4]PF_6$ compound recorded at 193 K shows similar results concerning the bridging hydrides H_a, however the hydrides H_b and H_c were reported to be a broad triplet and a broad singlet, respectively. This is probably due to the high fluxionality in $[Ir_2(\mu\text{-}H)_3H_2(PPh_3)_4]PF_6$ even at this temperature.

Upon warming to room temperature, the signals corresponding to $(H_a+H_{a'})$, H_b and $(H_c+H_{c'})$ in the ^1H NMR spectrum coalesce to give two broad peaks centred at −8.25 and −22.1 ppm, respectively. Furthermore, the signals corresponding to $(P_a+P_{a'})$, $(P_b+P_{b'})$ in the $^{31}P\{^1H\}$ NMR coalesce gradually to give a broad peak centred at 87.3 ppm (Fig. 2). Two mechanisms are proposed for this exchange process: (i) a rapid rotation of the outer part of the octahedron constructed by H_c, P_a and P_b or $H_{c'}$, $P_{a'}$ and $P_{b'}$ around an axis of order three passing through the iridium centres and thus keeping the other part of the molecule fixed, which eventually will lead to the equilibration of these nuclei on the NMR time scale, or (ii) dissociation of one phosphorus atom of the chelated ligand dippe, followed by a rotation of 180° before coordination to iridium(III) which also causes $P_a = P_b$, or $P_{a'} = P_{b'}$, however this may lead to an exchange between the terminal and the bridging hydrides and thus would appear less likely.

Attempts to prepare the target compound IrH_5(dippe) from $[Ir_2(cod)(dippe)]PF_6$ (**1**) under alternative conditions (10 atm H_2, 30 equivalents $HN(Pr^i)_2$, $pK_b = 1.95$, NEt_3, $pK_b = 3.25$)[8] have proven to be unsuccessful, providing also $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ (**2**) in 40% yield. It is possible that the enforced *cis* arrangement of the phosphorus donor atoms in the chelate phosphine complex disfavours the formation of the mononuclear species "IrH_5(dippe)", for which a *trans* phosphine geometry is preferred. However, another argument could be proposed, the neutral intermediate hydrido species either "IrH(dippe)" or "IrH_3(dippe)" is intercepted by the cationic species, either

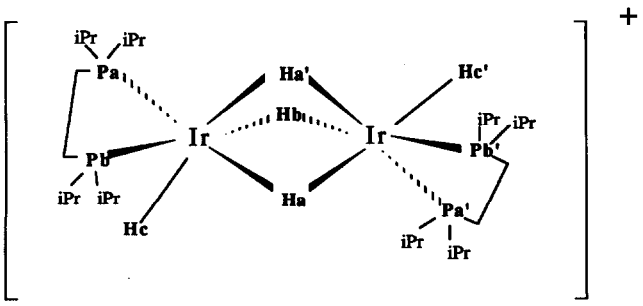

Fig. 1. Structure of $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]^+$.

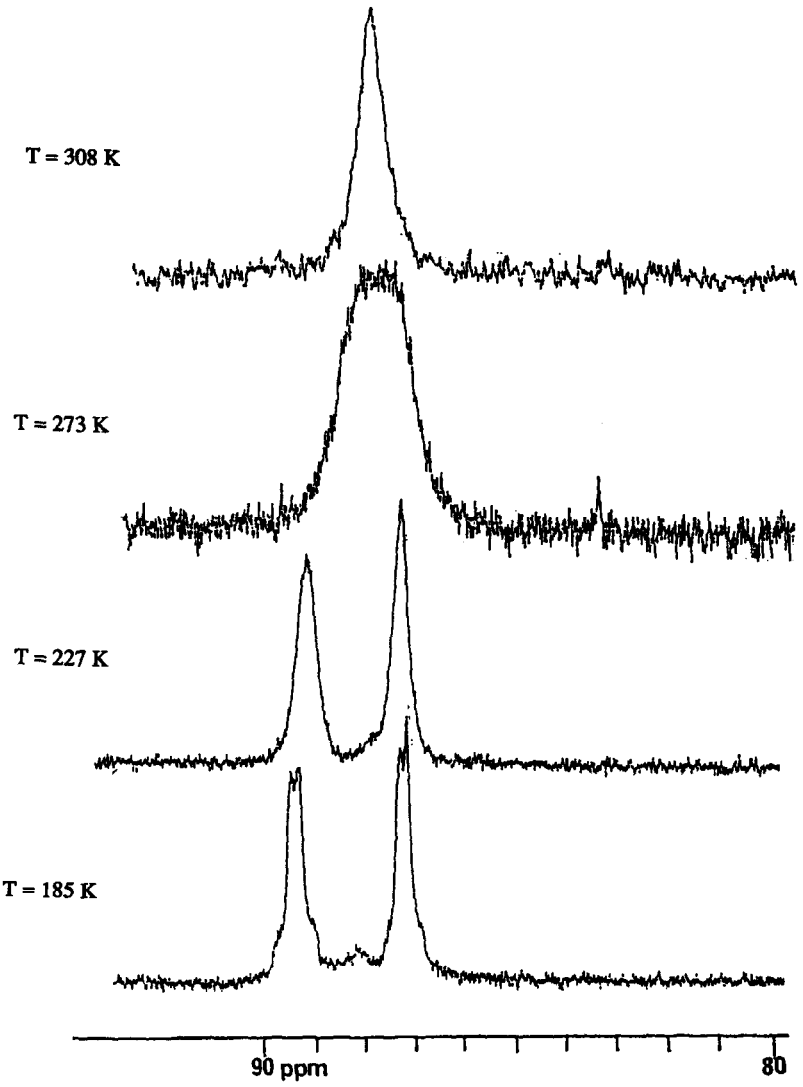

Fig. 2. Variable temperature $^{31}P\{^1H\}$ spectra for the polyhydride cationic complex $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]^+$, CD_2Cl_2 solution, 101 MHz.

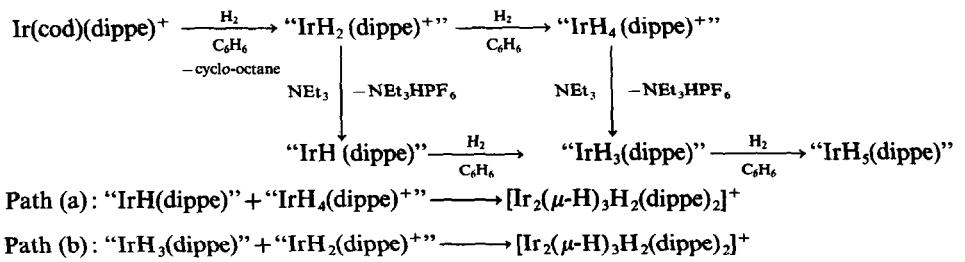
"$IrH_4(dippe)^+$" or "$IrH_2(dippe)^+$", to form the product **2** more rapidly than reacting with H_2 [see Scheme 1 below, path (a) and path (b)]:

Indeed, hydrogenation of $[Ir(cod)(dippe)]PF_6$ (**1**) in benzene employing *t*-BuOK (stronger base than NEt_3 and $HN(Pr^i)_2$), affords a white microcrystalline species after extraction with hexane and passing through an alumina column under hydrogen (yield *ca* 10%). The IR spectrum does not show the characteristic strong absorption at 830 cm^{-1}



Scheme 1.

for ν(P—F) of free PF_6^-, but investigations are in progress to identify this new complex, the results of which will be presented in due course.

EXPERIMENTAL

Manipulations were carried out using a vacuum line under argon and employing standard Schlenk techniques. In the case of the hydrogenation reaction, argon was replaced by hydrogen.Solvents were purified and dried prior to use by conventional distillation techniques under nitrogen. IR spectra were recorded on a Perkin–Elmer 297 IR spectrometer as Nujol mulls. NMR spectra were recorded on a Bruker AM-250 instrument and chemical shifts are relative to Me_4Si or 85% H_3PO_4 (^{31}P). Data are presented as proton decoupled with down field chemical shifts as positive.

Elemental analyses were performed by the service of microanalyses, CNRS, Gif-sur-Yvette, France. The ligand, 1,2 bis(diisopropylphosphino)ethane (dippe), was synthesized from bis(1,2 dichlorophosphino)ethane ($Cl_2P(CH_2)_2PCl_2$) and the Grignard reagent $(CH_3)_2CHMgBr$, following the procedure of Chatt and co-workers.[9]

Synthesis of $[Ir(cod)(dippe)]PF_6$ **(1)**

A solution of dippe (269 mg, 1.03 mmol) in C_6H_6 (5 cm^3) was transferred via canula to a well-stirred solution of $[Ir(cod)Py_2]PF_6$ (530 mg, 0.87 mmol) in CH_2Cl_2 (15 cm^3), causing a rapid colour change from yellow to deep red. The solution was concentrated under vacuum and addition of diethyl ether provided a deep red product. The solid was filtered and washed successively with benzene and diethyl ether to yield a deep red microcrystalline product (581 mg, 94%. Found: C, 37.2 H, 6.1; P, 13.5 Calc. for $C_{22}H_{44}P_3F_6Ir$: C, 37.2; H, 6.2; P, 13.1%. ^1H NMR ($CDCl_3$) 5 ppm (s, 4H—CH=CH—); 2.5 ppm (sep, 4H—$CH(CH_3)_2$; 2.15 ppm (s, 8H—CH_2—CH_2—); 1.97 ppm (dd, second-order 4H P—$(CH_2)_2$—P); 1.29 ppm (m, 24H $(CH_3)_2CH$—). $^{31}P\{^1H\}/CDCl_3$ 66 ppm (s, 2P); −140 ppm (sep, PF_6^- ^1J(P—F) = 718 Hz).

Synthesis of $[Ir_2(\mu\text{-}H)_3H_2(dippe)_2]PF_6$ **(2)**

Hydrogen was bubbled through a suspension of $[Ir(cod)(dippe)]PF_6$ (250 mg, 0.35 mmol) in C_6H_6 (20 cm^3) in the presence of NEt_3 (0.483 cm^3, 3.5 mmol). The colour of the reaction mixture changed from red to light yellow. After 1 h the solvent was evaporated and the residue was extracted with ethanol (10 cm^3). The light yellow solution of ethanol was concentrated under vacuum until a creamy-yellow microcrystalline product started to precipitate. The product was filtered and washed with cold hexane. Recrystallization from dichloromethane–diethyl ether yielded cream coloured crystals (80 mg, 43%). Found: C, 31.8; H, 6.5. Calc. for $C_{24}H_{61}P_5F_6Ir_2$ C, 31.7; H, 6.5%. ^1H NMR (CD_2Cl_2) $T = 180$ K: 2.1 ppm (m, 16H P—$(CH_2)_2$—P, $CH(CH_3)_2$); 1.1 ppm (m, 48H $(CH_3)_2CH$—); −8.16 ppm (d, $H_{a'}$, H_a, $^2J(P_a—H_a) = {}^2J(P_{a'}—H_{a'}) = 73$ Hz); −8.35 ppm (m, Hb $^2J(P_b—H_b) = {}^2J(P_{b'}—H_b) = 122$ Hz, $^2J(P_a—H_b) = {}^2J(P_{a'}—H_b) = 62$ Hz); −21.9 ppm (dd, $H_{c'}$, H_c, $^2J(P_a—H_c) = {}^2J(P_{a'}—H_{c'}) = 16$ Hz, $^2J(P_b—H_c) = {}^2J(P_{b'}—H_{c'}) = 20$ Hz). $^{31}P\{^1H\}$ NMR/CD_2Cl_2 $T = 185$ K: 87 ppm (d, $P_b+P_{b'}$); 89.1 ppm (d, $P_a+P_{a'}$) $^2J(P_a—P_b) = {}^2J(P_{a'}—P_{b'}) = 15$ Hz; −140 ppm (sep, PF_6^- ^1J(P—F) = 718 Hz). IR/Nujol ν(Ir—H) = 2200 cm^{-1} (s); ν(P—F) = 830 cm^{-1} (*vs*).

DIFFERENCE IN THE POLAROGRAPHIC CATALYTIC CURRENTS OF VANADIUM(III)–EDTA AND VANADIUM(IV)–EDTA WITH THE NITRATE ION

NAKAHIDE KATO

Department of Chemistry, College of Science, Rikkyo University, 3-34 Nishi-Ikebukuro, Toshimaku, Tokyo 171, Japan

(*Received* 13 *June* 1988; *accepted* 10 *March* 1989)

Abstract—Addition of the nitrate ion to V^{III}–EDTA or V^{IV}–EDTA solutions increases the reduction current of vanadium(III) to vanadium(II), and the mechanisms of both cases are considered to be similar. However, the catalytic current of V^{IV}–EDTA was smaller than the V^{III}–EDTA due to the presence of the reaction of vanadium(II) with vanadium(IV).

The polarographic behaviour of V^{III}–EDTA* and its analogous complexes, and the mechanisms of their catalytic waves, have been previously investigated.[1–4] However, the vanadium(III) complex is not stable and undergoes slow oxidation to vanadium(IV) in air, whereas the vanadium(IV) complex is very stable under many conditions.[5] Therefore, V^{IV}–EDTA was used instead of V^{III}–EDTA in the study of the catalytic wave in the present work. Although one would expect[5–7] that the mechanism of the catalytic current of V^{IV}–EDTA is the same as that of V^{III}–EDTA, the observed catalytic current of V^{IV}–EDTA was smaller than that of V^{III}–EDTA. This phenomenon had not been considered hitherto and its mechanism is studied in the present work.

EXPERIMENTAL

The vanadium(IV) stock solution was prepared by dissolving vanadium(IV) oxide sulphate in 1.0 mol dm^{-3} sulphuric acid solution, and its concentration was determined by titration with potassium permanganate. The vanadium(III) stock solution was prepared by air-oxidizing a vanadium(II) solution obtained by electrolysis of the vanadium(IV) stock solution at −1.6 V vs SCE.

An oxygen-free solution containing 0.25 mol dm^{-3} of sodium acetate, 0.35 mol dm^{-3} of potassium chloride and 0.01 mol dm^{-3} of EDTA was poured into an H-type cell. After bubbling nitrogen gas for 10 min, the required amount of vanadium stock solution was added to the solution and the electrochemical measurements were carried out at pH 5.5.

RESULTS AND DISCUSSION

The polarogram of V^{III}–EDTA in the acetate buffer solution contained one wave which corresponded to the reduction of V^{III} to V^{II}.[1/2] When the nitrate ion was added to the V^{III}–EDTA solution, the wave height of V^{III}–EDTA was increased, that is, a catalytic wave appeared. The apparent rate constant k_{app} of the catalytic reaction between V^{II}–EDTA and the nitrate ion was calculated from the ratio of i_c/i_d,[8] where i_d is a diffusion current and i_c is a catalytic current. According to the literature,[7,8] the greater the k_{app}, the greater the catalytic current. The experimental relationship between k_{app} and the concentration of the nitrate ion is shown in Fig. 1, curve (1). As the value of k_{app} decreases with increasing concentration of nitrate ion, it is proposed that the mechanism of the catalytic reaction varies with concentration of

* Ethylenediaminetetraacetatovanadium(III): V^{III}–EDTA.

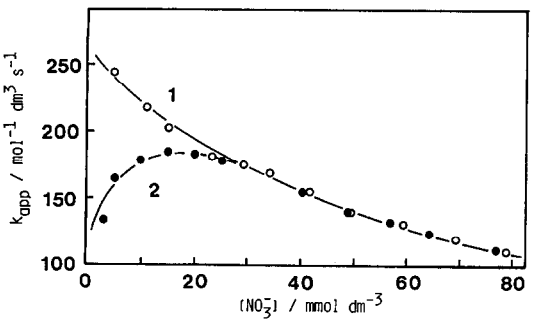

Fig. 1. Relation between k_{app} and the concentration of nitrate ion at pH 5.7. ○ : V^{III}–EDTA and ● : V^{IV}–EDTA.

nitrate ion.[3]* This mechanism was proposed as follows:

$$V^{III}\text{–EDTA} \xrightarrow{e^-} V^{II}\text{–EDTA (diffusion current: } i_d) \quad (1)$$

$$\nu V^{II}\text{–EDTA} + NO_3^- \xrightarrow[k_{app}]{} \nu V^{III}\text{–EDTA} \xrightarrow{\nu e^-} \nu V^{II}\text{–EDTA} \quad (2)$$

(catalytic current: i_c),

where ν represents the stoichiometric factor of the catalytic reaction.

Vanadium(IV)–EDTA produced two polarographic waves of the same height, which correspond to the stepwise reduction to V^{III} and then to V^{II}. When nitrate ion was added to the V^{IV}–EDTA solution, the height of the second wave was enhanced, whereas the height of the first wave remained constant. Therefore, the mechanism of the catalytic wave of V^{IV}–EDTA was considered to be similar to that of V^{III}–EDTA. However, the apparent rate constant, k_{app}, in eq. (2), calculated from the current of the second wave of V^{IV}–EDTA, is smaller than that in the case of V^{III}–EDTA in a low concentration of nitrate ion, as shown in curves (1) and (2) of Fig. 1; although the difference between the rate constants of them becomes smaller with increasing concentration of nitrate ion. That is, the observed catalytic current of V^{IV}–EDTA is smaller than that of V^{III}–EDTA.

When V^{IV}–EDTA was electrolysed at a constant potential corresponding to the reduction of V^{IV} to V^{II} in the acetate buffer solution [eq. (3)], not only V^{II}, but also V^{III} complexes, were found in the bulk solution. This showed that the reaction between V^{II} and V^{IV} (comproportionation)[9,10] occurred after electrolysis [see eq. (4)]:

$$V^{IV}\text{–EDTA} \xrightarrow{2e^-} V^{II}\text{–EDTA (diffusion current)} \quad (3)$$

$$V^{IV}\text{–EDTA} + V^{II}\text{–EDTA} \xrightarrow[\text{comproportionation}]{} 2V^{III}\text{–EDTA} \xrightarrow{2e^-} 2V^{II}\text{–EDTA}. \quad (4)$$

Multi-sweep cyclic voltammetry of V^{IV}–EDTA was carried out with a slow scan rate and a cyclic voltammogram was obtained as shown in Fig. 2. At first sweep, one cathodic shoulder (A) and a peak (B) due to the stepwise one-electron reduction of V^{IV} to V^{II} and an anodic wave (C) due to the oxidation of V^{II} to V^{III} were observed. However, the shape of the voltammogram changed in the direction of the arrows shown in Fig. 2 after repeating the sweeps, and shoulder (A) corresponding to

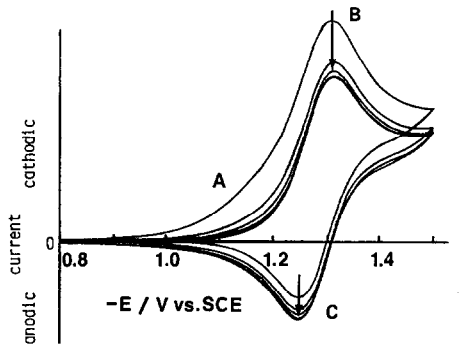

Fig. 2. Multi-sweep cyclic voltammogram of V^{IV}–EDTA at pH 5.7 [V^{IV}–EDTA] = 1.0 mmol dm^{-3}. Scan rate: 0.05 V s^{-1}.

* As the apparent second-order rate constant k_{app} is represented by the product of stoichiometric factor ν and the second-order rate constant k_c,[8] the reaction rate is described as follows:

$$\text{Reaction rate} = \nu k_c[V^{II}\text{–EDTA}][NO_3^-] = k_{app}[V^{II}\text{–EDTA}][NO_3^-].$$

When the concentration of nitrate ion was slightly higher than that of V–EDTA, stoichiometric factor ν was equal to 8. Therefore, the catalytic reaction was considered as follows:

$$8V^{II}\text{–EDTA} + NO_3^- + 10H^+ \rightarrow 8V^{III}\text{–EDTA} + NH_4^+ + 3H_2O.$$

However, when the concentration of nitrate ion was increased, the reaction products of nitrate ion were varied. Therefore, it is considered that the variation of k_{app} is due to that of the stoichiometric factor ν and the concentration of nitrate ion (Fig. 1).

the reduction of V^{IV} to V^{III} disappeared. Then, the steady state cyclic voltammogram of V^{IV}–EDTA became similar to that of V^{III}–EDTA. Therefore, also in the vicinity of electrode surface, the same reaction occurs between V^{II} and V^{IV} as in the bulk solution and the V^{III}–EDTA produced is reduced to V^{II} [see eq. (4)].

In the case of the polarographic behaviour of V^{IV}–EDTA, however, as two electrons should be consumed in both cases [see eqs (3) and (4)], the diffusion current of V^{IV}–EDTA cannot be affected by the reaction represented in eq. (4). The observed total wave height of V^{IV}–EDTA corresponds to a two-electron reduction. Therefore, the validity of eq. (4) cannot be elucidated from the diffusion current of V^{IV}–EDTA.

It has been proposed that the reaction between vanadium(II) and vanadium(IV) complexes produced the monomer and dimer of the vanadium(III) complexes in the bulk solution.[11] However, if the decrease in k_{app}, obtained from the catalytic wave of V^{IV}–EDTA, was caused by the formation of dimer, the height of the second wave of V^{IV}–EDTA should be smaller than that of the first wave in the absence of nitrate ion, because a dimer is generally reduced at more negative potentials than the monomer.[1,12,13] But in the present case, since the difference in the wave heights between the first and second waves of V^{IV}–EDTA has not been observed, it is assumed that the dimer is not formed.

Therefore, the reason for the difference in the catalytic currents of V^{III}–EDTA and V^{IV}–EDTA may be concluded as follows: in the case of V^{IV}–EDTA, two competitive reactions [see eqs (2) and (4)], that is, the reactions of V^{II}–EDTA with nitrate ion and with V^{IV}–EDTA occur in the vicinity of the electrode surface. Namely, V^{II}–EDTA produced by electrolysis, reacts not only with the nitrate ion but also with V^{IV}–EDTA. As the comproportionation does not contribute to the increase of the limiting current, the decrease of the apparent catalytic current can be observed when the concentration of the nitrate ion is low. On the other hand, the catalytic current of V^{III}–EDTA does not decrease due to the absence of V^{IV}–EDTA in the bulk solution.

STUDY ON THE COORDINATION OF VITAMIN D_3 TO CALCIUM(II) AND CADMIUM(II) IN SOLUTION

LIU QITAO,* LIU YI and ZHANG FENG

Department of Chemistry, Liaoning University, Shenyang, P.R.C.

(*Received* 25 *January* 1989; *accepted* 10 *March* 1989)

Abstract—The coordination of vitamin D_3 to calcium(II) and cadmium(II) has been studied by potentiometric pH titrations in a 70% (v/v) ethanol–water solution at 37 ± 0.1°C and at 0.10 (KNO_3) ionic strength. The results show that both of the metal ions form 1 : 1 and 1 : 2 complexes with vitamin D_3 and the coordinating tendency of the second ligand to the 1 : 1 complex is unusually strong. This anomalous situation has been explained by intramolecular hydrophobic ligand–ligand interactions in these complexes. The inter-promoting or inter-restraining absorption between these metals and vitamin D_3 in organisms has also been discussed.

It is well known that the absorption of calcium in organisms can be effectively promoted by vitamin D.[1] The inter-restraint of calcium and cadmium when absorbed by organisms has also been published by many authors.[2–4] Again, it has been reported in some papers[4] that the metabolism of vitamin D_3 in animals can partially be affected by calcium and cadmium. According to recent research,[5] the accumulation of cadmium in rats' liver can be effectively reduced if the rats are fed with cadmium, and with calcium or vitamin D_3 at the same time (compared with rats that were fed with cadmium only). These facts show that there must be some complicated interaction between calcium, cadmium, vitamin D and other bioligands existing in the organisms. From the viewpoint of coordination chemistry, it is expected that some useful information can be obtained for explaining the above physiological phenomena by studying the coordination of calcium(II) and cadmium(II) with vitamin D_3, inspecting the species of the complexes, and determining their stabilities in solution. In this paper, the coordination equilibria of Ca^{II}–VD_3 and Cd^{II}–VD_3 systems have been studied by potentiometric pH titrations in 70% (v/v) ethanol–water solution, and some interesting results have been obtained.

EXPERIMENTAL

Apparatus and chemicals

A Radiometer pHM-84 pH meter (Denmark, accuracy ± 0.001) and a 2401B compound glass electrode (U.S.A.) were used for all pH measurements. The temperature of the determining solution system was kept at 37 ± 0.1°C, using a jacketed beaker which permits the circulation of water through it. Calcium(II) and cadmium(II) solutions were prepared, respectively, from A.R. grade pure calcium carbonate (dissolved in 1 : 1 hydrochloric acid and heated slowly to eliminate the extra hydrochloric acid) and high purity cadmium (content is above 99.99%, dissolved in 1 : 3 nitric acid). Vitamin D_3 was of food grade purity (Merck, content >99%). Other chemicals used were all A.R. or G.R. grade pure reagents and not purified further. The water used in all the experiments was double distilled.

Method

The potentiometric pH titrations were carried out in a 70% (v/v) ethanol–water solution at 37 ± 0.1°C and 0.10 ionic strength (maintained with KNO_3) under a high purity N_2 flow. The acidic formation constant of vitamin D_3 was determined by preparing solutions (0.01920 g of vitamin D_3, 35.00 cm^3 of ethanol, 2.00 cm^3 of 0.04454 M nitric acid

* Author to whom correspondence should be addressed.

[a] The values in parentheses were obtained by a graphical method.[8]

and 5.00 cm^3 of 1.0 M KNO_3, finally, diluted with water to 50.00 cm^3) and carrying out pH titrations with 0.08829 M carbonate-free sodium hydroxide solution (the details were as described before[6]). The same procedure was used in the determination of the stability constants of the metal complexes, except 5.00 cm^3 of a Ca^{II} or Cd^{II} solution were added to 50 cm^3 of determining solution system (5×10^{-4} M). The concentration ratio of metal to ligand was 1 : 2 in each solution.

Calculation

The TITFIT Basic program[7] (APPLE II HKC8800A computer) has been used for calculating the acidic formation constants of the ligand and the stability constants of the metal complexes. The activity coefficient of the H^+ ion was determined by titrating 50 cm^3 of standard nitric acid solution (the conditions were the same as above) and evaluated using the above program ($\gamma_{H^+} = 0.289 \pm 0.001$ were obtained). The ionic production of water in this mixed solvent was also evaluated in the calculation process of the acidic formation constants of vitamin D_3 to be $pK_w = 15.60 \pm 0.02$ (37°C).

RESULTS AND DISCUSSION

The calculation values, along with the values obtained by graphical methods,[8] are given in Table 1. The results agree quite well. It is evident that each calcium(II) and cadmium(II) can coordinate with vitamin D_3 and form 1 : 1 and 1 : 2 complexes. The stability of the cadmium(II) complex is much higher than that of calcium(II). It is interesting that the stepwise stability constants of a 1 : 2 binary complex of either calcium(II) or cadmium(II) are even higher than the first one. In Table 2, the stepwise stability constants of these complexes, log K_i, and the values of Δ log K are listed. Both of the Δ log K values are positive. This is very unexpected, because the stepwise stability constants of complexes should successively decrease on consideration of either the electrostatic or stereo effects. For the systems in which only the 1 : 1 and 1 : 2 binary complexes are formed, the ratio of the stepwise stability constants, K_2/K_1, should be *ca* 0.25, or the Δ log K value should be *ca* -0.6 on the grounds of statistical considerations.[9] The experimental values of Δ log K listed in Table 2 are much higher than this statistically expected value. This shows that some special process must exist that stabilizes the 1 : 2 binary complexes.

Calcium (alkaline earth metal) is very different from cadmium (d^{10} metal) in electronic structure, but the difference in Δ log K values is rather small, therefore the factors that stabilize the 1 : 2 binary complexes are assumed to be mainly due to the ligand, vitamin D_3. The molecular structure of vitamin D_3 is shown in Fig. 1. The phenolic hydroxyl is the only group that can be coordinated to the metal. In addition, the other side of the molecule consists of a huge hydrophobic group. Therefore, it is possible that if two molecules of vitamin D_3 coordinate simultaneously to the metal ion, the two

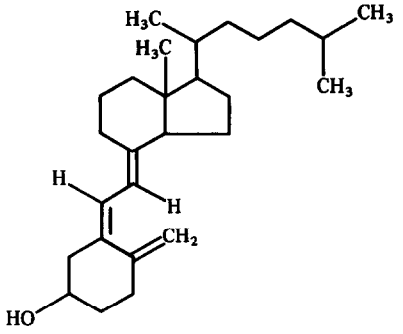

Fig. 1. The structure of the vitamin D_3 molecule.

hydrophobic groups of the vitamin D_3 molecules will close in on each other to form a hydrophobic bond[10] in terms of bridging by the metal ion. The formation of this hydrophobic bond will greatly enhance the stability of the complexes. The possible intramolecular hydrophobic ligand–ligand interaction is illustrated in Fig. 2.

Hydrophobic interactions, as a type of important non-covalent interaction, are significant in the determination of the configuration of some biomolecules, e.g. protein, nucleic, etc., and many other important biological phenomena.[11] It has often been reported in some papers[12–14] that the stability of binary and ternary metal complexes can be enhanced by intramolecular hydrophobic ligand–ligand interactions, however, it is rare that the binary 1 : 2 complexes, like the ones reported in this paper, have such large $\Delta \log K$ values as shown in Table 2. This is probably because most of the research previously reported is about mini-molecule amino acid ligands such as leucine, isoleucine, tryptophan etc., of which the hydrophobic groups are all much smaller than those in vitamin D_3. It can be assumed that a more effective hydrophobic bond could be formed by vitamin D_3. Meanwhile, research into the influence of solvent on the hydrophobic interactions between ligands in complex molecules[15] shows that the addition of an organic solvent (such as dioxane, ethanol, etc.) to an aqueous solution is favourable for the intramolecular hydrophobic interactions in metal complexes in a definite range. Therefore, it is possible that the hydrophobic interactions lead to the positive values of $\Delta \log K$ for the two metal–vitamin D_3 complexes studied in this paper. As the hydrophobic interactions exist not only between vitamin D_3 molecules in the complexes, but also between the vitamin D_3 molecules (that have coordinated to metal) and other biomolecules carrying hydrophobic groups, this should exert a significant influence on the physiological functions of some metal complexes of vitamin D_3. It is known that the best approach for the promotion of vitamin D_3 to calcium absorption is promoting the combination of calcium with the protein of the intestine mucous cell.[1] In addition to the possibility that the calcium which has coordinated with vitamin D_3 further combines with an amino acid residue of a protein (usually with aspartic acid or glutamic acid residues) to form ternary complexes, the hydrophobic interactions existing between the huge hydrophobic group of the vitamin D_3 molecule (coordinated to calcium) and other hydrophobic groups that exist in many biomolecules, will inevitably promote this approach for carrying the calcium through the cell membrane and bridging it closer to the protein molecules. Cadmium is the second two-valent metal ion which can easily coordinate with the calcium-binding proteins (only weaker than calcium),[1] and it should be expected that they restrain each other in the absorption by organisms. On the other hand, for the restraint of vitamin D_3 to cadmium absorption, in addition to indirectly restraining cadmium absorption in terms of promoting calcium absorption and increasing the content of calcium in body, it is also possible that the vitamin D_3 molecules stably coordinate to cadmium (the stability constants of the first complex is larger by three orders than that of calcium, and the second complex is larger by six orders than that of calcium) to restrain the combination of cadmium with biomolecules in the body, and to be excreted directly.

SOLVENT EXTRACTION OF N-ETHYL-GLYOXYLANILIDE OXIME AND OF ITS COPPER(II) AND NICKEL(II) COMPLEXES INTO CHLOROFORM

A. IZQUIERDO,* R. COMPAÑÓ, M. GRANADOS and X. DUARRI

Departament de Química Analítica, Universitat de Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 13 *January* 1989; *accepted* 10 *March* 1989)

Abstract—The distribution equilibria of N-ethyl-glyoxylanilide oxime (NEG) and of the Cu^{II}–NEG and Ni^{II}–NEG complexes in the water–chloroform system have been studied at 25°C. From the graphical treatment of the equilibrium data it has been deduced that NEG dimerizes in the organic phase, copper is extracted as the CuL_2 complex and nickel as NiL_2 or $NiL_2(HL)$ depending on the NEG concentration. These models have been checked by treating the data with the program LETAGROP–DISTR and the following equilibrium constants have been obtained: NEG, $pK_a = 9.32 \pm 0.03$, $\log K_{DR} = 0.99 \pm 0.04$, $\log K_2 = 1.78 \pm 0.07$; CuL_2, $\log \beta_2 = 7.24 \pm 0.10$, $\log \beta_2 = 12.83 \pm 0.06$, $\log K_{DC} = 2.54 \pm 0.04$; NiL_2, $\log K_{ex} = -8.7 \pm 0.2$; $NiL_2(HL)$, $\log K_{ex} = -6.20 \pm 0.08$.

Mono-oximes formed by the condensation of aromatic amines with chloral and hydroxylamine, with the —NR—CO—CH=N—OH grouping (R = H or alkyl radical), have been widely studied as analytical reagents for metal ions, especially for copper(II), nickel(II), cobalt(II) and palladium(II).[1–4]

These ligands act as bidentate agents, via CO and oximic nitrogen, forming chelating five-membered rings.

The complexes are sparingly soluble in water, but they can be extracted into organic solvents, chloroform being the one that produces the higher values of the recovery factor. While there appear to be analytical applications of these ligands, there have been no solvent extraction studies using this class of reagents. In this work, the distribution equilibria of NEG and of its copper(II) and nickel(II) complexes in the water–chloroform system have been studied. From the effects of the different experimental variables on the distibution ratio, and by means of graphical and numerical methods, the nature of the species which participate in the distribution equilibria has been determined, as well as the constants which control these equilibria.

EXPERIMENTAL

Reagents

N-Ethyl-glyoxylanilide oxime (NEG) was synthesized following the procedure of Sandmeyer,[5] modified by Marvel and Hiers.[6] By double recrystallization from water, NEG was obtained as light yellow crystals with a melting point of 171°C.

A stock solution of copper (1 g dm^{-3}) was prepared by dissolving $Cu(NO_3)_2 \cdot 3H_2O$ (analytical reagent grade) in water, and was standardized by iodometry.[7]

A stock solution of nickel (1 g dm^{-3}) was prepared by dissolving $Ni(NO_3)_2 \cdot 6H_2O$, and was standardized gravimetrically as dimethylglyoximate.[7]

All other chemicals were of analytical grade and used without further purification.

Apparatus

A Beckman Acta MVII spectrophotometer, with 1 cm quartz cells, and an atomic absorption spectrophotometer (Perkin–Elmer 4000) with an air–acetylene flame or a graphite furnace (Perkin–Elmer HGA 500), were used. The samples were manually injected into the graphite furnace using a 0.02 cm^3 Eppendorf pipette. A Radiometer pH-meter PHM64, equipped with a Ross combination

pH electrode, standardized with buffer solutions at pH 4.008 and 6.865 (25°C) prepared from Merck salts according to DIN 19266, was also used.

PROCEDURE

Distribution of NEG

10 cm^3 of an aqueous buffer solution with an ionic strength of 0.1 M and saturated with chloroform, and 10 cm^3 of chloroform, saturated with water, containing NEG (10^{-3}–10^{-1} M), were shaken together at 25.0 ± 0.1°C in 30 cm^3 glass stoppered vials for 10 min. After phase separation, an aliquot of the aqueous phase was transferred to a volumetric flask and diluted to the mark with NaOH (0.1 M), and its absorbance was measured at 265 nm against a blank. Finally the pH of the aqueous phase was measured at 25.0 ± 0.1°C.

Distribution of copper(II) *and nickel*(II) *complexes*

10 cm^3 of the aqueous phase saturated with chloroform, containing appropriate concentrations of metal ion, and 10 cm^3 of chloroform saturated with water, containing NEG, were shaken until equilibrium was attained [15 min for copper(II), 30 min for nickel(II)]. The pH of the aqueous phase was adjusted with an acetic acid–sodium acetate buffer when the distribution of copper(II) was studied, and with a potassium dihydrogen phosphate–potassium hydroxide buffer in the case of the nickel(II) study. Potassium nitrate was added to give a constant ionic strength of 0.1 M. After phase separation, the equilibrium concentration of copper(II) or nickel(II) in the aqueous phase was determined by flame AAS or graphite furnace AAS, depending on the concentration level, under the usual conditions. The metal concentration in the organic phase was calculated by difference. The pH of the aqueous phase was measured at 25.0 ± 0.1°C.

RESULTS AND DISCUSSION

Distribution of NEG *in the water–chloroform system*

The distribution ratio values obtained at pH 4.65 and 9.97, with shaking times between 5 and 60 min, show that 5 min of shaking is enough to attain the distribution equilibrium. In subsequent experiments, an extraction time of 15 min was adopted. The influence of the reagent concentration on the distribution ratio values (Fig. 1) points out that, in the concentration range studied, molecular association in the organic phase must be taken into account. Figure 2 shows the plots of log D vs pH obtained with 10^{-2} and 10^{-3} M NEG solutions in chloroform.

Calculation of the equilibrium constants. Assuming that only the monomeric NEG is capable of distributing into the aqueous phase, and that only one polymeric species exists in the organic

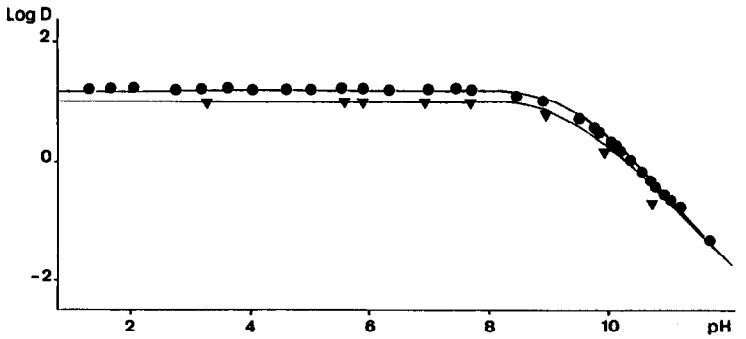

Fig. 2. Influence of pH on the distribution ratio of NEG. ● $C_{HL} = 10^{-2}$ M; ▼ $C_{HL} = 10^{-3}$ M. The full curves are calculated with the program HALTAFALL using the constants given in Table 1.

Table 1. Dissociation constant of NEG and its distribution and dimerization constants in the water–chloroform system

Method	pK_a	$\log K_{DR}$	$\log K_2$	$\sigma(\log D)$
Graphical	9.25	0.95	1.89	
LETAGROP–DISTR[a]	9.32±0.03	0.99±0.04	1.78±0.07	0.03
Spectrophotometric[b]	9.32±0.02			

[a] The limits given for the constants correspond to $\log[K \pm 3\sigma(K)]$; $\sigma(\log D) = [\Sigma(\log D_{exp} - \log D_{calc})^2/N]^{1/2}$.

[b] The limits given for the constant correspond to $-\log[K_a \pm 3\sigma(K_a)]$ obtained by the SQUAD treatment.

phase, the distribution ratio of NEG is given as:

$$D = \frac{[HL]_o + [(HL)_n]_o}{[HL]_w + [L^-]} = \frac{K_{DR}[HL]_w + nK_nK_{DR}^n[HL]_w^n}{[HL]_w + K_a[H^+]^{-1}} \quad (1)$$

where HL represents NEG, and K_{DR}, K_a and K_n are, respectively, the distribution, dissociation and polymerization constants of the reagent. The subscripts o and w denote the organic and the aqueous phase respectively. When $[H^+] \gg K_a$ the following equation is obtained:

$$D = K_{DR} + nK_nK_{DR}[HL]_w^{n-1}. \quad (2)$$

A curve-fitting method[8,9] was applied to the data plotted in Fig. 1 to determine n, K_n and K_{DR}. By introducing $D^* = D/K_{DR}$ and $u = K_n^{1/(n-1)} K_{DR}[HL]_w$ in eq. (2), a family of normalized curves $D^* = 1 + nu^{(n-1)}$ is obtained. In Fig. 1, these curves are plotted superimposed onto the experimental points, log D vs log $[HL]_w$, under the conditions of best fit. The experimental points fit the curve corresponding to $n = 2$, which means that the polymeric species is a dimer. The values obtained for $\log K_{DR}$ and $\log K_2$ are shown in Table 1.

In order to determine K_a and because there is an increase in D due to the formation of dimers in the organic phase, corrected values of D have been calculated $\{D_{corr} = [HL]_o/([HL]_w + [L^-])\}$ and another curve-fitting method was used. In Fig. 3, the experimental curve, log D_{corr} vs pH, and the normalized curve, log D^* vs log u, under the conditions of best fit are shown. The normalized variables are defined by $D^* = D_{corr}/K_{DR}$ and $u = [H^+]/K_a$, and the normalized curve by $D^* = 1/(1+u)$. The pK_a value obtained is shown in Table 1.

The values of the constants obtained graphically were refined by means of the program LETAGROP–DISTR;[10] the final values and their standard deviations are given in Table 1. There is good agreement between the constants obtained by the two methods, as well as between the pK_a obtained spectrophotometrically[11] and refined with the program SQUAD.[12]

The distribution of NEG among the various species, as well as the theoretical log D values, were calculated by HALTAFALL.[13] The calculated log D values are plotted in Fig. 2, superimposed on the experimental points. The good agreement between them confirms the proposed model. The species distribution diagram is shown in Fig. 4.

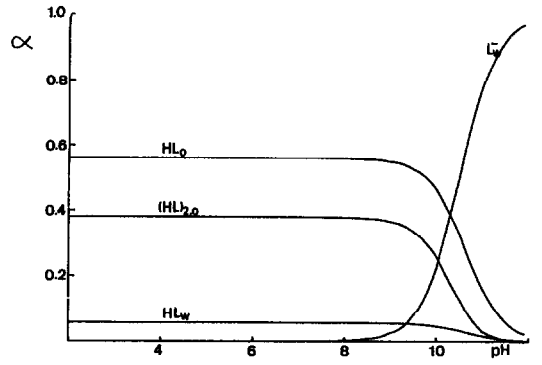

Fig. 4. Distribution diagram of species, $C_{NEG} = 10^{-2}$ M.

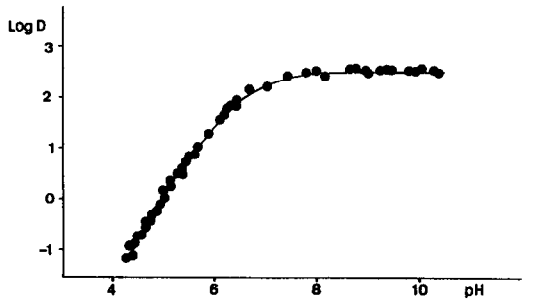

Fig. 5. Influence of pH on the distribution ratio of copper(II). $C_{NEG} = 10^{-2}$ M; $C_{Cu} = 6.3 \times 10^{-5}$ M. The full curve is calculated with the program HALTAFALL using the constants given in Tables 1 and 2.

Distribution of the copper complex

The distribution ratio values obtained with shaking times between 5 min and 3 h, show that the distribution equilibria is attained after 5 min of shaking. In subsequent experiments an extraction time of 15 min was adopted. In order to ascertain the influence of salts used to adjust the ionic strength, series of extractions varying the concentration of ClO_4^-, SO_4^{2-} and NO_3^- at constant pH and NEG concentration were carried out. The distribution ratio increases with the ClO_4^- concentration, for concentrations higher than 10^{-2} M, suggesting that perchlorate is involved in the distribution equilibria. Concentrations above 4×10^{-3} M SO_4^{2-} cause a decrease in the distribution ratio, that can be attributed to the formation of non-extractable Cu^{II}–SO_4^{2-} complexes in the aqueous phase. On the other hand, any influence of nitrate concentration was observed in the range studied (2×10^{-2}–4×10^{-1} M). In subsequent experiments the ionic strength was adjusted to 0.1 M with KNO_3.

Because the pH of the aqueous phases was adjusted with an acetic acid–sodium acetate buffer, the influence of acetate on the distribution equilibrium was studied by varying its concentration over the 10^{-3}–10^{-1} M range. The distribution ratio is independent of the acetate concentration up to 10^{-2} M. At higher acetate concentration, a slight decrease in the log D values was observed. In subsequent experiments the buffer concentration was 5×10^{-3} M.

The influence of metal concentration was studied at pH 4.65 with a NEG concentration of 10^{-2} M. The copper concentration was varied between 6.3×10^{-6} and 1.57×10^{-4} M. The distribution ratio is independent of the metal concentration for concentrations lower than 10^{-4} M. At higher concentrations the distribution ratio increases with the metal concentration, suggesting that polynuclear species are extracted under these conditions. In subsequent experiments a copper concentration of 6.3×10^{-5} M was used.

The influence of pH on the distribution ratio was studied for 10^{-2} M NEG. Figure 5 shows the variation of log D with pH. To determine the effect of the ligand concentration on the distribution ratio, a series of extractions with NEG concentrations between 10^{-3} and 10^{-1} M was performed. In Fig. 6 the values of log D are plotted vs log $[HL]_o$.

Composition of the extracted species and calculation of the equilibrium constants. Since under the experimental conditions only mononuclear species are extracted, and complexes with nitrate, acetate and hydroxide ions[14] can be neglected in the aqueous phase, the metal distribution ratio is given by:

$$D = \frac{\Sigma_n \Sigma_m [ML_n(HL)_m]_o}{[M]_w + \Sigma_p [ML_p]_w}, \qquad (3)$$

where M represents the metal and HL the extracting agent. The subscripts o and w denote the organic and the aqueous phase, respectively. Charges have been omitted for simplicity. If only the $ML_n(HL)_m$

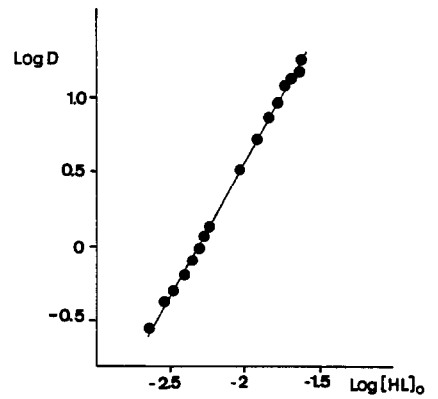

Fig. 6. Influence of reagent concentration on the distribution ratio of copper(II). pH = 5.03; $C_{Cu} = 6.3 \times 10^{-5}$ M.

Table 2. Survey of the equilibrium constants for the extraction of copper(II) with NEG into chloroform

Method	$\log \beta_1$	$\log \beta_2$	$\log K_{DC}$	$\sigma(\log D)$
Graphical	7.04	12.40	2.52	
LETAGROP–DISTR	7.24±0.10	12.83±0.06	2.54±0.04	0.05

species is extracted and the metal is present in the aqueous phase predominantly as the cation M^{n+}, the following equation can be obtained:

$$\log D = \log K_{ex} + n\mathrm{pH} + (n+m)\log[\mathrm{HL}]_o, \quad (4)$$

where K_{ex}, the extraction constant of $ML_n(HL)_m$, is $K_m K_{DC} \beta_n K_a^n / K_{DR}^m$ (β_n: formation constant of ML_n; K_{DC}: distribution constant of ML_n; K_m: adduct formation constant in the organic phase; K_a and K_{DR}: dissociation and distribution constants of the reagent, respectively).

In these conditions, if $\log D$ is plotted vs pH, at constant $[HL]_o$, or vs $\log [HL]_o$ at constant pH, straight lines with slopes n and $n+m$ will be obtained.

When species other than ML_n can be neglected in the organic phase, a plot of $\log D$ vs pH will give a straight line with a slope of zero; in this case the following equation is valid:

$$\log D = \log(K_m K_{DC}) + m \log[\mathrm{HL}]_o. \quad (5)$$

Graphical treatment: the slope of the curve in Fig. 5 ($\log D$ vs pH) varies progressively from a value near to 2, at the lowest pH studied, to zero at pH above 7.3. On the other hand, the values of $\log D$ vs $\log [HL]_o$ give a straight line of slope 1.9 (Fig. 6). According to eqs (4) and (5) this suggests that the simple chelate CuL_2 is the extracted species. The distribution constant of CuL_2 evaluated as the average of the distribution ratios obtained at pH values above 7.3, is $\log K_{DC} = 2.52$ ($s = 2 \times 10^{-2}$).

To calculate K_{DC} and the stability constants of CuL^+ and CuL_2 in the aqueous phase, Sillén's curve-fitting method was applied to the data. The normalized curves are given by $D^* = u^2/(1+pu+u^2)$, where the normalized variables and the parameter p are defined by $D^* = D/K_{DC}$, $u = \beta_2^{1/2}[L^-]$ and $p = \beta_1/\beta_2^{1/2}$. The values of the constants calculated by this method are given in Table 2.

Numerical treatment: the values of the constants obtained graphically were refined by means of the LETAGROP–DISTR program. The results are given in Table 2. The distribution of copper amongst the various species, as well as the theoretical $\log D$ values, were calculated by HALTAFALL. The calculated $\log D$ values have been plotted in Fig. 5 superimposed on the experimental points; the good agreement between them confirms the proposed model. The distribution diagram of species is shown in Fig. 7.

Distribution of the nickel complex

The distribution ratio values obtained with shaking times between 10 min and 3 h, show that the distribution equilibrium is attained after 10 min of shaking. In subsequent experiments an extraction time of 30 min was adopted.

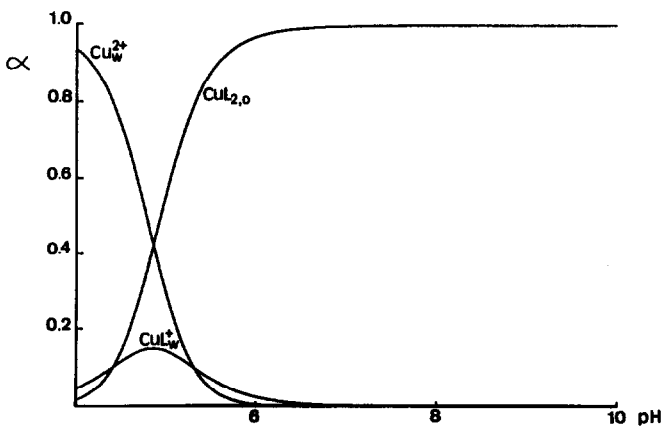

Fig. 7. Distribution diagram of species, $C_{HL} = 10^{-2}$ M; $C_{Cu} = 6.3 \times 10^{-5}$ M.

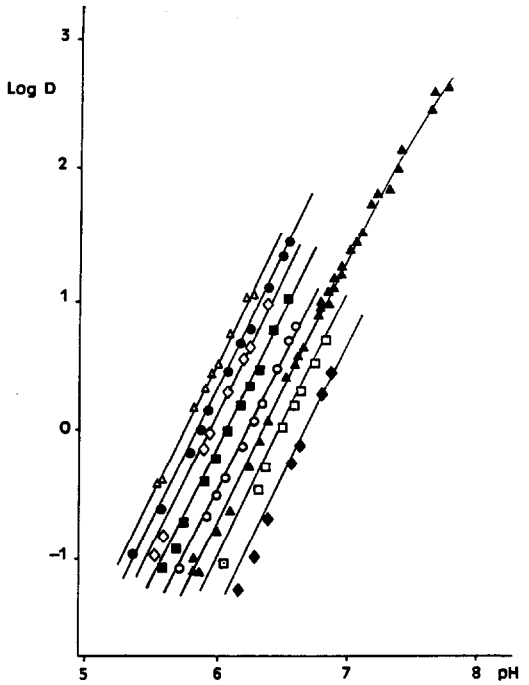

Fig. 8. Influence of pH on the distribution ratio of nickel(II). $C_{Ni} = 6.8 \times 10^{-5}$. C_{HL}: ◆ = 0.005 M; □ = 0.008 M; ▲ = 0.010 M; ○ = 0.015 M; ■ = 0.020 M; ◇ = 0.030 M; ● = 0.040 M; △ = 0.050 M. The full curves are calculated with the program HALTAFALL using the constants given in Tables 1 and 3.

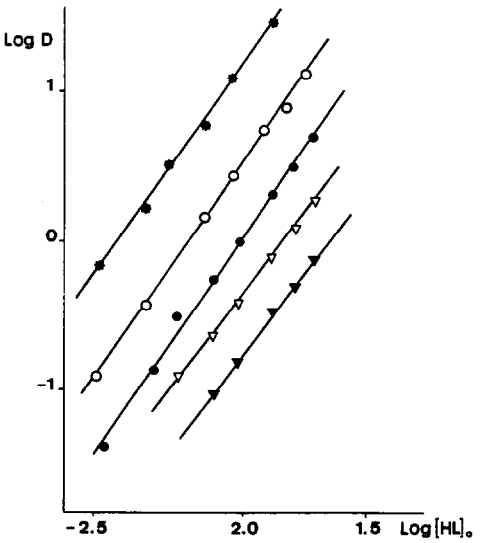

Fig. 9. Influence of the reagent concentration on the distribution of nickel(II). $C_{Ni} = 6.8 \times 10^{-5}$ M. pH: * = 6.6; ○ = 6.3; ● = 6.1; ▽ = 5.9; ▼ = 5.7.

The influence of nitrate was studied by varying its concentration over the range 4×10^{-2}–4×10^{-1} M. The distribution ratio, at constant pH and NEG concentration, was independent of the nitrate concentration. In the rest of the work the ionic strength was adjusted to 0.1 M with KNO_3.

In order to study the influence of the phosphate ion, used to adjust the pH of the aqueous phase, on the distribution equilibrium, the concentration of this substance was varied over the range 5×10^{-3}–1.25×10^{-3} M. The distribution ratio is independent of the phosphate concentration in the range studied. In subsequent experiments the buffer concentration was 1.25×10^{-3} M.

At nickel concentrations below 9×10^{-5} M the metal concentration has no effect on the distribution. For nickel concentrations greater than 9×10^{-5} M the distribution ratio increases with the metal concentration, suggesting that polynuclear species are extracted under these conditions. In subsequent experiments a nickel concentration of 6.8×10^{-5} M was used.

The influence of pH on the distribution ratio was studied for eight different ligand concentrations, ranging between 5×10^{-3} and 5×10^{-2} M. The results of these experiments are plotted in Fig. 8.

To examine the influence of NEG concentration on the distribution ratio, at constant pH, the values of log D corresponding to each reagent concentration were calculated from the curves in Fig. 8 at pH 5.7, 5.9, 6.1, 6.3 and 6.6. These values, plotted against log $[HL]_o$, are given in Fig. 9.

Composition of the extracted species and calculation of the equilibrium constants. Graphical treatment: the curves log D vs pH (Fig. 9) are straight lines with slopes between 2.0 and 2.2. In accordance with eq. (4), this suggests that $n = 2$. The values of log D plotted vs log $[HL]_o$ give straight lines with slopes between 2.8 and 2.9, a fact that, according to eq. (4) suggest that $m = 1$, although the presence of a mixture of NiL_2 and $NiL_2(HL)$ in the organic phase must be considered, $NiL_2(HL)$ being the predominant species.

Table 3. Survey of the equilibrium constants for the extraction of nickel(II) with NEG into chloroform

Method	log $K_{1,2}$	log $K_{1,3}$	σ(log D)
Graphical	−8.72	−6.21	
LETAGROP–DISTR	−8.7±0.2	−6.20±0.08	0.07

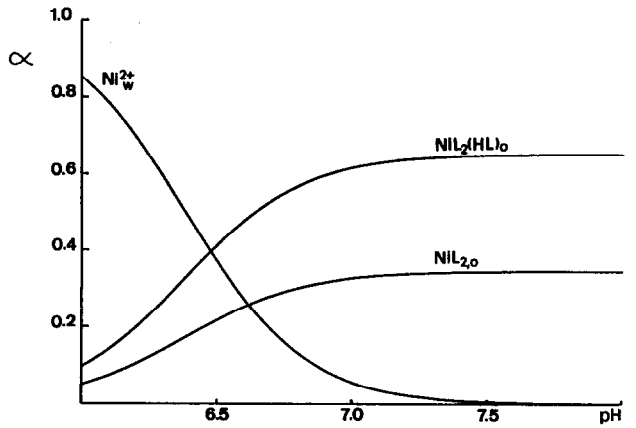

Fig. 10. Distribution diagram of species, $C_{HL} = 10^{-2}$ M; $C_{Ni} = 6.8 \times 10^{-5}$ M.

To calculate the extraction constants of the species NiL_2 ($K_{1,2}$) and $NiL_2(HL)$ ($K_{1,3}$), a curve-fitting method has been used. Superimposing the curve log $D-2$pH vs 2 log $[HL]_o$ on the normalized curve, log Y vs log u, in the conditions of best fit, the values shown in Table 3 are obtained. The normalized variables are defined by $u = (K_{1,3}[HL]_o/K_{1,2})^2$ and $Y = D[H^+]^2K^2_{1,3}/K^3_{1,2}$, and the normalized curve by $Y = u(1+u^{1/2})$.

Numerical treatment: the values obtained graphically were refined by means of the program LETAGROP–DISTR. The results obtained are given in Table 3. The value obtained for $K_{1,3}$ is better defined than that obtained for $K_{1,2}$, because NiL_2, under the experimental conditions, is always a minority species in the organic phase, as can be seen in the species distribution diagram (Fig. 10) calculated by means of the HALTAFALL program. Theoretical log D values have been calculated with HALTAFALL and have been plotted in Fig. 8, superimposed onto the experimental points; good agreement between them confirms the proposed model.

The high percentage of extraction of copper and nickel N-ethyl-glyoxylanilide oximates into chloroform (Fig. 11) means that this reagent can be used for the concentration of micro amounts of these elements.

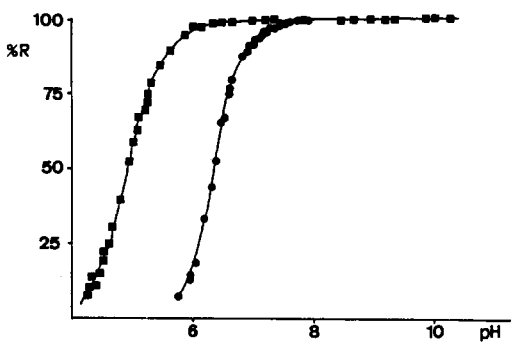

Fig. 11. Effect of pH on the extraction percentage of the N-ethyl-glyoxylanilide oximates of copper(II) (■) and nickel(II) (●). $C_{HL} = 10^{-2}$ M; $C_{Cu} = 6.3 \times 10^{-5}$ M; $C_{Ni} = 6.8 \times 10^{-5}$ M.

COORDINATION COMPOUNDS WITH A BIOMIMETIC N_2S_2 LIGAND, RESULTING IN LONG METAL–THIOETHER BONDS. THE CRYSTAL AND MOLECULAR STRUCTURE OF [1,7-BIS(5-METHYL-4-IMIDAZOLYL)-2,6-DITHIAHEPTANE]BIS(THIOCYANATO-N)COBALT(II)

(*Received* 12 *December* 1988; *accepted* 10 *March* 1989)

Abstract—The biomimetic N_2S_2 ligand, 1,7-bis(5-methyl-4-imidazolyl)-2,6-dithiaheptane (abbreviated bidhp) forms coordination compounds M(bidhp)X_2, with M = Mn, Co, Ni, Cu and X = Br, Cl, NCS. In all compounds, the metal ions are hexacoordinated by both anions and the tetradentate ligand. The ligand-field spectra agree with a distorted octahedral coordination. However, the distortion from octahedral, as indicated by the ligand-field spectrum, is so large in the case of the cobalt chloride and bromide compounds, that the sulphur atoms of the ligand must be at a very large distance from the metal ion. The crystal structure of Co(bidhp)$(NCS)_2$ was determined at room temperature: monoclinic, space group $P2_1/n$, $a = 15.034(3)$, $b = 8.544(3)$, $c = 18.289(4)$ Å, $\beta = 113.24(2)°$, $Z = 4$. The structure was solved by heavy-atom methods and refined by least-squares methods to a residual R value of 0.045 for 1498 significant reflections. The coordination geometry of the cobalt ion is distorted octahedral, with the two thiocyanate nitrogens and the two thioether sulphurs in *cis* positions, and the two imidazole nitrogens in *trans* positions. The cobalt–nitrogen distances are 2.043(7), 2.054(6), 2.058(6) and 2.067(7) Å, and the cobalt–sulphur distances are 2.656(2) and 2.618(2) Å. The cobalt–sulphur distances are significantly longer than in related compounds.

The crystal structure determinations of the Type I or blue copper proteins, plastocyanin[1] and azurin,[2] initiated the design of biomimetic ligands with two heterocyclic nitrogen and two aliphatic sulphur donor atoms.[3] Copper(I) and copper(II) compounds with such ligands, including the title ligand, have been studied intensively.[4] It is also important to investigate the ligating properties of the ligands in a wider sense, that is to investigate the coordination behaviour with respect to other transition metals. Improved insight into the coordinating properties of the ligand will be of use in the study of the copper compounds, and hence the copper proteins. For instance: some spectroscopic techniques offer more characterization possibilities with other metal ions than with copper(II), like NMR (zinc, silver), and ligand-field spectroscopy (nickel, cobalt). This so called substitution technique has also been applied in metal-substituted copper proteins.[5,6]

Furthermore, the coordination chemistry of the other transition metals with this special ligand system may also be of interest in itself because of the greater preference for a certain coordination geometry, especially for cobalt(II) and nickel(II), whereas copper(II) is flexible or shows plasticity, often resulting in isomers or temperature-dependent structures.[7–9]

The N_2S_2 ligand, 1,7-bis(5-methyl-4-imidazolyl)-2,6-dithaheptane (bidhp), which contains two imidazole groups and two thioether atoms, yielded a copper(II) chloride compound with very long copper(II)–thioether bonds. In fact these bonds are comparable in length with the Cu—S bond in plastocyanin and azurin.[10] Whether the copper(II)

* Author to whom correspondence should be addressed.

properties or the ligand constraints are responsible for the occurrence of these long metal–sulphur bonds is not clear. Comparison with related coordination compounds, differing in metal ion and with a different chelate skeleton, should show the particular influence of the propylene bridge in the case of bidhp.[11–15] In this paper we report the synthesis and spectroscopic properties of a number of coordination compounds with bidhp and the crystal structure determination of $Co(bidhp)(NCS)_2$.

EXPERIMENTAL

Most chemicals were commercially available, of reagent quality and used as received.

The synthesis of the bidhp ligand from 4(5)-hydroxymethyl-5(4)-methylimidazole and 1,3-propanedithiol, was described earlier.[4,16]

Synthesis of $M(bidhp)X_2$ (M = Mn, Co, Ni or Cu; X = Cl, Br or NCS)

A solution of 1.1 mmol of the appropriate metal(II) salt (hydrate) in 10 cm^3 of absolute ethanol was added to a warm solution of the ligand (1 mmol) in 10 cm^3 of absolute ethanol (25 cm^3 in case of copper). The colour changed immediately. Most products precipitated after addition of small amounts (5–10 cm^3) of diethyl ether and subsequent cooling to −15°C. They were filtered and dried at ambient temperature and pressure. With copper(II), the products precipitated immediately. Some products were recrystallized from a hot solution after the addition of 10 cm^3 of water. With $NiCl_2$, concentrating the solution to 5 cm^3 was necessary to induce precipitation. The manganese(II) halides precipitated immediately and appeared to be insoluble. As most metal(II) thiocyanates are not commercially available, a solution of 2–2.5 mmol NH_4NCS and 1 mmol of the ligand in absolute ethanol was added to a solution of a metal(II) nitrate or perchlorate. With freshly prepared copper(II) and nickel(II) thiocyanate the same products were obtained.

Single crystals of $Co(bidhp)(NCS)_2$, suitable for X-ray diffraction, were obtained by slow diffusion of solutions of the ligand and the metal salt [as $Co(NO_3)_2 \cdot 6H_2O$ and NH_4NCS (1 : 2)].

Elemental analyses and spectroscopic measurements

Metal contents were determined complexometrically by indirect complexometrical titration with Na_2H_2edta and zinc acetate after destruction of the sample in a boiling mixture of sulphuric acid and hydrogen peroxide (in a volume ratio 2 : 1).[17] Halogen contents were determined by potentiometric titration after combustion of the sample according to Schoeniger.[18] Other elements (C, H, N, S) were analysed at Pascher's Microanalytical laboratory (Bonn, F.R.G.) or the Microanalytical Laboratory of University College (Dublin). IR spectra were recorded on a Perkin–Elmer 580 spectrometer. Samples were prepared as alkali halide pellets (KBr, CsCl, CsI) and as Nujol mulls. Ligand-field spectra were recorded on a Perkin–Elmer 330 spectrophotometer in the diffuse reflectance mode with MgO as the reference. EPR spectra were recorded on a Varian E-3 X-band spectrometer at room temperature for powdered solids. X-ray powder diffractograms were recorded on a Guinier–De Wolff camera.

X-ray diffraction and structure determination

Crystal data. $C_{15}H_{20}CoN_6S_4$, MW = 471.54 g mol^{-1}, monoclinic, $P2_1/n$, $a = 15.034(3)$, $b = 8.544(3)$, $c = 18.289(4)$ Å, $\beta = 113.24(2)°$, $V = 2159(1)$ $Å^3$, $Z = 4$, $D_{calc} = 1.45$ g cm^{-3}, $\mu = 11.76$ cm^{-1}, $F(000) = 975$.

Data collection and structure refinement. A violet plate-shaped crystal of $Co(bidhp)(NCS)_2$ was mounted on a Nonius CAD-4 diffractometer. Cell dimensions were determined by least-squares refinement from the setting angles of 24 reflections ($9 < \theta < 13$). X-ray intensities, using graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) were collected at room temperature by the ω–θ scan technique for $2 < \theta < 22$, with $-15 < h < 15$, $0 < k < 9$, $-19 < l < 19$. The number of measured reflections was 5706, of which 2856 were independent; from these reflections 1498 were considered as significant [$I > 2\sigma(I)$]. The data were corrected for Lorentz and polarization effects in the usual way and for absorption by using de Graaff's method.[19] This correction was considered necessary as the transmission coefficients varied from 0.90 to 1.06. $R_{int} = 0.029$.

The position of the cobalt ion was determined from a Patterson map. All other non-hydrogen atoms were determined using the Autofour program.[20] The structure was refined by least-squares calculations with anisotropic thermal parameters for the non-hydrogen atoms, using a weighting scheme with factors proportional to $[\sigma(I)]^{-2}$. Scattering factors were taken from ref. 21 for the non-hydrogen atoms and ref. 22 for the hydrogen atoms. The carbon atoms in the bridge between the sulphur atoms showed disorder. Attempts to determine these positions more accurately were unsuccessful. Some hydrogen atoms were found in difference-Fourier maps, others were

placed at 1.00 Å from the parent atoms. The hydrogen atoms were kept at fixed distances to the parent atoms, their isotropic thermal parameters were coupled to one another with a final value of 12.8 Å^2. The refinement converged to R values of $R_f = 0.045$ and $R_w = 0.051$. The final shifts were less than 0.2 times the standard deviations. The highest and lowest remaining peaks in the final difference-Fourier map were +0.47 and −0.42 e Å^{-3}. The atomic coordinates and thermal parameters are available as supplementary material, together with a table of observed and calculated structure factors and analytical data. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Description of the structure of Co(bidhp)(NCS)$_2$

An ORTEP[23] drawing of the structure, also showing the atomic numbering scheme, is depicted in Fig. 1. In Table 1 the relevant bonding distances and bond angles are listed; full tables are available as supplementary material. The asymmetric unit consists of one molecule of Co(bidhp)(NCS)$_2$. There appears to be a pseudo two-fold rotation axis within the molecule through the atoms Co(1) and C(5), with the largest deviations in the orientations of the methyl groups, thiocyanate ions and the dithiaheptane bridge. The cobalt ion is coordinated by two imidazole nitrogen atoms, two thioether sulphur atoms and two thiocyanate nitrogen atoms in a *cis*-distorted octahedral geometry, with the imidazole groups *trans* to each other and the sulphur atoms and thiocyanate anions on mutual *cis* positions. The four, more or less equal, Co—N distances are comparable to those found in related compounds.[24,25] The Co—S distances are quite large, thereby constituting the main (*cis*-)distortion factor. The other distortions from an ideal octahedral geometry, like the small S—Co—N coordination angle of about 78°, originate from steric constraints imposed by the quadridentate ligand.

The ligand bond distances and angles are within the expected range, except for the apparently too short C(4)—C(5) bond and deviating bond angles around C(5). This is obviously the result of the disorder in the aliphatic chain, which is most notably for C(5). The imidazole rings are planar with deviations less than 0.005 Å. The angle between the aromatic rings amounts to 49.9(3)°. Both NCS anions are linear. The bend coordination at N(31) is remarkable, compared to the almost

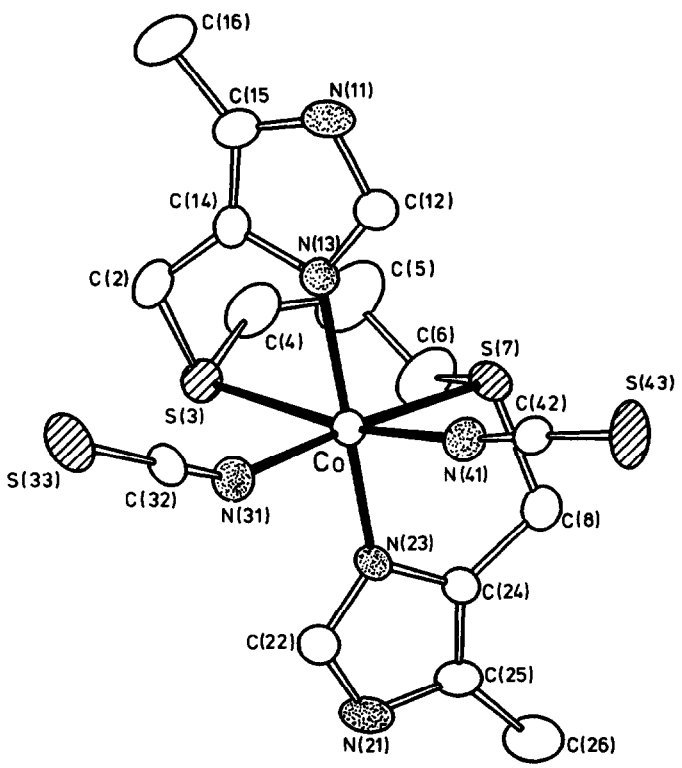

Fig. 1. ORTEP projection[23] and atomic labelling of Co(bidhp)(NCS)$_2$. The hydrogen atoms are omitted for clarity.

linear coordination at N(41). This may be caused by stronger intermolecular hydrogen bonding (*vide infra*) and crystal packing.

Each molecule of Co(bidhp)$(NCS)_2$ contains four hydrogen bridges, between the N(1) atoms of the imidazole groups and the sulphur atoms of the thiocyanate anions connecting three neighbouring molecules: viz. between N(11) and S(22) and *vice versa* through a crystallographic centre of inversion, and between N(21) and S(43) to the ones below and above it through the crystallographic screw axis parallel to *b*. Stacking between the aromatic rings is not as complete as in Cu(bidhp)Cl_2;[10] the smallest intermolecular distance between some aromatic atoms is 3.82 Å. The other intermolecular distances are larger than, or close to, the sum of the van der Waals radii.

Spectroscopic properties

The coordination compounds all analyse as M(bidhp)X_2; the analysis data are available as supplementary material. The crystal structure determinations show a distorted octahedral geometry for Co(bidhp)$(NCS)_2$ and for Cu(bidhp)Cl_2.[10] The IR spectra of all compounds show the presence of ligand bands, some of which have shifted due to coordination, but do not yield detailed information. In fact, the IR spectra of all compounds reported here resemble each other quite well, the spectra of the chloride and bromide compounds are even identical. These compounds also appear to have the same X-ray powder pattern; the manganese, cobalt and nickel chlorides and bromides are isomorphous, while the X-ray patterns of the copper chloride and bromide compounds are only slightly different, probably as a result of a slight Jahn–Teller adaption. In Table 2 the colours, X-ray and IR type, and the ligand field and EPR data are summarized. The powder EPR spectrum of the copper halide compounds is typical for a compressed geometry with a d_{z^2} ground state. The equally intensive, ligand-field maxima agree with such a coordination geometry, and have been assigned to the $d_{xz}, d_{yz} \rightarrow d_{z^2}$ and $d_{xy}, d_{x^2-y^2} \rightarrow d_{z^2}$ transitions, respectively, on the basis of a C_2 (distorted octahedral) symmetry. The charge-transfer bands around 26×10^3 cm^{-1} are presumably due to a $\pi_{\text{N-imidazole}}$–d_{Cu} transition. In the thiocyanate series more variation is encountered. The compounds are not X-ray isomorphous; but their IR spectra are quite similar. The EPR spectrum of the copper thiocyanate compound is definitely rhombic, but still indicates a d_{z^2} ground state.

The ligand-field spectra of the cobalt compounds show a distortion from octahedral towards tetrahedral symmetry. This phenomenon has also been observed with other (benz)imidazole-thioether

Table 2. Colours, X-ray and IR type, LF and EPR data of the bidhp compounds

Compound	Colour	X-ray type	IR type	LF ($\times 10^3$ cm^{-1}) and EPR (solid)
$Mn(L)Cl_2$	White	A	I	
$Co(L)Cl_2$	Purple	A	I	18.8; 15.0; 9.3; 5.0(br)

$Cu(L)(NCS)_2$	Green	E	III	26.0 (CT); 13.5; 9.5 (sh); $g_1 = 2.24$; $g_2 = 2.17$; $g_3 = 2.03$

ligands.[14,15] This can be understood by assuming pseudo-tetrahedral $N_2N'_2$, N_2Cl_2 and N_2Br_2 ligand fields, as a consequence of the very long Cu—S bonds. In $Co(bidhp)(NCS)_2$, the $N_{imidazole}$—Co—$N_{imidazole}$ coordination angle is 164.6°, significantly smaller than the ideal of 180° for an octahedron, whereas the $N_{thiocyanate}$—Co—$N_{thiocyanate}$ angle is larger than 90°, namely 98.8°. These deviations from octahedral, together with the weak interaction of the sulphur atoms, must be the origin of the "tetrahedral-like" ligand-field spectra of the cobalt compounds.

Comparison with related structures

The structure of $Co(bidhp)(NCS)_2$ is *cis*-distorted octahedral (*vide supra*), with four more or less equal Co—N distances and two long Co—S distances. The distortion from octahedral is less than would be expected from the ligand-field data. In the compound $Co(memi)_2(NCS)_2$[25] (where memi = 5-methyl-4-ethylmercaptomethylimidazole, a bidentate NS ligand) all like donor atoms are in *trans* positions, resulting in a less distorted octahedral geometry. Although in the memi compound the sulphur atoms are on "loose ends" (that is, are more flexible), they are coordinated at shorter distances (2.55 Å).[25] It appears that the propylene bridge between the sulphur atoms gives rise to a more constrained ligand, resulting in longer coordination distances.

In $Ni(bidhx)(NCS)_2$[24] (where bidhx = 1,6-bis(5-methyl-4-imidazolyl)-2,5-dithiahexane, the ethylene N_2S_2 analogue of bidhp) the Ni—S distances are 2.52 Å. The occurrence of these shorter distances may originate from:

(1) the strong preference of nickel for an octahedral geometry, or

(2) the shorter bridge in the ligand bidhx, which forces the sulphur atoms closer to the metal ion.

Both arguments could be valid in the case of Ni $(bidhx)(NCS)_2$. With copper(II), only the second argument may play a role. A comparison of the copper chloride compounds of the two ligands, bidhp[4] and bidhx,[15] shows that both compounds indeed have a comparable coordination geometry (compressed octahedral, which also results in similar EPR signals). However, in $Cu(bidhp)Cl_2$[4] the Cu—S distances are very long (2.8–2.9 Å), whereas in $Cu(bidhx)Cl_2$[15] the sulphur coordination distances are considerably shorter (2.6–2.8 Å). This clearly indicates the effect of the "bridges" in these ligands, whereby the longer bridge maintains the sulphur atoms at a longer distance from the central metal ion.

CONCLUDING REMARKS

The compounds described in this paper clearly indicate that the bis(imidazole)thioether ligand, bidhp, is a very good chelating ligand for the transition metals, manganese(II), cobalt(II), nickel(II) and copper(II). Isomorphous products, all having a distorted octahedral geometry, are formed with these metal halides. The degree of distortion is strongly dependent on the metal ion; in the case of copper, a compressed geometry is obtained, whereas in the case of cobalt, a *cis*-distorted geometry is observed, which results in tetrahedral-type ligand-field spectra.

SYNTHESIS, STRUCTURE AND SPECTROSCOPIC PROPERTIES OF SOME 2-PHENYLPHENOXIDE DERIVATIVES OF MOLYBDENUM

MICHAEL J. BARTOS, CHARLES E. KRILEY, JOYCE S. YU, JUDITH L. KERSCHNER, PHILLIP E. FANWICK and IAN P. ROTHWELL*†

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 9 *February* 1989; *accepted* 14 *March* 1989)

Abstract—Treatment of the molybdenum dimethylamido compounds, $Mo(NMe_2)_4$ and $Mo_2(NMe_2)_6$ (Mo≡Mo), with 2-phenylphenol (HOAr-2Ph), leads to formation of the aryloxide compounds, $Mo(OAr\text{-}2Ph)_4(HNMe_2)_2$ (**1**) and $Mo_2(OAr\text{-}2Ph)_6(HNMe_2)_2$ (**2**), respectively. A single crystal X-ray diffraction analysis of **1** shows a *trans* arrangement of dimethylamine ligands about the octahedral MoO_4N_2 core, while in **2** an unbridged $O_3NMo{\equiv}MoNO_3$ central coordination environment is present. Spectroscopic studies on **2** indicate a significant barrier to rotation about the unbridged molybdenum–molybdenum triple bond, presumably due to the steric demands of the OAr-2Ph ligands. Crystal data for $MoO_4N_2C_{52}H_{50}$ (**1**) at 21°C: $a = 9.617(6)$, $b = 10.199(1)$, $c = 12.315(7)$ Å, $\alpha = 107.04(2)$, $\beta = 106.29(5)$, $\gamma = 95.46(2)°$, $Z = 1$, $d_{calc} = 1.317$ g cm^{-3} in space group $P\bar{1}$; for $Mo_2O_6N_2C_{83}H_{70}$ (**2**) at 19°C: $a = 22.890(2)$, $b = 13.854(4)$, $c = 24.337(2)$ Å, $\beta = 113.969(8)°$, $Z = 4$, $d_{calc} = 1.303$ g cm^{-3} in space group $P2_1/c$.

A considerable amount of research effort has been focused over the last few years on exploring the transition metal chemistry that can be supported by alkoxide,[1–3] siloxide[4] or aryloxide[5–9] ligation. A particularly important development has been the use of sterically demanding oxygen-donor ligands attached to early transition metal centres to generate both novel and complementary organometallic chemistry. In this context, our group has recently demonstrated a diverse spectrum of reactivity that can be supported by 2,6-diphenylphenoxide ligands.[7–9] Besides simple σ-coordination through the oxygen atom, this phenoxide can undergo chelation to metal centres via formation of a σ-aryl bond (cyclometallation) or via an η^6-arene interaction.[8,9] Furthermore, the activation and hydrogenation of the side arene rings by niobium hydride groups has been shown to be possible.[10] For the Group 6 metal, molybdenum, both types of chelation have been identified, as well as simple mononuclear and dinuclear derivatives of OAr-2,6Ph$_2$ ligation.[9,11] In this paper we wish to report the synthesis and characterization of some simple molybdenum derivatives of 2-phenylphenoxide (OAr-2Ph). Unlike its more bulky counterpart, OAr-2,6Ph$_2$, more extensive substitution by this ligand is found possible and there is a definite decrease in its tendency to undergo intramolecular CH bond activation.

RESULTS AND DISCUSSION

Both of the molybdenum dimethylamido substrates, $Mo(NMe_2)_4$[12] and $Mo_2(NMe_2)_6$ (Mo≡Mo),[13] react rapidly with 2-phenylphenol (HOAr-2Ph) in hydrocarbon solvents. In the case of the mononuclear compound, reaction with 4 equivalents of HOAr-2Ph causes a rapid loss of the deep-purple colour of $Mo(NMe_2)_4$ and the formation of a deep-red solution. Work-up of the reaction mixture allows the isolation of deep-red crystals of stoichiometry $Mo(OAr\text{-}2Ph)_4(HNMe_2)_2$ (**1**) in good yield. The routine spectroscopic data on **1** is inconclusive as regards its actual structure and whether or not cyclometallation has occurred. The d^2-nature of the Mo^{IV} centre in **1** results in very broad, contact shifted ^{1}H NMR spectra which are

difficult to interpret, while the only significant absorption in the IR spectrum is the presence of a band assignable to a $\bar{\nu}$(N—H) stretch of a dimethylamine ligand. A single crystal X-ray diffraction analysis of **1** was carried out in order to accurately determine its molecular structure (Fig. 1). Some selected bond distances and angles are collected together in Table 1. It can be seen that the ligands adopt an almost perfect octahedral environment about the metal centre with *trans*-dimethylamine groups. A crystallographically-imposed inversion centre is present and the unmetallated 2-phenylphenoxide groups are solely oxygen bound. The molecular structure of **1** is closely related to that previously reported for the siloxide compound, $Mo(OSiMe_3)_4(HNMe_2)_2$.[14] The Mo—O distances in **1**, 1.963(3) and 1.972(3) Å, compare favourably with the distances of 1.950(4) and 1.951(4) Å in $Mo(OSiMe_3)_4(HNMe_2)_2$ and 1.919(2)–1.976(2) Å in the cyclometallated compound $Mo(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(HNMe_2)$.[7] The Mo—N distances in these three compounds are also very similar, but much longer than found for molybdenum–dialkylamido ligands.[15] The Mo—O—Ar angles in **1** have values of 138.7(3) and 139.6(3)°. These angles are smaller than the almost linear values found in the related siloxide compound, and smaller than typically found for 2,6-diphenylphenoxide ligands bound to related metal centres. Previous work on aryloxide derivatives of early transition metals has shown this structural parameter to be extremely flexible,[5,16] and the smaller angles observed in **1** may be a consequence of packing effects for the asymmetric aryloxide within the coordination sphere.

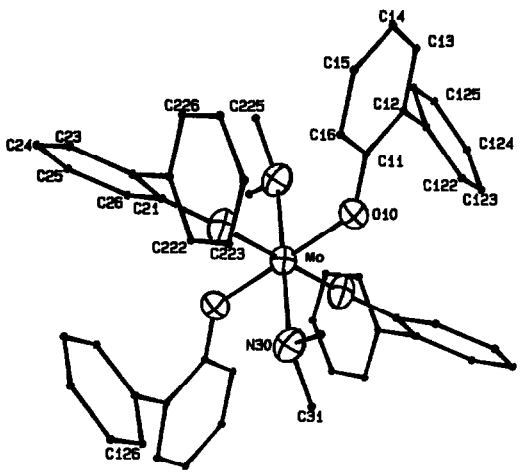

Fig. 1. ORTEP view of $Mo(OAr\text{-}2Ph)_4(HNMe_2)_2$ (**1**), emphasizing the central coordination sphere.

Closely related reactivity is seen between the dinuclear compound $Mo_2(NMe_2)_6$ and HOAr-2Ph. Hence, treatment of bright yellow solutions of the dimethylamido compound with HOAr-2Ph (6 equiv) leads to the formation of reddish-brown solutions from which the hexa-aryloxide $Mo_2(OAr\text{-}2Ph)_6(HNMe_2)_2$ (**2**) can be obtained in almost quantitative yields. Compound **2** belongs to a large and well-characterized class of dimolybdenum and ditungsten compounds of stoichiometry $M_2(OR)_6(L)_2$, that contain an unbridged $\sigma^2\pi^4$ metal–metal triple bond.[17,18] The formation of the amine adduct, **2**, contrasts with the only partial substitution observed on reacting $Mo_2(NMe_2)_6$ with 2,6-diphenylphenol,[11] and the reduction to quadruply bonded $Mo_2(OAr)_4(HNMe_2)_4$ (Mo≡Mo) compounds observed for non-bulky phenoxides.[19] The ^{1}H NMR of diagmagnetic **2** is shown in Fig. 2. The presence of two doublets due to the diastereotopic methyl groups of a Me_2NH ligand, as well as a broad septet due to the N*H* proton, are clearly evident. However, also of particular interest is the presence in the ^{1}H NMR spectrum of two doublets well separated from the aromatic region at $\sim\delta$ 9 and 4 ppm (Fig. 2). Integration of these doublets shows them to be of the same intensity as the N*H* proton signals. Hence, it would appear that they are due to protons on the central, phenolic ring of two different OAr-2Ph ligands. Previous work on dimolybdenum aryloxide anions of the type $[(L)(ArO)_2Mo(\mu\text{-}OAr)_3Mo(OAr)_2(L)]^-$ containing confacial bi-octahedral coordination environments, has shown the presence of contact shifted ^{1}H NMR signals.[19]

These arise due to the fact that this geometry does not allow strong metal–metal bonding to occur between these particular d^3-metal centres. Hence, low-lying paramagnetic states are available for thermal population, causing temperature dependent, contact-shifted ^{1}H NMR spectra.[19] In order to conclusively characterize the coordination environment in **2**, a single crystal X-ray diffraction analysis was undertaken. An ORTEP representation of the molecular structure of **2** is given in Fig. 3. It can be seen that the structure of **2** consists of two four-coordinate, approximately square-planar molybdenum atoms bound together by an unbridged metal–metal bond. The Mo—Mo distance of 2.247(1) Å compares very favourably with distances typically associated with $\sigma^2\pi^4$ triple bonds between

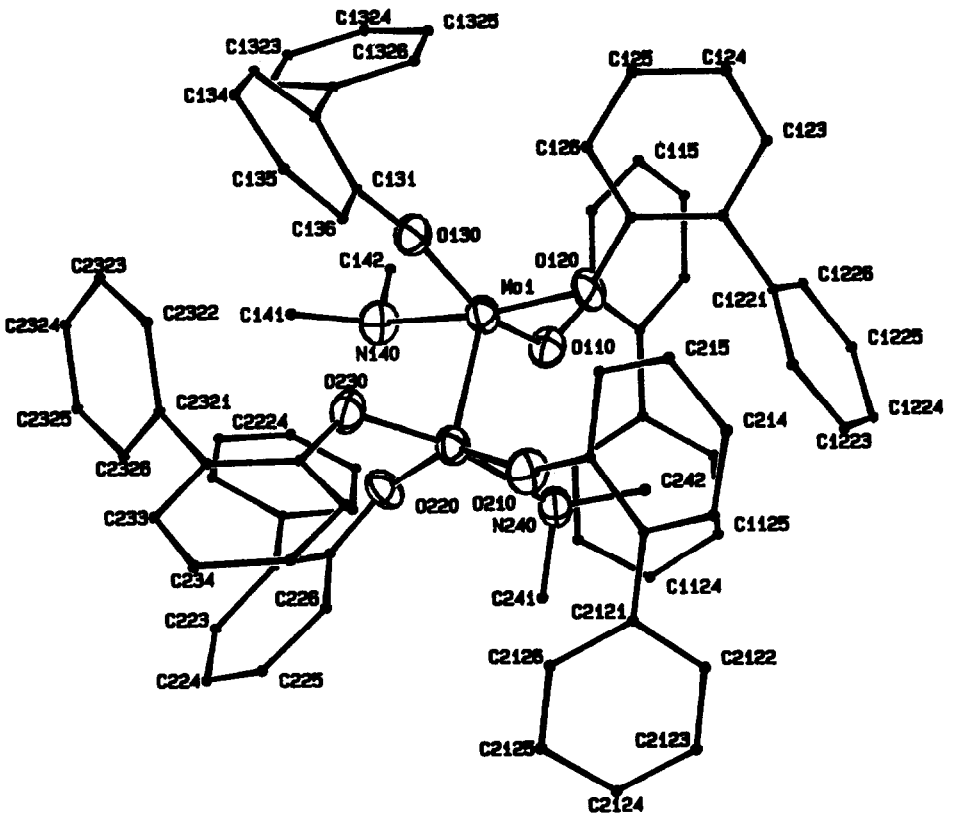

Fig. 3. ORTEP view of $Mo_2(OAr\text{-}2Ph)_6(HNMe_2)_2$ (**2**).

molybdenum atoms.[17,18] The arrangement of the donor atoms about the central dimetal core is of some interest. Newman projections down the metal–metal bond of a generalized 1,2-$Mo_2O_6N_2$ core show that there are two staggered and three eclipsed possible ideal conformations. Previous studies on base adducts of dimolybdenum and ditungsten hexa-alkoxides have shown that the arrangement of the donor atoms is not very regular.[18] However, nearly all of the compounds can be grouped into two classes, those with N—Mo—Mo—N torsion angles of 45–60°, and those with angles of 110–130°. These correspond most closely to the two staggered rotamers. However, in one previous case, that of $W_2(OPr^i_6)(HNMe_2)_2$, a torsion angle of 95° was observed with a structure approaching that of an eclipsed conformer.[18c] It can be seen (Fig. 4) that the solid-state structure of **2** also more closely approximates to an eclipsed geometry, although the N—Mo—Mo—N torsion angle of 97.6(3)° shows a definite distortion towards a staggered structure. The ^1H NMR spectrum of **2** at ambient temperatures clearly shows the presence of two, diastereotopic methyl groups for the $HNMe_2$ ligands. We can hence conclude that dissociation of these ligands is not rapid, and furthermore that rotation about the Mo≡Mo triple bond is not facile on the NMR time scale.[20]

Another interesting structural feature of compound **2** concerns the bonding and orientations of the 2-phenylphenoxide ligands. As a general rule the alkoxide ligands in $M_2(OR)_6L_2$ type compounds can be separated into two types, the four *cis* to the neutral donor atom and the two that are located *trans* in this group. Typically the oxygen atom *trans* to the nitrogen donor has a slightly shorter bond distance, typically of the order of 0.1 Å, than the distances to the two mutually *trans* alkoxide oxygen atoms.[18] This particular manifestation of the *trans* influence appears to be completely lacking in compound **2**. Instead, two of the aryloxide ligands *cis* to the amine ligand, O(130) and O(210), have much shorter contacts with the molybdenum atom than the other aryloxide oxygen atoms (Table 2). Furthermore, these aryloxide ligands contain very large Mo—O—Ar angles of 158.2(6) and 167.9(7)°; 30–40° wider than found for the other groups. These two parameters, shorter Mo—O distance and larger M—O—Ar angles, imply the presence of more oxygen-*p* to metal-*d* π-bonding taking place from these two aryloxide ligands compared to their longer bound counterparts. However, we believe that the ability of these aryloxide ligands to π-donate to the metal is controlled not so much by the position of the oxygen atom in the coordination sphere, but by the packing of their substituent aryl groups. It can be seen from Fig. 3 that the stronger bound aryloxide ligands differ from the other 2-phenylphenoxide groups in that they are oriented so that their phenyl substituents are pointing away from, or *distal* to, the metal–metal bond. The other ligands adopt the exact opposite orientation with their phenyl substituents pointed towards, or *proximal* to, the metal–metal bond. The consequence of the resulting steric crowding over the dimetal centre is that the *proximal* aryloxide ligands have to bend back at their oxygen atom linkage in order to relieve steric

pressure. However, for the distal aryloxide, the lack of any steric crowding in the position *trans* to the metal–metal bond means that the ligand is free to adopt a more linear Mo—O—Ar angle, thus allowing more π-donation to the metal centre to take place. The other aryloxides which are held by steric constraints to Mo—O—Ar angles of 120–135°, cannot be as effective at π-donation even when they are located *trans* to a weakly bound amine ligand.

A further consequence of the packing of the 2-phenylphenoxide ligands about the dimetal centre is the presence of restricted rotation about the Mo≡Mo triple bond.[20] Furthermore, the ^1H NMR spectrum of **2** (Fig. 2) shows non-equivalent aryloxide ligation, consistent with restricted rotation about the Mo—O—Ar bonds. Unequivalent assignment of the two, well separated aryloxide doublets at δ +9 and +4 ppm is not easy. However, we believe they arise from the two-position hydrogens of two of the non-equivalent aryloxide ligands. The dramatic chemical shift separation between these signals can be ascribed to the strong diamagnetic anisotropy associated with the $\sigma^2\pi^4$ triple bond in **2**.[17] It can be seen (Fig. 3) that the aryloxide ligands bound through O(130) and O(210) are oriented so that the hydrogen atoms in the two-position of the phenoxy ring lie above the metal–metal bond. This should have the effect of deshielding these protons. Hence the doublet at δ 9.0 ppm can tentatively be assigned as being due to these hydrogen atoms. The doublet at δ 4.1 ppm presumably arises from the hydrogen atoms in the two-position of two of the other aryloxide ligands. Both of the other types of aryloxide groups are oriented so that this particular proton is brought into a position distal to the Mo≡Mo bond. Hence, shielding of these protons should occur. However, it is impossible on the basis of the existing data to accurately assign this resonance.

EXPERIMENTAL

All operations were carried out under a dry N_2 atmosphere or *in vacuo*, either in a Vacuum Atmospheres Dri-Lab or by Standard Schlenk techniques. Hydrocarbon solvents were dried by distillation from sodium benzophenone. $Mo_2(NMe_2)_6$[13] and $Mo(NMe_2)_4$[12] were obtained by previously reported procedures. ^1H and ^{13}C NMR spectra were recorded on Varian Associates XL-200 and Varian Associates Gemini 200 spectrometers, and were referenced to Me_4Si using proton impurities of commercial benzene-d_6 or toluene-d_8 as internal standards. Microanalytical data were obtained from the Purdue Microanalytical Laboratory.

$Mo(OAr\text{-}2Ph)_4(NHMe_2)_2$ (1)

To a solution of $Mo(NMe_2)_4$ (0.20 g, 0.74 mmol) in benzene (15 cm^3), was added HOAr-2Ph (0.506 g, 2.98 mmol). The solution was stirred at room temperature for 12 h. Concentration of the benzene solution followed by addition of hexane, produced well-formed red crystals of the product. Yield: 0.37 g (58%). Found: C, 72.7; H, 5.9; N, 3.5. Calc. for $MoC_{52}H_{50}N_2O_4$: C, 72.4; H, 5.8; N, 3.2%. IR (Nujol mull): $\tilde{\nu}$(N—H) = 3233 cm^{-1}.

$Mo_2(OAr\text{-}2Ph)_6(HNMe_2)_2$ (2)

To a solution of $Mo_2(NMe_2)_6$ (1.0 g, 2.2 mmol) in toluene (20 cm^3), was added HOAr-2Ph (2.28 g, 13.4 mmol). An immediate colour change from yellow to red was noted. After being stirred for 3 h, the solvent was removed *in vacuo* and the crude product was recrystallized from toluene by addition of hexane. Yield: 70%. Found: C, 70.6; H, 5.3; N, 2.3. Calc. for $Mo_2O_6N_2C_{76}H_{68}$: C, 70.4; H, 5.3;

N, 2.2%. ^{1}H NMR (C_6D_6, 30°C) δ 9.2 (d), 1.47 (d, HN*Me*$_2$); 5.12 (m, *H*NMe$_2$) 4.18 (d), 8.95 (d, 6.48–7.75 aryl H's).

CRYSTALLOGRAPHIC STUDIES

Selected crystal data and data collection parameters are collected together in Table 3.

A suitable crystal for each of the two compounds was mounted in a glass capillary in a random orientation. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement using the scattering angle of 25 reflections in the range $14.6 < \theta < 20.2°$ for **1** and $14.8 < \theta < 18.9°$ for **2**, as measured by the computer controlled diagonal slit method of centring. Systematic absences and subsequent least-squares refinement indicated the space group $P\bar{1}$ for **1** and $P2_1/c$ for **2**. The data were collected at room temperature in both cases using the ω–θ scan technique. The scan rate varied from 2 to 20° min^{-1} in ω, and data were collected to a maximum 2θ of 45°. Moving crystal, moving counter background counts were made by scanning an additional 25% above and below the scan width. The counter aperture was adjusted as a function of θ. For intense reflections, an attenuator (factor 12.9) was automatically inserted in front of the detector. As a check on crystal and electronic stability, three standard reflections were remeasured every 5000 s of beam time. No decay in standards was observed

for **1**, while for **2**, a decay correction was applied (overall decay of 12%).

The structures were solved using the Patterson heavy-atom method to reveal the position of molybdenum atoms. The remaining heavy atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were located and added to the structures, but their positions were not refined. All calculations including the full-matrix least-squares refinement were performed using Enraf–Nonius SDP on a VAX computer.

BRIDGING AMIDO COMPLEXES FROM REACTIONS IN LIQUID AMMONIA. X-RAY CRYSTAL STRUCTURE OF $[Pt(PMe_2Ph)_2(\mu\text{-}NH_2)_2Pt(PMe_2Ph)_2](BF_4)_2$

CAROLINE A. O'MAHONEY, IVAN P. PARKIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 24 *February* 1989; *accepted* 15 *March* 1989)

Abstract—Treatment of HBF_4 and a slight excess of sodium in liquid ammonia with $PtCl_2(PR_3)_2$ produces $[M(PR_3)_2(\mu\text{-}NH_2)_2M(PR_3)_2](BF_4)_2$ (**2**) (M = Pt, $PR_3 = PMe_3$, PMe_2Ph, $PMePh_2$, PEt_3, $1/2Ph_2PCH_2CH_2PPh_2$; M = Pd, $PR_3 = 1/2Ph_2PCH_2CH_2PPh_2$) in >80% isolated yield. The products were characterized by ^{31}P and ^1H NMR, IR and microanalysis, and in the case of $PR_3 = PMe_2Ph$ (**2a**), by X-ray crystallography. In **2a**, the cation contains a butterfly Pt_2N_2 ring with a dihedral angle of 32°.

We are involved in the study of the reactivity of sulphur–nitrogen compounds with transition metal centres in liquid ammonia.[1,2] For example, addition of $SOCl_2$ to liquid ammonia, followed by *cis*-$PtCl_2(PR_3)_2$ (**1**), gives *cis*-$Pt(NSO)_2(PR_3)_2$.[3] During the course of the reaction between a NH_3(liq) solution of $[S_3N_2NH_2]BF_4$ and **1**, we obtained the title complex **2** containing μ-NH_2 bridges. However, further investigations led us to the conclusion that this was a product of the reaction of **1** with NH_3(liq). Here, we report on the preparation and characterization of **2**.

EXPERIMENTAL

All solvents were dried prior to use and reactions were performed under an inert atmosphere (N_2, Ar). The bis-phosphineplatinum (palladium) dichlorides were made as previously described.[4] Ammonia (BOC) and $HBF_4 \cdot 2Et_2O$ (Aldrich) were used as supplied. Sodium (BDH) was washed free of oil with hexane prior to use. ^{31}P-{^1H} and ^1H NMR spectra were obtained using a JEOL FX90Q spectrometer operating at 36.21 and 89.55 MHz and are referred to external 85% H_3PO_4 and internal TMS, respectively. IR spectra were recorded as pressed KBr discs using a Perkin–Elmer 1720X instrument. Elemental analysis were performed by the microanalytical service at Imperial College.

Preparation of $[M(PR_3)_2(\mu\text{-}NH_2)_2M(PR_3)_2](BF_4)_2$ (M = Pt, $PR_3 = PMe_3$, PMe_2Ph, $PMePh_2$, PEt_3, $1/2Ph_2PCH_2CH_2PPh_2$; M = Pd, $PR_3 = 1/2Ph_2PCH_2CH_2PPh_2$)

In a typical reaction, $HBF_4 \cdot 2Et_2O$ (0.11 mmol) was added cautiously, dropwise to NH_3 (liq) (5 cm^3) at −78°C, followed by sodium (0.13 mmol) to generate a dark blue solution. $MCl_2(PR_3)_2$ (0.08 mmol) was added and the resultant brown–blue suspension was stirred for 0.5 h at −78°C. The ammonia was then allowed to evaporate slowly under nitrogen as the reaction warmed to room temperature, leaving a white solid. Extraction with CH_2Cl_2 (5 cm^3) and removal of solvent *in vacuo* gave $[M(PR_3)_2(\mu\text{-}NH_2)_2M(PR_3)_2](BF_4)_2$ (0.03 mmol, *ca* 80%). Crystals suitable for X-ray analysis were grown by hexane diffusion into a CH_2Cl_2 solution of **3**. ^{31}P NMR, NH IR vibrational frequencies, microanalyses and yields are given in Table 1.

$Z = 4$ (the molecule is disposed about a two-fold axis), $D_c = 1.76$ g cm^{-3}. μ(Cu-K_α) = 116 cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 2719$.

Data collection and processing

Nicolet $R3m$ diffractometer, ω-scan method, ($2\theta \leqslant 116°$), graphite monochromated Cu-K_α radiation; 3555 independent measured reflections, 3359 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction (ellipsoidal) based on 360 azimuthal measurements. Maximum and minimum transmission factors 0.128 and 0.041 respectively.

Structure analysis and refinement

The structure was solved by the heavy atom method and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U$ eq(C) and allowed to ride on their parent carbons. The methyl groups were refined as rigid bodies. One of the BF_4^- groups is disorded about a two-fold axis and was refined in two orientations. Refinement was by block-cascade full-matrix least-squares to $R = 0.031$ ($R = \Sigma[|F_o| - |F_c|]/\Sigma(|F_o|)$, $R_w = 0.033$ ($w^{-1} = \sigma^2(F) + 0.00028F^2$). The maximum and minimum residual electron densities in the final ΔF map were 1.53 and −0.56 e Å^{-3}, respectively. The mean and maximum shifts/error in the final refinement cycle were 0.003 and 0.011, respectively.* Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[5]

RESULTS AND DISCUSSION

There have been surprisingly few reports of binuclear amido-bridged platinum complexes.[6–8] It was claimed in 1967[6] that reaction of *cis*-$PtCl_2(PPh_3)_2$ with hydrazine gives crystals which are a mixture of $[(Ph_3P)_2Pt(NNH)_2Pt(PPh_3)_2]^{2+}$ and $[(Ph_3P)_2Pt(NH_2)_2Pt(PPh_3)_2]^{2+}$ (from X-ray studies), but no ^{31}P NMR data was given. More recently,[7] a neutral NH_2-bridged species, [(Ph_2MeP)(Ph_2PO)Pt(NH_2)$_2$Pt(P(O)Ph_2)(PMePh_2)] (**3**), was obtained from the reaction between $PtCl_2$(dppm) (dppm = $Ph_2PCH_2PPh_2$), NaOH and liquid ammonia. Finally,[8] $[(Ph_3P)MePt(NH_2)_2PtMe(PPh_3)]^{2+}$ (**4**) was obtained by deprotonation of *trans*-$[PtMe(NH_3)(PPh_3)_2]^+$. After observing the formation of **2** from reactions in liquid ammonia containing $[S_3N_2NH_2]BF_4$, we investigated whether the sulphur–nitrogen molecule was the source of the NH_2 bridges or was simply affecting the pH of the solution. Thus, if HBF_4 is added to liquid ammonia and then titrated with sodium until there is a slight excess of sodium (as evinced by a pale blue colouration), addition of **1** results in formation of **2** in high yield. The reaction can be represented by eq. (1) (note that only a slight excess of sodium is required). Attempts to prepare **2** by direct reaction of $NaBF_4$ in liquid ammonia were unsuccessful, suggesting that the pH of the solution is very important:

$$2cis\text{-}PtCl_2(PR_3)_2 + NaNH_2(\text{trace}) + 2NaBF_4 \xrightarrow{NH_3(liq)} [(R_3P)_2Pt(NH_2)_2Pt(PR_3)_2](BF_4)_2, \quad (1)$$

Compounds **2** have been characterized spectro-

* Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Table 2. Selected bond lengths and angles in **2a**

Pt—P(1)	2.246(1)	Pt—P(2)	2.254(2)

P(2)—Pt—N(1′)	91.7(1)	N(1)—Pt—N(1′)	77.2(2)

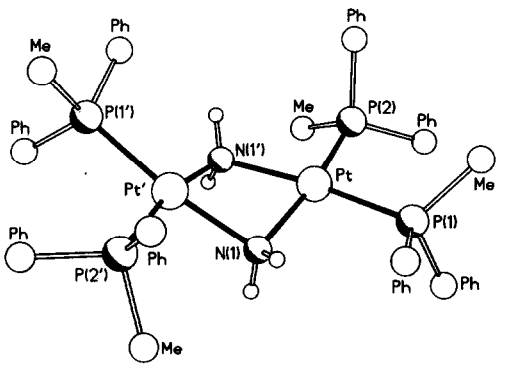

Fig. 1. The X-ray structure of the core of the cation in **2a** showing the atom numbering. Phenyl rings and BF_4^- anions are omitted for clarity.

scopically (Table 1) and in the case of PR_3 = $PMePh_2$ (**2b**) by X-ray crystallography. The ^{31}P NMR spectra are as expected with $^1J\{^{31}P-^{195}Pt\}$ couplings which are appropriate for platinum(II) compounds. In the IR spectra, each compound exhibits two ν(NH) vibrations. The unambiguous location (from a ΔF map) of the protons on the bridging nitrogen atoms in the crystal structure of **2a** (Table 2, Fig. 1) confirms the cation to be a *bis*-amido-bridged species. The molecule has crystallographic C_2 symmetry with the geometry about each platinum being distorted square planar; the P(1)—Pt—P(2) plane is rotated by *ca* 7° relative to that of the N(1)—Pt—N(1′) plane. The Pt—N distance in **2a** is slightly reduced compared to those in the neutral analogues, **3** and **4**, whilst the Pt—Pt′ separation (3.134(1) Å in **2**) is significantly longer (3.087(1) and 3.106(1) Å for **3** and **4**, respectively). The N—Pt—N′ angle (77.2(2)°) does not differ significantly from those previously reported. As in both **3** and **4**, the Pt_2N_2 ring in **2a** is also folded, although in this instance by significantly less (32° in **2** vs *ca* 45° in **3** and **4**). There are no hydrogen bonding interactions between the amido groups and the BF_4^- counterions.

ORGANOLANTHANIDES—XIV.* PREPARATION AND STRUCTURE OF BIS(η^5-CYCLOPENTADIENYL)BIS(TRIPHENYLPHOSPHINE OXIDE)YTTERBIUM(II)—THE FIRST X-RAY CRYSTAL STRUCTURE OF A PHOSPHINE OXIDE–ORGANOLANTHANIDE(II) COMPLEX

G. B. DEACON,† B. M. GATEHOUSE and P. A. WHITE

(*Received* 17 *January* 1989; *accepted* 16 *March* 1989)

Abstract—Reaction of $Cp_2Yb(DME)$ (Cp = cyclopentadienyl; DME = 1,2-dimethoxyethane) with triphenylphosphine oxide yields $Cp_2Yb(OPPh_3)_2$. The X-ray crystal structure shows eight-coordinate ytterbium with a pseudo-tetrahedral arrangement of two oxygen donor atoms and the centroids of two eclipsed η^5-cyclopentadienyl rings. Surprisingly short Yb—O distances (2.30(2); 2.33(2) Å) and the absence of major inter-ligand contacts indicate an uncrowded arrangement.

Triphenylphosphine oxide complexes of the oxophilic lanthanide(III) ions are well-known,[2] and phosphine oxides have been used in solvent extraction of lanthanides.[3] Thus, it is surprising that few triphenylphosphine oxide (or other phosphine oxide) complexes of organolanthanides have been prepared.[4–8] The sole crystal structures are those of *cis*- and *trans*-$[(C_5Me_5)_2Sm^{III}OPPh_3]_2(\mu\text{-}OCH{=}CHO)$ (**I** and **II**), where the presence of the phosphine oxide results from attempts to crystallize the novel product(s) of the redox reaction between bis(η^5-pentamethylcyclopentadienyl)samarium(II) and carbon monoxide.[6] There are only two known organolanthanide(II) complexes with triphenylphosphine oxide, viz. $(C_5Me_5)_2M(THF)(OPPh_3)$ (M = Sm[7] or Yb;[8] THF = tetrahydrofuran), and these have been characterized spectroscopically. We now report the preparation and crystal structure of $Cp_2Yb(OPPh_3)_2$ (Cp = cyclopentadienyl). The sole previous X-ray structure of an *un*substituted cyclopentadienyllanthanide(II) complex is that of $Cp_2Yb(DME)$ (DME = 1,2-dimethoxyethane), in which the sites of the cyclopentadienyl ligands are disordered.[9] Organolanthanide(II) X-ray structures are dominated by those of bis(η^5-pentamethylcyclopentadienyl)- derivatives,[5] probably owing to their ease of crystallization.

RESULTS AND DISCUSSION

Preparation and spectroscopic data

Reaction of bis(η^5-cyclopentadienyl)(1,2-dimethoxyethane)ytterbium(II) with triphenylphosphine oxide (mole ratio, 1:2) in DME, gave a black precipitate of bis(η^5-cyclopentadienyl)bis(triphenylphosphine oxide)ytterbium(II) in good yield:

$$Cp_2Yb(DME) + 2Ph_3PO \longrightarrow Cp_2Yb(OPPh_3)_2\downarrow + DME. \quad (1)$$

Although oxidation of $Cp_2Yb(DME)$ by trimethylamine oxide giving $(Cp_2Yb)_2O$ has been observed,[10] a similar reaction was not expected with triphenylphosphine oxide, since $(C_5Me_5)_2Sm(THF)(OPPh_3)$ has been prepared[7] and $(C_5Me_5)_2Sm$ is a much more powerful reductant[5,11] than Cp_2Yb.[12] However, an attempt to prepare an analogous triphenylarsine oxide complex resulted in oxidation presumably in accordance with reaction (2):

$$2CpYb(DME) + Ph_3AsO \longrightarrow Ph_3As + (Cp_2Yb)_2O + 2DME. \quad (2)$$

[a] Based on those for coordinated triphenylphosphine oxide[13] (terminology is that of Whiffen[14]) and η^5-cyclopentadienyl ligands.[15]

^{1}H NMR and mass spectra confirmed the presence of both ligands in $Cp_2Yb(OPPh_3)_2$. The IR spectrum (Table 1) was of considerable interest, showing two ν(P=O) frequencies. One corresponds to that (1193 cm^{-1})[13] of free triphenylphosphine oxide, whilst the other is lowered from the free ligand value, as expected[16] on coordination. This suggests either that solid $Cp_2Yb(OPPh_3)_2$ contains seven-coordinate $Cp_2Yb(OPPh_3)$ and a molecule of uncoordinated triphenylphosphine oxide,* or the two ν(P=O) bands are the antisymmetric and symmetric stretching modes of an eight-coordinate complex with only a small average shift (8 cm^{-1}) from the free ligand value. A crystal structure was needed to resolve the structural alternatives.

The black crystals dissolve in THF to give a purple–brown solution with the visible maximum shifted only 9 nm from that of Cp_2Yb in THF.[18] This result and the insolubility of the complex in DME suggest that dissolution in THF involves at least partial dissociation of triphenylphosphine oxide:

$$Cp_2Yb(OPPh_3)_2 + THF \rightleftharpoons Cp_2Yb(THF)(OPPh_3) + Ph_3PO.$$

X-ray crystal structure

Single crystals of $Cp_2Yb(OPPh_3)_2$ were obtained on partial evaporation of a solution in THF. The crystal structure (Fig. 1) is the first of an organolanthanide(II)–phosphine oxide complex or any Ph_3PO–lanthanide(II) ion complex. It shows eight-coordinate ytterbium with a distorted pseudo-tetrahedral arrangement of two oxygen donor atoms and the centroids (CT) of two eclipsed cyclopentadienyl rings. Selected bond lengths and angles are given with Fig. 1. All O—Yb—CT angles are near 109°, but CT(1)—Yb—CT(2) and O(1)—Yb—O(2) are markedly larger and smaller than tetrahedral, respectively, as is observed in $Cp'_2M(THF)_2$ ($Cp' = Me_3SiC_5H_4$, M = Yb; $Cp' = C_5Me_5$, M = Sm).[5] However, O—M—O and CT—M—CT angles of the present complex are larger and smaller, respectively, than those[5] of $Cp'_2M(THF)_2$, owing to greater steric repulsion between the substituted cyclopentadienyl groups.

The presence of η^5-cyclopentadienyl groups in $Cp_2Yb(OPPh_3)_2$ is indicated by the small variation in Yb—C bond lengths. Greater bond length differences are observed for the η^5-bonded $Cp'_2M(THF)_2$ complexes[5] and $Cp_2Yb(DME)$.[9] Further support for η^5-bonding is provided by the 90° Yb—CT—C angles. Predominantly ionic cyclopentadienyl–metal bonding is indicated[9,19] by the value (1.62 Å) for the effective ionic cyclopentadienyl radius[19] (the average Yb—C distance minus the ionic radius of eight-coordinate Yb^{2+} (1.14 Å)[20]). The Yb—O distances (Fig. 1) are markedly shorter (by 0.16 $Å_{av}$) than those of $Cp_2Yb(DME)$,[9] the only other crystallographically-determined structure of a Cp_2Yb complex. In **I** and **II** (see Introduction), the Sm^{III}—$OPPh_3$ distances are *ca* 0.08 Å shorter than average Sm^{III}—O(THF) bond lengths.[6] The distance (*d*), obtained by subtraction of the appropriate lanthanide ionic radii[20] from lanthanide–oxygen bond distances, also illustrates the shortness of the Yb—O bonds. For most Ph_3PO—M^{3+} (M = lanthanide) complexes[2] and the organometallics **I** and **II**,[6] $d = 1.29 \pm 0.03$ Å (cf. 1.34 ± 0.06 Å for most organolanthanide(II or III) complexes with ethers[9]). Exceptions are two highly hindered tris(bis(trimethylsilyl)amido)lanthanum (III) complexes,[21] for which $d = 1.50$ and 1.52 Å, and the uncrowded $Ce(NO_3)_4(OPPh_3)_2$,[22] for which $d = 1.15$ Å. Values for $Cp_2Yb(OPPh_3)_2$ (1.19, 1.16 Å) approach the last, indicating a relatively uncrowded structure and/or some covalency in the Yb—O bonds.

The sum of the solid cone angle factors (Σc.a.f.) for $Cp_2Yb(OPPh_3)_2$ (0.61), calculated from the X-ray structure parameters using the first-order cone angle model,[23] is within the stable region (0.57–0.77) for organolanthanide(II) complexes.[24] Although significant second-order repulsion[23] involving Ph_3PO molecules may be expected, the

* See, e.g. $LiI(OPPh_3)_5$ which contains $[Li(OPPh_3)_4]^+$ and a molecule of uncoordinated Ph_3PO.[17]

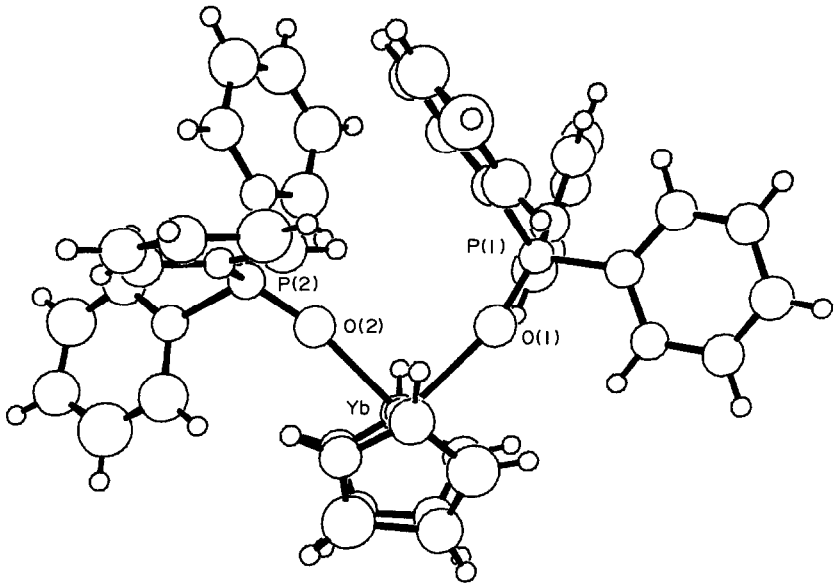

Fig. 1. Crystal structure of $Cp_2Yb(OPPh_3)_2$. Selected bond lengths (Å) and angles (°):

CT(1)—Yb—O(2)	105.9(7)	$(Yb—CT—C)_{av}$	90.0(12)
CT(2)—Yb—O(1)	108.7(8)		

location is well displaced from the metal ion and the donor atom owing to the spear-like nature of the ligand. There are no significant inter-ligand contacts (cf. $La(N(SiMe_3)_2)_3(OPPh_3)$[21]), and the phenyl rings are well separated from the cyclopentadienyl groups (Fig. 1). Since Σc.a.f. for $Cp_2Yb(OPPh_3)_2$ is at the low end of the stable range, second-order effects are not expected to lead to overcrowding. A meaningful value for the second-order cone angle factor cannot be calculated owing to the substantial variation in O—Yb—*o*-H angles (23–61°).

Despite the short Yb—O bonds, the P—O distances (Fig. 1) are close to the free ligand value (1.46(1) Å)[25] and correlate with the very small shift of ν(P=O) from that of free Ph_3PO. This contrasts with $Ce(NO_3)_4(OPPh_3)_2$,[22] for which the short Ce—O distances are (more expectedly) associated with a large shift in ν(P=O) and larger P—O distances (1.531(8), 1.526(8) Å). In fact, the present P—O distances are shorter than those of all crystallographically characterized Ph_3PO–lanthanide complexes.[2,6] Although many of the differences are within experimental error, the overall trend is clear. Metal–O—P angles in triphenylphosphine oxide complexes are generally near 150°,[26] which is midway between the value (120°) for full covalent bonding and that (180°) for electrostatic bonding and minimum steric repulsion.[26] In lanthanide–$OPPh_3$ complexes, larger angles are usually observed[2] and approach linear in the highly hindered $La(N(SiMe_3)_2)_3(OPPh_3)$.[21] The values for $Cp_2Yb(OPPh_3)_2$ (Fig. 1) are relatively small for lanthanide complexes, and contrast with the larger values[22] for $Ce(NO_3)_4(OPPh_3)_2$ [169.2(5), 173.2(4)°].

EXPERIMENTAL

General

Syntheses were carried out in greaseless Schlenk apparatus under purified (BASF R3/11 oxygen-removal catalyst and molecular sieves) nitrogen. Solids were handled under purified nitrogen or argon in a recirculating atmosphere drybox

(Vacuum Atmospheres HE43-2 Drilab or Miller-Howe 100). Details of solvent purification, handling procedures and spectroscopic methods have been given in previous papers.[18,27-29] The IR spectrum (Table 1) was recorded on a mull of the compound in dry degassed Nujol. For mass spectrometry, the complex was briefly exposed to the atmosphere (with resulting decomposition), before insertion into the spectrometer. For ^{1}H NMR spectroscopy, perdeuterotetrahydrofuran was degassed and distilled from sodium–benzophenone. It contained an aromatic impurity, probably benzene from decomposition of Ph_2CO, hence meaningful integration could not be obtained. Chemical shifts are in ppm downfield from internal TMS.

When $Cp_2Yb(OPPh_3)_2$ was analysed for ytterbium by the reported method (H_2SO_4/HNO_3 digestion, followed by titration with disodium dihydrogen ethylenediaminetetraacetate),[27-29] a satisfactory titrimetric end point could not be obtained. Accordingly, accurately weighed samples (*ca* 0.2 g) were dissolved in pure THF (5 cm^3) and were decomposed with dilute sulphuric acid (2 M, 5 cm^3). The solution was extracted with dichloromethane and the organic layer separated and washed with water. The aqueous layer and washings were heated under a stream of nitrogen. Aliquots of this solution were than buffered to pH 4.5 with hexamethylenetetraamine, and titrated by the standard methods.[27-29] The method was validated by analysis of $Cp_2Yb(DME)$.

Reagents

Triphenylphosphine oxide (K&K) was sublimed under vacuum to decompose any hydrate[26] present, and triphenylarsine oxide (from a modification of the reported preparation[30]) was dehydrated by azeotropic distillation. Both compounds were shown to be anhydrous by IR spectroscopy. $Cp_2Yb(DME)$ was obtained by the reported method.[18]

Preparation of bis(η^5-cyclopentadienyl)bis(triphenylphosphine oxide)ytterbium(II)

Bis(η^5-cyclopentadienyl)(1,2-dimethoxyethane) ytterbium(II) (0.15 g, 0.38 mmol) and triphenylphosphine oxide (0.22 g, 0.79 mmol) reacted immediately on addition of 1,2-dimethoxyethane (5 cm^3) to give a black, highly air- and water-sensitive crystalline precipitate of the title complex, which was filtered off and washed with the solvent (yield, 0.20 g, 61%) (Found: Yb, 20.7. $C_{46}H_{40}O_2P_2Yb$ requires: Yb, 20.1%). ^{1}H NMR: 5.60, s, Cp; 7.4–7.7, m, Ph. Mass spectrum: *m/z* 277 [100%, $C_{18}H_{14}OP^+$], 201 [19, Ph_2PO^+], 185 [10, Ph_2P^+], 183 [15, $C_{12}H_8P^+$], 152 [10, $C_{12}H_8^+$], 77 [24, Ph^+], 66 [12, $C_5H_6^+$], 51 [16, $C_4H_3^+$]. UV–vis–near-IR(300–1100 nm): $\lambda_{max}(\varepsilon)$ 382(sh), 516(130)nm. The filtrate from the synthesis was virtually colourless, suggesting near quantitative precipitation. A similar preparation in THF (25 cm^3) yielded a purple solution, which, on partial evaporation of the solvent, gave black crystals of the title complex (yield, 24%) (Found: Yb, 20.7%), with spectroscopic properties identical with those of the product from the first preparation.

Reaction between $Cp_2Yb(DME)$ *and triphenylarsine oxide*

Dissolution of triphenylarsine oxide (0.82 g, 2.5 mmol) and $Cp_2Yb(DME)$ (0.50 g, 1.3 mmol) in THF (20 cm^3) gave an immediate yellow solution, followed (after *ca* 1 min) by formation of a white precipitate, which redissolved on further stirring. After 12 h, the solution had turned brown, and the vis–near-IR spectrum: λ_{max} 870, 916, 925, 950, 986, 1021, 1032 nm, was indicative[31] of ytterbium(III).

X-ray crystallography

Crystals of $Cp_2Yb(OPPh_3)_2$ were grown by slow distillation of solvent from a solution in THF in a sealed double Schlenk tube, and were stored under dry, degassed Nujol. Selected crystals were mounted under purified argon in 0.8 mm Lindemann capillaries and held in place by high vacuum grease. Crystal data $YbC_{46}H_{40}O_2P_2$: monoclinic, space group $P2_1/c$, $a = 10.925(8)$, $b = 21.942(12)$, $c = 16.839(10)$ Å, $\beta = 99.83(15)°$, $V = 3977.32$ Å^3, $Z = 4$, D_m (air-sensitive material, density not measured), D_c 1.44 g cm^{-3}; Mo-K_α radiation (0.7107 Å), $\mu = 24.8$ cm^{-1}; Philips PW 1100 diffractometer, graphite monochromator, ω–2θ scans at a scan speed of 0.25° s^{-1} (the relatively high speed was used due to a high decomposition rate of several crystals in the X-ray beam) with $6 \leqslant 2\theta \leqslant 40°$ and scan width $(1.20+0.2\tan\theta)°$ at 22°C. 3698 unique reflections, 1656 observed [$F_o \geqslant 6\sigma(F_o)$], absorption correction based on indexed crystal faces (min-max transmission = 0.478/0.673). Solution by Patterson method and subsequent difference Fourier techniques, refinement by full-matrix least-squares methods. Hydrogen atoms inserted in geometrically calculated positions and refinement of position and thermal parameters (anisotropic for ytterbium, phosphorus and oxygen and a single isotropic parameter for hydrogen atoms) resulted in $R = 0.057$,

and $R_w = 0.051$. All calculations were carried out with SHELX76.[32] Atomic scattering factors for neutral atoms[33] were corrected for anomalous dispersion. Full details of the crystal structure results are available on request from the Editor. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

Abstract—The determination of the crystal and the molecular structure of a five-coordinate palladium(II) complex and its ^1H and ^{31}P NMR studies are described. The crystals of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-phen})][BF_4]_2$ ($C_{38}H_{45}N_2P_3PdB_2F_8$) are monoclinic, space group $P2_1/n$, with $Z = 4$ and unit cell dimensions: $a = 23.346(6)$, $b = 13.429(2)$, $c = 12.929(2)$ Å, $\beta = 91.96(2)°$. The structure was determined by a heavy-atom method from diffractometer data and refined to an R value of 0.048 for 4601 unique observed reflections. Three phosphorus atoms from the three dimethylphenylphosphines, and a nitrogen atom from the 2,9-dimethyl-1,10-phenanthroline (2,9-Me_2-phen), form an approximately square-planar configuration about the palladium atom; Pd—P(1) 2.283(1), Pd—P(2) 2.395(2), Pd—P(3) 2.407(2) and Pd—N(1) 2.164(5) Å. The remaining nitrogen atom is at the apex of a distorted square pyramid, Pd—N(10) 2.588(5) Å. The ^1H NMR spectrum shows fluxional motion which averages the two halves of the 2,9-Me_2-phen.

We have previously described five-coordinate palladium(II) and platinum(II) complexes containing azaheterocyclic ligands[1–3] which are undergoing coordination site exchange of their two nitrogen atoms. From variable temperature ^1H NMR of $[ML(2,9\text{-}R_2\text{-}4,7\text{-}R'_2\text{-phen})_2][X]_n$ (M = Pt, L = PPh_3, R = R′ = H, X = BF_4^-, $n = 2$; M = Pd, L = PPh_3, R = H, R′ = Me or Ph, X = BF_4^-, $n = 2$; M = Pd, L = Cl, R = Me, R′ = H, X = PF_6^-, $n = 1$), the averaging process of the two halves of aza-

* Author to whom correspondence should be addressed.

heterocyclic ligands has best been explained by two synchronous rearrangement systems: one, the twist motion from a trigonal bipyramid to a tetragonal pyramid, and the other, the concurrent oscillation.[3] The crystal structure of $[PdCl(PPh_3)_2(phen)][BF_4]$[2] is a distorted square pyramid with elongation of the apical bond length Pd—N(10) 2.68 Å (2.09 Å for Pd—N(1) at the basal plane). Such elongation of the apical M—L bond length is relatively common in a square-pyramidal structure.[5-8] In the analogous platinum(II) complexes, $[PtCl(PEt_3)_2(phen)]^+$ (two phosphines are mutually *cis* at the basal plane)[6] and $[Pt(CN)(phen)_2]^+$,[4] the corresponding apical bond lengths are 2.84 (2.14) and 2.76 Å (2.05 Å), respectively. Their fluxional behaviour in solution, however, does not seem to proceed via dissociation of the azaheterocyclic ligand, since the observance of ^{195}Pt satellites in the ^1H and ^{13}C NMR spectra shows no such indication. Therefore, the apical bond length M—L, crystallographically determined in the five-coordinate complex, does not seem to be a main factor in determining its fluxional motion. However, the solution structure of $[PdCl(PPh_3)_2(phen)]^+$ is close to a square-planar conformation with an unusual unidentate phen ligand. Fluxional motion of $[PdL_1L_2L_3(2,9\text{-}R_2\text{-}phen)][BF_4]_n$ (L_1 = Cl, $L_2 = L_3 = PPh_3$, R = Me or H, $n = 1$; L_1 = Cl, L_2 or $L_3 = PPh_3$, or $P(OMe)_3$, $n = 1$; L_1 = Cl, $L_2 = L_3 = P(OMe)_3$, $n = 1$; $L_1 = L_2 = L_3 = PMe_2Ph$, R = H or Me, $n = 2$) is thus still ambiguous as to whether it corresponds to an oscillation (intramolecular) or to a dissociation process taking place via an intermolecular pathway.

This paper deals with the crystal structure of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$ in comparison with the solution structure by ^{31}P and ^1H NMR.

EXPERIMENTAL

Yellow crystals of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$ were grown from an acetone–ethanol mixed solution under isothermal vaporization. A crystal of approximate dimensions $0.10 \times 0.13 \times 0.20$ mm was used during the measurements, made using Mo-K_α radiation with a graphite crystal monochromator, on a Rigaku AFC-5 four circle diffractometer ($\lambda = 0.71069$ Å).

Crystal data: $M_r = 453.61$, monoclinic, $a = 23.346(6)$, $b = 13.429(2)$, $c = 12.929(2)$ Å, $\beta = 91.96(2)°$, $U = 4051.3(16)$ Å^3, space group $P2_1/n$, $Z = 4$, $D_x = 1.40$ g cm^{-3}, $F(000) = 1840$, μ(Mo-K_α) = 6.060 cm^{-1}. The cell parameters were refined by least-squares methods on the basis of 25 2θ values with $33 < 2\theta < 38°$. The space group was determined from the systematic absences of reflections ($0k0$; k odd, $h0l$; $h+l$ odd). The intensity data were measured using the ω–2θ scan technique, with a scan speed of 2° s^{-1}. The intensity of the incident beam was monitored throughout the data correction by measuring three reference reflections, and these showed no significant change in intensities ($0.98 < F_o < 1.04$). 7643 reflections were measured ($0 \leqslant h \leqslant 27$, $0 \leqslant k \leqslant 15$, $-15 \leqslant l \leqslant 15$), among those, 1224 were zero intensities, and 1818 were weak [$|F_o| \leqslant 3\sigma(|F_o|)$] and were classified as unobserved. 4601 non-zero unique reflections were corrected for Lorentz and polarization effects, but not for absorption. The position of the palladium atom was obtained from a Patterson synthesis. All other atoms were located by Fourier difference syntheses. The structure was refined by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogen atoms. The R values for the final refinement were $R = 0.048$ and $R_w = 0.051$. The function minimized was $\Sigma\omega||F_o|-|F_c||^2$, with $\omega = 1/[\sigma^2(F_o)]$. Goodness-of-fit, S, was 2.58. The maximum shift over error ratio Δ/σ in the last cycle was less than 0.3 for non-hydrogen atoms and 0.9 for hydrogen atoms. The maximum and minimum heights in a final difference Fourier map were ± 0.2 eÅ^{-3}. A FACOM-M782 computer at the Data Processing Center, Kyoto University, and the UNICSII computation programs system[9] were used for all calculations in the data reduction and the structure analysis. The atom scattering factors were taken from the *International Tables for X-ray Crystallography*.[10]*

RESULTS AND DISCUSSION

Crystal structure of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$

The bond lengths and bond angles are given in Table 1 and the least-squares planes around the palladium atom are given in Table 2. A perspective view of the complex cation with the numbering scheme is given in Fig. 1, whilst the palladium atom and the coordinate atoms are given in Fig. 2.[11]

The crystal structure of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$ consists of separate $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ cations and two crystallographically independent $[BF_4]^-$ anions. In the co-

*Tables of atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c values have been deposited as Supplementary Material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Table 1. Intramolecular bond distances (Å) and bond angles (°) (ESDs are in parentheses and are in the units of the least significant digit)

(a) Bond distances (Å)			
Pd—P(1)	2.283(1)	Pd—N(1)	2.164(5)
Pd—P(2)	2.395(2)	Pd—N(10)	2.588(5)
Pd—P(3)	2.407(2)		
Pd···C(15)	3.845(7)	Pd···C(16)	3.145(7)
(b) Bond angles (°)			
P(1)—Pd—P(2)	95.0(1)	P(2)—Pd—N(1)	87.7(1)
P(1)—Pd—P(3)	92.1(1)	P(2)—Pd—N(10)	85.3(1)
P(1)—Pd—N(1)	164.5(1)	P(3)—Pd—N(1)	85.6(1)
P(1)—Pd—N(10)	123.5(1)	P(3)—Pd—N(10)	90.3(1)

N(1)—Pd···C(15)	110.0(2)	N(1)—Pd···C(16)	50.6(2)

ordination sphere around the palladium atom, the interatomic distances of the two nitrogen atoms in 2,9-Me_2-phen from the palladium atom are unequal (Pd—N(1), 2.164(5) and Pd—N(10), 2.588(5) Å). This is not uncommon in square-pyramidal structures studied so far in palladium(II) and platinum(II) complexes. One nitrogen atom with a longer distance [N(10)] is at the apex of a distorted square-pyramidal structure (Fig. 2), in which three phosphorus atoms of $(PMe_2Ph)_3$ occupy three corners of the square basal plane, while the N(1) atom occupies the remaining corner. The angle N(1)—Pd—N(10) is 71.90°. This angle is larger than 68.2° in $[PtCl(PEt_3)_2(phen)]^+$,[6] 70.2° in $[PdCl(PPh_3)_2(phen)]^+$[2] and 69.7° in $[Pt(CN)(phen)_2]^+$.[4]

Table 2. Least-squares planes and deviations (Å) of individual atoms

Basal plane of tetragonal pyramid

$$0.28688X+0.94693Y+0.14498Z = 3.81896$$

P(1)	0.0017(56)	N(1)	0.0101(52)
P(2)	0.0112(60)	Pd*	0.0022(56)
P(3)	−0.0170(67)	N(10)*	−1.4116(62)

Basal plane of trigonal bipyramid

$$0.82481X-0.37552Y+0.42270Z = 1.09412$$

P(1)	0.0097(9)	Pd	−0.0211(2)
N(1)	0.0090(31)	P(2)*	−2.4052(10)
N(10)	0.0024(30)	P(3)*	2.3800(9)

The equations of the planes are in the form $AX+BY+CZ = D$, where $X = ax+cz\cos\beta$, $Y = by$ and $Z = cz\sin\beta$ are coordinates in orthogonal angstrom space. Asterisks indicate the atoms not included in the calculation of the planes. ESDs in parentheses are in the units of the least significant digit.

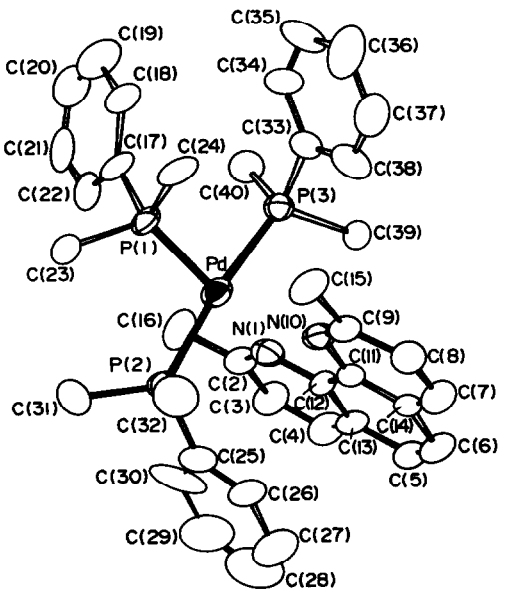

Fig. 1. A perspective view of the complex cation $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ and the numbering schemes.

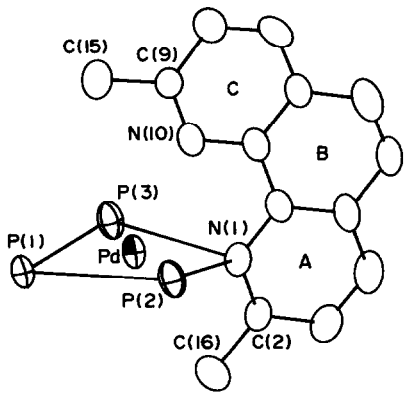

Fig. 2. The palladium atom and the coordinate atoms.

The Pd—N(1) bond length of 2.164(5) Å in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ [N(1) is *trans* to P(1)] is slightly longer than the bond length of 2.094(5) Å found in $[PdCl(PPh_3)_2(phen)]^+$ [N(1) is *trans* to Cl]. This may be explained by the larger *trans* influence of phosphorus than chlorine. In fact, this observation in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ is comparable with the Pt—N(1) bond length of 2.137(19) Å found in $[PtCl(PEt_3)_2(phen)]^+$ [N(1) is *trans* to P], which is larger than 2.053(5) Å found in $[Pt(CN)(phen)_2]$ [N(1) is *trans* to N(3)]. The Pd—P bond lengths in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ are 2.395(2) and 2.407(2) Å for Pd—P(2) and Pd—P(3), respectively, and 2.283(1) Å for Pd—P(1). The P(1), P(2), P(3) and N(1) atoms deviated markedly from the plane (Table 2). The N(1) atom occupies a position slightly displaced from the tetragonal plane in the opposite direction to the N(10) atom. The bond angles around the palladium atom, with the four atoms in the basal plane, deviate a few degrees from 90° (Table 1). The P(2) and P(3) atoms are displaced towards the N(1) atom and away from the P(1) atom. This distortion is due to ligand–ligand repulsion and is in fact in the opposite direction to that found in $[PdCl(PPh_3)_2(phen)]^+$, in which the size of the Cl atom (*trans* to N) is very small in comparison with that of the (PMe_2Ph) group.

The distance, 2.81(2) Å, of the non-bonding N(1)···N(10) is slightly longer than those observed in the bidentate phenanthrolines[12] (2.63–2.73 Å), in the phenanthroline crystal (2.724 Å)[13] and in the free phenanthroline in $[Cu\{SC(NH_2)_2\}(phen)]I(phen)$ (2.767 Å).[14] The least-squares mean plane calculated for the three rings of the phen group shows that the maximum deviation of the atoms from the mean plane is 0.046(7) Å at C(15). This least-squares mean plane contains the Pd and P(1) atoms. The deviation of the Pd and P(1) atoms, though not included in the calculation of the plane, are 0.0271(3) and 0.0950(13) Å, respectively. The structure is so distorted from an ideal square pyramid that it approaches a trigonal bipyramidal structure, which resembles $[PdCl(PPh_3)_2(phen)]^+$. The dihedral angles between three phenyl rings *A*, *B* and *C* (Fig. 2) are 0.69(15), 1.80(16) and 1.68(4)° for *A* and *B*, *A* and *C*, and *B* and *C*, respectively. For the methyl C(15), which is near the apex of the pyramid, the distance between the Pd atom and the C(15) atom is 3.845(7) Å and the angle N(1)—Pd—C(15) is 110.0(2)°. For the other methyl C(16) which is attached to atom C(2) and is at the reverse side of the apex with respect to the basal plane, the distance between the Pd and C(16) atoms is 3.145(7) Å and the angle N(1)—Pd—C(16) is 50.6(2)°. Frenz and Ibers[12] have shown for a series of phen complexes, that an increase of the N—M—N bond angle is correlated with a decrease of the N—M bond distance. This propensity is also observed in the corresponding bond angle and bond length between $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ and $[PdCl(PPh_3)_2(phen)]^+$. Although the $[PdCl_2(PMe_2Ph)_3]$ molecule possesses pseudo-symmetry of roughly a mirror plane, $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ has no symmetry element. The reason for this difference may be that 2,9-Me_2-phen has a larger rigid skeleton than the two chlorine atoms.

The two BF_4 anion groups occupy the cavities surrounded by the cation groups. The thermal factors of the component atoms are large. The shortest distance between a palladium atom and a fluorine atom among the BF_4 groups is 4.617(8) Å in Pd···F(23).

The solution structure by ^1H *and* ^{31}P *NMR*[1]

In the solid state, the 2,9-Me_2-phen molecule of the complex has no symmetry element. ^1H NMR exhibits, however, an equivalency of the two nitrogen atoms. This ^1H NMR spectrum corresponds either to fluxional motion or to symmetrical environments around the two halves of the azaheterocyclic ligand. The conductivity data show that the complex has a tight ion-pair and the anion does not interact with palladium(II).[1] As the crystal structures show, the elongation of the apical M—N distance in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ is not so pronounced as those observed in $[PdCl(PPh_3)_2(phen)]^+$,[2] $[PtCl(PEt_3)_2(phen)]^+$,[6] and $[Pt(CN)(phen)_2]^+$.[4] Yet, this elongation of the apical M—N distance still raises a question as to whether the nitrogen atom is in the inner sphere or not. The latter two platinum(II) complexes in solution exhibiting fluxional motion do not display any dissociation, as the observance of ^{195}Pt satellites in resonances arising from the azaheterocyclic ligand [^1H, ^{13}C NMR] indicate. It should be noted that the present d^8 system, by allowing five-coordination, becomes coordinatively saturated. This condition slightly differs from $[PdCl(PPh_3)_2(phen)]^+$, in which dissociation of one nitrogen atom may make the d^8 species coordinately unsaturated. Such a distinction has in fact been observed in the visible absorption spectra. The visible spectrum of $[PdCl(PPh_3)_2(phen)]^+$ shows absorption maxima at 335–355 nm, which resemble those of the seldomly ion-paired complexes $[Pt(PEt_3)_2(phen)]^{2+}$ and $[PdCl(PPh_3)(phen)]^+$.[1] On the other hand, the absorption maximum of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ is observed at 412 nm ($\varepsilon = 1060$), which resembles that of $[PdCl_2(PMe_2Ph)_3]$ at 410 nm ($\varepsilon = 1020$).[5] The transition may be due to the charge-

transfer bands ($M \rightarrow L$, $L \rightarrow M$). The *d–d* band was probably not resolved owing to its combination with the intense charge-transfer bands at the higher wave number. Therefore, the visible absorption of the present complex is most likely to be characteristic of five-coordination (a bidentate 2,9-Me_2-phen). A fluxional motion which averages two halves of the 2,9-Me_2-phen in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ may be explained by oscillation. We have observed a relatively large ^1H NMR downfield shift for 2,9-Me- and 3,8-protons of the azaheterocyclic rings upon coordination. Such a coordination shift is due to paramagnetic anisotropy.[15] Another possible explanation may be the trigonal bipyramidal structure with stereochemical rigidity. This, however, can be excluded by comparing its ^{31}P NMR spectrum with that of an analogous 1,10-phen complex, $[Pd(PMe_2Ph)_3(phen)][BF_4]_2$ (*vide infra*).[1] The ^{31}P NMR spectrum of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)]^{2+}$ indicates an AB_2-spin system with $J_{AB} = 20$ Hz: the ^{31}P triplet appears at higher field than the ^{31}P doublet. Its $^{31}P—^{31}P$ coupling constant is close to the value of 26 Hz for $[PdCl(PMe_3)_3]^+$,[16] and 21 Hz for $[PdCl_2(PMe_3)_3]^+$,[16] which both have a square-pyramidal structure in which three phosphorus atoms are arranged at the coordination plane. These coupling constants are quite different from those observed in a trigonal bipyramidal structure, which have coupling constants equal to 10 Hz for $[PdBr_2(PMe_3)_3]$,[16] and 4 Hz for $[PdI_2(PMe_3)_3]$.[16] Therefore, three phosphines in $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$ are, as consistent with the solid state, coplanar including the palladium(II) atom. Any differences in $J(^{31}P—^{31}P)$ between the PMe_2Ph complex and its PMe_3 analogues may not be significant because the corresponding coupling constant of $[PtCl(PMe_2Ph)_3][BF_4]$[17] is 22 Hz, which is in agreement with that observed in $[PtCl(PMe_3)_3]^+$.[18] On the other hand, the ^{31}P NMR spectrum of the analogous phen complex, $[Pd(PMe_2Ph)_3(phen)][BF_4]_2$, shows a reversed pattern of chemical shifts: the ^{31}P doublet appears at higher field than the ^{31}P triplet. The $J(^{31}P—^{31}P)$ value of 23 Hz is close to that of the 2,9-Me_2-phen complex. This means that the environment around the three phosphines in the phen complex is similar to that of the 2,9-Me_2-phen complex. In the five-coordinate palladium(II) and platinium(II) complexes so far studied, axial phosphines or phosphites appear at higher field regions than the equatorial ones.[18–20] Thus, the structure of $[Pd(PMe_2Ph)_3(phen)]^{2+}$ is most likely to be trigonal bipyramidal with two axial phosphines, in which two equatorial bonds, Pd—N, may be arranged at equal distances.[21]

The coordination of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-}phen)][BF_4]_2$ in the solid state may be described as the five-coordinate distorted square pyramid, involving a bidentate 2,9-Me_2-phen, one nitrogen atom of which is at the apex of the square pyramid with a weaker interaction between the nitrogen and palladium atoms, rather than the four-coordinate square-planar structure, in which the second nitrogen atom is on the outside of the coordination sphere of the palladium atom.

SYNTHESES AND X-RAY STRUCTURES OF MOLECULAR METAL POLYSELENIDE COMPLEXES $[M(Se_4)_2]^{2-}$ M = Zn, Cd, Hg, Ni, Pb

R. M. HERATH BANDA, JOHN CUSICK, MARCIA L. SCUDDER, DON C. CRAIG and IAN G. DANCE*

School of Chemistry, University of New South Wales, PO Box 1, Kensington, NSW 2033, Australia

(*Received* 4 *January* 1989; *accepted* 21 *February* 1989)

Abstract—Bis-tetraselenide complexes $[M(Se_4)_2]^{2-}$ M = Zn (**1**), Cd (**2**), Hg (**3**), Ni (**4**) and Pb (**5**) are readily prepared by the reaction of Se, Na and MCl_2 in DMF, and crystallized with Ph_4P^+. Crystal structure determinations reveal pseudo-tetrahedral coordination in **1**, **2** and **3**, slightly distorted square-planar coordination in **4**, and in **5** a four coordinate stereochemistry interpreted as primary trigonal orthogonal, plus one secondary bond. There is no evidence of variable size in the metallapolyselenane chelate rings, in contrast with data for comparable polysulphide complexes.

Although aqueous polysulphide reagents are long known, the use of non-aqueous solvents in the preparations of metal complexes has enabled the crystallization and structural characterization of molecular homoleptic metal polysulphides with wide structural variety, containing from one to six metal atoms.[1,2] We expected that many other molecular structures would exist in metal polysulphide solutions, and have deployed metal NMR to confirm that sulphur atom redistribution reactions are facile, and that metal complexes with different metallapolysulphane ring sizes are in equilibrium. Thus, in cadmium polysulphide solutions, the complexes $[Cd(S_x)(S_y)]^{2-}$, $(x,y) = (5,5); (5,6); (6,6); (6,7)$ are in equilibrium, interchanging slowly on the ^{113}Cd NMR time scale at 300 K, with $\Delta\delta_{Cd} \sim 50$ ppm for Δx or $\Delta y = 1$.[3] Comparable results are obtained for complexes $[Hg(S_x)(S_y)]^{2-}$.[4] Metallapolysulphane ring conformations in these compounds occur on a relatively flat potential energy surface, as indicated by the frequent conformational disorder in crystals, and by the absence of Cd or Hg NMR evidence for conformers even at low temperatures.

We are extending these investigations to metal polyselenides and polytellurides, and communicate here preparative and structural results for five $[M(Se_4)_2]^{2-}$ complexes.

Reactions of metal halide, selenium and sodium in DMF generate solutions of metal polyselenide complexes. When the metal precursor is MCl_2, M = Zn, Cd, Hg, Ni, Pb, and the solutions are treated with Ph_4PBr,† brown–black crystals of the compounds $(Ph_4P)_2[M(Se_4)_2]$, M = Zn (**1**), Cd (**2**), Hg (**3**), Ni (**4**), Pb (**5**), are obtained. Compounds

* Author to whom correspondence should be addressed.

† The general preparative procedure involves MCl_2, Se, Na in molar ratios 1 : 8 : 4 in DMF under dinitrogen, with Ph_4PBr slowly diffused into the filtered reaction solution. The cadmium complex (**2**) was prepared with $Cd(NO_3)_2 \cdot 4H_2O$ as precursor.

2–5 have been characterized by crystal structure determination: **1** is isostructural with **2**.*

The $[M(Se_4)_2]^{2-}$ complexes in **2** (M = Cd) and **3** (M = Hg) possess unexceptional tetrahedral coordination, as shown for **2** in Fig. 1. The $CdSe_4$ rings in **2** are fully ordered, while three of the four crystallographically independent $HgSe_4$ rings in **3** are conformationally disordered. Average dimensions in **2** and **3**, respectively, are:† M—Se = 2.643(9), 2.65(2) Å; Se—Se = 2.35(4), 2.32(2) Å; intrachelate Se—M—Se = 104(2), 102(3)°.

The $[Ni(Se_4)_2]^{2-}$ ion in **4** has approximately square-planar coordination, with a slight tetrahedral distortion: the donor selenium atoms lie 0.33 Å to either side and the nickel atom lies within the least-squares plane through the $NiSe_4$ set. Mean dimensions are Ni—Se = 2.297(7) Å; intrachelate Se—M—Se = 102.0(4)°; and interchelate Se—M—Se = 80.0(1)°. Unlike the homologous $[Ni(S_4)_2]^{2-}$ ion crystallized with Et_4N^+,[5,6] and Ph_4P^+,[6] the Se_4^{2-} rings in $[Ni(Se_4)_2]^{2-}$ are not conformationally disordered.

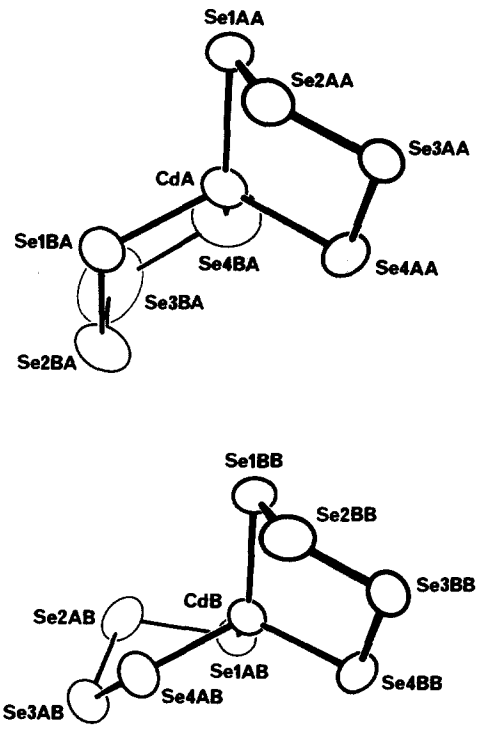

Fig. 1. The two independent $[Cd(Se_4)_2]^{2-}$ complexes in **2**, with atoms outlined at the 50% probability level.

Figure 2 shows the irregular coordination stereochemistry of the molecular complex $[Pb(Se_4)_2]^{2-}$ in **5**. Although the Pb—Se bond lengths are distinctly different, three Pb—Se bonds [to Se(1B), Se(4B) and Se(1A)] are 0.3–0.4 Å shorter than the fourth, and subtend Se—Pb—Se angles that are close to orthogonal. Therefore we interpret the geometry in terms of *trigonal orthogonal* primary coordination, with a longer secondary connection [to Se(4A)] also in a pseudo-orthogonal location, and with two vacant orthogonal positions [*trans* to Se(1A), Se(1B)]. An alternative but less realistic interpretation of the coordination stereochemistry in **5** involves a trigonal bipyramid with one vacant equatorial position.

Complexes **1–4** have polysulphide analogues. However, molecular lead polysulphides have not yet been reported, and **5** is a unique lead polychalcogenide. The trigonal orthogonal primary coordination in **5**, with secondary connections also part of the orthogonal array, is analogous to that

* Crystal data (Enraf–Nonius CAD4 diffractometer); least squares refinement included rigid phenyl groups (**2** and **3**) and slack constraints on disordered MSe_x rings in **3**: **1**, $C_{48}H_{40}ZnP_2Se_8$, $M = 1375.86$, $a = 10.159(5)$, $b = 14.020(4)$, $c = 34.26(1)$ Å, $\beta = 92.11(2)°$, $V = 4875(3)$ Å^3, space group $P2_1$; **2**, $C_{48}H_{40}CdP_2Se_8$, $M = 1422.89$, monoclinic, $a = 10.185(5)$, $b = 14.137(4)$, $c = 34.39(2)$ Å, $\beta = 92.22(2)°$, $V = 4948(4)$ Å^3, space group $P2_1$, $D_{calc} = 1.91$ g cm^{-3}, $Z = 4$, $\mu = 63.6$ cm^{-1}, max/min transmission coefficients 0.70/0.45, 3459 independent observed ($I/\sigma(I) > 3$) reflections (Mo-K_α), $R = 0.046$, $R_w = 0.055$; **3**, $C_{48}H_{40}HgP_2Se_8$, $M = 1511.07$, monoclinic, $a = 23.128(7)$, $b = 20.311(5)$, $c = 23.956(8)$ Å, $\beta = 119.43(1)°$, $V = 9801(5)$ Å^3, space group $P2_1/c$, $D_{calc} = 2.05$ g cm^{-3}, $Z = 8$, $\mu = 91.2$ cm^{-1}, max/min transmission coefficients 0.28/0.16, 4609 independent observed ($I/\sigma(I) > 3$) reflections (Mo-K_α), $R = 0.041$, $R_w = 0.047$; atom labels for the two independent $[Hg(Se_4)_2]^{2-}$ complexes in the asymmetric unit, in the principal conformations are Hg(A), Se(*n*AA) (*n* = 1–4), Se(*n*BA) (*n* = 1–4), Hg(B), Se(*n*AB) (*n* = 1–4), Se(*n*BB) (*n* = 1–4); Se(2AA′) and Se(3AA′) occur in 9% of the unit cells, Se(3AB′) and Se(4AB′) in 13%, and Se(1BA′), Se(2BA′) and Se(3BA′) in 46%; **4**, $C_{48}H_{40}NiP_2Se_8$, $M = 1369.18$, monoclinic, $a = 10.934(6)$, $b = 15.531(3)$, $c = 14.313(7)$ Å, $\beta = 92.54(2)°$, $V = 2428(2)$ Å^3, space group $P2_1$, $D_{calc} = 1.87$ g cm^{-3}, $Z = 2$, $\mu = 64.3$ cm^{-1}, max/min transmission coefficients 0.83/0.71, 2557 independent observed ($I/\sigma(I) > 3$) reflections (Mo-K_α), $R = 0.037$, $R_w = 0.041$; **5**, $C_{48}H_{40}PbP_2Se_8$, $M = 1517.68$, triclinic, $a = 10.349(3)$, $b = 10.759(4)$, $c = 23.034(9)$ Å, $\alpha = 77.03(3)$, $\beta = 83.52(3)$, $\gamma = 78.78(3)°$, $V = 2445(2)$ Å^3, space group $P\bar{1}$, $D_{calc} = 2.06$ g cm^{-3}, $Z = 2$, $\mu = 94.7$ cm^{-1}, max/min transmission coefficients 0.58/0.28, 4354 independent observed ($I/\sigma(I) > 3$) reflections (Mo-K_α), $R = 0.037$, $R_w = 0.044$. Tables of atomic positional and thermal parameters, and lists of observed and calculated structure factors have been deposited as supplementary material with the Editor, and atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

† Standard deviations of the sample in parentheses.

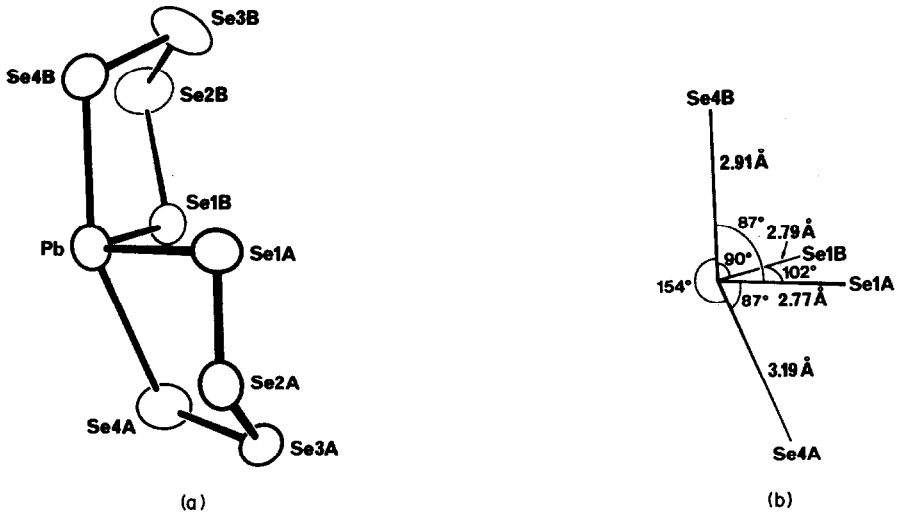

Fig. 2. The $[Pb(Se_4)_2]^{2-}$ complex in **5**, (a) with the atoms drawn as 50% probability ellipsoids and (b) with the principal coordination bond lengths and angles.

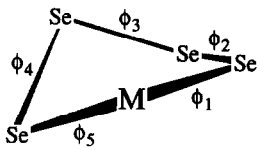
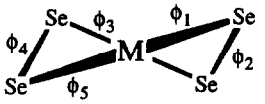
which occurs in $[Pb_2(SCH_2CH_2NMe_3)_5](PF_6)_4$[7] and is regarded as characteristic of lead chalcogenide coordination.

There are patterns in the conformations of the MSe_4 rings in **2**–**5**. These conformations are expressed in terms of the five torsional angles within the ring, ϕ_1, ϕ_2, ϕ_3, ϕ_4, ϕ_5 (see Table 1), defined in **I**



I



II

and **II** with reference to the two idealized conformations, namely the envelope (symmetry C_s, torsional angles 0, +, −, +, −, or the inverse) and the half-chair (symmetry C_2, torsional angles +, −, +, −, +, or the inverse). The MSe_4 rings in **2** and **3** adopt distorted envelope conformations as in **I**, with the "flap" opposite one of the M—Se bonds, and with the distortion towards the half-chair con-

Table 1. Torsional angles (°) in MSe_4 rings[a]

Compound, ring	ϕ_1	ϕ_2	ϕ_3	ϕ_4	ϕ_5
2, AA	9.2	27.8	−63.8	61.0	−41.5
2, BB	12.9	23.6	−60.0	60.9	−43.4
2, BA	0.9	−32.3	60.0	−52.8	32.0
2, AB	−5.2	−30.9	63.3	−59.3	38.0
3, AA[b]	−5.1	37.6	−63.1	53.3	−28.7
3, BB	4.8	−37.4	62.7	−53.3	28.5
3, BA[b]	8.8	−37.5	59.0	−48.4	23.1
3, AB[b]	7.9	−37.5	57.0	−47.3	23.8
4, A	14.0	−43.7	53.3	−48.2	20.9
4, B	14.5	−41.9	49.8	−44.9	18.9
5, A	−10.4	−24.4	59.6	−67.5	41.6
5, B	18.3	−50.4	66.3	−51.8	18.9

[a] See **I** and **II** for definition of the torsional angles ϕ (which is unambiguous in all cases): ϕ_1 is assigned to be the smallest (ideally 0° in the envelope conformation), while in the half-chair conformation $\phi_1 = \phi_5$, $\phi_2 = \phi_3$.

[b] For the principal conformations.

formation in which the metal lies on the two-fold axis. Apart from conformational inversion, the four rings in **3** are almost identical. Details of the conformations are metal dependent: in **2**, ϕ_1 and ϕ_5 are of opposite sign, while in **3** they have the same sign, which is a manifestation of the fact that the $HgSe_4$ rings are closer to the half-chair conformation. In **4**, both $NiSe_4$ ring conformations are half-chair as in **II**, while in **5** one $PbSe_4$ ring (B) is also half-chair (but more angular than the $NiSe_4$ ring), while the other has the distorted envelope conformation which occurs in **2**.

Full details of the crystal structures will be published separately. We are exploring extensions of the preparative method to other metals and to different polyselenide chain lengths: preliminary ^{113}Cd and ^{199}Hg measurements indicate that metallapolyselenane ring sizes are less variable than metallapolysulphane analogues.

COMMUNICATION

SYNTHESES AND STRUCTURES OF ANIONIC METAL POLYSELENIDE COMPLEXES $[(C_5H_5)Mo(Se_4)_2]^-$ AND $[Sn(Se_4)_3]^{2-}$, CRYSTALLIZED WITH Ph_4P^+

R. M. HERATH BANDA, JOHN CUSICK, MARCIA L. SCUDDER, DON C. CRAIG and IAN G. DANCE*

School of Chemistry, University of New South Wales, PO Box 1, Kensington, NSW 2033, Australia

(*Received* 22 *February* 1989; *accepted* 16 *March* 1989)

Abstract—Reaction of $(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_6$ with selenium and sodium in DMF yields $[(\eta^5\text{-}C_5H_5)Mo(Se_4)_2]^-$ (**1**), which was crystallized with Ph_4P^+ and characterized by crystal structure determination. With two chelating tetraselenide ligands, **1** is the first member of a new class of mono(cyclopentadienyl)-bis(polychalcogenide) metallates, distinct from existing compounds which are formulated $[(\eta^5\text{-}C_5R_5)_2M(E_x)]$ (E = S, Se; x = 3, 4, 5). $(Ph_4P)_2[Sn(Se_4)_3]$ (**2**), from reaction of selenium, sodium, $SnCl_2$ and Ph_4PBr in DMF, shows no evidence in its crystal structure of the disordered ring size and conformation found in polysulphide homologues.

We have previously communicated the preparations and crystal and molecular structures of the metal polyselenide complexes, $(Ph_4P)_2[Cu_4(Se_4)_{2.4}(Se_5)_{0.6}]$ and $(Ph_4P)_2[Ag_4(Se_4)_{2.1}(Se_5)_{0.9}]$,[1] and $(Ph_4P)_2[M(Se_4)_2]$ (M = Zn, Cd, Hg, Ni and Pb).[2] These compounds were synthesized in a direct procedure involving *in situ* reduction of selenium in the presence of a suitable metal precursor. This preparative method has now been applied to a cyclopentadienyl metal carbonyl, $(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_6$, yielding $(Ph_4P)[(\eta^5\text{-}C_5H_5)Mo(Se_4)_2]$ (**1**). We also report here the preparation of $(Ph_4P)_2[Sn(Se_4)_3]$ (**2**) from $SnCl_2$, and the structures of **1** and **2**.

A mixture of $(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_6$ (3.8 mmol) and selenium (29.1 mmol Se) in DMF was treated with sodium (14.8 mmol) and stirred at 60°C under dinitrogen, and the colour changed from deep red to dark green after 90 min. After cooling and addition of Ph_4PBr in acetonitrile, black needles of **1** were collected and characterized by crystal structure determination.†

The molecular structure of the $[(\eta^5\text{-}C_5H_5)Mo(Se_4)_2]^-$ ion is shown in Fig. 1. There is a small but significant asymmetry in the chelation of both Se_4^{2-} ligands: Mo—Se(1A) = 2.463(1), Mo—Se(4A) = 2.533(1); Mo—Se(1B) = 2.474(1) and Mo—Se(4B) = 2.542(1) Å. The intrachelate Se—Mo—Se angles are both 88°, and the interchelate angles Se(1A)—Mo—Se(4B) and Se(4A)—Mo—Se(1B) are 74.8 and 72.4°, respectively.

Despite a large volume of research on cyclopentadienyl metal polysulphide compounds,[3,4]

* Author to whom correspondence should be addressed.

† Crystal data (Enraf–Nonius CAD4 diffractometer, Mo-K_α radiation): **1**, $C_{29}H_{25}MoPSe_8$, M = 1132.12, triclinic, a = 8.778(3), b = 11.500(4), c = 16.710(6) Å, α = 104.56(2), β = 97.02(2), γ = 93.77(2)°, V = 1612.3(9) Å^3, space group $P\bar{1}$; D_{calc} = 2.33 g cm^{-3}, Z = 2, μ = 94.1 cm^{-1}, max./min. transmission coefficients 0.56/0.30, 3757 independent observed ($I/\sigma(I) > 3$) reflections (Mo-K_α), R = 0.030, R_w = 0.036; ligand atom labels are CpC_n (n = 1–5), Se(nA) (n = 1–4), Se(nB) (n = 1–4); the Se_4^{2-}, ligand A, is disordered with a minor conformation involving atoms Se(2A′) (9%) and Se(3A′) (7%). The largest peak on the final difference electron density map was 0.63 e Å^{-3}. Tables of atomic positional and thermal parameters, and lists of observed and calculated structure factors have been deposited as supplementary material with the Editor, and atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

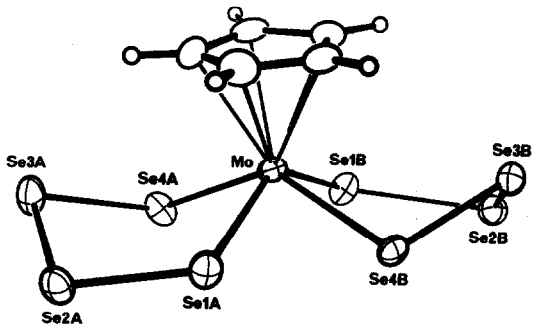

Fig. 1. The $[(\eta^5\text{-}C_5H_5)Mo(Se_4)_2]^-$ ion in **1**, with atoms outlined at the 20% probability level. Se—Se bond lengths are 2.399, 2.310, 2.381 Å and 2.419, 2.343, 2.365 Å in numerical sequence around ligands A and B, respectively. See text for other dimensions.

there is no report of a polysulphide analogue of **1**, or of any mono(cyclopentadienyl)-bis(polychalcogenide)metallate in the general class $[(\eta^5\text{-}C_5R_5)M(E_x)_2]^z$ (E = S, Se). Reactions of a variety of cyclopentadienyl metal carbonyls with elemental sulphur or selenium yield instead, uncharged compounds, usually dimetallic, with bridging E atoms or E_x groups,[4] for example $(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}S_4)_2Rh(\eta^5\text{-}C_5Me_5)$[5] and $(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}Se)(\mu,\eta^2\text{-}Se_4)Rh(\eta^5\text{-}C_5Me_5)$.[6] Reactions of $(\eta^5\text{-}C_5R_5)_2MX_n$ precursors with polychalcogenide ions in solution yield the bis-cyclopentadienyl derivatives $[(\eta^5\text{-}C_5R_5)_2M(E_x)]$, such as $[(\eta^5\text{-}C_5H_5)_2M(E_5)]$ (M = Ti, Zr, Hf; E = S, Se),[7-11] $[(\eta^5\text{-}C_5Me_5)_2Ti(S_3)]$,[12] $[(\eta^5\text{-}C_5H_5)_2V(E_5)]$[9,13] and $[(\eta^5\text{-}C_5H_5)_2M(E_4)]$ (M = Mo, W; E = S, Se).[14-17] There is one recent report of a reaction that (like that described here) generates an anionic complex: that is the reaction of $(\eta^5\text{-}C_5H_5)_2Mo_2(CO)_6$ and $(Et_4N)_2Se_6$ in ethanol to form the molybdenum(II) product, $[(\eta^5\text{-}C_5H_5)Mo(CO)_2(\mu,\eta^2\text{-}Se_2)]^-$.[18] Thus **1** is unique as an anionic cyclopentadienyl metal bis-polychalcogenide. It does, however, bear comparison with the molybdenum(IV) compounds, $[XMo(E_4)_2]^{2-}$ (X = O, S, Se; E = S, Se).[19-21]

Table 1. Torsion angles (°) in MSe_4 rings

Compound, ring	Bond M—Se(1)	Se(1)—Se(2)	Se(2)—Se(3)	Se(3)—Se(4)	Se(4)—M
1, A	−30.2	+0.3	+32.3	−56.6	+50.3
1, B	−24.6	−9.5	+41.8	−63.4	+51.1
2, A	−3.9	+37.5	−62.8	+58.0	−31.0
2, B	+13.5	−45.0	+63.5	−50.8	+21.7
2, C	−17.9	+48.4	−62.9	+47.2	−17.4

When a solution of $SnCl_2 \cdot 2H_2O$ in DMF was added to a solution of Na_2Se_6 similarly generated in DMF, followed (after filtration) by a solution of Ph_4PBr in acetonitrile, dark red crystalline $(Ph_4P)_2[Sn(Se_4)_3]$ (**2**) separated and was characterized by X-ray structure determination.* Unlike the homologous polysulphide complexes[22,23] which are heavily disordered in length (S_4, S_5, S_6) and conformation of the polysulphide chain, there is no disorder in **2**. The mean Sn—Se bond length is 2.706(14) Å,† the mean intrachelate Se—Sn—Se angle is 95.9(9)°† and the mean Se—Se distance 2.320(10) Å.†

The torsional angles in the MSe_4 chelate rings, listed in Table 1, show that in **1** ring A adopts the envelope conformation with the flap at Se(4A), ring B is between an envelope [flap at Se(4B)] and half-chair [two-fold axis through Se(1B)], while in **2**, ring A is approximately an envelope [flap at Se(3A)] and rings B and C are close to half-chairs (two-fold axes through tin).

Acknowledgements—The Australian Development Assistance Bureau (R.M.H.B.), the Australian Postgraduate Award Scheme (J.C.) and the Australian Research Council are gratefully acknowledged for support of this research. We thank Marram Kassis for a sample of $Cp_2Mo_2(CO)_6$.

Abstract—Reaction of $CpW(CO)_3$—C≡CPh with $Os_3(CO)_{10}(CH_3CN)_2$ or $Ru_3(CO)_{12}$ in refluxing toluene gives trinuclear mixed-metal acetylide clusters, $CpWOs_2(CO)_8(C{\equiv}CPh)$ (**1**) and $CpWRu_2(CO)_8(C{\equiv}CPh)$ (**3**); the acetylide ligands of these two complexes are related to each other by a 120° rotation as indicated by X-ray diffraction studies. In solution, the variable temperature ^1H and ^{13}C NMR spectra suggest that the acetylide ligand of **3** undergoes a 360° rotation on the face of the WRu_2 triangle.

The C_2 hydrocarbyl ligands hold a key position in the development of dinuclear, trinuclear and polynuclear organometallic chemistry. This position is in part due to a belief that the chemistry of the C_2 hydrocarbyl ligands in the organometallic complexes is analogous to those adsorbed on metal surfaces. Among the many interesting properties of the C_2 ligands is their fluxionality and mobility on the coordination sphere of the transition metal complexes. Related studies on the C_2 hydrocarbyl ligands have attracted the attention of many theoretical and synthetic chemists. Schilling and Hoffmann[1] have reported the extended Hückel calculation of some hydrocarbyl ligands on the triangular face of homonuclear transition metal complexes. For the C_2 vinylidene complex, $Co_3(CO)_9(CCHR)^+$, Norton and co-workers[2] have reported the disrotatory correlated rotation about the $Co_3(CO)_9$—C vector and C—CHR bond by variable-temperature ^{13}C NMR studies. Stone and co-workers[3] and Shapley and co-workers[4] have both described the so-called "windscreen-wiper" type of motion of a coordinated alkyne ligand on a W_2Os triangular face. For the closely related C_2 acetylide ligand, although the syntheses of many transition metal acetylide clusters have been reported in the literature,[5] no paper has ever focused on the subject of site selectivity and solution fluxionality. We now report the structural and NMR studies of a series of acetylide complexes, which permit an analysis of the solution dynamics of the acetylide ligand.

$LWM_2(CO)_8(\mu_3\text{-}\eta^2\text{-}C{\equiv}CPh)$	M	L	Yield
(1)	Os	C_5H_5	9%
(2)	Os	C_5Me_5	2%
(3)	Ru	C_5H_5	50%
(4)	Ru	C_5Me_5	57%

Treatment of $LW(CO)_3C{\equiv}CPh$[6] with the substance $Os_3(CO)_{10}(CH_3CN)_2$ in refluxing toluene (110°C, 30 min) provided, in addition to a red tetranuclear complex $LWOs_3(CO)_{11}(C{\equiv}CPh)$,[7] a pale yellow trinuclear complex (L = C_5H_5, **1**; L = C_5Me_5, **2**)* in low yield. The $^{13}C\text{-}\{^1H\}$ NMR spectrum of **1** showed two signals at δ 137.5 and 73.8, reminiscent of those reported for the two acetylide carbon nuclei (δ 172.9 and 112.7) in the analogous $CpWFe_2(CO)_8(C{\equiv}CTol)$.[8] The latter is a mixed-metal cluster in which the acetylide ligand functions as a five-electron donor, σ-bonded to the tungsten atom, while employing its two orthogonal alkyne π-bonds to bridge the unique Fe—Fe edge. However, since the colour, as well as the IR spectra of these osmium complexes in the region of CO absorption are substantially different from the complex of iron triads, an X-ray diffraction study was carried out on **1**.†

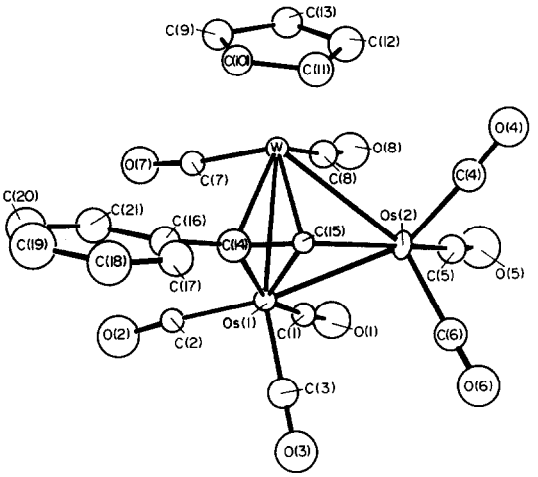

Fig. 1. The ORTEP diagram of **1**. Bond lengths (Å): W—Os(1), 2.8294(19); W—Os(2), 2.9160(18); Os(1)—Os(2), 2.8114(18); W—C(15), 2.20(3); Os(1)—C(15), 2.16(3); Os(2)—C(15), 1.96(3); Os(1)—C(14), 2.17(4); W—C(14), 2.36(4); C(14)—C(15), 1.23(5); C(16)—C(14), 1.47(5). Bond angles (°): Os(2)—C(15)—C(14), 159(3); C(15)—C(14)—C(16), 148(4).

The molecular structure of **1** is shown in Fig. 1, together with some important bond parameters. The molecule has a triangular WOs_2 core structure in which the tungsten atom is coordinated to a Cp ring and two CO ligands, while each of the osmium atoms is linked to three, mutually orthogonal, terminal CO ligands. The most important feature is the orientation of the phenyl acetylide moiety, which is σ-bonded to an osmium atom and at the same time forms a transverse bridge across the second W—Os bond. Therefore, the structure of **1** is related to $CpWFe_2(CO)_8(C{\equiv}CTol)$ by a 120° rotation of the acetylide ligand.

In order to further study the preferred orientation of the acetylide ligand over the triangular face of the trinuclear mixed-metal complexes, we have carried out the syntheses and structural determination of the tungsten–diruthenium analogues. Complexes **3** and **4**‡ were similarly obtained in good yield using $Ru_3(CO)_{12}$ as reagent. Crystals of **3** suitable for X-ray structural determination were obtained by recrystallization from CH_2Cl_2–hexane at room temperature. The structure of **3** is shown in Fig. 2

* Selected spectroscopic data **1**: IR (C_6H_{12}) ν(CO) 2077(s), 2043(vs), 2005(vs), 1995(s), 1965(s), 1924(m); ^1H NMR (CD_2Cl_2, RT): δ 7.68 (d, 2H), 7.37 (t, 2H), 7.20 (t, 1H), 5.29 (s, 5H); $^{13}C\text{-}\{^1H\}$ NMR (CD_2Cl_2, RT): δ 208.3 (J_{W-C} = 165 Hz, W—CO), 204.1 (J_{W-C} = 157 Hz, W—CO), 179.4 (Os—CO), 137.5 (*C*CPh), 73.8 (C*C*Ph, J_{W-C} = 16 Hz). **2**: IR (C_6H_{12}) ν(CO) 2076(s), 2041(vs), 2004(vs), 1991(s), 1963(m), 1905(w); ^1H NMR ($CDCl_3$): δ 7.62 (d, 2H), 7.31 (t, 2H), 7.20 (t, 1H), 1.93 (s, 15H).

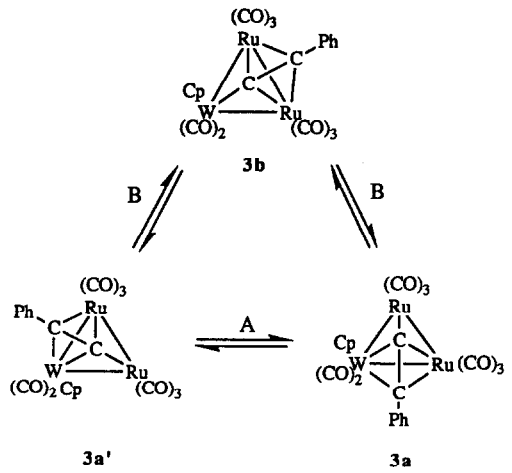

Scheme 1.

with selected structural parameters.* The WRu_2 triangle is near-isosceles and the phenyl acetylide moiety is now σ-bonded to the W atom and, quasi-symmetrically, π-bonded to the two ruthenium atoms. Therefore, we conclude that complex **3** is not isostructural with **1** but rather with the iron-containing complexes.

The solution dynamics of these WRu_2 complexes is of particular interest. Both the ^1H NMR and IR spectra in the region of CO absorption suggest the presence of two isomers. Based on the structural information, we proposed that the isomerization is due to a 360° rotation of the acetylide ligand over (**3a** : **3b** = 1 : 1.2) the WRu_2 triangle (Scheme 1). The assignment of each individual isomer is identified by its characteristic ^{13}C NMR data.

The ^{13}C NMR spectrum of **3** at 205 K exhibits three W—CO signals at δ 210.8, 210.5 and 207.3 in the ratio of 1 : 1 : 2.4. Therefore, the first two resonance lines are assigned to the "asymmetric" isomer (**3a**, acetylide C—C bond is orthogonal to the W—Ru bond) and the third one to the "symmetric" isomer (**3b**, acetylide C—C bond is orthogonal to the Ru—Ru bond). This assignment is not unreasonable because the free rotation of the $CpW(CO)_2$ unit in the asymmetric isomer would be expected to encounter the steric interaction of the phenyl group, whereas in isomer **3b** this process should have a smaller activation energy. Furthermore, five signals at δ 202.5, 200.8, 196.0, 194.2 and 192.4 with an intensity ratio of 1 : 1 : 1 : 1 : 2 can be assigned to the Ru—CO resonances of **3a** to support the assignment; the signal at δ 192.4 is double the intensity of the other four signals and therefore corresponds to two coincident signals.

The Ru—CO signals of **3b** were not observed in this spectrum. However, while the temperature was decreasing to 190 K, its W—CO signal broadened and collapsed, suggesting the slow-down of the $CpW(CO)_2$ rotation, and three very broad Ru—CO signals at δ 203, 198.5 and 189 appeared in the spectrum, consistent with the symmetric nature of **3b**, as suggested by the solid-state structural studies. Interpretation of the ^{13}C NMR data for **4** followed similar studies. From the relative intensities of the methyl signals in the ^1H NMR spectrum at room temperature, it is deduced that an isomer ratio **4a** : **4b** of 1 : 5.5 prevails.

The kinetic parameters of the acetylide ligand rotation have also been calculated from the data of the variable-temperature ^{13}C and ^1H NMR spectroscopies. The racemization process of **3a** consists of a simultaneous correlated rotation of the $CpW(CO)_2$ moiety around an axis through tungsten and a 120° rotation of the acetylide ligand over the tungsten atom (step A, **3a** ↔ **3a'**, Scheme 1). Therefore, the coalescence of the two W—CO resonances, as well as the coalescence of the six

* Crystal data for **3**: $C_{21}H_{10}O_8W_1Ru_2$, $M = 776.29$, monoclinic, space group $P2_1/n$, $a = 12.4756(13)$, $b = 13.216(4)$, $c = 13.395(4)$ Å, $\beta = 97.993(17)°$, $V = 2186.95$ Å^3, $Z = 4$, $D_c = 2.358$ g cm^{-3}, $F(000) = 1447.68$, Nonius diffractometer with graphite-monochromated Mo-K_α radiation, $\lambda = 0.70930$ Å, μ(Mo-K_α) = 6.74 mm^{-1}. ψ scan absorption correction made, 3840 unique reflections were measured and 2851 reflections with $I > 2\sigma(I)$ were used in refinement. Refinement of 42 atoms and 290 parameters converged to $R_F = 0.029$ and $R_w = 0.027$, G.O.F. = 1.583.

Ru—CO resonances in **3a**, would provide the appropriate kinetic data for step A. In fact, both the W—CO and the Ru—CO resonance lines have broadened and merged into single lines during the temperature rise to 300 K. A free energy of activation ($\Delta G^{\ddagger}$), calculated from the dynamic behaviour of the W—CO resonance lines, is estimated to be 62 kJ mol^{-1}.*

In contrast to the racemization of **3a**, isomerization between **3a** and **3b** is consistent with a 120° rotation from a W—Ru edge to the Ru—Ru edge (steps B, **3a** ↔ **3b** or **3a'** ↔ **3b**). Because only two Cp signals were observed in the ^1H NMR spectrum at 300 K, we conclude that the energy barrier of rotation of the $CpW(CO)_2$ unit is much too small to affect the energy barrier of steps B. The free energy of activation ($\Delta G^{\ddagger}$), calculated from the coalescence of the Cp signals, is 67 kJ mol^{-1} at 338 K, providing an estimate of the energy barrier of steps B.

Interestingly, the acetylide ligand of the WOs_2 complexes is static on the time scale of ^{13}C NMR spectroscopy. THe ^{13}C NMR spectrum of **1** at 295 K (d_8-toluene) exhibits two W—CO signals at δ 208.6 and 204.0, a sharp $Os(CO)_3$ line at δ 179.7, and two very broad Os—CO signals at δ 178.8 and 173.4. The exchange of the Os—CO resonances is not due to the rotation of the acetylide ligand, but to a localized $Os(CO)_3$ rotation around an axis through the two different osmium atoms. When the temperature is increased to 350 K, the sharp $Os(CO)_3$ signal remained unchanged and the broad Os—CO signals became a relatively sharp signal at δ 176.5, confirming that the racemization of **1** has not occurred at this temperature.

*The free energy of activation $\Delta G^{\ddagger}$ calculated from the ^{13}C NMR data recorded on d_8-toluene solution is 70 KJ mol^{-1}. This data suggests that the rotation of the acetylide ligand possibly involves a transition state in which the acetylide C—C bond is perpendicular to the WRu_2 triangle.

A COBALT(III)–COPPER(II) BINUCLEAR COMPLEX

BRIAN V. CROOK, HIDEO DOINE, FRANK F. STEPHENS, MARTHA J. CANNON and RODERICK D. CANNON*

School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

(*Received* 30 *January* 1989; *accepted* 11 *April* 1989)

Abstract—The mixed-metal macrocyclic complex $[Co^{III}Cu^{II}LCl_3]$, where L is the 2:2 condensation product of 2,6-diformyl-4-methyl phenol and 1,3-diaminopropane, has been prepared and characterized spectroscopically and electrochemically. Cyclic voltammetry (in DMF) indicates reversible reduction at the copper(II) centre and a relatively slow intramolecular copper(I) to cobalt(III) electron transfer.

Mixed-metal complexes are important in studies of magnetic and electronic coupling.[1] Complexes of the type $[MM'L]^{2+}$, where M and M′ are divalent metals and L is the binucleating ligand shown in Fig. 1, have been extensively used in such work. Our interest is in the electron-transfer behaviour of the complexes containing potentially oxidizing and reducing metal centres in the same molecule. Here we report the first example of a mixed-metal complex of this class containing a trivalent metal, namely $[Co^{III}Cu^{II}CuLCl_3]$.

First, the complex $[Co^{II}Cu^{II}L]^{2+}$ was generated, by two routes. (1) Following the previous template syntheses of homobinuclear complexes,[2] the organic components $CH_3C_6H_2(OH)(CHO)_2$ (**I**) and 1,3-diaminopropane (**II**) were reacted in the presence of equimolar quantities of $CoCl_2$ and $CuCl_2$, and the mixture of CoCo, CoCu and CuCu complexes was separated by fractional crystallization. (2) Following Okawa and Kida,[3,4] the mononuclear complex $[CH_2(CH_2N:CHC_6H_2(CH_3)(CHO)O)_2Co]$ was obtained from **I**, **II** and $CoCl_2$, then successively reacted with $CuCl_2$ and with **II**. Both products analysed well as $CoCuLCl_2 \cdot H_2O$, and their identity was confirmed by IR and UV spectra. A useful feature is the narrow band which occurs at 372 and 356 cm^{-1} in CoCo and CuCu complexes, and at 365 cm^{-1} in the CoCu complex (molar extinction coefficients $\varepsilon_{max} = 10.7$, 12.1 and 15.9×10^3 M^{-1} cm^{-1}). The mixed-metal spectrum is not an average of the two homonuclear spectra (Fig. 2).

Spectrophotometric titration of the homonuclear cobalt complex, $[CoCoL]^{2+}$, with bromine, indicated successive oxidation to $Co^{III}Co^{II}$ and $Co^{III}Co^{III}$ species. A similar titration of the mixed complex $[CoCuL]^{2+}$ proceeded in one stage to $Co^{III}Cu^{II}$. Controlled oxidation of $[CoCuL]^{2+}$ with chlorine in methanol, yielded the new complex $[CoCuLCl_3]$, a brown solid. Composition was determined by total elemental analysis (nitrogen by Kjeldahl method, cobalt and copper by atomic absorption) and the oxidation state of cobalt(III) was confirmed

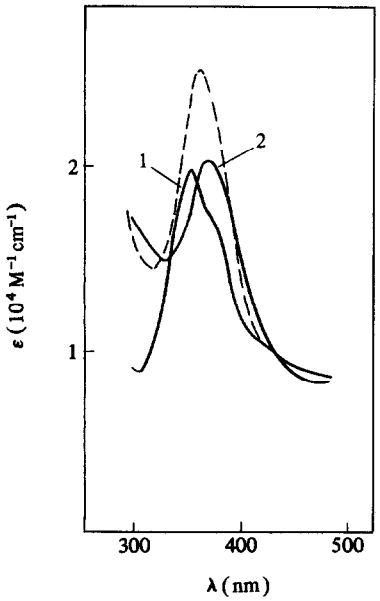

Fig. 2. Near-UV absorption spectra of complexes $[MM'L]^{2+}$. Full-line spectra: **1**, MM′ = CuCu; **2**, CoCo. Broken line, MM′ = CuCo. Chloride salts in methanol, 2.2×10^{-5} M.

by reaction with Fe^{2+} and back-titration. Analysis and Ir spectra showed that there are no solvent molecules of crystallization. The visible band at 675 nm (Fig. 3) is consistent with a *d–d* transition of the $Co^{III}O_2N_2Cl_2$ chromophore (cf. *trans*-$[Co(en)_2Cl_2]^+$, 618 nm[5]).

In agreement with previous reports,[2c,4,6] cyclic voltammetry of the dicopper complex, $[Cu_2L]^{2+}$, showed two nearly reversible one-electron redox processes, assigned as $Cu^{II}Cu^{II}/Cu^{II}Cu^{I}$ and $Cu^{II}Cu^{I}/Cu^{I}Cu^{I}$. The homovalent dicobalt complex $[Co_2L]^{2+}$ gave three waves. One at $E_{mid} = -1.04$ V is assigned as cobalt reduction, $Co^{II}Co^{II}/Co^{II}Co^{I}$, by comparison with the reported potential for [Co^{II}(salen)], $E^{\theta} = -1.19$ V.†[7] The two overlapping waves at 0.41 and 0.52 V are assigned as $Co^{III}Co^{II}/Co^{II}Co^{II}$ and $Co^{III}Co^{III}/Co^{III}Co^{II}$, respectively. The mixed-metal complex $[Co^{II}Cu^{II}L]^{2+}$ showed a reversible wave corresponding to the one-electron process Cu^{II}/Cu^{I}, at $E_{mid} = -0.625$ V, and in addition, a very broad oxidation wave, *ca* +0.4 V, which we assign to a highly irreversible couple Co^{III}/Co^{II} [Fig. 4(a)]. The absence of an oxidation wave corresponding to Co^{II}/Co^{I} may imply a rapid internal electron transfer process, $Co^{II}Cu^{II} + e^- \rightarrow Co^{I}Cu^{II} \rightarrow Co^{II}Cu^{I}$.

For the oxidized mixed-metal complex [$Co^{III}Cu^{II}LCl_3$], a typical voltammogram is shown in Fig. 4(b). In contrast to the Co^{II} Cu^{II} complex, the Cu^{II}/Cu^{I} wave varies with scan rate, from highly irreversible, with a reduction wave only, at the slowest scan, to a nearly symmetrical, quasi-reversible wave at rapid scan, with $E_{mid} = -0.625$ V. At the fastest scan rates only, the irreversible oxidation of the Co^{III}/Co^{II} couple appears. These observations are consistent with a mechanism in which the electron is initially accepted at the copper centre, but is transferred to the cobalt at a relatively rapid rate:

$$Co^{III}Cu^{II} + e^- \longrightarrow Co^{III}Cu^{I} \quad (1)$$

$$Co^{III}Cu^{I} \xrightarrow{k_{et}} Co^{II}Cu^{II}. \quad (2)$$

The alternative initial step in which the electron is accepted at the cobalt centre apparently does not occur in spite of the fact that the cobalt centre is thermodynamically more oxidizing than the copper

† All quoted potentials are relative to $E^{\theta}(Fe(C_5H_5)_2^{+/0}) = 0.400$ V.

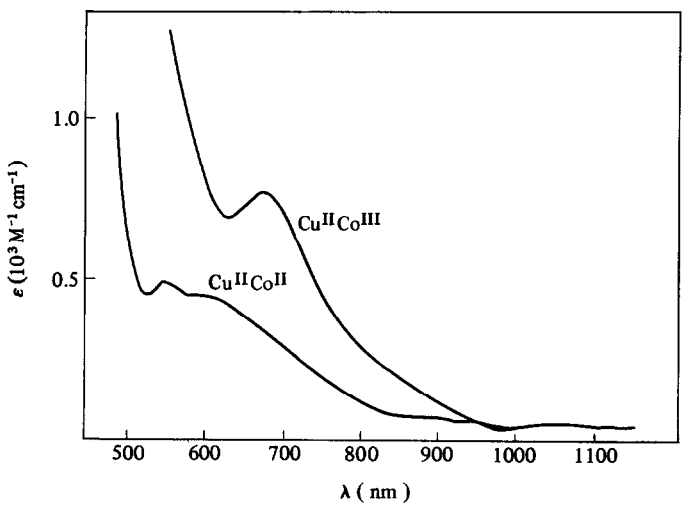

Fig. 3. Visible spectra of $[Co^{II}Cu^{II}L]Cl_2$ and $[Co^{III}Cu^{II}LCl_3]$, in methanol, 5.6×10^{-4} M.

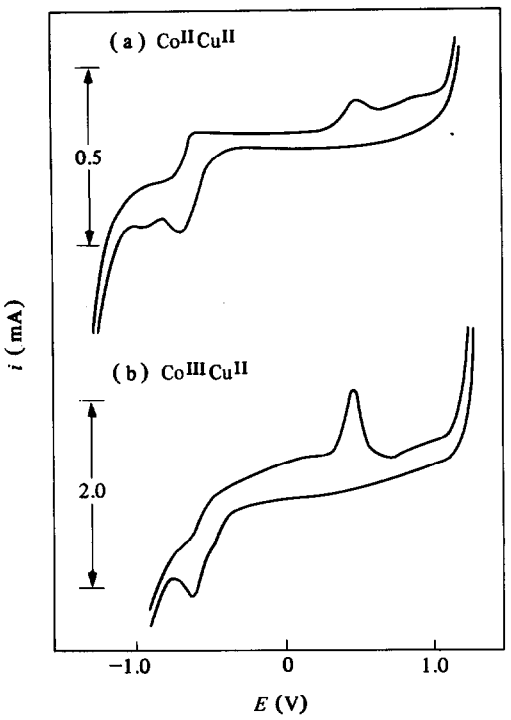

Fig. 4. Cyclic voltammograms of $[Cu^{II}Co^{II}L]^{2+}$ (2.6×10^{-3} M, scan rate 100 mV s^{-1}) and $[Cu^{II}Co^{II}LCl_3]$ (1.8×10^{-3} M, scan rate 50 mV s^{-1}). Both in DMF, 1.0 M $[n\text{-}Bu_4N]BF_4$, 20°C, under N_2 atmosphere. Voltage scale is relative to $E^{\theta}(Fe(C_5H_5)^{2+/0}) = 0.400$ V under the same conditions.

(compare for example the E^{θ} values, $Co^{II}Cu^{II}/Co^{II}Cu^{I}$ and $Co^{III}Co^{II}/Co^{II}Co^{II}$, -0.625 and $+0.61$ V, respectively). Evidently in this complex, as in other complexes of the Schiff base type, the Co^{III}/Co^{II} couple is less reversible than the Cu^{II}/Cu^{I} couple. Following arguments of Nicholson and Shain,[8] the change of the latter couple, from irreversible to reversible, with cycle time, leads to a value of the order 0.5 s^{-1} for k_{et}, the rate constant of the intramolecular electron-transfer reaction (2).

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry—Boron—3rd Supplement. Vol. 4. G. Heller, A. Meller, T. Onak. Boron and Cl, Br, I, S, Se, Te, carboranes. Edited by K.-Ch. Buschbeck and K. Niedenzk. Springer, Berlin, 1988. ISBN 3-540-93567-3, 19 figs. xviii, 256pp.

The volume of 256 pages concludes the third supplement issue on boron compounds, and covers the compounds with Cl, Br, I, S, Se, Te and Po. The final chapter of just over 100 pages deals with carboranes and some of their metalla-derivatives, with a useful listing of carborane-containing polymers. The references cover the literature up to the end of 1984.

The first section deals with the boron–chlorine system, starting with some properties of the transient species BCl and the BCl_2 radical, before considering BCl_3. The chemical behaviour of BCl includes sections on chemical vapour deposition of materials (B, BN, metal borides) using BCl_3, dry etching processes, various adducts, substituted derivatives R_xBCl_{3-x} (R = H, organyl, alkyl, aryl, etc; $x = 1, 2$), $Cl_xB(NR_2)_{3-x}$, ClBO, and various heterocyclic compounds. The description of the boron–bromine and –iodine compounds follows a similar pattern, and these three sections account for the first 100 pages of this volume.

The next 50 pages are concerned with compounds with S, Se, Te and Po, although only six pages are devoted to the Se, Te and Po compounds. The comprehensive section on B—S derivatives includes an initial discussion of the interesting B_8S_{16} and $[B_{10}S_{18}]^{6-}$ ion, and the little-investigated thioborates. This is followed by a discussion of species containing H or an organic moiety $[R_xB(SR)_{3-x}$, $x = 0, 1, 2]$; B—S heterocycles, compounds with B—S—O and B—S—N bonds, together with various derivatives of these systems, including heterocyclic compounds.

The last major section is devoted to the carboranes and metalla-carboranes, and deals with the compounds containing from one up to 42 boron atoms. While the maximum number of boron atoms in a single cage is 11, as in $1\text{-}CB_{11}H_{11}\text{-}1\text{-}Me_2NH$, there are several examples of compounds containing cages linked together. Thus, in the carborane containing 20 boron atoms, $(1,2\text{-}C_2B_{10}H_{11}\text{-}9\text{-}S\text{-})_2CH_2$, two carborane icosahedra are linked by a —S—CH_2—S— group. The presentation contains useful tables of NMR data, and synthetic reagents used to prepare the carboranes, in conjunction with the appropriate references.

Since only three authors are involved (G. Heller, A. Meller and T. Onak), there is a good continuity of style in the volume, and each article is well written. The volume as whole continues the high standard set by its predecessors, and will serve as an invaluable source book, both to those already working in the area, and to those who require a convenient source of references as an introduction to the topics discussed.

REACTION BETWEEN THE $[MgCl_4]^{2-}$ ANION AND TITANIUM CHLORIDES. THE CRYSTAL STRUCTURE OF $[NBu_4][trans\text{-}TiCl_4(THF)_2]\cdot THF$*

PIOTR SOBOTA,† MUHI O. MUSTAFA and TADEUSZ LIS

Institute of Chemistry, University of Wrocław, 14 Joliot-Curie Str., 50-383 Wrocław, Poland

(*Received* 23 *November* 1988; *accepted* 10 *March* 1989)

Abstract—The reaction between $[TiCl_4(THF)_2]$ and $[NBu_4]_2[MgCl_4]$ in tetrahydrofuran (THF) gave the compound $[NBu_4]_2[TiCl_6]$ (**I**). Under the influence of light in THF solution, the compound undergoes reduction to $[NBu_4][trans\text{-}TiCl_4(THF)_2]\cdot THF$ (**II**). Compound **II** was also obtained by the direct reaction between $[TiCl_3(THF)_3]$ and $[MgCl_4]^{2-}$ ions. Crystals of **II** are orthorhombic, space group $P2_12_12_1$ with $a = 12.18(1)$, $b = 17.09(1)$ and $c = 18.57(2)$ Å; $Z = 4$. The structure was refined by full-matrix least-squares methods to $R = 0.064$ for 1569 independent non-zero reflections.

Reactions between $MgCl_2$ and $TiCl_4$ in THF, depending on molar ratio, produce the following compounds:[1,2] $[Mg(THF)_6][TiCl_5(THF)]_2$, $[(THF)_4Mg(\mu\text{-}Cl)_2TiCl_4]$ and $[Mg_2(\mu\text{-}Cl)_3(THF)_6][TiCl_5(THF)]$. These compounds are used in the ethylene polymerization process.[3] However, $MgCl_2$ and $TiCl_3$ in THF do not react mutually, because, in the simplest sense, the acid–base properties of $MgCl_2$ and $TiCl_3$ are similar. Instead, $MgCl_2$ on reaction with $[NBu_4][BF_4]$ yields $[MgCl_4]^{2-}$ and $[MgCl(THF)_5]^+$ ions:[4,5]

$$3[MgCl_2(THF)_2] + 2[NBu_4][BF_4] \xrightarrow{THF} [NBu_4]_2[MgCl_4]\cdot 2THF + 2[MgCl(THF)_5][BF_4]. \quad (1)$$

The reactivity of the $[MgCl_4]^{2-}$ anion was unknown until now. It was expected that $[MgCl_4]^{2-}$ and $TiCl_4$ or $TiCl_3$ would react mutually to produce new products which should bear useful relations between the structure and mechanism involved in some Ziegler–Natta polymerization systems.

EXPERIMENTAL

All reactions were carried out under N_2 using dried solvents and Schlenk-tube techniques. $[TiCl_4(THF)_2]$, $[TiCl_3(THF)_3]$ and $[NBu_4]_2[MgCl_4]\cdot 2THF$ were obtained by literature methods.[4,6] The crystalline $[NBu_4]_2[MgCl_4]\cdot 2THF$ under vacuum, liberates two THF molecules from the crystal lattice and yields $[NBu_4]_2[MgCl_4]$. Microanalyses were performed at the University of Wrocław. ESR spectra were obtained on a Varian E9 spectrometer and solid-state magnetic moments were determined by the Gouy method. IR spectra were obtained using a Perkin–Elmer 180 spectrometer.

*Bis(tetra-*n*-butylammonium)hexachlorotitanate*(IV) (**I**)

$[TiCl_4(THF)_2]$ (1.5 g, 4.5 mmol) and $[NBu_4]_2[MgCl_4]$ (1.8 g, 2.76 mmol) were dissolved separately in 30 and 40 cm^3 of THF, respectively. The solutions were mixed and the stirring was continued until the compounds dissolved. The solution was filtered off and the volume was reduced *in vacuo* to *ca* 20 cm^3. After 24 h, the yellow compound was filtered off, washed with *n*-pentane (3 × 10 cm^3) and dried *in vacuo*. Yield *ca* 1.9 g; 57%. Found: N, 3.7; Cl, 31.1; Ti, 6.6. $C_{32}H_{72}N_2Cl_6Ti$ requires N, 3.8; Cl, 28.5; Ti, 6.4%. Density 1.28 g cm^{-3}.

*Tetra-*n*-butylammonium tetrachlorobis(tetrahydrofuran)titanate*(III) *tetrahydrofuran* (**II**)

(a) $[NBu_4]_2[TiCl_6]$ (1.5 g, 2 mmol) was dissolved in 50 cm^3 of THF and during slow diffusion of *n*-pentane, yellow crystals appeared. The yellow crys-

tals, in the same solution, under the influence of light (near a window), very slowly (1 month) changed colour to blue and simultaneously a white $[NBu_4][Cl]$ salt precipitated. The compound was separated mechanically. The blue crystals were identified by X-ray crystallography as the ionic salt $[NBu_4][trans\text{-}TiCl_4(THF)_2]\cdot THF$. The formation of $[NBu_4][Cl]$ was proved by elementary analysis.

(b) $[TiCl_3(THF)_3]$ (3.2 g, 8.7 mmol) and $[NBu_4]_2[MgCl_4]$ (3.4 g, 5.2 mmol) were suspended in 75 and 65 cm^3 of THF, respectively, and stirred until the solution became light-blue. The solution was filtered off and its volume was reduced to 25 cm^3 and this was left in a refrigerator until crystallization occurred. After 12 h, the crystals were filtered off, washed with THF (2×5 cm^3) and dried *in vacuo*. Yield 3.1 g; 55%. Found: N, 2.3; Cl, 23.5; Ti, 6.7. Calc. for $C_{28}H_{60}Cl_4NO_3Ti$: N, 2.2; Cl, 21.9; Ti, 7.4%.

The good quality, multi-faced crystals for X-ray examination were taken directly from the post-reaction mixture obtained by method (a). The same crystals may be obtained by slow diffusion of *n*-pentane into the compound obtained by method (b) dissolved in THF. The density was measured by flotation in a mixture of $n\text{-}C_4H_9Cl$ and 1,1-dichloroethane. Crystal data. $[N(C_4H_9)_4]^+[(C_4H_8O)_2Cl_4Ti]^-\cdot C_4H_8O$; $M = 648.5$, orthorhombic, $a = 12.18(1)$, $b = 17.09(1)$, $c = 18.57(2)$ Å; $U = 3865(6)$ Å^3, $Z = 4$, $D_c = 1.114(2)$ g cm^{-3}, $D_m = 1.084$ g cm^{-3}, space group $P2_12_12_1$, Mo-K_α radiation $\lambda = 0.71069$ Å, $\mu = 5.3$ cm^{-1}.

A specimen, $0.8\times0.7\times0.6$ mm, was cut from a large crystal and sealed in a capillary. A Syntex $P2_1$ diffractometer, Mo-K_α radiation and a graphite monochromator were used for lattice parameters and intensity measurements at $T = 300(2)$ K. Intensities were measured by the 2θ–ω scan technique up to $2\theta = 48°$. From 3425 measured reflections, 1569 with $I > 3\sigma(I)$ were used for structure determination. The structure was solved by the heavy-atom method and refined using SHELX-76.[7] The thermal parameters of the atoms in the non-bonded THF molecules and some of the carbon atoms in the $[NBu_4]^+$ cations were very high and some of the interatomic distances were rather unrealistic. For that reason, calculations were continued with constraints for non-bonded THF molecules and methyl carbon atoms of the $[NBu_4]^+$ cations. All methylene hydrogen atoms were introduced in calculated positions with d(C—H) = 1.08 Å and were not refined. The refinement was completed by using anisotropic thermal parameters for all non-hydrogen atoms and gave final $R = 0.064$ and $R_w = 0.058$ (the refinement of the parameters for the inverted structure gave $R = 0.065$ and $R_w = 0.059$). Residual electron density in the final difference Fourier map was within -0.25 and 0.25 e Å^{-3}. Attempts to measure data at liquid nitrogen temperature failed because the crystal probably undergoes a phase transition.

Atomic coordinates, displacement factor coefficients and a list of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The addition of the $[NBu_4]_2[MgCl_4]$ salt to $[TiCl_4(THF)_2]$ (1:1 molar ratio) in THF, gave a yellow precipitate of $[NBu_4]_2[TiCl_6]$ (I):

$$[TiCl_4(THF)_2]+[NBu_4]_2[MgCl_4]\longrightarrow [NBu_4]_2[TiCl_6]+[MgCl_2(THF)_2]. \quad (2)$$
(I)

The IR spectrum of compound I presents the ν(Ti—Cl) stretching mode at 385 cm^{-1}, which is typical for $[TiCl_6]^{2-}$ anions e.g. in M_2TiCl_6 (M = K, Rb or Cs).[8]

The yellow crystals in THF solution in light under N_2, slowly (1 month) changed their colour from yellow to blue, and simultaneously a white $[NBu_4][Cl]$ salt precipitated:

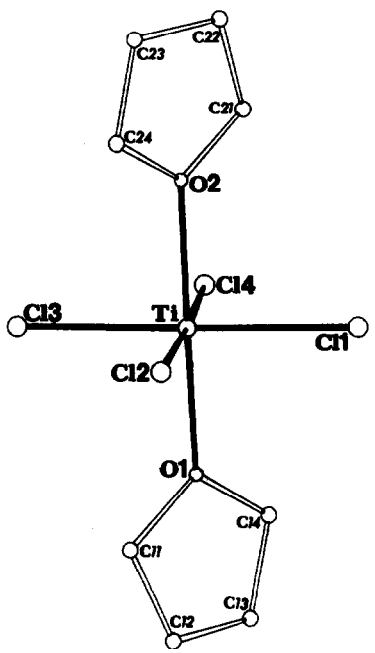

Fig. 1. The overall view of the $[trans\text{-}TiCl_4(THF)_2]^-$ anion.

Table 1. Principal bond lengths (Å) and angles (°) in the [*trans*-$TiCl_4(THF)_2$]$^-$ anion

Bond lengths			
Ti—Cl(1)	2.387(5)	Ti—Cl(2)	2.408(4)
Ti—Cl(3)	2.392(5)	Ti—Cl(4)	2.392(4)
Ti—O(1)	2.083(10)	Ti—O(2)	2.115(10)
Interbond angles			
Cl(1)—Ti—Cl(2)	91.2(2)	Cl(1)—Ti—Cl(3)	178.8(2)
Cl(1)—Ti—Cl(4)	91.7(2)	Cl(2)—Ti—Cl(3)	89.8(2)
Cl(2)—Ti—Cl(4)	177.1(2)	Cl(3)—Ti—Cl(4)	87.3(2)
Cl(1)—Ti—O(1)	89.5(3)	Cl(1)—Ti—O(2)	90.0(3)
Cl(2)—Ti—O(1)	90.8(3)	Cl(2)—Ti—O(2)	88.8(3)
Cl(3)—Ti—O(1)	91.2(3)	Cl(3)—Ti—O(2)	89.3(3)
Cl(4)—Ti—O(1)	89.0(3)	Cl(4)—Ti—O(2)	91.5(3)
O(1)—Ti—O(2)	179.3(4)		

$$[NBu_4]_2[TiCl_6] \xrightarrow[THF]{h\nu} [NBu_4][\textit{trans}\text{-}TiCl_4(THF)_2]\cdot THF \quad \textbf{(II)} + [NBu_4][Cl] + 1/2HCl + C_4H_7OCl. \quad (3)$$

Blue $[NBu_4][\textit{trans}\text{-}TiCl_4(THF)_2]\cdot THF$ **(II)** is also formed in the direct reaction between $[TiCl_3(THF)_3]$ and $[MgCl_4]^{2-}$ ions:

$$2[TiCl_3(THF)_3] + [NBu_4]_2[MgCl_4] \longrightarrow 2[NBu_4][\textit{trans}\text{-}TiCl_4(THF)_2]\cdot THF \quad \textbf{(II)} + [MgCl_2(THF)_2]. \quad (4)$$

Compound **II** is paramagnetic, with $\mu_{eff} = 1.6$ at room temperature. The ESR spectra in the solid state and in CH_2Cl_2 are broad and typical for Ti^{3+}. In $[NBu_4][\textit{trans}\text{-}TiCl_4(THF)_2]\cdot THF$, the titanium atom exists as Ti^{3+}, and the reduction of Ti^{4+} (in **I**) to Ti^{3+} (in **II**) is caused by the influence of light in THF. The post-reaction mixture revealed (MS–GL) the presence of HCl and C_4H_7OCl. The mechanism of these reactions has not yet been explained.

The geometry of the [*trans*-$TiCl_4(THF)_2$]$^-$ anion is presented in Fig. 1. Selected bond lengths and angles are summarized in Table 1. The titanium atom is six-coordinate with four square-planar chlorine atoms and two *trans*-THF molecules.

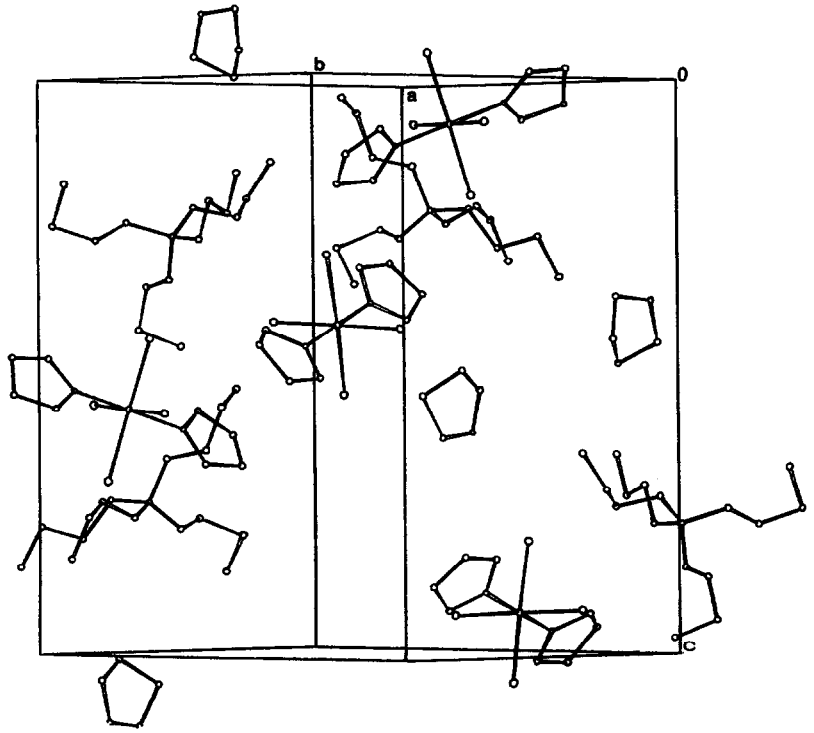

Fig. 2. The packing of the $[NBu_4][\textit{trans}\text{-}TiCl_4(THF)_2]\cdot THF$ crystal. The hydrogen atoms are omitted for clarity.

The $TiCl_4O_2$ unit forms a distorted octahedron. The average Ti—Cl and Ti—O bond lengths are equal, 2.395(9) and 2.10(1) Å, and are similar to 2.352(3) and 2.118(7) Å in $[TiCl_3(THF)_3]$.[10] The structure of [*trans*-$TiCl_4(THF)_2$]$^-$ is similar to that of the [*trans*-$MoCl_4(THF)_2$]$^-$ anion.[11] The parameters presented for the coordinated THF are close to those in $[TiCl_3(THF)_3]$ and the [*trans*-$TiCl_2(THF)_4$]$^+$ cation.[9] The $[NBu_4]^+$ cation has the *cis*-carbon-chain configuration and differs from the *trans* conformation observed earlier[4,12] (see Fig. 2).

The $[MgCl_4]^{2-}$ anion was shown to react easily with $TiCl_4$ and $TiCl_3$, to form the anions $[TiCl_6]^{2-}$ and [*trans*-$TiCl_4(THF)_2$]$^-$, respectively. In our opinion, $MgCl_2$ as a support could react directly with $TiCl_4$ to form the ionic or molecular compounds presented at the beginning of the paper, or undergo ionization under the influence of polar solvents (THF, esters, etc.) to form $[Mg(solvent)_6]^{2+}$, $[MgCl(solvent)_5]^+$ cations and $[MgCl_4]^{2-}$ anions, which would react further with titanium compounds to form the pre-catalyst.

EQUILIBRIA IN AQUEOUS SOLUTION BETWEEN BERYLLIUM(II) AND D,L-ASPARTIC ACID AND D,L-METHIONINE

A. MEDEROS,* E. MEDINA and J. J. ALVAREZ COLOMER

Departamento de Química Inorgánica, Universidad de La Laguna, Tenerife, Canary Islands, Spain

and

F. BRITO

Laboratorio de Equilibrios en Solución, Escuela de Química, Facultad de Ciencias, Universidad Central de Venezuela, Caracas, Venezuela

(*Received* 6 *December* 1988; *accepted* 10 *March* 1989)

Abstract—The complex species formed in aqueous solution between beryllium(II) and D,L-aspartic acid (ASP) and D,L-methionine (MET) were studied at 25°C and 0.5 M ionic strength in $NaClO_4$. The application of the least-squares computer program LETAGROP to the experimental potentiometric data, taking into account hydrolysis of the beryllium(II) ion, upon varying the ligand–metal ratios 4 : 1, 1 : 1 and 1 : 2, at beryllium(II) concentrations of 1, 3 and 6 mM, indicates that only the dihydroxide complexes ($[Be(OH)_2L']^{2-}$ for ASP, H_2L' ligand; $[Be(OH)_2L]^-$ for MET, HL ligand) are formed in significant amounts. The complex species begins to form at pH > 5.5. The formation constants β_{pqr} were determined.

Beryllium(II) is perhaps the most toxic of metallic cations.[1] The most dangerous mode of entry into the body is by the respiratory tract, and the effects are predominantly pulmonary.[2] Animal experiments and blood investigations on beryllium-exposed persons support the supposition that beryllium is bound to a protein as a hapten to form beryllium–protein complexes. *In vitro*, the beryllium ion inhibits numerous enzymes which are competitive towards magnesium or potassium and non-competitive in the form of beryllium binding to the enzymes. Chelating agents for the removal of deposited tissue beryllium have been explored.[2] We have confirmed that six-membered ring chelates are the most stable for beryllium(II), in a similar manner to other elements of the first short period, such as boron and carbon, while copper(II), nickel(II), lanthanides and other heavier elements prefer five-membered ring chelates,[3] and ligands containing propionic groups may be better sequestering agents.

The coordinating properties of beryllium(II) in aqueous solution with aminoacids or polyaminocarboxylic acids have, in general, been very little studied,[4–6] probably because of the strong tendency of the small beryllium(II) cation to hydrolyse.[7] In our studies, in aqueous solutions of the IDA–Be^{II}[8] (IDA = iminodiacetic acid), NTA–Be^{II}[3] (NTA = nitrilotriacetic acid) and EDTA–Be^{II}[9,10] (EDTA = ethylenediaminetetraacetic acid) systems, we have found upon analysing the experimental potentiometric data by means of the NERNST/LETA/GRAFICA version[11] of the LETAGROP program,[12] that the species resulting from the hydrolysis of beryllium(II) must be taken into consideration in the calculations, in order to determine the complex species present in the solution and to obtain correct values of the stability constants.

Beryllium(II) tends towards tetracoordination.[13] EDTA,[9,10] a potentially hexadentate ligand, forms the complexes $[BeHL''']^-$ and $[BeL''']^{2-}$ (H_4L''' ligand). NTA and NTP[3] (NTP = nitrilotripropionic acid), potentially tetradentate ligands, fulfill the coordination requirements of beryl-

* Author to whom correspondence should be addressed.

lium(II) and form the complex $[BeL'']^-$ (H_3L'' ligand). IDA and its analogues,[8] potentially tridentate ligands, only form the monohydroxide complex $[Be(OH)L']^-$ (H_2L' ligand) in significant amounts. The OH^- group will occupy the fourth place in the tetrahedron of coordination.

The present work is a continuation of our studies on the coordinating capacity in aqueous solution of aminoacids with beryllium(II), of D,L-aspartic acid (ASP), a potentially tridentate ligand, and D,L-methionine (MET), a potentially bidentate ligand. No references to the ASP–Be^{II} and MET–Be^{II} systems were found in the tables of stability constants.[4,5] However, Singh and Srivastava[6,14] for the ASP–Be^{II} system, and Perkins[15] for both systems, have determined from potentiometric measurements the stability constants of the complexes BeL' and BeL'_2 (ASP, H_2L' ligand; MET, HL ligand; charges being omitted for simplicity), with contradictory results. But these authors have not taken into consideration the hydrolysis of beryllium(II) in their calculations.

EXPERIMENTAL

Reagents

ASP and MET were prepared by recrystallization of ASP (BDH biochemicals, chromatographically homogeneous) and MET (Flucka puriss.), respectively.

The solution of $Be(ClO_4)_2$ was prepared by reacting metallic beryllium (Spex Industries Inc.) with an excess of $HClO_4$ (Merck, analytical grade), its free acidity[16] being determined, as well as the concentration of beryllium(II), in aqueous solution which was evaluated gravimetrically.[17,18] A carbonate-free sodium hydroxide solution was prepared according to the School of Sillén[19] and standardized against potassium hydrogen phthalate. $NaClO_4$ was prepared by recrystallization of $NaClO_4$ (Merck, analytical grade).

Apparatus and titration procedures

The potentiometric titrations were carried out in an inert argon atmosphere, at 25 ± 0.05°C, $I = 0.5$ M in $NaClO_4$, using a Radiometer Type PHM-64 potentiometer, a Radiometer G 202 B glass electrode and a K 401 calomel electrode. The cell constants were determined according to the method of Biedermann and Sillén,[20] the liquid junction potentials were found to be negligible within the margins of $[H^+]$ studied. It was found that $pK_w = 13.72$, in excellent agreement with reported data.[21] Measurements of the ligands alone were taken at the following concentrations: ASP, $C_L = 3.4$ and 1.2 mM (titration with NaOH) and $C_L = 1.2$ mM (titration with $HClO_4$); MET, $C_L = 4.4$ and 1.6 mM (titration with NaOH) and $C_L = 4.4$ mM (titration with $HClO_4$). Measurements of the ligands in the presence of beryllium(II) at the following concentrations and ligand:metal ratios were also taken: $C_M = 1$, 3 and 6 mM, ratios 4:1 and 1:1 for ASP; $C_M = 1$, 3 and 6 mM; ratios 4:1, 1:1 and 1:2 for MET.

Data treatment

The experimental potentiometric data were analysed by means of the NERNST/LETA/GRAFICA version[11] of the LETAGROP program,[12] based on a generalized form of the least-squares method that establishes the best model and best values of the β_{pqr} constants, minimizing the function $U = \Sigma(Z_{exp} - Z_{calc})^2$, Z being the average number of dissociated protons for the concentration of ligand (Z_c) or for the total concentration of metal (Z_B). The LETAGROP calculations also give standard deviations, $\sigma(Z)$ and $\sigma(\log \beta_{pqr})$.[22] The computations were performed on a Burroughs 6700 computer (Facultad de Ciencias, Universidad Central de Venezuela, Caracas).

Hydrolysis of beryllium(II) was previously studied under the same experimental conditions.[8] The $Be(OH)_2$ species is also found to be present in dilute solutions ($C_M < 10$ mM)[23,24] and at pH > 4.5. This species should also be taken into account since it competes with the hydroxy complexes. For equilibrium (1):

$$Be^{2+} + 2H_2O \rightleftharpoons Be(OH)_2 + 2H^+, \qquad (1)$$

it has been found that $-\log \beta_{-21} = 11.60 \pm 0.10$, which is in good agreement with the literature.[23,24]

RESULTS AND DISCUSSION

Ionization constants of the acids

From the values obtained for the β_{pr} constants corresponding to equilibria (2) and (3):

$$\text{ASP}, pH^+ + rH_2L' \rightleftharpoons [H_p(H_2L')_r]^{p+} \qquad (2)$$

$$\text{MET}, pH^+ + rHL \rightleftharpoons [H_p(HL)_r]^{p+}, \qquad (3)$$

the ionization constants of the acids (K_i) could readily be determined (see Table 1).

The values found for the pK_i are in good agreement with those previously found for the two ligands at the same ionic strength and temperature,[5] unless pK_0 (equilibrium H_2L^+/HL) for MET. The diagrams of the species distribution as a function of $-\log [H^+]$ (Fig. 1(a), ASP; Fig. 1(b), MET), calculated in accordance with the values of $-\log$

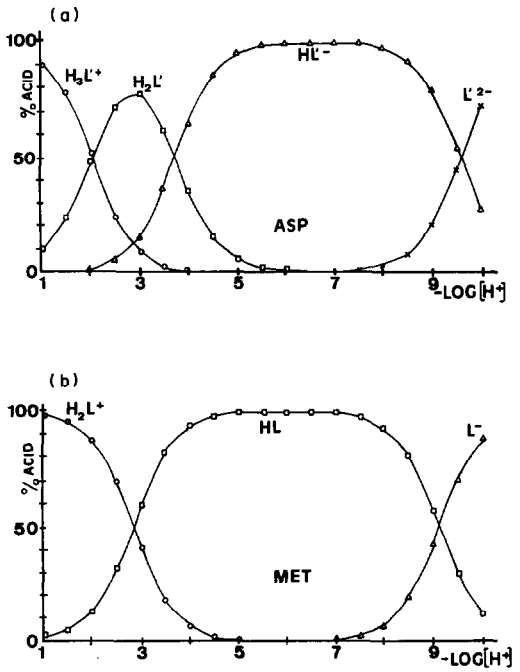

Fig. 1. Species distribution as a function of $-\log [H^+]$: (a) ASP and (b) MET.

β_{pr} given in Table 1, show that the monoprotonated species (HL'^- for ASP; HL for MET), with a fundamentally betainic structure,[25] is practically alone at $-\log [H]$ 5.5–7.5 for ASP and 5–7 for MET.

Formation constants of the complexes formed

The formation constants, β_{pqr}, are defined by means of equilibria (4) and (5)

$$\text{ASP}, pH^+ + qBe^{2+} + rH_2L' \rightleftharpoons [H_pBe_q(H_2L')_r]^{(p+2q)+} \quad (4)$$

$$\text{MET}, pH^+ + qBe^{2+} + rHL \rightleftharpoons [H_pBe_q(HL)_r]^{(p+2q)+}. \quad (5)$$

Taking into account the presence of the hydrolytic species $[Be_2(OH)]^{3+}$, $[Be_3(OH)_3]^{3+}$ and $Be(OH)_2$, an analysis is carried out first of the possible presence of the complex species supposed by Sing and Srivastava[6,14] and Perkins,[15] −211, BeL′, and −421, $[BeL'_2]^{2-}$, for ASP, and −111, $[BeL]^+$, and −212, BeL_2, for MET. For these species, $p/r = 2$ (ASP) and $p/r = 1$ (MET). These species were rejected ($\beta_{pqr} = 0$).

Figure 2(a) shows for ASP, that in the ligand–metal ratio 1:1, $Z_C > 2$, and in the ratio 4:1, $Z_C > 1.25$, at pH > 5.9. This is qualitative proof of the presence of hydroxo complexes with $p/r > 2$. Analogously, Fig. 2(b) shows for MET, that in the ratio 1:1, $Z_c > 1$, and in the ratio 4:1, $Z_C > 0.25$, at pH > 5.9, indicating the presence of hydroxo complexes with $p/r > 1$. In this pH zone, these complexes will, of course, compete with the formation of the $Be(OH)_2$ species [equilibria (1) and (8)] (Fig. 3). The existence of these complexes is short, since at pH ≈ 6.5 the turbidity of the solutions begins.

Thomas and co-workers[26–28] have shown that the trimer species, $[Be_3(OH)_3(H_2O)_6]^{3+}$, is not destroyed if the ligands are mono- or bidentate, since tetracoordination of beryllium(II) is then maintained, displacing one or two molecules of water for each atom of beryllium(II). The possible presence of bi- and trinuclear hydroxo complexes is therefore analysed as: −522, $[Be_2(OH)L'_2]^-$, and −933, $[Be_3(OH)_3L'_3]^{3-}$, for ASP; and −322, $[Be_2(OH)L_2]^+$, and −633, $Be_3(OH)_3L_3$, for MET.

These complexes were accepted, but their β_{pqr} constants are not well-defined, indicating that either the bi- and trinuclear hydroxo complexes are present in the solution in very negligible amounts, or that other hydroxo complexes are present, there being the monomer −311, $[Be(OH)L']^-$ and/or −411, $[Be(OH)_2L']^{2-}$, for ASP, and −211, Be(OH)L, and/or −311, $[Be(OH)_2L]^-$, for MET. Finally, the joint presence of the complexes −522, −933, −311 and −411 for ASP is tested, the simultaneous fit of the six potentiometric titrations studied being verified. The LETAGROP program

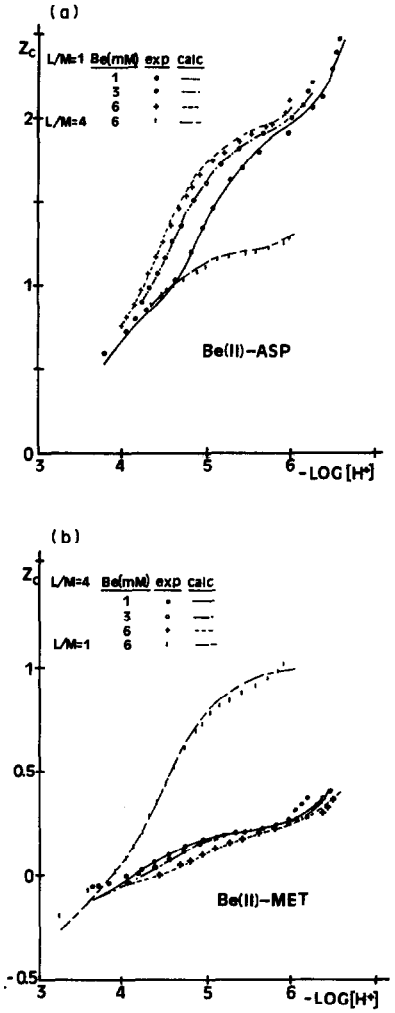

Fig. 2. Z_C vs $-\log [H^+]$ curves: (a) ASP–Be^{II} system and (b) MET–Be^{II} system. The curves have been calculated using the β_{pr} (Table 1), β_{pqr} (Table 2) and β_{pq} constants.

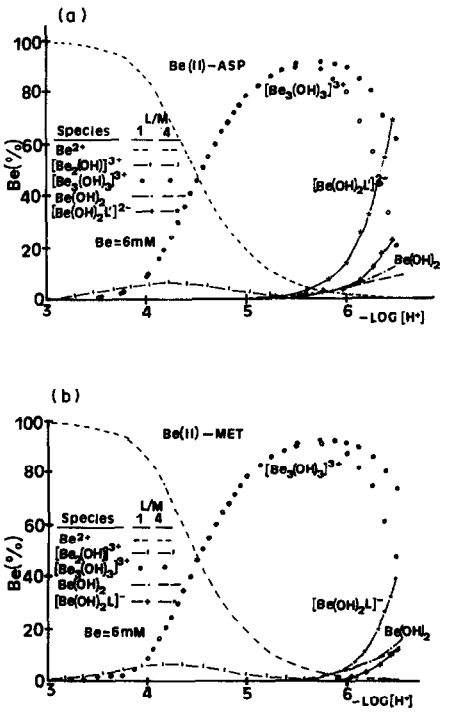

Fig. 3. Species distribution as a function of $-\log [H^+]$: (a) ASP–Be^{II} system and (b) MET–Be^{II} system.

only accepts complex -411, $[Be(OH)_2L']^{2-}$, with the value of β_{-411} indicated in Table 2. The remaining complexes are not present in significant amounts ($\beta_{pqr} \approx 0$). Similarly for MET, the joint presence of the complexes -322, -633, -211 and -311 is proven. The simultaneous fit of the nine potentiometric titrations studied, shows the sole presence, in significant amounts, of complex -311, $[Be(OH)_2L]^-$, with the value of β_{-311} indicated in Table 2. The remaining complexes are not present in significant amounts ($\beta_{pqr} \approx 0$).

The diagram of species distribution presented in Fig. 3(a) for ASP and Fig. 3(b) for MET, shows that the dihydroxo complexes begin to form at pH > 5.5. The limiting margin of existence of the species, $[Be(OH)_2L']^{2-}$ for ASP and $[Be(OH)_2L]^-$ for MET, is conditioned by the greater stability of the hydrolytic species, $[Be_3(OH)_3]^{3+}$. In Fig. 3, it

Table 2. Formation constants (β_{pqr}) and stability constants (K) of the ASP and MET complexes with beryllium(II) (25°C, $I = 0.5$ M in $NaClO_4$)

	No. of titrations/ No. of exptl points	$-\log [H^+]$ range	$\sigma(Z)^a$	pqr	$-\log \beta_{pqr}$	Equilibrium	$\log K$
ASP	6/160	3.79–6.57	0.038	−411	19.23±0.07	[b]	21.52
				−311	≈0		
				−933	≈0		
MET	9/164	3.08–6.50	0.046	−311	15.92±0.15	[c]	20.65
				−211	≈0		
				−633	≈0		

[a] Standard deviation.
[b] Equilibrium: $Be^{2+} + 2\,OH^- + L'^{2-}/[Be(OH)_2L']^{2-}$.
[c] Equilibrium: $Be^{2+} + 2\,OH^- + L^-/[Be(OH)_2L]^-$.

is shown that as the concentration of the ligand increases, the proportion of the dihydroxide complexes increases, and that of the species $[Be_3(OH)_3]^{3+}$ decreases. Since at pH $\approx$ 6 (Fig. 1), the ligands are present in the betainic form, HL'^- (ASP), HL (MET), the complexes are formed fundamentally by means of equilibria (6) and (7):

$$\text{ASP, } 1/3\,[Be_3(OH)_3]^{3+} + HL'^- \rightleftharpoons [Be(OH)_2L']^{2-} + 2H^+ \quad (6)$$

$$\text{MET, } 1/3\,[Be_3(OH)_3]^{3+} + HL \rightleftharpoons [Be(OH)_2L]^- + 2H^+. \quad (7)$$

The formation of these dihydroxo complexes explains the values of Z_C observed in Fig. 2 at pH > 5.9.

The hydrolytic species $Be(OH)_2$ is also formed from $[Be_3(OH)_3]^{3+}$ [equilibrium (8)]:

$$1/3\,[Be_3(OH)_3]^{3+} + OH^- \rightleftharpoons Be(OH)_2, \quad (8)$$

and competes with the dihydroxo complexes, but is present in a smaller proportion than these (Fig. 3).

The ASP and MET ligands behave, therefore, like bidentate ligands. The OH^- will occupy the third and fourth place in the tetrahedron of coordination as observed in the structures proposed for the complexes, $[Be(OH)_2L']^{2-}$ (Fig. 4, ASP) and $[Be(OH)_2L]^-$ (Fig. 5, MET).

The ligands form the complexes from the betainic structure, with loss of the betainic acidity [Figs 1–3, equilibria (6) and (7)], which involves the coordination of the nitrogen atom and an oxygen atom of the carboxylate group. The ASP behaves like a bidentate ligand forming a six-membered chelate ring, these being the most stable for beryllium(II)[3] (Fig. 4). MET forms the five-membered chelate ring as expected (Fig. 5).

These results are in agreement with the stability constants, K, of both dihydroxo complexes (presented in Table 2), which are readily calculated from β_{pqr} (Table 2), β_{pr} (Table 1) and K_w, the ionic product of water. The ASP complex is somewhat more stable than that of MET, since for beryllium(II) the six-membered chelate rings[3] are more stable than the five-membered ones.

ASP behaves like a tridentate chelating agent towards divalent transition cations such as cobalt(II), copper(II) and nickel(II).[29] Its isomer, iminodiacetic acid (IDA) behaves, moreover, as a tridentate chelating agent towards beryllium(II),[8] stabilizing the monohydroxo complex $[Be(OH)L']^-$ and forming five-membered chelate rings. ASP behaves differently towards beryllium(II): it should potentially form a more stable six-membered ring with beryllium(II) and another five-membered one, but this additional ring would be submitted to strong tensions in the tetrahedric coordination with a small cation such as beryllium(II) and would be unstable. The monohydroxo complex of ASP, $[Be(OH)(H_2O)L']^-$, would therefore be formed initially from $[Be_3(OH)_3]^{3+}$ [Fig. 3(a)], a molecule of water occupying the fourth coordination site, and quickly hydrolysing, finally stabilizing the dihydroxo complex $[Be(OH)_2L']^{2-}$. MET, a bidentate ligand, would also initially form the monohydroxo complex $[Be(OH)(H_2O)L]$, the coordinated molecule of water hydrolysing rapidly, and finally stabilizing the dihydroxo complex $[Be(OH)_2L]^-$.

(*Received* 20 *January* 1989; *accepted* 10 *March* 1989)

Abstract—Two sugar-containing chiral complexes are formed by the reaction of *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ and D-arabinose at pH 6. Complex **I** is a mixed valence cobalt(II)/cobalt(III) paramagnetic species, whereas complex **II** is a mononuclear cobalt(III) complex. Their syntheses and characterization are described. Visible absorption spectra and IR spectra were recorded. Optical activity was measured via circular dichroism spectra and optical rotatory dispersion. Complex **I** undergoes anomerization in aqueous solution, the rate of this process being pH and chiral complex dependent. Complex **II** does not retain its optical activity in aqueous solution as a result of decomposition. Spectral data support the coordination scheme proposed for each complex.

In previous work we reported the preparation and optical activity of ammino complexes of cobalt(III) containing D-ribose, L-sorbose and D-glucosamine as the second ligand.[1] We also reported the optical rotatory dispersion (ORD) curves of ammino complexes of cobalt(III) and L- or D-arabinose in aqueous solutions.

This work was initialy aimed at isolating D-arabinose complexes which we assumed would have a composition similar to that of the complexes previously mentioned. However, two kinds of chiral compounds containing the sugar were obtained in the same reaction: one of them unexpectedly turned out to be the salt of a mixed valence binuclear cobalt(II)/cobalt(III) complex, **I**; whereas the other was a mononuclear complex salt, **II**.

This paper reports the optical, spectral, magnetic and chemical characteristics of these complexes and we relate these properties to structural models.

EXPERIMENTAL

Materials

Most of the carbohydrates were from Merck. All were used without further purification.

Methods

Visible absorption spectra were measured on a Zeiss PMQ-2 spectrophotometer in 10^{-2}–10^{-3} M aqueous solutions. Optical rotatory dispersion measurements were run on a Perkin–Elmer 141 polarimeter modified with a Baush & Lomb monochromator, with 10^{-2} M aqueous solutions, using a 2 cm pathlength cell, connected to a thermostated bath.

The circular dichroism spectra were recorded on a Cary 60 spectropolarimeter using 10^{-2} M aqueous solutions in 1 cm pathlength cells. IR spectra of complexes were recorded on a DIGILAB FTIR with a spectral resolution of 2 cm^{-1} and KBr pellets, and also on a Leitz Wetzlar IIIG IR spectrometer. The chloride forms of complexes **I** and **II** were employed to avoid the strong sulphate bands.

Carbon, hydrogen and nitrogen were analysed with a Perkin–Elmer 240-C analyser. The Co content was determined by atomic absorption spectroscopy with a Perkin–Elmer 305 spectrometer. The sulphate content was determined by conductimetric titration with a standard $BaCl_2$ solution[2] in a YSI model 32 conductivity meter.

Magnetic susceptibility measurements at 298 K were carried out by the Gouy method. The susceptibility was also determined in the 2.5–300 K

* Author to whom correspondence should be addressed.

range with an SHE magnetometer connected to an SQUID sensor.

Kinetic measurements

The anomerization process developed by the binuclear complex was studied at 15°C in buffered (acetic acid (1M)/sodium acetate) solutions. Optical activity changes were followed on 8.5×10^{-3} M solutions at 550 nm, using 2 cm pathlength thermostated cells and a modified Perkin–Elmer 141 polarimeter, until constant rotations were achieved.

Preparation of the binuclear compound, complex I

Cis-$[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3 \cdot 3H_2O$ (1.685 g, 2.5 mmol) and D-arabinose (3.750 g, 25 mmol) were dissolved in 50 cm^3 of water, and the pH was adjusted to 6 with ammonia. The mixture was maintained at 25°C and the reaction was complete after 3 h. The products were then isolated. Methanol (60 cm^3) was added dropwise to the solution with constant stirring and a well-known tetranuclear ammino complex, $[Co\{(OH)_2Co(NH_3)_4\}_3](SO_4)_3 \cdot nH_2O$, ($n$ = 2–9),[3] was first precipitated, which was separated by filtration. Methanol (100 cm^3) was then added to the stirred solution and a red microcrystalline solid precipitated on the walls of the beaker. This product was collected by vacuum filtration, washed with methanol and ethanol, and dried in a vacuum desiccator. The yield was approximately 300 mg. The residual solution was a deep pink colour and was optically active.

Purification of the binuclear complex

Freshly-prepared binuclear complex was dissolved in 10 cm^3 of water and was poured dropwise into 80 cm^3 of methanol containing 100 mg $NaClO_4$, which prevented formation of a colloidal suspension. Constant stirring was maintained during this process and a pink solid precipitated, which was isolated by vacuum filtration, washed with methanol and ethanol, and dried in a vacuum desiccator. This procedure was repeated until the amplitude of the Cotton-effect, centred at 545 and 475 nm, levelled off. The yield of pure binuclear complex was *ca* 150 mg.

The product is very soluble in water, but insoluble in most organic solvents. It is stable as a solid and retains its optical activity when stored in a dry atmosphere. The compound is also paramagnetic. Optical activity of the aqueous solution of this compound drops slowly until the sign of the Cotton-effect, centred at 500 nm, reverses (see Fig. 1), while the absorption spectrum suffers no variation.

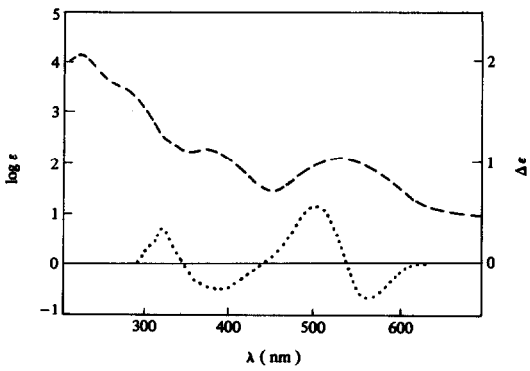

Fig. 1. Visible absorption spectrum (———) and circular dichroism (·····) of aqueous solutions of Complex I.

Analysis for $[Co_2(NH_3)_4(OH)_2(H_2O)_2$ D-arabinose$]_2(SO_4)_3 \cdot 4H_2O$: Found: Co, 20.5; SO_4, 24.8; C, 10.4; H, 4.8; N, 9.5. Calc: Co, 20.8; SO_4, 25.3, C, 10.6; H, 5.3; N, 9.9%.

Preparation of the mononuclear compound, complex II

400 cm^3 of the methanolic residual solution from the previous preparation were concentrated to 120 cm^3 on a 2 dm^3 evaporating dish under a cool air stream. The aqueous solution obtained was precipitated by dropwise addition of 200 cm^3 of absolute ethanol, under vigorous stirring for 30 min. Once pink crystals appeared, the resulting solution was kept at 4°C in the dark for a further 1/2 h before the next stage.

Precipitation was continued by adding another 500 cm^3 of absolute ethanol dropwise to the cold solution. A hygroscopic purple solid appeared, which covered the walls of the beaker. The resulting pink supernatant was discarded and the purple solid was redissolved in 5 cm^3 of distilled water. This concentrated solution was added dropwise to 120 cm^3 of a cold methanol–propanone (1 : 2) mixture, with vigorous stirring. The purple solid quickly covered the bottom of the beaker and a pink suspension developed. Once again the pink supernatant was discarded and the purple solid was easily washed off using 80 cm^3 of cold propanone with vigorous magnetic stirring. The purple solid obtained was quickly transferred to a dark container and dried *in vacuo* overnight. The yield of the purple solid was 230 mg.

Elemental analysis for $[Co(NH_3)_4$ D-arabinose$](NH_4)(SO_4)_2 \cdot 3H_2O$: Found: Co, 10.6; SO_4, 35.5; C, 11.8; H, 5.9; N, 12.5. Calc: Co, 10.9; SO_4, 35.5; C, 11.1; H, 5.2; N, 12.9%.

The resulting mononuclear compound is heat- and light-sensitive, so it was kept in the refrigerator

in a dry container. Under these conditions the compound lasted for at least 3 months without loss of optical activity. Optical activity of the aqueous solutions of this complex decreases very slowly at room temperature in the dark. However, this process speeds up in dim light or acidic media. Cobalt(II) was identified as one of the decomposition products.

The chloride form of complexes I and II were obtained either by anion exchange on Dowex 1X8 or by precipitation with $BaCl_2$ solution. Aqueous solutions so obtained were evaporated and dried in a desiccator.

Regarding the synthesis of the chiral complexes, it must be remembered that the reacting complex *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ in aqueous solution at pH 6 and 25°C, spontaneously forms the tetranuclear ammino complex of cobalt(III) previously mentioned. The formation of this product is enhanced as the pH and temperature increase. The same chiral products containing arabinose were even obtained from a reaction with a 1:1 mole ratio of the reagents, although poorer yields were achieved. The large excess of carbohydrate employed in the present synthesis shifts the course of the reaction with formation of the sugar-containing chiral complexes.

RESULTS AND DISCUSSION

Magnetic susceptibility measurements of the binuclear complex at 298 K and 1 kG gave a magnetic moment, $\mu = 4.49$ BM. The data were corrected to compensate for the diamagnetism of the constituent atoms (Pascal constants). Susceptibilities measured over the range 2–300 K showed a linear dependence of the reciprocal susceptibility on temperature, confirming the presence of one cobalt(II) in the complex. The calculated value of the magnetic moment is higher than the spin only moment for three unpaired electrons (3.89 BM). This is the normal situation for high-spin octahedral cobalt(II) complexes, since they have a very high orbital contribution.[4]

Conductimetric titrations of the binuclear complex with hydrochloric acid showed two inflections due to non-bridged OH groups.[5] This agrees with the Co–SO_4 molar ratio, thus indicating the coordination of two OH ligands.

Table 1 shows that the visible absorption spectrum of the binuclear complex consists of two bands: the first one has $\lambda_{max} = 527$ nm, ($\varepsilon = 109$), whereas the second one is a shoulder at 370 nm, which corresponds to a *d–d* absorption overlapped by a charge-transfer absorption, Fig. 1. This spectrum is similar to that found for ammino complexes

Table 1. Visible absorption and circular dichroism data

	Absorption		CD	
	λ(nm)	$\varepsilon(M^{-1}cm^{-1})$	λ(nm)	$\Delta\varepsilon(M^{-1}cm^{-1})$
Complex I	527	109	562	−0.568
			497	0.994
	370(s)	129	380	−0.419
			318	0.426
Complex II	530	46.38	560	0.38
			495	−0.65
	373	80	375	0.31
			310	−0.567

of cobalt(III) containing ribose, sorbose and glucosamine,[1] where cobalt(III) is surrounded by four nitrogen and two oxygen atoms.

Two circular dichroism signals of opposite sign appear under the first absorption band, detected at 562 and 497 nm. Of the two CD signals, the one with the lower energy corresponds to the $^1A_2$ state, and the other to the ^1E state, both of them derived from the first $^1T_{1g}$ excited state of cobalt(III) in octahedral symmetry, see Fig. 2. These CD signals exhibit the same signs sequence as that of the chiral compounds formed by an ammino complex of cobalt(III) with D-glucosamine, L-sorbose and D-ribose.

The CD spectrum of the binuclear complex also has two signals at 380 and 318 nm, corresponding to the low wavelength visible absorption spectrum. The lower energy signal should correspond to an ^1E state derived from the magnetically forbidden $^1T_{2g}$ state of cobalt(III).[6] The higher energy signal could correspond to a ligand-to-metal charge-transfer state (see Table 1).

The visible spectra of the mononuclear and binuclear complexes are similar, Table 1. In the mononuclear complex, the first band appears at

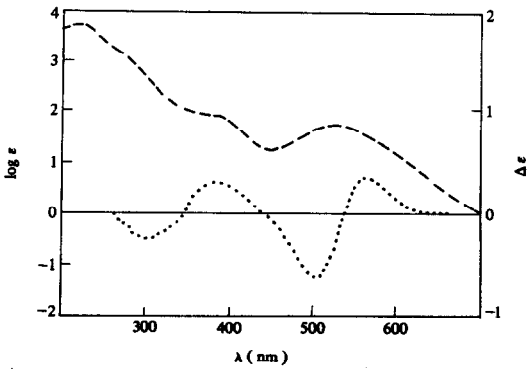

Fig. 2. Visible absorption spectrum (———) and circular dichrosim (·····) of aqueous solutions of Complex II.

530 nm ($\varepsilon = 46$) and there is a shoulder at 373 nm ($\varepsilon = 180$), which is better resolved than that of the binuclear species. There are two circular dichroism signals under the first visible absorption band, Fig. 2. Their signs are opposite to those of the corresponding band of the binuclear complex: one is at 565 nm and the other one at 505 nm.

Circular dichroism signals under the second visible absorption band of cobalt(III) are detected at 385 and 310 nm. The lower energy signal has *d–d* character, corresponding to a transition derived from the $^1T_{2g}$ state. The positive circular dichroism signal at 218 nm in the binuclear complex and the negative one at 310 nm in the mononuclear complex have similar $\Delta\varepsilon$ values. Considering their energies we think that both signals correspond to a ligand-to-metal charge-transfer transition.[7]

The different rotation signs for the same kind of transition in the mono- and the binuclear complexes might originate from an opposite helical distribution of the chelate ring around the cobalt(III) ion in each species.

Solutions of the binuclear complex suffer an inversion of the Cotton-effect signs in the visible spectral region (Fig. 3). This process follows first-order kinetics with complex concentration. It is also first order regarding proton concentration. The specific rate constant at 15°C (288 K), measured under pseudo-first-order conditions at pH 5.4 (buffered solution) is 1.5×10^{-3} min^{-1}. We ascribe this behaviour to anomerization. It is slower than that of D-arabinose solutions at the same pH and temperature, ($k = 1.99 \times 10^{-2}$ min^{-1}).

D-Arabinose is known to exist in the alternative form, with an anomeric composition, 68% α- and 34% β-anomers.[8,9] The cobalt(III) ion can coordinate to this carbohydrate forming five-membered chelate rings through the O(1)H—O(2)H, or O(2)H—O(3)H or O(3)H—O(4)H positions.

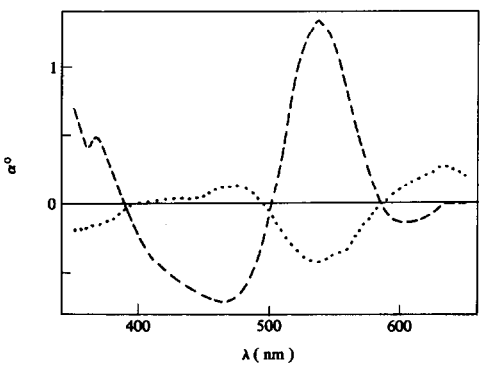

Fig. 3. Optical rotatory dispersion change of a 0.0055 M solution of Complex **I**, pH 5.4, 15°C, 1 cm pathlength cell. Starting solution (–––); same solution after 100 min. (·····).

Chirality is the same, λ, for each one of these in the case of the β-anomer [Fig. 4(a)]. In the case of the α-anomer, chirality originating by bonding through the O(1)H—O(2)H positions is opposite, δ, to that resulting from bonding through the two other coordination positions [Fig. 4(b)].

The Cotton-effect signs under the first visible absorption band and the phenomenon of complex anomerization led us to think that the cobalt(III) ion bonds to the O(1)H group of the β-D-arabinose, in which case the other site of coordination would be O(2)H. Bonding to the ring oxygen atom O(5) is sterically hindered for the alternative conformation of D-arabinose.

Coordination of D-arabinose to the cobalt(II) ion in the binuclear complex has not been discussed yet. Scale models show that simultaneous bonding of O(3)H and O(4)H, or O(4)H and ring oxygen O(5) atoms of the sugar to the metal are feasible.

The FTIR spectrum of the chloride form of complex **I** is not as well-resolved as that of complex **II** in the 3500–3200 cm^{-1} range. However, a clear shift of the CO group ring vibrations of the carbohydrate to lower frequencies can be observed. In this way, the bands in the neighbourhood of 1136, 1093, 1052, 1000 and 943 cm^{-1}, assigned as ν(CO)+

3235 b	ν(O(2)—H···O(3)H)	10(a)	3239 shoulder 3195 sharp–strong 3175 sharp–strong 3159 sharp–strong
3000 w	ν(C(5)—H)	10(a)	3000 sharp–weak
2970 sh	ν(C(4)—H)	10(a)	— shoulder
2953 sh	ν(C(3)—H)	10(a)	— no band
2940 m	ν(C(2)—H)	10(a)	2945 medium
—	δ(O—H(2))		1635 strong
—	δ(N—H(3))	11	1595 strong
1402 vw	δ(CH(2))+δ(COH)	10(a)	1415 strong
—	δ(N—H(3))	11	1308 medium
1134 vs	ν(CO)+ν(CC)	10(a)	1145 sharp–weak 1115 sharp–weak
1002 s	ν(CC)+ν(CO)	10(a)	1080 broad–medium 1045 sharp–weak
893 s	δ(COH)α	10(b)	855 broad–weak

ν(CC), ν(CO), ν(CO)+δ(CCO) and ν(CO)+δ(CCH), respectively,[10] are broadened and shifted towards 1108, 1075, 1030 and 983 cm^{-1}, thus suggesting that the CO group could be involved in bonding to the cobalt(II) ion.

In the mononuclear complex, under the same pH and temperature conditions, the optical activity drops to zero. At the same time, the intensity of the first visible absorption band decreases as a result of decomposition of the complex species.

The FT–IR spectra of complex **II** in the chloride form show three major frequency ranges (3500–3200, 1415 and 1145–1045 cm^{-1}), as shown in Table 2. From 3500 to 3200 cm^{-1} the OH···O stretching bands are shifted towards lower frequencies compared with free sugar, thus showing shorter OH···O bridging between O(3)H and O(2)H. However, O(4)H and O(1)H were almost unperturbed compared to UO_2–sugar complexes obtained by Tajmir-Riahi.[10a] In addition, no CH stretching bands were observed for C(4)H and C(3)H, but they were observed for C(1)H, C(2)H and C(5)H. COH and CCH deformation modes of sugar complexes appeared as a strong band at 1415 cm^{-1}. This, together with a set of four unresolved bands (ν(CO)+ν(CC) 1145–1045 cm^{-1}), are indicative of metal–sugar coordination.[10a]

Complex **II** Cotton-effect signs under the first absorption band, which are opposite to those of **I**, might arise from coordination of cobalt(III) to O(1)H and O(2)H atoms of the α-anomer of D-arabinose in its alternative form. This possibility looks more attractive to us, although it cannot be forgotten that the same sequence of Cotton-effect signs could arise from bonding of the metal ion to the O(1)H—O(2)H or O(3)H—O(4)H positions of normal β-D-arabinose. Data provided by the FT–IR spectrum seem to point towards the third proposal.

CHARACTERIZATION OF THE 18-CROWN-6–LANTHANUM(III) COMPLEX IN METHANOL USING ^{139}La NUCLEAR MAGNETIC RESONANCE

ZHIGANG CHEN, HEATHER DETTMAN and CHRISTIAN DETELLIER*

Ottawa-Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ontario K1N 9B4, Canada

(*Received* 2 *November* 1988; *accepted* 14 *March* 1989)

Abstract—The complex formed between $LaCl_3 \cdot 7H_2O$ and the macrocyclic ligand 18-crown-6 (18C6) in methanol has been characterized by ^{139}La NMR. Two sites in very slow exchange on the ^{139}La NMR chemical shift time scale coexist in methanolic solutions: solvated and 1 : 1 complexed $^{139}La^{III}$. Both chemical shift and relaxation rate data point to the participation of the chloride counteranion and of the crown ether in the first coordination sphere of lanthanum(III). The equilibrium constant of formation of the complex, determined from the populations of the two ^{139}La NMR sites, is in excellent agreement with previously determined data from the literature.

Complexes of lanthanide cations with macrocyclic ligands have attracted considerable interest in the past decade.[1] A large variety of macrocyclic ligands have been involved in the design, synthesis and isolation of these complexes, which are characterized by various stoichiometries.[1–3] The crown ethers[4] have been shown to be very versatile in the nature and the structure of the complexes that they form with lanthanide cations.[1] Numerous reports on the crystal structure determination of such complexes have appeared.[5] However, the studies of their properties in solution are rather scarce.[1,6]

NMR of metallic nuclei is a very useful tool for investigating the properties of the alkali metal cation complexes with crown ethers in solution.[7] More particularly, the stoichiometry of such complexes present in small amounts in solution could be determined.[8] Since ^{139}La with its natural abundance of 99.91% and its receptivity relative to ^{13}C of 342 ($I = 7/2$, $Q = 0.21 \times 10^{-28}$ m^2) is one of the most promising nuclei among the early transition elements,[9] ^{139}La NMR is a good candidate for becoming a useful probe in the study of the La^{III} solution chemistry.

The first ^{139}La NMR experiment was performed as early as 1949.[10] Since, a number of ^{139}La NMR studies have been reported.[11] Most of these investigations focussed on the nature of outer- and inner-sphere lanthanum complexes formed by various anions in aqueous solutions.[11a–c]

This communication is the first report of a ^{139}La NMR study of a La^{III}–crown ether complex in solution.

EXPERIMENTAL

18-Crown-6 (Aldrich, 99%) was purified and vacuum-dried as described previously.[12] $LaCl_3 \cdot 7H_2O$ (Aldrich, 99.9%) and methanol (BDH, Assured) were used as received. All the spectra were recorded within 48 h after the preparation of the sample.

^{139}La NMR spectra were obtained at 42.37 MHz on a Varian XL-300 spectrometer using a 10 mm probe. A 0.1 M solution of $LaNO_3 \cdot 6H_2O$ in D_2O–H_2O (20 : 80) was used as an external reference for the chemical shifts. The 90° pulse width was 16 μs. Typically, pulse widths between 10 and 16 μs were used, without any significant alteration of the spectral region of interest. The delay between the end of the 90° pulse and the beginning of the acquisition was chosen as short as possible, and was always $\leqslant 5$ μs. In the case of Lorentzian lineshapes, the transverse relaxation rates, T_2^{-1}, were obtained directly from the linewidths. The temperature in the probe was measured as described previously.[13] All

the experiments reported in Fig. 1 and Table 1 were performed at 300.0 ± 0.5 K.

Analyses of the ^{139}La spectral lineshapes were carried out on an Amdahl mainframe computer using a non-linear least-squares regression.[14] The adjustable parameters were C, p_A, T_{2A}, T_{2B} and ϕ (defined below). ν_A and ν_B were obtained directly from the spectra at $\rho = [18C6]/[La^{III}] = 0$ and $\rho = 1.4$, respectively, and were fixed during the regression. Data were transferred to the mainframe from the spectrometer using an IBM-clone PC intermediate and Kermit software. A program was

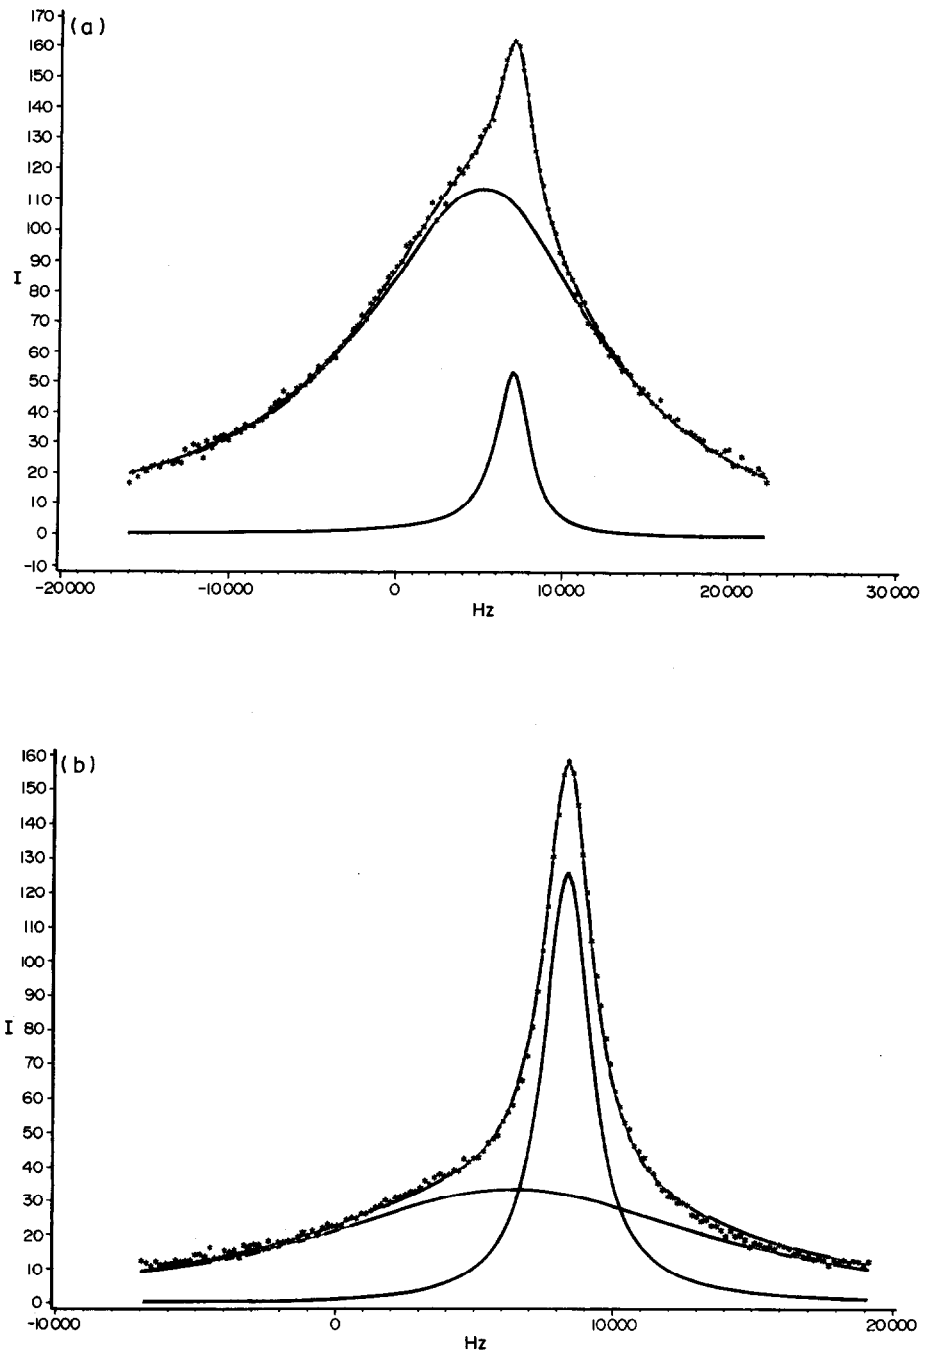

Fig. 1. ^{139}La NMR spectra, at 42.37 MHz, of $LaCl_3 \cdot 7H_2O$ in methanol in the presence of 18-crown-6 ($T = 300.0 \pm 0.5$ K). The points (*) have been obtained from the original spectra, and the solid lines result from a non-linear regression on eq. (1). RESULTS AND DISCUSSION

The ^{139}La NMR spectrum of a 0.2 M solution of $LaCl_3 \cdot 7H_2O$ in methanol consists of a single, broad, Lorentzian line, characterized by a chemical shift of 165 ppm, and a linewidth of 1.90 kHz. The addition of 18C6 to the solution resulted in the appearance of a much broader line resonating at lower frequency. The lineshapes were also invariant with temperature variations (300 K < T < 330 K). This is an indication of two species in very slow exchange on the chemical shift time scale. Figure 1 shows the ^{139}La NMR spectra of two solutions of hydrated lanthanum chloride in methanol in the presence of 18C6. Since the crown ether is known to form a 1:1 complex with La^{III} in methanol,[15] the simplest interpretation for the observed ^{139}La spectra is that they result from the superposition of two Lorentzian absorption lines corresponding to the uncomplexed La^{III} solvated cation, and to the 1:1 La^{III}–18C6 complex.

The spectrum resulting from the superposition of two Lorentzian signals can be described by eq. (1),[16,17] which is the two-site slow exchange case ($k \to 0$) of the general equation given by Gold and Zdunek[17] for an imperfectly phase-corrected spectrum:

$$I(\nu) = C[(M+N)\cos\phi + (P+Q)\sin\phi] + B, \quad (1)$$

$$M = T_{2A}P_A/(1+4\pi^2T_{2A}^2(\nu_A-\nu)^2)$$

$$N = (1-P_A)T_{2B}/(1+4\pi^2T_{2B}^2(\nu_B-\nu)^2)$$

$$P = T_{2A}^2P_A(\nu_A-\nu)/(1+4\pi^2T_{2A}^2(\nu_A-\nu)^2)$$

$$Q = (1-P_A)T_{2B}^2(\nu_B-\nu)/(1+4\pi^2T_{2B}^2(\nu_B-\nu)^2).$$

T_{2A}, T_{2B} and ν_A, ν_B correspond to the transverse relaxation times and the chemical shifts of the solvated (A) and complexed (B) sites, respectively; C is a scaling factor; and P_A is the population of site A (here, uncomplexed $^{139}La^{III}$). It was difficult to adequately adjust the phase and baseline of the broad, overlapping peaks. Consequently, the simulation of these spectra required phase (ϕ) and baseline (B) parameters to be included in the lineshape equation.

Table 1 gives the results of the deconvolution of the observed spectra on the basis of eq. (1), for three La^{III} total concentrations and several values of the ratio $\rho = [18C6]_0/[La^{III}]_0$. The transverse relaxation rate characterizing the solvated site, T_{2A}^{-1}, was found to be constant, within experimental error, for a given total La^{III} concentration: 6.8 kHz (0.2 M), 6.3 kHz (0.1 M) and 5.1 kHz (0.05 M). The decrease of the relaxation rate as the concentration decreases is an indication of ionic association. This is further confirmed by the variation of the chemical shift for the solvated La^{III}: 165, 194 and 230 ppm, respectively, for $[La^{III}]$ = 0.2, 0.1, and 0.05 M. The same trend is observed, but to a lesser extent, for the chemical shifts of the complex species: 130, 150 and 167 ppm. All these observations point to the evidence of the participation of the chloride anion in the first coordination sphere of the lanthanum cation, both in the solvated and complexed species. This has recently been shown to be the case in the solid state for a hydrated gadolinium chloride complex with 18C6.[5b] McCain[18] has studied concentrated solutions of $LaCl_3$ in methanol, water and binary mixtures of methanol and water, by ^{139}La and ^{35}Cl NMR. The ^{139}La chemical shift of a 1.45 M $LaCl_3$ solution in methanol was found to be 293 ppm, and the linewidth was 3800 Hz. These values

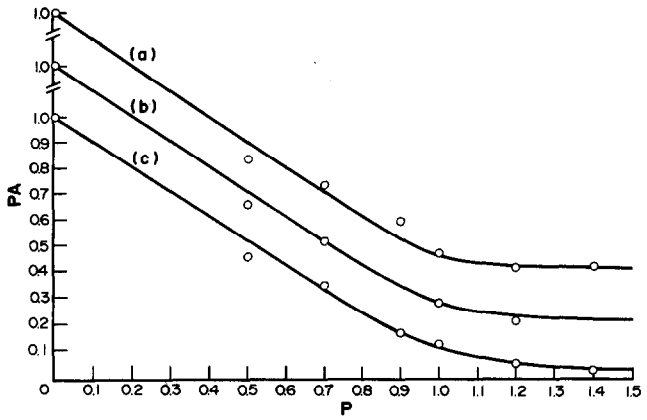

Fig. 2. Normalized populations of uncomplexed La^{III} as a function of $\rho = [18C6]_0/[La^{III}]_0$. $T = 300.0 \pm 0.5$ K. The data points have been obtained from the non-linear regression analysis on eq. (1) shown in Fig. 1 and the solid lines have been calculated on the basis of $\log K_f = 3.2$. $[La^{III}]_0$ = (a) 0.200, (b) 0.100 and (c) 0.050 M.

are of the same order of magnitude as reported in this study. In the binary mixtures, there was evidence for the formation of an La—Cl inner-sphere complex when the precentage of methanol was greater than 66%.

Despite the fact that the nature of the coordinating atoms (oxygens) is the same in the solvent and in the macrocyclic ligand, substantial chemical shift differences between the solvated and the complexed cations can be observed. This could be an indication that, in methanol solution, the crown ether occupies the first coordination sphere of the La^{III} cation. However, due to the paucity of ^{139}La data in the literature, and the lack of possible comparison with similar systems, this point will have to be checked in further studies. Only an estimate could be obtained for the value of the transverse relaxation rate of the complexed $^{139}La^{III}$, which is in the range 28–65 kHz. This very large value reflects a large quadrupolar coupling constant resulting from a strong dissymmetry of the electric charges in the first coordination shell of the La^{III} cation. Again, this is in good agreement with a direct coordination of the crown ether on La^{III}.

From the populations of the solvated (see Table 1) and of the complexed lanthanum cation, it was possible to calculate an equilibrium constant of formation for the 1:1 La^{III}–18C6 complex. A mean value of $\log K_f = 3.2 \pm 0.5$ was obtained. This value is in excellent agreement with the result obtained by Izatt *et al.* on the same system,[15] using titration calorimetry ($\log K_f = 3.29$). Figure 2 shows the population of the solvated La^{III} as a function of the ratio $[18C6]_0/[La^{III}]_0$. The data points are experimental and the solid lines have been calculated from the value of $\log K_f = 3.2$.

In conclusion, the present work demonstrates the potential of ^{139}La NMR to become a very useful technique for probing the structure of lanthanum cations in solution. In the particular case studied here, of hydrated $LaCl_3$ in the presence of 18C6 in methanol, both chemical shift and relaxation rate data point to the participation of the chloride counteranion and of the crown ether in the first coordination sphere of La^{III} in methanolic solutions. Further work is in progress in our laboratory to collect ^{139}La NMR data on other systems, and to access the kinetic parameters of the exchange between the various species in equilibrium in solution.

(*Received* 30 *January* 1989; *accepted* 15 *March* 1989)

Abstract—In light petroleum at reflux temperatures, the compounds $[W(Me)(\eta\text{-}C_2H_4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (R = C_6H_4Me-4 or C_6H_4OMe-2) afford the ditungsten complexes $[W_2(\mu\text{-CR})(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$. The structure of the product with R = C_6H_4OMe-2 has been established by X-ray diffraction. The W—W bond (2.761(1) Å) is spanned symmetrically by the CC_6H_4OMe-2 group (μ-C—W, 2.01(1) Å). One tungsten atom carries a cyclopentadienyl ligand and two carbonyl groups, one of which weakly semi-bridges the metal–metal bond (W—C—O, 168.3(9)°). The other tungsten atom is ligated by a cyclopentadienyl ring, and by a carbonyl and a methyl group (W—CH_3, 2.24(2) Å).

We have previously reported[1] that UV irradiation of mixtures of the compounds $[M(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (M = Mo or W) and $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (R = C_6H_4Me-4 or C_6H_4OMe-2) in light petroleum affords the complexes $[MW\{\mu\text{-}C(R)C(O)Me\}(CO)_4(\eta\text{-}C_5H_5)_2]$ (**1**). This reaction involves a coupling of methyl, carbonyl and alkylidyne groups at a dimetal centre. However, the pathway by which these products were formed was by no means clear. Herein we describe related reactions between the ethylene complex $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ and the alkylidine–tungsten species $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$, which yield products relevant to the formation of compounds **1**.

RESULTS AND DISCUSSION

The complex $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ was generated by irradiating $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ with UV light in the presence of ethylene.[2] It was then treated with $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$; the mixture being refluxed in light petroleum. Separation of products by column chromatography on alumina gave purple crystals of the ditungsten compound $[W_2(\mu\text{-}CC_6H_4Me\text{-}4)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2a**), a trace of the previously characterized complex $[W_2\{\mu\text{-}C(C_6H_4Me\text{-}4)C(O)Me\}(CO)_4(\eta\text{-}C_5H_5)_2]$ (**1b**)[1] and an unidentified exceedingly insoluble green material. In a similar reaction, the compounds $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ and $[W(\equiv CC_6H_4OMe\text{-}2)(CO)_2(\eta\text{-}C_5H_5)]$ gave a chromatographical separable mixture of $[W_2(\mu\text{-}CC_6H_4OMe\text{-}2)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2b**), a trace of **1d** and the μ-alkyne complex $[W_2\{\mu\text{-}C_2(C_6H_4OMe\text{-}2)_2\}(CO)_4(\eta\text{-}C_5H_5)_2]$ (**3**).

The IR and NMR data for the compounds **2** and **3** were in accord with the formulations proposed. Moreover, as described below, the structure of **2b** was confirmed by an X-ray diffraction study. The IR spectrum of **2a** in the carbonyl region shows three bands at 1941, 1908 and 1835 cm^{-1}, as expected. The absorption at 1835 cm^{-1} may be attributed to a semi-bridging carbonyl group. The ^1H NMR spectrum showed all the expected peaks, including a resonance for the WMe group at −0.40 ppm (J(WH) 7 Hz). The $^{13}C\text{-}\{^1H\}$ NMR spectrum displayed a diagnostic resonance for the μ-C nucleus at δ 360.7 ppm, with two sets of $^{183}W\text{–}^{13}C$ satellite peaks [J(WC) 120 and 101 Hz]. This pattern is in agreement with the $\mu\text{-}CC_6H_4Me$-4 ligand being attached to non-equivalent tungsten

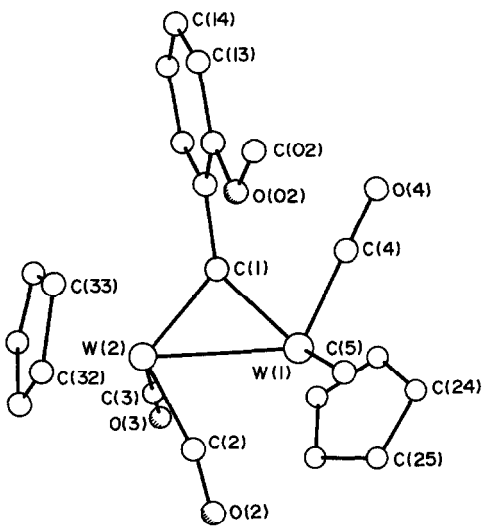

Fig. 1. The molecular structure of $[W_2(\mu\text{-}CC_6H_4OMe\text{-}2)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2b**) showing the atom-numbering scheme.

atoms. Moreover, the observed chemical shift is relatively deshielded. This is in accord with a structure in which the C≡W fragment is functioning formally as a four-electron donor,[3] thereby leading to a stable but electronically unsaturated 32 valence-electron species. The three carbonyl groups in **2a** give rise to resonances at δ 238.3, 223.2 and 221.9 ppm. There are two signals (δ 97.7 and 94.1 ppm) for the non-equivalent C_5H_5 ligands, and a characteristic[4] peak for the WMe fragment at δ −15.9 ppm [J(WC) 88 Hz].

Examination of the NMR spectra of **2b** showed that peaks were present corresponding to the presence of two isomers, but discussion is deferred until the results of the X-ray diffraction study are described. The structure is shown in Fig. 1, and selected bond distances and angles are listed in Table 1. The W—W bond (2.761(1) Å) is spanned symmetrically by the alkylidyne group (μ-C—W, 2.01(1) Å). The metal–metal distance is perceptibly shorter than the W—W single bond distances $[W_2(\mu\text{-}HC_2H)(CO)_4(\eta\text{-}C_5H_5)_2]$ (2.987 (1) Å),[5] $[W_2(\mu\text{-}EtC_2Et)(CO)_4(\eta^5\text{-}C_5Et_4C_6H_4Me\text{-}4)(\eta\text{-}C_5H_5)]$ (3.003(1) Å)[6] and $[N(PPh_3)_2][W_2\{\mu\text{-}C(H)C_6H_4Me\text{-}4\}(CO)_7(\eta\text{-}C_5H_5)]$ (3.111(1) Å).[7] However, the W—W separations in the electronically unsaturated 32 valence-electron ditungsten complexes, $[W_2(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(L)(\eta^5\text{-}C_9H_7)(\eta^5\text{-}C_2B_9H_9Me_2)]$ [L = $N_2C(C_6H_4Me\text{-}4)_2$ (2.777(1) Å) or O (2.761(1) Å), C_9H_7 = indenyl],[8] are very similar to the metal–metal bond distance in **2b**. Moreover, the fact that C(1) symmetrically spans the W(1)—W(2) bond is also in accord with the electronic unsaturation of **2b** and with electron delocalization within the μ-CW_2 ring. In structures in which an alkylidyne ligand edge-bridges a W—W bond, and the two metal centres have 18 electron shells, the two μ-C—W separations are perceptibly different,[9] indicating the presence of more localized C—W and C=W bonds within the ring. It is noteworthy that the μ-C—W distances in **2b** (2.01(1) Å) are shorter than W=C separation

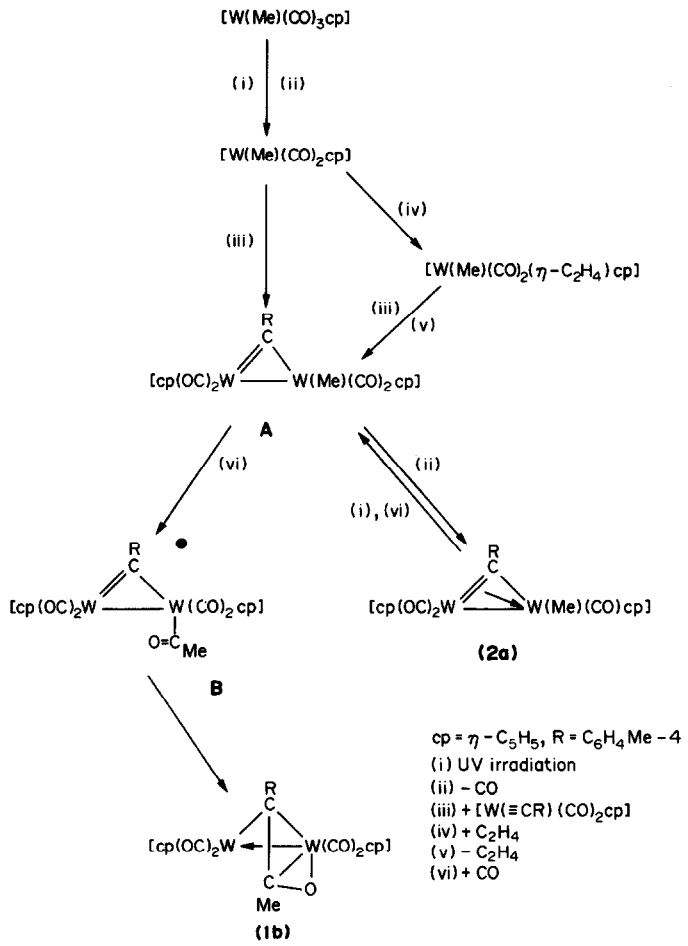
(2.14(2) Å) in $[W(=CPh_2)(CO)_5]$,[10] a molecule in which tungsten has an 18 electron shell.

The W(2) atom in **2b** carries a C_5H_5 ring and two CO groups. However, whereas C(3)O(3) has an essentially linear attachment to the tungsten, the ligand C(2)O(2) weakly semi-bridges the metal–metal bond (W(2)—C(2)—O(2), 168.3(9)°). This is in agreement with the appearance of an IR band at 1835 cm^{-1}, mentioned above. The W(1) atom is ligated by a C_5H_5 ring, a terminal CO ligand and a methyl group. The W(1)—C(5) separation (2.24(2) Å) is within the range expected (2.1–2.3 Å)[11] for σ bonds between tungsten and sp^3 carbon atoms. The *o*-anisol ring in **2b** lies at 99.0° to the plane defined by C(1)W(1)W(2), but with the OMe group and the Me substituent on W(1) on the same side of the μ-CW_2 ring.

The compounds **2** are isolobally mapped with the complex $[W(Me)(CO)(\eta\text{-}C_2H_2)(\eta\text{-}C_5H_5)]$, in which the ethyne molecule functions as a four-electron donor.[12] As mentioned above, complex **2b** is formed as a mixture of two diastereoisomers, a property revealed by the ^1H and $^{13}C\text{-}\{^1H\}$ NMR spectra (see Experimental). The relative intensity of peaks in the spectra indicate that in $CDCl_3$ solution the proportion of the two isomers was *ca* 3 : 1. We suggest that the isomerism arises as a result of the Me and OMe groups being either cisoid (on the same side), or transoid (on the opposite sides) of the μ-CW_2 ring. In the reaction between $[W(\equiv CC_6H_4OMe\text{-}2)(CO)_2(\eta\text{-}C_5H_5)]$ and $[WMe(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$, the formation of the μ-alkyne complex **3** was unexpected, because in the corresponding reaction involving $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$, the compound $[W_2\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)_2]$ was not formed. The latter complex is, however, often produced in reactions of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ with low-valent metal species.[9,13] Compounds of the type $[M_2(\mu\text{-alkyne})(CO)_4(\eta\text{-}C_5H_5)_2]$ (M = Mo or W) in solution show dynamic behaviour on the NMR timescale,[14,15] and **3** is no exception. Although good quality spectra were not obtained, at −40°C, peaks corresponding to the presence of two isomers were observed, including four CO resonances in the $^{13}C\text{-}\{^1H\}$ NMR spectrum. At room temperature no CO resonances were seen in the spectrum.

In spite of its electronic unsaturation, compound **2a** was unreactive towards PMe_3 or PPh_3 in refluxing tetrahydrofuran (THF), and UV irradiation of **2a** in the presence of PMe_3 was equally fruitless. However, irradiation of **2a** in THF with a stream of CO gas passing through the solution, resulted in the disappearance of the IR bands due to **2a** and the appearance of new carbonyl absorptions at 2018vs, 1972s, 1926s, 1864m, 1678w and 1671w cm^{-1}. On removing the UV source and replacing the CO atmosphere with N_2, these bands gradually disappear, and are replaced by those due to **1b**. Column chromatography of the mixture led to the isolation of **1b** in yields greater than 70%.

Possible pathways to compounds **1b** and **2a** are shown in the Scheme 1, and similar processes can be invoked to account for the formation of the other species, **1** and **2**. The synthesis of **1b** from $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ proceeds upon UV irradiation of solutions containing a mixture of the two reagents.[1] It is likely that the methyltungsten compound is activated with release of a molecule of CO to give the coordinatively unsaturated species $[W(Me)(CO)_2(\eta\text{-}C_5H_5)]$.[16] The latter could then capture a molecule of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ to give intermediate **A**. Reaction of **A** with CO, present in the solutions or scavenged from one of the reactants, might yield the acyl–dimetal complex, **B**, which could collapse to give **1b**. The formation of **2a** from $[W(Me(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ proceeds in hydrocarbon solvents but only under reflux conditions. Presumably intermediate **A** is again formed, but in the absence of appreciable amounts of free CO in the mixture it releases CO to afford primarily **2a**. The observation that traces of **1b** are formed in the reaction demonstrates the relationship between **2a** and **1b** with the probability of a common intermediate. As mentioned above, UV irradiation of **2a** in the presence of CO gives **1b** in high yield. However, during this conversion the IR spectrum of the mixture shows bands due to a transient species at 1678 and 1671 cm^{-1}, characteristic of an acyl group, as invoked for **B**. The presence of two absorptions near 1675 cm^{-1} may be due to the existence of more than one isomer of **B**. It is noteworthy that **2a** does not react with CO in the absence of UV irradiation. This suggests that **2a** requires initial activation, perhaps to give an intermediate $[W_2(\mu\text{-}CC_6H_4Me\text{-}4)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ in which the $(\eta\text{-}C_5H_5)(OC)_2W\equiv CC_6H_4Me\text{-}4$ moiety acts as a two-electron donor to the $W(Me)(CO)(\eta\text{-}C_5H_5)$ fragment. The latter would then possess a 16 electron tungsten centre which would capture a CO molecule to give **A**; which via additional CO could yield **1b**, through the intermediacy of **B**. The conversion of **B** into the product **1b** may involve more than one step. Thus, transfer of the acyl group to the μ-$CC_6H_4Me\text{-}4$ fragment might produce a μ-$C(C_6H_4Me\text{-}4)C(O)Me$ ligand in a species containing a W=W bond. This intermediate (not shown), with the bridging group functioning as a two-electron donor, could transform into **1b**, in which the organic group contributes



Scheme 1.

four electrons to the ditungsten system. The process would be similar to the transfer of a terminally bound formyl group to a μ-thio-alkylidyne ligand, as in the formation of the complexes $[Fe_2\{\mu\text{-}C(SMe)C(H)O\}(\mu\text{-}CO)(CO)(\eta\text{-}C_5H_5)_2]$.[17] We have attempted to isolate intermediates such as **A** or **B** by UV irradiation of CO saturated solutions of **1b**, but no reaction was observed.

EXPERIMENTAL

Light petroleum refers to that fraction of bp 40–60°C. All reactions were carried out under N_2, using Schlenk tube techniques. Chromatography columns employed BDH alumina (Brockman activity II). The compounds $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (R = C_6H_4Me-4 or C_6H_4OMe-2) were prepared by procedures described elsewhere,[3,18] while $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$[2] was obtained by irradiating $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ in light petroleum with UV light (Hanovia medium pressure mercury vapour lamp) under a stream of C_2H_4, the reagent thus prepared being used *in situ*. IR spectra were measured (in CH_2Cl_2) with Nicolet MX-1 and 5ZDX FT spectrophotometers. The NMR spectra were recorded in $CDCl_3$ using JNM JEOL FX90Q, GX270 and GX400 FT spectrometers. The $^{13}C\{^1H\}$ chemical shifts are to high frequency of $SiMe_4$ (0.0 ppm).

Synthesis of the compounds $[W_2(\mu\text{-}CR)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$

(i) The complex $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (1.75 g, 5.0 mmol) in light petroleum (300 cm^3) was irradiated with UV light at −20°C for *ca* 4 h; the conversion to $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ being monitored periodically by IR. The compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (1.43 g, 3.5 mmol) was added, and the mixture was refluxed for 6 h. Removal of solvent *in vacuo* gave a brown residue which was dissolved in CH_2Cl_2 (10 cm^3) and chromatographed (3 × 20 cm column). Elution with light petroleum removed traces of $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$. Elution with CH_2Cl_2–light petroleum (2 : 1) gave a purple fraction and a red

fraction. Removal of solvent *in vacuo* from the purple eluate, and crystallization of the residue from CH_2Cl_2–light petroleum (15 cm^3, 1:10) at −78°C gave purple *microcrystals* of $[W_2(\mu\text{-}CC_6H_4Me\text{-}4)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2a**) (0.51 g, 21%), ν_{max}(CO) at 1941m, 1908vs and 1835m cm^{-1}. (Found: C, 35.3; H, 3.0. $C_{22}H_{20}O_3W_2 \cdot CH_2Cl_2$ requires: C, 35.2; H, 2.8%). NMR: ^1H, δ −0.40 [s, 3H, WMe, J(WH) 7 Hz], 2.43 (s, 3H, Me-4), 5.34, 5.36 (s × 2, 10H, C_5H_5), 6.29–7.16 (m, 4H, C_6H_4). $^{13}C\text{-}\{^1H\}$, δ 360.7 [μ-C, J(WC) 120 and 101], 238.3 [CO, J(WC) 156], 223.2 [CO, J(WC) 170], 221.9 [CO, J(WC) 168], 165.5 [$C^1(C_6H_4)$], 134.2, 127.7, 127.4, 122.4, 119.0 (C_6H_4), 97.7, 94.1 (C_5H_5), 21.1 (Me-4), and −15.9 ppm [MeW, J(WC) 88 Hz].

The red eluate from the column was identified by IR as containing a trace of **1b**. A final elution of the column with THF recovered a green eluate, which after removal of solvent *in vacuo* gave green microcrystals (*ca* 0.2 g), as yet unidentified.

(ii) In a similar experiment, the compound $[W(Me)(CO)_2(\eta\text{-}C_2H_4)(\eta\text{-}C_5H_5)]$ (prepared from $[W(Me)(CO)_3(\eta\text{-}C_5H_5)]$ (1.75 g, 5.0 mmol) and C_2H_4) was treated with $[W(\equiv CC_6H_4OMe\text{-}2)(CO)_2(\eta\text{-}C_5H_5)]$ (1.48 g, 3.5 mmol). Separation of products, as described above, afforded purple *microcrystals* of $[W_2(\mu\text{-}CC_6H_4OMe\text{-}2)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2b**) (0.45 g, 18%), red *microcrystals* of $[W_2\{\mu\text{-}C_2(C_6H_4OMe\text{-}2)_2\}(CO)_4(\eta\text{-}C_5H_5)_2]$ (0.30 g) and a trace of red **1d**.

For **2b**, ν_{max}(CO) at 1939m, 1907vs and 1830m cm^{-1}. NMR (peaks with asterisk due to minor isomer), ^1H, δ −0.41*, −0.25 [s × 2, 3H, MeW, J(WH) 7], 3.55*, 3.58 (s × 2, 3H, OMe), 5.30, 5.32*, 5.33, 5.36* (s × 4, 10H, C_5H_5), 6.22–6.95 (m, 4H, C_6H_4). $^{13}C\text{-}\{^1H\}$ (measured at −40°C), δ 359.9, 357.3* (μ-C), 237.9 (CO, both isomers), 225.7, 224.0*, 223.2*, 222.2 (CO), 157.9, 157.8* [$C^1(C_6H_4)$], 150.4*, 150.0, 127.3, 127.1*, 125.2, 121.4*, 120.5*, 120.2, 112.1*, 111.2 (C_6H_4), 98.4*, 98.0, 95.0*, 94.6 (C_5H_5), 56.8*, 56.4 (OMe), −12.3, and −15.7* [MeW, J(WC) 87 Hz]. For $[W_2\{C_2(C_6H_4OMe\text{-}2)_2\}(CO)_4(\eta\text{-}C_5H_5)_2]$ (**3**), ν_{max}(CO) at 1969vs, 1937s and 1845m cm^{-1}. NMR (at −40°C); ^1H, δ 3.46*, 3.66 (s × 2, br, 6H, OMe), 5.56 (sbr, 10H, C_5H_5), 6.82–7.32 (m, 8H, C_6H_4). $^{13}C\text{-}\{^1H\}$, δ 231.1, 225.6, 221.4, 213.2 (CO), 164.2*, 157.0, 146.1, 144.3, 134.4*, 131.9*, 127.5, 124.5*, 122.2, 120.2, 112.6*, 110.6 (C_6H_4), 94.3, 91.7* (C_5H_5), 55.6* and 54.5 (OMe).

Crystal structure determination of $[W_2(\mu\text{-}CC_6H_4OMe\text{-}2)(Me)(CO)_3(\eta\text{-}C_5H_5)_2]$ (**2b**)

Crystals of **2b** were grown as dark purple prisms from Et_2O–light petroleum. Diffracted intensities were recorded at 298 K on a crystal of dimensions *ca* 0.2 × 0.2 × 0.4 mm. Of the 3624 reflections ($2\theta \leqslant 50°$), measured on a Nicolet R3m/μ four-circle diffractometer (θ–2θ scans), 2690 had $F \geqslant 3.0\sigma(F)$, and only these were used in the solution and refinement of the structure. Intensity data were corrected for Lorentz, polarization and X-ray absorption effects, the latter by an empirical method based on azimuthal scan data.[19]

Crystal data. $C_{22}H_{20}O_4W_2$, M = 716.1, monoclinic, a = 15.462(2), b = 16.354(2), c = 8.406(1) Å, β = 105.31(1)°, U = 2050(1) $Å^3$, D_c = 2.32 g cm^{-3}, Z = 4, $F(000)$ = 1328, space group $P2_1/a$ (No. 14), Mo-K_α X-radiation (graphite monochromator, $\bar{\lambda}$ = 0.71073 Å), μ(Mo-K_α) = 114.8 cm^{-1}.

The structure was solved, and all non-hydrogen atoms were located, by conventional heavy-atom and difference-Fourier methods. Hydrogen atoms were included in calculated positions (C—H 0.96 Å) with common refined isotropic thermal parameters for groups of related hydrogen atoms. All remaining atoms were given anisotropic thermal parameters. Refinement by full-matrix least-squares, with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.0009|F|^2]$, converged at R = 0.034 (R' = 0.036).* The final electron-density difference synthesis showed no peaks $\geqslant$1.5 or $\leqslant$−1.1 e $Å^{-3}$. Scattering factors, with corrections for anomalous dispersion, were from ref. 20. All calculations were carried out on a DEC micro-Vax II computer with the SHELXTL PLUS system of programs.[19]

MERCURY THIOETHER CHEMISTRY: THE SYNTHESIS AND STRUCTURE OF $[Hg([9]aneS_3)_2](PF_6)_2$ ([9]aneS$_3$ = 1,4,7-TRITHIACYCLONONANE)

ALEXANDER J. BLAKE, ALAN J. HOLDER, TIMOTHY I. HYDE, GILLIAN REID and MARTIN SCHRÖDER*

Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh EH9 3JJ, Scotland, U.K.

(*Received* 27 *January* 1989; *accepted* 15 *March* 1989)

Abstract—Reaction of $HgSO_4$ with 2 molar equivalents of [9]aneS$_3$ in refluxing H_2O–MeOH (1:1 v/v) for 1 h affords a colourless solution from which the complex $[Hg([9]aneS_3)_2](PF_6)_2$ can be isolated by addition of NH_4PF_6. $[Hg([9]aneS_3)_2](PF_6)_2 \cdot \frac{1}{3}H_2O$ crystallizes in the monoclinic space group $I2/a$, with $a = 11.8667(10)$, $b = 15.1631(23)$, $c = 14.454(4)$ Å, $\beta = 90.224(19)°$, $V = 2600.7$ Å^3, $D_c = 2.18$ g cm^{-3}, $Z = 4$. The single crystal X-ray structure of the complex shows a crystallographically centrosymmetric cation with hexathia coordination at mercury(II), with Hg—S(1) = 2.728(3), Hg—S(4) = 2.638(3) and Hg—S(7) = 2.712(3) Å. This structure closely resembles that of the silver(I) analogue, $[Ag([9]aneS_3)_2]^+$, which also shows hexathia coordination. Cyclic voltammetry of $[Hg([9]aneS_3)_2]^{2+}$ shows a chemically reversible reduction at $E_{1/2} = -0.15$ V ($\Delta E_p = 80$ mV) vs Fc/Fc^+ at a scan rate of 90 mV s^{-1}.

The chemistry of macrocyclic thioether complexes is of intense current interest.[1,2] We have concentrated our studies on the coordinative properties of tri-, tetra-, penta- and hexathia crowns with the platinum group metal ions,[1] and have found a correspondence between the structures of these complexes and their redox behaviour. The coordinative ambivalence of [9]aneS$_3$ towards metal ions has been central to these studies and had led to the isolation of a range of metal oxidation state species.[3–6]

Few non-porphyrinoid macrocyclic complexes of third-row metal ions have been reported.[7] This is primarily due to the kinetic inertness of these metal ions and the stability of metal complex intermediates leading to full metal insertion. The trithia crown, [9]aneS$_3$, is a particularly attractive ligand for the complexation of third-row metal ions since it incorporates three soft sulphur donors which are pre-organized for facial coordination.[8,9] Binding of [9]aneS$_3$ to a large, inert metal ion, therefore, does not involve metal insertion into a macrocyclic cavity as such, since the formal hole size of [9]aneS$_3$ is too small. We have studied the binding of [9]aneS$_3$ with a range of third row transition metal ions with d^n-configurations from d^5 to d^{10}, e.g. $Os^{II/III}$,[1,3] $Ir^{I/II/III}$,[1] $Pt^{II/III/IV}$,[1,4] $Au^{I/II/III}$.[5] As a continuation of this work, we report herein the synthesis and structure of the d^{10} mercury(II) complex, $[Hg([9]aneS_3)_2]^{2+}$.

The coordination chemistry of [9]aneS$_3$ and related crown ligands with d^{10} metal ions such as zinc(II),[10] cadmium(II),[10] silver(I),[11–14] and gold(I)[5] has been studied. Hexathia coordination at zinc(II)[10] and silver(I)[10–14] has been confirmed. However, the gold(I) species, $[Au([9]aneS_3)_2]^+$, is anomalous, since it adopts a stereochemistry intermediate between that of tetrahedral and linear coordination, with two long and two short Au—S bond lengths i.e. [2+2] coordination.[5] The binding of [14]aneS$_4$ to mercury(II) to afford the dimeric complex $[Hg_2([14]aneS_4)Cl_4]$ has been described previously.[15] This species involves *exo* coordination of two thioether donors of [14]aneS$_4$ to each tetrahedral $HgCl_2$ moiety.[15] Hence, binding of macrocyclic thioether donors to mercury(II) has precedents in the literature,[14,15] and suggested that binding of mercury(II) with [9]aneS$_3$ would be a viable target.

RESULTS AND DISCUSSION

Reaction of $HgSO_4$ with 2 molar equivalents of [9]aneS$_3$ in refluxing H_2O–MeOH (1 : 1 v/v) for 1 h gave a colourless solution. Addition of NH_4PF_6 afforded a white product which was recrystallized from H_2O. On the basis of elemental analysis and spectroscopic data the complex was assigned as $[Hg([9]aneS_3)_2](PF_6)_2$. The ^1H NMR spectrum of $[Hg([9]aneS_3)_2](PF_6)_2$ showed a characteristic ABCD pattern for the methylene protons of the macrocyclic ligands (Fig. 1). The ^{13}C NMR spectrum of $[Hg([9]aneS_3)_2]^{2+}$ showed a single resonance at $\delta = 26.6$ ppm assigned to the methylene carbon atoms of [9]aneS$_3$. These data indicated the presence of a single product in solution, with two equivalent [9]aneS$_3$ ligands bound facially to the mercury(II) centre. A single crystal X-ray structure determination was undertaken to confirm the stereochemistry of the complex cation.

Crystals of $[Hg([9]aneS_3)_2](PF_6)_2$ were obtained from H_2O. A view of the cation is shown in Fig. 2. The single crystal X-ray structure of the complex shows a centrosymmetric complex cation: the mercury(II) cation occupies a crystallographic inversion centre with all six thioether donors coordinated to it. Interestingly, the Hg—S distances are not identical: two are significantly shorter (Hg—S(4) = 2.638(3) Å) than the remaining four (Hg—S(1) = 2.728(3), Hg—S(7) = 2.712(3) Å, ∠S(1)HgS(4) = 82.64(9), ∠S(1)HgS(7) = 81.01(8), ∠S(4)HgS(7) = 82.86(9)°), indicating a small but significant

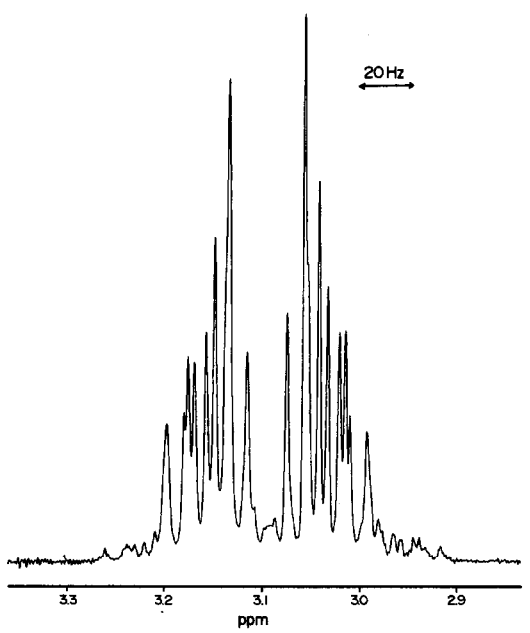

Fig. 1. ^1H NMR spectrum (360 MHz, CD_3CN, 298 K) of $[Hg([9]aneS_3)_2]^{2+}$.

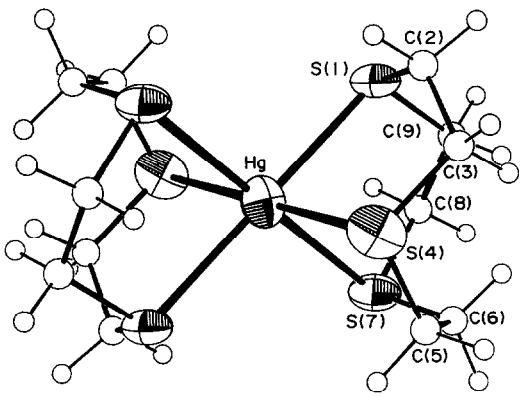

Fig. 2. Single crystal X-ray structure of $[Hg([9]aneS_3)_2]^{2+}$ with numbering scheme adopted.

tetragonal compression for the cation. The related d^{10} complex, $[Ag([9]aneS_3)]^+$, also shows hexathia coordination, with Ag—S bond lengths varying from 2.6665(12) to 2.7813(10) Å, ∠SAgS = 80.35(3), 77.43(3)°.[11] The mercury(II) and silver(I) complexes, therefore, show similar structural features, with the silver(I) species incorporating slightly longer M—S bond lengths reflecting the larger ionic radius of silver(I) over mercury(II) (1.15 vs 1.02 Å[16]). The structural features for these silver(I) and mercury(II) complexes may be interpreted as a compromise between the tendency of second- and particularly third-row d^{10} metal ions to adopt linear coordination, and the preference of [9]aneS$_3$ for facial binding: in the case of mercury(II) and silver(I) the latter appears to dominate.

Interestingly, d^{10} gold(I), which has a particularly strong preference for linear coordination, only binds four thioether donors in $[Au([9]aneS_3)_2]^+$, (Au—S = 2.302(6), 2.350(7), 2.733(8), 2.825(8) Å) to give a structure that is a combination of linear and tetrahedral coordination at gold(I).[5] This contrasts with the recently reported structure of $[Zn([9]aneS_3)_2]^{2+}$ where there is no significant variation in Zn—S bond lengths:[10] these occupy a narrow range (2.491(3)–2.497(3) Å) consistent with the tight coordinative fit of octahedral zinc(II) with facially binding [9]aneS$_3$.

Cyclic voltammetry of $[Hg([9]aneS_3)_2]^{2+}$ shows a chemically reversible reduction at $E_{1/2} = -0.15$ V ($\Delta E_p = 80$ mV) vs Fc/Fc^+ at a scan rate of 90 mV s^{-1} (Fig. 3). Coulometry at 298 K in CH_3CN (0.1 M $^nBuN_4PF_6$) at platinum electrodes shows the reduction to be a two-electron process. However, no stable mercury(I) or mercury(0) species could be isolated under these conditions, with decomposition of the reduction products occurring in solution. The parent mercury(II) complex could not be regenerated from the reduced solution.

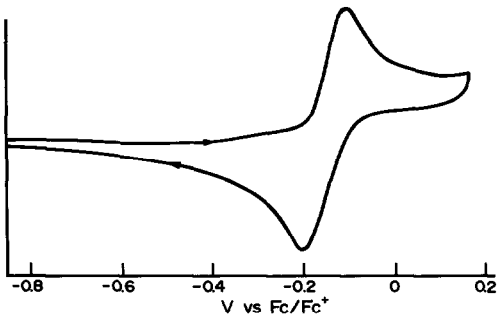

Fig. 3. Cyclic voltammogram of $[Hg([9]aneS_3)_2](PF_6)_2$ in CH_3CN (0.1 M $^nBu_4NPF_6$) at platinum electrodes. Scan rate = 90 mV s^{-1}, 298 K.

We can only speculate at the binding characteristics of [9]aneS$_3$ with $d^{10}s^1$ mercury(I) and/or $d^{10}s^2$ mercury(0). Our previous work has shown that [9]aneS$_3$ binds to gold(I) rather weakly, with the complex $[Au([9]aneS_3)_2]^+$ being highly labile and reactive in solution. Binding of [9]aneS$_3$ to mercury(I) and mercury(0) would be expected to be weaker than with gold(I), explaining the ready decomposition of these low valent mercury complexes in solution. Work is underway to try to stabilize these species at lower temperatures and in alternative solvents.

EXPERIMENTAL

IR spectra were measured as Nujol mulls, KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department microanalytical service. ESR spectra were recorded as solids or as frozen glasses down to 77 K using a Bruker ER200D X-band spectrometer. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBF_4$ as the supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag/AgCl reference electrode. All potentials are quoted versus ferrocene/ferrocinium (Fc/Fc$^+$). Mass spectra were obtained by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^{1}H NMR spectra were recorded at 200 and 360 MHz on Bruker WP200 and WH360 spectrometers respectively. ^{13}C NMR spectra were recorded at 50.32 MHz on a Bruker WP200 spectrometer.

Synthesis of $[Hg([9]aneS_3)_2](PF_6)_2$

$HgSO_4$ (0.1 g, 0.34 mmol) was treated with [9]aneS$_3$ (0.13 g, 0.72 mmol) in H_2O–MeOH (30 cm^3, 1:1 v/v) under reflux for 1 h. Addition of excess NH_4PF_6 to the resulting solution afforded a white precipitate, which was collected and recrystallized from water to give $[Hg([9]aneS_3)_2](PF_6)_2$ (0.18 g, 62% yield). Found: C, 16.7; H, 2.91. Calc. for $[Hg([9]aneS_3)_2](PF_6)_2$: C, 16.8; H, 2.90%. ^{1}H NMR spectrum (360 MHz, CD_3CN, 293 K): $\delta = 3.06$ ppm (CH_2, m). ^{13}C NMR spectrum (50.32 MHz, CD_3CN, 293 K): $\delta = 26.6$ ppm (CH_2).

X-ray structure determination of $[Hg([9]aneS_3)_2](PF_6)_2 \cdot \frac{1}{3}H_2O$

A colourless lath (1.00 × 0.173 × 0.078 mm) suitable for X-ray analysis was obtained by recrystallization from hot water.

Crystal data. $C_{12}H_{24}S_6Hg^{2+} \cdot 2PF_6^- \cdot \frac{1}{3}H_2O$, monoclinic, space group $I2/a$ (a non-standard setting of $C2/c$, No. 15), $M = 857.2$, with $a = 11.8667(10)$, $b = 15.1631(23)$, $c = 14.454(4)$ Å, $\beta = 90.224(19)°$, $V = 2600.7$ Å^3, $D_c = 2.18$ g cm^{-3}, [from 2θ values of 20 reflections measured at $\pm\omega$ ($2\theta = 30 \rightarrow 32°$, $\bar{\lambda} = 0.71073$ Å)], $Z = 4$; $F(000) = 1647$, μ(Mo-K_α) = 65.37 cm^{-1}.

Data collection and processing. Stoë STADI-4 four-circle diffractometer, ω–2θ scans with ω scan width $(1.40 + 0.347 \tan\theta)°$, 1722 unique reflections measured ($2\theta_{max} = 45°$, h $-12 \rightarrow 12$, k $0 \rightarrow 14$, l $0 \rightarrow 15$) giving 1236 with $F \geqslant 6\sigma(F)$. Initial absorption correction based on 72Ψ scans (minimum and maximum transmission factors: 0.1036 and 0.1644, respectively). Correction for linear, isotropic crystal decay (*ca* 25%) applied during data reduction.

Structure analysis and refinement. The mercury atom was located from a Patterson synthesis. Iterative rounds of least-squares refinement and difference Fourier synthesis[17] located all other non-hydrogen atoms. At isotropic convergence, final corrections for absorption were made using DIFABS.[18] Anisotropic thermal parameters were refined for mercury, sulphur, phosphorus and the carbon atoms of the cation, and for the two fully occupied fluorine atoms of the disordered PF_6^- ions. Partial occupancies were refined for all other fluorine atoms using fixed isotropic thermal parameters ($U_{iso} = 0.10/0.15$). Hydrogen atoms were included in fixed, calculated positions.[17] The weighting scheme $w^{-1} = \sigma^2(F) + 0.000331F^2$ gave satisfactory agreement analyses. At convergence, R, $R_w = 0.0421$ and 0.0539, respectively, for 156

TIN–PHOSPHORUS NUCLEAR-SPIN COUPLING IN OCTAHEDRAL COMPLEXES OF TIN(IV)

WILLIAM McFARLANE* and NICHOLAS H. REES

Department of Chemistry, City of London Polytechnic, Jewry Street, London EC3N 2EY, U.K.

(*Received* 21 *February* 1989; *accepted* 15 *March* 1989)

Abstract—Heteronuclear magnetic multiple resonance experiments are used to show that the large values of $^1J(^{119}Sn^{31}P)$ found in tertiary phosphine complexes of tin tetrahalides are negative [corresponding to a positive $^1K(SnP)$], suggesting that the mean excitation energy approximation can provide a valid description of the Fermi contact contribution to this spin coupling interaction, in contrast to the situation for other types of Sn—P interaction over one bond.

Nuclear-spin scalar (J) coupling over one bond has been reported for four main types of tin–phosphorus interaction: (a) tetrahedral Sn^{IV}—P^{III};[1–4] (b) tetrahedral Sn^{IV}—P^V;[2,4] (c) octahedral Sn^{IV}—P^V;[5–7] and (d) trigonal Sn^{II}—P^V,[8] typical ranges for $^1J(^{119}Sn^{31}P)$ being +530–+840, +50–+430, 1400–3000 and 1280–1670 Hz, respectively, with the last two of unknown sign. Note that as $\gamma(^{119}Sn)$ is negative, the corresponding reduced coupling constants $^1K(SnP)$ [defined[9] as $4\pi^2J(^{119}Sn^{31}P)/h\gamma(^{119}Sn)\gamma(^{31}P)$] are negative in cases (a) and (b). This has been attributed[4] to a small s-overlap integral for the tin–phosphorus bond which leads to a breakdown of the mean excitation energy approximation used in certain[10] calculations of the Fermi contact contribution to the coupling constant. However, the *algrebraic increase* in $^1K(SnP)$ between (a) and (b) closely parallels that found[11] in $^1K(PC)$ accompanying the transformation $P^{III} \rightarrow P^V$ for many organophosphorus compounds, although $^1K(PC)$ itself is usually positive in the latter instance. For any discussion[8,12] of the remaining cases it is therefore essential to know the sign of $^1K(SnP)$, and we report here such a determination for species of type (c).

Sign-determining magnetic multiple resonance experiments were performed upon the species $(Et_3P)_2SnCl_4$ and $(Et_3P)(Bu_3P)SnCl_4$. These can be expected to have a *trans* configuration on the basis of X-ray diffraction,[12] IR,[13] Raman[13] and Mössbauer[12,14] spectroscopic studies of related species, and this was confirmed by certain of the NMR spectra as mentioned below.

(i) A 2D $^{13}C/^1H$ chemical shift correlation experiment on $(Et_3P)_2SnCl_4$, using the Bax[15] sequence to achieve simultaneous homonuclear proton decoupling, related carbon and proton transitions associated with particular spin states of the two ^{31}P nuclei, and hence showed for the CH_3 groups $N(^{31}P^{13}C)$ [i.e. $^2J(^{31}P^{13}C)+{}^4J(^{31}P^{13}C)$] to be of opposite sign to $N(^{31}PH)$ [i.e. $^3J(^{31}PH)+{}^5J(^{31}PH)$]. Since $^3J(^{31}PH)$ is generally positive[11] and $^5J(^{31}PH)$ will be negligible, it follows that $N(^{31}P^{13}C)$ is negative.

(ii) Owing to the low natural abundance of ^{13}C, the CH_3 groups and ^{31}P nuclei in $(Et_3P)_2SnCl_4$ form a AA′X spin system [A,A′ = ^{31}P, X = ^{13}C] under conditions of broad band proton decoupling. The ^{31}P spectrum of this system contains weak outer lines whose positions depend upon $^2J(^{31}P^{31}P)$ and they were located by the ^{13}C–{^{31}P} spin tickling experiments[16] shown in Fig. 1. These experiments also showed $^2J(^{31}P^{31}P)$ and $N(^{31}P^{13}C)$ to be of like sign, i.e. negative.

(iii) If attention is confined to magnetically active tin and phosphorus nuclei then the symmetry of $(Et_3P)_2SnCl_4$ precludes relating $^2J(^{31}P^{31}P)$ to $^1J(^{119}Sn^{31}P)$. However, a mixture of $(Et_3P)_2SnCl_4$ and $(Bu_3P)SnCl_4$ was found to contain *ca* 50% of the unsymmetrical species $(Et_3P)(Bu_3P)SnCl_4$, for which $^2J(^{31}P^{31}P)$ is directly measurable at 44.7 Hz. This is almost

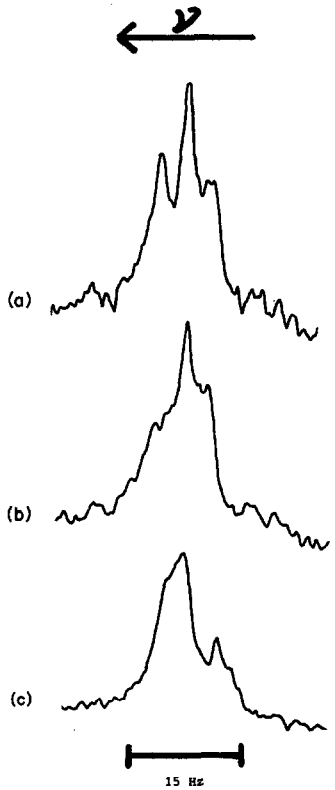

Fig. 1. Proton-decoupled ^{13}C resonance at 22.5 MHz of the methyl groups of *trans*-$(Et_3P)_2SnCl_4$: (a) normal spectrum; (b) with simultaneous irradiation of a weak outer line in the ^{31}P spectrum to high frequency of the central resonance; (c) with simultaneous irradiation of a weak outer line in the ^{31}P spectrum to low frequency of the central resonance.

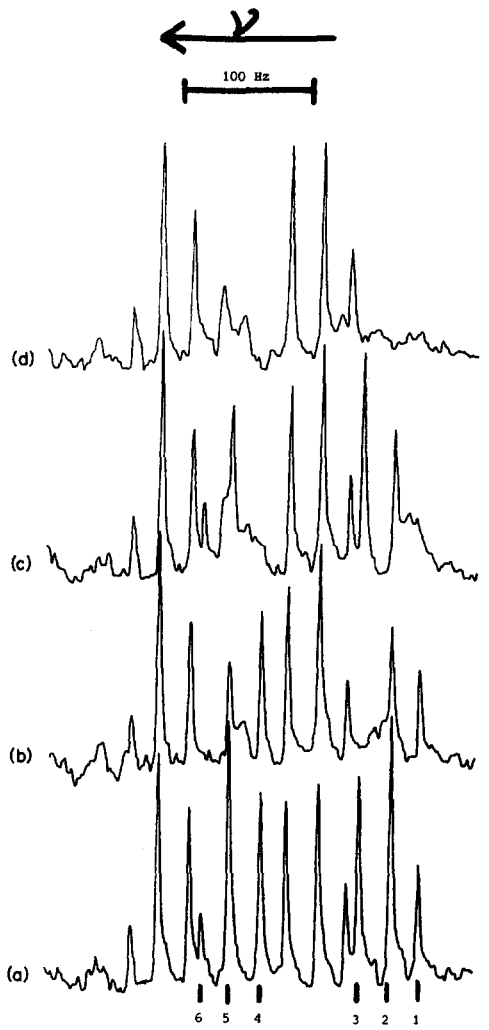

Fig. 2. Low-frequency tin satellites in the proton-decoupled ^{31}P spectrum at 36.2 MHz of a mixture of *trans*-$(Et_3P)_2SnCl_4$ and *trans*-$(Bu_3P)_2SnCl_4$: (a) normal spectrum: lines 5 and 2 are the ^{119}Sn satellites of the Et_3P and Bu_3P resonances, respectively, in the symmetrical species, and lines 6 and 4, and 3 and 1 are the corresponding signals in the mixed species *trans*-$(Et_3P)(Bu_3P)SnCl_4$. The separations 6–4 and 3–1 are equal to $^2J(^{31}P^{31}P)$ in this species. Un-numbered lines are ^{117}Sn satellites; (b) with simultaneous irradiation at $\nu(^{119}Sn)-\frac{1}{2}J(^{119}Sn^{31}P_{Bu})-\frac{1}{2}J(^{119}Sn^{31}P_{Et})$, lines 3 and 6 are removed and lines 2 and 5 lose intensity; (c) with simultaneous irradiation at $\nu(^{119}Sn)+\frac{1}{2}J(^{119}Sn^{31}P_{Bu})+\frac{1}{2}J(^{119}Sn^{31}P_{Et})$, lines 1 and 4 are removed and lines 2 and 5 lose intensity; (d) with simultaneous irradiation at $\nu(^{119}Sn)$, lines 1–6 are removed. Note that as the differences in $\nu(^{119}Sn)$ for the three species are small, some lines from each species are perturbed in each experiment.

identical with its magnitude determined indirectly in $(Et_3P)_2SnCl_4$ and it is therefore reasonable to assume it too is negative. Figure 2 shows expansions of the ^{117}Sn and ^{119}Sn satellites at low frequency in the proton-decoupled ^{31}P spectrum of the mixture. The $^{31}P-\{^{119}Sn\}$ experiments illustrated then show the signs of $^1J(^{119}Sn^{31}P)$ and $^2J(^{31}P^{31}P)$ to be the same (after allowing for the negative γ of ^{119}Sn), and hence $^1J(^{119}Sn^{31}P)$ is negative, and $^1K(SnP)$ is positive.

(iv) Experiments similar to (i) and (ii), but involving the CH_2 groups, were also performed to confirm some of the above signs and to give the results summarized in Table 1.

Table 2 gives a selection of known and newly measured values of $^1J(^{119}Sn^{31}P)$ for species of type (c). From their pattern it is clear that all are of the same negative sign, corresponding to a positive $^1K(SnP)$. This positive sign of the reduced coupling constant and its relatively large magnitude (*ca* 13 nm^{-3}) indicate that the Fermi contact interaction is dominant, and that there is a substantial *s*-overlap integral for the tin–phosphorus bond, so that the mean excitation energy approximation[10] can

be used, as an earlier treatment has *assumed*.[12] It should then follow that the *magnitude* of $^{1}J(^{119}Sn^{31}P)$ will increase with increasing effective nuclear charge on tin, and this is borne out by the values in Table 2, where stepwise replacement of chloride by bromide brings about a systematic stepwise reduction in the coupling constant. This implies that the energies of the bonding *s*-orbitals of tin(IV) and phosphorus(V) do not differ greatly for case (c), whereas for case (b) there is a substantial difference in these energies. It is also of interest that in the mixed Cl/Br solutions the number of species formed and their ^{31}P and ^{119}Sn spectral types are fully consistent with the proposed *trans* configuration, there being no signals that could be attributed to *cis* species.

Malone and Mann[5] have pointed out that the correlation of a large $^{2}J(^{31}P^{31}P)$ with a *trans* configuration for many transition metal complexes does not extend to derivatives of octahedral tin; we note here further that for complexed tin, the *trans* coupling is also of opposite sign to that usually found in the transition metal case. In addition, for transition metal complexes, $^{1}J(M^{31}P)$ is determined

by the *trans* influence of groups *trans* to phosphorus, whereas for the octahedral tin(IV) complexes, the nature of the groups *cis* to phosphorus has the dominant effect.

EXPERIMENTAL

Samples were prepared and examined in 10 mm o.d. NMR tubes, by the addition of equimolar amounts of the tertiary phosphine and the appropriate tin tetrahalide to dried CH_2Cl_2 under nitrogen at 0°C. The spectra were recorded at 22°C on a JEOL FX 90Q multinuclear spectrometer operating at 89.6, 22.5, 36.2, and 33.3 MHz for ^1H, ^{13}C, ^{31}P and ^{119}Sn, respectively. The 2-D $^{13}C/^1H$ chemical shift correlation spectrum was acquired into a 1024×256 data matrix using a sequence due to Bax,[15] and was manipulated using standard JEOL software. $^{31}C-\{^{31}P\}$ and $^{31}P-\{^{119}Sn\}$ heteronuclear multiple resonance experiments were conducted under conditions of complete proton decoupling and with time-sharing of the irradiation and receiver channels, by applying r.f. power from a GenRad model 1061 frequency synthesizer to the normal proton decoupler coils of the spectrometer.

(*Received* 3 *August* 1988; *accepted after revision* 15 *March* 1989)

Abstract—The first single crystal structure of a complex of potassium picrate and Schiff base type bis-benzo-15-crown-5 with a rigid *meta*-phenylene bridge is reported. Experimental results show that an intermolecular 2:2 (bis crown ether: potassium ion) sandwich complex is formed. The crystals are monoclonic, space group $P2_1/n$, with $a = 19.0924(35)$, $b = 20.4413(30)$, $c = 25.5996(56)$ Å, $\beta = 108.472(15)°$, $V = 9476.07$ Å^3, $D_c = 1.403$ g cm^{-3}. All the structure parameters were refined with the 10,485 observed reflections to give a final $R = 0.089$. The bridging (*meta*-phenylene) units essentially retain their flat rigid structure in the complex. Each potassium ion coordinates with the 10 oxygen atoms of two crown rings. The K—O bond lengths are in the range of 2.799–3.070 Å. The shortest distance between the oxygen atoms of the picrate anion and the K^+ ion is 6.050 Å. The picrate anion is linked to the large cation by ionic bonding. The $CHCl_3$ and H_2O solvent molecules in the crystal are distributed at random.

There has been rapid growth in the research on bis crown ethers in recent years. The commonly used aliphatic chains linking the two crown units are of the ester,[1,2] ether,[3,4] amide[5] and Schiff base types[6] etc. All these crown ethers may exhibit highly selective alkali metal cation complexation by formation of intramolecular complexes in which the cation is sandwiched between the two adjacent crown ether rings. Fan, Hu *et al.* first reported that the complex of potassium thiocyanate and N,N-(4,6-dinitro-1,3-phenylene)-bis(4′-amino benzo-15-crown-5) has a 2:1 intramolecular sandwich crystal structure.[7]

In the previous paper, we reported that the PVC membrane potassium electrode with aromatic ring bridged Schiff base bis(benzo-15-crown-5) as a neutral carrier shows very high selectivity toward K^+ ions.[8] However, because of the rigidity arising from the aromatic ring in the bridge, the two crown units are in a *trans* position and when complexing with the K^+ ion cannot act cooperatively. In order to establish the mode of complexation we therefore prepared single crystals of the complex of potassium picrate and N,N′-(*m*-phenylene dimethylidyne)di-3,4-(1,4,7,10,13-pentaoxacyclopentadeceno)aniline and determined its crystal structure. The result reveals that intermolecular 2:2 (bis crown ether: potassium ion) sandwich type complexes were formed instead of the intramolecular sandwich complexes. This type of complex has not been reported before.

EXPERIMENTAL

Synthesis of the complex

Bis crown ether (0.1 g, 0.15 mmol) and potassium picrate (0.04 g, 0.15 mmol) were dissolved in chloroform and methanol respectively and then mixed together. The mixture was refluxed for 2 h, cooled and then filtered. The solvents were allowed to evaporate at room temperature, and the product filtered off, washed with ethanol–chloroform to give light yellow crystals, m.p. 166–168°C (decomp.). Found: C, 51.5; H, 4.6; N, 7.4; K, 3.8. Calc. for $(C_{42}H_{46}N_5O_{17}K)_2 \cdot CHCl_3 \cdot H_2O$: C, 51.0; H, 5.0; N, 7.0; K, 3.9%. IR (KBr disc) 1123, 1227, 1046 cm^{-1}. The characteristic absorption bands of the bis crown ether were found at 1130, 1263, 1054 cm^{-1}. The corresponding absorptions in the complex all moved to lower frequencies, indicating that the oxygen atoms on the ether rings have taken part in complexing with K^+ ion.

Collection of the X-ray diffraction data

A transparent yellow single crystal of dimensions $0.25 \times 0.24 \times 0.30$ mm^3 was mounted on a R3M/E four circle X-ray diffractometer and monochromic CuK_α radiation was used with a θ–2θ scan to collect data in the range $3° \leqslant 2\theta \leqslant 100°$. 12,278 independent reflections were measured of which the observable reflection data with $I > 2.5\sigma(I)$ number 10,485. The crystal has monoclinic symmetry, space group $P2_1/n$, with cell parameters $a = 19.0924(35)$ Å, $b = 20.4413(30)$ Å, $c = 25.5996(56)$ Å, $\beta = 108.472(15)°$; $V = 9476.07$ Å^3. The cell contains four $[C_{36}H_{44}N_2O_{10}K]_2^+$ $[C_6H_2(NO_2)_3O^-] \cdot CHCl_3 \cdot H_2O$ units with the chloroform and water coming from the solvents; $F_{000} = 4175.41$ and $D_c = 1.403$ g cm^{-3}.

Structure determination

The crystal structure was solved by the heavy atom method and developed from electron density syntheses. The coordinates of non-hydrogen atoms and isotropic thermal vibration parameters were then refined by least squares. Anisotropic thermal vibration parameters were then introduced to give $R = 0.0888$ (unit weighting factor).

All the above calculations were performed on an Eclipse/S140 computer with SHELXTL program. The least square method used was the block diagonal matrix approximation. Selected bond lengths, bond angles and least square plane data are listed in Tables 1–4 respectively. The molecular configuration of the bis crown ether complex, in two views, is shown in Figs 1 and 2.

RESULTS AND DISCUSSION

For the convenience of discussion, the two crown ether molecules are designated by A and B respectively and shown in Fig. 1. The corresponding crown rings are represented as C (C_1–C_{10}), D (C_{29}–C_{38}), E (C_{15}–C_{24}), F (C_{43}–C_{52}) respectively. The results of the structure determination revealed that when forming the complex, the crown rings C and D, E and F in bis crown A and B have different space orientations. The crown ring C in molecule A and crown ring F in molecule B share the same space orientations and the same situation occurs in crown ring D in A and crown ring E in B. When the two bis crown molecules A and B form the complex with two potassium ions K_1^+ and K_2^+, two pairs of crown rings with different space orientations C and E, D and F coordinate with each other, forming a bimolecular sandwich complex, with the potassium ion having a coordination number of 10.

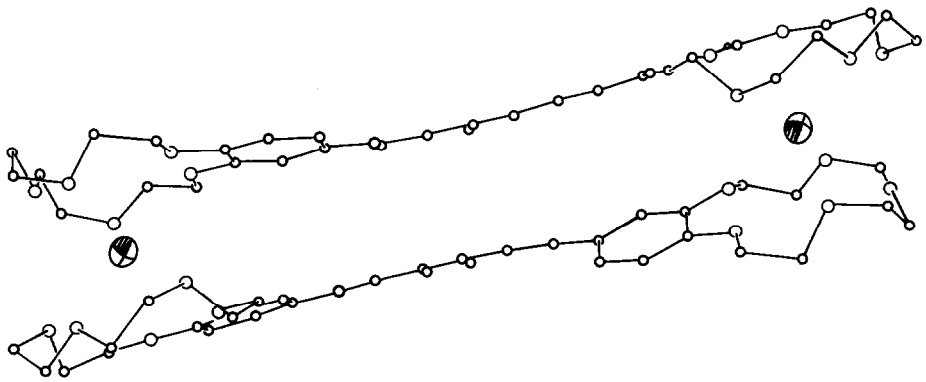

Fig. 2. A perspective view of the molecular framework of the complex.

It is usually thought that bis crown ethers form 1 : 2 intramolecular sandwich complexes with metal ions with a large diameter. The average K—O bond length is 2.906 Å.[7] The Schiff base type bis crown ethers, however, due to their molecular rigidity, form intermolecular sandwich complexes instead. The K—O bond lengths are in the range of 2.799–3.070 Å, the average values are 2.899 Å and 2.910 Å respectively (Table 1), similar to that in the above mentioned 1 : 2 complexes. The values are larger than the sum (2.73 Å) of the ion radius of K^+ (1.33 Å) and the van der Waals radius of oxygen atom (1.40 Å), thus proving that the coordination interaction between K^+ ion and oxygen atoms in our structure is mainly of ion–dipole interaction.

The oxygen atoms in each crown ring are not in good coplanarity (Table 3), showing that the crown rings are largely distorted to satisfy the requirement of lower energy coordination. The two crown rings which form a sandwich structure have their least square planes principally parallel, e.g. the least square planes I and II, and III and IV have dihedral angles 8.9 and 5.1° respectively. The distances of the K_1^+ from the plane of the two crown rings are 1.736 and 1.684 Å respectively, and that of K_2^+ are 1.746 and 1.732 Å. The coordination situation for

the two potassium ions are slightly different due to the different packing environment. It is noteworthy that the two picrate anions do not take part in coordination. The shortest distance between the O^- on the picrate anion and the K^+ ion is 6.050 Å. The picrate anions interact with the large cation only through electrostatic attraction.

The crystal also contains disordered chloroform solvent molecules and a water molecule situated close to the two picrate ions respectively. The results of elemental analysis are consistant with this conclusion.

The angles between the normals to the benzene planes V–VI and VI–X are rather large (23.2 and 26.9° respectively), but all the other benzene planes have relatively small dihedral angles with each other (13°). (Table 4). This indicates that the bridging chains in the two bis crown ethers retain their flat rigid structures in the complexes and this is probably favourable considering the energy and the symmetry of the complexes.

It can be concluded that the good performance of the PVC membrane potassium ion selective electrode based on the Schiff base type bis benzo 15-crown-5 is most probably due to the formation of intermolecular complexes.

Abstract—The formation of mixed ligand complexes was studied in the $Al(edta)^-$, $Ga(edta)^-$, $In(edta)^-$ and $Tl(edta)^-$-halide and -sulphide ion systems by potentiometry, using glass and anion-selective electrodes. The stability constants (log K^F_{ML}) of the mixed ligand complexes $M(edta)F^{2-}$ were found to be 4.8 ± 0.2, 1.9 ± 0.1 and 0.9 ± 0.1 for Al^{3+}, Ga^{3+} and In^{3+}, respectively. Values of log $K^X_{ML} = 2.3\pm0.2$, 3.5 ± 0.15 and 5.9 ± 0.2 were measured for $Tl(edta)X^{2-}$, X = Cl^-, Br^- and I^-, respectively. Complexes $M(edta)S^{3-}$ are described. The values of log K^S_{ML} were calculated to be 10.3, 10.6 and 9.4 for Al^{3+}, Ga^{3+} and In^{3+}, respectively. Ionic–covalent interactions in the mixed complexes are discussed. The stability constant of $Tl(edta)^-$ was reinvestigated via spectrophotometric study of the competition reaction in the Tl^{3+}–H^+–$(edta)^{4-}$–X^- system.

The complex-forming properties of the III/B elements change drastically from Al^{3+} to Tl^{III}. Al^{3+}, Ga^{3+} and In^{3+} are considered to be "hard" cations, while Tl^{III} is classified as a typical "soft" cation.[1] However, all these elements form hydroxo complexes of high stability, which must be taken into account in the study of their complexes in aqueous solution.

Formation of the ethylenediaminetetraacetate [$(edta)^{4-}$] complexes of Al^{3+}, Ga^{3+} and In^{3+} has been studied by several authors. The stability constants are well known and increase with increasing atomic number.[2] However, extremely different stability constants have been obtained for $Tl(edta)^-$, the reported log K values ranging between 22.6 and 37.8.[3–7]

Formation of the mixed ligand complexes M(edta)X (X is a secondary ligand) has been observed for a number of metal ions.[8–12] This can be a result of the pentadentate nature of the coordinated $(edta)^{4-}$ or of a higher coordination number of the metal ion. Al^{3+}, Ga^{3+}, In^{3+} and Tl^{III} ions complexed with $(edta)^{4-}$ do not form polynuclear hydroxocomplexes, but the formation of mixed ligand complexes $M(edta)(OH)^{2-}$ is known.[2]

The complex-forming properties of the metal ions can be changed by the presence of a coordinated multidentate ligand, e.g. a change in the "hard" character of the Zn^{2+} ion was reported when it was surrounded by the hydrophobic carbonic anhydrase

(CA) in the Zn^{2+}–Ca–halide ion system.[13] "Hard" cations such as Ga^{3+} and In^{3+} can also interact with "soft" ligands containing charged sulphur donor atoms.[14–16] In studies of the formation of the mixed ligand complexes of Al^{3+}-, Ga^{3+}-, In^{3+}- and Tl^{III}-edta with halide and sulphide ions, the trend of the stability constants indicates whether any alteration takes place in the properties of metals.

The formation of mixed ligand complexes may also be of practical importance. The determination of fluoride with an ion-selective electrode can be disturbed in the presence of Al^{3+} when $(edta)^{4-}$ is used as a masking agent,[17–19] due to the formation of mixed ligand complexes $Al(edta)F^{2-}$.

The stability constants of the mixed complexes $M(edta)X^-$ have been obtained via simultaneous pH and pX measurements using glass and ion-selective electrodes. Under the conditions applied, assumption of the dissociation of the complexes $M(edta)^-$ was not necessary, but formation of the complexes $M(edta)(OH)^{2-}$ was taken into account. In the $Tl(edta)^-$–X^- systems, the halide ions can compete with the $(edta)^{4-}$. From studies of the competition reactions by means of spectrophotometry, the stability constant of $Tl(edta)^-$ has been obtained.

EXPERIMENTAL

Chemicals and analysis

Stock solutions of $Al(NO_3)_3$, $Ga(NO_3)_3$ and $In(NO_3)_3$ were prepared by dissolving 5 N gallium (Timföldgyár és Aluminiumkohó, Ajka, Hungary), aluminium and indium (p.a., Reanal) in nitric acid. Freshly prepared Tl_2O_3 was dissolved in perchloric acid to obtain $Tl(ClO_4)_3$ solution. Tl_2O_3 was prepared by oxidation of Tl_2SO_4 (p.a. Schuchardt) with $K_3[Fe(CN)_6]$.[20] Metal ion concentrations were determined by complexometric titration with $Na_2H_2(edta)$ (Reanal). The acid content of the stock solution was measured by pH-potentiometry.[21] Solutions with appropriate $M(edta)^-$/$M(edta)(OH)^{2-}$ ratio were prepared by mixing calculated volumes of metal stock solution, $Na_2H_2(edta)$ and KOH or NaOH solutions. The metal to ligand ratio was 1:1 in all potentiometric experiments. The ratio of $M(edta)^-$ and $M(edta)(OH)^{2-}$ was checked by pH-potentiometric titration with the addition of KOH/NaOH or HNO_3 titrant. These titration curves were used to evaluate the protonation constant (K^{H}_{ML}) and the hydrolysis constant (K^{OH}_{ML}).

KOH and NaOH solutions were kept in argon atmosphere. Their concentrations were analysed pH-potentiometrically using potassium hydrogen phthalate (Merck).

The Na_2S stock solution was prepared by dissolution of recrystallized $Na_2S \cdot 9H_2O$ (Merck) in deaerated distilled water and was stored under argon gas. Sulphide concentration was analysed by oxidation with KIO_3[22] and by precipitation titration with $AgNO_3$.[23] The results coincided well.

NaF, NaCl, NaBr, NaI, KCl, KBr and KI (Reanal) were weighed and dissolved in distilled water for halide titrant solutions.

Procedure

Potentiometric measurements were carried out in argon atmosphere using Radelkis OP 208/1 and Radiometer PHM 84 pH-meters. GK2401B combined, G202B glass (Radiometer), OP-F-0711, OP-Cl-0711P, OP-Br-0711P, OP-I-0711P, OP-SCN-0711, OP-S-0711P anion-selective and OP-8202 Ag/AgCl double junction reference electrodes (Radelkis) were used. Sodium chloride and nitrate solutions were used in the combined electrode and the salt bridge of the reference electrode, respectively, in the case of $NaClO_4$ ionic medium for Tl^{III} systems.

Halide-selective electrodes were calibrated in the range $2 < pH < 8$ for $X = Cl^-$, Br^- and I^-, and $5.5 < pH < 8$ for $X = F^-$. The total concentration of halide varied in the range: $2 \cdot 10^{-4}$ mol $dm^{-3} < C_x < 5 \cdot 10^{-2}$ mol dm^{-3} for $X = Cl^-$, Br^- and I^-, and $2 \cdot 10^{-3}$ mol $dm^{-3} < C_x < 5 \cdot 10^{-2}$ mol dm^{-3} for $X = F^-$. The calibration of the sulphide electrode was described earlier.[16]

Spectrophotometric measurements were made with a Beckman-DB-GT spectrophotometer using 0.1 and 0.2 cm cells.

Constant ionic medium was maintained at $25 \pm 0.2°C$: $I = 0.5$ mol dm^{-3} KNO_3 except for Tl^{III} systems, where $I = 1.0$ mol dm^{-3} $NaClO_4$ ($HClO_4$). The total concentration of metal ions was 0.01 mol dm^{-3} for M = Al, Ga and In, and $2.5 \cdot 10^{-3}$ mol dm^{-3} and $2.5 \cdot 10^{-4}$–$2 \cdot 10^{-5}$ mol dm^{-3} for M = Tl in potentiometric and spectrophotometric experiments, respectively.

The stoichiometric equilibrium constants were calculated from the measured pH values with the method by Irving *et al.*[24] The stoichiometric ionic product of water was found to be $pK_w = 13.83 \pm 0.01$ and $pK_w = 13.70 \pm 0.02$ for $I = 0.5$ mol dm^{-3} KNO_3 and $I = 1.0$ mol dm^{-3} $NaClO_4$, respectively.

Stability constants were calculated from the titration curves and UV spectra with the PSEQUAD program.[25]

RESULTS AND DISCUSSION

The formation of mixed ligand complexes was followed by potentiometric titration using anion-selective and pH electrodes simultaneously. The starting pH of the solutions differed, depending on the optimal selectivity range of the ion-selective electrodes or the required pH limit of the calibration procedure.[16] Typical experimental curves are shown in Figs 1–3.

The stability constants of the complexes

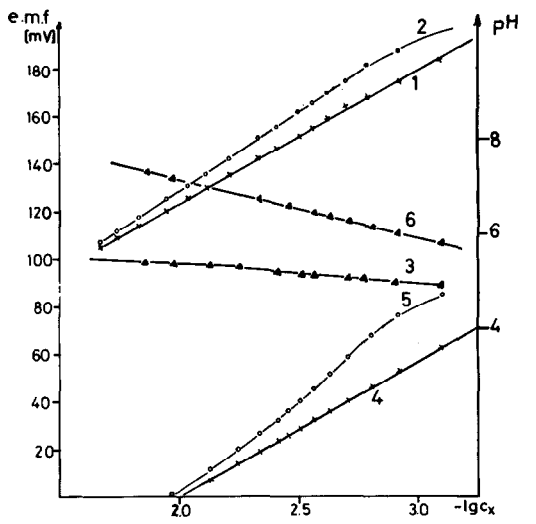

Fig. 2. Formation of Tl(edta)X^{2-}. EMF and pH vs C_X- (C_{TlL} = 0.0025 mol dm^{-3}): EMF calibration curves of chloride-selective (1) and bromide-selective (4) electrodes (1.0 mol dm^{-3} $NaClO_4$); EMF (2) and pH (3), X = Cl^-; EMF (5) and pH (6), X = Br^-.

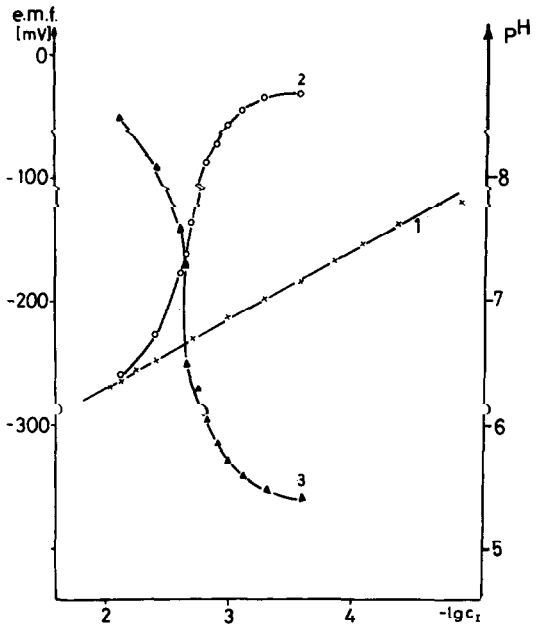

Fig. 3. Formation of Tl(edta)I^{2-}. EMF and pH vs C_{I^-}: (1) EMF calibration of iodide-selective electrode (1.0 mol dm^{-3} $NaClO_4$). EMF (2) and pH (3) in the presence of 0.0025 mol dm^{-3} Tl(edta)$^-$.

M(edta)$^-$ are high enough for dissociation not to occur at a moderate concentration of the halide ion and in a suitable pH range. Thus, only simple equilibrium reactions were taken into account, as follows:

Protonation of complexes:

$$M(edta)^- + H^+ \rightleftharpoons MH(edta) \quad (1)$$

$$K_{ML}^{H} = \frac{[MH(edta)]}{[M(edta)^-]\cdot[H^+]}. \quad (2)$$

Formation of mixed hydroxocomplexes at higher pH:

$$M(edta)\cdot aq^- + H_2O \rightleftharpoons M(edta)(OH)^{2-} + H_3O^+ \quad (3)$$

$$K_{ML}^{OH} = \frac{[M(edta)(OH)^{2-}\cdot[H_3O^+]}{[M(edta)^-]}. \quad (4)$$

Formation of mixed halide (X^-) or sulphide complexes:

$$M(edta)^- + X^- \rightleftharpoons M(edta)X^{2-} \quad (5)$$

$$K_{ML}^{X} = \frac{[M(edta)X^{2-}]}{[M(edta)^-]\cdot[X^-]} \quad (6)$$

$$M(edta)^- + S^{2-} \rightleftharpoons M(edta)S^{3-} \quad (7)$$

$$K_{ML}^{S} = \frac{[M(edta)S^{3-}]}{[M(edta)^-]\cdot[S^{2-}]}. \quad (8)$$

$M(edta)S^{3-d}$	10.3	10.6	9.4	—[f]

[a] $I = 0.5$ mol dm^{-3} KNO_3 for M = Al, Ga and In, and $I = 1$ mol dm^{-3} $NaClO_4$ for M = Tl.

[b] Three titration curves, about 120 points, $\overline{\delta v} = 0.008$ cm^3.

[c] Three titration curves, about 60 points, C_{AlL} and $C_{GaL} = 0.01$ and $5 \cdot 10^{-3}$ mol dm^{-3}, $C_{InL} = 0.01$ mol dm^{-3}, $C_{TlL} = 2.5 \cdot 10^{-3}$ mol dm^{-3}, $\overline{\delta v} = 0.02$ cm^3 or $\overline{\delta U} \leqslant 1$ mV.

[d] Values calculated with the use of eq. (14).

[e] No interaction was found at $C_{ML} = 0.01$ mol dm^{-3}, $C_x = 0$–0.5 mol dm^{-3}, pH = 3.8–7.0.

[f] Probably Tl_2S_5 [Tl(I)polysulphide, red] was formed.

with the standard deviations, are listed in Table 1. EMF and pH values of the titration curves were simultaneously used for the calculations. Optimization of $\delta\bar{v}$ (cm^3) or $\overline{\delta U}$ (mV) was carried out independently, which resulted in practically the same stability constant values (see footnotes to Table 1).

The stability constants of MH(edta) and $M(edta)(OH)^{2-}$ agree well with the literature data except for that of InH(edta). Both repeated experiments using different In^{3+} stock solutions and calculations with refined values of the acid content of the stock solution resulted in a much lower protonation constant as compared to log $K^{H}_{ML} = 1.5$ ($I = 0.1$ mol dm^{-3} $NaClO_4^2$). No $Al(edta)(OH)_2^{3-}$ could be identified below pH = 11, and precipitation occurred at pH > 11.

Formation of mixed ligand halide complexes

The titration curves in Fig. 1 indicate the formation of $M(edta)F^{2-}$. It can be seen that the largest effect of the free F^- concentration was caused by $Al(edta)^-$ (curve 2), but the titration curves of $Ga(edta)^-$ (curve 3) and $In(edta)^-$ (curve 4) did not coincide with the calibration curves (curve 1) either. The increase in pH values (curves 5–7) can be explained by the shift of equilibrium reactions (eq. 3) to the left because of the formation of $M(edta)F^{2-}$. At a higher excess of F^- (pH > 8), at least partial replacement of $(edta)^{4-}$ from $Al(edta)^-$ by F^- should be presumed. The equilibrium system was very complicated: constant potentials could not be observed and the solution became very viscous. In agreement with the literature[17] a value log $K^{F}_{ML} = 4.8 \pm 0.2$ was calculated for the range of pH = 5.8–8.0. A similar effect was not observed in the $Ga(edta)^-$ and $In(edta)^-$–F^- systems.

The high stability of the mixed complex $Al(edta)F^-$ and the formation of complexes $AlF_x^{(3-x)+}$ via the competition reaction explain why the complexones do not have an optimal masking effect for the determination of F^- with an ion-selective electrode in the presence of Al^{3+}.[18,19]

The trend of the stability constants of $M(edta)F^{2-}$ is the same as the trend for the parent complexes of Al^{3+}, Ga^{3+} and In^{3+}.[12] Space for the "second" F^- in the inner sphere is the smallest in $Al(edta)^-$, but, in contrast with the results obtained with bulky ligands, steric effects have no role in the case of F^-; thus, the interaction between $M(edta)^-$ and F^- is dominated by electrostatic forces.

No interaction can be detected between $Al(edta)^-$, $Ga(edta)^-$ or $In(edta)^-$ and Cl^-, Br^-, I^- or SCN^-. This result is not surprising, because the stability constants of the parent complexes in aqueous solution are known to be quite low.[12] Titrations were carried out at pH ≈ 3–4, where the formation of $M(edta)(OH)^{2-}$ can be neglected, and at pH ≈ 7, where this complex exists, but neither the change in potential of the ion-selective electrode nor the pH change revealed any interaction between $M(edta)^-$ and X^- up to $C_x = 0.5$ mol dm^{-3}. Values of $K^{X}_{ML} \approx 1$ were measured by Friedman *et al.*[26] for $In(edta)X^{2-}$ (X = Cl^-, Br^-, I^-, S^{2-} and SCN^-) using an In-amalgam electrode at very high concentrations of X. (The ionic strength was not kept constant.) Supposing $K \approx 1$ under our experimental conditions, δ EMF < 0.3 mV can be

estimated, which is about the same as the uncertainty in the measured EMF.

However, the formation of mixed ligand complexes is found for $Tl(edta)^-$. Typical titration curves obtained in the $Tl(edta)^- - X^-$ ($X^- = Cl^-$, Br^- and I^-) systems are shown in Figs 2 and 3. The trend of the calculated mixed stability constants (Table 1) follows the stability sequence of the Tl^{III}–halide parent complexes: $I^- > Br^- > Cl^-$. The values of the stability constants $\log K^X_{ML}$ are similar to those of $\log K^X_4$ for $TlCl_4^-$ and $TlBr_4^-$.[27-34] There is good agreement for the estimated $\log K_4$ of TlI_4^-,[35] too.

The stability constant of $Tl(edta)^-$

The equilibria in the $Tl(edta)^- - X^-$ systems at high excess of halide ions were studied by means of spectrophotometry. $TlCl_4^-$, $TlBr_4^-$ and TlI_4^- have an absorption maximum at 244, 270 and 292 nm, respectively, while $Tl^{3+}\cdot aq$, $Tl(OH)^{2+}$, $Tl(edta)^-$, $Tl(edta)Cl^{2-}$, $Tl(edta)Br^{2-}$ and $Tl(edta)I^{2-}$ absorb at $\lambda < 230$ nm. Spectra recorded at different pH, different edta concentrations and a high excess of halide ions are plotted in Figs 4–6.

The absorbance of $TlCl_4^-$ decreases with increasing pH, and at pH > 2 the spectrum of $Tl(edta)Cl^{2-}$ can already be seen (Fig. 4a). At lower pH, Cl^- ions

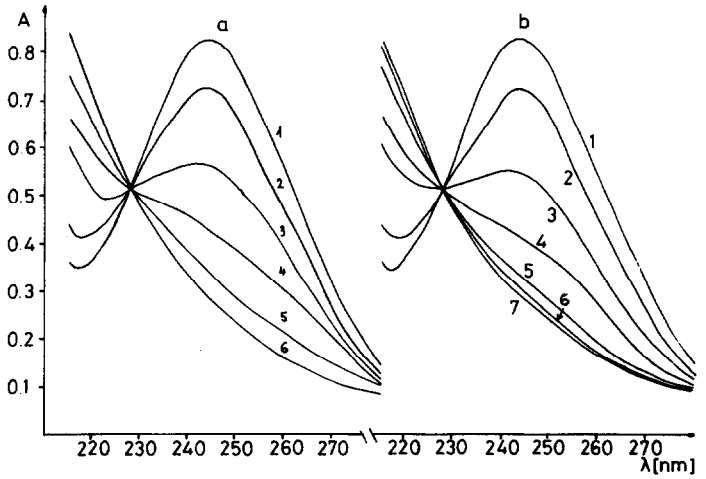

Fig. 4. UV spectra of Tl^{III}–$(edta)^{4-}$–H^+–Cl^- system (a) $C_{TlL} = 5\cdot10^{-4}$ mol dm^{-3}, $C_{Cl^-} = 0.78$ mol dm^{-3}: pH = 0.286 (1), 0.840 (2), 1.100 (3), 1.298 (4), 1.535 (5), 1.987 (6). (b) pH = 1.33, $C_{Cl} = 0.893$ mol dm^{-3}, $C_{Tl} = 5\cdot10^{-4}$ mol dm^{-3}; C_{edta} [mol dm^{-3}] = 0 (1), $1\cdot10^{-4}$ (2), $3\cdot10^{-4}$ (3), $5\cdot10^{-4}$ (4), $1\cdot10^{-3}$ (5), $1.5\cdot10^{-3}$ (6) and $2\cdot10^{-3}$ (7).

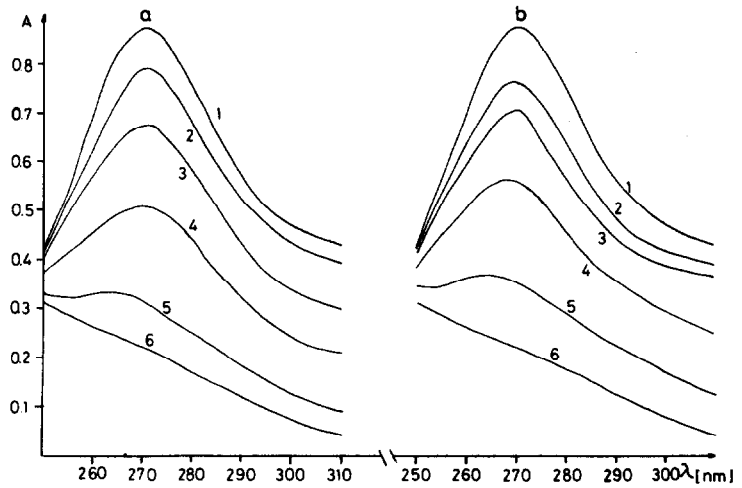

Fig. 5. UV spectra of Tl^{III}–$(edta)^{4-}$–H^+–Br^- system. $C_{Br} = 0.5$ mol dm^{-3}, (a) $C_{Tl(edta)} = 5\cdot10^{-4}$ mol dm^{-3}, pH = 1.230 (1), 1.89 (2), 2.127 (3), 2.411 (4), 2.915 (5), 4.648 (6). (b) pH = 2.07, $C_{Tl} = 5\cdot10^{-4}$ mol dm^{-3}, C_{edta}[mol dm^{-3}] = 0 (1), $3\cdot10^{-4}$ (2), $5\cdot10^{-4}$ (3), $1\cdot10^{-3}$ (4), $2.5\cdot10^{-3}$ (5), $5\cdot10^{-3}$ (6).

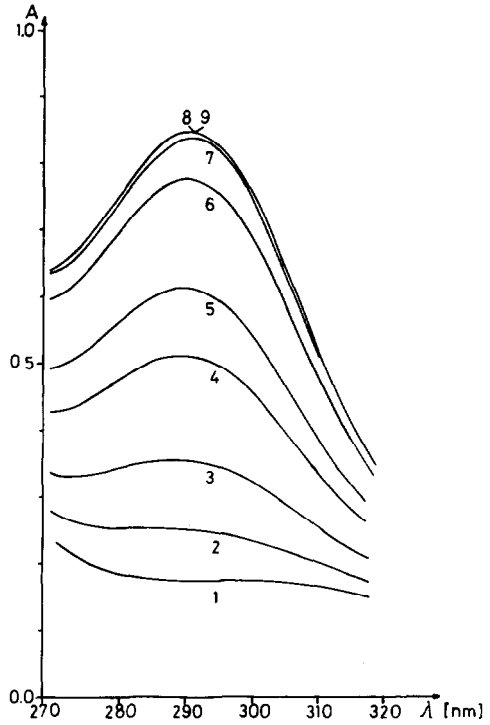

Fig. 6. UV spectra of Tl^{III}–(edta)$^{4-}$–H^+–I^- system. $C_{TIL} = 2.5 \cdot 10^{-4}$ mol dm^{-3}, $C_{I^-} = 5 \cdot 10^{-3}$ mol dm^{-3}: pH = 6.190 (1), 3.845 (2), 3.383 (3), 2.955 (4), 2.717 (5), 3.356 (6), 2.050 (7), 1.813 (8) and 1.592 (9).

replace the ligand edta$^-$ and $TlCl_4^-$ is formed; at higher pH, the apparent stability constant of Tl(edta)$^-$ is high enough to prevent the dissociation of the complex. The isosbestic point at 228 nm suggests the presence of two species only, $TlCl_4^-$ and Tl(edta)Cl^{2-}. The same isosbestic point can be seen in Fig. 4b, which shows the spectra of equilibrium systems at constant pH and Cl^- concentration at different concentrations of edta.

The spectra in Figs 5 and 6 can be explained in the same way for the Tl(edta)$^-$–Br^- and Tl(edta)$^-$–I^- systems. The stability constants of $TlBr_4^-$ and TlI_4^- are higher than that of $TlCl_4^-$; thus, Tl(edta)X^{2-} (X = Br^- and I^-) is formed only at pH > 3.5 and pH > 5, respectively. There are no isosbestic points, because of the higher absorbance of Br^- and I^-.

The equation of the competition reaction can be written as follows:

$$Tl(edta)X^{2-} + 3X^- + nH^+ \rightleftharpoons TlX_4^- + H_n(edta)^{(4-n)-} \quad (9)$$

where $n = 4$, 5 or 6. The equilibrium constant K_x of eq. (9) for $n = 5$ is as follows:

$$K_x = \frac{[TlX_4^-] \cdot [H_5(edta)^+]}{[Tl(edta)X^{2-}] \cdot [X^-]^3 \cdot [H^+]^5}. \quad (10)$$

Values of K_x were evaluated with the program PSEQUAD[25] from the spectra recorded at constant concentration of Tl(edta)$^-$ at different pH, or at constant pH and Tl^{III} concentration with different concentrations of edta. Known protonation constants log K_{H_5L} and log K_{H_6L}[36] were used for the calculation. The following log K_x values were obtained: log $K_{Cl} = 2.83 \pm 0.15$, log $K_{Br} = 7.72 \pm 0.20$ and log $K_I = 17.7 \pm 0.2$. If the concentrations in eq. (10) are expressed with the known constants, the following equation can be obtained:

$$\log K_{TIL} = \log \beta_{TlX_4} + \log \beta_{H_5L} - \log K_x - \log K_{TIL}^X. \quad (11)$$

The calculated values of log K_{TIL} are shown in Table 2, together with the literature data for log β_{TlX_4}. Unfortunately, the constants for log β_{TlX_4} are referred to $I = 3$ mol dm^{-3} $NaClO_4$ or $LiClO_4$, while the determination of log K_{H_5L} and log K_{H_6L} and our experiments were carried out at $I = 1$ mol dm^{-3} $NaClO_4$. The values of log K_{TIL} calculated from eq. (11) are different, but these differences are acceptable with regard to the very large stability constant. It seems from the data in Table 2 that the log K_{TIL} data published by Anderegg *et al.*[6] and Gorelov *et al.*[7] are acceptable.

There are much lower values of log K_{TIL} in the literature: 22.5[4] and 24.0.[5] These are due to the

Table 2. Values calculated for log K_{TIL} with the use of different values of log β_{TlX_4}

	$TlCl_4^-$			$TlBr_4^-$		TlI_4^-
log β_{TlX_4}	17.36[a]	18.5[b]	19.45[c]	26.43[c]	25.7[d]	35.7[e]
log K_{TIL}	34.4	36.6	36.6	37.5	36.8	34.4

[a] 3 mol dm^{-3} $NaClO_4$, $HClO_4$.[27,30]
[b] 3 mol dm^{-3} $LiClO_4$.[28]
[c] 1 mol dm^{-3} $NaClO_4$, 3 mol dm^{-3} $HClO_4$.[29]

[e] 1 mol dm^{-3} $NaClO_4$, 3 mol dm^{-3} $HClO_4$.[35]

inadequate experimental conditions. Busev *et al.* investigated the competition reaction of Cl^- and $(edta)^{4-}$, but the experiments were carried out at pH ≈ 3.5, where the concentration of TlX_4^- is very low, and the formation of $Tl(edta)X^{2-}$ was not taken into account either.

Log K_{TlL} was evaluated by Kornev *et al.* using the Tl^{III}–Fe^{III} competition at pH ≈ 2, in the presence of Cl^-, but neither the hydrolysis of Tl^{III} [37] nor the formation of $Tl(edta)X^{2-}$ was presumed.

$Tl(edta)^-$ was found to be sensitive to UV light in solution. Investigation of the photochemical reaction of oxidative decarboxylation is in progress.[38]

Formation of mixed ligand sulphide complexes

Titration curves of the $M(edta)(OH)^{2-}$–HS^- systems are shown in Fig. 7. The titration curve (3) of $In(edta)(OH)^{2-}$ differs considerably from the calibration curve, but the interactions of $Al(edta)(OH)^{2-}$ (curve 1) and $Ga(edta)(OH)^{2-}$ (curve 2) with HS^- are also clearly demonstrated. The equilibrium reaction can be described as follows:

$$M(edta)(OH)^{2-} + HS^- \rightleftharpoons M(edta)S^{3-} + H_2O \quad (12)$$

$$K_{ML}^{HS} = \frac{[M(edta)S^{3-}]}{[M(edta)(OH)^{2-}]\cdot[HS^-]}. \quad (13)$$

The values of log K_{ML}^{HS} calculated for M = Al, Ga and In are 2.2±0.1, 2.4±0.1 and 3.7±0.1, respectively. It should be mentioned that reaction (12) is equivalent to the reaction $M(edta)(OH)^{2-} + HS^- \rightleftharpoons M(edta)(OH)(HS)^{3-}$, but the presence of OH^- and HS^- in the inner sphere is not probable. However, there is no reason to suppose a simple substitution of OH^- by HS^-, i.e. $M(edta)(OH)^{2-} + HS^- \rightleftharpoons M(edta)(HS)^{2-} + OH^-$, because of the experimental fact that the formation of mixed sulphido complexes was not suppressed by the increased pH (i.e. higher values of pH–p[HS^-] in Fig. 3). The substitution reaction $Ga(OH)_4^- + HS^- \rightleftharpoons Ga(OH)_2S^{4-} + OH^- + H_2O$ should be proposed for the $Ga(OH)_4^-$–HS^- system, as indicated by the pH-dependence of the equilibrium reaction.[35]

The stability constants log K_{ML}^{S} shown in Table 1 can be calculated by using log K_{ML}^{OH} and the protonation constant of S^{2-} ($K_1^H = [HS^-]/[H^+]\cdot[S^{2-}]$) log $K_1^H = 13.9$[39] as follows:

$$\log K_{ML}^{S} = \log K_{ML}^{HS} + \log K_1^H + \log K_{ML}^{OH}. \quad (14)$$

The stability constants log K_{ML}^{S} are surprisingly high as compared with the only published stability constant of $In(HS)^{2+}$.[40,41] It can be stated that the differences between the titration curves in Fig. 3 can be explained mainly by the different stabilities of the mixed hydroxo complexes $M(edta)(OH)^{2-}$, and only slight effects are exerted by the stability of $M(edta)(S)^{3-}$. This means that even the typically "hard" Al^{3+} can interact with the typically "soft" S^{2-} if the metal ion is "protected" against hydrolysis by forming a complex with a multidentate ligand. The interaction is predominantly electrostatic, particularly for Al^{3+} but the values of log K_{ML}^{S} (Table 1) do not decrease with increasing ionic size (from Al^{3+} to In^{3+}) as was observed for the mixed complexes $M(edta)F^{2-}$. To explain the relatively strong interaction between the complexed Ga^{3+} or In^{3+} and the sulphide ion, resulting in the high log K_{ML}^{S} values for $Ga(edta)S^{3-}$ and $In(edta)S^{3-}$, the importance of covalent interactions must be assumed. Some of the electronic density of the filled orbitals of Ga^{3+} and In^{3+} can be transferred to the empty *d*-orbitals of the sulphide ion, which contributes to the electronic interaction between the metal ion and the charged sulphide ligand.

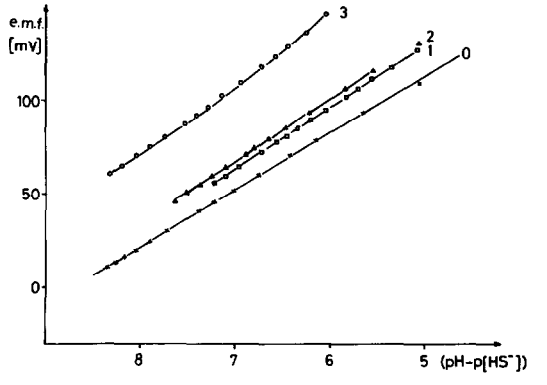

Fig. 7. Formation of $M(edta)S^{3-}$. EMF vs (pH–p[HS^-]) (C_{ML} = 0.01 mol dm^{-3}): (0) calibration curve of sulphide-selective electrode (0.5 mol dm^{-3} KNO_3); (1) $Al(edta)^-$; (2) $Ga(edta)^-$ and (3) $In(edta)^-$.

PROTONATION AND ZINC COMPLEX FORMATION OF INSULIN

F. GAIZER

Department of Inorganic and Analytical Chemistry, A. József University, Szeged, P.O. Box 440, Hungary

(*Received* 30 *January* 1989; *accepted* 15 *March* 1989)

Abstract—The protonation and zinc complex formation of insulin were studied by pH-metry. Computer evaluation of the experimental data was applied to describe the titration curves by assuming 12 protonation equilibria out of the possible 16. In solutions containing zinc and insulin in a ratio of 1:1, the presence of 11 zinc complexes was substantiated, while in solutions with a Zn:insulin ratio of 2:1, five dizinc complexes were assumed besides the monozinc complexes. A probable assignment of the protonation constants to the functional groups is given and the confidence level of the stability constants is discussed.

The insulin molecule contains 16 functional groups capable of protonation or deprotonation in the pH range 2–12. To determine the values of the protonation constants of the individual functional groups, Tanford and Epstein[1] performed pH-metric titration. From their experimental data, they were able to calculate the values of six protonation constants. On the basis of our previous results,[2,3] it was possible to presume that a computerized evaluation would result in more than six constants. The primary aim of the present work was of a chemical nature: to determine as many protonation constants of insulin as possible; to obtain information about the behaviour of the functional groups of the amino acids in the molecule in comparison with that of the free amino acids and, if there is any difference between them, to try to explain this. The secondary aim of our experiments was to examine the possibility of evaluating such complicated systems, i.e. how many models can describe our data; if there is more than one, what the difference between them is, further, how the individual protonation steps are separated from each other, and what the reliability of the assignment of the individual protonation constants to the individual functional groups is.

To obtain information about the compositions and stabilities of the zinc–insulin complexes, we made pH-metric measurements on solutions containing insulin and zinc ions in different ratios.

EXPERIMENTAL

Chemicals

The beef insulin examined was a product of NOVA. All other chemicals used were of analytical grade.

pH-Metric measurements

These were carried out in solutions with an ionic strength of 0.3 M using sodium chloride as swamping salt, and at 25 ± 0.1°C. An ORION 701/A digital potentiometer (with an accuracy of 0.1 mV) was used. As measuring electrode, a Radiometer G 22 B glass electrode was used. The reference electrode was a Radelkis OP 820 Ag/AgCl electrode with 0.3 M sodium perchlorate as separating electrolyte solution. During the experiments 10.0 cm^3 solutions containing 0.01 M hydrochloric acid were titrated with 0.1 M sodium hydroxide in a nitrogen atmosphere. In the sequence insulin, zinc, the composition of the solutions (expressed in mmol) were as follows: A: 0.9932, 0; B: 1.0041, 1.0027; and C: 0.99998, 2.0053.

The evaluation of the experimental data was carried out with the developed version[4] of the previously published[5] least-squares program. As protonating and complex-forming species, the totally unprotonated insulin molecule was considered. In

the course of refinements, that log β values of the protonating and/or complex forming species resulted in the minimum of the squares of the residuals of electromotive forces $[\Sigma(\Delta E)^2]$ were sought. As a measure of fit, the standard deviations of the residuals, $\sqrt{\Sigma(\Delta E)^2/(NMP-NP-1)}$, are given in Tables 1 and 2 (NMP and NP are the number of experimental points and parameters refined).

RESULTS

The pH-metric titration curves and the Z_H (the average number of protons bound by the insulin) vs a (the number of base equivalents added to the titrant) curves derived from the E vs cm^3 data are plotted in Fig. 1.

The data on the solution containing insulin only were evaluated by considering the peptide as both a monomer and a dimer. The optimum log β values, their errors expressed in hundredths, and the stepwise protonation constants are listed in Table 1.

In the case of solution B, which contained insulin and zinc ions in a ratio of 1 : 1, the evaluation was carried out as follows: insulin was taken as a monomer, the 12 log β's were kept constant, and the composition and stability constants of the zinc–insulin complexes improving the fit were searched for. As a result of the refinements, all the species free of zinc were practically completely transformed to zinc–insulin complexes, and a good fit could be achieved without the protonation constants. The best fit was obtained with the complexes and constants listed in Table 2.

When the data on solution C (ins : Zn = 1 : 2) were evaluated, only the monozinc complexes were taken into consideration and the dizinc–insulin complexes improving the fit were searched for. The compositions of the species and the stability constant values resulting in the optimum fit can also be seen in Table 2.

DISCUSSION

Numerous examinations have been carried out to establish the state of insulin in solution. On the basis of the results obtained by different methods (in spite of a few opposite findings), it may be concluded that insulin is not a monomer in solution, but mainly a dimer, and probably a tetramer and hexamer, too. In conformity, the authors presume an equilibrium of associates and a predominance of the dimer. The association constants of the monomer–dimer equilibrium have been determined by several authors and different methods, and found to

be 10^4–10^5 dm^3 mol^{-1} (e.g. Jeffrey and Coates:[6] 1.2×10^4, UC, pH = 2; Lord *et al.*:[7] 4×10^4, UV, pH = 2; Pekar and Frank:[8] 1.4×10^5, equil. sediment., pH = 7; Goldman and Carpenter:[9] 2.2×10^5, UC, pH = 8 and Jeffrey *et al.*:[10] 1.1×10^5, UV, pH = 7).

Our calculations showed that when insulin was treated as a monomer or dimer the experimental data could be fitted by 12 or 14 log β's, respectively. The fit was somewhat better with the dimer model. However, when the experimental circumstances were taken into consideration, the difference between the two fits was not enough to substantiate the dimeric state of insulin. Therefore, the present data were explained by regarding insulin as a monomer.

It can be seen from the distribution curves in Fig. 2 that all the species relating to the 12 protonation constants are important. The individual protonation steps are not separated in the flat part

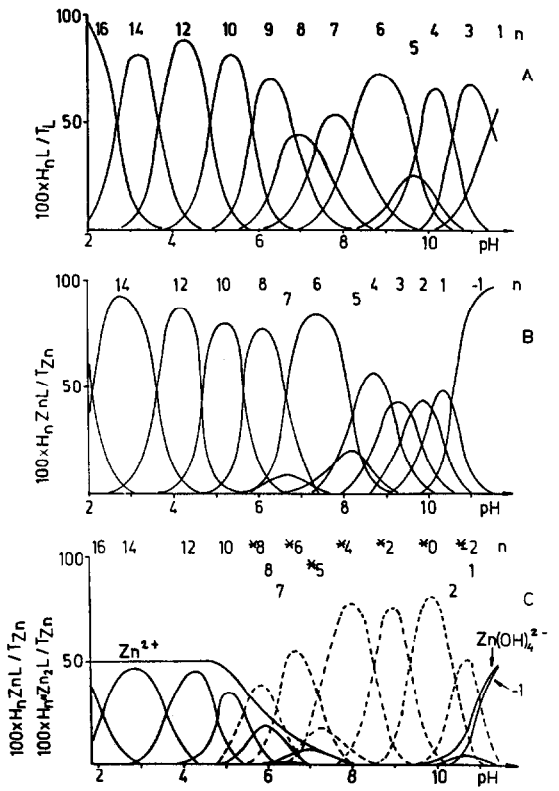

Fig. 2. Distribution of species calculated with constants of Table 2. $T_{Ins} = 1$ mmol dm^{-3}. A: insulin only, B: insulin : Zn = 1 : 1, and C: insulin : Zn = 1 : 2. Numbers are numbers of protons bound by unprotonated insulin.

of the titration curve, which corresponds to our expectations.

From the log β values obtained, we calculated the stepwise protonation constants. It may be concluded that with the exception of carboxyl groups the values of all the protonation constants are smaller than those of free amino acids.[11,12] The reason for this might be the formation of hydrogen bonds between the individual functional groups. It is easy to see that if a hydrogen bond is formed between, for example the guanidine group of arginine and an amino group, their protonation will be hindered. On the other hand, when a hydrogen bond is formed between phenolate and amino groups, the uptake of the first proton proceeds much more easily, and consequently, the values of the protonation constants will be larger than those in the free amino acids. For the formation of hydrogen bonds, insulin has a highly favourable structure. Due to the three disulphide bonds in the molecule, about 30 amino acids (i.e. more than half of the groups capable of protonation) are situated near to each other. Moreover, as the other amino acids are in three chains consisting of 5–11 units, association can easily take place between the chains, and also between the chains and the central part of the molecule. This results in a very complicated situation, even if the molecule is a monomer. With regard to all these effects, it is not probable that the first eight

protonation constants can be correctly assigned to the proper functional groups. Of course, it cannot be excluded, that the assignment in Table 1 is the correct assignment; the arrangement there followed the sequence of the protonation constants of the free amino acids.

When the experimental data on the interaction of insulin and zinc ions were evaluated, the peptide was considered to be a monomer. From the data on the 1 : 1 solution, it was possible to calculate the stability constants of 13 zinc–insulin complexes. As concerns the composition of these species, however, it must be stressed that they are only formal ones, because some of them, and especially those that form in the alkaline region, might be hydroxo complexes. This seems to be substantiated by the fact that it was necessary to assume the presence not only of the species H_2ZnL, but also of ZnL and $H_{-1}ZnL$. Naturally, we tried to substantiate the presence of $Zn(OH)_4^{2-}$ too, but this did not improve the fit.

On the basis of our results, the stability of the monozinc–insulin complexes is definitely high and, as can be seen in Fig. 2, the formation of these complexes even occurs in the pH range where all the potential donor atoms with the exception of carboxylate groups are protonated. This suggests that zinc ions are bound by one of the carboxylates first. The considerable stability of the hydroxo complexes formed in the alkaline region appears from the fact that they do not decompose up to pH 11.5, because there is no precipitate formation in the solution and the presence of the possible product $Zn(OH)_4^{2-}$ cannot be proved.

The experimental data on the insulin : Zn = 1 : 2 solution could be fitted with seven dizinc–insulin complexes, besides the 13 monozinc species. As can be seen from the data in Table 2, the binding of the second zinc to the peptide is much weaker than that of the first one. Another unexpected phenomenon is that the formation of dizinc complexes occurs only above pH 5–6. The weak binding of the second zinc ion is substantiated by the fact that, to achieve an acceptable fit, formation of the tetrahydroxozincate ion had to be assumed, through splitting-off of the second zinc ion.

It must be mentioned finally that, like Tanford and Epstein,[1] we too observed a weak opalescence in the solution at pH 3–3.5. The zinc-free and zinc-containing solutions clarified at pH 7–8 and 9–10, respectively. Our repeated measurements and those carried out in perchlorate medium resulted in constants spreading within the limits of experimental errors. These results, together with the fair agreement between the stability constants calculated from the present measurements and those of Tanford and Epstein[1] suggest that no irreversible precipitate formation takes place in the solutions.

CONCLUSIONS

As a result of the computerized simulation of the pH-metric titration curves, we succeeded in obtaining more information about the protonation equilibria of insulin than could be obtained with non-computerized calculation methods. It seems that the protonation and complex formation steps are well separated in the steep part of the titration curve, and the errors in the log β values of the individual equilibria are realistic. In spite of all this, in our view the acceptance of the data obtained requires much greater caution than could be expected from, e.g. the errors in the stability constants. As mentioned previously, on the basis of our measurements the monomer–dimer question cannot be settled; the reason for this may be that our experimental data contain information that can be described, depending on the model, only with polynomials of order 12–14. The dimeric treatment of insulin results in rather uncertain equilibrium constants, but the monomer assumption is probably a simplification, involving several further questions. On this basis the protonation constants presented here may be regarded only as good semiquantitative data.

Some uncertainty might arise about the monozinc complexes, due to the fact that there is not a large difference between the Z_H values obtained in the solutions containing insulin only or insulin + zinc ions. However, these are independent measurements and it may be assumed that the main conclusions (i.e. the strong binding of the first zinc ion and the weak binding of the second zinc, the compositions of most of the species formed, the relation of the stability constants, etc.) are acceptable.

On the basis of the experience acquired in the course of the evaluation, and the reliability of the information obtained, it may be concluded that peptides containing as many functional groups as insulin can be regarded as the limit of the possibility of evaluation by means of computerized simulation. In our view, stability constants acceptable in every respect result only when the number of functional groups in a molecule is not more than 8–12.

HYDROLYSIS OF ACTINIDES AND LANTHANIDES: HYDROLYSIS OF SOME TRIVALENT ACTINIDE AND LANTHANIDE IONS STUDIED BY EXTRACTION WITH THENOYLTRIFLUOROACETONE

P. K. MOHAPATRA* and P. K. KHOPKAR

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400 085, India

(*Received* 24 *October* 1988; *accepted after revision* 22 *March* 1989)

Abstract—In the solvent extraction studies of trivalent Am, Cm, La, Eu and Lu using thenoyltrifluoroacetone (HTTA) in xylene as the extractant, the pH variation experiments at a fixed extractant concentration revealed a reduction in slope from three to two when log D was plotted vs pH. While the plots of log D vs log $[HTTA]_{org}$ gave slopes of three at lower pH values, those at higher pH values showed a slope of two, thus suggesting the extraction of hydroxo chelates $MOH(TTA)_2$ in the higher pH region. The points of intersection of the lines of slopes three and two in the log D vs pH plots are not affected significantly by the nature and concentration of the extractant, and these are shown to be numerically equal to the negative logarithm of the first hydrolysis constants K_h, whose values increase with decreasing ionic radii of the metal ions. The changes in the K_h values on varying ionic strength are as expected from a known empirical relation.

Hydrolysis of trivalent actinides and lanthanides has been extensively studied over the last few decades using different methods such as solvent extraction,[1–5] pH titration,[6–10] electrophoresis,[11] electromigration,[12] solubility[13] and several other methods.[14–18] It is observed from the published data (Table 1) that the values of the first hydrolysis constant for the same metal ion differ widely—in some cases by even five orders of magnitude—and further work in this field is highly desirable in view of the basic importance of the problem by itself, as well as for understanding the chemical behaviour of these metal ions (especially actinides) in various natural environments. Many of the published values of the first hydrolysis constants (K_h) for the trivalent actinides and lanthanides (log $K_h = -6$ to -10) indicate that there is negligible hydrolysis of the ions (e.g. Am^{3+} and Cm^{3+}) below pH 6.[1–5,8,13] However, it is observed[19] that in aqueous solutions of these metal ions which do not contain any complexing agents, serious adsorption problems on the walls of containers are encountered at pH values even lower than 6 but, are negligible at pH < 4. As hydrolysis should be the most likely precursor to adsorption[19] of these ions at the higher pH values, this would indicate that they are probably hydrolysed at pH values lower than 6. Preliminary work carried out earlier[20] in this laboratory with Am^{III} using solvent extraction with thenoyltrifluoroacetone (HTTA), showed that hydrolysis of Am^{III} may be appreciable near pH ~ 3.6. In the present work, hydrolytic behaviour of Am^{III}, Cm^{III}, La^{III}, Eu^{III} and Lu^{III} has been investigated using solvent extraction with HTTA in xylene.

EXPERIMENTAL

Materials

Tracer solutions of the actinides ^{241}Am, ^{244}Cm and the lanthanides ^{140}La, $^{152,154}Eu$ and ^{177}Lu were prepared as described previously.[21] Specific activity of the lanthanide tracers was high enough to maintain the final concentration of all the metal ions $\leqslant 10^{-6}$ M in order to minimize the possibility of polymeric species formation at higher pH. Radioassay of the tracers was carried out by γ-scintillation

counting, using a well-type NaI(Tl) counter with appropriate settings, except for ^{244}Cm where liquid scintillation counting was used. HTTA (E. Merck Pro analysi, m.p. 43.4°C) and HBTA (Penn. Chem. Res. Inc., m.p. 39.4°C) were of AR grade and were used after recrystallization. HPMBP (1-phenyl-3-methyl-4-benzoyl pyrazolone-5) was synthesized in the laboratory.[22] All other reagents are of AR quality. All HTTA, HBTA and HPMBP solutions prepared for the experiments were initially equilibrated for 6 h with 0.1 M $HClO_4$ in order to establish keto–enol equilibrium. All studies are carried out at 30±0.1°C due to the prevailing higher ambient temperatures (~27°C).

pH variation experiments

pH measurements were made with an EMCO (India) pH meter, with an accuracy of ±0.01 pH units, after standardizing with three standard buffers of pH values 4.01, 3.56 and 6.86.[23] 2 cm^3 of the aqueous phase containing the required tracer and pre-adjusted to different pH values [pH adjustment was carried out with 0.01 M acetate or chloroacetate buffer (Table 2)] were equilibrated with 1 cm^3 of 0.1 M HTTA in xylene, in a thermostated bath maintained at 30±0.1°C, for 1 h. Equilibrium was attained well within this time. After settling for 30 min, aliquots of both the phases were removed for radio-assay. Mass balance was strictly checked to ensure that no adsorption is taking place in the aqueous phase. Equilibrium pH of the aqueous phase was also recorded. In order to study the effect of ionic strength on the hydrolytic behaviour of Am^{III}, pH variation experiments were also carried out without using any buffer ($\mu \leqslant 10^{-3}$ M) and with aqueous solutions containing 0.1 M $NaClO_4$. Also additional experiments, using 0.1 M HTTA in xylene (no buffer was used) as well as 0.2 M HBTA and 0.2 M HPMBP, were carried out for determining the effect of the concentration and nature of the extractant on the values obtained for hydrolysis constants.

HTTA variation experiments

2 cm^3 of 0.01 M acetate buffer solutions containing required tracer and adjusted to constant pH values (3.80 for Am, Cm and Eu and 4.60 for La) were equilibrated with 1 cm^3 of HTTA solutions of

different concentrations in the range 0.12–0.40 M for 1 h and later assayed as described earlier.

RESULTS AND DISCUSSION

The extraction of trivalent actinides by HTTA from aqueous solutions is usually represented by the equilibrium

$$M^{3+}_{aq} + 3HTTA_{org} \rightleftharpoons M(TTA)_{3_{org}} + 3H^{+}_{aq} \quad (1)$$

where a binary species, namely $M(TTA)_3$ is extracted. Thus, while plotting log D (where $D = \Sigma[M]_{org}/\Sigma[M]_{aq}$) vs pH a slope of 3 is expected. However, as Fig. 1 indicates, for Am^{III} (as will be shown later for Cm^{III}, Eu^{III}, La^{III} and Lu^{III} also) a deviation from the slope 3 is observed at pH ~ 3.5 and above which the slope is reduced from 3 to 2. This observation was confirmed by repeating this experiment several times. The results shown in Fig. 1 are those obtained by pH variation experiments done by using 0.1 and 0.2 M HTTA in xylene from aqueous solutions containing 10^{-4} to 10^{-3} M HCl. Two distinctly different slopes are observed. The actual values of the slopes are obtained by a least square program and the fitted lines are plotted by the computer, using a x–y plotter (Table 2). Now, even though the slope of 3 at the lower pH region can be accounted for by eq. (1), the slope of 2 obtained at higher pH values is quite intriguing. One of the explanations could be the existence of a precursor such as $MTTA^{2+}$ (which has probably a very fast formation rate) which subsequently gives $M(TTA)_3$ by eq. (2). The other possibilities are given by eqs (3) and (4) which presuppose the formation of a hydroxo species (due to partial hydrolysis of the metal ion) which can subsequently react with 3 and 2 molecules of HTTA respectively

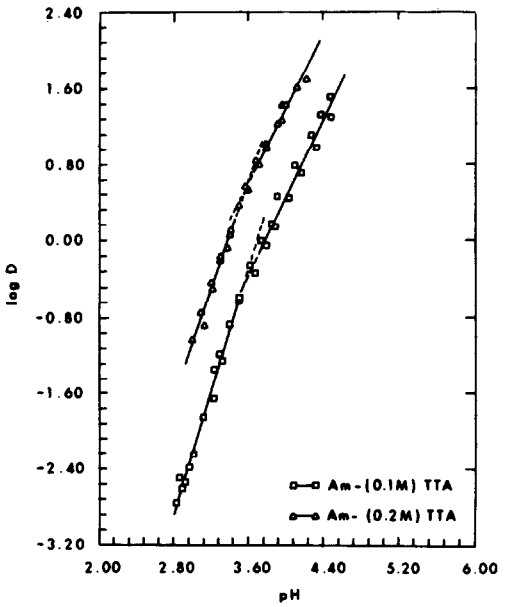

Fig. 1. Variation of log D with pH using 0.1 and 0.2 M HTTA in xylene.

$$MTTA^{2+}_{aq} + 2HTTA_{org} \rightleftharpoons M(TTA)_{3_{org}} + 2H^{+}_{aq} \quad (2)$$

$$MOH^{2+}_{aq} + 3HTTA_{org} \rightleftharpoons M(TTA)_{3_{org}} + H_2O + 2H^+_{aq} \quad (3)$$

$$MOH^{2+}_{aq} + 2HTTA_{org} \rightleftharpoons MOH(TTA)_{2_{org}} + 2H^+_{aq}. \quad (4)$$

Using the values of stability constants for the Am^{III}—TTA complex as reported by Keller and Schreck[24] it can be easily shown that under the present experimental conditions (using the partition coefficient of HTTA as 33.73 ± 0.84[25] and its pKa as 6.23[24] in the aqueous phase) negligible proportion of Am^{III} exists in the form of Am TTA^{2+}, hence ruling out the possibility of the extraction of $M(TTA)_3$ complex, by eq. (2). As will be discussed later, a similar behaviour is also observed when other extractants are used, thus eliminating complexing of the metal ion by the extractant anions in the aqueous phase as the reason for the decrease in the slope from 3 to 2.

In order to ensure which one of the equilibria, eqs (3) or (4), is occurring, variation of HTTA at a constant pH was done in the pH region where a slope of 2 was observed. Figure 2 shows such plots, which are plotted by using a least square program, the fitted slope values with errors being given in Table 3. For americium the pH was kept constant at 3.80 and the results show a straight line with a slope very much closer to 2 than to 3 (Table 3). Thus, the species extracted is certainly not $Am(TTA)_3$ as reported by several workers[1,4] and is probably $Am(OH)(TTA)_2$. A similar species being extracted was reported by Keller and Schreck[24] in the extraction of Ac^{III}. Similarly, the HTTA variation experiments, done for Cm^{III}, La^{III}, Eu^{III} at constant pH, confirm this aspect showing a HTTA dependency of 2 (Fig. 2 and Table 3). HTTA variation experiments were also carried out at a constant pH value in the lower pH region (slope 3 region of Fig. 3) for these metal ions and a dependency of 3 was observed which indicates that different species are extracted before and after the intersection point (Fig. 3) and the extraction of the hydroxo species at higher pH values implies the occurrence of probable hydrolysis.

Table 3. Variation of log D with log $[HTTA]_{org}$ at constant pH values

Metal ion	pH[a]	Slope[b]
Am^{III}	3.80	2.28 ± 0.03
Eu^{III}	3.80	2.16 ± 0.03
Cm^{III}	3.80	2.07 ± 0.09
La^{III}	4.60	1.97 ± 0.08

[a] 0.01 M acetate buffer.
[b] From log D vs log $[HTTA]_{org}$ plots (Fig. 3).

Referring to Fig. 1 the pH regions where slopes of 3 and 2 are observed can be taken as the regions where the species Am^{3+} and $AmOH^{2+}$ respectively exist, and it can be concluded that the pH value at which the above mentioned lines intersect could be

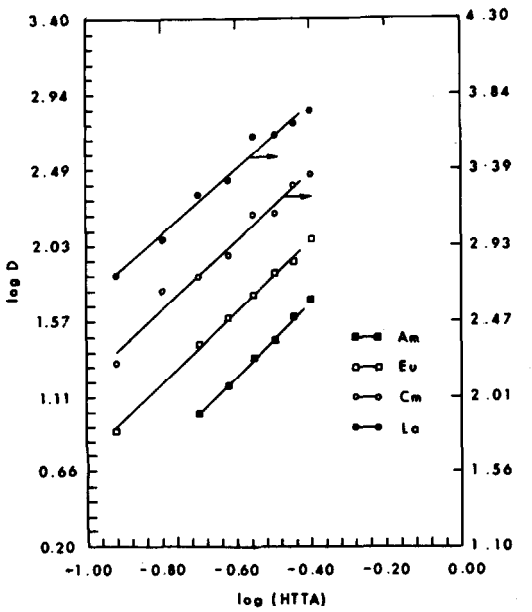

Fig. 2. Variation of log D with log $[HTTA]_{org}$ for Am^{III}, Cm^{III}, Eu^{III} and La^{III}, pH = 3.80 (Am, Cm, Eu) and 4.60 (La).

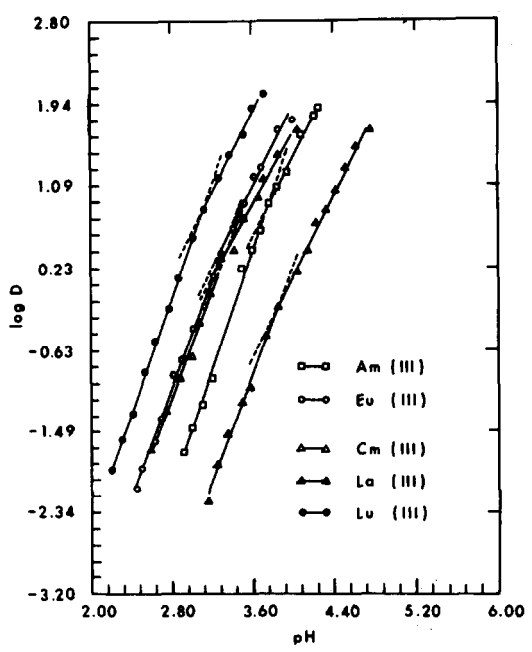

Fig. 3. Variation of log D with pH for some trivalent actinides and lanthanides, 0.01 M acetate buffer (Am, La); 0.01 M chloroacetate buffer (Cm, Eu, Lu).

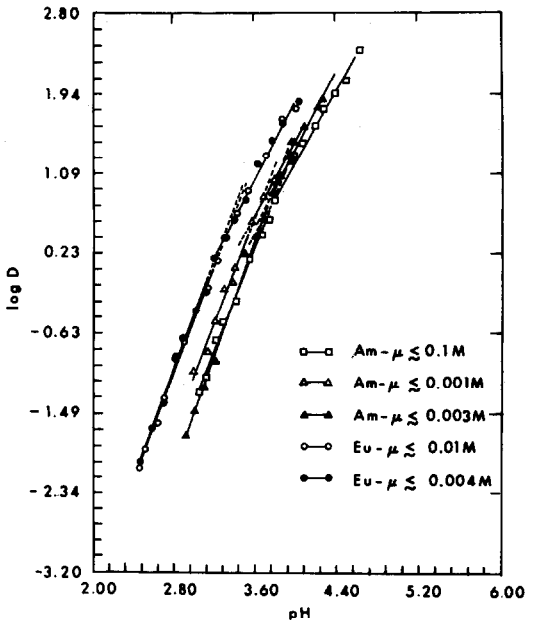

Fig. 4. Variation of log D with pH for Am^{III} and Eu^{III} at different ionic strengths.

the pH where both Am^{3+} and $AmOH^{2+}$ exist with equal concentrations. It can easily be shown that this pH equals the negative logarithm of the first hydrolysis constant, K_h, which pertains to eq. (5)

$$Am^{3+} + H_2O \overset{K_h}{\rightleftharpoons} AmOH^{2+} + H^+. \qquad (5)$$

Figure 4 gives plots of log D vs pH for the extraction of Am^{III} from aqueous solutions of various ionic strengths while Fig. 5 shows similar plots for

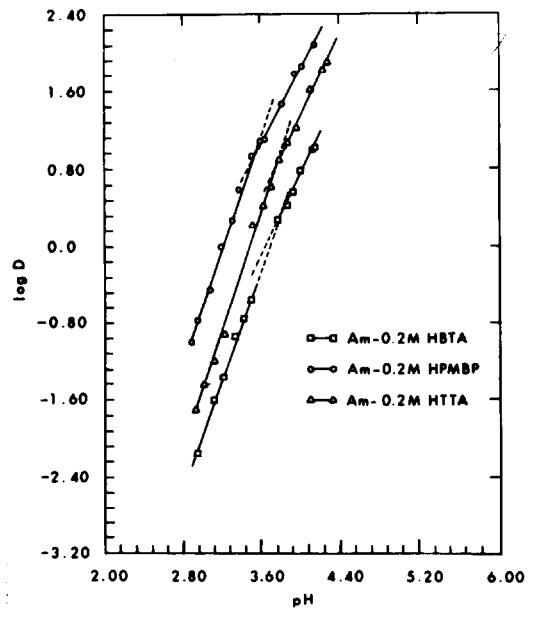

Fig. 5. Variation of log D with pH for Am^{III} using 0.2 M HTTA, HBTA and HPMBP in xylene as extractants.

Am^{III} using three different extractants, namely HTTA, HBTA and HPMBP of the same concentration in xylene. The plots in both figures are similar to those given in Fig. 1, in the sense that they consist of two intersecting lines of slopes ~ 3 and ~ 2 whose exact slopes with errors are given in Table 2 along with the pH values at the points of intersection of these corresponding pair of lines. From Table 2 it is clear that with different extractants the observed behaviour is also similar, the intersection points being centred around pH 3.65 and well within experimental errors. Thus, from a series of experiments the mean value of the first hydrolysis constant for Am^{III} is $10^{-3.65\pm0.1}$.

The low concentration of Am ($\lesssim 10^{-6}$ M) employed, ensures the probable non-occurrence of polymeric species which, as discussed later, can be a source of error in methods such as pH titration and solubility for which use of macro-concentration is mandatory.

The values of hydrolysis constants reported at different ionic strengths can be correlated with each other by an empirical relation[26] which states that the log K_h values decrease with increasing ionic strength by 0.37 units for 0.1 M $NaClO_4$, 0.6 units for 0.5 M $NaClO_4$ and 0.7 units for 1 M $NaClO_4$ at 25°C. In the present study a decrease of ~ 0.2 units is observed for a two order increase in ionic strength (Table 2) which closely follows the relation.[26] The values reported by us at 0.01 M ionic strength (Tables 1 and 4) are obtained from the experimental values using the empirical relation. However, it is seen from Table 1 that values of hydrolysis constants reported by several authors, obtained at different ionic strengths, even after correction (following the empirical relation) are widely different, which will be discussed shortly.

Figure 3 presents plots of log D vs pH for Am^{III},

Table 4. First hydrolysis constants for the reaction $M^{3+} + H_2O \rightleftharpoons MOH^{2+} + H^+$ ($\mu \simeq 0.01$ M; temp. = 30±0.1°C)

Metal ion	Estimated first hydrolysis constants[a] ($-\log K_h$)	$\log \beta^{OH}$ [b]	Effective ionic radii (Å)[c]
La^{3+}	3.85±0.1	10.15±0.1	1.160
Am^{3+}	3.65±0.1	10.35±0.1	1.090
Cm^{3+}	3.30±0.1	10.70±0.1	1.085
Eu^{3+}	3.30±0.1	10.70±0.1	1.086
Lu^{3+}	3.10±0.1	10.90±0.1	0.977

[c] Ref. 27.

Cm^{III}, La^{III}, Eu^{III} and Lu^{III} using 0.2 M HTTA in xylene as the extractant and the aqueous phase containing 0.01 M acetate or chloroacetate buffer as the case may be (acetate buffer for Am^{III} and La^{III} and chloroacetate buffer for Eu^{III}, Cm^{III} and Lu^{III}). As seen from Table 2, the plots for La^{III}, Eu^{III}, Cm^{III} and Lu^{III} clearly show two different slopes which are close to 3 and 2. Thus, following the arguments as given for Am^{III}, the K_h values can be obtained from the points of intersection. The first hydrolysis constant values of these ions show an interesting decreasing trend as the ionic radii of them increase (Table 4). The lower value for Eu^{III} than expected, is not surprising. The anomalously low value of the stability of Eu^{III} complexes in comparison with that of the other lanthanides has been observed in other systems earlier.[21]

The increasing stabilities of the first hydroxo complexes of the metal ions with decreasing ionic radii, irrespective of the nature of metal ions, indicate that these are essentially ionic inner complexes. Participation of 5*f*-orbitals in the hydroxo complexes of Pu^{III} and Am^{III} suggested by Nair *et al.*[8] is not compatible with the values obtained in the present work. The monotonic increase in the K_h values (or β_{OH} values) obtained with decrease in ionic radii is very similar to the behaviour of the first fluoride complexes of lanthanides as seen from the values reported in the literature.[28] As both fluoride and hydroxide ions are small hard donors which are expected to form essentially ionic complexes, the similarity of their complexing behaviour is hardly surprising. The decrease in the values of K_h from Sm^{III} to Er^{III} as well as the lower K_h values for Am^{III} and Cm^{III} as observed by Guillaumont *et al.*[2] (who have also used solvent extraction with HTTA) probably arises from their assumption of extraction of $M(TTA)_3$ in the organic phase throughout the pH range employed in their extraction studies which is contrary to that observed in the present work.

The values of K_h obtained in the present work for Am^{III} and Eu^{III} are close to those obtained by Marin and Kikindai[11] (electrophoresis method) and by Shalinets and Stepanov[12] (electromigration method). Caceci and Choppin[4] and Rao *et al.*[5] have used a competitive complexing anion in their solvent extraction methods for the determination of K_h and have assumed *a priori* that no hydrolysis occurs below pH 6 and 4 respectively. The values of K_h for Am^{III} obtained by them ($-\log K_h = 7.54$ and 6.80 respectively) are much lower than those obtained in this study. The lower values obtained in the pH titration[9,7,17] and solubility[13] methods are probably affected due to the existence of polymeric species in the macro concentrations of the metal ions necessarily used in these methods.

Abstract—Results of magnetic resonance spectra (^1H and ^{31}P) and potentiometry for aqueous solutions of the title acid, H_{10}DTPMP, and for its cadmium and lead complexes, are correlated to give information about the species present. The central nitrogen atom is an anomalously weak base.

Since the discovery[1] by Schwarzenbach, Ackermann and Ruchstuhl of the calcium binding by nitrilodiaceticmethylenephosphonic acid, a whole new class of chelating agents containing aminophosphonate groups has surfaced. Initial studies by Martell's group of the stability of their metal complexes[2–6] were fuelled by their close analogy to the successful oligo-amino-oligo-carboxylates such as H_4EDTA. The mutual repulsion between two or more negative phosphonate groups[2] tends to lower the coordinating ability and denticity of the aminophosphonates with respect to their carboxylate analogues, and also makes them more selective for cations with an enhanced capacity for coordination.[7,8]

The aminocarboxylates (such as nitrilotriacetic acid (NTA), EDTA and DTPA) have been used for decades as scavenging agents for unwanted metal ions in textile and paper processing, e.g. preventing precipitation of insoluble salts. Over the last 15 years, emphasis has swung towards the use of organophosphonates including DNTMP‡ and DTPMP, under various trade names, those for the latter including BRIQUEST 543-45AS and DEQUEST 2060. Their advantage is that they not only form stable complexes, but also act as detergents by dispersing and suspending soil in solution, preventing its redeposition on goods, an ability not shown by aminocarboxylates. In addition, the organophosphonates but not the aminocarboxylates show a so-called threshold effect. Rizkalla studied[9] retardation of $BaSO_4$ precipitation by DTPMP and other organophosphonates, although the "active acid content" of H_{10}DTPMP was determined by titration with NaOH, and the purity calculated on the basis of base compound per equivalent of acid.

When bleaching paper pulp with H_2O_2, the major cost is due to consumption of peroxide, and any loss through decomposition leads to decreased efficiency and increased cost. Trace amounts of metal ions (manganese, iron, copper, chromium and nickel are all present in woodpulp) in bleaching baths can lead to considerable loss of peroxide. $H_nDTPMP^{(10-n)-}$ has recently been shown[10] to be very effective in the prevention of H_2O_2 decomposition in the presence of metal ions.

Detailed assessment of the efficacy of H_{10}DTPMP in such applications requires knowledge of the micro-equilibria in aqueous solution, and we report here our initial work on this.

‡ Often called ENTMP, especially in technological literature.

The structures of the polyaminopolycarboxylate chelates and their metal complexes in solution have been extensively studied by the use of electronic (including circular dichroism[11]), infrared and nuclear magnetic resonance (NMR) spectroscopy.[12,13] The solution structures of the polyaminopolyphosphonates have not been so extensively examined, apart from NMR work on ethylenediamine - N,N,N′,N′ - tetrakis(methylenephosphonic) acid (ENTMP) and di-ethylenetriamine-N,N,N′,N″,N″-pentamethylenephosphonic acid (DTPMP).[14–16] Simple structural spectroscopy on solid metal derivatives of $H_nDTPMP^{(10-n)-}$ has also been published.[17]

RESULTS AND DISCUSSION

The acid, $H_{10}DTPMP$

The titration curve for the free ligand shows three buffer regions with inflections at $\alpha \simeq 2.5$ and 7.0 (α is the number of moles of NaOH added per mole of ligand). The shape of the curve suggests that dissociation occurs in three steps, as shown in Scheme 1. The assumption that all phosphonates are deprotonated prior to nitrogen deprotonation is an over-simplification (*vide infra*).

Reported protonation constants[18,19] of DTPMP are shown in Table 1. The intermediate values of pK are in reasonable agreement, although the extreme values differ considerably. In the medium of ionic strength 3 M which we have employed, the log K values would be depressed as shown[20,21] previously for ENTMP. The first three protonation constants are all greater for DTPMP than for DTPA, implying that nitrogens bonded to methylene-phosphonates are more basic, an effect attributed[2] to the double negative charges of the phosphonate groups, shifting negative charge toward the nitrogen atoms.

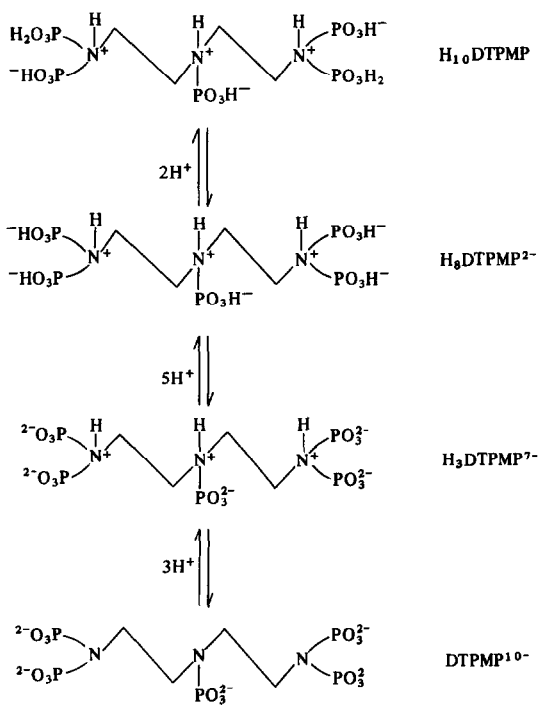

Scheme 1.

As an aside, relating to our main objective of surveying structures of metal complexes, which we shall address in later papers, it is evident from inspection of the titration curves in the presence of equimolar concentrations of metal ions that the stability sequence of the complexes under these conditions is Sr < Mg < Ca ~ Fe < Mn < Co ~ Ni ~ Pb < Cd < Zn < Cu, as expected from the Irving–Williams series.[22] Copper(II) forms by far the most stable chelate, its titration curve starting at a significantly lower pH than those of the other doubly charged metal ions

Insight into protonation schemes of aminocarboxylates[23–26] and aminophosphonates[15] has been obtained largely through the use of ^{1}H NMR based on the observation of chemical shift changes of non-labile protons (protons attached to carbon) as a function of pH. Chapman *et al.*[27] and Kula *et al.*[24] first investigated the protonation of the EDTA tetra-anion using ^{1}H NMR.

^{13}C NMR has been of more limited use in the study of polyaminopolycarboxylate[28–30] and polyaminopolyphosphonate[31] ligands. ^{31}P NMR has been used in the study of metal complexes of polyaminopolyphosphonate ligands,[15,31,32] and, for example, revealed[29] chemical shifts of 5.8 ppm downfield on complexation of cadmium(II) by ENTMP. Coupling constants for carboxylate ^{13}C and phosphonate ^{31}P with spin-1/2 metal nuclides have also been reported.[31,32]

We recorded the ^{1}H, ^{13}C and ^{31}P spectra of DTPMP at various pH values and temperatures. The solutions for NMR were adjusted to the required pH/pD with NaOH/NaOD, and although Na^{+} may complex weakly with $H_nDTPMP^{(10-n)-}$, the spectra have been interpreted as, and will be referred to as, free ligand spectra.

A typical ^{1}H NMR spectrum of $H_nDTPMP^{(10-n)-}$ with assignments is shown in Fig. 1. The two doublets are assigned to the methylenic protons adjacent to the phosphonate groups, and the two triplets to the protons of the non-equivalent carbons of the ethylenic groups. The geminal phosphonate protons are equivalent and couple with the ^{31}P nuclei to give the expected AX doublet. A typical value of J_{H-P} is 12 Hz, with little dependence on pH or temperature. The ethylenic proton resonances are A_2X_2 triplets resulting from coupling between neighbouring methylenes. At neutral values of pH, the difference in chemical shift ($\Delta\delta_{bc}$) is large and much greater than the coupling between them (J_{bc}), so a first order pattern is observed (a partial second order nature is suggested by the slight enhancement in the intensity of the inner lines of the triplets, although this effect is very small). $\Delta\delta_{bc}$ is about 190 Hz at pH = 8.0, reduced to 79 Hz at pH = 1.0, with convergence of peaks at pH = 14.0 ($\delta_b = \delta_c$). The second order nature increases as these limits of pH are approached, as shown by the increased intensities of the inner lines of the triplets. J_{bc} is typically 6.5 Hz. The clarity of the triplet varies from an obvious triplet at pH = 8–10, to a single peak with flanking shoulders at other values of pH.

The pH dependence of the non-labile proton resonances is shown in Fig. 2. Addition of a proton to a basic site produces the greatest change in the signals of the CH_2 groups linked directly to the electron-donating atom. The large change of chemical shift (0.66 and 0.85 ppm downfield) for the (a) and (b) proton resonances on lowering the pD from 14 to 9 reflects extensive protonation of terminal nitrogens in this pD range. This conclusion is based on the size of the shifts relative to those in the pD range from 9 to 1 (shifts of 0.29 and 0.17 ppm downfield), and the similarity between the curves for the (a) and (b) proton resonances in the pD range from 9 to 14 (protonation on O^{-} of phosphonate would cause a shift only of the (a) resonance). In addition, the signal due to the (c) protons is shifted by 0.35 ppm downfield on lowering the pD from 14 to 9. This agrees with published shifts for protons situated two bonds away from a nitrogen site undergoing protonation. The (d) proton signal is less shifted (0.14 ppm), indicating only partial protonation of the central nitrogen. On lowering the pD from 10 to 8, a slight upfield movement of the (d) proton resonance is observed. This coincides with an increased downfield shift for the (a) and (b) protons, and may reflect slight deprotonation of the central nitrogen, and increased protonation of the terminal nitrogens (increased protonation at the terminal nitrogens may lead

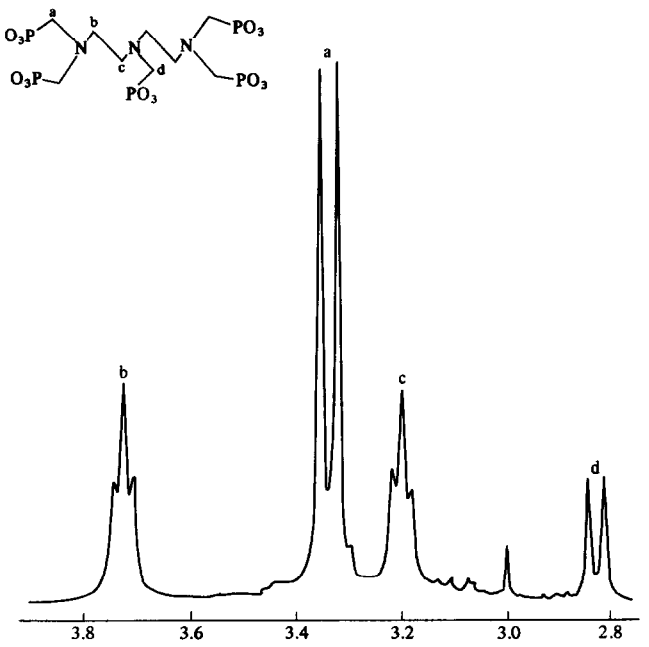

Fig. 1. 360 MHz ^{1}H NMR spectrum of $H_{10}DTPMP$ solution at pD *ca* 8.0 (using a Bruker WM-360 spectrometer).

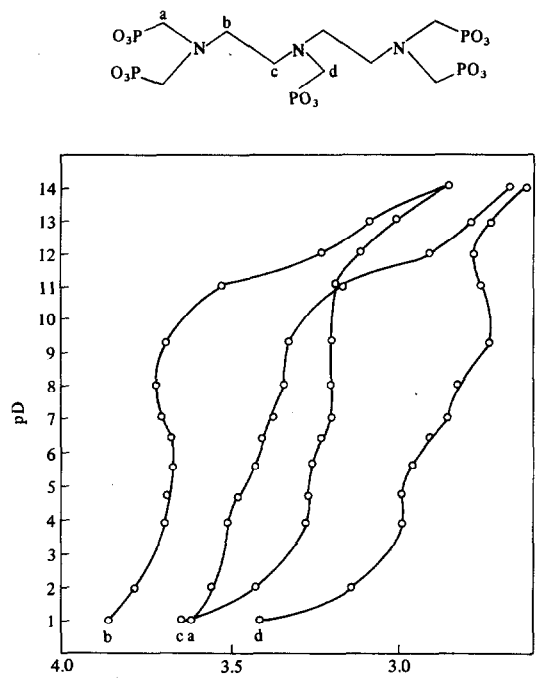

Fig. 2. Variation of the chemical shifts (δ in ppm versus DSS reference) of the non-labile protons of H_{10}DTPMP with pD.

to deprotonation of the central nitrogen as a result of a coulombic repulsion effect as seen[33] with aminopolycarboxylates). Alternatively, the central nitrogen may deprotonate slightly because of partial protonation of the phosphonate groups.

The largest change in δ for the (c) and (d) proton resonances of DTPMP occurs in the pD range from 1 to 4, suggesting enhanced protonation at the central nitrogen. The shift of the resonance due to the (c) protons approximates that for the (d) protons, so the possibility of phosphonate protonation producing these changes is dismissed. The downfield shift of δ for the (c) and (d) signals is greater in the pD range from 4 to 1 than in the range from 14 to 9 (allowance being made for the shift induced in the (c) proton signals as a result of terminal nitrogen protonation of 0.35 ppm). This suggests that the central nitrogen cannot be protonated more than 50% of the time at values of pD > 4. Since the average number n of labile hydrogens attached to each $H_nDTPMP^{(10-n)-}$ moiety is at least six at pD = 4, phosphonate groups must be protonated to a substantial degree before complete protonation of the central nitrogen. In this case, the assumption that nitrogen protonation is complete before phosphonate protonation starts does not apply, and equations of the type often used (e.g. for DTPA[34] and for ENTMP[15]) to deduce variation of percentage times of protonation of labile sites from the observed variance of chemical shift with pD outlined earlier are inapplicable.

At pD = 8.5–9.0, the terminal nitrogens are protonated *ca* 100% of the time. The average number of protons, n, attached to each $H_nDTPMP^{(10-n)-}$ ligand at this pD is 2.0–2.5. Assuming that the terminal nitrogens are deprotonated at pD = 14, and fully protonated at pD = 9, a downfield shift of 0.66 ppm for the (a) proton resonance and 0.65 ppm for the (b) proton resonance is associated with protonation of the adjacent terminal nitrogen. These values are in good agreement with those for oligo-amino-oligocarboxylates[23] and ENTMP.[15] In the pD range from 1 to 9, the δ change for the (a) protons is 0.29 ppm downfield. If the ligand is fully protonated (in the zwitterionic form) at pD = 1, each terminal phosphonate group is doubly protonated approximately 75% of the time: thus, this degree of phosphonate protonation produces a change in δ of 0.29 ppm. Of this shift, 0.15 ppm occurs in the pD range from 4 to 9, and is evidence for monoprotonation of terminal phosphonates before pD = 4. Based on the close analysis of the pD–δ curves, the dominant microspecies and microequilibria associated with the di-, tetra-, and hexaprotonated DTPMP moieties are shown in Figs 3 and 4.

In H_6DTPMP^{4-}, the terminal nitrogens are protonated 100% of the time, the terminal phosphonates are monoprotonated *ca* 75% of the time, and the central nitrogen is protonated not more than 50% of the time. All representations are based solely on the ^1H NMR δ changes with pD (and conformers are ignored). All microspecies interchange rapidly, so that an average distribution only is observed in the NMR spectrum.

Structure 1 in H_4DTPMP^{6-} suggests an increasing basicity of phosphonate groups on protonation at their adjacent nitrogens, contrary to the situation for carboxylate groups.[39] This may be a consequence of the inherent differences between the PO_3^{2-} and COO^- groups. Protonation at PO_3^{2-} is expected to minimize repulsion between neighbouring phosphonates.

The ^{31}P NMR spectra of DTPMP consist of two triplets of relative intensity 4:1, which collapse to singlets on decoupling from the methylene protons. A typical value of J_{P-H} is 11.6 Hz, in agreement with the coupling constant obtained from the ^1H spectra. The larger signal is assigned to the four equivalent phosphorus atoms of the terminal phosphonates, and the smaller peak to the unique phosphorus of the central phosphonate. The variation of the ^{31}P chemical shifts with pH is shown in Fig. 5. The variations observed are in good agreement with the scheme described for the variation of pro-

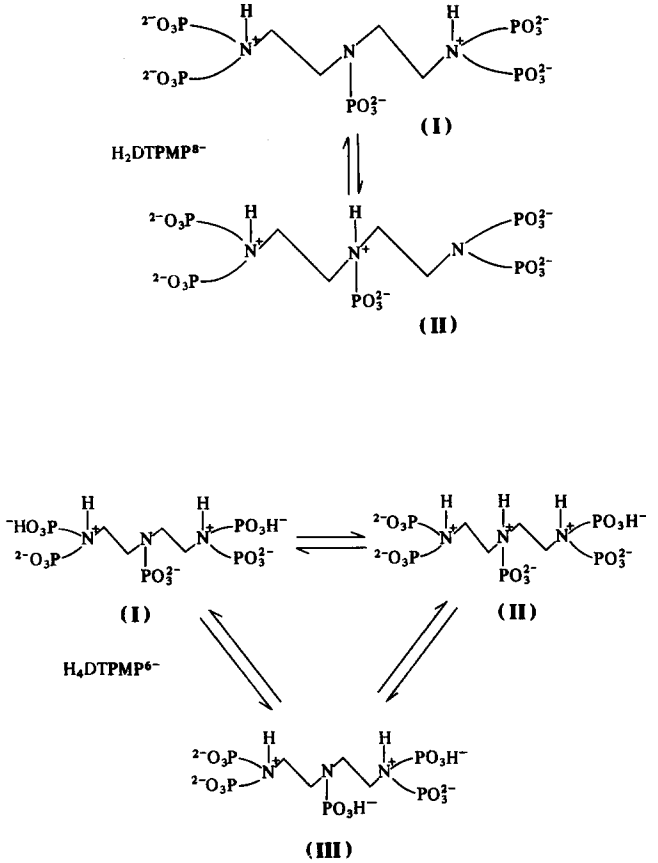

Fig. 3. Dominant diprotonated and tetraprotonated microspecies, $(H_2DTPMP)^{8-}$ and $(H_4DTPMP)^{6-}$.

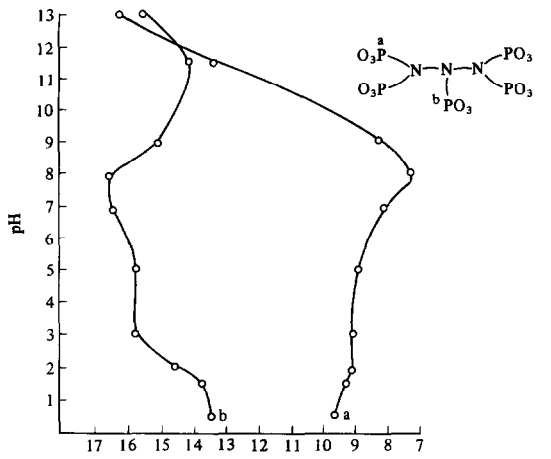

Fig. 5. Variation of ^{31}P NMR chemical shifts for DTPMP as a function of pH.

ton-δ with pD, although the presence of valence *p*-electrons on phosphorus produces a downfield shift on increasing the electron density around the ^{31}P nuclei, i.e. on deprotonating DTPMP (the opposite is true for ^{1}H where only valence *s*-electrons are present). The large downfield shift (7.8 ppm) observed for the terminal ^{31}P phosphonate resonance in the pH range from 9 to 13 indicates that nitrogen protonation has a greater effect on the ^{31}P signal than does protonation of phosphonate oxygens. This is somewhat surprising, because the nitrogen site is more distant with respect to the phosphorus atom than the oxygen site. However, protonation of adjacent oxygens has been shown to produce relatively small δ shifts, e.g. protonation of PO_4^{3-} to give $(HO)_3PO(H_3PO_4)$ produces[35] an upfield shift of only 5.7 ppm.

No great dependence on pH of the carbon-13 resonance signals of DTPMP is observed. (All peaks are coupled to the methylene protons to give triplets in the decoupled spectra: a typical J_{C-H} value is 54 Hz). Such insensitivity of these resonances to pH changes accords with[28,29] aminopolycarboxylate ligands.

Complexes of DTPMP with diamagnetic metal ions

The Cd^{2+}–DTPMP and Pb^{2+}–DTPMP systems were studied at various temperatures and values of pD. Typical spectra are shown in Figs 6 (Cd) and 7 (Pb). Spectral characteristics of the free ligand evidently persist for the lead complex at lower values of pD, but not for cadmium, reflecting its stronger complexing.

The Cd–DTPMP spectrum at pD = 11.0 shows some interesting features. The doublet of the central phosphonate protons is retained, but the terminal

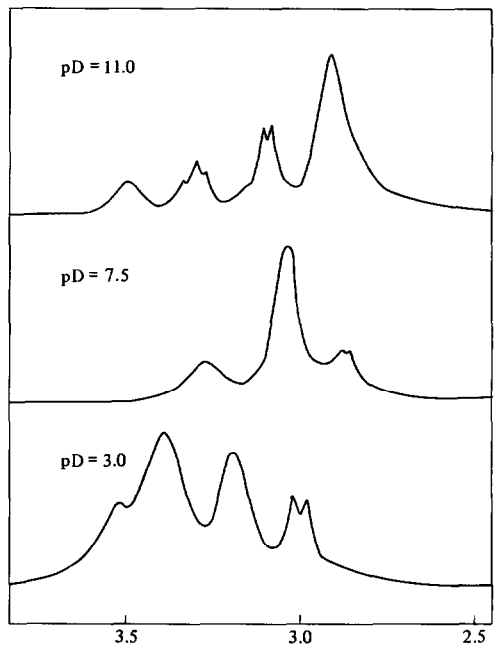

Fig. 6. 360 MHz ^{1}H NMR spectra of Cd^{2+}–DTPMP at selected pD values.

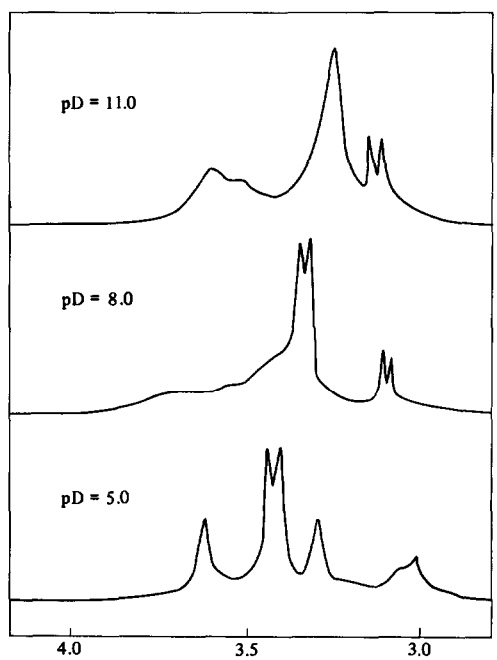

Fig. 7. 360 MHz ^{1}H NMR spectra of Pb^{2+}–DTPMP at selected pD values.

phosphonate doublet is replaced by a large asymmetrical singlet, whose broadness and asymmetry suggest that it may be an unresolved multiplet. Such splitting would arise if the geminal protons of the terminal methylenephosphonate groups became inequivalent as a result of relatively long-lived Cd—N bonds (Fig. 8). In the free ligand spectra,

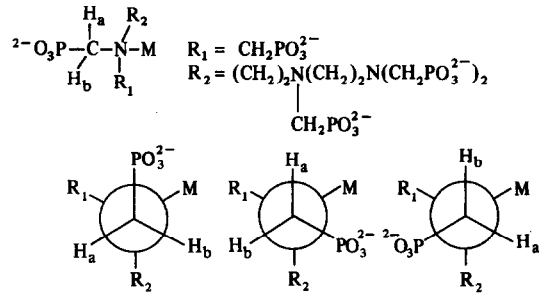

Fig. 8. Non-equivalence in geminal protons produced by long-lived M—N bonds. The non-equivalence of the phosphonate protons is caused by the inherent dissymmetry of the situation and/or the different amounts of time each proton spends in the various rotational conformations.

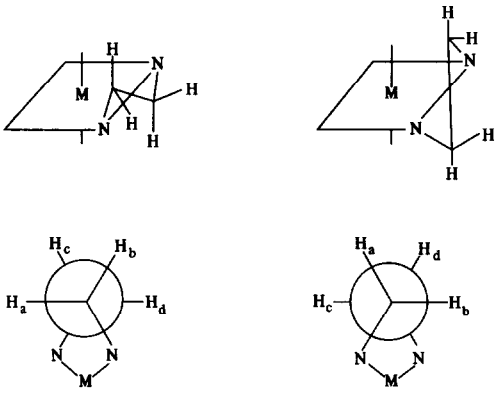

Fig. 9. Conformations of one ethylenic group of DTPMP in a complex with long-lived metal–ligand bonds. If the rate of interconversion of these two forms is slow, the geminal ethylenic protons become inequivalent.

the geminal (a) protons are made equivalent by the rapid umbrella inversion of the nitrogen atom, split only by coupling to ^{31}P, giving a simple doublet. Where such inversion is prevented by the formation of M—N bonds long-lived on the NMR time scale, these geminal protons are no longer equivalent and mutually couple to give an AB quartet (Fig. 8). This pattern would be further complicated in DTPMP by coupling with the ^{31}P nuclei. The observation of an asymmetrical singlet as opposed to a multiplet in the Cd–DTPMP spectrum may suggest that J_{X-Y} approximates to $\Delta\delta_{XY}$ (X and Y are the geminal phosphonate protons). Alternatively, the poor resolution may be associated with bond lifetimes only slightly longer than or comparable to the NMR time scale. The simple doublet for the (d) protons may reflect a shorter Cd—$N_{central}$ bond lifetime, or a non-interacting central phosphonate group. The former situation reflects a reduced basicity of N_{cent} relative to N_{term} as for the free ligand, where the proton affinity of $N_{term} > N_{cent}$. In the case where the phosphonate is non-interacting, a simple doublet would occur if rotational motion produced a time averaged plane of symmetry through the central methylene–phosphonate group.

The spectral appearance and peak integrals indicate that the ethylenic protons are represented by four separate resonances (two clearly visible, one underlying the central phosphonate doublet, and a further one lost beneath the large singlet) in the Cd–DTPMP spectrum at pD = 11.0. This may be associated with a non-equivalence in the geminal ethylenic protons produced by increased rigidity of the chelate, and hindrance of the "wagging" motion of the ethylenic backbone. This situation is summarized in Fig. 9.

The pD dependence of the proton resonances of Cd–DTPMP is shown in Fig. 10. The downfield shift of the (d) proton signal at high pD may reflect

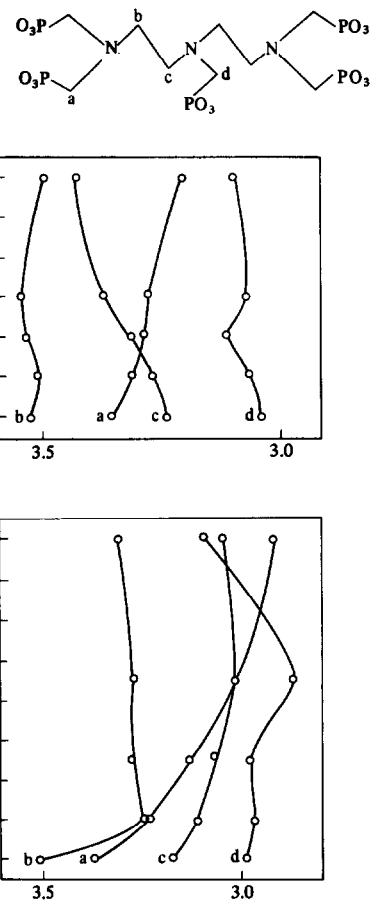

Fig. 10. Variation of ^1H NMR chemical shifts for the Cd^{2+} (lower) and Pb^{2+} (upper) complexes of DTPMP as a function of pD.

an increased degree of protonation at the central phosphonate. This would coincide with an increased interaction between the ligand and cadmium, and is further evidence for a non-interacting central phosphonate group.

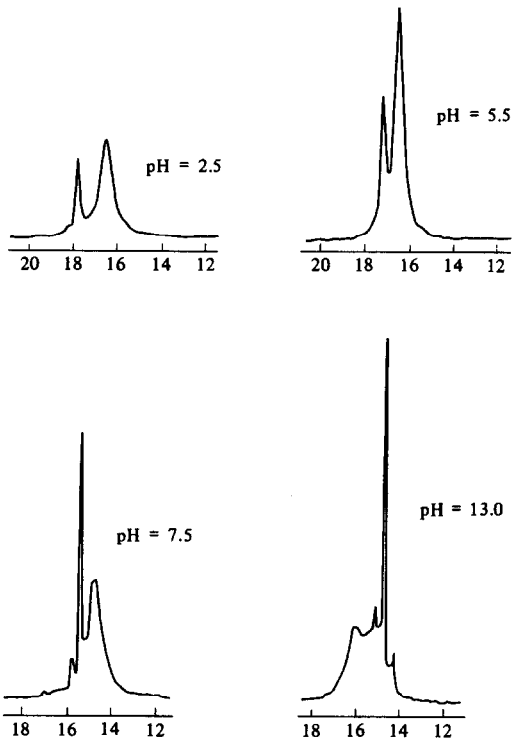

Fig. 11. ^{31}P NMR spectra of Cd^{2+}–DTPMP at selected pH values. Chemical shift values (in ppm) relative to 85% H_3PO_4.

The results of ^{31}P (proton decoupled) NMR studies of Cd–DTPMP at variable pH are summarized in Fig. 11. The peaks are broad at lower pHs, like those[31] of Cd–ENTMP. The central phosphonate peak converts to a sharp singlet at higher pH, but the terminal phosphonate resonance remains broad (26 Hz at peak half-width compared with 3.6 Hz for free DTPMP at pH = 7.5). This broadening increases as the solution becomes more alkaline (Fig. 11), and is indicative of Cd—O_{term} bond lifetimes comparable to the NMR time scale, i.e. the intramolecular exchange of phosphonate donor groups between positions in-plane and out-of-plane with respect to the nitrogen donors is not sufficiently rapid for the terminal phosphonates to allow the observation of a single sharp ^{31}P resonance. The sharp singlet for the central phosphonate may be the result of its restriction to one type of position only, or because[34] the central phosphonate is non-interacting as in Cd–DTPA. At pH = 13.0, the ^{31}P spectrum consists of a broad mound with a sharp singlet flanked by two smaller peaks (Fig. 11). The sharp singlet is assigned to the central phosphonate. The flanking peaks, equidistant from the sharp singlet, may be satellites from coupling between the central phosphorus and the spin-1/2 nuclides of cadmium (^{111}Cd and ^{113}Cd total 25% natural abundance), a phenomenon already observed[32] with Cd–ENTMP. The ^{31}P-$\{^{111/113}Cd\}$ coupling may be mediated through the M—N—C—P or M—O—P linkages. The latter was thought more likely for Cd–ENTMP, although the central phosphonate group is thought not to coordinate in Cd–DTPMP, suggesting coupling through the nitrogen and carbon to phosphorus. This is also supported by the lower J_{P-Cd} value for Cd–DTPMP; only 14.5 Hz compared with 45.9 Hz in[32] Cd–ENTMP. Six peaks are present in the ^{13}C spectrum at pH = 13, supporting the idea of non-equivalent ethylenic and/or methylene–phosphonate groups in Cd–DTPMP.

The ^{1}H spectra for Pb–DTPMP are simpler than those of the cadmium complex (Fig. 7), reflecting more labile Pb—O and Pb—N bonds. This observation arises because all protons equivalent in the free ligand are made equivalent in the lead complex by internal averaging. At pD = 12 and 5°C, three singlets are observed of relative intensity 6:2:1. The large peak contains 12 protons and is assigned to the terminal phosphonates and a coinciding ethylenic resonance. The two smaller peaks then comprise one ethylenic resonance representing four protons, and the (d) proton signal of the central phosphonate. Some line broadening is evident and is associated with a decreased lability of the Pb—L bonds. At 60°C, the large doublet is resolved and only two peaks are observed. The pD–δ curves shown in Fig. 10 reveal only slight shifts in the resonances from pD = 5 to 11.

The proton decoupled ^{31}P spectra for Pb–DTPMP are broad at lower pHs but sharpen as the pH is raised, until only one peak is observed at pH = 13. This singlet reflects equivalence of all phosphonate groups produced by rapid internal exchange of these groups and/or a negligible non-equivalence for ^{31}P in the in-plane and out-of-plane positions. No coupling with ^{207}Pb (21% naturally abundant spin-1/2 isotope) is observed.

CONCLUSIONS

Addition of H^+ to the DTPMP deca-anion induces protonation at the terminal nitrogens initially, then protonation of phosphonate groups. The central nitrogen is not protonated extensively until the pH is below 4. This is contrary to the situation encountered with DTPA, where all three nitrogens are appreciably more basic than the carboxylate groups.

The ^{1}H and ^{31}P NMR spectra of the complexes of DTPMP depend on the strength of the individual metal–ligand bonds, and the structure of the complexed ligand. The ^{13}C spectra are less variable.

The most complicated spectra (discussed elsewhere) occur with the trivalent metal ions, where all M—L bonds may be long-lived, and the coordination number of the metal commonly exceeds six. The M^{2+}–DTPMP (here M = Cd or Pb) complexes give simpler spectra indicative of shorter bond lifetimes and less asymmetrical complexes, and some features permit us to comment on structures in complex ions.

EXPERIMENTAL

Materials

H_{10}DTPMP (purity not less than 93%) in the full acid form was a white powder from Albright and Wilson Ltd., Oldbury. It had as sole impurity a methyl group in place of one of the terminal methylene-phosphonate groups. Thermogravimetric analysis showed the acid to contain 5% water by wt, corresponding to a composition of H_{10}DTPMP · $1.5H_2O$. All metal nitrates and chlorides were of BDH Analar grade (or equivalent), and were used as supplied. Solutions were prepared in distilled or doubly distilled water (potentiometric work) using grade A or precalibrated grade B glassware.

Measurements[36]; *Potentiometric*

Accurately prepared 1.71×10^{-3} M solutions of DTPMP (50 ml) were measured potentiometrically in the absence and presence of the metal ion as a function of added CO_2-free NaOH solution. The solutions were titrated in a sealed jacketed glass cell thermostatted at 25 ± 0.05°C. Dilution effects were minimized by the use of strong base (*ca* 3.5 M) as the titrant, added through two microsyringes of maximum capacity 250 and 25 μl, respectively. The total volume change after addition of base was 0.55%. Activity coefficients were held constant by the use of $NaNO_3$ as a supporting electrolyte (ionic strength was 3 M). The pH of the solutions was monitored using a Radiometer pHM85 pH meter with a GK2401B (or GK2401C) combined electrode, and the expression,[37] for magnetic resonance experiments, true pD = 0.40 + pH measured in D_2O.

^{31}P *NMR*

Solutions (0.06 M) of DTPMP (with and without an equivalent amount of metal ion) for ^{31}P NMR were prepared in 10 ml of H_2O with sufficient D_2O to obtain a lock signal. The ionic strength was maintained at 3 M by the use of $NaNO_3$. The pH was adjusted with 8.4 M NaOH and measured with comparator indicator papers. The ^{31}P spectra were recorded using 10 mm tubes with a Jeol FX-90-Q spectrometer (specifically tuned for ^{31}P) at a working frequency of 36.21 MHz. Measurements were usually made at ambient temperature (*ca* 27°C). The chemical shift values were measured with respect to 85% H_3PO_4 as an external reference.

ONE-STEP SYNTHESIS OF A C-FUNCTIONALIZED PHOSPHA-ALKENE: X-RAY CRYSTAL STRUCTURE OF 2,4,6-^{t}Bu$_3$C$_6$H$_2$P=C(H)CN

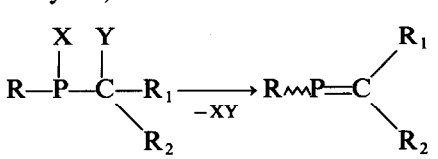
ALAN H. COWLEY,* CHRISTINE M. NUNN and MAREK PAKULSKI

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 7 *March* 1989; *accepted* 31 *March* 1989)

Abstract—The reaction of 2,4,6-^{t}Bu$_3$C$_6$H$_2$PCl$_2$ with two equivalents of LiCH$_2$CN results in the exclusive formation of the *cis* (i.e. *Z*) isomer of the C-functionalized phospha-alkene, 2,4,6-^{t}Bu$_3$C$_6$H$_2$P=C(H)CN (**1**). The structure of **1** was established by X-ray crystallography.

Sterically protected phospha-alkenes provide the opportunity of studying the phosphorus–carbon double bond free of resonance effects or transition metal fragments. Following the report of PhP=C(^{t}Bu)(OSiMe$_3$) by Becker,[1] acyclic phospha-alkenes with localized P=C bonds have been prepared in large numbers.[2] The most general strategy for the construction of the P=C functionality involves at least a two-step process, the salient features of which are the attachment of an appropriately substituted carbon fragment to phosphorus followed by a 1,2-elimination.



Alternative synthetic procedures, such as metathesis[3] or the reaction of lithiated silylphosphines with aldehydes or ketones,[4] are also multistep in character. We report a convenient one-step synthesis of a functionalized phospha-alkene starting with the readily available[5] dichlorophosphine, ArPCl$_2$ (Ar = 2,4,6-^{t}Bu$_3$C$_6$H$_2$).

EXPERIMENTAL

Dry, powdered LiCH$_2$CN[6] (0.9 g, 19.0 mmol) was added over a 30 min period to a stirred solution of 2,4,6-^{t}Bu$_3$C$_6$H$_2$PCl$_2$ (3.47 g, 10.0 mmol) in 60 cm^3 of THF at −78°C. The resulting deep red reaction mixture was allowed to warm slowly to room temperature. A ^{31}P{^{1}H} NMR assay of the reaction mixture revealed the presence of **1** (359 ppm), traces of 2,4,6-^{t}Bu$_3$C$_6$H$_2$PCl$_2$ (155 ppm) and several very low intensity peaks in the range +60 to −10 ppm. After removing the solvent and volatiles *in vacuo*, the crude product was purified by column chromatography (silica gel/2:1 hexane–toluene eluant) and recrystallized from hexane at −20°C. The yield of colourless crystalline **1** was 67.2%.

NMR (C$_6$D$_6$, 25°C): ^{1}H (300 MHz) 1.21 ppm (s, 9H, *para*-^{t}Bu), 1.23 ppm (s, 18H, *ortho*-^{t}Bu), 5.88 ppm (d, 1H, PCH, $^2J_{PH}$ = 21 Hz), 7.37 ppm (s, 2H, C$_6$H$_2$); ^{13}C{^{1}H} (75.4 MHz): 31.3 ppm (s, *para*-C(*C*H$_3$)$_3$), 34.0, 34.1 ppm (s, *ortho*-C(*C*H$_3$)$_3$), 38.0 ppm (s, *C*(CH$_3$)$_3$), 122.4 ppm (s, *meta*-C$_{arom}$), 134.8 ppm (d, *ortho*-C$_{arom}$, $^2J_{PC}$ = 37 Hz), 153.0 ppm (d, CH, $^1J_{PC}$ = 200 Hz); ^{31}P{^{1}H} (121.5 MHz): 359 ppm (d, $^2J_{PH}$ = 21 Hz). IR (C$_6$D$_6$): ν_{CN} = 2268, 2279 cm^{-1}. Electron-impact MS (70 eV): *m/e* 315 (M$^+$, 30%).

The structure of **1** was determined by X-ray crystallography: C$_{20}$H$_{30}$NP, M_r = 315.44, monoclinic, $P2_1/c$, a = 10.898(5), b = 10.338(1), c = 18.164(3) Å, β = 102.95(2)°, V = 1994.4 Å^3, Z = 4, D_c = 1.050 g cm^{-3}, μ = 1.31 cm^{-1} for Mo-K_α radiation (λ = 0.71073 Å). Intensity data: Enraf–Nonius diffractometer, θ–2θ scan mode, 3924 unique reflections in the range $3.0 \leqslant 2\theta \leqslant 52.0°$. The structure of **1** was solved by direct methods and refined

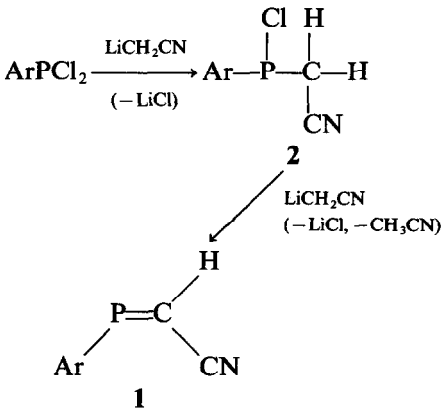
(full-matrix, least-squares) by using 1780 reflections with $I > 3.0\sigma(I)$. The final residuals were $R = 0.0956$ and $R_w = 0.1041$.*

RESULTS AND DISCUSSION

The reaction of $ArPCl_2$ (Ar = 2,4,6-$^tBu_3C_6H_2$) with $LiCH_2CN$ in THF proceeds in one step to afford the phospha-alkene, **1**. We were not able to detect the presumed intermediate monochlorophosphine, **2**.



The presence of the phosphorus–carbon double bond in **1** was evident from the $^{31}P\{^1H\}$ NMR chemical shift of +359 ppm; moreover, the presence of C—H, Ar and CN moieties was established by ^1H, $^{13}C\{^1H\}$ NMR or IR spectroscopy. However, use of these data did not permit unequivocal assignment of the isomeric preference, hence an X-ray crystal structure was undertaken. Compound **1** adopts a *cis* (i.e. *Z*) structure in the solid state (Fig. 1). This represents an interesting contrast with ArP=C(H)Ph (**2**), a phospha-alkene with somewhat similar substituents.[4] In this case, the *E* isomer is the ground state and photolysis is necessary to effect conversion to the more sterically hindered *Z* isomer. The P—C—C and C—P—C bond angles in **1** [126.4(7) and 103.4(4)°] lie between those found for **2*E*** [125.4(4) and 100.5(3)°] and **2*Z*** [139.1(2) and 105.8(1)°], suggesting that **1** is less sterically congested than **2*Z***. This view is supported by the fact that the P=C bond length in **1** [1.660(9) Å] is towards the low end of the range observed for acyclic phospha-alkenes. Subtle electronic effects may also be operative.

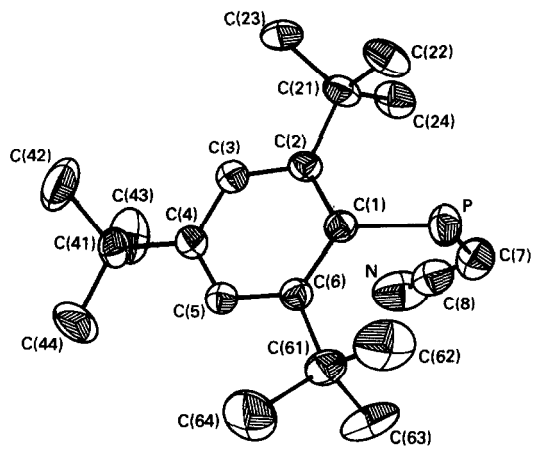


Fig. 1. View of 2,4,6-$^tBu_3C_6H_2P$=C(H)CN (**1**) showing the atom numbering scheme. Important bond lengths (Å) and angles (°): P—C(1) 1.834(7), P—C(7) 1.660(9), N—C(8) 1.140(14), C(1)—P—C(7) 103.4(4), P—C(7)—C(8) 126.4(7), C(7)—C(8)—N 179(1).

(*Received* 13 *April* 1989; *accepted* 28 *April* 1989)

Abstract—The oxidative degradation of *arachno*-6-$SB_9H_{12}^-$, using formaldehyde as an oxidizing agent, affords *arachno*-4-SB_8H_{12} in practically quantitative yield; the deprotonation of 4-SB_8H_{12} with NaH produces the new *arachno*-4-$SB_8H_{11}^-$ anion, in quantitative yield.

There is a current resurgence of interest in polyhedral heteroboranes of the chalcogens, and we have long had some interest in this area. A recent report[1] by Kang and Sneddon improves (to 20%) our original reported yield (14%)[2] for the preparation of *arachno*-4-SB_8H_{12}. So that exploration of this area of chemistry can be better facilitated, we now report details of a straightforward procedure that readily affords this compound in practically quantitative yield. The procedure makes use of formaldehyde as an oxidizing agent [formal stoichiometry as in eq. (1)], rather than $FeCl_3$ as used by Kang and Sneddon, and the thiaborane starting material, $Cs[SB_9H_{12}]$, is easily obtained from $B_{10}H_{14}$ in *ca* 90% yield[3] by well-tried procedures. We describe a typical procedure.

$$[SB_9H_{12}]^- + HCHO + H_3O^+ + 2H_2O \longrightarrow SB_8H_{12} + CH_3OH + B(OH)_3 + H_2. \quad (1)$$

To a suspension of $Cs[SB_9H_{12}]$ (2.563 g, 9.34 mmol; prepared as in ref. 3) in H_2O (20 cm^3), was added CH_2Cl_2 (20 cm^3), an aqueous solution of formaldehyde (*ca* 38% solution; 5 cm^3) and aqueous hydrochloric acid (*ca* 18% solution; 3 cm^3). The mixture was stirred for 20 min at ambient temperature, and the CH_2Cl_2 layer separated and dried over $CaCl_2$. Evaporation to dryness gave the crude product in approximately quantitative yield. NMR spectroscopy (CD_2Cl_2 solution)‡ showed that the product was pure and, in particular, free from *nido*-SB_9H_{11}.[4] Careful sublimation (25°C; 1.3 Pa; cold surface at −70°C) gave 4-SB_8H_{12} as a colourless, stinking, volatile solid (0.987 g; 81% yield based on $Cs[SB_9H_{12}]$ consumed).

The yield can be improved by very careful sublimation, but *ca* 80% is perhaps a more realistic target for normal laboratory preparation of the compound as starting material for further investigation. Alternatively, for synthetic purposes, it is often convenient to use the $CaCl_2$-dried CH_2Cl_2 solution directly, with the presumption that the

‡ NMR data for 4-SB_8H_{12} are as follows {ordered as: assignment $\delta(^{11}B)$/ppm [$\delta(^1H)$/ppm]}: BH(7) +14.5 [+3.96], BH(5,9) −3.4 [+3.12], BH(1) −12.4 [+2.76], BH(6,8) −13.5 [+1.24 (*exo*) and −0.68 (*endo*)-type], BH(2,3) −13.3 [+0.73], and H(μ-5,6; μ-8,9) −[−1.87]; CD_2Cl_2 solution at 294 K.

$SB_9H_{12}^- \rightarrow SB_8H_{12}$ conversion has occurred quantitatively. Thus, for example, with $[Pt(PPh_3)_4]$ we have obtained [9,9-$(PPh_3)_2$-*arachno*-6,9-$SPtB_8H_{10}$] in 95% yield based on $Cs[SB_9H_{12}]$.

Pure 4-SB_8H_{12} itself appears to be unstable to storage, and is best prepared freshly; it appears to be more stable under certain acid conditions (e.g. in CH_2Cl_2 in the presence of CF_3COOH). It can be simply and quantitatively deprotonated, using the standard borane/NaH/OEt_2 technique, to give the new *arachno*-[4-SB_8H_{11}]$^-$ anion;* this is stable for weeks as its Na^+ salt, which may be prepared by removing the OEt_2 *in vacuo* and drying the residue at 25°C and 1.3 Pa. Quantitative reprotonation to give neutral SB_8H_{12} can be simply effected with stoichiometric quantities of acids such as CF_3COOH, in solvents such as CH_2Cl_2.

Abstract—The salt $Na_3[Ru(CN)_5(en)]\cdot 2H_2O$ (en = ethylenediamine) has been prepared and characterized by its IR and electronic spectral properties. The dissociation rate constant, k_{-L}, was found to be dependent on pH, as expected from the protonation of the unbound N-site of the en ligand. From the values of $k_{-en} = 6.2\times10^{-5}\ s^{-1}$ and $k_{-Hen^+} = 1.07\times10^{-4}\ s^{-1}$ (25°C) and activation parameter data, as well as considering the dependence of the rate on the concentration of reactants, a dissociative mechanism was postulated. The pK_a of the Hen^+ ligand was shown to be 9.7 (25°C), only slightly lower than for free (aqueous) Hen^+ (9.98). The formation rate constants, k_L, were determined for L = en (0.89 $M^{-1}\ s^{-1}$) and L = Hen^+ (0.83 $M^{-1}\ s^{-1}$); the kinetic analysis suggests an ion pair–dissociative interchange mechanism, as well as the action of solvation effects. From k_{-L} and k_L, values of the stability constants, K_{st} (M^{-1}), were calculated. A comparative discussion is made with the aid of data from related complexes of the $[Ru(CN)_5L]^{n-}$ and $[Fe(CN)_5L]^{n-}$ series.

Among the cyano complexes of the transition metals,[1] the pentacyanoruthenates are presently being intensively studied, as they offer a possibility for developing a systematic work on structure and reactivity.[2–6] The interest is enhanced by the rich chemistry presented by the $[Fe(CN)_5L]^{n-}$ system;[7] a wide availability of L ligands (which may bind through σ-only or σ–π interactions) has allowed the latter complexes to be employed in substitutional[7–12] and electron-transfer reactivity studies.[13,14] When L is potentially biphilic, bridged species may be generated and mixed-valence systems may be constructed when attaching, for instance, some other $M'X_5$ moiety (e.g. $Fe(CN)_5^{2-}$, $Ru(NH_3)_5^{3+}$) to the unbound L site in the $M(CN)_5L^{n-}$ complex.[15,16]

A particular group of ligands L is formed by oxidizable species such as hydrazine or ethylenediamine (en); these molecules form stable, unidentate complexes with $Fe(CN)_5^{3-}$;[17–19] for hydrazine, an autoxidation process is set up when the $[Fe(CN)_5(N_2H_4)]^{3-}$ ion is placed in contact with dissolved oxygen;[20] also, ligand dehydrogenation processes have been found to occur in the bidentate ion, $[Fe(CN)_4(en)]^{2-}$.[21]

According to the above-mentioned picture, the case of L = en merits special concern among the complexes of the $[Ru(CN)_5L]^{n-}$ series; ligand dehydrogenation reactions have been observed in some ruthenium(II) complexes,[22] and they could be seemingly also operative in the pentacyanoruthenate system, as suggested by the highly oxidizing properties expected for the $[Ru(CN)_5L]$ (II,III) couple.[16] As a previous step to studies concerning the reactions of coordinated en, the basic structural and substitution kinetic features of the latter ligand are needed; this is the subject of the present work.

EXPERIMENTAL

(a) *Preparation of* $Na_3[Ru(CN)_5(en)] \cdot 2H_2O$

In a preliminary step, $Na_4[Ru(CN)_6] \cdot 10H_2O$ was obtained by a double decomposition reaction: an aqueous solution [0.050 g in 10 cm^3 of potassium hexacyanoruthenate (Ventron)] was treated with a slight excess of $AgNO_3$ and the resulting precipitate was filtered off; then, aqueous sodium iodide in stoichiometric proportions was added to the solid and the mixture was filtered again. The resulting solution was concentrated at 25°C until the volume was 2 cm^3, and crystals of the desired salt were obtained by adding cold acetone. To a solution of 0.1 mmol of $Na_4[Ru(CN)_6] \cdot 10H_2O$ in 5 cm^3 of water, 1 mmol of en was added and then, slowly, 1.7 cm^3 of aqueous bromine solution (0.0117 M in Br_2 and 0.0117 M in NaBr). The mixture was left for 30 min at room temperature and then more en was added (1 mmol). After 24 h, the solution was concentrated in a rotavap at 25°C, until the volume was 1 cm^3; a precipitate was obtained by adding 5 cm^3 of acetone to the solution, at 0°C. The solid was highly hygroscopic and was stored under $CaCl_2$. Found: C, 19.5*; H, 3.2; N, 24.4; Na, 16.7. Calc.: C, 21.2; H, 3.0; N, 24.7; Na, 17.4%. Water was determined by thermal loss (100°C): Found: 9.4. Calc.: 9.1%.*

(b) *Electronic and IR spectra*

The visible-near UV spectrum was obtained in a Shimadzu UV 210A double-beam spectrophotometer. The IR spectrum was run on a Perkin–Elmer 580B spectrophotometer, with the solid sample pressed into KBr discs.

(c) *Kinetic measurements*

A single-beam Metrolab 325 spectrometer, interfaced with a recorder was used. The temperature was controlled in a thermostatted optical cell with the aid of a circulating bath (Lauda MGW).

(i) *Dissociation kinetics.* The starting solutions were prepared by dissolution of the solid complex or, alternatively, by the *in situ* generation of the $[Ru(CN)_5(en)]^{3-}$ complex from sodium pentacyano(nitrosyl)ruthenate(II) dihydrate,† by the reaction with aqueous hydrazine in a molar ratio 1:0.75, at pH 8.5 and in the presence of a 50-fold excess of en. The solutions contained $[Ru(CN)_5(en)]^{3-}$ (5×10^{-5} M) and free en (2×10^{-3} M); the concentration of the entering ligand, pyrazine (pyz), was 0.1 M in most of the experiments (saturation kinetics conditions, see below) and the ionic strength was 1 M (NaCl). The experiments at 25°C were performed at different pHs, covering the range 6–13. The temperature was varied in the range 25–45°C, for the extreme values, 6.0 and 13.0, i.e. for conditions where the predominant complex ions were $[Ru(CN)_5(Hen)]^{2-}$ (Hen^+ = monoprotonated unidentate en) and $[Ru(CN)_5(en)]^{3-}$, respectively. The kinetic runs were monitored by following the increase of absorbance at 370 nm, the maximum of the $[Ru(CN)_5(pyz)]^{3-}$ ion.[2,‡] Pseudo-first-order rate constants, k_{exp}, were obtained by plotting $\ln(A_\infty - A_t)$ vs time; a linear behaviour was observed for a period always higher than two half-lives. Activation parameters were calculated by least-squares fitting from Eyring plots; errors were obtained by an analysis of variance about regression, employing Student's t values for 90% confidence limits.

A set of experiments was performed for variable concentrations of pyz, from 2×10^{-3} to 0.1 M (T = 25°C, pH 7.0 and 13.0); k_{exp} increased with the concentration of pyz, attaining limiting values for concentrations higher than 0.05 M. This rate saturation behaviour has also been found in the kinetics of the dissociation reactions for other $[Ru(CN)_5L]^{n-}$ ions.[4–6]

(ii) *Formation kinetics.* The $[Ru(CN)_5(H_2O)]^{3-}$ ion was generated in solution through the reaction of aqueous bromine with $[Ru(CN)_6]^{4-}$.[2,5] As the $[Ru(CN)_5(en)]^{3-}$ and $[Ru(CN)_5(Hen)]^{2-}$ complexes do not show a sufficiently high absorption in the visible-near UV region, a direct method could not be used, as with other $[Ru(CN)_5L]^{n-}$ complexes

---

* Low values for carbon are currently found with the cyano complexes; better values could not be obtained through extended heating. Nevertheless, the quoted results for the other elements, as well as the stoichiometric experiment with isonicotianamide (see below), strongly suggests that the solid material is the title compound. The presence of binuclear impurities can be reasonably discarded on the grounds of the synthetic procedure employed (a high excess of en was used), as well as considering the consistency of the kinetic results.

† A low yield of $Na_2[Ru(CN)_5(NO)] \cdot 2H_2O$ is obtained by the published procedure;[3] well behaved solutions of the $Ru(CN)_5(NO)^{2-}$ ion could be prepared by mixing solutions of $Ru(CN)_6^{4-}$ (1×10^{-3} M) with equimolar aqueous bromine and adding solid $NaNO_2$ (final concentration 2×10^{-3} M), at pH 6.

‡ A consistent final value for the absorbance of the $[Ru(CN)_5(pyz)]^{3-}$ ion was obtained when starting with either of the described procedures for generating the $[Ru(CN)_5(en)]^{3-}$ ion; a complementary check was also done by using isonicotinamide (ison) as a scavenger (a reliable value of the molar absorbance for the $[Ru(CN)_5(ison)]^{3-}$ ion has been recently obtained from pure solid samples).[4]

with L being a *N*-heterocyclic ligand. Thus, we used a competitive technique under similar conditions as employed for the study of formation reactions in related complexes.[23] To a solution of the $[Ru(CN)_5(H_2O)]^{3-}$ ion (5×10^{-5} M), mixtures with a variable content of en ($0.5–3 \times 10^{-3}$ M) and a fixed concentration of pyz (1×10^{-3} M) were added (pseudo-first-order conditions) with $I = 0.1$ M (NaCl). The rate of the reaction was followed by measuring the increase of absorbance of the $[Ru(CN)_5(pyz)]^{3-}$ ion, and k_{exp} values were calculated as mentioned above for the dissociation process. Activation parameters were obtained from experiments at pH 7 and 13 (range 25–43°C) for a fixed value of en concentration (1×10^{-3} M); values of k_{en} and k_{Hen^+} were calculated from k_{exp} and previously quoted values of k_{pyz} for the different temperatures.[5]

RESULTS AND DISCUSSION

The IR spectrum

The results for $Na_3[Ru(CN)_5(en)] \cdot 2H_2O$ are presented in Table 1. A tentative assignment is made by comparison with related complexes and free en.[19] The intense band at 2045 cm^{-1} is typical of the stretching mode of cyanide coordinated to a ruthenium(II) centre.[2,24] The bands at 580 and 380 cm^{-1} may be assigned to bending ($\delta_{C—Ru—C}$) and stretching ($\nu_{Ru—C}$) modes, by comparison with similar bands observed for $K_4[Ru(CN)_6]$.[24] An additional band at 465 cm^{-1} is probably related to a $\delta_{C—Ru—N}$ vibration. The other bands correspond to vibrations associated to coodinated en or bound water. The spectrum is rather complex and we are not presently attempting a detailed analysis of the latter bands.

The electronic spectrum

A single absorption maximum was found at 280 nm ($\varepsilon = 550$ M^{-1} cm^{-1}); the energy and intensity were independent of pH in the range 7–12. As will be shown later, the $[Ru(CN)_5(Hen)]^{2-}$ ion is predominantly found at pH 7, while the deprotonated complex, $[Ru(CN)_5(en)]^{3-}$, is formed at pHs higher than 12; thus we conclude that the influence of the state of protonation of the en ligand on the relevant energy levels of the electronic transition is undetectable. The assignment of the band may be readily performed on comparing with results recently reported for other $[Ru(CN)_5L]^{n-}$ complexes (L = H_2O, NH_3, pyz, dimethylsulphoxide, CN^-);[6] in the latter series, the energy of the transition was found to increase in the above-mentioned order. The presently reported value for L = en is in fact very close to that for L = NH_3 (285 nm), as expected from the similar nature of the coordinating atoms. The results are consistent with a ligand-field model for tetragonally distorted low-spin d^6 complexes, which has also been applied to $[Co(CN)_5L]^{n-}$ [25] and $[Fe(CN)_5L]^{n-}$ [8,9] complexes. According to this model, the observed band is assigned to the orbitally allowed $^1A_1 \rightarrow {}^1E_1(1)$ transition; other possible transitions should be either of lower intensity or be buried in the tail of the growing absorption observed for wavelengths lower than 250 nm. The model predicts a dependence of the energy on the type of ligand L; thus, the relative position of the excited state, $^1E_1(1)$ (which is mainly d_{z^2}, antibonding), is influenced by the σ-bonding properties of L; as L becomes stronger, the $^1E_1(1)$ state becomes higher in energy, as found in the $[Ru(CN)_5L]^{n-}$ series.

When comparing with the $[Fe(CN)_5L]^{n-}$ series, it is found that the energies for corresponding bands are shifted to higher values (about 0.12–0.14 μm^{-1}) for the ruthenium(II) complexes;[6] (cf. the value of the $^1A_1 \rightarrow {}^1E_1(1)$ transition in the $[Fe(CN)_5(Hen)]^{2-}$ ion, 402 nm).[19] The degree of back-bonding interaction with $\pi^*(CN^-)$ orbitals is lower in iron(II) compared to ruthenium(II); thus, the value of 10 *Dq* increases when going from the first to the second transition series for a given $[M(CN)_5L]^{n-}$ type of complex; the old assertion proposing similar values of 10 *Dq* for $[Ru(CN)_6]^{4-}$ and $[Fe(CN)_6]^{4-}$ has been recently revised on the grounds of new experimental evidence and alternative assignments for the ligand-field bands in the $[Ru(CN)_6]^{4-}$ ion.[6]

Kinetics of the dissociation and formation reactions

The previously discussed structural features are nicely reflected in the kinetic behaviour of

$[Ru(CN)_5(en)]^{3-}$ and $[Ru(CN)_5(Hen)]^{2-}$ complexes toward the interchange of the L ligand; a dissociative loss of (H)en is accomplished when the complexes are placed in contact with a ligand such as pyz, which binds strongly to $Ru(CN)_5^{3-}$ [eq. (1)]

$$[Ru(CN)_5(H)en]^{n-} + pyz \longrightarrow [Ru(CN)_5(pyz)]^{3-} + (H)en. \quad (1)$$

The pseudo-first-order rate constant, k_{exp}, showed a dependence on the concentration of pyz. The results are shown in Table 2, for two extreme values of pH, 6 and 13. The following conclusions can be drawn from these results: (1) a saturation value is obtained for k_{exp} at high concentrations of pyz; (2) as the concentration of pyz falls to zero, k_{exp} tends towards a value close to k_{-pyz}, the rate dissociation constant for the loss of pyz from the $[Ru(CN)_5(pyz)]^{3-}$ ion;[5] (3) a plot of $1/k_{exp}$ vs 1/[pyz] shows a linear behaviour for low values of 1/[pyz], with a downward curvature for the higher values of 1/[pyz]. All of the latter results are consistent with a dissociative mechanism, as has been fully demonstrated in the behaviour of $[Fe(CN)_5L]^{n-}$ and $[Ru(CN)_5L]^{n-}$ complexes.[4-6] Within the latter framework, the saturation value of k_{exp} is shown to be equal to k_{-L}, the rate dissociation constant for the loss of ligand L.

A particular fact is shown by the dependence of the limiting value of k_{exp} with pH (Fig. 1), which is characteristic of systems where a protonation of the L ligand is feasible (cf. the case of L = en,[27] N_2H_4[18] and some aminoacids[11] coordinated to $Fe(CN)_5^{3-}$).

Table 2. Pseudo-first-order rate constants for the dissociation of $L = Hen^+$ and L = en from the $[Ru(CN)_5L]^{n-}$ ions, at different concentrations of the scavenger ligand, pyrazine[a]

$[Ru(CN)_5(Hen)]^{2-}$[b]		$[Ru(CN)_5(en)]^{3-}$[c]	
10^2[pyz] (M)	$10^5 k_{exp}$ (s^{-1})	10^2[pyz] (M)	$10^5 k_{exp}$ (s^{-1})
15.0	11.4	15.0	6.3
10.0	11.4	10.0	6.3
5.0	11.0	7.5	6.2

1.25	7.1	2.5	5.0
0.60	5.7	1.25	4.2
0.30	4.4	0.60	3.8
0.15	3.5	0.30	3.6
		0.15	3.4

[a] $[Ru] = 5 \times 10^{-5}$ M; $[en] = 2 \times 10^{-3}$ M; $I = 1$ M (NaCl); $T = 25°C$.
[b] pH 6.0.
[c] pH 13.0.

The pH dependence may be accounted for by the following reaction sequence [eqs. (2–4)]:

$$[Ru(CN)_5(Hen)]^{2-} \underset{}{\overset{k_{-Hen^+}}{\rightleftharpoons}} Ru(CN)_5^{3-} + Hen^+ \quad (2)$$

$$[Ru(CN)_5(Hen)]^{2-} \overset{K_a}{\rightleftharpoons} [Ru(CN)_5(en)]^{3-} + H^+ \quad (3)$$

$$[Ru(CN)_5(en)]^{3-} \overset{k_{-en}}{\rightleftharpoons} Ru(CN)_5^{3-} + en, \quad (4)$$

followed by

$$Ru(CN)_5^{3-} + pyz \longrightarrow [Ru(CN)_5(pyz)]^{3-}. \quad (5)$$

In this scheme, the dependence of k_{exp} (saturation value) on pH should be as in eq. (6):

$$k_{exp} = (k_{-Hen^+}[H^+] + k_{-en}K_a)/([H^+] + K_a). \quad (6)$$

A good fit of eq. (6) to the data in Fig. 1 was obtained by taking $k_{-Hen^+} = 1.07 \times 10^{-4}$ s^{-1}, $k_{-en} = 6.20 \times 10^{-5}$ s^{-1} and $pK_a = 9.7$. When comparing with k_{-Hen^+} and k_{-en} for the $[Fe(CN)_5L]^{n-}$ system (1.04×10^{-2} s^{-1}, 5.6×10^{-3} s^{-1}, respectively), the presently reported values are shown to be considerably lower. The result may be explained by taking into account the higher Ru—N σ-interaction. The rate quotient, $k_{-Hen^+}/k_{-en} = 1.8$, is very close to the one found for the pentacyanoferrate system (1.9). An analysis of the significance of changes in this reactivity quotient, related to the influence of solvation effects in the dissociation reactions of several $[Fe(CN)_5(diamine)]^{3-}$ complexes, may be found elsewhere.[26]

It is a well-known fact that the rate dissociation

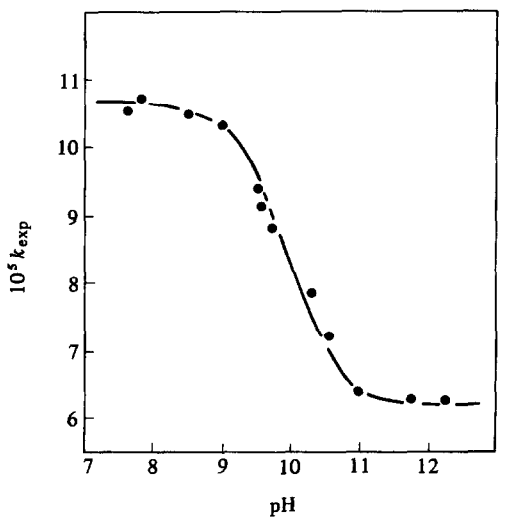

Fig. 1. Plot of k_{exp}, the pseudo-first-order rate dissociation constant, against pH. $[Ru] = 5 \times 10^{-5}$ M; $[en] = 2 \times 10^{-3}$ M; [pyz] = 0.1 M (saturation conditions); $T = 25°C$; $I = 1$ M (NaCl).

constant values, k_{-L}, are strongly dependent on the nature and type of bonding of L. The presently reported values for L = en and L = Hen$^+$ are close but slightly lower than $k_{-NH_3} = 3.7 \times 10^{-4}$ s^{-1} (25°C); [6] this is in keeping with the "σ-only" bonding character of the ligands and with the fact that en is slightly more basic than NH_3. The k_{-L} values for other $[Ru(CN)_5L]^{n-}$ complexes with π-acceptor ligands (L = pyz, dimethylsulphoxide, CN^-) were shown to be substantially lower (range 10^{-5}–10^{-8} s^{-1}). [6] It is also remarkable that the k_{-L} values for the complexes with (H)en can be adequately fit to the linear correlation between $\log k_{-L}$ and the energy of the $^1A_1 \rightarrow {}^1E_1(1)$ transition, which was shown to hold for several $[Ru(CN)_5L]^{n-}$ complexes. [6]

The value found for $pK_a = 9.7$ is 0.3 units lower than pK_a for aqueous Hen$^+$. [28] The shift is only modest but seems to be significant and merits discussion. The lowering of pK_a for a ligand upon coordination should be considered as a normal fact; however, no shift could be detected with the $[Fe(CN)_5(Hen)]^{2-}$ ion, [27] while a lowering of two pK_a units was found with the $[Fe(CN)_5(N_2H_5)]^{2-}$ ion. [18] These results were interpreted as being due to the influence of the different distances of the positive charge to the metal centre in both iron(II) complexes. [18] In the present case, the lowering for $[Ru(CN)_5(Hen)]^{2-}$, in contrast to $[Fe(CN)_5(Hen)]^{2-}$, may be interpreted as additional evidence for the higher σ-interaction in the ruthenium(II) complex compared to the iron(II) one.

From k_{-L} values at different temperatures (Table 3), activation parameters for the dissociation reactions were calculated: $\Delta H_d^{\ddagger} = 111 \pm 3$ kJ mol^{-1}, $\Delta S_d^{\ddagger} = 55 \pm 5$ J mol^{-1} deg^{-1} for L = Hen$^+$, and $\Delta H_d^{\ddagger} = 122 \pm 5$ kJ mol^{-1}, $\Delta S_d^{\ddagger} = 49 \pm 7$ J mol^{-1} deg^{-1} for L = en. The $\Delta H_d^{\ddagger}$ and $\Delta S_d^{\ddagger}$ values for both complexes fall within the range found for other members of the $[Ru(CN)_5L]^{n-}$ series. Although the values are consistent with the proposed dissociative mechanism, the interpretation of activation parameter data should be carefully considered, in view of the influence of solvent effects (cf. ref. 26 for the $[Fe(CN)_5(H)(en)]^{n-}$ system).

The rate of formation of the $Ru(CN)_5^{3-}$ complexes with Hen$^+$ and en, starting from the $[Ru(CN)_5(H_2O)]^{3-}$ ion and en at the appropriate pH, were found to be first order in each of the reagents. Under competitive conditions with pyrazine (see Experimental), eq. (7) holds:

$$k_{exp} = k_{en}[en] + k_{pyz}[pyz]. \quad (7)$$

A similar relation holds for L = Hen$^+$. The specific second-order rate constants, k_{Hen^+} and k_{en}, were obtained by plotting k_{exp} (25°C) against the concentration of (H)en, as shown in Fig. 2; thus, $k_{Hen^+} = 0.83$ M^{-1} s^{-1} and $k_{en} = 0.89$ M^{-1} s^{-1}. These values are of the same order as previously found for other $[Ru(CN)_5L]^{n-}$ complexes. [5] The results may be interpreted in terms of an ion pair–dissociative interchange mechanism [eqs (8) and (9)]:

$$[Ru(CN)_5(H_2O)]^{3-} + L \overset{K_{ip}}{\rightleftharpoons} \{[Ru(CN)_5(H_2O)]^{3-}, L\} \quad (8)$$

$$\{[Ru(CN)_5(H_2O)]^{3-}, L\} \overset{k_{-H_2O}}{\rightleftharpoons} [Ru(CN)_5L]^{n-} + H_2O. \quad (9)$$

In this mechanism, $k_L = K_{ip} k_{-H_2O}$; the rate-determining loss of water in the outer-sphere complex, k_{-H_2O}, should be little influenced by the type of ligand L. This should also be the case with K_{ip}, if the charge on L is not varied. On the above grounds, we should expect higher values for k_{Hen^+} than for k_{en}; both values are, however, nearly equal and the reason is probably associated to the remote distance

Table 3. Specific rates of dissociation and formation of pentacyanoruthenate(II) complexes of Hen$^+$ and en, at different temperatures

Dissociation reactions[a]				Formation reactions[b]			
pH 6.0		pH 13.0		pH 7.0		pH 13.0	
T (°C)	$10^5 k_{-Hen^+}$ (s^{-1})	T (°C)	$10^5 k_{-en}$ (s^{-1})	T (°C)	k_{Hen^+} (M^{-1} s^{-1})	T (°C)	k_{en} (M^{-1} s^{-1})
25	11.4	25	6.3	25	0.83	25	0.89
31	32.1	30	16.4	29	1.39	29	1.46
35	55.8	35	31.1	33.5	2.31	32.5	2.43
39.5	98.6	39.5	63	39	3.67	39	4.60
43	173	43	126	43	5.18	44	7.53

[a] [Ru] = 5×10^{-5} M; [en] = 2×10^{-3} M; [pyz] = 0.1 M (saturation conditions); I = 1 M (NaCl).

[b] [Ru] = 5×10^{-5} M; [en] = 1×10^{-3} M; [pyz] = 1×10^{-3} M; I = 0.1 M (NaCl). Values of k_{en} and k_{Hen^+} were obtained from eq. (9), taking k_{pyz} at the different temperatures from ref. 5.

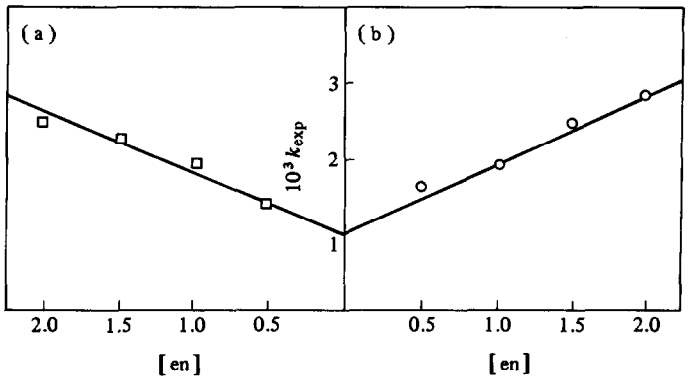

Fig. 2. Plot of k_{exp}, the pseudo-first-order rate formation constant, against the concentration of ethylenediamine [eq. (7)]. (a) pH 7.0; (b) pH = 13.0 [Ru] = 5×10^{-5} M; [pyz] = 1×10^{-3} M; $T = 25°C$; $I = 0.1$ M (NaCl).

of the positive charge to the coordinating site (the rate of coordination of en should also be favoured on statistical grounds). Deviations from the expected k_L values have also been observed in the formation reactions of some pentacyano(amino acid)ferrate(II) complexes.[11]

From data presented in Table 3, the activation parameters for the formation reactions were: $\Delta H_f^{\ddagger} = 85 \pm 3$ kJ mol^{-1}, $\Delta S_f^{\ddagger} = 42 \pm 6$ J mol^{-1} deg^{-1} for L = Hen$^+$, and $\Delta H_f^{\ddagger} = 83 \pm 2$ kJ mol^{-1}, $\Delta S_f^{\ddagger} = 33 \pm 5$ J mol^{-1} deg^{-1} for L = en. The $\Delta H_f^{\ddagger}$ values are about 15 kJ higher than the values found for the entry of N-heterocyclic ligands into the $[Ru(CN)_5(H_2O)]^{3-}$ ion.[5] The positive $\Delta S_f^{\ddagger}$ values, in turn, contrast with the negative values found in the same system (cf. however, ref. 4). It is likely that an "isokinetic" relation, leading to mutually compensatory $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$ values is operative in the formation reactions of $[Ru(CN)_5L]^{n-}$ systems. This type of behaviour is usually found in a series of related reactions governed by a common mechanism and seems to be characteristic of the influence of solvation effects.[29]

From k_{-L} and k_L values, the stability constants, K_{st} (M^{-1}), corresponding to reaction (10) may be calculated:

$$[Ru(CN)_5(H_2O)]^{3-} + L \underset{k_{-L}}{\overset{k_L}{\rightleftharpoons}} [Ru(CN)_5L]^{n-} + H_2O. \quad (10)$$

Values of K_{st} of 7.5×10^3 and 1.4×10^4 M^{-1} were found for L = Hen$^+$ and L = en, respectively. Although the complexes are shown to be moderately stable, it is likely that aquation and dimerization processes could be set up in aqueous solutions, in the absence of excess ethylenediamine. In the above-mentioned conditions, and provided that ethylenediamine is the bridging ligand, favourable conditions could be found for auto-oxidation processes leading to coordinated di-imine products.

Abstract—The extraction of iron(III) from aqueous solutions by di(2-ethylhexyl)phosphoric acid (DEHPA, HA) in hexane at constant ionic strength (0.5 M $NaNO_3$), has been investigated under acidic conditions by means of metal distribution measurements. Iron(III) was extracted by ion-exchange reactions via the species: $FeA_3(HA)_3$, $Fe_2A_3(HA)_5$ and $Fe_3A_3(HA)_3$ in the organic phase. The corresponding stability constants were determined as: $\log \beta_1 = 16.87$, $\log \beta_2 = 25.02$ and $\log \beta_3 = 18.39$, respectively.

Iron(III) often co-exists with other metal ions and its separation e.g. by solvent extraction, is of practical significance. Investigations on the extraction of iron by di(2-ethylhexyl)phosphoric acid (DEHPA, HA) have been reported by several authors.[1–6] In some of these studies the stability constants of the extracted species were determined. In other cases only the stoichiometric relationship of metal–extractant in the organic phases is given. The information on the species responsible for the extraction of iron(III) by DEHPA is not well established. Baes[1,2] suggests the formation of the $FeA_3(HA)_3$ and $Fe_3A_8ClO_4$ species when the Fe^{III}/DEHPA ratio is higher than 0.1. Sato and co-workers[3,4] studied the extraction of iron(III) from two different aqueous solutions; in hydrochloric acid solutions, the $FeA_3(HA)_3$[3,4] and $Fe_2A_{10}H_4$[3] species were obtained, while in highly concentrated nitric acid solutions, only the $Fe(NO_3)_3 \cdot 3HA$ species were reported to be formed.

A related study of the kinetics of the extraction of iron(III) by DEHPA was performed by Coleman and Roddy,[5] who suggested that the $FeA_3(HA)_3$ species existed in the organic phase. Table 1 summarizes the various studies performed using different aqueous media and diluents at 25°C.

On the other hand, the extraction of iron(II) by DEHPA has been recently reported by Sastre and Muhammed,[7] who explain the process by the formation of the $FeA_2(HA)_2$ and $FeA_2(HA)_4$ species in the organic phase. Such species are found to be independent of the aqueous ionic media.

In the present work we report a systematic study of the extraction of iron(III) from acidic solutions in 0.5 M $NaNO_3$ by di(2-ethylhexyl)phosphoric acid (DEHPA) in hexane.

EXPERIMENTAL

Reagents and solutions

Ferric nitrate (Merck, AR) was used to prepare stock solutions in 0.5 M NO_3^-. The iron(III) content and free acid were determined by standard procedures.[8,9] Pure $NaNO_3$ (Probus, AR), purified as described in ref. 10, was used as the ionic media. A $^{59}Fe(NO_3)_3$ radioactive stock solution was prepared from the corresponding ferric citrate (General Radioquimica S.A., Paris), 0.2 mCi cm^{-3}

activity, and used in the radiometric analysis. Solutions of HNO_3 in 0.5 M NO_3^- were employed to adjust the pH of the aqueous solutions. The pH of the aqueous solutions was measured by a CRISON Model DIGILAB 517 pH meter, provided with a combined INGOLD glass electrode. Solutions of di(2-ethylhexyl)phosphoric acid (DEHPA, HA) were prepared from DEHPA (BDH) in hexane (Probus, AR). The γ-activity of radioactive solutions was measured with a well-type NaI scintillation counter (Berthold Model LB 6628 U).

Method of investigation

The distribution of iron(III) has been studied as a function of both the metal concentration in the aqueous phase and the ligand concentration in the organic phase. The general composition of the aqueous phase (AS) was:

$$AS = B \text{ mM } Fe^{3+};\ H \text{ mM } H^+;$$

$$(500 - H - 3B) \text{ mM } Na^+;\ 500 \text{ mM } NO_3^-.$$

A few drops of $^{59}Fe(NO_3)_3$ solution were added to the aqueous phase and the pH was kept constant at 0.7 in all aqueous solutions. The composition of the organic phase was C mol dm^{-3} of DEHPA in hexane, where C varies from 0.075 to 0.0075 M.

The experimental procedure was as follows: equal volumes (10 cm^3) of organic and aqueous solutions were placed in stoppered glass tubes and were shaken mechanically with a rotary rack for 12 h. The phases were centrifuged, separated and measurement of the γ-radiation of each phase was then performed to determine the distribution coefficient, D, of iron(III) for each experiment. D is obtained by:

$$D = I_o/I_a, \tag{1}$$

where I_o represents the number of cpm in the organic phase and I_a the cpm in the aqueous phase. Some examples of the experimental data are collected in Fig. 1 in the form of log D vs log [HA].

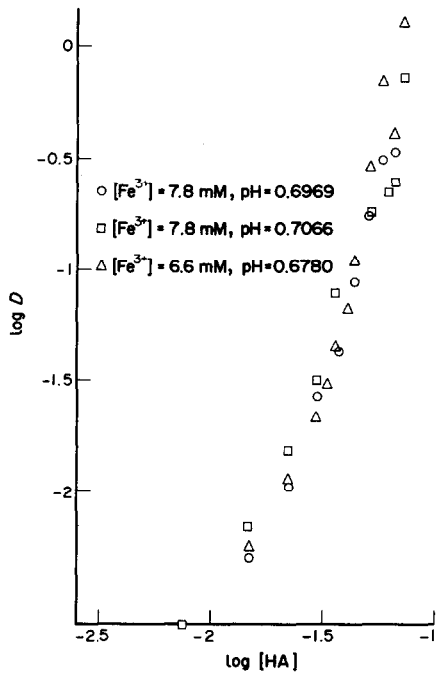

Fig. 1. Experimental data for the extraction of iron(III) from aqueous NO_3^- 0.5 M by DEHPA.

RESULTS

The extraction of iron(III) by DEHPA in hexane may be represented by:

$$nFe^{3+} + m(HA)_{2\,org} \rightleftarrows Fe_nA_3(HA)_{2m-3\,org} + 3H^+;\quad \beta_n, \tag{2}$$

where:

$$\beta_n = \frac{[Fe_nA_3(HA)_{2m-3\,org}][H^+]^3}{[Fe^{3+}]^n[(HA)_{2\,org}]^m}. \tag{3}$$

DEHPA is known to exist as dimers in aliphatic diluents:[11]

$$2(HA)_{org} \rightleftarrows (HA)_{2\,org};\quad K_d = \frac{[(HA)_{2\,org}]}{[(HA)_{org}]^2}. \tag{4}$$

The distribution coefficient, D, is defined by:

$$D = \frac{[Fe^{III}_{org}]}{[Fe^{III}_{aq}]} = \frac{\Sigma n[Fe_nA_3(HA)_{2m-3\,org}]}{[Fe^{3+}]}, \quad (5)$$

where $[Fe^{III}_{org}]$ and $[Fe^{III}_{aq}]$ are the total concentration of iron(III) in the organic and aqueous phases, respectively. In the acidity range used in the aqueous solution, we have assumed that the hydrolysis of iron(III) is practically suppressed. Using eqs (2) and (3), the distribution coefficient, D [eq. (5)], can be expressed in a logarithmic form:

$$\log D = \log K_{n,m} + m \log[(HA)_2] + 3pH. \quad (6)$$

Further, by taking into account the high K_d value of eq. (4), it is possible to rewrite eq. (6) as follows:

$$\log D - 3pH = \log K_{n,m} + m \log(C/2). \quad (7)$$

The experimental data were plotted in the form $\log D - 3pH$ vs $\log(C/2)$ (Fig. 2). An average slope, m, of this representation is found to be approximately three, which indicates that three molecules of DEHPA dimers may be associated with iron(III) in the organic phase.

Computer calculations

The distribution data were analysed numerically using the computer program LETAGROP–DISTR[12] on the basis of eq. (2). In these calculations a set of species is assumed to exist and their formation constants are determined by minimization of the error-square sum defined by:

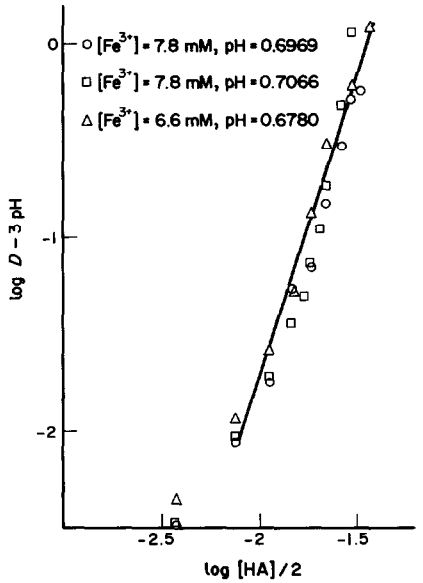

Fig. 2. Graphical treatment of experimental data. The average slope is equal to three.

$$U = \Sigma_{Np}(\log D_{calc} - \log D_{exp})^2, \quad (8)$$

where D_{exp} are the experimental values of the distribution coefficient and D_{calc} is a corresponding value calculated by the program. Np is the number of experimental points.

As a starting point in this treatment, we have considered the speciation and stability constants for this system that are reported in the literature.[1–6] Table 2 summarizes the results from the numerical

Table 2. Results of the numerical treatment of experimental data in the extraction of iron(III) by DEHPA

Model	U	σ	$\log\beta_n$	Remarks

treatment. As seen, the best fit for our experimental data is accomplished by the model including the $FeA_3(HA)_3$, $Fe_2A_3(HA)_5$ and $Fe_3A_3(HA)_3$ species in the organic phase.

These results are expressed by the following reaction equations and corresponding formation constants:

$$Fe^{3+} + 3(HA)_{2\,org} \rightleftarrows FeA_3(HA)_{3\,org} + 3H^+; \quad \log\beta_1 = 16.87 \quad (9)$$

$$2Fe^{3+} + 4(HA)_{2\,org} \rightleftarrows Fe_2A_3(HA)^{3+}_{5\,org} + 3H^+; \quad \log\beta_2 = 25.02 \quad (10)$$

$$3Fe^{3+} + 3(HA)_{2\,org} \rightleftarrows Fe_3A_3(HA)^{6+}_{3\,org} + 3H^+; \quad \log\beta_3 = 18.39. \quad (11)$$

DISCUSSION

The extraction of iron(III) from acidic solutions in 0.5 M NO_3^- by DEHPA in hexane, is found to proceed via the formation of the species, in the organic phase, represented by eqs (9)–(11). This seems to follow the general behaviour of the extraction of metals by alkylphosphoric acids.[13]

Two of these species, $Fe_2A_3(HA)_5$ and $Fe_3A_3(HA)_3$, appear to be electrically charged and it is assumed that they form ion pairs with nitrate ions. From these considerations the results obtained will be conditional on the media employed in this study.

Our results generally agree with the data reported in Table 1. The $FeA_3(HA)_3$ species have been suggested by several authors,[1–5] however, the species of the type $FeA_{10}H_4$ proposed by Sato,[3,4] was rejected in our calculations (cf. Table 2). In this case it is observed that such stoichiometry does not follow the general equation (2). For the sake of comparison, Fig. 3 represents experimental points in the form log $D-3$pH vs log [HA], the various solid lines represent calculated values based on different literature models. As seen in this representation, the model proposed in this work is the most consistent with the experimental data.

The distribution of species in the organic phase, as function of extractant concentration, is represented in Fig. 4. As can be seen in this figure, predominance of the $FeA_3(HA)_3$ and $Fe_2A_3(HA)_5$ species is found, whereas the $Fe_3A_3(HA)_3$ species is only slightly relevant (less than 1%) in the iron(III) and DEHPA iron(III) concentration ranges studied.

The model obtained in this study shows a general tendency to form polynuclear species in the organic phase, on the other hand, it seems to be logical that nucleation of species is a successive process which,

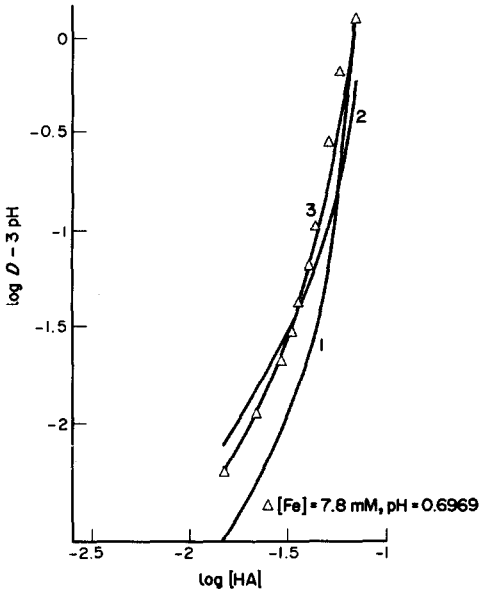

Fig. 3. Correlation of experimental and calculated points from different models. Model 1 corresponds to ref. 3, model 2 to ref. 2 and model 3 to this work.

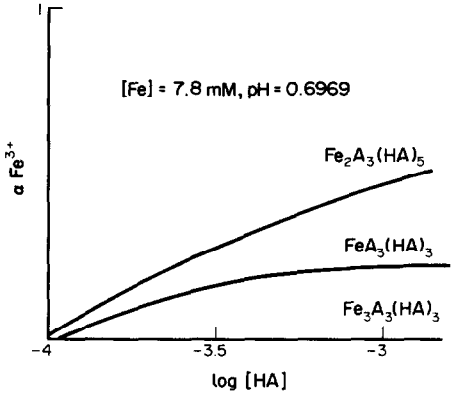

Fig. 4. Distribution of species in the organic phase as a function of the extractant concentration.

in our case, is represented by the $Fe_2A_3(HA)_5$ and $FeA_3(HA)_3$ species. Comparison of these results with those reported for Fe^{II}–DEHPA[7] extraction shows a fundamental difference which is related to the nucleation of the metal species in the organic phase. Thus, iron(II) does not present polynuclear species, while iron(III), in the organic phase, confirms its tendency to form polynuclear complexes in aqueous solutions.

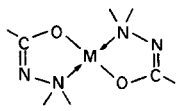
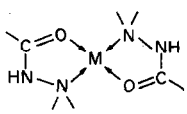
Abstract—The coordination complexes of formylferrocene benzoylhydrazone (HL) with lanthanide elements, $LnL_3 \cdot nH_2O$ (where Ln = lanthanide and Y, n = 1–3), have been prepared by the reaction of HL with the metal(III) chlorides in acetonitrile. The elemental analyses, IR and UV spectra, molar conductance and thermal analyses show that the ligand coordinates to the metals in the enolic form with a molar ratio of 3:1. We propose a plausible structure and discuss the thermal properties for the complexes.

Due to their biological activities and variable bonding when forming complexes with metal ions, the coordination chemistry of acid hydrazones have attracted the attention of many investigators.[1–6] Acid hydrazones can coordinate to metal ions in (a) the enolic form or (b) the keto form:



(a)



(b)

In general, they coordinate to central ions in the keto form when complexing with metal chlorides, nitrates, sulphates and thiocyanates etc., but in the enolic form with metal acetates in ethanol.

We have previously reported on the lanthanide complexes of some aroylhydrazones coordinated in the keto form which have not been studied so far by other investigators.[7–9] The present work describes Y^{III} and lanthanide(III) complexes with formylferrocene benzoylhydrazone coordinated in the enolic form, which were prepared by the reaction of the hydrazone with metal chlorides in acetonitrile rather than with acetates.

EXPERIMENTAL

Materials

The lanthanide(III) chlorides were prepared from their oxide and hydrochloric acid. Formylferrocene was prepared according to the literature method.[10] The other chemicals were analytic reagent grade.

Preparation of formylferrocene benzoylhydrazone (HL)

The HL was prepared by refluxing equimolar quantities of formylferrocene and benzoylhydrazine in ethanol until the appearance of some precipitate, concentrating the solution to one-third of its original volume and collecting the reddish-orange crystals obtained on a Büchner funnel, washed several times with cold ethanol and dried. Yield 85.2%, m.p. 186–187°C. Found: C, 65.0; H, 4.9; N, 8.4. Calc. for $C_{18}H_{16}FeN_2O$: C, 65.1; H, 4.8; N, 8.4%. ^{1}H NMR: δ(DMSO), 4.23 (s, 5H)

* Author to whom correspondence should be addressed.

(C_5H_5Fe); 4.46 (t, 2H) (protons on 3,4-positions of C_5H_5Fe); 4.65 (t, 2H) (protons on 2,5-positions of C_5H_5Fe); 7.45–7.95 (m, 5H) (phenyl); 8.30 (s, 1H) (azomethine); 11.58 (s, 1H) (—NH which disappears on deuteration) ppm.

Preparation of complexes

Lanthanide(III) or yttrium(III) chlorides (0.20 mmol) were dissolved in 20 cm^3 of acetonitrile and 2 cm^3 of triethyl orthoformate under heating. 0.8 mmol of HL in 20 cm^3 of acetonitrile was added dropwise into the above solution and maintained for 7–10 h under heating and stirring until the reddish-orange solution changed to brown. After cooling, the precipitate was filtered and washed several times with cold acetonitrile and ether. Yield > 76%. The elemental analyses of these complexes along with their formulae are listed in Table 1.

Physical measurements

IR spectra were made on KBr pellets using a Nicolet 5DX spectrophotometer in the 400–4000 cm^{-1} region. UV spectra were measured with a DU-7B ultraviolet–visible spectrometer in the 190–700 nm region using a solution in DMF. Electrolytic conductance measurements were carried out by a DDS-IIA molar conductometer and DMF as solvent at 25°C. Thermal characterization studies were made with a Du Pont 1090 thermal analyzer in a nitrogen atmosphere.

[a] Calculated values are given in parentheses.

RESULTS AND DISCUSSION

The complexes of lanthanide elements with formylferrocene benzoylhydrazone are amorphous brown powders. They are insoluble in water and petroleum ether, sparingly soluble in diethyl ether, benzene and methylene chloride, but soluble in methanol, ethanol, DMSO and DMF. Their elemental analyses show that $LnCl_3 \cdot nH_2O$ form complexes with loss of chloride ions and they conform to the formula $LnL_3 \cdot 1\text{–}3H_2O$.

IR spectra

The IR spectra (Table 2) show that the characteristic frequencies of these complexes exhibit significant changes as compared with those of the parent ligand. The bands at 3213, 1648, 1557 and 1287 cm^{-1} attributed to ν(N—H), ν(C=O)(amide I), amide II and ν(C—N)(amide III) have disappeared, whereas three new bands at around 1595, 1360 and 1237 cm^{-1} due to ν(C=N—N=C), ν(N=CO^-) and ν(C—O) are observed. The strong and broad bands at 3376–3395 cm^{-1} indicate the presence of water molecules associated in the complexes. It is clear that the ligand undergoes enolization in acetonitrile and then coordinates to lanthanide ions in enolic form, accompanied by the release of all chloride ions. In addition, the characteristic frequencies of the ferrocenyl appear at *ca* 1440, 1150, 820 and 480 cm^{-1}, and those of phenyl at *ca* 1600 and 1490 cm^{-1} in the ligand and all complexes.

UV spectra

The UV spectra of the ligand and its complexes are shown in Table 3. It can be seen that the UV spectra of all complexes are similar, but different from that of the ligand. The characteristic bands of the complexes at 295–297 nm arising from π–π^* transition (B band) of the cyclopentadienyl ring hardly shift as compared with their ligand. The band at 316 nm in the ligand is attributed to the *K* band (π–π^* transition), which is shifted to a longer wavelength by 30–43 nm in complexes. It is possible that the metal *f*-orbital overlap with the *p*-orbital of the ligand makes the whole molecule form a large conjugate system after enolizing and coordinating, and the formation of which decreases the transition energy required between π and π^* orbitals. Thus, this leads to a more bathochromic shift of the *K* band of the complexes. Band 3 at 455 nm of the ligand is weak and broad due to a charge-transfer transition between cyclopentadienyl ring and iron, which vanishes in the complexes, perhaps by virtue of a bathochromic shift of the *K* band and a hyp-

sochromic shift of band 3 after forming complexes. It is possible that a bathochromic shift of the *K* band and a hypsochromic shift of band 3 are due to the formation of a large conjugate system in the molecule.

Molar conductance

Dissolving the lanthanide complexes in DMF afforded a brown solution. The molar conductance values (Table 4) of the complexes in DMF lie in the range 20–41 $ohm^{-1}\ cm^2\ mol^{-1}$. A comparison of these values with those previously reported in the literature[11] for 1:1 electrolytes in DMF (65–90 $ohm^{-1}\ cm^2\ mol^{-1}$) shows the non-electrolytic nature of the complexes in DMF.

[a] Calculated values are given in parentheses.

Thermal analysis

Thermal analysis data of the complexes, $LaL_3 \cdot 3H_2O$, $SmL_3 \cdot 2H_2O$ and $LuL_3 \cdot H_2O$, are shown in Table 5. It can be seen that the thermal properties of these complexes are analogous. First of all, they lose their water molecules at about 60°C showing that the water molecules are not coordinated to the metal ions. The anhydrous complexes decompose and lose three $C_6H_5CO^+$ groups at about 290–310°, and the remaining organic groups at 310°C. The residues decompose completely at 606–830°C leaving Fe_3Ln.

Summarizing our results, three molecules of the ligand coordinate to a lanthanide(III) ion through their nitrogen atom in azomethine and oxygen atom (in enolic form) in acetonitrile, accompanied by the release of three chloride ions, their coordination numbers are equal to six. Thus, we propose a plausible structure for our complexes as shown in Fig. 1.

SYNTHESIS AND THERMAL STABILITY OF CYCLOPENTADIENYL LANTHANIDE COMPLEXES CONTAINING *o*-ALDEHYDOPHENOLATO OR FURFURALCOHOLATO LIGAND

ZHONGZHI WU,* ZHONGWEN YE and ZHENNAN ZHOU

Institute of Organic Chemistry, Anhui Normal University, Wuhu, Anhui Province, P.R.C.

(*Received* 26 *January* 1989; *accepted* 15 *March* 1989)

Abstract—Eight new complexes of the type $Cp_nLn(sal)_{3-n}$ or $Cp_nLn(fur)_{3-n}$ ($n = 1, 2$; $Cp = C_5H_5$, Ln = Nd, Yb; sal = *o*-aldehydophenolato, fur = furfuralcoholato) have been synthesized and characterized. These complexes are not very stable to heat and tend to disproportionate at moderately high temperatures. Their relative stability has been determined and discussed. The disproportionation reactions are reversible.

It is well known that the labile behaviour of η^5-cyclopentadienyl complexes of *f*-transition metals might (under certain condition) lead to a mixture of disproportionation products.[1] Up to now, however, the published articles dealing with the disproportionation reaction of η^5-cyclopentadienyl lanthanide complexes are rare. Recently, we have reported that either dicyclopentadienyl samarium acetate and halides or lanthanide organometallics involving both cyclopentadienyl and β-diketonato chelate ligands are not very stable to heat and tend to disporportionate at moderately high temperatures.[2,3] The purpose of this paper is to extend the investigation of thermal stability and disproportionation reactions to the cyclopentadienyl lanthanide complexes involving *o*-aldehydophenolato or furfuralcoholato chelate ligands.

RESULTS AND DISCUSSION

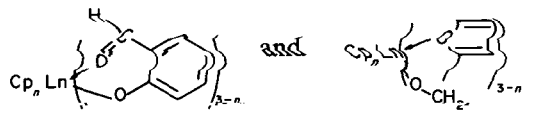
By adopting the very versatile method of liberating cyclopentadiene from a Cp_3Ln moiety by the action of acids stronger than C_5H_6, we have synthesized eight complexes by the reaction of Cp_3Nd or Cp_3Yb with salicylaldehyde (Hsal) or furfuralcohol (Hfur). They are:

1 : 1 ratio of reactants		1 : 2 ratio of reactants	
$Cp_2Nd(sal)$	(I)	$CpNd(sal)_2$	(II)
$Cp_2Nd(fur)$	(III)	$CpNd(fur)_2$	(IV)
$Cp_2Yb(sal)$	(V)	$CpYb(sal)_2$	(VI)
$Cp_2Yb(fur)$	(VII)	$CpYb(fur)_2$	(VIII)

All these complexes were characterized by elemental analysis, IR (Table 1), XPS (Table 2) and MS (Table 3) spectroscopy.

The IR spectra of all the complexes show absorptions at about 750, 780, 1010, 1440, 3100 cm^{-1}, characteristic of η^5-cyclopentadienyl ligand.[4] The band of C=O stretching vibration for the free CHO in complexes I, II, V and VI is shifted from 1695 cm^{-1} to a lower frequency 1595–1632 cm^{-1}.[5] The band of C—O—C stretching vibration for the epoxy ring in complexes III, IV, VII and VIII is shifted from 1050 cm^{-1} to a lower frequency 1005–1011 cm^{-1}. So, in these complexes one could postulate the O → M dative bond.

As both *o*-aldehydophenolato and furfuralcoholato are bidentate ligands, the cryoscopic method for molecular weight determination in benzene of all the complexes has been made. It appears that all eight complexes are present as monomers. From the data of XPS (Table 2), it is revealed that in each complex the binding energy of the metal is decreased, as compared with the corresponding substances for reference. Thus, it is confirmed that all the eight complexes are chelates. This is in agreement with the fact that the greatest tendency to form chelate complexes is found in polyfunctional ligands whose donor atoms are separated by two or three carbon atoms. The ring produced by chelate formation will be five- or six-membered. The structure proposed for these complexes may be:



$n = 1, 2$; Ln = Nd, Yb

[a] MS data are given for the isotopes ^{142}Nd, ^{174}Yb, ^{16}O, the peak patterns correspond to theoretical values based on the natural abundance of isotopes.

For the purpose of studying the thermal stability of these complexes, the mass spectra of them were recorded at different temperatures of vaporization. We found that complexes of the type Cp_2LnL (L = *o*-aldehydophenolato or furfuralcoholato) are thermally more stable than those of the type $CpLnL_2$. During the course of raising the temperature, $CpLnL_2$ first disproportionates into Cp_2LnL and LnL_3, and then into Cp_3Ln and LnL_3. The disproportionation reaction presumably involves the following equilibria:

$$2CpLnL_2 \rightleftharpoons Cp_2LnL + LnL_3$$

$$3Cp_2LnL \rightleftharpoons 2Cp_3Ln + LnL_3.$$

The reversibilities of the above disproportionation have been verified by their reverse reactions. The purified products of the reverse reactions, $CpLnL_2$ and Cp_2LnL, are all characterized by elemental analysis and MS.

We suggest that lability of η^5-Cp ligands is the cause of the disproportionation reactions. It is also possible that the disproportionation reaction takes place via an intermediate bimolecular complex in which the Cp groups are bonded in an η^5-fashion to one molecule and in an η^1-fashion to the second molecule of the complex. The transfer of one Cp group from one molecule to another may initiate the disproportionation. Since the transfer of one Cp group is more facile than the transfer of two groups at the same time, $CpLnL_2$ is thermally less stable than Cp_2LnL.

In view of the MS data, complexes of Yb, either of the type Cp_2LnL or $CpLnL_2$, are thermally more stable than the analogues of Nd. At about 160°C, the disproportionations of four Nd complexes (I–IV) are apparently complete. But even at 250°C, all four Yb complexes (V–VIII) are only partially disproportionated. We suppose that the greater thermal stability of Yb complexes compared with their Nd analogues is due to the lanthanide contraction. Compared with Nd^{3+}, the radius of Yb^{3+} is smaller and the attraction of the Ln—L bond formed by Yb^{3+} and an anionic ligand will be stronger. Another reason for the superior thermal stability of the Yb complexes may be due to the greater steric saturation present around the smaller metal centre.[6,7]

Probably due to the large radii and coordination unsaturation of lighter lanthanides, their organometallics involving both Cp and Cl ligands, such as Cp_2LnCl and $CpLnCl_2$ (Ln = La, Ce, Pr and Nd) have not been synthesized. Here, the facile preparation of the unsolvated and room-temperature stable Cp_nNdL_{3-n} ($n = 1$, 2; L = *o*-aldehydophelato, furfuralcoholato) is obviously due to stabilization of the species by the chelation effect.

EXPERIMENTAL

All operations on these organolanthanide complexes were performed under prepurified argon using Schlenk techniques or in a glovebox. All solvents were refluxed and distilled over finely divided $LiAlH_4$ or blue sodium benzophenone under argon immediately before use. Salicylaldehyde and furfuralcohol were dried and distilled under argon. Cp_3Nd and Cp_3Yb were prepared by a published procedure.[8]

Metal analyses of lanthanides were accomplished by using the direct complexometric procedure with disodium EDTA. The elemental analysis data for C and H were obtained on a Yanaco MT-2 analyzer. IR were recorded on a Perkin–Elmer 983(G) (CsI crystal plate, Nujol and Fluorolube mulls) instrument. XPS data were obtained on a VG MK-II X-ray photoelectron spectrometer. MS were recorded on a VG ZAB-HS organic mass spectrometer.

Preparation of complexes I, II, V and VI

A 20 cm^3 THF solution of salicylaldehyde (1.5 or 3.0 mmol) was added dropwise with stirring to a 30 cm^3 THF solution of Cp_3Nd or Cp_3Yb (1.5 mmol). The reaction mixture was allowed to stir for 24 h at room temperature. The resulting solution was concentrated *in vacuo* to about 15 cm^3. By addition of 30 cm^3 of *n*-hexane, a solid precipitated out which was recrystallized from THF/*n*-hexane and washed with *n*-hexane to afford the product. Yields, analyses and physical properties of all four complexes are listed in Table 1.

Preparation of complexes III, IV, VII and VIII

A 20 cm^3 THF solution of furfuralcohol (1.5 or 3.0 mmol) was added dropwise with stirring to a 30 cm^3 THF solution of Cp_3Nd or Cp_3Yb (1.5 mmol), and gradually a precipitate was produced. After stirring for 24 h at room temperature, the reaction mixture was centrifuged. The precipitate was separated from the solution, washed twice with THF and dried under vacuum. Yields, analyses and physical properties of all four complexes are listed in Table 1.

Preparation of $Ln(sal)_3$

A THF solution of three equivalents of salicylaldehyde and one equivalent of Cp_3Nd or Cp_3Yb

was stirred at room temperature for 24 h. The resulting solution was concentrated *in vacuo*. By addition of equi-volume *n*-hexane, an orange product precipitated out, which was recrystallized from THF/*n*-hexane and dried *in vacuo* to afford $Ln(sal)_3$. Their analytical data are as follows: $Nd(sal)_3$: Yield 90%. Found: Nd, 28.5; C, 50.3; H, 3.0. Calc. for $C_{21}H_{15}O_6Nd$: Nd, 28.4; C, 49.7; H, 3.0%. $Yb(sal)_3$: Yield 92%. Found: Yb, 32.4; C, 46.8; H, 2.8. Calc. for $C_{21}H_{15}O_6Yb$: Yb, 32.3; C, 47.2; H, 2.8%.

Preparation of $Ln(fur)_3$

A mixture of three equivalents of furfuralcohol and one equivalent of Cp_3Nd or Cp_3Yb in THF was allowed to react at room temperature. After stirring for 24 h, the resulting solution was concentrated *in vacuo*. Upon addition of *n*-hexane brown precipitates were formed, filtered off, recrystallized from THF/*n*-hexane and dried *in vacuo*. $Nd(fur)_3$: Yield 53%. Found: Nd, 33.3; C, 40.7; H, 3.3. Calc. for $C_{15}H_{15}O_6Nd$: Nd, 33.1; C, 41.4; H, 3.5%. $Yb(fur)_3$: Yield 70%. Found: Yb, 37.4; C, 38.5; H, 3.2. Calc. for $C_{15}H_{15}O_6Yb$: Yb, 37.3; C, 38.8; H, 3.5%.

Reaction of $Nd(sal)_3$ *and* $Cp_2Nd(sal)$

A mixture of $Nd(sal)_3$ (1 mmol) and $Cp_2Nd(sal)$ (1 mmol) in 20 cm^3 THF was stirred for 24 h at room temperature. The resulting solution was centrifuged and concentrated to about 10 cm^3 *in vacuo*. By addition of 20 cm^3 *n*-hexane a yellow solid precipitated out which was recrystallized from THF/*n*-hexane twice. The product, $CpNd(sal)_2$ (II), was characterized by elemental analyses and MS.

According to a similar procedure, the reaction of $Nd(sal)_3$ with Cp_3Nd (mol ratio, 1:2) gave $Cp_2Nd(sal)$ (I), the reaction of $Yb(fur)_3$ with $Cp_2Yb(fur)$ (mol ratio, 1:1) gave $CpYb(fur)_2$ (VIII) and the reaction of $Yb(fur)_3$ with Cp_3Yb (mol ratio, 1:2) gave $Cp_2Yb(fur)$ (VII). All the three products were also characterized by elemental analyses and MS.

STABILITY CONSTANTS OF THALLIUM(I)-BENZO-15-CROWN-5 COMPLEX IN ALCOHOLS

EWA LADA and MAREK K. KALINOWSKI*

Department of Chemistry, University of Warsaw, Pasteura 1, 02-093 Warszawa, Poland

(*Received* 7 *February* 1989; *accepted* 15 *March* 1989)

Abstract—The complexation of thallium(I) by benzo-15-crown-5 was studied in methanol, ethanol, propanol-1, butanol-1,2-methylpropanol, 4-hydroxy-4-methyl-2-pentanone, pentanol-1, ethylene glycol and 2-aminoethanol by employing polarographic techniques.

The stability constants of the complexes, K_s, were found to vary with the nature of solvent; it has been observed that linear correlation between the $\log K_s$ values and the Kirkwood term, $(\varepsilon-1)/(2\varepsilon+1)$, of the solvents exists. The results are discussed in the frame of the changes of the Tl^I ion solvation.

It is well known that macrocyclic polyethers, viz. crown ethers, are capable of forming stable complexes with many cations; most of the results can be found in a compilation given by Izatt *et al.*[1] Interest in this phenomenon was stimulated when it was found that these synthetic ligands are similar in their structures and reactivity to many naturally occurring compounds of the macrocyclic type which are known to exhibit selective cation complexation. There are at least three factors that make a significant contribution to the binding of cations by the crowns: (i) the cation radius–hole size relation, (ii) the number of the donor sites participating in the binding and (iii) the properties of a solvent. Of these factors, the third will be considered in the present article.

The solvent effect on K_s, the stability constant of complexation

$$M^+_{solv} + crown_{solv} \rightleftharpoons (crown, M^+)_{solv} \quad (1)$$

$$K_s = (c_{crown,M^+})/c_M + c_{crown} \quad (2)$$

remains largely unknown (note that the subscript, "solv" marks the species in a solvated form). Complexation [eq. (1)] can be formally analysed as a phenomenon accompanied by desolvation (or at least partial desolvation) of the M^+ ion and the ligand, and then by solvation of a newly formed species, viz. the (crown, M^+) complex. Thus in order to form this complex in solution the following inequality must be fulfilled[2]

$$\Delta G^0_{compl} + \Delta G^0_{solv}(crown, M^+) < \Delta G^0_{solv}(M^+) + \Delta G^0_{solv}(crown) \quad (3)$$

where ΔG^0_{compl} is the free energy of binding of M^+ by a given ligand. Obviously, all ΔG^0_{solv} terms are influenced upon changing the solvent. Thus, it is clear from eq. (3) that in addition to the free energy of solvation of the cations, the free energies of solvation for the complexed cation and the ligand should be considered.

We wish to report here the complexation of thallium(I) by benzo-15-crown-5 in the solvents: methanol, ethanol, propanol-1, butanol-1, 2-methylpropanol, pentanol-1, 4-hydroxy-4-methyl-2-pentanone, ethylene glycol, and 2-aminoethanol. The stability constants were calculated from polarographic data; 0.05 M tetrabutylammonium perchlorate was used as the supporting electrolyte.

EXPERIMENTAL

Polarographic and cyclic voltammetric curves were determined in a three electrode system; a Radelkis OH 105 apparatus being used. The working electrode was either a mercury drop electrode with a mechanically controlled drop time of 2.0 s or a hanging mercury drop electrode.[3] The potentials were measured against an aqueous SCE, a two part salt bridge being used. In one arm of this bridge was solvent and electrolyte exactly as in the polarographic vessel. All solutions were deaerated by pure argon which was passed through molecular sieves, 0.4 nm, and presaturated by bubbling through the

* Author to whom correspondence should be addressed.

solvent. The measurements were performed at a temperature of 23 ± 0.1°C.

Methanol, ethanol and propanol-1 of spectral grade were used without purification. All remaining alcohols were rectified at reduced pressure under an argon atmosphere. Tetrabutylammonium perchlorate was prepared by conversion of $(n\text{-}C_4H_9)_4NI$; it was recrystallized several times from water and dried *in vacuo* at 60°C. Benzo-15-crown-5 and $TlClO_4$ (Merck) were used without further purification.

RESULTS AND DISCUSSION

Thallium(I) reduces at a dropping mercury electrode forming a single diffusion-controlled one electron wave in all the solvents under investigation (see also ref. 4 and references therein). The wave is reversible; this follows clearly from the shape of cyclovoltammograms and from the slope of polarographic curves. We have registered the cyclic voltammetric curves with the difference $E_{pa} - E_{pc}$ about 60 mV and with equal peak currents in the cathodic and anodic sweep (scan rate 0.05 V s^{-1}). Semilogarithmic analysis gives $\Delta E/\Delta \log[(i/i_0 - i)]$ values close to the 60 mV/log unit. Thus, the cathodic reduction of Tl^+ can be considered as the process:

$$Tl^+ + e \rightleftharpoons Tl(Hg) \qquad (4)$$

and, consequently, corresponding half-wave potentials may be assumed as equal to the formal potentials ($E^0_{1/2}$) for eq. (4). Addition of benzo-15-crown-5 shifts these potentials in a negative direction in all the solvents under study. Cyclic voltammetric curves indicate that the reversibility of the electrochemical processes is preserved as before, so the polarographic method may be used for the calculation of K_s, the stability constants. For this purpose we have examined the effect of the crown concentration (c_{crown}) on the half-wave potential and the limiting current of Tl^+. It should be pointed out that the measurements were carried out at fixed ionic strength; it was kept approximately constant by the electrolyte used in the experiments.

It can be shown that for 1 : 1 complexation[5]

$$\Delta E_{1/2} = (RT/F) \ln (K_s c_{crown}) + (RT/F) \ln (i_{crown,Tl^+}/i_{Tl^+}) \qquad (5)$$

$\Delta E_{1/2}$ is defined as $E_{1/2} - E^0_{1/2}$ where $E_{1/2}$ stands for the potential determined at a given c_{crown} value; the ratio of the limiting currents, $i_{crown,Tl^+}/i_{Tl^+}$, is attributed to a change in the diffusion coefficient of Tl^+ on complexation. The assumption made in deriving eq. (5) is that the crown concentration is much larger than the concentration of the thallium(I) ions, so that the ligand concentration at the electrode surface may be assumed equal to the concentration in the bulk. Table 1 indicates that this condition has been fulfilled in our experiments.

The K_s values calculated according to eq. (5) are collected also in Table 1. The data indicate that complexation is visibly dependent on the nature of the solvent. We have considered this finding using correlation analysis.

Earlier results for dibenzo-18-crown-6, K^+ binding in aprotic solvents show that some interaction exists between the solvent and the complex.[7] However, the effect is not large and stabilization of the complex may be primarily considered in terms of the potassium cation desolvation. Since solvent donicities correlate reasonably well with $\Delta G_{solv}(M^+)$, the donor numbers[8] and the K_s values were compared in some papers.[2,9-11] Let us add here

Table 1. Stability constants, K_s ($dm^3\ mol^{-1}$), for benzo-15-crown-5,Tl^+ complex in alcohols

Solvent	$(\varepsilon-1)/(2\varepsilon-1)$	c_{Tl} (mM)	c_{crown} (mM)	log K_s
Methanol	0.4773	0.125	2–10	3.05 3.00[a]
Ethanol	0.4698	0.187	1.7–4.3	3.30
Propanol	0.4629	0.025	1.6–4.5	3.44
Butanol-1	0.4574	0.017	2–4.6	3.63
2-Methylpropanol	0.4588	0.019	1.7–5.7	3.60
4-Hydroxy-4-methyl-2-pentanone	0.4599	0.164	1.5–7.5	3.54
Pentanol-1	0.4479	0.015	1.2–3.7	3.95
Ethylene glycol	0.4804	0.030	0.5–8	2.86
2-Aminoethanol	0.4808	0.035	0.4–11	2.95

[a] Determined polarographically.[6]

Errors in the determination of K_s do not exceed ±20%.

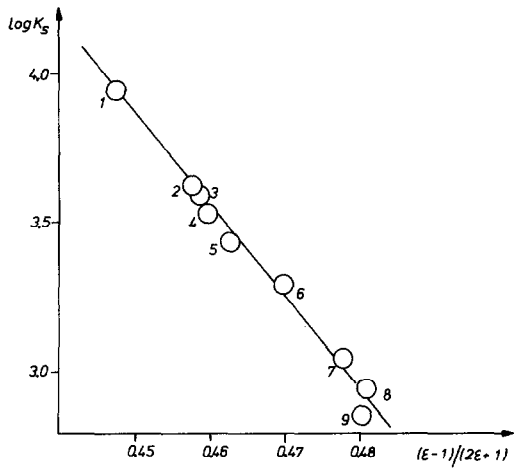

Fig. 1. Dependence of log K_s values of thallium (I)-benzo-15-crown-5 complex in alcohols on Kirkwood term $(\varepsilon-1)/(2\varepsilon+1)$. (1) pentanol-1, (2) butanol-1, (3) 2-methylpropanol, (4) 4-hydroxy-4-methyl-2-pentanone, (5) propanol, (6) ethanol, (7) methanol, (8) 2-aminoethanol, (9) ethylene glycol.

that it is not known yet whether crown complexes show the effect of ligand solvation; although this phenomenon was widely demonstrated for the [2,2,2]-cryptand, Na^+ complex.[12]

The variation in the K_s values for benzo-15-crown-5,Tl^+ complex with the solvent (Table 1) cannot be discussed in terms of the Lewis basicity of alcohols. On the basis of our results one can prove a greater contribution to solvation from non-specific, long-range interactions. The function $(\varepsilon-1)/(2\varepsilon+1)$ from the Kirkwood model was chosen as the parameter describing those interactions (ε is the electric permittivity). Indeed, the following relationship can be obtained for the log K_s values in nine solvents.

$$\log K_s = (-30.96 \pm 1.16) * (\varepsilon-1)/(2\varepsilon+1) + (17.80 \pm 0.54) \quad (6)$$

(errors are standard deviations).

The correlation coefficient of the regression is $r = 0.995$ and F test yields 705.5 which means that the measurement errors can explain the deviations from the assumed model completely. Thus, the solvent change of the log K_s values should be treated as limited by the ΔG^0_{solv} terms of the ionic species, viz. $\Delta G^0_{solv}(Tl^+)$ and ΔG^0_{solv}(crown, Tl^+). Of course, the relative contribution due to the energetics of complexation seems to be much greater for the thallium(I) ions (cf. text above).

As can be seen from eq. (6), solvent effects on the K_s values are manifested in the changes of long-range intermolecular forces. In other words, we may conclude that this relation does not reflect any specific viz. short-range solvation effects. A reasonable explanation seems to be that we have the solvents characterized by approximately the same Lewis basicities. These are the reasons why the present study was restricted to alcohols as the solvents.

Acknowledgements—The authors are grateful to Prof. Ulrich Mayer (Vienna, Austria) for samples of the crown ether. This work was sponsored as a part of Problem CPBP 01.15.

SYNTHESIS AND STRUCTURE OF A TRIPLY-CHLORO-BRIDGED DIMER OF A HOMOBINUCLEAR Rh^I COMPLEX: $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+[Rh(CO)_2Cl_2]^-$

H. EL-AMOURI, A. A. BAHSOUN, J. A. OSBORN,* M. T. YOUINOU and J. FISCHER

Laboratoire de Chimie des Métaux de Transition et de Catalyse, UA au CNRS n° 424, Université Louis Pasteur, Institut Le Bel, 4, rue Blaise Pascal, 67000 Strasbourg, France

(*Received* 10 *February* 1989; *accepted* 15 *March* 1989)

Abstract—The tripod ligand $HC(PPh_2)_3$ reacts with $Mo(CO)_3(CH_3CN)_3$ yielding $Mo(CO)_3(CH_3CN)(HC(PPh_2)_3)$. Reaction of this Mo^0 complex with $[Rh(CO)_2Cl]_2$ gives unexpectedly the tetranuclear species $[Rh_2(CO)(HC(PPh_2)_3)]_2(\mu\text{-}Cl)_3^+$ (**3**) which crystallizes as the $Rh(CO)_2Cl_2^-$ salt (**3a**). This complex crystallizes in the monoclinic space group $P2_{1/c}$ with $Z = 4$, with all dimensions $a = 19.685(3)$, $b = 19.524(3)$, $c = 22.657(4)$ Å, and $\beta = 96.96(2)°$. A direct route to the PF_6^- salt of **3** (**3b**) is also presented. The ^{31}P NMR data show **3a** and **3b** to be identical and that the tetranuclear structure is retained in solution, i.e. two units of binuclear Rh^I species bridged by three chlorine atoms. In each binuclear unit, the tripod ligand spans two Rh^I which are linked directly by a metal–metal bond (Rh—Rh = 2.696 Å).

The assembling ligand $HC(PPh_2)_3$ (**1**) has been used with some success for the synthesis of bimetallic[1] and trimetallic[2] species. One of our more recent objectives has been the synthesis of heterobimetallic complexes capable of activating small molecules by means of their simultaneous interaction with two different metals.[3] The strategy involves, firstly the synthesis of a precursor complex in which a single metal centre is chelated by two phosphorus atoms of **1**, followed by a second reaction in which the pendant non-coordinated phosphorus atom reacts with a second labile metal complex. This approach depends implicitly on the stability of the precursor complex under the reaction conditions of the second reaction. Here we illustrate a constraint of its use where an attempt to synthesize a Mo—Rh complex resulted unexpectedly in the isolation of a tetranuclear rhodium species.

EXPERIMENTAL

All experiments were carried out on a high vacuum line or in a nitrogen filled glove box. Solvents were dried prior to use by conventional distillation under nitrogen and the appropriate reagent, e.g. THF (sodium benzophenone), acetone ($CaSO_4$), and MeOH, CH_2Cl_2 and acetonitrile (CaH_2).

Infrared spectra were recorded on a Perkin Elmer 597 spectrophotometer as Nujol mulls and/or in solution (0.1 mm KBr cells). NMR spectra were acquired on a Bruker SY-200 (^1H, ^{13}C, ^{31}P) and a AM-400 (^{31}P) instrument; chemical shifts are relative to Me_4Si (^1H, ^{13}C) or 85% H_3PO_4 (^{31}P). Data are presented as proton decoupled with downfield chemical shifts as positive. Elemental analyses were performed by the Service Central d'Analyses of the CNRS.

Materials

$RhCl_3, nH_2O$ was purchased from Johnson Matthey Chimie, the ligand[4] $HC(PPh_2)_3$ (tripod), the complexes $[Rh(CO)_2Cl]_2$,[5] and $Mo(CO)_3(MeCN)_3$[6] were prepared as previously described.

Preparations

$Mo(CO)_3(CH_3CN)[HC(PPh_2)_3]$, (**2**). A yellow solution of $Mo(CO)_3(MeCN)_3$ (1.07 g, *ca* 3.50

* Author to whom correspondence should be addressed.

mmol) in 60 cm^3 of CH_2Cl_2/MeCN (10:1) was added dropwise under nitrogen for 30 min at room temperature to a well stirred solution of tripod (2.06 g, 3.64 mmol) in CH_2Cl_2. The solution darkened to deep yellow and the microcrystalline, pure $Mo(CO)_3(MeCN)[HC(PPh_2)_3]$ precipitated, and was separated, washed twice with hexane and dried *in vacuo* (yield 65%). IR (cm^{-1}, in Nujol) ν (CO) 1925 (s), 1840 (ms), 1780 (s); ^{31}P NMR [$(CD_3)_2CO/CH_2Cl_2$ (+1 drop CH_3CN)]: δ (ppm) 24.9 (d, 2P), −21.9 (t, 1P), J(P–P) = 25 Hz. Found: C, 63.9; H, 4.3; N, 1.8; P, 11.5. Calc for $C_{42}H_{34}O_3NP_3Mo$ (mol. wt 789): C, 63.9; H, 4.3; N, 1.8; P, 11.8%.

$[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+[Rh(CO)_2Cl_2]^-$, (**3a**). A solution of $[Rh(CO)_2Cl]_2$ (0.287 g, 0.737 mmol) in 4 cm^3 of THF was added to a rapidly stirred yellow slurry of **2** (0.38 g, 0.48 mmol) in 9 cm^3 of THF. The mixture changed from yellow to give a deep red solution. Stirring was continued for 20 h during which a yellow orange compound precipitated. Purification was achieved by recrystallization from an acetone–ether mixture yielding pure yellow orange crystals of **3a** · $2CH_3COCH_3$ (**3a′**) which were suitable for X-ray determination. IR (cm^{-1}, Nujol mull) ν(CO) 2065 (ms), 1995 (s), 1970 (s), 1960 (vs); ^{31}P NMR (see text).

$[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+(PF_6)^-$ (**3b**). Method 1. **3a** (0.300 g, *ca* 0.155 mmol) was added to NH_4PF_6 (0.100 g, 0.60 mmol) in THF. The mixture was stirred for 24 h, then the yellow slurry filtered and the product **3b** washed several times with THF. Method 2. A tripod $HC(PPh_2)_3$ solution in 40 cm^3 (0.381 g, *ca* 0.67 mmol) was added in a dropwise fashion for 10–15 min to a well-stirred solution of $[Rh(CO)_2Cl]_2$ (0.236 g, *ca* 0.61 mmol) and NH_4PF_6 (0.493 g, ca 3.0 mmol) in 60 cm^3 of THF. Stirring the solution at room temperature under a slow flow of argon for three days yielded an orange coloured solution which was taken to dryness *in vacuo*. The orange product was washed successively with MeOH (2 × 15 cm^3) and with Et_2O (2 × 30 cm^3) and then dried *in vacuo*. Pure complex **3b** was recovered in 70% yield. IR (cm^{-1}, Nujol mull) ν(CO) 1985 (sh), 1975 (s), 1965 (s). Found: C, 48.6; H, 3.6; Cl, 5.7; F, 6.0; P, 11.0. Calc for $C_{76}H_{62}O_2Cl_3F_6P_7Rh_4$ (mol. wt 1855.5): C, 49.1; H, 3.4; Cl, 5.7; F, 6.1; P, 11.6%.

X-ray experiments. All data for **3a′** were collected on a Philips PW 1100/16 diffractometer equipped with a low temperature device using graphite monochromated Mo-K_α radiation (λ 0.71063 Å). The crystal data and data collection parameters are summarized in Table 1. No significant intensity changes were observed for three standard reflections monitored every hour during the data collection period. The Enraf-Nonius SDP package was used[7] on a PDP 11/60 computer for the computations, except that a local data reduction program was employed. The initial step-scan data were converted to intensities by the Lehmann–Larson method[8] and then corrected for Lorentz, polarization and absorption factors, the latter computed by the empirical method of Wacker and Stuart.[9]

The structure was solved by using direct methods which revealed positions of the metals and some of the phosphorus and chloride atoms. The remaining non-hydrogen atoms were located from difference Fourier maps computed after blocked-cascade least-squares refinement. After refinement of the heavy atoms, a difference Fourier map revealed maxima of residual electron density close to the positions expected for hydrogen atoms; they were introduced into the structure factor calculations at their calculated positions (C—H 0.95 Å) and with isotropic temperature factors defined as B(H) = 1 + B eq(C) Å^2 but were not refined (hydrogens of the solvates not included). Full least-squares refinements minimizing $\Sigma w(|F_o| - |F_c|^2)$ with $\sigma^2(F^2) = \sigma^2_{counts} + (0.08\ F^2)^2$ converged to the

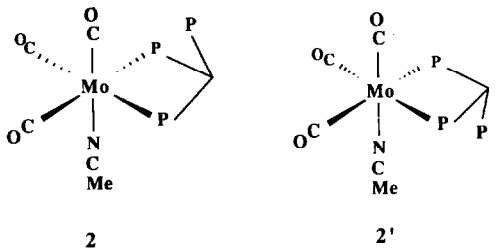
conventional R factors shown in Table 1. Final difference maps revealed no significant maxima. The scattering factor coefficients and anomalous dispersion coefficients come respectively from references 10a and 10b.*

RESULTS AND DISCUSSION

Complex formation

The tripod ligand $HC(PPh_2)_3$ reacts with $Mo(CO)_3(CH_3CN)_3$ in CH_2Cl_2 at room temperature under an argon atmosphere to form yellow $Mo(CO)_3(CH_3CN)HC(PPh_2)_3$ (**2**) displacing two CH_3CN molecules. The complex **2** was characterized by elemental analysis, IR, and NMR spectroscopy. The IR spectrum of **2** shows strong carbonyl absorptions at 1925, 1840 and 1780 cm^{-1} which can be compared with the IR of fac-$Mo(CO)_3(CH_3CN)_3$ which exhibits terminal carbonyl bands at 1913 and 1790 cm^{-1}. The $^{31}P\{^1H\}$ NMR sprectrum of **2** displays a doublet in the downfield region at 25.0 ppm $J(P_1—P_2) = 25$ Hz assigned to two P atoms of the ligands chelating the Mo centre, while a triplet centred at −21.9 ppm $J(P_1—P_2) = 25$ Hz results from the P atom of the uncoordinated arm of tripod. These observations are consistent with a mononuclear Mo^0 complex, with the CO ligands bonded in a fac-configuration. The spectroscopic features do not allow a distinction between the two possible isomers (Scheme 1). In either case, **2** or **2′** possesses a P_2 atom available for the formation of a binuclear complex although **2′** would seemingly more easily form a metal–metal-bonded species. Thus in order to investigate the construction of heterobinuclear complexes combining early and late transition metals by this approach the reaction of $Mo(CO)_3(CH_3CN)HC(PPh_2)_3$ with the labile Rh^{I} species, $[Rh(CO)_2Cl]_2$, was studied.

When $[Rh(CO)_2Cl]_2$ was added to $Mo(CO)_3(CH_3CN)HC(PPh_2)_3$ (molar ratio 1.5 : 1) a yellow-orange microcrystalline compound **3a** precipitated. IR spectrum of **3a** shows four absorptions resulting from terminal carbonyl ligands at 2065, 1995, 1970 and 1960 cm^{-1}, and the $^{31}P\{^1H\}$ NMR spectrum



Scheme 1.

of the complex exhibits several resonances, all of which showed large P—Rh couplings namely a doublet of triplets of doublets centred at 31.5 ppm and two somewhat overlapping quartets of broad doublets at 3.5 ppm (*vide infra* the spectroscopic features of **3b**). The elemental analysis and the above spectroscopic data did not allow us to determine a detailed structure for **3a**. Accordingly, an X-ray diffraction analysis was carried out on a single crystal of this complex.

Crystallographic study of $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+[Rh(CO)_2Cl_2]^- \cdot 2\,CH_3COCH_3$, **3a′**. The ORTEP view of the cation of **3a′** with the labelling scheme used is given in Fig. 1 and appropriate bond distances and angles are listed in Table 2. The crystal structure of **3a′** consists of four discrete molecules of $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+$ with $[Rh(CO)_2Cl_2]^-$ as the counter anion. Each tetrameric core consists of two sets of binuclear units linked by three bridging chloride atoms in a slightly asymmetric fashion [Rh(1)—Cl(3) = 2.391(3) Å; Rh(4)—Cl(3) = 2.404(3) Å; Rh(2)—Cl(1) = 2.405(3) Å; Rh(4)—Cl(1) = 2.403 (3) Å; Rh(2)—Cl(2) = 2.419(3) Å; Rh(3)—Cl(2) =

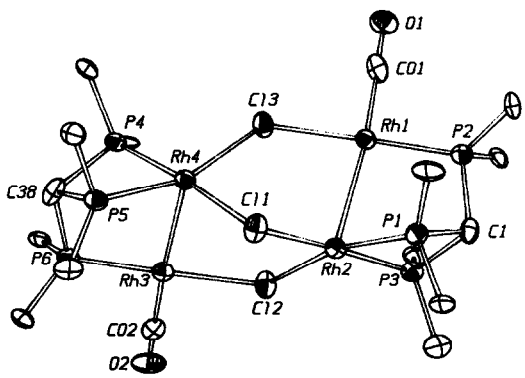


Fig. 1. ORTEP view of the cation of complex **3a′**; each phenyl group is reduced to its *ipso* carbon atom (50% probability thermal ellipsoids). Hydrogen atoms are omitted.

*Complete tables of final fractional coordinates (Tables 3 and 4), anisotropic temperature factors (Table 5), observed and calculated structure factor amplitudes (× 10) for all observed reflections for **3a′** (34 pages) have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

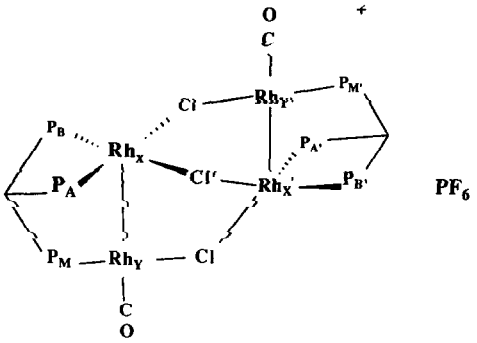
2.417(3) Å]. The rhodium atoms in each binuclear unit are clasped together by the tripod ligand, each rhodium possessing a different geometry. One rhodium is surrounded by two chloride atoms and two phosphorus atoms [Rh(2)—P(1) = 2.188(3) Å and Rh(2)—P(3) = 2.193(3) Å] forming the basal plane of a distorted square pyramid, with the apical position occupied by the second rhodium at a distance 2.704(1) Å corresponding to a single metal–metal bond between Rh(1)—Rh(2). The second rhodium centre displays an approximate square planar arrangement and is bound to one carbonyl group [Rh(1)—CO(1) = 1.80(1) Å] *trans* to Rh(2), to one chloride and to one phosphorus atom of the tripod ligand [Rh(1)—P(2) = 2.216(3) Å]. The planes defined by Cl(1), Cl(2), P(1), P(3) and Cl(3), CO(1), Rh(1), P(2) are nearly perpendicular (93°8). The bond distances from the phosphorus atoms of the tripod ligand to the rhodium atoms range from 2.188 to 2.220 Å and are slightly shorter than those recently reported[11] in a binuclear rhodium(I) complex containing the same ligand. These observations as well as the shortening of the Rh—Rh bond (mean 2.696 Å) in **3a'** compared to 2.745 Å may[11] result from the constraint due to the existence of the stable tetranuclear unit. The array of the four rhodiums held together by three bridging chloride atoms is thus best described as two binuclear units, assuming a pseudo two-fold axis of symmetry perpendicular to the $(Rh)_4$ core and passing through the Cl(1) atom. Such a frame of four Rh atoms has however a precedent, thus the structure[12] of $[\{Rh_4(\mu\text{-}Cl)_2(\mu\text{-}L)_2(\mu\text{-}CO)_2(CO_2)(nbd)_2\}]$, [L = pyrrolo-(2,3-b)pyridine anion, nbd = norbornadiene] shows analogously two binuclear units of Rh^I, (Rh—Rh = 2.686 Å) bridged together through two chloride atoms forming a quasi-planar Rh_4Cl_2 core.

Synthesis and spectroscopic features of $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+(PF_6)^-$, **3b**. Although an anion exchange reaction of **3a** with NH_4PF_6 occurs in THF to yield $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+(PF_6)^-$, **3b**, a more convenient route to prepare the latter was investigated. When tripod (1 eq) was added in a dropwise fashion to a mixture of $[Rh(CO)_2Cl]_2$ with excess NH_4PF_6 in

THF, **3b** could be isolated from the orange-red solution as the major product in good yield. We have found that the use of a large volume of THF is necessary for this purpose otherwise precipitation of the complexes **3a** and **3b** will occur simultaneously. The IR spectrum of **3b** shows typical stretching frequencies for terminal bonded carbonyls at 1985 (sh), 1975 (s), and 1965 (s) cm^{-1} and the vibrations characteristic of the PF_6^- anion. At room temperature, the 81 MHz $^{31}P\{^1H\}$ NMR spectrum of **3b** shows essentially an identical pattern of shifts and couplings in the low field region to that of **3a**; an additional resonance (septet) due to PF_6^- is observed at −145 ppm in the spectrum of **3b**.

The $^{31}P\{^1H\}$ spectrum was also carried out at 161.9 MHz to permit unambiguous assignments of the chemical shift and coupling constant data (Fig. 2). The complex pattern suggests that the solid state structure is maintained in solution. A schematic diagram of the structure of **3** derived from the X-ray structure (Scheme 2) shows that all four Rh as well as all six P environments should be magnetically distinct. The spectrum however can be analysed in terms of a ABMXY system (A, B, M = P; X, Y = Rh) indicating that the couplings between the two halves of the molecule do not significantly affect the spectrum or are zero, as we have supposed for this simulation. The essential features of this analysis are: (i) The occurrence of a pair of triplets of doublets centred at δ 53.0 that arises from spin coupling of the phosphorus nucleus P_M directly linked to Rh_Y [$^1J(P_M—Rh_Y) = 175$ Hz] and



Scheme 2.

through the methine carbon to the two other P nuclei P_A and P_B of the tripod ligand, $^2J(P_M—P_A) = 10$ Hz and $^2J(P_M—P_B) = 9$ Hz; each line of the triplets is further split into a doublet by a two bond coupling [$^2J(P_M—Rh_X) = 3.5$ Hz]. Such weak interaction between P and Rh nuclei through a metal–metal bond was previously observed for the heterobinuclear[1] complex $[(CO)_5FeRh(HC(PPh_2)_3)]^+$, ($^2J_{P—Fe—Rh} = 1.8$ Hz). (ii) Two partially overlapping sets of complex quartets chemically well shifted from the P_M signals. In this case each quartet can be regarded as the AB pattern expected for a pair of mutually coupled non-equivalent phosphorus nuclei P_A and P_B $^2J(P_A—P_B) = 98$ Hz, two sets of quartets arising from phosphorus–rhodium coupling $^1J(P_A—Rh_X) = {}^1J(P_B—Rh_X) = 144$ Hz. However the two lowest field resonances (A part of the AB pattern) of each quartet appear as a doublet of doublets whereas the highest field resonances (B

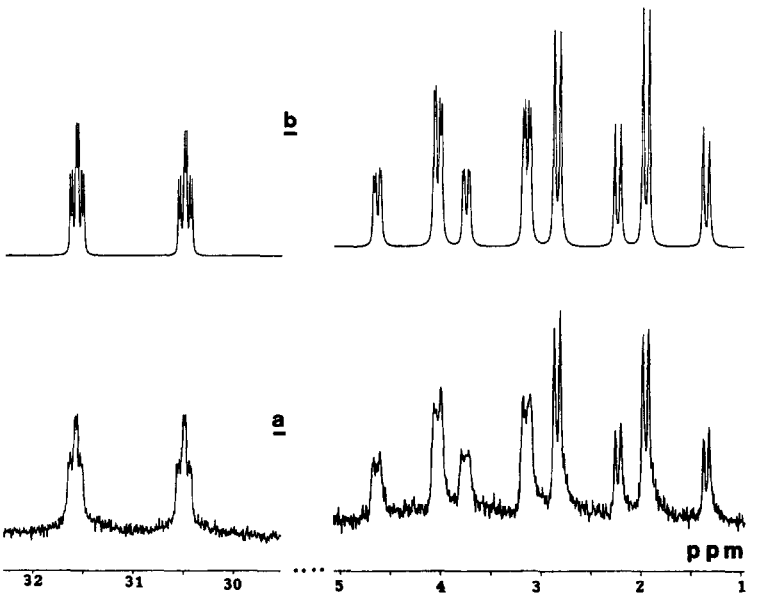


Fig. 2. $^{31}P\{^1H\}$ NMR spectrum of **3b**, $[\{Rh_2(CO)(HC(PPh_2)_3)\}_2(\mu\text{-}Cl)_3]^+(PF_6)^-$ at 25°C, 161.9 MHz. (a) Experimental spectrum; (b) simulated spectrum using the Bruker's PANIC computer program.

part) arise clearly as an unperturbed doublet. The perturbations within each quartet are associated with the different couplings of the phosphorus nuclei P_A and P_B respectively with the Rh_Y centre through a metal–metal bond. The most feasible interpretation is to assume that the splitting as a doublet of doublet in one case is due to P_A—P_M coupling [$^2J(P_A—P_M) = 10$ Hz] with a further very small splitting of each line from P_A—Rh_Y coupling [$^2J(P_A—Rh_Y = 3$ Hz]. In contrast the phosphorus P_B arises as a proper doublet $^2J(P_B—P_M) = 9$ Hz and $^2J(P_B—Rh_Y) = 0$ at highest field. The computer simulation reproduces the experimental spectrum accurately (see Fig. 2) with δ P_B 2.15 and δ P_A 3.85 and using the various coupling constants cited above. We note the one bond coupling $^1J(P_M—Rh_Y) = 175$ Hz for square planar phosphine P_M is *ca* 20% larger than for the phosphines P_A and P_B, $^1J(P_A—Rh_X) = {}^1J(P_B—Rh_X) = 144$ Hz chelated to a Rh^I in a square pyramidal configuration. The rather high values of such ^1J(P—Rh) couplings are consistent with the P nucleus lying *trans* to halogen atoms.[13]

In conclusion, although our objectives to synthesize mixed bimetallic systems have not been successful in this case, the isolation and characterization of the tetranuclear Rh^I complex enabled us to envisage and synthesize other bimetallic complexes of this type such as $[Rh_2(CO)_2(CH_3CN)_2$ (tripod)$]^{2+}$.[11] Further, the synthesis of mixed bimetallic systems involving Rh^I have been achieved using for example [Rh(tripod)(diene)]$^+$ as precursor.[14]

INTRAMOLECULAR ISOMERIZATION OF CHROMIUM AND TUNGSTEN BIS(TRIFLUOROPHOSPHINE)CARBONYLS

LEIGH DENHAM BOTTOMLEY,* RONALD J. CLARK† and TOMAS G. BERGER

Department of Chemistry, Florida State University, Tallahassee, FL 32306-3006, U.S.A.

(*Received* 10 *September* 1988; *accepted after revision* 31 *March* 1989)

Abstract—The thermally induced isomerization of chromium and tungsten bis(trifluorophosphine) carbonyl compounds was analysed by gas chromatography. These hexacoordinate chromium and tungsten compounds were found to isomerize intramolecularly without bond breakage. Rates of the isomerization were calculated from the Simplex optimized fit of first-order decay to the data. Activation parameters were also calculated. This example of intramolecular isomerization was concluded to be under steric control.

The intramolecular isomerization of hexacoordinate zero-valent d^6 metal complexes is not common. Muetterties discussed the possibility of octahedral isomerization using his topological representations as early as 1968.[1] He concluded that the activation barriers would be too large to accommodate a non-bond-breaking mechanism. However, soon he and co-workers found the first case of intramolecular isomerization.[2] That example concerned the isomerization of dihydrido complexes, H_2ML_4, where M = Fe or Ru, L = phosphine or phosphite. It was concluded that the isomerization occurred via hydrogen transversal of the tetrahedral face of the phosphorus atoms for a variety of ligands. Later, Pomeroy and Graham[3] observed the *cis–trans* isomerization of $M(CO)_4(SiCl_3)_2$, where M = Ru or Os. The stereochemical non-rigidity of $W(CO)_5P(OMe)_3$ was unambiguously established by Darensbourg and Baldwin.[4] They employed a double labelling experiment and incorporated ^{13}C and ^{18}O, and then monitored the ^{13}C NMR shift induced by ^{18}O to delineate stereospecific sites. Ligand rearrangements were observed to occur with bonds intact.

Examples of intramolecular isomerization of substituted six-coordinate carbonyls are on the increase. The first full kinetics study of this phenomenon was by Darensbourg,[5] concerning the *cis–trans* isomerization of $Mo(CO)_4(P—n\text{-}Bu_3)_2$. Another more recent illustration[6] is the study of the *cis–trans* isomerization of labelled $Mo(CO)_4(^{13}CO)PR_3$. Finally, recent work by Howell[7] on chromium, molybdenum and tungsten compounds of the type $Mo(CO)_4L_2$ illustrates the same process. Related intramolecular processes have been found by Angelici in thiocarbonyl complexes.[8] While there are examples in the literature of hexacoordinate stereochemical non-rigidity, there have been very few kinetic studies of the metal carbonyls substituted with phosphines. We undertook this study with trifluorophosphine ligands to see if the small size of the ligand would affect the rate of the isomerization or the equilibrium concentration of the two species.

EXPERIMENTAL

Compounds

Cis- and *trans*-bis(trifluorophosphine)metal carbonyls were synthesized by the photochemical techniques previously published.[9] They were separated by preparative gas chromatography and purity was checked by GC prior to thermal induction.

Apparatus

Sealed liquid samples were equilibrated at various temperatures in a silicone oil bath that was capable of maintaining temperatures to two-tenths of a degree.[10] Analysis was carried out on a Varian Autoprep A-700 gas chromatograph. The column

* Present address: Department of Chemistry, Agnes Scott College, Decatur, GA 30030, U.S.A.

† Author to whom correspondence should be addressed.

was a 7 m, 1/4 in. copper tube packed with 35% DC 702 on Chromosorb P (30/60 mesh). The GC was equipped with a thermal conductivity detector.

Procedure

Pure samples of either *cis*- or *trans*-$M(PF_3)_2(CO)_4$, (M = Cr or W) were dried by vacuum sublimation through granular P_4O_{10} (Baker Chemicals). Samples (0.01 cm^3) were then sealed in 3 mm i.d. glass tubing of approximately 10 cm length under vacuum, after several freeze–pump–thaw cycles to remove oxygen. Samples were placed in a constant temperature bath and were removed at various time intervals. Samples were kept at −196°C until they were analysed by GC. The GC conditions were set so that the *cis* and *trans* peaks were baseline resolved. The column temperatures used were the lowest temperatures consistent with reasonably rapid analysis. *Cis–trans* peaks eluted within 10 min. Pure compounds were often trapped and re-analysed to check if decomposition or isomerization occurred due to the separation process, but none was found. The column temperatures used were 80°C for chromium complexes and 100°C for tungsten complexes. The thermal conductivity detector was calibrated with known amounts of all compounds and small correction factors applied to area measurements accordingly. Area measurements were made by cut and weigh. Labelling experiments were carried out on both the chromium and tungsten *trans* compounds. A several-fold molar excess of 90% ^{13}CO (Monsanto) was sealed in a 30 cm^3 tube with the pure *trans* compound. After heating, the *cis*- and *trans*-$M(PF_3)_2(CO)_4$ were separated from each other and examined carefully by IR spectroscopy.

RESULTS AND DISCUSSION

Upon heating neat *cis*-$Cr(PF_3)_2(CO)_4$ at elevated temperatures (100–140°C), isomerization to a *cis–trans* mixture was observed. No decomposition occurs and 100% of the starting material can be accounted for. Similar behaviour is seen starting with *trans*-$Cr(PF_3)_2(CO)_4$. The samples are in such small volume tubes that the carbonyl should be predominantly in the liquid phase. The phase of the reactant seems to be of little significance to the rates of reaction. Preliminary work done in the gas phase shows similar rates of transformation. The kinetic behaviour of *cis*-$Cr(PF_3)_2(CO)_4$ at 100°C is illustrated in Fig. 1. The same *cis–trans* ratio is reached from either pure compound. No other components are detected by GC, except at the highest temperature and longest times. Scrambling products comprise no more than 1% of the total peak area under these conditions. Analysis by GC is capable of detecting all mononuclear six-coordinate species and the isomeric distribution of di- and tri-substituted metal carbonyls. Tungsten exhibits the same kinetic behaviour as chromium, giving a clean *cis–trans* isomerization but at slower rates. The reactions appear to proceed via a non-bond breaking mechanism because no other scrambling products are detected. Photochemical activation of the same compounds, which is known to be a bond-breaking process, results in a full array of $M(PF_3)_x(CO)_{6-x}$ species.

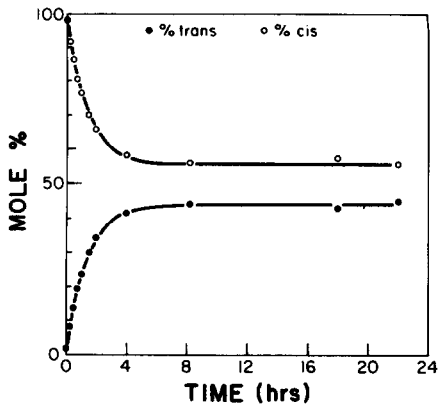

Fig. 1. Isomerization of *cis*-$Cr(PF_3)_2(CO)_4$ at 100°C.

The assumption that the thermal isomerization occurs by an intramolecular process is confirmed by ^{13}C studies. The *trans*-diphosphines of both chromium and tungsten isomerize to the *cis* isomer in the presence of 90% labelled ^{13}CO, without any incorporation of the label into the product. The size of the ^{13}CO peaks in the IR spectrum of the isolated isomer did not increase above natural abundance, indicating no bond breakage. The samples for the ^{13}C exchange were placed in containers of larger volume than the regular samples and existed primarily in the gas phase. Therefore, the solubility of CO in the liquid phase is not of concern. However, the same systems in the presence of UV light yield both isomerization and substitution products, all containing extensive ^{13}CO incorporation.

The rates of isomerization for chromium and tungsten were analysed as opposing first-order reactions, as in eq. (1), in which $K_{eq} = k_1/k_{-1} = [trans]/[cis]$.

$$cis\text{-}M(PF_3)_2(CO)_4 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} trans\text{-}M(PF_3)_2(CO)_4. \quad (1)$$

The integrated rate equation[11] is:

$$\ln \frac{C_e}{C_e - C} = (k_1 + k_{-1})t, \quad (2)$$

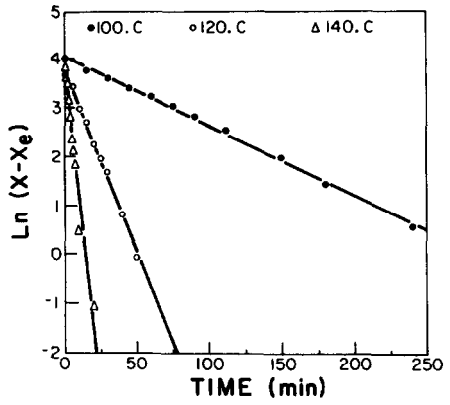

Fig. 2. Natural log of $C - C_e$ vs t for *trans*-$Cr(PF_3)_2(CO)_4$.

where C_e is the concentration of *cis* or *trans* at equilibrium and C is the concentration of *cis* or *trans* at any time t. A plot of $\ln(C - C_e)$ vs t should be linear, the slope being equal to the sum of the rate constants. Figure 2 illustrates these plots for *trans* to *cis* isomerization of $Cr(PF_3)_2(CO)_4$ at 100°C. This plot is shown to illustrate that the reactions are first-order and reversible. A model, $C = C_e \exp[-(k_1 + k_{-1})t] + C_e$ [exponential form of eq. (2)], was fitted to the kinetic data for *cis*- and *trans*-$M(PF_3)_2(CO)_4$ for the chromium and tungsten compounds. The model was fit to the data using a BASIC Simplex iterative routine. Simplex is known to be an excellent method of curve fitting. The BASIC program used was an adaptation of the PASCAL version by Cacerci and Cacheris.[12] The equilibrium concentration, C_e, and the sum of the rate constants were the adjustable parameters. The results of the program were used to calculate k_1 and k_{-1} from the known K_{eq}. The results are listed in Table 1.

Table 1 gives the sum of the rate constants, the equilibrium ratio of *cis–trans*, and the forward and reverse rate constants for chromium and tungsten disubstituted metal carbonyls at three temperatures. The rates increase smoothly with increasing temperature. The rate for the *cis–trans* isomerization (k_1) is 1.5–2 times faster than the reverse *trans–cis* isomerization (k_{-1}) for a given metal. For example, the ratio of k_1/k_{-1} for tungsten is 2.0, 2.1 and 2.2 at 100, 120, 140°C, respectively. This is also equal to K_{eq}. The equilibrium constant increases only slightly with increasing temperature. The equilibrium constant, and therefore the relative *cis* concentrations, increases from chromium to tungsten reflecting the relative sizes of the metals. The average K_{eq} for chromium is 1.36 and for tungsten is 2.09.

Activation parameters of chromium and tungsten were calculated from the plots of $\ln k$ vs $1/t$ illustrated in Fig. 3 and are reported in Table 2. The entropies for chromium and tungsten are negative, indicating that the transition state is more ordered than the ground state. These data are similar to those of Darensbourg for the intramolecular isomerization of $Mo((PBu)_3)_2(CO)_4$.[5] He observed negative entropies and a $\Delta H^{\ddagger}$ of ~ 24 kcal mol^{-1} for this complex.

The thermodynamic equilibrium concentrations

of the *cis* and *trans* isomers appear to be a combination of steric and electronic contributions. Metal carbonyls disubstituted with phosphine prefer the *trans* configuration when steric effects alone are considered. Indeed, many of the bulkier phosphine ligands are known to yield complexes that exist only in the *trans* form.[7,13] If the electronic effects are considered alone then the complex prefers the *cis* configuration due to a *trans* effect. Rather than one CO competing with another CO for electron density from the metal *d* orbitals, CO prefers to reside *trans* to a poorer π-bonding acceptor making the carbonyls *cis* to one another. The experimental findings which result from those two effects can be seen in Table 3. The table combines our data with those of Howell.[7] Listed in that table are the K_{eq} values for the *cis–trans* isomerization of several chromium and tungsten phosphine and phosphite complexes. The smaller the ligand cone angle, the larger the proportion of *cis* at equilibrium. Further, the larger the metal atom (W > Cr), the larger the concentration of *cis*. For chromium and a ligand having a cone angle of 130°, there is very little *cis* isomer present. As the cone angle decreases to 104° for PF_3, the *cis* form becomes the preferred isomer, with a K_{eq} of 1.36 at 100°C. The *cis–trans* ratios for the larger tungsten are 2.09. Strictly random isomerization would yield a K_{eq} of 4 (12 *cis* combinations, compared to three *trans*) if no electronic or steric effects were present.

[a] Data from ref. 10.
[b] Data from ref. 7.
[c] This work.

This study supports the previous findings of Darensbourg,[5] Howell[7] and others, proving that intramolecular processes offer the lowest energy pathway for isomerization of chromium and tungsten carbonyls disubstituted with phosphine ligands. This work adds to the small but growing body of literature on intramolecular octahedral isomerizations. It is clear that the coordination sphere of d^6 metals is not rigid. The reaction of the bis(trifluorophosphine) molybdenum carbonyls is not as straightforward as the chromium and tungsten compounds. Isomerization and substitution/ligand scrambling reactions occur simultaneously under identical reaction conditions. While the ligand scrambling must occur via an intermolecular route, the isomerization products appear to occur via both inter- and intramolecular routes. The different reaction chemistry for molybdenum bis(trifluorophosphine) carbonyl compounds is being studied.[14]

The disubstituted carbonyl complexes are not the only compounds thought to be fluxional. Experiments on scrambling of ^{13}CO in *cis*-$M(CO)_4(^{13}CO)(P(OMe)_3)$ (M = Cr, Mo and W) indicate that site exchange occurs for the $M(CO)_5PR_3$ species as well.[4,15] The exchange was intramolecular for chromium and tungsten and dissociative for molybdenum, similar to our results. Preliminary studies on the meridional and facial isomers of the triphosphines, $M(PF_3)_3(CO)_3$, show the same type of thermal reactions as found with the diphosphines.[14]

Abstract—The synthesis, crystal structure, spectroscopic and magnetic properties are reported for catena-bis(N-salicylidene-L-methioninato)aquadicopper(II), Cu-SALENMET. The compound crystallizes in the orthorhombic space group $P2_12_12_1$, with $Z = 4$. Lattice constants: $a = 5.077(1)$, $b = 13.229(1)$, $c = 37.602(2)$ Å, and $V = 2525(8)$ Å^3. Least-squares refinement of 171 parameters led to a final $R = 0.052$ for 1208 independent reflections having $I > 3\sigma(I)$. The asymmetric unit consists of two copper atoms and two SALENMET (N-salicylidene-L-methioninato) groups. Each metal atom is directly attached to a single SALENMET group. The first of the two copper atoms has a (4+2) tetragonally elongated coordination geometry. The SALENMET group directly attached to it and the oxygen atom of a coordinated water molecule occupy four of the coordination sites. The coordination sphere is completed by two carboxylic oxygen atoms, one belongs to a SALENMET group of an adjacent ($x-1$, y, z translation) asymmetric unit and the other belongs to the SALENMET group which is directly attached to the other copper atom within the asymmetric unit. This second copper atom has a (4+1) tetragonally elongated square pyramidal coordination geometry. Three of the coordination sites are occupied by the SALENMET group directly attached to it, one of them by the last above mentioned carboxylic oxygen atom. In this way, this oxygen atom is coordinated to both copper atoms within the asymmetric unit and the two SALENMET groups become linked through a Cu—O—Cu bridge. The coordination sphere is completed by two carboxylic

‡ Author to whom correspondence should be addressed.

oxygen atoms which belong to SALENMET groups of an adjacent asymmetric unit ($x-1$, y, z translation). The crystal structure consists of discrete polymeric units generated only by translation along the crystallographic a axis. The polymeric units are built by bonds through adjacent asymmetric units as described above. Magnetic susceptibility data reveal antiferromagnetic interactions that may be described by the Heisenberg alternating-chain theory. The best fit of the magnetic susceptibility data yields values for the exchange coupling constant and alternation parameter (J, α) of -62.9 cm^{-1} and 0.58, respectively.

A previous report[1] described the synthesis and spectroscopic properties of an anhydrous Cu^{II} compound with a Schiff base derived from salicylaldehyde and L-methionine having the empirical formula $CuSNO_3C_{12}H_{13}$ which exhibits magnetic susceptibility data that may be described by the Heisenberg dimer model.[2] Starting from this anhydrous compound, we have prepared the hydrated catena-bis(N-salicylidene-L-methioninato)aquadicopper(II), Cu-SALENMET, which is a good example of alternating Heisenberg exchange coupled S = 1/2 chains. The synthesis, crystal structure, spectroscopic properties and results of magnetic measurements are discussed in this article.

EXPERIMENTAL

Synthesis

All chemicals were reagent grade and used as received. Cu-SALENMET was prepared by the following general method: salicylaldehyde (0.05 mol) was dissolved in 400 cm^3 of ethanol; the amino acid (0.05 mol) was dissolved in a minimum quantity of water and added dropwise, with stirring, to the salicylaldehyde solution. Copper(II) acetate monohydrate (0.05 mol) was then dissolved in 200 cm^3 of water and added dropwise to the Schiff base solution. After the mixture was refluxed at 80°C overnight, a bright green precipitate was collected and dried *in vacuo*. Successive recrystallizations from aqueous ethanolic solutions of the bright green powder, characterized as the anhydrous $CuSNO_3C_{12}H_{13}$ complex, produced fine dark green needles. The compound was collected by filtration and dried in air. Cu-SALENMET is soluble in most common organic solvents. Found: C, 44.5; H, 4.3; N, 4.3; Cu, 19.6. Calc. for $CuSNO_{3.5}C_{12}H_{14}$: C, 44.5; H, 4.4; N, 4.3; Cu, 19.6%.

Chemical analyses of C, H and N were determined with a Carlo Erba 1106 elemental analyser. Copper analyses were carried out by atomic absorption with a Perkin–Elmer 305 apparatus.

Crystallographic data collection and refinement of the structure

An examination of the crystal by precession methods established that the compound crystallizes in the orthorhombic system. The space group $P2_12_12_1$ was confirmed by the structure solution. The dark green crystal used for intensity measurements with approximate dimensions $0.6\times0.35\times0.05$ mm was mounted on a glass fibre approximately along the crystallographic a axis. The six faces were identified as belonging to {100}, {001} and {010}. The lattice constants, determined by least-squares calculation based on the setting angles of 25 automatic centred reflections on an CAD-4 Enraf Nonius diffractometer, equipped with graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å), are: $a = 5.077(1)$, $b = 13.229(1)$, $c = 37.602(2)$ Å; $V = 2525(8)$ Å^3; $Z = 4$. The calculated density for four formula units of $Cu_2N_2S_2O_7C_{24}H_{28}$ (mol wt = 647.71) in the unit cell is 1.772 g cm^{-3}. The intensity data were collected in the range $0° < 2\theta < 50°$; the ω-2θ scan technique was employed, with a take-off angle of 1.2°. The reflections were scanned at 1° min^{-1} in zig-zag mode. The intensities of three standards reflections were measured every hour and showed no significant variations during data collection. A total of 2598 independent reflections were measured (at 22°C); of these, 1208 were found having $I > 3\sigma(I)$ and used in the solution and refinement of the structure. Data were corrected for Lorentz and polarization effects but not for absorption ($\mu = 18.35$ cm^{-1} for Mo-K_α).

The copper and sulphur atoms were located from a Patterson synthesis. Least-squares of these four atoms followed by a difference Fourier synthesis revealed the position of the oxygen and nitrogen atoms. The remaining non-hydrogen atom coordinates were obtained on a subsequent difference Fourier map. The hydrogen atoms were included in the final refinement model at their calculated positions (C—H = 1.08 Å) with overall isotropic parameter $U = 0.06$ Å^2.

The final full-matrix least-squares refinement with anisotropic thermal parameters for non-

hydrogen atoms and fixed isotropic hydrogen contribution converged to $R = 0.052$ and $R_w = 0.049$ (for 171 parameters and 1208 observed reflections). The function minimized was $\Sigma_w(|F_o|-|F_c|)^2$, and $w = [\sigma^2(F_o)+0.00073F_o^2]^{-1}$. Anomalous dispersion terms and atomic scattering factors were taken from ref. 3. The final atomic positional parameters and equivalent isotropic temperature factors[4] for the non-hydrogen atoms are listed in Table 1. All calculations were performed with the SHELX-76 package of programs.[5]‡

‡ Listings of observed and calculated structure factors, anisotropic thermal parameters, hydrogen atom coordinates, and bond lengths and angles pertaining to the ligand are available as supplementary material.

Electronic, infrared and EPR spectroscopies

The diffuse reflectance spectrum in the 300–900 nm region was carried out on a Beckman DU-2 spectrophotometer after dilution of the sample in $BaSO_4$. The IR spectrum was recorded with a Perkin–Elmer 681 spectrophotometer in KBr pellets as support, in the 625–4000 cm^{-1} spectral range. The room and low temperature EPR spectra were recorded on a Bruker X-band ER 200D spectrometer using a 100 kHz modulation.

Magnetic susceptibility measurements

The magnetic susceptibility data were measured on powdered samples on a Faraday type micro-

balance between 4.2–308 K. The data were corrected for the diamagnetism of the ligand system and for the temperature independent paramagnetism (taken to be 60×10^{-6} emu mol^{-1}). The correction for the diamagnetism was estimated by use of Pascal's constants[6] and found to be -180×10^{-6} emu mol^{-1}.

RESULTS AND DISCUSSION

Description of the structure

Tables 2 and 3 contain the interatomic distances and angles relevant to the copper coordination spheres, respectively. The asymmetric unit, shown in Fig. 1, consists of a dimeric part which includes two copper atoms and two SALENMET groups (where SALENMET is the N-salicylidene-L-methioninato group). Each copper atom is directly attached to a single SALENMET group and linked through a carboxylic oxygen atom O(1′). Both copper centres have four relatively short bonding interactions and additional longer contacts. The Cu(1) atom is bonded to O(1), O(3) and N(1) of the SALENMET group directly attached to it and to an oxygen atom O(W) from a water molecule. The coordination sphere is completed by two carboxylic oxygen atoms, one [O(2)] belonging to an adjacent ($x-1$, y, z translation) asymmetric dimeric unit, and the remaining [O(1′)] belonging to the SALENMET group which is directly attached to the second copper atom within the asymmetric unit. The equa-

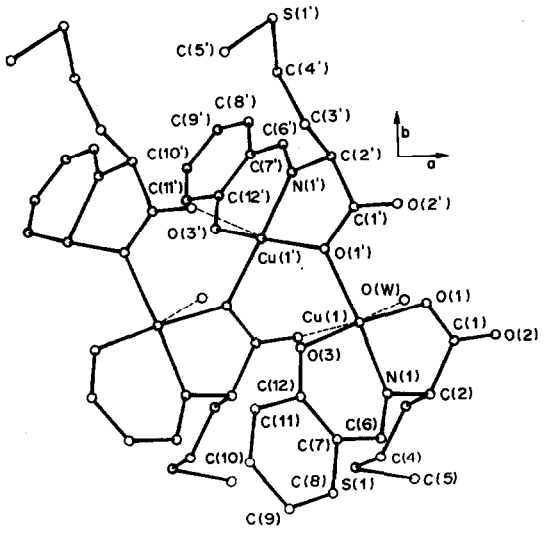

Fig. 1. ORTEP drawing of the molecular packing arrangement in Cu-SALENMET, showing the contacts between adjacent asymmetric dimeric units related through the symmetry operation $x-1, y, z$. Unlabelled atoms are related to the labelled atoms by the symmetry operation.

torial plane of this tetragonally elongated octahedron is made up of atoms O(1), O(3), N(1) and O(1′). As shown in Table 4, the deviation of these atoms from the mean plane is −0.203, −0.186, 0.209 and 0.180 Å, respectively. The displacement of Cu(1) with respect to the mean plane of the O(1)O(3)N(1)O(1′) entity is −0.074 Å, being less than those of the plane determining atoms. In the equatorial plane the coordination bond lengths vary for Cu(1)—O bonds from 1.89(1) to 2.04(1) Å, while the Cu(1)—N bond length is 1.96(1) Å. The axial Cu(1)—O(W) and Cu(1)—O(2)* (* = $x-1, y, z$ translation) bond lengths are 2.45(2) and 2.65(1) Å, respectively.

The second copper atom in the asymmetric unit, Cu(1′), is bonded to O(1′), O(3′) and N(1′) of the SALENMET group directly attached to it. The O(1′) atom is coordinated to both copper atoms within the asymmetric unit in such a way that the two SALENMET groups become linked through a Cu(1)—O(1′)—Cu(1′) bridge. The coordination sphere around Cu(1′) is completed by two carboxylic oxygen atoms belonging to SALENMET groups of an adjacent ($x-1, y, z$ translation) asymmetric dimeric unit, O(1)* and O(2)*. The equatorial plane of this tetragonally elongated square pyramid is made up by the atoms O(1′), O(3′), N(1′) and O(1)*, with the deviations of these atoms from the mean plane being 0.126, 0.132, −0.136 and −0.122 Å, respectively (Table 4). The displacement of Cu(1′) from the mean plane of the O(1′)O(3′)N(1′)O(1)* entity is only −0.020 Å. The equatorial coordination bond lengths vary for Cu(1′)—O bonds from 1.89(1) to 2.05(1) Å, whilst

3–4	78.8

the Cu(1′)—N bond length is 1.92(1) Å. The axial Cu(1′)—O(2′)* distance is 2.55(1) Å. The O(2) atom from a SALENMET group of an adjacent ($x-1$, y, z translation) asymmetric dimeric unit located at 2.80(1) Å gives a severely distorted octahedron, with interatomic angles N(1′)—Cu(1′)—O(2)* and O(1)*—Cu(1′)—O(2)* of 132.2(5) and 53.0(4)°, respectively. The contacts between adjacent asymmetric dimeric units are shown in Fig. 1.

Defining the coordination numbers of each copper atom may be a matter for personal choice, but rigorously in terms of strongly bound ligands, four-coordination would be appropriate.

The bond lengths and angles around the metal atoms are in fairly good agreement with the values given for Cu^{II} complexes with Schiff bases derived from salicylaldehyde and L-glycine,[7] L-tyrosine[8] and L-phenylalanine.[9]

The crystal structure of Cu-SALENMET consists of discrete polymeric units generated only by translation along the crystallographic a axis. The polymeric units are built by the bonds through adjacent asymmetric dimeric units as described above. As shown in Fig. 1, adjacent asymmetric dimeric units are connected via the carboxylic oxygen atoms O(2′), O(1) and O(2), through Cu(1)—O(2)*—C(1)*—O(1)*—Cu(1)*, Cu(1′)—O(1)*—Cu(1)* and Cu(1′)—O(2′)*—C(1′)*—O(1′)*—Cu(1′)* bridges.

The Cu(1)—Cu(1′) distance within the asymmetric unit is 3.621(4) Å, whilst the Cu(1′)—Cu(1)* separation between adjacent asymmetric units is 3.662(3) Å. The Cu(1)—O(1′)—Cu(1′) bridge angle is 124.3(5)°, whilst the bridge angle between adjacent asymmetric units Cu(1′)†—O(1)—Cu(1) († = $1+x$, y, z translation) is 133.8(6)°.

Other structural features of the asymmetric dimeric unit are the O(1)—C(1)—O(2) and O(1′)—C(1′)—O(2′) angles of 124(1) and 125(1)°, respectively, and the C(1′)—O(1′)—Cu(1′) and C(1)—O(1)—Cu(1) angles involving equatorial oxygen atoms of 112(1) and 117(1)°, respectively. The Cu(1)—O(1′)—C(1′)—O(2′)—Cu(1′)† and Cu(1)—O(1)—C(1)—O(2)—Cu(1)† bridge adjacent asymmetric units lengths are 7.13 and 7.38 Å, respectively.

All the intramolecular bond distances and angles in the SALENMET groups fall in the normal range. All the interpolymeric separations are greater than 4 Å.

Electronic, infrared and EPR spectroscopies

The room temperature diffuse reflectance spectrum exhibits a maximum centred around 680 nm; its shape and *d–d* band position agree with those reported for octahedral and square pyramidal Cu^{II} stereochemistries. A shoulder at 480 nm, of similar intensity to the former, has been previously associated with tetragonally distorted octahedral Cu^{II} environments.[10] In agreement with the structural data, the IR spectrum of Cu-SALENMET shows a broad band around 3400 cm^{-1} which is assignable to ν(O—H) vibrations of the coordinated water molecule. A broad and strong band around 1660–1595 cm^{-1} may be attributed to ν(C=N), asymmetric ν(OCO) and phenyl ring stretching vibrations. The ν(C—O) band must be that appearing at 1520 cm^{-1}.

The room temperature X-band EPR spectrum of a powdered sample of the compound shows only one broad (peak to peak separation *ca* 500 G) signal centred at $g = 2.12$. Lowering the temperature of the sample to 4.2 K has no effect on the shape of the signal which decreases in intensity.

Magnetic properties

The experimental corrected magnetic susceptibilities are shown graphically in Fig. 2. The rounded maximum around 116 K indicates the presence of antiferromagnetic interactions. An attempt to fit the susceptibility curve to the classical Heisenberg dimer model was unsuccessful as well as a fitting using the Bonner and Fisher chain model.[11] The structure of Cu-SALENMET and the possibility of various exchange pathways led us to use the alternating linear chain model studied by Duffy

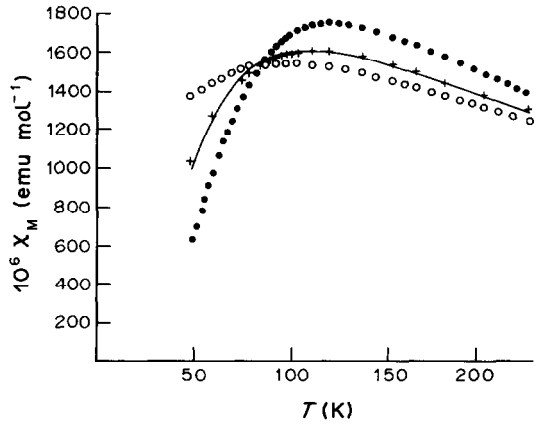

Fig. 2. Magnetic susceptibility data versus temperature for Cu-SALENMET. The solid line through the data was generated by the expression given in the text for Heisenberg exchange in an alternating chain with an exchange coupling of -62.9 cm^{-1}, and an alternation parameter of 0.58. The "best fit" to the data obtained for (●) $\alpha = 0$ ($2J = -73.4$ cm^{-1}, $g = 2.22$ and $\theta = -96$ K) and (○) $\alpha = 1$ ($J = -54.8$ cm^{-1} and $g = 2.13$) are also shown.

and Barr[12] and more recently by Hatfield.[13] The Hamiltonian for the Heisenberg alternating linear chain may be written as:

$$H = -2J \sum_{i=1}^{n/2} (\hat{S}_{2i}\hat{S}_{2i} + \alpha \hat{S}_{2i}\hat{S}_{2i+1}),$$

where J is the exchange integral between a spin and one of its nearest neighbours, and αJ is the exchange integral between that spin and its other nearest neighbour.

The temperature dependence of the magnetic susceptibility of Heisenberg alternating chains with $J < 0$ and $1 \geqslant \alpha \geqslant 0$ is given through an expression:[14]

$$\chi_M = Ng^2\mu_B^2/kT(A + Bx + Cx^2) \times (1 + Dx + Ex^2 + Fx^3)^{-1},$$

where $x = |J|/kT$, α is the alternation parameter, and the coefficients A to F are power series in terms of α.[13,14] The agreement factor $[\Sigma(\chi_{cal} - \chi_{obs})^2/\Sigma(\chi_{obs})^2]^2$ could be lowered down to 0.016 by using an alternation parameter $\alpha = 0.58$, an exchange integral $J = -62.9$ cm^{-1}, and a g-value equal to the EPR experimentally determined 2.12. The best agreement factors which could be reached for the dimer and uniform Heisenberg chain models were 0.034 and 0.070, respectively. Figure 2 shows the experimental points and the three calculated curves for $\alpha = 0$, $\alpha = 0.58$ and $\alpha = 1$.

The ability of the alternating linear chain model to describe the magnetic behaviour of Cu-SALENMET may be interpreted in terms of the different super-exchange pathways created by the crystallographic translation along the a axis. Between the Cu^{II} ions, the magnetic exchange can only occur via the $d_{x^2-y^2}$ orbitals which contain in the case of the elongated octahedral and square pyramidal stereochemistries the single electron, and the appropriate bridging atoms' orbitals. The different magnitude of the exchange integrals may be related to the structural data which implies not only the possibility of different super-exchange pathways (Cu—O—Cu or Cu—O—C—O—Cu) but also significant differences in the bonding distances and angles.

Finally, the comparison of the antiferromegnatic $|J|$ value for Cu-SALENMET with that observed for the anhydrous Cu^{II} compound which served as the starting material in the preparation of Cu-SALENMET, for which a presumable Cu^{II} acetate binuclear structure has been suggested,[1,2] with $2J = -339.2$ cm^{-1}, clearly indicates that the Cu^{II} ions within a pair are less coupled in the hydrated complex. Changes in the magnetic behaviour must be associated with the structural rearrangement during the hydration. It is unfortunate that it has not been possible to grow single crystals of the anhydrous species for an X-ray structural analysis.

(*Received* 31 *October* 1988; *accepted after revision* 5 *April* 1989)

Abstract—The isomorphic crystals of dysprosium(III) and holmium(III) complexes with proline of formula $[Ln(C_5H_9NO_2)_2(H_2O)_5]Cl_3$ (compound **I** holmium; compound **II**, dysprosium) were synthesized and characterized by crystal structures and spectroscopic properties.

The space group is $P2_1$ with lattice parameters: **I** $a = 11.968(2)$, $b = 11.030(2)$, $c = 8.309(2)$ Å, $\beta = 106.97(3)°$; **II** $a = 11.968(4)$, $b = 11.038(4)$, $c = 8.302(2)$ Å, $\beta = 107.00(3)°$. The structures of the title compounds differ significantly from that of $[Nd(proH)_3(H_2O)_2](ClO_4)_3$, with different bonding modes for the proline ligands. The holmium and dysprosium structure contains one-dimensional polymers with the chains lying along the *y*-axis. Absorption spectra of the holmium monocrystal were measured along the *a*-axis at room temperature. Intensities of *f–f* transitions were analysed on the basis of Judd theory.

The influence of the bonding mode of the carboxyl group on the intensity of the $^5I_8 \rightarrow {}^5G_6$ hypersensitive transition of the Ho^{3+} ion was considered and confronted for all spectroscopy data available for holmium carboxylate monocrystals.

Spectroscopic properties of the lanthanides are widely used in the study of biomolecular structure. Applications include the different aspects of absorption and luminescence spectroscopy leading to determination of discrete equilibrium structures, binding of ligands by metal ions to molecular systems, and other structural factors as well. For that reason the study of the model systems of lanthanide ions with amino acids, simple peptides, is important for the understanding of more complicated systems.

In order to study the Ln^{3+} ion interaction with amino acids, the series of crystal structures of lanthanide(III) complexes were investigated.[1–8]

All the determined structures are in dimeric or polymeric form. The kind of polymer in these complexes depends significantly on the stoichiometric relations of Ln^{3+}–amino acid (Ln–A).[2,4,6] The bonding mode of carboxyl groups in lanthanide carboxylate seems to depend on the stoichiometric relations in complexes as well.[9,10] But even for the same bonding mode of the carboxyl group *syn–syn*, *syn–anti* and *anti–anti* forms can exist giving many significant, structural possibilities in bonding to the metal ions. The whole series of lanthanide ions are able to form isomorphic compounds[1,2] with amino acids; however these rules can be broken.[5,6]

Recently in our laboratory, crystals of a neodymium complex of formula $[Nd(C_5H_9NO_2)_3(H_2O)_2](ClO_4)_3$ were synthesized, where the proline molecules were bound with lanthanide ions by simple bridges of the Nd—O—C—O—Nd type and the structure consisted of linear polymers lying along the *z*-axis, similar to those in the neodymium(III) complex with glycine.[2,4]

* Author to whom correspondence should be addressed.

To investigate the problem of ion size dependence on the structure of complexes as well as on the kind of polymers, the studies were extended to the holmium(III) and dysprosium(III) complexes with proline.

EXPERIMENTAL

The crystals of dysprosium and holmium complexes were grown from the concentrated aqueous solutions of $HoCl_3$ and $DyCl_3$ at pH ~ 4, 0; the amino acid concentration was maintained well below the lanthanide concentration.

Monocrystals of dimension $\sim 0.20 \times 0.25 \times 0.45$ mm were selected for the data collections. A Syntex $P2_1$ diffractometer and Mo-K_α radiation with a graphite monochromator were used for lattice-parameter and intensity measurements. The intensities of reflections were measured by the $\theta/2\theta$ scan technique up to $2\theta_{max} = 55.0°$. The scan rate varied from 2.0 to 29.3° min^{-1}. The data were corrected for Lorentz, polarization and absorption effects; 2525 reflections (for **I**) and 2440 reflections (for **II**) with $I > 4.0\sigma(I)$ were used for the structure determinations. All calculations were performed using Syntex XTL programs[11] and scattering factors for neutral atoms were taken from the *International Tables for X-ray Crystallography* (1974).[12]

The structure of the holmium complex was solved by the heavy-atom method, whereas the structure analysis of the dysprosium complex was commenced using the position parameters of atoms in the holmium complex. Full-matrix least-squares refinements were terminated at $R = 0.033$ ($R_w = 0.050$) for **I** and at $R = 0.032$ ($R_w = 0.048$) for **II**.*

Absorption spectra of the $[Ho(L\text{-}proH)_2(H_2O)_5]Cl_5$ single crystal along the *a*-axis were recorded at room temperature in the region of 8000–40,000 cm^{-1} on the Cary 14 spectrophotometer. Oscillator strengths of *f–f* transitions were estimated by means of the integrating program ICH 30.

Based on the Judd–Ofelt theory,[13,14] the intensities of *f–f* transitions were analysed and values of Ω_λ parameters were calculated from the following relation:

$$P_{JJ'} = \chi(8\pi^2 mc/3h) \sum_{\lambda=2,4,6} \Omega_\lambda \times \langle f^N\psi J \| U^{(\lambda)} \| f^N\psi' J' \rangle^2 \times (2J+1)^{-1},$$

where $\langle f^N\psi J \| U^{(\lambda)} \| f^N\psi' J' \rangle$ is the reduced matrix element of the unit tensor operator of $U^{(\lambda)}$, Ω_λ are treated as phenomenological parameters that may be derived from the experimental oscillator strengths by the least-squares method, and $\Omega_\lambda = (1.086 \times 10^{11}\chi)^{-1} \times \tau_\lambda$.

RESULTS AND DISCUSSION

The crystals of $[Ln(L\text{-}proH)_2(H_2O)_5]Cl_3$ (Ln = Ho, Dy) are not isomorphic with the crystal of the neodymium complex with L-proline.[4] There are two independent proline molecules (zwitterion form) in the title structures. Each of them has a different coordination mode to lanthanide ions. The proline 1 coordinates to one cation by only one carboxyl oxygen, whereas the proline 2 coordinates by both carboxyl oxygens to form a carboxylate bridge of the Ln—OCO—Ln type. In this way, the lanthanide ions are bridged to each other by single carboxyl bridges and the structures are different from the structure of the europium complex with L-α-alanine, which has the same stoichiometric ratio, lanthanide–amino acid = 1 : 2.[1,5] The structure of the title compounds differs significantly from the structure of $[Nd(proH)_3(H_2O)_2](ClO_4)_3$ as well. The zigzag chains of one-dimensional polymers are formed along the *y*-axis (see Fig. 1). The Ln—Ln distances in every chain are equal to 5.959(2) Å for **I** and

* The final atomic, positional and thermal parameters, lists of F_o/F_c values, have been deposited as supplementary material with the Editor, from whom copies are available on request.

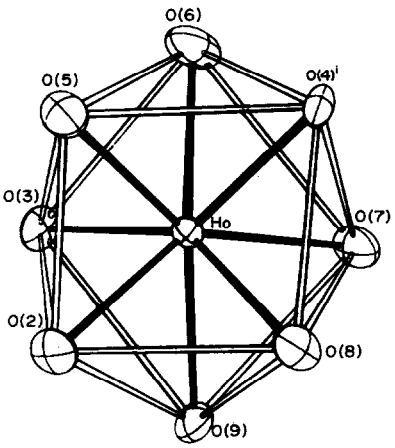

Fig. 2. The coordination polyhedron of $[Ho(L\text{-}proH)_2(H_2O)_5]Cl_3$.

5.963(4) Å for **II**. The average Ln—O distances in the coordination sphere of **I** and **II** are 2.365(9) and 2.373(9) Å, respectively.

The eight coordinating oxygen atoms (in which three derive from the carboxyl group of prolines and five derive from the water molecules) form a polyhedron which can be described as an intermediate between a dodecahedron and a square antiprism (Fig. 2). The atoms O(2), O(9), O(6), O(4^i) take positions A and the atoms O(3), O(8), O(5), O(7)—positions B in the dodecahedron. The parameter Δ is defined as $\Sigma d_i^2/8$, $i = 1$–8, d_i being the distance between the observed position of the i-th atom (vertex) and the relevant one in the ideal, least-squares-fitted[15] is 0.039 for both structures. When the coordination polyhedron is described as a square antiprism, the "square" faces are made up by atoms O(2), O(5), O(4^i), O(8) and O(3), O(6), O(7), O(9). In this case, $\Delta = 0.050$ for both structures, and the dihedral angles between these "square" planes are 1.9° and 2.6° for **I** and **II**, respectively. The interatomic distances and angles within the polyhedra are given in Table 1.

The ring conformations of proline molecules determined according to Ashida and Kakudo[16] and Cremer and Pople[17] exhibit E, C_s–C_α-endo type for proline 1 and T, C_2-C_γ-exo type for proline 2. The interatomic distances and angles for proline molecules are given in Table 2. The parameters determining conformations of the rings are given in Table 3. The torsion angles are given in Table 4.

The crystal structures are stabilized by the hydrogen bonds of O—H···O, O—H···Cl and N—H···Cl types (see Table 5).

The absorption spectra of the $[Ho(proH)_2(H_2O)_5]Cl_3$ monocrystal along the a-axis are shown in Fig. 3. It shows sets of lines in the range

8000–40,000 cm^{-1} owing to transitions from the $^5I_8$-ground state multiplet to various excited states.

The absorption bands are complex and correspond mainly to the electric dipole transitions. Only in a few cases are the intensities of magnetic transitions included.

The oscillator strength values were determined for all bands in the measured spectral range and are tabulated in Table 6. The values of P_{exp} and P_{calc} show satisfactory agreement. Among the f–f transitions in lanthanide ions, some satisfying the selection rule $|\Delta J\| \leqslant 2$ manifest an extraordinary sensitivity to the variation of ion environment. These transitions are termed the hypersensitive ones. The intensities of all f–f transitions do not differ significantly from these of other systems, but the intensity of the hypersensitive transition is essentially different from the intensity observed for the aquo ion, $HoCl_3$[18] and carboxylate monocrystal. The differences in intensity observed for the hypersensitive transition can be given by symmetry change, polarizability of the ligands,[19] or by some other effects. So it is reasonable to consider all of the

For the first two single crystals, the coordination mode of the carboxyl group is the same (simple bridge —O—C(=O)—O—) and in such a coordination of the carboxyl group, almost always the CN = 8 and the coordination polyhedra are distorted antiprism (SAP) or bicapped trigonal prism (BCTP).[1,4,5,20]

In the last two single crystal structures the coordination mode of the carboxyl group changed (there are two types of carboxyl group bonding mode[2,8] and CN = 9) however, the symmetry seems to be probably the same, C_{2v} for **4** and **5**.

If the Judd static model of intensity plays the main rôle we must observe the same intensity for four (**1**, **2**, **4** and **5**) monocrystals. However, if the polarizability mechanism takes part including the covalency effect one can expect the increase of intensity for the last three monocrystals. The bonding mode of the carboxyl group allows us to expect high covalency in **4** and **5** monocrystals, although the increase of intensity was observed for the glutamic acid monocrystal only.

In the case of complex **3** with proline the situation

is somewhat different. It is the first case among the complexes with amino acids where the carboxyl group is bonded with the Ln^{3+} ion not only by a simple bridge but also via only one oxygen of the carboxyl group of the second proline molecule (see Fig. 1). This type of coordination is very rarely represented in complexes of lanthanide carboxylates. The Ln—O bonding length for this type of coordination in the title compound is the shortest (Ln—O(2) = 2.318 Å). All Ln—O distances are even shorter than those observed in the complex with glutamic acid. The intensity of the hypersensitive transition is significantly higher for the title monocrystal in comparison with the data presented for the holmium complex with alanine and almost equal with that for glutamic acid.

In the presented data the lanthanide ions occupy C_{2v} point symmetry. Since the coordination polyhedron for the complex with proline can be described as an intermediate between dodecahedron and square antiprism, so the symmetry can change. In both cases distortion provides the reason why the symmetry becomes lower than in ideal polyhedra. In fact, we cannot observe the D_{2d} or D_{4d} symmetry, but only the lower one, i.e. D_2 or C_2. However, it is clear from the shape characteristics that the structure of the title compound is closer to the dodecahedron, so the D_2 point symmetry seems to be reasonable and higher than C_{2v}. We were not able to synthesize the europium complex with proline and we cannot confirm the point symmetry of the Ln^{3+} ion on the basis of luminescence spectra.

The intensity results of the hypersensitive transition indicate the increase of the oscillator strength value, which is similar for glutamic acid. Such a phenomenon can be explained by the covalency effect and/or by vibronic mechanism, which is similar to the case of the $[Nd(proH)_3(H_2O)_2](ClO_4)_3$ monocrystal.

CONCLUSIONS

(1) The new type of Ho^{3+} and Dy^{3+} compounds with proline were obtained which differ in the structure and coordination of proline molecules from those in the monocrystal of $[Nd(proH)_3(H_2O)_2](ClO_4)_3$.

(2) The linear polymer in the structure is formed in a different way when compared with the polymer in the $[Nd(proH)_3(H_2O)_2](ClO_4)_3$ structure.

(3) Analysis of spectroscopic data of monocrystal Ho^{3+} carboxylates led us to the conclusion that the covalency effect and vibronic mechanism can affect the intensity changes of hypersensitive transitions.

(4) The differences in the spectroscopic properties for the series of lanthanide carboxylates have been found.

(*Received* 6 *January* 1989; *accepted* 14 *April* 1989)

Abstract—The crystal structure of a potassium adduct with a substituted (phenylthio)acetic acid has been determined using X-ray diffraction, and refined to a residual $R = 0.043$ for 1932 observed reflections. The adduct, $[(KL)(LH)]_n$, where LH = (4-chloro-2,5-dimethylphenylthio)acetic acid, is triclinic, space group $P\bar{1}$, $Z = 2$, $a = 7.313(2)$, $b = 9.386(2)$, $c = 17.371(5)$ Å, $\alpha = 77.53(2)$, $\beta = 79.28(2)$, $\gamma = 84.95(2)°$. The K atom is surrounded by a distorted octahedron comprising five oxygens [K—O, 2.691–2.777(3) Å] and one sulphur atom [K—S, 3.349(2) Å], with oxygens also bridging in a polymer structure. There are two hydrogen atoms at special positions contributing to the one H^+. The compound is an example of a type A, $[(M^+)_2(HX_2^-)_2]$ system, with one hydrogen atom being shared by two crystallographically related X groups. There are two conformationally different (HX_2^-) groups in the structure.

This is an extension to the investigation of a group of disordered compounds $[M^+X^- \cdot HX]$ found for metal complexes of (phenylthio)alkanoic acids.[2] Speakman[3,4] classified two fundamental types of acid–salt $[M^+X^- \cdot HX]$ structures: type A, where the two X-units are crystallographically equivalent, and type B, where the two X-units are crystallographically non-equivalent, and occur as an anion and neutral molecule. In all of Speakman's type A cases, the intercarboxyl hydrogen bond occurs about either an inversion centre or a two-fold axis. In the present example, with formula (KL)(LH), where LH = (4-chloro-2,5-dimethylphenylthio)acetic acid, an unusual variation of the type A structure is found.

* For part XI see ref. 1.

EXPERIMENTAL

Preparation

The complex was prepared by reaction for *ca* 1 h at 90°C, of a 2:1 stoichiometric quantity of (4-chloro-2,5-dimethylphenylthio)acetic acid (as a 50% aqueous ethanolic solution) with potassium carbonate.[5] The filtered solution, on standing, gave crystals suitable for X-ray examination.

Elemental analysis

Found: C, 48.2; H, 4.3. Calc. for $C_{20}H_{21}Cl_2KO_4S_2$: C, 48.1; H, 4.2%.

Crystal data

$C_{20}H_{21}Cl_2KO_4S_2$, $M_r = 499.5$, triclinic, space group $P\bar{1}$, $a = 7.313(2)$, $b = 9.386(2)$, $c = 17.371(5)$ Å, $\alpha = 77.53(2)$, $\beta = 79.28(2)$, $\gamma = 84.95(2)°$, $V = 1142.5(5)$ Å^3, $Z = 2$, $D_c = 1.451$, $D_m = 1.457$ g cm^{-3}, $F(000) = 516$, μ(Mo-K_α) = 6.65 cm^{-1}, $t = 293$ K.

X-ray data collection and structure refinement

Data were collected from a single crystal (0.42 × 0.40 × 0.20 mm) on a Nicolet R3m four-circle diffractometer using monochromatic Mo-K_α radiation ($\lambda = 0.71069$ Å). 4526 reflections were collected up to $2\theta_{max} = 56°$. Data were processed using the profile fitting procedure of Diamond[6] and corrected for absorption (maximum, minimum transmission factors, 0.827 and 0.782, respectively). Of these, 1932 with $I > 2.5\sigma(I)$ were considered observed and used in structure analysis. The structure was solved by the Patterson method (SHELXS-86[7]) and refined using SHELX-76[8] on the University of Queensland's IBM 3081 computer. Blocked-matrix anisotropic refinement (100 variable parameters maximum) was used for all non-hydrogen atoms. All hydrogens were located from a difference-Fourier synthesis and their positional and thermal parameters refined. Residuals R, R_w and w were 0.043, 0.051 and $[0.74/(\sigma^2 F_o + 3.5 \times 10^{-3} F_o^2)]$, respectively. $\{R = [\Sigma||F_o| - |F_c||]/\Sigma|F_o|]$ and $R_w = [\Sigma w(||F_o| - |F_c||]^2/\Sigma w|F_o|^2)^{0.5}]\}$. Neutral atom scattering factors were used.[9]

Bond distances and angles about the coordination sphere are given in Table 1. Final atomic coordinates, anisotropic thermal parameters, intramolecular bond distances and angles, and observed and calculated structure factors have been deposited with the Editor as supplementary material and are available on request.

DISCUSSION

The structure of the compound is polymeric, based on a repeating centrosymmetric dimeric unit (Fig. 1). The irregular six-coordination about each

$[K_2(LHL)_2]_n$	6	2.691–2.777(3)	A	This work

PTAH = (phenylthio)acetic acid.
DCMPTAH = (2,4-dichloro-5-methylphenylthio)acetic acid.
PTPA = 2-(phenylthio)propionic acid.
LH = (4-chloro-2,5-dimethylphenylthio)acetic acid.

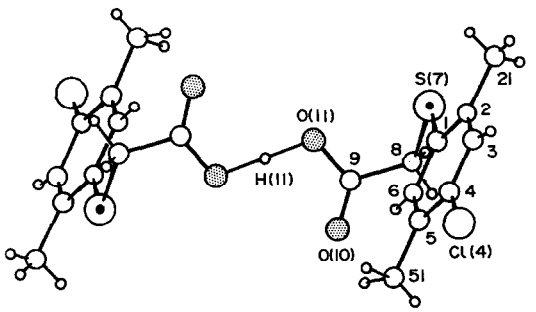

Fig. 2. Molecular conformation and atom number scheme for ligands. Only Ligand B is shown.

potassium comprises one sulphur atom [K—S, 3.349(2) Å] and five oxygens from four different carboxyl oxygens [K—O, 2.691(3), 2.777(3) Å; mean 2.742(3) Å], involving two different ligands. These ligands (A and B), are conformationally different, being either extended (A) or convoluted (B), and are related to their equivalent halves through inversion centres at (0, $\frac{1}{2}$, 0) and ($\frac{1}{2}$, 0, 0). The unusual feature of each of the ligand pairs is the location of protons at these inversion sites (Figs 2 and 3). Since each must have half-occupancy, the pair shares half a proton, making the formula of the complex $[(K^+)_2(LHL^-)_2]_n$. The protons are at intermediate positions between the two carboxyl oxygens with the O(11)—H(11) distances 1.224(2) Å (A) and 1.231(3) Å (B). Although this example represents a type B, $[M^+(L)(LH)]$ adduct[3,4] it has crystallographically different ligand and acid species both with protons at special positions with inversion-related ligands having shared half-protons. This has no precedent among the Group 1A carboxylates. However, an analogous example is found in the Group 1B metal complex adduct, silver(I) picolinate picolinic acid.[10] This present example is

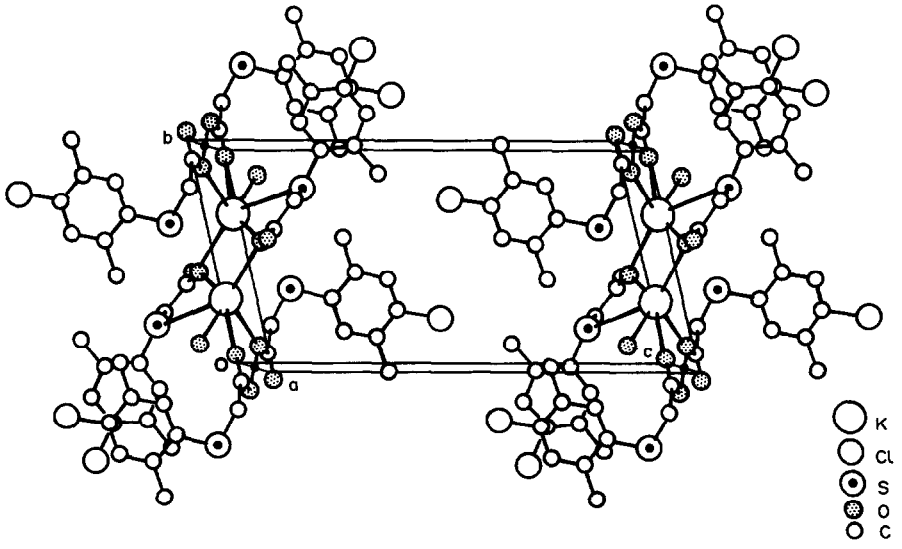

Fig. 3. Packing of the polymer molecules in the unit cell.

also the first among the structures of the Group 1A metal–(phenylthio)alkanoate complexes in which any metal to sulphur bonding is found. The result is a closure of a five-membered chelate ring such as is found in silver(I) (phenylthio)acetate.[11] All these complexes are polymeric (Table 2) with irregular coordination, while only one has a conventional "salt" structure [caesium 2-(phenylthio)propionate hydrate].[2] Among the others, both Type A and Type B examples are found, but the types of co-ordinating and bridging systems vary. With [Cs(PTA)(PTAH)]$_n$, [PTAH = (phenylthio)acetic acid], analogous bifurcated bridging oxygens are found but, in addition, bidentate (O, O′) carboxylates also bridge. In [Cs(DCMPTA)-(DCMPTAH)]$_n$ [DCMPTAH = 2,4-dichloro-5-methylphenylthio) acetic acid], the bridging is through carboxylato (O, O′) groups, while in [Cs(PTPA)(H_2O)]$_n$, [PTPAH = 2-(phenylthio)propionic acid], which is a conventional compound, there is an additional bridging water molecule.

(*Received* 16 *January* 1989; *accepted* 14 *April* 1989)

Abstract—Dinuclear palladium(II) complexes of the type $[Pd_2Cl_2(\mu\text{-}X)(\mu\text{-}SR)(PMe_2Ph)_2]$ (X = Cl or SR; R = Et or Pr^i) have been prepared and characterized. All these complexes adopt a *cis*-configuration. The structure of $[Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$ was established by X-ray crystallography: the crystals are triclinic, space group $P\bar{1}$ with $a = 9.273(3)$, $b = 10.412(3)$, $c = 13.767(6)$ Å, $\alpha = 80.84(3)$, $\beta = 81.62(3)$, $\gamma = 68.04(3)°$ and $Z = 2$. The geometry around one palladium is slightly distorted while the other one is almost square-planar.

Recently, we have reported mercapto bridged dinuclear platinum(II) and palladium(II) complexes.[1–3] For the palladium complexes[1,4] containing both chloro and mercapto bridges, an unambiguous differentiation between *sym cis–trans*-μ-chloro and *trans*-μ-mercapto could not be made in the absence of valuable couplings, although the former geometry was suggested. Here, we report the synthesis of $[Pd_2Cl_2(\mu\text{-}X)(\mu\text{-}SR)(PMe_2Ph)_2]$ (X = Cl, SR; R = Et, Pr^i) and the crystal and molecular structure of $[Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$.

RESULTS AND DISCUSSION

The complex $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ reacts with mercaptans RSH (R = Et, Pr^i), in acetone to yield dimercapto bridged palladium complexes which on treatment with the former complex in chloroform affords $[Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SR)(PMe_2Ph)_2]$. The dinuclear products have been characterized by elemental analysis (Table 1) and by NMR spectroscopy. All the complexes display single resonances in their ^{31}P NMR spectra in $CDCl_3$. The replacement of the bridging chloride by the SR group results in shielding of the ^{31}P resonance. The ^1H NMR spectra of dimercapto bridged complexes showed two sets of SR proton resonances as expected for *sym cis* configuration. The chloro–mercapto bridged complexes exhibited only one set of SR proton resonances. The ^1H NMR spectra displayed two doublets for the P—Me protons indicating non-equivalence of the methyl group on each phosphine due to the absence of a plane of symmetry containing the Pd—P axis as revealed from X-ray analysis.

Molecular structure of $[Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$

The bond lengths and bond angles are listed in Table 2. A PLUTO[5] plot of the molecule is shown in Fig. 1, while Fig. 2 depicts a stereoscopic pair of molecules. The coordination around one of the palladium sites [Pd(1)] is slightly distorted relative to the other. The deviations of the atoms from the least-squares plane are: Pd(1) = 0.0011(2), P(1) = −0.032(2), Cl(1) = −0.083(3), Cl(2) = −0.110(4) and S(1) = −0.019(2) Å which suggest a pyramidization at Pd(1). The corresponding values at the other palladium site are: Pd(2) = −0.001(1), P(2) = 0.001(2), Cl(3) = 0.001(3), Cl(2) = −0.001(3) and S(1) = 0.001(3). The Pd—S—Cl—Pd bridge is not planar and the two coordination planes are inclined to each other at 134.26(5)°. The Pd—P bond length [⟨2.227(2)⟩ Å] is, as usual, less than the radius sum. The bond distances Pd—Cl(terminal) [⟨2.334(2)⟩ Å], Pd—Cl(bridging) [⟨2.445(2)⟩ Å] and Pd—S [⟨2.280(2)⟩ Å] are in good agreement with the values reported in the literature.[6,7] These are also in keeping with the known *trans*-influence order P ≫ S > Cl. The average P—C distance [1.81(1) Å] is normal. The average C—C distance

in the two phenyl rings is 1.38 Å. The complex, as expected with bridging thiolato ligands, has a *sym cis–trans*-μ-chloro configuration.

The P—Pd—S bond angles at the two palladium atoms are significantly different. The angle at Pd(1) is very close to the ideal value 90° being 89.8(1)°, whereas at Pd(2) it is 93.5(1)°. In an earlier reported[8] platinum structure involving a dithiolato bridge, this angle is larger than 90° in order to minimize the steric crowding of the alkyl and aryl groups on the S and P atoms. The Cl—Pd—Cl bond angle [⟨94.4(1)°⟩] is normal, whilst the Cl(2)—Pd—S(1) angle [⟨84.7(1)°⟩] is considerably < 90° indicating the strain in the four-membered

ring. The Pd—S—Pd bond angle of 90.3(1)° lies within the wide range of values (83–92°) reported.[9,10] The angle at the bridging chlorine Pd—Cl(2)—Pd [⟨82.9(1)°⟩] is significantly smaller than that reported[11,12] in chloro bridged dinuclear palladium and platinum complexes but, agrees well with that observed in the analogous platinum derivative (Table 3). The two dimethyphenylphosphine ligands adopt different conformations. The methyl group C(7) on one of the P atoms [P(1)], lies very nearly in the plane of the phenyl ring attached to the same P atom. This is not seen at the other P atom. The mercaptoethyl group is in an axial configuration, with respect to the mean plane, through the Pd—Cl—S—Pd bridge atoms (Fig. 2). The two phenyl rings are inclined to each other at 128.0(3)° and make angles of 74.4(3)° and 89.8(2)° with their respective coordination planes. The Pd—Pd distance, as in the platinum derivative,[13] is 3.234(3) Å which is significantly shorter than hitherto reported[11,12] in halogen bridged dinuclear palladium(II) complexes. The structure, as seen from Table 3, seems to be isomorphous to the platinum derivative with the only significant difference being the angles P(1)—Pd(1)—S(1) and Pd(1)—S(1)—Pd(2), which are not as large as those observed in the platinum analogue. A comparison of the bond lengths and angles of the two homologous Pd and Pt complexes is given in Table 3. Figure 3 shows a packing of the two molecules in the unit cell.

EXPERIMENTAL

$[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ was prepared according to the literature method.[14] Analytical grade solvents were used throughout. General methods and spectroscopic techniques have been described previously.[1,2]

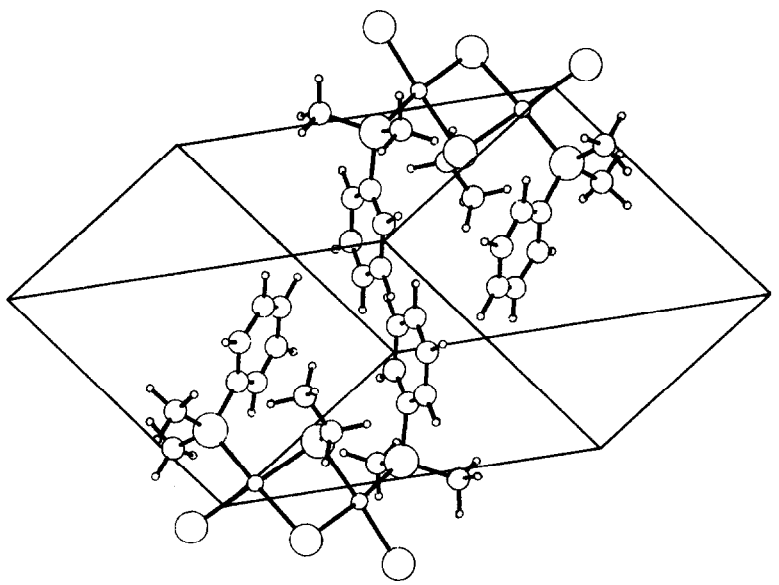

Fig. 3. Packing of two molecules in the unit cell.

Preparation of $[Pd_2Cl_2(\mu\text{-}SEt)_2(PMe_2Ph)_2]$

To an acetone suspension of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (406 mg, 0.64 mmol) excess of ethyl mercaptan (0.5 cm^3) was added and the reaction mixture stirred at room temperature for 3 h. The solvent was stripped off and the residue was recrystallized from chloroform–methanol mixture to give yellow crystals in 88% (388 mg) yield. ^1H NMR data in $CDCl_3$ S—CH_2 δ 2.20 (Q, 7 Hz), 2.98 (m)*; S—C—CH_3 δ 0.92 (t, 7 Hz), 1.44 (t, 7 Hz)*; P—Me δ 1.66 (d, 11 Hz), 1.76 (d, 11 Hz); P—Ph δ 7.38–7.69 (m) (**trans* to phosphine ligand). Similar reaction with excess Pr^iSH, however, gave a mixture of products as revealed by ^{31}P NMR spectroscopy, but when carried out in 1:4 stoichiometry in acetone, yielded the dimercapto complex which was recrystallized thrice from acetone–methanol mixture. [^1H NMR in $CDCl_3$ —S—CH< δ 3.75(m), 3.05(m); —CMe_2 δ 1.70 (d, 6 Hz), 1.09 (d, 6 Hz); PMe_2 δ 1.67 (d, 11 Hz), 1.74 (d, 11 Hz); P—Ph δ 7.35–7.72 ppm.] The chloro–mercapto bridged complexes were obtained by heating an equimolar mixture of $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ and $[Pd_2Cl_2(\mu\text{-}SEt)_2(PMe_2Ph)_2]$ in chloroform and recrystallizing them from chloroform–methanol. [^1H NMR in $CDCl_3$: $[Pd_2Cl_2(\mu\text{-}SEt)(\mu\text{-}Cl)(PMe_2Ph)_2]$: —$SCH_2$ δ 2.45 (q, 7 Hz, ^4J(P—H) 1.3 Hz); C—CH_3 δ 1.03 (t, 7 Hz); PMe_2 δ 1.92 (d, 12 Hz), 1.82 (d, 12 Hz); P—Ph δ 7.42–7.68 (m). $[Pd_2Cl_2(\mu\text{-}SPr^i)(\mu\text{-}Cl)(PMe_2Ph)_2]$: —SCH< δ 3.55 (m); —CMe_2 δ 1.15 (d, 6 Hz); PMe_2 δ 1.80 (d, 12 Hz), 1.91 (d, 12 Hz); PPh δ 7.33–7.81 (m).]

Crystallographic studies

(i) *Crystal data.* $C_{18}H_{27}P_2SCl_3Pd_2$, mol.wt. = 656.3, triclinic, $P\bar{1}$, $a = 9.273(3)$, $b = 10.412(3)$, $c = 13.767(6)$ Å, $\alpha = 80.84(3)$, $\beta = 81.62(3)$, $\gamma = 68.04(3)°$, volume = 1211.67 $Å^3$, $Z = 2$, $D_c = 1.80$ g cm^{-3}, $D_m = 1.78$ g cm^{-3}, $F(000) = 648$, $\mu = 18.68$ cm^{-1}.

(ii) *Data collection.* Intensity data for 4243 reflections were collected on an Enraf–Nonius CAD-4 diffractometer with graphite monochromator using Mo-K_α radiation ($\lambda = 0.7107$ Å) employing ω-2θ step scan in the range $2 \leqslant \theta \leqslant 25°$ with $0 \leqslant h \leqslant 11$, $-11 \leqslant k \leqslant 12$ and $-15 \leqslant l \leqslant 16$. Data were corrected for Lorentz and polarization effects. No absorption correction was applied.

(iii) *Structure determination.* The structure was solved by Patterson and successive Fourier methods. All hydrogen atoms were fixed at calculated positions. The non-hydrogen atoms were refined isotropically (five cycles) and anisotropically (three cycles) by the least-squares method. The final R for 3950 unique reflections [$I \geqslant 2.5\sigma(I)$] was 0.032 and wR = 0.049 with $[\Delta/ESD]_{max} = 0.709$. $\Delta\rho$ in the final difference map was 0.45 and -1.02 e $Å^{-3}$. Program SHELX76[15] and the ND-500 computer were used for all calculations, and the scattering factor for palladium was taken from *International Tables for X-ray Crystallography*, Vol. IV (1974).

(*Received* 2 *February* 1989; *accepted* 14 *April* 1989)

Abstract—Tris-isothiocyanato complexes of the general formula $[M(NCS)_3L]$ have been synthesized and characterized, in which M is yttrium(III) or europium(III) and L is an 18-member macrocyclic ligand with a six-nitrogen-donor cavity ($L_I = C_{22}H_{26}N_6$, $L_{II} = C_{18}H_{18}N_6$). X-ray analysis of the yttrium(III) and europium(III) complexes of ligand L_I showed the coexistence in the same crystal of two kinds of nine-coordinate molecules with different macrocycle conformations. The two complexes were isostructural and crystallized in the monoclinic *Cc* space group, with cell parameters $a = 33.244(3)$, $b = 11.976(2)$, $c = 14.164(2)$ Å, $\beta = 92.72(5)°$ for europium and $a = 33.226(3)$, $b = 11.986(2)$, $c = 14.102(2)$ Å, $\beta = 92.84(5)°$ for yttrium. The structure of the europium(III) complex, refined by block matrix least-squares, gave the final values $R = 0.0236$ and $R_w = 0.0244$; the structure of the yttrium(III) complex, refined by full matrix, resulted in $R = 0.042$ and $R_w = 0.039$.

A considerable number of lanthanide(III) complexes with the six-nitrogen-donor macrocyclic ligands L_I and L_{II} (Fig. 1) have been synthesized by metal-templated, Schiff-base cyclic condensation of appropriate diamine and diketone precursors.[1–9] A representative selection of these compounds has been characterized by single-crystal X-ray diffraction analysis,[1,4,6–9] as well as infrared (IR) and nuclear magnetic resonance (NMR) spectra.[1–7] A detailed luminescence study has been carried out for a europium(III) derivative.[10,11] Yttrium(III) complexes of the same six-nitrogen macrocycles have also been reported.[12] All these complexes shared as a common feature the presence of a highly inert macrocyclic entity accompanied by two or three labile oxygen-donor exocyclic ligands, linked to the central metal ion on opposite sides of the macrocycle. The presence of coordinating oxygen-donor counterions, such as acetate or nitrate, was

L_I L_{II}

Fig. 1. Schematic formulae of complexes of M^{3+} ions with the $L_I = C_{22}H_{26}N_6$ and $L_{II} = C_{18}H_{18}N_6$ macrocyclic ligands.

observed greatly to facilitate the metal-template synthesis of these macrocycles; however, substitution by non-coordinating counterions, or by counterions with different donor atoms, was shown to be feasible once the macrocyclic cations had been formed. In the present work, we set out to prepare and characterize a representative number of complexes of the L_I and L_{II} macrocycles with NCS^- counterions. The metals chosen were europium(III), for its potential as a monochromatic luminscent material, and yttrium(III), which being diamagnetic offers the opportunity for NMR studies.

EXPERIMENTAL

Starting materials and procedures

Sodium thiocyanate (Aldrich Chemical Co.) was dehydrated *in vacuo* over phosphorus pentoxide. The macrocyclic complexes of the general formula $ML(CH_3COO)_2Cl \cdot nH_2O$ (M = yttrium(III) and europium(III); L = $C_{22}H_{26}N_6$ (L_I) or $C_{18}H_{18}N_6$ (L_{II}); n = 3–6) were prepared as previously described.[5,12] All solvents were reagent grade and anhydrous unless stated otherwise. Thermogravimetric measurements were carried out on Perkin–Elmer TGS-2 thermogravimetric system, under a dry helium flow of 60 $cm^3\,min^{-1}$. IR spectra were taken with a Perkin–Elmer Model 160 FTIR spectrophotometer. Fluorescence spectra were taken with an SLM-Model 800 photon-counting spectrofluorometer. ^1H NMR spectra were obtained with a JEOL FX90 Q spectrometer. Microanalyses (C, H, N) were performed by Atlantic Microlabs, Atlanta, Georgia.

Preparation of the $[M(NCS)_3L]$ *complexes* (M = *yttrium*(III) *or europium*(III); L = L_I *or* L_{II})

All complexes were obtained by metathesis from the corresponding diacetate-chloride salts, following the procedure outlined here for the Y—L_I species. A filtered solution of $YL_I(CH_3COO)_2Cl \cdot 4H_2O$ in methanol (1 mmol in 75 cm^3) and a filtered solution of NaNCS in methanol (4 mmol in 35 cm^3) were each warmed to approximately 60°C and mixed. The resulting solution was stoppered lightly and allowed to stand at room temperature for several days. The off-white crystalline solid that formed was filtered, washed first with cold methanol and then with diethylether, and dried *in vacuo* over phosphorus pentoxide. Yields, *ca* 60%. Found: C, 47.1; H, 4.3; N, 19.8. Calc. for $Y(NCS)_3(C_{22}H_{26}N_6)$: C, 47.1; H, 4.1; N, 19.8%.

The other complexes of this series also had analyses corresponding to the anhydrous $[M(NCS)]_3L$ species.

X-ray measurements and structure determination

A single crystal of $[Eu(NCS)_3L_I]$, having approximate dimensions $0.41 \times 0.28 \times 0.40$ mm, was used for data collection on a Philips PW1100 diffractometer. Final lattice parameters, as determined from a least-squares refinement of $(\sin\theta)/\lambda^2$ values for 18 reflections ($2\theta < 25°$) accurately centred on the diffractometer, are given in Table 1 together with the details of data collection. The intensities were corrected for Lorentz, polarization and absorption following North and Phillips method.[13]

The structure of the Eu—L_I complex was solved via Patterson function and refined first in the space group $C2/c$, with a molecule of $[Eu(NCS)_3L_I]$ as the asymmetric unit. In this space group the refinement stopped at $R = 15\%$, with unrealistic values of bond distances and angles. Attempts to interpret the ligand structure with a statistical distribution of the atoms of the macrocyclic ligand were unsuccessful. Starting from two europium(III) positions of the $C2/c$ space group, and moving them out of the symmetry-related positions of $C2/c$ to partly eliminate the centrosymmetric solution for the rest of the molecule, we were able to interpretate the electron density residuals in terms of two independent $[Eu(NCS)_3L_I]$ units in the non-centrosymmetric Cc space group. Refinement was accomplished in blocks, refining alternatively the $[Eu(1)(NCS)_3L_I]$ and $[Eu(2)(NCS)_3L_I]$ units, with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogens were introduced at calculated positions (C—H = 0.98 Å), with fixed unique isotropic thermal parameter ($U = 0.07$ Å^2), and allowed to ride on associated carbon atoms. The refinement converged to $R = 0.0236$, $R_w = 0.0244$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$. The number of parameters for each block was 348. In the final difference map, $\Delta\rho$ was

$< |0.3|$ e Å^{-3}. Scattering factors and anomalous dispersion corrections were taken from the *International Tables for X-ray Crystallography*.[14] The programs used were SHELX 76[15] for the structure solution and refinement, ORTEP[16] and PLUTO[17] for drawing, and PARST[18] for geometrical calculations.

Data collection and treatment for the yttrium(III) compound were carried out as described for the europium(III) analogue. A single crystal of the yttrium(III) complex, having approximate dimensions 0.10 × 0.24 × 0.32 mm, was used for the analysis and crystallographic parameters are reported in Table 1. The $[Y(NCS)_3L_I]$ compound was isostructral with the europium(III) analogue and its structure was solved in a similar manner. (In this case, too, no reasonable results were obtained from a $C2/c$ centrosymmetric solution.) However, owing to the poor quality of the crystal, and consequently to the limited number of reflections observed (see Table 1), only the yttrium(III) and NCS groups were refined anisotropically, while the other non-hydrogen atoms were refined isotropically. The hydrogens were included in calculated positions, as described for the europium(III) complex. The number of parameters refined by full matrix least-squares was 398, and the refinement converged to $R = 0.042$ and $R_w = 0.039$. In the final difference Fourier map, $\Delta\rho$ was $< |0.35|$ e Å^{-3}.

Bond lengths and angles are given in Tables 2 and 3, and torsion angles are given in Tables 4 and 5. Supplementary material (tables of atomic coordinates, atomic vibrations and calculated structure amplitudes) has been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

General characteristics of the complexes

The $[M(NCS)_3L]$ complexes synthesized and investigated in this work were nearly colourless crystalline solids, stable to air and moisture and

extremely stable to heat; their thermogravimetric analysis showed only a gradual mass loss of < 1% up to 250°C. The IR absorption spectra of the yttrium(III) and europium(III) complexes of each macrocycle were identical to one another and those of complexes of the L_I and L_{II} macrocycles were extremely similar. Each spectrum showed the very strong characteristic ν(C≡N) absorptions at *ca* 1640 and 1590 cm^{-1}, together with the "fingerprint pattern" of the respective macrocycle[12] and the absorptions arising from the N-bonded NCS^- ligands. For the Y—L_I complex, the latter had the following values (cm^{-1}): ν(C≡N), 2062 sh, 2049 vs; ν(C—S), 813 m-w, partly overlaid by macrocycle absorption; ν(M—N), 488 sh, 474 w; similar values were observed for the other complexes. The splitting of the ν(C≡N) and the ν(M—N) absorptions was consistent with the low symmetry of the $M(NCS)_3$ moiety as determined by X-ray crystallography.

The $[M(NCS)_3L]$ complexes were insoluble in water and either insoluble or sparingly soluble in most organic solvents. This prevented the measurement of carbon-13 NMR spectra under the conditions of our experiment; however, the proton spectrum of the Y—L_I complex in deuterodimethylsulphoxide gave results consistent with the presence in solution of a highly symmetrical macrocyclic entity which did not undergo degradation over a period of several days. (^{1}H chemical

shifts, δ, ppm vs. TMS: 8.40–8.35, complex pattern, 6H, py; 3.95, 8H, CH_2; 2.55, 12H, CH_3.) These values were very similar to those previously reported for complexes of the same ligand with other diamagnetic metal ions and/or other counterions.[6,12] In the solid state, the tris-isothiocyanato complexes of europium(III) showed the modest ligand-mediated luminescence (most intense emissions: *ca* 615 nm) that has been observed for these same macrocycles in the presence of acetates as counterions.[11] In solution, the luminescence was almost completely quenched.

Crystal structure of the europium(III)—L_I *and yttrium*(III)—L_I *tris-isothiocyanato complexes*

The crystal of the europium complex was found to contain two distinct molecules, having the same formula, $[Eu(NCS)_3L_I]$, as well as the same metal coordination environment, but differing in the conformation of the L_I macrocyclic ligand. The structures of the two complex molecules are illustrated as ORTEP drawings in Figs 2a and 2b. In each molecule the Eu^{III} ion is linked to the six nitrogen atoms of the macrocyclic ligand, which consists of two approximately planar sections hinged at the —CH_2—CH_2— side chains to give a "folded butterfly" configuration. In addition, the Eu^{III} is linked to the three nitrogen atoms of the isothiocyanato ligands, two on the convex side of the macrocycle and the third on the opposite side. However, the two complex molecules differ in the conformations of the macrocyclic ligands, and two "planar" sections of which exhibit different foldings (111.3° for molecule *a* and 102.1° for molecule *b*). The torsion angles about the —CH_2—CH_2— side chains are also different: for molecule *a*, N(2)—C(8)—C(9)—N(3) is 55(1)° and N(5)—C(19)—C(20)—N(6) is 48(1)°; for molecule *b*, N(15)—C(49)—C(50)—N(16) is 50(1)° and

N(12)—C(38)—C(39)—N(13) is 43(1)°. Thus, even though the Eu^{III} ions are located close to the *C2/c* general positions, the conformations of the macrocyclic ligands cause the space group symmetry to be lowered to *Cc*. The coexistence of two species with different stoichiometries and/or slightly different conformations appears to be a common feature in macrocyclic complexes of the lanthanides.[6,12,19,20]

Examination of the europium(III) coordination sphere in molecules *a* and *b* shows some interesting features. In molecule *a*, where the folding of the macrocycle is smaller (111.3° for *a* vs 102.1° for *b*), each of the Eu—N_L bond distances is shorter than the corresponding distance in *b*, even though the same trends are observed for the Eu—N_{py} and Eu—$N_{aliphatic}$ distances. Conversely, the average Eu—NCS bond distance is longer for Eu(1) in *a* (2.505 Å) than for Eu(2) in *b* (2.427 Å). The NCS^- ligands themselves are all appreciably different from one another, even though each shows the same structural pattern. In each case the NCS group is linear but the Eu—NCS linkage is bent at the N atoms, with an average M—N—C angle of 142° in

both *a* and *b*; individual M—N—C angles range from 127.0 to 151.7°. A considerable variation is also observed in the bond lengths of the isothiocyanato ligands; the C—N distances range from 1.08 to 1.26 Å, whilst the C—S distances range from 1.55 to 1.69 Å. Considering that the two main resonance forms for a coordinated isothiocyanato ligand are M—N≡C—S (M—N—C angle, 180°; Pauling bond lengths: N≡C, 1.15 Å, C—S, 1.81 Å) and M—N=C=S (M—N—C angle, 120°; Pauling bond lengths:[21] N=C, 1.29 Å, C=S, 1.61 Å), the observed bond angles and distances suggest that both forms contribute, to only slightly different extents, to the Eu—NCS bonding in these molecules. Thus, the metal–NCS linkage in $[Eu(NCS)_3L_I]$ differs appreciably from that present in the salt $[(C_4H_9)_4N]_3[Er(NCS)_6]$, the only other isothiocyanato lanthanide(III) complex for which the structure is known.[22] In the octahedral $[Er(NCS)_6]^{3-}$ ion, the Er—N—C—S groups are nearly linear, with the N—C bond [1.10(3) Å] and the S—C bond [1.61(3) Å] just slightly shorter than expected for the linear resonance form above.[21]

A comparison among the bond angles and distances of the Eu(1)—NCS groups further reveals that, as the M—N—C angle decreases and approaches 120°, the corresponding C—N bond length increases while the C—S bond length decreases, each approaching its typical double bonded value; whilst the Eu(2)—NCS groups do fit into this pattern for that concerning the C—N bond distances and the M—N—C angles, also if the C—N average fits better into a triple bond value and the C—S into a single bond value. Inconsistencies of this kind have been observed for other metal–isothiocyanate complexes,[22] as steric factors and packing requirements can also play an important rôle in determining the NCS ligand geometries. The molecule packing of $[Eu(NCS)_3L_I]$, viewed down the *b* axis, is shown in Fig. 3. The structure is rather compact and shows a number of intermolecular contacts among sulphur atoms and also between sulphur atoms and macrocycle atoms; these contacts might be responsible for the peculiarities in bond angles and distances observed for the isothiocyanate ligands. Two rather short interactions are S(80)···S(3)′ ('$1/2+x$, $1/2-y$, z) of 3.718(9) Å and S(2)···S(60)″ ("x, $1-y$, $3/2+z$) of 3.592(7) Å. The S(70) atom is involved also in numerous contacts of the order of 3.5 Å with the carbon atoms of the adjacent molecules at x, $-y$, $1/2+z$ (for Eu(1)—L), and x, $1-y$, $-1/2+z$ (for Eu(2)—L). This could account for the highest bending for Eu(1)—N(70)—C(70) angle 127.0(9)°.

The structure of the yttrium(III) complex $[Y(NCS)_3L_I]$, was studied to obtain information on the effect of the metal ionic radius on the conformation of the macrocycle. The yttrium complex was found to be isostructural with the europium analogue and, similar to it, was characterized by the presence in the crystal lattice of two molecules of identical formula but different ligand conformations. The two "planar" halves of the L_I ligand formed an angle of 111.1(4)° for Y(1) and 103.2(4)° for Y(2), maintaining the trend observed for the europium analogue. The isothiocyanate ligands were again coordinated to the metal ion in an angular fashion, and their bond distances followed the general trend previously discussed for the europium species, the average values being N—C = 1.21(5) Å, C—S = 1.54(4) Å for Y(1), and N—C = 1.13(6) Å, C—S = 1.70(5) Å for Y(2). Unfortunately, the poor quality of the yttrium crystal, and consequently the high values of the ESDs, did not allow the observation of subtle differences in the bond lengths of Y(1) and Y(2). For example, the Y(1)—NCS average distance, 2.44(5) Å, was indistinguishable from the Y(2)—NCS average distance, 2.43(5) Å. Similarly, Y(1)—N_L and Y(2)—N_L had the same average value, 2.57(4) Å, coincident with the value of 2.570(8) Å reported for the nine-coordinated yttrium(III) complex $[Y(CH_3COO)_{1.5}(H_2O)_{0.5}L](CH_3COO)_{0.5}ClO_4$.[12] These yttrium(III)–ligand bond lengths, when compared to the corresponding values of the europium(III) species, reflect exactly the difference in ionic radii of the two metal ions for C.N. = 9, as given by Shannon.[23]

Attempts to describe the coordination polyhedron of the Eu^{III} and Y^{III} ions in the $[M(NCS)_3L_I]$ complexes in terms of their preferred nine-coordinate geometries, tricapped trigonal prism or monocapped square antiprism, were unsuccessful. We then attempted to describe the coordination of the macrocycle through the geometrical arrangement of the nitrogen atoms around the metal centre. The puckering analysis[24] on these six-nitrogen moieties gave the following results: with the smaller Y^{3+} ion, the puckering constants were $Q = 1.16(4)$, $\theta = 93(2)°$ and $\phi = 137(2)°$ for Y(1), and $Q = 1.16(4)$, $\theta = 85(2)°$ and $\phi = -42(2)°$ for Y(2) species; in each case the six-nitrogen ring was not planar but had a slightly twisted half-chair conformation. For the europium(III) analogue, the puckering constants were $Q = 1.10(1)$, $\theta = 90.5(6)°$, $\phi = 139.5(7)°$ in the Eu(1) species and $Q = 1.12(1)$, $\theta = 87.7(7)°$, and $\phi = -39.5(6)°$ in the Eu(2) species; the six-nitrogen ring had approximately the same half-chair conformation as in the yttrium(III) species. The only possible geometrical description of the coordination polyhedron is based on an approxi-

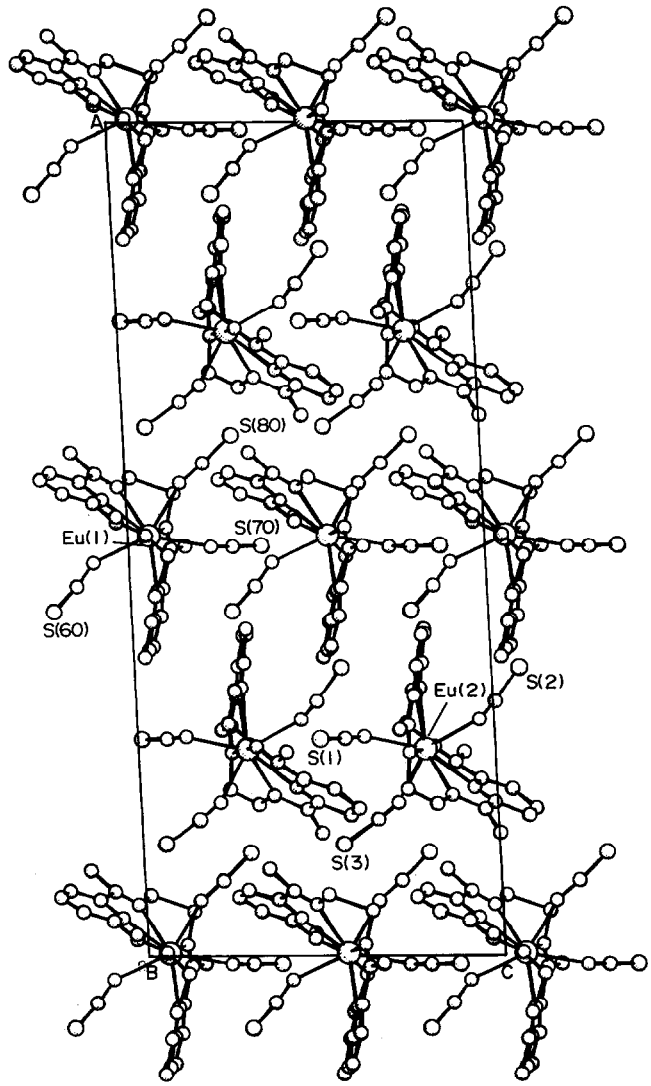

Fig. 3. Unit cell of $[Eu(NCS)_3L_I]$ viewed down the *b* axis.

mately planar pentagon defined by the two nitrogens of the pyridine rings, N(1) and N(4), and the three nitrogens of the NCS moieties N(60), N(70) and N(80), with deviations from the best mean plane ranging from −0.476(10) to 0.376(9) Å. The two nitrogens of one diamine moiety, N(2) and N(3), are below this five-nitrogen plane (−2.16(1) and −2.17(1) Å); those of the other diimine moiety, N(5) and N(6), are above it (2.23(1) and 2.22(1) Å). The values for Eu(1) do not differ appreciably from those for Eu(2), Y(1) and Y(2); they are reported as examples of this unusual geometrical situation.

Finally, it is instructive to compare the bending of the L_I macrocycle in the complexes reported here with that observed in complexes of the same ligand with other lanthanides and/or other negative ligands. The values of the macrocycle foldings are shown in Table 6, together with the coordination numbers and ionic radii of the central metals. For the nitrato-complexes, the progressive departure from planarity from lanthanum(III) to neodymium(III) was explained as a requirement to maintain six-coordination as the radius of the central metal decreased.[7] A similar trend was observed for the yttrium(III)[12] and lutetium(III)[6] with acetates as anionic ligands. In contrast, for the isothiocyanato complexes described in the present study, the folding of the macrocycle does not match the values of the ionic radii. Furthermore, the presence within the same crystal of two complex entities with the same formula but different foldings suggests that the NCS^- ligands, being less bulky than either nitrates or acetates, allow a greater flexibility of the macrocycle, so that the con-

Table 6. Dihedral angles for six-nitrogen macrocycles of the lanthanides

[a] In all these species, the macrocycle is bent towards the less hindering single ligand.
[b] According to Shannon for IX coordination.[23]

formation is influenced to a rather significant extent also by crystal packing requirements.

CONCLUSIONS

This work has shown that the trivalent yttrium and europium cations, when coordinated to the six-nitrogen cavity of the 18-member macrocyclic systems L_I and L_{II}, display an unusual preference for the N-donor atoms of the NCS ligands, compared to either the O-donor atoms of polar solvents (water, methanol) or those of negatively charged ligands such as acetates. The molecular tris-isothiocyanato complexes, $[M(NCS)_3L]$, are insoluble in water and either insoluble or sparingly soluble in most organic solvents; also, unlike most other salts of these macrocycle systems, they show no tendency to include solvent molecules in either the metal coordination sphere or the crystal lattice. The electronic and steric requirements of the central Y^{III} and Eu^{III} ion appear to be fully satisfied by coordination to nine nitrogen atoms—six from the macrocycle cavity and three from the isothiocyanato groups. The remarkable stability of this nine-nitrogen coordination sphere, not previously observed in compounds of yttrium(III) or the lanthanide(III) ions, is further emphasized by the nearly identical folding of the macrocycle in the yttrium(III) and europium(III) species, despite the difference in the ionic radii of these two elements. The coexistence of different macrocycle conformations within the same crystal, in the absence of external influences due to chlathrated solvent molecules, suggests that the conformation of the macrocycle is the result of several cooperative factors that include not only the ionic radius of the encapsulated metal ion but also crystal packing forces and steric requirements of the exocyclic ligands.

STRUCTURE, SYNTHESIS AND CHARACTERIZATION OF CHIRAL, PHOSPHIDO-PHOSPHINE, DIPHOSPHINE PLATINUM(II) MONO- AND DIMERIC COMPLEXES: THE MOLECULAR STRUCTURE OF BOTH $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]$ AND $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(S^*,S^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPrH\}]$

(*Received* 1 *February* 1989; *accepted* 14 *April* 1989)

Abstract—The preparation and spectroscopic characterization of the chiral phosphido-phosphine, diphosphine dimeric complex $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPr_2\}]$ (**3a**) is reported. The further isolation of $[PtCl_2(H^iPrPCH_2P^iPr_2)]$ (**1**) and $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]$ (**2b**) has led to a rationalization of the racemate's, **3a**, predomination, over other potential isomers, e.g. $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(S^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPr_2\}]$ (**3b**), in terms of its mechanism of formation. The mixed ligand dimer, $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(S^*,S^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPrH\}]$ (**4**), has also been prepared and characterized spectroscopically. The structures of **2b** and **4** have been elucidated via X-ray diffraction studies.

The use of diphosphine ligands of the type $R_2PCH_2PR_2$ in the stabilization of dimers against their degradation to mononuclear fragments has received significant attention.[1] The question as to when these ligands will bridge forming dimers, as opposed to coordinating in a chelate fashion generating mononuclear fragments, has been interpreted with regard to the steric bulk of the "R" substituents of the diphosphine.[2]

Unlike their tertiary analogues, secondary diphosphines of the type $HRPCH_2PR_2$ and $HRPCH_2PRH$ have received little attention, though they possess the same ability to stabilize multinuclear centres through bridging coordination modes.[2a,3] Further, these systems are of interest due to the potential of increasing nuclearity through phosphorus–hydrogen bond activation.

We now report the generation of complexes of the type $[Pt_2Cl_3(\mu\text{-}RPCH_2PR_2)(HRPCH_2PR'_2)]$ (R = ^{i}Pr, R′ = ^{i}Pr, H), which are formed through the chelating or bridging interactions of the ligands $H^iPrPCH_2P^iPr_2$ and $H^iPrPCH_2P^iPrH$ with platinum(II) centres.

RESULTS

Stoichiometric reaction of $[PtCl_2(SMe_2)_2]$ and $H^iPrPCH_2P^iPr_2$ affords the isolation of $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPr_2\}]$ (**3a**) in good yield. However, when the same reaction was carried out for shorter time periods, significant quantities of $[PtCl_2(H^iPrPCH_2P^iPr_2)]$ (**1**) were isolated. Further, small quantities of another complex, $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]$ (**2b**), were also isolated from these reaction systems (see Experimental).

The mononuclear complex, **1**, is readily characterized by the use of ^{31}P and ^1H NMR spectra. The ^{31}P NMR spectrum reveals two resonances at δ −27.6 and −80.0, a doublet and doublet of doublets, respectively. The shifts are to high field of the free ligand, as expected for chelating diphosphines, $\delta_{complex} - \delta_{free\ ligand}$: ΔP^a, −33.2, ΔP^b, −35.4.[4] The higher field resonance shows a $^1J(PH) = 404$ Hz due to the presence of the phosphorus–hydrogen bond. The ^1H NMR posseses a resonance at δ 4.33,

† Author to whom correspondence should be addressed. Present address: Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C. Canada V6T 1Y6.

^1J(PH) = 404 Hz, ^3J(HH) = 7 Hz, ^3J(HH) = 4 Hz due to the PH group of the diphosphine ligand. The two protons of the bridging methylene unit are observed as two independent resonances, δ 3.46 and 2.87, due to the non-equivalency induced by molecular asymmetry arising from the PH group of the diphosphine.

Complex **2b**, characterized by an X-ray diffraction study on its chloroform solvate as $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}{}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]\cdot 2CHCl_3$ (Fig. 1), consists of two distorted square-planar platinum(II) centres linked through a bridging phosphido-unit of a phosphido-phosphine ligand, $-P(^iPr)CH_2P^iPr_2$. The distortions arise from the steric strain involved in the generation of the four-membered heterocyclic rings. These distorted ring angles, P(6)Pt(1)P(8), 74.24(8)°; P(15)Pt(2)P(17), 73.57(8)°, are formed by the chelating diphosphine and phosphido-phosphine ligands.[3c,5] The phosphido-bridge in this complex is asymmetrically bound to the two platinum centres; Pt(1)P(6), 2.250(2) Å, Pt(2)P(6), 2.348(2) Å.

The ^{31}P NMR of complex **2b** possesses four non-equivalent phosphorus resonances each to high field of the corresponding free ligand shifts; P^a, δ −24.9; P^b, δ −68.8; P^c, δ −53.9 and P^d, δ −32.6. The high field shift of the resonances for P^a and P^b confirms the chelation of the diphosphine ligand within this complex; $\delta_{complex} - \delta_{free\ ligand}$: ΔP^a, −30.5; ΔP^b, −23.2.[4] The resonance for P^b possesses a large doublet splitting in the proton coupled spectrum, $^1J(P^bH)$ = 445 Hz. The resonance for P^c has two large one bond platinum couplings, $^1J(Pt^AP^c)$ = 2385 Hz, $^1J(Pt^BP^c)$ = 1926 Hz, indicating the presence of a phosphido-bridge. A large doublet splitting, $^2J(P^aP^c)$ = 367 Hz confirms that P^a and P^c are mutually *trans* to each other.

The ^{1}H NMR spectrum of complex **2b** reveals a resonance attributable to a PH functional unit; δ 5.08, $^1J(P^bH)$ = 443 Hz, $^2J(Pt^BH)$ = 45 Hz. Two resonances at δ 4.35 and 2.57 are assigned to the bridging methylene protons of the phosphido-phosphine ligand. This assignment is based on the observed chemical shifts and couplings of phosphido-phosphine ligands observed in related complexes **3a** and **4**. Resonances at δ 3.47 and 2.95 are therefore assigned to the bridging methylene protons of the diphosphine chelate. These chemical shifts are very similar to those observed in the mononuclear chelate, complex **1**.

The ^{31}P NMR of complex **3a**, as in complex **2b**, possesses four non-equivalent phosphorus resonances; P^a, δ 34.0; P^b, δ −5.0; P^c, δ −54.6; P^d, δ −27.8. However, two of the resonances are shifted to much lower field than the corresponding resonances in complex **2b**. Such relative chemical shifts confirm the presence of a bridging diphosphine; $\delta_{complex} - \delta_{free\ ligand}$: ΔP^a, +28.6; ΔP^b, +40.6. Resonances for P^a and P^d possess a large two-bond coupling, $^2J(P^aP^d)$ = 411 Hz, due to their mutual *trans* orientation. The resonance for P^c has two large one bond platinum–phosphorus coupling constants, $^1J(Pt^AP^c)$ = 2279 Hz and $^1J(Pt^BP^c)$ = 2978 Hz, due to the bridging phosphido-group of the phosphido-phosphine ligand. Only the resonance for P^b possesses a large one bond phosphorus–hydrogen coupling, $^1J(P^bH)$ = 411 Hz.

In the ^{195}Pt NMR spectra, two non-equivalent resonances are observed; Pt^A, δ −2539; Pt^B, δ −2801. The Pt^A resonance consists of three large one bond platinum–phosphorus couplings while the resonance for Pt^B possesses only two.

In the ^{1}H NMR spectra of complex **3a** the resonance attributed to the proton of the PH functional unit is readily observable at δ 4.62, $^1J(P^bH)$ = 410 Hz, ^3J(HH) = 12 Hz. Resonances at δ 5.23 and 2.81 are due to the bridging methylene protons of the chelating phosphido-phosphine ligand based on the results of selective phosphorus decoupling experiments.

A 1:1 reaction of $[PtCl_2(SMe_2)_2]$ with an equimolar mixture of $H^iPrPCH_2P^iPr_2$ and $H^iPrPCH_2P^iPrH$ yields a mixture of complex **3a** and $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}{}^iPrPCH_2P^iPr_2\}\{(S^*,S^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPrH\}]$ (**4**). Complex **4** was isolated in low yields as a pure white crystalline solid via fractional crystallization.

A sample of complex **4**, recrystallized from benzene, was found to contain 3/2 equivalents of solvated benzene through an X-ray diffraction study, Fig. 2. Structurally, it consists of a bridging chelate phosphido-phosphine ligand which forms a four-membered heterocyclic ring at the Pt^BCl metal centre. The Pt^ACl_2 and Pt^BCl centres are bridged by a disecondary diphosphine, thereby completing a six-membered heterocyclic ring in a twist boat configuration. This conformation minimizes the steric interactions of the isopropyl groups of P(10) and P(18). The four-membered ring possesses the typical strain of a chelating ligand system with a distorted ring angle, P(18)Pt(2)P(20), 73.3(1)°. The phosphido-bridge, unlike complex **2b**, is symmetrically bound to both metal centres.

As in the previously discussed dimers, complex **4** possesses four non-equivalent phosphorus resonances; P^a, δ −1.5; P^b, δ 5.5; P^c, δ −64.7; P^d, δ −24.1. Due to their lower field shifts the resonances for P^a and P^b are assigned to a bridging diphosphine. These two resonances are also observed to possess one bond phosphorus–hydrogen couplings; $^1J(P^aH)$ = 376 Hz, $^1J(P^bH)$ = 415 Hz. The resonance for P^c is assignable to that of the bridging

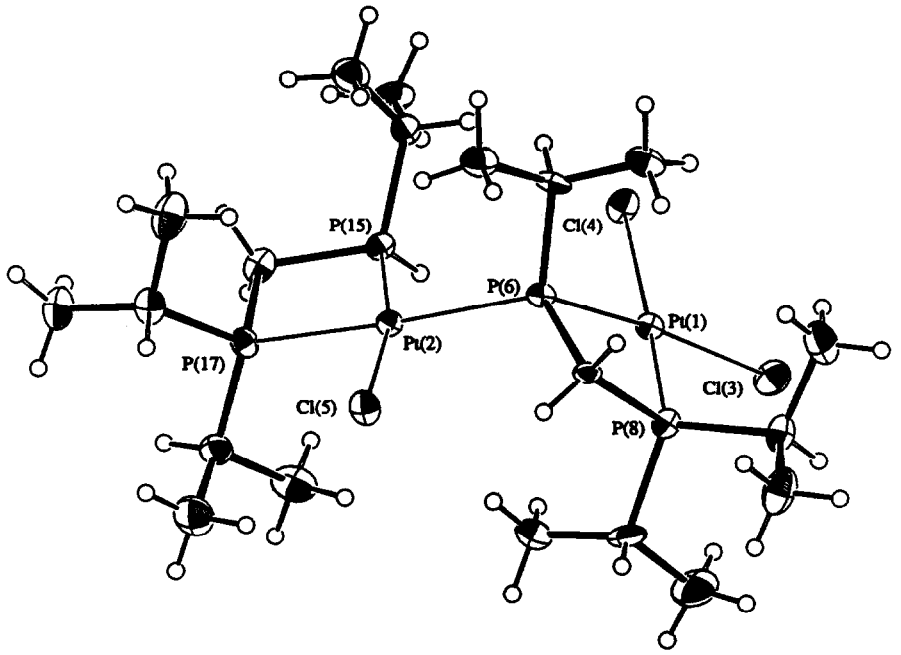

Fig. 1. The molecular structure of $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]\cdot 2CHCl_3$. Selected bond distances (Å) and angles (°) are:

Pt(1)Cl(3)	2.395(2)	Pt(1)P(6)	2.250(2)	Pt(2)P(17)	2.298(2)
Pt(1)Cl(4)	2.388(2)	Pt(2)Cl(5)	2.362(2)	Pt(2)P(6)	2.348(2)

Cl(4)Pt(1)P(8)	170.99(8)				

Selected non-bonding distances (Å) are: Pt(1)Pt(2) 3.985(1)

phosphido-group due to the presence of two large one bond platinum–phosphorus coupling constants; $^1J(Pt^AP^c) = 2103$ Hz, $^1J(Pt^BP^c) = 2965$ Hz. The two bond phosphorus–phosphorus coupling observable in the resonances for P^a and P^d, $^2J(P^aP^d) = 388$ Hz, confirms their mutual *trans* orientation.

The ^{195}Pt NMR spectra show two resonances; Pt^A, δ −2613; Pt^B, δ −2800. As for complex **3a**, the Pt^A resonance consists of three large one bond platinum–phosphorus couplings, while the Pt^B resonance possesses only two.

The ^1H NMR reveals the presence of two PH functional units; P^aH, δ 4.36, $^1J(P^aH) = 370$ Hz; P^bH, δ 5.02, $^1J(P^bH) = 415$ Hz. Selective phosphorus decoupling experiments confirm that resonances at δ 4.63 and 3.14 are due to the bridging methylene protons of the phosphido-phosphine ligand.

DISCUSSION

All of the observed complexes possess a sufficient number of chiral centres so as to generate a complicated isomeric mixture. The dinuclear platinum systems formed exclusively from the $H^iPrPCH_2P^iPr_2$ ligand possess two chiral centres which generate four stereochemical isomers. The asymmetry of the phosphine centres of the ligand and the two platinum centres of the dimer introduce the possibility of geometrical isomerism increasing the number of possible isomers to eight.[3c] In the mixed ligand system, from which complex **4** is generated, the bridging diphosphine is symmetrical eliminating the geometrical isomerism; however, the presence of a third chiral centre allows the possible generation of eight stereochemical isomers.

The mixed ligand product, complex **4**, was characterized as $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}$

{(S*,S*)-μ-H^{i}PrPCH$_2$P^{i}PrH}] by an X-ray diffraction study, Fig. 2. The bridging diphosphine, in this structure, has an isopropyl group on one of the phosphorus atoms in an axial position with the axial site of the other phosphorus atom occupied by a proton. This reduces steric strain within the system which results from diaxial interactions within bridging diphoshines, Fig. 2. Substitution of the proton on P(10) with an isopropyl group leads to the structural framework proposed for complexes **3a** and **3b**. However, two axial isopropyl groups on the bridging diphosphine would be expected to increase the steric interactions sufficiently so as to cause this structure to be that of a minor isomer, complex **3b**. Therefore the major isomer within this reaction system, complex **3a**, was proposed to be [Pt$_2$Cl$_3${(R*)-μ-^{i}PrPCH$_2$P^{i}Pr$_2$}{(R*)-H^{i}PrPCH$_2$P^{i}Pr$_2$}]. This parallels observations in the related palladium system reported earlier.[3c] These assignments are further supported by the observed ^{31}P NMR chemical shifts for the P^b resonances of complexes **4**, **3b** and **3a**. The chemical shift of the resonance for P^b would be expected to reflect greater variations in changes of chirality at P^b rather than structural changes at P^a (i.e. exchanging a proton for an isopropyl group). In Table 1 the chemical shifts for the P^b resonance in complexes 4, **3b** and **3a** are 5.5, 6.6 and −5.0, respectively. The similar chemical shifts of the resonance for P^b in complexes **4** and **3b** suggest that these complexes possess a common chirality at this specific phosphorus atom.

Complex **2b** was characterized as [Pt$_2$Cl$_3${(R*)-μ-^{i}PrPCH$_2$P^{i}Pr$_2$}{(R*)-H^{i}PrPCH$_2$P^{i}Pr$_2$}] by an X-ray diffraction study, Fig. 1. Structurally, it represents the product of a condensation reaction between two monomeric chelates, complex **1**, which release a molecule of HCl. The phosphido-bridge in this complex is much more asymmetrically bound, than in complex **4**, due to the differing *trans* influences of phosphorus and chlorine. The loss of only one proton in the generation of a single phosphido-bridge

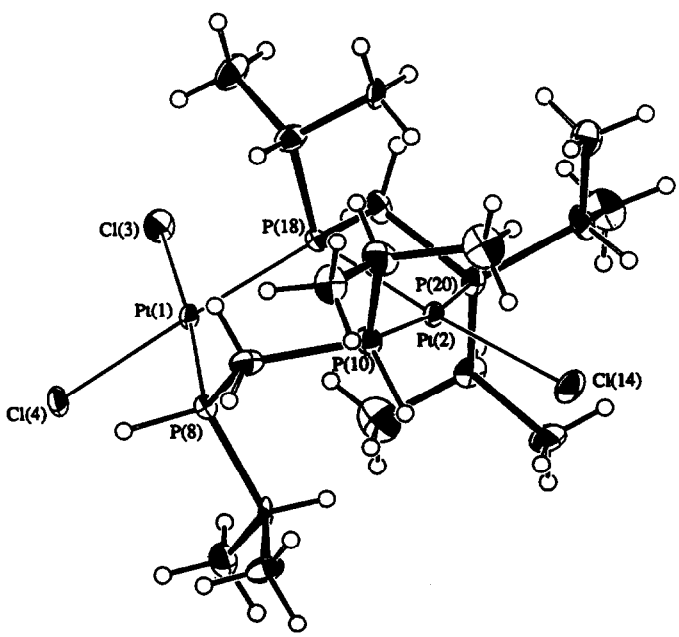

Fig. 2. The molecular structure of [Pt$_2$Cl$_3${(R*)-μ-^{i}PrPCH$_2$P^{i}Pr$_2$}{(S*,S*)-μ-H^{i}PrPCH$_2$P^{i}PrH}] · 3/2C$_6$H$_6$. Selected bond distances (A) and angles (°) are:

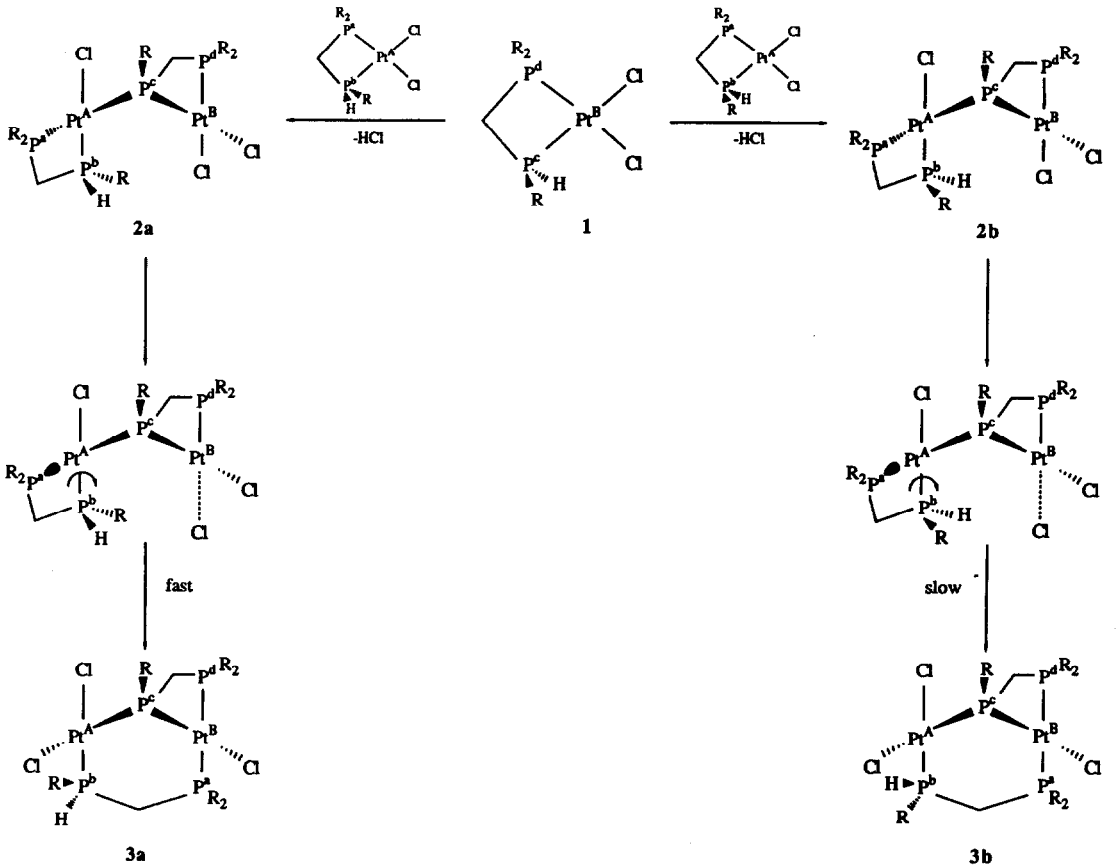
is totally attributable to the smaller backbone of the diphosphine ligands and the resultant steric strain that would result in further PH activation. This is not the case for diphosphines with longer carbon backbones, as shown by Meek and co-workers.[6] Complex **2b** represents a model of the likely intermediate species that would be formed enroute to bis-phosphido-phosphine dimers, $[Pt_2Cl_2\{\mu\text{-}RP(CH_2)_nPR_2\}]$. The steric strain induced by the distorted ring angles, P(6)Pt(1)P(8), 74.24(8)°; P(15)Pt(2)P(17), 73.57(8)°, of the four membered rings in complex **2b** presumably contributes to the observed instability of this complex in solution over long periods of time. Observation of complex **2b** by ^{31}P NMR over a 3-week period showed that 25% of this complex disproportionates into mononuclear chelates, complex **3a** and an unidentified monomer possibly formed from reaction of the free phosphido fragment and the chloroform solvent. Another 25% was observed to rearrange into complex **3b**. This rearrangement to complex **3b** may involve disproportionation; however, since the conversion is stereospecific, any intermediates formed by disproportionation would have to be sufficiently short-

lived as to prevent inversion at the phosphido-bridge. The stereospecific formation of complex **3b** is attributable to an exchange of Cl(4) and P(17) via the breaking of the P(17)Pt(2) bond, rotation about the P(15)Pt(2) bond, migration of Cl(4) and formation of the P(17)Pt(1) bond. The slow rate of this interconversion is probably due to the formation of a bridging diphosphine ligand which possess diaxial interactions between two sterically demanding isopropyl groups.

The isolation of these complexes suggests a mechanistic pathway for the formation of the diastereotopically related platinum dimers as shown in Scheme 1. It involves the condensation of two mononuclear chelates inducing the loss of HCl and the formation of a dinuclear dichelate. This system undergoes subsequent rearrangement to form the stereospecific dinuclear complex possessing the bridging diphosphine, either complex **3a** or complex **3b**. Observation of the reaction system by ^{31}P NMR spectroscopy confirms the formation of complex **1** within the reaction mixture followed by its disappearance over time. However, there is no evidence of the formation of a dinuclear dichelate intermediate to complex **3a**, complex **2a**. Therefore if this proposed mechanism is correct the conversion of the intermediate dichelate into complex **3a** must be sufficiently fast so as to account for its absence in the ^{31}P NMR spectra. The slow rate of conversion of complex **2b** to complex **3b** was attributed to the steric crowding of two isopropyl groups in the diaxial positions of the bridging diphosphine. However, complex **3a** has a proton and isopropyl group occupying the diaxial positions of the bridging diphosphine, a much less sterically demanding situation. Since complex **3a** lacks the steric demands of complex **3b**, complex **2a** might be expected to undergo this interconversion much more rapidly, thereby relieving the ring strain within its diphosphine chelate ring.

The products isolated from these systems are consistent with the formation of a dinuclear dichelate in which the phosphido linkage binds *cis* to the phosphorus atom of the diphosphine ligand bearing the proton and one isopropyl group, as opposed to the diisopropylphosphine end. This is presumably due to the reduced steric interaction at this site. This rationalizes the absence of the geometric isomer to



Scheme 1.

complex **3a**, in which the proton bearing phosphorus of the bridging diphosphine is bound to the $Pt^{B}ClP_3$ centre. Without the formation of the dichelate there is no obvious reason why both geometric isomers should not be formed in identical yield; however, steric effects controlling the conformation of the dichelate indirectly dictate which dimer is formed. The presence of the phosphido-bridge *cis* to the secondary phosphine end of the diphosphine leads to the coordination of the tertiary phosphine end to the $Pt^{B}Cl$ metal centre, after rearrangement. This steric effect is further evidenced by mixed ligand reactions of $H^iPrPCH_2P^iPr_2$ and $Ph_2PCH_2PPh_2$ or $^iPr_2PCH_2P^iPr_2$ with $[PtCl_2(SMe_2)_2]$ in which no mixed ligand products could be isolated, only $[PtCl_2(Ph_2PCH_2PPh_2)]$, $[PtCl_2(^iPr_2PCH_2P^iPr_2)]$ and complex **3a**. The steric bulk of the alkyl and aryl substituents on the phosphorus prohibit coordination of the phosphido-bridge fragment and therefore formation of the mixed ligand dimers.

EXPERIMENTAL

^1H NMR spectra were recorded on Nicolet NT 360, Varian XL 300 and Bruker WP 500 spectrometers. ^{31}P and ^{195}Pt spectra[7] were recorded on Nicolet NT 360 spectrometer. Chemical shifts are quoted with respect to Me_4Si (^1H), 85% H_3PO_4 (^{31}P), and K_2PtCl_4/D_2O (^{195}Pt).

$[PtCl_2(SMe_2)_2]$ was prepared by the literature method. The ligands $H^iPrPCH_2P^iPr_2$ and $H^iPrPCH_2P^iPrH$ were prepared by the literature method.[3b] All syntheses and reactions involving the phosphine ligands were carried out under N_2(g).

$[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPr_2\}]$ (**3a**)

In a typical reaction $H^iPrPCH_2P^iPr_2$ (3.4 g) was added dropwise to a stirring solution of $[PtCl_2(SMe_2)_2]$ (6.1 g) in ~ 200 cm^3 of CH_2Cl_2. After 24 h, the solvent was removed and the resultant yellow oil was redissolved in a minimum of hot methanol. This was allowed to cool slowly to room temperature after which it was stored at ~ -10°C over a 40 h period. A white solid was isolated and dried *in vacuo*, yield 5.7 g. From this sample crystals could be obtained by dissolution in $CHCl_3$ followed by slow evaporation of the solvent. The crystalline product could be isolated in nearly quantitative yields > 90%. NMR ($CDCl_3$): ^1H: 4.62 [dd, ^1J(PH) = 410 Hz, ^3J(HH) = 12 Hz, *H*P]; 5.23 [m, ^2J(HH) = 16.2 Hz, ^4J(PH) = 2.4 Hz, ^2J(PH) = 9.1. X-ray crystallographic study of $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(R^*)\text{-}H^iPrPCH_2P^iPr_2\}]$ (**2b**) *and* $[Pt_2Cl_3\{(R^*)\text{-}\mu\text{-}^iPrPCH_2P^iPr_2\}\{(S^*,S^*)\text{-}\mu\text{-}H^iPrPCH_2P^iPrH\}]$ (**4**)

A locally modified Picker four-circle diffractometer system was used in a moving crystal-moving detector mode for both studies. A molybdenum source and oriented graphite monochromator were utilized. Cooling was provided by a liquid nitrogen boil-off cooling system. The diffractometer system, cooling system and techniques used have been described in detail previously.[8] Both structures were

solved by a combination of direct methods (MULTAN78) and Fourier Techniques, and refined by full-matrix least-squares. In both cases hydrogen atoms were placed in fixed idealized geometries.

(*Received* 31 *March* 1989; *accepted* 17 *April* 1989)

Abstract—The ruthenium(II) and osmium(II) complexes $MCl_2(PPh_3)_3$, undergo oxidative substitution reactions with β-diketones under aerobic conditions in warm benzene to afford ruthenium(III) and osmium(III) β-diketonate complexes, MCl_2(β-diketonate)$(PPh_3)_2$. Generally these products appear to adopt the less sterically hindered *trans*-phosphine stereochemistry, but one example, $RuCl_2\{CF_3C(O)CHC(O)CF_3\}(PPh_3)_2$, deposits from hot and cold reactions as yellow (*trans*-phosphines) and red (*cis*-phosphines) isomers, respectively.

The ruthenium(II) complexes $RuCl_2(PPh_3)_n$ ($n = 3$ or 4) and their osmium analogues $OsCl_2(PPh_3)_n$, have been extensively employed as precursors in ligand (L) substitution reactions leading to a wide variety of ruthenium(II) and osmium(II) species, $MCl_2L(PPh_3)_3$ or $MCl_2L_2(PPh_3)_2$.[2] They are also susceptible to aerobic oxidation in solution yielding ill-characterized ruthenium(III) or osmium(III) products. The combination of these two processes—substitution and oxidation—was first achieved some 9 years ago in this laboratory, when a series of carboxylates, $MX_2(O_2CR)(PPh_3)_2$, were obtained by treatment of the complexes $MX_2(PPh_3)_3$ with carboxylic acids in benzene solution under aerobic conditions.[3] We have subsequently shown that a parallel reaction involving 1,3-diaryltriazene affords a range of ruthenium(III) and osmium(III) triazenide derivatives, MX_2(ArNNNAr)$(PPh_3)_2$.[4] The extension of our oxidative-substitution technique to the synthesis of ruthenium(III) and osmium(III) β-diketonate complexes, MCl_2(β-diketonate)$(PPh_3)_2$, is now reported.

EXPERIMENTAL

For general experimental details see ref. 4. β-Diketones were used as purchased without further purification. Melting points, analytical data and selected IR data are given in Tables 1 and 2.

Synthesis of dichloro(2,4-pentanedionato)bis(triphenylphosphine)ruthenium(III)

Dichlorotris(triphenylphosphine)ruthenium (0.3 g, 0.31 mmol) was added to a solution of 2,4-pentanedione (0.1 g, 1 mmol) in benzene (10 cm^3) and the mixture stirred at 70°C for 1 h under aerobic conditions. Upon cooling, the dark green solution was diluted with light petroleum and allowed to stand for 12 h, over which time the product precipitated. Recrystallization from dichloromethane–ethanol, followed by washing the precipitate with ethanol and light petroleum and drying *in vacuo*, afforded green crystals (0.21 g, 81.0%).

The following were prepared by the same method:

Dichloro(3-methyl-2,4-pentanedionato)bis(triphenylphosphine)ruthenium(III) as green needle crystals (52.0%).

Dichloro(3-ethyl-2,4-pentanedionato)bis(triphenylphosphine)ruthenium(III) as green needle crystals (29.0%).

nato)bis(triphenylphosphine)ruthenium(III) (red isomer) as red platelets (71.5%) from reactions conducted at room temperature.

Dibromo(2,4 - pentanedionato)bis(triphenylphosphine)ruthenium(III) was similarly prepared from dibromotris(triphenylphosphine)ruthenium as orange–brown needles (45.0%).

Synthesis of dichloro(2,4-pentanedionato)(pyridine)(triphenylphosphine)ruthenium(III)

Dichloro(2,4 - pentanedionato)bis(triphenylphosphine)ruthenium(III) (0.15 g, 0.2 mmol) was added to a solution of pyridine (0.5 g, 6 mmol) in benzene (10 cm^3) and the mixture refluxed for 10 min. The green solution rapidly turned orange, accompanied by precipitation of the product which was collected by filtration. Recrystallization from dichloromethane–ethanol, followed by washing the precipitate with ethanol and light petroleum and drying *in vacuo*, afforded pink crystals (0.1 g, 86.5%).

The following were prepared by the same method:

Dichloro(1,1,1 - trifluoro - 2,4 - pentanedionato)(pyridine)(triphenylphosphine)ruthenium(III) as red–orange platelets (64.0%).

Dichloro(1,1,1,5,5,5 - hexafluoro - 2,4 - pentanedionato)(pyridine)(triphenylphosphine)ruthenium (III) as orange needle clusters (63.0%), using the "yellow isomer" precursor.

Synthesis of chloro(carbonyl)(1,1,1,5,5,5 - *hexafluoro* - 2,4 - *pentanedionato)bis(triphenylphosphine)ruthenium*(II)

A solution of dichloro(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)bis(triphenylphosphine)ruthenium (III) ("red isomer") (0.15 g, 0.17 mmol) in benzene (15 cm^3) was refluxed under a carbon monoxide atmosphere for 6 h. After cooling, the orange solution was evaporated to dryness under reduced pressure. The resulting oil was recrystallized from dichloromethane–ethanol. Washing the precipitate with ethanol and light petroleum, followed by drying *in vacuo*, afforded orange crystals (0.07 g, 45.0%).

The same compound can also be prepared from the "yellow isomer" under identical reaction conditions.

Synthesis of dichloro(2,4-pentanedionato)bis(triphenylphosphine)osmium(III)

Dichlorotris(triphenylphosphine)osmium (0.3 g, 0.3 mmol) was added to a solution of 2,4-pentanedione (0.15 g, 1.5 mmol) in benzene (10 cm^3) and the mixture stirred at 70°C for 1 h. Upon cooling, the solution was diluted with light petroleum and allowed to stand for 12 h, over which time the product precipitated. Filtration of the solution, followed by washing of the precipitate with ethanol and light petroleum and drying *in vacuo*, afforded red–brown microcrystals (0.15 g, 59.0%).

The following were prepared by the same method:

Dichloro(1,1,1 - trifluoro - 2,4 - pentanedionato)bis(triphenylphosphine)osmium(III) as red–brown platelets (31.5%).

Dichloro(1,1,1,5,5,5 - hexafluoro - 2,4 - pentanedionato)bis(triphenylphosphine)osmium(III) as orange–brown platelets (53.0%).

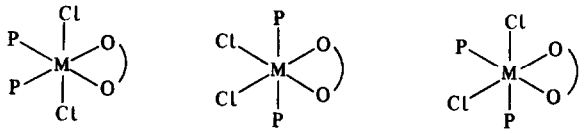
RESULTS AND DISCUSSION

The "oxidative substitution" reactions:

$$MX_2(PPh_3)_3 + RCO_2H \xrightarrow{O_2} MX_2(O_2CR)(PPh_3)_2$$

(M = Ru, Os; X = Cl, Br)

first reported from this laboratory in 1979,[3] and subsequently extended to cover other weak organic acids—1,3-diaryltriazenes[4] and selected Schiff bases[5]—have now been shown to provide a convenient route to new ruthenium(III) and osmium(III) β-diketonate complexes, MCl_2(β-diketonate)$(PPh_3)_2$. The new β-diketone derivatives, which with one exception appear to exist in a single isomeric form, are obtained as green (M = Ru) or red–orange–brown (M = Os), air-stable, crystalline solids by addition of the complexes $MCl_2(PPh_3)_3$ to solutions of β-diketones in warm (or cold) benzene under aerobic conditions. In contrast, the exception, $RuCl_2\{CF_3C(O)CHC(O)CF_3\}(PPh_3)_2$, deposits in red and yellow isomeric forms from cold and warm benzene, respectively. All the complexes are paramagnetic with magnetic moments (*ca* 1.8 BM) corresponding to low spin d^5 systems with one unpaired electron. Because of their magnetic properties the complexes do not give narrow line NMR spectra. Furthermore, their IR spectra (Table 2), while confirming the presence of β-diketonate ligands, do not permit unambiguous distinction between the three possible geometric isomers **I**, **II** and **III**. Consequently, stereochemical assignments were confirmed by a combination of X-ray and chemical methods. X-ray diffraction studies on the red and yellow isomers, $RuCl_2\{CF_3C(O)CHC(O)CF_3\}(PPh_3)_2$, reported elsewhere[6] reveal *cis*- and *trans*-phosphine arrangements (**I** and **II**), respectively. Attempts to differ-



(M = Ru, Os; P = PPh_3)

(I) **(II)** **(III)**

entiate isomers **I** and **II** by chemical means centred on ligand substitution reactions. Carbonylation (CO, 1 atm, benzene, 6h) reduced *both* isomers to the known[7] ruthenium(II) carbonyl complex $RuCl\{CF_3C(O)CHC(O)CF_3\}(CO)(PPh_3)_2$, although the product from the red isomer was contaminated with $RuCl_2(CO)_2(PPh_3)_2$ [ν(CO 2060, 1995 cm^{-1} $CHCl_3$ solution]. However, substitution with pyridine (solution in refluxing benzene, 10 min) occurred only for the yellow isomer (**II**). Reactions of the other ruthenium(III) complexes with pyridine gave similar pyridine substitution products, $RuCl_2$(β-diketonate)py(PPh_3), thus suggesting, that like the "yellow" isomer, they possess the less sterically congested *trans*-phosphine geometry. Failure of the corresponding osmium complexes to undergo pyridine substitution may indicate that they adopt the *cis*-phosphine structure (**I**), but seems more likely to reflect the greater kinetic inertness of the osmium(III) centre relative to ruthenium(III), particularly since the related osmium(III) carboxylate, $OsBr_2(O_2CMe)(PPh_3)_2$, has already been shown[8] by diffraction methods to possess *trans*-phosphine stereochemistry.

Only hexafluoroacetylacetone gave "red" and "green" isomers, other β-diketones investigated gave a single isomer irrespective of reaction temperatures (70 and 25°C) employed. Attempts to convert the "red" isomer to the "green" form by heating in benzene alone or the presence of added hexafluoroacetylacetone, triphenylphosphine or pyridine were unsuccessful. Finally, attempts to perform the reaction under anaerobic conditions gave unchanged starting materials.

REACTIVITY OF NEODYMIUM(III) ISOPROPOXIDE DERIVATIVES: SYNTHESIS, CHARACTERIZATION AND CRYSTAL STRUCTURE OF $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$

OLIVIER PONCELET and LILIANE G. HUBERT-PFALZGRAF*

(*Received* 21 *February* 1989; *accepted* 21 *April* 1989)

Abstract—Reaction between neodymium chips and isopropanol led to the isolation of $[Nd(O^iPr)_3]_4 \cdot 4^iPrOH$. Its desolvation results in a soluble polynuclear neodymium(III) oxoisopropoxide, whose reactivity has been investigated. Reaction with acetylacetone produced a compound analysing as $Nd_2(OH)(acac)_5$, which has been characterized by IR and ESR spectroscopy, as well as by X-ray diffraction. It crystallizes in the monoclinic $P2_1/n$ system with unit cell dimensions $a = 14.52(5)$, $b = 14.20(4)$, $c = 15.25(5)$ Å, $\beta = 101.4°$ and $Z = 4$. Least-squares refinement converged to a final $R_w = 0.050$. The molecule is a centrosymmetric, tetranuclear neodymium(III) hydroxo acetylacetonate cluster, $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$. Two dinuclear $Nd_2(OH)(acac)_5$ units are linked by two triply bridging pyramidal μ-hydroxo ligands and by two bridging-chelating β-diketonate ligands. The metal atoms are eight-coordinated with a distorted square antiprism geometry.

High purity neodymium derivatives are of interest for optical fibers,[1] various non-linear optic materials[2] and high temperature superconductors.[3] Moreover, neodymium alkoxide, β-diketonates and related derivatives often display the highest activity among rare earth catalysts for polymerization reactions.[4] The commonest neodymium alkoxide, the trisisopropoxide, was reported to be obtained by oxidation of the metal by isopropanol,[5] as well as by a metathesis reaction between neodymium chloride and sodium isopropoxide.[6] However, this latter reaction appears complex, as it also forms $[Nd_6(\mu_6\text{-}Cl)(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_9(OR)_6]$ (R = ^{i}Pr), which has been structurally characterized.[7] Contamination of alkoxides by chloride residues might preclude their use as molecular precursors for high-tech oxide-based materials[8] via sol-gel or chemical vapour decomposition techniques.

Thus, the simple and direct synthetic approach, starting from the metal and isopropanol, appeared more attractive for obtaining pure neodymium(III) isopropoxide. This led to the isolation in high yields of a soluble, non-volatile polynuclear oxoisopropoxide. Investigation of its reactivity led to the isolation of a neodymium(III) hydroxo-acetylacetonate, which was characterized by X-ray diffraction. It corresponds to a tetranuclear cluster, $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$ (acacH = $C_5H_8O_2$, acetylacetone).

EXPERIMENTAL

All reactions were routinely performed under dry, oxygen-free argon, using Schlenk tubes and vacuum-line techniques. Solvents were purified by standard methods. ESR and IR spectra were registered on Bruker ER-200D and IR S45 spectrometers, respectively. Microanalytical data were obtained from the Centre de Microanalyse du CNRS.

$Nd_4(O^iPr)_{12} \cdot 4^iPrOH$ (1)

Neodymium chips (23.4 g, 0.164 mol) were allowed to react with isopropanol in toluene (300 cm^3, 1:1 in volume). The catalyst ($HgCl_2$ + $Hg(OAc)_2$ 1:1, 15 mg) was added after heating at 80°C for 1 h and refluxing was maintained for

* Author to whom correspondence should be addressed.

a further 48 h. The hot reaction medium was filtered and light blue–pink crystals were obtained by cooling (46.9 g, 75.6%). Found: C, 37.4; H, 6.9. Calc. for $C_{48}H_{116}O_{16}Nd_4$: C, 37.7; H, 7.7%.

X-ray quality crystals were obtained directly from the reaction medium. Their structure could only be partially solved so far as a result of disorder problems due to the presence of coordinated isopropanol. Cell parameters: $a = 20.604(8)$, $b = 20.724(10)$, $c = 14.660(5)$ Å, orthorhombic.

Drying of **1** under vacuum at room temperature led to a progressive loss of alcohol and isopropylether with the formation of a compound analysing as $[Nd_6O_5(O^iPr)_8]$ (**2**) (30.9 g, 80%) after 48 h. Complex **2** is soluble in common organic solvents, including pentane (although dissolution is slow in this case). Found: C, 19.8; H, 4.0. Calc. for $C_{24}H_{56}O_{13}Nd_6$: C, 20.3; H, 4.0%.

By contrast with yttrium, no attack of the neodymium chips was observed in the absence of a mercury catalyst. No reaction occurs between neodymium and methanol or *t*-butanol in conditions similar to that of the synthesis of the isopropoxide derivative.

$Nd_2(OH)(acac)_5$ (**3**)

A solution of acetylacetone (6.3 cm^3, 60.3 mmol) in 15 cm^3 of toluene was added over 1 h to a solution of **2** (2.07 g, 1.46 mmol). After 24 h, the light blue solution was evaporated to dryness, and after recrystallization in acetone 1.9 g (88%) of $Nd_2(OH)(acac)_5$, only slightly air-sensitive, soluble in the common organic solvents (toluene, THF, $CHCl_3$ . . .) was obtained. Found: C, 37.6; H, 4.6. Calc. for $C_{25}H_{96}O_{11}Nd_2$: C, 37.5; H, 4.5%. IR (Nujol, cm^{-1}): 1607 [ν(C=O)], 1520 [ν(C=C)], 1258 [π_{as}(C—O)], 1016, 916, 650; 523, 449 [ν(Nd—O)]. MS (m/e^+, %): Nd(acac)$_3$ (40%), Nd(acac)$_2$ (23%), Nd(OH)(acac) (5%), NdO (5%), acacH (25%), C_3H_7O (100%).

X-ray crystallography of $Nd_2(OH)(acac)_5$ (**3**)

A light blue–pink parallelepiped crystal, grown from acetone solution at room temperature, was introduced into a Lindemann capillary and mounted onto an Enraf–Nonius CAD-4 automatic diffractometer. The Laue symmetry and systematic absences, $h0l$ for $h+1 = 2n+1$ and $0k0$ for $k = 2n+1$, indicate monoclinic symmetry and space group $P2_1/n$. The lattice parameters were determined from 25 computer-centred reflections. The unit cell parameters and basic information about data collection and structure refinement are given in Table 1. Corrections for Lorentz and polarization effects were applied, but not for absorption. The atomic scattering factors were taken from Cromer and Waber.[9]

The structure was solved on a PDP 11/44 computer using the Enraf–Nonius SPP program.[10] The atomic positions were obtained by direct methods and subsequent Fourier differences series. Complex **3** is a dimer with a centre of symmetry at $\frac{1}{2},0,\frac{1}{2}$. Refinement of coordinates and thermal parameters, first isotropic and then anisotropic, of the 38 independent non-hydrogen atoms led to final values of 0.043 for R and 0.050 for R_w. The function minimized was $w = (|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$. Hydrogen parameters were not introduced in the refinement.

Positional parameters and equivalent isotropic thermal parameters are given as supplementary material.*

RESULTS AND DISCUSSION

Reactions between isopropanol and neodymium have been reported to lead to the isolation of $Nd(O^iPr)_3$.[5] Indeed, crystals, solvated by isopropanol (ν(OH): 3348 cm^{-1} in the IR) and analysing as $[Nd(O^iPr)_3]\cdot{}^iPrOH$ (**1**) were obtained from the reaction medium in high yields ($\simeq$ 75%). Their structure could only partially be solved so far, as a result of disorder problems and loss of the alcohol molecules, but appears to correspond to a tetranuclear species, $Nd_4(\mu_3\text{-}O^iPr)_2(\mu\text{-}O^iPr)_4(O^iPr)_6(^iPrOH)_4$.[11] The analytical data of these light blue–pink crystals showed, after removal of the alcohol (drying *in vacuo* at room temperature for 48 h), a too-low carbon and hydrogen content with respect to a $Nd(O^iPr)_3$ composition, but were found to be in agreement with an oxoalkoxide of empirical formula $Nd_6O_5(O^iPr)_8$ (**2**). Complex **2** is highly soluble in common solvents including hydrocarbons, but its paramagnetic character precluded the obtaining of structural information by NMR techniques.

We have previously shown with yttrium, that although $Y(O^iPr)_3$ species solvated by alcohol are predominant in solutions, their isolation is achieved as a complex structural unit: $Y_5O(O^iPr)_{13}$.[12] Stabilization of other *f* element isopropoxides $Ln(O^iPr)_3$ as similar polymetallic oxoisopropoxides has also been observed for ytterbium[13] or lan-

* Supplementary material. Tables of final fractional coordinates, anisotropic thermal parameters, complete bond lengths and angles (4 pp.), tables of calculated and observed structure factors (18 pp.) have been deposited with the Cambridge Structural Data File.

thanum.[14] Although the origin of the oxo ligands may be multiple, we have established in the case of yttrium, that aggregation of metals into a closed polyhedral moiety represents an alternative for a trivalent metal to achieve high coordination numbers despite the loss of the labile isopropanol molecules. Thermal gravimetric analyses have shown that desolvation and condensation by elimination of diisopropyl ether occur simultaneously.[14]

Similar results are obtained in the case of neodymium. Although the structure of the polynuclear oxoalkoxide could not be established by X-ray diffraction so far, its formation in reproducible and high yields excludes accidental hydrolysis. Comparison of the reactions between the reaction medium and **2** with an excess of $Al(O^iPr)_3$ was made in a refluxing toluene–alcohol medium. No reaction was observed when starting from **2**, while that with the reaction medium offered, by fractional distillation, the heterometallic alkoxide[15] $Nd[Al(O^iPr)_4]_3$ in high yield (70%). These results are also supported by the behaviour of the yttrium isopropoxide derivatives: the reactivity of the species formed *in situ* and the isolated oxoalkoxide $Y_5O(O^iPr)_{13}$ are definitely different.[12]

In order to achieve the characterization of **2**, its reactivity was investigated, especially towards other potential oxygen mono- or bidentate ligands, which could also lead to molecular precursors of oxides.

No reaction occurred between **2** and *t*-butanol, in refluxing toluene; alkoxo exchange reactions and/or reactions involving the oxo ligands could however be achieved with acetic acid or acetylacetone, offering compounds analysing as $Nd_6O_3(OAc)_4(O^iPr)_8$ and $Nd_2(OH)(acac)_5$ (**3**), respectively. The solubility of **3** is attractive, by contrast with the poor solubility of the carboxylate derivative. Its IR spectra confirmed the obtaining of a species different from $Nd(acac)_3$, previously obtained by reaction between $[Nd(O^iPr)_3]_n$ and acetylacetone,[16,17] the main spectral differences being the presence of an additional absorption band at 725 cm^{-1} and a notable shift to higher frequencies (40 cm^{-1}) for the stretching ν_s(C=O) mode. By contrast with the isopropoxides derivatives **1** and **2**, which were ESR silent down to 100 K (probably due to very short relaxation times,

Fig. 1. ESR spectrum of $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$ in toluene solution at 298 K.

as often observed for lanthanide compounds), **3** displays a spectrum at room temperature (Fig. 1). However, since ESR spectra of *f* elements are mainly an illustration of spin–orbit effects,[18] an X-ray structure determination of **3** was undertaken.

The crystal structure of $[Nd_4(OH)_2(acac)_{10}]$ consists of a centrosymmetric tetranuclear cluster (Figs 2 and 3). Relevant interatomic distances and angles are collected in Table 2.

Two dinuclear $Nd_2(OH)(acac)_5$ units are linked by two triply bridging hydroxo and two bridging-chelating β-diketonate ligands. Although the hydrogen atoms were not crystallographically located, an unambiguous assignment as μ_3-hydroxo was made on the basis of several criteria. The sum of the Nd—O—Nd angles is 326.5 around O(1), close to the value (328.4) expected for pure sp^3 hybridized atoms.[19] Moreover, an oxo ligand would lead to mixed valency Nd^{III}–Nd^{IV} species. Although the stabilization of neodymium(IV) is possible with some ligands,[20] no molecular neodymium(IV) compounds have been reported so far. Finally, an O—H stretching mode is observed at 3450 cm^{-1} in the IR spectrum, confirming the presence of hydroxo ligands in the aggregate. Although both the metal atoms are eight-coordinated, with Nd—O bond lengths ranging from 2.370(7) to 2.654(6) Å, Nd(1) and Nd(2) have slightly different environments. The coordination polyhedra around the two metals are distorted square antiprisms (Fig. 4), but Nd(2) is surrounded by two hydroxo ligands, one chelating and three bridging-chelating acetylacetonato groups, while Nd(1) is linked to only one hydroxo group.

The Nd—O bond distances fall in the range of the values previously reported in the literature for neodymium oxide derivatives or Nd—O coordination bonds,[21,22] but are much longer than the values observed for terminal Nd—O^{i}Pr linkages.[7] The longest Nd—O bond distances correspond to β-diketonate oxygen atoms in bridging positions. The Nd—O bond lengths involving chelating acac ligands are significantly different (2.38, 2.44 Å), but close to the values determined in $Nd(acac)_3 \cdot 2H_2O$.

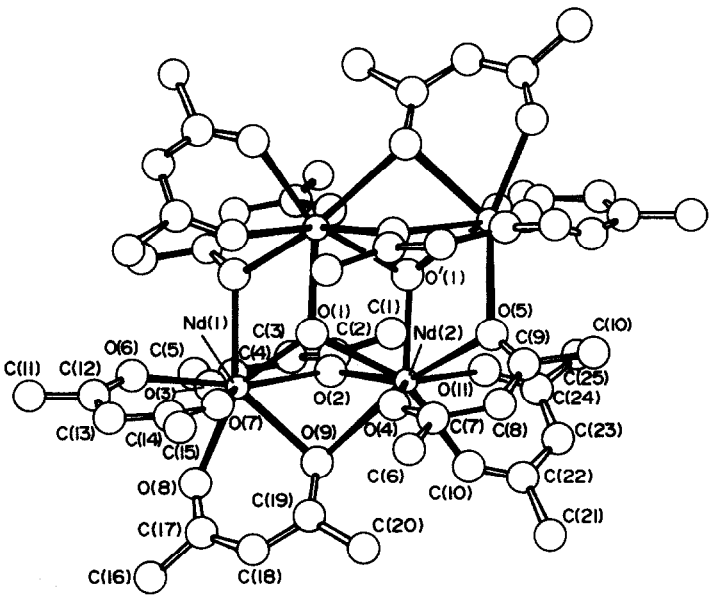

Fig. 2. ORTEP view of $[Nd_4(\mu_3\text{-}OH)_2(\mu_2,\mu_1\text{-}acac)_6(acac)_4]$, showing the atom numbering scheme.

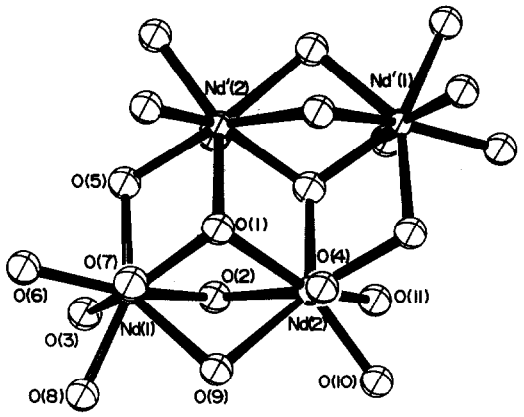

Fig. 3. Neodymium oxygen core of **3**.

The Nd(μ_3-OH) linkages are in agreement with the value observed for other triply bridged metal–hydroxo bonds.[19]

The rest of the bonding in the acac ligands appears normal, with C—O and C—C bond lengths ranging from 1.25(1) to 1.31(2) Å and from 1.38(1) to 1.52(2) Å, respectively. Close intermolecular contacts between most oxygen atoms are noted, as commonly observed for β-diketonate derivatives. The bridging-chelating ligands, especially those of the $Nd_2(OH)(acac)_5$ unit, display a larger bite and more deviation towards planarity of the cycle than the simple chelating ones. The shortest metal–metal distances correspond to those of the dinuclear $Nd_2(OH)(acac)_5$ unit with a value of 3.833 Å.

The synthesis of $[Nd_4(\mu_3\text{-}OH)_2(acac)_{10}]$ from the oxoalkoxide in nearly quantitative yield implies that the oxo ligands, or at least some of them, are reactive towards acetylacetone, as also previously observed for oxo species of various elements.[23] The hydroxo ligand can thus result from direct reactivity with the β-diketone or from further hydrolysis of an $Nd(acac)_3$ species, since water appears as a byproduct. Hydroxo species formulated as $Ln(acac)_2OH$ have been previously suggested to form by hydrolysis of $Ln(acac)_3$ or by thermal decomposition of their hydrates, but were not characterized.[23,24] Complex **3** belongs to the very few hydroxide lanthanide derivatives structurally characterized[25] and is the first one for neodymium.

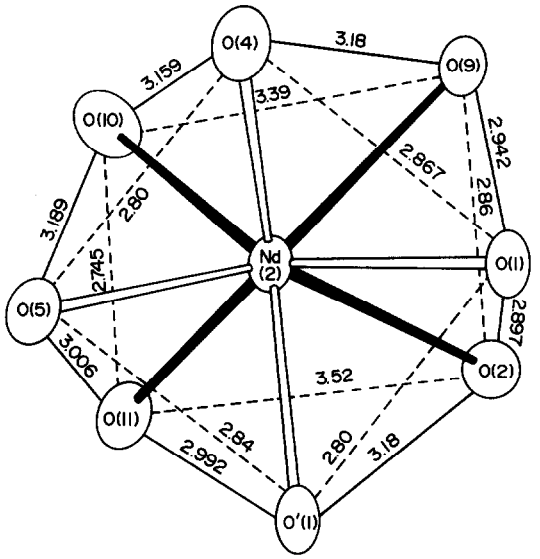

Fig. 4. Coordination polyhedron around Nd(2), showing the extent to which the faces are distorted from the ideal square.

Octacoordination appears to be favoured for the lanthanides in β-diketonate derivatives, as illustrated by the structural data of $Ln(acac)_3 \cdot nH_2O$ (Ln = Y, La, Nd, Eu; $n = 2$ or 3) and $[Ln(dpm)_3]_2$ (Ln = Pr, Er; dpmH = dipivaloylmethane).[20,23] Thus formation of a tetranuclear cluster for $[Nd_4(\mu_3\text{-}OH)_2(acac)_{10}]$, the first example of such a structural unit for neodymium, allows the metal to attain this coordination number.

These results, as well as those obtained on yttrium with the formation of $Y_5O(O^iPr)_{13}$,[12] suggest extensive and promising oxopolymetallic chemistry for lanthanides with anionic oxygen donor ligands.

REDUCTION OF METAL ACYL COMPLEXES PROMOTED BY MONOHYDRIDES, $Cp_2M(CO)H$ (M = Nb, Ta)

A. DORMOND and C. MOISE*

Laboratoire de Synthèse et d'Electrosynthèse Organométalliques associé au CNRS (UA 33), Faculté des Sciences, 6 bd Gabriel 21000 Dijon, France

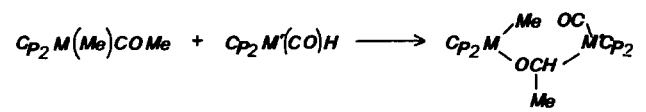
(*Received* 7 *March* 1989; *accepted* 24 *April* 1989)

Abstract—Niobium or tantalum monohydrides reduce η^2-acyl zirconium and hafnium complexes and provide models for the CO stoichiometric conversion in ethylene. A plausible reduction mechanism implies a proton transfer to the carbon atom of the acetyl unit.

The reduction of carbon monoxide by transition metal hydrides is of great economic and fundamental interest. Studies of stoichiometric "model" reactions between hydride complexes and "activated" carbon monoxide might help to improve known catalyst systems or to discover new effective types. Stoichiometric reductions of CO[1] and of methyl carbonyl derivatives[2,3] have been achieved by the hydrido zirconium complex, $Cp_2^*ZrH_2$; moreover, products arising from hydrogen transfer to a η^2-acetyl unit have been obtained with the group 6 transition metal hydrides, Cp_2MoH_2 and Cp_2WH_2.[4] We have recently shown that the d^2 hydrido carbonyl complexes, $Cp_2M'(CO)H$ (M' = Nb, Ta), are able to function as hydrogen transfer reagents, when opposed to organic substrates.[5,6] We report here that these monohydrides are also capable of hydrogenating metal acyl complexes, a reaction which is viewed as a fundamental step in CO hydrogenation reactions.

RESULTS AND DISCUSSION

The reaction of the zirconium or hafnium acyl complexes, $Cp_2M(COMe)Me$ (**1**) or (**2**), with the monohydrides, $Cp_2M'(CO)H$ (**3a**, M' = Nb) or (**3b**, M' = Ta), proceeded rapidly in toluene solution as evidenced by a fast colour change from purple to green; the binuclear complexes, **4** or **5**, can be isolated as green crystals in high yield, eq. (1):



(1)

1 M = Zr; **2** M = Hf; **3**(a,b); **4**(a,b) M = Zr; **5**(a,b) M = Hf

a = M' = Nb ; b = M' = Ta

Using the acetyl titanium derivatives $Cp_2Ti(COCH_3)Cl$, the monochlorides $Cp_2M'(CO)Cl$ were formed by a metathetical reaction, but the titanium component was not identified.

The structure of the binuclear complexes, **4** and **5**, is easily established by their elemental analyses and spectroscopic data (Table 1).

The IR spectra show one intense absorption near 1890 cm^{-1} due to the M' bonded carbonyl stretching. The ^1H NMR spectra show for both the Cp_2Zr (or Cp_2Hf) and Cp_2Nb (or Cp_2Ta) units non-equivalence of the Cp ligands due to the chiral centre of the —OCHMe— bridge.

The monohydrides, $Cp_2M'(CO)H$ **3a** or **3b**, are thus able to reduce zirconium or hafnium acyl complexes. A reaction involving a simple hydride addition seems unlikely in view of the poor hydridic character of these monohydrides which do not react with methanol or acetone. The basic properties of the d^2 complexes (**3a** or **3b**)[6,7] and the well-known carbenic character of the carbon in the η^2-acetyl ligand suggest a mechanism with the initial

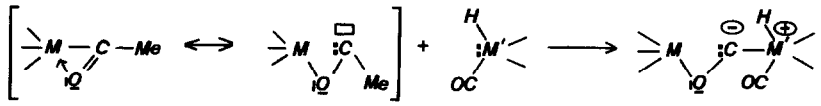
formation of an acid–base adduct A, followed by a H^+ internal migration from the niobium or tantalum atom [eq. (2)]. We have postulated a similar prototropy to account for the reduction of acylchlorides into aldehydes.[5]

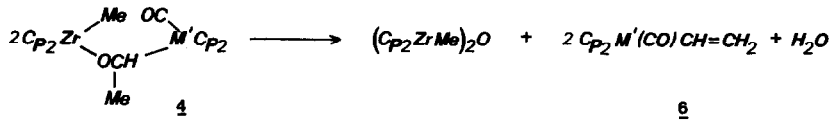


(2)

A

The lifetime in solution of the zirconium complexes **4** is limited (about 2 days). As shown by periodic ^{1}H NMR monitoring, the resonance signals of **4a** or **4b** slowly disappear with a concomitant growth of two sets of signals. The former includes two singlets at 5.74 and 0.26 ppm and is attributed, by comparison with an authentic sample, to $(Cp_2ZrMe)_2O$.[8] The latter set shows one singlet for the Cp ligands and one AMX system in the olefinic region (Table 2).

These resonances are assigned to the ethylenic derivatives $Cp_2M'(CO)CH{=}CH_2$ (**6**) and the evolution of the complexes **4** can be summarized as follows:



4 6

By treating complexes **6** with HCl, evolving ethylene is detected and the chlorocarbonyl derivatives $Cp_2M'(CO)Cl$[5] are formed in quantitative yields.

The results described above are an example of a stoichiometric synthesis of ethylene incorporating carbon from CO. According to the hypotheses previously postulated by Caulton,[4] a cleavage of the C—O bond in **4**, leading to $Cp_2Zr(Me)O^-$ and $Cp_2M'(CO)CHMe^{\oplus}$ could be assumed as a preliminary step in the formation of $(Cp_2ZrMe)_2O$ and ethylenic complexes, **6**.

It is noteworthy, however, that such an evolution does not occur with the hafnium complexes, **5**, but the reasons why are not clear.

These studies possess features reminiscent of those reported by Caulton and co-workers using Cp_2MoH_2 and Cp_2WH_2 and illustrate the closely related properties of the group 5 monohydrido complexes $Cp_2M'(CO)H$. In both series, the reduction of the dihapto acyl group could be achieved by

a H^+ donation from an early transition metal complex.

EXPERIMENTAL

All operations were carried out under an argon atmosphere by standard Schlenk techniques. All solvents were dried and distilled from sodium benzophenone. The IR data were obtained using a Perkin–Elmer 580B spectrophotometer and the ^1H NMR spectra (references to Me_4Si) were recorded with a JEOL FX100 apparatus. The monohydrido carbonyl complexes, $Cp_2M'(CO)H$, were obtained according to ref. 9 (M′ = Nb) and ref. 6 (M′ = Ta); the dimethyl derivatives Cp_2MMe_2 (M = Zr, Hf) were prepared from Cp_2MCl_2 and MeLi and purified by sublimation.[10]

Satisfactory elemental analyses have been obtained for complexes **4** and **5**.

Complexes **4** *and* **5**

These are obtained by the following general procedure.

$Cp_2M(CH_3)_2$ (1 mmol) and $Cp_2M'(CO)H$ (1 mmol) were mixed in toluene (25 cm^3) under CO (1 atm) and the solution was stirred for 2 h at room temperature. The solvent was removed and the green solid was recrystallized from a mixture of toluene–heptane on fast cooling. Yield 70%.

HYDROGEN TRANSFER FROM METHANOL TO THE DOUBLE BONDS OF AN OLEFINIC TERTIARY PHOSPHINE COMPLEX OF RHODIUM(I)*

MARTIN A. BENNETT† and LEE L. WELLING

Research School of Chemistry, Australian National University, G.P.O. Box 4, Canberra, A.C.T. 2601, Australia

(*Received* 4 *April* 1989; *accepted* 28 *April* 1989)

Abstract—On heating with anhydrous sodium carbonate in methanol, the five-coordinate rhodium(I) complex [RhCl(*o*-CH_2=$CHC_6H_4PPh_2$)$_2$], containing (2-vinylphenyl)diphenylphosphine, is converted into the planar rhodium(I) carbonyl complex, *trans*-[RhCl(CO)(*o*-$CH_3CH_2C_6H_4PPh_2$)$_2$], containing (2-ethylphenyl)diphenylphosphine. The added hydrogen and CO are derived from methanol, probably via an intermediate formaldehyde complex.

The ligand (2-vinylphenyl)diphenylphosphine, *o*-CH_2=$CHC_6H_4PPh_2$ (**1**) (sometimes referred to as *o*-styryldiphenylphosphine and abbreviated SP), forms a five-coordinate rhodium(I) complex $RhCl(SP)_2$ (**2**) in which both vinyl groups are coordinated.[1–3] Complex **2** reacts with CO to give a salt, $[Rh(CO)(SP)_2]Cl$ (**3**) (ν(CO) *ca* 2040 cm^{-1}), which readily reverts to **2** in the absence of CO; in the presence of $NaBF_4$, NH_4PF_6 or $NaBPh_4$, stable salts of the five-coordinate cation $[Rh(CO)(SP)_2]^+$ can be isolated. Treatment of **2** with $AgBF_4$ generates a four-coordinate, presumably planar cation, $[Rh(SP)_2]^+$ (**4**), which takes up ligands (L) such as CO, C_2H_4, SO_2, CS_2, pyridine and tertiary phosphines to give five-coordinate species $[RhL(SP)_2]^+$.[4,5]

Brookes[2] reported that reaction of $RhCl(SP)_2$ with a suspension of anhydrous Na_2CO_3 in methanol gave a complex **5** of empirical formula $RhCl(CO)(SP)_2$. This compound, unlike its apparent isomer **3**, did not seem to lose CO readily, was a non-electrolyte in nitromethane, and had a C≡O stretching frequency of only 1964 cm^{-1} in its IR spectrum. The poor solubility of **5** in organic solvents prevented NMR studies, so Brookes was unable to determine whether the vinyl groups, which he assumed to be present, were coordinated or free. We report here our reinvestigation of the nature of complex **5**.

RESULTS AND DISCUSSION

In order to obtain a more soluble cationic derivative, **5** was treated with $AgBF_4$ in CD_3CN, cf. the formation of $[Ir(CO)(CH_3CN)(PPh_3)_2]BF_4$ from $IrCl(CO)(PPh_3)_2$ and $AgBF_4$ in acetonitrile.[6] The

† Author to whom correspondence should be addressed.

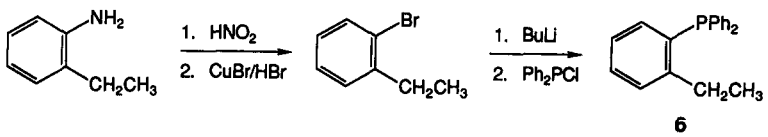
^{1}H NMR spectrum of the yellow solution obtained after removal of precipitated AgCl showed no resonances attributable to vinyl protons; instead there was a triplet at δ 0.95 and a quartet at δ 3.05 (J_{HH} = 7.5 Hz) typical of an ethyl group. This observation immediately suggested that the ligand present in **5** was (2-ethylphenyl)diphenylphosphine, *o*-$EtC_6H_4PPh_2$ (**6**), and that **5** was its planar rhodium(I) carbonyl complex, [RhCl(CO)(*o*-$EtC_6H_4PPh_2)_2$]. The cationic acetonitrile complex was isolated as an uncrystallizable yellow oil from the reaction of **5** with $AgBF_4$ in CH_3CN. It analysed fairly satisfactorily for [Rh(CO)(CH_3CN)(*o*-$EtC_6H_4PPh_2)_2$]BF_4, and showed a strong band at 2000 cm^{-1} due to ν(CO) and a weak band at *ca* 2300 cm^{-1} due to ν(CN) in its IR spectrum.

Treatment of **5** with sodium cyanide, in hot aqueous 2-methoxyethanol, gave free (2-ethylphenyl)diphenylphosphine (**6**) as an oil, which showed a parent ion peak in its mass spectrum. The ^{1}H NMR spectrum of **6** showed a triplet at δ 1.12 (J_{HH} = 7 Hz) and a doublet of quartets at δ 2.88 (J_{HH} = 7 Hz, J_{PH} = 2 Hz) due to the CH_3 and CH_2 protons, respectively, and was identical with that of the tertiary phosphine isolated from the reaction of [Rh(SP)$_2$]BPh_4 with hydrogen, which gives Rh(η-$C_6H_5BPh_3$)(SP) and *o*-$EtC_6H_4PPh_2$.[5]

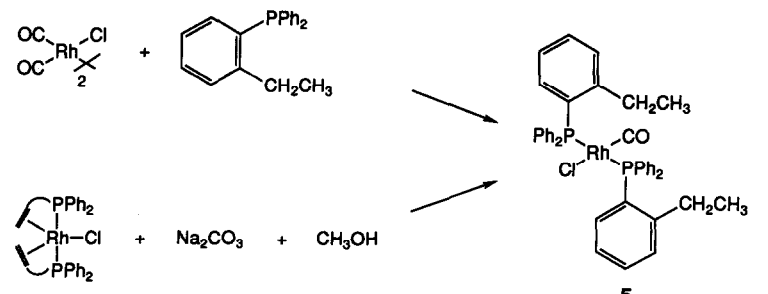
Compound **6** was also synthesized independently in two steps from 2-ethylaniline [eq. (1)]. It reacted immdiately at room temperature with [$RhCl(CO)_2]_2$ in benzene to give a lemon–yellow precipitate whose spectroscopic properties were identical with those of complex **5** prepared from $RhCl(SP)_2$ (**2**) and sodium carbonate in methanol [eq. (2)].

The ^{31}P{^{1}H} NMR spectrum of **5** consisted of a doublet due to equivalent phosphorus atoms, the magnitude of J_{RhP} (125.5 Hz) being typical of planar rhodium(I) complexes of the type *trans*-$RhCl(CO)L_2$.[7] The reported ν(CO) and ν(RhCl) data,[2] which we confirm, are also typical of this class of compound.[7,8] The ^{1}H NMR spectrum of **5**, measured on a more sensitive instrument than was available either to us or to Brookes in the earlier work, was initially ambiguous because the sample prepared according to the original procedure contained ethanol of solvation; this was not removed completely even on heating *in vacuo*. The ^{1}H NMR spectrum (in CD_2Cl_2) of a sample that had been washed with methanol instead of ethanol showed a pattern typical of an ethyl group, consisting of a triplet at δ 1.05 and a quartet at δ 3.19 (J_{HH} = 7.4 Hz), in addition to aromatic resonances in the region δ 6.9–7.8.

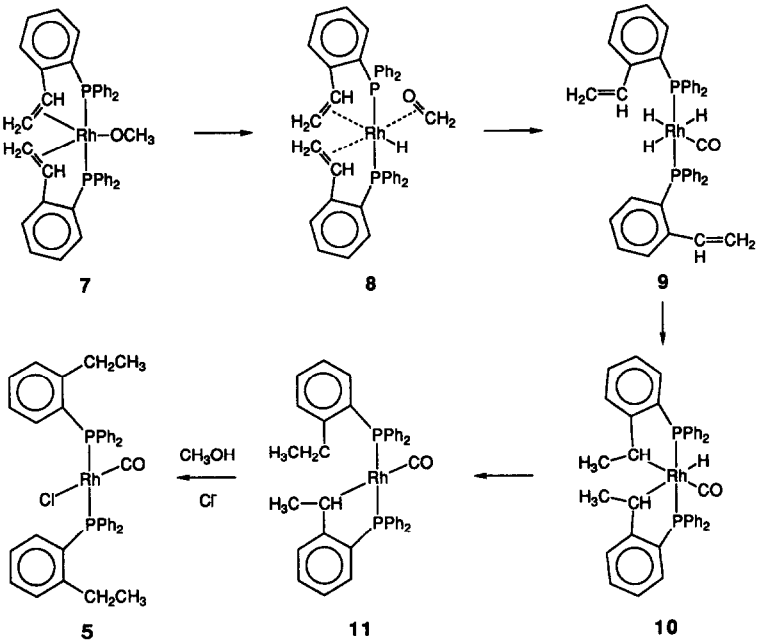
To confirm that methanol was the source of the hydrogen added to **2**, a sample of complex **2** was heated with sodium carbonate suspended in [D_4]-methanol, and the resulting complex (**5a**) was treated with sodium cyanide. The ^{1}H NMR spectrum of the liberated tertiary phosphine (**6a**) contained a pair of complex multiplets centred at δ 1.15 and 2.9 with an intensity ratio of 2 : 1, and the ^{2}H NMR spectrum showed two poorly resolved multiplets at δ 1.1 and 2.9 with an intensity ratio of *ca* 1 : 1. These observations suggest that dideuterated compounds such as *o*-$CH_2DCHDC_6H_4PPh_2$ are the main species present. In agreement, the mass spectrum



(1)



(2)



Scheme 1. Generation of (2-ethylphenyl)diphenylphosphine from (2-vinylphenyl)diphenylphosphine on rhodium.

showed intense peaks due to [*M*] and [*M*—H] at *m/z* 292 and 291 (cf. 290 and 289 in the mass spectrum of **6**), but there was also a peak at *m/z* 293 suggestive of the presence of some trideuterated compounds; these could be formed by base-catalysed H/D exchange at the benzylic carbon atom.

The stoichiometry of the reaction of **2** with methanolic Na_2CO_3 is presumed to be as shown in eq. (3):

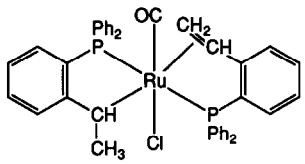
$$RhCl(o\text{-}CH_2{=}CHC_6H_4PPh_2)_2 + CH_3OH \longrightarrow RhCl(CO)(o\text{-}CH_3CH_2C_6H_4PPh_2)_2 \quad (3)$$
(**5**)

When tertiary phosphine halide complexes of the *d*-block elements are heated with alcohols under basic conditions, hydrido or hydrido (carbonyl) complexes are often formed.[9,10] In these reactions the hydride ligand probably arises by β-elimination of aldehyde or ketone from an intermediate alkoxide. A plausible mechanism based on this premise for the formation of **5** from **2** is shown in Scheme 1. In the first step, the chloride ligand of **2** is replaced by methoxide, and the resulting methoxo complex **7** undergoes β-elimination to give a rhodium–hydride and formaldehyde; the latter probably remains in the coordination sphere as complex **8**. In the next step, formaldehyde undergoes oxidative addition to rhodium to give the hydrido (carbonyl) complex **9**, a process in which a hydrido(formyl) complex is a likely intermediate.[11,12] Two of the three hydride ligands of **9** then add to the pendant vinyl groups to give the bis(alkyl)rhodium(III) chelate complex **10**, and reductive elimination of the remaining hydride ligand with one of the rhodium(III)–carbon σ-bonds forms the five-coordinate rhodium(I) chelate alkyl **11**, which contains one (2-ethylphenyl)diphenylphosphine ligand. Finally, protonolysis of the remaining rhodium–carbon σ-bond in the presence of chloride ion forms the second (2-ethylphenyl)diphenylphosphine ligand, thus giving complex **5**.

We suggest in Scheme 1 that intermediates **9**–**11** contain a five-membered chelate ring, Rh{*o*-CH(CH$_3$)C$_6$H$_4$PPh$_2$}. An octahedral ruthenium(II) compound, **12**, containing such a ring is formed when $RuCl_2(CO)_2(SP)_2$ is heated in 2-methoxyethanol,[13] a reaction that is closely related to that described here. Also, complexes of this type have been obtained by the protonation of SP coordinated to low-valent metals such as iron(0),[14] ruthenium(0),[14] palladium(0),[15] platinum(0)[16] and rhodium(I),[17] and by the reaction of metal hydrides, such as $MnH(CO)_5$[18] and $PtHCl(PPh_3)_2$,[19] with SP. The reaction of $ReH(CO)_5$ with SP, however, gives the alternative six-membered ring compound [Re(*o*-CH$_2$CH$_2$C$_6$H$_4$PPh$_2$)(CO)$_4$],[18] and the possibility that compounds **9**–**11** contain six-membered rings cannot be excluded.

The suggestion that free or coordinated formaldehyde is an intermediate in the conversion of **2** to **5** is supported by the observation that

$[Rh(SP)_2]BF_4$ (**4**) reacted on heating with paraformaldehyde to give a yellow solid which had a strong ν(CO) band at 1990 cm^{-1}. Although this compound



12

could not be isolated in a pure state, it probably contained *trans*-$[Rh(CO)_2(o\text{-}EtC_6H_4PPh_2)_2]BF_4$, because, on treatment with lithium chloride, it gave a poorly soluble yellow solid that was identical in its spectroscopic features with **5**. Moreover, of the simple monohydric alcohols, only methanol can supply the units of CO and four H required to convert **2** into **5**, thus accounting for the observation[2] that the reaction does not proceed in ethanol.

There are several examples in the literature of the addition of dihydrogen to the double bonds of olefinic tertiary phosphines when these ligands are coordinated to rhodium(I). Treatment of $[Rh(SP)_2]BPh_4$ with dihydrogen gives the η^6-tetraphenylborate complex, $Rh(SP)(\eta^6\text{-}C_6H_5BPh_3)$, and free (2-ethylphenyl)diphenylphosphine.[5] But-3-enyldiphenylphosphine, $CH_2{=}CHCH_2CH_2PPh_2$ (mbp), which is a more flexible ligand than SP, is converted into coordinated *n*-butyldiphenylphosphine by the addition of dihydrogen to methanolic solutions of $RhCl(mbp)_2$ and $RhCl(CO)(mbp)_2$.[20] In these cases, however, the methanol is not a source of H_2, but only serves to promote ionization of the chloride ion in the coordination sphere. This favours oxidative addition of H_2 to the cationic rhodium centre and permits transfer of the hydride ligands to the adjacent double bonds.

EXPERIMENTAL

The following instruments were used for spectroscopic measurements: Jeol PMX 60 and Varian HA 100 (^{1}H NMR), Varian XL 200 (^{1}H NMR, ^{31}P NMR at 80.98 MHz), Bruker B-KR-322S (^{31}P NMR at 24.3 MHz), Bruker CXP 200 (^{31}P NMR at 80.96 MHz), Bruker HFX 270 (^{2}H NMR at 41.45 MHz), PE 683 (IR, 4000–400 cm^{-1}), PE 225 (IR, 4000–200 cm^{-1}), Hitachi FIS-3 (IR, 400–50 cm^{-1}), VG Micromass 7070 (mass spectra at 70 ev). Analyses were carried out in the Microanalytical Laboratory of this School.

(2-Vinylphenyl)diphenylphosphine[21] and $[RhCl(CO)_2]_2$[22] were prepared by literature procedures. 2-(Bromo)ethylbenzene was made from redistilled commercial 2-ethylaniline by the usual method of diazotization and treatment with CuBr, although the yield of product after steam distillation was only 20%.

All operations requiring tertiary phosphines and their metal complexes were carried out under purified nitrogen or argon by the use of standard Schlenk procedures.

Preparation of (2-ethylphenyl)diphenylphosphine, o-$EtC_6H_4PPh_2$ **(6)**

A solution of 2-(bromo)ethylbenzene (16 g, 0.088 mol) in ether (10 cm^3) was added to a solution of 1.6 M butyllithium (55 cm^3) in ether (50 cm^3) and the mixture was stirred at 0°C. The clear, colourless solution was cooled to −40°C and treated dropwise with a solution of chlorodiphenylphosphine (15.9 g, 0.072 mol) in ether (20 cm^3). The mixture was allowed to warm to room temperature, stirred for 0.5 h and then cooled again to 0°C. Saturated aq. NH_4Cl was added, the ether layer was separated and washed with water, and the aqueous layer was extracted with ether. The combined ether extracts were dried over magnesium sulphate and evaporated to give the product as a thick, colourless oil. Yield: 22.7 g (90%). The crude product contained some phosphine oxide, as shown by a strong band at *ca* 1190 cm^{-1} in the IR spectrum and by the ^{31}P NMR spectrum. No attempt was made to remove the impurity. ^{1}H NMR ($CDCl_3$, 60 MHz) δ 1.1 (t, $J = 7$ Hz, CH_3), 2.9 (q, CH_2), 6.8–7.4 (m, Ar). $^{31}P\{^1H\}$ NMR ($CHCl_3$, 24.3 MHz) δ −15.3(s) due to **6**, +31.8(s) probably due to phosphine oxide, intensity ratio *ca* 8 : 1.

Preparations of carbonylchlorobis{(2-ethylphenyl)-diphenylphosphine}rhodium(I), $[RhCl(CO)(o\text{-}EtC_6H_4PPh_2)_2]$ **(5)**.

(1) *From* $[RhCl(o\text{-}CH_2{=}CHC_6H_4PPh_2)_2]$ **(2)**. The procedure was as described by Brookes.[2] Complex **2** (800 mg, 1.12 mmol) and finely divided anhydrous Na_2CO_3 (552 mg, 5.21 mmol) were suspended in methanol (40 cm^3) and heated under reflux for 3 h. At *ca* 60°C the bright yellow suspension turned orange and at *ca* 80°C it became dark yellow. The yellow precipitate was washed first with water, then with ethanol or methanol, and dried *in vacuo*. Yield: 622 mg (74%). IR (cm^{-1}, Nujol) 1955 [ν(CO)], 309 [ν(RhCl)]. ^{1}H NMR (CD_2Cl_2, 200 MHz) δ 1.05 (t,

J = 7.4 Hz, CH_3), 3.19 (q, CH_2), 6.9–7.8 (m, Ar). $^{31}P\{^1H\}$ NMR (CD_2Cl_2) δ 25.6 (d, J_{RhP} = 125.5 Hz). Found: C, 65.8; H, 5.2; Cl, 4.2; P, 7.75. Calc. for $C_{41}H_{38}ClOP_2Rh$: C, 65.9; H, 5.1; Cl, 4.75; P, 8.3%.

The deuterated complex, [RhCl(CO)(*o*-[D$_2$]EtC$_6$H$_4$PPh$_2$)$_2$] (**5a**), was prepared similarly from complex **2** and anhydrous Na_2CO_3 in [D_4]-methanol.

(2) *From* [RhCl(CO)$_2$]$_2$ *and* *o*-EtC$_6$H$_4$PPh$_2$ (**6**). A solution of [RhCl(CO)$_2$]$_2$ (374 mg, 0.96 mmol) in benzene (20 cm^3) was treated dropwise with a solution of *o*-EtC$_6$H$_4$PPh$_2$ (**6**) (1.12 g, 3.85 mmol) in benzene (15 cm^3). Gas came off immediately and a lemon–yellow solid precipitated. The IR spectrum of this solid was identical with that of the compound prepared from complex **2** and methanolic Na_2CO_3.

(3) *From* [Rh(*o*-CH$_2$=CHC$_6$H$_4$PPh$_2$)$_2$]BF$_4$ *and formaldehyde*. A suspension of [RhCl(*o*-CH$_2$=CHC$_6$H$_4$PPh$_2$)$_2$] (**2**) (0.50 g, 0.70 mmol) in dichloromethane (10 cm^3) was treated with a suspension of $AgBF_4$ (0.137 g, 0.70 mmol) in dichloromethane (10 cm^3), and the mixture was stirred for 1 h. The precipitated AgCl was removed by centrifuging and the resulting red solution was evaporated to dryness under reduced pressure to give [Rh(*o*-CH$_2$=CHC$_6$H$_4$PPh$_2$)$_2$]BF$_4$ (**4**) as a reddish-yellow solid. Yield: 0.58 g, quantitative. This solid was taken up in THF and the yellow solution was treated with paraformaldehyde (420 mg, *ca* 10-fold excess). The mixture was heated under reflux for 1 h to give a yellow–brown solid, which showed a strong ν(CO) band at 1990 cm^{-1} and a broad strong band at *ca* 1100 cm^{-1} characteristic of BF_4^-. On treatment with lithium chloride in methanol, this compound gave an immediate dark yellow precipitate whose IR spectrum matched that of [RhCl(CO)(*o*-EtC$_6$H$_4$PPh$_2$)$_2$] (**5**).

Preparation of [Rh(CO)(CH$_3$CN)(*o*-EtC$_6$H$_4$PPh$_2$)$_2$]BF$_4$

A suspension of [RhCl(CO)(*o*-EtC$_6$H$_4$PPh$_2$)$_2$] (**5**) (80 mg, 0.11 mmol) in acetonitrile or [D_3]-acetonitrile (3 cm^3) was treated with a solution of $AgBF_4$ (18 mg, 0.09 mmol) in the same solvent (0.5 cm^3). The precipitated AgCl was removed by centrifugation and solvent was evaporated from the supernatant liquid to leave a yellow oil, which could not be induced to crystallize. The yield was almost quantitative. ^1H NMR (CD_3CN, 100 MHz) δ 0.95 (t, J = 7 Hz, CH_3), 3.05 (q, CH_2), 7.0–7.7 (m, Ar). IR (cm^{-1}, Nujol) 2033 w [ν(CN)], 2000 vs [ν(CO)], *ca* 1050 vs, br [BF_4]. Found: C, 59.7; H, 4.8; N, 1.8; P, 7.3. Calc. for $C_{43}H_{41}NOP_2Rh$: C, 61.5; H, 5.0; N, 1.7; P, 7.35%.

Displacement of (2-*ethylphenyl*)*diphenylphosphine* (**6**) *from* [RhCl(CO)(*o*-EtC$_6$H$_4$PPh$_2$)$_2$] (**5**)

A suspension of complex **5** (514 mg, 0.69 mmol) in 2-methoxyethanol (30 cm^3) was treated with a solution of sodium cyanide (648 mg, excess) in water (30 cm^3). The mixture was stirred at 100°C overnight to give a light brown oil and a clear, colourless mother liquor. The latter was removed by decantation, and the oil was washed with water and dried *in vacuo*. It was identified as *o*-EtC$_6$H$_4$PPh$_2$ (**6**) by comparison of its spectroscopic properties with those of a sample of **6** prepared independently. ^1H NMR (100 MHz, $CDCl_3$) δ 1.12 (t, J_{HH} = 7 Hz, CH_3), 2.88 (dq, J_{HH} = 7 Hz, J_{PH} = 2 Hz, CH_2), 6.8–7.3 (m, Ar). $^{31}P\{^1H\}$ NMR (24.3 MHz, $CHCl_3$) δ −15.6(s). Mass spectrum: m/z 290.1224 (M, most intense peak), calc. for $C_{20}H_{19}P$: 290.344; 289(M−H).

The deuterated ligand *o*-[D$_2$]EtC$_6$H$_4$PPh$_2$ (**6a**) was obtained from complex **5a** by a similar procedure. ^1H NMR (100 MHz, $CDCl_3$) δ 1.0—1.2 (m, 2*H*, CH_2D), 2.7–3.0 (m, 1*H*, CHD). ^2D NMR (41.45 MHz, $CDCl_3$) δ 1.1 (br s, 1*D*, CH_2D), 2.9 (br s, 1*D*, CHD). Mass spectrum: m/z 293, 292(M), 291(M−H), 290(M−D).

EQUILIBRIUM AND KINETIC STUDIES OF THE INTERACTION OF $[Ru^{III}(EDTAH)(H_2O)]$ WITH CO

M. M. TAQUI KHAN,* AMJAD HUSSAIN, M. A. MOIZ and R. M. NAIK

Discipline of Coordination Chemistry and Homogeneous Catalysis, Central Salt & Marine Chemicals Research Institute, Bhavnagar—364 002, India

(*Received* 31 *October* 1988; *accepted* 26 *April* 1989)

Abstract—Interaction of $[Ru(EDTAH)(H_2O)]$ (**1**), $MHL(H_2O)$, with CO in aqueous solution was investigated by potentiometry, spectrophotometry and electrochemistry. Complex **1** reacted with CO in the pH range 2–3.5 to form the protonated and the normal carbonyl complexes, MHLCO (**2**) and MLCO (**3**), respectively (L = EDTA, HL = EDTAH). Complex **3** combined with **1** to form the μ-CO—μ-OH dimer, [ML(CO)(OH)ML] (**4**). The log of the stability constants, determined spectrophotometrically, for the formation of complexes **2**, **3** and **4** at 25°C (μ = 0.1 M) are 2.4, 4.9 and 3.72, respectively. The kinetics of the formation of complexes **2**–**4** were studied spectrophotometrically. The complexes constitute the first series of ruthenium(III)–carbonyls in aqueous solution, by the direct interaction of a soluble aquo Ru^{III}–EDTA complex with CO.

Carbonylation and hydroformylation reactions of olefins offer efficient routes for the manufacture of valuable chemicals.[1–5] Necessary feed stocks for industrial processes can also be produced by utilization of these reactions.[6] Carbonyl complexes are formed as intermediates[1–5] in hydroformylation with cobalt, rhodium, palladium and ruthenium complexes in the course of these reactions. Apart from their importance as homogeneous catalysts in carbonylation and oxo reactions, carbonyl complexes are important in their own right due to the types of bonding and structures exhibited by these complexes.[7] Much of the understanding about carbonyl complexes comes from the study of metal complexes in lower oxidation states,[7] partly due to the stabilization of these oxidation states by CO and cluster formation in the case of the carbonyls of ruthenium, osmium, rhodium and iridium.[8] Except for the kinetics of some of these complexes[9] in non-aqueous media, very few equilibrium or kinetic studies have been carried out on the metal carbonyls of these metal ions in aqueous solution.[10–14] The reason may be the instability of the lower oxidation states and the hydrolytic tendency of the higher oxidation states of these metal ions in aqueous solution. For instance, chloro complexes of ruthenium(III) become aquated in acidic medium[15] and complexes such as ruthenium(III)–aminopolycarboxylates are hydrolysed[16] at pH between 4 and 5. This may be the reason why no serious attempts seem to have been made to study the carbonyl complexes in aqueous solution. With interest now being directed to water-soluble catalysts,[17] there is a need to develop the aqueous solution chemistry of ruthenium, rhodium and osmium carbonyl complexes in general and that of ruthenium complexes in particular, since these complexes have been found to be excellent catalysts in certain carbonylation reactions.[18]

Except for ruthenium(III)–aminopolycarboxylates[11,16,19–21] and to a certain extent chlororuthenium complexes,[15] no systematic equilibrium studies on ruthenium(III) complexes in aqueous solution have been attempted. Equilibrium data for the replacement of H_2O by various ligands in the aquo ruthenium(II) amine complex have been reported.[12] Enthalpy for interaction of CO with $[Ru(NH_3)_5H_2O]^{2+}$ was evaluated calorimetrically.[13] Reaction of $RuCl_3 \cdot xH_2O$ with CO, in acidic medium, was studied in solution by IR techniques.[10] Kinetics of the formation of carbonyl complexes by the interaction of CO and HCOOH and their conversion to other species was reported.[22]

* Author to whom correspondence should be addressed.

In this paper, we report the solution equilibria and kinetic studies of the interaction of [Ru(EDTAH)(H_2O)] with CO in aqueous medium.

EXPERIMENTAL

Materials

Ruthenium trichloride, $RuCl_3 \cdot xH_2O$, was purchased from Johnson Mathey (U.K.). A.R. grade Na_2EDTA, purchased from BDH, was used as obtained. The nitrogen used was of analar grade (4 ppm O_2) and was purified by passing it through vanadous sulphate and alkaline pyrogallate solution. Carbon monoxide was prepared by the reaction of sodium formate and H_2SO_4, and purified by passing through a tower of KOH pellets.[23] K[Ru(EDTAH)Cl] was prepared by the known procedure.[24]

Potentiometry

Potentiometric titrations were carried out under nitrogen as described previously.[20] For the titration under CO, the solution was saturated with the gas by bubbling CO for an hour and the titrations were carried out under an atmosphere of CO until the titration was complete. All titrations were carried out at 5, 15, 25 and 35°C and $\mu = 0.10$ (KCl). Protonation constants were computed by a curve fitting method using PROGRAM PKAS.[25]

Spectrophotometry

For recording electronic absorption spectra and carrying out spectrophotometric experiments, a Shimadzu UV-160 spectrophotometer equipped with a temperature controller TCC-240A was used. Matched 10 or 2 mm cells were used to record the spectra. All measurements were taken at 5, 15, 25 and 35°C and $\mu = 0.10$ (KCl).

The wavelength of the maximum absorbance (λ_{max}) for the carbonyl complexes was found by passing CO through the solution of [Ru(EDTAH)(H_2O)] (**1**) and recording the spectra.

All spectrophotometric experiments were carried out at the λ_{max} (390 nm) corresponding to the formation of the carbonyl complexes. The ε_{max}^{390} value was found by noting the absorbance of the 390 nm peak in the presence of a 10-fold excess of CO at the pH of maximum absorbance, as obtained from the pH–absorbance profile (Fig. 3). The ε_{max}^{390} value was then calculated using Beer's law.

In order to study the effect of $[H^+]$, the pH of complex **1** was adjusted to the required value and then CO was passed through the solution and the $[H^+]$ noted. The absorbance was taken for solutions ranging in pH from 0.0 to 4.0.

For determination of the formula of the carbonyl complexes, two sets of experiments were performed. In the first set, the concentration of complex **1** or CO was of the order of 10^{-5} M and in the second set, the concentrations were of the order of 10^{-4} M. In each of these sets two sets of experiments were carried out: (1) in the first set the concentration of CO was kept constant and that of complex **1** varied; (2) in the second set the concentration of complex **1** was kept constant and that of CO varied. The formula of the complexes formed was determined by plotting absorbance vs concentration of the variant.

Stability constants of the carbonyl complexes were determined by carrying out the experiments at two different concentrations of complex (10^{-5} and 10^{-4} M). The λ_{max} and ε_{max} values at the lower concentration correspond only to the formation of **3**. For the solution of higher concentration (set 2), the species present at pH 3–4 were complexes **3** and **4**. The concentration of species **3** and **4** were determined by the application of Beer's law and their formation constants were calculated by setting up and solving algebraic equations.[27]

Electrochemistry

DPP and CV were recorded on a PAR electrochemical system 174, equipped with a precision X–Y recorded and Model 173 galvanostat, as described previously.[20] For recording CV and DPP at different pH the same procedure as for absorption spectra was followed.

Kinetics

A freshly prepared saturated solution of CO in doubly distilled water was used in all kinetic measurements. The concentration of CO in the saturated solution was calculated from its solubility at a given temperature and 1 atm. The CO concentration in the experiment was varied by diluting the saturated solution to the desired concentration. The concentrations of CO and complex **1** were varied over a wide range (10^{-5}–10^{-3} M). The reactants were equilibrated at 35°C for 1/2 h before mixing, and the pH of the solution was adjusted to a desired value with HCl or NaOH solutions using a pH meter calibrated with HCl and NaOH.[20]

The change in the absorption of the 390 nm band was used to monitor the reaction as a function of time under pseudo first-order conditions of [complexes] and [CO]. The required quantity of complex **1** solution was taken in a cuvette and the necessary

volume of saturated CO solution was added. The spectra were then recorded as a function of time. The total volume of the solution in each experiment was kept constant.

For studying the effects of varying the complex concentration, on the rate of reaction, different quantities of complex **1** solution were used, while maintaining a constant CO concentration in the solution. All kinetic runs were carried out at 5, 15, 25 and 35°C and $\mu = 0.1$ M (KCl).

RESULTS AND DISCUSSION

Equilibrium studies

Equilibrium studies were carried out using potentiometric, spectrophotometric and electrochemical techniques.

The potentiometric titration curve of complex **1** under CO exhibited an inflection at $a = 1.5$ (Fig. 1), indicating the release of $1\frac{1}{2}$ equivalents of proton per metal ion. The pH at $a = 0$ showed that $1\frac{1}{2}$ equivalents of proton are completely liberated. Thus, the equilibrium was completely shifted to the right and the potentiometric data between $a = 0$ and 1.5 could not be utilized for the calculation of stability constants.

Beyond $a = 1.5$, however, the dimeric, carbonyl complex becomes further hydrolysed as follows:

$$(ML)_2CO(OH) \overset{K_D^{OH}}{\rightleftharpoons} (ML)_2CO(OH)_3 + 2H^+ \quad (1)$$

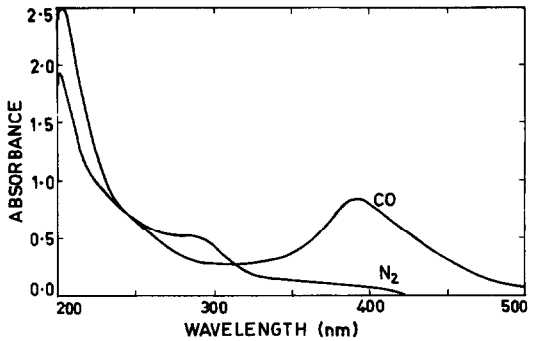

Fig. 2. Absorption spectra of [Ru(EDTAH)(H$_2$O)] solution (1×10^{-3} M) under N_2 and CO at 35°C, $\mu = 0.1$ M KCl.

$$K_D^{OH} = [(ML)_2CO(OH)_3][H^+]^2/[(ML)_2CO(OH)].$$

The value of K_D^{OH} was found to be $10^{-8.22}$ at 35°C ($\mu = 0.1$ M KCl).

Since there was a large drift in the pH after $a = 2.5$, the data was not used for any stability constant calculations.

For the equilibrium studies under CO between $a = 0$ and 1.5, the spectrophotometric method was used. The absorption spectra of complex **1** under N_2 and CO are given in Fig. 2 and the data are tabulated in Table 1. The spectrophotometric results indicate that at low metal ion concentrations (of the order of 10^{-5} M) a monomer exists, while at higher concentrations (of the order of 10^{-4} M) a

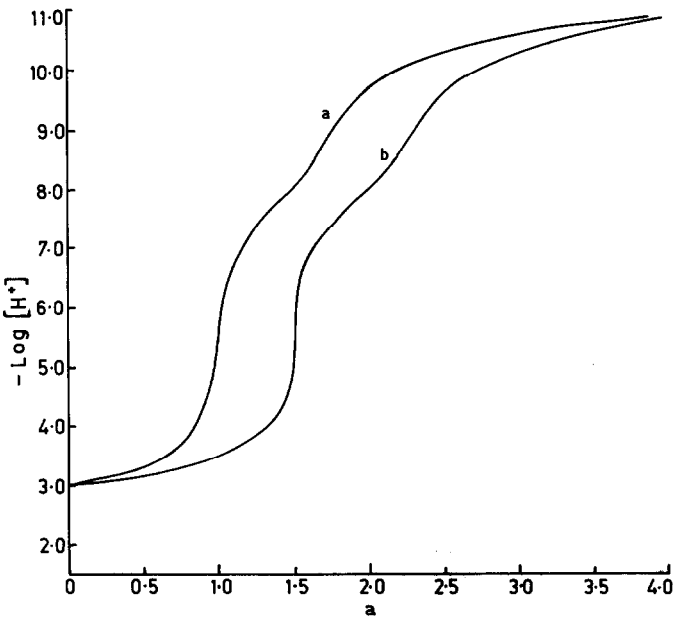

Fig. 1. Potentiometric titration curves of [Ru(EDTAH)(H$_2$O)] solution (1×10^{-3} M) at 35°C and $\mu = 0.1$ M KCl in presence of (a) N_2 (b) CO.

vs—very strong; s—strong; sh—shoulder; wsh—weak shoulder.

dimer exists in solution. This was further supported by plotting the change in absorbance vs the concentration of the variant ([ML] or [CO]) and noting the break in the graph.

From the above observations it is evident that the reactions taking place between $a = 0$ and 1.5 can be written as:

$$\underset{\textbf{(1a)}}{ML} + CO \overset{K_{CO}}{\rightleftharpoons} \underset{\textbf{(2)}}{MLCO} \qquad (2)$$

$$K_{CO} = [MLCO]/[ML][CO]$$

$$MLCO + ML \overset{K_D}{\rightleftharpoons} \underset{\textbf{(3)}}{(ML)_2CO(OH)} + H^+ \qquad (3)$$

$$K_D = [(ML)_2CO(OH)][H^+]/[MLCO][ML].$$

The stability constant K_{CO} was determined by using low concentrations (10^{-5} M) of complex **1** and CO. Since at this concentration complex **2** is the only absorbing species at λ_{max}. The value of K_{CO} was found to be $10^{4.90}$. At higher concentrations of complex **1** (10^{-4} M) a dimer, **3**, also exists. The overall stability constant for the formation of the dimer, β_{CO}^{OH}, was found to be $10^{8.62}$:

$$2ML + CO \overset{\beta_{CO}^{OH}}{\rightleftharpoons} \underset{\textbf{(3)}}{(ML)_2CO(OH)} + H^+ \qquad (4)$$

$$\beta_{CO}^{OH} = [(ML)_2CO(OH)][H^+]/[ML]^2[CO].$$

The constant for reaction (3) was calculated from the expression:

$$K_D = \beta_{CO}^{OH}/K_{CO} \qquad (5)$$

and has the value $10^{3.72}$.

At very low pH (around 1.0) a protonated carbonyl species, MLHCO, is formed, as expressed by the equilibria:

$$MLH + CO \overset{K_{CO}^{H}}{\rightleftharpoons} MLHCO \qquad (6)$$

$$K_{CO}^{H} = [MLHCO]/[MLH][CO]$$

$$MLCO + H^+ \overset{K_H^2}{\rightleftharpoons} MLHCO \qquad (7)$$

$$K_H^2 = [MLHCO]/[MLCO][H^+].$$

K_H^2 can be determined as follows: a plot of absorbance at 264.5 nm against pH shows an inflection between pH 1.15 and 1.35.

At the minimum of the inflection, equilibrium (7) completely shifts to the right and only the MLHCO species is present in solution, while at the maximum only the MLCO species is present. At the midpoint of the inflection, [MLHCO] = [MLCO] and thus

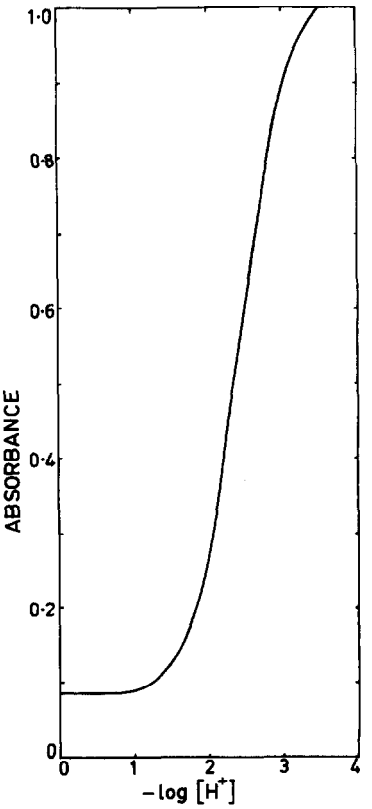

Fig. 3. Change in absorbance of 390 nm peak with $-\log[H^+]$ at 35°C, $\mu = 0.1$ M KCl.

$K_H^2 = [H^+]^{-1}$. The value thus obtained is $10^{1.24}$. K_{CO}^H is given by the expression:

$$K_{CO}^H = K_{CO}/K_H^1 K_H^2,$$

where K_H^1 is the protonation constant for ML under N_2

$$ML + H \overset{K_H^1}{\rightleftharpoons} MLH \qquad (8)$$

$$K_H^1 = [MLH]/[ML][H^+] = 10^{2.36}.$$

Since the errors involved in the calculation of the thermodynamic parameters associated with the constants K_{CO}^H, K_{CO} and K_D do not justify their separate calculations, the thermodynamic parameters ΔH^0, ΔS^0 for the overall reaction (4), as represented by the constant β_{CO}^{OH} for **4**, were calculated. The value of ΔH^0 for reaction (4) calculated in the temperature range 5–35°C is −14.2 kcal mol^{-1} and ΔS^0 at 35°C is −3.2 e.u. The enthalpy of formation of $[Ru(NH_3)_5CO]^{2+}$ from $[Ru(NH_3)_5H_2O]^{2+}$ and CO was reported[16] to be −38.0 kcal mol^{-1}.

The lower endothermic value of ΔH^0 for **4**, as compared to $[Ru(NH_3)_5CO]^{2+}$, reflects the lower stability of the M—CO bond in the ruthenium(III) complex **4**, as compared to ruthenium(II) complexes. As expected, the entropy for the formation of the dimer **4** is more negative compared to the mononuclear carbonyl species.

Electrochemical studies were carried out to confirm the oxidation state of ruthenium in the carbonyl complexes **2**–**4**. The DPP and CV of complex **1** in the absence and presence of CO are presented in Figs 4(a) and (b), respectively. In the absence of CO, DPP of **1** [Fig. 4(a)] exhibits peaks at −0.350, −0.800, −1.110 V, corresponding to Ru^{3+}/Ru^{2+}, Ru^{2+}/Ru^{+}, $H^+/\frac{1}{2}H_2$ couples, respectively[20] (Table 2). The Ru^{3+}/Ru^{2+} couple of **1** shifts to more negative potentials on increasing the pH, which is due to hydrolysis of **1**. In the absence of CO, the CV of complex **1** [Fig. 4(b)] exhibits two reversible peaks (Table 2). Cathodic (Ep_c) and anodic (Ep_a) peaks with $ipc/ipa = 1$ were observed for the reversible

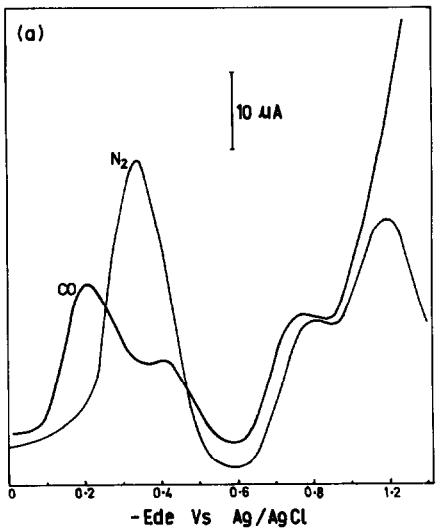

Fig. 4(a). Differential pulse polarograms of [Ru(EDTAH) Ru^{3+}/Ru^{2+} couple, with an $E_{1/2}$ value of 0.350 pH = 3.0, T = 25°C, μ = 0.1 M KCl.

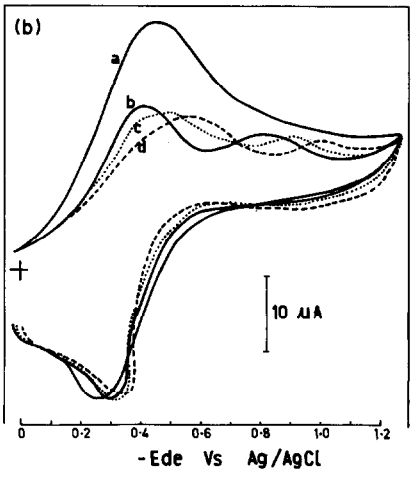

Fig. 4(b). Cyclic voltammograms of [Ru(EDTAH)(H$_2$O)] solution (1×10^{-3} M) at 25°C, μ = 0.1 M KCl, (a) under N_2 at "a" ([NaOH]/[ML]) = 0.0; (b)–(d) under CO at a = 0.0, 0.5, 1.0, respectively.

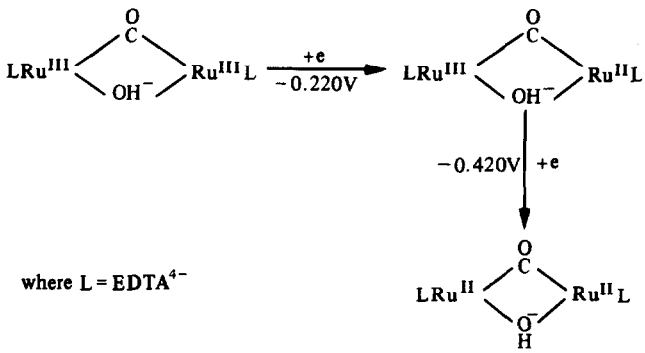
Table 2. DPP and CV data of complex formed by interaction of K[Ru (EDTAH)(H$_2$O)] with CO at 35°C and μ = 0.10 M (KCl)

	DPP	CV	
Complex	$-E_{1/2}$ (V) (vs Ag/AgCl)	$-Ep_c$ (V)	$-Ep_a$ (V)
1 under N_2	0.350, 0.800, 1.110	0.400, 0.795	0.300
1 under CO	0.220, 0.420, 0.765	0.220, 0.490, 0.780	0.180



Scheme 1.

Ru^{3+}/Ru^{2+} couple, with an $E_{1/2}$ value of 0.350 V, the same as observed in DPP.[20] The other two couples, viz. Ru^{2+}/Ru^{+} and $H^{+}/\frac{1}{2}H_2$, are irreversible.

On passing CO into the solution of **1**, the peak due to the Ru^{3+}/Ru^{2+} couple splits and two peaks are exhibited at -0.220 and -0.420 V (see Scheme 1) in DPP and -0.220 and -0.490 V in CV. Such split peaks are characteristic of dimers[20,26] and result from the stepwise reduction of metal ions in dimer **4**. This further confirms the formation of dimer complex **4**, as was discussed in the potentiometric results. The peak due to Ru^{2+}/Ru^{+} appears at -0.765 V, but no peak appears for $H^{+}/\frac{1}{2}H_2$ in the dimer.

The peaks due to the Ru^{3+}/Ru^{2+} couple in complex **4** is pH dependent and shifts to more negative potentials on increasing the pH. This is due to further hydrolysis of the dimer [reaction (5)] to the hydroxo species. In the CV of **4** the potential due to the Ru^{3+}/Ru^{2+} couple shifts to more negative values until $a = 2.5$, beyond which, new peaks are exhibited due to the decomposition of complex **4** to unidentified species. No study was, therefore, carried out above $a = 2.5$.

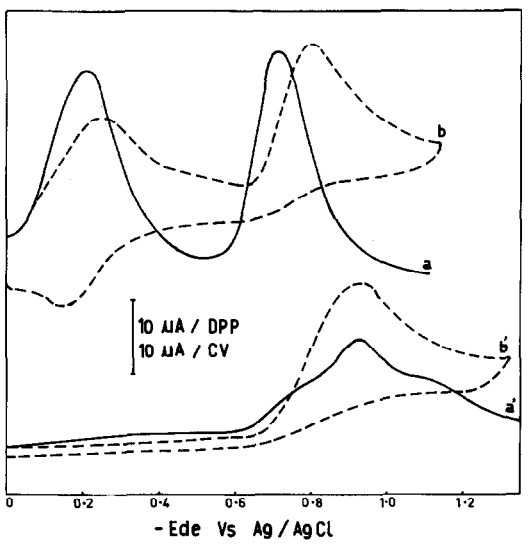


Fig. 5. Differential pulse and cyclic voltammograms at 25°C, $\mu = 0.1$ M KCl. (a) and (b) DPP and CV of [Ru^{III}(EDTAH)(H_2O)] solution (1×10^{-3} M) refluxed under a CO atmosphere. (a′) and (b′) DPP and CV of [Ru^{II}–EDTA–CO] solution (1×10^{-3} M).

In order to confirm the oxidation state of the metal ion in complexes **2–4**, a solution of **1** was refluxed under a CO atmosphere for 3 h. The DPP and CV of such a solution are shown in Figs 5(a) and (b). It may be seen that the Ru^{3+}/Ru^{2+} peak is still seen even under refluxing conditions. As a further check, an authentic sample of Ru^{II}–EDTA–CO was prepared by the reduction of MLH with H_2/Pt under CO.[27] DPP and CV of such a solution did not exhibit any peak due to Ru^{3+}/Ru^{2+} [Fig. 5(a′) and (b′)]. Thus complexes **2–4**, formed in solution on reaction of **1** with CO, are stable ruthenium(III) carbonyl species.

Kinetics of the formation of complexes **2**, **3** *and* **4**

The kinetics of the carbonylation reaction were followed spectrophotometrically by recording repetitive scans (Fig. 6) of the reaction between complex **1** and CO by monitoring the growth of the peak at 390 nm with the formation of CO complexes. The peaks due to complex **1** at 203, 283 and 365 nm (Fig. 6) decrease with the formation of complexes **2**, **3** and **4**. An isobestic point (Fig. 6) was observed at 310 nm, which showed the existence of two species in equilibrium.

The kinetics of complex formation were found to follow first-order dependence in the concentration of complex **1**, as well as in [CO], over a wide range of concentration (10^{-5}–10^{-3} M) of either reactant. The values of the pseudo first-order rate constants, K_{obs}, were obtained from the slopes of a plot of $\log(A_\infty - A_t)$ vs time. The values of A_∞ were

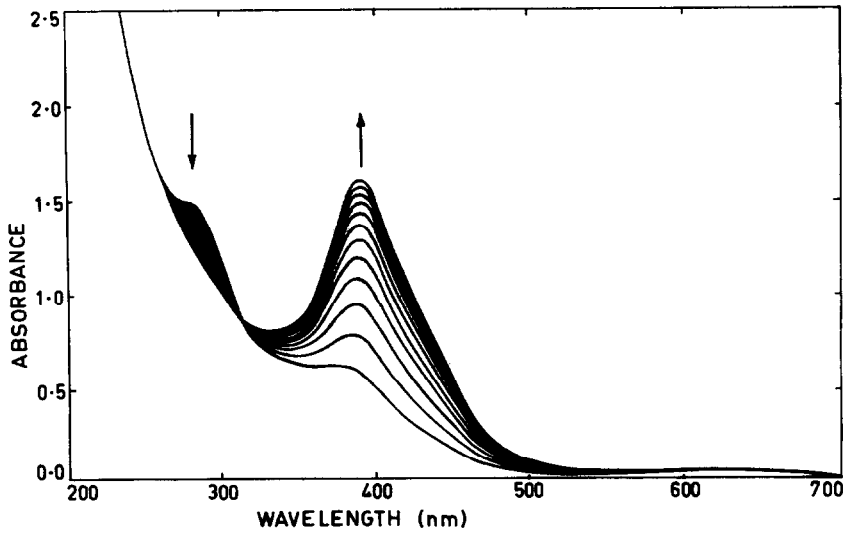

Fig. 6. Repetitive scan at 2 min intervals of the reaction between [Ru(EDTAH)(H$_2$O)] (1×10^{-5} M) and [CO] (4.64×10^{-4} M) at 25°C, $\mu = 0.1$ M KCl.

obtained by allowing the reaction to proceed to more than five times the half-life of the reaction. The first-order dependence plot of k_{obs} vs [CO] is given in Fig. 7.

The reaction between **1** and CO was studied in the pH range 2.5–3.8. The rate was found to increase with pH in the range 2.5–3.2, while it remained constant in the pH range 3.2–3.8 (Fig. 8). In the pH range investigated, complex **1** exists in two forms: [Ru(EDTAH)(H$_2$O)] (**1**) and the "normal" form [Ru(EDTA)(H$_2$O)]$^-$ (**1a**).

Our experimental observations on the complexation of **1** with CO enabled us to suggest the most plausible mechanism for the present reaction system using eqs (9)–(11):

$$\underset{\textbf{(1)}}{[Ru(EDTAH)(H_2O)]} + CO \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} \underset{\textbf{(2)}}{[Ru(EDTAH)CO]} + H_2O \quad (9)$$

$$\underset{\textbf{(1a)}}{[Ru(EDTA)(H_2O)]^-} + CO \underset{k_{-b}}{\overset{k_b}{\rightleftharpoons}} \underset{\textbf{(3)}}{[Ru(EDTA)(CO)]^-} + H_2O \quad (10)$$

$$\underset{\textbf{(3)}}{[Ru(EDTA)(CO)]^-} + \underset{\textbf{(1a)}}{[Ru(EDTA)H_2O]^-} \underset{k_{-c}}{\overset{k_c}{\rightleftharpoons}} \underset{\textbf{(4)}}{[(RuEDTA)_2(CO)(OH)]^{3-}} + H^+. \quad (11)$$

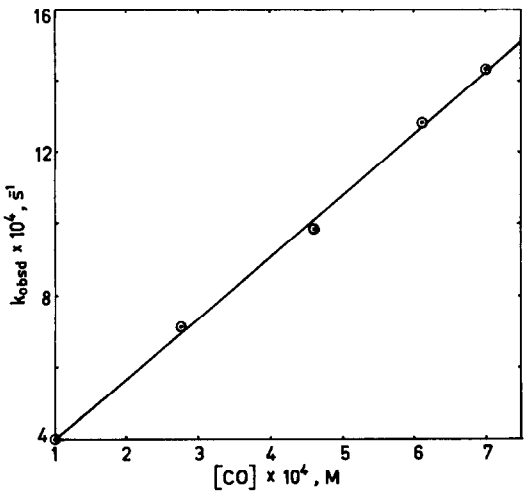

Fig. 7. First-order dependence kinetic plot in [CO] at pH = 3.0, $T = 25$°C, $\mu = 0.1$ M KCl.

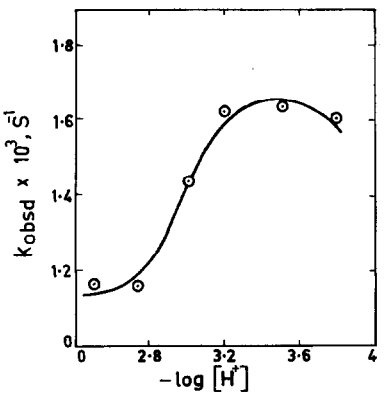

Fig. 8. pH dependence of observed rate constants for the reaction of [Ru(EDTAH)(H$_2$O)] (5×10^{-5} M) with [CO] (7×10^{-4} M) at 25°C, $\mu = 0.1$ M KCl.

In the proposed mechanism both the protonated and normal complexes, **1** and **1a**, combine with CO to form complexes **2** and **3**, respectively. Complex **3** further reacts with **1a** to give complex **4**.

The rate expression for reactions (9)–(11) can be written in terms of the specific rate constants, k_1, k_a, k_b, k_c and by expressing the concentrations of complex **1** in terms of **1** and **1a**.

$$k_1\left(1+\frac{K_{1a}}{[H^+]}\right)=k_a+\frac{k_bK_{1a}}{[H^+]}+\frac{k_c(K_{1a})^2K_{CO}[1a]}{[H^+]^2}, \quad (12)$$

where

$$k_1=\frac{\text{rate}}{[1]_T[CO]}; \quad K_{1a}=\frac{1}{K_H^1}.$$

At pH < 3.8 the last term on the RHS of eq. (12) drops out and a plot of the LHS of the expression vs $1/[H^+]$ yields a straight line. The intercept and slope of which give k_1 and k_2 as 1.02 and 2.42 M^{-1} s^{-1}, respectively (see Fig. 9).

At pH 3.8 all the constants in eq. (12) except k_c are known. By substituting the values of the known quantities into eq. (12), k_c was found to be 1.45×10^{-3} M^{-1} s^{-1}, which is about three orders of magnitude lower than k_a and k_b and hence is the rate-determining step.

From the values of the equilibrium constants for reactions (1), (2) and (3), the values of the "off rates" k_{-a}, k_{-b} and k_{-c} are 4.06×10^{-3} s^{-1}, 3.05×10^{-5} s^{-1}, 2.76×10^{-7} M^{-1} s^{-1}. The off rates are much slower than the "on rates" and decrease in the order $k_{-a} > k_{-b} > k_{-c}$. In fact for reactions (1)–(3), the rate of formation "on rates" are therefore the equilibrium controlling rates. The most unstable complex, **2**, is readily deprotonated to form **3**. The formation of **2** is, therefore, promoted in acidic solution.

The values of the activation parameters, $\Delta H^\ddagger$ and $\Delta S^\ddagger$, corresponding to the slow step, k_c, in the temperature range 15–45°C are $\Delta H^\ddagger = 9.5$ kcal mol^{-1} and $\Delta S^\ddagger = -25.5$ e.u. The values of $\Delta H^\ddagger$ and $\Delta S^\ddagger$ reported[10] for the ruthenium(III) carbonyl, $[Ru^{III}Cl_5(H_2O)]^{2-}$, are 24.0 kcal mol^{-1} and 7.0 e.u., respectively. The value of $\Delta H^\ddagger$ is more exothermic by about 16.0 kcal mol^{-1} for the carbonylation of complex **1** than for the pentachloro ruthenium(III) species. Since the overall reaction involves a displacement of the H_2O molecule by CO the enthalpies should depend on the labilization of the H_2O molecule in the complexes. The lability of the H_2O molecule in these complexes depends[14] on the extent of σ-donation and π-back-bonding of the ligands present in the coordination sphere of the metal ion. A good σ-donor increases[14] the electron density on ruthenium(III) and assists in the labilization of the H_2O molecule in a nucleophilic displacement reaction. The presence of a strong σ-donor in the coordination sphere of ruthenium(III) in **1** makes the H_2O molecule much more labile than in the pentachloro complex, reflecting on the favourable enthalpy of activation. The entropy of activation, $\Delta S^\ddagger$, for the formation of dimer **4** is much more negative than the monomeric chloro ruthenium(III) complex.

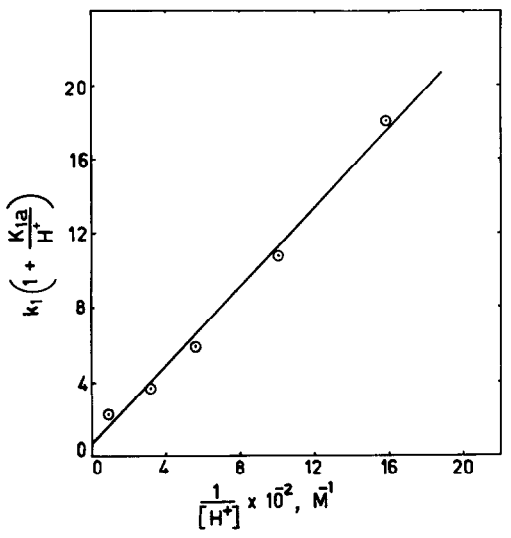

Fig. 9. Plot of $k_1(1+(K_{1a}/[H^+]))$ vs $[H^+]^{-1}$; [Ru (EDTAH)(H_2O)] = 5×10^{-5} M, [CO] = 7×10^{-4} M at 25°C, μ = 0.1 M KCl.

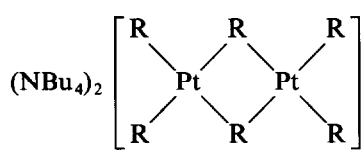
Abstract—The reactions between $Q_2[Pt_2(\mu\text{-}C_6F_5)_2(C_6F_5)_4]$ (Q = NBu_4, PPN) and 2,2′-bipy (molar ratio 1:1) in CH_2Cl_2 afford the binuclear $Q_2[(C_6F_5)_3Pt(\mu\text{-}2,2'\text{-bipy})Pt(C_6F_5)_3]$ complex, which contains the 2,2′-bipy acting as a bridging ligand. A similar reaction with 1,10-phen renders *cis*-$Pt(C_6F_5)_2$phen and $Q_2[Pt(C_6F_5)_4]$ (Q = NBu_4). On the other hand, $(NBu_4)_2[Pd_2(\mu\text{-}C_6F_5)_2(C_6F_5)_4]$ reacts in CH_2Cl_2 with either bipy or phen (N—N) (1:1), yielding in both cases *cis*-$Pt(C_6F_5)_2$(N—N) and $(NBu_4)_2[Pd(C_6F_5)_4]$. The structure of the binuclear platinum complex (Q = PPN) which contains for the first time a 2,2′-bipy bridging ligand has been determined by X-ray crystallography.

2,2′-Bipyridine (bipy) and 1,10-phenanthroline (phen) have been much used[1] in coordination chemistry as powerful chelating ligands. The rigid geometry of phen forces the two donor nitrogen atoms into a *cis*-position, but since the bipy molecule is not rigid and the free ligand adopts a *trans*-configuration in the solid state,[2] it should be expected that the formation of binuclear complexes containing bridging *trans*-bipy might be feasible. Only a few complexes have been reported[3–8] for which such a bridging structure has been invoked, always on indirect evidence; to the best of our knowledge, no definite structural evidence based on X-ray studies has been given, so far.† Here, we report the synthesis of the first well-authenticated binuclear complex with a bridging *trans*-bipy ligand, as demonstrated by single crystal X-ray crystallography.

Addition of 2,2′-bipy to a yellow dichloromethane solution of $(NBu_4)_2[Pt_2(\mu\text{-}C_6F_5)_2(C_6F_5)_4]$[9] (1:1 molar ratio, room temperature) gives, after 1 h stirring, a colourless solution from which after evaporation to dryness and washing the residue with ^{i}PrOH, the binuclear $(NBu_4)_2[Pt_2(\mu\text{-}2,2'\text{-bipy})(C_6F_5)_6]$ (1) [eq. (1)] in 74% yield, as a consequence of the symmetric cleavage of the bridge in the binuclear precursor.



$(NBu_4)_2[R_3Pt(\mu\text{-}2,2'\text{-bipy})PtR_3]$. (1)

As expected, substitution of the 1,10-phen for 2,2′-bipy [in eq. (1)] causes the unsymmetric cleavage of the bridge system in the precursor to afford *cis*-$Pt(C_6F_5)_2$phen[10] (insoluble in the CH_2Cl_2 solution) and $(NBu_4)_2[Pt(C_6F_5)_4]$,[11] thereby illustrating the constraint imposed by the structural rigidity of the phen molecule.

Notwithstanding, the analogous binuclear palladium complex $(NBu_4)_2[Pd_2(\mu\text{-}C_6F_5)_2(C_6F_5)_4]$[12] reacts with both bipy or phen under unsymmetric

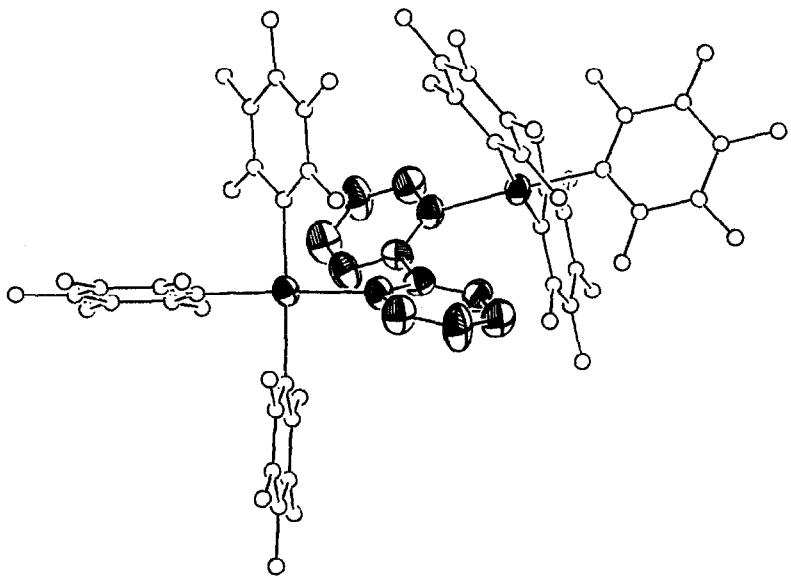

Fig. 1. An ORTEP view of the $[(C_6F_5)_3Pt(\mu\text{-bipy})Ph(C_6F_5)]^{2-}$ anion. The carbon and fluorine atoms of the C_6F_5 groups are drawn with arbitrary radii for clarity.

Distances:

Pt—C(6)	2.117(7)	Pt—C(18)	2.039(4)	C(1)—C(1′)	1.501(25)
Pt—C(12)	2.107(6)	Pt—N(1)	2.115(7)		

Angles:

C(12)—Pt—C(18)	90.4(2)	C(6)—Pt—N(1)	89.4(3)
C(18)—Pt—C(6)	88.1(2)	N(1)—Pt—C(12)	92.2(3)

cleavage of the bridge to give *cis*-$Pd(C_6F_5)_2(bipy)$[10] and $(NBu_4)_2[Pd(C_6F_5)_4]$[11] or, respectively, *cis*-$Pd(C_6F_5)_2(phen)$[10] and $(NBu_4)_2[Pd(C_6F_5)_4]$.[11]

Complex **1** gives microanalytical and spectroscopic data which are in accordance with the proposed formulae,* but all attempts to grow suitable crystals for X-ray studies failed since only thin filiform specimens were obtained. Thereafter, the similar $(PPN)_2[Pt_2(\mu\text{-}2,2'\text{-bipy})(C_6F_5)_6]$ (**2**) was prepared and suitable crystals were grown by slow diffusion (*ca* 2 weeks, −30°C) of *n*-hexane into a CH_2Cl_2 solution of **2**.†

The structure of the anion, $[Pt_2(\mu\text{-}2,2'\text{-bipy})(C_6F_5)_6]^{2-}$, is shown in Fig. 1, it lies on a crystallographic C_2 axis and comprises two fragments "$Pt(C_6F_5)_3$" bridged by the bipy ligand. Each platinum atom is in a nearly regular square-planar environment, formed by three carbon atoms of the C_6F_5 groups and a nitrogen atom of the bridging bipy. The Pt—C distances are in the range 2.039(4)–2.117(7), similar to Pt—C distances found in other pentafluorophenyl platinum complexes,[15–18] the shortest Pt—C distance being that corresponding to carbon *trans* to the nitrogen atom of the bipy, in accordance with the low *trans*-influence of the amine donor ligand.

The C—C and C—N distances and bond angles within the pyridine rings, are similar to those found in the free ligand.[2] Each pyridine ring is practically planar, and the largest deviation of any atom from the least-squares best plane is 0.019 Å,[19] however the entire coordinated bipy is not planar; both pyridine rings are rotated around the C(1)—C(1′) bond, the dihedral angle formed by the least-squares pyridine planes is 41.89°, the nitrogen atoms being in *trans*-positions.

SPECTROPHOTOMETRIC DETERMINATION OF THE REACTION STOICHIOMETRY OF THE REDUCTION OF OCTACYANOTUNGSTATE(V) BY HYDROXYLAMINE IN ACIDIC AND BASIC MEDIA

J. H. POTGIETER

Department of Chemistry, University of Pretoria, Pretoria 0002, Republic of South Africa

(*Received* 3 *April* 1989; *accepted* 4 *May* 1989)

Abstract—The stoichiometry of the reduction of octacyanotungstate(V) by hydroxylamine in basic and acidic media has been studied by a spectrophotometric technique. It was found that the stoichiometric ratio between $W(CN)_8^{3-}$ and hydroxylamine was 2:1 in a basic medium and 1:1 in an acidic medium, in agreement with previously proposed values.

The reaction of hydroxylamine with a variety of oxidizing agents has been studied[1] and various oxidation products, i.e. NH_3, $H_2N_2O_2$, N_2 and N_2O have been reported. These investigations were performed in acidic solutions of pH 0.4–5.6. Jindal *et al.*[2] found that the oxidation of hydroxylamine by $Fe(CN)_6^{3-}$ in a weak acidic medium produced N_2 as the main reaction product.

Although the oxidation of hydroxylamine in acidic solution has been extensively investigated, very little is known about the reaction in alkaline media. Van Wyk *et al.*[3] have conducted a kinetic study of the oxidation of hydroxylamine by octacyanotungstate(V) over a wide pH range and have found that the reaction occurred quickly in alkaline media, but was slow in acidic media. It was also observed that N_2 was generated by the reaction between $W(CN)_8^{3-}$ and hydroxylamine at pH values of ~ 6. The present investigation is a continuation of the work by Van Wyk *et al.* and is also part of a research project on the redox properties of the cyano complexes of molybdenum, tungsten and iron.

EXPERIMENTAL

$Cs_3W(CN)_8 \cdot 2H_2O$ was prepared as described by Leipoldt and co-workers,[4,5] and was used as a primary standard[6] after recrystallization. Hydroxylammonium chloride (Merck *pro analisi*) was used as a source of hydroxylamine. The hydroxylammonium chloride solution was neutralized with sodium hydroxide. This solution was renewed daily. All other reagents used were analytical-grade, and redistilled water was used throughout.

Spectrophotometric measurements were made in both alkaline and acidic media using buffer mixtures made with KH_2PO_4 or sodium hydroxide solutions at constant ionic strength. Stoichiometric data were obtained by monitoring the decrease in $[W(CN)_8^{3-}]$ after reaction with various hydroxylamine concentrations on a Pye-Unicam SP 1700 spectrophotometer at 357 nm. All measurements were taken at 25°C.

In the alkaline medium the absorbance of the $W(CN)_8^{3-}$ solution was measured immediately after mixing with the hydroxylamine, while 3 h waiting time was allowed in the acidic medium before any measurements were made.

RESULTS AND DISCUSSION

The absorbance of different, partly reduced $W(CN)_8^{3-}$ solutions in basic and acidic media by increasing amounts of hydroxylamine are summarized in Table 1.

The absorbance of a 5.0×10^{-4} mol dm^{-3} $W(CN)_8^{4-}$ solution was 0.110. The graphical representation shown in Fig. 1 allows calculation of

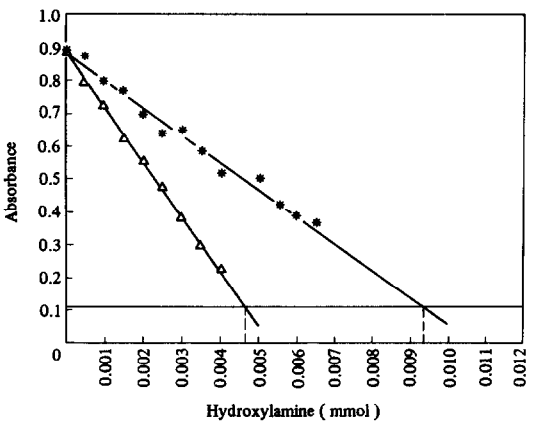

Fig. 1. Absorbance of different, partly reduced $W(CN)_8^{3-}$ solutions as a function of the amount of hydroxylamine added.

the stoichiometric relationship for the reaction between $W(CN)_8^{3-}$ and hydroxylamine in both media.

From the two intersection values of the curves in Fig. 1 the stoichiometric ratio between $W(CN)_8^{3-}$ and hydroxylamine is calculated to be ≃ 2 : 1 in the basic medium and ≃ 1 : 1 in the acidic medium. The reaction between $W(CN)_8^{3-}$ and hydroxylamine can therefore by represented by the following balanced equations:

Basic medium:

$$4W(CN)_8^{3-} + 2NH_2OH + 4OH^- \longrightarrow 4W(CN)_8^{4-} + N_2O + 5H_2O$$

Acidic medium:

$$2W(CN)_8^{3-} + 2NH_2OH \longrightarrow 2W(CN)_8^{4-} + 2H^+ + N_2 + 2H_2O.$$

These results are in agreement with the proposed stoichiometric values used in the reaction scheme for the kinetic study of the oxidation of hydroxylamine by octacyanotungstate(V) by Van Wyk *et al.*[3]

THE PREPARATION AND X-RAY STRUCTURES OF $Pt(SeSN_2)(PMe_2Ph)_2$ AND $[Pt(SeSN_2H)(PMe_2Ph)_2]BF_4$

CAROLINE A. O'MAHONEY, IVAN P. PARKIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 4 *April* 1989; *accepted* 17 *May* 1989)

Abstract—Reaction of $[Se_2SN_2]_2Cl_2$ with $PtCl_2(PMe_2Ph)_2$ in liquid ammonia gives $Pt(SeSN_2)(PMe_2Ph)_2$ (**4**), which may be protonated with HBF_4 to form $[Pt(SeSN_2H)(PMe_2Ph)_2]BF_4$ (**5**); the new compounds being characterized by IR, NMR and X-ray crystallography.

Recently, we have described the synthesis of metalla–sulphur–nitrogen complexes containing $S_2N_2^{2-}$, $S_2N_2H^-$ or S_3N^- ligands.[1–4] Complexes of the type $[Pt(S_2N_2H)(PR_3)_2]X$ (**1**) are of particular interest since they form one dimensional stacked structures with channels of cations and anions. Clearly, it would be advantageous to replace the sulphur atoms by seleniums in the PtSN rings to enhance the electronic interactions between the layered cations, a strategy that has been found to be useful for organic metals. However, the synthesis of selenium substituted analogues of **1** is non-trivial since there is a paucity of suitable starting materials, although we have been able to prepare $Pt(Se_3N)Cl(PMe_2Ph)$ in low yield from a high temperature reaction involving Se_4N_4.[5] One very successful strategy for the preparation of M—S—N complexes has been to perform the reaction in liquid ammonia using cations such as $[S_3N_2Cl]^+$ or $[S_4N_3]^+$.[6] Here, we report on the reaction of $[Se_2SN_2]_2Cl_2$ (**2**) with *cis*-$PtCl_2(PMe_2Ph)_2$ (**3**) in liquid ammonia to give $Pt(SeSN_2)(PMe_2Ph)_2$ (**4**) [eq. (1)], which can be protonated using HBF_4 to give $[Pt(SeSN_2H)(PMe_2Ph)_2]BF_4$ (**5**) [eq. (2)]. Compounds **4** and **5** are the first examples of complexes containing S—Se—N anions as ligands.

$$cis\text{-}PtCl_2(PMe_2Ph)_2 + 1/2[Se_2SN_2]_2Cl_2 \xrightarrow{\text{liq. } NH_3} Pt(SeSN_2)(PMe_2Ph)_2 + SeCl_2 + NH_4Cl \quad (1)$$

$$Pt(SeSN_2)(PMe_2Ph)_2 + HBF_4 \longrightarrow [Pt(SeSN_2H)(PMe_2Ph)_2]BF_4. \quad (2)$$

In a typical reaction, **2** (1 mmol) was dissolved in liquid ammonia (5 cm^3) at −78°C and **3** (1 mmol) was added. After stirring for 1 h the reaction was allowed to warm to room temperature and the ammonia allowed to evaporate off. The product, **4**, was obtained by extraction into CH_2Cl_2 and crystallized from CH_2Cl_2–petrol ether (yield *ca* 0.7 mmol, 70%). Protonation of **4** to form **5** was carried out in THF–benzene, the isolated yield being 70%.†

The spectroscopic properties of **4** and **5** are as expected.‡ The ^{31}P NMR spectra are of the AX type with ^{195}Pt and ^{77}Se satellites; the chemical

shifts and coupling constants being similar to the M—S—N analogues. The mass spectra show the parent ion with the appropriate isotopic substitution pattern for compounds containing one selenium and one platinum atom.

Despite the significantly larger covalent radius of selenium relative to sulphur, the X-ray structures* of **4** and **5** are isostructural with their PtS_2N_2 analogues.[2] In the neutral compounds both the $PtS_2N_2/PtSeSN_2$ rings display similar rotational disorder. Figure 1 shows a schematic representation of the disorder in **4**. Despite the disorder, the analysis shows unequivocally that the selenium atom is bound to platinum. Because of the inevitably poor accuracy of the bond lengths and angles in the $PtSeSN_2$ ring in the structure of **4** we determined the structure of the protonated compound **5**. In **5**, as a consequence of the synthetic route employed, the selenium atom is again bound to platinum and furthermore, the structure still displays the characteristic stacking seen previously

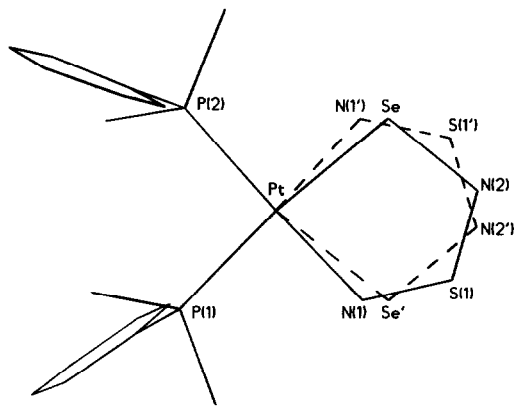

Fig. 1. A schematic representation of the disordered structure of $Pt(SeSN_2)(PMe_2Ph)_2$ (**4**).

for $[Pt(S_2N_2H)(PR_3)_2]X$ compounds.[3] The bond lengths for atoms not connected to selenium in **5** are the same as in $[Pt(S_2N_2H)(PMe_2Ph)_2]BF_4$ (**6**), there being a characteristic shortening of the Pt—P(2) bond length (*trans* to nitrogen) relative to Pt—P(1). With the exception of the angle at platinum (85.5(2) in **5**, cf. 84.6(2)° in **6**), the angles within the metallacycle are contracted in **5** compared to **6** as a result of the longer bonds around the selenium atom. There is a hydrogen bond (3.19 Å) between N(1)—H in the cation and F(1) in the anion. (The X-ray structure of **5** is shown in Fig. 2.) As mentioned above, the

COPPER(II) PROMOTED DESULPHURIZATION OF *N*-PHENYLTHIOUREA. THE SYNTHESIS AND X-RAY STRUCTURE OF [{Cu(bipy)(pc)$_2$}$_2$] (bipy = 2,2′-BIPYRIDINE, pc = PHENYLCYANAMIDE)

MARK L. BRADER, ERIC W. AINSCOUGH,* EDWARD N. BAKER and ANDREW M. BRODIE*

(*Received* 19 *April* 1989; *accepted* 17 *May* 1989)

Abstract—The reaction of *N*-phenylthiourea with a copper(II) acetate/2,2′-bipyridine ethanol solution affords the phenylcyanamide complex, [{Cu(bipy)(pc)$_2$}$_2$] (bipy = 2,2′-bipyridine, pc = phenylcyanamide), and elemental sulphur. An X-ray structure of the phenylcyanamide complex shows it to be a centrosymmetric dimer with each copper having a distorted tetragonal pyramidal geometry. The pc anions exhibit two different coordination modes: (a) monodentate, coordinating through the cyano nitrogen and (b) bidentate, bridging two copper atoms via the cyano and amido nitrogens.

The interaction of thiones, such as heterocyclic thioamides[1] and thioureas,[2] with copper(II) salts normally results in the reduction of the metal and the formation of complexes of copper(I) in which the ligand remains intact. Occasionally copper(II) complexes are obtained.[1–6] However, some exceptions to this reactivity pattern have been reported. For example, the reaction of benzothiazoline-2-thione in chloroform with solid copper(II) perchlorate hexahydrate yields a copper(I) complex containing the trisulphide of the reactant thioamide,[7] and 1-methylimidazoline-2(3*H*)-thione reacts with a variety of copper(II) salts in methanol[8,9] or nitromethane[10,11] to afford copper(II) complexes of the monosulphide, bis(1-methylimidazol-2-yl)sulphide, coordinated as an N-donor chelate. In contrast to these latter results, we have found that while thioazolidine-2-thione in nitromethane is also desulphurized by copper(II), the products are copper(I) or copper(II) complexes of the N,S-chelate, 3-(2-thiazolin-2-yl)thiazolidine-2-thione.[12] As an extension to this work we have examined the reactivity of *N*-phenylthioureas with the copper(II) acetate/2,2′-bipyridine system in ethanol, and report in this paper that the copper(II) promoted desulphurization of the thiourea occurs to afford coordinated phenylcyanamide, as for example in the complex [{Cu(bipy)(pc)$_2$}$_2$] (bipy = 2,2′-bipyridine, pc = phenylcyanamide).

Addition of a solution of *N*-phenylthiourea (0.30 g, 2 mmol) in ethanol (10 cm^3) to a solution of copper(II) acetate monohydrate (0.20 g, 1 mmol) and 2,2′-bipyridine (0.16 g, 1 mmol) in the same solvent (30 cm^3) gave an intense green solution. This was filtered and allowed to stand for a few days whereupon a yellow solid (*ca* 0.02 g), identified as sulphur, on the basis of its IR spectrum and m.p. 111–112°C (ref. 13, 113°C), was deposited. The sulphur was removed by filtration and after a further few days, dark red crystals (0.27 g) were obtained.

The IR spectrum showed the compound did not contain *N*-phenylthiourea since ν(N—H) absorptions in the 3000–3500 cm^{-1} range were absent. Instead, intense bands at 2175, 2147 and 2103 cm^{-1}, characteristic of ν(C≡N) frequencies were observed. The IR spectrum gave no evidence for the presence of the acetate ion, indicating it had been replaced by a new anionic species. Spectroscopic and magnetic data were typical for a

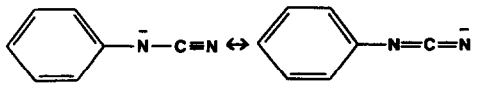
copper(II) complex (λ_{max}(dimethylsulphoxide) 496 (1900), 658 (400) nm (ε/dm^3 mol^{-1} cm^{-1}); ESR (ethanol, 110 K) g_{11} 2.28, A_{11} 181 × 10^{-4} cm^{-1}, $g_\perp$ 2.07; μ_{eff} 1.98 BM). Microanalytical data* indicated the loss of sulphur. On the basis of these results the dark red compound was formulated as a copper(II)–phenylcyanamide complex with 2,2′-bipyridine as a co-ligand, and this was confirmed in a preparation using phenylcyanamide itself as a starting reagent. The dimeric nature of the complex, *viz.* $[\{Cu(bipy)(pc)_2\}_2]$, and the mode of phenylcyanamide to copper binding were determined from a single-crystal X-ray structure.†

The complex consists of a centrosymmetric dimer (see Fig. 1) with dimerization being achieved via the end-to-end NCN bridging of two phenylcyanamide ligands to the two copper atoms. The two phenylcyanamide ligands in the asymmetric unit exhibit different coordination modes. One is monodentate, coordinating through the terminal cyano nitrogen, N(3), and the other is bidentate, binding to two different copper atoms through the cyano, N(1), and amido, N(2), nitrogen atoms. Each copper atom has a distorted tetragonal geometry. The disorder associated with the N(4) and C(8) atoms of the monodentate phenylcyanamide ligand prevents accurate comparison of its bond parameters with those of the bridging phenylcyanamide. The bond lengths for this latter ligand [N(1)—C(1) 1.169(7), C(1)—N(2) 1.293(7), N(2)—C(2) 1.409(7) Å] suggest, however, that both resonance structures are important, although **A** predominates.

* Found: C, 63.3; H, 4.1; N, 18.4. $C_{24}H_{18}CuN_6$ requires: C, 63.5; H, 4.0; N, 18.5%.

† Crystal data at 153 K for $[\{Cu(bipy)(pc)_2\}_2]$: $C_{48}H_{36}Cu_2N_{12}$, M = 907.0, monoclinic, space group $P2_1/c$, a = 9.625(3), b = 20.945(5), c = 9.956(3) Å, β = 97.10(2)°, V = 1992(1) Å^3, D_c = 1.51 g cm^{-3}, D_o = 1.53 g cm^{-3}, Z = 2, $F(000)$ = 932, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 10.63 cm^{-1}; 2702 measured intensities ($5 \leqslant 2\theta \leqslant 45°$), 1689 unique with $I > 3\sigma(I)$. Structure solved by heavy-atom methods and refined by full-matrix least-squares to R = 0.0429 and R_w = 0.0432. The refinement included equally occupied disorder sites for the N(4) and C(8) atoms of the terminal phenylcyanamide ligand, with C(10) as an alternative site for bonding to the phenyl.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.



(A) (B)

The desulphurization reaction of *N*-phenylthiourea can be attributed to the redox activity of copper(II). The initial interaction of the thiourea with the copper(II)–bipy system would be expected to lead to an unstable copper(II)–*N*-phenylthiourea complex. The observation of highly coloured transient copper(II)–thiourea species has been noted previously[2,14] and thiourea (tu) itself forms the complex $[Cu(bipy)_2(tu)]ClO_4$ which has been characterized by X-ray crystallography,[4] although the interaction of thioureas with copper(II) normally results in copper(I) compounds.[2] The most likely initial oxidation product of *N*-phenylthiourea is the formamidinium disulphide cation, $[(PhNH)(NH_2)CS—SC(NH_2)(NHPh)]^{2+}$. Disulphide salts of this type have been shown to arise from the oxidation of substituted thioureas with copper(II) perchlorate[14] and are known to decompose in neutral or acidic solution with the precipitation of sulphur.[15] The subsequent re-oxidation of copper(I) to copper(II), in the presence of the formed phenylcyanamide and 2,2′-bipyridine, would yield the characterized complex $[\{Cu(bipy)(pc)_2\}_2]$. A number of halogen-substituted phenyl thioureas also give rise to phenylcyanamide complexes,[16] and it has recently been shown that a similar reaction occurs when unsubstituted thiourea itself reacts with the $[Cu(C_9H_{21}N_3)(H_2O)_2]^{2+}$ ($C_9H_{21}N_3$ = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane) cation.[17] It would appear, therefore, that the desulphurization of thioureas by copper(II) in the presence of a Lewis base has the potential to provide a convenient route into copper–cyanamide chemistry.

BOOK REVIEW

Advances in Boron and the Boranes. Edited by J. F. Liebman, A. Greenberg and R. E. Williams. VCH Publishers, Weinheim, F.R.G., 1988, 547 pp., $84.00.

A book containing 22 articles on boron chemistry is to be welcomed. This is especially true when it has been compiled in honour of Professor Anton B. Burg, who with H. I. Schlesinger in the 1930s at Chicago University carried out seminal researches on the chemistry of diborane. Indeed, from these early studies stemmed the multifacet chemistry of the boranes and their derivatives as we know it today. For almost 60 years Anton Burg has continued to make significant contributions to our knowledge of the boranes, and in the first chapter of the book he presents an overview of his research and the philosophy behind his endeavours. He omits, however, to refer to his seemingly inexhaustible supply of energy, allowing him to work very long hours with great dedication, and his ability to "inspire" his co-workers to do the same. This Reviewer looks back with amusement to his arrival in sunny Southern California in 1951, an area almost smog free at the time; joining Burg's group, and being told not to allow the climate to interfere with daily attendance in the laboratory.

Among the Contributors to the book are many who have made important contributions to boron chemistry over a long period. The subject matter reviewed and the authors for Chapters 2–22 are as follows:

2. Classical Pentaborane(9) Chemistry Applied to the Preparation of Higher Boron Hydride Systems and Some Newer Aspects of the Chemistry of Pentaborane(9) and Decaborane(14).
   James R. Wermer and Sheldon G. Shore
3. Syntheses and Reactions of 9- and 10-Atom Carboranes and Heteroboranes

22. The Unsynchronized–Resonating–Covalent–Bond

Theory of the Structure and Properties of Boron and the Boranes
Linus Pauling and Zelek S. Herman

Most of the articles focus on the research results of their Authors. In this context, Chapters 2–7, 11, 12, 14 and 20 are essential reading for anyone wishing to keep up with progress at the frontiers of boron chemistry. The Editors are to be congratulated for arranging for the inclusion of such a wealth of material within one book. Moreover, there is a very useful General Index, largely based on compound formulae, which enables a reader to locate subject matter. The book should be available in all libraries claiming to have a modicum of coverage of the chemical "litterature".*

F. GORDON A. STONE
Department of Inorganic Chemistry
The University
Bristol BS8 1TS, U.K.

* As pointed out by A. B. Burg in Chapter 1, the word "litterature" is from the fourth paragraph of the preface to the long novel "Sylvie and Bruno" by Lewis Carroll. It describes the piles of scraps which make up that novel.

KINETIC STUDY OF THE MOLYBDENUM(VI)–L-HISTIDINE AND MOLYBDENUM(VI)–IMIDAZOLE SYSTEMS

D. O. MÁRTIRE, M. R. FÉLIZ* and A. L. CAPPARELLI†‡

Instituto de Investigaciones Fisicoquimicas Teóricas y Aplicadas (INIFTA), Facultad de Ciencias Exactas, Universidad Nacional de La Plata, Casilla de Correo 16, Sucursal Nro. 4, (1900) La Plata, República Argentina

(*Received* 21 *September* 1988; *accepted after revision* 20 *February* 1989)

Abstract—Using the temperature-jump technique, the study of the kinetics of the complexation of the oxomolybdate anion with l-histidine has been carried out in aqueous solutions at pH 5.0–7.0, ionic strength 0.1 M ($NaClO_4$) and 25°C. A reaction scheme for the formation of the 1 : 1 complex is proposed, which accounts for the observed relaxation rates. This investigation included the study of the polymerization of molybdenum(VI) in the same pH range. The molybdenum(VI)–imidazole system was also studied in order to determine the possible participation of the imidazole nitrogen of histidine in its coordination to molybdenum(VI).

Molybdenum is present in cofactors of several enzymes. Some of them are involved in important biochemical processes such as nitrogen fixation.[1–3] As a result, structural,[4–14] thermodynamic[15–25] and kinetic[26–34] studies of the complexation between molybdate and different chelating ligands have been the subject of several investigations.

The specific reaction between molybdenum(VI) and histidine is of special biochemical interest.[35–37] In the present paper, the kinetics of complex formation between molybdate and histidine at 25°C and ionic strength 0.1 M ($NaClO_4$) was studied. The equilibria of molybdenum(VI) in slightly acid solutions are complex since various polynuclear species are formed. Different sets of species have been proposed in order to assign the equilibria in molybdate solutions.[38–42]

Sasaki and Sillén[39] and Aveston *et al.*[38] proposed the presence of heptameric and octameric species in these solutions. The data of Sasaki and Sillén (μ = 3 M $NaClO_4$, 25°C) and those of Aveston *et al.* (1 M NaCl, 25°C) were more recently re-interpreted.[41,42]

Since the formation of a 1 : 1 complex between molybdate and histidine takes place in the same pH region,[43,44] a kinetic study of this reaction requires the knowledge of the rate constants of the polymerization reactions involved. Honig and Kustin[45] investigated the relaxation kinetics of polymer formation of molybdate using the temperature-jump technique at 25°C and 1.0 M ionic strength. However, since the equilibria involved are strongly dependent on ionic strength,[38,39,42] it is necessary to study the kinetics of the polymerization processes at 0.1 M ionic strength.

Furthermore, the interpretation of Kustin's data was based on the results of Aveston *et al.*[39] According to the new interpretation of Aveston's data,[42] octameric species of molybdenum(VI) should not be considered under the experimental conditions of Kustin's investigation. Such considerations have motivated a kinetic study of molybdenum(VI) polymerization in this work.

The molybdenum(VI)–imidazole system was also studied, in order to determine whether the imidazole nitrogen of this histidine participates in its coordination to molybdate.

EXPERIMENTAL

All the chemicals used were of a reagent grade. Solutions were prepared with de-ionized distilled water.

The ionic strength was maintained at 0.1 M with sodium perchlorate. The pH was adjusted to within pH ±0.02, as read on a Metrohm AG-pH-meter.

* Member of CICPBA.
† Member of CONICET.
‡ Author to whom correspondence should be addressed.

The hydrogen ion concentrations were obtained from pH readings, assuming the activity coefficients of the hydrogen ion to be 0.73 under all experimental conditions of this work.

To obtain unambiguous data, the study of the systems, molybdenum(VI)–histidine and molybdenum(VI)–imidazole, was performed in the presence of excess metal. The reaction was followed by measuring the absorbance change of a pH indicator. The indicators used were phenol red, chlorophenol red and tymol blue.

The temperature-jump equipment consisted of the SBA-7 model from Studientgesellschaft mbH Gottingen, F.R.G., with spectrophotometric detection. The temperature jump was 5°C and the final temperature 25°C. The temperature of the reaction solution was controlled to ± 0.2°C using a thermoelectric circulating bath.

The relaxation times, obtained from an average of at least four relaxation curves, are affected by a maximum uncertainty of $\pm 10\%$.

RESULTS

The results obtained with the three systems will be discussed separately in the following sections.

(I) *Polymerization of molybdenum*(VI)

The traces obtained in these experiments showed the presence of only one relaxation process. The experimentally determined relaxation time for the reaction is summarized in Table 1. Above pH 6 no relaxation processes were detected. The equilibria involved in the polymerization of molybdate have not been studied at 0.1 M ionic strength.

According to the re-interpretation of the data of Aveston *et al.*[42] ($\mu = 3$ M) and those of Sasaki and Sillén[41] ($\mu = 1$ M), only monomeric and heptameric species of molybdate should be present within the molybdate concentration and pH ranges of the present work.

It is known that the stability of polymeric species increases with increasing ionic strength. The effect of the ionic medium on condensation equilibria was ascribed by several authors to the complexation between medium cations and highly charged polymetalate anions[38,46,47] or to decreased water activity.[42]

The dependence of these equilibria on the medium leads us to assume that under the conditions of the present investigation ($\mu = 0.1$ M), the only polymeric species are those postulated at ionic strength 1 M.[41] In this way, the molybdate equilibria can be written as shown:

Table 1. Study of condensation reactions of molybdate at 25°C and 0.1 M ionic strength. Experimental and calculated relaxation times

τ_{exp}—experimental relaxation times. PR—phenol red, CR—chlorophenol red, $[Mo]_0$ is the analytic concentration of molybdenum(VI)

[a] The quantities in parentheses are reciprocal calculated relaxation times.

$$MoO_4^{2-} + H^+ \rightleftharpoons MoO_4H^- \quad (K_1) \qquad (1)$$

$$7MoO_4^{2-} + 8H^+ \rightleftharpoons Mo_7O_{24}^{6-} + 4H_2O \quad (K_6) \qquad (2)$$

$$Mo_7O_{24}^{6-} + H^+ \rightleftharpoons Mo_7O_{24}H^{5-} \quad (K_3). \qquad (3)$$

Scheme 1.

The protolytic reactions are very rapid, so that they may be assumed to be equilibrated at all times compared with reaction (2).

The relaxation time derived for this mechanism is

$$1/\tau = k_6 X + k_{-6} \qquad (4)$$

where:

$$X = 8[M]^7[H]^7(-\delta H/\delta Hept) + 7[H]^8[M]^6(-\delta M/\delta Hept), \qquad (5)$$

with $Hept = Mo_7O_{24}^{6-}$.

The expressions for $(-\delta H/\delta Hept)$ and $(-\delta M/\delta Hept)$ were derived as in ref. 45 and are given in Appendix 1.

The equilibrium constants used in the analysis of the experimental data are presented in Table 2. Concentrations were calculated on a computer using a Newton Raphson iteration.

The values of K_6 and K_3 are not known under the present experimental conditions. They were handled as parameters, taking as entry values those at $\mu = 1$ M.[42]

Table 2. Equilibrium constants used in this work

Reaction	log K
$MoO_4^{2-} + H^+ \rightleftharpoons MoO_4H^-$	3.74[a]
$MoO_4H^- + H^+ \rightleftharpoons MoO_4H_2$	3.77[a]
$7MoO_4^{2-} + 8H^+ \rightleftharpoons Mo_7O_{24}^{6-} + 4H_2O$	52.03[a]
$Mo_7O_{24}^{6-} + H^+ \rightleftharpoons Mo_7O_{24}H^{5-}$	4.78[b]
$hist^- + H^+ \rightleftharpoons histH$	8.87[c]
$histH + H^+ \rightleftharpoons histH_2$	14.90[c]
$histH_2 + H^+ \rightleftharpoons histH_3$	16.61[c]
$MoO_4^{2-} + hist^- + 2H^+ \rightleftharpoons MoO_3hist^- + H_2O$	16.76[c]
$PR^- + H^+ \rightleftharpoons PRH$	7.95[d]
$CR^- + H^+ \rightleftharpoons CRH$	9.0[e]
$TB^- + H^+ \rightleftharpoons TBH$	5.9[e]

hist—histidinate, RF^-, CR^- and TB^-—the basic forms of the indicators phenol red, chlorophenol red and tymol blue, respectively.

[e] H. Strehlow and W. Knoche, *Relaxation Chemical Kinetics*. Springer, Berlin (1977).

As was expected, the value of K_6 which best fitted the experimental data was lower than that at $\mu = 1.0$ M. A least-squares analysis has been carried out on the data shown in Table 1 to determine the best values of the rate parameters in eq. (5). The values thus obtained are $k_6 = (6.09 \pm 0.37) \times 10^{52}$ and $k_{-6} = 28.7 \pm 4.2$. The correlation coefficient was 0.98.

Honig and Kustin's data[45] could be re-analysed on the basis of the set of monomeric and heptameric species proposed by Cruywagen and co-workers[42] for this system under the same experimental conditions. These are the species shown in Scheme 1. Thus the reaction shown in Scheme 1 could also describe the behaviour of these data.

Honig and Kustin[45] observed two relaxation times in some experiments, the relative error being $\pm 25\%$ for the longer and $\pm 50\%$ for the shorter one, but both being of the same order of magnitude. This implies that the existence of the shorter relaxation time is indeed doubtful. In this case, we could re-interpret Kustin's data on the basis of Scheme 1 by considering the longer relaxation time for those experiments where two relaxation times were reported.

A least-squares analysis on Kustin's $1/\tau$ against X determined the following values for k_6 and k_{-6}:

$$k_6 = 9.8 \times 10^{52} \quad (6)$$

$$k_{-6} = 16.4, \quad (7)$$

with a correlation coeffcient of 0.99.

(II) *Molybdenum*(VI)–*histidine system*

Histidine-indicator blanks were run at each pH. The results were negative. The extension of the pH range above 6 suggests the molybdenum(VI)–histidine interaction. Since polymerization reactions are not observed above pH 6, experiments will be separated into two groups: (a) pH > 6 and (b) pH < 6.

(a) pH > 6. Experimental relaxation rates belonging to this pH zone are summarized in Table 3. The magnitude of the relaxation amplitudes increases with increasing molybdate concentration and with decreasing pH. Above pH 6.8, the amplitude of relaxation curves is very small.

Johansen and Jones[44] found the following stoichiometry for complex formation:

$$MoO_4^{2-} + L^- + 2H^+ \rightleftharpoons MoO_3L^- + H_2O, \quad (8)$$

where L^- denotes histidinate.

The stoichiometry allows at least two possible reaction pathways which are shown in the following scheme:

$$MoO_4^{2-} + LH_2^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MoO_3L^- + H_2O \quad \text{(a)} \quad (9)$$

$$MoO_4H^- + LH \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} MoO_3L^- + H_2O \quad \text{(b)}, \quad (10)$$

Table 3. Study of the complexation of molybdenum(VI) with histidine (pH > 6)

pH	InH	[Mo] × 10^2 (M)	τ_{exp} (ms)	$1/\tau$ (s^{-1})[a]
6.00	PR	3	29.7	33.6 (35.1)
6.10	TB	2	45.6	21.9 (24.8)
6.11	CR	3	33.0	30.3 (30.5)
6.15	CR	2	42.7	23.4 (23.8)
6.20	PR	2	45.3	22.1 (22.6)
6.22	CR	3	32.1	31.1 (26.7)
6.23	PR	1	70.0	14.3 (18.0)
6.35	TB	0.8	65.1	15.4 (17.4)
6.35	PR	3	41.3	24.2 (23.1)
6.37	CR	1	56.2	17.8 (17.9)
6.41	CR	2	48.5	20.6 (19.7)
6.47	CR	3	45.1	22.2 (21.1)
6.55	PR	2	45.0	22.2 (18.4)

[a] The quantities in parentheses are reciprocal calculated relaxation times. For abbreviations see Table 1. In the pH range 6.6–7.00, the measured relaxation amplitudes are too small to obtain reliable relaxation times. At higher pH, no relaxation processes are detected.

where only the reactant species present at major concentrations were included. Reactions (a) and (b) are indistinguishable.

Assuming protolytic reactions to be equilibrated, the following expression for $1/\tau$ can be obtained:

$$1/\tau = k_F([M](-\delta LH_2/\delta C)+[LH_2](-\delta M/\delta C)) + k_R = k_F Y + k_R, \quad (11)$$

where

$$k_F = k_1 + k_2 K_3/K_4 \quad (12)$$

$$k_R = k_{-1} + k_{-2} \quad (13)$$

and

$$K_3 = [LH][H]/[LH_2] \quad (14)$$

$$K_4 = [M][H]/[MH]. \quad (15)$$

Application of mass balance and equilibrium conditions for the protolytic reactions leads to the following expressions for $\delta M/\delta C$ and $\delta LH_2/\delta C$.

$$\delta LH_2/\delta C = (-1+(d_1+[H][LH])/\Delta) \quad (16)$$

$$\delta M/\delta C = -(1+\delta MH/\delta C), \quad (17)$$

with

$$\Delta = d_1 - [H]d_2 \quad (18)$$

$$d_1 = K_3(\beta K_4+[M])+[LH]K_4+[H]([LH]+\beta K_3) \quad (19)$$

$$d_2 = [M]+\beta(K_4+[H]) \quad (20)$$

$$\beta = (K_5+[H]+[I])/(K_5+[H]) \quad (21)$$

and

$$\delta MH/\delta C = [H]([LH]-[M]) + \beta[H](K_3+[H])/\Delta. \quad (22)$$

Experimental $1/\tau$ against Y are plotted in Fig. 1. The experimental $1/\tau$ values were treated with a linear least-squares routine to obtain the best fit rate constants. These constants are

$$k_F = (1.4\pm0.2)\times10^3 M^{-1}s^{-1} \quad (23)$$

$$k_R = (15.8\pm1.2)s^{-1}. \quad (24)$$

From these experimental rate constants, the following limit values for k_1, k_2, k_{-1} and k_{-2} can be obtained

$$k_1 \leqslant 1.4\times10^3 \quad (25)$$

$$k_2 \leqslant 7.2\times10^5 \quad (26)$$

$$k_{-1} \leqslant 15.8 \quad (27)$$

$$k_{-2} \leqslant 15.8. \quad (28)$$

(b) pH < 6. Experimental relaxation times belonging to this pH zone are summarized in Table 4. Despite the presence of heptamers below pH 6, according to Johansen and Jones, a 1 : 1 complex between molybdate and histidine is formed. Then, monomeric molybdate should be the active species of molybdenum(VI). Since the polymerization mechanism is known (see above), the complete mechanism should be given by the following scheme:

$$M+LH_2 \rightleftharpoons C+H_2O \quad (K_2) \quad (29)$$

$$MH+LH \rightleftharpoons C+H_2O \quad (30)$$

$$MH \rightleftharpoons M+H \quad (K_I^{-1}) \quad (31)$$

$$7M+8H^+ \rightleftharpoons Hept+4H_2O \quad (K_6) \quad (32)$$

$$HeptH \rightleftharpoons Hept+H \quad (K_d), \quad (33)$$

where only the specis of higher concentrations were included.

The assumption of rapid protolytic reactions allows the system to be described by two rate equa-

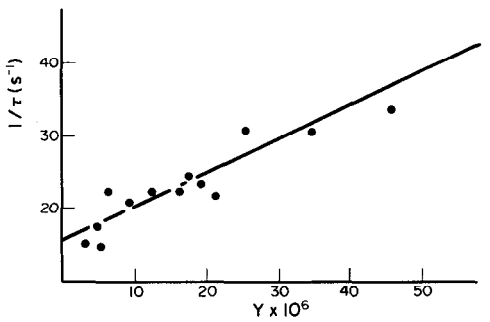

Fig. 1. Molybdenum(VI)–L-histidine system: experimental relaxation rate ($1/\tau$) vs Y, as given by eq. (11).

Table 4. Study of complexation of molybdenum(VI) with histidine: experimental and calculated relaxation times (pH < 6)

pH	InH	$[M]_0\times10^2$ (M)	τ_1 (ms)	τ_2 (ms)	τ_{exp} (ms)
5.39	CR	2	48	5.3	6.1
5.55	CR	2	45	6.7	6.5
5.60	PR	1	79	30	30
5.75	CR	2	62	26	12

tions,

$$d\delta C/dt = k_F([M]\delta LH_2 + [LH_2]\delta M) - k_R\delta C \quad (34)$$

$$d\delta Hept/dt = k_6(8[M]^7[H]^7\delta H + 7[H]^8[M]^6\delta M) - k_{-6}\delta Hept. \quad (35)$$

The reciprocal relaxation times[48] are given by

$$1/\tau_{+,-} = 1/2\left(-(a_{11}+a_{22}) \pm \sqrt{(a_{11}+a_{22})^2 - 4(a_{11}a_{22}-a_{12}a_{21})}\right). \quad (36)$$

The expressions for the a_{ij} terms are given in Appendix 2.

Even though a system of coupled reactions can give rise to two relaxation times, only one may be observed.[48,49]

The values for τ_+ and τ_- are also summarized in Table 4. As can be seen in Table 4, we are observing τ_-, whose main contribution arises from the polymerization steps.

This observation does not necessarily mean that the complexation between molybdate and histidine is unimportant; it only means that the observed response is only sensitive to the polymerization pathway. The fit of τ_{exp} to τ_- is reasonably good.

(III) *Molybdenum*(VI)–*imidazole system*

Experimental relaxation times are summarized in Table 5. As can be seen in Table 5, relaxation processes are observed in the same pH region in which the polymerization of molybdenum(VI) occurs. Above pH 6, no relaxation curves were detected. This behaviour suggests that in both systems the process which is responsible for the relaxation may be the same. Then, eq. (5) should be valid for the experimental data.

The experimental $1/\tau$ values are plotted against X in Fig. 2. The following values for k_6 and k_{-6} were calculated by a least-squares treatment of the data

$$k_6 = (6.12 \pm 0.52) \times 10^{52} \quad (37)$$

$$k_{-6} = (37.8 \pm 5.3). \quad (38)$$

5.89	PR	3	16.7	59.7 (64.2)

For abbreviations see Table 1.

Although polymerization is the process responsible for relaxation, the existence of a complex between molybdenum(VI) and imidazole could be possible. To discard this possibility, the quantity X was recalculated assuming a 1 : 1 complex between both reactives. However, the best fit of the experimental data was found when the equilibrium constant for the complex formation tended to zero. This behaviour shows that under these experimental conditions, there is no complexation between molybdenum(VI) and imidazole. Furthermore, to our knowledge, no complexes of this ligand with molybdenum(VI) have been reported.

DISCUSSION

The histidine molecule presents three potential coordination sites in aqueous solution. The carboxyl group, the imidazole nitrogen and the amino

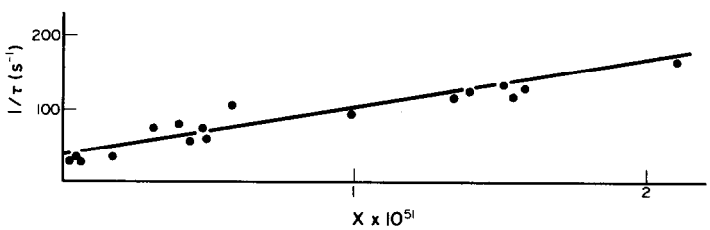

Fig. 2. Molybdenum(VI)–imidazole system: experimental relaxation rate ($1/\tau$) vs X, as given by eq. (5).

nitrogen become available for complexation as the pH increases.

Spence and Lee[43] found no evidence of complex formation between molybdenum(VI) and the compounds L-alanine or N-acetyl-L-histidine. But, for the L-histidine methyl ether,[43] they obtained very similar results to those of histidine. According to their observations, these authors propose that histidine acts as a bidentate ligand and uses the amino group and the 1-nitrogen of the imidazole ring for complex formation with molybdenum(VI).

The lack of imidazole reactivity which was found in the present paper, can also be attributed to the need of both the amino and imidazole nitrogens to be present in the ligand to form the complex.

Wilkins and co-workers[10] proposed that histidine behaves as a tridentate ligand towards molybdenum(VI) in the solid phase.

The complexation of molybdate with L-histidine shows the following features:

—two protons are required according to reaction (8). To account for this stoichiometry, reaction pathways (a) and (b) are proposed. Both reactions are indistinguishable.

—thermodynamic as well kinetic results show that no complexation takes place above pH 7. The postulation of MoO_4H^- as a reactive species has been considered in the literature, even at higher pH.[27,28,33] If the contribution of reaction pathway (b) was significant, complexation should take place in basic solutions. However, as stated, no complex is formed above pH 7. Therefore, it can be inferred that reaction (b) should not significantly contribute to the reaction rate.

The previous considerations leave LH_2^+ as the ligand reactive species and $k_F = k_1$. The complete ionization scheme for histidine is shown in Fig. 3.

According to this scheme, there are three LH_2^+

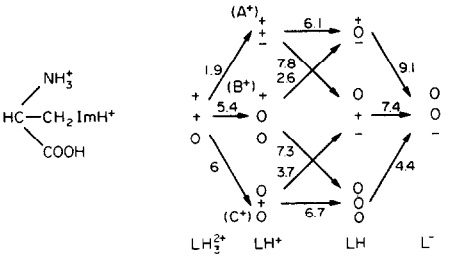

Fig. 3. Ionization scheme for histidine. The microscopic pK values were taken from ref. 50.

Table 6. Experimental kinetic values for 1 : 1 molybdate complex formation

species (A, B and C). However, the concentration of A is at least 10^3 times higher than those of B and C.[50] Then, the limit value of the rate constant k_1, should be assigned to the following reaction:

$$MoO_4^{2-} + H_3N{-}\underset{\displaystyle COO^-}{\underset{|}{CH}}{-}CH_2{-}ImH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C + H_2O, \quad (39)$$

where Im denotes the imidazole ring. This means that the active species of the ligand has protonated both amino and imidazole nitrogens.

Until recently, only two empirical correlations between the rate constants of molybdenum(VI) complex formation and basicity of ligands were discussed in the literature.[26,29]

We recently predicted, [34] on theoretical grounds, a correlation between $\log k_1$ (k_1 is the rate constant of the reaction between MoO_4^{2-} and the monoprotonated ligand) and the pK of the ligand. This correlation is based on an associative mechanism, where a chelating group attacks at one of the faces of the tetrahedral molybdate.[29–34] Another chelating group, which is protonated, interacts with an oxo group, the reaction being controlled by the proton transfer from the ligand to an oxo group. This process weakens the Mo—O bond, thus allowing the coordination sphere expansion.

If the determining step is the deprotonation of one of the sites of the ligand, the reaction rate should be dependent on the ligand nature and, to some extent, independent of the degree of protonation of other chelating sites of the ligand. Therefore, the correlation found in the literature,[34] could be extended to include all active species, LH_n, for a given ligand. The available values of experimental kinetic rate constant values (k) for 1 : 1 molybdate complex formation are presented in Table 6. The correlation equation found is shown below

$$\log k = -0.57\text{p}K + 8.23, \quad (40)$$

where the pK vaues are those corresponding to the deprotonation of the chelating group involved in the limiting reaction step.[34]

This correlation enables us to predict the value of $\log k$ for the molybdenum(VI)–histidine complex. If we attribute the rate-determining step to the deprotonation of the imidazole nitrogen (pK = 6.03), the expected value of $\log k$ is 4.79. On the other hand, if the determining step is attributed to deprotonation of amino nitrogen (pK = 8.87), the value of $\log k$ predicted by the correlation is 3.17. Since the upper limit value determined in the present paper is 3.14, we propose the deprotonation of the amino nitrogen as the rate-determining step.

APPENDIX I

From conservation conditions of metal, protons and indicator, the following equations can be written:

$$\delta M/\delta Hept = (X_2X_6 - X_3X_5)/\Delta \quad (A1.1)$$

$$\delta H/\delta Hept = (X_3X_4 - X_1X_6)/\Delta, \quad (A1.2)$$

where

$$X_1 = 1 + K_1[H] \quad (A1.3)$$

$$X_2 = K_1[M] + 7K_3[Hept] \quad (A1.4)$$

$$X_3 = 7(1 + K_3[H]) \quad (A1.5)$$

$$X_4 = K_1[H] \quad (A1.6)$$

$$X_5 = \beta + K_1[M] + 9K_3[Hept] \quad (A1.7)$$

$$X_6 = 8 + 9K_3[H], \quad (A1.8)$$

with

$$\Delta = 1 + K_1[H] + K_1[M] + 9K_3[Hept] + 2K_1K_3[H][Hept] \quad (A1.9)$$

$$\beta = (K_5 + [H] + [I])/(K_5 + [H]) \quad (A1.10)$$

and

$$K_5 = [I][H]/[IH]. \quad (A1.11)$$

APPENDIX II

From conservation relations for the molybdate, hydrogen and indicator, and assuming rapid protolytic equilibra, the following relations can be written:

$$a_{11} = k_F([M]T_1 + [LH_2]Z_1) - k_R \quad (A2.1)$$

$$a_{12} = k_F([M]T_2 + [LH_2]Z_2) \quad (A2.2)$$

$$a_{21} = k_6(8[M]^7[H]^7Y_1 + 7[H]^8[M]^6Z_1) \quad (A2.3)$$

$$a_{22} = k_6(8[M]^7[H]^7Y_2 + 7[H]^8[M]^6Z_2) - k_{-6}, \quad (A2.4)$$

where

$$T_1 = R_1K_6[H] + 2[L][H]K_6Y_1 \quad (A2.5)$$

$$T_2 = R_2K_6[H] + 2[L][H]K_6Y_2 \quad (A2.6)$$

and

$$Z_1 = (X_3X_9 + X_1X_6 - X_2X_9)/\Delta \quad (A2.7)$$

$$Z_2 = (X_5(X_1X_6 - X_2X_9) - X_1X_3X_8)/\Delta \quad (A2.8)$$

$$Y_1 = -(X_4X_9 + X_1X_7)/\Delta \quad (A2.9)$$

$$Y_2 = X_1(X_4X_8 - X_5X_7)/\Delta \quad (A2.10)$$

$$R_1 = (-X_3X_7 + X_4X_6 + X_2X_7)/\Delta \quad (A2.11)$$

$$R_2 = X_2(X_5X_7 - X_4X_8)/\Delta \quad (A2.12)$$

$$\Delta = X_1(X_3X_7 - X_4X_6) + X_2X_4X_9 \quad (A2.13)$$

with

$$X_1 = 1 + K_d[H] + K_6[H]^2 \quad (A2.14)$$

$$X_2 = [L](K_d + 2K_6[H]) \quad (A2.15)$$

$$X_3 = K_1[M] + 7K_3[Hept] \quad (A2.16)$$

$$X_4 = 1 + K_1[H] \quad (A2.17)$$

$$X_5 = 7(1 + K_3[H]) \quad (A2.18)$$

$$X_6 = 1 + \alpha + K_1[M] + 9[Hept]K_3 + K_d[L] + 4[L][H]K_6 \quad (A2.19)$$

$$X_7 = K_1[H] \quad (A2.20)$$

$$X_8 = 8 + 9K_3[H] \quad (A2.21)$$

$$X_9 = K_d[H] + 2K_6[H]^2 \quad (A2.22)$$

$$\alpha = ([IH] + [I])K_5/([H] + K_5)^2. \quad (A2.23)$$

THERMODYNAMIC PROPERTIES OF ACTINIDE COMPLEXES. URANYL(VI)– AND THORIUM(IV)–ASPARTATE SYSTEMS

ARTURO BISMONDO* and LUIGI RIZZO

Istituto di Chimica e Tecnologia dei Radioelementi, Area della Ricerca del CNR, Corso Stati Uniti 4, 35020 Padova, Italy

(*Received* 29 *September* 1988; *accepted after revision* 22 *March* 1989)

Abstract—Stability constants, enthalpies and entropies in the formation of uranyl(VI) and thorium(IV) with aspartic acid have been determined at 25.0°C in a 1.0 mol dm^{-3} aqueous solution of sodium perchlorate by means of the potentiometric and calorimetric techniques. Because of precipitation of solid compounds, only two complexes of 1 : 1 and 1 : 2 stoichiometry were observed in the uranyl(VI)–asparate system and only one complex of 1 : 1 stoichiometry in the thorium(IV)–aspartate system. Comparison of values of stability constants and enthalpy and entropy changes with the corresponding values of some mono- and di-carboxylate ligands suggests that the binding of both metal ions involves one carboxylate group only, the one furthest from the positive amino group.

In previous works we have reported the changes in the thermodynamic functions for the uranyl(VI) and thorium(IV) complex formation with some aminomonocarboxylate ligands.[1–3] From the values of the stability constants and enthalpy and entropy changes, it was deduced that those ligands bind to metal ion through the carboxylate group only, whereas the amino group, in the experimental conditions used, is protonated. We have examined the coordination behaviour of some amino acids, which have two carboxylic groups in the chain, in order to evaluate the influence of another group on the capacity of amino acids to form stable bonds to actinide ions. For this purpose, we have chosen initially aspartic acid, an α-amino acid with an additional carboxylic acid group in the side chain.

Complexation of the uranyl(VI) ion with aspartate in solution below pH 3.5 was studied by potentiometry,[4] where it was reported that the uranyl(VI) was bound to one of the carboxylic groups only, and by NMR spectroscopy[5] where it appears that the aspartate is bound via two carboxylic groups with the uranyl ion. A more recent study of uranyl(VI) ion by means of the solvent extraction technique[6] suggests that, at pH 8, the binding of aspartate involves both the carboxylate groups, but there is no uranyl–amino group interaction.

In order to clarify the question whether aspartic acid coordinates via one or two carboxylate groups to uranyl(VI) and thorium(IV) ions, in the range of pH below 3, we have examined these systems by carrying out potentiometric and calorimetric measurements.

EXPERIMENTAL

Stock solutions of uranyl(VI) and thorium(IV) perchlorate, containing an excess of perchloric acid, were prepared and standardized as reported before.[1] Aspartic acid (Baker product) was recrystallized from water and dried at 100°C, before weighing to prepare the appropriate buffer solution. For each system several potentiometric and calorimetric titrations were carried out by adding a known amount of buffer solutions of ligand to a known volume of a solution containing the metal ion (C_M^0 = 10–30 mmol dm^{-3}) and perchloric acid (C_H^0 = 10–20 mmol dm^{-3}).

Potentiometric measurements were carried out with a Radiometer pH 64; the titration vessel was equipped with a glass electrode (Metrohm EA-157) and a double junction Ag/AgCl reference electrode (Metrohm EA-440). The reaction heats were determined by a Tronac model 450 calorimeter; the reaction vessel was a rapid response, silvered glass vacuum Dewar of 25 cm^3 capacity. The burette capacity was 5 cm^3 and the titrant delivery rate was

* Author to whom correspondence should be addressed.

0.2119 cm^3 min^{-1}. The precision and accuracy of the equipment were checked by standard methods. The procedures and titration techniques have been described earlier.[1] The calculations were performed by a CDC computer 6700.

RESULTS AND DISCUSSION

Proton–ligand system

Under the experimental conditions of this work, the ligand exists as zwitterion form and thus the pK_a value of the amino group was not determined, because it is not needed for the calculations. The values calculated for the equilibrium constants and the enthalpy changes relative to the protonation of two carboxylic groups were determined by adding known volumes of $HClO_4$ or NaOH standard solutions to solutions containing different concentrations of the ligand. The values obtained (see Table 1) are sufficiently in agreement with the data available in the literature taking into account the different experimental conditions[9] ($\log \beta_{011} = 3.66\ M^{-1}$, $\Delta H_{011} = -4.6$ kJ mol^{-1}, $\log \beta_{021} = 5.56\ M^{-1}$, $\Delta H_{021} = -10.5$ kJ mol^{-1}).

Metal–ligand systems

For the uranyl(VI)–aspartate system the potentiometric measurements were limited to small concentrations of ligand in relation to the small solubility in aqueous solution of the acidic form and to the limitation of using the salt of the ligand because of the high tendency of free uranyl ion to hydrolyse. In addition, precipitation of uranyl(VI) compounds occurred at low pH values and for this reason the measurements were limited to the pH range up to about 3.4. The elemental analysis of precipitates indicated the formation of hydrolysis products. As a result, the $\bar{n}$ range of complex formation was limited to values of 1.6 and calculations were made for complexes with no more than two ligands. This is shown in Fig. 1, where the complex formation curves are plotted. The data show that $\bar{n}$ values are not dependent on C_M, therefore no polynuclear complexes are formed and, in the pH range used, hydrolytic reaction of the uranyl(VI) is negligible.

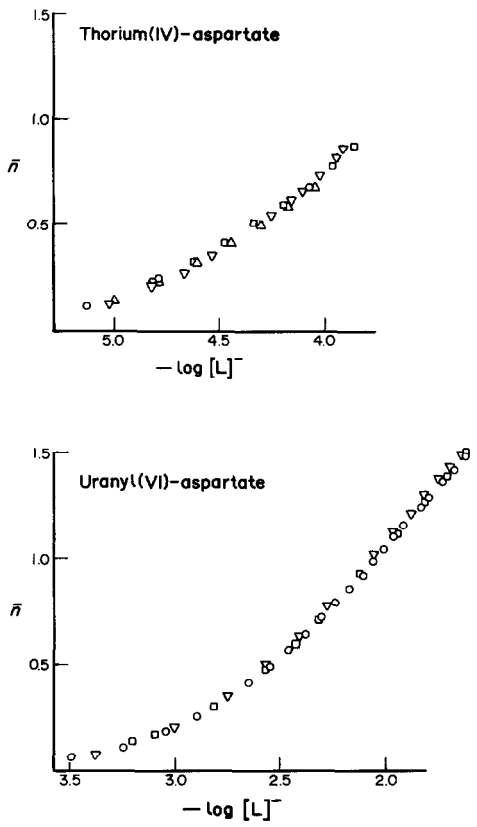

Fig. 1. The complex formation curves of uranyl(VI)– and thorium(IV)–aspartate systems. Concentrations in 10^{-3} mol dm^{-3}; $\delta = HL/L^-$. For uranyl(VI) system: ○, □, ▽ denote $C_M^0 = 20.59$, $C_H^0 = 14.67$, $C_M^0 = 30.89$, $C_H^0 = 15.50$ and $C_M^0 = 10.30$, $C_H^0 = 13.97$ titrated with $\delta = 0.12$ buffer; for thorium(IV) system: ○, □, △, ▽ denote $C_M^0 = 30.24$, $C_H^0 = 22.50$, $C_M^0 = 20.16$, $C_H^0 = 22.55$, $C_M^0 = 27.21$, $C_H^0 = 20.25$ and $C_M^0 = 10.08$, $C_H^0 = 10.86$ titrated with $\delta = 0.15$ buffer.

Table 1. The stability constants and changes in enthalpy and entropy for the formation of proton–, uranyl(VI)–, and thorium(IV)–aspartate complexes at 25.0°C in 1.0 mol dm^{-3} sodium perchlorate medium

p	q	r	Reaction	$\log \beta_{pqr}$	ΔH (kJ mol^{-1})	ΔS (J mol^{-1} K^{-1})
0	1	1	$H+L \rightleftarrows HL$	3.72±0.02	−5.9±0.2	51
0	2	1	$2H+L \rightleftarrows H_2L$	5.77±0.03	−10.3±0.2	76
1	0	1	$UO_2+L \rightleftarrows UO_2L$	2.41±0.03	8.9±0.4	76
1	0	2	$UO_2+2L \rightleftarrows UO_2L_2$	4.14±0.04	10.5±0.6	114
1	0	1	$Th+L \rightleftarrows ThL$	4.21±0.03	10.9±0.4	117

For the thorium(IV)–aspartate system, the experimental conditions were more restrictive. For this system, because of precipitation at low pH values (pH < 2.3), the $\bar{n}$ range of complex formation ($\bar{n} < 0.7$) was too low to allow any reliable calculation of complex formation with more than one ligand. As can be seen in Fig. 1, the complex formation curves for this system too, indicate that both polynuclear and hydrolytic reactions are negligible. The calorimetric measurements for both systems were limited by the above mentioned experimental conditions and by relatively small amounts of complexation heat in the titrations. Hence, no very accurate information could be obtained about the ΔH values of both systems.

The obtained values of the thermodynamic functions log β_{pqr}, ΔH and ΔS for the examined systems are reported in Table 1. The limits of error refer to three standard deviations as obtained from the computer programs Miniquad 75 and Letagrop Kalle. In order to perform a comparison, the available data on the complex formation of uranyl(VI) and thorium(IV) with some mono- and di-carboxylate ligands are reported in Table 2.

The value of the stability constant for the uranyl(VI)–monoaspartate system, obtained by us, is in fairly good agreement with that reported in the literature,[4] i.e. log $\beta_{101} = 2.63$, taking into account the different experimental conditions. In that work it was reported that uranyl(VI) ion is bound to aspartate ligand by one of the carboxylate groups only, the one furthest from the positive amino group. Our data confirm that hypothesis. In fact we can notice that the value of the stability constant for the first complex of the uranyl(VI) with aspartate is relatively smaller than that for the 1 : 1 uranyl(VI)–monosuccinate system (see Table 2). These values would indicate that there is a possible loss of the chelate effect with respect to succinate system (the succinate behaves as a bidentate chelating agent through the two carboxylate groups coordinated to the metal ion). Moreover, the value of the 1 : 1 stability constant for the uranyl(VI)–aspartate complex is comparable with that for the succinic monoprotonated acid log $K_{111} = 2.28$. This analogous behaviour is confirmed by the enthalpy changes, as their values are relatively low and both close to the value for the uranyl(VI)–acetate system (see Table 2). As the value of the stability constant of the 1 : 1 uranyl(VI)–glycine complex is smaller than that of the aspartate complex, it should be possible to show that the β-carboxylate group is bound to the metal ion. The values of the entropy changes suggest this hypothesis. In Table 2, the value for the succinate system ($\Delta S = 146$) shows that this ligand binds through both carboxylate groups, having a value comparable with that for the diacetate system,[8] while the values for acetate, succinate monoprotonate and aspartate ($\Delta S = 87, 79, 76$ respectively) show that these ligands bind through one carboxylate group only. Moreover, as the ΔS value of the glycine system ($\Delta S = 35$) is smaller than that of the aspartate system ($\Delta S = 76$), it is reasonable to assume that the uranyl(VI) ion is bound to the β-carboxylate group, while the α-carboxylate group is deprotonated in correspondence with the protonation of the amino group.

Similar results seem to hold for the thorium(IV)–aspartate system. Comparing the values of the 1 : 1 stability constant for the aspartate complex (log $\beta_{101} = 4.21$) with that for the succinate complex (log $\beta_{101} = 6.44$) it would seem that there is no interaction of thorium with both of the carboxylate groups. By analogy with uranyl(VI), the values of enthalpy and entropy changes for the thorium(IV)–aspartate system are comparable in magnitude with those of the complex with the succinic monoprotonated acid. In fact the values of ΔH and ΔS for the thorium–succinate complex, where the ligand binds via both carboxylate groups, are higher than the values for aspartate complex, while the last values ($\Delta H = 10.9$, $\Delta S = 117$) are comparable to

Table 2. The stability constants and the changes in enthalpy and entropy for the formation of uranyl(VI) and thorium(IV) 1 : 1 complexes at 25.0°C in 1.0 mol dm^{-3} sodium perchlorate medium

	Uranyl(VI)				Thorium(IV)			
Ligands	log β	ΔH (kJ mol^{-1})	ΔS (J mol^{-1} K^{-1})	Ref.	log β	ΔH (kJ mol^{-1})	ΔS (J mol^{-1} K^{-1})	Ref.
Acetate	2.46	11.8	87	9	3.86	11.3	112	10
Diacetate	4.38	17.9	144	9	6.97	15.8	186	10
Succinate	3.85	21.7	146	11	6.44	18.6	186	12
H-Succinate	2.28	10.0	79	11	3.60	8.5	97	12
Glycine	1.16	3.9	35	1	2.55	4.2	63	1
Aspartate	2.41	8.9	76	—	4.21	10.9	117	—

the values for the thorium monoacetate complex ($\Delta H = 11.3$, $\Delta S = 112$). Therefore it is reasonable to presume that, for the aspartate, one carboxylate group only binds to the metal ion. The fact that the values of thermodynamic functions for the thorium glycine system are all smaller than those for the aspartate system and, on the other hand, the last values are comparable to the acetate system, can show that the aspartate ligand binds through the furthest carboxylate group from the amino group.

MOLECULAR REORIENTATION IN CRYSTALS OF NEUTRAL METAL CARBONYL CLUSTERS: A POTENTIAL ENERGY APPROACH

DARIO BRAGA* and FABRIZIA GREPIONI

Dipartimento di Chimica "G. Ciamician", Universita' di Bologna, Via F. Selmi 2, 40126 Bologna, Italy

(*Received* 24 *November* 1988; *accepted* 24 *April* 1989)

Abstract—The occurrence of reorientational motions of parts or of entire molecules of neutral metal carbonyl clusters in the solid state is explored by means of the pairwise potential energy method developed to study analogous phenomena in organic crystals. The method is applied, here, mainly to species which show dynamic behaviour in the solid on the basis of MAS NMR experiments. The nature (whether static or dynamic) of the disorder observed in crystals of $[Fe_3(CO)_{12}]$ and $[Co_4(CO)_{12}]$ is also discussed.

There is increasing interest in the solid-state behaviour of neutral metal carbonyl clusters now that spectroscopic techniques (mainly ^{13}C MAS NMR) are providing information on the occurrence of dynamic processes for these species also in the condensed state of matter.[1] In fact, ^{13}C MAS NMR has afforded remarkable results in the metal cluster field, showing that the phenomenon of "fluxionality" (in the broad sense of CO ligand migrational processes around the metal cores) must be invoked to explain the spectral patterns recorded at different temperatures for a number of solid binary metal carbonyl clusters. The averaging mechanism implied by the solid-state NMR experiments is essentially of two kinds: (i) reorientation of the metal polyhedron within the carbonyl envelope and (ii) migration of the CO ligands around the metal frame usually through a bridge–terminal exchange. Mechanism (i) has been invoked in the cases of $[Fe_3(CO)_{12}]$[2] and $[Co_4(CO)_{12}]$,[3] while (ii) has been found to occur for $[Co_2(CO)_8]$.[4] In the former case the migrational motion has also been related to the well-known disorder present in crystals of $[Fe_3(CO)_{12}]$ and $[Co_4(CO)_{12}]$.[5,6]

Recently, a different interpretation of the dynamic behaviours shown by these species in the solid state has been proposed in terms of small amplitude librations involving both the inner metal frames and the surrounding CO ligands.[7] These motions do not imply extensive molecular reorientation but only displacements of the metal and CO nuclei around equilibrium positions, which are frozen out as the temperature is decreased, in agreement with the appearance of static structures on the NMR time scale.[8]

In general, molecular motions in crystals can be distinguished in two broad classes (with no clear borderline, however) on the basis of their amplitudes.[9a] Small amplitude displacements are usually related to rigid-body librations and/or translations or to intramolecular motions (bond bending, torsions, etc.) along the normal coordinates of the systems,[9b] and are characterized by weak restoring forces (compared with those implied by bond stretchings). Displacements of this kind are associated with "potential energy wells" having steep walls, but more or less flat bottoms. Large amplitude molecular motions are otherwise related to the presence of rather smooth potential energy surfaces, along which large displacements and reorientational jumps can easily occur. The forces opposing such motions are mainly, if not entirely, intermolecular. In this context, jumps between energy minima are often related to the occurrence of "dynamic" disorder in the crystal structures.[10,11] Molecular crystals of organic substances are known to show both kinds of phenomena, which are the subject of continuing investigations.

We now intend to apply some concepts and procedures developed in this neighbouring field to the investigation of molecular motions of some "fundamental" metal carbonyl clusters in the solid state.

*Author to whom correspondence should be addressed.

Although molecular motions of these latter species present essentially the same features as those of organic molecules, there are significant differences arising from the peculiar nature of the bonding interactions between the CO groups and the metal frame, the availability of substantially different coordination modes of almost equivalent energy for the ligands which can bound in terminal and various bridging fashions, the nature of the atomic species involved (transition metal atoms), let alone the very special structural non-rigidity implied by the phenomenon of fluxionality.[12] Nonetheless, the goal of this paper is to show that, in spite of the substantial simplifications required in dealing with transition metal clusters, the study of the potential energy terms associated with molecular motions of these species can afford relevant information in this rather unexplored area of the solid-state chemistry. Recently, the same approach, combined with an analysis of the observed mean square displacement parameters, has been applied to study the reorientational motion of the C_5H_5 ligands in *cis*- and *trans*-$[(C_5H_5)_2Fe_2(CO)_4]$, showing that a correlation is possible between the dynamic behaviours observed by MAS NMR, the height of the potential energy barriers in the solid and the orientation of the mean square displacement parameters.[13]

The following discussion will be devoted to the examination of species for which ^{13}C MAS NMR spectroscopy information is available, and whose solid-state structures are well studied. In particular $[Ru_3(CO)_{12}]$, which is "static",[14] and the "dynamic" species $[Fe_3(CO)_{12}]$, $[Co_4(CO)_{12}]$ and $[Co_2(CO)_8]$ mentioned above, will be studied. In the cases of $[Fe_3(CO)_{12}]$ and $[Co_4(CO)_{12}]$, a discrimination between "dynamic" disorder, arising from rigid-body reorientation of the entire molecules, and "static" disorder, generated either by random occupation of the crystal sites by the molecules in two alternative orientations or by differently oriented domains in the crystals, will also be attempted.

METHOD

The potential energy of a crystal made up of discrete molecular units, interacting by Van der Waals interactions and with no contribution of ionic nature, can be calculated as follows.[15] The potential energy (p.e.) is obtained as a simple function of the intermolecular atomic separations by using "conventional" repulsion–attraction potential energy terms of the kind

$$\text{p.e.} = \sum_i \sum_j Ae^{-BR_{ij}} - CR_{ij}^{-6}$$

acting between a central reference molecule and the surrounding ones, which are distributed according to the crystal symmetry. No coulombic interactions between permanent atomic charges or bond polarities are taken into account at the present stage of the investigation. The coefficients A, B and C are taken from the literature.[9a,16] No such coefficients are available for transition metal atoms and this constitutes an *a priori* drawback for these kind of calculations. However, it should be stressed that the aim of this work is not the exact evaluation of packing energies associated with a given crystal structure, but a comparison of the energy barriers associated with molecular reorientational processes. The peculiar features of the species under examination (a metal core encapsulated within a CO shell) simplify the problem: the potential energy barriers opposing the motion are largely dominated by outer CO···CO intermolecular interactions with little contribution (if any at all) coming from the inner metal core. We have proved this assumption by attributing to the metal atoms the values of A, B and C of the corresponding noble gases and of several main group elements whose values are available,[16] showing that neither the shape of the energy profiles, nor the height of the energy barriers, are significantly different from the ones obtained without metal contribution, while the absolute "depth" of the potential wells shows more marked changes. The comparison of the potential energy curves obtained for $[Ru_3(CO)_{12}]$ with different choices of A, B and C for the metal atoms and without metal contribution is shown in Fig. 1 for a complete rotation between -180 and $180°$ around an axis perpendicular to the Ru_3 triangle (also see below). All other curves were then obtained by taking into account only carbon and oxygen atom contributions. It should be pointed out that all molecular reorientations, whether of entire molecules or of parts of them, were performed by considering a static molecular environment, with no cooperation by the molecule surrounding the reorienting one. This limitation is known to cause overestimation of the potential energy barriers.[17] Although a detailed analysis of the intermolecular cooperation ("gear-like" motion of the molecules surrounding the reference one) requires further work and will be the subject of a future report,[18] it can be anticipated that the effect is never such as to "flatten" down the very high energy barriers (usually hundreds of kcal mol^{-1}) experienced by the reorienting molecule during the rigid-body motion. It is also important to note, at this stage, that the absolute minima for all the species under examination are invariably observed at 0° rotations, thus showing that the method correctly

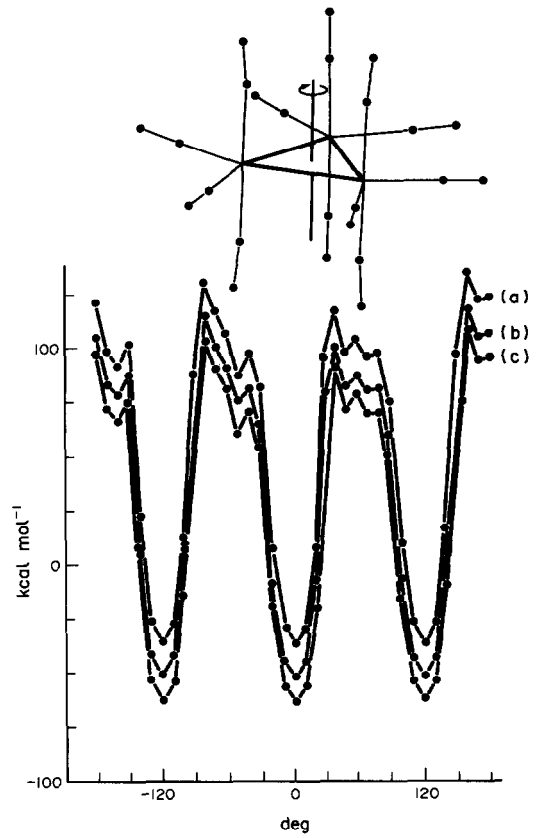

Fig. 1. $[Ru_3(CO)_{12}]$: Potential energy profiles for a rotation around the molecular three-fold axis, obtained without metal contribution (a) and by treating ruthenium as argon (b) and xenon (c).

attributes the lowest energy to the observed crystal structure.

Atomic coordinates and space groups were taken from the original papers. All calculations were performed by using a slightly modified version of the program OPEC, Organic Packing Energy Calculations and Volume Analysis.[19] References 16 and 19 give more details on the computational procedures.

RESULTS AND DISCUSSION

Reorientation and disorder in $[Fe_3(CO)_{12}]$

$[Fe_3(CO)_{12}]$ has been shown to be disordered in its crystal structure,[5] having the molecule lying around an inversion centre in the $P2_1/n$ space group, which generates a second image of the Fe_3 triangle and of the 12 CO groups. The molecule possesses idealized C_2 symmetry with the pseudo two-fold axis passing through the Fe—Fe bond, which bears the two asymmetric bridging COs, and the opposite Fe atom (see top of Fig. 2).

In order to perform the potential energy calculations, a model crystal was built in the acentric space group $P2_1$ with only one independent ordered molecule in the asymmetric unit. The molecule was then allowed to rotate from -180 to 180°, and the p.e. calculated every 10° step around an axis perpendicular to the Fe_3 plane and corresponding to the largest moment of inertia of the molecule. The p.e. profile is reported in Fig. 3. There are three interesting features which should be pointed out: (i) the molecule lies in a rather deep potential well (-34.65 kcal mol^{-1} if no iron contribution is taken into account), with steep walls which lead to rapidly increasing p.e. barriers on both sides; (ii) "sub-minima" are observed after 60 and -120° rotations, although associated with much higher p.e. values; (iii) a negative minimum, almost equivalent to the one at 0°, is observed after a 180° (or -180°) rotation from the original orientation. Analogous behaviour, but without sub-minima, is observed if the rotation is carried out around the minor inertia axes, which are coplanar with the Fe_3 triangle.

These facts indicate that the rotation around the

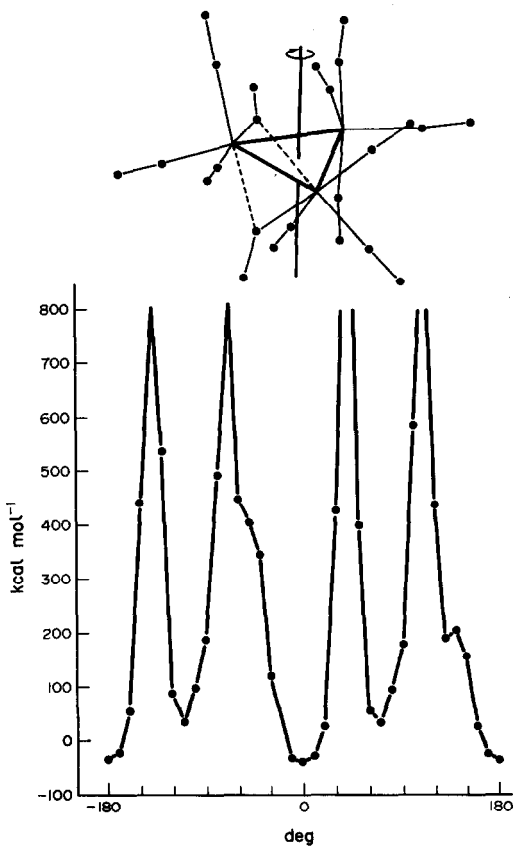

Fig. 2. $[Fe_3(CO)_{12}]$: Potential energy profile for a rotation around the molecular two-fold axis.

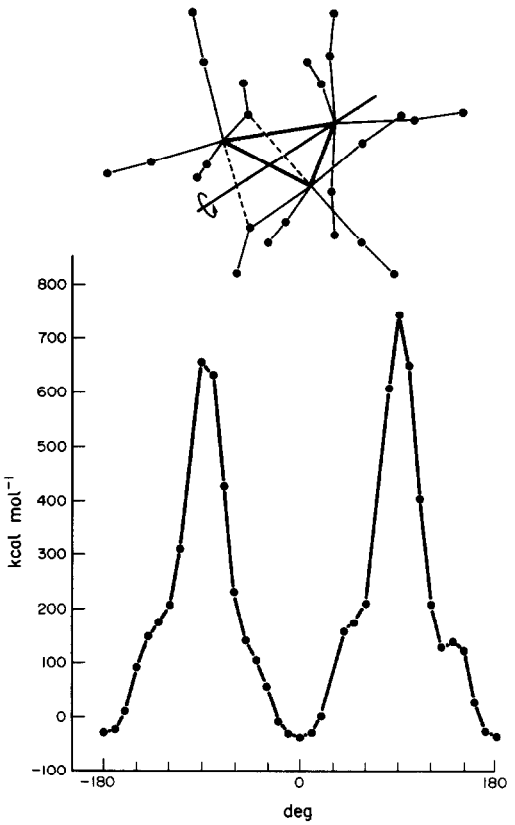

Fig. 3. $[Fe_3(CO)_{12}]$: Potential energy profile for a rotation around the major inertia axis.

inertia axis is prevented by the upsurge of very high p.e. barriers, thus ruling out the possibility of a full-scale rotational motion of the molecule as a rigid body. Furthermore, the crystal environment does not discriminate between the molecule in one orientation or in the reverse one. This latter observation is in keeping with a model of static disorder arising from random occupation of the crystal sites by the molecule in two "packing-equivalent" orientations, determined by the quasi-icosahedral peripheral polyhedron described by the 12 CO ligands. The possibility of a domain disorder generated by short-range order (say of a few hundred Å) within domains having different orientations in the crystal, can be ruled out.

Concerning the ^{13}C MAS NMR evidence for the occurrence of dynamic processes in solid $[Fe_3(CO)_{12}]$,[2] it must be stressed that there are no means, beside quantum-mechanical calculations, of evaluating the energy barriers associated with the proposed rotation of the Fe_3 triangle *within* the CO shell. It is otherwise possible to explore the displacement of the Fe_3 triangle and of the surrounding ligands around the molecular two-fold axis. As illustrated elsewhere,[7] such motion is enough to bring about the change of the molecular symmetry from C_2 to D_3 in the solid, so accounting for the equilibration of the carbon atom nuclei observed on the NMR time scale. The librational motion can be simulated by allowing displacement of the terminal and bridging ligands around an axis passing through the middle of the bridged Fe—Fe bond and the opposite iron atom as illustrated in Fig. 2. The p.e. associated with this motion remains negative within a fairly large angular range ($\pm 20°$) and is constant at about the value of the minimum between $\pm 10°$. All this may be taken as a qualitative indication that the crystal packing does not hinder a limited swinging of the ligands around their equilibrium positions, which causes, *inter alia*, increased degree of asymmetry of the bridging ligands and, ultimately, the adoption of quasi-terminal positions. Such a dynamic process is the only one which can explain the solid-state NMR spectral pattern without requiring large jumps of the metal core between the crystallographic observed positions.[2] Obviously, additional potential energy terms that couple CO group deformation with the librational modes would be required for a better assessment of the fundamental modes that could lead to exchange on the NMR time scale.

Reorientational motion and disorder in $[Co_4(CO)_{12}]$

Similar reasoning may be applied to $[Co_4(CO)_{12}]$, which also shows disorder and dynamic behaviour in the solid state.[3,6] $[Co_4(CO)_{12}]$ crystallizes in the orthorhombic space group *Pccn*, with the molecule lying around a crystallographic two-fold axis which generates a second orientation of the cluster at 180°.[6] A model crystal containing only ordered molecules was built in the monoclinic space group $P2_1/c$ (with $\beta = 90°$). The molecule was allowed to rotate from -180 to 180°, first around the two-fold axis of the disorder model and then around each of the tetrahedron three-fold axes. In the former case the p.e. pattern is very much modulated (see Fig. 4) showing sub-minima every 60° and two minima of energy almost identical to that calculated at 0° after a 180 or $-180°$ rotation. If the same rotation is carried out around one of the other two axes comprising an atom of the bridged base, similar patterns are observed. If the molecule is instead allowed to rotate around the idealized molecular three-fold axis (the one comprising the apical cobalt atom bearing three terminal COs and passing through the centre of the opposite triangular face, see Fig. 5), the minimum at 180° disappears, while p.e. minima are observed every 120°. These latter minima correspond to swapping the sites occupied by the basal ligands and by the terminal COs of the apical atom.

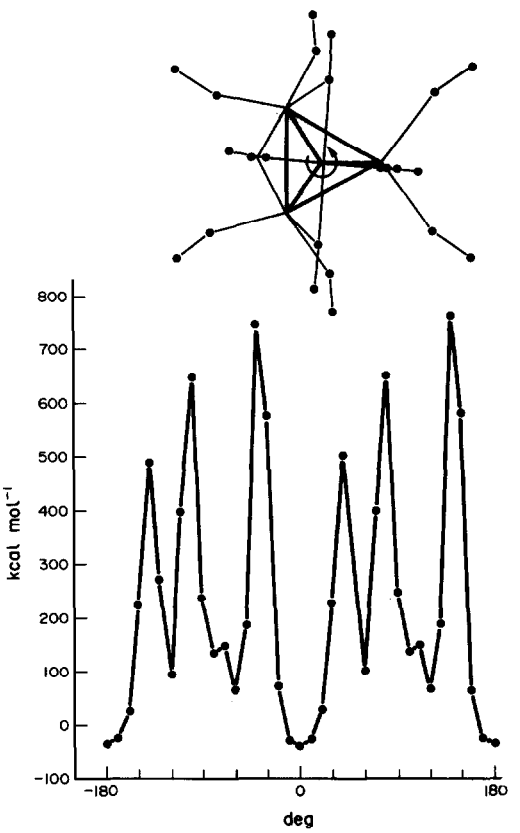

Fig. 4. $[Co_4(CO)_{12}]$: Potential energy profile for a rotation around the crystallographic two-fold axis of the disordered crystal.

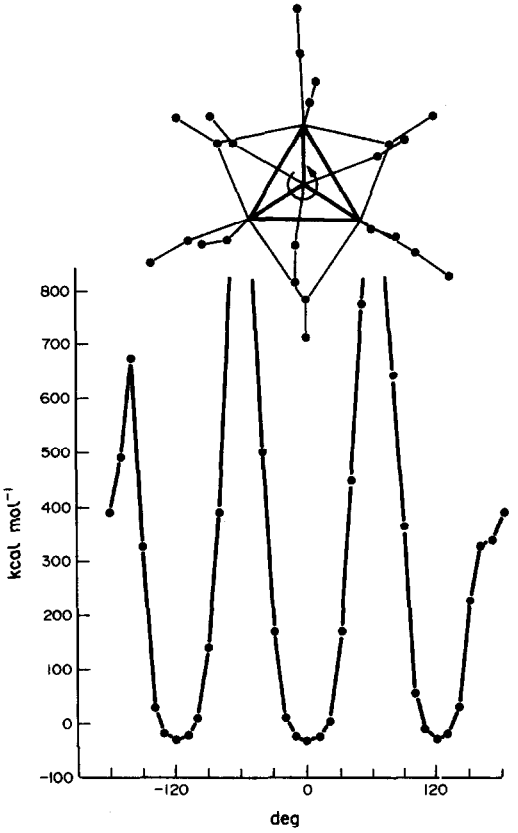

Fig. 5. $[Co_4(CO)_{12}]$: Potential energy profile for a rotation around the molecular three-fold axis.

From the above results it can be concluded that, as observed for $[Fe_3(CO)_{12}]$, the disorder has random rather than domain nature.

Molecular reorientation in $[Ru_3(CO)_{12}]$

$[Ru_3(CO)_{12}]$ has been reported to be static in the solid state,[14] so that it is well suited as a test case for the method. The p.e. profiles reported in Fig. 1 have been calculated, analogously to $[Fe_3(CO)_{12}]$, by allowing rotation of the molecule around its major inertia axis, which corresponds to the molecular three-fold axis passing through the middle of the Ru_3 triangle. It is worth recalling that the crystal structure of $[Ru_3(CO)_{12}]$ does not show disorder.[21] The p.e. profile shows three—almost identical—minima centred at 0, −120 and 120°, which correspond to site-swapping between the three $Ru(CO)_4$ units constituting the cluster. These minima are separated by fairly large energy barriers, though somewhat less pronounced than in the previous cases. It should be pointed out, however, that the height of the barriers is not necessarily related to the overall packing "efficiency",[20] but rather reflects the nature of the obstacles encountered by the molecule during the hypothetical motion through the crystal. On the other hand, the p.e. value corresponding to the crystal structure (0° rotation) is the lowest obtained for the species discussed herein, even if no metal atom contribution is taken into account (−36.6 kcal mol^{-1}). This fact is in strict accord with the existence of a tight molecular packing for $[Ru_3(CO)_{12}]$, evidenced by the value of its packing coefficient (0.72), as discussed elsewhere.[20]

Molecular reorientation and libration in $[Co_2(CO)_8]$

$[Co_2(CO)_8]$ is the only species for which the occurrence of a CO scrambling process in the solid (of the kind commonly observed in solution) has been invoked in order to account for the features and temperature dependence of the ^{13}C MAS NMR spectra.[4] The structure of $[Co_2(CO)_8]$ also has been subjected to independent studies,[22] which have shown that two independent "half" molecules are related to the other "halves" by a crystallographic mirror plane bisecting the Co—Co bond and con-

taining the two bridging CO ligands. In order to approach the ligand motion around the molecule, the crystal of $[Co_2(CO)_8]$ (space group $P2_1/m$) has been described in the isomorphous subgroup $P2_1$ with two independent entire molecules in the asymmetric unit.

It should be emphasized that there is no simple reorientational motion which can describe the cyclic CO exchange between crystallographic independent sites able to equilibrate bridging and terminal ligands on the NMR time scale. It is only possible to simulate some components of the motion by allowing rotations around appropriately selected axes. The effect of a rotation around the Co—Co axis of the terminal COs bound to one or both cobalt atoms, which is probably one of the possible intermediate stages of the fluxionality process in solution, is shown in Fig. 6. Minima, separated by high potential barriers, are observed every 120°. More interesting appears to be the effect of slightly rotating three terminal and one bridging CO belonging to one of the CO atoms around an axis perpendicular to the Co—Co bond and parallel to the vector joining the bridging COs (see Fig. 7). This motion may simulate the "opening up" of a CO bridge to lead from the bridged structure to an intermediate stage with all terminal ligands. The p.e. profile associated with this motion, although

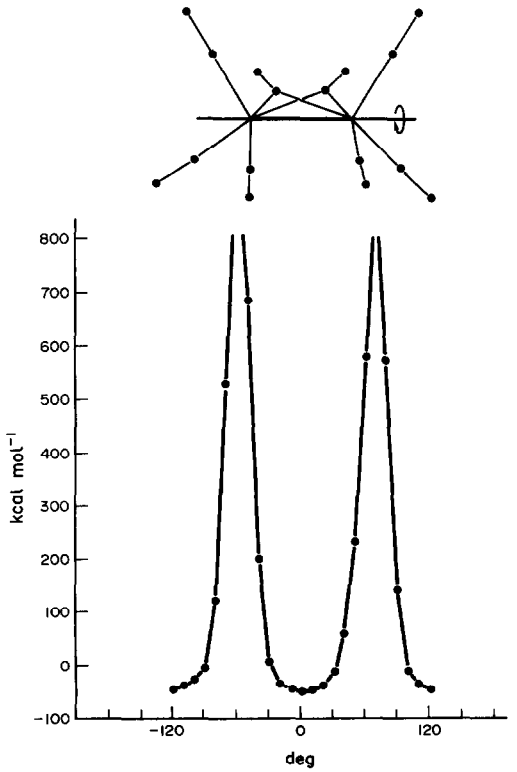

Fig. 6. $[Co_2(CO)_8]$: Potential energy profile for a rotation of the terminal CO ligands around the Co—Co axis.

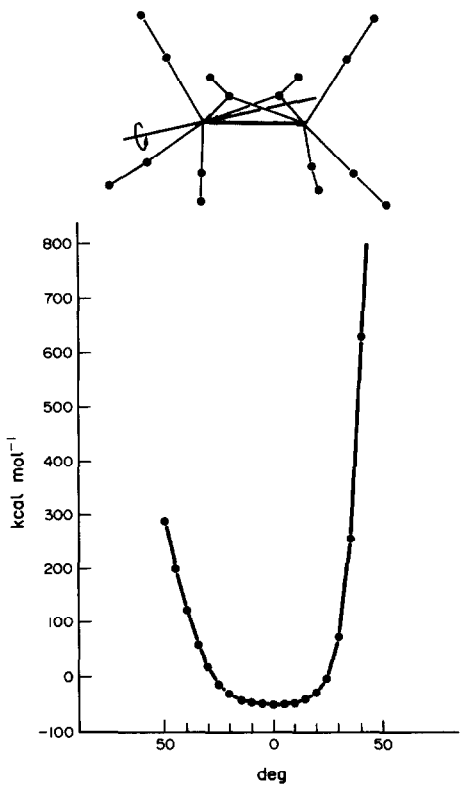

Fig. 7. $[Co_2(CO)_8]$: Potential energy profile for a libration of three terminal and one bridging CO around an axis perpendicular to the Co—Co bond and passing through one cobalt atom.

obtained without contributions of intramolecular nature, is rather flat (p.e. values remain negative between −28 and 24°), indicating that the ligands can be displaced to a fairly large extent without encountering excessive steric hindrance by the neighbouring molecules. This observation is important because it offers the possibility to envisage a swinging motion of the ligands around the cobalt centres, possibly accompanied by slight tilting of the Co—Co axis around its centre of mass, which can suffice in equilibrating the carbon nuclei of terminal and bridging ligands as required by the MAS NMR experiments. This all occurs with no need for site exchange among the ligands.

CONCLUSIONS

We have shown that potential energy studies, though confined to atom-pair non-bonded interactions, are a useful tool for the investigation of dynamic processes in the solid state even for transition metal complexes, and also offer a discriminating criterion to distinguish between static and dynamic disorder and between random and domain disorder. The results obtained are very much qualitative and admittedly based on large

(and sometimes simplistic) assumptions and approximations of various kinds. Although no "absolute" energy values can be obtained, the present analysis correctly recognizes the possible relationship between the different phenomena taken into account: effect of crystal packing, occurrence of disorder, dynamic behaviour as evidenced by spectroscopic techniques. The main outcomes of this work can be summarized as follows:

(1) There is no evidence for facile reorientational processes of molecules regarded as rigid-bodies in crystals of transition metal clusters. The energy barriers associated with these motions are enormous when compared with those calculated for "dynamic" organic molecules such as benzene and naphthalene derivatives[16] or adamantanes,[23] although, at first sight, the molecules' shapes (spheres, cylinders, etc.) would seem very similar. It should be pointed out, however, that most carbonyl clusters of low nuclearity are better described as "lumpy" objects with the oxygen atoms sticking out of the surfaces and fitting in the interstices of the surrounding molecules. Thus it is not surprising that the energy barriers associated with the reorientations should be generally higher than for other more globular molecules, where the problem of atoms pushing past the surrounding ones can be less dramatic.

(2) The salient symmetry features of the molecules are recognized by the crystal packing during the motions, showing minima for orientations made equivalent by the idealized molecular symmetries.

(3) In this context, the appearance of energy minima corresponding to genuinely alternative orientations of molecules such as $[Fe_3(CO)_{12}]$ or $[Co_4(CO)_{12}]$, but in contrast with the molecular symmetry, even in model crystals built up of ordered units, is an indication that the whole crystal is modulated around an average object generated by the superposition of the two orientations. Therefore the possibility of a mosaic crystal made up of differently oriented domains being the cause of disorder can be ruled out. It should be mentioned, in passing, that MAS NMR should be affected differently by a sample showing random or domain disorder.

(4) The alternative interpretation of the dynamic behaviour observed for $[Fe_3(CO)_{12}]$, $[Co_4(CO)_{12}]$ and $[Co_2(CO)_8]$, based on concerted small-amplitude librations of the metal frames and of the CO ligands, appears to be somewhat substantiated by the presence of broad potential energy minima associated with limited displacements of the ligands whose motion is involved in the equilibration process.

(*Received* 30 *January* 1989; *accepted* 26 *April* 1989)

Abstract—Crystalline dimorphs of *fac*-$[Ir(py)_3Cl_3]$ are described and characterized. They give identical solutions and one converts irreversibly to the other.

Even in single solid phases containing individual uncharged molecules (including octahedral compounds—for example,[2] *fac*-$Ir(CH_3)_3(PMe_2Ph)_3$—there are many examples of differing geometry for such molecules at inequivalent positions within the unit cell.

The existence of distinct crystalline forms of such molecular structures seems likely to be common. Though not so commonly noticed, there are in fact plenty of cases. For example,[3] $[Pt(bipy)Cl_2]$ molecules may pack in the common yellow form and a less common red form.

We describe here a new case, that of *fac*-$[Ir(py)_3Cl_3]$, ostensibly a well known compound, in the sense that many properties have been reported (such as far-IR and Raman, and its electronic spectrum). However, all such reports seem (so far as we can see) to relate to measurements on samples actually provided by Delepine or his associates, so we describe our preparations in detail.

Delepine first synthesized[4] *fac*- and *mer*-$[Ir(py)_3Cl_3]$, both via extensive heating of chloro- or pyridinechloro-precursors ($IrCl_3 \cdot 3H_2O$, K_3IrCl_6, *cis*- or *trans*-$[Ir(py)_2Cl_4]^-$ and others) with pyridine. Some picoline (i.e. methylpyridine) analogues have also been described, by his students: *fac*- and[5] *mer*-$[Ir(3\text{-pic})_3Cl_3]$, and[6] $[Ir(2\text{-pic})_3Cl_3]$ (probably the *mer*-isomer).

The *fac*-isomer was isolated here as a by-product in the synthesis of the *trans*-$[Ir(py)_4Cl_2]^+$ cation: we recently reported[7] the structure of one dimorph of the chloride hexahydrate of this. A more recent report[8] of the analogous dibromorhodium compound is of an isostructural lattice.

EXPERIMENTAL

fac-$[Ir(py)_3Cl_3]$ (*Form* A)

$K_3IrCl_6 \cdot 3H_2O$ (0.521 g) dissolved in water (18 cm^3) and heated (steam bath) was treated with a mixture of pyridine (6.5 cm^3) and ethanol (3 cm^3). Reaction to a yellow solution was complete after ~ 15 min; the solution was evaporated to ~ 20 cm^3 (to remove ethanol and some pyridine), and allowed to cool. Yellow crystals (Form **A**) slowly formed; these were collected. The filtrate was concentrated to ~ 10 cm^3 giving a second crop. Contaminating *trans*-$[Ir(py)_4Cl_2]Cl \cdot nH_2O$ in this second crop was extracted with hot water. Total yield of **A** = 0.065 g (13.5%). Other similar preparations, and one using $IrCl_3 \cdot 3H_2O$ gave yields in the range 12–18%. With propan-2-ol (instead of ethanol) as catalyst/solvent the yield improved to 29%.

Form B

$K_3IrCl_6 \cdot 3H_2O$ (0.104 g) dissolved in water (1.5 cm^3), pyridine (0.1 cm^3), propan-2-ol (0.5 cm^3) and chloroform (2.0 cm^3) was set to reflux very slowly in a 5 cm^3 foil-covered flask. After 8 h, yellow crystals had formed in the chloroform layer. The reflux was continued overnight, then the yellow crystals were removed by filtration and washed with chloroform. Yield = 0.026 g (27%).

Properties

Form **B** differs from Form **A** in the vibrational spectrum, X-ray diffraction and thermogravimetric analysis, although both show the same solubility properties: they dissolve (giving

identical solutions) only very slowly in cold solvents: CH_2Cl_2, $CHCl_3$, pyridine, H_3CCN and 50 : 50 H_2O–pyridine; although both are insoluble in water. Both are slightly soluble in propan-2-one (acetone) and hardly soluble (if at all) in CS_2.

Form **A** was dissolved in 50% v/v aqueous pyridine, passed through an anion exchange resin (Sephadex A25) and recovered by steam distilling pyridine (i.e. evaporating the solution to remove pyridine vapour but keeping the volume constant by adding water): 95% of the original mass of complex was recovered as long needles entirely of Form **B**.

Form **A** can be recrystallized from 20–50% v/v aqueous pyridine with varying degrees of success (0–100%). However, in no instance was it possible to obtain Form **A** from Form **B**.

Both forms were neutral, since (dissolved in 50% v/v aqueous pyridine) they pass through anion and cation (Sephadex A25 and C25, respectively) exchange resins; if the solutions are allowed to age, then the *anion* exchange resin retains some complex, suggesting slow base hydrolysis to $[Ir(py)_2Cl_3(OH)]^-$. Analyses are given in Table 1.

The solution electronic spectra from both forms indicate that the basic structural unit is the same (Table 2): the band positions of Jorgensen are in good agreement with ours; the figures[10] of Rio and Lareze for absorption wavelengths of the *fac*-isomer differ slightly; they included extinction coefficients.

Vibrational spectra are presented in Table 3, and in Figs 1 and 2. IR spectra were measured using Perkin–Elmer 557 and Pye Unicam SP3-200 spectrometers (calibrated with polystyrene) on NaCl or CsI plates for mulls in Nujol or fluorolube.

X-ray diffraction: there is a small difference

between the two powder patterns, illustrated in Fig. 3. The diffraction patterns have not been previously reported, nor are any crystallographic details yet known: crystal morphology is so far poor.

RESULTS AND DISCUSSION

The distinguishing differences between the spectra of the two *fac* forms are: a slight difference in a number of band positions, especially M—L/M—Cl bands; the change in activity of two bands (ligand modes): ν_{16} has medium intensity in Form **A**, but is almost absent in Form **B**, and vice versa for ν_{17}; a distinctive difference in the splitting of ligand modes ν_{10}, ν_{25} and ν_{26} (Fig. 1) and a different structure in the C—H stretching region (Fig. 2: **A** at *3144, 3116, 3084, 3071, 3048, 3032 and 3009; **B** at 3115, 3083, 3074, *3058, *3045, 3023 and 2001 cm^{-1}. The bands marked * have no counterpart in the spectrum of the other dimorph).

There are two published studies[11,12] of the IR spectra of *fac*-$[Ir(py)_3Cl_3]$, both on samples supplied by Delepine. The spectrum of Clark and Williams is limited to the far-IR, and agrees closely with the present Form **A**. Harbelin *et al.* record more of the spectrum (4000–1000 cm^{-1}). While their spectrum agrees better with that of Form **A**, the detail is poor: it appears to be a hybrid, containing some peaks of Form **A** and others of Form **B**. It probably represents chiefly Form **A** since the authors describe ν_{16} as a prominent band (it is almost undetectable in our Form **B**).

The splitting of the ligand modes in the *fac* form **B** is most similar to that reported for *fac*-$[Rh(py)_3Cl_3]$.

The IR spectra and corresponding Raman spectra (Table 3) are very similar in the M—L/M—Cl stretching region.

Isolated molecules of *fac*-$[Ir(py)_3Cl_3]$ have a three-fold axis of symmetry only if the pyridine ligands are equivalent, i.e. (i) freely rotating with a period less than that of the detection method, (ii) fixed in an orientation where all three planes make equal angles with the axis which passes through the iridium ion and the centre of the triangle defined by the three chloride ligands or (iii) all three rotating in phase through successive conformations like those in (ii). Evidently, the molecules actually possess no such C_3 symmetry in either Form **A** or **B**, since some pyridine ring vibrations are no longer equivalent and splitting occurs. This probably arises from the site symmetry(ies) of the complex molecules. While this inequivalence is much less pronounced for Form **B**, there is fine structure on many bands.

The earlier suggestion[13] that the Raman vibration ν_9 is insensitive to environment but sen-

sitive to the configuration of the complex molecules seems to be borne out, in that the *mer*-isomer shows two bands of relative intensity, approximately 1 : 2, corresponding to *cis*- and *trans*-ligands, respectively, while the *fac*-isomer gives only a single band at 1025 cm^{-1} (Table 3).

Form **A** seems metastable with respect to **B**, at least in 50% v/v aqueous pyridine as solvent, so may be viewed as a metastable intermediate in the sense of Ostwald's law. The kinetic conditions necessary to produce Form **A** depend subtly on the original reaction conditions (e.g. temperature or concentration of aqueous pyridine) or on the presence of a trace of some other complex, e.g. *trans*-$[Ir(py)_4Cl_2]^+$, which determines the form by its presence when nucleation begins, or by being incorporated in trace amounts into the crystal lattice.

The present example again demonstrates the frequency of occurrence of various distinct solid forms of individual coordination compounds, and the care needed to identify the particular phase in hand.

COMPLEXATION OF THE URANYL ION BY CROWN ETHERS, DIAZA-CROWN ETHERS AND ANALOGOUS ACYCLIC LIGANDS IN SOLUTION

J. LAGRANGE, J. P. METABANZOULOU, P. FUX and P. LAGRANGE*

URA 405 au CNRS, EHICS, 1 rue Blaise Pascal, 67000 Strasbourg, France

(*Received* 1 *March* 1989; *accepted* 26 *April* 1989)

Abstract—The complexation of uranyl ion, UO_2^{2+}, with several crown ethers (15C5; 18C6; 21C7; 24C8; 30C10) substituted or not by benzo or carboxylic groups and with several diaza-crown ethers (21; 22; 23 coronands) substituted or not by alkyl chains have been investigated in propylene carbonate and in acetonitrile (in the presence of 0.1 M tetraethylammonium perchlorate). The results are compared with those obtained for the complexation of UO_2^{2+} by analogous acyclic ligands. The inclusion of UO_2^{2+} in the cavity of the 18C6 ligand family is demonstrated. The substitutions of the ligands have, in general, only small effects on the complexation.

The inclusion of the uranyl ion in a crown ether (or a diaza-crown ether) of the appropriate size has been demonstrated in the solid state, by structural determinations.[1–5] In solution, the uranium inclusion is in competition with the solvation of the ligand cavity, and the complexation of uranium itself is also in competition with the solvation. Only weak complexes are observed with crown ethers in water: the coordination between the uranyl ion and the complexing groups of the ligand occurs with hydrogen bond formation between the hydrogen atoms of the water molecules solvating the uranium and the oxygen atoms of the crown ether.[6] In water, the uranyl ion is only stable in acidic medium. Thus, the polyaza-crown ethers are not useful, because the amino functions of the ligand are protonated[7] in this acidic medium.

In this work, we have determined the nature and the stability constants of the complexes formed between the uranyl ion and the ligands mentioned below (Fig. 1), in propylene carbonate, principally, and in acetonitrile. These two organic solvents have been chosen for their solvating properties. They both have sufficiently high dielectric constants to provide good dissociation of the strong electrolytes, but the metallic cations are less solvated by these organic solvents than by water. Thus, the complexation and inclusion of the uranyl ion in a macrocyclic ligand must be more facile in propylene carbonate or in acetonitrile than in water.

The ligands are: 1,4,7,10,13-pentaoxacyclopentadecane (15C5); 1,4,7,10,13,16-hexaoxacyclooctadecane (18C6); 1,4,7,10,13,16,19-heptaoxacycloheneicosane (21C7); 2,3,11,13,-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene (DB18C6); 2,3,14,15-dibenzo-1,4,7,10,13,16,19,22-octaoxacyclotetracosa-2,14-diene (DB24C8); 1,4,7,10,13,16-hexaoxacyclooctadeca-2,3,11,12-tetracarboxylic acid (18C6TCA); 1,4,10-trioxa-7,13-diazacyclopentadecane (21); 1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (22); 1,7,10,13,19-pentaoxa-4,16-diazacycloheneicosane (23); 4,13-dimethyl-1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (22DM); 4,13-didecyl-1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (22DD); 4,13-dihydroxyethyl-1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (22DETOH); diethylamine (DEA); diethyl ether (DEE); 2,5,8,11,14-pentaoxapentadecane (TeEG); 1,8-diaminooctane (DAO); 1,8-diamino-3,6-dioxaoctane (DAOO); tris[2-(2-methoxyethoxy)-ethyl]-amine (TDA).

EXPERIMENTAL

Reagents

Uranium(VI) perchlorate was obtained from Ventron and tetraethylammonium perchlorate

* Author to whom correspondence should be addressed.

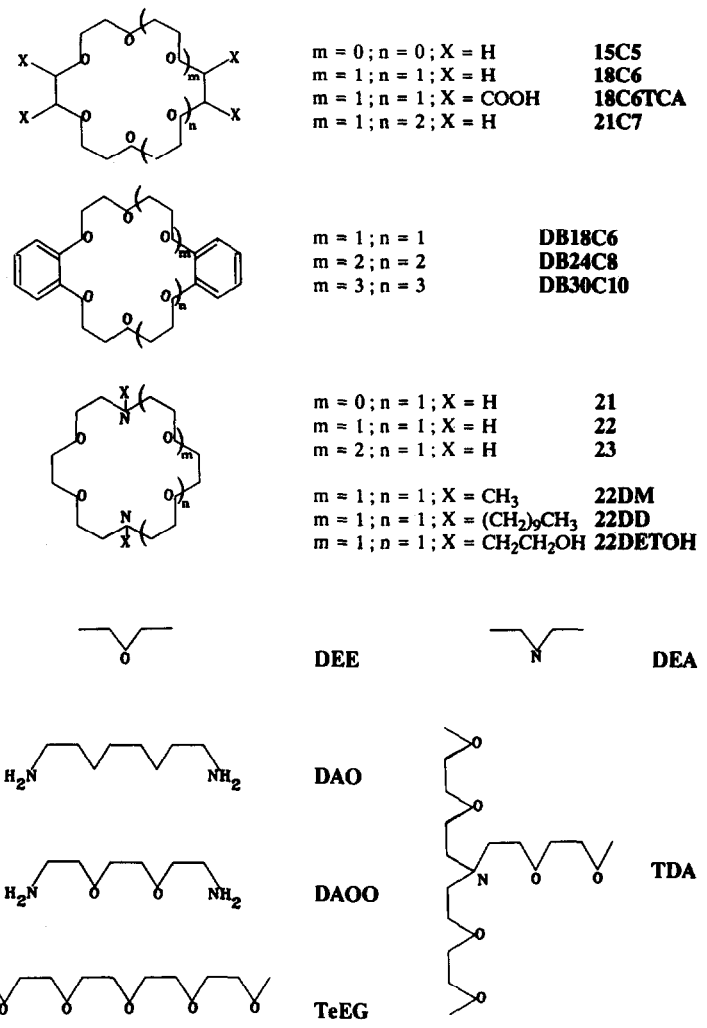

Fig. 1. The ligands.

(Fluka) was recrystallized twice from water and carefully dried *in vacuo*. The ligands were obtained from Merck, except for 21C7 (from Parish), 22DM and 22DETOH (synthesized by Gramain *et al.*[8] Propylene carbonate (Fluka) was purified according to Gosse.[9] Acetonitrile, Uvasol, was purchased from Merck.

The ionic strength was maintained at 0.1 M by the addition of tetraethylammonium perchlorate, $(TEA)ClO_4$.

The residual water content was determined by a Karl Fischer titration. All test solutions contained less than 150 ppm of water.

Spectrophotometric measurements

Spectrophotometric measurements were performed with a Kontron Uvikon 860 spectrophotometer between 230 and 350 nm, in quartz cells, at 25 ± 0.1°C. The absorbances of the solutions containing between 10^{-4} and 10^{-6} M of uranyl ion and between 10^{-3} and 10^{-6} M of a given ligand were recorded at 5 nm intervals. Data treatments were conducted using the Sillen's generalized least-squares method LETAGROP–SPEFO.[10] (The computer was an IBM 3081.) The calculation allows us to choose the stoichiometry and stability constant of the formed complexes which gives the most appropriate model.

RESULTS

Each formed complex, $(UO_2)_xL_y^{2x+}$, is characterized by its stoichiometry, $(x:y)$. The logarithms of the stability constants, β, of the equilibria:

$$xUO_2^{2+} + yL \rightleftharpoons (UO_2)_xL_y^{2x+},$$

are tabulated in Table 1 for the complexation of UO_2^{2+} by crown ethers in propylene carbonate, in Table 2 by diaza-crown ethers in propylene carbonate, in Table 3 by acyclic ligands in propylene carbonate, and in Table 4 for the complexation in acetonitrile. In acetonitrile, the low solubility of the aza ligands did not allow us to carry out measurements using these aza complexing agents. The uncertainty limits quoted are twice the computed standard deviations.

DISCUSSION

The discussion will take into account the following points: the possibility of the uranyl ion inclusion in crown ethers and in diaza-crown ethers, the influence of the presence of substituting groups on the ligands, and the influence of the solvent.

Complexation by crown ethers and analogous linear ligands

The uranyl ion complexation by crown ethers shows only the formation of 1:1 complexes, when they are observed. The inclusion in the ligand hole is only possible if this cavity has a diameter greater than the ionic diameter of the uranyl ion (2.8 Å),[11] measured in the equatorial plane. Thus, 15C5 which has a cavity diameter of *ca* 1.8 Å[12] does not complex the uranyl ion. Furthermore, the ether function is a weak complexing group and the uranyl ion is being complexed only by poly-coordinating ligands having more than one ether group. Diethyl ether does not provide observable complexation with the uranyl ion, but TeEG gives a stable 1:1 chelate. The complexation by 18C6 shows a complex 200 times more stable than those formed with TeEG in propylene carbonate and in acetonitrile. This effect must be due to the inclusion of the cation in the ligand cavity (macrocyclic effect), but the stability increase is limited by the difficulty encountered by UO_2^{2+} to penetrate into the hole of the crown ether.[13] The best crown ether seems to be 18C6 with its adapted cavity (diameter around 2.9 Å).[12]

Table 4. Complexation in acetonitrile (— indicates that no complex was observed)

Ligand	Complex	log β
DEE	—	—
TeEG	1:1	1.47±0.12
15C5	—	—

DB18C6	1:1	6.00±0.40
DB24C8	1:1	5.16±0.35

Complexation by diaza-crown ethers and analogous ligands

Amines are better complexing agents than ether and a complexation by diethylamine is observed in propylene carbonate: formation of a stable 1:2 complex. The metals have a greater affinity for nitrogen atoms than for oxygen atoms. Thus, we can conclude that "exclusive" or "inclusive" complexes can be observed with the diaza-crown ethers. The inclusion of the uranyl ion in the ligand cavity is more complicated with the diaza-crown ethers than with the crown ethers, because 1:1 and 1:2 complexes are observed with the "diaza" ligands. However, the 1:1 complexes with 21 or 22 or 23 ligands are 100–1000 times more stable than the analogous complexes formed with the acyclic ligands: DAO, DAOO and TDA. Thus, this macrocyclic effect allows us to conclude that, at least, a partial inclusion of the uranyl ion in the diaza-crown ether must be probable. The best ligand is the 22 coronand which is analogous to 18C6.

Influence of the substituting groups of the ligands

With the crown ethers, the benzo groups increase the complexing power of the ligands. These substitutions maintain the ligand cavity open and entry for the cation is easier. The carboxylic acid substituents can also assist the entry of the cation into the ligand cavity. In conclusion, these substitutions only have a small effect on the complexation in propylene carbonate, but a more important effect for "benzo" groups in acetonitrile.

With the diaza-crown ethers, the complexation is inhibited by the alkyl chains bonded to the ligand 22. This effect increases with the length of the chains. The decyl groups could be inside the coronand cavity and the possibility of inclusion of the uranyl ion in the crown ether decreases strongly. The presence of two methyl groups or two alcohol groups has a very weak influence on the complexation. These observations present limitations in the use of alkyl chains which can immobilize these macrocyclic ligands on a polymer matrix.

Influence of the solvent

Only the complexation of uranyl ion by crown ethers and analogous linear ether ligands has been carried out in propylene carbonate and in acetonitrile. The "aza" ligands are not soluble enough in acetonitrile. We notice that the ligands without "benzo" groups are better complexing agents of the uranyl ion in propylene carbonate than in acetonitrile. A decrease in the stability constants is observed when the solvent has a greater solvating property of the metallic cation, as we can see in Table 5 for the complexation of the uranyl ion by 18C6. The structure of the complexes changes from "inclusive" in propylene carbonate to "outer sphere" in water.

Table 5. Logarithm of the stability constant of the 1:1 complexes formed between UO_2^{2+} and 18C6 in different solvents

Propylene carbonate	Acetonitrile	MeOH–H_2O (90:10%)	H_2O
5.29	3.80	3.15[a]	2.0[b]

[a] Reference 14. [b] Reference 6.

The influence of the "benzo" substituting groups of the crown ethers is greater in acetonitrile than in propylene carbonate because they hinder the solvation of the hole in the coronands, which is easier for acetonitrile than for propylene carbonate. A similar effect has been previously observed by Kolthoff *et al.*[15] for the complexation of K^+ and Na^+. The crown ether cavities are probably more strongly solvated by the acetonitrile molecules than by the larger propylene carbonate molecules.

THEORETICAL STUDY OF HYDROXAMIC ACIDS

N. J. FITZPATRICK*

Department of Chemistry, University College, Belfield, Dublin 4, Ireland

and

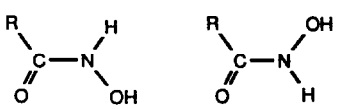
R. MAGESWARAN

Department of Chemistry, University of Jaffna, Jaffna, Sri Lanka

(*Received* 7 *March* 1989; *accepted* 26 *April* 1989)

Abstract—*Ab initio* molecular orbital calculations on formohydroxamic and acetohydroxamic acids give stabilities in the order: *E*-keto > *Z*-keto > *Z*-enol > *E*-enol. However, on hydration the *E*-keto and *Z*-keto order is reversed, in agreement with NMR results. Methyl substituted forms are also considered, and the importance of hydrogen bonding is noted.

Hydroxamic acids can occur as many isomers and conformers. Recently *cis–trans* isomerism in monoalkylhydroxamic acids has been studied by ^{1}H, ^{13}C and ^{15}N NMR spectroscopy,[1] where it was predicted that, in the keto form, *Z*- and *E*-isomers can exist, if restricted rotation about the C—N bond occurs.



Z E

Also tautomerism would lead to enolic hydroxamic acid, RC(OH)NOH, forms. The experimental NMR spectra show that both the *Z* and *E* forms exist in solution, as do the enol forms. However the X-ray crystal structure of acetohydroxamic acid hemihydrates indicates that in the crystal the *Z*-keto form is found,[2] which is similar to propionohydroxamic acid.[3] Also, ^{1}H and ^{13}C NMR studies on N-substituted hydroxamic acids have shown that the *Z*–*E*-isomer ratio is solvent dependent; the *Z*-isomer predominates in polar solvents like DMSO-d_6. The predominance of the *Z*-isomer in DMSO-d_6 may be due to the preferential stabilization of the *Z*-isomer by solvation/hydrogen bonding with some residual water present.[4]

The stabilities of different forms of the isolated and hydrated hydroxamic acids in this study were examined using *ab initio* molecular orbital calculations. Previously, the geometry of formohydroxamic acid was studied using the INDO–MO formalism.[5] In the present study the Gaussian 82 program[6] with 3–21*g* basis sets[7] was used to consider formohydroxamic and acetohydroxamic acids and their hydrated forms, as well as methyl substituted species.

RESULTS AND DISCUSSION

(a) *Formohydroxamic acid*

It has been shown that formohydroxamic acid[4] occurs in different isomers and conformers. Figure 1 shows the optimized geometries for the structures considered. The global minimum is the non-planar *E*-keto structure, with an energy of −242.35827 au. This is 32.9 kJ mol^{-1} more stable than the form with a planar geometry. The energies of the other optimized structures, relative to the global minimum, are also shown in Fig. 1. All the structures in the figure do not correspond to a critical point of order zero; however the four lowest energy forms (*E*- and *Z*-keto and enol) had order zero critical points.

It is noteworthy that the nitroso structure, the highest energy form considered, is 189.2 kJ mol^{-1} above the global minimum. The second lowest

* Author to whom correspondence should be addressed.

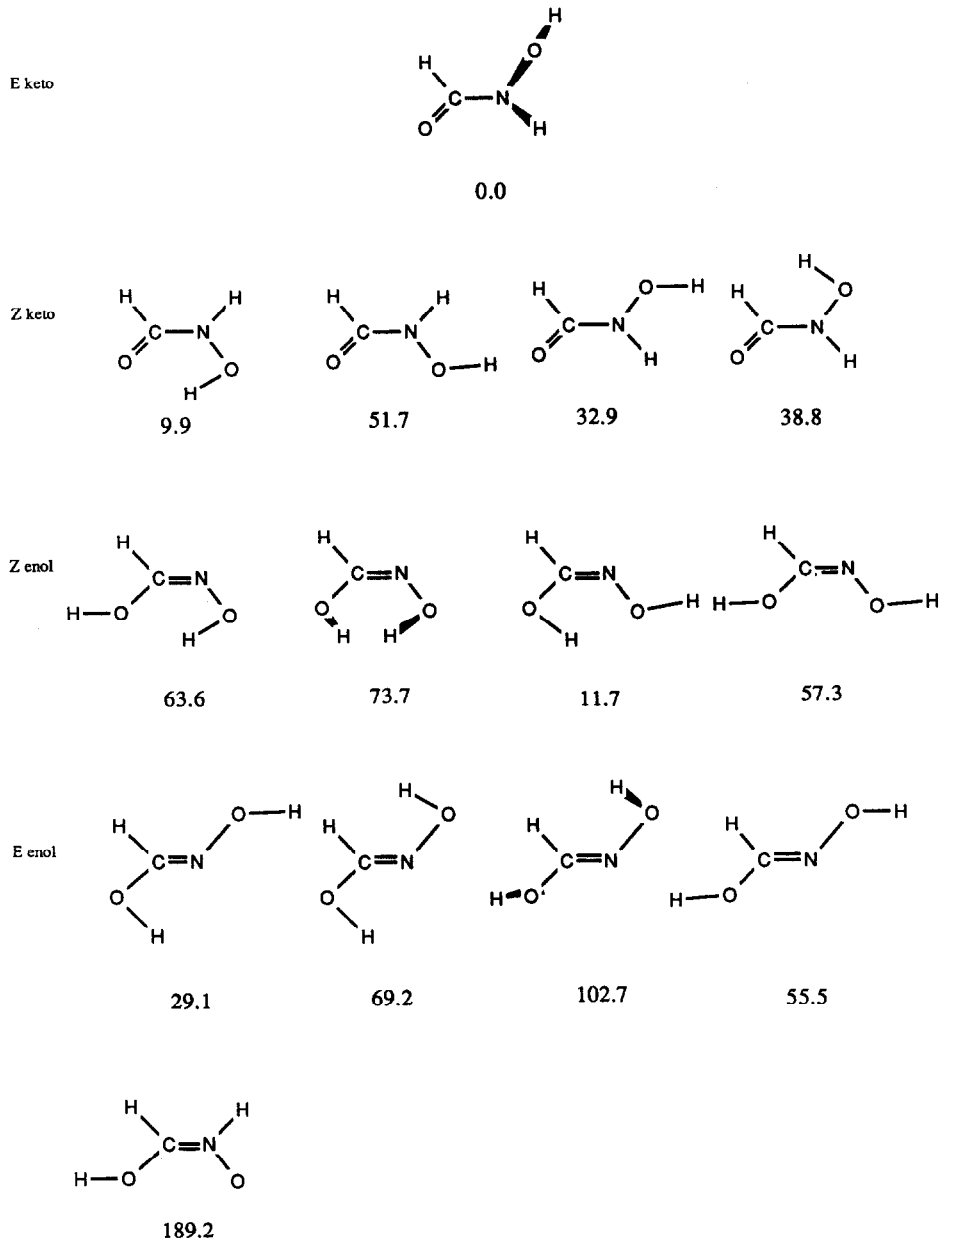


Fig. 1. Optimized structures and relative energies (kJ mol^{-1}) of formohydroxamic acid.

energy form is the *Z*-keto form, which is 9.9 kJ mol^{-1} above the global minimum. The next most stable structure is the *Z*-enol form (11.7 kJ mol^{-1} above the global minimum), and next in stability to this is the *E*-enol form at 29.1 kJ mol^{-1} above the minimum. Both the most stable *Z*- and *E*-enol forms have HOCN dihedral angles of 0° and CNOH dihedral angles of 180°, indicating the stabilizing effect of having the C(OH) group closer to the C=N double bond and the N(OH) group further away. The *Z*-enol form is more stable than the *E*-enol one, illustrating the influence of intramolecular hydrogen bonding in the isolated molecules.

Figure 2 shows the geometries, charge distributions and overlap populations between appropriate atoms of the most stable structures. In both the keto and enol *Z* forms, the intramolecular hydrogen bonding is indicated by the overlap populations, which are 0.049 for the keto and 0.046 for the enol form. The charge on the carbonyl oxygen in the *Z*-keto form is −0.632, while the charge on the other oxygen is −0.479; the strong electronic repulsion between these two oxygens outweighs the intramolecular hydrogen bonding in the *Z*-keto form, thus the *E*-keto form is energetically favoured. Again in the *Z*-enol form, the hydrogen bonding and the oxygen–oxygen repulsion act in

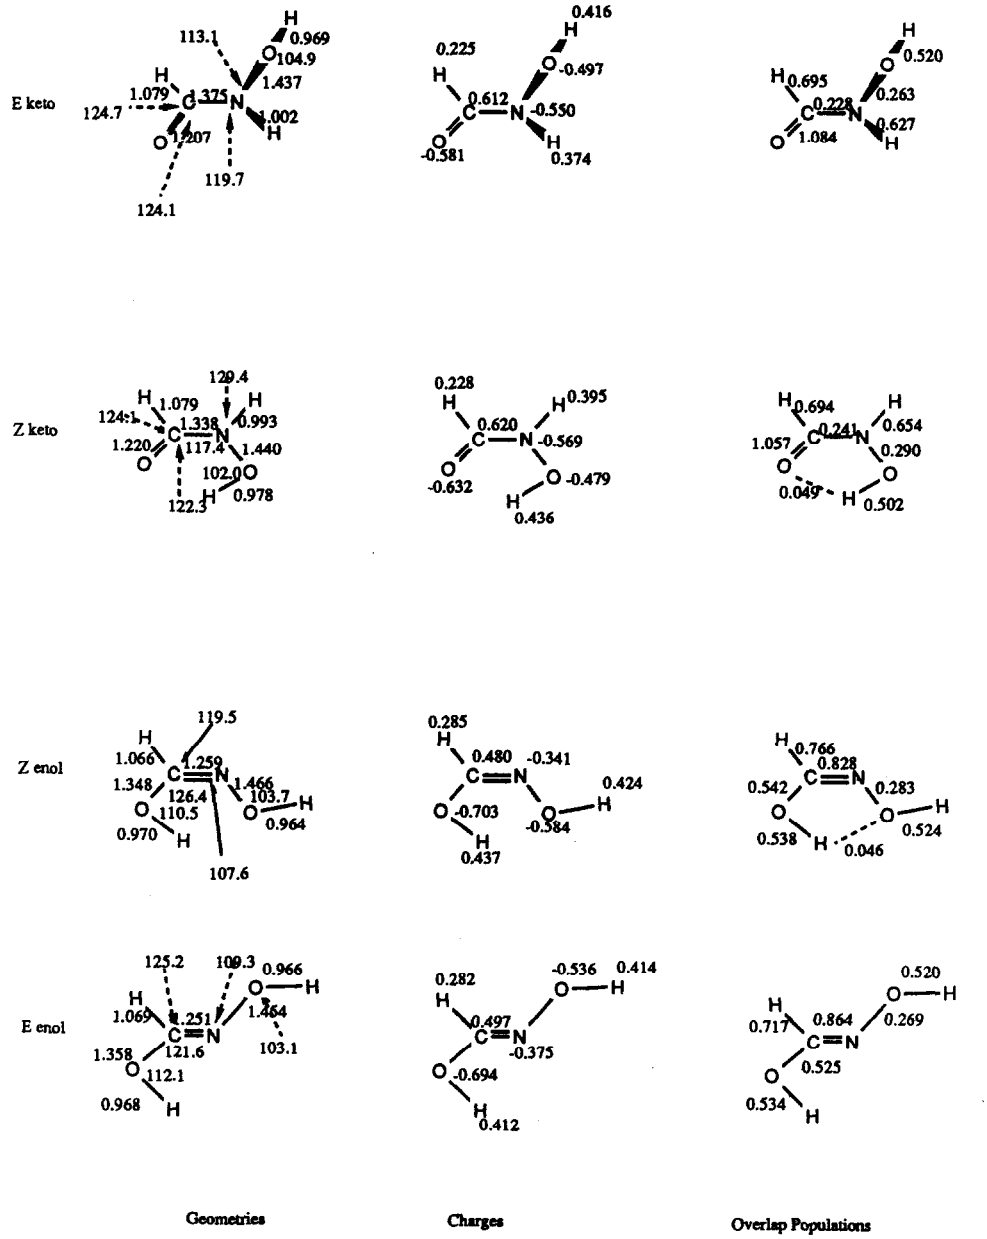

Fig. 2. Geometries, charges and overlap populations for the most stable forms of formohydroxamic acid. Bond lengths in Å, bond angles in degrees. In the *E*-keto form the dihedral angles are: HNCH = 157.0°; ONCH = 21.0°; HONC = 116.2°.

opposite directions. However, in this case the hydrogen bonding is more important and the *Z*-enol form is more stable than the corresponding *E*-enol one. The C—H bond lengths in the four most stable structures vary little, from 1.079 to 1.066 Å. Also the NH (from 1.002 to 0.993 Å) and OH (from 0.978 to 0.964 Å) bond lengths show little variation. However, the NO bond lengths vary by a reasonable amount in changing from the keto to the enol forms as expected, 1.437–1.454 Å (*E* forms) and 1.440–1.466 Å (*Z* forms). The C=O bond lengths are 1.207 Å (*E*) and 1.220 Å (*Z*), while the corresponding C—O distances in the enol forms are 1.358 Å (*E*) and 1.348 Å (*Z*). Thus the C=O bond lengthening in the *Z*-keto form, where there is hydrogen bonding, relative to the *E*-keto form, is noted. The C—N lengths are 1.375 Å (*E*) and 1.338 Å (*Z*), while the corresponding C=N distances are 1.251 and 1.259 Å. Thus the C=N bond distance differs little in the *E*- and *Z*-enol forms, but the C—N single bond distance is smaller in the *Z*-keto form, showing the effect of delocalization of the nitrogen lone pair in the planar *Z* form. The calculated XH (X = C, O, N) bond lengths are close

to the standard values of Pople and Beveridge.[8] However, the calculated N—O bond lengths are found to be greater than the standard value, as are the C—N bond lengths (the standard C—N bond length in the N—C=O groups is 1.32 Å), particularly in the *E*-keto form, where the nitrogen lone pair is not delocalized, due to non-planarity of the molecule, to the extent that it is in the *Z*-keto form. Most of the angles around carbon are close to 120°, while the NOH angle varies little (102.0–104.9°).

The charges on the oxygen atoms are large and negative in all of the four most stable structures. In the keto forms, carbons have large positive and nitrogen large negative charges; the absolute values of these are smaller (Fig. 2) in the enol forms due to the drift of electrons towards oxygen [N—C=O].

The overlap populations (Fig. 2) clearly show the bond order differences. The C—N bond orders are low, indicating ease of rotation about the C—N bond, even though hydrogen bonding may hinder rotation from the *Z* form. It is noteworthy that the *Z*-keto form has higher C—N and lower C=O overlap populations, showing more delocalization than the *E*-keto form. In the enol forms, the *Z* structure has lower C=N and higher C—O overlap populations, again showing the effects of delocalization. The extent of intramolecular hydrogen bonding in the *Z*-keto and -enol forms is also shown by the appreciative O···H overlap populations (0.049 in the keto, 0.046 in the enol; Fig. 2).

(b) *Hydrated formohydroxamic acids*

X-ray crystallographic studies have shown that in the solid state, acetohydroxamic acid exists in the *Z* form with a water molecule hydrogen bonded to two molecules of acetohydroxamic acid.[2] Preliminary NMR studies indicate that the *Z*-keto isomer predominates in DMSO-d_6, where there is the possibility of hydrogen bonding with the trace amount of water present, stabilizing the *Z* form.[4] Therefore it was decided to consider the four most stable forms of formohydroxamic acid (*E*- and *Z*-keto and enol forms) with varying amounts of water coordinated. Figure 3 shows the structures of the hydrated forms of formohydroxamic acid with varying amounts of coordinated water and their relative energies (kJ mol^{-1}).

From Fig. 3 it is seen that the most stable form, with one molecule of water coordinated, is now the *Z*-keto form, followed by the *E*-keto form. The enol forms with one molecule of water are at higher energy than the keto forms, while within the enol forms the *Z* structure has the lower energy.

In summary, with one molecule of coordinated water the stability order is *Z*-keto > *E*-keto > *Z*-enol > *E*-enol, while for the isolated species the order is *E*-keto > *Z*-keto > *Z*-enol > *E*-enol. In the most stable form with one molecule of water coordinated, there is appreciable hydrogen bonding; the (HO)H···O(=C) overlap population is 0.106 and the $(H_2)O\cdots H(ON)$ value is 0.164. The corresponding hydrogen–oxygen distances are 1.776 and 1.623 Å, respectively. In the *E*-keto form the hydrogen bonding is less; the (HO)H···O(=C) overlap population is 0.088 and the $(H_2)O\cdots H(N)$ value is 0.126. In this case the corresponding hydrogen–oxygen distances are 1.912 and 1.870 Å, respectively. Also, in the *Z*-keto form with one molecule of water, compared with the unhydrated form, the ONC angle is increased from 117.4 to 121.3°, and the O···O distance is increased from 2.666 to 2.824 Å, thus the oxygen–oxygen repulsion descreases.

In the enol forms, there are two possibilities. The oxygen atom of the water can be hydrogen bonded to either (CO)H or (NO)H. In both the *Z* and *E* forms, the former has the lower energies. In the enol form, as in the isolated molecules, the *Z* form has a lower energy than the *E* form. The hydrogen bonding is stronger in the *Z* form, where the $(H_2)O\cdots H(O)$ and (HO)H···O(N) overlap populations are 0.182 and 0.098, and the corresponding hydrogen–oxygen distances are 1.581 and 1.759 Å. In the *E*-enol form the corresponding overlap populations are less, $(H_2)O\cdots H(O) = 0.150$, $(HO)H\cdots N(O) = 0.073$; the corresponding distances are greater, 1.662 and 2.045 Å, respectively. The H···O overlap populations are greater than the H···N values and the corresponding hydrogen bond distances are in the reverse order.

The charge distributions in the hydrated molecules are of interest. The absolute value of the charge on the oxygen and hydrogen atoms involved in hydrogen bonding in both the *Z*-keto and -enol forms are larger than in the unhydrated form. In general, the addition of a molecule of water increases the absolute values of the negative charges on the oxygen attached to carbon and the nitrogen due to a drift of electrons: O → N → C → O.

The study was extended to formohydroxamic acid with two molecules of water. As seen from Fig. 3, the trend is the same as with one molecule of coordinated water. The order of stability in both cases is *Z*-keto > *E*-keto > *Z*-enol > *E*-enol. It is of interest to note that the spread of energies for the *Z*-keto, *E*-keto and *Z*-enol forms is small, only 12.8 kJ mol^{-1}, while the *E*-enol form is much higher in energy (58.8 kJ mol^{-1}) than the lowest energy *Z*-keto form. In the *E*-enol form with two water molecules the second water molecule, close to H(ON), pushes the first water molecule away from this group, reducing the hydrogen bonding between

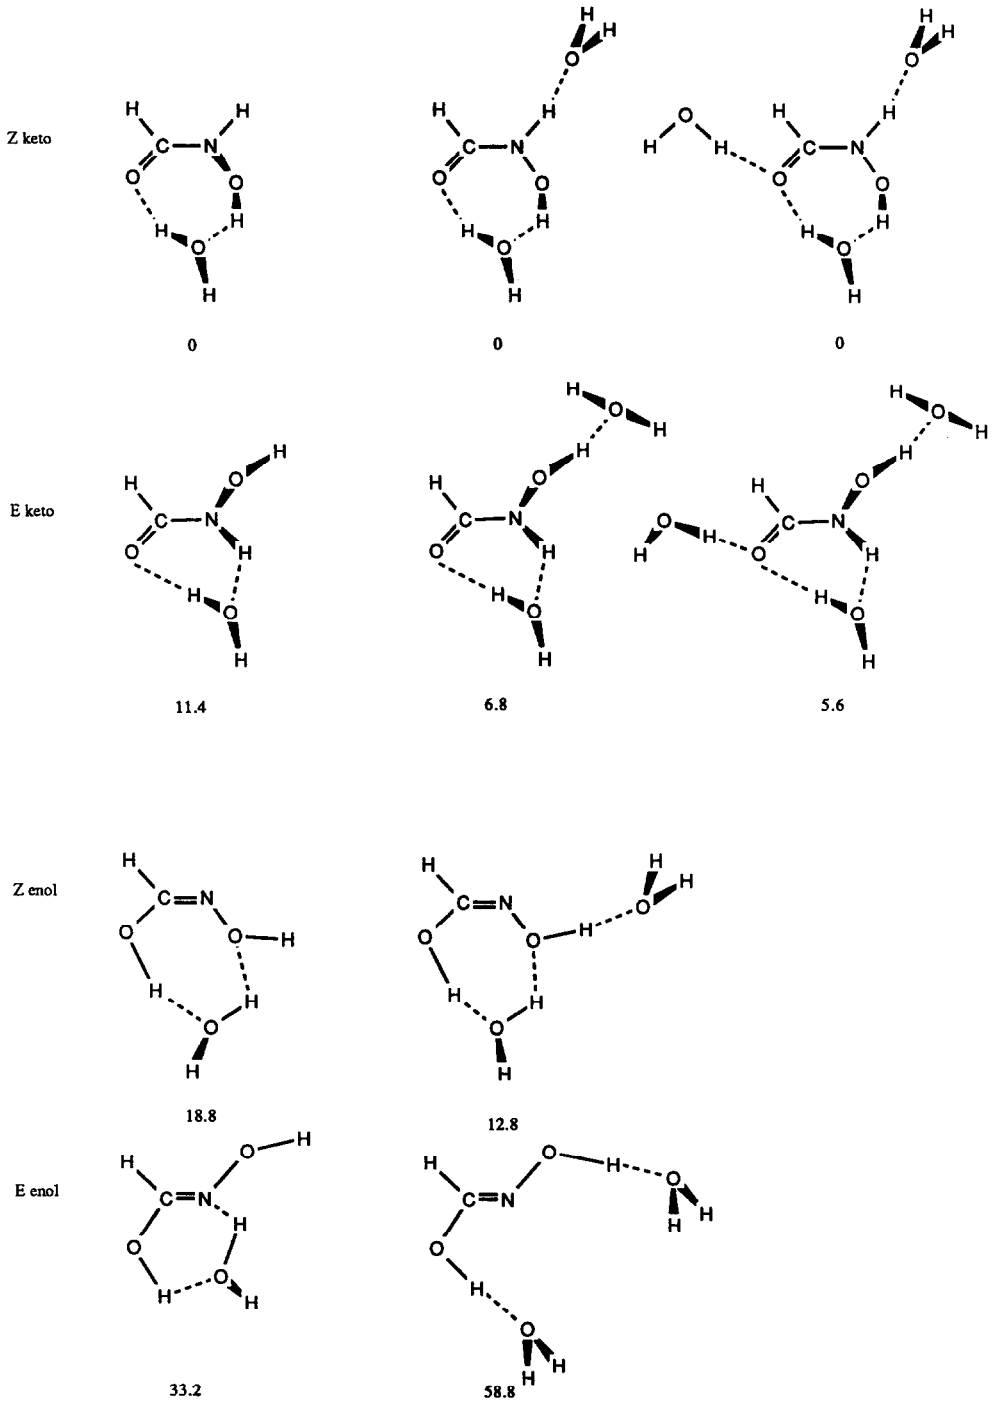

Fig. 3. Optimized structures and relative energies (kJ mol^{-1}) of formohydroxamic acid water complexes.

the hydrogen in the first water molecule and the nitrogen atom. The addition of a second molecule of water closer to H(N) in the *Z*-keto form, has a tendency to push the electron density $H \rightarrow O \rightarrow N \rightarrow C \rightarrow O$. In all forms the C–O distances are longer and the C–N distances shorter, with two water molecules coordinated than with one and the CO bond orders are decreased and the CN bond order increased by adding the second water molecule.

In the crystal structure of acetohydroxamic acid, the carbonyl oxygen is hydrogen bonded to two hydrogen atoms. Therefore the influence of a third molecule of water closer to the carbonyl oxygen was considered for the *Z*- and *E*-keto forms. Again the *Z* form was found to have the lower energy.

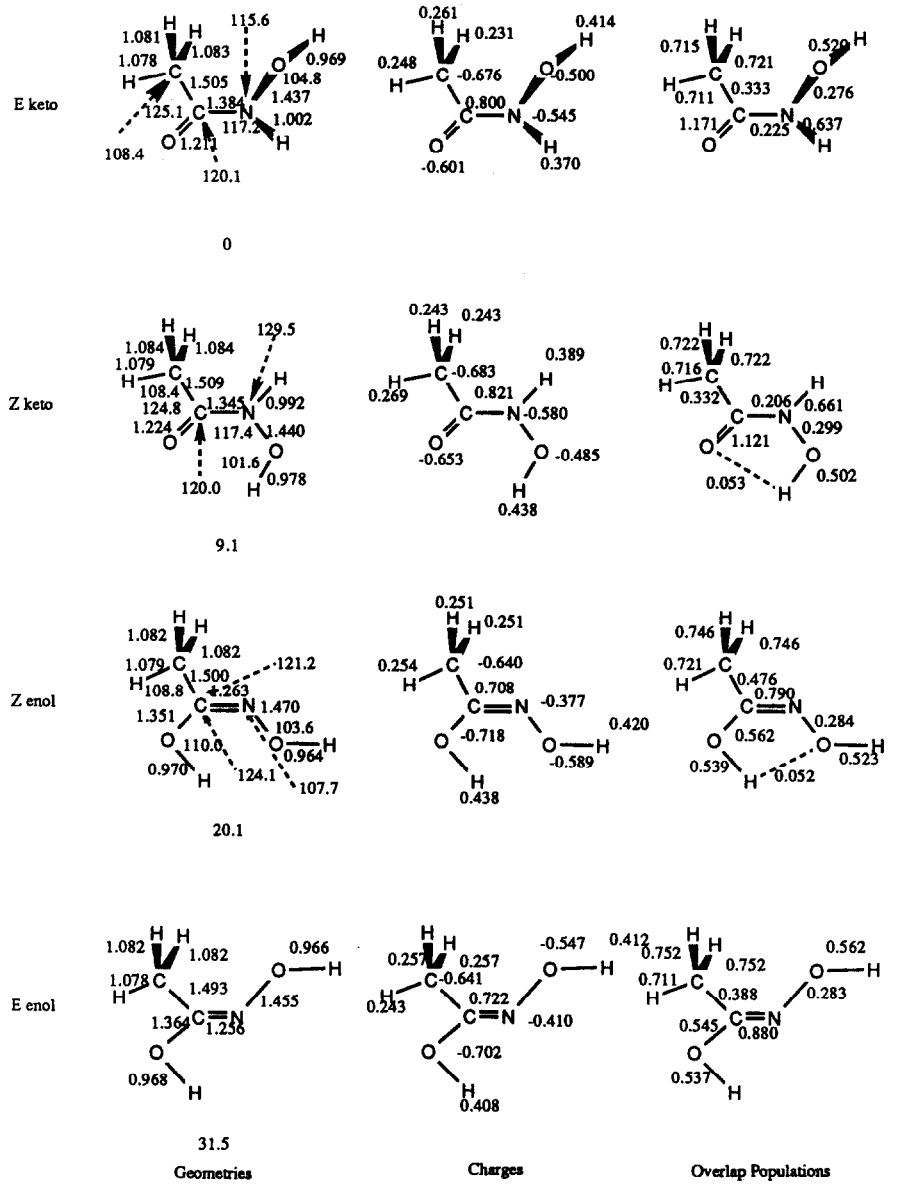

Fig. 4. Geometries, charges and overlap populations for the most stable forms of acetohydroxamic acid. Bond lengths in Å, bond angles in degrees. In the *E*-keto form the dihedral angles are: $HNCC(H_3) = 159.1°$; $ONCC(H_3) = 24.3°$.

The addition of a third molecule of water decreases the CN bond length and increases the corresponding CO value.

The energy of the *Z*-keto forms of HC(O)NH(OH) is −242.35451 au. The successive addition of water molecules lowers the energy by 75.62226, 75.60740 and 75.60167 au; thus the addition of the first water molecule to the isolated formohydroxamic acid has the greatest effect.

(c) *Acetohydroxamic acid*

The theoretical studies were extended to acetohydroxamic acid; the optimized structures are summarized in Fig. 4. As in the case of formohydroxamic acid, the lowest energy form is *E*-keto (−281.19064 au). The next lowest is *Z*-keto, followed by *Z*-enol and then *E*-enol; the same trend was calculated for formohydroxamic acid. The *Z*-keto, *Z*-enol and *E*-enol forms are 9.1, 20.1 and 31.5 kJ mol^{-1} above the *E*-keto structure, which are close to the values obtained for formohydroxamic acid. Thus the methyl substituent does not appreciably change the order or values of the relative energies. The CC(O)NH(OH) portion of the *Z*-keto and the CC(OH)=N(OH) portions of the *Z*- and *E*-enol forms are planar, which is analogous to the formohydroxamic results. The $ONCC(H_3)$ and

$HNCC(H_3)$ angles of the non-planar and stable *E* (keto) form are 24.3 and 159.1°, respectively. The carbonyl group charges show that replacement of a hydrogen by a methyl group increases the absolute values of the oxygen and carbon charges, but the remaining charges differ little in the two molecules. In the *Z*-keto form the importance of hydrogen bonding is indicated by the C=O···H overlap population (0.053), which is slightly greater than the corresponding value in formohydroxamic acid. Other changes in going from the *E*- to *Z*-keto forms of acetohydroxamic acid parallel those of the formohydroxamic acid.

Comparing the enol forms, it is noted that the (CO)H···O(N) overlap population (0.052) in *Z*-enol acetohydroxamic acid is slightly greater than the corresponding value in formohydroxamic acid (0.046). The absolute values of the O, N and C(O) charges in both the *Z*- and *E*-enol forms of acetohydroxamic acid are greater than those in the corresponding formohydroxamic acid. The changes in going from the *Z*- to *E*-enol forms parallel those of formohydroxamic acid. In the *Z*-enol form the C=N overlap population is appreciably less than that in the *E*-enol form, supporting the delocalization of electron density around the five-membered ring, as was found in the corresponding formohydroxamic acid.

Unlike formohydroxamic acid, it is possible to get methylene analogues by enolization of acetohydroxamic acid. Figure 5 shows the optimized geometries and relative energies of the different conformers considered. Of these, the lowest energy form, with energy of −281.15488 au is 93.9 kJ mol^{-1} above that of the most stable *E*-keto isomer of acetohydroxamic acid.

It is interesting to note that:

(i) not all, but most, of the conformers in Fig. 5 are planar;
(ii) in both the lower energy *E* and *Z* forms the H(OC) atom is on the same side of the OC bond as the methylene group;
(iii) in the most stable form, the geometry of the CNH(OH) group has not changed appreciably from the geometry in *E*-keto acetohydroxamic acid.

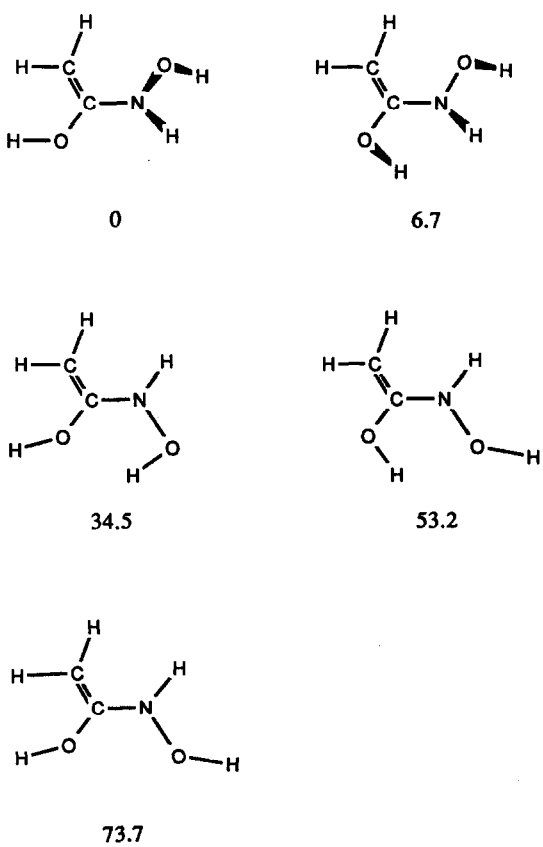

Fig. 5. Optimized structures and relative energies (kJ mol^{-1}) of CH_2=C(OH)NH(OH). The most stable form is 93.9 kJ mol^{-1} above the *E*-keto form of acetohydroxamic acid.

(d) *Hydrated acetohydroxamic acid*

Since the ^1H NMR indicated that in DMSO-d_6 $CH_3CONH(OH)$ may exist mainly in the *Z* form, it was decided to consider the two most stable forms of acetohydroxamic acid with one molecule of coordinated water. The optimized structures are shown in Fig. 6. As is the case of formohydroxamic acid,

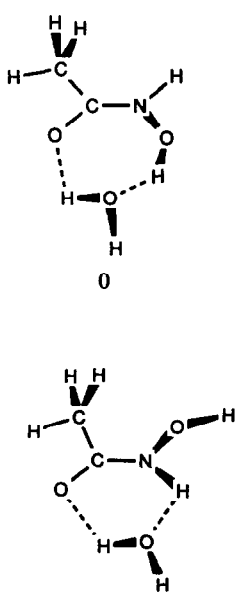

Fig. 6. Optimized structures and relative energies (kJ mol^{-1}) of acetohydroxamic acid water complexes.

the *Z*-keto form (−356.80822 au) was calculated to be more stable than the *E*-keto form; the energy difference is 8.9 kJ mol^{-1}. Thus, as in the case of formohydroxamic acid, hydration reverses the stability order of the keto forms. The difference in energy between the isolated *Z*-keto acetohydroxamic acid and its hydrated form (75.62103 au) is similar to the corresponding formohydroxamic value (75.62226 au).

N-*methyl and* O-*methyl acetohydroxamic acids*

Since it is possible that the *Z*–*E* ratios of N- and O-methylacetohydroxamic acids may vary in different solvents,[4] it was decided to consider the stabilities of these substituted acetohydroxamic acids. The results are shown in Figs 7 and 8, respectively. The N- or O-methyl substitution did not change the order of stability, since in both cases the *E*-keto forms are the most stable ones. The C(O)···H(ON) overlap population in the *Z*-keto form of N-methylacetohydroxamic acids (0.056) is slightly greater than that in acetohydroxamic acid (0.053), and the energy difference between the *Z*- and *E*-keto forms of $CH_3C(O)N(CH_3)OH$ (14.5 kJ mol^{-1}) is slightly greater than that in acetohydroxamic acid (9.1 kJ mol^{-1}). It is noteworthy, that in the N-methyl species, the two forms considered differ little in energy, indicating the importance of hydrogen bonding in the *Z*-keto form.

In O-methylacetohydroxamic acid, there is no NOH group to participate in hydrogen bonding, the *Z*-keto form is 39.8 kJ mol^{-1} above the *E*-keto form. Thus the importance of hydrogen bonding in

stabilizing structures in this series is noted. The calculations show that the *Z*- and *E*-enol forms, which have hydrogen bonds, are more stable than the *Z*-keto form. The order of stability is: *E*-keto > *Z*-enol > *E*-enol > *Z*-keto. The *Z*-enol form is 19.7 kJ mol^{-1} more stable than the *Z*-keto form, whereas the energy difference between the *E*-enol and *Z*-keto forms is smaller (8.7 kJ mol^{-1}). The other structures with the OH and OCH_3 groups rotated by 180° were considered and their energies are appreciably higher (Fig. 8). Figure 9 shows conformers of $CH_2{=}C(OH)NH(OCH_3)$. In all cases the energies are higher than the species in Fig. 8.

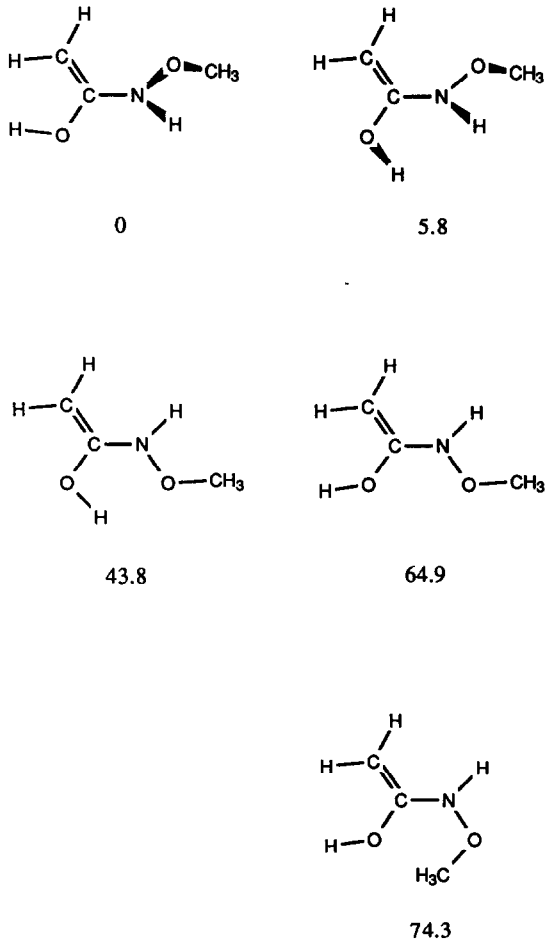

Fig. 9. Optimized structures and relative energies (kJ mol^{-1}) of CH_2=C(OH)NH(OCH_3). The most stable structure is 106.2 kJ mol^{-1} above the *E*-keto form of O-methylacetohydroxamic acid.

CONCLUSION

Ab initio molecular orbital calculations show that the isolated *E*-keto forms of formohydroxamic and acetohydroxamic acids have the lowest energy and that they are non-planar. Even though hydrogen bonding in the planar *Z*-keto species can occur, the *Z*-keto forms are less stable. However on hydration, oxygen–oxygen interactions decrease and hydrogen bonding increases, thus the *Z*-keto forms become the most stable. The importance of hydrogen bonding is noted in the *Z*-keto and in the enol forms. In the case of O-methylacetohydroxamic acid, where there is no possibility of hydrogen bonding the *Z*-keto form, the *Z*- and *E*-enol forms become more stable than the *Z*-keto form.

Abstract—Treatment of $[Mo(CO)_6]$ in tetrahydrofuran, with 1,1′-dilithioferrocene in light petroleum, followed by $(CF_3CO)_2O$ and tmeda ($Me_2NCH_2CH_2NMe_2$) affords the ferrocene-substituted bis(alkylidynemolybdenum) complex $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(O_2CCF_3)_2(CO)_4(tmeda)_2]$. The latter with $K[HB(pz)_3]$ [$HB(pz)_3$ = hydrotris(pyrazol-1-yl)borate] in CH_2Cl_2 gives $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$, which with $[Pt(cod)_2]$ (cod = cyclo-octa-1,5-diene), in light petroleum saturated with ethylene, yields the tetranuclear metal complex $[Mo_2FePt(\mu\text{-}\sigma,\sigma',\sigma'':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$. The structure of this product was established by *X*-ray diffraction, and the results of this study are compared with those obtained for related compounds in which the two metal–metal bonds of an acyclic trimetal system, in this case Mo—Pt—Mo, are each spanned by an alkylidyne group and semi-bridged by a carbonyl ligand.

The complexes $[M(\equiv CR)(CO)_2L]$ (M = W, Mo or Cr; R = alkyl or aryl; L = η-C_5H_5, η-C_5Me_5, or $HB(pz)_3$) have been widely employed as precursors for the synthesis of compounds containing heteronuclear metal–metal bonds.[1,2] The methodology involves addition of coordinatively unsaturated metal–ligand fragments to the C≡M triple bonds of the alkylidyne–metal reagents. This process can be carried out sequentially in some circumstances to construct molecular arrays in which chains or rings of metal atoms are held together by bridging alkylidyne ligands.[3]

The trimetal compounds $[M_2M'(\mu\text{-}CR)_2(CO)_4L_2]$ (**1**), obtained by treating the species $[M(\equiv CR)(CO)_2L]$ with zero-valent metal–alkene complexes $[M'(alkene)_n]$ (M′ = Ni, Pd or Pt; n = 3 or 4),[4] are important intermediates in many syntheses. This is because they are unsaturated, and metal–ligand fragments can be added to the dimetallacyclopropene ring systems present in **1**. The structures of three compounds of this class, **1a**,[4a] **1c**[4a] and **1q**,[4c] have been firmly established by *X*-ray diffraction studies. The molecules have essentially linear M—M′—M spines, with the two metal–metal bonds each bridged by an alkylidyne ligand and semi-bridged by a carbonyl group. The two alkylidyne fragments lie on the same side of the M—M′—M axis.

In this paper we describe the synthesis and structure of the novel tetranuclear metal complex $[Mo_2FePt(\mu\text{-}\sigma,\sigma',\sigma'':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$ (**2**), a species related to the compounds **1** but with the bridging alkylidyne carbon atoms linked by a ferrocene moiety. It was hoped that **2** might be a starting point for further syntheses based on addition of metal–ligand fragments to the C≡Mo bonds. Moreover, the structure of **2** was of interest, since the ferrocene group would constrain the positions of the ligated alkylidyne–carbon atoms. The possibility of a donor Fe→Pt bond also arises, since were such a linkage present it would provide a mechanism for relieving the electronic unsaturation at the platinum atom. In the compounds **1** the d^{10} metal atoms have formally 14-

electron shells, unless it is assumed that the RC≡ $M(CO)_2L$ ligands are each contributing either three or four electrons to the M′ centres rather than two.[5] If an Fe→Pt electron-pair donor bond was a feature of the structure of **2** the situation would be somewhat akin to that in the compound $[FePd(\mu\text{-}\sigma,\sigma':\eta^5\text{-}SC_5H_4)_2(PPh_3)]$ (**3**) which has an Fe→Pd linkage.[6]

RESULTS AND DISCUSSION

Compound **2** was prepared by treating a THF (tetrahydrofuran) solution of the bis(alkylidyne-molybdenum) compounds $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$ (**4**) with an ethylene-saturated THF solution of $[Pt(cod)_2]$ (cod = cycloocta-1,5-diene). Complex **4**, required for this synthesis, was obtained from the reaction between $K[HB(pz)_3]$ and $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(O_2CCF_3)_2(CO)_4(tmeda)_2]$ (**5**). The latter, the starting point for the sequence of reactions leading to **2**, was prepared via a procedure developed by Mayr and co-workers[7] for the synthesis of alkylidyne–metal compounds. For **5**, this involved treating a THF suspension of $[Mo(CO)_6]$ with 1,1′-dilithioferrocene, followed by addition of trifluoroacetic anhydride and tmeda.

Spectroscopic data characterizing compounds **4** and **5** are given in the Experimental. The IR spectra of both complexes show two terminal CO bands. For **4** these absorptions are at 1987 and 1904 cm^{-1}, and for **5** they are at 1992 and 1909 cm^{-1}. In addition, the IR spectrum of **5** shows a C=O absorption for the O_2CCF_3 group at 1735 cm^{-1}. In the $^{13}C\{^1H\}$ NMR spectra of **4** and **5** diagnostic peaks for alkylidyne–carbon nuclei occur at δ 293.2 and 286.9 ppm, respectively. Although it was possible to prepare **4** from **5** in virtually quantitative yield, the latter was obtained only in low and variable yield (*ca* 3–15%).

The synthesis of **2** proceeded smoothly in high yield (*ca* 80%). The IR spectrum displayed three CO stretching bands at 1970, 1941 and 1821 cm^{-1}. Although the two C_5H_4 groups in **2** are equivalent, each has two pairs of non-equivalent CH groups. Consequently, the ^1H NMR spectrum shows two signals for these groups at δ 4.22 and 4.72. In the

$^{13}C\text{-}\{^1H\}$ NMR spectrum the μ-C nuclei resonate at δ 300.6 ppm. This may be compared with the signal for the μ-C atoms in the spectrum of **1t** at δ 310.7 ppm.[4c] Interestingly, the CO ligands of **2** give rise to only a single peak at δ 231.1 ppm, in contrast with the related "bow-tie" type compounds (**1**), all of which show two peaks for the carbonyl groups in their $^{13}C\text{-}\{^1H\}$ NMR spectra.[4] To explain this observation a dynamic process is invoked for **1**, involving an oscillatory or rocking motion of the $Mo(CO)_2\{HB(pz)_3\}$ fragments so that exchange of CO ligands between terminal and semi-bridging sites occurs. This proposal is consistent with the rest of the spectrum which shows only three peaks for the carbon atoms of the $HB(pz)_3$ groups (δ 143.5, 134.5 and 104.6 ppm), when nine would be expected for a static structure. Similarly, there are only three resonances for the carbon atoms of the ferrocene group, that at δ 99.6 ppm being assigned to C^1 of the C_5H_4 rings and the peaks at δ 72.5 and 71.0 arising from the $C^{2,5}$ and $C^{3,4}$ carbons of the rings. Of particular interest is the $^{195}Pt\text{-}\{^1H\}$ NMR spectrum which shows a single peak at δ 76.8 ppm. This is in contrast with the platinum-containing trimetallic species, **1**, which show resonances in the range δ 1340–1750 ppm.[4b,c] It was thought initially that this large difference in chemical shift was due to the presence of a direct iron–platinum interaction in **2**, of the kind mentioned in the Introduction. However, this was disproved by an *X*-ray crystallographic study, the results of which are summarized by the data given in Table 1. The molecular structure is shown in Fig. 1.

Several features of the structure are of interest. Each molybdenum atom carries one terminal and one semi-bridging carbonyl group [Mo(1)—C(3)—O(3) 166.0(8) and Mo(2)—C(1)—O(1) 167.4(8)°]. The Mo—Pt separations (2.716 Å) are the same as those found (mean 2.716 Å) for the W—Pt distances in **1q**.[4c] Moreover, the μ-C—Mo and μ-C—Pt separations in **2** are also very similar to the μ-C—W and μ-C—Pt distances in **1q**. The Mo(1)—Pt—Mo(2) angle (167.9(1)°) in **2** may be compared with the corresponding W—Pt—W angle (172.8(1)°) in **1q**.

The Fe—Pt separation (3.715 Å) in **2** is clearly non-bonding, in contrast with the Fe—Pd distance (2.878 Å) in **3**.[6] Moreover, the C_5H_4 rings of the ferrocene moiety are not tilted, as would occur if a weak Fe—Pt interaction were to develop. It seems likely that the constraints imposed by the geometry around the sp^2 carbon atoms, C(10) and C(20), in **2** inhibit a closer approach of the iron and platinum atoms. In contrast, in **3** the sulphur atoms would be able to adjust to the more acute angle required to accommodate an Fe—Pd bond. Another important difference between **2** and **3**, however, relates to the respective oxidation states of the platinum and palladium atoms. The former in the zero oxidation state would seek to have a tetrahedral arrangement of ligating groups, whereas the latter in the oxidation state +II would have a preference for a square-planar arrangement of the coordinating groups.

In compound **2** the dihedral angle between the two dimetallacyclopropene rings (131°) is appreciably larger than those found previously (Table 2) for these rings in the structures of **1a**,[4a] **1c**[4a]

Table 2.

Complex	M—M′—M angle (°)	Dihedral angle (°)[a]	M μ-C
$[Mo_2FePt(\mu\text{-}\sigma,\sigma',\sigma'':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$ (**2**)	167.9	131	$[W_2Pt(\mu\text{-}CC_6H_4Me\text{-}4)_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (**1c**)	165.5	97	$[W_2Ni(\mu\text{-}CC_6H_4Me\text{-}4)_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (**1a**)	174.5	93	$[W_2Pt(\mu\text{-}CMe)_2(CO)_4\{HB(pz)_3\}_2]$ (**1q**)	172.8	79	$[W_2Au(\mu\text{-}CC_6H_4Me\text{-}4)_2(CO)_4(\eta\text{-}C_5H_5)_2]^+$ (**6**)	162.8	62	
[a] Dihedral angle between the two dimetallacyclopropene rings. Angles greater than 90° reflect a distortion towards a square-planar geometry with a *cis*-C_2M' fragment. Conversely, angles less than 90° reflect a distortion towards a square-planar geometry with a *trans*-C_2M' fragment. The constraints of the two dimetallacyclopropene rings lead to μ-C—M′—M angles which are significantly less than those expected for idealized tetrahedral (or square-planar) geometries.[4a]

and **1q**,[4c] and in the salt $[W_2Au(\mu\text{-}CC_6H_4Me\text{-}4)_2(CO)_4(\eta\text{-}C_5H_5)_2][PF_6]$ (**6**).[8] The latter has the smallest inter-planar dihedral angle, but the structure differs from those of the other compounds by the absence of semi-bridging carbonyl groups. The large dihedral angle between the two dimetallacyclopropene rings in **2** may be attributed to the constraint imposed by the ferrocene fragment, resulting in C(10) and C(20) (Fig. 1) becoming distorted away from a pseudo-tetrahedral coordination around the platinum. However, the geometries of the metallacyclopropene rings in all these compounds, with their μ-C—M′—M angles of *ca* 45°, result in angles at the central metal atom, M′, which are far from tetrahedral.[4a]

The synthesis of complex **2** represents a novel addition to the class of compounds of type **1**. Unfortunately the use of **2** in the preparation of polynuclear metal species is currently inhibited by the poor yields in the synthesis of its precursor, **5**.

EXPERIMENTAL

All experiments were carried out under nitrogen, using Schlenk tube techniques. Solvents were rigorously dried before use. Light petroleum refers to that fraction of b.p. 40–60°C. Alumina used for chromatograhy columns was BDH aluminium oxide (Brockman activity II). The instrumentation employed for the spectroscopic measurements has been reported previously.[9] NMR chemical shifts (δ) are in ppm, and coupling constants are in Hz. The reagents $[Pt(cod)_2]$[10] and 1,1′-dilithioferrocene[11] were prepared by the methods described earlier.

Preparation of ferrocene-substituted alkylidyne molybdenum compounds

(i) A THF (50 cm^3) suspension of $[Mo(CO)_6]$ (5.3 g, 20.0 mmol) was treated with a hexane (100 cm^3) suspension of the tmeda complex of 1,1′-dilithioferrocene (0.10 mol dm^{-3}, 10 mmol). Sufficient light petroleum (*ca* 50 cm^3) was then added to the red–brown solution to complete the separation of a dark oil. The supernatant liquid was discarded, and the residual oil was washed twice with light petroleum (100 cm^3) and once with Et_2O (100 cm^3); ultrasonic irradiation being used each time to agitate the mixtures. The oily solid was then dried *in vacuo*, dissolved in THF (100 cm^3), and cooled to *ca* −80°C. Trifluoroacetic anhydride (3.0 cm^3, 25 mmol) was added, followed by tmeda (3.5 cm^3, 20 mmol). The mixture was warmed to room temperature, stirred for 30 min, and then filtered through an alumina plug (5 × 5 cm). Solvent was removed *in vacuo*, and the residue was dissolved in a minimum of CH_2Cl_2 (*ca* 15 cm^3) and chromatographed on alumina (4 × 30 cm column). Elution with CH_2Cl_2 removed a yellow uncharacterized side product. Subsequent elution with CH_2Cl_2–THF (3:2) gave a red fraction. Removal of solvent *in vacuo*, followed by crystallization of the residue from a mixture of CH_2Cl_2 (10 cm^3) and hexane (30 cm^3) at −78°C, gave pink–red *microcrystals* of $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(O_2CCF_3)_2(CO)_4(tmeda)_2]$ (**5**) (1.0 g, 10%). IR: ν_{max} (in THF) at 1992s, 1909vs(CO) and 1735m cm^{-1} (C=O). NMR ($CDCl_3$): ^1H, δ 2.60, 2.72, 2.95 (s × 3, 32 H, tmeda), 4.43 and 4.56 [s(br) × 2, 8 H, C_5H_4]; $^{13}C\text{-}\{^1H\}$, δ 286.9 (C≡Mo), 225.0 (CO), 160.6 [q, C=O, J(FC) 19.5], 116.3 [q, CF_3, J(FC) 291], 90.5 [$C_{ipso}(C_5H_4)$], 70.9, 70.4 [$C^{2-5}(C_5H_4)$], 59.8, 55.7 and 50.0 (tmeda).

(ii) A CH_2Cl_2 (50 cm^3) suspension of **5** (0.42 g, 0.43 mmol) and $K[HB(pz)_3]$ (0.25 g, 0.86 mmol) was stirred for 5 h. Solvent was removed *in vacuo*, and the residue was dissolved in a mixture of CH_2Cl_2 (5 cm^3) and toluene (10 cm^3), and chromatographed on a water-cooled alumina column (5 × 20 cm). Elution with the same solvent mixture removed a red band. Solvent was evaporated *in vacuo*, and the residue was crystallized at −78°C from a mixture of CH_2Cl_2 (3 cm^3) and hexane (20 cm^3) to afford pink *microcrystals* of $[Mo_2Fe(\mu\text{-}\sigma,\sigma':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$ (**4**) (0.40 g, 94%). (Found: C, 43.8; H, 3.0; N, 17.0. $C_{34}H_{28}B_2FeMo_2N_{12}O_4$ requires: C, 43.5; H, 3.0; N, 17.9%.) IR: ν_{max} (in CH_2Cl_2) at 1987s and 1904vs cm^{-1} (CO). NMR (in $CDCl_3$): ^1H, δ 4.50, 4.76 [s(br) × 2, 8 H, C_5H_4], 6.17, 7.65, 7.91 (m × 3, 18 H, $C_3H_3N_2$); $^{13}C\text{-}\{^1H\}$, δ 293.2 (C≡Mo), 225.4 (CO), 143.4, 142.2, 134.6, 104.6 ($C_3H_3N_2$), 89.9 [$C_{ipso}(C_5H_4)$], 71.2 and 70.9 [$C^{2-5}(C_5H_4)$].

Preparation of $[Mo_2FePt(\mu\text{-}\sigma,\sigma',\sigma'':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$

The compound $[Pt(cod)_2]$ (0.17 g, 0.41 mmol) was dissolved portion-wise in cold (0°C) ethylene-saturated THF (25 cm^3). This mixture was then transferred (ethylene pressure) via a flexible steel cannula to a THF (25 cm^3) solution of **4** (0.38 g, 0.41 mmol), and the reactants were stirred for 3 h. Solvent was removed *in vacuo*, and the residue was dissolved in CH_2Cl_2–light petroleum (10 cm^3, 2:1) and chromatographed. Elution with the same solvent mixture removed a dark red fraction from which solvent was removed *in vacuo*. The residue was crystallized from CH_2Cl_2–EtOH (10 cm^3, 1:5) to give red *crystals* of $[Mo_2FePt(\mu\text{-}\sigma,\sigma',\sigma'':\eta^5\text{-}CC_5H_4)_2(CO)_4\{HB(pz)_3\}_2]$ (**2**) (0.37 g, 82%). [Found: C, 30.2; H, 2.0. $C_{34}H_{28}B_2FeMo_2N_{12}O_4Pt$

requires: C, 29.7; H, 1.8%.] IR: ν_{max} (in CH_2Cl_2) at 1970s, 1941vs and 1821m(br) cm^{-1} (CO). NMR (in CD_2Cl_2): ^1H, 4.22, 4.72 (s × 2, 8 H, C_5H_4), 6.17, 7.68 and 8.15 (s × 3, 18 H, $C_3H_3N_2$); ^{13}C-{^1H}, δ 300.6 (μ-C), 231.3 (CO), 143.5, 134.5, 104.6 ($C_3H_3N_2$), 99.6 [$C_{ipso}(C_5H_4)$], 72.5 and 71.0 [$C^{2-5}(C_5H_4)$]; ^{195}Pt-{^1H}, δ 76.8 (to high frequency of Ξ (^{195}Pt) $\simeq$ 21.4 MHz).

Crystal structure determination

Dark red prisms of **2** were grown from CH_2Cl_2–light petroleum. That chosen for data collection (*ca* 0.56 × 0.56 × 0.60 mm) was sealed under nitrogen in a Lindemann glass capillary. Diffracted intensities were collected (θ–2θ scans) at 298 K in the range $3.0 \leqslant 2\theta \leqslant 50°$, on a Nicolet *P3m* four-circle diffractometer. Of 5190 unique reflections, 3929 had $F \geqslant 4\sigma(F)$, and only these data were used in the solution and refinement of the structure. Corrections were applied for Lorentz, polarization and *X*-ray absorption effects; the latter by a procedure based on azimuthal scan data.[12]

Crystal data for **2**. $C_{34}H_{28}B_2FeMo_2N_{12}O_4Pt \cdot 1.5CH_2Cl_2$, $M = 1260.5$, monoclinic, $a = 16.188(4)$, $b = 13.585(6)$, $c = 20.820(8)$ Å, $\beta = 103.67(3)°$, $U = 4449(2)$ Å^3, $Z = 4$, $D_c = 1.89$ g cm^{-3}, $F(000) = 2520$, space group $P2_1/a$, Mo-K_α *X*-radiation ($\bar{\lambda} = 0.71069$ Å, graphite monochromator), μ(Mo-K_α) = 43.2 cm^{-1}.

The structure was solved, and all non-hydrogen atoms located, by conventional heavy-atom and difference Fourier methods. Hydrogen atoms were included in calculated positions (C—H, 0.96 Å) with fixed isotropic thermal parameters. The metal atoms and carbon atoms of the C_5H_4 and CO groups were refined anisotropically; the remaining atoms were refined isotropically. Refinement by blocked-cascade least-squares converged at $R = 0.048$ ($R_w = 0.047$) with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.000325|F|^2]$.* The final electron-density difference synthesis showed no residual peaks $\geqslant 0.99$ or $\leqslant -0.85$ eÅ^{-3}. Scattering factors and corrections for anomalous dispersion were taken from ref. 13. All calculations were carried out using a DEC micro-Vax II computer with the SHELXTL PLUS system of programs.[12]

*Atomic positional and thermal parameters, bond lengths and angles, and structure factor values have been deposited as supplementary material with the Editor. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

COMPOUNDS WITH PLATINUM–MOLYBDENUM OR –TUNGSTEN BONDS DERIVED FROM THE ALKYLIDYNE METAL COMPLEXES $[M(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (M = Mo OR W; R = C_6H_4Me-4 OR $C_6H_3Me_2$-2,6)

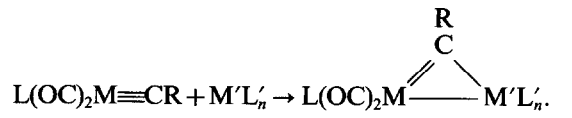
THOMAS P. SPANIOL and F. GORDON A. STONE*

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, U.K.

(*Received* 12 *April* 1989; *accepted* 28 *April* 1989)

Abstract—The compound $[Pt(C_2H_4)_2(PPr^i_3)]$ in light petroleum reacts with the reagents $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (M = W or Mo) to afford the electronically unsaturated 30 valence electron dimetal complexes $[MPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(\mu\text{-}CO)(CO)(PPr^i_3)(\eta\text{-}C_5H_5)]$. The latter readily add a molecule of CO or CNR (R = Bu^t or $C_6H_3Me_2$-2,6) to give the compounds $[MPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(PPr^i_3)(L)(\eta\text{-}C_5H_5)]$ (M = W, L = CO or CNR; M = Mo, L = CO). Protonation of these species with $HBF_4\cdot OEt_2$ affords the salts $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(PPr^i_3)(L)(\eta\text{-}C_5H_5)][BF_4]$ (L = CO or CNR) and $[MPt\{\mu\text{-}\sigma:\eta^3\text{-}C(H)C_6H_3Me_2\text{-}2,6\}(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (M = Mo or W). Whereas the xylylidyne compounds $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ react with the complexes $[Pt_3(CNR)_6]$ to yield the dimetal species $[MPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNR)_2(\eta\text{-}C_5H_5)]$, the *p*-tolylmethylidyne analogues $[M(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ on treatment with the platinum isocyanide reagents give the trimetal complexes $[MPt_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_2(CNR)_4(\eta\text{-}C_5H_5)]$. NMR data for the new compounds are reported and discussed.

The carbon–metal triple bonds of the alkylidyne complexes $[M(\equiv CR)(CO)_2L]$ [M = W, Mo or Cr; R = alkyl or aryl; L = η-C_5H_5, η-C_5Me_5 or $HB(pz)_3$ {hydrotris(pyrazol-1-yl)borate}] readily add low-valent metal–ligand fragments, thereby providing a versatile route to compounds having heteronuclear metal–metal bonds:[1]



By this procedure, dimetal species involving most of the transition elements have been obtained.[2] Among the first reactions of this type to be studied were those between the tungsten compound, $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$, and the zero-valent platinum species, $[Pt(C_2H_4)(PR_3)_2]$ (R = Me or Ph). In this manner the compounds $[WPt(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(PR_3)_2(\eta\text{-}C_5H_5)]$ (**1**) were prepared.[3] As a consequence of the success of this early work, the *p*-tolylmethylidyne tungsten complex became the reagent of choice for testing the general applicability of this method of synthesizing dimetal compounds.[1c] However, later studies with other alkylidyne metal complexes $[M(\equiv CR)(CO)_2L]$ [M = Cr, Mo or W, R = $C_6H_3Me_2$-2,6, L = η-C_5H_5;[2a] M = Mo, R = C_6H_4Me-4, L = η-C_5H_5;[2d] M = W, R = C_6H_4Me-4, L = $HB(pz)_3$ or η-C_5Me_5;[2e,f] M = W, R = $SiPh_3$, L = C_5H_5[4a]] revealed that the nature of the products obtained depends on the metal M, the group L, and the substituent R on the ligated carbon atom of the C≡M bond. Thus, for example, by varying L or R the C≡M moiety can function formally towards an $M'L'_n$ fragment as either a two- or a four-electron donor.[2a,f] Moreover, changing the ligands L′ present in the $M'L'_n$ moiety can also influence the structure of the heteronuclear dimetal compounds isolated.

Further extending the scope of this area of heteronuclear metal–metal bond chemistry, we report herein reactions of the compounds $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (M = Mo or W) with the zero-valent platinum reagents $[Pt(C_2H_4)_2(PPr^i_3)]$[4] and $[Pt_3(CNR)_6]$ (R = Bu^t or $C_6H_3Me_2$-2,6).[5] The platinum species function as

* Author to whom correspondence should be addressed.

sources of the 12-electron $Pt(PPr^i_3)$ and 14-electron $Pt(CNR)_2$ fragments, respectively. A comparison can thus be made with the earlier results involving $Pt(PR_3)_2$ groups,[3] mentioned above. Moreover, an extension of studies[2a,6] with the reagents $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ was of particular interest, since the presence of the bulky xylyl group on the alkylidyne-carbon atom has been shown to influence the nature of the products obtained, compared with analogous reactions employing the species $[M(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. Indeed, as described below, a further example of the differing patterns of behaviour is revealed in the reactions involving the triplatinum isocyanide complexes.

RESULTS AND DISCUSSION

In light petroleum at 0°C, the compound $[Pt(C_2H_4)_2(PPr^i_3)]$, generated *in situ* from $[Pt(cod)_2]$ (cod = cyclo-octa-1,5-diene), PPr^i_3 and C_2H_4, reacts with the species $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (M = W or Mo) to give the dimetal complexes $[MPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(\mu\text{-}CO)(CO)(PPr^i_3)(\eta\text{-}C_5H_5)]$ [M = W (**2a**) or Mo (**2b**)], characterized by the data given in Tables 1–3. In their IR spectra both compounds show a band at *ca* 1750 cm^{-1}, suggesting the presence of a bridging carbonyl ligand. The $^{13}C\text{–}\{^1H\}$ NMR spectra were informative (Table 2). For both compounds only one CO resonance was observed, indicating that the two carbonyl groups undergo rapid site-exchange on the NMR time scale. The carbonyl signals are doublets due to $^{31}P\text{–}^{13}C$ coupling, and these signals also show ^{195}Pt satellite peaks. These couplings support the IR evidence for a bridging CO ligand. Resonances for the ligated carbon nuclei of the xylylidyne ligands were observed at δ 290.4 (**2a**) and 307.9 ppm (**2b**). These chemical shifts are little different from those found for the terminally bound xylylidyne groups in the spectra of the precursors $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (M = W, δ 297.4 ppm; M = Mo, δ 310.5 ppm).[2a] Moreover, although the resonances for the alkylidyne μ-C nuclei in compounds **2a** and **2b** show $^{31}P\text{—}^{13}C$ and $^{195}Pt\text{–}^{13}C$ couplings, the values observed (Table 2) are about half those associated with the corresponding signals in the $^{13}C\text{–}\{^1H\}$ NMR spectra of the complexes **1** [J(PC) *ca* 60; J(PtC) *ca* 750 Hz].[3] Also in the spectra of the latter, the chemical shifts of the μ-C nuclei (*ca* δ 340 ppm) are appreciably more deshielded than those in the spectra of **2a** and **2b**. As discussed previously,[7] these data provide strong evidence that in **2a** and **2b** the xylylidyne ligands asymmetrically bridge the metal–metal bonds, being much closer to the tungsten or molybdenum atoms than to the platinum. In the complex $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(PEt_3)(\mu\text{-}\sigma:\eta^5\text{-}$

[a] Chemical shifts (δ) in ppm, ^1H decoupled, coupling constants in Hz, measurements in CD_2Cl_2.
[b] Chemical shifts are positive to high frequency of 85% H_3PO_4 (external).
[c] Chemical shifts are positive to high frequency of Ξ (^{195}Pt) 21.4 MHz.
[d] Isomeric mixture, see text. Asterisk denotes peak due to minor isomer.

$C_2B_9H_8Me_2$)] (**3**), for which an asymmetrically bridging μ-$CC_6H_3Me_2$-2,6 group has been established by X-ray diffraction,[7] the μ-C resonance in the ^{13}C–{^1H} NMR spectrum occurs as a doublet at δ 279.9 ppm, with J(PC) 22 Hz; values comparable with those observed for **2a**. The ^{13}C–{^1H} NMR data for the recently reported compound [WPt(μ-CSiPh$_3$)(μ-CO)(CO)(PPr$^i_3$)(η-C_5H_5)] (**2c**) are also relevant.[4a] This species, prepared by treating [W(≡CSiPh$_3$)(CO)$_2$(η-C_5H_5)] with [Pt(C_2H_4)$_2$(PPr$^i_3$)], has also been assigned a structure with a bridging carbonyl group (ν_{max} 1764 cm^{-1}), and with the alkylidyne ligand asymmetrically spanning the metal–metal bond. Although the chemical shift (δ 339.4 ppm) for the μ-C ligand is more deshielded than those for this nucleus in the spectra of **2a** and **2b**, the values of the coupling constants for **2c** [J(PC) 31, J(PtC) 382 Hz] are very similar to those of **2a** (Table 2).

The compounds **2** and **3** are formally electronically unsaturated, being 30 valence electron dimetal species. Reflecting this property, compound **3** reacts readily with carbon monoxide yielding [WPt(μ-$CC_6H_3Me_2$-2,6)(CO)$_3$(PEt$_3$)(μ-σ: η^5-$C_2B_9H_8Me_2$)], a 32 valence electron dimetal complex containing a Pt(CO)(PEt$_3$) fragment. Similarly, treatment of **2a** or **2b** in CH_2Cl_2 with CO affords the complexes [MPt(μ-$CC_6H_3Me_2$-2,6)(CO)$_3$(PPr$^i_3$)(η-C_5H_5)] [M = W (**4a**) or Mo (**4b**)] in essentially quantitative yield. The spectroscopic properties (Tables 1–3) are in agreement with the structures proposed. The IR spectra show three bands in the CO stretching region; those at 1846 (**4a**) and 1847 cm^{-1} (**4b**) suggesting the presence of semi-bridging ligands. The ^{13}C–{^1H} NMR spectra show diagnostic μ-$CC_6H_3Me_2$-2,6 resonances at δ 330.9 [J(PtC) 835] (**4a**) and at 357.9 ppm [J(PtC) 900 Hz] (**4b**). The absence of ^{31}P–^{13}C coupling on these signals strongly suggests that the μ-C and PPr$^i_3$ groups are *cisoid* to one another. The values observed for the chemical shifts, and the ^{195}Pt–^{13}C couplings, are very similar to those found for the compounds **1**. The latter have structures in which the bridging alkylidyne groups form strong σ-bonds to the platinum atom.[3] Hence from the ^{13}C–{^1H} NMR data this is likely to be true for the species **4a** and **4b** also. Therefore the asymmetric bridging of the μ-C atoms in the compounds **4a** and **4b** is very probably less pronounced than in the compounds **2**. In the ^{13}C–{^1H} NMR spectra of **4a** and **4b** (Table 2) there are two CO resonances corresponding to the M(CO)$_2$ (M = W or Mo) and PtCO groups. Evidently the peaks for the two carbonyls ligating the tungsten or molybdenum atoms are time-

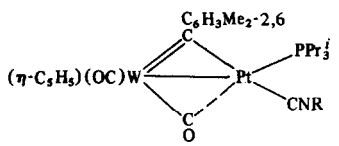
averaged. As expected, the ^{195}Pt–^{13}C couplings observed on these signals are much smaller than those for compounds **2a** or **2b**, in which carbonyl bridging is more pronounced.

The dimetal complexes **4a** and **4b** are analogues of the compounds $[WPt(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_3(PR_3)(\eta\text{-}C_5H_5)]$ [PR_3 = PMe_3 (**4c**), PMe_2Ph (**4d**), $PMePh_2$ (**4e**) or PPh_3 (**4f**)], previously prepared by treating the species **1** with CO.[3b] In these reactions it is the PR_3 group *transoid* to the μ-CC_6H_4Me-4 ligand which is substituted by CO leading to a *cisoid* μ-$CPtPR_3$ configuration, as proposed for **4a** and **4b**.

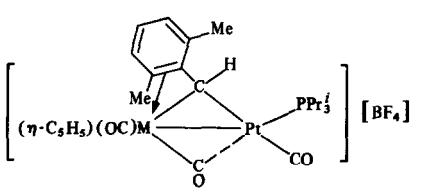
Compound **2a** also readily reacts with the isocyanides CNR (R = $C_6H_3Me_2$-2,6 or Bu^t) to afford the complexes $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNR)(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**5**). Data characterizing these species are given in Tables 1–3. Examination of the NMR spectra of the product from $CNBu^t$ revealed, however, that it was formed as a mixture of two isomers (*ca* 3.5 : 1, based on peak intensities). In the ^{13}C–$\{^1H\}$ spectrum the signals for the major isomer indicate a structure **5b** similar to that of **5a**, with the PPr^i_3 group *cisoid* to the μ-C nucleus. Thus the μ-C resonance at δ 336.8 ppm shows no ^{31}P coupling, in agreement with a *cisoid* μ-CPtP arrangement. In contrast, the less intense μ-C signal for the minor isomer at δ 326.0 ppm is a doublet [J(PC) 46 Hz], in accord with a *transoid* μ-CPtP configuration. Also as expected, in the ^{31}P–$\{^1H\}$ NMR spectrum (Table 3) the resonance for the major isomer, **5b** (δ 44.2 ppm), displays a larger ^{195}Pt–^{31}P coupling than the peak for the minor isomer, **5c** (δ 43.2 ppm), in agreement with the former species having a *transoid* PPtW arrangement and the latter a *cisoid* PPtW configuration.

Protonation of complexes **4a**, **4b** and **5** was next investigated. Treatment of **4a** in Et_2O with $HBF_4 \cdot OEt_2$ afforded an inseparable mixture of the isomeric compounds $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**6a**) and $[WPt\{\mu\text{-}\sigma\text{: }\eta^3\text{-}C(H)C_6H_3Me_2\text{ - }2,6\}(CO)_3(PPr^i_3)(\eta\text{ - }C_5H_5)][BF_4]$ (**7a**). In contrast, addition of $HBF_4 \cdot OEt_2$ to **4b** yields exclusively $[MoPt\{\mu\text{-}\sigma\text{: }\eta^3\text{-}C(H)C_6H_3Me_2\text{-}2,6\}(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**7b**), a species structurally similar to **7a**. Protonation of **5a** or **5b** (isomeric mixture) also affords a single product. However, the salts $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNR)(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ [R = $C_6H_3Me_2$-2,6 (**6b**) or Bu^t (**6c**)] obtained are μ-hydrido species analogous to **6a**. Data for these compounds, summarized in the tables, are in agreement with the structures proposed. Moreover, we have previously shown that protonation of the compounds **1a**–**1c** affords the salts $[WPt\{\mu\text{-}\sigma\text{: }\eta^3\text{-}C(H)C_6H_4Me\text{-}4\}(CO)_2(PR_3)_2(\eta\text{-}C_5H_5)][BF_4]$ [PR_3 = PMe_3 (**8a**), PMe_2Ph (**8b**) or $PMePh_2$ (**8c**)]; the nature of **8a** being firmly based on an X-ray diffraction study.[8a] The structures of these salts are similar to those of **7**, with the bridging CHR group adopting a $\mu\text{-}\sigma\text{: }\eta^3$ bonding mode.

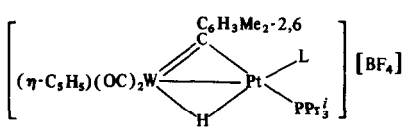
The ^1H NMR spectra of the μ-hydrido complexes **6** all show the expected highfield resonance with ^{195}Pt and ^{183}W satellite peaks (Table 2). For **6a** and **6b** these signals appear as doublets due to ^{31}P–^1H coupling, but this is weak (*ca* 3 Hz); a result strongly suggesting a *cisoid* $HPtPPr^i_3$ arrangement with a consequential *transoid* μ-$CPtPPr^i_3$ configuration. That the PPr^i_3 ligand is *transoid* to the μ-$CC_6H_3Me_2$-2,6 group in the complexes **6** is supported by the appearance of the μ-C signals as



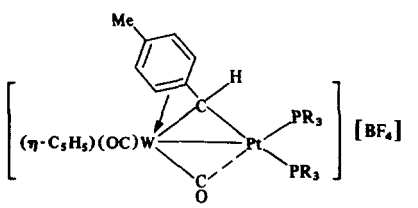
R
(**5a**) $C_6H_3Me_2$-2,6
(**5b**) Bu^t



M
(**7a**) W
(**7b**) Mo



L
(**6a**) CO
(**6b**) $CNC_6H_3Me_2$-2,6
(**6c**) $CNBu^t$



PR_3
(**8a**) PMe_3
(**8b**) PMe_2Ph
(**8c**) $PMePh_2$

doublets [J(PC) 40–48 Hz] in the $^{13}C-\{^1H\}$ NMR spectra.

Examination of the NMR spectra of the isomeric mixture of **6a** and **7a** revealed that these two isomers are formed in a *ca* 2:1 ratio, based on the relative intensity of the signals (Tables 2 and 3). It is likely that **6a** is an intermediate in the formation of **7a**, since when **4b** is protonated **7b** is the sole product, no molybdenum analogue of **6a** being formed. Interestingly, the stereochemistry about the platinum atom is different in complexes **4**, **5a**, **5b** and **7** from that in **6**. In the latter the tertiary phosphine groups are *transoid* to the μ-alkylidyne ligands whereas in **4**, **5a**, **5b** and **7** they are *cisoid* to the μ-C fragments. Not surprisingly, the NMR spectra of the compounds **7** show common features with those of **8**.[8a] In the $^{13}C-\{^1H\}$ NMR spectrum of **7b** there is a diagnostic singlet resonance at δ 126.9 ppm [J(PtC) 682 Hz] for the μ-CH nucleus. The μ-σ:η^3 bonding mode for the μ-CH($C_6H_3Me_2$-2,6) group results in non-equivalence of all the carbon atoms of the $C_6H_3Me_2$-2,6 moiety. Unlike several other compounds described herein, the salts, **7**, do not undergo dynamic behaviour on the NMR time scale since site-exchange of carbonyls does not occur, there being three distinct resonances for these groups (Table 2).

The compounds **8** react reversibly with CO affording the tricarbonyl complexes [WPt{μ-CH(C_6H_4Me-4)}$(CO)_3(PR_3)_2(\eta$-$C_5H_5)$][BF_4].[8b] The η^2-bonding of the arene ring in the complexes **7** may be similarly lifted by treating CH_2Cl_2 solutions with a stream of CO. In this manner the tetracarbonyl compounds [MPt{μ-CH($C_6H_3Me_2$-2,6)}$(CO)_4(PPr^i_3)(\eta$-$C_5H_5)$][BF_4] [M = W (**9a**) and Mo (**9b**)] are obtained. Moreover, it was observed that the isomeric mixture of **6a** and **7a** was quantitatively converted to **9a**, a result supporting the idea suggested above that **6a** is an intermediate in the formation of **7a**. Data for the compounds **9** are listed in Tables 1–3. However **9b** was unstable, readily reverting to **7b**, hence microanalytical data were not obtained. The NMR data for the complexes **9** show features similar to those of the tricarbonyl species [WPt(μ-CHR)$(CO)_3(PR_3)_2(\eta$-$C_5H_5)$][BF_4] derived from **8**.[8b] Thus in the $^{13}C-\{^1H\}$ NMR spectra diagnostic signals for the μ-CH groups are seen for **9a** at δ 85.5 ppm [J(PtC) 633, J(WC) 31 Hz] and for **9b** at δ 106.7 ppm [J(PtC) 683 Hz].

(13)

Reactions of the alkylidyne complexes [M(≡CR)(CO)$_2$(η-C$_5$H$_5$)] (M = Mo or W, R = C$_6$H$_4$Me-4 or C$_6$H$_3$Me$_2$-2,6) with the platinum compounds [Pt$_3$(CNR)$_6$] (R = Bu^t or C$_6$H$_3$Me$_2$-2,6) were next investigated. Treatment of [Pt$_3$(CNBu^t)$_6$] in CH_2Cl_2, or [Pt$_3$(CNC$_6$H$_3$Me$_2$-2,6)$_6$] in Et_2O, with [Mo(≡CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(η-C$_5$H$_5$)] affords, respectively, the compounds [MoPt(μ-CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(CNR)$_2$(η-C$_5$H$_5$)] [R = Bu^t (**10a**) or C$_6$H$_3$Me$_2$-2,6 (**10b**)]. Similarly, addition of [W(≡CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(η-C$_5$H$_5$)] to a CH_2Cl_2 solution of [Pt$_3$(CNC$_6$H$_3$Me$_2$-2,6)$_6$] yields the complex [WPt(μ-CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(CNC$_6$H$_3$Me$_2$-2,6)$_2$(η-C$_5$H$_5$)] (**10c**). The compounds **10**, characterized by the data given in Tables 1–3, are structurally similar to the complexes (**1**). As expected, the ^{13}C–{^{1}H} NMR spectra of the species **10** all show diagnostic resonances for the μ-C nuclei at δ 348.6 (**10a**), 350.3 (**10b**) and 327.2 ppm (**10c**), these signals showing ^{195}Pt–^{13}C coupling of the expected magnitude (*ca* 700 Hz) (Table 2). Peaks in the spectrum of **10b** at δ 159.8 and 149.4 ppm are assigned to the *C*NR nuclei on the basis of the strong ^{195}Pt–^{13}C couplings of 1376 and 1755 Hz, respectively.

The alkylidyne metal compounds [M(≡CC$_6$H$_4$Me-4)(CO)$_2$(η-C$_5$H$_5$)] (M = Mo or W), containing the C$_6$H$_4$Me-4 group which is less sterically demanding than C$_6$H$_3$Me$_2$-2,6, react with the isocyanide complexes [Pt$_3$(CNR)$_6$] to afford the trimetal species [MPt$_2$(μ_3-CC$_6$H$_4$Me-4)(CO)$_2$(CNR)$_4$(η-C$_5$H$_5$)] [R = Bu^t, M = Mo (**11a**); R = C$_6$H$_3$Me$_2$-2,6, M = Mo (**11b**) or W (**11c**)]. It seems probable that these trimetal compounds are produced via the intermediacy of initially formed dimetal complexes akin to **10**. Addition of Pt(CNR)$_2$ fragments to these intermediates would yield the compounds **11**. The formation of trimetal compounds via such a pathway is well established.[1,9]

The products **11** are structurally similar to the complexes **12** which are formed, together with **4c**–**4f**, upon treatment of the compounds **1** with CO.[3b] The NMR data (Tables 2 and 3) for the trimetal compounds **11** are in agreement with the structures proposed. In the ^{13}C–{^{1}H} NMR spectra, resonances at δ 229.9 (**11a**), 234.8 (**11b**) and 219.9 ppm (**11c**), all with ^{195}Pt–^{13}C satellite peaks [*J*(PtC) *ca* 500 Hz], are assigned to the μ_3-C nuclei. These signals are appreciably less deshielded than those generally found for μ_3-C resonances (*ca* 250–300 ppm).[9] However, in the spectra of the compounds **12** the μ_3-C resonances have similar chemical shifts [*ca* 230 ppm, with *J*(PtC) *ca* 550 Hz].[3b]

In the ^{13}C–{^{1}H} NMR spectra of the complexes **11** two resonances are observed for the ligated carbon atoms of the isocyanide ligands. These occur at δ 145.9 and 137.3 ppm for **11a**, at δ 159.4 and 147.6 ppm for **11b** and at δ 161.2 and 148.8 ppm for **11c**. These assignments are strongly supported by the observation of large ^{195}Pt–^{13}C couplings in the range 1378–1672 Hz.

The two series of compounds **11** and **12** are formulated with two semi-bridging CO ligands on the basis of an X-ray diffraction study on **12c** which established this structural feature.[3b] In the IR spectrum of each compound, however, there is a band at *ca* 1760 cm^{-1}, suggesting the presence of fully bridging CO groups. It is possible that the complexes **11** and **12** adopt different structures in solution. The X-ray diffraction study of **12c** revealed a "butterfly" arrangement of the core atoms with the platinum atoms at the wing-tips [Pt····Pt 2.989 Å] and the C—W fragment forming the body of the butterfly. This leads to an 18 valence electron shell at the tungsten atom and 16 electron configurations at the platinum atoms, assuming no Pt····Pt interaction in accord with the observed distance. If in solution a direct Pt—Pt bond was formed, and this was accompanied by movement of the CO ligands to fully bridging positions, processes requiring little energy, the tungsten atom would have a 16 valence electron shell and the two platinum atoms would have filled shells. Indeed dynamic exchange between the butterfly and *closo* core-atom arrangements may occur in solution.

As described above, protonation of the dimetal compound **4a** gave a mixture of the salts **6a** and **7a**. In contrast, protonation of **10c** yields the μ-hydrido complex [WPt(μ-H)(μ-CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(CNC$_6$H$_3$Me$_2$-2,6)$_2$(η-C$_5$H$_5$)[BF$_4$] (**13**) as the only product. Data characterizing **13** are listed in Tables 1–3. The presence of the μ-H ligand was clearly revealed by the appearance in the ^{1}H NMR spectrum of a high-field resonance at −8.24 ppm, with *J*(PtH) 503 Hz. The diagnostic signal for the μ-C nucleus in the ^{13}C–{^{1}H} NMR spectrum is seen at δ 308.6 ppm [*J*(PtC) 592 Hz].

In summary, the reactions described herein show that the compounds [Pt(C$_2$H$_4$)$_2$(PPr$^i_3$)] or [Pt$_3$(CNR)$_6$] (R = Bu^t or C$_6$H$_3$Me$_2$-2,6) in combination with the reagents [M(≡CC$_6$H$_3$Me$_2$-2,6)(CO)$_2$(η-C$_5$H$_5$)] (M = Mo or W) afford a variety of dimetal complexes with bridging xylylidyne ligands. Moreover, protonation of some of the initially formed products gives either μ-hydrido species or compounds in which the metal–metal bonds are spanned by μ-σ: η^3-C(H)C$_6$H$_3$Me$_2$-2,6 groups. Evidence was obtained indicating that the complexes **7** containing the latter group form via the intermediacy of hydrido species, e.g. **6a**. This result implies that the salts **8** also form on protonation of the compounds **1** via μ-hydrido species akin to **6a**, with subsequent transfer of the hydrido

ligand to the μ-C atom. Whereas the reagents $[Pt_3(CNR)_6]$ react with the species $[M(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ to give dimetal compounds **10**, the analogous species $[M(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$, containing the less bulky *p*-tolylmethylidyne group, afford trimetal complexes **11**.

EXPERIMENTAL

All experiments were carried out under nitrogen, using Schlenk tube techniques. Solvents were rigorously dried before use. Light petroleum refers to that fraction b.p. 40–60°C. The spectroscopic measurements were made with instrumentation described previously.[10] The compounds $[Pt(cod)_2]$,[11] $[Pt_3(CNR)_6]$ (R = Bu^t or $C_6H_3Me_2$-2,6),[5] and $[M(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (M = Mo or W, R = C_6H_4Me-4 or $C_6H_3Me_2$-2,6)[2a,12] were obtained via methods previously described in the literature. Alumina used for chromatography columns was BDH aluminium oxide (Brockman Activity II). The reagent $HBF_4 \cdot OEt_2$ consisted of a 54% solution of HBF_4 in Et_2O. Analytical and physical data for the new compounds are given in Table 1.

Preparation of the platinum–tungsten and –molybdenum compounds

(i) The compound $[Pt(cod)_2]$ (0.50 g, 1.22 mmol) was added in small portions with stirring to 20 cm^3 of ethylene-saturated light petroleum cooled to 0°C. The solution was treated with PPr^i_3 (1.22 cm^3 of a 1 mol dm^{-3} solution in light petroleum) and stirring was continued for 15 min to generate $[Pt(C_2H_4)_2(PPr^i_3)]$ *in situ*.[13] The complex $[W(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (0.51 g, 1.22 mmol) was then added, and the mixture was warmed to room temperature and stirred for 3 h, during which period the colour turned dark brown. Solvent was removed *in vacuo*, the residue was dissolved in light petroleum–CH_2Cl_2 (15 cm^3, 4:1) and chromatographed at −30°C. Elution with the same solvent mixture removed traces of unreacted starting materials and side-products, followed by a brown eluate. Removal of solvent *in vacuo* afforded brown *microcrystals* of $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(\mu\text{-}CO)(CO)(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**2a**) (0.85 g).

(ii) In a similar experiment, $[Pt(C_2H_4)_2(PPr^i_3)]$ {0.47 mmol, generated from $[Pt(cod)_2]$ (0.19 g, 0.47 mmol)}, dissolved in light petroleum (40 cm^3) at 0°C was treated with $[Mo(\equiv CC_6H_3Me_2\text{-}2,6)(CO)_2(\eta\text{-}C_5H_5)]$ (0.16 g, 0.46 mmol). The mixture was warmed to room temperature and stirred for 3 h. It was then filtered through a Celite pad (2 × 4 cm). Solvent was removed *in vacuo* from the filtrate to give brown *microcrystals* of $[MoPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(\mu\text{-}CO)(CO)(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**2b**) (0.27 g).

(iii) Complex **2a** (0.17 g, 0.22 mmol) in CH_2Cl_2 (25 cm^3) was treated with a stream of CO gas for *ca* 1 min, the colour of the solution immediately turning from brown to orange. Removal of solvent *in vacuo*, followed by dissolving the residue in CH_2Cl_2, and column chromatography, gave an orange eluate. Removal of solvent *in vacuo* afforded orange *microcrystals* of $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**4a**) (0.17 g).

(iv) The compound $[MoPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**4b**) (0.20 g) was similarly obtained from **2b** (0.21 g, 0.31 mmol) and CO.

(v) Compound **2a** (0.13 g, 0.17 mmol) in light petroleum (20 cm^3) was treated with $CNC_6H_3Me_2$-2,6 (0.02 g, 0.17 mmol), and the mixture was stirred. After *ca* 5 min, solvent was removed *in vacuo*, and the residue was dissolved in Et_2O–light petroleum (10 cm^3, 1:4) and chromatographed. Elution with the same solvent mixture gave an orange eluate, from which solvent was removed *in vacuo* to afford orange–red *microcrystals* of $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNC_6H_3Me_2\text{-}2,6)(PPr^i_3)(\eta\text{-}C_5H_5)]$ (**5a**) (0.10 g).

(vi) In a similar manner, **2a** (0.35 g, 0.45 mmol) in Et_2O (20 cm^3) with CNBu^t (0.45 mmol) gave, after column chromatography eluting with Et_2O, $[WPt(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNBu^t)(PPr^i_3)(\eta\text{-}C_5H_5)]$ (isomers **5b** and **5c**) (0.35 g).

(vii) Compound **4a** (0.23 g, 0.28 mmol) in Et_2O (5 cm^3) was treated with *ca* 7 drops of $HBF_4 \cdot Et_2O$ (large excess) and the mixture was stirred for *ca* 5 min. The precipitate was allowed to settle, and the supernatant liquid removed with a syringe. The residue was washed with Et_2O (2 × 1 cm^3) and dried *in vacuo* yielding 0.24 g of the isomeric compounds $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**6a**) and $[WPt\{\mu\text{-}\sigma\text{:}\ \eta^3\text{-}C(H)C_6H_3Me_2\text{-}2,6\}(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**7a**).

(viii) The salt $[MoPt\{\mu\text{-}\sigma\text{:}\ \eta^3\text{-}C(H)C_6H_3Me_2\text{-}2,6\}(CO)_3(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**7b**) (0.16 g) was similarly prepared from **4b** (0.15 g, 0.21 mmol) and $HBF_4 \cdot OEt_2$.

(ix) Addition of $HBF_4 \cdot OEt_2$ in excess (*ca* 7 drops) to **5a** (0.41 g, 0.46 mmol) in Et_2O (10 cm^3) gave, after removal of solvent *in vacuo*, yellow *microcrystals* of $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNC_6H_3Me_2\text{-}2,6)(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**6b**) (0.37 g).

(x) Similarly, $[WPt(\mu\text{-}H)(\mu\text{-}CC_6H_3Me_2\text{-}2,6)(CO)_2(CNBu^t)(PPr^i_3)(\eta\text{-}C_5H_5)][BF_4]$ (**6c**) (0.19 g) was prepared from **5b** (0.18 g, 0.21 mmol) and $HBF_4 \cdot OEt_2$.

(xi) A CH_2Cl_2 (10 cm^3) solution of $[Pt_3(CNBu^t)_6]$

(0.16 g, 0.15 mmol) was treated with [Mo(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (0.15 g, 0.43 mmol) in the same solvent (10 cm^3), and the mixture was stirred for 6 h. Solvent was removed *in vacuo*, and the residue was dissolved in CH_2Cl_2–light petroleum (3 cm^3, 1 : 1) and chromatographed. Elution with the same solvent mixture gave orange–red *microcrystals* of [MoPt(μ-$CC_6H_3Me_2$-2,6)$(CO)_2(CNBu^t)_2(\eta$-$C_5H_5)$] (**10a**) (0.19 g), after removal of solvent from the eluate.

(xii) The compound [MoPt(μ-$CC_6H_3Me_2$-2,6)$(CO)_2(CNC_6H_3Me_2$-2,6)$_2(\eta$-$C_5H_5)$] (**10b**) (0.13 g) was similarly obtained from [$Pt_3(CNC_6H_3Me_2$-2,6)$_6$] (0.19 g, 0.14 mmol) and [Mo(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (0.14 g, 0.42 mmol) in Et_2O (50 cm^3).

(xiii) Similarly, [WPt(μ-$CC_6H_3Me_2$-2,6)$(CO)_2(CNC_6H_3Me_2$-2,6)$_2(\eta$-$C_5H_5)$] (**10c**) (0.34 g) was prepared from [$Pt_3(CNC_6H_3Me_2$-2,6)$_6$] (0.18 g, 0.13 mmol) and [W(≡$CC_6H_3Me_2$-2,6)$(CO)_2(\eta$-$C_5H_5)$] (0.17 g, 0.40 mmol) in CH_2Cl_2 (20 cm^3).

(xiv) Treatment of **10c** (0.14 g, 0.16 mmol) in Et_2O (35 cm^3) with $HBF_4 \cdot OEt_2$ (8 drops, excess) with stirring afforded a yellow precipitate. The supernatant liquid was removed with a syringe, and the residue was washed with Et_2O (2 × 3 cm^3) to give yellow *microcrystals* of [WPt(μ-H)(μ-$CC_6H_3Me_2$-2,6)$(CO)_2(CNC_6H_3Me_2$-2,6)$_2(\eta$-$C_5H_5)$][BF_4] (**13**) (0.15 g).

(xv) A CH_2Cl_2 (10 cm^3) solution of [$Pt_3(CNBu^t)_6$] (0.14 g, 0.13 mmol) was treated with [Mo(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] (0.06 g, 0.19 mmol), dissolved in the same solvent. The mixture was stirred (15 min) and then chromatographed. Elution with CH_2Cl_2, and removal of solvent *in vacuo*, gave yellow *microcrystals* of [$MoPt_2(\mu_3$-CC_6H_4Me-4)$(CO)_2(CNBu^t)_4(\eta$-$C_5H_5)$] (**11a**) (0.17 g).

(xvi) In a similar experiment, treatment of [$Pt_3(CNC_6H_3Me_2$-2,6)$_6$] (0.18 g, 0.13 mmol) in Et_2O (80 cm^3) with [Mo(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] (0.07 g, 0.22 mmol), in the same solvent (10 cm^3), gave yellow *microcrystals* of [$MoPt_2(\mu_3$-CC_6H_4Me-4)$(CO)_2(CNC_6H_3Me_2$-2,6)$_4(\eta$-$C_5H_5)$] · $2CH_2Cl_2$ (**11b**) (0.14 g), after the chromatography column had been eluted with CH_2Cl_2.

(xvii) Similarly, [$WPt_2(\mu_3$-CC_6H_4Me-4)$(CO)_2(CNC_6H_3Me_2$-2,6)$_4(\eta$-$C_5H_5)$]·CH_2Cl_2 (**11c**) (0.20 g) was prepared from [$Pt_3(CNC_6H_3Me_2$-2,6)$_6$] (0.19 g, 0.14 mmol) in Et_2O (80 cm^3) and [W(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] (0.11 g, 0.27 mmol) in Et_2O (10 cm^3). The product was removed from the chromatography column with CH_2Cl_2.

THE SINGLE CRYSTAL ELECTRONIC SPECTRA OF DICHLORODIPYRIDINENICKEL(II) AND DICHLORODIQUINOLINENICKEL(II) COMPLEXES*

MOHAMMAD M. SEIFOLLAHI and J. R. PERUMAREDDI†

Department of Chemistry, Florida Atlantic University, Boca Raton, FL 33431, U.S.A.

(*Received* 27 *December* 1988; *accepted* 4 *May* 1989)

Abstract—The single crystal electronic spectra of tetragonal $[NiL_2Cl_2]$, where L = pyridine and quinoline, complexes have been measured with polarized light at liquid N_2 temperature. The bands in the spectra of the dipyridine complex were polarized and thus assigned on the basis of the D_{4h} vibronic intensity mechanism, whereas the spectra of the diquinoline complex did not show any distinctive polarization characteristics and were assigned assuming the same order of energy levels as in the dipyridine complex. Our assignments of the spectra of both systems differ from those published earlier by others. The assigned absorption maxima in the dipyridine system were fitted with the predicted energy equations by extracting electron repulsion, spin–orbit, and ligand-field symmetry parameters and compared with those obtained earlier by us for the $[Ni(py)_4Cl_2]$ system. It was found that either the ligand-field symmetry parameters or the translated molecular orbital bonding parameters are not transferable between these two systems.

The polarized electronic spectral studies of tetragonal nickel(II) complexes which have been made to date,[1–6] are mostly on systems with negative *Dt*, with the exception of $[Ni(NH_3)_4(NO_2)_2]$ which has a positive *Dt*.[2] We are interested in studying polarized crystal spectra of systems with positive *Dt*. The systems that are expected to have positive *Dt*, as determined from mull or reflectance spectral studies, are the following:[7–16] $[NiL_2X_2]$, X = Cl, Br, L = NH_3,[8] py,[7–10] an,[8,11] im;[16] $[NiL_2Cl_2]$, L = qu,[10,12] CH_3CN,[13] H_2O;[8] $[Ni(CH_3CN)_2(ClO_4)_2]$;[14] $[NiLCl_2]$, L = py,[10] CH_3CN,[14] qx;[15] $[Ni(im)X_2]$, X = Cl, Br.[16]‡

We have prepared a number of these complexes, but only succeeded in growing single crystals of two of them: $[Ni(py)_2Cl_2]$ and $[Ni(qu)_2Cl_2]$. We have studied the polarized electronic spectra of these two systems.

EXPERIMENTAL

Preparation of the complexes

The complexes were prepared as described in the literature.[10,12]

Growing single crystals

Dichlorodipyridinenickel(II), $[Ni(py)_2Cl_2]$. Single crystals of this complex were grown by slow evaporation of a filtered, saturated solution of the complex in methanol at 55°C. (This procedure is the same as used by Morosin[17] for growing single crystals of $[Co(H_2O)_2Cl_2]$, except Morosin used water as the solvent at a temperature of 70°C.) The evaporation occurred over a period of 5 days in a thermostatted oil bath. The growing of these single crystals necessitated great care in sealing the evaporation chamber in order to maintain a slow, uniform evaporation rate. The crystals were green in colour and exhibited a strong green to pink dichroism. The size of the crystals obtained by this method never exceeded 0.025 in. diameter.

Dichlorodiquinolinenickel(II), $[Ni(qu)_2Cl_2]$. To

‡ Abbreviations: py = pyridine; an = aniline; im = imidazole; qu = quinoline; qx = quinoxaline.

grow single crystals of this compound, 5 cm^3 of a saturated solution of the complex in methanol was placed in a large test tube and carefully covered with a large volume of ice-cold acetone so that two layers formed. The test tube was stoppered and placed in a refrigerator, and the layers were allowed to diffuse for 48 h. By this time crystals had appeared at the original junction of the layers. These crystals were olive green in colour and moderate in size.

Spectral measurements

The spectra were recorded as described earlier.[6]

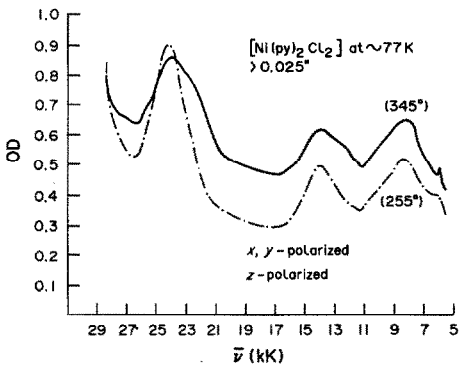

Fig. 1. Polarized crystal spectra of $[Ni(py)_2Cl_2]$ at liquid nitrogen temperature

RESULTS AND DISCUSSION

Although the crystals of the pyridine complex gave electronic spectra with polarized bands, the crystals of the quinoline complex always resulted in spectra with no discernible polarization characteristics of the absorption maxima. We thus present a detailed analysis of the electronic spectrum of the $[Ni(py)_2Cl_2]$ complex and will discuss the interpretation of the unpolarized spectrum of the $[Ni(qu)_2Cl_2]$ complex on the basis of the results obtained for the $[Ni(py)_2Cl_2]$ system and other similar systems.

The complete X-ray crystal structure analysis of $[Ni(py)_2Cl_2]$ has not been carried out yet, but it has been found to be isomorphous[18a] with violet $[Co(py)_2Cl_2]$, which has a polymeric structure with bridging chlorides and the two pyridines axially coordinated to the metal giving six-coordination.[18b] The exact site symmetry will depend on the orientation of the pyridine ligands and any distortions of the chlorides from planarity. However, we will assume the symmetry in this study to be D_{4h} on the basis of the tetragonal chromophore *trans*-$[NiN_2Cl_4]$, where two nitrogens are the coordinating atoms of the two pyridine ligands. The crystals of $[Ni(py)_2Cl_2]$ showed a clear dichroism from green to pink with exact extinctions at 90° angles. The polarized spectra have been measured along these optic axes. We will assume that the optic axes are aligned along the directions of the molecular axes, namely, the tetragonal axis containing the pyridine ligands and an axis orthogonal to it in the equatorial plane of the chlorine ligands. These two axes have been called z (or ∥) and x,y (or ⊥).

The polarized spectra of $[Ni(py)_2Cl_2]$ and the unpolarized spectrum of $[Ni(qu)_2Cl_2]$, measured at ~ 77°K, are presented in Figs 1 and 2. We shall firstly discuss the assignment of the spectrum of $[Ni(py)_2Cl_2]$. On the basis of the vibronic intensity mechanism for the d^8 configuration in D_{4h} symmetry, whereas both components of each of the three cubic parentage bands are allowed in ⊥ polarization, only one component of each of the three cubic bands is allowed in ∥ polarization.[6] The spectrum measured at a 345° angle extinction direction shows the three spin-allowed cubic bands at 8.30, 14.00 and 24.15 kK, which are of broad maxima with asymmetry leading to shoulders on the red side of each band. The spectrum obtained at the 255° angle extinction direction, however, shows three symmetric bands with no identifiable shoulders at about the same energies (8.40, 14.15 and 24.40 kK) as the three band maxima in the previous spectrum. Thus, we conclude that these two spectra correspond to x,y- and z-polarizations, respectively. The ill-defined resolution of the split components, i.e. showing shoulders instead of bands, could be due to the molecular axes not being exactly aligned along the extinction directions. The three maxima at 8.40, 14.15 and 24.40 kK of the z-polarized spectrum should be assigned as the ^3E_g components of the $^3T_{2g}(^3F)$, $^3T_{1g}(^3F)$ and $^3T_{1g}(^3P)$, respectively, and the estimated maxima of the three shoulders at ~ 7.50, ~ 13.00 and ~ 23.30 kK of the x,y-

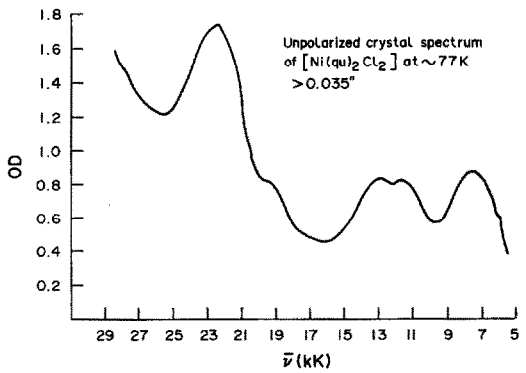

Fig. 2. Unpolarized crystal spectrum of $[Ni(qu)_2Cl_2]$ at liquid nitrogen temperature.

polarized spectrum which disappear in the *z*-polarization, correspond to the transitions $^3B_{2g}[^3T_{2g}(^3F)]$, $^3A_{2g}[^3T_{1g}(^3F)]$ and $^3A_{2g}[^3T_{1g}(^3P)]$, respectively. In addition to these spin-allowed transitions, bands of low intensity appear at ~ 11.90 (in both polarizations), ~ 26.00 (in *x*,*y*-polarization) and ~ 6.10 kK (in *x*,*y*-polarization and somewhat reduced in intensity in *z*-polarization), the last one being a sharp peak. The bands at 11.90 and 26.00 kK are obviously spin-forbidden transitions and their assignment as the tetragonal components of cubic $^1E_g(^1D)$ and $^1T_{1g}(^1G)$ levels is made on the basis of the energy fitting calculations as explained later. The low intensity sharp peak of 6.10 kK has been shown to be a C—H stretching vibration overtone by Chiang and Drago[8] in their mull spectral study of the same compound at liquid N_2 temperature. These authors showed that the peak disappears if pyridine-d_5 is substituted for pyridine in the complex. It should be noted, however, that the mull spectrum[8] shows the sharp peak sitting over a low intensity broad absorption maximum at the same energy, which does not disappear on deuteration of the pyridines and which was left unassigned except perhaps as resulting from interactions between the chains or from the presence of some impurities such as $NiCl_3^-$ fragments in the chain. We have not observed such a low intense broad absorption under the sharp peak in the crystal spectrum, however. The observed maxima of the ligand-field absorption bands and their assignments are collected in Table 1.

Table 1. Observed band maxima (kK) and their assignments in the spectrum of $[Ni(py)_2Cl_2]$

Band maximum (kK)[a]	Assignment, $^3B_{1g} \rightarrow$
(7.50)	$^3B_{2g}$
8.40	^3E_g
(11.90)	$^1A_{1g}$, $^1B_{1g}$
(13.00)	$^3A_{2g}$
14.15	^3E_q
(23.30)	$^3A_{2g}$
24.40	^3E_g
(26.00)	^1E_g

[a] Shoulders are in parentheses.

A comparison of our spectral data on $[Ni(py)_2Cl_2]$ with those obtained earlier by others is presented in Table 2. Goodgame *et al.*[10] and Lever *et al.*[7] studied the diffuse reflectance spectrum of the powder at room temperature, whereas Drago and coworkers[9a,8] studied the mull spectrum at liquid N_2 temperature. The mull spectrum shows better resolution of all the bands compared with the reflec-

tance spectrum and, surprisingly, even compared with the crystal spectrum. In the early studies where a reflectance spectrum was obtained, the two high energy spin-allowed bands (24.10 and ~ 14.10 kK) exhibited shoulders which were broad on the low frequency side, with no evidence of the presence of low intensity spin-forbidden transitions which are expected to appear at about the same energy regions as the shoulders. Hence, the assignments of these shoulders made by the two different groups of authors differed; Lever *et al.*[7] assigned them as spin-forbidden transitions assuming that the two maxima at 13.99 and 24.10 kK are the unsplit $^3T_{1g}(^3F)$ and $^3T_{1g}(^3P)$ cubic transitions, respectively, whereas Goodgame *et al.*[10] assigned the shoulders as the split tetragonal components assuming that the spin-forbidden transitions did not appear because of low intensity. With the assumption that the more intense component represented a transition to the orbital doublet ^3E, Goodgame *et al.* assigned the shoulders as the $^3A_{2g}$ and the peaks as the ^3E_g components. The mull and crystal spectra, however, resolved the shoulders, giving them comparable intensity to the main peaks and also uncovered the spin-forbidden transitions in these energy regions. More importantly though, our crystal spectrum presented polarization characteristics of the shoulders showing that they are the $^3A_{2g}$ transitions as we assigned them above. (It should be noted that both tetragonal $^1A_{1g}$, $^1B_{1g}$ components of cubic $^1E_g(^1D)$, expected to appear at ~ 12.00 kK, are allowed in both polarizations, whereas among the $^1B_{2g}$, ^1E_g components of cubic $^1T_{2g}(^1D)$ and the $^1A_{1g}$ of cubic $^1A_{1g}(^1G)$, expected to appear at ~ 21.00 kK, the ^1E_g and $^1A_{1g}$ are allowed in both polarizations, but $^1B_{2g}$ only in the x,y-polarization.[6]) Our assignments differ from those of Drago and co-workers,[8,9a] who assigned the shoulders as the ^3E_g and the main peaks as the $^3A_{2g}$ transitions on the basis of an assumption that the ordering of levels in $[Ni(py)_2Cl_2]$ should be the reverse of that in $[Ni(py)_4Cl_2]$. Although such an assumption will result in consistent values for bonding parameters, there is no justification for such an assumption. We will discuss this question further, later.

We now describe the fitting of the assigned band positions with the energy equations. Firstly we attempted to fit the observed band maxima without spin–orbit interaction.* The procedure is briefly as follows.[6] The energy of the $^3B_{2g}(^3T_{2g})$ is $10Dq$ including configuration interaction. We choose an initial value of Dt to fit the ^3E_g component of $^3T_{2g}$. With this initial value of Dt, values of Ds and B are varied, respectively, to fit the energy splitting of the second cubic band, $^3T_{1g}$, into its components $^3A_{2g}$, ^3E_g, and their positions. The $^3A_{2g}$, ^3E_g components of the third cubic band, $^3T_{1g}$, are then calculated. The calculated energies of the third band components may not agree with the observed values, in which case B and Ds are varied until as close agreement as possible is reached between observed and calculated positions of all four components of the two high energy cubic bands. Although the splitting of the first cubic band is determined by Dt alone, with no configuration interaction, when the configuration interaction is included it is affected by the values of Ds and B. Thus, finally Dt also should be varied along with Ds and B to fit all six tetragonal components.

When we applied such a procedure, it became very difficult to fit all four components of the two high energy cubic bands exactly for a set of Ds and B values, with Dt extracted by the fitting of the first band splitting. The reason for this is that with positive Dt and when ^3E_g is the higher energy component, $^3A_{2g}$ being the lower energy component for both the $^3T_{1g}$ cubic bands, the configuration interaction is such that although the splitting of the low energy $^3T_{1g}$ increases rapidly with κ, which is the ratio Ds/Dt, the splitting of the high energy $^3T_{1g}$ increases very slowly as shown in Fig. 3. The observed splittings, however, of these two cubic

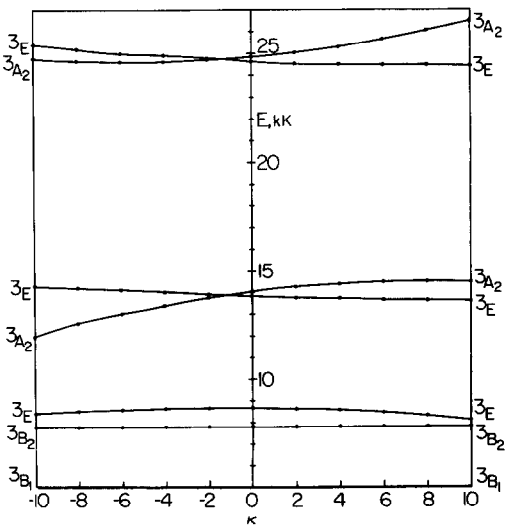

Fig. 3. Electronic energy levels of a quadrate nickel(II) system as a function of κ in the limit of zero spin–orbit interaction. Other parameters are (in kK): $Dq = -0.750$, $Dt = 0.110$ and $B = 0.850$.

* The complete energy matrices with and without spin–orbit interaction were derived earlier[19] by perturbing weak-field cubic levels, firstly by axial ligand field component and then by spin–orbit interaction.

transitions are 1.15 and 1.10 kK. This means that the interpretation of this system should be carried our by including spin–orbit interaction.[19] When spin–orbit interaction is included, the ^3E_g component splits into five spin–orbital levels, Γ_i, $i = 1$, 2, 3, 4, 5, and both the $^3A_{2g}$ and $^3B_{2g}$ components split into two spin–orbital levels, Γ_1, Γ_5 and Γ_3, Γ_5. It is well known that the free-ion value for the spin–orbit constant parameter for nickel(II) is 0.66 kK and that this value will be reduced in its complexes. We can therefore vary the spin–orbit parameter below 0.66 kK until the observed bands can be fitted either with one of the spin–orbital levels or with an average of all of them in each group. The fitting of the spectral data using such a procedue is shown in Table 3.

The fitting presented here is the best we could do for this system. Even with inclusion of the spin–orbit interaction, it is not possible to obtain a calculated splitting of ~ 1.10 kK for the highest energy cubic band to fit the observed splitting. Thus, using one spin–orbital level to fit the observed maximum (23.670 kK for the $^3A_{2g}$ component and 24.225 kK for the ^3E_g component), the calculated splitting is still 0.555 kK, as against an observed splitting of ~ 1.10 kK. Although the theory seems to be deficient at this point to explain the observed data, any further theoretical studies, we believe, should

be deferred until better resolution of the observed bands is achieved, even perhaps to the extent of identifying spin–orbital levels experimentally.

The calculations to fit the data produced an interesting result. It is the mixing of the spin–orbital levels of the $^3A_{2g}$ component with the corresponding levels of the ^3Eg component and *vice versa* in the case of the two high energy cubic bands. We have included in Table 3 the purities of spin–orbital levels whenever they are less than 90.0%, and listed in each such case the per cent contribution of other eigenvector components. It should be noted that the Γ_1, Γ_5 spin–orbital levels of the $^3A_{2g}[^3T_{1g}(^3F)]$ band are only 22.6 and 63.0% pure and have 57.7 and 20.0% of the corresponding levels of $^3E_g[^3T_{1g}(^3F)]$ mixed in, whereas the same spin–orbital levels of $^3E_g[^3T_{1g}(^3F)]$ are 33.2 and 71.1% pure and have 31.6 and 16.1% of the $^3A_{2g}[^3T_{1g}(^3F)]$ levels mixed in. Because of this mixing of one component with the other, the $^3A_{2g}$ is expected not to be wiped out completely and the ^3E_g is expected to decrease in intensity, in z-polarization. This may be the reason (other than the molecular axes probably not being aligned along the optic axes) why both $^3A_{2g}$ and ^3E_g components decrease in intensity in z-polarization, rather than $^3A_{2g}$ disappearing and ^3E_g having the same intensity as in the x,y-polarization. (For the purpose of this discussion, it is actually the total of a given component from both ^3F and ^3P that should be considered for purity as well as for mixing.) Similarly, the spin–orbital levels of $^3A_{2g}[^3T_{1g}(^3P)]$ are 60.1 and 58.1% pure and contain 20.9 and 17.0% of the corresponding levels of $^3E_g[^3T_{1g}(^3P)]$, whereas the same levels of $^3E_g[^3T_{1g}(^3P)]$ are 71.5 and 71.6% pure and contain 19.6 and 18.0% levels of $^3A_{2g}[^3T_{1g}(^3P)]$. Thus, the mixing of the components in this case is only about half that of the $^3T_{1g}(^3F)$ components.

It should be noted that the fitting procedure that we have used here necessarily involves an uncertainty in the derived parameters, in particular of *Ds* and *B*. However, the negative sign of *Ds* and the value of $\kappa(= Ds/Dt)$ being -3 or greater to explain the $\sim$ 1.00 kK splitting of both the $^3T_{1g}$ transitions is definitive. Finally, the *C* value is derived by fitting the observed positions of the spin-forbidden bands with the energies of such transitions that are likely to appear in these energy regions.

Before we discuss the significance of the spectral parameters derived for $[Ni(py)_2Cl_2]$, we would like to present the spectral data obtained from the unpolarized spectrum of $[Ni(qu)_2Cl_2]$. The band positions and the assignments assuming that the ordering of levels is the same as that in the pyridine system are summarized in Table 4, along with the room temperature reflectance spectral data

Table 4. Comparison of the observed band maxima (kK)[a] and assignments (excited states) in the spectrum of $[Ni(qu)_2Cl_2]$

[b] Reflectance spectrum at room temperature (Ref. 10).

obtained by Goodgame *et al.*[10] Our band positions agree with those reported, except the highest energy spin-allowed band in our crystal spectrum displays asymmetry on the low energy side. We attribute this asymmetry at $\sim$ 21 kK to the $^3A_{2g}$ tetragonal component leaving the low intensity $\sim$ 19.5 kK peak as a spin-forbidden transition. Similarly as for $[Ni(py)_2Cl_2]$, we attribute the $\sim$ 6.00 kK to a C—H overtone of quinoline and not to the tetragonal component of the lowest energy $^3T_{2g}$ cubic transition. Thus, we assign the 7.60 kK band maximum as the $^3B_{2g}$ component of $^3T_{2g}$ and assume that the corresponding ^3E_g component which should appear at higher energy is not resolved in our spectra. Since the $^3E_g(^3T_{2g})$ transition is not uncovered, the *Dt* value cannot be obtained for this system, which implies that it is not possible to fit the other bands to derive the spectral parameters. From the position of $^3B_{2g}$ and the magnitudes of splittings of the two higher energy cubic bands and the positions of their components, however, it is obvious that the values of *Dt*, *Dq* and *Ds* parameters for this system will be about the same, and the *B* and *C* parameters will be somewhat less than those of the dipyridine system.

We will now present a discussion of the significance of the derived parameters for $[Ni(py)_2Cl_2]$. The *B*, *C* electron repulsion parameters and ζ spin–orbit interaction parameter are reduced in the complex from the free-ion values, as expected. The ligand-field parameters and their significance in terms of bonding are of paramount importance.

The *Dq*, *Dt* and *Ds* ligand-field symmetry parameters obtained for the $[Ni(py)_2Cl_2]$ system are given in Table 5. The *Dq* value that is obtained by fitting the experimental data is that for the equatorial ligand, which is chloride in this case. The *Dq* of the axial ligand, namely, pyridine, is calculated

Table 5. Ligand-field and molecular orbital parameters (kK) of some nickel(II) complexes

[d] This work.

from the relationship $Dt = 4/7(Dq_{ax} - Dq_{eq})$. We have also listed in this table the values for the spectral fitting parameters Dq_{py}, Dt and Ds, and for the calculated parameters Dq_{Cl} obtained earlier by us from the $[Ni(py)_4Cl_2]$ system.[6] The Dq values of octahedral systems $[(Me_4N)NiCl_3]$ and $[Ni(py)_6](NO_3)$ are also given in this table for a comparison. It is immediately obvious that these parameters are not transferable from one system to another. Thus, although the octahedral Dq of the chloride ligand remains the same as we go from the hexa-coordinated chloro complex to the tetragonal $[Ni(py)_4Cl_2]$, it increases by $\sim 14\%$ in the tetragonal $[Ni(py)_2Cl_2]$. Similarly, the octahedral Dq of the pyridine ligand changes very slightly as we go from the hexa-coordinated pyridine complex to the tetragonal complex $[Ni(py)_2Cl_2]$, but increases by $\sim 20\%$ in the tetragonal $[Ni(py)_4Cl_2]$ complex. This also means that the Dt values will be different between the two tetragonal systems, $[Ni(py)_2Cl_2]$ and $[Ni(py)_4Cl_2]$. If the ligand-field parameters are transferable, not only the Dq values of a given ligand are expected to be the same in the complexes $[Ni(py)_2Cl_2]$ and $[Ni(py)_4Cl_2]$, but also the value of the Dt parameter, as well as that of Ds parameter for the two systems, should be of the same magnitude but of opposite sign. The reason that these parameters change between the two systems is because the bonding nature of the ligands changes depending upon whether they are in the equatorial positions or in the axial positions of the tetragonal complex. In the case of $[Ni(py)_4Cl_2]$, where the pyridine is in the equatorial position, pyridine is more σ-antibonding and somewhat less π-antibonding than chloride. In the $[Ni(py)_2Cl_2]$ system, where the pyridine is in the axial position, pyridine is still less π-antibonding than chloride, but is is also less σ-antibonding.

The relative antibonding powers of the chloride and pyridine ligands can be calculated either in terms of the semi-empirical molecular orbital parameters $\delta\sigma$, $\delta\pi$[20,21] or of the angular overlap model (AOM) parameters $(\Delta_{\sigma_{ax}}-\Delta_{\sigma_{eq}})$, $(\Delta_{\pi_{ax}}-\Delta_{\pi_{eq}})$.[22] The calculated values of both sets of parameters for the complexes $[Ni(py)_2Cl_2]$ and $[Ni(py)_4Cl_2]$ are also given in Table 5.* The $\delta\sigma$ values show that although pyridine is more σ-antibonding than chloride in $[Ni(py)_4Cl_2]$, it is slightly less σ-antibonding than chloride in $[Ni(py)_2Cl_2]$. The $\delta\pi$ values show that pyridine is less π-antibonding than chloride in both systems, although more so in $[Ni(py)_2Cl_2]$. The AOM parameters reflect the same conclusion. The difference in the bonding nature of the ligands could be due to the fact that the chloride ligands in $[Ni(py)_2Cl_2]$ are bridged, whereas in $[Ni(py)_4Cl_2]$ they are terminal. On the other hand, the changes in Dq values of chloride and pyridine ligands, as noted earlier, are not consistent and systematic for the ligation of chloride, whether it is bridging or terminal. It seems that the bonding nature of ligands in a given complex depends on the complex as an entirety and is not characteristic of an individual ligand, which means that the ligands cannot be treated as single entities allowing single-ligand parameters to be transferable from one system to another.

*The AOM parameters given in this table for $[Ni(py)_4Cl_2]$ have been extracted from spectral data obtained earlier by us.[6] Our spectral data on this system differ somewhat from that reported by Schreiner and Hamm,[23] giving rise to different AOM parameters.[22b]

SYNTHESIS AND CHARACTERIZATION OF $Ir(\eta^4\text{-}C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$. A NON-FLUXIONAL FIVE-COORDINATE IRIDIUM(I) COMPLEX CONTAINING AN η^4-BUTADIENE LIGAND

MICHAEL D. FRYZUK,* KIRAN JOSHI and STEVEN J. RETTIG†

(*Received* 13 *February* 1989; *accepted* 4 *May* 1989)

Abstract—The reaction of the square-planar iridium(I) η^2-cyclooctene complex, $Ir(\eta^2\text{-}C_8H_{14})[N(SiMe_2CH_2PPh_2)_2]$, with excess 1,3-butadiene generates excellent yields of the five-coordinate iridium(I) 1,3-butadiene complex, $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$. Both the NMR spectral data and the single crystal X-ray structure reveal that the tridentate amido–diphosphine ligand is coordinated in a quasi facial manner and the 1,3-butadiene unit is bound in a s-*cis*-η^4-π mode with some σ^2–π component to the bonding. In solution, the butadiene complex shows no fluxional behaviour even at temperatures as high as 85°C.

The coordination chemistry of the mixed-donor, tridentate ligand $^-N(SiMe_2CH_2PPh_2)_2$ with both iridium(I) and iridium(III) has allowed access into a number of areas in organometallic chemistry. For example, formation of the methylidene complex $Ir(=CH_2)[N(SiMe_2CH_2PPh_2)_2]$ via photolysis[1] of iridium(III) dialkyls, unusual activation[2] of dihydrogen by methyl–iridium halides and phosphides, and thermal carbon–hydrogen bond activation,[3] are all observed with the above amido–diphosphine ancillary ligand bound to iridium. In almost every example,[4] the tridentate ligand binds to the metal centre in a planar fashion having *trans*-disposed phosphorus donors, regardless of the metal geometry. Examples are the square-planar derivatives[5] $Ir(L)[N(SiMe_2CH_2PPh_2)_2]$ (where L = olefin, phosphine, CO or acetylene), square-pyramidal complexes[6] of the formula $Ir(CH_3)X[N(SiMe_2CH_2PPh_2)_2]$ (X = halide), trigonal bipyramidal bis(hydrocarbyl)[7] derivatives, $Ir(R)R'[N(SiMe_2CH_2PPh_2)_2]$, and various octahedral complexes.[2b,6,8]

Although 1,3-dienes are considered to be fairly common ligands for the later transition elements, there are few examples of iridium derivatives.[9] Our combined interest in the coordination of this tridentate ligand system with both early and late transition elements and the activation of 1,3-dienes by one[10] or more[11] metal centres provided the incentive to examine the reaction of 1,3-butadiene with a later transition metal derivative incorporating this ligand, in this case iridium(I). In this paper we describe the solid-state and solution-phase structures of a complex of s-*cis*-1,3-butadiene attached to the $Ir[N(SiMe_2CH_2PPh_2)_2]$ moiety. Of particular note is the unusual coordination mode of the tridentate ligand. In addition, the resultant five-coordinate complex is stereochemically rigid on the NMR time scale.

RESULTS

The previously reported[5] η^2-cyclooctene complex, $Ir(\eta^2\text{-}C_8H_{14})[N(SiMe_2CH_2PPh_2)_2]$, reacts with excess 1,3-butadiene (≈ 5 equiv) in toluene solution, at room temperature without any discernable colour change. From the orange solution, light yellow crystals of the formula $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ can be isolated in $> 90\%$ yield.

$$Ir(\eta^2\text{-}C_8H_{14})[N(SiMe_2CH_2PPh_2)_2] + 1,3\text{-butadiene} \longrightarrow Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2] + \text{cyclooctene}.$$

The solid-state structure of the $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ complex is shown in Fig. 1. The

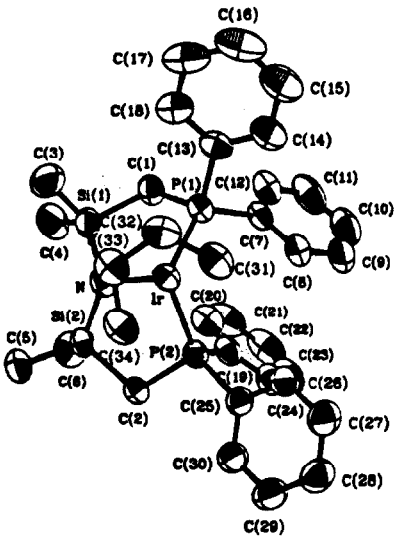

Fig. 1. ORTEP drawing of the $Ir(\eta^4\text{-}C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ molecule. Hydrogen atoms are omitted for clarity.

complex is five-coordinate and the amido–diphosphine tridentate ligand adopts a facial coordination mode as indicated by the P(1)—Ir—P(2) angle of 107.01(4)° (Table 1). Interestingly, the Ir—NSi_2 unit of the ligand backbone is still planar [see Fig. 2(a)], as determined by the sum of the angles involved (Ir—N—Si(1)+Ir—N—Si(2)+Si(1)—N—Si(2) = 360°). The Ir—P and Ir—N bond lengths are not unusual, and compare to other standard bond lengths.[1,2,6,7] The iridium centre is bonded to each carbon of the butadiene unit with the following bond lengths: Ir—C(31), 2.139(4); Ir—C(32), 2.167(4); Ir—C(33), 2.183(4); and Ir—C(34), 2.182(4) Å (Table 2). The butadiene unit is asymmetrically bound to the iridium; the metal–carbon bond lengths parallel the *trans*-influence[12] order, i.e. P > N, since C(31) being *trans* to the amide possesses a shorter bond to iridium than C(34) which is *trans* to the phosphorus ligand, P(2). The C—C bond lengths are only slightly different,

[a] Bu refers to the centroid of the butadiene ligand.

having the following values: C(31)—C(32), 1.430(7); C(32)—C(33), 1.409(7); and C(33)—C(34), 1.421(7) Å.

There are two methods reported[13] to compare metal–diene interactions, in particular, to gauge the component of η^4–π versus σ^2–π character of the bonding from the crystallographic data. The first method deals with the dihedral angle, θ (subtended by the C(31)—Ir—C(34) and the C(31)—C(32)—C(33)—C(34) planes), and the difference in the bond distances of the metal from the inner and outer carbons of the diene ligand, Δd, defined as $\Delta d = [d\{\text{Ir—C(31)}\} + d\{\text{Ir—C(34)}\}]/2 - [d\{\text{Ir—C(32)}\} + d\{\text{Ir—C(33)}\}]/2$. For the vast majority of middle and late transition metal diene complexes, which generally assume the η^4-π-*cis*-1,3-diene structure, the dihedral angle, θ, is in the range 75–90° and Δd is between −0.1 and 0.1 Å. For the early transition metal diene complexes,[14] it is generally found that θ is greater than 90° and Δd varies from −0.5 to 0 Å, and this is considered diagnostic of the σ^2–π form of bonding. For the iridium derivative $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$, the value of θ is 92.9° and Δd is −0.01 Å, thus strongly suggesting a η^4–π bonding mode of the diene ligand, but with some σ^2–π component present.

In the second mode of comparison, there is an approximate linear increase in the dihedral angle, θ, with the difference in the C—C bond lengths, Δl, where $\Delta l = [l\{\text{C(31)—C(32)}\} + l\{\text{C(33)—C(34)}\}]/2 - l\{\text{C(32)—C(33)}\}$. For the later transition metals, Δl is between −0.1 and 0.0 Å, whereas in the case of early transition metals, Δl falls in the range of 0.0–0.2 Å. The calculated value of Δl for the $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ complex is 0.02 Å, which again is close to that expected for a typical late transition element, i.e. η^4–π, but also suggestive of some component of σ^2–π.

In solution, $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ has a rigid structure even at temperatures as high as 85°C. The ^{1}H NMR spectrum of the isolated complex shows four singlets of equal intensity for the silylmethyl groups ($Si(CH_3)_2$) protons in the hybrid tridentate ligand and, hence indicates quite an asymmetry in the molecule. The methylene protons on the ligand backbone (PCH_2Si) are multiplets centred at 1.85 and 2.12 ppm. Hardly any separation of the *ortho*-protons' resonance from that of the *meta*/*para*-protons' resonance of the phenyl rings is observed, thus suggesting a quasi-facial arrangement of the tridentate ligand (*cis*[15]-phosphine donors). The butadiene moiety shows six proton resonances ranging from −0.60 to 5.37 ppm. The corresponding four ^{13}C resonances for the coordinated diene ligand were identified by the use of 2D ^{13}C–^{1}H heteronuclear correlation maps (Fig. 3). Three of the four carbon resonances of the 1,3-butadiene ligand in the $^{13}C\{^1H\}$ NMR spectrum have some coupling to ^{31}P, but one carbon nucleus in particular has an additional large coupling to one of the phosphorus nuclei of the tridentate ligand (33.75 ppm, dd, $^2J_{P—C} = 41.6$ Hz, $^2J_{P—C} = 3.3$ Hz). The gated decoupled ^{13}C NMR spectrum shows $^1J_{C—H}$ for the inner carbons of the diene unit to be 165.5 Hz which is typical of the sp^2 bonded carbon centre, however, $^1J_{C—H}$ for the outer or terminal carbons are lower (~ 150.0 Hz), but are still suggestive of the sp^2 character around these carbon centres. These coupling constant results mirror the structural data in the solid state which suggest mostly η^4–π but with some σ^2–π character for the butadiene–iridium interaction. The $^{31}P\{^1H\}$ NMR spectrum consists of two singlets and is virtually temperature independent from −80 to +85°C. The fact that no coupling is observed between the inequivalent ^{31}P nuclei is somewhat unusual but is consistent with their *cis* disposition.

DISCUSSION

From the solid-state data, the complex $Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$ has a distorted five-coordinate structure with the tridentate ligand coordinated to the metal with *cis*-phosphine donors, or in a quasi-facial manner. Interestingly, the adoption of this *cis*-phosphine geometry does not result in the disilylamido unit deviating from planarity. The 1,3-butadiene ligand adopts the s-*cis* planar structure and binds to the iridium in a η^4–π fashion but with a small component of σ^2–π.

In solution, the solid-state structure is completely maintained. Not only is the five-coordinate complex stereochemically rigid on the NMR time scale, but the *cis*-butadiene unit remains asymmetrically disposed on the iridium even to temperatures as high as 85°C. This can be confirmed by the observed large $^2J_{P—C}$ coupling which we ascribe to that between P(2) and C(34) in the molecule [Fig. 2(b)].

Five-coordinate d^8 complexes have been studied[16] as the prototypes for stereochemical nonrigidity in organotransition metal chemistry. Since the bonding of the butadiene to iridium is mainly η^4–π, at least from the solid-state data, the oxidation level of the metal centre is therefore iridium(I). To rationalize the observed lack of fluxionality, it is probable that the tridentate ligand constrains the coordination environment and destabilizes any traverses through stereochemical manifolds that require geometry changes. Even access to square-planar derivatives having an η^2-bound butadiene is

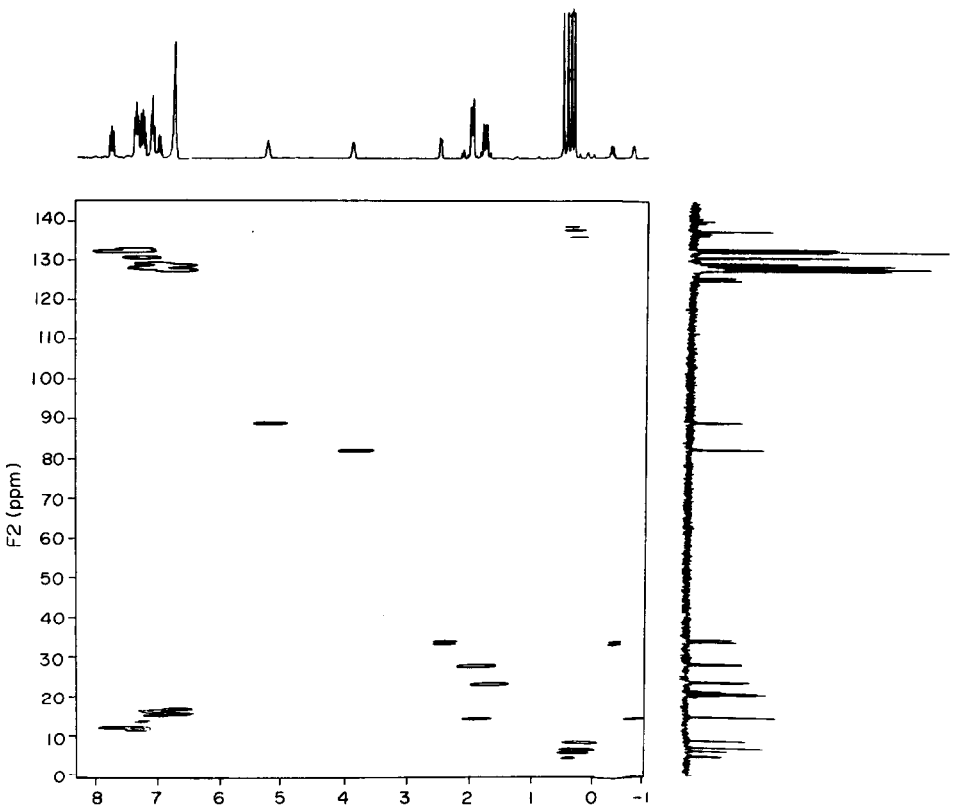

Fig. 3. Heteronuclear shift correlated 2-D (^{13}C–^1H) NMR spectrum of $Ir(\eta^4\text{-}C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$.

apparently denied since this would be easily detectable in the ^1H NMR spectroscopic parameters.

EXPERIMENTAL

All manipulations were performed under prepurified nitrogen in a Vacuum Atmospheres HE-553-2 glovebox equipped with a MO-40-2H purification system, or in a standard Schlenk-type glassware on a dual vacuum–nitrogen line. 1,3-Butadiene was purchased from Matheson and used without further purification. Hexanes were dried over CaH_2, followed by distillation from sodium–benzophenone–ketyl under argon. Toluene was also distilled from sodium–benzophenone–ketyl under argon. Deuterated solvents, C_6D_6, and C_7D_8, were dried over activated 4 Å molecular sieves, vacuum transferred and deoxygenated by freeze–pump–thaw cycles prior to use. Carbon, hydrogen and nitrogen analyses were performed by Mr P. Borda of our department. ^1H NMR spectra were recorded on a Bruker WH-400 spectrometer and are referenced to C_6D_5H at 7.15 ppm; coupling constants are in Hz and the numbers of the carbons in the preparation below refer to the numbers of the carbon atoms in the X-ray structure (Fig. 1). ^{13}C NMR spectra (referenced to C_6D_6 at 128.00 ppm or $CD_3C_6D_5$ at 20.4 ppm) were run at 75.429 MHz, and $^{31}P\{^1H\}$ NMR spectra (referenced to external $P(OMe)_3$ set at +141.00 ppm) were run at 121.421 MHz, on a Varian XL-300 spectrometer. ^{13}C–^1H heterocorrelation maps were also recorded on the Varian XL-300 spectrometer.

$Ir(\eta^4\text{-}C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$

A solution of $Ir(\eta^2\text{-}C_8H_{14})[N(SiMe_2CH_2PPh_2)_2]$ (100 mg, 0.120 mmol) in toluene (5 cm^3) was loaded in a thick-walled, reactor bomb equipped with a 5 mm Kontes needle valve. The vessel was attached to a vacuum line, degassed and cooled to liquid N_2 temperature. Excess 1,3-butadiene ($\approx$ 5 equiv) was condensed in the bomb and the valve sealed. The reaction mixture was stirred for 1 h at room temperature. Toluene was removed *in vacuo* and the residue recrystallized from toluene–hexanes at room temperature. Yield: 88 mg (95%). Found: C, 53.3; H, 5.5; N, 1.6. X-ray crystallographic analysis of $Ir(\eta^4\text{-}C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$

Crystallographic data appears in Table 3. The final unit-cell parameters were obtained by least-squares on $2\sin\theta/\lambda$ values for 25 reflections with $2\theta = 41$–$46°$. The intensities of three check reflections, measured after each hour of X-ray exposure time throughout the data collection, showed only small random fluctuations. Data were processed

[a] Temperature 294 K, Enraf–Nonius CAD4-F diffractometer, Mo-K_α radiation ($\lambda_{K_{\alpha_1}} = 0.70930$, $\lambda_{K_{\alpha_2}} = 0.71359$ Å), graphite monochromator, take-off angle 2.7°, aperture $(2.0 + \tan\theta) \times 4.0$ mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C-B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m-n))^{1/2}$. Values given for R, R_w and S are based on those reflections with $I \geqslant 3\sigma(I)$.

[b] Reduced cell.

and corrected for absorption (numerical integration).[17]

The structure was solved by conventional heavy-atom methods. The iridium, phosphorus and silicon coordinates were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier synthesis. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions [$C(sp^2)$—H = 0.97 Å, $C(sp^3)$—H = 0.98 Å, methyl groups staggered, thermal parameters proportional to that of the bound atom]. An isotropic Type I extinction correction[18–21] was applied, the final value of g being 3.7×10^4.

Final positional and equivalent isotropic thermal parameters (U_{eq} = 1/3 trace diagonalized U), bond distances, bond angles, intra-annular torsion angles, calculated hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and observed and calculated structure factors have been deposited with the Cambridge Crystallographic Data Centre.

ELECTROCHEMICAL STUDIES ON SIMPLE AND MIXED LIGAND COMPLEXES USING A HANGING MERCURY DROP ELECTRODE FOR STATIONARY ELECTRODE VOLTAMMETRY

HAMADA M. KILLA

Chemistry Department, Faculty of Science, Zagazig University, Zagazig, Egypt

(*Received* 31 *March* 1989; *accepted* 4 *May* 1989)

Abstract—A hanging mercury drop electode (HMDE) was used to study the simple and mixed ligand complexes of 1,3-diaminopropane (DAMP) and malonate (Mal) with cadmium(II) at constant ionic strength (μ = 1.0 M, $NaNO_3$) and 25°C, using linear-scan and cyclic modes. The reduction of the simple and mixed complexes is reversible and diffusion controlled. The composition and stability constants of simple and mixed species have been studied, as well as the mixing constants for the mixed complexes. The overall formation constants of the mixed species were calculated statistically using the Watters and DeWitt method and compared with the observed values. The equilibria between the various mixed ligand complexes in solution and their equilibrium are also given.

Stationary electrode voltammetry was adopted as an electroanalytical technique much later than polarography. The first theoretical considerations of the reversible process were published by Randles[1] and Ševčik.[2] The development of stationary electrode voltammetry has been markedly enhanced by the introduction of the hanging mercury drop electrode (HMDE).[3,4]

The hanging mercury drop electrode has been widely used in analysis and physico-chemical investigations.[3,5–7] It has also been employed in studies of the mechanism of electrode processes and has been found to be particularly useful in investigations of mechanisms of oxidation and reduction of organic compounds.[8–10]

The modern electroanalytical techniques offer considerable advantages compared to conventional DC polarography, in particular for the determination of formation constants of metal complex ions in solution.[11] In my previous paper[12] the HMDE has been used for the determination of formation constants of simple complexes. In the present work, the HMDE was extended to study the mixed-ligand complexes of cadmium(II) with malonate (Mal) as the primary ligand and 1,3-diaminopropane (DAMP) as the secondary ligand.

EXPERIMENTAL

The linear-scan and cyclic voltammograms were measured with a princeton Applied Research Model 174 A Polarographic analyser. Potential–current curves were recorded on an X–Y recorder Type Advance AR-2000. A conventional three-electrode cell with saturated calomel electrode (SCE) was employed. The working electrode in linear-scan and cyclic measurements was a PAR 9323 (stationary) hanging mercury drop electrode and the electrode area normally employed was 0.0408 cm^2. The scan rate was 100 mV s^{-1}.

For differential pulse (d.p.) polarography, a drop time of 1.0 s, a scan rate of 5 mV s^{-1} and a potential pulse of 50 mV, were used throughout the measurements.

All measurements were made at 25°C and an ionic strength of 1.00 M was maintained by using sodium nitrate. The concentration of Cd^{2+} ions was 2×10^{-4} M.

Reagent-grade chemicals, deionized water and mercury (Merck) were employed in all cases. A maximum suppressor was not used.

Theory

The DeFord–Hume[13] method for determining the stability constants of simple complexes has been modified by Killa[12] when using the HMDE for stationary electrode voltammetry instead of DC polarography. The expression may be written as:

$$F_0(X) = B_j C_x^j$$

$$= \text{antilog}\{0.434(nF/RT)\Delta E_p + \log(i_p)_s/(i_p)_c\}, \quad (1)$$

where B_j is the overall stability constant for the jth complex; C_x is the analytical concentration of the ligand which is always taken in large excess over the metal ion concentration, and is, therefore, considered as the total ligand concentration; $\Delta E_p = (E_p)_s - (E_p)_c$ is the shift in the linear-sweep voltammetry (l.s.v) peak potential caused by complexation; and the subscripts s and c refers to the simple and complex ions, respectively.

Nicholson and Shain[14] have shown that the peak potential (E_p) for a reversible process, obtained from a stationary electrode polarogram, is related to the half-wave potential of DC polarography ($E_{1/2}$) by:

$$E_p = E_{1/2} - \frac{28.5}{n}. \quad (2)$$

According to eq. (2), the shift in the half-wave potential, $(E_{1/2})_s - (E_{1/2})_c = \Delta E_{1/2}$, is equal to the shift in the peak potential obtained from the stationary electrode polarogram, $(E_p)_s - (E_p)_c = \Delta E_p$.

Similarly, the determination of stability constants of mixed-ligand complexes using Schaap and McMaster's[15] expression, might be modified for the l.s.v polarogram:

$$F_{00}(XY) = \text{antilog}\{0.434(nF/RT)\Delta E_p + \log (i_p)_s/(i_p)_c\}, \quad (3)$$

where $\Delta E_p = (E_p)_s - (E_p)_c$ is the shift in the peak potential due to complexation. The term $\log (i_p)_s/(i_p)_c$ is normally small because it makes little contribution to the $F_{00}(XY)$ function. Thus, eq. (3) can be simplified to give an expression of the form:

$$F_{00}(XY) = \text{antilog}\{0.434(nF/RT)\Delta E_p\}. \quad (4)$$

The formation constants of the mixed-ligand complex can then be determined by using eq. (4), as described by Schaap and McMaster.[15]

RESULTS AND DISCUSSION

The reduction of simple and mixed complexes was found to be reversible, involving two electrons as indicated by the difference in potential between the cathodic and anodic peaks ($E_{p_a} - E_{p_c}$), which is close to the value of the following expression:[16,17]

$$E_{p_a} - E_{p_c} = \frac{59}{n} \text{ mV}, \quad (5)$$

where E_{p_a} and E_{p_c} are the anodic and cathodic peak potentials, respectively, of the HMDE using the cyclic voltammetry mode. The $(E_{p_a} - E_{p_c})$ values of mixed-ligand complexes are given in Tables 1 and 2.

The reversibility of the systems under investigation, simple and mixed, was confirmed using d.p. polarography in nitrate medium; the half-peak widths were 62 ± 1 mV with 50 mV pulse amplitude, which are in good agreement with the calculated values by Dillard and Hanck.[18]

It should be noted that for a reversible system using stationary electrode voltammetry, E_p is independent of scan rate (V) and i_p is proportional to $V^{1/2}$,[19] which indicates diffusion control and is analogous to the variation of i_d with $h^{1/2}$ in DC polarography. In the present work, the plots of i_p against $V^{1/2}$ were linear, indicating that the reduction of the simple and mixed system in nitrate medium was diffusion controlled.

It should be noted that linear diffusion has been assumed, which is not strictly correct for the HMDE with the scan rate and electrode radius used

in this work, and errors of the order of 2% are expected. Also, the peak potentials (E_p) were measured within ± 0.5 mV. However, in all cases the results were within the experimental error.

Cadmium(malonate) system

In each solution the concentration of Cd^{2+} ions was maintained constant at 2×10^{-4} M and the malonate (Mal) concentrations were varied from 0.01 to 0.4 M. The stability constants were calculated by the graphical extrapolation method using the DeFord–Hume expression, as modified for the case of the stationary electrode (HMDE).[12] The results showing the existence of 1:1, 1:2 and 1:3 complex species with overall stability constants: $\log B_{01} = 1.85$, $\log B_{02} = 2.76$ and $\log B_{03} = 3.65$, agreed well with those obtained by Khurana and Gupta[20] if the differences in experimental conditions are considered.

Cadmium(1:3-diaminopropane) system

The concentration of DAMP was varied from 0.01 to 0.4 M. Three complex species were formed with stability constants: $\log B_{10} = 5.48$, $\log B_{20} = 7.59$ and $\log B_{30} = 8.31$, evaluated by the DeFord–Hume expression modified for the case of the HMDE.[12] The results are in good agreement with the previously reported values by Gupta *et al.*[21] using DC polarography and Killa and Zaky[22] using d.p. polarography.

Cadmium(diaminopropane)(malonate) system

The malonate ion concentrations were kept constant at 0.10 and 0.25 M, because at these concentrations 1:1 and 1:2 cadmium(malonate) complexes were found to be the predominant species. The concentration of DAMP was varied. The E_p values were greater compared to those obtained in the absence of malonate, thereby showing the formation of mixed complexes.

The formation constants of mixed-ligand complexes were determined by the graphical extrapolation method of Schaap and McMaster using eq. (4) for the linear-sweep voltammetry (l.s.v) wave. The l.s.v results using HMDE as a stationary electrode are given in Tables 1 and 2. The values of F_{00}, F_{10}, F_{20} and F_{30}, as well as the results of $\log A$, $\log B$, $\log C$ and $\log D$ at 0.10 and 0.25 M malonate concentrations, are also given in Tables 1 and 2, respectively.

The results reveal the existence of three mixed-ligand complexes with overall stability constants: $\log B_{11} = 6.72$, $\log B_{12} = 7.51$ and $\log B_{21} = 8.13 \pm 0.04$, respectively. It can be noted that $\log B_{30}$ and $\log D$ agree, as predicted by theory.

The equilibria between various species existing in the mixed-ligand system together with the log stepwise stability constant values ($\log K$) are represented schematically in Fig. 1. The $\log K$ values for addition of Mal to [Cd(Mal)] and $[Cd(DAMP)]^{2+}$ are 0.91 and 1.24. Likewise, the tendency to add DAMP to [Cd(Mal)] and $[Cd(DAMP)]^{2+}$ are 4.87 and 2.11. The $\log K$ values obtained for the addition of neutral DAMP as a third ligand to $[Cd(Mal)_2]^{2-}$, [Cd(DAMP)(Mal)] and $[Cd(DAMP)_2]^{2+}$ are 4.75, 1.41 and 0.72, respectively. It is clear from these results, that the tendency for mixed-ligand complex formation is favoured. It is also obvious from the schematic diagram that the $\log K$ values for the addition of DAMP to the saturated complexes $[Cd(Mal)_3]^{4-}$, [Cd(DAMP)

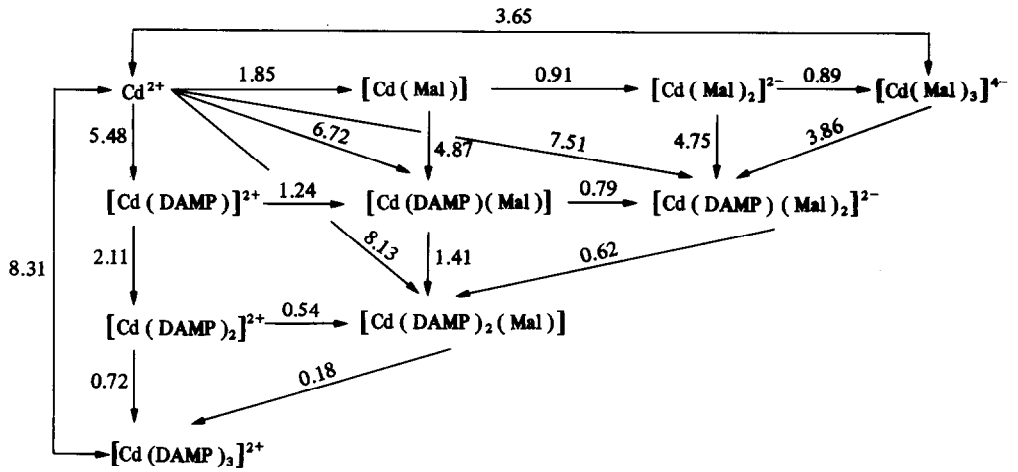

Fig. 1. The equilibria between mixed-ligand species and log K values for these equilibria.

$(Mal)_2]^{2-}$ and $[Cd(DAMP)_2(Mal)]$ are 3.86, 0.62 and 0.18, respectively, which indicates that the saturated complex can replace Mal by DAMP. This also indicates that the malonate ligand is much weaker than the neutral ligand, DAMP, and indicates the relative stability of mixed-ligand complexes over the parent binary complexes.

The mixing constant ($\log K_M$) for the reaction:

$$\tfrac{1}{2}[Cd(DAMP)_2]^{2+} + \tfrac{1}{2}[Cd(Mal)_2]^{2-} = [Cd(DAMP)(Mal)] \quad (6)$$

indicates the relative stability of the mixed species in solution compared to parent binary complexes. This is given by the following relation:[23,24]

$$\log K_m = \log B_{11} - \tfrac{1}{2}(\log B_{02} + \log B_{20}). \quad (7)$$

This yields $\log K_m = +1.545$ for reaction (6). Moreover, the stabilization constant ($\log K_s = \log K_m - \log 2$)[25] is equal to +1.244. The positive values of mixing and stabilization constants show the stability of mixed species compared with simple complexes.

Watters and DeWitt[26] have derived the following expression for the prediction of stability constants of mixed-ligand complexes from statistical factors:

$$B_{11} = 2[4/9B_{02} \times B_{20}]^{1/2}$$

$$B_{12} = 3B_{30}^{1/3} \times B_{03}^{2/3}$$

$$B_{21} = 3B_{30}^{2/3} \times B_{03}^{1/3}.$$

The values of stability constants (log values) calculated from the above expressions are 5.29, 5.67 and 7.22, respectively. The experimental values for the mixed complex species are higher than the statistically calculated values. This has been explained by many workers[15,27] by considering the cooperative effects of electrostatic forces between different kinds of ligands and steric effects. This may also account for the neutralization of charge.[24]

The formation of neutral ternary complexes from the parent complexes can be represented as follows:

$$[Cd(DAMP)_2]^{2+} + [Cd(Mal)_2]^{2-} \rightleftharpoons 2[Cd(DAMP)(Mal)]. \quad (8)$$

Many workers[28-30] have observed that charge neutralization favours formation of mixed-ligand species. In addition to Coulombic effects, such a neutralization of charge would be expected to be accompanied by a positive entropy change due to decreased orientation of the solvent molecule. The present results are in agreement with this postulate.

(*Received* 31 *March* 1989; *accepted* 4 *May* 1989)

Abstract—The IR spectra of the title compounds, abbreviated *trans*-[Ni(acac)$_2$(H$_2$O)$_2$], [Cu(acac)$_2$], [Zn(acac)$_2$(H$_2$O)] (acac = 2,4-pentanedionate anion), [M(Nacac)$_2$] (M = Ni, Cu; Nacac = 4-imino-2-pentanonate anion), [M(Sacac)$_2$] (M = Ni, Cu, Zn; Sacac = 4-thioxo-2-pentanonate anion) and [Ni(SacSac)$_2$] (SacSac = 2,4-pentanedithionate anion) have been examined over the range 4000–50 cm^{-1} with a view to determining band assignments based on the effects of metal ion substitution and the establishment of spectra–structure correlations for these complexes. The ^{1}H and ^{13}C NMR spectra of the diamagnetic complexes are reported and discussed.

Substitution of nitrogen or sulphur for oxygen in the complexes of nominal formula [M(acac)$_2$] yields square-planar complexes with the exception of [Zn(Sacac)$_2$] which is tetrahedral. Despite the interest which attaches to these novel β-ketoenol analogues, their IR spectra have received rather limited attention,[1–13] and coverage of this field has been piecemeal rather than systematically embracing all of these molecules under similar experimental conditions as in the presently described work. The effect of substitution of the metal ion considered in relation to the established structures of these molecules assists in solving the assignment problem.[14]

EXPERIMENTAL

The complexes were prepared using methods described in the literature.[1–13,15] Composition and purity were established by microanalysis (Table 1).

The ^{1}H and ^{13}C NMR spectra were obtained at ambient temperature on a Varian VXR-200, using $CDCl_3$ and CD_3COCD_3 as solvents with TMS as reference. IR spectra were determined as Nujol mulls (4000–1500 and 1300–300 cm^{-1}) or hexachlorobutadiene mulls (4000–1700 and 1500–1300 cm^{-1}) between CsI plates on a Perkin–Elmer 983 spectrophotometer, and as Nujol mulls between polyethylene plates (500–50 cm^{-1}) on a Digilab FTS-16 B/D interferometer.

RESULTS AND DISCUSSION

IR spectra

The frequencies and assignments are given in Table 2 and the spectra are depicted in Fig. 1.

The 2,4-*pentanedionates,* trans-[Ni(acac)$_2$(H$_2$O)$_2$], [Cu(acac)$_2$] *and* [Zn(acac)$_2$(H$_2$O)]

Numerous studies of the IR spectra of the parent acac complexes of the three metals discussed here: nickel(II), copper(II) and zinc(II) have been reported[15,16] and these will be the preliminary basis for our discussion of the effects of oxygen-donor substitution by nitrogen or sulphur. Since anhydrous [Ni(acac)$_2$]$_n$ has a complex polymeric octahedral structure,[15] we will employ the simpler bis(aquo) octahedral complex *trans*-[Ni(acac)$_2$(H$_2$O)$_2$] as the basis for comparison[17] with N- and S-substituted derivatives of nickel. [Cu(acac)$_2$]

is a simple square-planar monomer[15] and therefore entirely analogous, structurally, with $[Cu(Nacac)_2]$ and $[Cu(Sacac)_2]$, while zinc(II) forms a square-based pyramidal monohydrate with 2,4-pentanedionate[15] of formula $[Zn(acac)_2(H_2O)]$, differing structurally from the tetrahedral molecule $[Zn(Sacac)_2]$. Assignments for the three metal acac complexes discussed here have been made on the basis of normal coordinate analyses[18–21] and isotopic labelling studies.[16,22]

We have reconsidered our assignments of $[Zn(acac)_2(H_2O)]$ which were based on a combination of ^{18}O- and $^{64,68}Zn$-labelling.[22] This study showed conclusively that the bands at 555, 420, 388, 239 and 171 cm^{-1} are metal–ligand bands, but did not serve to distinguish between the Zn—O stretching and O—Zn—O bending modes. We now consider that the bands listed above all have Zn—O stretching character except for that at 171 cm^{-1} which is assigned to the δ(O—Zn—O) bending mode. These amended assignments are based on the finding that bands near 300 cm^{-1} in the IR spectra

[a] This band has been assigned to a C—C—C bend since it is unaffected by ^{18}O- or $^{64,68}Zn$-labelling.[22]
[b] Assigned to τ(C—CH$_3$) (ref. 3).

of metal acac complexes are more sensitive to metal isotope labelling than those near 450 cm^{-1}.[18]

The 4-imino-2-pentanonates, $[M(Nacac)_2]$ (M = Ni, Cu)

Substitution of one oxygen atom of 2,4-pentanedione by the imino group —NH leads to *trans*-square-planar complexes, $[M(Nacac)_2]$ (M = Ni, Cu).[1-3] These complexes have C_{2h} point group symmetry and we therefore expect to observe two ν(M—L) and four δ(L—M—L) bands in their IR spectra. Comparison of the spectra of $[Cu(acac)_2]$ and $[Cu(Nacac)_2]$, both of which are square-planar, reveals markedly similar band patterns. The ν(M—L) vibrations at 454 and 288 cm^{-1} in $[Cu(acac)_2]$ are observed at 463 and 277 cm^{-1} in the Nacac complex. In the square-planar $[Ni(Nacac)_2]$ complex these bands are shifted to 481 and 315 cm^{-1}, respectively. The higher frequency vibration (481 cm^{-1}) is insensitive to nitrogen deuteration[3] and is therefore assigned as ν(Ni—O) and the band at 315 cm^{-1} as ν(Ni—N). The relatively low intensity of the lower frequency band is typical of ν(M—N) modes.[23] Two very weak bands observed at 408 and 334 cm^{-1} for $[Cu(Nacac)_2]$ (for which no analogous $[Cu(acac)_2]$ bands exist) are shifted to 421 and 361 cm^{-1} when substituting nickel for copper. These two bands may be attributed to IR forbidden ν(M—L) modes which are observed due to lowering of the symmetry of the $[M(Nacac)_2]$ complexes. The skeletal deformations of 430 and 265 cm^{-1} in $[Cu(acac)_2]$ occur at 436 and 296 cm^{-1} in $[Cu(Nacac)_2]$. The sensitivity of the upper band to metal substitution implies strong coupling to the metal–ligand mode.

Below 250 cm^{-1}, assignment of δ(L—M—L) at 228, 185 and 120 cm^{-1} in $[Cu(Nacac)_2]$ is readily made by comparison with $[Cu(acac)_2]$. The nickel complex is similar. The band at 230 cm^{-1} in the copper complex spectrum is unaffected by metal ion substitution and this supports its assignment on the basis of normal coordinate analysis to a $\tau(C—CH_3)$ torsional mode.[3]

It is of interest to note that, if the ν(M—L) assignments which have been proposed above are correct, bands in the spectrum of the nickel complex are at higher frequencies than corresponding bands in the copper complex. In octahedral complexes the stability sequence Ni < Cu is usually observed because of the extra stabilization which is conferred on the copper complex by Jahn–Teller distortion.[14] However, in square-planar symmetry, the expected stability sequence is Ni > Cu because the copper complex has an additional antibonding electron.[24] The ν(M—L) frequency order for these complexes is Ni > Cu and this observation supports the proposed assignment.

The 4-thioxo-2-pentanonates, $[M(Sacac)_2]$ (M = Ni, Cu, Zn)

The *cis*-square-planar configuration of the nickel and copper complexes implies C_{2v} point group symmetry. Group theory predicts four ν(M—L) and seven δ(L—M—L) modes. The zinc complex probably adopts a tetrahedral coordination geometry[8] and, as such, may be assigned C_2 symmetry. Of the IR allowed bands, four ν(M—L) and nine δ(L—M—L) are expected.

A band occurs very close to 500 cm^{-1} in all three complexes. On the basis of a normal coordinate analysis[8] a split band at 498, 492 cm^{-1} in the spectrum of the nickel complex was assigned to $\delta(C—CH_3)$+ring def. We agreed with this assignment so far as the 498 cm^{-1} component is concerned, since this component is not shifted by metal ion substitution. However, the 492 cm^{-1} component shifts to 471 cm^{-1} on substitution of copper for nickel and this suggests that it should be correctly assigned to ν(M—O) [probably[8] coupled to $\delta(C—CH_3)$]. The frequency order ν(Ni—O) > ν(Cu—O) would be anticipated for a band assigned to ν(M—O) [or for that matter, to ν(M—S)] for the reasons advanced above in the case of the Nacac complexes. In the tetrahedral zinc(II) complex, only one band occurs near 500 cm^{-1} and this is assigned to ν(Zn—O)+ring def.+ $\delta(C—CH_3)$.[6] These assignments are at variance with those of the normal coordinate analyses by Siimann *et al.*[6,8] They assign a band at 648 cm^{-1} to ν(M—O). We observe this band to be less sensitive to metal substitution than those at lower frequencies. We therefore prefer to assign it to an out-of-plane ring deformation which is coupled with ν(M—L).

Both the nickel and copper complexes exhibit three bands between 410 and 360 cm^{-1}. The two upper bands at 409 and 396 cm^{-1} in the nickel complex are shifted to 387 and 379 cm^{-1} on substituting nickel by copper. These bands are accordingly assigned as ν(M—O) and ν(M—S). The lowest band at 373 cm^{-1} in the nickel complex is not as sensitive to metal substitution and is attributed to a ring deformation.[8] Only two bands are observed in this region of the $[Zn(Sacac)_2]$ spectrum, although a shoulder on the upper band indicates coincident vibrations. A weak band at 308 cm^{-1} in the spectrum of $[Ni(Sacac)_2]$ reported variously at 300 and 285 cm^{-1} by Siimann *et al.*[6,8] is strongly metal sensitive in the expected sequence Ni > Cu. It is assigned to ν(M—S) due to both its low intensity

and the fact that it is reasonably close to the calculated ν(Ni—S) frequency.[6] The band at 252 cm^{-1} in the spectrum of [Ni(Sacac)$_2$] is assigned as δ(L—M—L). Although previously attributed to a stretching vibration,[9] the occurrence of this band at approximately half the frequency of ν(M—O) (492 cm^{-1}) supports our assignment. In addition, all four expected ν(M—L) are already assigned. The weak band at 196 cm^{-1} is observed at 194 cm^{-1} in the Raman spectrum and it is assigned as a further ν(Ni—S) mode.[9] However, substitution of copper for nickel causes the band to shift only 12 cm^{-1} and, in addition the δ(S—Ni—S) bands in [Ni(SacSac)$_2$] occur near 200 cm^{-1}. For these reasons assignment to a metal–ligand bending mode is preferred.

The remaining vibrations below 200 cm^{-1} are assigned to δ(L—M—L) and lattice modes, with the exception of the band near 150 cm^{-1} which is attributed to a ring deformation on the grounds of its insensitivity to metal substitution. This is consistent with the normal coordinate analysis of Siimann and Fresco.[6] The assignment of two bands at 396, 308 cm^{-1}, and 379, 264 cm^{-1} in the spectra of the nickel and copper complexes, respectively, is consistent with the sequence Ni > Cu, expected for ν(M—S) modes. These bands are also reasonably located at lower frequencies than the ν(M—O) modes due to the greater mass of the sulphur atom, as well as the fact that the M—O force constant is greater than the M—S force constant.[8] In the zinc(II) complex, the ν(Zn—S) bands occur at 386 and 274 cm^{-1}. The greater number of bending vibrations observed in this spectrum is consistent with the C_2 symmetry of the zinc complex.

Bis(2,4-*pentanedithionato*)*nickel*(II), [Ni(SacSac)$_2$]

The square-planar nickel complex has D_{2h} point group symmetry and is therefore analogous to [Cu(acac)$_2$] for which two ν(M—L) are expected. Assignments are straightforwardly made as only one type of metal–ligand mode is present, *viz.* ν(Ni—S). Thus the region 550–400 cm^{-1}, where ν(M—O) was found for the [Ni(Nacac)$_2$] and [Ni(Sacac)$_2$] complexes, is free from any bands. The band at 390 cm^{-1} clearly qualifies for assignment to ν(Ni—S). This is consistent with normal coordinate analyses performed for this square-planar complex and its cobalt(II) analogue.[11,12] In addition, it supports the assignment of the band at 396 cm^{-1} in [Ni(Sacac)$_2$] to ν(Ni—S). The assignment of the band at 286 cm^{-1} to ν(Ni—S) is also consistent with these normal coodinate analyses. Similarly, the band at 374 cm^{-1} may be assigned to a ring deformation. The bands at 240, 227 and 216 cm^{-1} are clearly δ(S—Ni—S) modes occurring at approximately half the frequency of the corresponding stretches. Their appearance at these frequencies supports our assignment of the 252 and 196 cm^{-1} bands in the spectrum of the mixed donor atom complex, [Ni(Sacac)$_2$], to bending modes rather than the previously proposed stretching bands (*vide infra*). The vibration at 149 cm^{-1} is unshifted on changing from [Ni(Sacac)$_2$] to [Ni(SacSac)$_2$], further supporting its assignment as a ring deformation.

Spectra in the mid-IR region

In the acac complex spectra, the presence of coordinated water in the nickel and zinc complexes yields ν(OH) bands near 3400 cm^{-1} (nickel) and 3300 cm^{-1} (zinc). The methyl groups give rise to ν(C—H) bands within the range 2900–3200 cm^{-1} in all of the spectra. The stretches of the γ-methine groups are observed weakly just above 3000 cm^{-1}. In the Nacac complexes the single expected ν(N—H) is a strong band near 3300 cm^{-1}.

The carbonyl region is of particular interest in view of the alternative assignments for ν(C=O) and ν(C=C) bands which have been given by the normal coordinate analysis of [Cu(acac)$_2$]. The bands observed near 1580 and 1520 cm^{-1} were assigned[19] to ν(C=C) and ν(C=O), respectively, but these assignments were subsequently reversed by ^{18}O-labelling studies and a revised normal coordinate treatment.[21,22] It is now generally accepted that the band of higher frequency is predominantly ν(C=O) in 2,4-pentanedionates. This is supported by the absence of this higher frequency band in the [Ni(SacSac)$_2$] complex spectrum.

Bands which are unique to the spectra of the Nacac complexes are attributed to vibrations involving the nitrogen atom. The ν(C—N) mode occurs near 1380 cm^{-1}, which is similar to that found in the free ligand.[25] As expected, this band is absent from the acac complex spectra. The metal-sensitive vibration near 1470 cm^{-1} is assigned to the δ(N—H) in-plane mode, while a doublet between 830 and 800 cm^{-1} is assigned to the δ(N—H) out-of-plane mode. Extensive splitting of vibrations in Nacac complex spectra may be attributed to their lower symmetry and solid state effects.[3]

For complexes of Sacac, Chaston *et al.*[26] assigned a band in the region 1270–1190 cm^{-1} to ν(C—S) and tentatively assigned a band between 837 and 805 cm^{-1} to a coupled ν(C—S) and δ(CH_3) mode. However, subsequent normal coordinate analyses on complexes of both the Sacac[8] and the SacSac[11,12] ligands have shown the C—S stretching frequency to occur near 700 cm^{-1}. This is further supported by the assignment of ν(C—S) in the region 850–550

cm^{-1} in dithiooxalato complexes,[27,28] dithiooxamido complexes[29] and xanthato complexes.[30] Our assignment of ν(C—S) near 720 cm^{-1} is supported by the observed shifts of 9 and 17 cm^{-1}, on substituting nickel with copper and zinc, respectively. This vibrational frequency is low for a carbon–sulphur double bond. However, bonding in the chelate ring of [Ni(Sacac)$_2$] most resembles the resonance structure with a single carbon–sulphur bond.[6] The band observed at 985 cm^{-1} in [Ni(Sacac)$_2$] is shifted 25 cm^{-1} on substituting copper for nickel. This metal sensitivity may be due to extensive coupling to ν(C—S) as observed for vibrations near 1050 cm^{-1} in dithiooxalato complexes.

^{1}H *and* ^{13}C *NMR spectra*

The ^{1}H and ^{13}C NMR data are listed in Table 3, and are consistent with the tetracoordinate structures that have been proposed earlier. The square-planar copper complexes and octahedral [Ni(acac)$_2$(H$_2$O)$_2$] complexes are paramagnetic and their spectra were not determined.

Although the data have been used primarily to characterize the complexes, a few points of interest may be mentioned. Firstly, in the ^{1}H NMR spectrum it is the methine proton which is most sensitive to metal ion and ligand donor atom substitution, whereas in the ^{13}C NMR the methine carbon atom as well as the carbon atoms attached to the ligand donor atoms are sensitive to substitution. Secondly, the ^{1}H and ^{13}C resonances associated with the chelate ring are shifted considerably on ligand donor atom substitution and only slightly on metal ion substitution.

Finally, the complexes [Ni(Nacac)$_2$] and [Ni(Sacac)$_2$] have the possibility of existing as *cis* or *trans* isomers. However, it is concluded either that one isomer predominates at ambient temperature or that rapid exchange is taking place (as seen in similar systems[31]).

(*Received* 16 *March* 1989; *accepted* 4 *May* 1989)

Abstract—The molecular structures and spectroscopic properties of the compounds $[Cu(NCS)_2(L)_2]$ (L = 6-methyl[1,2,4]triazolo[1,5-*a*]pyrimidine, $C_6N_4H_6$, abbreviated 6mtp, and L = 5-methyl[1,2,4]triazolo[1,5-*a*]pyridimine, $C_6N_4H_6$, abbreviated 5mtp) are described. The structures of $[Cu(NCS)_2(6mtp)_2]$ (**1**) and $[Cu(NCS)_2(5mtp)_2]$ (**2**) have been determined by single-crystal X-ray diffraction. Compound **1** is monoclinic, space group $C2/c$, with $a = 12.096(9)$, $b = 8.466(6)$, $c = 18.327(7)$ Å, $\beta = 101.95(9)°$, $Z = 4$. Compound **2** is monoclinic, space group $P2_1/c$, with $a = 12.451(7)$, $b = 8.952(5)$, $c = 8.061(5)$ Å, $\beta = 106.53(2)°$, $Z = 2$. Both structures have been solved from diffractometer data by Patterson and difference Fourier methods, and refined by full-matrix least-squares to $R = 0.0365$ for 1400 observed reflections (**1**) and to $R = 0.0370$ for 1195 independent observed reflections (**2**). In **1** mononuclear complexes are present, in which each copper atom is surrounded by four donor nitrogen atoms: two N-atoms of two N(3)-coordinating 6mtp ligands, and two N-atoms of the non-bridging NCS-ions in a distorted tetrahedral arrangement (Cu—N = 1.931(3)–1.975(2) Å, N—Cu—N = 93.5(1)–143.5(1)°). In **2** four donor nitrogen atoms, from two N(3)-coordinating 5mtp ligands and two monodentate NCS-ions, give square-planar copper in a *trans* configuration (Cu—N = 1.921(4)–2.020(4) Å, N—Cu—N = 91.2(1)–88.8(2)°). Two N(1)-atoms of the 5mtp ligands of neighbouring complexes, at a rather long distance of 2.677 Å, complete the elongated octahedral coordination of the metal and join the complexes in layers.

Coordination compounds of [1,2,4]triazolo[1,5-*a*]pyrimidines have been considered as model systems for various naturally occurring metal coordination compounds.[1] Their three possible N-donor sites account for several different coordination modes.

In Fig. 1 the IUPAC numbering system is compared with the biochemical numbering system for purine ligands. Unless stated otherwise, the IUPAC numbering is used throughout this manuscript.

By coordinating in an adenine-type bidentate mode via N(3) and N(4), these triazolopyrimidines act as a model system for purine-type ligands.[2–5] On the other hand, the 1,2,4-triazole ring has a

* Author to whom correspondence should be addressed.

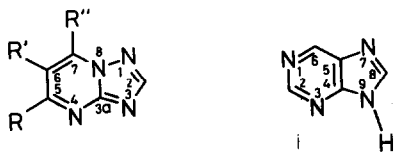

Fig. 1. IUPAC numbering of triazolopyrimidines and biochemical numbering of purines.

geometry and electronic structure similar to that of imidazole.[6] When bridging through N(1)—N(3), [1,2,4]triazolo[1,5-*a*]pyrimidine is therefore especially suited for mimicking imidazolato bridges in model compounds for metalloproteins such as superoxide-dismutase.[7-8] In fact, a few of these compounds have already been reported.[9a]

The substitution of methyl groups onto the triazolopyrimidine can influence the favoured coordination mode to a certain extent. Earlier, the ligand 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (abbreviated dmtp) was studied. The methyl groups seemed to cause too much steric hindrance, allowing no coordination mode other than monodentate bonding through the N(3)-atom to occur.[10-13] Only in one case was an adenine-type, dinucleating mode via N(3)- and N(4)-atoms observed.[14]

Recently the preparation of several polynuclear metal coordination compounds with the unsubstituted [1,2,4]triazolo[1,5-*a*]pyrimidine (abbreviated tp) has been reported.[9b] It was concluded that tp could not only coordinate in the monodentate mode through N(3), but could also be more or less forced to act as a bridging ligand through both non-bridgehead triazole nitrogen atoms, N(1) and N(3).

To further investigate the influence of methyl groups on substituted triazolopyrimidines, two related ligands, 6-methyl[1,2,4]triazolo[1,5-*a*]pyrimidine (abbreviated 6mtp) and 5-methyl[1,2,4]triazolo[1,5-*a*]pyrimidine (abbreviated 5mtp), differing only very slightly in structure from dmtp, were prepared. Theoretically, these ligands too can use N(1), N(3) and N(4) for coordination. Two copper(II) coordination compounds were obtained having the general formula $[Cu(NCS)_2(L)_2]$ (L = 5mtp and 6mtp). As in $[Cu(NCS)_2(dmtp)_2]$ (α- and β-isomer)[10a,11] and α-$[Cu(NCS)_2(tp)_2]$,[9b] the complexes are dinuclear and pseudo-polynuclear, respectively, the determination of the structures of $[Cu(NCS)_2(6mtp)_2]$ and $[Cu(NCS)_2(5mtp)_2]$ appeared to be a good opportunity to investigate the effect of the 5- and 6-methyl substituents on the coordination behaviour of the triazolopyrimidine ligand. Their molecular structures and spectroscopic properties will be compared with those of earlier prepared copper(II) thiocyanate compounds.

EXPERIMENTAL

Materials

The metal salts used for the preparations were reagent grade and used without further purification. The 6mtp ligand was prepared from 3-amino-1,2,4-triazole and 2-methyl-1,1,3,3-tetraethoxypropane according to a published method for the preparation of the unsubstituted compound tp.[15] The substance was characterized by melting point, NMR and mass spectroscopy. The results were in agreement with the data found for 6mtp as prepared by Brown and Nagamatsu.[16] The 5mtp ligand was prepared from 3-amino-1,2,4-triazole and 4,4-dimethoxy-2-butanone, similar to tp. This compound too was characterized by melting point, NMR and mass spectroscopy. The data agreed with those found by Bajwa and Sykes.[17] Compounds **1** and **2** were prepared by treating freshly synthesized $Cu(NCS)_2$ dissolved in methanol (2 mmol in 40 cm^3) with 4 mmol of ligand dissolved in 30 cm^3 of methanol. Dark red–brown (**1**) and lustrous green (**2**) crystals appeared on standing at room temperature after several hours. All crystals were separated by filtration, dried and analysed for metal, carbon, hydrogen and nitrogen. The compounds analysed as $[Cu(NCS)_2(L)_2]$. Found for **1**: C, 37.3; H, 2.6; N, 31.3; Cu, 14.4. Calc. for $[Cu(NCS)_2(6mtp)_2]$: C, 37.4; H, 2.7; N, 31.1; Cu, 14.2%. Found for **2**: C, 37.2; H, 2.5; N, 31.2; Cu, 13.9. Calc. for $[Cu(NCS)_2(5mtp)_2]$: C, 37.4; H, 2.7; N, 31.1; Cu, 14.2%.

Physical measurements

Ligand-field spectra were taken on a Perkin–Elmer 330 UV–vis–IR spectrophotometer using MgO as a reference in the diffuse reflectance technique. IR spectra were recorded on a Perkin–Elmer 580B IR spectrophotometer as Nujol mulls between KRS-5 [Tl(Br,I)] and polyethene (below 400 cm^{-1}), and as CsCl discs.

Crystal structure determination of **1**

A prismatic dark red–brown crystal of dimensions $0.25 \times 0.21 \times 0.20$ mm was selected and mounted on an Enraf–Nonius CAD4 diffractometer. Intensities were collected at room temperature using graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Crystallographic data and relevant information on data collection and refinement have been summarized in Table 1. The data were corrected for Lorentz and polarization effects. Absorption correction was unnecessary.

Table 1. Relevant crystallographic and experimental data of $[Cu(NCS)_2(6mtp)_2]$ (**1**) and $[Cu(NCS)_2(5mtp)_2]$ (**2**)

Number of independent reflections	1934	2008
Number of significant reflections	1406	1195
θ range (°)	2–26	3–27
Data collection range	$-14 < h < 14$, $0 < k < 10$, $-22 < l < 22$	$-15 < h < 15$, $0 < k < 11$, $0 < l < 9$
$F(000)$	908	454
Final $R(R_w)$	0.036 (0.047)	0.037 (0.050)

All 1934 measured independent reflections with $I > 2\sigma(I)$ and θ in the range of 2–26° were used in the analysis. The structure was solved by standard Patterson and Fourier methods. Calculations were carried out on the Leiden University IBM 3038 computer. Refinements were calculated by full-matrix least-squares cycles, using at first isotropic and later anisotropic thermal parameters for all non-hydrogen atoms. All six hydrogen atoms were found by a difference Fourier synthesis. The final residual indices are defined as $R = \{\sum(||F_c| - |F_o||)/\sum|F_o|\}$ and $R_w = \{\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2\}^{1/2}$.

Crystal structure determination of **2**

A thin prismatic green crystal of approximate dimensions $0.05 \times 0.24 \times 0.55$ mm was used for the X-ray analysis. Data were collected at room temperature on a Siemens AED diffractometer using Nb-filtered Mo-K_α radiation ($\lambda = 0.71069$ Å). The relevant parameters of crystal data collection are given in Table 1. The structure amplitudes were obtained after the usual Lorentz and polarization reduction; no correction for absorption was necessary. Of 2008 independent reflections, 1195, having $I > 2\sigma(I)$, were considered observed and used in the analysis. The structure was solved by Patterson and Fourier methods, and refined by full-matrix least-squares using the SHELX system of computer programs,[18] first with isotropic and then with anisotropic thermal parameters for all non-hydrogen atoms; all hydrogen atoms were localized from a difference Fourier map, but not refined. All calculations were carried out on the CRAY X-MP/12 computer of the "Consorzio per la Gestione del Centro di Calcolo Elettronico Interuniversitario del Italia Nord-Orientale" (CINECA, Casalecchio, Bologna). For both **1** and **2**, fractional coordinates of the non-hydrogen and the hydrogen atoms, anisotropic thermal parameters, bond lengths and angles dealing with hydrogen atoms as well as a list of structure factors have been deposited as Supplementary Material and are available on request. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Description of the structure of $[Cu(NCS)_2(6mtp)_2]$ (**1**)

Relevant angles and bond distances of **1** are given in Table 2. In the crystal structure of $[Cu(NCS)_2(6mtp)_2]$, depicted in Fig. 2, the complex has an imposed C_2 symmetry; the copper atom is surrounded by two symmetry-related 6mtp molecules and two N-bonding thiocyanates in a distorted tetrahedral arrangement. Each ligand coordinates monodentately to the metal atom through N(3). The six bonding angles (values of 93.5(1),

[a] The primed atoms are related to the unprimed ones by the transformation $x, -y, 1/2+z$.

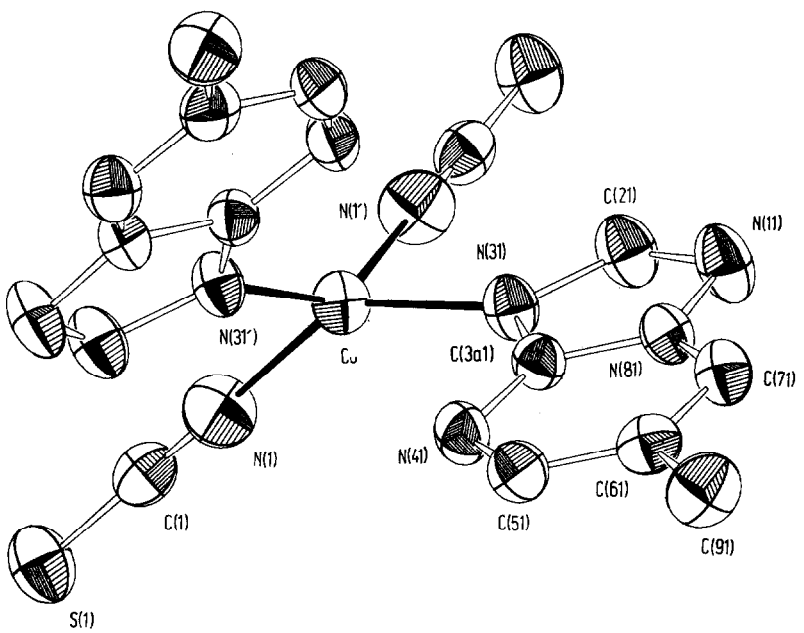

Fig. 2. ORTEP drawing of $[Cu(NCS)_2(6mtp)_2]$ (1). Hydrogen atoms are omitted for clarity.

96.3(2), 99.3(1) and 143.5(1)°) differ significantly from the value expected for a regular tetrahedron (109.45°), with the two N(31)—Cu—N(1) angles being exceptionally large: 143.5(1)°. No semi-coordinating nitrogen atom could be found. On searching for a semi-coordinating sulphur atom of another $Cu(NCS)_2(6mtp)_2$ unit, the shortest intermolecular Cu—S distance appeared to be 4.895 Å, which is far too long for any significant Cu—S interaction (Fig. 3). No stacking of the heterocyclic rings was observed. Since hydrogen bridges are not present, either in or between the units, the geometry around the copper atoms can only originate from a basically square-planar structure forced into a distorted tetrahedron by ligand–sulphur packing effects.

It is a well-known fact that a tetrahedral geometry is more suitable for a copper(I) compound than for a copper(II) system. Therefore, the tetrahedral distortion of the geometry of **1**, indicated by the unusually low energy ligand field maximum at 12.8×10^3 cm^{-1}, probably results in a reduction towards a more monovalent character of the metal ions. This is also reflected in the intense charge-transfer band at 19.7×10^3 cm^{-1}.

Although the occurrence of copper(II) in a genuine tetrahedral coordination is very unusual, it has been reported that several copper(II) complexes with chelating ligands, possessing a $Cu(NN)_2$ chromophore, occur in a more or less distorted tetrahedral configuration, the manner of distortion depending upon the nature of the ligand.[19–22] Some monomeric copper(II) compounds of the type $[Cu(L)X_2]$ and $[Cu(L)_2X_2]$ have been found to possess a distorted tetrahedral geometry, too.[23–25] The more or less tetrahedral configuration of **1** is comparable to that found for *trans*-dichlorobis(N-methylimidazole)copper(II),[25] in which the Cl—Cu—Cl and N—Cu—N angles are 143.7(6) and 149.7(1)°, respectively, and the others are in the range 94.0(1)–95.4(1)°. In all the copper(II) compounds mentioned above, the steric repulsions between the ligands appear to be the most important factor for copper(II) complexes to exhibit a configuration which deviates from planarity to varying degrees.

Description of the structure of $[Cu(NCS)_2(5mtp)_2]$ **(2)**

Table 3 lists the bond distances and angles for **2**. The copper atom and the four nitrogen donor atoms of a $[Cu(NCS)_2(5mtp)_2]$ unit are in a square-planar arrangement. The two N(3)-atoms of the 5mtp ligands are coordinated in a *trans* mode at a bond distance of 2.020(4) Å. The Cu—N(thiocyanate group) distance is 1.921(4) Å (Fig. 4). Two N(1)-atoms of the organic ligands in neighbouring $[Cu(NCS)_2(5mtp)_2]$ units, coordinating axially at a distance of 2.677(5) Å, complete the elongated octahedral geometry around the copper atoms.

[a] The primed atoms are related to the unprimed ones by the transformation x, $-1/2-y$, $-1/2+z$.

By acting in such a bidentate mode between the metal centres, the 5mtp ligands build a two-dimensional system (Fig. 5). When the molecular structure of **2** is compared to that of α-$[Cu(NCS)_2(tp)_2]$, published earlier,[9b] clearly both structures are very similar, and **2** can be best described as a pseudo-layered system with semi-coordination.

However, when compared to previously reported metal thiocyanate compounds containing tp, of the general formula $[M(NCS)_2(tp)_2]$ (for M = Fe, Co, Ni, Mn), in which the triazolopyrimidine ligands too, acted in a bridging mode via N(1)—N(3),[9a] the metal–metal distances in **2** should be significantly longer. Instead, in spite of the longer Cu—N(1)

[a] IUPAC numbering.

coordination distances, in **2** the Cu—Cu distance of 6.02 Å is shorter than the M—M distance in $[M(NCS)_2(tp)_2]$ (6.46 Å). This is a consequence of the σ-character of both the M—N interactions in $[M(NCS)_2(tp)_2]$, as suggested by the co-planarity of the metal atoms with respect to the tp ligands. In **2**, the σ-character can be attributable only to the shorter Cu—N(3) distance. The non-σ-character of the Cu—N(1) bond is reflected in the fact that this bond is remarkably out of the plane passing through the corresponding tp molecule.

CONCLUSIONS

Table 4 compares the spectroscopic and geometric data of copper(II) thiocyanate compounds with tp and dmtp to that of **1** and **2**.

Comparing the structure of **1** to structures determined before (Table 4), the ligand behaviour of the NCS-group and of the 6mtp molecule differ dramatically from that found for these ligands in related compounds. In both (α and β) $[Cu(NCS)_2(dmtp)_2]$ compounds, dmtp acts as a monodentate ligand through the usually favoured triazole N(3)-atom (even when both non-bridgehead triazole nitrogen atoms are available for coordination), and the NCS-anions act both as N-bonded monodentate ligands and as bidentate bridges between the copper atoms.[10a,11] In **2** and in α-$[Cu(NCS)_2(tp)_2]$, the NCS-group binds exclusively monodentate via its nitrogen atom, but the organic ligands are acting in a bridging mode by semi-coordination through the N(1)-atom to the neighbouring copper atoms.[9b] Also, while the metal atom in both $[Cu(NCS)_2(dmtp)_2]$ compounds is surrounded by five donor atoms, and in **2** and α-$[Cu(NCS)_2(tp)_2]$ by six donor nitrogen atoms, the copper in **1** possesses a coordination geometry of only four ligands. A methyl substituent at C(5) does not seem to greatly influence the coordination mode of the triazolopyrimidine ligand towards copper(II) ions. In that respect, it is not fully understood why a comparably minor alteration of the triazolopyrimidine ligand by the substitution of a methyl group at C(6) causes such a relatively large difference in the coordination behaviour of the ligand and that of the anions. Since in **1** the C(91)—N(41) separation is 3.778(3) Å, and the C(91)—N(11) separation is 4.914(3) Å, the steric effects of the 6-methyl group on the coordination ability of both nitrogen atoms theoretically cannot be large enough to exclude any ligand bridging.

Further investigations are needed to fully comprehend the factors that influence the nature of the coordination mode of [1,2,4]triazolo[1,5-*a*]pyrimidines in copper(II) thiocyanate systems.

(*Received* 7 *March* 1989; *accepted* 4 *May* 1989)

Abstract—The Schiff base disulphide ligands N,N′-[1,1′-dithiobis(phenylene)]bis(salicylideneimine), designated hereunder as H_2salps, and N,N′-[1,1′-dithiobis(ethylene)]bis (salicydeneimine), designated hereunder as H_2sales, react with nickel(II) acetate tetrahydrate in methanol giving two mononuclear complexes: [Ni(salps)(MeOH)]·MeOH and [Ni(sales)], respectively. These complexes have been characterized by spectral, magnetic and electrochemical methods. The structure of [Ni(salps)(MeOH)]·MeOH has been determined by X-ray diffraction analysis. This complex crystallizes in the triclinic crystal system, space group $P\bar{1}$, $Z = 2$, $a = 9.476(1)$, $b = 11.297(3)$ and $c = 13.215(3)$ Å, $\alpha = 106.66(1)$, $\beta = 97.10(1)$, and $\gamma = 99.94(1)°$ and $V = 1312.3(3)$ Å^3. The refinement converged to $R = 0.034$ and $R_w = 0.045$ based on 2599 reflections with $I > 3\sigma(I)$. The salps functions as a quinquedentate ligand coordinating through the two phenolate oxygen atoms, the two imine nitrogen atoms and only one of the disulphide sulphur atoms. The sixth coordination site is occupied by the oxygen atom from a methanol molecule. The octahedron core, NiN_2O_3S, is highly distorted as indicated by the range in bond distances (from 2.063(3) to 2.531(1) Å) and angles (from 79.47(8) to 100.4(1)°). The Ni—S bond distance is 2.531(1) Å, while the S—S bond distance is 2.066(1) Å. On the other hand, the spectral and magnetic properties of [Ni(sales)] suggest a square-pyramidal structure with a Ni—S bond. The complexes show non-conjugated and irreversible redox processes in cyclic voltammetry, in DMF. The processes at −1.30 and −1.43 V have been attributed to the reduction of the disulphide group, whereas the oxidation process at *ca* +0.74 V has been attributed to the nickel(II) oxidation.

Although many ligands containing a disulphide group, RS—SR, are reduced by reaction with metal ions, this is not always the case. Several complexes of copper,[1–7] cobalt,[8–10] rhenium,[11,12] iridium,[13] nickel,[14–16] iron,[17] mercury,[18] cadmium[19] and manganese[20] have been synthesized, and their structures have been determined by X-ray diffraction analysis. Therefore, the existence of the M—S(disulphide) bond has been clearly demonstrated. In a few cases a weak covalent bond has been observed (bond lengths ~ 3.0 Å)[2,19] and in only two cases is this bond non-existent. In recent years the synthesis and study of new compounds exhibiting a M—S(disulphide) bond has been encouraged due to their probable relevancy with certain redox processes in biological systems. For example, in stellacyanin (a type I blue copper protein), a disulphide sulphur

atom has been postulated as the probable ligand in the fourth coordination site of the copper ion.[23] Likewise, in certain model complexes, related to molybdenum enzymes, a partial bond formation between two coordinated RS ligands at a molybdenum(VI) centre has been observed.[24] On the other hand, new synthetic routes for the conversion of coordinated thiolate to coordinated unsymmetrical disulphide have been reported.[10,25–27] Nevertheless, the electrochemical studies of metal–disulphide complexes, in order to investigate the redox behaviour of the bonded disulphide group, are rather scarce in the literature.[20]

In this paper we report the synthesis, spectral, magnetic and electrochemical properties of the complexes formed by the nickel(II) ion with two Schiff base ligands containing a disulphide group, N,N′-[1,1′-dithiobis(phenylene)]bis(salicylideneimine) (H_2salps)* and N,N′-[1,1′-dithiobis(ethylene)]bis (salicylideneimine) (H_2sales).* We have also determined the structure of the complex [Ni(salps)(MeOH)]·MeOH by X-ray diffraction analysis.

EXPERIMENTAL

Chemicals

Cystamine·2HCl and bis-2-aminophenyldisulphide were purchased from Aldrich Chemical Company, while salicylaldehyde was obtained from BDH Laboratory Chemical Division. Nickel(II) acetate tetrahydrate was purchased from Merck. Reagent grade solvents were distilled and dried by standard methods.

Physical measurements

IR spectra were recorded in KBr and polyethylene discs on a Perkin–Elmer 599 spectrophotometer. Electronic spectra were recorded on a Carl Zeiss DMR-22 spectrophotometer using $CHCl_3$ and DMF Uvasol solvents, and in Nujol. ^{1}H NMR spectra were obtained on a Varian T-60 spectrometer using $CDCl_3$ as solvent. Raman spectra were obtained in the solid state at room temperature on a Raman Spex Compact 1301 spectrometer. Cyclic voltammetry measurements were made with a home-made potentiostat of conventional design, using a three-electrode cell with platinum working and auxiliary electrodes and a saturated calomel reference electrode (SCE). All measurements were carried out at 25±2°C in dry deaerated DMF, with 0.1 mol dm^{-3} tetraethylammonium perchlorate (TEAP) as the supporting electrolyte and a nickel complex concentration of 1.0 mmol dm^{-3} in the case of [Ni(salps)MeOH]·MeOH and 0.5 mmol dm^{-3} in the case of the sparingly soluble complex [Ni(sales)]. Controlled potential coulometry was performed using a platinum mesh electrode with a nickel complex concentration of 0.1 mmol dm^{-3}. Magnetic measurements were performed at 25°C by the Faraday method using a Cahn Ventron RTL magnetic balance and $[Ni(en)_2]S_2O_3$ as standard. Diamagnetic corrections were made by employing Pascal's constants.[28] Melting points were determined using a Kofler apparatus and were not corrected.

Preparation of Schiff base ligands

N,N′-[1,1′-*dithiobis(phenylene)*]*bis(salicylideneimine)*. Salicylaldehyde (20 mmol) was dissolved in EtOH (30 cm^3) and then added to bis-2-aminophenyldisulphide (10 mmol), and the reaction mixture was refluxed for 2 h. On cooling, the yellow solid obtained was filtered, washed with cold EtOH and dried. Finally, the product was recrystallized from $CHCl_3$–EtOH and dried *in vacuo*. Yield: 87.5%. ^{1}H NMR δ (in $CDCl_3$): 6.84–7.76 (m, 16H, $4C_6H_4$); 8.60 (s, 2H, 2HC=N); 12.9 (s, 2H, 20H).

N,N[1,1′-*dithiobis(ethylene)*]*bis(salicyldeneimine)*. The ligand was obtained as a yellow solid by the same method as above and recrystallized from EtOH. In this case, the free base cystamine was obtained by neutralization of cystamine dichlorohydrate with KOH in EtOH. Yield: 95%. ^{1}H NMR δ (in $CDCl_3$): 3.03 (t, 4H, $2CH_2S$); 3.90 (t, 4H, $2CH_2N$); 6.80–7.49 (m, 8H, $2C_6H_4$); 8.40 (s, 2H, 2HC=N); 14.1 (s, 2H, 20H).

Preparation of complexes

[Ni(salps)(MeOH)]·MeOH. The ligand salps (1.0 mmol) dissolved in MeOH (30 cm^3) at 50°C was added to nickel(II) acetate tetrahydrate (1.0 mmol) dissolved in MeOH (30 cm^3). The solution was stirred for 1 h at 50°C. On cooling, the brown microcrystalline solid obtained was filtered, washed with cold MeOH and Et_2O, and recrystallized from MeOH–DMF to give crystals suitable for X-ray analysis. Yield: 64%.

* Abbreviations used: H_2salps = N,N′-[1,1′-dithiobis(phenylene)]bis(salicylideneimine); H_2sales = N,N′-[1,1′-dithiobis(ethylene)]bis(salicydeneimine); H_2salen = N,N′-ethylenebis(salicylideneimine); H_2saldaes = N,N′-[2,2′-thiobis(ethanediyl)]bis(salicylideneimine); H_2salhn = N,N′-(1,6-hexanediyl)bis(salicylideneimine); pms = bis(2-(2-pyridylmethyl)aminoethyl)disulphide; dtpp = 2,2′-di(pyrid-2-ylmethyleneimine)diphenyldisulphide; H_2cbps = N,N′-[bis((2-hydroxyphenyl)phenylmethylene)-4-thiaheptane-1,7-diimine]; ps = bis(2-aminophenyl)disulphide.

[Ni(sales)]. The ligand sales (1.0 mmol) dissolved in MeOH (30 cm^3) at 50°C was added, with stirring, to nickel(II) acetate tetrahydrate (1.0 mmol) dissolved in MeOH (30 cm^3). Immediately, a green solid was formed, and the suspension was stirred for 1 h. The solid was sparingly soluble in common solvents and was subsequently used without recrystallization. Yield: 35%.

X-ray data collection and structure determination

An air-stable crystal of approximate dimensions 0.28 × 0.22 × 0.10 mm was mounted on a thin glass fibre on a Philips PW 1100 diffractometer. Lattice parameters were obtained from a least-squares refinement of the setting angles of 25 automatically centred reflections having 2θ between 23.8 and 32.8°. The cell constants and other parameters including conditions of data collection are summarized in Table 1.

Data were collected at room temperature (20°C) in the ω–2θ scan mode between 4 and 46° in 2θ. Two reflections (700, 7$\bar{2}$7) were monitored every hour to check stability. Their intensity fluctuated only slightly, *ca* ±2%, during the course of the experiment. The data were corrected for Lorentz and polarization effects but not for absorption.

The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the structure. Computations were performed by using the CRYSTALS system[29] adapted for a VAX 11/725. The structure was solved by conventional heavy-atom methods. All the hydrogen atoms were located on difference electron density maps and included in the least-squares refinement. Anisotropic thermal parameters were refined for all non-hydrogen atoms. The position and isotropic thermal parameters of the two hydrogen atoms involved in hydrogen bonding [H(41) and H(51)] were refined. Positions of all other hydrogen atoms were held fixed with a fixed isotropic thermal parameter of 0.065 Å^2. During the final cycles of refinement the weighting scheme employed a three-term Chebyshev series: $w = w'[1-\{\Delta F/\sigma(F)\}^2]^2$ with $w' = [2.748t_0(x)+0.950t_1(x)+2.228t_2(x)]$, where $x = F_0/F_{max}$ and t_n is the polynomial function.[30] Scattering factors and corrections for anomalous dispersion were taken from ref. 31. A final difference electron density map was essentially featureless, the maximum peak being about 0.3 e Å^{-3}. Interatomic distances (Å) and angles (°) are given in Table 2.

RESULTS AND DISCUSSION

Synthesis of ligands and complexes

Two Schiff base ligands, H_2salps and H_2sales, containing a disulphide group, and two new nickel

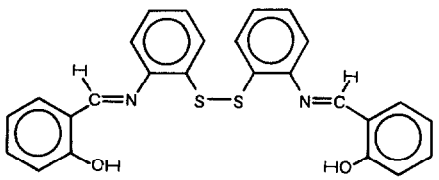
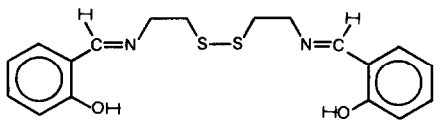
(II) complexes, [Ni(salps)(MeOH)]·MeOH and [Ni(sales)], were synthesized and characterized (Table 3). The ligands were synthesized, in good yield, by reacting bis-2-aminophenyldisulphide, $(NH_2C_6H_4)_2S_2$, or bis-2-aminoethyldisulphide, $(NH_2CH_2CH_2)_2S_2$, with salicylaldehyde (1:2) in refluxing EtOH. The bis-N-salicylidene derivatives have six donor atoms: ONSSNO (Scheme 1), and they are able to behave as quinquedentate ligands if one disulphide sulphur atom is coordinated to the nickel(II) ion. The complexes were synthesized in MeOH by reacting each ligand with nickel(II) acetate tetrahydrate in equimolar quantities. The synthesis of two different complexes, one solvated and one unsolvated, under the same experimental conditions, suggests differences in coordination in each case. The complexes are crystalline, air-stable species. [Ni(salps)(MeOH)]·MeOH is very soluble in DMF, $CHCl_3$ and THF, whereas [Ni(sales)] is sparingly soluble in all the common solvents tried. Solvolysis of the disulphide group of complexes to give binuclear species was not observed.



H_2salps



H_2sales

Scheme 1.

[Ni(salps)(MeOH)]·MeOH

The room temperature magnetic moment, 3.12 BM in the solid state, is compatible with a high spin d^8 electron configuration in an octahedral complex. The electronic spectrum in $CHCl_3$ shows six absorption bands (Table 3), of which the two lower energy bands at 1020 and 620 nm were assigned as typical *d–d* transitions in an octahedral geometry.[32] However, the third *d–d* band corresponding to the $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transition, predicted at *ca* 350 nm, was not observed and was probably lost amongst the more intense charge-transfer and intraligand bands in the UV region. The strong bands at 420 and 295 nm have been assigned as intraligand transitions by comparing them with the bands exhibited by the free ligand, H_2salps (Fig. 1). Finally, the bands occurring at 460 and 245 nm can be attributed, though not unequivocally, to charge-transfer transitions from a disulphide sulphur atom to a nickel(II) ion (i.e. $S\pi \rightarrow d$ and $S\sigma \rightarrow d$, respectively).[33] When [Mn(salps)(MeOH)]·MeOH, the analogous complex of [Ni(salps)(MeOH)]·MeOH, is dissolved in acetonitrile, benzene, toluene or dichloromethane, the coordinated methanol is displaced and the dimeric material $[\{Mn(salps)\}_2]$ is formed.[20] Such a type of dimerization via phenolate oxygen atoms has also been

observed in [{Cu(salen)}$_2$],[34] [{Fe(salen)Cl}$_2$][35] and [{Co(salen)X}$_2$].[36] However, in the present case, attempts to obtain [{Ni(salps)}$_2$] by refluxing the monomeric adduct in acetonitrile or other non-donor solvents were unsuccessful; only unmodified complex was recovered after each treatment.

The IR spectrum obtained in the polyethylene disc shows a weak band at 328 cm^{-1} which is assigned to ν(Ni—S) stretching on the basis of previous assignments in similar complexes, [Ni(dtpp)X] (X = Cl, Br).[37]

These observations are in total agreement with the X-ray crystallographic data (*vide infra*).

Description of the structure

Molecular structure. The molecular structure of [Ni(salps)(MeOH)] is very similar to those previously reported for [Mn(salps)(MeOH)][20] and [Fe(salps)Cl].[17] Indeed [Ni(salps)(MeOH)]·MeOH and [Mn(salps)(MeOH)]·MeOH[21] are isostructural compounds.

As illustrated in Fig. 2, salps functions as a quinquedentate ligand coordinating through the two phenolate oxygen atoms O(1) and O(21), the two imine nitrogen atoms N(1) and N(21), and only one of the disulphide sulphur atoms S(1). The sixth coordination site is occupied by the oxygen atom O(41) from a methanol molecule. Although the distortion of the octahedron core, MN_2O_3S, is less severe than in [Mn(salps)(MeOH)],[20] substantial strain is still present, as indicated by the range in bond distances (from 2.063(3) to 2.531(1) Å) and angles (from 79.47(8) to 100.4(1)°) for the nickel coordination sphere. The Ni—S bond distance of 2.531(1) Å is only slightly longer than those found in octahedral nickel(II) complexes containing quinquedentate organic disulphides; 2.472(5) Å in [Ni(pms)Cl],[14] 2.456(2) Å in [Ni(pms)Br][16] and 2.470(5) Å in [Ni(dtpp)Cl],[16] the S—S distance is 2.066(1) Å, which is in agreement with the distances reported for [Mn(salps)(MeOH)][20] (2.065(1) Å) and [Fe(salps)Cl][17] (2.046(5) Å). As previously stated,[15] the CSSC group appears to be unaffected by coordination to nickel(II), except for the sterically induced alteration of the dihedral angle and the resulting effect on the bond lengths. The CSSC dihedral angle of 71.6° in [Ni(salps)(MeOH)] is intermediate between the value of *ca* 85° in [Ni(pms)Cl][14] and [Ni(pms)Br],[16] and that of 55.4° in [Ni(dtpp)Cl].[15] The mean Ni—N distance of 2.067 Å is in agreement with the mean Ni—H bond length of 2.061 Å in [Ni(dtpp)Cl].[15]

Hydrogen bonding. Each methanol molecule is involved in an intermolecular hydrogen bond. Firstly, the non-coordinated methanol molecule is connected to the [Ni(salps)(MeOH)] molecule through hydrogen bonding to one phenolate oxygen atom. Secondly, the second phenolate oxygen atom interacts with the hydroxylic hydrogen atom of the coordinated methanol molecule of a second [Ni(salps)(MeOH)] molecule ($\bar{x}\bar{y}\bar{z}$). This results in centrosymmetric [Ni(salps)(MeOH)]·MeOH pairs. Geometrical data are indicative of fairly strong hydrogen bonding: O(51)—H(51) = 0.85(5) Å: H(51)···O(1) = 1.90(5) Å; the angle at H(51) is 178.6°. O(21)···H(41)′ = 2.09(5) Å; H(41)—O(41) = 0.64(5) Å; O(21)—H(41)′—O(41)′ = 171.9°. In [Mn(salps)(MeOH)]·MeOH the solvated methanol is not involved in hydrogen bonding.[20]

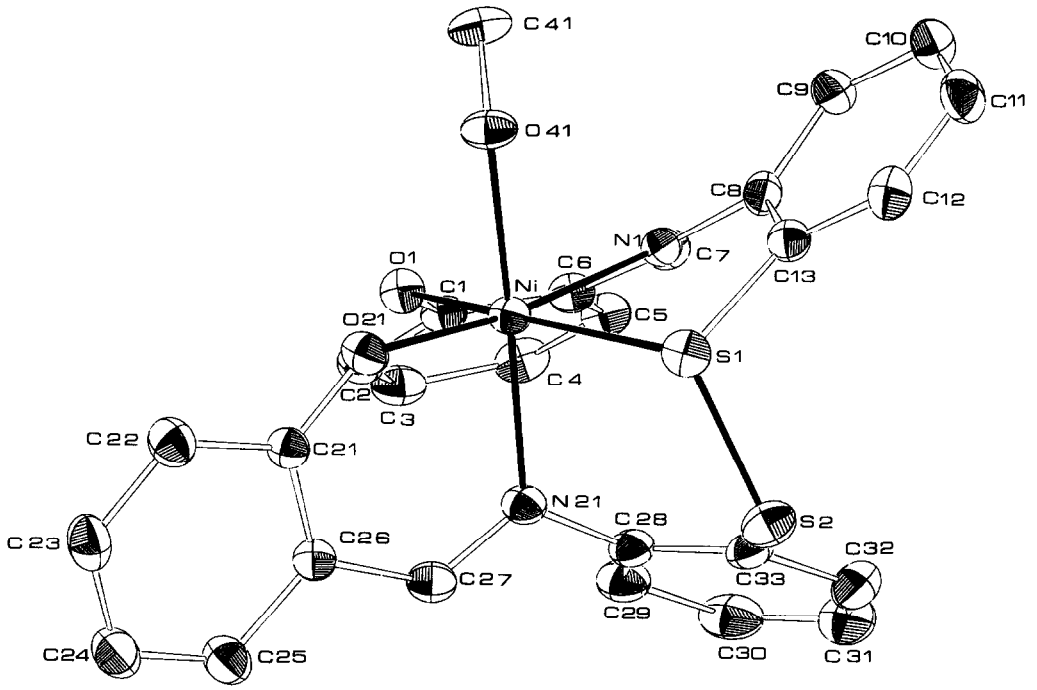

Fig. 2. Molecular structure of [Ni(salps)(MeOH)] showing 30% probability ellipsoids and the atom labelling scheme.

[Ni(sales)]

In contrast to [Ni(salps)(MeOH)]·MeOH, the room temperature magnetic moment of 0.84 BM for [Ni(sales)] is indicative of a low-spin nickel(II). As all tetrahedral and almost all six-coordinate nickel(II) complexes have a high-spin electronic configuration, whereas all known square-planar nickel(II) complexes are diamagnetic,[38] the small deviation from diamagnetism is possibly due to the presence of some high-spin octahedral, tetrahedral, or five-coordinate impurity in a low-spin square-planar, or five-coordinate complex.[39,40] Another mechanism which might account for the small paramagnetism is a spin state isomerism between singlet and triplet states for a five-coordinate complex.[39]

[Ni(sales)] will now be compared to two related complexes with potentially ONSNO quinquedentate ligands: [Ni(saldaes)] and [Ni(cbps)] and also to [Ni(salhn)], a nickel(II) complex with a quadridentate ligand (see ref. 29 for ligand abbreviations).

[Ni(saldaes)] is believed to have a distorted low-spin square-pyramidal or trigonal-bipyrimidal structure,[39,41] whereas the data for [Ni(cbps)] are consistent with a high-spin, distorted square-pyramidal structure.[42]

The electronic spectra of H_2sales, [Ni(sales)] and [Ni(salhn)] in DMF are shown in Fig. 3. The spectrum of [Ni(sales)] is characteristic of low-spin square-planar nickel(II) Schiff base complexes.[40,43] The UV–vis spectrum has spectral bands at 620, 390(sh) and 377 nm. Although this spectrum shows some resemblance to that of [Ni(salhn)], the two spectra are clearly distinct, suggesting different environments for the nickel(II) ion in these two complexes. On the other hand, the spectrum of [Ni(sales)] is quite different from that of high-spin [Ni(cbps)] which displays bands at 1150, 950(sh) and 600(sh) nm,[42] but is similar to that of low-spin [Ni(saldaes)] which has bands at 623, 433 and 322 nm.[39,41] These observations support similar low-spin five-coordinate structures for [Ni(sales)] and [Ni(saldaes)]. Further support for this conclusion comes from the IR spectrum showing a weak band at 325 nm which is tentatively assigned to a Ni—S stretch. Coordination of a sulphur atom is expected to shift the S—S Raman stretching band which is observed at 505 cm^{-1} in the free ligand. Unfortunately the Raman spectrum of [Ni(sales)] could not be recorded due to strong absorption of the 632.8 nm laser line by the green complex.

When dissolved in strongly coordinating solvents (i.e. propylamine), [Ni(sales)] and [Ni(salhn)] give identical spectra. This suggests facile solvolysis of the Ni—S bond in [Ni(sales)] and the formation of six-coordinate adducts, [NiL(solvents)$_2$].

Electrochemical studies

Cyclic voltammograms of [Ni(salps)(MeOH)]·MeOH, [Ni(sales)] and the corresponding ligands in DMF are shown in Fig. 4, with principal peak potentials listed in Table 4. The nickel(II) complexes exhibit non-conjugated and irreversible redox processes.

[Ni(salps)(MeOH)]·MeOH and [Ni(sales)] exhibit a reduction wave at -1.30 and -1.43 V, respectively, and a single oxidation wave at *ca* $+0.74$ V. By comparison with the cyclic voltammograms of ps, H_2sales and H_2salps* (Table 4), the cathodic process observed in the complexes was assigned to the reduction of the disulphide group.

The additional cathodic peak observed in H_2sales at -1.75 V was attributed to the azomethine group reduction, in agreement with the electrochemical behaviour of H_2salen. This wave was not observed either in both complexes or in H_2sales, probably because of overlap with the solvent discharge. The irreversible process exhibited by the complexes at *ca* $+0.74$ V can be assigned to the nickel(II) oxidation. Comparatively, [Ni(salen)] shows a reversible nickel(II)/nickel(III) redox couple centred at $+0.75$ V. The irreversibility observed in our complexes can be explained by the presence of the disulphide group. The nickel(III)—disulphide species may experience an internal redox reaction assisted by the solvent, following the same pattern described for the reaction of copper(II) with disulphide ligands in donor solvents. Finally, controlled-potential electrolysis of complexes and ligands indicated some complexity, and failed in all cases to give the actual number of electrons involved in any process. These results can be attributed to the adsorption of sulphur compounds onto the platinum electrode.

COMMUNICATION

SYNTHESIS AND STABILITY OF TWO-COORDINATE N-TRIFLUOROMETHYLIMINOARSINE, $CF_3N{=}AsH$

H. G. ANG* and F. K. LEE

Chemistry Department, National University of Singapore, Lower Kent Ridge Road, Singapore 0511, Republic of Singapore

(*Received* 3 *May* 1989; *accepted* 31 *May* 1989)

Abstract—The reactions between CF_3NO and AsH_3 afforded a relatively unstable new π-bonded iminoarsine, $CF_3N{=}AsH$, which decomposed to give CF_3H, N_2 and arsenic. A free radical mechanism of decomposition is proposed.

There has been growing research interest in recent years on the chemistry of unsaturated compounds of the main group elements with low coordination numbers. Within the Group 15 elements, a number of stable phosphorus derivatives that have been synthesized contain the following p_π–p_π bonds: P=C, P=N, P=P, P=As, and P=Sb, P=Si and P=Ge.[1–6] Some X-ray data are now available.[7–9] The stability of such compounds has been attributed to the presence of bulky substituents like *t*-Bu, Me_3Si, $(Me_3Si)_2N$ and 2,4,6-*t*-$Bu_3C_6H_2$ which shield the reactive sites. However, we have recently shown that compounds such as $(CF_3)_2NON{=}MR$ [M = P, As; R = H, $ON(CF_3)_2$], formed by the condensation reactions involving $(CF_3)_2NONO$ and PH_3 and AsH_3, respectively, are stabilized by the highly electronegative $(CF_3)_2NO$ group(s). We now report on the synthesis and stability of a new iminoarsine, $CF_3N{=}AsH$.

Trifluoronitrosomethane reacted with arsine in a 1:1 molar ratio at −120°C to afford N-trifluoromethyliminoarsine (**A**) in 14% yield and water, according to the equation:

$$CF_3NO + AsH_3 \longrightarrow CF_3N{=}AsH + H_2O. \quad (A)$$

The condensation reactions follow a similar course to those reported earlier between $(CF_3)_2NONO$ and AsH_3. The iminoarsine, **A**, was isolated at −126°C trap as a white solid and water at −60°C trap on trap-to-trap vacuum fractionation. The compound began to undergo decomposition even at temperatures as low as −110°C. On standing for about 4 min at room temperature, the compound decomposed to afford a bluish-black metallic film of arsenic metal, trifluoromethane and a non-condensable gas which was presumably nitrogen. A fast scan of the IR spectrum of **A** gave peaks located at 2234 cm^{-1} [ν(As—H)]; 1319, 1285 and 1222 cm^{-1} [ν(C—F)]; 994 cm^{-1} [ν(C—N)]; 873 cm^{-1} [ν(As=N)] and 724 cm^{-1} [δ(C—F)].

The iminoarsine, **A**, is therefore unstable under ambient conditions, and the decomposition products can be rationalized in terms of the following free radical mechanisms:

$$CF_3N{=}AsH \longrightarrow CF_3^{\bullet} + H^{\bullet} + As + 1/2N_2$$

$$CF_3^{\bullet} + H^{\bullet} \longrightarrow CF_3H.$$

EXPERIMENTAL

The IR spectra were recorded on a Perkin–Elmer 983G. Trifluoronitrosomethane was prepared by an established method.

Trifluoronitrosomethane (0.2759 g, 2.78 mmol) and arsine (0.2212 g, 2.80 mmol) were sealed under vacuum in a glass ampoule, which was then immersed in a −126°C slush bath. The blue colour of trifluoronitrosomethane was gradually discharged. On standing for about 10 min, the temperature of the reaction bath rose to −119°C and a metallic bluish-black solid began to form on the side of the ampoule. This reaction mixture was quickly subjected to trap-to-trap fractionation *in vacuo* to

* Author to whom correspondence should be addressed.

afford (a) water (0.0412 g, 2.28 mmol) at −60°C trap; (b) a white solid (0.0615 g) at −126°C trap (passed −96°C trap), becoming a colourless gas, **A**, on warming to room temperature and its IR spectrum gave the following peaks: 2235m, 1319vs, 1285vs, 1222vs, 994m, 873m and 724m cm^{-1}; and (c) a mixture of unreacted trifluoronitrosomethane and arsine at the liquid nitrogen trap.

Upon allowing a portion of the colourless gas, **A**, to stand in an evacuated ampoule at room temperature for about 4 min, a metallic black film appeared on the side of the ampoule. Vacuum trap-to-trap fractionation of the products gave (a) a non-condensable gas, presumably nitrogen and (b) a volatile gas trapped at the liquid nitrogen trap, whose IR spectrum which gave the following peaks 2911, 1370, 1209, 1162 and 720 cm^{-1} was similar to that of fluoroform. Its molecular weight determined by Regnault's method gave 70 g mol^{-1} (calc. for CF_3H, 70 g mol^{-1}). Elemental analysis shows that the metallic substance is solely arsenic metal.

(*Received* 24 *October* 1988; *accepted after revision* 31 *March* 1989)

Abstract—Reactions of the trisaminomethanes, **1** (R = H) and **2** (R = Me), with cycloheptatrienyl molybdenum tricarbonyl afforded their respective molybdenum tricarbonyl complexes; **3** and **4**. Structures of these products have been determined by X-ray diffraction studies. Complex **3** crystallizes in the monoclinic space group $P2_1/m$ with $a = 7.7364(6)$, $b = 12.505(1)$, $c = 7.774(1)$ Å, $\beta = 107.70(1)°$, $Z = 2$, μ(Mo-K_α) = 0.90 mm^{-1}. Its molybdenum coordination sphere features unusually small ligand bite angles (N—Mo—N) of 57.7(1)–58.0(1)°. The unique bridgehead methinyl hydrogen was not located, but its existence has been confirmed by IR and solid-state NMR spectroscopy. Complex **4** crystallizes in the orthorhombic space group *Pcmn* with $a = 7.7537(2)$, $b = 12.3176(4)$, $c = 15.6563(7)$ Å, $Z = 4$, μ(Mo-K_α) = 0.87 mm^{-1}. Similarly, pinched N—Mo—N angles of 58.8(1)° are observed. Significantly, the methyl to bridgehead carbon bond is shortened by 0.04 Å relative to the free ligand value, consistent with a reduced negative hyperconjugation upon complexation.

Tricyclic trisaminomethanes, having all three nitrogens bound to a common carbon, are potentially tridentate ligands. The unusually stable ligands **1** and **2**,[1–4] derived from 1,5,9-triazacyclododecane, have each been shown to be biased towards the all-*trans* configuration in solutions of non-polar solvents (Fig. 1).

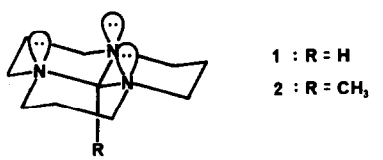

Fig. 1. All-*trans* trisaminomethanes, **1** and **2**.

In this geometry the three nitrogen lone pairs are constrained to be antiperiplanar (*app*) to C—R. Major strereochemical consequences of this upon spectra,[1–5] bond lengths[6] and reactivity[2,3,5] have already been delineated. By contrast, the donor ability and the effect of complexation upon the parent trisaminomethane geometry have not been demonstrated. We report herein the first transition metal complexes of these triaza ligands.

RESULTS AND DISCUSSION

Synthesis and characterization

Reaction of cycloheptatrienyl molybdenum tricarbonyl with tricyclic trisaminomethanes, **1** and **2**, afforded the respective complexes **3** and **4** in good yields as light yellow solids which are insoluble in all but the most polar organic solvents.

The carbonyl IR stretching frequencies of **3** and **4** (Table 1) are consistent with the *fac*-$M(CO)_3$ structure, suggesting that the trisaminomethanes are indeed behaving as tridentate ligands. Interestingly, the prominent Bohlmann bands (C—H stretch *app* to N-lone pair)[7] present below 2800 cm^{-1} in **1** and **2**, including the unusually low frequency series (2400–2600 cm^{-1}) due to the methine of **1**,[3] are absent or shifted in complexes **3** and **4** (Table 1). The insolubility of **3** in most organic solvents and its decomposition in polar solvents, like DMSO, precluded determination of its solution NMR spectrum. Its solid-state MAS ^{13}C NMR spectrum, however, is readily obtained and shown in Fig. 2. Compared to the solution spectrum of the

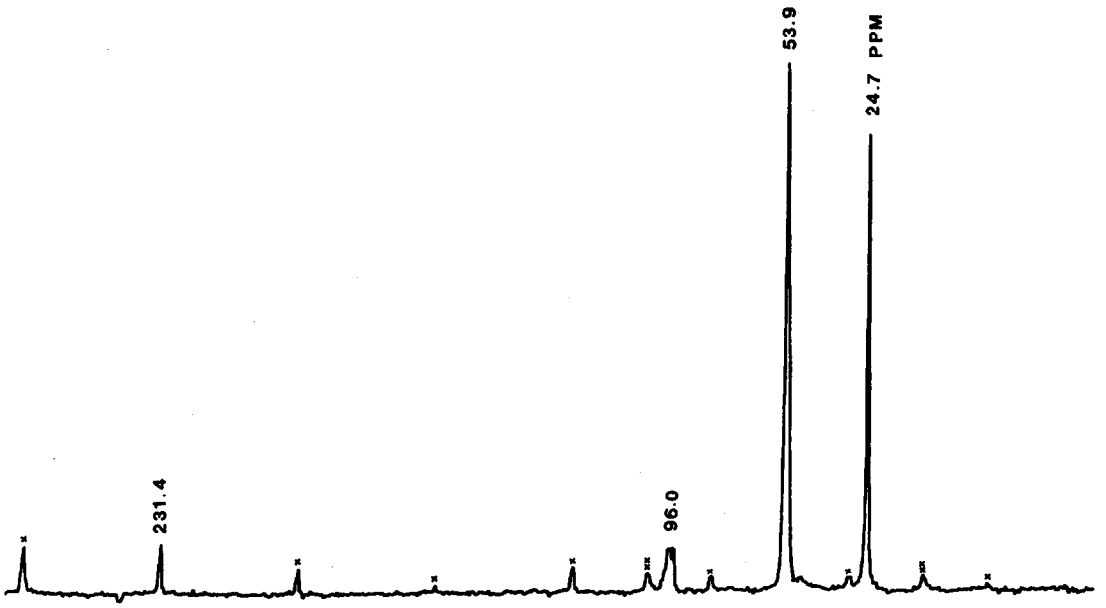

Fig. 2. Solid-state MAS ^{13}C NMR spectrum of **3** (crosses denote spinning sidebands).

free ligand **1** (Table 1), the only significant coordination shift is that of the bridgehead carbon from δ_C +99.8 in **1** to +96.0 ppm in **3**. Solution ^{13}C NMR spectral data (DMSO-d_6) for **2** and **4** are presented in Table 1. The −0.8 ppm $\delta_C(CH_3)$ of **2** in DMSO-d_6 is indicative of an approximately 2:1 equilibrium mixture of all-*trans*-**2** and *cis,cis,trans*-**2** (based upon the known methyl shifts of the individual configurations in acetone-d_6 solution).[4b] The −2.8 ppm $\delta_C(CH_3)$ of **4** (DMSO-d_6) is consistent with conversion of the ligand to the all-*trans* configuration in the complex. The lower field $\delta_C(CH_3)$ of **4** relative to that of pure all-*trans*-**2** (δ_C −6.2 ppm in acetone-d_6),[4b] is probably at least partly due to the diminution of $n_N \rightarrow \sigma^*_{C-CH_3}$ negative hyperconjugation in **4** relative to that in **2**.

Structure of complex **3**

The molecular structure of **3** has been determined and its geometry is shown in Fig. 3. Selected bond distances and angles are listed in Table 2. The molecule uses the crystallographic mirror symmetry with atoms Mo, O(1), C(1), N(1), C(7) and C(8) being on this plane. Most significant is the unusually small N—Mo—N angles of 57.7(1)–58.0(1)°. For comparison, analogous angles are 73.8(6)–87.5(6)° in (trien)Mo(CO)$_3$.[8] An average Mo—N distance of 2.40(1) Å in **3** is lengthened from the corresponding value of 2.32(1) Å in the trien complex. The tricyclic system retains the all-*trans* configuration and bond lengths are similar to those reported for the free ligand.[9] Average sums of C—N—C angles about nitrogen ($\Sigma\alpha_N$) are also very similar (332 and 331°, respectively, for **3** and **1**), indicating that the three nitrogens have not become significantly more pyramidal upon complexation. The central N—C—N angles, however, do decrease from 109.7°(av.) in **1** to 106.3°(av.) in **3**, a compression that allows the nitrogen lone pairs to converge better on the metal. This pinching is reflected in ring torsion angle changes: $\theta_{N-C-N-C}$ and $\theta_{N-C-C-C}$ are more puckered and flattened, respectively, in **3**.

The three *fac*-carbonyls are coordinated with C—Mo—C angles compressed to 82.3(2) and 84.5(2)°, smaller than the average value of 85.3(4)° in (triene)Mo(CO)$_3$.[8] The Mo—C distances are similar at 1.93 and 1.94 Å.[8]

Interestingly, molecules of **3** were found to pack in sheets featuring head-to-tail chains (Fig. 4). The unique carbonyl oxygen [O(1)] of each molecule is

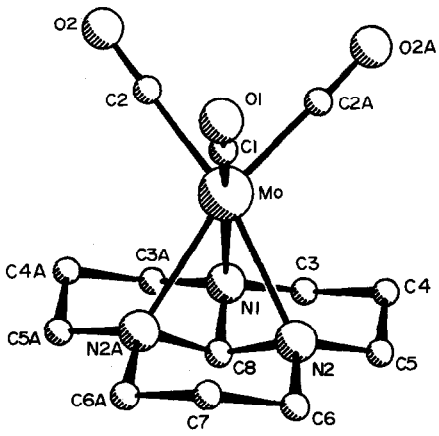

Fig. 3. Molecular structure of complex **3**.

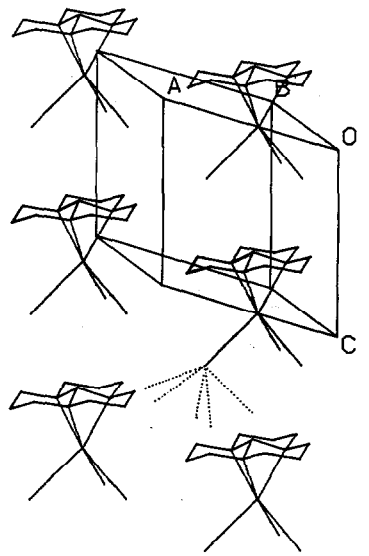

Fig. 4. Crystal packing of **3**. Only half a cell along **b**-axis is shown. Dotted lines show the five contacts from a carbonyl oxygen O(1) to CH's of neighbouring molecules.

Table 2. Selected bond distances (Å) and angles (°) for complex **3**

Mo—C(1)	1.920(4)	C(1)—Mo—C(2)	84.5(2)
Mo—C(2)	1.933(4)	C(2)—Mo—C(2A)	82.3(2)
Mo—N(1)	2.382(4)	N(1)—Mo—N(2)	58.0(1)
Mo—N(2)	2.407(3)	N(2)—Mo—N(2A)	57.7(1)
N(1)—C(8)	1.462(7)	N(1)—C(8)—N(2)	105.2(3)
N(2)—C(8)	1.460(4)	N(2)—C(8)—N(2A)	105.5(3)

positioned within 2.75–2.92 Å (dotted lines in Fig. 4) of five hydrogens from two neighbouring molecules. These include two equatorial hydrogens on C(3) and C(3A) belonging to a molecule from an adjoining chain. The other three close contacts are made with the next molecule along the same chain: two axial hydrogens on C(6) and C(6A), as well as its bridgehead methinyl hydrogen.

Although not located in the X-ray study, the existence of this methinyl hydrogen has been confirmed spectroscopically using both IR and solid-state NMR techniques. Specifically, a band at 2775 cm^{-1} in **3**, which we assign to this C—H stretch, is absent in the deuterated analogue. Solid-state ^{13}C NMR of **3** with magic angle spinning (MAS) and non-quaternary suppression (NQS) of carbon resonances resulted in the disappearance of all except the carbonyl peaks, indicating that the bridgehead C (δ +96.0) is indeed bonded to a hydrogen. Furthermore, dipolar MAS 2-D ^{13}C NMR also confirmed the presence of a single hydrogen on this carbon at a calculated distance of 1.15 Å.[10,11]

Structure of complex **4**

The molecular structure of **4** is shown in Fig. 5. Selected bond distances and angles are presented in Table 3. Again, the molecule adopts the crystallographic mirror plane with atoms Mo, O(1), C(1), N(1), C(7), C(8) and C(9) on this plane. Angles around the molybdenum atom are compressed as in **3**, with N—Mo—N at 58.8(1)° and C—Mo—C ranging from 81.0(2) to 86.3(3)°. The Mo—N distances are 2.355(4) Å, slightly shorter than those in **3**. The central N—C—N angle pinching in **4** (101°) is even more pronounced than in **3** and the nitrogens become slightly pyramidized compared to the free ligand **2** values ($\Sigma\alpha_N$ = 331 and 338°, respectively). Of special interest is the methyl to bridgehead carbon [C(8)—C(9)] distance of 1.52(1) Å. This is shortened by 0.04 Å compared to the free ligand value and is accompanied by a lengthening of the central C—N bonds, e.g. C(8)—N(1), by about 0.02 Å. The methyl to carbon bond shortening is consistent with a lessening of the dramatic negative hyperconjugative effect ($n_N \rightarrow \sigma^*_{C-CH_3}$) recently reported for free ligand **2**.[6]

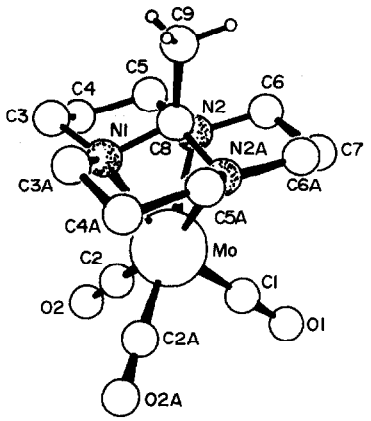

Fig. 5. Molecular structure of complex **4**.

Like **3**, the crystal packing of the molecules of **4** also results in sheets, although without head-to-tail chains (Fig. 6). Weak methyl–hydrogen interactions with two neighbouring molecules' carbonyl oxygens, including a H---O contact 0.3 Å below the van der Waals radii sum, may be responsible for this packing arrangement.[6]

EXPERIMENTAL

All reactions were carried out in a prepurified nitrogen atmosphere in standard Schlenkware. Cycloheptatrienyl molybdenum tricarbonyl,[12] 1,5,9-triazatricyclo[7.3.1.0^{5,13}]tridecane (**1**) and 13-methyl-1,5,9-triazatricyclo[7.3.1.0^{5,13}]tridecane (**2**) were prepared by literature procedures.[1–4] Methylene chloride was freshly distilled from calcium hydride. DMSO-d_6 was vacuum-distilled from CaH_2

Solution NMR were performed on JEOL-FX 90Q or Bruker AM-360 spectrometers. NMR samples were degassed and sealed under vacuum before use. Both ^1H and ^{13}C shifts were referenced to internal solvent shifts. Solid-state dipolar 2-D ^{13}C MAS NMR spectra were collected on a Bruker CXP-200 instrument operating at 50.33 MHz. Di-

polar 2-D spectra were acquired using the pulse sequence described by Munowitz *et al.*[10,11] Spectra were run at ambient temperature with the sample spinning at 2–3 kHz. IR spectra were recorded as KBr discs or CCl_4 solutions on a Perkin–Elmer 283B instrument. Elemental analyses were performed on a Perkin–Elmer 240 B elemental analyser.

Synthesis of complexes **3** *and* **4**

Complex **1** (100 mg, 0.55 mmol) was stirred with cycloheptatrienyl molybdenum tricarbonyl (90 mg, 0.33 mmol) in 5 cm^3 of methylene chloride. The clear red solution rapidly became turbid with precipitation of a light yellow solid. After a further hour of stirring, the suspension was filtered and washed with hexane to give 150 mg (75% yield) of **3**. Complex **4** was similarly prepared from **2** in 70% yield. Crystals for X-ray studies were grown by slow diffusion of a THF solution of the ligand into a methylene chloride solution of cycloheptatrienyl molybdenum tricarbonyl. C, H, N analyses of complex **3**: Found: C, 43.4; H, 5.5; N, 11.5. Calc. for $C_{13}H_{19}MoN_3O_3$: C, 43.2; H, 5.3; N, 11.6%. C, H, N analyses for complex **4**: Found: C, 44.7; H, 5.6; N, 11.2. Calc. for $C_{14}H_{21}MoN_3O_3$: C, 44.8; H, 5.6; N, 11.2%. ^1H NMR data at 360 MHz for **4** (DMSO-d_6): δ 1.94 (m, 12H), 1.45 (m, 6H), 1.16 (s, 3H).

X-ray diffraction study of **3**

A summary of crystal data, data refinement, and structure refinement is presented in Table 4. The intensities of a $0.2 \times 0.18 \times 0.04$ mm crystal were collected on a Nonius CAD-4 diffractometer to give a total of 1270 unique reflections of which 1153 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Cell parameters were obtained by least-squares

refinement of the setting angles of 98 reflections with $2\theta > 45°$. The molybdenum atom was located from a Patterson map. A *D*-map revealed the remainder of the structure except for the bridgehead hydrogen. The structure was refined by full-matrix least-squares with non-hydrogens anisotropic and hydrogens isotropic. All calculations were performed on the NRCVAX system of programs.[13] Scattering factors were taken from the *International Tables for Crystallography*.[14] Atomic coordinates, thermal parameters and distance–angle tables are included in the supplementary material.

X-ray diffraction study of **4**

A summary of crystal data, data refinement and structure refinement is presented in Table 4. The intensities of a $0.08 \times 0.18 \times 0.18$ mm crystal were collected to give 1376 unique reflections of which 1145 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. The structure was solved by direct methods and refined by full-matrix least-squares. Final atomic positions, thermal parameters and distance–angle tables are included in the supplementary material.

(*Received* 10 *March* 1989; *accepted* 10 *May* 1989)

Abstract—Deprotonated *cis*-$[M(CO)_4(PhPO_2)_2H_3]^-$ (M = Cr, Mo, W) are tetradentate ligands capable of displacing two carboxylate bridges each in $Mo_2(acetate)_4$ to give mixed-valent tetrametallic complexes of the type $Mo_2[M(CO)_4(PhPO_2)_2]_2^{4-}$ (M = Cr, Mo, W). The molecular structure of $(n\text{-}Bu_4N)_2H_2Mo_2[Mo(CO)_4(PhPO_2)_2]_2$ has been determined by X-ray crystallography. It crystallizes in the orthorhombic system, space group *Pbca*, with cell parameters $a = 20.858(1)$, $b = 17.131(1)$, $c = 21.072(1)$ Å, $V = 7529.14$ Å^3 and $Z = 4$. A total of 3262 reflections were considered significant and used in the refinement, yielding final $R_f = 0.056$ and $R_w = 0.063$. The tetraanion has a centre of symmetry and features a Mo^{II}—Mo^{II} bond of 2.186(2) Å spanned by two *cis*-$Mo(CO)_4(PhPO_2)_2$ metallo-ligands. Chemically, only weak interactions are found between this tetraanion and potential axial ligands like tertiary amines, pyridine, phosphine and isonitrile. Its iodination occurred at the molybdenum(0) tetracarbonyl sites with CO loss to give $Mo_2[Mo(CO)_3I_2(PhPO_2)_2]_2^{4-}$.

Metal complexes containing *cis*-coordinated phosphonites can potentially present a square or rectangular array of oxygen nucleophiles upon deprotonation (Fig. 1). Recently we have used *cis*-$[M(CO)_4(PhPO_2)_2]^{4-}$ (M = Cr, Mo, W; complexes **1**, **2**, **3**) in preparing adamantane-like cage complexes of the type $[M(CO)_4[PhPO]_4M(CO)_4]$, where the metals are linked by POP bridges.[1] Since P—O ligands with their soft/hard donor combination are known for their ability to bridge heterometallic and mixed-valent centres,[2] we have investigated the use of **1–3** as metallo-ligands. We report here their employment as doubly-bridging groups for the quadruply-bonded Mo_2^{4+} dimer.

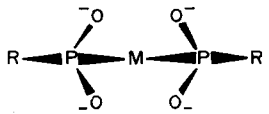

Fig. 1.

RESULTS

Synthesis and spectra

Deprotonation of the tetrabutylammonium salts of *cis*-$[M(CO)_4(PhPO_2)_2H_3]^-$ (M = Cr, Mo, W; complexes **4**, **5**, **6**, respectively)[1] with sodium hydride in THF afforded the corresponding tetraanions: **1**, **2** and **3**. Substitution of two of these for the bridging acetates in $Mo_2(OAc)_4$ proceeded readily at room temperature:

$$2\,cis\text{-}[M(CO)_4(PhPO_2)_2]^{4-} + Mo_2(OAc)_4 \longrightarrow Mo_2[M(CO)_4(PhPO_2)_2]_2^{4-} + 4OAc^-$$

(7–9)
(M = Cr, Mo, W).

These tetrametallic products were isolated as disodium di(*n*-butylammonium) salts in moderate yields and are air-stable orange–red solids (**7**, **8**, **9** for M = Cr, Mo, W, respectively). They are soluble in polar organic solvents such as THF, DMSO,

[c] d_6-DMSO.

acetonitrile and acetone, moderately soluble in methylene chloride, and insoluble in ether.

Typical *cis*-$M(CO)_4L_2$ carbonyl bands (C_{2v}) are observed for the tetraanionic complexes **7–9** with A_1 stretches below 2000 cm^{-1} (Table 1). Their $^{31}P\{^1H\}$ NMR spectra (Table 1) exhibited singlets which are all shifted downfield by about 70 ppm from the corresponding precursor (complexes **4–6**) values of δ 170.0, 145.5 and 120.5 ppm, respectively.[1] Electronic spectra of **7–9** featured absorptions at 338 nm ($\varepsilon = 4.4 \times 10^3$ M^{-1} cm^{-1}) for **7**, 351 nm ($\varepsilon = 9.6 \times 10^3$) for **8**, and 341 nm ($\varepsilon = 5.4 \times 10^3$) for **9**.

Structure of complex **8**

Recrystallization of **8** from methylene chloride–hexane yielded orange crystals of the tetraanion as the $(n\text{-}Bu_4N)_2H_2$ salt. Elemental analyses and ^1H NMR of the crystals confirmed the exchange of two sodium cations for two protons. Electronic and ^{31}P NMR spectra further corroborated retention of the basic Mo_2^{4+} unit. The molecular structure of the complex is shown in Fig. 2. Important bond distances and angles are listed in Table 2. The tetrametallic anion possesses an inversion centre which relates the pair of molybdenum(II) centres, Mo(1) and Mo(1a), as well as the two $Mo(CO)_4$ moieties, around Mo(2) and Mo(2a). Each *cis*-$Mo(CO)_4(PhPO_2)_2$ metallo-ligand doubly bridges the Mo_2^{4+} unit using all four oxygen donor sites. Around each molybdenum(II), the Mo—Mo quadruple bond is 2.186(2) Å, while the Mo—O distances range from 1.988(7) to 1.998(7) Å. At the zerovalent molybdenum centres, average axial Mo—CO distances are marginally longer at 2.02(2) Å compared to the equatorial average of 1.96(2) Å. Metal–phosphorus bonds average 2.518(4) Å. The tetrabutylammonium cations fill the packing vacancies and exhibit no unusual contacts with the anion.

Reactions of complex **8**

Lewis bases form only weak adducts with **8** in solution presumably by coordination at the vacant axial sites of the Mo_2^{4+} dimeric unit. For example, a $^{31}P\{^1H\}$ NMR spectrum indicated formation of a complex with pyridine (δ 214 ppm). However, no adduct could be isolated as the Lewis base was lost upon solvent evaporation. Only the better donating 4-dimethylaminopyridine (DMAP) formed an isolable 2:1 adduct, complex **10**. π-Acceptor ligands like triphenylphosphine and *t*-butylisocyanide failed to react with **8** even under forcing conditions.

Reaction of 2 equivalents of iodine with **8** resulted in CO evolution and formation of a tetramolybdenum(II) product, complex **11** ($^{31}P\{^1H\}$ NMR in THF: δ 195, broad singlet; IR (KBr): ν_{CO} 2002, 1941, 1881 cm^{-1}; ν_{PO} 881 cm^{-1}; CHN analyses consistent with $(n\text{-}Bu_4N)_2Na_2Mo_2[MoI_2(CO)_3(PhPO_2)_2]_2 \cdot 2THF$). This orange, crystalline solid rapidly decomposed with loss of CO upon standing.

DISCUSSION

Syntheses and spectra of complexes **7**, **8** *and* **9**

The feasibility of using the metallo-ligands *cis*-$[M(CO)_4(PhPO_2)_2]^{4-}$ (M = Cr, Mo, W) as tetradentate donors has been confirmed. Replacement of two carboxylates in $Mo_2(OAc)_4$ by each ligand proceeded at ambient temperature in THF. Previously, reactions of phosphinates with Mo_2^{4+} produced only polymeric species that are weakly paramagnetic and devoid of multiple bonds.[3] The chromium reaction was complete within 1 h, while

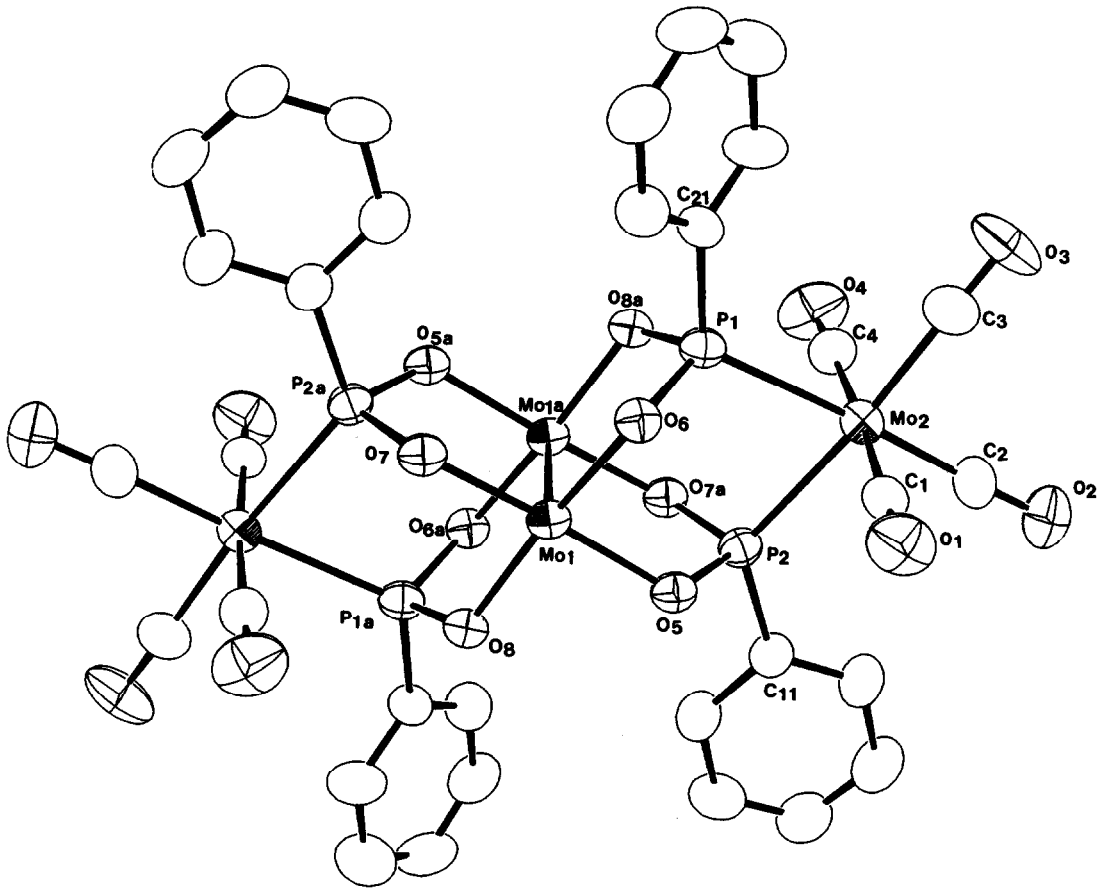

Fig. 2. Molecular structure of $Mo_2[Mo(CO)_4(PhPO_2)_2]_2^{4-}$ (**8**) with atoms at 50% probability ellipsoids.

the molybdenum and tungsten substitutions required 1 day. Monitoring of the reaction of $[Mo(CO)_4(PhPO_2)_2]^{4-}$ (**2**) with $Mo_2(OAc)_4$ by ^{31}P NMR spectroscopy revealed an intermediate resonance at δ 197 ppm in addition to singlets at 142 (**2**) and 217 (**8**). It is reasonable to assign the transient resonance to a partially-substituted intermediate:

$$Mo_2(OAc)_4 + [Mo(CO)_4(PhPO_2)_2]^{4+} \longrightarrow$$
$$2OAc^- + Mo_2(OAc)_2[Mo(CO)_4(PhPO_2)_2]^{2-}.$$

The substantial and uniform 67–76 ppm downfield coordination shift observed in the ^{31}P NMR spectra of complexes **7–9** can be attributed to the diamagnetic anisotropic deshielding of the Mo—Mo quadruple bond.[4] These chemical shifts are also solvent dependent; for example, in acetone, complex **8** has δ at 222, in THF it is at δ 217 and in pyridine at δ 214. Adduct formation at the vacant Mo_2^{4+} axial sites can be expected to reduce diamagnetic anisotropy.

Complexes **7–9** each has an absorption maximum in the region 338–351 nm with extinction coefficients of the order of 10^3 M^{-1} cm^{-1}. Burlitch and co-workers have reported an absorption at 334 nm ($\varepsilon = 6.4 \times 10^3$) for $Mo_2(S_2PEt_2)_4$.[3] As previously discussed by Trogler and Gray, assignment of these bands is problematic in the absence of polarized spectra.[5]

Structure of complex **8**

The value of 2.186(2) Å for the Mo—Mo bond in **8** is slightly longer than any other Mo—Mo quadruple bond spanned by four bridging ligands.[6] For example, $Mo_2(SO_4)_4^{4-}$ at 2.140(1) Å, $Mo_2(OAc)_4$ at 2.093(2) Å, $Mo_2(S_2PEt_2)_4 \cdot THF$ at 2.137(1) Å, $Mo_2(OSPEt_2)_4 \cdot THF$ at 2.128(2) Å and $Mo_2[O_2P(OPh)_2]_4 \cdot 2THF$ at 2.141(2) Å.[3,6,7] For comparison, $Mo_2[SO_4]_4^{3-}$ with a Mo—Mo bond order of 3.5 has a similar separation of 2.17 Å.[8] Significantly, the average Mo—O bond length in **8** at 1.99(1) Å is shorter than those in $Mo_2(OAc)_4$ (2.11(1) Å), $[Mo_2(SO_4)_4]^{4-}$ (2.14(1) Å), $Mo_2(OSPEt_2)_4 \cdot THF$ (2.15(3) Å), $Mo_2[O_2P(PEt)_2]_4$ (2.15 Å), and is at least as short as the 2.01(1) Å found in the triply-bonded dimolybdenum(III)

anion $[Mo_2(HPO_4)_4]^{2-}$.[3,6,9] The formally dianionic $PhPO_2$-bridging ligand should be significantly more electron-rich than the monanionic $(PhO)_2PO_2$ and acetate, for example. Qualitatively, mixing of oxygen lone-pairs with the Mo_2^{4+} dimer should strengthen the Mo—O bonds at the expense of Mo—Mo bonding. This is consistent with the observed structural data and the low tendency of **8** to adduct axial ligands.

Comparing the molybdenum(0) coordination geometry with that found in the $[Mo(CO)_4[PhPO]_4Mo(CO)_4]$ cage complex,[1] we note the slightly lengthened Mo—P distance at 2.518(4) Å vs 2.435(2) Å. Otherwise, metal–carbonyl geometrical data are quite similar. Using Kepert's definition of ligand bite angle ($b = 2\sin(\theta/2)$, where θ is the P—Mo—P angle), each molybdenum(0) centre in **8** is chelated by a diphosphine ligand with a b value of 1.27.[10]

Reactions of complex **8**

Like its precursor, $Mo_2(OAc)_4$, **8** appears to have little tendency to form stable axial adducts with hard donors.[8] Only the strong σ-donor 4-dimethylaminopyridine afforded an isolable 2:1 adduct, complex **10**. In contrast to $Mo_2(OAc)_4$,[8] complex **8** is also inert to π-acid ligands. Neither triphenylphosphine nor butylisonitrile gave any indication of adduct formation.

Halogenation oxidation of **8** could occur at either the molybdenum(0) or the molybdenum(II) dimeric unit. Iodination clearly resulted in oxidative elimination at the $Mo(CO)_4$ sites. Spectral and analytical data are consistent with the product being $Mo_2[Mo(CO)_3I_2(PhPO_2)_2]_2^{4-}$ (**11**). In contrast to **8**, this readily crystallizes with two molecules of THF, presumably in the axial positions. Variable-temperature $^{31}P\{^1H\}$ NMR of **10** in d_6-acetone

Table 3. Elemental analytical data

Complex	Calculated %C	%H	%N	Found %C	%H	%N

showed a limiting spectrum at −45°C of a singlet at δ 195.1 ppm, as well as a smaller set of AB doublets at δ 202.2 and 190.0 ppm ($J = 83$ Hz). While structural details are not yet available, the ligand bite angle of **8** ($b = 1.27$) would suggest capped trigonal prism or capped octahedron as most likely geometries at the seven-coordinate $Mo(CO)_3I_2P_2$ centres (Fig. 3).[10] Complex **11** is very unstable towards CO loss upon exposure to air, completely decomposing to a poorly-characterized dark grey residue after 24 h.

EXPERIMENTAL

All operations were carried out under an atmosphere of prepurified nitrogen using standard Schlenk techniques. Solvents were dried by conventional methods and distilled under nitrogen. (n-Bu_4N)$M(CO)_4(PhPO_2)_2H_3$ (M = Cr, Mo, W) were prepared from *cis*-$M(CO)_4(PhPCl_2)_2$ as described previously.[1] $Mo_2(OAc)_4$ was synthesized according to the literature procedure.[8]

NMR spectra were recorded on a Bruker AM-360, JEOL-FX90Q, or a Varian 360A. IR spectra were run on a Perkin–Elmer 283B instrument. Electronic spectra were recorded using a Cary 219 spectrophotometer. Elemental analyses were performed at the University Instrumentation Center with a Perkin–Elmer 240B Elemental Analyser and the results are included in the supplementary material. All compounds below gave satisfactory (within 0.4%) carbon, hydrogen and nitrogen analyses.

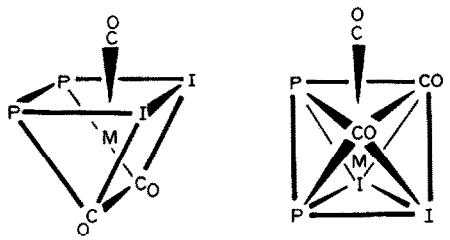

Fig. 3. Possible geometries at the $Mo(CO)_3I_2P_2$ portions of complex **11**.

Synthesis of (n-Bu_4N)$_2Na_2Mo_2[Cr(CO)_4(PhPO_2)_2]_2$ (**7**)

(n-Bu_4N)$Cr(CO)_4(PhPO_2)_2H_3$ (1.452 g, 2.1 mmol) was dissolved in THF (25 cm^3). Sodium hydride (*ca* 1 g of a 50% dispersion in oil) was added and the suspension stirred until effervescence ceased. The excess NaH was filtered off with a sintered-glass frit and $Mo_2(OAc)_4$ (0.226 g, 0.5 mmol) was added to the filtrate. The solution colour changed from yellow–brown to red. After 1 h of stirring, a white solid (NaOAc) was removed by filtration and 5 cm^3 of toluene was added to the filtrate. A brown solid was obtained. This was filtered off and recrystallized from THF–ether to give brown, rectangular crystals of **7** (0.39 g, 53% yield).

Synthesis of (n-Bu_4N)$_2Na_2Mo_2[Mo(CO)_4(PhPO_2)_2]_2$ (**8**), *and* (n-Bu_4N)$_2Na_2Mo_2[W(CO)_4(PhPO_2)_2]_2$ (**9**)

Complexes **8** and **9** were prepared as above from the respective (n-Bu_4N)$M(CO)_4(PhPO_2)_2H_3$ salt, except that the reaction mixtures were allowed to stir at ambient temperature for 24 h. Yield of **8** is 65% of orange crystals. The yield of **9** is 40% of orange microcrystals.

Synthesis of (n-Bu_4N)$_2Na_2Mo_2[Mo(CO)_4(PhPO_2)_2]_2 \cdot 2$DMAP (**10**)

Complex **8** (0.209 g, 0.125 mmol) was dissolved in 10 cm^3 of THF. Dimethylaminopyridine (0.032 g, 0.258 mmol) was added and the solution stirred for 1 h. The orange precipitate was filtered off, washed with THF and dried to give **10** (0.165 g, 68% yield).

Synthesis of (n-Bu_4N)$_2Na_2Mo_2[Mo(CO)_3I_2(PhPO_2)_2]_2 \cdot 2$THF (**11**)

Complex **8** (0.163 g, 0.09 mmol) was dissolved in 10 cm^3 of THF. With stirring, iodine (0.049 g, 0.19 mmol) was added and effervescence and darkening of the solution was observed. After 2 h, the suspension was filtered, the residue washed with THF and dried to give **11** (0.136 g, 70% yield). This orange, crystalline solid readily decomposed upon air-exposure to give a dark grey powder.

X-ray structural determination of (n-Bu_4N)$_2H_2Mo_2[Mo(CO)_4(PhPO_2)_2]_2$ (**8**)

Crystals of **8** were grown from methylene chloride–hexane by layering in a Schlenk tube. ^{1}H NMR of the resulting red–brown crystals in d_6-

acetone revealed the presence of two protons (δ 2.79 in d_6-acetone) which have been exchanged for the two sodium cations during the recrystallization. Elemental analyses (Table 3): Calc. for $C_{64}H_{94}Mo_4N_2O_{16}P_4$: C, 46.44; H, 5.68; N, 1.69. Found: C, 46.18; H, 5.76; N, 1.66%. An ethanol solution of the crystals has an absorption maximum at 350 nm in the visible region. Its ^{31}P NMR singlet signal was found at +222.5 ppm (d_6-acetone). Furthermore, ^{31}P NMR of a mixture of **8** before and after recrystallization gave a *single* resonance at +222.5 ppm in acetone. This is possible only if the Mo_2^{4+} unit has remained intact. A summary of crystal data, data refinement and structure refinement is presented in Table 4. The intensities of a $0.2 \times 0.40 \times 0.40$ mm crystal were collected with monochromatized Mo-K_α radiation using the θ–2θ scan technique and line profile analysis.[11] 6654 unique reflections were collected, of which 3262 were judged significant at the 3σ(Inet) level. Corrections were applied for Lorentz and polarization effects but absorption corrections were not made ($\mu = 0.78$ mm^{-1}).[12] Cell parameters were obtained from the setting angles of 56 reflections with $2\theta > 40°$. The structure was solved by MULTAN and hydrogen positions were calculated. The structure was refined by full-matrix least-squares to final residuals of $R_F = 0.056$ and $R_{WF} = 0.063$. The final atomic positional parameters of non-hydrogen atoms and equivalent isotropic thermal factors, as well as complete bond distance and angle tables are included in the supplementary materials.

(*Received* 16 *January* 1989; *accepted* 4 *May* 1989)

Abstract—The interactions of copper(II) with chlorogenic acid [1,3,4,5-tetrahydroxycyclohexanecarboxylic acid 3-(3,4-dihydroxycinnamate)] and related compounds such as 3,4-dihydroxyphenylacetic acid (3,4-DHPA), 3,4-dihydroxyphenylpropionic acid (3,4-DHPP) and *trans*-3-(3,4-dihydroxyphenyl)propenoic acid (caffeic acid) in aqueous solution have been investigated by pH-metric and spectroscopic (ESR and electronic absorption) methods. It has been found that these ligands exhibit a real ambidentate character, i.e. in addition to the chelation via the catecholate sites, the separated carboxylate can also coordinate to the copper(II) ion. The simultaneous coordination of both types of binding sites leads to the formation of various oligomeric species.

Phenolic hydroxyl-containing ligands, which are known to be present in the root exudates, may participate in the transport processes of metal ions from the surrounding soil to the plant roots.[1,2] Of special interest are *trans*-3-(3,4-dihydroxyphenyl)propenoic acid (caffeic acid), which is believed to participate in the transport and in the reduction of iron(III) to iron(II) in the soil environment,[1] and chlorogenic acid [1,3,4,5-tetrahydroxycyclohexanecarboxylic acid 3-(3,4-dihydroxycinnamate)], which is a precursor of caffeic acid.

Earlier studies on the binding ability of caffeic acid[3,4] and chlorogenic acid[5] came to contradicting conclusions. Linder and Voye[3] concluded that caffeic acid easily forms oligomeric structures with copper(II) ions, while Bizri *et al.*[4] and Lamy *et al.*[5] found only simple monomeric complexes, probably involving the catechol-type of coordination. Recent results on several dihydroxybenzoic acids have provided strong evidence that both the catechol and the carboxyl sites may be involved in the copper(II) ion binding,[6–8] and different dimeric or trimeric complexes can be formed.[6]

In this paper the pH-metric results on chlorogenic and caffeic acids and some other 3,4-dihydroxybenzoic acid derivatives (3,4-DHPA, 3,4-DHPP) confirm the speciation model of Linder and Voye[3] and extends it by measuring spectroscopic (absorption and ESR) properties of the complexes formed in order to characterize their bonding modes.

EXPERIMENTAL

Potentiometric studies

Stability constants for proton and copper(II) complexes were determined by pH-metric titration of 25 cm^3 samples. The concentration of the ligand in the samples was 0.004 or 0.002 mol dm^{-3}. Metal-to-ligand molar ratios of 1 : 1, 1 : 1.5, 1 : 2, 1 : 4 and 1 : 6 were used in the titrations and the ionic strength was adjusted to 0.2 mol dm^{-3} with KCl. The titrations were performed in the pH range from 2.7 till precipitation, up to a pH between 5 and 8 depending on the ligand excess. The precipitates were analysed by AAS and it was found that the metal ion-to-ligand ratios were around 1.3–1.4 : 1, which suggested the formation of polynuclear species.

The pH was measured with a Radiometer pHM 64 instrument with G2040B glass and K4040 calomel electrodes, in a TTA 80 titration unit in an argon atmosphere. The electrode system was calibrated by the method of Irving *et al.*[9] In all cases the temperature was 25°C. The concentration stability constants were calculated using the PSEQUAD computer program.[10]

Spectroscopic studies

Absorption spectra were recorded on a Beckman Acta MIV spectrophotometer, and ESR spectra (X-band) were measured on a Varian E 9 spectrometer at 110 K. The measurements were made under argon with concentrations similar to those used in the potentiometric studies.

RESULTS AND DISCUSSION

Proton complexes

The proton dissociation constants of the ligands are listed in Table 1, together with some reference data. The data shows that the COOH group of chlorogenic acid is more acidic than that of the other ligands, due to the adjacent alcoholic hydroxyl function. Similarly, as with simple diphenol catechol, both phenolic groups of the ligands undergo dissociation at pH below 13.5 (Table 1). The very weak acidity of the third dissociable proton can be attributed to the electrostatic attraction of the adjacent negative charge and to hydrogen-bond formation involving the phenolic hydroxyl proton.

Copper(II) *complexes*

Evaluation of the copper(II)–ligand titration curves with the assumption of only monomeric complexes resulted in a set of five species: $CuAH_2$, CuAH, CuA, $CuAH_{-1}$ and CuA_2 (A denotes the completely deprotonated ligand). The fit between the experimental and the calculated titration curves, however, was not satisfactory, and other speciation models were therefore tried in the calculation (see later). The $CuAH_2$ species, which has two phenolic hydroxyl groups protonated, involves only the carboxylate donors in metal coordination. This species is clearly seen in the ESR spectra at below pH 5, with $g_{\parallel} = 2.36$–2.37 and $A_{\parallel} = (154$–$157) \times 10^{-4}$ cm^{-1}. The spectra also allowed the identification of the species CuA and CuA_2 involving the cate-

cholate-type of coordination (see Table 2). The ESR parameters are very close to those found earlier for the same type of coordination (see for example ref. 7). $CuAH_{-1}$ is presumably a mixed hydroxo complex formed by the hydrolysis of CuA. The species CuAH might have different donor atom arrangements. The ligands can coordinate to the copper(II) ion via their phenolate groups, with a protonated side-chain carboxylic group.[4,5] The pK values of the CuAH complexes, however, are much higher (see pK_{CuAH} values in Table 3) than those of the carboxylic group of the free ligands (see Table 1). Since the catechol and carboxylic terminals of the ligands are very distant from each other, the observed decrease in acidity cannot be attributed to the electron-releasing effect of the coordinated phenolate groups. Linder and Voye[4] suggested chelation via the singly protonated catecholate site. This bonding mode has not been found for the copper(II) complexes of other 3,4-dihydroxyphenyl derivatives, with the only exception being copper(II) 3,4,-di-*t*-butylpyrocatechol,[11] in which the low solubility of the complexes formed did not allow a very precise equilibrium study, however. When evaluating the titration data, we found that, through the assumption of a dinuclear complex Cu_2A, this monoprotonated species could be omitted completely without any significant decrease in the fitting parameter. The simultaneous metal ion coordination to both carboxyl and catechol sites and the formation of oligomeric complexes seems to be a general tendency for ligands possessing two coordinating sites.[3,6,12,13] The assumption of other

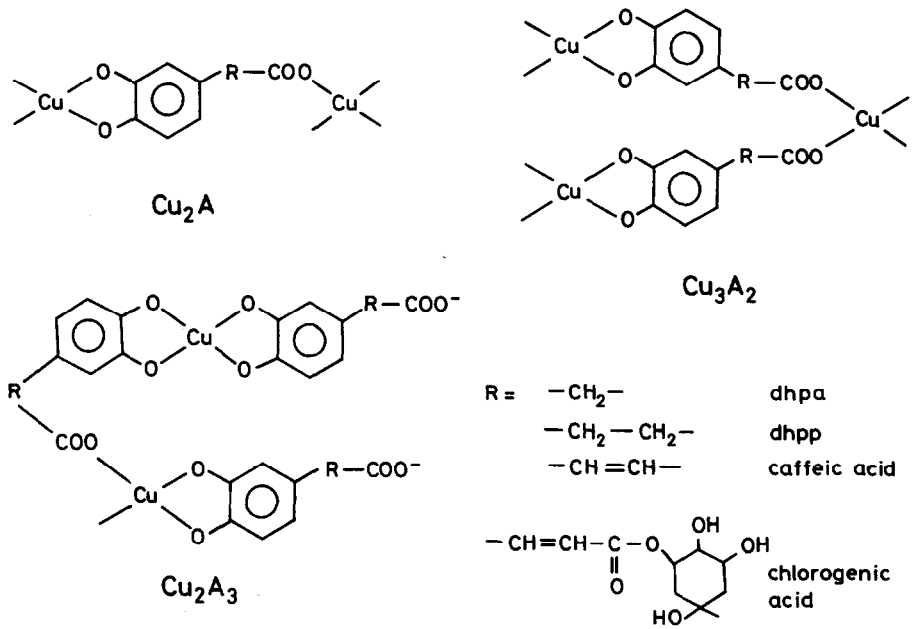

Scheme 1.

oligomeric complexes, such as Cu_2A_3 and Cu_3A_2, improved the fitting by about 50–80% and it then fell within the limits of experimental error. The formation of such species was suggested in the copper(II)–caffeic acid[3] and in the copper(II)–3,4-DHB systems.[6]

As an illustration, the concentration distribution curves of the complexes formed in the copper(II)–3,4-DHPA and in the copper(II)–chlorogenic acid systems are depicted in Figs 1 and 2. The spectroscopic results are in good agreement with the coordination modes suggested. For example, the signals detected in the formation pH range of the species Cu_3A_2 and Cu_2A_3 of 3,4-DHPA and 3,4-DHPP exhibit parameters which may be assigned to the following donor sets: $g_\parallel = 2.34$ and $A_\parallel = (162–164) \times 10^{-4}$ cm^{-1} to (COO^-,COO^-); $g_\parallel = 2.31–2.32$ and $A_\parallel = (170–173) \times 10^{-4}$ cm^{-1} to (O^-,O^-); $g_\parallel = 2.25$ and $A_\parallel = 202 \times 10^{-4}$ cm^{-1} to $2 \times (O^-,O^-)$; and $g_\parallel = 2.28$ and $A_\parallel = 183 \times 10^{-4}$

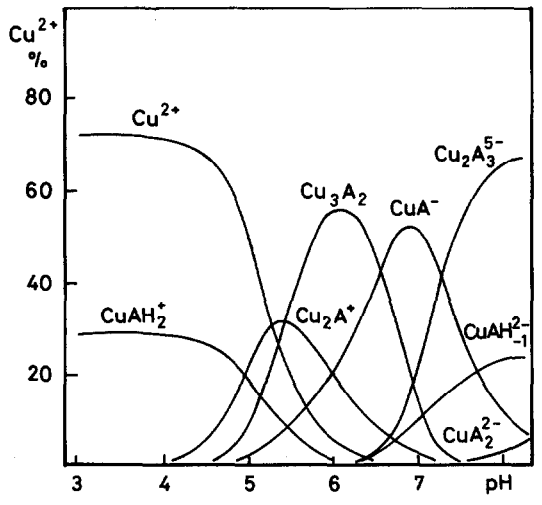

Fig. 1. Concentration distribution curves of the complexes formed in the copper(II)–3,4-DHPA system as a function of pH. $C_{Cu} = 0.002$ mol dm^{-3} and $C_{ligand} = 0.004$ mol dm^{-3}.

cm^{-1} to (O^-,O^-,COO^-) (see Table 2). As expected, the parameters of the various coordination modes in the oligonuclear species are almost the same as those for the corresponding chromophores in the monomeric species.

It can be seen from Table 3 and Figs 1 and 2 that, compared with the other 3,4-dihydroxyphenylcarboxylates, chlorogenic acid has a lower tendency to form oligomeric species. It behaves as a catechol derivative with a subordinate possibility of carboxylate coordination. Accordingly, the $\log(K_1/K_2)$ value characteristic for the stepwise formation of the (O^-,O^-)-coordinated complexes corresponds well with that for catechol ($\log K_1/K_2 = 2.95$).[13] With the other ligands, as shown in Fig. 1, the trimeric species Cu_3A_2 is formed in significant concentration in the pH range 5–6. In this species, the copper(II) ion acts as a link between two CuA species by coordinating to the carboxylate sites. At higher pH values, the major species is the dinuclear complex Cu_2A_3, and the monomeric bis-catecholato complex CuA_2 is formed only in very low concentration. This means that the enhanced tendency towards the formation of oligomeric species hinders the simple catecholate coordination of the second ligand, which instead behaves as a bridge between two CuA species by coordinating to them via both metal binding sites.

The preferred formation of these oligomeric complexes is also reflected in the equilibrium constants calculated for the various part processes (see Table 3). The data show that the copper(II)–COO^- interaction is stronger if the coordinating ligand is already bound to copper(II) at the catecholate site.

In the electronic spectra the appearance of a charge-transfer band (range 365–420 nm) above pH 5, characteristic of the copper(II)–phenolate interaction, is an indication that catecholate bonding modes are involved in the coordination. The strong absorption of chlorogenic acid and caffeic acid in the 400 nm region did not allow the catecholate coordination to be followed via this charge-transfer transition. The *d–d* absorption maxima corresponding to the principal chromophores involved in coordination are similar to those already reported,[7] and they are particularly observed around 730 nm for (O^-,O^-), 620 nm for $2\times$(O^-,O^-) and 680 nm for (O^-,O^-,OH^-), though a precise evaluation of the molar absorptivity values was generally not possible.

The results presented above clearly indicate the ambidentate nature of these 3,4-dihydroxycarboxylates in their copper(II) complexes. Hence, besides chelation via the catecholate site, the separated carboxylate can also take part in the coordination, by forming monomeric complexes at low pH and oligomeric complexes (in which both binding sites of the ligands are involved in the coordination) at higher pH values.

(*Received* 1 *April* 1989; *accepted* 10 *May* 1989)

Abstract—UV irradiation of a solution of $[Ru_4(CO)_{11}(\mu_4\text{-}S)_2]$ (**1**) and $[W(CO)_5\{C(Ph)NMe_2\}]$ yielded the two new higher nuclearity carbene-containing cluster complexes $[Ru_4(CO)_{10}\{C(Ph)NMe_2\}(\mu_4\text{-}S)_2]$ (**2**) 20%, and $[Ru_4(CO)_{10}\{C(Ph)NMe_2\}(\mu_4\text{-}S)(\mu_5\text{-}S)\{W(CO)_5\}]$ (**3**) 1%, by transfer of the carbene ligand from the tungsten complex to a ruthenium atom of the cluster. Compound **3** was obtained in 50% yield by UV irradiation of solutions of **2** and $W(CO)_6$. Compounds **2** and **3** were both characterized by single-crystal X-ray diffraction methods. Crystal data for **1**: $Ru_4S_2O_{10}NC_{19}H_{11}$, $M = 881.7$, $P2_1/n$, (No. 14), $a = 11.847(1)$, $b = 11.773(2)$, $c = 19.310(2)$ Å, $\beta = 104.685(8)°$, $V = 2597(1)$ Å^3, $D_c = 2.26$ g cm^{-3}, $Z = 4$, λ(Mo-K_α) = 0.71069 Å (graphite monochromator), $\mu = 24.3$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 3383 reflections ($F^2 \geqslant 3\sigma(F^2)$), ($1 \leqslant 2\theta \leqslant 47°$), gave R and R_w values of 0.032 and 0.043. Data/parameters ratio = 10.4, highest peak in final difference Fourier = 0.82 e Å^{-3}. Crystal data for **2**: $WRu_4S_2O_{15}NC_{24}H_{11}$, $M = 1205.6$, monoclinic, $P2_1/n$ (No. 14), $a = 15.268(1)$, $b = 11.451(1)$, $c = 19.121(2)$ Å, $\beta = 99.731(8)°$, $V = 3295.0(6)$ Å^3, $D_c = 2.43$ g cm^{-3}, $Z = 4$, λ(Mo-K_α), graphite monochromator, $\mu = 56.2$. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 4444 reflections ($F^2 \geqslant 3\sigma(F^2)$), ($1 \leqslant 2\theta \leqslant 48°$), yielded $R = 0.026$, $R_w = 0.032$. Data/parameters ratio = 10.5. Compound **2** consists of a square-planar cluster of four ruthenium atoms with two quadruply bridging sulphido ligands and one terminally coordinated phenyl(dimethylamino)carbene ligand. Compound **3** consists of a cluster of **2** with a $W(CO)_5$ group added to one of the quadruply bridging sulphido ligands.

Metal complexes containing carbene ligands have been recognized for over 25 years.[1,2] Recently, complexes containing carbene ligands have been utilized as reagents in a variety of novel organic syntheses.[3,4] Although there are a variety of methods for preparing carbene ligands in cluster complexes,[5] the number of examples of these complexes is still relatively small. In fact, there are only two reports of cluster complexes with carbene ligands that have more than three metal atoms.[6,7] In cluster complexes, the carbene ligands can adopt terminal **A** and a variety of bridging coordination modes **B**–**D**. The multicentre metal site can provide new avenues for the activation and transformation of the carbene ligand.[5,8]

This report describes the synthesis and structural characterizations of two new higher nuclearity cluster complexes containing the phenyl(dimethylamino)carbene ligands, prepared by the carbene ligand transfer method that was developed by Fischer[9] and Stone.[10]

EXPERIMENTAL

General

All reactions were performed under a nitrogen atmosphere. Reagent grade solvents were dried over 4 Å molecular sieves and purged with nitrogen prior to use. $[Ru_4(CO)_{11}(\mu_4\text{-}S)_2]$[11] and $[W(CO)_5\{C(Ph)NMe_2\}]$[2] were prepared as previously reported. $Ru(CO)_5$ was prepared from $Ru_3(CO)_{12}$ just prior to use.[13] UV irradiations were performed by using an externally-positioned high pressure mercury lamp on the reaction solutions in Pyrex glassware.

All chromatographic separations were performed in air. TLC separations were performed on silica gel plates (0.25 mm Kieselgel 60 F254, E. Merck, F.R.G.). IR spectra were recorded on a Nicolet 5DXB FT–IR spectrophotometer. ^1H NMR spectra were recorded on a Brüker AM-300 spectrometer operating at 300 MHz. Elemental analyses were performed by Desert Analytics, Tucson, Arizona.

Reaction of $[Ru_4(CO)_{11}(\mu_4\text{-}S)_2]$ (**1**) *with* $[W(CO)_5\{C(Ph)NMe_2\}]$ *in the presence of UV irradiation*

$[W(CO)_5\{C(Ph)NMe_2\}]$(97 mg, 0.21 mmol) was added to a suspension of **1** (55 mg, 0.070 mmol) in 140 cm^3 of THF. The solution was photolysed under a continuous purge of nitrogen for 8 h, and the colour of the solution changed from orange to orange–red. The solvent was removed *in vacuo* and the residue was chromatographed by TLC using a hexane–CH_2Cl_2 (7:3) solvent mixture. The following bands were obtained in order of elution: trace amounts of $W(CO)_6$; 2 mg of **1**; 31 mg of $[W(CO)_5\{C(Ph)NMe_2\}]$; 13 mg of golden-yellow $[Ru_4(CO)_{10}\{C(Ph)NMe_2\}(\mu_4\text{-}S)_2]$, (**2**), 20%; and 1 mg of orange $[Ru_4(CO)_{10}\{C(Ph)NMe_2\}(\mu_4\text{-}S)(\mu_5\text{-}S)\{W(CO)_5\}]$ (**3**), 1%. For **2**: IR (in hexane) 2075(s), 2056(w), 2036(vs), 2027(vs), 2011(s), 1982(s), 1855(m), 1816(m) cm^{-1}. ^1H NMR (δ in $CDCl_3$) 6.87 (m, 3H), 6.29 (m, 2H), 4.50 (s, 3H), 3.25 (s, 3H). Found: C, 25.9; H, 0.91. Calc.: C, 25.9; H, 1.26%. For **3**: IR (in hexane) 2085(m), 2076(w), 2067(m), 2042(s), 2036(s), 2019(sh), 1991(s), 1939(vs), 1935(vs), 1862(w), 1823(w). ^1H NMR (δ in $CDCl_3$) 6.89 (m, 3H), 6.27 (m, 2H), 4.57 (s, 3H), 3.27 (s, 3H). Found: C, 23.8; H, 0.89. Calc.: C, 23.9; H, 1.10%.

The reaction of **2** *with* $W(CO)_6$ *in the presence of UV irradiation*

A mixture of **2** (10 mg, 0.011 mmol) and $W(CO)_6$ (20 mg, 0.057 mmol) was dissolved in 30 cm^3 of hexane solvent and photolysed under a continuous purge with nitrogen for 40 min. The colour of the solution changed from yellow to a brownish-yellow. The solvent was removed *in vacuo* and the residue was separated by TLC. Elution with a hexane–CH_2Cl_2 (7:3) solvent mixture yielded 6 mg of **3** (50% based on the amount of **2** consumed) and 1.2 mg of unreacted **2**.

Crystallographic analysis

Crystals of **2** and **3** were grown by the slow evaporation of solvent from hexane–CH_2Cl_2 (3:1) solutions at 5°C. The data crystals were mounted in thin-walled glass capillaries. Diffraction measurements were made on a Rigaku AFC6 automatic diffractometer using graphite-monochromatized Mo-K_α radiation. Unit cells were determined from 25 randomly selected reflections obtained by using the AFC6 automatic search, centre, index and least-squares routines. Crystal data, data collection parameters and results of the analyses are listed in Table 1. All data processing was performed on a Digital Equipment Corporation MICROVAX II computer by using the TEXSAN structure solving program library (v 2.0) obtained from the Molecular Structure Corporation, The Woodlands, Texas. Neutral atom scattering factors were calculated by the standard procedures.[13a] Anomalous dispersion corrections were applied to all atoms.[13b] Full-matrix least-squares refinements minimized the function:

$$\sum_{hkl} w(|F_o| - |F_c|)^2,$$

where

$$w = 1/\sigma(F)^2, \quad \sigma(F) = \sigma(F_o^2)/2F_o,$$

and

$$\sigma(F_o^2) = [\sigma(I_{raw})^2 + (PF_o^2)^2]^{1/2} Lp.$$

Both compounds crystallized in the monoclinic crystal system in the space group $P2_1/n$. The latter was established in each case from the systematic absences observed during the collection of the data. The structures were solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses. All non-hydrogen atoms were refined using anisotropic thermal parameters. Hydrogen

atom coordinates were calculated by assuming idealized geometries and C—H distances of 0.95 Å. Their scattering contributions were included in the structure factor calculations, but their positions were not refined. Error analyses were calculated from the inverse matrix obtained from the final cycle of refinement.

RESULTS AND DISCUSSION

The reaction of $[Ru_4(CO)_{11}(\mu_4\text{-}S)_2]$ (**1**) with $[W(CO)_5\{C(Ph)NMe_2\}]$ in the presence of UV irradiation yielded the new carbene-containing cluster complex $[Ru_4(CO)_8\{C(Ph)NMe_2\}(\mu\text{-}CO)_2(\mu_4\text{-}S)_2]$ (**2**) in 20% yield and a trace of the higher nuclearity carbene cluster complex $[Ru_4(CO)_8\{C(Ph)NMe_2\}(\mu\text{-}CO)_2(\mu_4\text{-}S)(\mu_5\text{-}S)\{W(CO)_5\}]$ (**3**) in 1% yield. Both products were characterized by IR and ^{1}H NMR spectroscopy, and by single-crystal X-ray diffraction analyses. An ORTEP drawing of **2** is shown in Fig. 1. Selected intramolecular bond distances and angles are listed in Tables 2 and 3. The molecule consists of an approximately square-planar cluster of four ruthenium atoms with one quadruply bridging sulphido ligand on each side of the square plane. The two shortest Ru—Ru bonds, Ru(2)—Ru(4) = 2.7339(6) Å and Ru(3)—Ru(4) = 2.7236(6) Å, are bridged by carbonyl ligands which are believed to contribute to the shortness of the Ru—Ru distances. The Ru(1)—Ru(2) bond, 2.7823(6) Å, contains a semibridging carbonyl ligand, C(12)—O(12), Ru(1)—C(12)—O(12) = 162.7(6)°. The longest Ru—Ru bond, Ru(1)—Ru(3) = 2.8065(6) Å, has no bridging or semibridging carbonyl ligands. The quadruply bridging sul-

Angles are in degrees. Estimated standard deviations in the least significant figure are given in parentheses.

phido ligands are bonded asymmetrically to the tetraruthenium cluster. The Ru—S distances to Ru(4), 2.576(1) and 2.647(1) Å, are significantly longer than those to the other three ruthenium atoms, range 2.413(1)–2.483(1) Å. This could be due to steric crowding about atom Ru(4). Formally, Ru(4) has a coordination number of eight, while the other three ruthenium atoms have a coordination of seven. The structure of **2** is very similar to that of $[Ru_4(CO)_7(PMe_2Ph)_2(\mu\text{-}CO)_2(\mu_4\text{-}S)_2]$ (**5**).[15] Compound **2** contains 10 carbonyl ligands: two bridges, one semibridge and seven linear terminal ligands distributed as shown in Fig. 1, but the most interesting ligand is the phenyl(dimethylamino)carbene ligand which is terminally coordinated to the Ru(4) atom. As with other aminocarbene ligands,[2] the nitrogen atom is planar and the C—N distance is short, 1.308(7) Å, and indicative of partial C—N multiple bonding due to the interaction of the lone pair of electrons on the nitrogen atom with the carbene carbon atom. This results in a hindered rotation about the C—N bond and the observation of separate resonances (^{1}H NMR) for the inequivalent methyl groups on the nitrogen atom. The Ru—C bond to the carbene ligand of 2.033(5) Å is slightly longer than those to the terminally coordinated carbonyl ligands, 1.853(6)–1.915(7) Å. This feature is similar to that found in mononuclear metal carbonyl carbene complexes.[2] The plane of the phenyl group is nearly perpendicular (86.8°) to the plane of the carbene ligand. This precludes the existence of π-bonding between the phenyl ring and the carbene carbon atom. The phenyl(dimethylamino)carbene ligand in the cluster complex $[Os_3(CO)_8\{C(Ph)NMe_2\}(\mu_3\text{-}S)(\mu\text{-}H)_2]$ contained a similar structure.[16]

An ORTEP drawing of the molecular structure of **3** is shown in Fig. 2. Selected intramolecular bond distances and angles are listed in Tables 4 and 5. Compound **3** can be viewed as an adduct of compound **2** and a $W(CO)_5$ group. The $W(CO)_5$ group is attached to one of the quadruply bridging sulphido ligands. This sulphido ligand is, thus, pentacoordinate and overall possesses a square-pyramidal

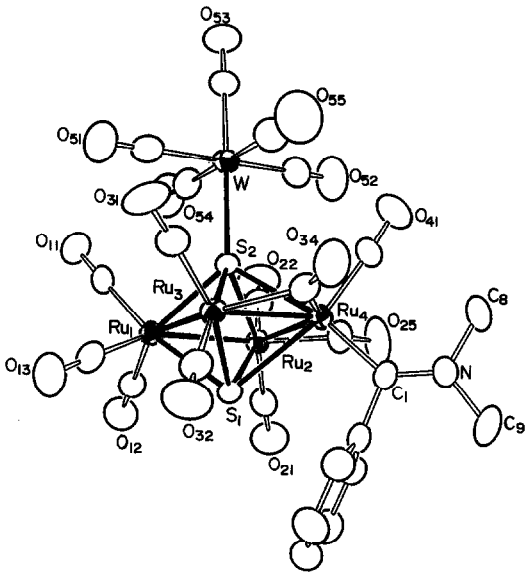

Fig. 2. An ORTEP drawing of $[Ru_4(CO)_8\{C(Ph)NMe_2\}(\mu\text{-}CO)_2(\mu_4\text{-}S)(\mu_5\text{-}S)\{W(CO)_5\}]$ (**3**) showing 50% probability thermal ellipsoids.

geometry. Similar quintuply bridging sulphido ligands were observed in the complexes $[Ru_4(CO)_7(PMe_2Ph)_2(\mu\text{-}CO)_2(\mu_4\text{-}S)(\mu_5\text{-}S)\{W(CO)_4PMe_2Ph\}]$ (**6**) and $[Os_5(CO)_{15}(\mu_5\text{-}S)\{W(CO)_4PPh_3\}]$ (**7**).[17] The W—S bond can be viewed as an S → W donor–acceptor bond. The tungsten atom thus achieves an 18 electron configuration, and the sulphido ligand donates its four remaining valence electrons to the ruthenium cluster. The W—S bond distance of 2.533(2) Å is slightly longer than found in **6**, 2.486(2) Å, and **7**, 2.48(2) and 2.44(2) Å. This could be attributed to the stronger structural *trans*-effect of the CO ligand *trans* to the W—S bond in **4** than the *trans*-phosphine ligands in **6** and **7**. The dimensions of the cluster of **2** contained in compound **3** are very similar to those of **2** alone. However, the CO ligands on Ru(1) in **3** are arranged significantly differently from those in **2**. In particular, there is no semi-bridging carbonyl ligand on Ru(1). Instead, C(11)—O(11) on Ru(1) lies above the Ru_4 plane, and C(12)—O(12) and C(13)—O(13) lie below it. It is believed that the rearrangement of the carbonyl ligands on Ru(1) may be caused by non-bonded repulsive interactions between the equatorial carbonyl ligands on the tungsten atom and the four terminal carbonyl ligands, C(11)—O(11), C(22)—O(22), C(31)—O(31) and C(41)—O(41), that lie on the tungsten side of the tetraruthenium plane. As a result of these repulsions, the $W(CO)_5$ group has adopted a rotational conformation that places the equatorial tungsten carbonyl groups midway between adjacent pairs of the four carbonyl groups on the cluster. The carbene ligand in **3** has very similar dimensions to the one in **2**. It lies on the side of the Ru_4 plane that is opposite to that of the $W(CO)_5$ group, probably for steric reasons.

In both **2** and the unit of **2** in **3**, the cluster

Angles are in degrees. Estimated standard deviations in the least significant figure are given in parentheses.

contains 62 valence electrons. This is in accord with the Polyhedral Skeletal Electron Pair theory,[18] but is two less than that required by the Effective Atomic Number rule.

Details of the transfer of the carbene ligand from $[W(CO)_5\{C(Ph)NMe_2\}]$ to **1** are obscure in the absence of reaction intermediates. We doubt that **3** is an intermediate in the formation of **2**, since very little **3** was isolated from that reaction. It is suspected that **3** was formed from **2** by the capture of a $W(CO)_5$ fragment. The credibility of this reaction was demonstrated by our synthesis of **3** in 50% yield by the irradiation of solutions of **2** and $W(CO)_6$.

Acknowledgement—This research was supported by the National Science Foundation under Grant CHE-8612862.

Tables of anisotropic thermal parameters, and observed and calculated structure factors for **2** and **3** have been deposited as supplementary material with the Editor, from whom copies are available upon request. Atomic coordinates have been submitted to the Cambridge Crystallographic Data Centre.

Abstract—The complexes $[Mo_2(OAc)_3(BAII)]$, where BAII is either bis(pyridylimino) isoindoline or bis(4,6-dimethylpyridylimino)isoindoline, have been synthesized. A detailed interpretation of their ^1H NMR spectra has been made. The structure of the bis(pyridylimino)isoindoline derivative has been determined by X-ray analysis to facilitate the assignment of the resonance lines in the NMR spectra. The complex is triclinic belonging to the space group $P\bar{1}$ with $a = 8.241(3)$, $b = 12.274(4)$, $c = 15.390(6)$ Å, $V = 1490.1(9)$ Å^3 and $D_{calc} = 1.66$ g cm^{-3}. The final R value was 0.058. The structure consists of a quadruply bonded dimolybdenum unit which is bound to three bridging acetates and one bridging BAII ligand. The BAII ligand is bound to one molybdenum by an imino nitrogen and to the other molybdenum by the isoindoline nitrogen and a pyridyl nitrogen. The pyridyl nitrogen is bound in a position approximately co-axial with the metal–metal bond. The Mo—Mo bond distance is 2.109(1) Å.

One useful way of probing the electronic structures of dimolybdenum compounds has been the investigation of the spectroscopic and electrochemical trends found within series of structurally related compounds. Most attention has been focused on the compounds of the series $Mo_2X_4(LL)_2$ and $Mo_2X_4L_4$, where X is halogen, LL is bidentate phosphine and L is monodentate phosphine.[1] We decided to synthesize and investigate a new series of dimolybdenum compounds based on the bis(arylimino)isoindoline, BAII, ligand in order to extend, and complement, the previous studies. The general structures of the BAII ligands are shown below. The BAII system was chosen since it is fairly easy to synthetically alter the aromatic nitrogen heterocycle portion of the ligand.[2] As a result, the BAII ligands afford the opportunity to study a large series of complexes. Unlike other series, the donor atoms attached directly to the molybdenums in the BAII series remain the same, but peripheral ligand substituents can be altered. We have synthesized an extensive series of complexes with the formula $[Mo_2(OAc)_3(BAII)]$. The series now includes 11 complexes in which the N-heterocycle portion of the ligand is pyridine, alkyl pyridines, halopyridines, thiazoles and pyrazine. However, studies of the spectroscopic and electrochemical properties of these complexes had been hindered by the fact that X-ray quality crystals had been difficult to produce and thus the exact structures of the complexes were not known. We have now obtained X-ray quality crystals of the dimolybdenum complex of the BAII ligand derived from unsubstituted pyridine. The structure of this complex is reported herein. Knowledge of the structure has allowed detailed interpretation of the ^1H NMR spectrum of the unsubstituted pyridine derivative. This has in turn allowed the ^1H NMR characterization of the structures of the other complexes in the series.

EXPERIMENTAL

Materials and methods

All synthetic procedures were performed under an atmosphere of argon using standard Schlenk techniques or a glove box. Methanol was refluxed with calcium sulphate. Benzene and hexane were refluxed over Na–benzophenone and distilled just prior to use. Molybdenum acetate was prepared from $Mo(CO)_6$ using the method of Wilkinson.[3] Bis(pyridylimino)isoindoline and bis(4,6-dimethylpyridylimino)isoindoline were prepared by the method of Siegl in which 2-aminopyridine or 2-amino-4,6-dimethylpyridine was reacted with 1,2-dicyanobenzene in refluxing butanol in the presence of a small amount of anhydrous calcium chloride.[2]

NMR spectra were obtained in $CDCl_3$ or d^6-acetone, with TMS as internal standard, using a GE QE-300 spectrophotometer. The samples were prepared under an argon atmosphere in a glove box.

Synthesis of complexes

An improved version of the previously reported method was used.[4]

$[Mo_2(OAc)_3(BAII)]$ (BAII = *bis(pyridylimino) isoindoline*). $Mo_2(OAc)_4$ (1 g) was added as one portion to a solution of bis(pyridylimino)isoindoline in 35 cm^3 of dry, degassed methanol. The resulting yellow mixture slowly turned emerald green. After stirring overnight a green precipitate formed, which was filtered, washed with hexane under argon and then dried *in vacuo*. This procedure resulted in about 75% yield. X-ray quality crystals were obtained by dissolving the green product in a minimum volume of benzene, followed by addition of one third the volume of hexane. Over several days large, dark green blocks were deposited.

$[Mo_2(OAc)_3(BAII)]$ (BAII = *bis(4,6-dimethylpyridyl)isoindoline*). The procedure for the reaction of $Mo_2(OAc)_4$ with bis(4,6-dimethylpyridylimino) isoindoline was the same as that used for the unsubstituted pyridine derivative. However, the mixture had to be stirred for 10 days before the reaction was complete. The yield was about 60%.

Single-crystal X-ray analysis

A dark green crystal was surveyed, and cell dimensions were obtained by a least-squares fit of setting angles of 21 high-angle reflections ($2\theta > 18°$). A data set was collected on a Nicolet R3m/μ diffractometer equipped with a graphite monochromator and molybdenum radiation (λ = 0.71069 Å). Systematic absence indicated that the crystal belonged to the triclinic space group $P\bar{1}$. Two check reflections collected after every 98 reflections showed a decrease in intensity of 61 and 48% showing decomposition of the crystal. The data were corrected using the package supplied by Nicolet in which the average decrease of the two reflections is used to correct the intensities in blocks. Of the 4339 unique reflections recorded in the range $3° < \theta < 45°$, 2766 of these (having $I > 1.5\sigma(I)$) were used in the structure analysis. Data were corrected for Lorentz and polarization effects but not for absorption owing to the low absorption coefficient (8.7 cm^{-1}). An isotropic secondary extinction correction was made (secondary extinction coefficient = 1.4×10^{-7}). Atomic scattering factors for all atoms were taken from the *International Tables for X-ray Crystallography*.[5] Pertinent crystal, data collection, and refinement parameters are summarized in Table 1.

The molybdenum atoms were located by the direct-methods program SOLV of the crystallographic program package *SHELXTL*.[6] The remaining non-hydrogen atoms were found by conventional difference Fourier techniques to give a trial structure. The structure was refined by the block-diagonal least-squares technique using *SHELXTL* on a Data General Microeclipse computer. The quantity minimized was $\sum w(\Delta F)^2$, where $w = 1/(\sigma^{F^2} + 0.00015F^2)$. The non-hydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms were placed in calculated positions 0.96 Å away from the attached carbon atom and were not refined. The final R indices are given in Table 1. The refined structure was plotted by using the *SHELXTL* graphics package.

RESULTS AND DISCUSSION

Structure of $[Mo_2(OAc)_3(BAII)]$

The structure and atom labelling scheme for $[Mo_2(OAc)_3(BAII)]$ are shown in Fig. 1. Selected bond distances are reported in Table 2 and selected angles in Table 3.

The compound $[Mo_2(OAc)_3(BAII)]$ crystallizes in the triclinic $P\bar{1}$ space group with one benzene of solvation per complex molecule. No intermolecular contacts between molybdenum atoms and acetate oxygens are found. This type of contact has been found in numerous other dimolybdenum complexes which possess bridging acetates.

The structure of the complex consists of a dimol-

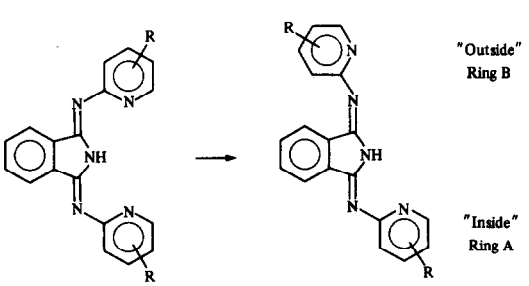
ybdenum unit which is bridged by three acetates and a BAII ligand. The remarkable feature of the structure is the binding mode of the BAII ligand. Three BAII complexes with copper and one with manganese have been reported previously.[7-9] In all of these complexes the ligands have been shown to be planar tridentate species which bind only one metal using the two nitrogens from the aromatic nitrogen heterocycles and the nitrogen from the isoindoline portion of the molecule. In the present case rotation about one of the imino bonds has made the non-bonding pair of electrons on one of the imino nitrogens available for donation to a molybdenum. This rotation has placed a pyridine in a position where it may not bind to the dimetal unit, Scheme 1. The result is two inequivalent pyridine rings: ring A in Scheme 1, the "inside" ring, which is coordinated to the axial position of one of the molybdenum atoms, and ring B, the "outside" ring, which is not bound to a molybdenum atom.

The BAII thus bridges the dimetal unit by binding one molybdenum with the isoindoline nitrogen and the other molybdenum with an imino nitrogen. In addition, one of the pyridine nitrogens binds to one of the axial positions of the dimolybdenum unit. The five-membered ring which includes the two molybdenums and the bridging BAII ligand forms a common structural feature in dimolybdenum chemistry. There have been a number of complexes of derivatives of 2-aminopyridine,[10] 2-aminothiazole,[11] and acetamidines[12] reported in which the N—C—N linkage bridges the metal–metal bond. The various angles and M—N distances within the five-membered ring in $[Mo_2(OAc)_3(BAII)]$ are comparable to those in these other molecules.[13] The N—C—N portion of the BAII ligand which bridges the dimolybdenum unit can be thought of as being isoelectronic with acetate.

A comparison can be made between the angles and distances within the BAII ligand itself and those of BAII ligands in complexes of other metals. The bond angles and distances within the six-membered chelate ring that includes Mo(2), the isoindoline nitrogen and the inside pyridyl nitrogen are quite similar to those in the equivalent rings in the manganese and three copper structures, except that the N—Mo—N angle is not 90°. This angle might be expected for achievement of maximum overlap between the pyridine lone pair and an appropriate orbital on the molybdenum. It is possible for the BAII ligand to obtain a geometry in which this angle is 90°, as has been demonstrated in the three copper complexes. The N—C—N angle for the three bridging atoms has been contracted significantly to only 117.3(7)°, as compared to 128.7(8)° for the equivalent angle on the side of the ligand which includes the inside pyridine, and to 131.8, 129.6, 129.6 and 129.3° in the manganese and the three copper structures, respectively. This is apparently due to the fact that the imino nitrogen is pulled in to achieve maximum bonding interaction with Mo(1). This notion is supported by comparing the N—C—N angle with the same angle in other dimolybdenum complexes in which the metal is bridged by the N—C—N group. For example, this angle is 117.8(9) and 114.9(5)° in the 2-aminopyridine derivatives $Mo_2(map)_4$ and $Mo_2(PhNpy)_4$, respectively, and 117.0(1), 115.7(5) and 117.4(5)° in the acetamidine derivatives $Mo_2(PhC(NPh)_2)_4$, $Mo_2[(PhN)_2CCH_3]_3(OAc)$ and $Mo_2[[(2,6\text{-xylyl})N]CCH_3]_2(OAc)_2$.

The outside pyridine ring is twisted out of the plane of the isoindoline group. Mean planes were calculated for this pyridine and for the isoindoline group. The dihedral angle is 45.5°. The ring is undoubtedly twisted into this particular position in the crystalline solid, in part, because of crystal packing forces. In fact the closest approach of the solvent molecule to the complex molecule occurs between the benzene ring and C(24) and N(5) of the outside pyridine ring. But, in addition, with the ring oriented as it is in the solid benzene solvate the protons on C(17) and C(21) are 2.431 Å apart. If the pyridine ring were made co-planar with the isoindoline group and all bond angles and distances were maintained, these protons would only be approximately 0.8 Å apart. It seems clear that some twisting of the pyridine ring should occur to minimize interaction of these protons.



Scheme 1.

The axial interaction of Mo(2) with the inside pyridyl nitrogen can be compared with the same interaction in similar structures of other ligands. In particular, one other structure has been reported in which a pendant aromatic nitrogen heterocycle is bound to an axial position in a dimolybdenum molecule. $Mo_2(OAc)_2(tpb)_2$, where tpb is tris(pyrazolyl)borate, has two *cis*-bridging acetates and two bidentate tpb ligands, each of which is bound through only two pyrazole nitrogens.[14] Each tpb ligand thus has a pendant pyrazole ring associ-

ated with it. One of the pendant pyrazole rings is bound to the axial position of the dimetal unit. The second pyrazole ring is not bound. The Mo—N bond to the axial pyrazole ring is quite long at 2.45(1) Å. This is about the same as the length of the Mo—N bond to the axial pyridine ring in $[Mo_2(OAc)_3(BAII)]$ which is 2.466(7) Å. More interestingly, Mo—Mo—$N_{(ax)}$ bond angles in the two compounds are remarkably similar, 169.0(2)° in the BAII complex and 170.1(5)° in the tbp complex. It seems possible that ligand constraints force the heterocycle into this position. However, in the compound $Mo_2(O_2CCF_3)_4(py)_2$, which has two axial pyridines, the average Mo—Mo—$N_{(ax)}$ angles are 171.0(2)°.[15] This evidence seems to suggest that electronic factors may be involved in determining this bond angle. In the axial pyridine adducts $Mo_2[(xylyl)NC(CH_3)O]_4 \cdot py$ and $Mo_2[(xylyl)NC(CH_3)O]_4 \cdot Me\text{-}py$[12b] the Mo—Mo—N bond angle is close to 180°, but the presence of large phenyl groups in the area around the axial position may force the pyridine into this orientation.

$[Mo_2(OAc)_3(BAII)]$ possesses the first structure reported for a dimolybdenum compound with three bridging acetates, although the trifluoroacetate complex $Mo_2(O_2CCF_3)_3Cl(C_2H_5CN)$ has been reported.[16] The Mo—Mo bond distance in $[Mo_2(OAc)_3(BAII)]$ is 2.106(1) Å. This is slightly, but significantly, longer than the 2.0934(8) Å distance found in $Mo_2(OAc)_4$, but is shorter than the 2.147(3) Å metal–metal bond distance in the tpb complex. There are probably two factors involved in determining the metal–metal bond distance in the BAII complex. It is well known that axial ligation by the molybdenum–molybdenum quadruple bond causes lengthening of the bond.[1] Thus the metal–metal bond in the BAII complex is longer than the same bond in $Mo_2(OAc)_4$. It is not as long as the metal–metal bond in the tpb complex, however, because of the presence of three rather than two acetates. It has been suggested that acetate π-orbitals become involved with metal–metal bonds in such a way as to strengthen them.[17] We must conclude that the molybdenum atoms in dimolybdenum compounds tend to be resistant to chelation by planar tri- and tetradentate ligands; so much so that the BAII ligand is forced into a highly unusual conformation in preference of a bridging rather than chelating mode. There has been only one complex reported in which one or both molybdenum atoms is chelated by a planar multidentate ligand. This is the porphyrin complex of Collman which was prepared by deoxygenation of an oxomolybdenum porphyrin complex[18] and not from a metal–metal bonded precursor. The crystal structure of this compound has not been reported.

NMR spectra of BAII *complexes of dimolybdenum*

It is believed that the overall structures of the complexes in the series are the same as that of the unsubstituted pyridine derivative reported in this manuscript based on the detailed interpretation of their NMR spectra. Two major features characterize the spectra of BAII ligands which have become coordinated to a dimolybdenum unit. First, in each case two resonances appear in the 2–3 ppm region in a ratio of 2 : 1. These are due to the three acetate groups, two that are *cis* to the BAII group and one that is *trans*. Second, the BAII portion of each spectrum becomes very complicated. It is now possible to interpret the spectrum of the unsubstituted pyridine derived BAII complex. However, an equivalent interpretation can be made for each of the complexes. Therefore, only the spectrum of the 4,6-dimethylpyridine derived complex will be discussed in detail. The spectrum of this complex is simpler to discuss since only singlet resonances should arise from the protons on the pyridine moieties of the ligand.

The spectrum of the uncoordinated ligand is as expected and is shown in Figs 2(a) and 3(a). Singlet resonances representing the two types of pyridine methyl groups occur at 2.36 and 2.49 ppm. The aromatic region displays two singlet resonances representing the two types of pyridine hydrogens at 6.80 and 7.03 ppm. The benzo protons from the isoindoline portion of the ligand generate a typical AA′BB′ pattern. This is actually two doublets of doublets centred around 7.65 and 8.06 ppm.

Upon coordination to the dimolybdenum unit the two pyridine rings become inequivalent. As a result the two pyridine methyl peaks are replaced by four methyl peaks of equal intensity at 2.21, 2.27, 2.33 and 2.43 ppm, see Fig. 2(b). In addition, four singlet resonances appear for the pyridine hydrogens at 6.52, 6.77, 6.83 and 6.96 ppm, see Fig. 3(b). The asymmetry produced in the ligand has a dramatic effect on the benzo proton resonances with the AA′BB′ pattern being replaced by an ABCD pattern. The α-protons are represented by doublets, one that occurs at 8.00 ppm, and one which has been greatly shifted to 6.71 ppm. Each resonance line in these doublets shows further splitting. In each case the main doublet results from coupling with the adjacent β-proton and the secondary splitting results from coupling with the other β-proton. The β-protons are represented by triplets of doublets centred at 7.24 and 7.31 ppm. These patterns result from splitting of the β-resonance line by coupling with the adjacent α-proton to give a doublet. Each resonance line of the doublet is further split by coupling with the adjacent β-proton. This results

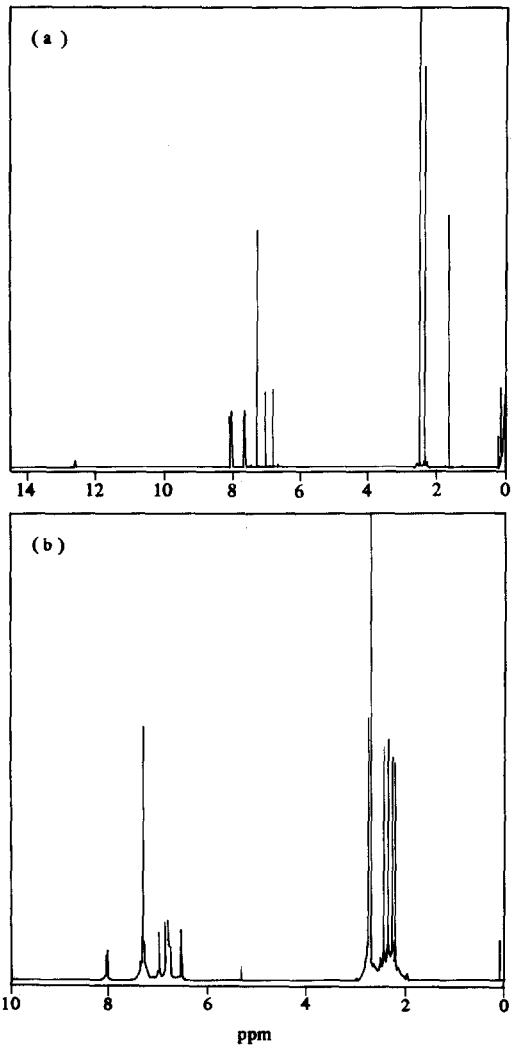


Fig. 2. ^{1}H NMR spectra of (a) bis(4,6-dimethylimino)isoindoline and (b) $[Mo_2(OAc)_3(BAII)]$ (BAII = bis(4,6-dimethylpyridylimino(isoidoline).

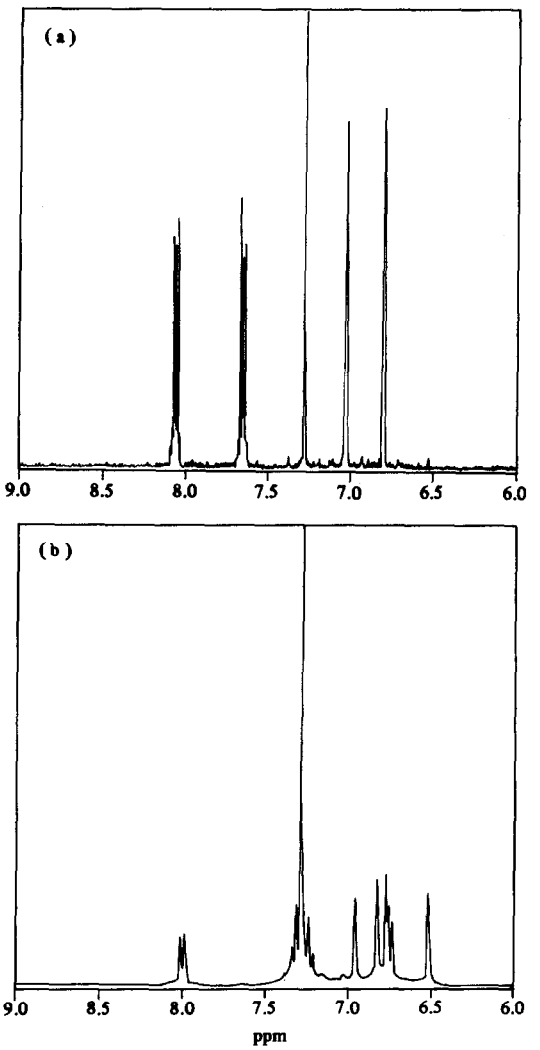

Fig. 3. ^{1}H NMR spectra of the aromatic region of (a) bis(4,6-dimethylpyridylimino)isoindoline and (b) $[Mo_2(OAc)_3(BAII)]$ (BAII = bis(4,6-dimethylpyridylimino)isoindoline).

in two triplets each with an intensity ratio of 1 : 2 : 1 due to coincidence of the two centre resonances. Each resonance of the triplet is then split into two resonances due to coupling with the non-adjacent α-proton. These assignments are supported by standard decoupling experiments and by the appropriate coupling constants.

The remarkable feature of the change in the aromatic region of the BAII ligand upon coordination is the 1.3 ppm shift of the resonance of the α-proton on C(17) which is closest to the outside pyridine. This behaviour is apparently caused by the close proximity of this proton to the inside of the ring current of the outside pyridine ring. In addition, the resonance frequencies of this proton and the pyridine hydrogens of the outside pyridine are strongly solvent dependent. For example, while the α-proton resonance occurs at 6.71 ppm in chloroform, it is shifted upfield to 6.47 ppm in acetone. At the same time two of the resonances associated with the pyridine hydrogens are shifted in the opposite direction. The resonances at 6.96 and 6.77 ppm are unaffected by solvent change, while the 6.83 and 6.52 ppm resonances are shifted downfield to 6.91 and 6.59 ppm, respectively. Whether this effect is related to interaction of the solvent with the pyridine nitrogen or changes in the dihedral angle between the outside pyridine and the iso-

indoline plane is not known. Further studies are now under way to address this problem.

In conclusion, the spectrum of each of the BAII complexes shows the same general features as those described above and thus it seems reasonable to assume that they have the same general structure.

HETEROLEPTIC POLYPYRAZOLYLBORATE DERIVATIVES OF THE LANTHANIDE IONS. THE SYNTHESIS OF OXALATE COMPLEXES

MICHAEL A. J. MOSS and CHRISTOPHER J. JONES*

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 21 *March* 1989; *accepted* 18 *May* 1989)

Abstract—The lanthanide oxalate complexes $[\{LnL_2\}_2(C_2O_4)]$ (Ln = Y, Sm, Dy, Yb or Lu and L = $HB(C_3N_2H_3)_3$) have been isolated and characterized by elemental analyses, mass spectroscopy and, except for Ln = Dy, by ^1H NMR spectroscopy. The physical properties of these materials are consistent with their formulation as binuclear complexes in which the oxalate ligand forms bidentate five-membered chelate rings with two lanthanide ions. Similar compounds are formed with Ln = La, Ce and Nd, but their low solubilities in polar organic solvents have precluded purification.

Synthetic and structural studies have shown that the $\{LnL_2\}^+$ (Ln = a lanthanide or yttrium; L = $HB(C_3N_2H_3)_2$) moiety can form remarkably stable complexes of formula $[LnL_2X]$ with a variety of bidentate ligands X, including X = β-diketonate, tropolonate or carboxylate.[1–7] These studies have revealed that, as the size of the chelate ring formed between Ln and X is decreased, the range of lanthanide elements forming complexes $[LnL_2X]$, which are soluble in polar organic solvents, is also decreased. Thus the complexes $[LnL_2(OC(Me)CHC(Me)O)]$, in which the bidentate acetylacetonate ligand forms a six-membered chelate ring, are soluble for all of the lanthanide ions.[2] Reduction of the co-ligand chelate ring size to five in the tropolonate complexes $[LnL_2(O_2C_7H_5)]$, results in complexes which are poorly soluble in CH_2Cl_2 for Ln = La–Pr, but which are freely soluble for Ln = Nd–Lu.[3] In a continuation of this trend the benzoate complexes $[LnL_2(O_2CC_6H_5)]$ were found to be insoluble in CH_2Cl_2 for Ln = La to Nd, but soluble for Ln = Sm to Lu.[4] Structural studies have revealed monomeric eight-coordinate structures[1–5] for $[CeL_2(OC(Me)CHC(Me)O)]$, $[YbL_2(OC(Me)CHC(Me)O)]$, $[YbL_2(O_2C_7H_5)]$ and $[YbL_2(O_2CC_6H_5)]$ in the solid state. In order to further extend this study of heteroleptic lanthanide complexes containing the $\{LnL_2\}^+$ moiety we have now investigated the synthesis and properties of some representative heteroleptic oxalate complexes.

Homoleptic oxalate complexes of the lanthanides may be prepared by the reaction of a lanthanide salt with oxalic acid in aqueous solution. This reaction precipitates a decahydrate, $Ln_2(C_2O_4)_3 \cdot 10H_2O$, when Ln = La, Nd, Gd.[8] However, the smaller lanthanide ions, Ln = Y, Dy, Er, Yb, precipitate a trihydrate, $[Ln(C_2O_4)(C_2O_4H)(H_2O)] \cdot 2H_2O$. In 1970, $[Er(C_2O_4)(C_2O_4H)(H_2O)] \cdot 2H_2O$ was the first lanthanide oxalate complex to be structurally characterized and the oxalate ions were found to bridge between two metal ions, forming five-membered chelate rings with both.[9] Four oxalate ions surround the lanthanide ion spanning between the two squares of the distorted square antiprism which they form, a water molecule capping the larger square of the antiprism.[9] If ammonia is dripped into the acidic lanthanide–oxalic acid solution, the binary complexes, $[(NH_4)Ln(C_2O_4)_2(H_2O)]$ (Ln = Y, Sm–Tm), are formed. The yttrium complex, $[(NH_4)Y(C_2O_4)_2(H_2O)]$, was structurally characterized 3 years before $[Er(C_2O_4)(C_2O_4H)(H_2O)] \cdot 2H_2O$, and is nine-coordinate with the same coordination sphere.[10]

EXPERIMENTAL

Potassium hydrotris-(pyrazol-1-yl)borate was prepared by the literature method.[11] Hydrated lanthanide trichlorides were obtained from Ventron

GMBH and were used without further purification. ^{1}H NMR spectra were recorded using a JEOL JNM GX270 spectrometer. Deuterated NMR solvents were obtained from Aldrich Chemicals Ltd, and chemical shifts are reported with tetramethylsilane as internal reference at 293 K. IR spectra were recorded using potassium bromide pellets and a Perkin–Elmer 297 spectrometer. Mass spectra were obtained using a Kratos MS80RF mass spectrometer, ions being produced by electron impact. Elemental analyses were performed by the Microanalytical Laboratory, School of Chemistry, University of Birmingham.

Oxalatobis[bis{hydrotris(pyrazol - 1 - yl)borato} yttrium(III)]

$K\{HB(C_3N_2H_3)_3\}$ (0.5 g, 2 mmol) and sodium oxalate (0.07 g, 0.5 mmol) were dissolved in water (30 cm^3) and added to a stirred solution of $YCl_3 \cdot 6H_2O$ (0.30 g, 1 mmol) in water (15 cm^3); stirring was continued for 10 min. The resulting white amorphous precipitate was collected by filtration (yield = 98%). Recrystallization from CH_2Cl_2–hexane gave large, white crystals which fractured on drying (yield = 75%), m.p. = 325–327°C.

The corresponding complexes were prepared similarly with samarium, dysprosium, ytterbium and lutetium using the appropriate lanthanide trichloride hydrate. Complexes containing lanthanum, cerium and neodymium were also prepared, but were essentially insoluble so that the crude precipitate obtained by following the above procedure could not be recrystallized. Details of yields, melting points and elemental analyses are given in Table 1. All of the new complexes were colourless except that containing neodymium which was purple.

RESULTS

The reaction between oxalate, L^- and Ln^{3+} (Ln = Y, La, Ce, Nd, Sm, Dy, Yb and Lu) in aqueous solution leads to the formation of complexes which have a comparatively high melting point, *ca* 325°C, compared with $[YbL_2(acac)]$ (m.p. = 198°C) and $[YbL_2(trop)]$ (m.p. = 265°C) which are both monomers. This observation suggests that the complexes are probably dimeric and may be formulated as $[\{LnL_2\}_2(C_2O_4)]$. They are soluble in polar organic solvents for the smaller lanthanide ions Ln = Y, Sm–Lu, but are insoluble for the larger lanthanide ions Ln = La, Ce and Nd. The low solubilities of these latter complexes with the larger lanthanide ions has precluded complete purification of these materials so that these compounds were only isolated in crude form.

All of the oxalate complexes $[\{LnL_2\}_2(C_2O_4)]$ (Ln = Y, La, Ce, Nd, Sm, Dy, Yb and Lu) have essentially identical IR spectra, with a strong C=O band at 1660–1620 cm^{-1}. In the case of the insoluble complexes with Ln = La, Ce and Nd, the bands at *ca* 1400 and 1300 cm^{-1} are split into doublets and the C=O band appears at a lower frequency than for the soluble complexes. The frequency of this vibration increases with atomic number from 1615 cm^{-1} for lanthanum to 1660 cm^{-1} for lutetium.

The 270 MHz ^{1}H NMR spectra of the soluble oxalate complexes are unremarkable. Essentially identical diamagnetic spectra are observed for the

[a] Values for m/z were calculated using the mass of the most abundant isotope of each element i.e. ^{12}C, ^1H, ^{14}N, ^{16}O and ^{11}B (80.2%); the lanthanide isotopes used and their natural abundances are given in parentheses.

[b] $C_3N_2H_4$ = pzH.

appear at $\delta = 8.76$, 6.03 and 4.85 ppm (Sm) or 15.6, 3.6 and 0.7 ppm (Yb). Resolved spectra of the dysprosium complex could not be obtained. The resonance at 15.6 ppm in the spectrum of $[(YbL_2)_2(C_2O_4)]$ is intermediate in shift between the corresponding resonances in the spectra of the analogous acetylacetonate (10.0 ppm)[5] and troplonate (25.4 ppm)[3] complexes. These complexes contain six- and five-membered chelate rings, respectively. In contrast, the complexes $[YbL_2(O_2CMe)]$ and $[YbL_2(O_2CPh)]$, which contain four-membered chelate rings,[4] exhibit resonances at 33.5 and 33.1 ppm, respectively. These findings are consistent with the oxalate ion being bound with the formation of a five-membered chelate ring, in accord with the structural precedents.[9,10]

The mass spectra of the new compounds are summarized in Table 2. These confirm the binuclear formulation proposed above for the complexes $[\{LnL_2\}_2(C_2O_4)]$ (Ln = Nd, Sm, Dy, Yb and Lu), since high mass fragments corresponding to the presence of a bimetallic ion were observed; although these fall in the m/z range 1100–1300 mass units, which is at the limit of the instrument calibration. The lanthanum and cerium complexes do not yield a volatile fragment containing oxalate by electron impact, the highest mass fragments seem to be derived from $[LnL_3]$, this may be a significant component of the insoluble material isolated or a volatile trace impurity. In either case it appears that completely pure samples of $[\{LnL_2\}_2(C_2O_4)]$ were not obtained for Ln = La or Ce, although the IR spectra confirm the presence of oxalate in the product. The $[LnL_3]$ could arise from disproportionation reactions involving the heteroleptic complexes $[\{LnL_2\}_2(C_2O_4)]$ (Ln = La or Ce). Such disproportionation reactions do appear to occur in the related acetate complexes, $[LnL_2(O_2CMe)]$. However, it must be said that no evidence for disproportionation was observed with the related troplonate complexes. Structural studies of the new complexes using single crystal X-ray diffraction methods have not been possible since the crystals were found to fracture on removal from the solvent. Attempts to mount crystals in capillaries containing the mother liquor were unsuccessful.

In a continuation of the trend observed for the complexes $[LnL_2(O_2C_7H_5)]$, for which the three largest lanthanide ion complexes are poorly soluble, the complexes of the four largest lanthanide ions are insoluble when oxalate co-ligands are present in place of tropolonate.

(*Received* 4 *April* 1989; *accepted* 18 *May* 1989)

Abstract—Reaction of $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][PF_6]$ with 1 equivalent of L ($L = H_2NNHCSNH_2$ or $R'R''CNNHCSNH_2$ where $R' = R'' = Me$; $R' = H$, $R'' = Ph$; $R' = H$, $R'' = p\text{-}NO_2Ph$; $R' = Me$, $R'' = p\text{-}MePh$; $R'R'' = C_5H_{10}$) in $CHCl_3$ at 50°C gave good yields of $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$ by displacement of the acetone. The crystal structure of $[Fe(CO)_2(PhCHNNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ was determined by single crystal X-ray diffraction studies refined to $R = 0.067$ for 1389 reflections above background. The coordination geometry about the iron may best be described in terms of a "piano stool" or pseudo-octahedral structure. The $C_5H_5^-$ ligand occupies three sites in the octahedron with the carbonyls and the sulphur atom of the thiosemicarbazone in the other three sites. The Mössbauer isomer shifts of these compounds have values which lie between that of $[Fe(CO)_3(\eta^5\text{-}C_5H_5)]^-$ and those for $[Fe(CO)_2X(\eta^5\text{-}C_5H_5)]$ showing the thiosemicarbazone sulphur to be a poorer π-acceptor than CO and a better π-acceptor than the halides. The similarity of the spectroscopic data for all the compounds suggests that they all have the same structure. The monodentate S-bonded nature of the thiosemicarbazide in solutions of $[Fe(CO)_2(NH_2NHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ is confirmed by its reaction with benzaldehyde to give the compound $[Fe(CO)_2(PhCHNNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$.

Since 1934 when the first thiosemicarbazide complexes of nickel(II) were reported,[1] a wide range of "classical" coordination compounds formed by transition metal ions with thiosemicarbazides and thiosemicarbazones have been described.[2] Thiosemicarbazones have a wide range of pharmacological activity against, amongst other things, protozoa, influenza, smallpox, leprosy and certain kinds of tumour, and have been suggested as possible pesticides and fungicides (see references cited in the two reviews[2]). Following Liebermeister's demonstration that copper ions enhanced the antitubercular activity of *p*-acetamidobenzaldehyde thiosemicarbazone,[3] the role of metal ions in thiosemicarbazone has been either proved or suspected in many other cases.

Most "classical" coordination compounds formed by thiosemicarbazides and thiosemicarba-

* Author to whom correspondence should be addressed.

zones are with first row transition metal ions in the +2 and +3 oxidation states, i.e. with hard or marginally soft acids, and the other ligands in the coordination sphere, where present, are usually halides. In most of the compounds these ligands are bidentate and coordinate through sulphur and the hydrazinic nitrogen.[2] In a small number of cases thiosemicarbazide and thiosemicarbazones have been shown to coordinate as monodentate ligands through the sulphur atom. In these cases the metal ion is a soft acid, e.g. Ag^{I}, Hg^{II} and Co^{II} in $CoI_2(C_6H_5CHNNHCSNH_2)_2$.[2,4]

In organotransition metal compounds the metal centre is normally soft and most of the ligands bound to it are π-acceptors. Such compounds might therefore prove suitable to test the conditions under which thiosemicarbazones form monodentate complexes. We have previously described[5] the first organotransition metal compounds, $[MoX(CO)_2$(thiosemicarbazone)$(\eta^3\text{-}C_3H_4R)]$, containing a thiosemicarbazone as an attached ligand. In these compounds the thiosemicarbazone is found to be bidentate. We have also reported[6] the corresponding semicarbazone compounds $[MoX(CO)_2$(semicarbazone)$(\eta^3\text{-}C_3H_4R)]$ and here too the semicarbazone ligand is bidentate. Preliminary results of our work describing the first organoiron thiosemicarbazide and thiosemicarbazone complexes $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$, where L is $NH_2NHCSNH_2$ or $R_1R_2CNNHCSNH_2$ and is found to be monodentate, have already been published.[7] In this paper we wish to describe this work in full and to report the X-ray structure of $[Fe(CO)_2(C_6H_5CHNNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$.

EXPERIMENTAL

The reactions described in this paper were carried out under an atmosphere of nitrogen using standard Schlenk techniques. The complex $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][PF_6]$ was prepared by the literature method,[8] and the thiosemicarbazone ligands by the method described by Sah and Daniels.[9] All other chemicals were purchased from commercial sources.

The elemental analyses for carbon, hydrogen and nitrogen were recorded on a Carlo Erba Elemental Analyser MOD 1106 using helium as the carrier gas. IR spectra were recorded, as KBr discs on a Perkin–Elmer 397 IR spectrophotometer. The ^1H NMR spectra were recorded either on a Bruker WH 400 MHz spectrometer at the University of Warwick or on a Jeol GX-270 at Thames Polytechnic (all spectra were calibrated against tetramethylsilane). The Mössbauer spectra were recorded on a Cryophysics microprocessor controlled Mössbauer spectrometer and spectra were calibrated against Fe-57 enriched iron foil.

(1) $[Fe(CO)_2(H_2NNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$

$H_2NNHCSNH_2$ (0.06 g, 0.66 mmol) was added to a stirred solution of $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][PF_6]$ (0.25 g, 0.66 mmol) in $CHCl_3$ (20 cm^3) warmed to 50°C. After 90 min the yellow $[Fe(CO)_2(H_2NNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ which had separated was filtered, washed with $CHCl_3$ (3×5 cm^3) and dried in a desiccator over silica gel (0.16 g, 59%).

(2) $[Fe(CO)_2(cy\text{-}C_5H_{10}CNNCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$

The $cy\text{-}C_5H_{10}CNNHCSNH_2$ (0.09 g, 0.53 mmol) was added to a stirred solution of $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][PF_6]$ (0.20 g, 0.53 mmol) in $CHCl_3$ (20 cm^3) warmed to 50°C. After 2 h the orange $[Fe(CO)_2(cy\text{-}C_5H_{10}CNNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ which had separated was filtered, washed with $CHCl_3$ (3×5 cm^3) and dried in a desiccator over silica gel (0.18 g, 72%).

The thiosemicarbazone complexes (**3**–**6**) were prepared in an analogous manner by reaction of $[Fe(CO)_2(OCMe_2)(\eta^5\text{-}C_5H_5)][PF_6]$ with an equimolar quantity of L [$L = R'R''CNNHCSNH_2$, where $R' = R'' =$ Me (**3**); $R' =$ H, $R'' =$ Ph (**4**); $R' =$ H, $R'' = p\text{-}NO_2Ph$ (**5**) and $R' =$ Me, $R'' = p$-MePh (**6**)] in $CHCl_3$ at 50°C. For colours, yields and decomposition points see Table 1.

Reaction of $[Fe(CO)_2(H_2NNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ *with* PhCHO

PhCHO (0.04 g, 0.24 mmol) was added to a stirred solution of $[Fe(CO)_2(H_2NNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ (0.10 g, 0.24 mmol) in $CHCl_3$ (20 cm^3) warmed to 50°C. After 2 h the orange solid $[Fe(CO)_2(PhCHNNHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ which had separated was filtered, washed with Et_2O (2×5 cm^3) and dried in a desiccator (0.06 g, 50%). Found: C, 34.5; H, 2.9; N, 9.8. $C_{15}H_{14}N_3FeO_2PS$ requires C, 35.9; H, 2.8; N, 8.4%.

ν(max) (KBr) 3500 m, 3371 m, 3319 m and 3126 w (NH), 3026 (CH), 2060 s and 2024 s (CO), 1591 s and 1544 s (NH_2), 1429 w and 1017 w (C—C or ring def.) and 846 s br cm^{-1} (PF_6).

RESULTS AND DISCUSSION

The ligands L ($L = NH_2NHCSNH_2$ or $R_1R_2CNNHCSNH_2$) do not displace CO from $[Fe(\eta^5\text{-}C_5H_5)(CO)_3][PF_6]$ even with UV irradiation but

they will displace a labile group S from species $[Fe(\eta^5\text{-}C_5H_5)(CO)_2S]^+$. When S is H_2O the yields are very poor, *ca* 1%, but when S is Me_2CO good yields from 50 to 80% are obtained on refluxing $[Fe(\eta^5\text{-}C_5H_5)(CO)_2(Me_2CO)][PF_6]$ with the ligand L in $CHCl_3$. Attempts to prepare these compounds from $Fe(\eta^5\text{-}C_5H_5)(CO)_2I$ in the presence of $NaBF_4$ or $AgBF_4$ were unsuccessful. Surprisingly there was no evidence at all that the thiosemicarbazone displaces I from this complex. The compounds (**1**–**8**) (see Table 1) have been fully characterized by microanalysis (Table 1), IR (Table 2), ^1H NMR

(Table 3) and Mössbauer spectroscopy (Table 4). The complexes are stable in air in the solid state and only slowly decompose in solution. The compounds are insoluble in non-polar solvents, and only sparingly soluble in CH_2Cl_2 and $CHCl_3$. They are, however, very soluble in Me_2SO.

Crystallography

Crystals of the title compound suitable for X-ray investigation were obtained from $CHCl_3$ as orange plates.

Crystal data $[C_{15}H_{14}N_3O_2SFe]^+[PF_6]^-$, M =

500.16, monoclinic, $a = 7.103(1)$, $b = 18.637(3)$, $c = 15.193(2)$ Å, $\beta = 90.76(1)$, $U = 2011.1$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.652$ g cm^{-3}, $F(000) = 788$, μ(Mo-K_α) = 9.9 cm^{-1}.

Data collection

Accurate unit cell parameters were measured on an Enraf–Nonius CAD4 diffractometer using 25 accurately centred reflections ($13° < \theta < 15°$) from a crystal of dimensions $0.4 \times 0.4 \times 0.1$ mm. Reflection data were collected to a θ-limit of 24° using graphite-monochromated Mo-K_α radiation in a ω–2θ scan mode. 3555 reflections were measured which after averaging and rejection of systematic absences reduced to 3142 (1389 for which $I > 3\sigma(I)$ were considered observed). No decay of the crystal was noted during the total X-ray exposure time (71 h). No absorption correction was applied.

Structure determination and refinement

The structure was solved using a combination of MULTAN[10] and Fourier techniques. The three heaviest peaks from a default run of Multan were assumed to correspond to the iron, phosphorus and sulphur atoms. Two cycles of Fourier/structure factor calculations located all the remaining non-hydrogen atoms with $R = 0.23$. Full-matrix least-squares refinement was carried out using isotropic thermal parameters and an empirical absorption correction. DIFABS[11] was applied (minimum correction 0.757, maximum 1.184, average 0.993) prior to refinement with anisotropic thermal parameters. Because of limitations in the SDP package[12] used for the calculations, hydrogen atoms could not be included. The weighting scheme $\omega = 1/[\sigma^2(F_o) + 0.07(F_o)^2]$ gave a satisfactory agreement analysis and refinement was terminated with a final R and R_w of 0.067 and 0.087.

Selected bond lengths and angles are given in Table 5. Fractional atomic coordinates, anisotropic temperature factors, a complete list of bond lengths and angles, and F_o/F_c tables have been deposited as supplementary data with the Editor.

The structure and the numbering scheme are shown in Fig. 1. The structure consists of discrete cations and $[PF_6]^-$ anions. Within the cation, the coordination geometry about the iron atom is best described in terms of a "piano-stool" or pseudo-octahedron. The C_5H_5 moiety occupies three sites, with the two carbonyls and the sulphur atom of the thiosemicarbazone occupying the remainder. Although the Cambridge Crystallographic Database reveals almost 100 complexes containing coordinated thiosemicarbazones, there appear to be only two reported examples of monodentate S-bonded thiosemicarbazones. One of these is bis (acetophenonethiosemicarbazone)cobalt(II) iodide[4(i)] while the other is an organometallic compound, acetone thiosemicarbazone pentacarbonyl tungsten(0), $W(CO)_5$(TSCAC).[13] In the present case, as in the case (above) of the cobalt(II) iodide complex, the reason for the monodentate binding of the thiosemicarbazone is probably stereochemical, further coordination through N(3) being effectively blocked by the remaining ligands. Thus, the thiosemicarbazone is found with the  group in an essentially extended linear conformation. The Fe—S(1) distance (2.279(4) Å) compares favourably with that

found in other iron complexes with bidentate ligands,[14,15] but the Fe—S(1)—C(3) angle is much more obtuse (111.3°) compared with the value of about 98° generally found for the M—S—C angle. Other bond lengths and angles in the thiosemicarbazone moiety are similar to values reported for other complexes. In particular, they are identical within experimental error to those found for $W(CO)_5$(TSCAC).[13]

IR data

The IR spectra of the complexes show absorptions characteristic of the thiosemicarbazide moiety, that is ν(NH) between 3500 and 3100 cm^{-1}, $\delta(NH_2)$ in the 1650–1600 cm^{-1} region, various coupled modes in the 1600–1000 cm^{-1} region, as well as a strong absorption due to PF_6^- at about 845 cm^{-1} which masks the mainly ν(CS) vibration in the 700–800 cm^{-1} region. The similarity of the spectra suggest that the thiosemicarbazide/-one ligand is bound to the iron in the same way in all these complexes, i.e. through sulphur as shown by the X-ray diffraction study of **4**.

The expected two ν(CO) absorptions are found in all the spectra. The band positions in solution and in the solid (KBr) differ by only a few cm^{-1}. The values of the ν(CO) absorptions (in cm^{-1}) are significantly lower than those found in the spectrum of $[Fe(CO)_3(\eta^5\text{-}C_5H_5)][PF_6]$ but similar to those found for $[Fe(CO)_2(SC_4H_9)(\eta^5\text{-}C_5H_5)][PF_6]$. This suggests that CO is a better π-acceptor than $\rangle C{=}S$ or $\rangle CS^-$.

The IR spectrum of the semicarbazone analogue of **4**, $[Fe(CO)_2(C_6H_5CHNNHCONH_2)(\eta^5\text{-}C_5H_5)][PF_6]$, clearly shows that the semicarbazone is not bonded through the $\rangle C{=}O$ group, the ν(C=O), $\delta(NH_2)$ and amide II frequencies being identical to those of the free ligand (1690, 1651 and 1598 cm^{-1}, respectively), whereas in the IR spectra of the molybdenum semicarbazone complexes[6] the ν(C=O) band frequency is 20–30 cm^{-1} lower than in the free ligands. The semicarbazone must therefore be bound through the hydrazine nitrogen $\left(-N{=}C\right\rangle$. The position of the carbon monoxide stretching frequencies (see Table 2) is higher than for the thiosemicarbazone compounds, which is compatible with $-N{=}C\rangle$ being a better π-acceptor than $S{=}C\rangle$.

^{1}H *NMR data*

In the NMR spectrum of complex **1** the proton resonances of the thiosemicarbazide ligand are all shifted downfield by several ppm relative to their positions in the free ligand (see Table 3), which indicates that a net decrease in electron density has occurred. Similarly, a downfield shift, although somewhat smaller, is observed for the proton resonances of the thiosemicarbazone ligands in complexes **2**–**8**. In the spectrum of the semicarbazone ligand $[Fe(CO)_2(PhCHNNHCONH_2)(\eta^5\text{-}C_5H_5)][PF_6]$, on the other hand, the proton resonances of the semicarbazone ligand all show an

upfield shift, those of the semicarbazide moiety being between 2 and 3 ppm. This would indicate a net increase in electron density on the ligand.

Since the bonding between iron and either >C=S or >C=N can involve both an L—M σ-bond and an M—L π-bond, the net change in electron density on complex formation will depend on the relative importance of the two components. The net decrease in electron density in the complexed thiosemicarbazide/-one ligands shows that back donation is less important than the σ-bonding. The relatively large size of the sulphur and the positive charge on the iron(II) undoubtedly leads to poor overlap between the >C=S π^*-orbital and the appropriate *d*-orbital, i.e. to an energy mismatch. In the case of the semicarbazone ligand the >C=N group may well be a poorer σ-donor than >C=S but is clearly a better π-acceptor, since there is an overall increase in electron density on complex formation.

Mössbauer data

The Mössbauer parameters of compounds **1–7**, together with those of $[Fe(CO)_2(PhCHNNHCONH_2)(\eta^5\text{-}C_5H_5)][PF_6]$, $[Fe(CO)_3(\eta^5\text{-}C_5H_5)][PF_6]$ and $[Fe(CO)_2(\eta^5\text{-}C_5H_5)Cl]$ which are included for comparison, are shown in Table 4. The isomer shift values of compounds **1–7** are more positive than the value for $[Fe(CO)_3(\eta^5\text{-}C_5H_5)][PF_6]$ but less positive than that of $[Fe(CO)_2(\eta^5\text{-}C_5H_5)Cl]$, i.e. the *s*-electron density at the ^{57}Fe nucleus is less than in $[Fe(CO)_3(\eta^5\text{-}C_5H_5)][PF_6]$ and more than in $[Fe(CO)_2(\eta^5\text{-}C_5H_5)Cl]$. The ligand contributes to the total *s*-electron density at the ^{57}Fe nucleus by σ-donation which increases the 4*s* electron density and by π-acceptance which removes 3*d*-electrons and thus decreases the shielding of the *s*-electrons. Hence, the thiosemicarbazide/-one ligands of **1–7** must either be better σ-donors or poorer π-acceptors than CO. The IR and NMR evidence (see above) indicates that they are poorer π-acceptors. The isomer shift of $[Fe(CO)_2(PhCHNNHCONH_2)(\eta^5\text{-}C_5H_5)][PF_6]$ is virtually the same, within experimental error, as that of its sulphur analogue, **4**. Again, the net effect of $\sigma+\pi$ bonding is a decrease in *s*-electron density but in this case the IR and NMR evidence (see above) shows it to be a better π-acceptor than **4** so that it must be a poorer σ-donor. The electric field gradient at the iron nucleus arises largely from the π-bonding ligands, but for compounds such as those considered containing two or three such ligands it is difficult to relate changes to a single factor. The only significant point is that the quadruple splitting (QS) values of **1–7** are smaller than that of $[CpFe(CO)_3][PF_6]$, while the QS value of the semicarbazone analogue of **4** is larger.

Reactions

It is significant that compound **1**, $[Fe(CO)_2(NH_2NHCSNH_2)(\eta^5\text{-}C_5H_5)][PF_6]$, reacts smoothly with benzaldehyde in trichloromethane at 50°C to give the benzaldehyde thiosemicarbazone, **4**. This confirms that the thiosemicarbazide is monodentate and S-bonded even in solution, since thiosemicarbazone formation occurs by reaction of the hydrazinic-NH_2 group with the carbonyl group of the aldehyde or ketone. Furthermore, in compound **1** the —NH_2 must be sterically unhindered. However, attempts to prepare alkyl thiosemicarbazone complexes such as **3** by reaction of **1** with the corresponding ketone failed, only starting material being recovered.

The compound $[Fe(CO)_2(PPh_3)(\eta^5\text{-}C_5H_5)][PF_6]$ reacts with $NaBH_4$ to give $[Fe(CO)_2(PPh_3)(C_5H_6)]$, while $[Fe(CO)_3(\eta^5\text{-}C_5H_5)][PF_6]$ reacts to give $[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ as the main product.[15] Reaction of **4** with sodium borohydride yielded three fractions after chromatographic separation, of which the major one proved to be $[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$. Clearly the thiosemicarbazone is more readily displaced from the coordination sphere than PPh_3 and the reaction may go via the formation of a hydride such as $[Fe(CO)_2H(\eta^5\text{-}C_5H_5)]$.

Acknowledgement—We wish to thank O. W. Howarth at the University of Warwick for measuring the ^1H NMR spectra of several of the complexes.

(*Received* 11 *April* 1989; *accepted* 18 *May* 1989)

Abstract—Reaction of Ag^+ with $(Bu_4N)_2S_6$ in acetonitrile, in the presence of Me_4NCl, yields the orange compound $_\infty[Ag(S_5)^-](Me_4N^+)$ (**1**). Unlike all other silver polysulphide complexes, **1** is non-molecular in one-dimension, with propagation by a glide plane. Each silver atom is tetrahedrally coordinated by sulphur atoms from three different $(S_5)^{2-}$ ions, and each $(S_5)^{2-}$ ion makes four connections to three different silver ions, including an AgS_4 chelate ring involving a non-terminal sulphur atom. The structure is different in detail from that of NH_4CuS_4. Crystal data: space group *Cc*, $a = 10.860(10)$, $b = 18.313(7)$, $c = 9.177(9)$ Å, $\beta = 139.77(3)°$, $V = 1179(2)$ Å^3. $D_{calc} = 1.93$ g cm^{-3} ($Z = 4$). 963 independent observed $[I/\sigma(I) > 3]$ reflections (Mo-K_α), $R = 0.044$, $R_w = 0.052$.

We report here the first one-dimensionally non-molecular silver polysulphide compound, $_\infty[Ag(S_5)^-](Me_4N^+)$ (**1**). The preparation of a comparable copper polysulphide NH_4CuS_4 (**2**), by reaction of $Cu^{2+}_{(aq)}$ and aqueous ammonium polysulphide solution has been known for a long time,[1,2] and its one-dimensionally non-molecular crystal structure $_\infty[Cu(S_4)^-](NH_4^+)$ was reported in 1980.[3]

In recent years, solutions of polysulphide ions have been generated in non-aqueous solvents, through reactions of NH_3 (g), S_8 and H_2S (g) in varying proportions. By addition of $AgNO_3$ to these solutions in acetonitrile, Müller *et al.* have crystallized (with Ph_4P^+ in each case) $[(S_6)Ag(S_8)Ag(S_6)]^{4-}$ (**3**),[4] $[Ag_2(S_6)_2]^{2-}$ (**4**)[5] and the monocyclic molecule $[Ag(S_9)]^-$ (**5**).[5] These three compounds have quite different structures in their crystals, but all are structurally molecular. Analogous reactions with a range of copper precursors have led to the crystallization and structure determination of the copper(I) complexes $[Cu_6(S_4)_3(S_5)]^{2-}$ (**6**),[6–8] $[Cu_4(S_5)_m(S_4)_{3-m}]^{2-}$, $m = 0$–3,[9] $[Cu_3(S_x)_3]^{3-}$, $x = 4$,[10] 6,[11] and $[(S_6)Cu(S_8)Cu(S_6)]^{4-}$.[10] The gold(I) analogue of **5** is also known,[12] as is $[Au_2(S_4)_2]^{2-}$.[9]

The use of non-aqueous and aprotic solvents clearly increases the thermodynamic activity of the polysulphide ions and permits access to a range of homoleptic metal polysulphide complex equilibria known only at very much lower concentrations in water.[13] The use of gaseous reagents in the Müller preparative method can introduce uncertainty in stoichiometry, and therefore we have investigated alternative methods for controlled generation of polysulphide ions and metal polysulphide complexes in non-aqueous solution. One alternative is to use $(Bu_4N)_2S_6$[14] as a well-defined quantitative source of $(S_6)^{2-}$ in non-aqueous solution. In this paper we describe one product, **1**, of the reaction of $(Bu_4N)_2S_6$ with Ag^+ in acetonitrile.

RESULTS AND DISCUSSION

Preparations

Partial dissociation, $(S_6)^{2-} \rightleftharpoons 2(S_3)^-$, occurs in acetonitrile solutions of $(Bu_4N)_2S_6$, as indicated by their green–brown colour.[14,15] Addition of methanol or Ag^+ causes instantaneous reversion to the red colour, characteristic of coordinated and uncoordinated polysulphide ions. Halide ions in solution cause only transient precipitation of silver halide. Provided the solvent is aprotic, such as acetonitrile, $AgNO_3$ can be added up to a Ag^+–$(S_6)^{2-}$ ratio of 0.8 without permanent formation of a black precipitate, presumed to be Ag_2S. A small amount of sul-

* Author to whom correspondence should be addressed.

phur is formed, presumably due to oxidation by NO_3^- : oxidation of polysulphide ions by NO_3^- in aprotic media has been observed in other systems. In the presence of Me_4N^+, solutions with an $AgNO_3$–$(S_6)^{2-}$ stoichiometry of 0.6 have crystallized **1** in 83% yield (Ag).

Description of the structure of **1**

Crystals of **1** contain parallel chains of $_\infty[Ag(S_5)^-]$ separated by the Me_4N^+ ions, as shown in Fig. 1: the chain is propagated by the *n* glide operation of the space group *Cc*. The detailed connectivity of the chain is shown in Fig. 2. Each silver atom is tetrahedrally coordinated by sulphur atoms from three different $(S_5)^{2-}$ ions, and each $(S_5)^{2-}$ ion makes four connections to three different silver ions. One end of the $(S_5)^{2-}$ chain, S(1), bridges two silver atoms, with Ag—S distances of 2.540 and 2.562 Å, while the other end, S(5), is bonded to a third silver atom at 2.526 Å. The third type of Ag—S bond is Ag—S(4), involving a β-sulphur atom of the S_5 chain, at a slightly longer distance of 2.683 Å. Significant bond distances and angles are presented in Table 1.

Structure **I** is a diagrammatic representation of the chain, showing the connectivities. We note that the alternative connection pattern **II**, of AgS_5 cycles would avoid the coordination to the β-sulphur

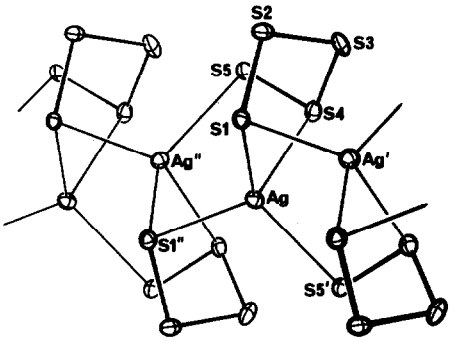

Fig. 2. The $_\infty[Ag(S_5)^-]$ chain in **1**.

atom. There are no inter-chain Ag—S contacts of < 4 Å. The shortest non-bonding contact for silver is Ag—H(2)C(4) of 3.0 Å. The Ag—Ag distances along the chain are all 3.63 Å.

With linear metal polysulphide chains surrounded and separated by cations, the crystal structures of **1** and **2** are similar. The chain in **2** consists of CuS_4 cycles, propagated along a 2_1 axis of the crystal, with connections between nearest (2_1 generated) and the next-nearest (translated) CuS_4 cycles, as shown diagrammatically in **III**. There are, however, significant differences in the pattern of connections of the metal atoms to the polysulphide chains, as emphasized in the diagrams in Fig. 3. There are two other compounds where metal atoms

are bonded to non-terminal sulphur atoms of a polysulphide chain, namely **6** and $(Me_3P)_3MS_7$ (**7**), M = Ru, Os,[16] and the connectivity patterns for these are included in Fig. 3. In **1**, **2** and **3** the M—S distances to internal sulphur atoms are slightly longer (*ca* 0.1 Å) than those to terminal sulphur atoms, but in **7** the internal M—S distance is 0.1 Å shorter. In all structures the S—S distances involving the internal S—M bond are slightly longer than those not so connected. Other entwinements of metal and polysulphide ligands have been uncovered recently in cyclopentadienylmetal polysulphides.[17–19]

EXPERIMENTAL

$(Bu_4N)_2S_6$ was prepared by a modification[20] of the literature procedure.[14]

Preparation

Dioxygen was excluded from all solutions. $(Bu_4N)_2S_6$ (0.70 g, 1.0 mmol) was treated with acetonitrile (15 cm^3) and a solution of Me_4NCl (0.15 g, 1.2 mmol) in methanol (5 cm^3), producing a red–

[a] Data collection took place in space group $P\bar{1}$ with cell parameters 7.069, 9.177, 10.638 Å, 112.90, 106.08, 97.19°, and these crystal faces refer to this cell.

brown solution. A solution of $AgNO_3$ (0.10 g, 0.6 mmol) in acetonitrile (10 cm^3) was added slowly with stirring, causing transient white precipitation and permanent conversion to a red solution, that was stored at *ca* −20°C. Yellow crystals of sulphur that deposited within 24 h were removed, and the mother liquor allowed to stand at room temperature, yielding long yellow–orange prismatic needles of the product. After collection the crystals were washed with acetonitrile and vacuum dried: yield 0.17 g (83% per Ag). Found: C, 14.3; H, 3.9; N, 4.1. Calc. for $C_4H_{12}NAgS_5$: C, 14.0; H, 3.5; N, 4.1%. The solid compound is moderately stable to light and air exposure, but eventually becomes black.

Crystallography

The diffraction investigation followed procedures previously described.[21] Numerical details are presented in Table 2. Reflection weights used were $1/\sigma^2(F_o)$ with $\sigma(F_o)$ being derived from $\sigma(I_o) = [\sigma^2(I_o)+(0.04I_o)^2]^{1/2}$. Atomic scattering factors and anomalous dispersion parameters for silver, sulphur, carbon, nitrogen were from *International Tables for X-ray Crystallography*.[22] In the final refinement, all non-hydrogen atoms were given anisotropic thermal parameters. Hydrogen atoms were included in calculated positions each with an isotropic temperature factor equivalent to that of the atom to which it was bonded. The hydrogen atom positions were not refined.

Atomic coordinates, thermal parameters, tabulations of dimensions, and listings of structure factors have been deposited with the Editor.

(*Received* 18 *February* 1989; *accepted* 19 *May* 1989)

Abstract—The enthalpies of complexation of a number of thorium complexes with amine-N-polycarboxylic acids have been measured using titration calorimetry. Values of ΔH_{101} and ΔS_{101} were thus determined for nitrilotriacetic acid (NTA), N-(2-hydroxyethyl)ethylenedinitrilo-N,N′,N′-triacetic acid (HEDTA), ethylenedinitrilotetraacetic acid (EDTA) and diethylenetrinitrilopentaacetic acid (DTPA). A protonated species, ThHL, was necessary to interpret heats measured for EDTA and DTPA in low-pH solution, and thermodynamic parameters are reported for these complexes as well. Although the stability of these complexes is the result of strong entropy effects, the enthalpy values show important trends in the coordinate bonding of these species.

The interaction of metal ions with amine-N-polycarboxylic acids is of interest for a number of theoretical and practical reasons. From a theoretical veiwpoint, the polydentate nature of these ligands leads to species with high coordination numbers and results in some of the most stable metal complexes known.[1] In addition, their relatively simple chemical structures allow facile synthesis of analogues to elucidate factors important in the formation of strong metal–ligand complexes.

These compounds are used extensively in industry and are found in a number of consumer products, as well as having broad application in chemical laboratories. As a result of this widespread use, considerations of waste disposal require that a thorough knowledge of their chemical properties be available. Experience with the disposal of radioactive waste from laboratories has implicated EDTA as a dispersing agent for the migration of radionuclides from disposal sites.[2,3] Amine-N-polycarboxylate ligands are used to model metal complexation in natural waters by trace organics; such elucidation of metal speciation has applications to transport studies.[4]

This work reports values of the enthalpies of formation of some thorium amine-N-polycarboxylate complexes as determined by titration calorimetry.

EXPERIMENTAL

All solutions were prepared from analytical grade reagents without further purification. Thorium nitrate of 99.99% purity (Spex Industries) was used to prepare a 0.10 M stock solution, and working solutions were made from it by dilution. Determinant values of Th^{4+} concentration were checked by analytical EDTA titrations, and agreement within 1% was measured. The ionic strength (μ) of the working solution was adjusted to 0.10 M by the addition of HNO_3 and KNO_3. The acid was necessary to adjust the pH of these solutions to 1.3–2.4 to ensure no significant hydrolysis of thorium(IV).

The 0.15 M amine-N-polycarboxylate titrant solutions were prepared from > 99% pure reagents by dissolving the appropriate amount of compound in an approximately 1% stoichiometric excess of sodium hydroxide to remove all protons from the ligand species. No solubility problems were encountered with this tactic.

The sensitive, quasi-adiabatic (isoperibol) calorimeter employed for the measurement of the heats of reaction in this study has been previously

† Author to whom correspondence should be addressed.

described.[5] Typically, calorimetric measurements were made at two different metal concentrations having different pH values, and at two different titrant-addition volumes. All calorimetry runs were performed at 25.00 ± 0.01°C, with temperature stability of the thermostat maintained to ± 0.0003°C.

These experiments required an extrapolation procedure to obtain a valid blank correction, since there was a difference in ionic strength between the titrant and metal solutions. An endothermic heat-of-dilution was observed in the 0.1 M KNO_3 blank solution due to the heat-of-dilution of titrant. However, this endothermic heat was absent in the metal titrations because the reaction of Th^{4+} with L^{n-} only results in a small change in ionic strength. Consequently, the limiting heat observed for a blank titration was extrapolated to zero titrant volume to obtain the blank correction for the first few additions of titrant.

The resultant Th—L reaction heats were combined with computed solution speciation results in a weighted regression procedure to fit the data. This computational procedure has been amply described elsewhere.[6,7] All stability constants utilized in this study were obtained from critically-reviewed compilations of literature data.[8,9]

RESULTS AND DISCUSSION

Figure 1 shows a typical calorimetric titration of Th^{4+} with an amine-N-polycarboxylic acid. Because the formation constants of the metal–ligand complexes are so large ($> 10^{18}$), the complexation reactions go essentially to completion. In the figure, the initial additions (open circles) represent the exothermic heat arising from L^{n-} complexation with thorium, while a large increase in heat was observed later in the run. This increase in reaction heat was due to ligand protonation in the metal-ion solution following the exhaustion of uncomplexed Th^{4+}. A commensurate increase in the pH of the solution was also observed at these points.

Four amine-N-polycarboxylic acids were used in this study: ethylenedinitrilotetraacetic acid (EDTA), N-(2-hydroxyethyl)ethylenedinitrilo-N,N′,N′-triacetic acid (HEDTA), diethylenetrinitrilopentaacetic acid (DTPA), and nitrilotriacetic acid (NTA). HEDTA and EDTA are structurally identical except that one of the acetic acid functional groups is replaced by an ethanol group in the former compound. HEDTA, EDTA and DTPA provide three, four, and five carboxylate groups, respectively, for bonding to a central metal cation, while NTA has three carboxylates attached to a single nitrogen. All of these ligands are polydentate and capable of multiple coordination with a central cation to form extremely stable complexes. However, only NTA is expected to form metal–ligand species in which more than one ligand is attached to the metal.

Table 1 presents the results of the present investigation, along with a summary of thermodynamic parameters for the systems studied. Free-energy values were computed from the stability constant data, and entropies were calculated from the free energies and measured enthalpies.

Complexation enthalpy results were calculated from weighted, non-linear regression of the heat data to fit the equation:

$$-Q_{rxn} = \Delta n_{101} \cdot \Delta H_{101} + \Delta n_{111} \cdot \Delta H_{111} \left(+ \sum_{i=1}^{n} \Delta n_{0i1} \cdot \Delta H_{0i1} \right),$$

where values for moles of ThL (Δn_{101}), ThHL (Δn_{111}) and protonated ligand (Δn_{0i1}) were calculated from literature stability-constant data and

[a] From ref. 8.

mass- and charge-balance relationships as previously discussed.[6,7] (The indices "101" refer to the number of atoms of metal, hydrogen and ligand, respectively, in the complex. Thus, "101" indicates the reaction $M+L \rightleftarrows ML$, "011" indicates $H+L \rightleftarrows HL$, etc.) From an examination of the experimental data at two different pH values, it was evident that consideration of the ThHL species was necessary for EDTA and DTPA complexation. The HEDTA and NTA titrations showed no such pH dependency under our experimental conditions, however, so that $\Delta n_{111} = 0$ for these ligands. Analysis of the NTA data was complicated by the fact that the Th–NTA complex is very similar in strength to that of the protonated ligand. Consequently, fitted values for ligand protonation enthalpy were necessary to extract the heat of complexation of Th^{4+} from those data.

An attempt was made to measure the heat of complexation of thorium with ethylenedinitrilodiacetic acid (EDDA), an analogue of EDTA but with one carboxylic acid group on each terminal nitrogen. However, the observed heats of reaction were dominated by ligand protonation. This fact indicates that, at the low pH values required to prevent thorium(IV) hydrolysis, the H^+ in solution effectively competes with Th^{4+} for bonding sites on the EDDA anion.

Our results of -11.5 ± 0.2 and -11.9 ± 0.2 kJ mol^{-1} for EDTA ΔH_{101} and ΔH_{111} agree with the values of -12.9 ± 0.4 and -12.6 ± 0.2 kJ mol^{-1} reported by Doi using a batch titration procedure.[10] That experiment was very dependent upon knowledge of the protonation enthalpies of EDTA in order to correct for heats of protonation generated upon the addition of excess EDTA to an acidic thorium solution. Since our procedure involved an incremental addition of titrant, however, titration points devoid of significant ligand protonation could be isolated for data analysis.

CONCLUSIONS

The stability of thorium amine-N-polycarboxylate complexes is attributed to the large entropy effect obtained when the primary hydration sphere of the metal ion is displaced by a single multidentate ligand. ΔS_{101} represents a stabilization gain due to the number of water molecules displaced from the hydration sphere by the coordinating ligand. Plots of ΔS_{101} and $\log\beta_{101}$ thus climb linearly with the number of strongly interacting coordination sites on the ligand. Figure 2 shows the relationship between ΔS_{101} and the total ligand basicity (ΣpK_a) for thorium complexation, along with data for La^{3+} and Ca^{2+} for comparison. The fact that the entropy increases with cation charge for a given ligand can, of course, be understood qualitatively through simple electrostatic considerations: increasing polar attraction of the number of inner-sphere water molecules by the unreacted metal directly corresponds with the central charge.

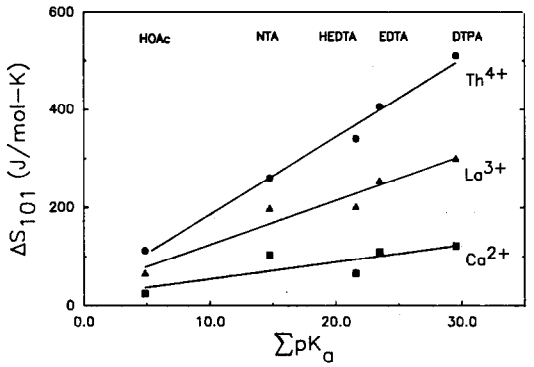

Fig. 2. Graph of ΔS_{101} vs ligand basicity, ΣpK_a, for Th^{4+}, La^{3+} and Ca^{2+} (data from this work and ref. 9).

In their analysis of lanthanide amine-N-polycarboxylate enthalpy data, Choppin *et al.* provided evidence that the entropy of complexation reflected a similar amount of dehydration for each additional coordinating carboxylate group in the ligand.[11] Extending this finding to the enthalpy of complexation, Choppin estimated that there was an enthalpy contribution of approximately 6.5 kJ mol^{-1} for each carboxylate group. The residual enthalpy of a complex ($d\Delta H_{101}$), then, was presumed to be a measure of the interaction between

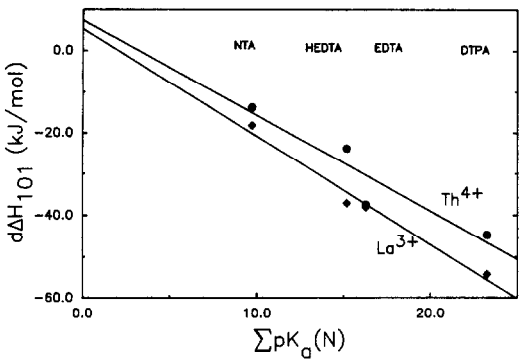

Fig. 3. Graph of $d\Delta H_{101}$ [$\Delta H_{101} - 6.5 \times$ (number of carboxylate groups)] vs total nitrogen basicity, $\Sigma pK_a(N)$, for Th^{4+} and La^{3+} (data from this work and ref. 9).

the lanthanide and the nitrogen donor atoms for each ligand. Figure 3 depicts a plot of $d\Delta H_{101}$ vs total nitrogen donor basicity [$\Sigma pK_a(N)$] for the present Th^{4+} measurements in comparison with La^{3+}. The similar behaviour indicates that the Th—N interaction is quite analogous to the Ln—N bonding for the ligands studied. Thus, the thermodynamic parameters obtained for the thorium amine-N-polycarboxylate complexes follow the same trends previously observed for the lanthanides.

(*Received* 14 *November* 1988; *accepted* 19 *May* 1989)

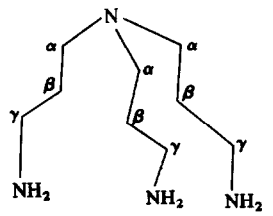
Abstract—The tripod quadridentate ligand 3,3′,3″-triaminotripropylamine (trpn) has been used to synthesize a series of *cis*-octahedral cobalt(III)–trpn complexes, including the type $[Cotrpn X_2](ClO_4)_n$ (X = F, Cl, Br, NO_3 and $n = 1$; X = CH_3CN and $n = 3$) as well as $[Cotrpn(CH_3CN)Br]BrClO_4$, where the coordinating groups are monodentate ligands. With chelating oxy-anions, preparation of the complexes $[Cotrpn(CO_3)](CF_3SO_3)$, $[Cotrpn(SO_4)]ClO_4$, $[Cotrpn(HSO_4)](ClO_4)_2$, $[Cotrpn(C_2O_4)]ClO_4$ and $[Cotrpn(H_2P_2O_7)]ClO_4$ are described. The visible, IR and ^{13}C NMR spectra have been used to characterize the isolated complexes.

In our previous studies, we have indicated the importance of *cis*/*trans* isomerism in metal ion promoted hydrolysis of ATP (adenosine 5′-triphosphate) and phosphate esters by tetraaminecobalt(III) complexes, where effective promotion was observed with complexes of *cis*-octahedral geometry.[1–5]

Metal complexes of the tripod quadridentate ligands of the type $X(Y)_3$, in which X is nitrogen, phosphorus or arsenic, the Y groups are R_2N, R_2P, R_2As, RS or RSe, where R is an alkyl group and where the connecting chains are $—(CH_2)_2—$ or $—(CH_2)_3—$, have been particularly shown to favour the formation of five-coordinate complexes.[6–11]

Complexes of the tripod tetraamine ligand 2,2′,2″-triaminotriethylamine $[N(CH_2CH_2NH_2)_3$ = tren] have been extensively studied.[12] The use of this ligand has led to the separation of five-coordinate[7,8,10] or *cis*-octahedral geometries,[13,14] and no tetrahedral complexes have been described.

Introduction of another CH_2 group into each of the ethylene bridging chains of tren produces a more facultative ligand.[15] This ligand, 3,3′,3″-triaminotripropylamine $[N(CH_2CH_2CH_2NH_2)_3$ = trpn],[16] has been little studied.[17–19] Recently, we have shown that cobalt(III) complexes of such a ligand represent a compromise between complexes



trpn

of fixed *cis*-octahedral geometry[20,21] (the tripod nature of the ligand enforces the remaining two positions in the octahedral complex to be oriented in the *cis* form), and extremely labile cobalt(III) complexes.[3,22] Consequently, because of the valuable information which can be extracted by using the trpn complexes in model studies, our immediate concern was the separation and characterization of some cobalt(III)–trpn complexes, and also to throw

* Author to whom correspondence should be addressed.

more light on the versatility of $[Cotrpn(CO_3)]ClO_4$ as a good starting material for the preparation of many cobalt(III)–trpn compounds in reasonable high yield.

EXPERIMENTAL

3,3′-3″-Triaminotripropylamine tetrahydrochloride hemihydrate (trpn · 4HCl · $\frac{1}{2}H_2O$) was supplied by Strem Chemical Company and trifluoromethanesulphonic acid, CF_3SO_3H, was obtained from Aldrich Chemical Company. All other chemicals were reagent grade quality.

CAUTION: The perchlorate complexes should be treated as potentially explosive and should be handled with appropriate care.

Synthesis of the complexes

The complexes $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$, $[Cotrpn(H_2O)(OCO_2H)](ClO_4)_2 \cdot \frac{1}{2}H_2O$, $[Cotrpn(H_2O)_2](ClO_4)_3 \cdot 2H_2O$ and $[Cotrpn(PO_4)] \cdot 5H_2O$ were prepared as previously described.[20,21,23]

Carbonato(3,3′,3″ - *triaminotripropylamine*)*cobalt* (III) *triflate*, $[Cotrpn(CO_3)]CF_3SO_3$

A solution of the free base, trpn (1.9 g/15 cm^3 H_2O), neutralized by 4 M CF_3SO_3H, was added with stirring to a slurry cold solution of $Na_3[Co(CO_3)_3] \cdot 3H_2O$[24] (3.6 g/25 cm^3 H_2O). The temperature of the stirred solution was raised to 70°C, followed by heating at this temperature for 2 h. During this time the colour changed to purple, with reduction in volume to $\simeq$ 20 cm^3. The solution was filtered through celite, using Fisher Quantitative P2 filter paper. Upon cooling in a refrigerator for several days, the crude solid which separated out was filtered, dissolved in $\simeq$ 60 cm^3 of ethanol at 70°C, and evaporated until dry. The red crystals obtained were filtered, washed with acetone and ether and air-dried. Further evaporation of the mother liquor on a steam bath produced a second crop. The total yield was $\simeq$ 1 g ($\simeq$ 20%).

Dichloro(3,3′,3″-*triaminotripropylamine*)*cobalt*(III) *perchlorate*, $[CotrpnCl_2]ClO_4$

This complex was prepared by adding 0.6 cm^3 of conc. HCl (37%) to the carbonato complex, $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (1 mmol). The effervescence was allowed to subside before each addition of acid. Upon gentle heating on a steam-bath for 5 min, a bluish-green solid separated out. Then 10 cm^3 of anhydrous methanol was added with vigorous swirling, followed by decantation. The process was repeated twice and the solid was filtered off, washed with methanol and ether, and dried *in vacuo* over P_4O_{10} (yield 37%). Found: C, 25.7; H, 5.8; N, 13.4; Cl, 25.4. Calc. for $[Co(C_9H_{24}N_4)Cl_2]ClO_4$: C, 25.9; H, 5.8; N, 13.4; Cl, 25.4%.

Attempted preparation of $[CotrpnCl_2]Cl$ by aerial oxidation of an aqueous solution of $CoCl_2$ + trpn + HCl was unsuccessful. Also, attempts to synthesize the dinitrito complex of cobalt(III)–trpn, as described for the preparation of $[Cotren(NO_2)_2]Cl$ by Collman *et al.*,[25] and then converting it into the dichloro complex by treatment with conc. HCl and evaporation, did not lead to the desired product; instead, the yellow crystalline complex $Codpt(NO_2)_3$ [dpt = dipropylenetriamine = $NH(CH_2CH_2CH_2NH_2)_2$] was isolated, which had been previously prepared and characterized.[26]

Dibromo(3,3′,3″-*triaminotripropylamine*)*cobalt*(III) *perchlorate*, $[CotrpnBr_2]ClO_4$

This complex was prepared by the same method used above for the chloro compound, where 1 mmol of $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ was treated with 0.25 cm^3 of conc. HBr (48%). The khaki fine solid which separated was filtered, washed with a generous amount of anhydrous methanol until the filtrate became colourless, and then dried *in vacuo* over P_4O_{10} (yield 65%). Found: C, 21.4; H, 4.8; N, 11.0; Cl, 7.0; Br, 31.5. Calc. for $[Co(C_9H_{24}N_4)Br_2]ClO_4$: C, 21.3; H, 4.8; N, 11.1; Cl, 7.0; Br, 31.5%.

Difluoro(3,3′,3″-*triaminotripropylamine*)*cobalt*(III) *perchlorate trihemihydrate*, $[CotrpnF_2]ClO_4 \cdot \frac{3}{2}H_2O$

In a polyethylene container, finely powdered $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (2.5 mmol) was treated with conc. HF. The acid was added very carefully, drop by drop, with gentle heating on a steam bath. Effervescence of CO_2 was allowed to subside before each addition. The addition of the acid was stopped when a purple solution had formed; this was heated for 5 min, followed by the addition of anhydrous methanol. After standing at room temperature the light violet solid, collected by filtration, was washed with a mixture of ice cold methanol–water (7 : 3 by volume), then ether, and dried for 2 days in a vacuum desiccator over P_4O_{10} (yield 37%). Found: C, 26.3; H, 6.4; N, 13.7; Co, 14.3. Calc. for $[Co(C_9H_{24}N_4)F_2]ClO_4 \cdot \frac{3}{2}H_2O$: C, 26.3; H, 6.6; N, 13.6; Co, 14.3%.

Bis(acetonitrile)(3,3′,3″ - *triaminotripropylamine*) *cobalt*(III) *perchlorate*, $[Cotrpn(CH_3CN)_2](ClO_4)_3$

The diaqua complex $[Cotrpn(H_2O)_2](ClO_4)_3 \cdot 2H_2O$ (1 mmol) was dissolved in 50 cm^3 of acetonitrile (dried over 4 Å Linde molecular sieves and then distilled). The resulting was refluxed for 1 h on a steam bath, followed by evaporation to a small volume. On cooling, the pink–red solid which separated out was filtered and recrystallized from acetonitrile. The product was collected by filtration, washed with ether, air-dried and stored in a vacuum desiccator over P_4O_{10} (yield 63%). Found: C, 25.1; H, 4.9; N, 13.5; Cl, 17.1. Calc. for $[Co(C_9H_{24}N_4)(CH_3CN)_2](ClO_4)_3$: C, 24.9; H, 4.8; N, 13.4; Cl, 16.9%.

Bromo(acetonitrile)(3,3′,3″ - *triaminotripropylamine)cobalt*(III) *bromide perchlorate*, $[Cotrpn(CH_3CN)Br]BrClO_4$

This complex was prepared by dissolving $[CotrpnBr_2]ClO_4$ (0.2 g) in 30 cm^3 of dry acetonitrile. After heating at 60°C for 30 min, the solution was cooled and the light green solid, which was collected by filtration, was washed with anhydrous methanol, ether and air-dried (yield 60%). Found: C, 24.4; H, 4.9; N, 13.0. Calc. for $[Co(C_9H_{24}N_4)(CH_3CN)Br]BrClO_4$: C, 24.1; H, 5.0; N, 12.8%.

Sulphato(3,3′,3″-*triaminotripropylamine)cobalt*(III) *perchlorate hemihydrate*, $[Cotrpn(SO_4)]ClO_4 \cdot \frac{1}{2}H_2O$

Finely powdered $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (0.25 mmol) was treated with conc. H_2SO_4 (25×10^{-3} cm^3). The resulting paste was warmed very carefully on a steam bath for 5 min, followed by the addition of 2 cm^3 of anhydrous methanol. The violet solid, which was collected by filtration, was washed with cold methanol, ether and then air-dried (yield 90%). Found: C, 23.8; H, 5.5; N, 12.1; Cl, 7.4; S, 7.0. Calc. for $[Co(C_9H_{24}N_4)SO_4]ClO_4 \cdot \frac{1}{2}H_2O$: C, 23.9; H, 5.6; N, 12.4; Cl, 7.8; S, 7.1%.

Bisulphato(3,3′,3″ - *triaminotripropylamine)cobalt* (III) *perchlorate*, $[Cotrpn(HSO_4)](ClO_4)_2$

Finely powdered $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (0.5 mmol) was treated with a few drops of 5 M $HClO_4$, followed by heating for 5 min at 60°C, and then diluted with water to 10 cm^3. To the above solution, 0.5 mmol of $KHSO_4$ was added and the solution was heated for 10 min at 70°C. Upon cooling to room temperature, bluish-violet crystals separated out; these were collected by filtration, washed with absolute ethanol, ether and air-dried (yield 74%). Found: C, 19.8; H, 4.5; N, 10.3; Cl, 12.9. Calc. for $[Co(C_9H_{24}N_4)(HSO_4)](ClO_4)_2$: C, 19.9; H, 4.6; N, 10.3; Cl, 13.1%.

Dinitrato(3,3′,3″ - *triaminotripropylamine)cobalt* (III) *perchlorate*, $[Cotrpn(NO_3)_2]ClO_4$

This complex was prepared using similar procedures to those described above for the corresponding sulphato complex, except for the use of conc. HNO_3 instead of conc. H_2SO_4. Found: C, 23.1; H, 5.1; N, 17.8; Cl, 7.5. Calc. for $[Co(C_9H_{24}N_4)(NO_3)_2]ClO_4$: C, 23.0; H, 5.1; N, 17.8; Cl, 7.5%.

Oxalato(3,3′,3″ - *triaminotripropylamine)cobalt*(III) *perchlorate monohydrate*, $[Cotrpn(C_2O_4)]ClO_4 \cdot H_2O$

Finely powdered $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (0.5 mmol), dissolved in 6 cm^3 of water, was acidified by 0.6 cm^3 of 6 M $HClO_4$, followed by heating on a steam bath for 15 min to expel CO_2. Oxalic acid dihydrate (0.5 mmol) was added and the resulting solution was heated for 30 min at 60°C. On cooling at room temperature, the pink solid which separated out was collected by filtration, washed with methanol and ether, and dried *in vacuo* over P_4O_{10} (yield 88%). Found: C, 29.5; H, 5.8; N, 12.5; Cl, 7.9. Calc. for $[Co(C_9H_{24}N_4)(C_2O_4)]ClO_4 \cdot H_2O$: C, 29.2; H, 5.8; N, 12.4; Cl, 7.8%.

Dihydrogen pyrophosphato(3,3′,3″ - *triaminotripropylamine)cobalt*(III) *perchlorate*, $[Cotrpn(H_2P_2O_7)]ClO_4$

The carbonato complex, $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$ (0.5 mmol), was treated with 0.5 cm^3 of 6 M $HClO_4$, followed by heating for 5 min at 60°C. The resulting diaqua complex was diluted to 5 cm^3 with water and then 0.5 mmol of $H_4P_2O_7$ was added. The pH of the resulting solution was adjusted to 6.2 by the addition of 2 M KOH, followed by heating with stirring, for 15 min at 70°C. The $KClO_4$ which precipitated out upon cooling at 0°C, was filtered off. Methanol (8 cm^3) was added and the solution was refiltered and kept *in vacuo* over P_4O_{10}. The bluish-violet solid which separated out after three days, was recrystallized from anhydrous methanol (yield 40%). Found: C, 20.8; H, 5.2; N, 10.6; P, 12.7; Co, 11.1. Calc. for $[Co(C_9H_{24}N_4)(H_2P_2O_7)]ClO_4$: C, 20.7; H, 5.0; N, 10.7; P, 11.8; Co, 11.3%.

The elemental analyses for the prepared complexes were performed by Atlantic Microlab. Inc., Atlanta, Georgia, except for the analyses for

$[Cotrpn(F_2)]ClO_4 \cdot \frac{3}{2}H_2O$ and $[Cotrpn(H_2P_2O_7)]ClO_4$ which were carried out by Galbraith Laboratories, Knoxville, Tennessee. pH measurements were made with an Orion Research pH meter model 601 A fitted with a combination electrode. Evaporations were carried out using a vacuum system attached to a Büchi rotary evaporator. IR spectra were recorded using a Perkin–Elmer 1310 IR spectrometer. Electronic spectra were recorded with a Cary 210 spectrophotometer. ^{13}C NMR spectra were measured with a Jeol FX 90Q FT spectrometer operating at 22.49 MHz with a deuterium internal lock. 1,4-Dioxane was used as the internal reference with D_2O as solvent. The ^{13}C NMR chemical shifts are recorded in ppm relative to TMS.

RESULTS AND DISCUSSION

Scheme 1 clearly demonstrates the versatility of $[Cotrpn(CO_3)]ClO_4 \cdot H_2O$[20] as a good source for the preparation of many cobalt(III)–trpn complexes. The reaction of the carbonato complex with conc. HNO_3 or conc. HX (X = F, Cl, Br) yielded the corresponding dinitrato or dihalo species, respectively. Also, some cobalt(III)–trpn–oxo-anion complexes were isolated from the reaction of acidified solutions of $[Cotrpn(CO_3)]ClO_4$ with SO_4^{2-}, HSO_4^-, $C_2O_4^{2-}$, PO_4^{3-} or $H_2P_2O_7^{2-}$ ions. On the other hand, while the reaction of $[Cotrpn(H_2O)_2](ClO_4)_3$ with dry acetonitrile afforded the corresponding bis-acetonitrile, the reaction of the dibromo species led to mono-acetonitrile; $[Cotrpn(CH_3CN)Br]BrClO_4$. The latter complex is sparingly soluble in acetonitrile and does not react further to produce the corresponding bis-aceto-nitrile, even with prolonged heating. The aqua-(bicarbonato) complex, $[Cotrpn(H_2O)(OCO_2H)](ClO_4)_2$, was isolated[20] by gentle treatment of the carbonato complex with a cold solution of 6 M $HClO_4$.

The electronic spectra of the isolated cobalt(III)–trpn complexes, collected in Table 1, show the presence of only two absorption bands in the vis–near UV region. The great similarity of the spectra to that of the $[Cotrpn(CO_3)]^+$ ion[20] argues for *cis*-octahedral geometry, which was already supported by X-ray structural determination for the carbonato complex.[21] Furthermore, in the visible region, the *trans*-dihalo(tetraamine)cobalt(III) complexes exhibit three absorption bands of lower molar absorptivities than the corresponding *cis* isomers, which show only two absorption bands.[27] Thus, all the isolated cobalt(III)–trpn complexes appear to have the *cis*-octahedral geometries, in which the trpn moiety is folded so that all four nitrogen atoms are coordinated to the cobalt(III) ion and enforce the remaining two positions to be oriented in the *cis* form.[21] The isolated sulphato, bisulphato and phosphato cobalt(III)–trpn complexes are tentatively assigned the monomeric *cis* configuration since their visible spectra resemble that of the $[Cotrpn(CO_3)]^+$ ion. This assignment, however, could not guarantee the existence of either monomeric four-membered chelates or *cis*-bis(μ-oxo-anion) bridges. Recently, it was pointed out that the previously described four-membered sulphato chelate, $[Co(en)_2(O_2SO_2)]^+$, has been shown to contain *cis*-bis(μ-sulphato) bridges.[28]

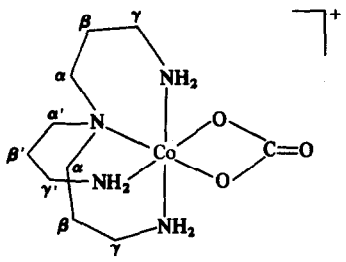
^{13}C NMR chemical shifts for some cobalt(III)–trpn complexes and their free ligands (trpn, CO_3^{2-}, HCO_3^- and $C_2O_4^{2-}$) are summarized in Fig. 1. The ^{13}C NMR signals for each of the methylene carbons in the complex ions $[Cotrpn(CO_3)]^+$, $[Cotrpn(C_2O_4)]^+$ and $[Cotrpn(H_2O)_2]^{3+}$ consist of two closely separated signals with ≃ 2:1 intensity rations. For each complex there are two α-carbons, two β-carbons and two γ-carbons in the arms which include the primary amine nitrogens that are *cis* to both coordinated oxygens. The other three carbons, α′, β′ and γ′, are in the arm which includes the primary and tertiary amine nitrogens and the two coordinated oxygens.[20] On the other hand, for $[Cotrpn(H_2O)(OCO_2H)]^{2+}$ more complex signals were observed for the trpn carbons (Fig. 1), due



$[Cotrpn(CO_3)]^+$

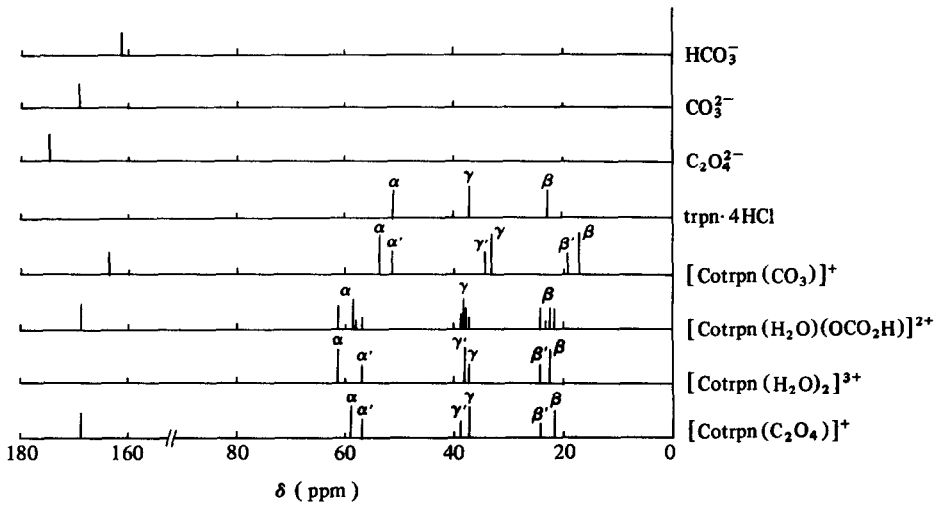


Fig. 1. Positions of ^{13}C NMR signals for the free ligands and their cobalt(III) complexes.

to the presence of six signals for each of the two geometrical isomers, depending on whether the OCO_2H^- ion is coordinated *cis* or *trans* to the coordinated tertiary amine nitrogen of the trpn.[20] The ^{13}C NMR chemical shifts for the carbon of the carbonyl group in the carbonato and oxalato complexes are shifted upfield by $\simeq$ 5–6 ppm, while for the bicarbonato complex, a downfield shift of 6.8 ppm was observed.[20]

In acidic medium the complex ions $[CotrpnCl_2]^+$ and $[CotrpnBr_2]^+$ hydrolyse very rapidly; complete-conversion of the dichloro complex to the diaqua species occurs in $\simeq$ 2 min.[22] The complex ion[21] $[Cotrpn(OH)(H_2O)]^{2+}$, which is the major species at pH $\simeq$ 6.5 (the pK_1 and pK_2 for the acid dissociation constants of coordinated water in $[Cotrpn(H_2O)_2]^{3+}$ are 4.82 and 7.52, respectively, at 25°C and $\mu = 0.1$ M), exhibits very large rate promotions for the hydrolysis of ATP[3] and rapid reaction for complex formation with phosphate.[23]

(*Received* 17 *August* 1988; *accepted after revision* 22 *May* 1989)

Abstract—Several new complexes of $M(RCOO)_2$ (where R = C_6H_5, 2-, 3- or 4-$O_2NC_6H_4$ and M = Co, Ni or Cu) with saturated diheterocyclic bases (L—L) of the type $M(RCOO)_2(L—L)_n$ (where n = 2, 1 or 0.5 and L—L = piperazine, 1-methylpiperazine, 2-methylpiperazine, 1-phenylpiperazine, 2,6-dimethylpiperazine, 2,5-dimethylpiperazine, 1,4-dimethylpiperazine and 4-methylmorpholine) and with saturated monoheterocyclic bases (L) of the type $M(RCOO)_2L_n$ (where n = 2 or 1 and L = 2-methylpiperidine, 3-methylpiperidine and 4-methylpiperidine) have been synthesized and characterized by elemental analyses, IR and electronic reflectance spectral and magnetic susceptibility measurement studies. In addition, most of the copper(II) complexes are also characterized by EPR spectral measurements. All complexes of cobalt(II) and nickel(II) are found to be magnetically dilute except $Co(2\text{-}O_2NC_6H_4COO)_2$(4Me-morl) (where 4Me-morl = 4-methylmorpholine) which is antiferromagnetic. Copper(II) forms both magnetically dilute and antiferromagnetic complexes with these bases. Probable structures have been assigned to all these complexes. The spin-exchange parameter, $-2J$, for antiferromagnetic complexes has been evaluated from both magnetic susceptibility and EPR measurements at different temperatures. No correlation between the value of $-2J$ and pK_a of the acid or terminal ligand could be established.

There has been considerable interest in the chemistry of metal(II) carboxylates and their complexation properties with nitrogen and oxygen donor ligands.[1–7] Depending upon the structure, the complexes show different magnetic behaviour. Many factors such as stoichiometry,[3,5] nature of carboxylic acid,[3,6,7] steric and electronic characteristics of the additional ligand[8–13] and conditions of the reaction[14] determine the structural priorities of the complex.

A literature survey reveals that although some workers have examined the role of "steric hindrance" or electronic nature of the substituent group on the pyridine type ligands[3,5–9] in their complexation behaviour with cobalt(II), nickel(II) and copper(II) carboxylates, no such systematic effort has yet been made for the saturated diheterocyclic bases (L—L) and monoheterocyclic bases (L). So the present work on the synthesis and magnetic and spectral properties for complexes of $M(RCOO)_2$ (where M = Co, Ni and Cu and R = C_6H_5, 2-, 3- or 4-$O_2NC_6H_4$) with ligands of different steric and electronic characteristics such as piperazine (pipz), 1-methylpiperazine (1Me-pipz), 2-methylpiperazine (2Me-pipz), 1-phenylpiperazine (1Ph-pipz), 1,4-

* Author to whom correspondence should be addressed.

dimethylpiperazine (1,4Me_2-pipz), 2,5-dimethylpiperazine (2,5Me_2-pipz), 2,6-dimethylpiperazine (2,6Me_2-pipz) and 1-methylmorpholine (1Me-morl), L—L; and 2-methylpiperidine (2Me-pipd), 3-methylpiperidine (3Me-pipd) and 4-methylpiperidine (4Me-pipd), L, has been undertaken. An additional incentive to undertake these studies was to see if the boat form of the diheterocyclic base could be stabilized in the complexed state.

EXPERIMENTAL

Starting materials

Liquid heterocyclic bases such as 1Me-pipz, 1Ph-pipz, 1,4Me_2-pipz (all from Fluka), 4Me-morl and 2-, 3- and 4Me-pipd's (all from K and K Laboratories) were dried by refluxing and distilling over sodium hydroxide pellets before use. Solid ligands viz. pipz, 2Me-pipz, 2,6Me_2-pipz and 2,5Me_2-pipz (K and K Laboratories) were kept over potassium hydroxide pellets in a vacuum desiccator for 3 days to dry. The purity of 2-, 3- and 4-nitrobenzoic acids (BDH, LR) was checked from their sharp melting points after recrystallization from ethanol. Other materials such as metal(II) chlorides (BDH) or sodium benzoate (BDH, AR) were used as such without any purification. Acetone, *n*-hexane, solvent ether and petroleum ether (40–60°C), all from BDH, were purified by the usual methods.

Preparation of metal(II) nitrobenzoates

A solution of nitrobenzoic acid (10.0 g, 60 mmol) in a minimum quantity of acetone was neutralized with aqueous sodium hydroxide solution. A small quantity (20 mg) of the nitrobenzoic acid was added to make the solution just acidic and the solution was then filtered. The stirring, aqueous solution of sodium nitrobenzoate thus formed was added to a filtered aqueous solution of metal(II) chloride ($\simeq$ 7 g, 30 mmol). All three copper(II) nitrobenzoates, cobalt(II) 3- and 4-nitrobenzoates and nickel(II) 4-nitrobenzoate separated out after the contents had been stirred for 0.5 h. Other metal(II) nitrobenzoates were obtained upon concentrating the reaction mixture and cooling it in a refrigerator. The separated product was filtered, washed with cold distilled water and dried in air. The air-dried product was then subjected to vacuum at 140°C for 4 h.

Copper(II) benzoate was similarly prepared by reacting sodium benzoate with copper(II) sulphate in water, which separated upon mixing the contents.

Preparation of complexes

A solution of the stoichiometric amount in general, and in the case of 1,4Me_2-pipz and 4Me-morl a 50% excess, of the saturated heterocyclic base dissolved in acetone (15 cm^3) was added dropwise to a continuously stirred solution/suspension of metal(II) carboxylate (1 g) in acetone (*ca* 50 cm^3). Most of the adducts of the diheterocyclic bases separated on stirring for 0.5 h, and these were completely precipitated by the addition of *n*-hexane or ether. Other complexes were separated on concentrating the reaction mixture to about a quarter of its original volume, cooling in the refrigerator for 4 h and adding solvent ether or *n*-hexane. The separated product was filtered through a G_4 filtration unit, washed with solvent ether and *n*-hexane, and dried under vacuum.

Elemental analyses and physical measurements

The metal content in the complexes was determined volumetrically by EDTA titration using Xylenol Orange as indicator. Carbon and hydrogen analyses were performed on an automatic Coleman-33 analyser, while nitrogen was estimated by Kjeldahl's method in the departmental microanalytical laboratory.

Room-temperature magnetic susceptibility of all the complexes was measured on a Gouy balance using $Hg[Co(NCS)_4]$ as calibrant. The magnetic susceptibility of some representative cobalt(II) complexes and antiferromagnetic copper(II) complexes at different temperatures was measured on a Curie Magnetic susceptibility with the NEC PC-980 Data Treatment System or on a Vibrating Sample Magnetometer (VMS) PAR-155 with a variable-temperature cryostat. The measured susceptibility was corrected for the diamagnetic susceptibility of the ligands. The correction for temperature independent paramagnetism was taken as -60×10^{-6} c.g.s. units per gram atom of copper(II) ions.

IR spectra of the acids, their anhydrous metal(II) and sodium salts and the complexes were recorded both as Nujol and hexachlorobutadiene mulls on an IR-20 spectrophotometer with sodium chloride plates as windows in the 4000–600 cm^{-1} region, while far-IR spectra in the range 600–250 cm^{-1} were measured as Nujol mulls in polythene film. Electronic reflectance spectra of the complexes were recorded on Unicam SP-700 UV–vis–near IR spectrophotometer with a SP-735 diffuse reflectance attachment. The EPR measurements of powdered samples at liquid nitrogen temperature (77 K) were carried out on a Varian E-4 EPR-spectrometer at X-

band frequencies (8.8–9.6 GHz). The X-band EPR measurements of powdered materials of antiferromagnetic complexes at different temperatures were made on a Varian E-12 EPR spectrometer using the E-257 variable-temperature assembly. Diphenylpicrylhydrazyl (DPPH) was used as calibrant.

The pK_as of some of the bases were determined pH-metrically at 37°C using an Elico (model 4-122) digital meter.

RESULTS AND DISCUSSION

Chemical formulae based upon elemental analyses, colour and room-temperature μ_{eff} values are listed in Table 1. Examination of Table 1 shows that these metal(II) carboxylates give rise to complexes of 1:0.5, 1:1 or 1:2 (metal–base) stoichiometry with these saturated heterocyclic bases. The different complexation behaviour of these bases will be discussed later. All complexes of cobalt(II) are red, pink or brown, except $Co(3\text{-}O_2NC_6H_4COO)_2$(2Me-pipd) which is green, while nickel complexes are green or pale green. Most of the copper(II) complexes are blue or light blue except for the antiferromagnetic complexes (**XCVII–CXI**) which are green.

IR spectral studies

Various structural possibilities for complexes of the stoichiometries $M(RCOO)_2L_n$ (where $n = 2$, 1 or 0.5) which depend upon the mode of coordination of the carboxylate group and the diheterocyclic base, have been discussed elsewhere.[15] IR studies are quite useful in determining the mode of coordination of these ligands.[5,16] On critically examining the positions and direction of the shifts of the ν_{as}(OCO) and ν_s(OCO) of the carboxylate group in the complexes, as compared to their positions in the sodium salts of the respective acids, the bridging bidentate mode for complexes **XIX**, **XLV**, **XLVII**, **XLIX** and **LVII** and, **XCVII–CXI** and the chelating bidentate mode of coordination of the carboxylate group for all other complexes can be suggested.[16,17] A shift to the lower energy region ($\simeq 50$ cm^{-1}) of the bands due to ν(N—H) vibrations in the complexes relative to those in the free bases ($\simeq 3300$ cm^{-1}) indicates the coordination of the bases through the nitrogen atom(s) of their N—H bond(s).[18,20] However, in the IR spectrum of 1Me-pipz complexes of the type $M(RCOO)_2$(1Me-pipz)$_2 \cdot 2H_2O$, this band is much too broad (due to it becoming mixed into ν(O—H) and enhanced effect of hydrogen bonding) to indicate any shift. An examination of the band around 2750 cm^{-1} due to ν(C—H) of N—CH_3 in the complexes of 1Me-pipz, 1,4Me_2-pipz and 1Me-morl shows that this band is observed at almost the same position as in the free bases for complexes of the type $M(RCOO)_2$(1Me-pipz)$_2$ or $Cu(RCOO)_2$(1Me-pipz) which indicates that the nitrogen atom of the N—CH_3 group remains uncoordinated, while this frequency disappears or undergoes large positive shifts for other complexes of these bases, showing the binding of this nitrogen atom to the metal.[20,21]

Additional bands in the complexes, compared with the IR spectra of uncomplexed metal(II) carboxylates and free bases in the region 370–440 cm^{-1} and 320–360 cm^{-1}, have tentatively been assigned to ν(M—O) and ν(M—N) modes, respectively.[18,19,22–24] In the region of absorption of diheterocyclic bases, the IR spectra of the complexes under study closely resemble those of the free bases, and no additional bands characteristic of the boat form are observed. This indicated that the ligands are coordinated in the chair form.[25,26]

Electronic reflectance spectral studies

All cobalt(II) complexes in the present study, other than $Co(3\text{-}O_2NC_6H_4COO)_2$(2Me-pipd) or **XXX** and $Co(2\text{-}O_2NC_6H_4COO)_2$(4Me-morl) or **XIX**, show two principal absorption bands around 8000 cm^{-1} (ν_1) and 19,000 cm^{-1} (ν_3) which are assigned, respectively, to the $^4T_{2g} \leftarrow {}^4T_{1g}(F)$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ transitions for the cobalt(II) ion in approximate octahedral environments (Fig. 1).[8,27] A weak band or a shoulder observed around 15,000 cm^{-1} (ν_2) for some of the complexes is assigned to the third spin-allowed but two-electron forbidden $^4A_{2g} \leftarrow {}^4T_{1g}(F)$ transition. The ratio of ν_2/ν_1 for these complexes lies in the range 1.9–2.10, which lends support to the above assignments.[27,28] The broadness or splitting observed for the ν_1 band can be attributed to the distortion of structure from cubic symmetry. The Dq and B values for these complexes (calculated from ν_3/ν_1) lie in the range 870–950 and 750–900 cm^{-1}, respectively.[8,18] Electronic diffuse reflectance spectra of **XIX** and **XXX** are similar to those of square-pyramidal and trigonal-bipyramidal environments around the cobalt(II) ion, respectively.[8]

All nickel(II) complexes under present discussion show bands around 8700 (ν_1) 14,000 (ν_2) and 26,000 (ν_3) cm^{-1} (but some show the last band around 21,000 cm^{-1}, viz. **XL**, **XLVIII**, **L** and **LXI**) in their electronic diffuse reflectance spectra. The number, shape and energies of these bands are the characteristics of *trans*-pseudo octahedral structure (D_{4h} symmetry) containing the NiO_4N_2 chromophore and are, therefore, assigned to the $^3T_{2g} \leftarrow {}^3A_{2g}(\nu_1)$,

Table 1. Elemental analysis data (%),[a] colour and room-temperature μ_{eff} values of the complexes

[a] Calculated values are given in parentheses.

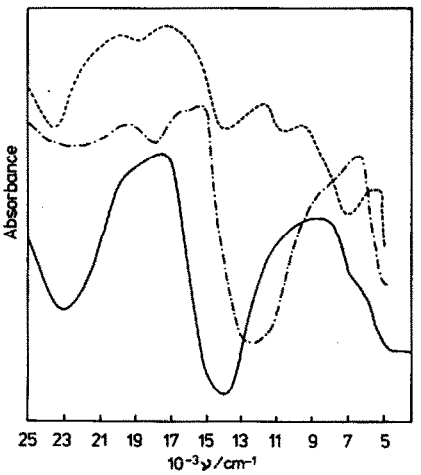

Fig. 1. Electronic reflectance spectra of $Co(4\text{-}O_2NC_6H_4COO)_2(3Me\text{-}pipd)_2$ (———), $Co(3\text{-}O_2NC_6H_4COO)_2(2Me\text{-}pipd)$ (–·–·–), and $Co(2\text{-}O_2NC_6H_4COO)_2(4Me\text{-}morl)$ (– – – –).

$^3T_{1g}(F) \leftarrow {}^3A_{2g}(\nu_2)$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}(\nu_3)$ transitions.[8,18,27] The ν_2 band is quite broad or is split into two components which can be ascribed to the large difference in the ligand-field strengths of the ligands in the present situation.[29] The low and high energy components of the ν_1 band can be assigned to the $^3B_{2g} \leftarrow {}^3B_{1g}(\nu_B)$ and $^3E_g \leftarrow {}^3B_{1g}(\nu_E)$ ligand-field transitions for the nickel(II) ion in D_{4h} environments.[8,29] Tetragonal parameters $Dq(xy)$, $Dq(z)$ and Dt, calculated from the energies of the above transitions, fall in the approximate ranges of 700, 1000 and -200 cm^{-1}, respectively. The position of the ν_3 band lies above 25,000 cm^{-1} for all complexes except the four complexes, i.e. $Ni(RCOO)_2(4Me\text{-}morl)$ (where R = 2-, 3-, and $4\text{-}O_2NH_4$) and $Ni(2\text{-}O_2NC_6H_4COO)_2(2,6Me_2\text{-}pipz)$, which exhibit this band at a much lower energy—around 21,000 cm^{-1}. It makes it a little doubtful to be considered as a ν_3 absorption of octahedral geometry. The value of Dq for most of the complexes, as calculated from the ratio ν_3/ν_1 or ν_3/ν_2, lies around 900 cm^{-1}, while the value of B shows variation between 800 and 1100 cm^{-1}. These results are in agreement with earlier reports on similar complexes of pseudo-octahedral geometry.[8,18,28] However, the B value for the four complexes having anomalous spectra comes out to be very small (550 cm^{-1}), which contradicts approximate octahedral structure (D_{4h} symmetry). However, we suggest a heavily distorted octahedral structure with C_{4v} symmetry for these complexes.

All magnetically dilute copper(II) complexes (**LXIII–XCVI** as in Table 1) under discussion show an electronic absorption band in the region 14,700–18,200 cm^{-1} which can be assigned to the $^2T_{2g} \leftarrow {}^2E_g$ ligand-field transition for an octahedral field. The broadness or splitting observed for this main band is ascribed to tetragonal distortion. The lower and higher energy components of this can be assigned, respectively, to the $^2B_{2g} \leftarrow {}^2B_{1g}$ (or $d_{xy} \rightarrow d_{x^2-y^2}$) and $^2E_g \leftarrow {}^2B_{1g}$ (or $d_{xz,yz} \rightarrow d_{x^2-y^2}$) ligand-field transitions for a tetragonal field.[30–32]

Two absorptions, one as a broad band in the region 12,500–14,500 cm^{-1} (band I) and the other as a shoulder around 26,000 cm^{-1} (band II), are observed for antiferromagnetic copper(II) complexes (**XCVIII–CXI**). Band I may be due to the absorption corresponding to the $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{xz,yz} \rightarrow d_{x^2y^2}$ electronic transitions for the copper(II) ion in tetragonal environments,[33] while band II can be assigned to the $2p_\pi$ (donor oxygen atom) $\rightarrow d_{x^2-y^2}$ charge-transfer transition. The appearance of this band is considered to be characteristic of the dimeric structure for the copper(II) carboxylate complexes.[33–35]

The X-band EPR curves of powdered materials for most of the magnetically dilute copper(II) complexes obtained at liquid nitrogen temperature are consistent with axial symmetry of the complexes except for $[Cu(C_6H_5\text{-}COO)_3(3Me\text{-}pipd)_2]$ which has an EPR spectrum typical of elongated rhombic geometry [g_z (2.33) > g_y(2.07) > g_x(2.05)]. The magnitudes $g_\parallel$ (2.20–2.27) and $g_\perp$ (2.05–2.09) obtained from the EPR spectrum for these complexes are consistent ($g_\parallel > g_\perp > 2.04$) with an elongated tetragonal type structure, which agrees with the results obtained from electronic absorption studies.[31,32] The observed range of $g_\parallel$ is in conformity with the CuO_4N_2 chromophore of the complex.[36] The absorptions for the $g_\parallel$ and g_z portions of the EPR spectra for $Cu(4\text{-}O_2NC_6H_4COO)_2(3Me\text{-}pipd)_2$ and $Cu(C_6H_5COO)_2(3Me\text{-}pipd)_2$, respectively, resolve into four components. The splitting is attributed to the hyperfine coupling due to ^{63}Cu ($I = 3/2$). The values of $A_\parallel = 0.0181$ cm^{-1} and $A_z = 0.0141$ cm^{-1} have been obtained, respectively, for these two complexes. The bonding parameters, $\alpha^2 = 0.829$, $\beta_1^2 = 0.854$ and $\beta^2 = 0.723$, have also been calculated for $Cu(4\text{-}O_2NC_6H_4COO)_2(3Me\text{-}pipd)_2$ by assuming D_{4h} symmetry for the copper(II) environments.[31,37,38]

The X-band EPR spectra at 300 K for powdered samples of antiferromagnetic complexes under present discussion contain absorption lines at field strengths of 800 (H_{z1}), 4600 ($H_\perp$) and 6100 G (H_{z2}), which are characteristic features of axially symmetric binuclear copper(II) species and correspond to the spin triplet state ($S = 1$) with $D > h\nu$ and $E = 0$.[39,40] The range of $g_\parallel$ or g_z (2.30–2.40), $g_\perp$ (2.05–2.10) and D (0.34–0.39 cm^{-1}) evaluated from the EPR spectra are comparable with the earlier

reported values for binuclear copper(II) carboxylate complexes.[4-7] For some complexes, the EPR absorption around 800 G is split into seven lines due to hyperfine coupling of the nuclear spins of two copper ions with the electron spin ($2nI+1$; $n=2$ and $I=3/2$ for ^{63}Cu). The value of $A_{\parallel}$ or A_z is found to be about half ($\simeq 0.008$ cm^{-1}) of that generally observed for magnetically dilute copper(II) in similar environments. This supports magnetic exchange taking place between two metal ions.[40,41] However, in addition to the above-mentioned absorptions, an absorption line around 3200 G is also observed. The intensity of this line increases while the intensity of the lines due to the triplet state, as expected, decreases with the lowering of temperature. This line is, therefore, attributed to the magnetically dilute copper(II) impurity which is commonly present in the copper(II) arylcarboxylate complexes.[39,42,43]

Magnetic susceptibility studies

The room-temperature μ_{eff} values for all cobalt(II) complexes lie in the range 4.60–5.02, which is considerably greater than the spin-only value (3.82) and hence supports nearly octahedral structure for these complexes.[8,18,27] The magnitude of μ_{eff} varies with A (ligand-field strength parameter), k (covalence parameter for the M—L bond) and v (parameter for distortion from cubic symmetry).[44,45] For perfectly octahedral systems ($v=0$) with $A=1.4$ ($A=1.4$ for complexes under discussion as calculated from electronic spectra) and $k=0.8$ (minimum possible value for nature of ligands), the theoretical μ_{eff} value at room temperature for the complexes under discussion should be 4.81 or greater.[44] But in the present case, for most of the complexes μ_{eff} is less than 4.81, which leaves the distortion from cubic symmetry to be the only reason responsible for the lowering of the μ_{eff} values. The magnetic susceptibility of six representative cobalt(II) complexes, viz. Co(4-$O_2NC_6H_4COO)_2$(1Ph-pipz)$_2$ (**V**), Co(4-$O_2NC_6H_4COO)_2$(3Me-pipd)$_2$ (**X**), Co(2-$O_2NC_6H_4COO)_2$(1,4Me$_2$-pipz)$_2$ (**XVI**), Co(2-$O_2NC_6H_4COO)_2$(4Me-morl) (**XIX**), Co(3-$O_2NC_6H_4COO)_2$(pipz) (**XXII**) and Co(3-$O_2NC_6H_4COO)_2$(1,4Me$_2$-pipz) (**XXVI**) has also been measured at different temperatures in the range 80–280 K. The magnitude of θ (10–54°) obtained from the plots of $1/\chi$ vs T, and the variation of μ_{eff} from 4.90 at 280 K to 4.2 at 80 K, which remains well above the spin-only value (except **XIX**), favours the $^4T_{1g}$ ground ligand-field term for these complexes with near octahedral structures.[45] The value of θ for the complex Co(2-$O_2NC_6H_4COO)_2$(4Me-morl) (**XIX**) is 110° and this large value can only be due to antiferromagnetic interactions. The magnetic moment value of this complex decreases rapidly with a decrease in temperature, i.e. it decreases from 4.55 BM at 280 K to 3.4 BM at 80 K, which becomes even less than the spin-only value for high-spin cobalt(II) complex. These observations clearly indicate the presence of antiferromagnetic interactions taking place in this complex.[5]

The room-temperature μ_{eff} value for nickel(II) complexes under present discussion lies in the range 3.00–3.35. These values are consistent with the near octahedral structure for these complexes. Room-temperature magnetic moment values for the copper(II) complexes **LXIII–XCVI** and **XCVII–CXI** lie in the ranges 1.81–2.20 BM and 1.40–1.60 BM, respectively. In view of the μ_{eff} value for the former complexes lying above the spin-only value and for the latter being close to the value reported for dinuclear or polynuclear complexes, where carboxylate group acts as a bridge between two metal ions, the copper(II) complexes have been categorized as (i) magnetically dilute and (ii) antiferromagnetic complexes.[1-7]

Antiferromagnetic copper(II) complexes have also been characterized by magnetic susceptibility measurements at different temperatures.[15] The magnetic moment value for all these complexes decreases with temperature, thus confirming their antiferromagnetic behaviour. The following modified equation based upon Bleaney and Bowers' model[46] was employed to evaluate the spin-exchange parameter ($-2J$) from magnetic susceptibility data at different temperatures:[42,43]

$$\ln\left[\frac{N\bar{g}^2\beta^2(1-x)}{kT\left(\chi_{Cu}-\frac{0.43x}{T}-N_\alpha\right)}-3\right]=\frac{-2J}{kT}$$

$$\text{or}\quad \ln(F-3)=\frac{-2J}{kT}.$$

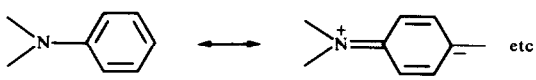
The unknown quantities in the above expression on the LHS were as follows: the value of $\bar{g}$ was determined from EPR measurements and the value of N_α was taken to be 60×10^{-6} e.g.s. units. The value of x, the mole fraction of paramagnetic impurity, was so chosen as to fit in well with the above expression. The value of $2J$ has been determined from the slope $[2J/k]$ of the straight line obtained from a plot of $\ln(F-3)$ vs $1/T$. The value of $2J$ was also calculated from the variation of intensity (I) of the EPR lines at the temperatures 300, 173 and 103 K using the relation:[39,43]

$$\frac{A_1}{A_2}=\frac{I_1}{I_2}=\frac{T_2(3+e^{-2J/kT_2})}{T_1(3+e^{-2J/kT_1})}.$$

The relative areas of curves $[A_1/A_2]$ at two different temperatures (T_1 and T_2) were estimated by the reported methods.[47,48] Uncertainties in the values of $-2J$ for the former and latter methods are ± 5 and ± 20 cm^{-1}, respectively. This is because both of these methods have their own limitations in evaluating the value of $2J$. The magnetic susceptibility method becomes complicated due to the presence of a magnetically dilute impurity which is usually present in antiferromagnetic copper(II) arylcarboxylate complexes. However, by allowing the presence of this impurity (x) in the above equation, reasonable evaluation of $2J$ can be obtained. The EPR method, though it is free from the presence of the magnetic impurity, suffers from the limitation in evaluating the accurate areas under EPR curves. Therefore the uncertainties in the EPR method are greater than in the magnetic susceptibility method. The values of $-2J$ determined by the two methods are comparable and lie between 280–330 cm^{-1}.

In spite of the high basicities of these bases ($pK_a \simeq 8$–9.6), this range of values of $2J$ is comparable to that for the earlier reported copper(II) carboxylate complexes with terminal ligands of low basicity, e.g. py, etc. No consistent trend of the variation of $-2J$ with pK_as of the acids or the ligand is obtained.

By combining all the studies conducted upon all these complexes, the distorted octahedral structure can be assigned to all complexes except for $Co(3\text{-}O_2NC_6H_4COO)_2$(2Me-pipd), $Co(2\text{-}O_2NC_6H_4COO)_2$(4Me-morl) and all antiferromagnetic copper(II) complexes (**XCVII–XCI**). The monomeric *trans*-pseudo-octahedral structure with the carboxylate group acting as a chelating bidentate unit and the base as a monodentate ligand has been assigned to the complexes of the type $M(RCOO)_2(L—L)_2 \cdot xH_2O$ and $M(RCOO)_2L_2$, where $x = 2$ for L—L = 1Me-pipz and $x = 0$ for L—L = 1Ph-pipz; and L = 2-, 3- or 4Me-pipd. Here, for the 1Me-pipz complexes, the two water molecules may be hydrogen bonded to the uncoordinated nitrogen atom, i.e. the N—CH_3 group of the base.[18] The absence of these water molecules in similar complexes of 1Ph-pipz may be attributed to the phenyl group using the lone pair of the uncoordinated nitrogen atom for delocalization (see below) and hence lessening the possibility of hydrogen bonding.



Leaving aside the antiferromagnetic complexes, the polymeric *trans*-pseudo-octahedral structure with the carboxylate group and the heterocyclic base acting, respectively, as a chelating bidentate and a bridging bidentate ligand between two metal atoms, has been assigned to all complexes of the type $M(RCOO)_2(L—L)$ except for $Ni(2\text{-}O_2NC_6H_4COO)_2(L—L)$ (where L—L = 2Me-pipz, 2,5Me_2-pipz, 1,4Me_2-pipz) and $Ni(3\text{-}O_2NC_6H_4COO)_2$(1,4-$Me_2$-pipz), for which the geometry with both L—L and the carboxylate group behaving as bridging bidentate groups is proposed. The trigonal bipyramidal structure has been suggested for $Co(3\text{-}O_2NC_6H_4COO)_2$(2Me-pipd). For antiferromagnetic complexes, the copper(II) acetate monohydrate-like dinuclear structure[49] for complexes of the type $M(RCOO)_2(L—L)$ and the $Cu(HCOO)_2(dioxane)_{0.5}$-like polymeric structure[50] containing binuclear units for complexes of the type $Cu(RCOO)_2(L—L)_{0.5}$ are proposed.

Our interest in the present work was to study the complexation behaviour of these saturated mono- and diheterocyclic bases, of different but high basicities and different steric characteristics, with metal(II) carboxylates. An additional interest was to see whether these bases form magnetically dilute or antiferromagnetic complexes. Out of these cases, 4Me-morl and 1,4Me_2-pipz are interesting ligands. 4-Methylmorpholine forms only 1 : 1 complexes (when added in excess) with all copper(II) carboxylates of the type $Cu(RCOO)_2$ (where R = C_6H_5, 2-, 3- and 4-$O_2NC_6H_4$); all of them are found to be antiferromagnetic. Out of all the cobalt(II) and nickel(II) complexes, the only antiferromagnetic complex to be isolated was also that of 4Me-morl with the formula $Co(2\text{-}O_2NC_6H_4COO)_2$(4Me-morl). 1,4-Dimethylpiperazine forms complexes of the type $Cu(RCOO)_2(1,4Me_2\text{-pipz})_{0.5}$ (where R = C_6H_5, 2- and 3-$O_2NC_6H_4$ and when R = 4-$O_2NC_6H_4$) and for all the cobalt(II) and nickel(II) nitrobenzoates, it affords complexes of 1 : 1 stoichiometry. Complexes having 1 : 0.5 stoichiometry are antiferromagnetic, while those of 1 : 1 stoichiometry are magnetically dilute. The 1Me-pipz and 1Ph-pipz ligands form complexes of 1 : 2, 1 : 1 and 1 : 0.5 (metal–base) stoichiometry with copper(II) carboxylates, while with cobalt(II) and nickel(II) they give 1 : 2 complexes. The complexes of 1 : 2 stoichiometry are magnetically dilute while the others are antiferromagnetic. These bases are of interest for copper(II) carboxylates, where one can change the stoichiometry and structural form of the complex and hence its magnetic behaviour by controlling only the amount of base added to the metal carboxylate solution. All other diheterocyclic bases form complexes of 1 : 1 stoichiometry, which are found to be magnetically dilute. Overall, the complexation behaviour of these diheterocyclic bases can be rationalized to some extent by the

following factors: (1) copper(II) carboxylates have more tendency to form antiferromagnetic complexes than their cobalt(II) and nickel(II) analogues; (2) bases with lower pK_a values and large steric hindrance (e.g. 4Me-morl and 1,4Me_2-pipz) prefer to form antiferromagnetic complexes.

Out of the monoheterocyclic bases, 2Me-pipd shows restricted complexation behaviour, compared with 3Me-pipd and 4Me-pipd, in its adduct formation with cobalt(II) and more so with nickel(II) nitrobenzoates, i.e. it does not form any adduct with nickel(II) nitrobenzoates and gives only 1:1 complexes with $Co(RCOO)_2$ (where R = 3- or 4-$O_2NC_6H_4$) and when R = 2-$O_2NC_6H_4$ a complex does not form; while its 3- and 4Me-pipd analogues give 1:2 complexes with all metal(II) carboxylates. These three bases behave similarly with copper(II) carboxylates to give 1:2 complexes. This can be partly justified due to the larger steric requirements of 2Me-pipd than the other ligands. The similarity in behaviour of the three bases for copper(II) may be due to large Jahn–Teller effects expected for copper(II) and especially its particular preferential mode, i.e. Jahn–Teller elongation which forces the complexes to adopt a *trans*-in-plane tetragonally elongated structure which results in relieving some steric congestion in the structure.[51,52] To some extent, this can also be justified by the larger affinity of the copper(II) ion than cobalt(II) and nickel(II) ions for complexation with highly basic nitrogen donors. These bases do not yield any antiferromagnetic complexes [not even with copper(II)], which can also be due to their highly basic nature.

Acknowledgements—We thank Dr T. Rs. Reddy, A. K. Puri and Dr Surjit Singh for EPR measurements. We are also grateful to Dr Kailash Chandra for his help with the magnetic susceptibility measurements. We would also like to thank the U.G.C. of India for financial support.

COMMUNICATION

CLEAVAGE OF THE PC TRIPLE BOND IN A PHOSPHA-ALKYNE IN THE ABSENCE OF A TRANSITION METAL

R. BARTSCH and J. F. NIXON*

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

(*Received* 26 *June* 1989; *accepted* 26 *June* 1989)

Abstract—The reaction of Bu^{t}C≡P with Na/Hg in monoglyme results in the formation of the 2,5-di-*t*-butyl-1,3,4-triphosphacyclopentadienyl (**1**) and 2,4,5-tri-*t*-butyl-1,3-diphosphacyclopentadienyl (**2**) anions. The reaction has been carried out in the absence of $[Ta(OAr)_2Cl_3]$ (Ar = 4-Me,2,6-*t*-$Bu_2C_6H_2$), which proves that the formation of **1** and **2** does not involve the phosphide intermediate $[Ta{\equiv}P(OAr)_2]$ previously postulated by Cowley and Hall (*Polyhedron* 1989, **8**, 849).

Recently Cowley and Hall[1] reported that reduction of $[Ta(OAr)_2Cl_3]$ (Ar = 4-Me,2,6-*t*-$Bu_2C_6H_2$) with Na/Hg, followed by treatment with 3 equivalents of Bu^{t}CP led to the formation of the di- and triphosphacyclopentadienide anions **1** and **2**. The authors speculated, without structure or spectroscopic data, that Bu^{t}CP is cleaved by a reduced tantalum species to afford the intermediates $[Ta{\equiv}P(OAr)_2]$ and $[Ta{\equiv}CBu^t(OAr)_2]$, which then could react with 2 moles of Bu^{t}CP to produce **1** and **2**, respectively. The source of the extra electrons for the formation of **1** and **2** is likely to be the alkali metal.

We wish to report that treatment of Bu^{t}CP with Na/Hg in monoglyme in the absence of $[Ta(OAr)_2Cl_3]$ yields **1** and **2** in the same proportions as described by Cowley and Hall.[1] This proves that the reaction occurs via direct cleavage of the PC bond in the phospha-alkyne by sodium, followed by cyclization with Bu^{t}CP to give **1** and **2**, respectively, without any involvement of a Ta≡P species. The ^{31}P NMR data for **1** and **2** are in satisfactory agreement with those previously reported by Becker *et al.*[2] and ourselves.[3] In recent work we have used this direct synthetic approach to subsequently oxidatively couple the anions **1** and **2** and to afford the novel cage compound $P_5C_5Bu^t_5$.[4]

ELECTRON TRANSFER BETWEEN BIS(DIMETHYLGLYOXIME)COPPER(II) AND DIGLYCYLETHYLENEDIAMINE COPPER(III). STABILIZATION OF COPPER(III) BY A DIOXIME LIGAND

YOUSIF SULFAB

Department of Chemistry, Kuwait University, P.O. Box 5969 Safat, 13060 Safat, Kuwait

(*Received* 19 *October* 1988; *accepted after revision* 15 *March* 1989)

Abstract—Bis(dimethylglyoxime)copper(II), $Cu^{II}(DMGH)_2$, is readily oxidized to the corresponding copper(III) complex. Cyclic voltammetry exhibited quasi-reversible one-electron transfer with peak-to-peak separation of ≈ 80 mV. The $E_{1/2}$ value varied linearly with $-\log[H^+]$ with a slope of -59 mV, showing the involvement of one proton in the electrode reaction. The kinetics of the oxidation of $Cu^{II}(DMGH)_2$ by $Cu^{III}(H_{-2}DGEN)^+$ (DGEN = diglycylethylenediamine) showed a first-order dependence on both the reductant and the oxidant. The second-order rate constant, k_2, varies with $[H^+]$ according to:

$$k_2 = k'_2 + k_3/[H^+].$$

The mechanism of electron transfer is discussed in terms of inner- and outer-sphere mechanisms.

The trivalent oxidation state of copper is often proposed as a highly reactive species in a number of organic and inorganic oxidations catalysed by copper(II) ions.[1–5] A number of copper(III) complexes have been identified in solution and a few have been isolated in the solid state.[6,7] Copper(III) has been shown to be stabilized by coordination to in-plane deprotonated amide groups as shown by the isolation of biuret[8] and oxamide[9] complexes. This has further been supported by the generation of copper(III)–peptide complexes by chemical and electrochemical oxidations of the corresponding deprotonated copper(II) complexes.[10,11] The chemistry of this oxidation state of copper has recently been reviewed.[7]

More than 50 years ago, Clarke and Jones[12] and Kolthoff[13] described a very sensitive method for the detection of copper at very low concentrations. The method involved the use of copper(II), dimethylglyoxime ($DMGH_2$) and an oxidant, $S_2O_8^{2-}$ or IO_4^- in buffered solutions. The nature of the reddish-violet product, which decomposes on standing, was not known. Morphurgo and Tomlinson[14] have also reported the oxidation of the tetramer $[Cu_2(DMGH)_2(OH)_2]_2$ by $S_2O_8^{2-}$ and claimed the formation of a species in which copper exists in the mixed oxidation states of II and III. These authors, however, claimed that $Cu^{II}(DMGH)_2$ is not oxidized to the corresponding copper(III) complex. In this study, we report the stabilization of the trivalent oxidation state of copper by $DMGH_2$, its electrochemistry and electron-transfer reaction with doubly deprotonated copper(III)–diglycylethylenediamine, $[Cu^{III}(H_{-2}DGEN)]^+$.

The ability of the dioxime ligands to conform to the geometrical preference of the d^8 copper(III) complex, with subsequent ligand-field stabilization, will favour the d^8 configuration relative to d^9.[11] Dioxime and pyridine–oxime ligands are reported to facilitate the oxidation and to stabilize higher oxidation states of nickel.[15] Recently, $Ni^{IV}(DMG)_3^{2-}$ has been isolated from basic solutions.[16] An uncommon +4 oxidation state has also been reported in organoaquabis(dimethylglyoxime) cobalt(IV) complexes.[17] We have also shown that the +3 oxidation of copper is stabilized by tetradentate imine–oxime ligands.[18]

EXPERIMENTAL

Solutions of copper(II)–dimethylglyoxime were prepared by reacting solutions of $Cu(ClO_4)_2$ with

the ligand in a 1:2.1 mole ratio. The pH of the $Cu^{II}(DMGH)_2$ (5.0×10^{-3} M) solutions was raised to ≈ 6 by the slow addition of 0.10 M NaOH, to ensure the complete formation of the complex. The diglycylethylenediamine ligand was prepared according to the literature method.[19] Solutions of copper(II)–diglycylethylenediamine were freshly prepared, with the ligand in 5% excess, and the pH adjusted to ≈ 10 with 0.10 M NaOH to form the doubly deprotonated complex, $Cu^{II}(H_{-2}DGEN)$. Fresh solutions of $[Cu^{III}(H_{-2}DGEN)]^+$ were prepared by electrochemical oxidation with a flow system in which the electrode arrangement included a graphite powder working electrode packed in a porous-glass column, wrapped externally with a platinum wire electrode.[20] The $Cu^{II}(H_{-2}DGEN)$ complex was oxidized at a potential of about 200 mV above its $E^0_{1/2}$ value. After electrolysis, the copper(III) solutions were weakly acidic and were diluted to the desired concentration and the ionic strength maintained at 0.1 M with $NaClO_4$. Stock solutions of the buffers, acetate, phosphate, 2(N-morpholino)ethanesulphonate (MES) and N-2-hydroxyethylpiperazine-N′-ethanesulphonate (HEPES) were made up by weight. A stock solution of sodium *meta* periodate (0.10 M) was made up by weight and wrapped with aluminium foil to avoid photochemical decomposition.[21]

The EPR spectrum of $Cu^{II}(DMGH)_2$ solutions, in the presence or absence of periodate, was recorded at room temperature at pH ≈ 6 using a Varian E-109 X-band EPR system modulated at 100 kHz. Cyclic voltammetry was performed at 25.0°C over a pH range, using various buffers, with a three-electrode system consisting of a carbon paste working electrode, a platinum wire auxiliary electrode and a saturated NaCl calomel reference electrode.

Voltammograms were generated using a Bioanalytical Systems Inc. CV-1 instrument and recorded on a Hewlett-Packard HP7035 X–Y recorder. The $E_{1/2}$ values were determined as the midpoint between the peak potentials with an accuracy of ± 5 mV. The electrode potential, at each pH, was obtained from an average of three separate cyclic voltammetric measurements. The $E_{1/2}$ values were determined in coordinating and non-coordinating buffers. Axial coordination has been reported[22] in $Cu^{II}(DMGH)_2$ to give a five-coordinate complex, and if this is significant with coordinating buffers, the $E_{1/2}$ values are likely to be affected.

The kinetics of the oxidation of $Cu^{II}(DMGH)_2$ by $[Cu^{III}(H_{-2}DGEN)]^+$ were followed at 530 nm, $T = 25.0$°C and $\mu = 0.10$ M ($NaClO_4$) using a Durrum stopped-flow spectrophotometer interfaced to a Hewlett-Packard Model 2115A general purpose computer.[23] Pseudo-first-order conditions were maintained in all kinetic runs with $[Cu^{II}(DMGH)_2] \geqslant 10\ [[Cu^{III}(H_{-2}DGEN)]^+]$. The effect of $[H^+]$ on the rate of electron-transfer was investigated over a pH range using different buffers. The pH was measured using a Radiometer PHM26 pH meter and the pH corrected for ionic strength effects ($-\log[H^+] = \text{pH} - 0.11$).

RESULTS

The EPR spectrum obtained for $Cu^{II}(DMGH)_2$ (10^{-4} M, pH ≈ 6) is identical to that reported in the literature.[24] On addition to a periodate solution (2.5×10^{-3} M), the EPR spectrum of the copper(II) complex disappears, indicating the formation of a diamagnetic species.

Cyclic voltammetry using solutions of $Cu^{II}(DMGH)_2$ gave current potential response curves consistent with a quasi-reversible one-electron oxidation. A plot of $E_{1/2}$ vs $-\log[H^+]$ is linear over the pH range 4.1–8.5, with a slope of -59.3 ± 0.7 mV, indicative of rapid acid–base equilibrium involving one proton per Cu^{II} complex. As shown in Fig. 1, the value of $E_{1/2}$ is independent of the type of buffer used.

The kinetics of the oxidation of $Cu^{II}(DMGH)_2$ by $[Cu^{III}(H_{-2}DGEN)]^+$ were investigated under pseudo-first-order conditions. With the copper(II) complex concentration being in at least ten-fold excess over that of the copper(III) complex, excellent first-order plots were obtained. The reaction showed a first-order dependence on the copper(III) complex, with the value of k_{obs} being independent of the initial concentration of the oxidant. The order of the reaction with respect to the copper(II) complex was examined by determining k_{obs} at various concentrations of $Cu^{II}(DMGH)_2$. The results in Table 1 show that k_{obs} varies linearly with copper(II) complex concentration, and is given by eq. (1):

$$k_{obs} = k_2[Cu^{II}(DMGH)_2]. \quad (1)$$

The effect of pH on the reaction rate was examined over the pH range 6.2–8.2. The results in Table 2 show that the second-order rate constant k_2 ($k_2 = k_{obs}/[Cu^{II}(DMGH)_2]$) increases with increasing pH, and a plot of k_2 vs $[H^+]^{-1}$ is linear with an intercept. The variation of k_2 with $[H^+]$ is described by eq. (2):

$$k_2 = k'_2 + k_3/[H^+]. \quad (2)$$

The values of k'_2 and k_3 were calculated from a linear least-squares analysis as $(1.95 \pm 0.49) \times 10^4$ $M^{-1}\ s^{-1}$ and $(8.58 \pm 0.11) \times 10^{-3}\ s^{-1}$, respectively, at 25.0°C and $\mu = 0.10$ M.

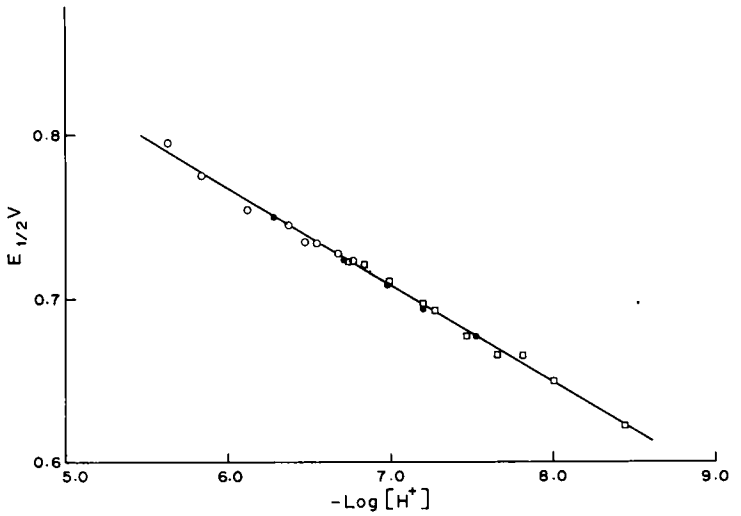

Fig. 1. $E_{1/2}$ vs $-\log[H^+]$ for $Cu^{II}(DMGH)_2$ in various buffers: MES(○), HEPES(□) and phosphate(●) at $\mu = 0.10$ M ($NaClO_4$), $T = 25.0°C$.

DISCUSSION

The disappearance of the EPR signals of the $Cu^{II}(DMGH)_2$ complex on the addition of periodate, is consistent with the formation of a diamagnetic d^8 copper(III) complex having a square-planar geometry. The cyclic voltammetry is consistent with a one-electron transfer, as indicated by peak-to-peak separations of ≈ 80 mV. The $E_{1/2}$ values of this complex are close to those obtained for the 3,9-dimethyl-4,8-diazaundeca-3,8-dien-2,10-dione-dioxime copper(II) complex under similar conditions.[18b] The dependence of $E_{1/2}$ on pH is given by eq. (3) and is consistent with the electrode reaction of eq. (4):

$$E_{1/2} = E^0_{1/2} - 0.059\,\mathrm{pH} \quad (3)$$

$$Cu^{III}(DMGH)(DMG) + H^+ + e \rightleftharpoons Cu^{II}(DMGH)_2. \quad (4)$$

A similar dependence of $E_{1/2}$ on pH has been reported for the copper(III)–imine–oxime complex.[18b] The standard electrode potential, $E^0_{1/2}$ of $Cu^{II}(DMGH)_2$ was calculated from eq. (3) as 1.12 V (vs NHE), assuming that eq. (3) holds over the entire pH region.

Bis(dimethylglyoxime)copper(II) is reported to be five-coordinated in the solid state.[25] In non-aqueous solvents it readily adds amines in the axial position and the formation constants with amines have been determined.[22] It is reasonable to assume that in aqueous solutions, an H_2O occupies an axial position. It has been reported that $Cu^{II}(DMGH)_2H_2O$ loses a proton and a pK_a of 10.6 has been estimated.[26]

It is claimed that the proton is lost from the coordinated H_2O to form the hydroxo complex, $[Cu^{II}(DMGH)_2(OH)]^-$. We have determined the pK_a value as 10.95 at 0.10 M ($NaClO_4$), which is in

Table 1. Variation of the pseudo-first-order rate constant with $Cu^{II}(DMGH)_2$ for the reaction with $[Cu^{III}(H_{-2}DGEN)]^{+a}$

$10^5[Cu^{II}(DMGH)_2]$	$10^6[[Cu^{III}(H_{-2}DGEN)]^+]$	k_{obs} (s^{-1})	$10^{-5}k_2^b$ ($M^{-1}\,s^{-1}$)
5.50	5.0	29.3±0.2	5.33
8.25	5.0	42.4±0.1	5.14
11.0	5.0	59.2±0.5	5.38
22.0	10.0	125±3.0	5.68
33.0	10.0	179±4.0	5.42
44.0	10.0	235±20	5.35

[a] At 25.0°C, $\mu = 0.10$ M ($NaClO_4$), [N-2-hydroxyethylpiperazine-N'-ethanesulphonate]$_T$ = 0.01 M, pH = 7.85.

[b] Average $k_2 = (5.38 \pm 0.24) \times 10^5\ M^{-1}\,s^{-1}$.

Table 2. Variation of the $Cu^{II}(DMGH)_2$–$[Cu^{III}(H_{-2}DGEN)]^+$ reaction with pH[a] [25.0°C, $\mu = 0.10$ M ($NaClO_4$)]

pH	k_{obs} (s^{-1})	$10^{-5}k_2$ ($M^{-1}s^{-1}$)
6.27	1.45	0.264
6.77	2.85	0.518
7.05	5.16	0.938
7.05[b]	4.90	0.980
7.27	7.81	1.42
7.34	9.49	1.73
7.39	11.40	2.07
7.45	12.04	2.19
7.54[c]	11.12	2.22
7.57[d]	147.7	2.69
7.57[e]	144.3	2.62
7.57[f]	145.9	2.65
7.58	15.88	2.89
7.71	19.10	3.47
8.06[b]	43.14	7.84
8.19	57.90	10.53

[a] Unless otherwise stated [N-2-hydroxyethylpiperazine-N′-ethanesulphonate]$_T$ = 0.01 M, $[Cu^{II}(DMGH)_2] = 5.50 \times 10^{-5}$ M, $[Cu^{III}(H_{-2}DGEN)]^+ = 5.0 \times 10^{-6}$ M.
[b] [phosphate]$_T$ = 0.01 M.
[c] $[Cu^{II}(DMGH)_2] = 5.50 \times 10^{-5}$ M.
[d] $[Cu^{II}(DMGH)_2] = 5.50 \times 10^{-4}$ M; $[Cu^{III}(H_{-2}DGEN)]^+ = 2.50 \times 10^{-5}$ M.
[e] $[Cu^{II}(DMGH)_2] = 5.50 \times 10^{-4}$ M; $[Cu^{III}(H_{-2}DGEN)]^+ = 3.6 \times 10^{-5}$ M.
[f] $[Cu^{II}(DMGH)_2] = 5.50 \times 10^{-4}$ M; $[Cu^{III}(H_{-2}DGEN)]^+ = 5.0 \times 10^{-5}$ M.

agreement with the literature value. However, we believe that the proton is lost from one of the dioxime ligands and not from the coordinated H_2O. This is based on the finding that the proton transfer reaction,

$$Cu^{II}(DMGH)_2H_2O + OH^- \rightleftharpoons [Cu^{II}(DMGH)(DMG)(H_2O)]^- + H_2O \quad (5)$$

could be measured using the pulsed-flow spectrophotometer.[27] This reaction would have been too fast to follow if the proton was abstracted from the coordinated H_2O, as the rate of this reaction would be diffusion-controlled.[28] Rate constants have been measured for the proton transfer reactions of $[Co^{III}(DMGH)_2(CN)_2]^-$ and $[Co^{III}(DMGH)_2(NH_3)_2]^+$.[29]

The kinetics of electron-transfer between $Cu^{II}(DMGH)_2H_2O$ and $[Cu^{III}(H_{-2}DGEN)]^+$ could be described by eqs (6)–(8).

$$Cu^{II}(DMGH)_2H_2O \rightleftharpoons [Cu^{II}(DMGH)(DMG)(H_2O)]^- + H^+ \quad K_a \quad (6)$$

$$Cu^{II}(DMGH)_2H_2O + [Cu^{III}(H_{-2}DGEN)]^+ \xrightarrow{k_4} Cu^{III}(DMGH)(DMG) + Cu^{II}(H_{-2}DGEN) + H_3O^+ \quad (7)$$

$$[Cu^{II}(DMGH)(DMG)(H_2O)]^- + [Cu^{III}(H_{-2}DGEN)]^+ \xrightarrow{k_5} Cu^{III}(DMGH)(DMG) + Cu^{II}(H_{-2}DGEN) + H_2O. \quad (8)$$

From the above reaction sequence [eqs (6)–(8)], the variation of the second-order rate constant, k_2, with $[H^+]$ is given by eq. (9):

$$k_2 = \frac{k_4[H^+] + k_5K_a}{K_a + [H^+]}. \quad (9)$$

Over the pH range covered in this study, $[H^+] \gg K_a$ and eq. (9) reduces to the form of eq. (10), which is similar to the experimental form of eq. (2):

$$k_2 = k_4 + k_5K_a/[H^+]. \quad (10)$$

Comparing eqs (2) and (10), it could be seen that $k'_2 = k_4$ and $k_3 = k_5K_a$. The value of k_5 is calculated as $\approx 8 \times 10^8$ $M^{-1}s^{-1}$ taking $K_a = 1.1 \times 10^{-11}$ M.

The mechanism by which the electron is transferred is not certain and both inner- and outer-sphere pathways may operate. The $[Cu^{III}(H_{-2}DGEN)]^+$ could be bridged to the protonated and unprotonated forms of the copper(II) complex via a H_2O molecule. The unprotonated copper(II) complex may also be bridged to the copper(III) complex via an oxime oxygen. An oxygen atom on the coordinated DGEN ligand may also be used as a bridging atom.

The electrode potential of the $[Cu^{III/II}(H_{-2}DGEN)]^{+/0}$ has been determined as 0.85 V vs NHE.[30] The electrode potentials of the fully protonated and completely deprotonated forms of the bis(dimethylglyoxime)copper(II) couples are unknown. It was not possible to measure these potentials because at high acid or base concentrations the copper(II) and copper(III) complexes decompose. Thus, it was not possible to apply the Marcus correlation[31] to compare the calculated and the experimental rate constants, and hence favour one mechanism over the other.

Acknowledgements—I would like to express my gratitude to Professor D. W. Margerum for making it possible for me to carry out this work in his laboratory and for providing me with the the ligand (DGEN) and other chemicals and research facilities. I would also like to

thank C. K. Murray for his help and for reading the manuscript.

STRUCTURE OF (CYANO-C)TRIS (TRIPHENYLPHOSPHITE)RHODIUM(I)

A. M. TRZECIAK,* J. J. ZIÓŁKOWSKI* and T. LIS

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 23 *January* 1989; *accepted* 14 *April* 1989)

Abstract—The crystalline complex $Rh[P(OPh)_3]_3CN$ was prepared by the reaction of $Rh[P(OPh)_3]_3Cl$ with NaCN in chloroform. The compound crystallizes from chloroform solution as a solvate of formula $RhCN[P(OPh)_3]_3 \cdot 1.5CHCl_3$. Crystals are triclinic, space group $P\bar{1}$ with $a = 11.51(1)$, $b = 10.91(1)$, $c = 24.05(2)$ Å, $\alpha = 92.25(8)$, $\beta = 97.91(8)$, $\gamma = 106.05(8)^\circ$, $U = 2865(5)$ Å^3, $Z = 2$. The rhodium atom has the square planar coordination. The ^{31}P NMR spectrum of $Rh[P(OPh)_3]_3CN$ is of the A_2BX type (A, B = ^{31}P, X = ^{103}Rh) with the same J(Rh—P) for all three phosphite ligands.

The complex $Rh[P(OPh)_3]_3CN$ was obtained for the first time by the reaction of Rh(acac)$[P(OPh)_3]_2 + P(OPh)_3 + HCN$ (acac = 1,3-dimethyl-1,3-propanedione).[1] The most interesting feature of this compound is the equivalence of all three phosphite ligands observed in the ^{31}P NMR spectrum.[1] The coupling constant J(Rh—P), of phosphoruses in *trans* and *syn* positions have almost the same values, 225.3 and 224.2 Hz, respectively. In all other complexes of the type $Rh[P(OPh)_3]_3X$, the value of J(Rh—P) of phosphorus *trans* is *ca* 60 Hz lower than that of phosphorus *cis*.[2] We have expected, that the geometry of the $Rh[P(OPh)_3]_3CN$ complex could influence its spectroscopic properties and for that reason we have started the structural investigations.

Up to now, the crystal structures of phosphite complexes with chelate ligands: Rh(acac)$[P(OPh)_3]_2$,[3] Rh(TFBA)$[P(OPh)_3]_2$[4] (TFBA = 1-phenyltrifluoromethyl-1,3-propanedione), Rh(Quin)$[P(OPh)_3]_2$[5] (Quin = 2-carboxyquinoline) and of the dimeric $(C_8H_{12})RhCl_2Rh[P(OPh)_3]_2$[6] and the cationic complex $\{Rh(C_6H_5Me)[P(OPh)_3]_2\}ClO_4$[7] were determined.

$Rh[P(OPh)_3]_3CN$ is the first example of a $Rh[P(OPh)_3]_3X$ type complex for which the crystal structure was established.

RESULTS AND DISCUSSION

The overall structure of the molecule $Rh[P(OPh)_3]_3CN$ is shown in Fig. 1, selected bond distances and bond angles are listed in Table 1.

The rhodium atom has almost square planar coordination as shown by calculations of the plane through the three phosphorus, the cyanide carbon and rhodium atoms.

The Rh—P distances in $Rh[P(OPh)_3]_3CN$, 2.266(3), 2.228(3), 2.250(3) Å are comparable with those observed in $Rh(2,4,6\text{-}Me_3C_6H_2)[P(OMe)_3]_3$.[8] In other rhodium(I) triphenylphosphite complexes, shorter Rh—P distances were found, e.g. 2.161(2), 2.150(2) Å in Rh(TFBA)$[P(OPh)_3]_2$,[4] 2.180(1), 2.188(1) Å in $\{Rh(C_6H_5Me)[P(OPh)_3]_2\}ClO_4$,[7] and 2.142 Å in $(C_8H_{12})RhCl_2Rh[P(OPh)_3]_2$.[6]

The Rh—C distance in $Rh[P(OPh)_3]_3CN$ [2.06(1) Å] is shorter than that observed in the molybdenum complex, $Mo(NO)(terpy)(CN)(HNO) \cdot 2H_2O$ [2.197(10) Å],[11] with relatively weak Mo—CN bonding. For rhodium cyano complexes no data are available. In complexes of other metals shorter M—C distances were noted, e.g. 1.931(6) Å in $Cu(N_3C_{15}H_{11})CN(NO_3) \cdot H_2O$, and 1.920(16) Å[9] in $[Pt(phen)_2(CN)]^+$.[10]

Bond distances and angles in the phosphite ligands are similar to those observed in other rhodium triphenylphosphite complexes.[3–7]

The main purpose of the X-ray investigations presented in this paper was to find the correlation

between spectroscopic and structural parameters of $Rh[P(OPh)_3]_3CN$. That correlation seems to be rather complicated. The J(Rh—P) values are independent of Rh—P distances. The coupling constants J(Rh—P) have the same values, but the Rh—P distances vary significantly. The planar structure of the $Rh[P(OPh)_3]_3CN$ seems not to be an important factor influencing the inequivalence of the phosphorus ligands. The other rhodium complexes of the type RhP_3X, e.g. $Rh(PPh_3)_3Cl$,[13] $Rh[PMe_3]_3Cl$,[14] and $Rh(2,4,6\text{-}Me_3C_6H_2)[P(OMe)_3]_3$[8] show only slight distortion from planar symmetry but the phosphorus ligands are inequivalent in the ^{31}P NMR. It is possible that the most important influence on spectroscopic properties of $Rh[P(OPh)_3]_3CN$ is the character of the CN ligand. As a strong σ donor and π acceptor, the CN ligand in a square-planar complex weakens the Rh—P bonding in the *trans* position. Therefore, the J(Rh—P) value of phosphorus in the *trans* position is lower than expected, and nearly equal to that of phosphoruses in the *cis* position to CN.

EXPERIMENTAL

Synthesis

$Rh[P(OPh)_3]_3Cl$[15] (0.051 g) in $CHCl_3$ (0.5 cm^3) and KCN (0.0032 g) in H_2O (0.3 cm^3) were mixed. Next, C_2H_5OH (1 cm^3) was added slowly under stirring. The homogeneous yellow solution was left to crystallize in a sealed flask.

Elemental analysis: Found (Calc): C 55.1 (54.8); H 3.4 (3.8); N 1.9 (1.1)%.

X-ray structure analysis

Crystal data: $C_{55}H_{45}NO_9P_3Rh \cdot 1.5CHCl_3$, $M = 1238.9$, triclinic, $a = 11.51(1)$, $b = 10.91(1)$, $c = 24.05(2)$ Å, $\alpha = 92.25(8)$, $\beta = 97.91(8)$, $\gamma = 106.05(8)°$, $U = 2865(5)$ Å^3, $Z = 2$, $D_c = 1.436(2)$ g cm^{-3}, $D_o = 1.415$ g cm^{-3}. Space group $P\bar{1}$, Cu-K_α radiation, $\lambda = 1.5418$ Å, $\mu = 56.4$ cm^{-1}.

A specimen (0.3 × 0.25 × 0.1 mm) was cut from a large crystal. A Syntex $P2_1$ diffractometer, Cu-K_α radiation and graphite monochromator were used for lattice-parameter and intensity measurements at $T = 294 \pm 2$ K. Intensities were measured by 2θ–ω scan technique. Reflections were collected in the ranges $4 < 2\theta < 50°$, $50 < 2\theta < 80°$, and $80 < 2\theta < 100°$, because the crystal suffered slow decomposition, most probably because of the loss of $CHCl_3$. The intensities of two standard reflections, which were monitored after every 50 intensities scan, decreased continually by approximately 20% over the period of the data collections. The data were scaled to the same relative scale using the intensities of the standard reflections. From 4887 measured reflections, 4538 with $I > 3\sigma(I)$ were used for structure determination. The structure was solved by the heavy atom method and refined by the blocked full-matrix least-squares technique using the *SHELX76* program.[16] The carbon-bonded H-atoms were included in geometrically calculated positions with d(C—H) = 1.08 Å. An absorption correction following the DIFABS procedure[17] applied on isotropically refined data; min and max absorption corrections were 0.813 and 1.237, respectively. Owing to the fact that there are three chloroform molecules in the unit cell, one of two crystallographically independent molecules is statistically distributed between symmetry equivalent positions near the centre of symmetry at $\frac{1}{2}$, $\frac{1}{2}$, 0. Since the interatomic distances in the statistically disordered molecule were rather unrealistic it was decided to refine this molecule as a rigid group with the same interatomic distances as in the ordered molecule. Refinement with anisotropic thermal parameters for Rh, P, Cl, O and C gave a final $R = 0.063$ and $R_w = 0.066$. The final difference Fourier synthesis showed a general background within -0.72 and 1.14 e Å^{-3}. Final atomic positions and thermal parameters and a list of F_o and F_c values have been deposited as supplementary data with the Editor from whom copies may be obtained on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

SYNTHESIS AND VIBRATIONAL (IR AND RAMAN) SPECTROSCOPIC STUDY OF TRIANGULAR THIO-COMPLEXES $[Mo_3S_{13}]^{2-}$ CONTAINING ^{92}Mo, ^{100}Mo AND ^{34}S ISOTOPES

V. P. FEDIN,* B. A. KOLESOV, YU. V. MIRONOV and V. YE. FEDOROV

Institute of Inorganic Chemistry, Siberian Branch of Academy of Sciences of the U.S.S.R., Novosibirsk, prospekt Lavrentyeva 3, 630090, U.S.S.R.

(*Received* 31 *March* 1989; *accepted* 4 *May* 1989)

Abstract—The triangular anionic thio-complex $[Mo_3S_{13}]^{2-}$ has been obtained by the reaction of the triangular molybdenum thiobromide $Mo_3S_7Br_4$ with an aqueous solution of S_x^{2-}. Starting from compounds containing ^{92}Mo, ^{100}Mo and ^{34}S isotopes, the following thio-complexes have been obtained: $[^{92}Mo_3S_{13}]^{2-}$, $[^{100}Mo_3S_{13}]^{2-}$, $[Mo_3{}^{34}S_{13}]^{2-}$, $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S^{34}S)_3(^{34}S_2)_3]^{2-}$ and $[Mo_3(\mu_3\text{-}^{34}S)(\mu_2\text{-}^{34}SS)_3(S_2)_3]^{2-}$. Along with the nucleophilic substitution of the Br ligands by the terminal S_2 ligands, elimination–addition of sulphur in μ_2-S_2 ligands also takes place. This allows preparation of thio-complexes containing μ_2-$^{34}S^{32}S$ ligands. IR and Raman spectra of the thio-complexes have been studied, normal vibrations have been calculated and the bond force constants determined.

Polynuclear and cluster thio-complexes of transition metals have been intensively studied in recent years.[1-3] These compounds contain different S_n ligands which, we believe, will play a potential role in a wide range of applications. Special attention has been given to thio-complexes of molybdenum since they are important for understanding the structure and mechanism of the action of some enzymes and catalysts. The thio-complexes are known to undergo reactions involving intramolecular oxidation–reduction, unexpected rearrangements, or insertion of some ligands into the M—S or S—S bonds. It is of great importance to understand the properties of compounds containing isotopes of sulphur at different sites. Such isotope-containing compounds are also useful in the interpretation of vibrational spectra and in the calculations of normal vibrations for obtaining force constants of the M—S and S—S bonds.

EXPERIMENTAL

Syntheses

The compounds with isotopes prepared from metallic molybdenum contain at least 95% of ^{92}Mo or ^{100}Mo isotopes, and those from elemental sulphur contain 99.95% of the ^{34}S isotope. The remaining reagents with natural isotopic abundances were of analytically pure grade.

$^{92}Mo_3S_7Br_4$, $^{100}Mo_3S_7Br_4$ and $Mo_3{}^{34}S_7Br_4$ were synthesized from the elements in evacuated ampoules made of quartz.[4] The experiments, unless otherwise stated, were carried out in air.

Preparation of the $Na_2{}^{34}S_x$ *solution*

$NaBH_4$ (1.00 g) was added to a suspension of 0.70 g of ^{34}S in 20 cm^3 of water and then the solution was boiled for 1 h until dissolution of the sulphur occurred. The solution was cooled, filtered and kept under argon.

Preparation of the $(NH_4)_2S_x$ *solution*

H_2S was passed through a suspension of 15 g of sulphur in 110 cm^3 of a 25% aqueous solution of NH_3 until complete dissolution of sulphur occurred. The solution was then kept under argon.

Preparation of $(NH_4)_2[Mo_3{}^{34}S_{13}]\cdot 2H_2O$

$Mo_3{}^{34}S_7Br_4$ (50 mg) and 5 cm^3 of a solution of $Na_2{}^{34}S_x$ were boiled for 30 min. Then NH_4Br (50 mg) was added and the solution was cooled. The

* Author to whom correspondence should be addressed.

precipitate was washed with water, alcohol, boiling benzene and dried *in vacuo*. Yield: 41 mg.

Similarly $(NH_4)_2Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S^{34}S)_3(^{34}S_2)_3\cdot 2H_2O$ was prepared from $Mo_3S_7Br_4$ and $Na_2{}^{34}S_x$.

Preparation of $(NH_4)_2Mo_3(\mu_3\text{-}^{34}S)(\mu_2\text{-}^{34}SS)_3(S_2)_3\cdot 2H_2O$

$Mo_3{}^{34}S_7Br_4$ (50 mg) and 5 cm^3 of a solution of $(NH_4)_2S_x$ were boiled for 2 h and the resulting precipitate was treated as described above. Yield: 39 mg.

Similarly, $(NH_4)_2[^{92}Mo_3S_{13}]\cdot 2H_2O$ and $(NH_4)_2(^{100}Mo_3S_{13})\cdot 2H_2O$ were obtained from $^{92}Mo_3S_7Br_4$ and $^{100}Mo_3S_7Br_4$.

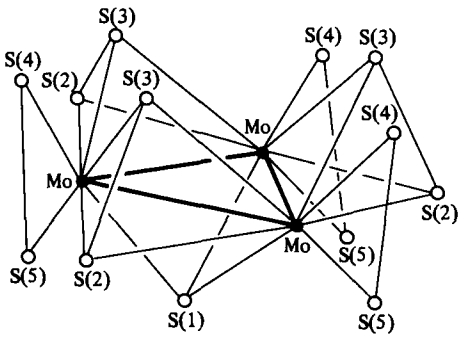
Physical measurements

The IR spectra were recorded on a IFS-113 Fourier spectrometer (Bruker) in polyethylene. The Raman spectra were obtained with a DFS-24 instrument using excitation by the 632.7 nm line of a He–Ne laser at 77 K.

RESULTS AND DISCUSSION

Syntheses of isotope-containing compounds

Müller and co-workers[5] obtained red crystals of the triangular $(NH_4)_2[Mo_3S_{13}]\cdot 2H_2O$ thio-complex by heating ammonium paramolybdate in an aqueous solution of ammonium polysulphide in air. According to the X-ray diffraction analysis[5] the $[Mo_3S_{13}]^{2-}$ cluster anion contains a μ_3-S(1) ligand, the rest of the sulphur atoms occurring as S_2 ligands: $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3(S_2)_3]^{2-}$ (see Structure 1). The bridging disulphide ligands of the $[Mo_3S_7]^{4+}$ cluster are arranged so that three sulphur atoms lie in the Mo_3 plane (equatorial S(2) atoms), while the other three point in the direction opposite to μ_3-S(1) (axial S(3) atoms). This complex is very convenient to study differences in the reactivity of S_2 ligands depending on the mode of coordination.



Structure 1.

Earlier, the triangular thio-halide complexes of molybdenum, $Mo_3S_7X_4$ (X = Cl, Br), were shown to react with ammonium polysulphide in water to produce almost quantitatively a triangular thio-complex:[6,7]

$$Mo_3S_7X_4 \xrightarrow{(NH_4)_2S_x+H_2O} (NH_4)_2[Mo_2S_{13}]\cdot 2H_2O. \quad (1)$$
(1)

In the present work this approach has been used to synthesize isotope-containing compounds using the following reactions:

$$^{92}Mo_3S_7Br_4 \xrightarrow{(NH_4)_2S_x+H_2O} [^{92}Mo_3S_{13}]^{2-} \quad (2)$$
(2)

$$^{100}Mo_3S_7Br_4 \xrightarrow{(NH_4)_2S_x+H_2O} [^{100}Mo_3S_{13}]^{2-} \quad (3)$$
(3)

$$Mo_3{}^{34}S_7Br_4 \xrightarrow{Na_2{}^{34}S_x+H_2O} [Mo_3{}^{34}S_{13}]^{2-} \quad (4)$$
(4)

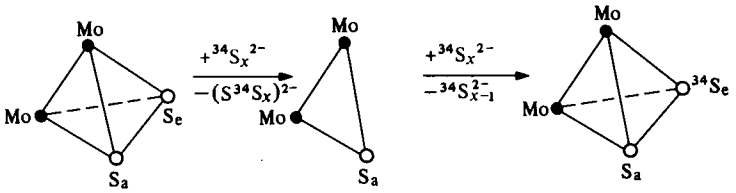
$$Mo_3{}^{34}S_7Br_4 \xrightarrow{(NH_4)_2S_x+H_2O} [Mo_3(\mu_3\text{-}^{34}S)(\mu_2\text{-}^{34}S_aS_e)_3(S_2)_3]^{2-} \quad (5)$$
(5)

$$Mo_3S_7Br_4 \xrightarrow{Na_2{}^{34}S_x+H_2O} [Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_a{}^{34}S_e)_3(^{34}S_2)_3]^{2-}. \quad (6)$$
(6)

In order to avoid losses of the ^{34}S isotope a solution of $Na_2{}^{34}S_x$ and not $(NH_4)_2{}^{34}S_x$ was prepared by the reaction:

$$x^{34}S + 4NaBH_4 + 7H_2O \longrightarrow Na_2S_x + Na_2B_4O_7 + 15H_2. \quad (7)$$

An aqueous solution of sodium polysulphide reacts with $Mo_3S_7Br_4$ similarly to the $(NH_4)_2S_x$ solution. The sodium salt of $[Mo_3S_{13}]^{2-}$ is readily soluble in water, but solid ammonium salts are obtained in high yield by adding a solution of NH_4Br. Reactions (5) and (6) are the most interesting ones. These reactions produced triangular anionic thio-complexes of molybdenum-containing μ_2-(^{34}S-S) ligands. Due to the use of isotope-containing compounds it was found that the reaction proceeds through elimination–addition of the equatorial sulphur atoms of the μ_2-S_2 ligands according to the following sequence:



Scheme 1.

Under the influence of the S_x^{2-} nucleophile, elimination of the S_e atom takes place first and then addition of the S_x^{2-} sulphur atoms to the μ_2-S_a ligands occurs. Such types of elimination reactions have been described in the literature. It was observed that the $[Mo_3S_7]^{4+}$ compounds are transformed to the $[Mo_3S_4]^{4+}$ complexes.[8-12] It is interesting to note the following example of mutual transformations of the $[Mo_3S_7]^{4+}$ and $[Mo_3S_4]^{4+}$ complexes:[12]

$$[Mo_3S_4(SCH_2CH_2S)_3]^{2-} \underset{Ph_3P,\,CN^-}{\overset{S_8}{\rightleftharpoons}} [Mo_3S_7(SCH_2CH_2S)_3]^{2-}. \quad (8)$$

In reactions (5) and (6) the ratio $Mo_3S_7Br_4/S_x^{2-}$ is greater than 1/50, and the isotopic substitution in the μ_2-S_2 ligands proceeds in good yield. According to vibrational spectroscopy data the $(NH_4)_2[Mo_3{}^{34}S_{13}]\cdot 2H_2O$ thio-complex was not observed, at 20 or 90°C, to undergo isotopic exchange with the $(NH_4)_2S_x$ solution within 1 h. The thiobromide complex, $Mo_3S_7Br_4$, also did not interact with $Na_2{}^{34}S_x$ at room temperature over 6 h.

Thus, in the reaction of S_x^{2-} with $Mo_3S_7X_4$ the cluster fragment $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S)_3]^{4+}$ is retained and two processes occur: (a) nucleophilic substitution of X^- by S_2^{2-} and (b) elimination–addition of sulphur at the axial site of the μ_2-S_2 ligand.

Vibrational spectra

The point group symmetry of the $[Mo_3S_{13}]^{2-}$ molecule is C_{3v}, its vibrational representation has the form:

$$\Gamma = 10A_1(\text{IR, Raman}) + 4A_2 + 14E(\text{IR, Raman}).$$

Calculations of the vibrational spectrum were performed within the approximation of the valence force field using the programs of Gribov and Dementjev.[13] The zero approximation of the diagonal constants has been taken from Kolesov *et al.*[14] Experimental frequencies below 200 cm^{-1} were not included in the calculation because of the strong mixing of external and internal vibrations. The final variant of the force field is shown in Table 1, where only the main bond force constants are listed. The observed vibrational frequencies together with the experimental and calculated isotopic shifts at a given force field are listed in Table 2. The calculated normal vibrations are shown in Table 3 as distributions of the potential energy amongst the groups of equivalent vibrational coordinates. Since Table 3 shows contributions of separate groups of coordinates to the overall vibration and not the shift of atoms in the coordinate space, there is no direct connection between the value of the isotopic shift of the frequencies and their contributions. For the IR and Raman spectra see Müller *et al.*[15]

Table 1. Stretching force constants in the $[Mo_3S_{13}]^{2-}$ complex

Bond	f (mdyn $Å^{-1}$)
Mo—Mo	1.2
Mo—S(1)	1.8
Mo—S(2)	1.5
Mo—S(3)	1.7
Mo—S(4)	1.7
Mo—S(5)	1.5
S(2)—S(3)	2.3
S(4)—S(5)	2.1

The ~ 200 cm^{-1} region mainly contains the Mo—Mo vibrations, but due to the above mentioned strong mixing of internal and external (translations and librations) vibrational frequencies the correct determination of the Mo—Mo force constant is difficult.

The 462 cm^{-1} frequency has medium intensity in both the IR and Raman spectra and is one of the most characteristic bands. This frequency belongs to the μ_3-S(1) vibration and from its shift it is easy to follow the conversion of μ_3-^{32}S to μ_3-^{34}S. The force constant of Mo—μ_3-S(1) bonds exceeds those of the other Mo—S bonds. The vibrations of the Mo—S_{br} [S_{br} = S(2), S(3)] and Mo—S_t [S_t = S(4), S(5)] bonds are not characteristic to such an extent as to permit detection of the corresponding lines in the spectrum, as was the case of Mo—μ_3-S and $(S—S)_{br}$, $(S—S)_t$ vibrations. The data in Table 3 indicate, nevertheless, that the Mo—S_t vibrations occur predominantly at 270–350 cm^{-1}. The force

constants of the Mo—S_{br} bonds are similar to those of Mo—S_t.

The bridging and the terminal S_2 ligands are six- and two-electron donor ligands, respectively, but this difference in coordination does not affect the S—S bond lengths significantly but, according to our data, there are differences in the force constants, f(S—S)$_t$ and f(S—S)$_{br}$, of the bonds. The 552 and 541 cm^{-1} frequencies are predominantly the valence vibrations of the μ_2-(S—S) ligands; the 513 and 506 cm^{-1} frequencies belong to the terminal S_2. On going from the ^{32}S to ^{34}S compounds these bands undergo shifts which are comparable to the greatest possible for a S_2 molecule. Noteworthy are the sharp differences in the Raman line intensities belonging to the S—S vibrations. Scattering in (S—S)$_t$ bond vibrations is many times weaker than in (S—S)$_{br}$. At the same time the IR absorption at the (S—S)$_t$ frequency is even more intense than that at (S—S)$_{br}$. This may be due to the asymmetry of the charge distribution in the (S—S)$_t$ pair.

It should be noted also that agreement between

the theoretical and experimental spectra for **5** and **6** is better when the exchange is assumed to occur at the equatorial sulphur atoms of the μ_2-S_2 ligands.

The results of the reactions of isotopically-substituted triangular $[Mo_3S_{13}]^{2-}$ with HCl to give the triangular thiochloride complex $[Mo_3S_7Cl_6]^{2-}$ will be the subject of a later communication.

THE CRYSTAL AND MOLECULAR STRUCTURE OF BROMO (η^5-PENTAPHENYLCYCLOPENTADIENYL)DICARBONYLIRON(II), $Fe(C_5Ph_5)(CO)_2Br$

L. D. FIELD, T. W. HAMBLEY, C. M. LINDALL and A. F. MASTERS*

Departments of Inorganic and Organic Chemistry, University of Sydney, NSW 2006, Australia

(*Received* 30 *March* 1989; *accepted* 18 *May* 1989)

Abstract—The preparation and characterization of $Fe(C_5Ph_5)(CO)_2Br$ by single crystal X-ray diffraction [refined to $R = 0.036$, $R_w = 0.039$ with 2974 data having $I \geqslant 2.5\sigma(I)$] are reported. The compound crystallizes from dichloromethane–hexane as discrete molecules in the orthorhombic space group *Pcab*, with $a = 14.503(5)$, $b = 18.015(2)$, $c = 21.873(6)$ Å, $U = 5715(1)$ Å^3 and $Z = 8$. The cyclopentadienyl ring is planar to within 0.01 Å, the Fe—C(C_5 ring) bond distances average 2.125(4) Å, the Fe—(C_5 ring plane) distance is 1.738(5) Å and the Fe—Br bond distance is 2.424(1) Å. Two Fe—C(CO) bond distances of 1.812(5) and 1.786(5) Å were observed. The phenyl substituents are canted relative to the cyclopentadienyl frame at between 49.1 and 142.8°.

Considerable effort has been devoted to the study of ring substituted cyclopentadienyl ligands as a means of conferring additional stability, solubility, different reactivity pathways or altered steric or electronic properties upon organometallic centres. We have been interested in the potential of the pentaphenylcyclopentadienyl ligand as a means of modifying and controlling the steric and electronic environments of transition metal organometallic fragments. In fact, isolated examples of complexes of the $C_5Ph_5^-$ ligand exhibiting structural and electronic differences from their $C_5H_5^-$ and $C_5Me_5^-$ analogues have already been described. Thus, the recent report of parallel C_5 rings in decaphenylstannocene provides a striking example of the steric effect of this ligand.[1] Conversely, the potential of ligand effects on the metal electron distribution is exemplified by the contrast between $Ni(C_5Ph_5)_2$ which is diamagnetic,[2] and $Nicp_2$, which has two unpaired electrons.[3,4]

The pentaphenylcyclopentadienyl anion is an attractive ligand, as its precursors are readily synthesized in large quantities and are air stable. The ligand precursors were first reported in 1925.[5] The $C_5Ph_5^-$ ligand appears to be more electron-withdrawing than the η^5-Cp^- and η^5-$Me_5C_5^-$ anions,[6] and its large volume is reported to confer enhanced kinetic stability to organometallic derivatives.[6] The title complex, $Fe(C_5Ph_5)(CO)_2Br$, was amongst the first reported organometallic derivatives of the ligand.[7] However, surprisingly few complexes of the $C_5Ph_5^-$ anion have been reported, and structural data is scarce,[1,8–10] with only one structure of a transition metal derivative having been reported.

In any assessment of the steric directing properties of the ligand, it is important to obtain benchmark data on a relatively sterically unencumbered system. $Fe(C_5Ph_5)(CO)_2Br$ is readily synthesized, is the only reported $C_5Ph_5^-$ derivative of iron, should seemingly be relatively sterically unencumbered, and although first prepared in 1965, has defied structural characterization. Accordingly, we report here the results of a single crystal X-ray crystallographic study of $Fe(C_5Ph_5)(CO)_2Br$.

RESULTS AND DISCUSSION

The structure of $Fe(L)(CO)_2Br$ consists of discrete molecules, each with a "piano stool" environment about the iron. Final atomic positional coor-

dinates, with estimated standard deviations, bond lengths and angles and anisotropic thermal parameters are deposited.* Selected interatomic bond distances and angles, with standard deviations derived from the refinement, and selected intramolecular non-bonded distances are given in Tables 1–3. The atomic nomenclature is defined in Fig. 1. Figures 1 and 2 illustrate the molecular geometry viewed along, and perpendicular to, the normal to the C_5 plane of the $C_5Ph_5^-$ ligand, respectively.

No intermolecular contacts of significance were observed in the solid, the closest intermolecular non-bonding approach between molecules being 2.69 Å between H(24) on molecule (x, y, z) and O(1) on molecule ($\frac{1}{2}+x$, $-y$, $1\frac{1}{2}-z$). The closest intermolecular non-bonding approaches to iron on molecule (x, y, z) are greater than 4.5 Å. The other close intermolecular contacts to molecule (x, y, z) are given in Table 3.

The iron environment

The iron environment in $cpFeL_2L_2L_3$ ($cp = C_5H_5^-$) derivatives of this type has been described as a distorted tetrahedron derived from an octahedron by the collapse of three facial points.[11] A pseudo-octahedral description of the present compound is consistent with the angles subtended at the iron atom by the bromine atom and the two carbonyl carbon atoms. In these $cpFeL_1L_2L_3$ derivatives, the three angles between Fe, L_1, L_2 and L_3 are generally found to be somewhat greater than 90°. The CO—Fe—CO and Br—Fe—CO angles of the title compound are all relatively acute and probably reflect the strong steric interactions between the pentaphenylcyclopentadienyl anion and the other ligands in the molecule.

The Fe—C(cp) and Fe—(ring centroid) [or Fe—(plane of C_5 ring)] distances of cpFe derivatives have been noted to fall into two groups.[11] Substantially undistorted $Fecp_2$ derivatives have Fe—C(cp) distances of approximately 2.04 Å, and Fe—(ring centroid) distances of between 1.645 and 1.66 Å. These features are exemplified by the structures of ferrocene,[12–15] 1,1,1,1,1-pentamethylferrocene,[16] decamethylferrocene,[17] bis(ferrocenyl)[18] and most clearly by a series of recently published ferrocenophane structures.[19,20] In contrast, cp $FeL_1L_2L_3$ derivatives generally have longer Fe—C (cp) (~2.10 Å) and Fe—(ring centroid) (~1.74 Å) distances which are said to reflect the ability of L_1, L_2 and L_3 to compete for the iron electrons.[11,21] The somewhat shorter Fe—C(cp) and Fe—(ring centroid) distances in the $[cpFe(CO)_3]^+$,[21] $[cpFe(CO)(CNMe)_2]^+$[22] and $[cpFe(CO)_2(CNMe)]^+$[23] cations are thought to reflect the positive charges on these ions.[11]

In the present case, the values of Fe—C(cp) [2.125(4) Å] and Fe—(plane of C_5 ring) [1.738(5) Å] are slightly towards the high end of the range for $cpFeL_1L_2L_3$ derivatives. These are small effects, but are consistent with the $C_5Ph_5^-$ ligand exerting a steric influence.

The distances between the iron and the nearer *ortho*-carbon atoms of the phenyl rings were found to vary between 3.42 and 3.77 Å.

The two Fe—CO distances in the present compound are just mathematically significantly different. The Fe—C(2)O distance is within, but at the long end of, the range observed for $cpFeL_1L_2L_3$ derivatives, whereas the Fe—C(1)O distance is equalled only by that in the $[cpFe(CO)_3]^+$ cation,[21] in which the long Fe—CO and short CO bonds were attributed to the decreased electron density of the cation. The C≡O bonds of the present compound are both extremely short, by comparison with those of $cpFeL_1L_2L_3$ derivatives. The C(1)≡O(1) bond is significantly shorter than the C(2)≡O(2) bond, consistent with the longer Fe—C(1)O bond. An elongation of Fe—CO bonds would be consistent with either steric or electronic influences of the $C_5Ph_5^-$ ligand. However, it is difficult to rationalize the different Fe—CO bond lengths within $Fe(C_5Ph_5)(CO)_2Br$ on electronic grounds. The different Fe—CO distances are probably a consequence of differing steric interactions with nearby phenyl rings. Thus, C(1) (which is involved in the longer Fe—CO bond) has two close contacts with the *ortho*-carbons of the surrounding

* The atomic coordinates and thermal parameters have been submitted as supplementary material for deposition at the Cambridge Crystallographic Data Centre (see Deposition of crystallographic data).

phenyl rings [3.33 Å to C(31), and 3.29 Å to C(21)], whereas C(2) (which is involved in the shorter Fe—CO bond) has only one such close contact [3.12 Å to C(15)]. The corresponding C(CO) to phenyl-H contacts are less than the sum of the van der Waals' radii (Table 3).

The pentaphenylcyclopentadienyl ligand

The C_5 nucleus of this ligand is planar to within 0.01 Å. All of the C—C bond lengths of the C_5 nucleus are equal within experimental error, but that bisected by the projection of the Fe—C(1)≡O bond is apparently slightly elongated. A similar effect has been noted in the molecular structure of $(C_5Ph_5)_2Co(CO)_2$, but was also beyond mathematical significance.[8] The average C—C bond length within the C_5 ring of 1.435(5) Å is greater than those in the C_5H_5 rings of ferrocene (1.389 Å)[13] and $Fe(cp)(C_5Me_5)$ (1.399(6) Å),[16] but close to those in $cpFeL_1L_2L_3$ derivatives, in the C_5Me_5 rings of $Fe(cp)(C_5Me_5)$ (1.408(6) Å)[16] and $Fe(C_5Me_5)_2$ (1.419(2) Å)[17] and in $(C_5Ph_5)_2Co(CO)_2$ (1.44(1) Å).[8] The bond angles within the C_5 ring are equal within experimental error and are normal for the C_5 rings of cyclopentadienyl and substituted cyclopentadienyl derivatives. The iron atom is displaced slightly from the projection of the centroid of the pentaphenylcyclopentadienyl ring. The *ipso*-carbon atoms of each of the phenyl rings are located above the C_5 plane by from 0.05 to 0.23 Å, with the average distance being 0.15 Å. This configuration is similar to that in $(C_5Ph_5)Co(CO)_2$.[8] Similarly, the methyl groups of $Fe(C_5Me_5)(cp)$[16] and of $Fe(C_5Me_5)_2$[17] lie above the C_5 ring plane, away from the iron. In contrast, the C_5H_5 hydrogens of $Fe(cp)_2$[12-15] and $Fe(C_5Me_5)(cp)$[16] are displaced slightly towards the iron. The phenyl rings are all also planar with normal dimensions, and are oriented at between 49.09 and 142.84° to the cyclopentadienyl C_5 frame. The phenyl ring defined by C(26) is almost perpendicular to the C_5 ring. The average deviation of the phenyl rings from coplanarity with the C_5 ring is 58.7°, which is similar to that in $(C_5Ph_5)Co(CO)_2$ (55.8°).[8] Clearly, extensive charge delocalization onto all the phenyl rings is unlikely.

Table 3. Selected non-bonded approaches (Å) to $Fe(C_5Ph_5)(CO)_2Br$ at (x, y, z)

Atoms	d (Å)	Atoms	d (Å)
C(1)···H(31)^{i}	2.66	C(1)···H(21)^{i}	2.98
C(2)···H(15)^{i}	2.71	H(24)···O(1)^{ii}	2.69
H(27)···Br(1)^{iii}	3.15		

The superscripts refer to the following transformations: i (x, y, z); ii ($\frac{1}{2}+x$, $-y$, $1\frac{1}{2}-z$); iii ($\frac{1}{2}+x$, $\frac{1}{2}-y$, z).

The pentaphenylcyclopentadienyl ring of $(C_5Ph_5)Ru(CO)_2Br$ is reported to have C—C bond distances of 1.241(8), 1.454(9), 1.266(8), 1.326(8) and 1.426(9) Å, and CCC angles of 106.9, 113.6, 110.8, 115.1 and 103.5°.[10] These values differ significantly from those of the present study.

Thus, the gross effects of the pentaphenyl-

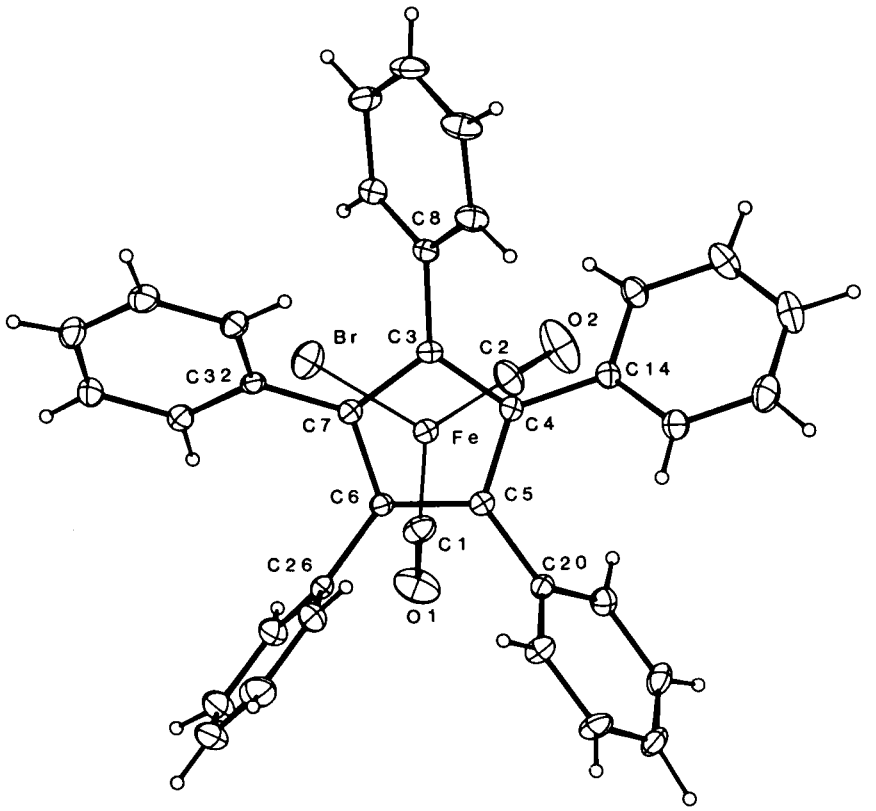

Fig. 1. ORTEP (50% probability) illustration of the molecular structure of $Fe(C_5Ph_5)(CO)_2Br$ showing the atom numbering. Viewed along the normal to the C_5Ph_5 plane.

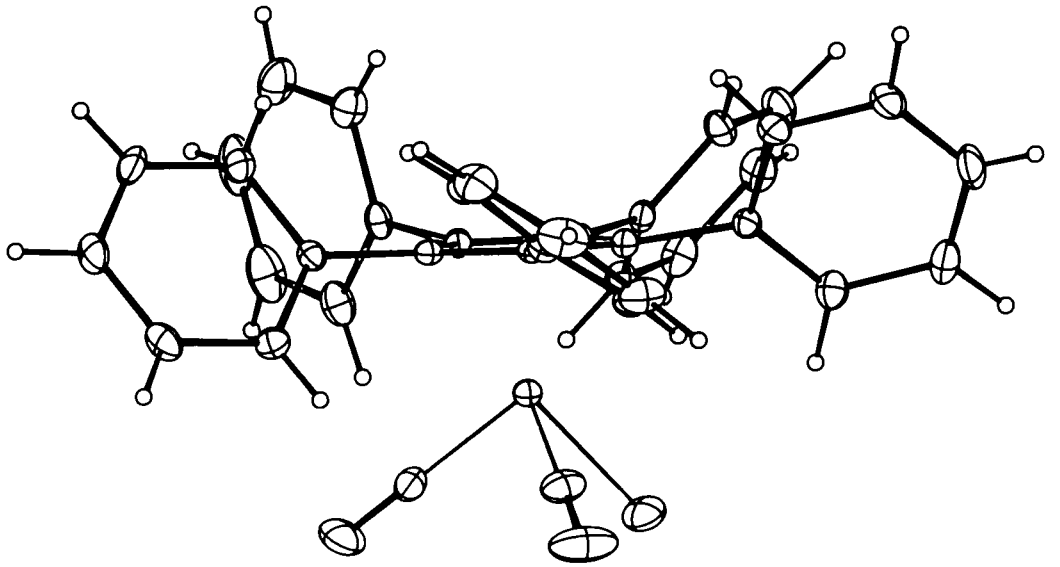

Fig. 2. ORTEP (50% probability) illustration of the molecular structure of $Fe(C_5Ph_5)(CO)_2Br$ viewed perpendicular to the normal to the C_5Ph_5 plane.

cyclopentadienyl ligand in $Fe(C_5Ph_5)(CO)_2Br$ are consistent with those of $cpFeL_1L_2L_3$ compounds. No electronic effect of the ligand on the structure can be detected. However, the ligand can be seen to exert significant steric pressures, even on the relatively sterically undemanding $Fe(CO)_2Br$ fragment.

EXPERIMENTAL

All synthetic manipulations were carried out under an inert atmosphere (nitrogen or argon). Benzene and *n*-hexane were distilled from sodium wire. Dichloromethane was distilled from phosphorus pentoxide. Pentacarbonyliron (Aldrich) was used as received. Pentaphenyl-2,4-cyclopentadienylbromide, C_5Ph_5Br, was prepared from tetracyclone.[6]

Preparation of bromo(η^5-pentaphenylcyclopentadienyl)dicarbonyliron(II)

Freshly distilled benzene (75 cm^3) was added to degassed pentaphenyl-2,4-cyclopentadienylbromide (1.0 g, 1.91 mmol) to give an orange solution. Iron pentacarbonyl (0.45 g, 2.28 mmol) was added via syringe. The solution immediately became red, and was left to stir for 24 h at room temperature. The solvent was removed and the product extracted into dichloromethane (30 cm^3). *n*-Hexane (15 cm^3) was added to precipitate unreacted pentaphenyl-2,4-cyclopentadienylbromide. The suspension was filtered and the solid washed with *n*-hexane (10 cm^3). The filtrate and *n*-hexane washings were allowed to stand overnight to yield dark red–purple crystals (0.45 g, 37%).

Structure determination

Cell constants were determined by a least-squares fit to the setting parameters of 25 independent reflections. Data were measured on an Enraf–Nonius CAD4-F diffractometer within the limit $2\theta_{max.} = 50°$, with Mo-K_α radiation, $\lambda = 0.71069$ Å, graphite monochromator, and operating in the ω–1.33θ mode. Data were reduced and Lorentz, polarization and decomposition corrections were applied using a local data reduction program. The structure was solved by Patterson and Fourier synthesis techniques, and was refined by full-matrix least-squares analysis with SHELX-76.[24] All non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were refined with isotropic thermal parameters. Scattering factors and anomalous dispersion corrections for iron were taken from the *International Tables for X-ray Crystallography*,[25] and for all others the values supplied in SHELX-76 were used. Absorption correction was by numerical integration.[26] Listings of atom coordinates, anisotropic thermal parameters, details of least-squares planes calculations and observed and calculated structure factor amplitudes have been deposited. Figures were drawn using the program ORTEP.[27]

Crystal data

$C_{37}H_{25}BrFeO_2$, $M = 637.4$, orthorhombic, space group, *Pcab*, $a = 14.503(5)$, $b = 18.015(2)$, $c = 21.873(6)$ Å, $U = 5715(1)$ Å^3, D_c ($Z = 8$) = 1.481 g cm^{-3}, $F(000) = 2592$, μ(Mo-K_α) = 19.02 cm^{-1}. Specimen: dark red brown prisms, $0.25 \times 0.20 \times 0.28$ mm. $N = 5739$, $N_0 = 2974$, range of *hkl* $0 \rightarrow 17$, $0 \rightarrow 21$, $0 \rightarrow 26$, merging $R = 0.01$, $R = 0.036$, $R_w = 0.039$, residual extrema ± 0.4 e Å^{-3}.

A NEW DEFINITION OF COORDINATION NUMBER AND ITS USE IN LANTHANIDE AND ACTINIDE COORDINATION AND ORGANOMETALLIC CHEMISTRY*

JOAQUIM MARÇALO† and ANTÓNIO PIRES DE MATOS

Departamento de Química, ICEN, LNETI, P-2686 Sacavém Codex, Portugal

(*Received* 13 *January* 1989; *accepted* 18 *May* 1989)

Abstract—A *steric coordination number* of a ligand is defined, based on the solid angle comprising the van der Waals' spheres of the atoms of that ligand, as an alternative to the *formal coordination number* in discussing structural aspects of lanthanide and actinide coordination and organometallic compounds. The study of the bond lengths in 274 structurally characterized compounds of the lanthanides (including Sc and Y), in oxidation states II and III, and the actinides (Th and U), in oxidation states III and IV, was the basis to derive *ligand effective radii* which are discussed in relation to bonding, coordination geometries, metal ionic radii and oxidation states. Potential uses of the new definition of coordination number and of the ligand effective radii obtained in molecular structure comparison and bond length prediction are also discussed.

COORDINATION NUMBER—THE VARIOUS DEFINITIONS

Werner's "secondary valence" introduced one of the most important concepts of coordination chemistry, that of *coordination number* (CN), later defined as the number of donor atoms associated with the central atom in a compound.[1]

In crystal chemistry the CN has been equally important and usually identified with the number of "nearest-neighbours" of a given central atom in a crystal. Rigorous definitions of CN in this field have been proposed by several authors to overcome the uncertainty in choosing the appropriate number of "nearest-neighbours".[2]

With the advent of *d*-transition metal organometallic chemistry, a new definition emerged to account for a whole new class of ligands and to be consistent with the 18-electron rule: this is the *formal coordination number* (CN_F)—the number of electron pairs involved in ligand-to-metal coordination.[3]

In *f*-transition element compounds bonding is generally considered highly ionic in character and a unifying principle such as the 18-electron rule is lacking. The number, size and shape of the ligands are then major factors determining the structural features of lanthanide (Ln) and actinide (An) compounds, and a definition of CN based on geometrical principles appears to be more adequate than the CN_F.

A NEW DEFINITION OF COORDINATION NUMBER

Here we define the *steric coordination number* (CN_S) of a ligand in a series of compounds, as the ratio of the solid angle comprising the van der Waals' spheres of the atoms of that ligand and the solid angle of a common ligand like chlorine, when placed at typical mean distances from the central metal atom.

With this definition we can build up a catalogue of ligand's CN_S and use them to obtain the CN_S of a compound. In Table 1 we can find the CN_S's of selected ligands, with solid angles computed either analytically or numerically‡ using Bondi's van der

* Presented in part at the XXVI International Conference on Coordination Chemistry, Porto, Portugal, 28 August–2 September 1988.

† Author to whom correspondence should be addressed.

‡ The solid angles considered in this work are the "real" geometrical solid angles which correspond to the areas defined on a unit sphere centred on the metal atom by the cones comprising the van der Waals spheres of the atoms of a ligand. The areas, which have different shapes according to the ligand, can be straightforwardly calculated either by numerical integration (using a simple BASIC program developed by J. P. Leal of our Department) or analytically, by partitioning the surfaces in spherical segments and spherical triangles whose areas can be easily calculated.

Waals' radii,[4] average metal–ligand distances (for Ln and An) and typical geometries of the ligands. The main sources of error in the values of Table 1 are, on one hand, the van der Waals' radii, which having been derived from intermolecular contacts may not be adequate for intramolecular contacts, and, more importantly, the geometries of the ligands which, in the individual structures may present different bendings, tiltings, etc.

The CN_S value defined here is related to other solid angle-based ligand steric parameters, like Tolman's cone angles,[5] extensively used in *d*-transi-

tion metal phosphine chemistry, in the original or modified versions,[6] or Bagnall and Li Xing-fu's solid angle factors,[7] used with some success in discussing stability, stereochemistry and reactivity of Ln and An compounds. Other solid angle approaches to steric effects were made by several authors and include organic reactivity,[8] the stereochemistry of Sn[9] and Th[10] complexes, stability of transition element compounds[11] and cluster chemistry.[12]

THE STERIC COORDINATION NUMBER AND *f*-TRANSITION ELEMENT CHEMISTRY

Ligand effective radii—CN_F *versus* CN_S

In this paper we are interested in using our definition of CN to discuss and extend Raymond's structural model for the bonding in organolanthanide and -actinide compounds.[13] In his approach, based on the CN_F, Raymond obtained linear correlations between different metal–ligand distances (namely Cp^-, COT^{2-} and $N(SiMe_3)_2^-$) and ionic radii for the metal ions taken from the widely used Shannon's table of ionic radii,[14] concluding that an ionic model was adequate to describe the bonding in *f*-transition element compounds.

The same approach was later used by Edelstein to study metal borohydride complexes[15] although, in this case, some doubts could arise regarding the CN_F values adopted for bidentate and tridentate BH_4^-.

Several other authors have used Raymond's approach, namely Deacon *et al.* in discussing the structures of Ln complexes containing oxygen- or nitrogen-donor ligands.[17]

Since the publication of Raymond's paper, *f*-transition element chemistry has grown impressively from about four dozen structurally characterized Ln and An organo compounds to a few hundred structures on which the same type of analysis can be performed.

In the following discussion we considered 274 structurally characterized Ln (including Sc and Y) and An (Th and U) coordination and organometallic compounds. The analysis is by no means exhaustive: uranyl compounds were not included, oligomeric or polymeric compounds were not considered except those involving bridging borohydride ligands, and compounds containing less-common ligands were also excluded. This left us with 16 Ln^{II}, 99 Ln^{III}, 15 An^{III} and 144 An^{IV} compounds, covering a wide range of coordination geometries.

In spite of the large number of complexes studied, there was a special incidence of U compounds (46%) and a good span of ionic radii was not obtained, so, in most of the cases, good linear relationships of metal–ligand distances vs metal ionic radius could not be observed. Nevertheless, better correlations were obtained when using the ionic radii derived from the CN_S. This led us to focus our discussion on *ligand effective radii* (R_{EF}), checking on the constancy and consistency of the values produced using CN_F and CN_S.

The ligand effective radii are presented in Table 2 and were calculated in the following way:

(a) Determination of CN_F and CN_S (from Table 1) for a given complex.

(b) Direct interpolation or extrapolation of metal ionic radii (R_i) from Shannon's table[14] (or David's table[18] for Th^{III} and U^{III} in CN 8) for the CN's determined in (a) (Shannon's ionic radii, in the range of CN 6–9, that include the great majority of CN_F and CN_S of the compounds considered in this study, can be fitted with linear equations, for each metal and oxidation state, with correlation coefficients better than 0.99; Pauling's equation for the dependence of ionic radii on CN used by Raymond[13] gives values that are not consistent with Shannon's values; some of the correlations of metal–ligand distances and ionic radii in Raymond's paper might have been affected by using this procedure).

(c) When two or more identical ligands are coordinated, an average metal–ligand bond length d_{M-L} is obtained from the molecular structure of the compound.

(d) Calculation of $R_{EF} = d_{M-L} - R_i$ for each complex and each CN used (formal or steric).

(e) Determination of the arithmetic mean of R_{EF} for each type of ligand; the values in parentheses are the sample standard deviations.*

From the values in Table 2 it is clear that for most of the ligands considered the R_{EF}'s obtained using the CN_F have larger standard deviations, indicating a wider spread of the individual R_{EF}'s. For instance, for L = alkyl, $(R_{EF})_F$ range from 1.34 Å in $UCp_3(^nBu)$[19] to 1.63 Å in $YbCl[CH(SiMe_3)_2]_3^-$,[20] while $(R_{EF})_S$ for the same complexes are 1.46 and 1.41 Å, respectively; another example is NPh_2^- for which $(R_{EF})_F$ is 1.50 Å in $U(NPh_2)_4$[21] and 1.20 Å in $UCp_3(NPh_2)$,[22] while $(R_{EF})_S$ are 1.32 and 1.30 Å,

* A more rigorous determination of the mean R_{EF}'s could be made considering all independent bond lengths in the different structures weighted by the corresponding standard deviations, so that the more accurately determined bond lengths have a larger weight. However, for the general purpose of this work, the simpler procedure followed above is quite reasonable.

respectively, in the same compounds. Other significant examples could be given, indicating the difficulties of the formal CN approach for dealing with sterically demanding ligands, especially those that formally donate one electron pair [e.g. $N(SiMe_3)_2^-$, NPh_2^-, OPh-2,6-$^tBu_2^-$, $CH(SiMe_3)_2^-$].

Another aspect which is apparent from Table 2 is that the R_{EF} values derived from the CN_S have a relative ordering which is in closer agreement with what is expected from the sizes and bonding capabilities of the different coordinating atoms (e.g. $(R_{EF})_F$ for C in alkyls is 1.45 Å, while for N in disilylamide it is 1.43 Å, when one would expect a larger difference which is retained by the corresponding $(R_{EF})_s$ values, 1.47 and 1.27 Å).

Ligand effective radii—trends in $(R_{EF})_s$

After showing some of the advantages of our definition of CN we will focus our attention now on $(R_{EF})_s$ and on some qualitative aspects that became apparent after studying such a large volume of structural data.

The first aspect is that two sets of $(R_{EF})_s$ had to be calculated for each type of ligand, one for Ln^{III} and An^{IV} compounds and another one for Ln^{II} and An^{III} compounds. In fact, it was verified that R_{EF}'s obtained from this last group of compounds were systematically lower than the corresponding R_{EF}'s obtained from Ln^{III} and An^{IV} compounds. The reason for this can probably be found from Shannon's ionic radii[14] which, having been derived from oxides and halides, were initially thought to be applicable to any kind of compound. This was later shown to be wrong and revised sets of ionic radii were reported for sulphides by Shannon[23] and for nitrides by Baur.[24] When comparing Shannon's oxide and sulphide sets, significant differences exist for the Ln and An ions, especially for U^{III}; $R_i(6) = 1.025$ Å from oxides, $R_i(7) = 0.99$ Å and $R_i(8) = 1.07$ Å from sulphides.

Other pertinent data concerning the size of the U^{III} ion result from the bond distances in structurally analogous compounds of U^{III} and Ln^{III}, for instance $MCp_3(THF)$,[25] which would place U^{III} between Nd^{III} and Pr^{III} ($d_{U-C} = 2.79$, $d_{U-O} = 2.55$Å; $d_{Pr-O} = 2.80$, $d_{Pr-O} = 2.56$ and $d_{Nd-C} = 2.78$, $d_{Nd-O} = 2.54$ Å), while Shannon's oxide table gives a U^{III} radius close to that of La^{III}) ($R_i(6) = 1.032$ Å), and larger than the radii of Nd^{III} ($R_i(6) = 0.983$ Å) and Pr^{III} ($R_i(6) = 0.99$ Å).

The differences between R_{EF} of compounds in higher and lower oxidation states might as well be attributed to covalency effects. Although these differences between $(R_{EF})_s$ are fairly constant for most of the ligand types in Table 2, significantly larger differences are seen for π-accepting ligands (isocyanide or phosphine). Incidentally, Andersen and co-workers have recently found evidence, based on structural data of isoleptic Ce^{III} and U^{III}

organometallic compounds, for the existence of π-back donation in the U^{III} compounds containing isocyanide and phosphine or phosphite.[25]

Another aspect is the sensitivity of the $(R_{EF})_s$ values to the coordination geometry and to the relative repulsivities of the different positions in coordination polyhedra like the trigonal and pentagonal bipyramids (TBP and PBP), the capped octahedron (CO), the dodecahedron (DD) and the tricapped trigonal prism (TCTP).[26] As examples, we can refer to two U compounds, prepared in our laboratories, displaying CO geometries, where $(R_{EF})_s$ for the oxygen atoms of the capping THF ligands are substantially larger than the mean value for that ligand in Table 2 (1.56 Å in $UCl_3[HB(3,5\text{-}Me_2Pz)_3](THF)$[27] and 1.60 Å in $UCl(OPh)_2[HB(3,5\text{-}Me_2Pz)_3](THF)$.[28] The same happens in two closely related U compounds with PBP geometries, where $(R_{EF})_s$ for the O atoms of the TPPO ligands in equatorial positions are larger than the mean value in Table 2 (1.36 Å in $UCl_2(acac)_2(TPPO)$ and 1.38 Å in $UCpCl(acac)_2(TPPO)$[29]).

This sensitivity to the position on the coordination polyhedron is more evident for neutral ligands and is reflected in the larger standard deviations of the corresponding $(R_{EF})_s$, when compared with the standard deviations of anionic ligands (e.g. ether and nitrile values in Table 2).

The different behaviour of neutral and anionic ligands are not surprising as larger repulsions would be expected between anionic ligands which would then preferentially occupy the coordination positions with smaller repulsitivities. This also has implications on the metal–ligand distances in charged complexes and is more evident from some of the $(R_{EF})_s$ in anionic complexes. For example, in $Er(NCS)_6^{3-}$,[30] $(R_{EF})_s$ is 1.49 Å, significantly larger than the mean values for NCS^- in Table 2; the same happens in UCl_6^{2-} where, for the more accurate structural determination of this species,[31] $(R_{EF})_s$ is 1.73 Å, again substantially larger than the mean value for Cl in Table 2.

APPLICATIONS OF CN_S AND $(R_{EF})_s$

The two main uses for the quantities presented in Tables 1 and 2 are molecular structure comparison and bond length prediction.

In the first application, the $(R_{EF})_s$ in Table 2 may serve as references in discussing a new structure, by comparison with the $(R_{EF})_s$ determined, as described before, for each ligand in the new complex. This enables us to see if we are in the presence of a "well-behaved" compound or if there are any unusual bond lengths and, in a certain way, try to explain its origin, for instance, in coordination geometry, covalency effects, intra- or intermolecular contacts or uncertainties in the structural determination.

The second application is obvious and, of course, dependent on the uncertainties of the values in Tables 1 and 2. The procedure is simple:

(a) Determination of the CN_S of the complex in question from the values in Table 1.

(b) Determination of the metal ionic radius by interpolation or extrapolation from Shannon's table.[14]

(c) Determination of metal–ligand distance by adding the appropriate $(R_{EF})_s$ value from Table 2 to the value obtained in (b).

(d) Introduction of corrections accounting for relative repulsivities in the expected coordination polyhedron (from ref. 26).

CONCLUDING REMARKS

The CN_S introduced above was shown to account for the general structural features of Ln and An compounds. The influence of steric effects on the bond lengths of a particular compound is, of course, more subtle, requiring a detailed analysis of the available structural data. Such a study is being undertaken, as well as extensions of the model to include uranyl complexes, new ligands and oligomeric compounds.

MERCAPTOPYRIDINE COMPLEXES OF DICYCLOPENTADIENYLMOLYBDENUM AND -TUNGSTEN: PREPARATION AND ELECTROCHEMISTRY. THE STRUCTURE OF $[Mo(\eta^5\text{-}C_5H_5)_2(2\text{-}SNC_5H_4)][PF_6]$

(*Received* 3 *April* 1989; *accepted* 18 *May* 1989)

Abstract—Neutral complexes of the type $[MCp_2(2\text{-}Spy)_2]$ and $[MCp_2(4\text{-}Spy)_2]$ and cationic complexes $[MCp_2(2\text{-}Spy)][PF_6]$ ($Cp = \eta^5\text{-}C_5H_5$; M = Mo, W; py = pyridine), where 2-mercaptopyridine is acting as a chelating ligand, have been prepared from the reaction of $[MCp_2Cl_2]$ and the corresponding mercaptopyridine in the presence of an excess of triethylamine. The protonated derivatives $[MCp_2(2\text{-}SpyH)_2][PF_6]_2$ and $[MCp_2(4\text{-}SpyH)_2][PF_6]_2$ have also been prepared by reacting the parent neutral compound with concentrated hydrochloric acid. Electrochemical studies, by cyclic voltammetry and coulometry, carried out in acetonitrile and dichloromethane, showed that these compounds follow the general trend of oxidation of the bis-thiolates $MCp_2(SR)_2$ (R = aryl or alkyl). The molecular structure of $[MoCp_2(2\text{-}SNC_5H_4)][PF_6]$ has been determined. The crystals are triclinic, space group $P\bar{1}$, $a = 10.577(3)$, $b = 7.644(2)$, $c = 10.783(1)$ Å, $\alpha = 99.26(2)$, $\beta = 96.29(2)$, $\gamma = 87.95(2)°$, $V = 855.26$ Å^3, $Z = 2$.

Our previous studies on the chemistry of substituted pyridine complexes[1] led us, in the case of 2-hydroxy- and 2-aminopyridine, to the synthesis of two unusual metallocycle complexes where the ligands chelate to one metal atom to form strained four-membered rings. As part of our continuing study of di-η^5-cyclopentadienylmolybdenum/tungsten complexes with substituted pyridine as co-ligands, we now report the reactions of *ortho-* and *para-*mercaptopyridines with MCp_2Cl_2. For the *ortho-*pyridine our purpose is to compare the strain and the reactivity on the metallocycle ring, when sulphur is the second coordinative atom on the chelating substituted pyridine, instead of nitrogen and oxygen as reported before.[1] The structure of $[MoCp_2(2\text{-}SNC_5H_4)][PF_6]$ was determined and the electrochemistry of the compounds was studied by cyclic voltammetry.

RESULTS AND DISCUSSION

Chemical studies

The coordination at the metal centres of the α- and γ-mercaptopyridines through the sulphur atom, can be either as a neutral ligand in the thione form[2] or as the corresponding conjugated anion.[3] However, the α-mercaptopyridines have shown a great versatility since they can either coordinate through the adjacent nitrogen atom of the heteronuclear ring to one metal centre, or they can bridge two metal centres. In the first case a strained four-membered ring system is obtained and only a few complexes of this type are known.[4] In the second case an unstrained system is achieved.[5]

In order to obtain mercaptopyridines as anionic ligands a general synthetic route to thiolato dicyclopentadienylmolybdenum and -tungsten derivatives was followed by direct reaction of the parent dihalide, MCp_2X_2, with the required mer-

captopyridines, in the presence of a strong deprotonating agent. It was observed that in the case of 2-mercaptopyridine, in addition to the formation of the bis-thiolate, the chelate compound was also isolated, in reasonable yield, as a product of the same reaction.

All the formulations were supported by analytical and conductivity data (Table 1) and also by the IR and ^{1}H NMR spectra (Table 2).

Typical bands confirm the presence of the MCp_2 fragment (~ 3100 cm^{-1}) in all the complexes, and the PF_6^- anion (840 and 560 cm^{-1}) in the cationic metal complexes. In addition, the protonated dicationic complexes $[MCp_2(2\text{-SpyH})_2]^{2+}$ and $[MCp_2(4\text{-SpyH})_2]^{2+}$ displayed a very strong band at 3330 cm^{-1}, assigned to an N—H stretch. Characteristic bands of substituted pyridine were also assigned, based on literature data.[6]

The ^{1}H NMR spectra for the free 2-mercaptopyridine has been interpreted in terms of the equilibrium, which explains the multiplet attributed to the 3,4 protons, the multiplet to the 5 proton and a doublet attributed to the proton on the 6 position (see Table 2). However, after deprotonation at the sulphur atom followed by coordination at the metal centre, this equilibrium no longer exists and a doublet attributed to H_3, two triplets attributed to H_4 and H_5 and a doublet due to H_6 are observed, as could be expected. After coordination the greater deshielding was observed on the *para*-protons of the pyridine ring. The ^{1}H NMR spectra for the protonated pyridine nitrogen compounds showed a greater deshielding for all the ring protons relative to the neutral parent compounds. The resonance of the amine protons is broadened by the quadrupole relaxation of the nearly asymmetric nitrogen, and for this reason is not seen in the proton spectra.

The ^{1}H NMR spectra for the 4-mercaptopyridinemolybdenum/tungsten derivatives showed more shielding on positions 3,5 and more deshielding on positions 2,6 relative to the free ligand. This decrease in chemical shifts can be explained by the smaller polarizability on the σ system relative to the π system, the *ortho*-protons being more sensitive to this polarization.[7]

The ionic formulation was suggested by the observed conductivity values (4–10 Ω^{-1} cm mol^{-1} for neutral, 133–143 Ω^{-1} cm mol^{-1} for mono-cations and 212–252 Ω^{-1} cm mol^{-1} for di-cations).[8]

Chemical oxidation of $[MoCp_2(2\text{-Spy})_2]$ *with the ferricinium cation.* Electrochemical studies carried out on the compounds prepared (see below), prompted us to chemically oxidize the neutral species $[MoCp_2(2\text{-Spy})_2]$. Thus, slow addition of a $[FeCp_2][PF_6]$ solution in dichloromethane, to a solution of $[MoCp_2(2\text{-Spy})_2]$ in the same solvent and same molar concentration, at room temperature, affords an orange-brownish compound, previously identified as being the chelate complex $[MoCp_2(2\text{-Spy})][PF_6]$.

This reaction follows the general trend of oxidation of bis-thiolates $[MCp_2(SR)_2]$ (M = Mo, W; R = alkyl or aryl) whose mechanism, based on chemical and electrochemical studies, had been suggested[9] to be as shown in Scheme 1.

When the ferricinium oxidation of $[MCp_2(SR)_2]$ was carried out in a non-coordinative solvent, e.g. CH_2Cl_2, the only product isolated was the dimer $[Cp_4M_2(SR)_4][PF_6]_2$ (path A).

However, as in our case, the two thiolate ligands are 2-mercaptopyridine, and an alternative pathway (path C) can occur after the reductive elimination of one of the ligands, the remaining 2-mercaptopyridine, which is coordinated through

sulphur can also become coordinated through the nitrogen atom, forming a chelate ring.

There are many examples in the literature of four-membered chelate rings containing sulphur atoms with ligands such as dithiocarbamates, thiocarbonates, and 1,1-dithiolates.[10] Recently, the complex $[Rh(2\text{-}Spy)_2(2\text{-}SpyH)_2]Cl$ has been reported and its structure shows two chelating 2-Spy^- ligands.[3b]

Crystallographic studies

Structure of $[MoCp_2(2\text{-}Spy)][PF_6]$. The crystal structure of this complex consists of discrete $[MoCp_2(2\text{-}SNC_5H_4)]^+$ cations and PF_6^- anions. The structure of the cation, with the atom numbering is shown in Fig. 1, and bond lengths and bond angles are given in Table 3. The metal atom

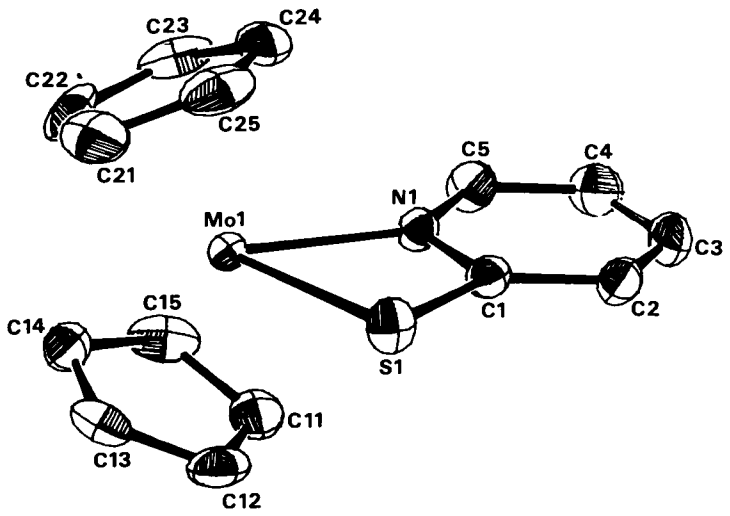

Fig. 1. Molecular structure of $[Mo(\eta^5\text{-}C_5H_5)_2(2\text{-}SNC_5H_4)]^+$ with 50% probability thermal ellipsoids showing the atom labelling scheme.

is coordinated to two η^5-cyclopentadienyl rings and to a bidentate ligand, 2-mercaptopyridine, with the usual distorted tetrahedral environment. The molybdenum is positioned at 1.967(1) and 1.970(1) Å from the cyclopentadienyl rings and the angle between the ring normals is 132.4(2)°. The planar cyclopentadienyl ligands adopt an eclipsed conformation.

This complex has a geometry very similar to that observed in the other two bis-cyclopentadienyl complexes previously reported,[1] $[MoCp_2(2\text{-}NHNC_5H_4)][PF_6]$ and $[MoCp_2(2\text{-}ONC_5H_4)][PF_6]$. Here again we find that the small angle at the molybdenum is primarily determined by the geometry and strain in the bidentate ligand, as demonstrated by EHMO calculations carried out for this type of ligand.[1] Naturally however, the angle at metal atom increases from the aminopyridine complex, 59.8(1)°, to the hydroxypyridine, 61.2(2)°, up to the mercaptopyridine, 64.9(1)°. In contrast, in $[MoCp_2(NH_3)(SC_6H_5)]$,[11] where coordination is also through nitrogen and sulphur, but as part of two different monodentate ligands, the equivalent angle S—Mo—N is 76.4(4)°. As demonstrated with many different structures,[1] no general correlation between the L—Mo—L′ and Cp—Mo—Cp angles seems to exist. However, in this particular context, where for the three complexes the bidentate ligand differs only in one of the atoms coordinated to the metal, a correlation was observed between these two angles. This is illustrated in Fig. 2.

In addition, the angle at this different coor-

Cp(1) is cyclopentadienyl defined by C(11)—C(15); Cp(2) is cyclopentadienyl defined by C(21)—C(25).

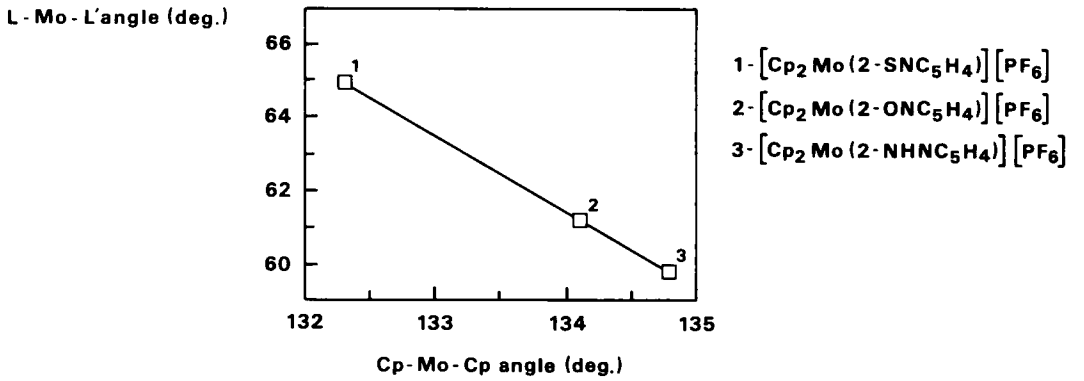

Fig. 2. Correlation between the N—Mo—(S,N,O) and Cp—Mo—Cp angles.

dinating atom, C(1)—(N,O,S)—Mo, varies as expected from compound **1** → **2** → **3** in a decreasing order: 98.4(5), 93.7(8), 81.2(2)°.*

The Mo—S and Mo—N distances lie close to those previously found, although the Mo—S distance in this complex is clearly at the end of the observed range (2.431–2.501 Å).[1,11]

The cyclopentadienyl rings are planar, with a maximum deviation from the least-squares planes of 0.001 and 0.0003 Å at each Cp.

Electrochemical studies

The oxidative electrochemistry of η^5-dicyclopentadienyl mercaptopyridine molybdenum and tungsten complexes. The electrochemical behaviour of the compounds $[MCp_2(2\text{-}Spy)_2]$, $[MCp_2(2\text{-}Spy)][PF_6]$, $[MCp_2(2\text{-}SpyH)_2][PF_6]$, $[MCp_2(4\text{-}Spy)_2]$ and $[MCp_2(4\text{-}SpyH)_2][PF_6]_2$ (M = Mo, W), listed in Table 4, was investigated in acetonitrile and dichloromethane with tetrabutylammonium salts as supporting electrolytes.

The oxidative electrochemistry of the neutral complexes, $[MCp_2(2\text{-}Spy)_2]$ and $[MCp_2(4\text{-}Spy)_2]$, is considerably more complex than that of the ionic mercaptopyridines derivatives studied in this work, appearing to follow the general oxidation of the $[MCp_2(SR)_2]$ complexes (M = Mo, W; R = alkyl or aryl).[9]

As can be seen in Fig. 3, where a typical cyclic voltammogram is shown, these compounds exhibit one first quasi-reversible redox process in the range 0.3–0.6 V, where current and reversibility depend on the switching potential. For example, if the potential sweep was switched at about 0.7 V when the compound was $[WCp_2(4\text{-}Spy)_2]$, the ratio I_c/I_a was ~ 1.0, but once the potential reached the second irreversible wave, the first wave no longer had a cathodic current. One implication of this observation is that the product of the second oxidation is rapidly decomposed (in an EEC process) faster than the first, depleting the diffusion layer of all the $[MCp_2(4\text{-}Spy)_2]$ species.

In the range 0.6–0.9 V, $[MCp_2(2\text{-}Spy)_2]$ complexes provide evidence for two redox processes, but the $[MCp_2(4\text{-}Spy)_2]$ analogues only present one wave. This behaviour was also observed in the bisthiolates derivatives $[MCp_2(SR)_2]$ with different R groups.[9] Both di-oxidation of the parent dithiolate

[a] All electrochemistry performed in CH_3CN containing 0.1 M Bu_4NPF_6. Potentials are referenced to a calomel electrode containing a saturated NaCl solution. Sweep rates of 200 mV s^{-1} were commonly used and the temperature was 20 ± 2°C. Solution concentration was generally about 1 mM.

[b] Calculated only on the waves with well-defined baselines.

and the oxidation of a monosubstituted acetonitrile complex can explain these waves in this potential range.

At higher potentials, one further redox wave was observed for all these neutral complexes, almost in the same position, *ca* 1.30 V. After bulk oxidation of $[MoCp_2(2\text{-}Spy)_2]$ at 0.48 V (1.0 Faraday/mol), in CH_3CN, the cyclic voltammogram of the solution showed only one electroactive species having an irreversible redox wave at almost the same potential as the higher irreversible wave in the parent compound.

The cyclic voltammogram of the chelate $[MCp_2(2\text{-}Spy)][PF_6]$ showed only one quasi-reversible wave at $E_{p/2}$ = 1.23 and 1.05 for molybdenum and tungsten derivatives, respectively. The position of this wave, at the same potential as the one observed at higher potential in the cyclic voltammograms of the neutral compounds $[MCp_2(2\text{-}Spy)_2]$ and $[MCp_2(4\text{-}Spy)_2]$, suggested that the formation of a chelate compound or a dimer with two bridging ligands could be one possible product, resulting from the oxidation of these compounds. This hypothesis prompted us to chemically oxidize the compound $[MoCp_2(2\text{-}Spy)_2]$ (which has a first oxidation wave at $E_{p/2}$ = 0.37 V) with a ferricinium salt. After work-up, the isolated product was identified as the chelate compound $[MCp_2(2\text{-}Spy)][PF_6]$.

The oxidative electrochemistry of the protonated cations, $[MCp_2(2\text{-}SpyH)_2][PF_6]_2$ and $[MCp_2(4\text{-}$

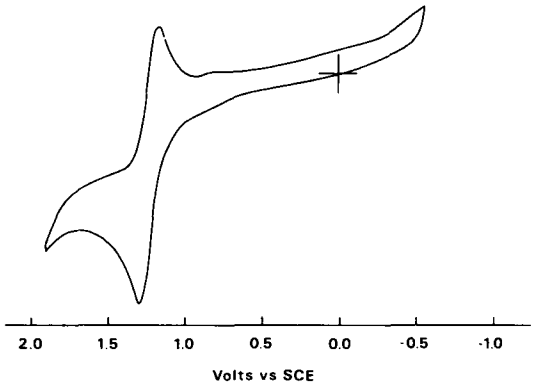

Fig. 4. Cyclic voltammogram of $[MoCp_2(2\text{-}Spy)][PF_6]$ (1 mM) in CH_3CN, containing 0.1 M Bu_4NPF_6. Scan rate 0.2 V s^{-1}.

$SpyH)_2][PF_6]_2$, showed only one redox wave at potentials generally higher than 1.0 V, with the trend that tungsten derivatives oxidize at lower potentials than the molybdenum analogues, as was observed before[9,12] for complexes of the type MCp_2X_2 where M is from group VIB.

It can also be observed, by comparing the oxidative electrochemistry of the neutral species $[MCp_2(2\text{-}Spy)_2]$ and $[MCp_2(4\text{-}Spy)_2]$, that the first compounds with *ortho*-substituted pyridines are easier to oxidize than the analogues which are *para*-substituted.

Although the oxidation wave for $[MoCp_2(2\text{-}Spy)][PF_6]$ (Fig. 4) has $\Delta E = 120$ mV (also when ferrocene was added as an internal reference this showed a higher value than the usual ΔE of ~ 60 mV), its quasi-reversible character can be suggested by the ratio $I_a/I_c = 0.9$ and the dependence of ΔE on the sweep scan rate.

However, electrochemical studies carried out on the analogous pyridine substituted complexes, where oxygen or N—H is the second coordinating atom, showed a totally irreversible wave for the oxidation of these compounds in this range of potentials.[13] This observation suggests more relative stability on the heterometallic ring in the sulphur case and this result is in agreement with the less strained structure found for this complex.

EXPERIMENTAL

All experiments were carried out under nitrogen by the use of standard Schlenk-tube techniques. IR spectra were measured on a Perkin–Elmer 457 spectrophotometer with KBr pellets. ^1H NMR spectra were recorded on a Jeol JNM-100 PFT spectrometer. Microanalyses were performed in our laboratories. The compounds $[MCp_2Cl_2]$ (M = Mo, W) were prepared from the parent dihydrides $[MCp_2H_2]$.[14]

Preparation of $[MCp_2(2\text{-}Spy)_2]$ *and* $[MCp_2(4\text{-}Spy)_2]$ (M = Mo, W)

To a suspension of $[MCp_2X_2]$ (~ 3.4 mmol) in 60 cm^3 of ethanol was added 13.5 mmole of mercaptopyridine in the presence of an excess of triethylamine. After a 2 h reflux, the solvent was evaporated to dryness affording a brownish solid. After the addition of water (50 cm^3) and filtration of the water solution (see below) a solid residue was obtained, which after being dried was recrystallized from CH_2Cl_2–ethanol. Yield $\approx 70\%$.

Preparation of $[MCp_2(2\text{-}Spy)][PF_6]$ (M = Mo, W)

To the water solution obtained from the work-up of the previous reaction, a NH_4PF_6 saturated water solution (5 cm^3) was added, affording an orange precipitate, which after being washed several times and filtered was dried. After recrystallization from acetone–ethanol the crystalline, salmon protonated salt was obtained. Yield $\approx 80\%$.

X-ray crystal structure of $[MoCp_2(2\text{-}SNC_5H_4)][PF_6]$

Data collection. X-ray studies were carried out using an Enraf–Nonius CAD4 diffractometer and graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). The unit cell and the orientation matrix were obtained by least-squares refinement of the setting angles for 25 automatically centred reflections. Intensity data were measured at room temperature, using the ω–2θ mode with $1.5 < \theta < 27.0°$ and $\omega = 0.8 \pm 0.35 \tan\theta$. A total of 3928 intensities were measured, 593 unobserved with $F_o < 3\sigma(F_o)$. Data were corrected empirically for absorption using the CAD4 software (minimum and maximum transmission factors of 0.9527 and 0.9993, respectively). Details of the data collection and refinement are given in Table 5. The structure was solved and refined using the SHELX76[15] program and all calculations were carried out on a VAX computer at the Instituto Superior Técnico.

Structure analysis and refinement. The structure was solved by a combination of Patterson and difference Fourier methods and refined by least-squares.

The molybdenum position was taken from the Patterson synthesis map, and sulphur, nitrogen and phosphorus positions from the subsequent difference Fourier synthesis. All the positions of the other

Largest peak in final difference Fourier (e Å^{-3})	1.23

$R = \Sigma(|F_o| - |F_c|)/\Sigma F_o$;
$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.

non-hydrogen atoms were localized in a subsequent difference Fourier synthesis, and after some cycles of refinement with isotropic temperature factors, $R = 0.1049$. Non-hydrogen atoms were then refined anisotropically. The hydrogen atoms were localized in the difference map and refined isotropically, although with geometrical constraint of the distance C—H = 1.08 Å.

The weighting scheme $w = k/(\sigma^2(F_0) + |g|F_0^2)$ was applied with the refined values of $k = 1.7998$ and $g = 0.000768$. Eight low angle and strong reflections thought to be affected by extinction were removed from the data. The final refinement converged at $R = 0.0362$ and $R_w = 0.0541$. A peak of 1.23 e Å^{-3} in the vicinity of the PF_6^- anion remained in the final electron density difference map.

Final atomic positional parameters and anisotropic thermal parameters for the non-hydrogen atoms, the hydrogen fractional atomic coordinates and isotropic temperature factors, and tables of observed and calculated structure factors have been submitted as supplementary material. The drawing was made using ORTEPII.[16]

Electrochemical apparatus

The electrochemistry instrumentation consisted of a Princeton Applied Research Model 173 potentiometer, a Model 175 voltage programmer, a Model 179 digital coulometer and an Omnigraphic 2000 X-T recorder from Houston Instruments. Potentials were referred to a calomel electrode containing a saturated solution of potassium chloride which was checked relative to a 1.0×10^{-3} M solution of ferrocene in acetonitrile containing 0.10 M $LiClO_4$ for which the ferricinium/ferrocene potential was in agreement with the literature.[17] The working electrode was made of a 2 mm piece of platinum wire for cyclic voltammograms, while the working electrode in the controlled potential electrolysis experiments was a platinum gauze. The secondary electrode was a platinum wire coil. Cyclic voltammetry experiments were performed in a PAR polarographic cell at room temperature, the solutions being used were 1 mM in solute and 0.1 M in supporting electrolyte, tetrabutylammonium hexafluorophosphate. Coulometry experiments were carried out in a three-compartment cell, where the working electrode compartment was separated from the auxiliary and reference electrodes by medium porosity glass frits.

The solvents, CH_3CN and CH_2Cl_2, which were reagent grade materials, were dried over CaH_2 and P_2O_5 and were distilled just before use under argon atmosphere. Solutions were degassed with dry nitrogen before each experiment and a nitrogen atmosphere was maintained over the solution during the experiments.

(*Received* 31 *March* 1989; *accepted* 22 *May* 1989)

Abstract—New cationic complexes $[Ni(\eta^3\text{-}CH_2C_6H_5)(PPh_3)_2]PF_6$ (**3**) and $[Ni(\eta^3\text{-}CH_2C_6H_5)((+)\text{-DIOP})]PF_6$ (**4**) were synthesized from the corresponding neutral compounds $[Ni(\eta^3\text{-}CH_2C_6H_5)X(PR_3)_2]$ (X = Cl, Br), by metathetical halide abstraction with $TlPF_6$. Complex **3** was characterized by X-ray crystallography and shown to have a distorted square-planar geometry with the benzylic group coordinated in a quasi-allylic fashion. Crystals are monoclinic, space group $P2_1/n$, $a = 11.798(5)$, $b = 19.251(2)$, $c = 18.561(3)$ Å, $\beta = 93.03°$, $V = 4208.6$ Å^3. Solution NMR studies showed benzyl fluxionality and phosphine lability in compound **3**, but not in **4**. The latter one is catalytically inactive towards styrene oligomerization, whereas **3** produces styrene oligomers ($\bar{M}_n \approx 1000$) with 67% isotactic content. Although $[Ni(\eta^3\text{-}CH_2C_6H_5)Cl(PCy_3)]$ and *trans*-$[Ni(Cl)(H)(PCy_3)_2]$ are inactive, addition of $TlPF_6$ induced catalytic activity with formation of highly isotactic (90%) styrene oligomers with similar $\bar{M}_n$ and a different terminal group.

In previous papers we reported the activity of the catalyst precursor $[Ni(\eta^3\text{-}CH_2C(CH_3)CH_2)(cod)]PF_6$ (**1**) (cod = 1,5-cyclooctadiene), either pure or modified by the addition of 1 equiv. of a phosphine, in the oligomerization of styrene.[1,2] In those studies we presented some evidence in favour of the intermediacy of η^3-benzylic complexes in the catalytic cycle. One such complex was isolated from the catalytic reaction mixture and characterized by ^{1}H NMR as being an η^3-α-methylbenzyl nickel species, which is believed to result from the insertion of a molecule of styrene into a nickel hydride bond:[2]

Since the phosphine modified catalysts yield styrene oligomers of relatively high, and in the case of PCy_3 very high isotactic content, we decided to prepare model complexes containing both phos-

1 (1)

phines and η^3-benzyl ligands and check their activity for the same oligomerization reaction.

Following our proposals[1,2] the active η^3-benzylic species should be cationic. A number of π-benzylic transition metal complexes exhibiting different hapticities are known[3-5] but no cationic Ni(η^3-benzyl) compound is known although a palladium analogue has been structurally characterized.[6]

RESULTS AND DISCUSSION

Synthesis of $[Ni(\eta^3\text{-}CH_2C_6H_5)(PR_3)_2]PF_6$ *complexes*

Our synthetic approach to the preparation of such complexes makes use of halide abstraction from η^1-benzyl complexes of the type $[Ni(\eta^1\text{-}CH_2C_6H_5)X(PR_3)_2]$ (X = Cl, Br), which can be prepared by oxidative addition of benzyl halides to Ni^0 complexes.[3,7] Indeed, treatment of $[Ni(\eta^1\text{-}CH_2C_6H_5)X(PPh_3)_2]$ (**2**) prepared *in situ* according to ref. 7, with $TlPF_6$, at $-20°C$ in THF, gives a deep red solution from which, after low temperature work-up, the complex $[Ni(\eta^3\text{-}CH_2C_6H_5)(PPh_3)_2]PF_6 \cdot CH_2Cl_2$ (**3**) can be isolated in *ca* 70% yield. Alternatively, it can be prepared in similar yield when a solution of $[Ni(cod)_2]$ and 2 equiv. of PPh_3, in THF, at $-20°C$, is treated with benzylhalide and the resulting solution further reacted with $TlPF_6$ and worked-up in the same way.

This latter procedure was used to prepare, also in very good yield, the complex $[Ni(\eta^3\text{-}CH_2C_6H_5)((+)\text{-DIOP})]PF_6$ (**4**)* but was ineffective for the preparation of the dppe (1,2-bis(diphenylphosphino)ethane) analogue which we have not yet achieved.

Attempts to prepare the corresponding $[Ni(\eta^3\text{-}CH_2C_6H_5)(PCy_3)_2]PF_6$, using this same procedure or starting from $[Ni(\eta^3\text{-}CH_2C_6H_5)X(PCy_3)]$ (**5**)[8] have been so far unfruitful. In fact, after the addition of $TlPF_6$ to the deep blue solution of **5** and 1 equiv of PCy_3, we observed a shift in the colour towards deep red, as in the case of **3**. After similar low temperature work-up an oil was formed which could be solidified by repeated washing with pentane. Analysis of this powder showed P–Ni ratios between 1 and 2. The presence of an η^3-benzyl complex is clearly seen in the ^1H NMR spectrum (δ 7–8 ppm), although contaminated with other unidentified species as confirmed by ^{31}P NMR. A different approach, namely the reaction of *trans*-$[Ni(Cl)(H)(PCy_3)_2]$ (**6**)[9] with 1 equiv. of styrene and $TlPF_6$ also failed to give the desired compound $[Ni(\eta^3\text{-}CH(CH_3)C_6H_5)(PCy_3)_2]PF_6$. However, both this reaction mixture and the mixture of **5** + 1 equiv. PCy_3 + 1 equiv. $TlPF_6$ gave styrene oligomers with the same characteristics as those obtained from **1** + PCy_3 (see below).

Crystal and molecular structure of $[Ni(\eta^3\text{-}CH_2C_6H_5)(PPh_3)_2]PF_6$ (**3**)

Crystals of compound **3** were easily obtained and a crystal structure determination was carried out. The molecular structure of the cation is shown in Fig. 1 and selected bond angles and distances are listed in Table 1.

The complex exhibits a distorted square-planar geometry with the benzyl group coordinated in a quasi-allylic fashion, via C(1), C(2) and C(7).

Due to the small bite of the benzyl ligand, the angle C(1)—Ni—C(7) is 68.4(4)°. Nevertheless, this is compensated for by the opening of the other angles, P(1)—Ni—P(2) = 104.3(2)°, C(7)—Ni—P(2) = 98.1(3)°, so that the sum around the nickel is 361.5(3)°. However, the angle between the planes defined by P(1)—Ni—P(2) and C(1)—Ni—C(7) is 14.5°.

The η^3-bonding mode for the pseudo-allylic group is unsymmetrical, having the shorter distance between the nickel and the methylene carbon and the longer one between the nickel and the *ortho* carbon. Similar features are observed in $[Ni(\eta^3\text{-}CH_2C_6H_4\text{-}o\text{-}Me)Cl(PMe_3)]$[3] and $[Co(\eta^3\text{-}CH_2C_6H_5)(P(OMe)_3)_3]$.[10] As in these complexes, the internal bond lengths in the benzylic group show a variation

*(+)-DIOP =

C(2)—C(7)—Ni(1)	61.7(4)	C(6)—C(7)—Ni(1)	127.4(6)
C(6)—C(7)—C(2)	119.7(8)		

which is associated with a difference in the double bond character of the C—C bonds. For the title complex the bond distances C(2)—C(3), C(4)—C(5) and C(6)—C(7) are longer (the average value is 1.393(13) Å) than those corresponding to C(3)—C(4) and C(5)—C(6) which have more double character (the average value is 1.362(13) Å). The benzyl ligand is planar with a maximum deviation from the plane of 0.061 Å at C(2). The methylene hydrogens were located and found to lie out of the benzylic plane: $\delta = 0.41$ for H(11) and $\delta = 0.08$ Å for H(7).

As a consequence of the asymmetry observed in the η^3-bonding the Ni—P bonds are different, with the bond *trans* to the methylene group, Ni—P(2), longer than the other one, Ni—P(1). This situation was also observed for the related $[Rh(\eta^3\text{-}CH_2C_6H_4\text{-}o\text{-}Me)(PPh_3)_2]$[11] and $[Rh(\eta^3\text{-}CH_2C_6Me_5)$

$(P(O^iPr)_3)_2]$.[12] Both Ni—P bond lengths are slightly longer than in $[Ni(\eta^3\text{-}CH_2C_6H_4\text{-}o\text{-}Me)Cl(PMe_3)]$.[3]

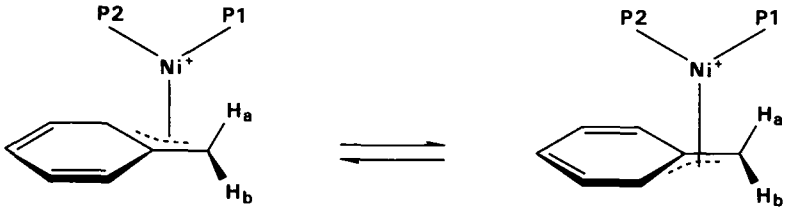
NMR characterization of **3** *and* **4**

The ^1H and ^{31}P variable temperature NMR spectra of $[Ni(\eta^3\text{-}CH_2C_6H_5)(PPh_3)_2]PF_6$ (**3**) agree with the molecular structure described above and reveal a fluxional behaviour, characteristic of η^3-benzylic complexes in solution.

At $-20°C$, the ^1H spectrum shows a triplet at 2.35 ppm arising from virtual coupling of the methylenic protons with the phosphorus nuclei ($J_{PH} \approx 5.4$ Hz), a doublet at 6.77 ppm for the *ortho* protons, the remaining benzylic aromatic protons being in the region 6.8–7.0 ppm, partially hidden by the *ortho* protons of the phosphine *trans* to the methylenic group. The other phosphine protons were found between 7.1 and 7.5 ppm.

At this temperature the $^{31}P\{^1H\}$ spectrum shows two 1 : 1 resonances at 31.44 and 26.34 ppm due to the non-equivalence of the two phosphine ligands. No significant changes on the ^1H and ^{31}P NMR spectra are observed upon cooling the solution of **3** in CD_2Cl_2 down to $-70°C$.

The observed equivalence of the two edges of the benzyl ligand down to $-70°C$ can be explained in terms of a rapid suprafacial shift as shown below:



(2)

This process still leaves the two phosphorus atoms non-equivalent and has been put forward to explain the same fluxional behaviour in other η^3-benzylic related complexes.[13–15]

A second and different dynamic process is operating above $-20°C$. In effect, when the temperature increases to 10°C, the benzyl methylenic triplet collapses into a singlet and a significant broadening of the phosphine protons and phosphorus resonances is observed. At this temperature, the ^{13}C NMR resonances of the benzyl ligand appear decoupled from the phosphorus atoms. These facts indicate the presence of a slow phosphine exchange process, operating at temperatures above $-20°C$, as observed with other benzylic complexes of nickel and palladium.[7,14,15]

The NMR spectra of the similar compound $[Ni(\eta^3\text{-}CH_2C_6H_5)((+)\text{-DIOP})]PF_6$ (**4**) display some features which suggest a less fluxional benzyl ligand. Some conformation interconversion in the seven-membered ring of (+)-DIOP also appears to be present.

The room temperature ^1H spectrum of this compound shows two doublets at 2.00 and 2.53 ppm ($^2J_{HH} = 4.9$ Hz) corresponding to the benzyl methylenic protons and two other doublets at 6.41 and 6.66 ppm ($^3J_{HH} = 7.8$ Hz) for the benzylic *ortho* protons. The other aromatic benzyl protons appear between 6.70 and 7.00 ppm. The observed non-equivalence of the benzyl methylene and *ortho* protons is maintained from -70 to 23°C, which is consistent with a very low degree of mobility for the benzyl ligand in **4**. The ^1H spectrum of coordinated (+)-DIOP consists of a methine multiplet at 3.68 ppm, a methylenic multiplet at 2.76 ppm and a broad methylenic multiplet at 2.40 ppm; the methyl groups appear as a singlet at 1.12 ppm. By cooling a solution of **4** in CD_2Cl_2, these resonances broaden and shift, but no limiting spectrum is obtained even at $-70°C$.

The dynamic process that tends to average the complex spectra of **4**, at room temperature, is also visible in the much simpler $^{31}P\{^1H\}$ variable temperature spectra. At $-70°C$, the spectrum consists of two 1 : 1 resonances at 18.59 and 12.14 ppm. As the temperature increases, these resonances broaden significantly and, at 30°C, they are practically merged into a broad signal centred at about 13.8 ppm. These changes may be assigned to a chair–boat conformational equilibrium occurring in the seven-membered ring of this ligand.[16] Further increase in temperature initiates decomposition of the complex.

Catalytic studies

The catalytic activity of complexes **2**–**6** in the oligomerization of styrene was tested under conditions similar to those previously reported for $[Ni(\eta^3\text{-}CH_2C(CH_3)CH_2)(cod)]PF_6$ (**1**) and **1**+PR_3 systems.[1,2] The results are summarized in Table 2.

Complex **3** is an effective catalyst for this type of reaction. Its activity, at 10°C, is comparable to that found for **1**+2 equiv. PPh_3 (TOR = 6.8 min^{-1}), but much lower than in the case of **1**+1 equiv PPh_3 (TOR $\approx$ 1000 min^{-1}). The ^1H and ^{13}C NMR

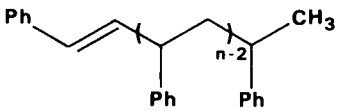
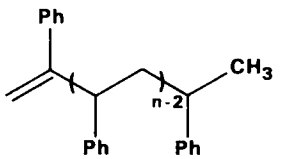
analyses of the obtained oligomers **7**, reveal that they are entirely similar to the ones obtained with catalysts **1** and **1**+PR_3 (R = Ph, *n*-Bu, OPh), including the same terminal groups and tacticity (isotactic contents ≈ 67–69%).[1] Furthermore, the values of $\bar{M}_n$ are rather constant and of the same order of magnitude as those found in the latter phosphine system.

Although we were unsuccessful in isolating the PCy_3 cationic benzyl analogue of **3**, we found that the addition of styrene to an *in situ* prepared mixture of **5**+1 equiv. PCy_3+1 equiv. $TlPF_6$ afforded styrene oligomers **8**, having the same features as the ones obtained with **1**+1 or 2 equiv. PCy_3, i.e. a different terminal end group and higher isotacticity (90%).[2] Moreover, the reaction of styrene with catalytic amounts of nickel hydride **6**+1 equiv. $TlPF_6$ also produced identical isotactic oligomers.



7



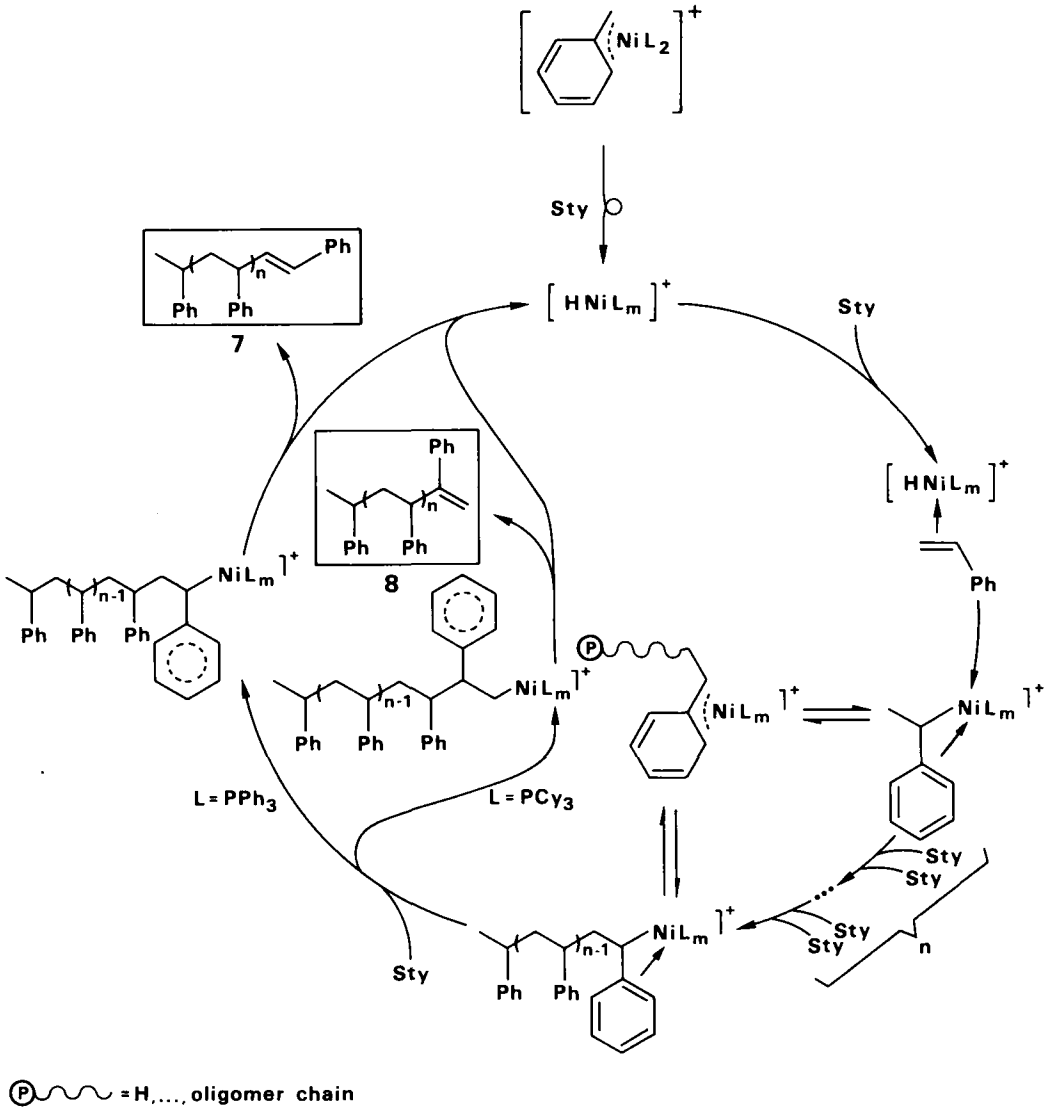
8

Both these reactions occurred with the simultaneous formation of small amounts (*ca* 5%) of a high molecular weight atactic polystyrene ($\bar{M}_n$ ≈ 35,000–50,000), probably resulting from some radicalar decomposition of the *in situ* prepared benzylic metal system. This may also explain the lower turnover rates obtained for these systems, when compared to those of **1**+1 or 2 equiv. PCy_3 (TOR = 0.7 min^{-1}).

Neutral precursors of our cationic complexes, namely [Ni(η^1-$CH_2C_6H_5$)Cl(PPh_3)$_2$] (**2**), [Ni(η^3-$CH_2C_6H_5$)Cl(PCy_3)] (**5**) and *trans*-[Ni(Cl)(H)(PCy_3)$_2$] (**6**) were found to be inactive towards the oligomerization of styrene, which seems to point out the importance of the electrophilic character of the metal centre in the activation of the olefinic double bond. The lability of the benzyl and phosphine ligands is also particularly important for the catalytic activity of this kind of benzylic complexes.

In effect, the low lability observed for cationic (+)-DIOP complex **4** somehow prevents insertion of a styrene molecule into the nickel–benzyl bond and explains its catalytic inactivity. For this reason, we were unable to evaluate the chiral diphosphine potential as a stereoregulating agent in the chain growth process (insertion steps).

All the reported results reinforce our previously suggested mechanism for the oligomerization of styrene,[1,2] in which the active species is a cationic



Scheme 1.

nickel hydride, generated in the reaction of the benzylic complexes with styrene (Scheme 1). Insertion of a new styrene molecule into the Ni—H bond gives rise to an η^3-α-methylbenzyl species, which undergoes further secondary insertion reactions, producing an oligomer growing chain stabilized through a $\eta^3 \leftrightarrow \eta^1$ bond to the metal. At a certain stage, β-elimination occurs, liberating oligomers **7** and regenerating the Ni—H species. In the case of the bulky PCy_3, this chain transfer process takes place when, probably due to a crowded coordination sphere, the styrene inserts in a primary mode being unable to stabilize the nickel–chain bond. In this mechanism, the η^3-coordination of the chain together with the PCy_3 size and basicity effects seem to be responsible for the obtention of isotactic oligomers **8**.

EXPERIMENTAL

All manipulations involving transition metal complexes were carried out under argon by the use of standard Schlenk tube techniques. Solvents and reagents were dried with anhydrous calcium sulphate (acetone, benzyl halides) and small amounts of sodium (ethanol, methanol) and distilled under an argon atmosphere with either sodium/benzophenone (THF, diethyl ether, toluene), P_2O_5 (CH_2Cl_2) or CaH_2 (pentane, hexane) and stored under argon. NMR solvents were dried over 4 Å molecular sieves, degassed by freeze–pump–thaw cycles and stored under argon. PCy_3 and PPh_3, from Aldrich, were recrystallized, respectively, from acetone and ethanol and stored under argon. (+)-DIOP and dppe, from Strem Chemicals, were

used as received. Phosphine purity was confirmed by ^{31}P NMR. Starting metal complexes $[Ni(CH_2{=}CH_2)(PPh_3)_2]$,[17] $[Ni(cod)_2]$,[18] $[Ni(\eta^1\text{-}CH_2C_6H_5)X(PPh_3)_2]$,[7] $[Ni(\eta^3\text{-}CH_2C_6H_5)X(PCy_3)]$[8] and *trans*-$[Ni(Cl)(H)(PCy_3)_2]$[9] were prepared according to the literature. IR spectra were recorded on a Perkin–Elmer 683 spectrophotometer. Microanalyses were performed in our laboratories.

Preparation of $[Ni(\eta^3\text{-}CH_2C_6H_5)(PPh_3)_2]PF_6 \cdot CH_2Cl_2$ (**3**)

Addition of benzyl chloride (0.18 cm^3, 1.56 mmol) to a solution of $[Ni(CH_2{=}CH_2)(PPh_3)_2]$ (1.00 g, 1.56 mmol) in THF (25 cm^3) at $-30°C$ and stirring for 1.5 h at this temperature, led to the formation of an intense deep blue solution. Addition of $TlPF_6$ (0.55 g, 1.57 mmol) with further stirring over 1 h, at the same temperature, afforded a deep red solution. After low temperature evaporation of the solvent and extraction with CH_2Cl_2, careful removal of TlCl from the mixture was made by filtration on a Celite bed. The solution was concentrated and the addition of hexane yielded, after 2 days, 0.97 g of deep red air-sensitive crystals of **3**, which were thoroughly washed with hexane and Et_2O and dried *in vacuo*. Yield: 69%. Good yields were also obtained starting from stoichiometric amounts of $[Ni(cod)_2]$, PPh_3, benzyl chloride, $TlPF_6$ and a similar work-up of the mixture. Experiments using benzyl bromide gave lower yields (50–60%). ^1H NMR (300 MHz, CD_2Cl_2, 10°C): δ 2.35 (s, 2H, $CH_2C_6H_5$), 6.77 (d, 2H, $^3J_{HH} = 5.9$ Hz, *ortho* benzylic), 6.8–7.0 (9H, aromatics + *para* and *meta* benzylic), 7.1–7.5 (24H, aromatics); $^{31}P\{^1H\}$ NMR (121.47 MHz, CD_2Cl_2, 10°C): δ 26.00 (s, *trans* to benzylic methylene), 30.94 (s, *cis*); $^{13}C\{^1H\}$ NMR (75.47 MHz, CD_2Cl_2, 10°C): δ 47.71 (br s, $CH_2C_6H_5$), 115.17 (s, benzylic *ipso*), 117.36 (s, benzylic *ortho*), 132.25 (s, benzylic *para*), 135.06 (s, benzylic *meta*), 128–134 (aromatics). $C_{44}ClF_6H_{39}NiP_3$: Found: C, 58.4; H, 4.5; P, 10.3. Calc.: C, 58.4; H, 4.4; P, 10.1%.

Preparation of $[Ni(\eta^3\text{-}CH_2C_6H_5)((+)\text{-DIOP})]PF_6$ (**4**)

Benzyl chloride (0.11 cm^3, 0.96 mmol) was added to a cold (−30°C) suspension of $[Ni(cod)_2]$ (0.26 g, 0.95 mmol) and (+)-DIOP (0.47 g, 0.95 mmol). The deep red solution obtained was stirred for 3 h. Addition of $TlPF_6$ (0.34 g, 0.97 mmol) immediately afforded a red–orange solution and a precipitate of TlCl, which were further stirred for 1 h. Low temperature work-up similar to that of **3** led to the obtention of an oil, that was sequentially washed with hexane, toluene and Et_2O. Repeated washing with pentane gave a brick-red powder (0.55 g), which was dried *in vacuo*. Yield: 73%. ^1H NMR (300 MHz, CD_2Cl_2, 23°C): δ 1.12 (s, 6H, diop methyl), 2.00 (d, 1H, $^2J_{HH} = 4.9$ Hz, methylenic *anti*), 2.40 (br m, 2H, diop methylene), 2.53 (d, 1H, $^2J_{HH} = 4.9$ Hz, methylenic *syn*), 2.76 (m, 2H, diop methylene), 3.68 (br m, 2H, diop methine), 6.41 (d, 1H, $^3J_{HH} = 7.8$ Hz, *ortho* benzylic), 6.66 (d, 1H, $^3J_{HH} = 7.8$ Hz, *ortho* benzylic), 6.7–7.0 (3H, *para* and *meta* benzylic), 7.2–7.9 (20H, aromatics); $^{31}P\{^1H\}$ NMR (121.47 MHz, CD_2Cl_2, −70°C): δ 12.14 (s, *trans* to benzylic methylene), 18.59 (s, *cis*). $C_{38}F_6H_{39}NiO_2P_3$: Found: C, 57.3; H, 5.0. Calc.: C, 57.5; H, 4.9%.

Catalytic reactions and oligomer treatment

The oligomerization reactions were carried out in Schlenk tubes immersed in a thermostatted water bath controlled to ±0.5°C and with a stirring rate of 500 rpm. In a typical experiment, styrene (19.86 g, 191 mmol) was introduced into the reaction vessel. Once thermal equilibrium had been reached, a thermostatted solution of **3** (0.179 g, 0.198 mmol) in CH_2Cl_2 (10 cm^3) was added. After 2 h, the reaction was terminated by flushing the solution with air to decompose the catalyst. For catalytic reactions related with **5** and **6**, *in situ* preparation of the catalyst was carried out by the addition of $TlPF_6$ to a mixture of styrene and neutral precursor in CH_2Cl_2.

The decomposed catalyst was removed from the reaction mixture by filtration on a silica gel bed. Evaporation of the solvent and unreacted styrene was followed by redissolution of the products in a minimum volume of CH_2Cl_2 and its precipitation in methanol. At that stage, the reaction products were separated into two fractions, respectively, methanol-soluble and methanol-insoluble oligomers.

The latter ones were characterized by gel permeation chromatography (GPC) using three columns of Microstyragel (100, 500, 10000 Å; 30 × 0.8 cm). THF was used as solvent at flow rate of 1.0 $cm^3\ min^{-1}$ and the detection was made with a Waters R401 refractometer.[19]

NMR measurements

^1H, ^{13}C and ^{31}P NMR characterization of **3** and **4** was performed on a CXP 300 Bruker spectrometer using CD_2Cl_2 as solvent. ^1H and ^{13}C chemical shifts are reported relative to TMS; ^{31}P chemical shifts are referenced to external 85% H_3PO_4.

^1H and ^{13}C NMR spectra of the polystyrene oligomers were run at 120°C in a solution of $CDCl_2CDCl_2$ and their isotactic content determined from the ^{13}C pattern of the aromatic *ipso* carbons.[20] Number average molecular weights ($\bar{M}_n$) were determined by comparing the intensities of the in-chain protons with those of the terminal groups.

X-ray data collection and structure determination for **3**

Crystals of **3**, suitable for diffraction measurements, were sealed in glass capillaries under argon.

Crystal data are given as follows: $C_{44}Cl_2F_6H_{39}NiP_3$, $M_r = 904.31$, monoclinic, space group $P2_1/n$, $a = 11.798(5)$, $b = 19.251(2)$, $c = 18.561(3)$ Å, $\beta = 93.30(3)°$, $V = 4208.6$ Å^3, $Z = 4$, $D_c = 1.77$ g cm^{-3}, μ(Mo-K_α) = 6.48 cm^{-1}.

All X-ray measurements were made at room temperature using an Enraf–Nonius CAD4 diffractometer and graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). Cell dimensions and the orientation matrix were obtained by least-squares refinement of setting angles for 25 automatically centred reflections with $8.5 \leqslant \theta \leqslant 19.5$. The intensities of 6056 unique reflections in the range $1.5 \leqslant \theta \leqslant 25.0$ were measured by the ω–2θ scan mode with ω scan widths of $0.80 + 0.35 \tan\theta$ and scan speeds of 0.785–5.49° min^{-1}. The data were empirically corrected for absorption using the Enraf–Nonius CAD4 software.

4728 reflections satisfied the criterium $F > 3\sigma(F)$ and were used for structure solution and refinement. The nickel position was located from a Patterson map and the positions of the other non-hydrogen atoms from subsequent difference Fourier synthesis. The phenyl groups were refined isotropically as rigid groups. Refinement was then continued with all the remaining non-hydrogen atoms refining anisotropically in a blocked-diagonal least-squares. The positions of the benzylic hydrogen atoms were located in the ΔF map and were included in refinement with individual isotropic thermal parameters, while the phenylic hydrogens were calculated and inserted in idealized positions. The weighting scheme $w = 1.4840/\sigma^2|F| + 0.000910F^2$ was found to give acceptable agreement analysis. The atoms on the PF_6^- anion have, as usual, very high thermal motion, thus limiting the overall accuracy in the refinement. Final refinement gave $R = 0.0632$ and $R_w = 0.0764$. Tables of final atomic positional parameters for the refined atoms, anisotropic displacement factor coefficients and positional parameters for idealized hydrogen, as well as lists of observed and calculated structure factors are available as supplementary data from the Authors. All the computations required to solve and refine the structure were made using SHELX76;[21] the drawing was made using ORTEP.[22]

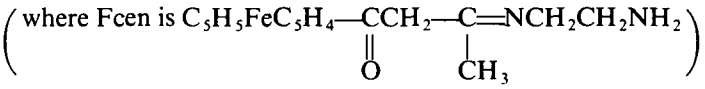
MONO-CONDENSED PRODUCT OF FERROCENYLFORMYL ACETONE WITH ETHYLENEDIAMINE AND ITS COMPLEXES OF LANTHANIDE CHLORIDES

PEIZHI HU, LUN ZHANG,* XIAOBING ZHU, XIYAN LIU, LICAI JI and YILONG CHEN†

Department of Chemistry, Wuhan University, China

(*Received* 10 *February* 1989; *accepted* 19 *May* 1989)

Abstract—A mono-condensed product (Fcen)



was obtained from the condensation of ferrocenylformyl acetone with ethylenediamine and five new Fcen complexes of lanthanide chlorides having the formula $Fcen_3LnCl_3$ (where Ln = La, Nd, Gd, Dy and Lu) were synthesized via the reaction of Fcen with lanthanides. These lanthanide complexes were characterized by microanalyses, IR, UV, Mössbauer spectra, molar conductivities and TG–DTA graphs. The ^1H NMR and MS spectra of Fcen were also recorded. In these complexes each Fcen is tridentately coordinated to the lanthanide ions and three chlorine atoms are outer-sphere anions.

Vishnyakova *et al.*[1] have prepared the bi-condensed product (Fc_2en) of ferrocenylformyl acetone with ethylenediamine and Eremina[2] has synthesized Fc_2en complexes of *d*-transition metals, but no complex of this ligand with lanthanide ions has been described in the literature up until now.

In this article, we wish to report the syntheses of the mono-condensed product of ferrocenylformyl acetone with ethylenediamine (Fcen) and its complexes with lanthanide chlorides. The physical properties (spectra, etc.) of Fcen and its complexes were measured and are discussed.

EXPERIMENTAL

Preparation of Fcen

To a solution of ethylenediamine (10 mmol) in 15 cm^3 of methanol, a solution of ferrocenylformyl acetone (10 mmol) in 15 cm^3 of methanol was added dropwise, and the reaction mixture was stirred for 0.5 h. After standing overnight the yellow precipitate was filtered off, washed three times with small quantities of cold methanol and ether, respectively, and dried *in vacuo* for 3 h to give 2.0 g of the condensed product (Fcen), yield 64%, m.p. 177–179°C. Elemental analysis for $C_{16}H_{20}N_2OFe$: Found: Fe, 17.9. Calc.: Fe, 17.8%.

Ferrocenylformyl acetone was synthesized according to the literature method.[3]

Coordination of Fcen *with lanthanide chlorides*

The coordination reaction of Fcen with lanthanide chlorides was carried out by using a general procedure that is illustrated below by the reaction of Fcen with $LaCl_3 \cdot xH_2O$.

La_2O_3 (0.3 mmol) was dissolved in 5 cm^3 of 1 M hydrochloric acid and solid $LaCl_3 \cdot xH_2O$ was obtained after concentration of the solution to dryness. The solid obtained was dissolved in 20 cm^3 of anhydrous ethanol, and was added dropwise with stirring to a solution of 2.4 mmol Fcen in 30 cm^3 of anhydrous ethanol; precipitation of product occurred immediately. The suspended substance was stirred for 2 h, the precipitate was filtered off, washed twice with small quantities of cold ethanol, then ether and dried *in vacuo* for 3 h. A complete

Table 1. Yields and microanalyses data for $Fcen_3LnCl_3$

$Fcen_3LnCl_3$	Yield (%)	Microanalyses Found (Calc.) (%) Ln	Fe	Cl
La	37	11.3 (11.7)	14.7 (14.8)	9.0 (9.0)
Nd	40	12.5 (12.1)	14.0 (14.1)	9.6 (9.0)
Gd	61	13.6 (13.1)	13.7 (13.9)	8.8 (8.8)
Dy	55	13.7 (13.4)	13.5 (13.9)	8.8 (8.8)
Lu	39	14.5 (14.3)	13.3 (13.7)	9.2 (8.7)

list of the complexes, yields and microanalyses are given in Table 1.

The lanthanide oxides, all of 99.9% purity, were obtained from Yue Long Chemical Plant (P.R.C.).

Physical measurements

A Shimadzu IR-450 spectrophotometer was used to obtain the IR spectra using KBr discs. UV spectra were recorded in DMF with a Shimadzu UV-240 spectrophotometer. ^1H NMR spectra were recorded in $CDCl_3$ with a JEOL JNM-PMX60SI spectrometer using TMS as internal standard. Mass spectra were obtained on a VG 7070E-HFMS instrument using an electron-impact ion source. Mössbauer spectra were recorded on an OXFORD MS 500 Mössbauer instrument at 290 K using $^{57}Co/Rh$ as the radio source. Molar conductivities were measured in DMF at 25°C with a Shanghai DDS-11A conductivity apparatus. TG–DTA graphs were recorded on a Beijing LCT-1 TG–DTA instrument in air using Al_2O_3 as reference.

RESULTS AND DISCUSSION

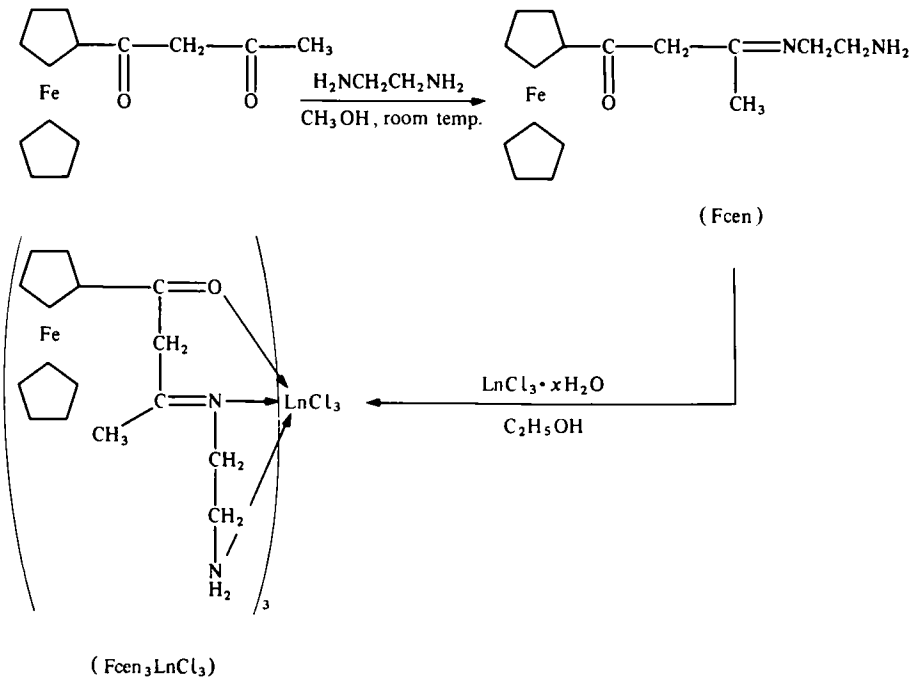
The condensation and coordination reactions can be outlined as in Scheme 1.

The condensation reaction must be carried out at room temperature, otherwise the bi-condensed product will be obtained.

Fcen and $Fcen_3LnCl_3$ are fine solids, which are soluble in DMF and DMSO, and insoluble in alcohol, ether, acetone, alkyl halides and water. At room temperature these complexes are stable to air, moisture and light.

Microanalyses (Ln, Fe, Cl) data of these complexes (Table 1) show that all the complexes have a 3 : 1 ratio of Fcen to lanthanide chloride stoichiometrically, which is in accordance with the general formula $Fcen_3LnCl_3$.

The important IR absorption data for the ligand and complexes are given in Table 2. The IR spectra of all these complexes are similar, with the free Fcen



Scheme 1. Ln = La, Nd, Gd, Dy and Lu.

bands undergoing shifts owing to complex formation. The free ligand exhibits $\nu(NH_2)$, $\nu(C{=}O)$, $\delta(NH_2)$ and $\nu(C{=}N)$ bands at 3430, 1600, 1557 and 1520 cm^{-1}, respectively, while in the spectra of the complexes they are shifted to lower wave numbers by 60, 7–10, 25–29 and 25–38 cm^{-1}, respectively. These observations suggest that Fcen is coordinated with the lanthanide ions as a tridentate ligand through its carbonyl oxygen, axomethine and amino nitrogen atoms (see Scheme 1).

The UV spectral data listed in Table 3 show that all the spectra of $Fcen_3LnCl_3$ are similar to the spectrum of Fcen. The absorption maxima (270 and 342 nm) of the ligand suffer slight blue shifts of 1–3 nm in the complexes. However, the values of the molar extinction coefficients of the complexes measured at identical wavelengths show significant increments when compared with that of the ligand (Table 3). In the 440–460 nm region, a flat, broad band is also observed for both the ligand and complexes (Fig. 1), but the position of λ_{max} and the value of ε can not be accurately determined.

Table 3. UV spectral data of Fcen and $Fcen_3LnCl_3$

Ligand or complexes	Band 1 λ_{max} (ε)	Band 2 λ_{max} (ε)	Band 3 λ_{max} (ε)
La	269(22,080)	340(36,960)	440–460
Nd	269(22,860)	341(43,920)	440–460
Gd	269(22,480)	341(39,040)	440–460
Dy	269(24,300)	339(36,120)	440–460
Lu	268(18,260)	340(26,540)	440–460
Fcen	270(7340)	342(17,820)	440–460
Ferrocene[a]	267(1569)	328(47)	441(93)

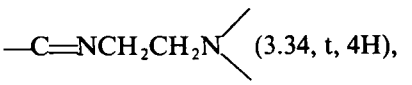
[a] The values of ferrocene measured in this work agree with the literature values.[6]

The significant differences between the UV spectra of ferrocene and Fcen are observed when an electron-withdrawing substituent is introduced into the cyclopentadienyl ring. The 267 and 328 nm bands of ferrocene are shifted bathochromically in Fcen, the former is shifted by 3 nm and the latter by 14 nm. The intensity (ε) of the 328 nm band, however, increases much more than that of the 267 nm band. The 441 nm band of ferrocene becomes a flat, weak band in Fcen, as mentioned above. Therefore, the 328 and 441 nm bands, which are sensitive to the substituent, can be attributed to the *d–d* transitions[4] of the ferrocene entity, while the 267 nm band may be attributed to the π–π^* transitions of the cyclopentadienyl ring.[5]

The fact that both the ligand and complexes have virtually identical absorption maxima and the values of ε increase in the complexes, indicates that the σ-orbitals of the oxygen and nitrogen atoms are substantially involved in bonding with the lanthanide ions.

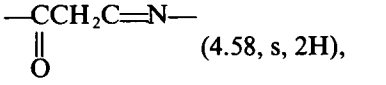
The ^1H NMR spectrum of Fcen clearly shows proton signals (δ, ppm) for

CH_3 (1.86, s, 3H),

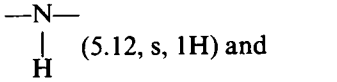


(3.34, t, 4H),

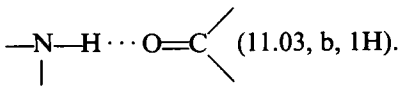
C_5H_5Fe (4.00, s, 5H), C_5H_4Fe (4.20, b, 4H),



(4.58, s, 2H),



(5.12, s, 1H) and



(11.03, b, 1H).

The signals at 5.12 and 11.03 ppm disappear on deuteration with D_2O which indicates that one of the amino nitrogen atoms is associated with the carbonyl oxygen atom to form a hydrogen bond.

The spectra of the complexes could not be taken due to their limited solubility.

The mass spectrum of Fcen exhibits its molecular ion peak at *m/z* 312. The following peaks are also found:

m/z 295

$$[C_5H_5—FeC_5H_4—\underset{\underset{O}{\|}}{C}CH_2—\underset{\underset{CH_3}{|}}{C}=NCH=CH_2]^+,$$

m/z 282

$$[C_5H_5FeC_5H_4—\underset{\underset{O}{\|}}{C}CH_2—\underset{\underset{CH_3}{|}}{C}=NCH_2]^+,$$

m/z 185 $[C_5H_5FeC_5H_4]^+$, *m/z* 121 $[C_5H_5Fe]^+$, *m/z* 65 $[C_5H_5]^+$ and *m/z* 56 $[Fe]^+$.

The data for ^1H NMR and MS spectra further support the composition and structure of Fcen.

The Mössbauer spectra of the ligand and complexes are similar to the spectrum of ferrocene, which exhibits a quadruple doublet (Fig. 2).

From the data in Table 4, it is clear that both Fcen and $Fcen_3LnCl_3$ have markedly lower isomeric shifts (IS) and quadrupole splitting (QS) compared with those of ferrocene, owing to the presence of the conjugated electron-withdrawing substituent[7] on the cyclopentadienyl ring. However, the differences in the Mössbauer parameters between Fcen and $Fcen_3LnCl_3$ are very small. They show that there is no significant charge-transfer between the iron nucleus and lanthanide after coodination of Fcen with the lanthanide chlorides.

The molar conductivity values for the La, Nd, Gd and Dy complexes are 222, 218, 240 and 194 Ω^{-1} cm^2 mol^{-1}, respectively, while the molar conductivity of $CrCl_3$ determined under the same conditions is 235 Ω^{-1} cm^2 mol^{-1}. It suggests that all these complexes behave as 1 : 3 electrolytes in DMF.

The TG–DTA graphs were recorded in the temperature range of 25–850°C. From the DTA curves, no melting points for the Fcen complexes are observed. However, the complexes have two decomposition points. The first is in the range of 172–196°C, corresponding to a sharp endothermic peak, while the second is in the range 248–368°C, corresponding to a broad and larger endothermic peak. On comparison with the endothermic peaks, the TG curves reveal two stages of weight loss. The initial decomposition temperatues for the La, Nd, Gd, Dy and Lu complexes are 190, 184, 172, 191 and 196°C, respectively.

EFFECTS OF SIDE-CHAIN DONOR GROUPS ON DEPROTONATION OF PEPTIDE AMIDE IN COPPER(II) COMPLEXES AT HIGH pH

E. FARKAS* and T. KISS

Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, H-4010 Debrecen, Hungary

(*Received* 1 *December* 1988; *accepted* 19 *May* 1989)

Abstract—The copper(II) complexes of the GlyAsp (glycyl–L-aspartic acid), GlyAsn (glycyl–L-asparagine), GlySer (glycyl–L-serine), GlyThr (glycyl–L-threonine), GlyPhe (glycyl–L-phenylalanine), SerGly (L-serylglycine), ThrGly (L-threonylglycine), PheGly (L-phenylalanylglycine) and GlyGly (glycylglycine) groups as a reference were studied by pH-metric, spectrophotometric and ESR methods at high pH and high ligand excesses (up to a metal-to-ligand ratio of 1 : 50). The influence of the side-chain donor groups and the aromatic ring on the competitive formation of the mixed hydroxo complex $[Cu(AH_{-1})OH]$ and the deprotonated complex $[Cu(AH_{-1})_2]$ was evaluated.

The copper(II) ion-induced deprotonation of the peptide amide group in simple dipeptides occurs at *ca* pH 4–5,[1–6] and a complex $[Cu(AH_{-1})]$ is formed, in which the amino nitrogen, the deprotonated peptide amido nitrogen and the carboxylate oxygen are involved in coordination. A hydroxide ion and a second ligand can compete with each other for the fourth equatorial coordination site. The bis-complex $[Cu(AH_{-1})A]$ is formed in the pH range 6–10. If the metal ion-to-dipeptide ratio is below 1 : 5, the A is displaced by a hydroxide ion above pH 9–10, and even the carboxylate group is replaced by a second OH ion above pH 12.0–12.5.[7–9] At a high ligand excess and at high pH, it was found in the copper(II)–GlyGly system that there is an equilibrium between this mixed hydroxo complex $[Cu(AH_{-1})OH]$ and the 1 : 2 deprotonated complex $[Cu(AH_{-1})_2]$.[10]

We have previously investigated numerous copper(II)–dipeptide systems.[11–16] In the present work we have extended the solution equilibrium study up to high ligand excess, 1 : 50, and high pH, *ca* 13.

EXPERIMENTAL

GlyGly, GlyAsp, GlyAsn, GlySer, SerGly, GlyPhe and PheGly were purchased from SIGMA. ThrGly and GlyThr were prepared by the method reported in ref. 17.

The pH-metric and spectrophotometric measurements were carried out for samples with metal-to-ligand ratios of 1 : 1, 1 : 2, 1 : 25 and 1 : 50. The concentrations of the copper(II) ion varied in the range 0.004–0.020 mol dm^{-3}. The measurements were performed at 25.0 ± 0.1°C, and the ionic strength was adjusted to 1.0 mol dm^{-3} with KCl.

The pH-metric titrations were performed over the pH range 3.0–13.0 in an argon atmosphere, using a Radiometer pHM 64 instrument, with a GK 2401B combined electrode and a Radiometer ABU 13 burette. The electrode system was calibrated by the method of Irving *et al.*[18]

Visible absorption spectra were recorded over the pH range 8.5–13.0 with a Beckman ACTA MIV double-beam recording spectrophotometer.

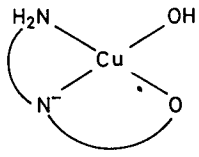
Concentration equilibrium constants were calculated by the simultaneous fitting of the pH and spectrophotometric experimental data with the aid of the computer program PSEQUAD.[19]

EPR spectra of the copper(II)–GlySer and copper(II)–SerGly systems were obtained on a JES-MF-3F spectrometer at liquid nitrogen temperature (77 K). The parameters g and A were calculated via the computer program of Rockenbauer *et al.*[20]

RESULTS AND DISCUSSION

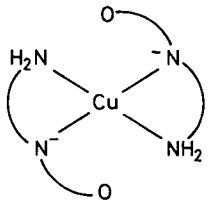
The equilibrium constants for the complexes present in the systems of copper(II) with GlyGly, GlyAsn, GlyAsp, GlySer, SerGly, GlyPhe and PheGly in the pH range 3–10 were reported earlier.[11,15,16]

* Author to whom correspondence should be addressed.



[Cu(AH$_{-1}$)OH]

Scheme 1.



[Cu(AH$_{-1}$)$_2$]

Scheme 2.

For this reason, only the constants for the copper(II)–ThrGly and copper(II)–GlyThr complexes, which have not been published before, are given in this paper.*

In the copper(II)–dipeptide systems the following equilibrium processes may take place at high pH, in competition with each other:

$$[Cu(AH_{-1})A] + 2H_2O \rightleftharpoons [Cu(AH_{-1})OH] + A + H_3^+O \quad (1)$$

$$[Cu(AH_{-1})A] + H_2O \rightleftharpoons [Cu(AH_{-1})_2] + H_3^+O. \quad (2)$$

The bonding modes of the complexes [Cu(AH$_{-1}$)OH] and [Cu(AH$_{-1}$)$_2$] are depicted in Schemes 1 and 2, respectively. (The overall charges of the complexes are omitted, as they depend on the type of ligand.)

As can be seen in Schemes 1 and 2, the mixed hydroxo complex [Cu(AH$_{-1}$)OH] has two nitrogen atoms in the coordination sphere, while the deprotonated one [Cu(AH$_{-1}$)$_2$] has four. This means that spectrophotometry can be used to distinguish between equilibrium processes (1) and (2).

The pH-dependences of the absorption maxima

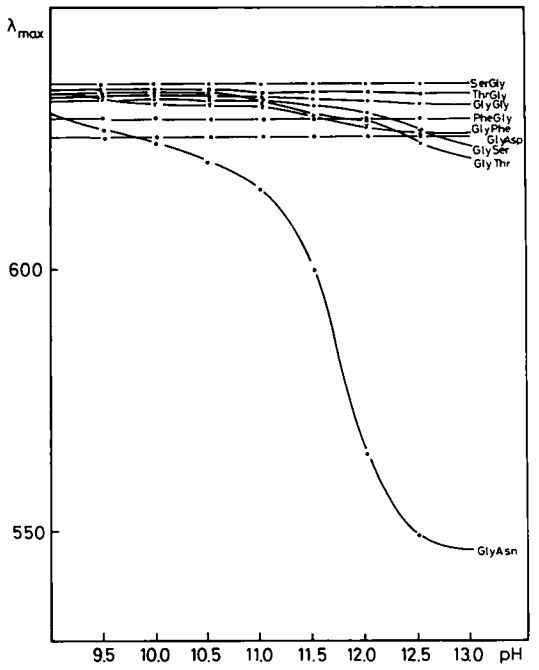


Fig. 1. pH-dependences of λ_{max} over the pH range 9.0–13.0 for the copper(II)–dipeptide systems at a metal-to-ligand ratio of 1 : 1.

(λ_{max}) for all of the studied systems, at metal-to-ligand ratios of 1 : 1 and 1 : 50, are depicted in Figs 1 and 2, respectively.

It can be seen from Fig. 1 that the λ_{max} values, except for those relating to the copper(II)–GlyAsn,

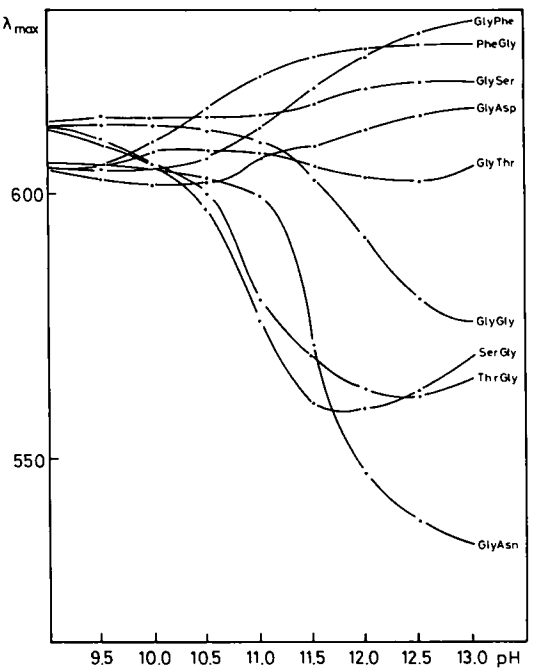

Fig. 2. pH-dependences of λ_{max} over the pH range 9.0–13.0 for the copper(II)–dipeptide systems at a metal-to-ligand ratio of 1 : 50.

* Formation constants ($\log\beta$) for proton and copper(II) complexes of GlyThr and ThrGly (I = 1.0 mol dm^{-3} (KCl), t = 25°C). GlyThr: HA: 8.25; H_2A: 11.41; [CuA]: 5.43; [CuAH$_{-1}$]: 1.12; [CuA$_2$H$_{-1}$]: 4.17; [CuAH$_{-2}$]: −8.43. ThrGly: HA: 7.46; H_2A: 10.67; [CuA]: 4.86; [CuAH$_{-1}$]: 1.09; [CuA$_2$H$_{-1}$]: 3.40; [CuAH$_{-2}$]: −8.57; [Cu(AH$_{-1}$)$_2$]: −6.90.

copper(II)–GlySer and copper(II)–GlyThr systems, lie at around 630 nm and do not show a noticeable pH-dependence at a metal-to-ligand ratio of 1 : 1. Perfect fitting can be obtained only if the formation of the species $[Cu(AH_{-1})OH]$ is assumed for all the experimental data (both pH and spectrophotometric data). For the copper(II)–GlySer and copper(II)–GlyThr systems, the λ_{max} values show a small decrease above pH 11.5, suggesting the already reported[8] deprotonation and coordination of the alcoholic hydroxy group, replacing the carboxylate, above pH 12. The marked increase in the *d–d* transition energy for the copper(II)–GlyAsn system above pH 9 has been ascribed to the formation of $[Cu(AH_{-2})OH]$, in which three nitrogen atoms (NH_2, deprotonated peptide amido and side-chain amido nitrogens) are involved in the coordination in addition to an OH^- ion.[11]

According to Fig. 2, there is a large increase in the *d–d* transition energy in the copper(II)–GlyAsn, copper(II)–SerGly and copper(II)–ThrGly systems at a metal-to-ligand ratio of 1 : 50 above pH 9 and in the copper(II)–GlyGly system above pH 11. In the other systems a small red shift can be seen,

when the pH is increased from 9 to 13. The pH-dependence of λ_{max} for copper(II)–GlyAsn at a ratio of 1:50 is similar to that at a ratio of 1:1. This means that in this system the species $[Cu(AH_{-2})OH]$ predominates even at a large ligand excess.

Equilibrium constants for processes (1) and (2) calculated from all of the experimental data are listed in Table 1. It can be concluded from Table 1 that, if the ligand excess is not higher than 50-fold, the complex $[Cu(AH_{-1})_2]$ is formed in measurable amounts only in the copper(II)–GlyGly, copper(II)–SerGly and copper(II)–ThrGly systems. In the other systems, the competition between equilibrium processes (1) and (2) is shifted strongly in favour of formation of the mixed hydroxo complex $[Cu(AH_{-1})OH]$ even at a ratio of 1:50.

The most probable explanation of the results is as follows: for GlyGly, because of the small size of the molecule, coordination of the second peptide is the least hindered. Thus, both $[Cu(AH_{-1})(OH)]$ and $[Cu(AH_{-1})_2]$ can be formed. As the size of the molecule increases, the formation of $[Cu(AH_{-1})_2]$ becomes more hindered. The deprotonated bis-complex is not formed either with GlyPhe or with PheGly, because of the bulky aromatic side-chain.

In GlyAsp there is a carboxylate group in the side-chain, thus the formation of $[Cu(AH_{-1})_2]$ is hindered electrostatically.

In the case of dipeptides containing an alcoholic hydroxy group (GlySer, SerGly, GlyThr and ThrGly), the competition between processes (1) and (2) depends greatly on the position of the alcoholic hydroxy group. SerGly and ThrGly, which contain the alcoholic hydroxy group in the side-chain near the amino terminal, have the strongest tendency to form the $[Cu(AH_{-1})_2]$ complex. In contrast, for GlySer and GlyThr only the mixed hydroxo complex is formed. As an illustration, the distribution curves of the complexes formed in the copper(II)–GlyThr and copper(II)–ThrGly systems at a metal-to-ligand ratio of 1:50 are presented in Fig. 3.

The difference in complex forming behaviour of the dipeptides containing an alcoholic hydroxy group was confirmed by EPR measurements on the copper(II)–GlySer and copper(II)–SerGly systems (see Table 2).

The EPR spectrum of copper(II)–SerGly can be simulated at *ca* pH 13 if the coordination of three or four nitrogen atoms is proposed. However, the spectra of copper(II)–GlySer can be simulated on the assumption of two nitrogen atoms at both *ca* pH 10 and *ca* pH 13. A possible explanation for the difference in behaviour of the dipeptides containing an alcoholic hydroxy group is that, in the cases of SerGly and ThrGly, the $[Cu(AH_{-1})_2]$ structure can be stabilized by hydrogen bonds between the non-coordinated carboxylate and alcoholic OH groups.

Acknowledgements—Thanks are due to Dr A. Rockenbauer (Central Chemical Research Institute, Budapest, Hungary) for his help in the recording and evaluation of the ESR spectra, and to Mrs Á. Gönczy and I. Hüse for their help in the experimental work. This work was supported financially by the Hungarian Ministry of Education (MM 46/86).

STABILIZATION OF COPPER(II) RELATIVE TO COPPER(I) IN TETRANUCLEAR $Cu_4OX_6L_4$ COMPLEXES

D. MAKÁŇOVÁ* and G. ONDREJOVIČ

Department of Inorganic Chemistry, Slovak Technical University, 812 37 Bratislava, Czechoslovakia

(*Received* 20 *March* 1989; *accepted* 25 *May* 1989)

Abstract—The complexes $Cu_4OCl_6(Ph_3P)_4 \cdot 0.5Et_2O$, $Cu_4OCl_6(Ph_3As)_4$, $Cu_4OCl_6(Ph_3As)_4 \cdot Et_2O$, $Cu_4OCl_6(MeOH)_2(Ph_3As)_2$, $Cu_4OCl_6(Ph_3Sb)_4 \cdot Et_2O$ and $Cu_4OBr_6(Ph_3P)_4 \cdot 1.5Et_2O$ were prepared and isolated. The electronic and IR spectra indicate a tetrameric structure with trigonal bipyramidal coordination of the copper(II) atom. On moderate heating the complexes undergo decomposition with reduction of copper(II) to copper(I). The influence of their specific structure on the stabilization of copper(II) relative to copper(I) is discussed.

The reduction of copper(II) to copper(I) by reaction of Ph_3E with copper(II) salts is well known. The reducing influence of Ph_3E (E = P, As, Sb) ligands in copper(II) complexes can be weakened or even eliminated. This was achieved by using tfac and hfac chelate ligands in $[Cu(tfac)_2 \cdot R_3P]$ (tfac = trifluoroacetylacetonate)[1] and $Cu(hfac)_2 \cdot L$ (hfac = hexafluoroacetylacetonate, L = R_3P, Ph_3As).[2]

It was observed that some structural types of copper(II) complexes can be effective in the stabilization[3] of copper(II) relative to copper(I). One of those structural types is the dimeric structure[4,5] of the copper(II) acetate monohydrate. The other structural type is that of the tetrameric $Cu_4OX_6L_4$ complexes[6] (Fig. 1) having a trigonal bipyramidal coordination[7] of copper(II).

This paper presents the preparation of $Cu_4OX_6L_4$ complexes (X = Cl, Br; L = Ph_3P, Ph_3As, Ph_3Sb), their characterization by electronic and IR spectra and temperatures of thermal decomposition.

EXPERIMENTAL

Preparation of complexes

The complexes $Cu_4OCl_6(Ph_3P)_4 \cdot 0.5Et_2O$ (**1**), $Cu_4OCl_6(Ph_3As)_4$ (**2**), $Cu_4OCl_6(Ph_3As)_4 \cdot Et_2O$ (**3**), $Cu_4OCl_6(MeOH)_2(Ph_3As)_2$ (**4**), $Cu_4OCl_6(Ph_3Sb)_4 \cdot Et_2O$ (**5**) and $Cu_4OBr_6(Ph_3P)_4 \cdot 1.5Et_2O$ (**6**) (Et_2O = diethyl ether) were prepared by the substitution of the methylalcohol (MeOH) in the starting complex, $Cu_4OX_6(MeOH)_4$, adding a stoichiometric quantity of Ph_3E in ether into a solution of $Cu_4OX_6(MeOH)_4$ in MeOH at a temperature of 213 K, under a nitrogen atmosphere. The preparation of the initial $Cu_4OX_6(MeOH)_4$ compounds was performed using a modification of the published method.[6] The separated complexes were kept under nitrogen at 263 K. The elemental analyses are listed in Table 1.

Measurements

The electronic spectra were obtained with SPECORD M 40 and UNICAM SP-700C spectrophotometers, while the IR spectra were recorded on a SPECORD 75 IR, using Nujol mulls. Thermal decomposition of the complex was recorded with a DERIVATIGRAPH OD-102.

RESULTS AND DISCUSSION

Table 2 presents the electronic and IR spectral data which may be considered to be diagnostic for $Cu_4OX_6L_4$ complexes and their structures are given in Fig. 1. The copper(II) atom has trigonal bipyramidal coordination with the ligand L in an axial position. The molecules of the solvent, which can be found in the structure, only slightly affect the bond distances and bond angles, compared with an unsolvated complex.[7,8] The electronic spectra of the complexes exhibit one or two bands in the region of 9900–13600 cm^{-1}, belonging to *d–d* transitions. As may be seen from Table 2, $Cu_4OX_6(Ph_3E)_4$ complexes exhibit a broad band in the region of 10,300–13,800 cm^{-1}, which may be the result of considerable overlapping of two bands.

For $Cu_4OX_6L_4$ complexes (X = Cl, Br; L = N-donor or O-donor ligands) to which the above structure is assigned,[6] the $\tilde{\nu}(Cu_4O)$ wave number values due to the characteristic tetrahedral arrangement of copper(II) atoms around the oxygen atom, were found in the region of 571–597 cm^{-1} for X = Cl and at 526–559 cm^{-1} for X = Br. For the

[b] During measurements of the spectra the complex decomposed on the reduction of copper(II) to copper(I).

complexes $Cu_4OX_6(Ph_3P)_4$ the $\tilde{\nu}(Cu_4O)$ values were observed at 539 cm^{-1} for X = Cl and at 518 cm^{-1} for X = Br.[6] The corresponding solvated complexes, **1** and **6**, show $\tilde{\nu}(Cu_4O)$ values at 535 and 540 cm^{-1}, respectively. Complexes with Ph_3As (**2** and **3**) and with Ph_3Sb (**5**) show, as expected, lower $\tilde{\nu}(Cu_4O)$ values, the band being split (Table 2). Complex **4** with mixed ligands of MeOH and Ph_3As exhibits a split band in the region of 480–500 cm^{-1}, similar to complexes **2** and **3**, and another band at a considerably higher wavenumber (600 cm^{-1}) which is near to the $\tilde{\nu}(Cu_4O)$ value for the pure methanol complex of $Cu_4OCl_6(MeOH)_4$.[6] The two or three $\tilde{\nu}(Cu_4O)$ bands in the spectra of complexes **2**, **3** and **4** suggest that in these complexes the tetrahedral grouping of Cu_4O is more distorted than for complexes **1** and **6**.

In the trigonal bipyramidal complexes $[Cu(chel)_2X]^{n+}nY^-$ (X = I^-, CN^-, NCS^-, thiourea; chel = bipy or phen; Y = ClO_4^-) the reducing ligand X is located in the trigonal plane. For these complexes the stabilization of copper(II) relative to copper(I) has been explained by a minimum overlap of X ligand orbitals with the d_{z^2} orbital of copper(II) which contains an unpaired electron.[9] Thus the conditions for the electron transfer $Cu^{II}-X \rightarrow Cu^{I}+X$ are unfavourable. However, in the structure of $Cu_4OX_6(Ph_3E)_4$ complexes the reducing ligand Ph_3E occupies the axial position of the trigonal bipyramid and thus there are favourable conditions for the reduction of copper(II) to copper(I).

In fact, the complexes $Cu_4OX_6(Ph_3E)_4$ are unstable and undergo decomposition due to the reduction of copper(II) to copper(I) at relatively low temperatures (Table 2), whereas the analogous complexes e.g. with pyridine and its methyl derivatives melt at temperatures[6] in the range 417–548 K.

The possibility of preparing the $Cu_4OX_6(Ph_3E)_4$ complexes is probably connected with the stabilizing influence of their specific structure, in which the coordination polyhedra are mutually coupled by the common oxygen-atom and by bridging X atoms, in contrast to the structure of $[Cu(chel)_2X]^{n+}nY^-$ complexes which is composed of the isolated coordination polyhedra.

REACTIONS OF POLYOXOMOLYBDATES WITH OXIMES. THE CRYSTAL AND MOLECULAR STRUCTURES OF $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2]\cdot CH_2Cl_2$ AND $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$

SHUNCHENG LIU, HUIZHE ZHU and JON ZUBIETA*

Department of Chemistry, State University of New York at Albany, Albany, NY 12222, U.S.A.

(*Received* 12 *April* 1989; *accepted* 31 *May* 1989)

Abstract—The reactions of $[(C_4H_9)_4N]_2[Mo_2O_7]$ with the oximes benzoinoxime and salicylaldoxime yielded the complexes $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2]\cdot CH_2Cl_2$ (**7**) and $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$ (**8**). The structures of **7** and **8** exhibit the $[Mo_2O_5]^{2+}$ core with the oximato moieties of the ligands functioning as μ_2-O,N bridging donors. The metrical parameters are consistent with the sp^2 hybridization of the oximato nitrogen with double bond character localized on the C—N bond. Crystal data: Compound **7**, monoclinic space group, $P2_1/c$, $a = 16.271(6)$, $b = 14.010(4)$, $c = 25.390(8)$ Å, $\beta = 101.34(2)°$, $V = 5672.9(19)$ Å^3, $D_{calc} = 1.30$ g cm^{-3} for $Z = 4$. Structure solution and refinement based on 4718 reflections with $F_o \geqslant 6\sigma(F_o)$(Mo-$K_\alpha$, $\lambda = 0.71073$ Å) converged at a conventional residual of 0.064. Compound **8**, rhombohedral space group (hexagonal setting) $R\bar{3}$, $a = b = 47.188(14)$, $c = 15.766(3)$ Å, $V = 30403.4(27)$ Å^3, $D_{calc} = 1.19$ g cm^{-3} for $Z = 18$. Structure solution and refinement based on 3015 reflections with $F_o \geqslant 6\sigma(F_o)$ converged at a value of 0.069 for the conventional R factor. Reaction of the related salicylhydroxamic acid with $[(C_4H_9)_4N]_2[Mo_2O_7]$ in methanol yielded the complex $[(C_4H_9)_4N][MoO_2\{C_6H_4(OH)C(O)NO\}\{C_6H_4(OH)C(O)NHO\}]$ (**11**), a species exhibiting both hydroximato(2−) and hydroxamato(1−) forms of the ligand. Crystal data: Compound **11**, monoclinic space group $P2_1/c$, $a = 10.261(2)$, $b = 17.864(4)$, $c = 18.270(3)$ Å, $\beta = 91.98(1)°$, $V = 3347.0(10)$ Å^3, $D_{calc} = 1.34$ g cm^{-3} for $Z = 4$. Structure solution and refinement based on 3406 reflections converged at a value of 0.049 for the conventional R factor.

Oxoanions of molybdenum(VI) react with hydroxylamines (**1**) to give complexes containing O,N-coordinated hydroxylamido(1−) ligands, (**2**).[1] With the analogous oximes (**3**), polynuclear complexes containing bridging O,N-coordinated oximato(1−) ligands have been described.[2] As an extension of our work on the coordination chemistry of polyoxomolybdate anions with nitrogen donor ligands,[3] we have studied the reactions of $[(C_4H_9)_4N]_2[Mo_2O_7]$ with the oxime ligands, benzoinoxime (**4**) and salicylaldoxime (**5**), and with the related salicylhydroxamic acid ligand (**6**). In this paper, we discuss the structures of $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2]\cdot CH_2Cl_2$ (**7**) and $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$ (**8**) and compare their geometries to those of related oxomolybdate hydroxylamido and oxomolybdate oximato complexes and with that of the salicylhydroxamic acid derived species, $[(C_4H_9)_4N][MoO_2\{C_6H_4(OH)C(O)NO\}\{C_6H_4(OH)C(O)NHO\}]$ (**11**).

RESULTS AND DISCUSSION

The reaction of 1 equivalent of $[(C_4H_9)_4N]_2[Mo_2O_7]$ with 2 equivalents of oximes (**4**) and (**5**) in dichloromethane, followed by addition of diethyl ether, yielded translucent crystals of $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2]\cdot CH_2Cl_2$ (**7**) and $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$ (**8**), respectively. Whereas the crystals of **8** were relatively stable under an atmosphere of nitrogen, crystals of **7** rapidly lost translucency upon removal of solvent, which required storage of **7** in the presence of the mother liquor.

Structural studies of the oximato complexes, **7** *and* **8**, *and of the hydroximato/hydroxamato species,* **11**

The structures of the complex anions of **7** and **8** are illustrated in Figs 1 and 2, respectively, the selected bond distances and angles for the structures are compared in Table 1. The structures are seen to contain the $[Mo_2O_5]^{2+}$ core coordinated to two oximato ligands functioning as chelating and bridging moieties.

The oximato units function as bridging groups, with the oxygen and nitrogen donors acting as μ_2-bridging ligands to the molybdenum centres. In addition, the oximate ligands coordinate through their alkoxy groups to complete the hexacoordinate geometry about the molybdenum centres.

The molybdenum centres of **7** display pseudo-octahedral $[MoO_5N]$ geometry by virtue of coordination to two terminal oxo groups, the bridging oxo group, a terminal alkoxy donor, and the nitrogen and oxygen donors of the bridging oximato moiety. One consequence of bridging through the N- and O-donors is the appearance of two cyclic units [Mo(1)—O(3)—Mo(2)—N(2)—O(6)] and [Mo(1)—O(3)—Mo(2)—O(8)—N(1)]. Furthermore, the two-atom bridge between the molybdenum centres requires that the Mo(1)—O(3)—Mo(2) angle expand from the usual value found with single donor bridges. Thus, the Mo—O—Mo angle in **7** of 131.5(3)° may be contrasted with that of 112.7(2)° in $[Mo_2O_5(phenanthraquinone)_2]$[4] which exhibits the more common single donor bridge.

Various coordination modes have been reported for molybdenum–oximato complexes. The most common is side-on coordination to a single molybdenum centre through the N- and O-donors,[5,6] a coordination geometry similar to that observed for hydroxylaminato complexes of molybdenum.[1,7] In addition, a number of tetranuclear molybdate complexes have been described in which the oximato group functions as a μ_4-bridging ligand.[2] The chelating, doubly bridging geometry adopted by **7** and **8** represents a third coordination type for the oximato ligand.

The ligand geometries of the various hydroxyl-

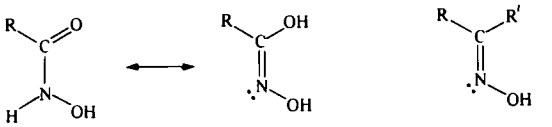
aminato- and oximatomolybdenum complexes serve to distinguish the two ligand types. In hydroxylaminato complexes, the nitrogen atom is sp^3 hybridized, requiring that the [R_2N—O—Mo] moiety be non-planar.[1] In contrast, the nitrogen donor of the oximato ligand is sp^2 hybridized, a feature consistent with the observed planarity of the chelate ring units in both **7** and **8**, and in the short C—N distances of *ca* 1.28(2) Å.

The structures of **7** and **8** differ significantly only in the chelate ring sizes and the identities of the organic substituents on the oximato ligands. In **7**, six-membered chelate rings [O—C—C—C—N—Mo] are formed by virtue of ligation to the alkoxy oxygen functionality and the oximato nitrogen. The entire ligand–molybdenum unit, [OC_6H_4CNOMo], is virtually planar. In contrast, the structure of **8** presents planar five-membered chelate rings, a feature which results in the contraction of the O—Mo—N chelate angle from a value of 79.1(3)° in **7** to the more constrained 73.2(5)° in **8**. Since C(8) and C(21) in **8** are sp^3 hybridized and rotation about the C(8)—C(9) and C(20)—C(21) axes is unhindered, the phenyl substituents of the oximato ligands of **8** do not lie in the plane of the chelate ring, in contrast to the geometry observed for **7**.

Although the enol form (**10**) of the hydroxamic acids is structurally similar to the oxime ligand (**3**), transition metal–hydroxamato nitrogen bonds are



(**9**) (**10**) (**3**)

extremely rare, with the only examples provided by the square-planar bis(glycinohydroxamato) nickel(II)[8] and [VO(salicylhydroximate)(CH_3OH)]$_3$.[9] Hence, it was not unexpected that the oxomolybdate–hydroxamate complex, [$(C_4H_9)_4N$][MoO_2{C_6H_4(OH)C(O)NO}{C_6H_4(OH)C(O)NHO}] (**11**), coordinates exclusively through the carbonyl and oxime oxygens of the ligand (see Table 2). As illustrated in Fig. 3, the structure of the anion of **11** consists of discrete mononuclear units with pseudo-octahedral molybdenum centres, coordinated to a *cis* terminal oxo group and to two carbonyl oxygens and two ozime oxygens from the ligand groups.

Table 2. Selected bond lengths (Å) and angles (°) for [$(C_4H_9)_4N$][MoO_2{C_6H_4(OH)C(O)NO}{C_6H_4(OH)C(O)NHO}] (**11**)

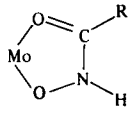
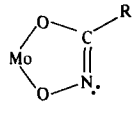
The most unusual feature of the structure is the presence of both hydroxamato(1−) (**12**) and

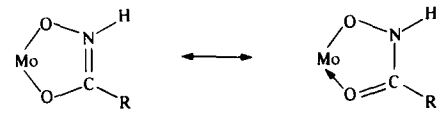


(12)



(13)

hydroximato(2−) (**13**) ligand types. The distinct ligand environments are readily identified both by the location of hydrogen atoms and by the structural parameters associated with the chelate rings. Thus, the final Fourier map for **11** reveals hydrogens H(O7) and H(O8), associated with the uncoordinated hydroxyl groups, and H(N1) at 0.93 Å from N(1) and hydrogen bonding to O(7). Furthermore, as shown in Table 3, comparison of the chelate ring parameters for the two distinct ligand types in **11** to the ring parameters for the hydroxamato(1−) ligands of $[Cr(benzohydroxamato)_3]$[10] and for the hydroximato(2−) ligands of $[Cr(benzohydroximato)_3]^{3-}$,[11] clearly establishes the identities of the ligand types. The most significant changes upon deprotonation of the hydroxamato unit are increases in the N—O and C—O bond distances by 0.02–0.05 Å and, in the specific case of **11**, a decrease in the C—N bond distance by 0.03 Å. This is accompanied by expansion of the O—C—N bond angle and O—N—C bond angle contraction. The C—N bond distances for both the hydroximato and hydroxamato ligands are significantly shorter than C—N single bonds (1.43–1.45 Å)[12] and slightly longer than the C=N bond of ethylbenzohydroximic acid (1.27 Å).[13] The chromium complexes display only a minor decrease in both the Cr—O_o and Cr—O_c bonds upon deprotonation. In contrast, the Mo—O_c distance for the hydroxamato interaction is *ca* 0.05 Å longer than the corresponding distance for the hydroximato ligand. The observed chelate metrical parameters have been interpreted in terms of the resonance structures **14** and **15** for the hydroxamato type and **16** and **17** for the hydroximato ligand.



(14) (15)

(16) (17)

From the observed bond lengths, form **15** dominates the electronic structure of the hydroxamato

ligand, while resonance structure **16** provides the major contribution to the hydroximato geometry. In fact, structure **17** is not expected to contribute significantly because of the charge localization on the oxime N—O unit.

EXPERIMENTAL

Materials and methods

All reactions were performed in freshly dried and distilled solvents. Dichloromethane was technical grade and was redistilled from $CaCl_2$ and P_4O_{10}. All other solvents were reagent grade. All other reagents were obtained from standard commercial sources without further purification.

The following instruments were used in this work: IR, Perkin–Elmer 283B IR spectrophotometer; UV–vis. spectra, Varian DMS 90 UV-vis. spectrophotometer; X-ray crystallography, Nicolet R3m diffractometer.

Preparation of complexes

$[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2] \cdot CH_2Cl_2$ (**7**). $[(C_4H_9)_4N]_2[Mo_2O_7]$ (1.5 g, 2 mmol) was dissolved in 30 cm^3 of CH_3CN. While stirring this solution vigorously, salicylaldoxime (0.5 g, 4 mmol) was added, whereupon the solution turned bright yellow. After overnight stirring at room temperature, the solution was concentrated to 10 cm^3 and layered with CH_2Cl_2–ether (2 cm^3/20 cm^3). Upon standing for 2 weeks at 4°C, translucent yellow crystals of block habit were obtained (yield: 40%). The crystals rapidly turn opaque upon standing in air in the absence of the mother liquor. Crystals for X-ray studies were mounted in capillary tubes in the presence of a drop of the mother liquor. Analysis (dry sample loses CH_2Cl_2 of crystallization): Found: C, 53.9; H, 8.11; N, 5.36. Calc. for $C_{46}H_{82}N_4O_9Mo_2$: C, 53.8; H, 7.99; N, 5.46%. IR (KBr pellet, cm^{-1}): 2970(s), 2880(m), 1600(w), 1470(s), 1440(s), 1320(m), 1270(s), 1200(w), 1065(s), 1035(s), 905(s), 880(s), 750(m), 710(s), 660(m), 615(s).

$[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$ (**8**). 2-Benzoin oxime (0.88 g, 4 mmol) was added to a solution of $[(C_4H_9)_4N]_2[Mo_2O_7]$ (1.5 g, 2 mmol) in CH_3CN (30 cm^3). After overnight stirring and concentration of the resultant yellow solution to 5 cm^3, the reaction solution was layered with diethyl ether (10 cm^3). After standing at room temperature for 2 weeks, pale yellow block-like crystals were obtained in 30% yield. Found: C, 59.6; H, 8.00; N, 4.77. Calc. for $C_{60}H_{94}N_4O_9Mo_2$: C, 59.7; H, 7.79; N, 4.64%. IR (KBr pellet, cm^{-1}): 2960(s), 2860(s), 1540(w), 1490(s), 1380(w), 1130(s), 1070(m), 1025(m), 900(s), 880(vs), 750(s), 700(s), 650(m).

$[(C_4H_9)_4N]$ $[MoO_2\{C_6H_4(OH)C(O)NO\}$ $\{C_6H_4(OH)C(O)NHO\}]$ (**11**). Salicylhydroxamic acid (0.6 g, 4 mmol) was added with vigorous stirring to a solution of $[(C_4H_9)_4N]_2[Mo_2O_7]$ (1.5 g, 2 mmol) in CH_3CN (30 cm^3). Overnight stirring at room temperature was followed by concentration to 10 cm^3 and layering with ether (15 cm^3). After 3 weeks of standing at room temperature, pale yellow crystals of **11** were collected in 55% yield. Found: C, 53.7; H, 7.14; N, 6.23. Calc. for $C_{30}H_{47}N_3O_8Mo$: C, 53.6; H, 6.84; N, 6.25%. IR (KBr pellet, cm^{-1}): 3310(m), 2965(s), 2880(s), 1600(s), 1550(m),

Table 4. Summary of the crystal data[a] and experimental details for the X-ray diffraction studies of $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_4(O)CHNO\}_2]\cdot CH_2Cl_2$ (7), $[(C_4H_9)_4N]_2[Mo_2O_5\{C_6H_5CH(O)C(NO)C_6H_5\}_2]$ (8) and $[(C_4H_9)_4N][MoO_2\{C_6H_4(OH)C(O)NO\}\{C_6H_4(OH)C(O)NHO\}]$ (11)

X-ray crystallography

The details of the crystal data, data collection methods and refinement procedures are given in Table 4. (The Supplementary Tables provide atomic positional parameters for the structures reported. Tables of bond lengths and angles, anisotropic thermal parameters and calculated and observed structure factors for all complexes are available.*) Full

details of the crystallographic methodologies may be found in Ref. 14.

In all instances, a cut-off value of $F\sigma \geqslant 6.0\sigma(F)$ was used. Since the crystal quality was only adequate for these species, it was found that use of a lower cut-off did not significantly improve the standard deviations in bond parameters, while the residuals were adversely affected.

In no instance was an extinction correction applied for the data. Idealized hydrogen atom positions were used throughout the analyses, with the C—H and N—H distances set at 0.96 and 0.94 Å, respectively. In the case of structure **11**, hydrogen atoms H(O7), H(O8) and H(N1) were located on the final Fourier map and introduced as fixed contributors to the final cycles of refinement.

The structures of **7**, **8** and **11** all exhibited some degree of disorder associated with the $(C_4H_9)_4N^+$ cations. As the final difference Fourier maps for all cases failed to reveal significant excursions of electron density in the region of the cations after inclusion of the appropriate number of atoms, no further attempts to model the disorder were attempted. Since the anionic molybdenum complexes were well-behaved and the species of interest, this appeared a reasonable recourse. The disorder is apparent in a number of large temperature factors and in the range of C—C bond lengths (1.20–1.65 Å) for the cations.

Abstract—The title macrocyclic ligand forms a seven-coordinate chloroindium complex which exists as a stable neutral hexacoordinate species in aqueous solution.

An attractive isotope for the γ-scintigraphic detection of tumours using radiolabelled monoclonal antibodies is indium-111 ($t_{1/2}$ = 2.81 days). In order to bind the indium radiolabel irreversibly to the antibody, different ligands have been sought which may be covalently attached to the protein. A series of hexacoordinating macrocyclic triaza-ligands have been examined—the [9]- to the [12]-membered triaza-triacid ligands (**1**–**4**)—of which **1** bound indium most quickly under ambient conditions[1] (pH 5, 0.1 M OAc^-, 97% radiolabelling yield in 30 min at [**1**] = 20 μM). These ligands form neutral indium complexes in solution, which are relatively insensitive to metal- or acid-promoted dissociation *in vivo*. Preliminary animal biodistribution data are in accord with this hypothesis, and perturbed angular correlation spectroscopic measurements suggest that **1** forms the most stable In^{3+} complex observed.

indium trichloride in deuteroacetate/deuteroacetic acid buffer ($I = 0.1$, pD = 5.0) was monitored by ^{1}H NMR, and gave a spectrum consistent with local C_3 symmetry for the complex. The diastereotopic ring protons resonated as an AA'BB' system centred at 3.20 ppm, while the methylene CH_2CO groups gave a sharp singlet at 3.75 ppm.

An identical spectrum was obtained when indium trinitrate was bound to **1** under the same experimental conditions. Desorption chemical ionization mass spectrometry revealed a molecular ion ($M^+ + 1$) at $m/z = 416$, consistent with formation of a neutral hexacoordinate complex. An admixture of $Ga(NO_3)_3$ and **1** ($I = 0.1$, pD = 5.0) gave a similar spectrum with methylene CH_2CO groups resonating as a singlet at 3.88 ppm and the diastereotopic CH_2N protons giving multiplets centred at 3.51 (6H) and 3.23 (6H) ppm. Given the attractive features of ^{67}Ga as a γ-emitting imaging radioisotope in radioimmunoscintigraphy[2] ($t_{1/2} = 78.1$ h), ligand **1** may prove suitable for both indium and gallium in this context. When **1** was allowed to react with $InCl_3$ stabilized in 0.04 M HCl, colourless crystals of a hydrated chloroindium complex (by microanalysis) were isolated by slow evaporation. The NMR spectrum in D_2O was identical to that obtained in an acetate butter, at the same pD. Crystals suitable for X-ray diffraction were obtained and were analysed independently at two sites. The molecular structure—showing the atomic numbering scheme—is illustrated in Fig. 1, with salient bond lengths and bond angles given in Table 1.

The molecule comprises an indium(III) ion in a pentagonal bipyramidal coordination environment in which the axial sites are occupied by a chloro ligand and by one tertiary amine (In—N(2) = 2.288(5) Å) of the [9]-N_3 macrocycle. The other two tertiary amine nitrogens occupy sites in the equatorial plane (In—N = 2.331 Å) at an angular separation of 78°; the remaining three equatorial sites are filled by an oxygen atom of the three pendant carboxymethyl groups—one of which is protonated (In—O = 2.284, 2.424, 2.116 Å). Indium in its complexes usually adopts five- or six-coordination although examples of formal eight-coordination have been reported,[3] so this seven-coordinate complex is unusual,[4] notwithstanding the elongated In—O(3) bond (2.413(6) Å) and the rather long indium–chlorine bond (2.460(4) Å). A μ-hydroxo tetrameric indium complex of the parent [9]-N_3 triamine has been reported[5] in which indium–nitrogen bond distances in the range 2.29–2.35 Å were defined. In $In(CH_3CO_2)_3$phen and $In(CH_3CO_2)_3$bpy, where the indium is formally eight-coordinate, indium–nitrogen bond lengths of 2.33 Å were reported,[6] while indium–oxygen bond lengths ranging from 2.14 to 2.87 Å have been described in $In(OH)_3$,[7] $[([9]\text{-}N_3)_2In(CH_3CO_2)_4(\mu\text{-}O)] \cdot 2NaClO_4$[5] and in an (acetato)(porphyrinato)-indium(III) complex.[8]

Symmetry operations are [a] = $[-x, 1-y, -z]$; [b] = $[0.5-x, 0.5+y, 0.5-z]$.

Both samples which were analysed contain waters of hydration in the same general sites but with different occupanices. In one, a water molecule [O(7)] is present with 0.46 occupancy and is hydrogen bonded to O(1)···O(7), 2.84(2) Å; a second water molecule is present in only 0.18 occupancy and is at hydrogen bonded distances from both O(7) (2.87(5) Å) and a symmetry related O(8) (across an inversion centre, O(8)···O(8), 2.94(7) Å). In the other sample, the occupancies of O(7) and O(8) are 0.48 and 0.32, respectively, and the corresponding hydrogen bonded distances are O(1)···O(7), 2.84; O(7)···O(8), 2.96; O(8)···O(8), 2.79 Å.

The molecules of the complex are linked into infinite chains about a two-fold screw axis by a short hydrogen bond involving carboxyl oxygens O(2) and O(4), with O(2)···O(4)(I) 2.487(6) Å in **1** and 2.497 Å in **2**. A difference map in a plane containing O(2) and O(4)(I) showed a clear maximum midway between the two oxygen atoms and this hydrogen-bonded H atom was positioned at this site and included (but not refined) in the final refinement cycles. In the other analysis, a maximum in a difference map at 1.08 Å from O(2) and directed towards O(4)(I), was ascribed to the hydrogen bonded H atom and it was included at this site but not refined in the subsequent calculations.

* Details of the second analysis are available from the authors on request.

EXPERIMENTAL*

Crystal data for [(L)InCl]·0.46(H_2O), 0.18(H_2O); $C_{12}H_{19}ClInN_3O_6$·0.64(H_2O), Mr = 463.1. Crystal dimensions 0.25 × 0.43 × 0.55 mm, monoclinic a = 7.017(3), b = 17.701(5), c = 14.083(3) Å, β = 99.02(2)°. U = 1728(2) Å^3, D_c = 1.78 g cm^{-3}, Z = 4. Space group $P2_1/n$, Mo-K_α radiation (λ = 0.71073 Å), μ(Mo-K_α) = 15.3 cm^{-1}, F(000) = 929.6.

Three-dimensional data were collected using a CAD4 diffractometer in the range $4 < 2\theta < 40°$ by the ω–2θ scan method. Collection of data in the range $40 < 2\theta < 54°$ was terminated because of rapid decay of the crystal soon after data collection for this shell started; there had been no significant decay during the initial data collection. Structure solution and refinement progressed with the 4–40° data set. The cell data were determined by a least-squares analysis of the setting angles of 25 reflections with $14 < 2\theta < 40°$. 3259 reflections were collected of which 2564 were unique (R-factor on averaging 1.6%). The data were corrected for absorption (max. and min. transmission coefficients: 0.734, 0.664) and during refinement for secondary extinction. The 1488 reflection with $I > 3\sigma(I)$ were labelled observed and used in structure solution and refinement. The structure was solved via the heavy-atom method and refined by full-matrix least-squares calculations. Two sites

corresponding to partially occupied water molecules were also located. No hydrogen of water molecules could be located from difference maps, but all hydrogens of the complex were clearly visible. The complex molecules are linked by a short O—H—O hydrogen bond (2.487(6) Å) and a difference map showed a clear maximum midway between the two oxygen atoms. All other hydrogen atoms were positioned geometrically (C—H, 0.95 Å) and were included but not refined in the refinement process. Refinement converged with $R = 0.039$, $R_w = 0.075$ (largest shift/error ratio 0.05). Scattering factor and anomalous dispersion data were taken from *International Tables for X-ray Crystallography*[9] and all calculations were done with SDP-Plus. In the refinement cycle, weights were derived from the counting statistics; a final difference map had no chemically significant maxima.

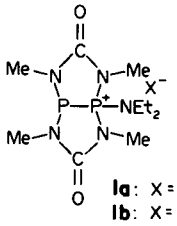
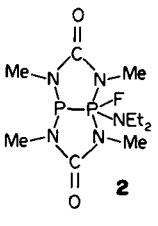
(*Received* 5 *April* 1989; *accepted* 2 *June* 1989)

Abstract—The reaction of $(C_2H_4)Pt(PPh_3)_2$ (**4**), with the ionic N,N′-dimethylurea-bridged $\lambda^3P\lambda^4P^+$ diphosphorus compound, **1b**, furnished the mononuclear platinum(II) complex, **6**, whose structure was determined by X-ray diffraction. The geometry at platinum shows significant deviation from planarity. The ionic diphosphorus compound, **3a**, reacted with **4** to give a PPtPPt four-membered ring system, **7**. By contrast, the reaction between the covalent mixed-valence $\lambda^3P\lambda^5P$ diphosphorus compound, **2**, and **4** proceeded without oxidation of the platinum centre. The ^{31}P and ^{195}Pt NMR parameters of **6** were ascertained by iterative analysis. The signs of the coupling constants were determined by a two-dimensional $^{31}P,^{31}P\{^1H\}$-COSY-45 experiment. The NMR investigation of **7** is also described. The $^1J(Pt,P)$ coupling constants within the ring are compared with those of similar compounds.

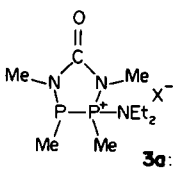
In recent years a variety of mixed-valence diphosphorus compounds have been reported which involve, as a central feature, a PP-system, bridged by one or two N,N′-dimethylurea groups.[1–4] A simple approach to this class of compounds consists of the reaction of N,N′-dimethyl-N,N′-bis(trimethylsilyl)urea with dialkylaminodichlorophosphines, R_2NPCl_2, or in the reaction of the bis (phosphorylated) urea, $[(Me)(Cl)PN(Me)]_2C(:O)$, with dialkylaminotrimethylsilanes, R_2NSiMe_3. Both types of PP-bonded products thus obtained may be subjected to further reactions.[2,5–7] Typical representatives of this type of compounds are the following:



1a: X = Cl
1b: X = CF_3SO_3



2



3a: X = Cl
3b: X = CF_3SO_3

* Author to whom correspondence should be addressed.

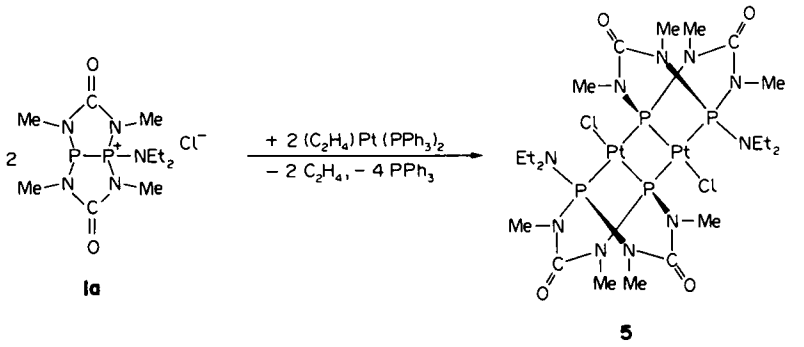
The bridging N,N′-dimethylurea groups serve as a clamp between the two phosphorus atoms, stabilizing the PP-bond. At the same time, these bridging groups are sufficiently flexible to permit substantial changes in the coordination number and electronic situation at phosphorus without affecting the basic molecular structure. The PP-bond in such compounds, especially those of types **1** and **2**, has been found to be exceptionally stable. Although several reactive centres are available, in principle, the coordination of the compounds of types **1–3** to metal centres, e.g. Fe^0, W^0, Rh^I and Pt^{II} occurs exclusively via the lone pair of electrons at λ^3P.[7]

By contrast, the reaction of **1a** with the platinum(0) complex, $(C_2H_4)Pt(PPh_3)_2$ (**4**), was found to proceed with cleavage of the PP-bond to yield the unusual platinum(II) complex, **5**, in good yield.[8] The formation of **5** is the result of a sequence of oxidative addition and substitution reactions which led to complete displacement of C_2H_4 and PPh_3, coordinated to platinum(0), in **4**.

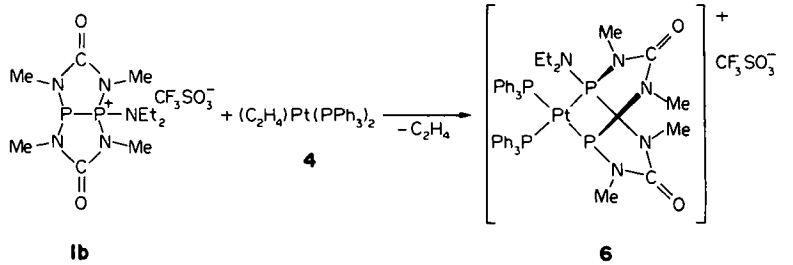
RESULTS AND DISCUSSION

Reaction of the λ^3P-substituted phosphonium salt, **1b**, *with ethylenebis(triphenylphosphine)platinum*(0) (**4**): *Synthesis of* **6**

In the course of the reaction of **1a** with **4**, ethylene and triphenylphosphine were completely stripped off the platinum atom; the facile formation of a PPtPPt four-membered ring was assisted, probably, by the high affinity of chlorine to platinum. By contrast, similar coordination of the $[CF_3SO_3]^-$ ion to platinum during the reaction of **1b** with **4** was not to be expected. In this case, a mononuclear complex, **6**, was formed as a result of the insertion of the $Pt(PPh_3)_2$ fragment into the PP-bond of **1b**. The reaction constitutes another example of the oxidative addition reaction of a diphosphorus compound to platinum(0), with formation of a platinum(II) complex.



1a **5** (1)



1b **4** **6** (2)

Oxidative addition reactions at metal centres which proceed with insertion of the metal into a PP-bond have repeatedly been reported (e.g. refs 9–12). The first reaction of this type was observed between the cage molecule P_4S_3 and Vaska's complex, $IrCl(CO)(PPh_3)_2$, in 1983.[9]

Complex **6** was formed in good yield as a yellow, air-sensitive solid. Solutions of **6** in $CDCl_3$ decomposed after 20 h at 50°C. It should be noted that the coordination number of one of the phosphorus atoms (bearing a lone pair of electrons) in **6** is unusually low. This is probably the principal reason

for the low stability of **6** in solution. The reactivity of **6** warrants further studies which have not, as yet, been initiated.

One- and two-dimensional ^{31}P *and* ^{195}Pt *NMR investigation of* **6**

At room temperature the ^1H-decoupled 81 MHz-^{31}P NMR spectrum of **6** shows some broadened featureless absorptions which point to chemical exchange taking place at an intermediate rate. An attempt to record the ^{31}P NMR spectra above room temperature in order to investigate the dynamic process was unsuccessful because **6** decomposes in solution (solvent: Cl_2CD–$CDCl_2$) at temperatures in excess of 70 C. On cooling a solution in CD_2Cl_2 to −30 C, the lines become sufficiently narrow for an iterative spectral analysis to be carried out.

The main signals which belong to the isotopomers not containing ^{195}Pt form a four-spin system from which the four ^{31}P chemical shifts and the absolute values of the six $^2J(PP)$ coupling constants can be extracted without difficulty. This four-spin system is almost first-order with respect to the number of transitions and the symmetry of the multiplet splittings. It shows only slight deviations from first-order line intensities and ensuing differences between chemical shifts and multiplet centres (a few Hz or $\leqslant$ 0.2 ppm).

The situation is different when one turns to the ^{195}Pt satellites in the ^{31}P spectrum, which form the ABCD part of an ABCDX spectrum (Fig. 1). Because of the large magnitude of the $J(Pt,P)$ coupling constants, some transitions of different nuclei approach each other to such an extent as to cause higher order effects that are evident, above all, from the asymmetric satellite multiplets. The appearance of these multiplets depends on the relative signs of the values of $J(PP)$.

By comparison with data typical of $^1J(Pt,P)$ and $^2J(PP,trans)$ in phosphine complexes,[16a] $^1J(Pt,P) = 619.6$ Hz and $^2J(PP,trans) = 68.8$ Hz for P_A are unusually small. Likewise, such small values were found in other platinum-substituted phosphines.[14]

The spectrum was analysed as follows: $^1J(Pt,P)$ couplings were taken as positive, in accordance with the literature.[15] Furthermore, since $^2J(PP)$ in phosphine–transition metal complexes is known to be large and positive for a *trans* orientation of the phosphorus nuclei and smaller and of either sign for a *cis* orientation,[16] the largest $^2J(PP)$ value (464.4 Hz) was taken as positive. Then, the 32 possible sign combinations were tested for the five remaining P,P-couplings. Only two of these produced calculated spectra which were compatible with the experimental spectrum. For both of these, iterative analyses were carried out and the results

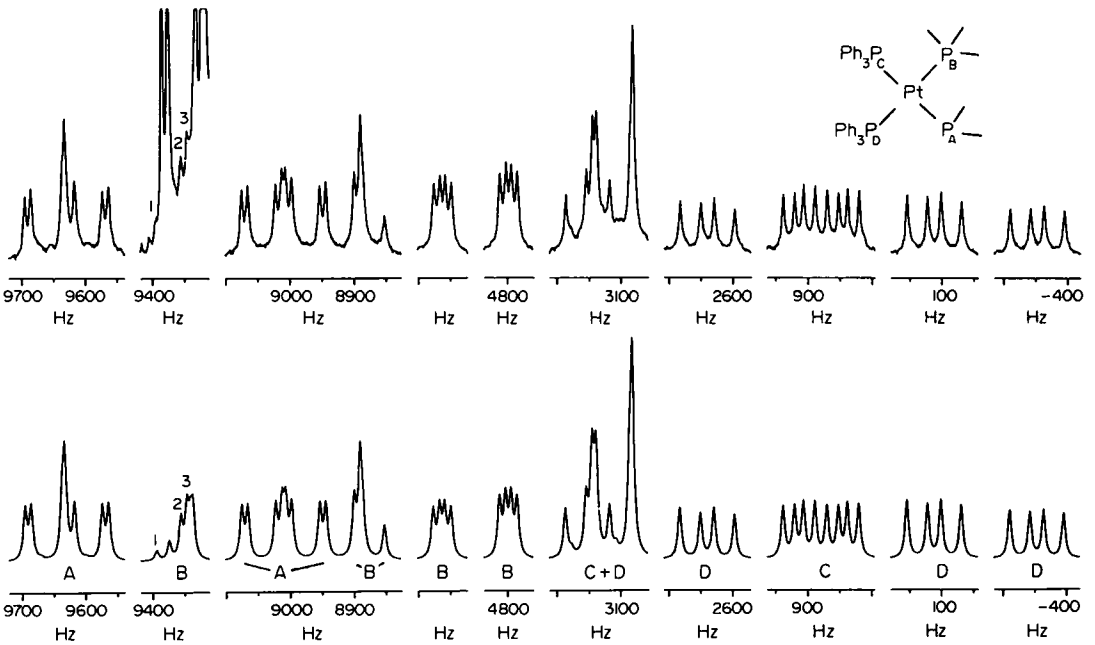


Fig. 1. ^{195}Pt satellites in the 81.0 MHz $^{31}P\{^1H\}$ NMR spectrum of **6** in CD_2Cl_2 solution at −30°C; top: experimental spectrum; bottom: spectrum simulated using the parameters obtained from the iterative analysis. Frequencies are relative to external H_3PO_4. Capital letters indicate the affiliation of the satellites to the ^{31}P nuclei.

differed essentially only in the sign of the 32.2 Hz coupling.

To determine the sign of this coupling constant and in order to confirm the signs of the other ^2J(PP) couplings obtained by simulation, a two-dimensional $^{31}P,^{31}P\{^1H\}$-COSY-45 spectrum[17] was recorded. The relevant sections of the contour plot are shown in Fig. 2.

A standard COSY experiment[19] (COSY-90) employing the pulse sequence $\pi/2$–τ–$\pi/2$ (τ = incremented delay) yields cross peaks between the chemical shifts of coupled nuclei which possess the multiplicities of both nuclei involved. In a four-spin system, at sufficient digital resolution, a cross peak consists of 8×8 peaks (ddd multiplicity in both dimensions). In contrast to this, the cross peaks in a COSY-45 spectrum contain responses only at the intersections of transitions which are directly connected in the energy level diagram, i.e. which share a common level. Thus a COSY-45 experiment furnishes the same information as a series of suitable spin-tickling experiments.[20]

In the case of a four-spin ABCD system, in which all coupling constants are different and non-zero, a cross peak in the COSY-45 spectrum contains only 16 responses (as opposed to 64 in a COSY-90 spectrum). The procedure of the analysis is shown taking the cross peak between nuclei C and D [coordinates: $x = \delta_D$, $y = \delta_C$, Fig. 2(a)] as an example. In this cross peak the positions of the responses form four squares Q_1–Q_4 with a side length of J(CD). The x-coordinates of Q_1 and Q_2 (and those of Q_3 and Q_4) differ by $\Delta x_{12} = J$(BD), the y-coordinates by $\Delta y_{12} = J$(BC). The line connecting the centres of Q_1 and Q_2 has a negative slope, i.e. $J(BC)/J(BD) < 0$: these two coupling constants are of opposite sign. Correspondingly, $\Delta x_{13} = J$(AD), $\Delta y_{13} = J$(AC) and $J(AC)/J(AD) > 0$; when the slope of the line connecting Q_1 and Q_3 is positive, the coupling constants involved are of the same sign. The other cross peaks are analysed in an analogous fashion [Figs 2(b)–(d)]. Table 1 lists the conclusions drawn from the COSY-45 spectrum.

An iterative analysis of the ^{195}Pt satellites in the

^{31}P spectrum that made use of the relative signs of the $J(PP)$ couplings determined above yielded the spectral parameters given in Table 2. The r.m.s. error of 0.12 Hz between observed and calculated line positions is relatively high for the results of an iterative analysis. It is caused by the *ca* 7 Hz line width of the ^{195}Pt satellites which may be due to insufficient slow-down of the chemical exchange and to rapid spin–lattice relaxation of the ^{195}Pt nucleus by the chemical shift anisotropy mechanism.[21] In accordance with the latter assumption, the main signals of the ABCD ^{31}P spectrum are only 3–4 Hz wide at half height.

Table 2. Results of the iterative NMR spectral analysis of **6**

Chemical shifts			
$\delta_P(A)$	115.031	$\delta_P(C)$	24.719
$\delta_P(B)$	87.200	$\delta_P(D)$	17.105
δ_{Pt}	−299.91		
	(relative to Ξ = 21.4 MHz[26])		
Spin–spin coupling constants (Hz)			
$J(P_A,P_B)$	9.5	$J(P_B,P_C)$	−18.0

$J(P_A,P_D)$	53.3	$J(P_C,P_D)$	−32.2
$J(Pt,P_A)$	619.6	$J(Pt,P_C)$	2247.4
$J(Pt,P_B)$	4089.6	$J(Pt,P_D)$	2991.1

r.m.s. error: 0.12 Hz.
Probable errors of ^{31}P shifts: 0.0005 ppm.
Probable errors of coupling constants: 0.05–0.09 Hz.
Assigned transitions: 53 of 66 (^{31}P only).

The $^{195}Pt\{^1H\}$ NMR spectrum of **6** was also recorded at −30°C. It is not a first-order spectrum and is unsymmetrical (Fig. 3). Its appearance depends on the sign of $^2J(P_BP_D)$ relative to that of the $^1J(Pt,P)$ couplings. For opposite signs of $^2J(P_BP_D)$ and $^1J(Pt,P)$, the calculated ^{195}Pt spectrum is the mirror image of the one shown in Fig. 3. Thus the assumption made above, $^2J(P_BP_D) > 0$, is proved experimentally.

X-ray structure of **6**

Selected bond distances and angles are shown in Table 3. The structure of the cation of **6** is displayed in Fig. 4.

The X-ray structure analysis proves that **6** exists

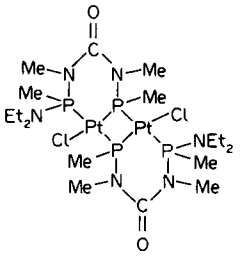
as a platinum complex with platinum(II) directly connected to four phosphorus ligands (two PPh_3 groups, a $P(NRR')_3$ group and a formally negatively charged $\{P(NRR')_2\}^-$ group). Pt—P bonds are in the usually observed range with the exception of Pt—P(4) which is one of the longest observed Pt—P bonds in such compounds and is 6.3 pm longer than the comparable bond, Pt—P(1). This lengthening is probably due to a strong "*trans* effect" of the negatively charged P(3) or to steric effects. The P—P bond is obviously broken.

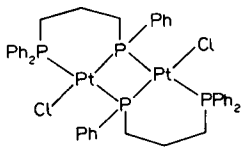
The platinum complex shows significant deviation from planarity. The dihedral angle between the plane defined by Pt, P(2), P(3), and that defined by Pt, P(1) and P(4) is 47.2°, showing that the geometry around the platinum atom is about midway between the square plane (0°) and the tetrahedron (90°). Because of the negative charge at P(3), P(3)—N bond distances are significantly longer than the corresponding bond distances to P(2) (172.5 and 172.6 pm compared to 166.1 and 167.0 pm). As is observed in similar compounds the exocyclic P—$N(Et)_2$ bond distance is shorter than the other P—N distances.[22] The bond angles at P(2) and P(3) are remarkably similar.

Reaction of the λ^3P-substituted phosphonium salt, **3a**, *with* **4**: *synthesis and NMR investigation of* **7**

In a manner similar to the reaction of **1a** with **4**, the binuclear platinum complex, **7**, was formed in the reaction of **3a** with **4**. Again, all ligands at platinum were displaced by the mixed-valence diphosphorus compound. Although the formation of several isomers would appear possible, only one of these was detected by NMR spectroscopy. While compound **5** is soluble only in dichloromethane, **7** is very soluble in several chlorinated or aromatic solvents. The characterization of **7** rests mainly on the analysis of its ^{31}P and ^{195}Pt NMR spectra.



7

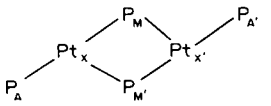


8

The ^{31}P and ^{195}Pt NMR spectra of the platinum(II) complex, **5**, were complicated because of the superposition of an $(AM)_2$, an $(AM)_2X$ and an $(AMX)_2$ spectrum. Chemical shifts and coupling constants were determined by iterative analysis.[8] Unusual values were obtained for ^1J(Pt,P) of the phosphido phosphorus atoms, P_M and $P_{M'}$. In view of the known *trans* influence,[23] ^1J(Pt,P) for the bonds *trans* to the chlorine ligands was expected to be larger than ^1J(Pt,P) for the bonds *trans* to phosphorus. The bond lengths observed for the PPtPPt four-membered ring confirm that chlorine exerts a less pronounced *trans* influence than phosphorus. The coupling constant in **5** between P_M *trans* to chlorine and Pt_X is, however, much larger than the corresponding coupling between $P_{M'}$ *trans* to phosphorus and Pt_X. By contrast, the expected trend in the coupling constants $[J(Pt_XP_{M'}) > J(Pt_XP_M)]$ was observed for **8**.[24] While in **5** phosphorus is bonded, besides platinum, only to nitrogen, there are only P—Pt and P—C bonds in **8**.

The NMR results for **7** must be viewed against this background. Its ^{31}P and ^{195}Pt NMR spectra are very similar to those of **5**. The chemical shifts and coupling constants of **7** are listed in Table 4. For comparison, the ^1J(Pt,P) values for the phosphido phosphorus atoms in compounds **5** and **8** are also included. The value of ^1J(Pt,P) for P_M and $P_{M'}$ in **7** are very similar and fall between those for **5** and **8**. This may be taken as an indication that the unexpected trend in ^1J(Pt,P) of the phosphido phosphorus atoms in **5** and **7** is caused by electronic effects of the N,N′-dimethylurea groups.

Table 4. Results of the NMR spectral analysis of **7**



Chemical shifts

$\delta(P_A) = \delta(P_{A'})$	87.6
$\delta(P_M) = \delta(P_{M'})$	−85.8
$\delta(Pt_X) = \delta(Pt_{X'})$	617 (relative to Ξ = 21.4 MHz[26])

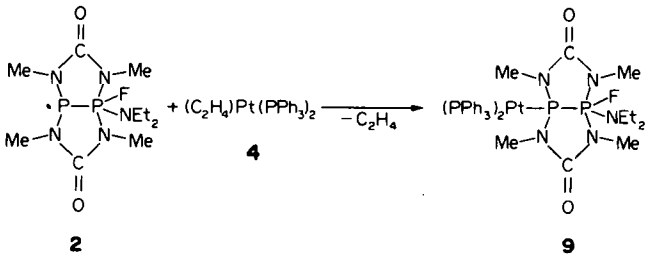
Spin–spin coupling constants (Hz)[a]

	5	**7**	**8**
$^2J(AM') = {}^2J(A'M)$		552.0	
$^2J(AM) = {}^2J(A'M')$		9.8	
$^4J(AA')$		5.9	
$^2J(MM')$		141.0	
$^1J(AX) = {}^1J(A'X')$		3143.0	
$^1J(MX) = {}^1J(M'X')$	2535.7	2148.2	1820.2
$^1J(MX') = {}^1J(M'X)$	2103.8	2169.3	2228.4
$^3J(AX') = {}^3J(A'X)$		29.8	
$^2J(XX')$		1209	

[a] For comparison: some coupling constants of **5** and **8**; signs of coupling constants were not determined.

Reaction of the λ^3P-substituted phosphorane, **2**, *with* **4**: *synthesis of* **9**

While the platinum(II) complexes **5**, **6**, and **7** were readily formed from mixed-valence diphosphorus compounds and **4**, the oxidation number of platinum was unchanged when the $\lambda^3P\lambda^5P$-diphosphorus compound **2** was allowed to react with **4**. In a simple substitution reaction the coordinated ethylene in **4** was displaced by **2**. The identity of the product, **9**, was ascertained by NMR spectroscopic (^{19}F,^{31}P) means. The compound is not stable in solution for more than a few days but undergoes further transformation reactions. This may explain why **9** could be isolated only in a moderate state of purity. Finally, an attempt to react **1a**, **1b** and **2** with Vaska's complex, $IrCl(CO)(PPh_3)_2$, was unsuccessful. In all cases the starting materials were recovered unchanged.



(3)

EXPERIMENTAL

All experiments were conducted with exclusion of air and moisture, using standard techniques.[25] The FD mass spectrum of **7** was recorded on a Finnigan MAT 8230 instrument. Melting points were determined in sealed tubes. Elemental analyses were performed at the Institut für Anorganische und Analytische Chemie, Technische Universität, Braunschweig.

NMR spectra

The NMR spectra of **6** were recorded on a Bruker AC 200 spectrometer operating at 81.0 MHz for ^{31}P and at 42.8 MHz for ^{195}Pt. The solvent was CD_2Cl_2. Protons were broadband-decoupled. The platinum spectrum was obtained at −30°C from 10,000 accumulations using *ca* 45° pulses 0.28 s apart. The digital resolution was 3.6 Hz/pt. Exponential line-broadening of 10 Hz was applied to the free induction decay, resulting in a linewidth of 15–20 Hz in the final spectrum. The observed NMR frequency for the position of the ^{195}Pt shift was 42.8155590 MHz. With the ^1H signal of tetramethylsilane in CD_2Cl_2 absorbing at 200.1327276 MHz, this gives $\Xi(Pt) = 21.3935819$ MHz or $\delta = -299.91$ relative to $\Xi = 21.4$ MHz.[26] For the 2D $^{31}P,^{31}P$-COSY-45 spectrum a spectral width of 9615 Hz, a data table and a transform size of 4K gave a digital resolution of 4.7 Hz/pt. 1024 increments in t_1 were used. Sixteen scans preceded by two dummy scans were accumulated per increment. Total measuring time was slightly over 5 h. One level of zero-filling was applied in t_1 and the data were multiplied with a $\pi/3$ shifted sinebell in both dimensions. Four megawords of data were obtained after the 2D transform. The solution for the 2D measurement contained *ca* 450 mg of **6** in *ca* 2.5 cm^3 of solvent in a 10 mm o.d. tube. The iterative spectral analysis was performed with Bruker's program PANIC which is based on LAOCN3.[27]

The ^{31}P and ^{195}Pt NMR spectra of **7** were measured on a JEOL FX 90 Q spectrometer at 36.4 and 25.26 MHz, respectively, on solutions in a CH_2Cl_2–CD_2Cl_2 mixture. Spectra were calibrated via the ^2D signal of the solvent and are referenced as described above. P—P coupling constants of **7** were extracted from the $(AM)_2$ spectrum of ^{31}P (digital resolution 1.8 Hz) and J(Pt,P) and J(Pt,Pt) were obtained by iteration of the $(AM)_2X$ and $(AMX)_2$ spectra of ^{31}P and ^{195}Pt, using the computer program NUMARIT.[28] The NMR spectra of **9** were recorded on a Bruker WM 400 spectrometer at 162.0 (^{31}P) and 376.5 MHz (^{19}F) for a $CDCl_3$ solution and referenced to external 85% H_3PO_4 and $CFCl_3$, respectively.

Preparation of compound **6**

A solution of 0.640 g (1.4 mmol) of **1b** in 5 cm^3 of benzene in a heavy-walled glass tube, fitted with a Teflon® stopcock, was degassed and cooled to −196°C. A solution of 1.05 g (1.4 mmol) of **4** in *ca* 10 cm^3 of deoxygenated benzene was filtered through a sintered glass disc and added to the solution of **1b**. The reaction mixture was degassed, and nitrogen was admitted. The tube was then sealed and allowed to warm up to room temperature over 1 h. After 1 day the yellow precipitate thus formed was washed with three portions of toluene (10 cm^3 each) and once with 5 cm^3 of diethyl ether, and recrystallized from 10 cm^3 of dichloromethane and *ca* 10 cm^3 of toluene over one day (using the diffusion method). The yellow, air-sensitive crystals of **6** were dried *in vacuo* (1 torr). Yield 1.15 g (70%); m.p. 210°C (dec.). Found: C, 47.2; H, 4.5; N, 5.7. Calc. for $C_{47}H_{52}F_3N_5O_5P_4PtS$ (1175.00): C, 48.0; H, 4.5; N, 6.0%. ^1H NMR spectrum ($CDCl_3$, 200.1 MHz): $\delta = 0.72$ (t, NCCH_3, ^3J(HH) = 6.9 Hz); 2.79 (m, NCH_2); 2.97 (d, NCH_3, ^3J(PH) = 11.9 Hz); 3.12 (d, NCH_3, ^3J(PH) = 7.0 Hz); 7.34 (br m, phenyl group); 7.44 (br m, phenyl group); ^{31}P NMR spectrum (CD_2Cl_2, 81.0 MHz, −30°C) and ^{195}Pt NMR spectrum (CD_2Cl_2, 42.8 MHz, −30°C): see Table 2.

X-ray analysis of **6**

Crystals of **6** obtained by recrystallization from dichloromethane–toluene have orthorhombic sym-

metry, space group $P2_12_12_1$. The unit cell which has the parameters $a = 1266.0(2)$, $b = 1812.4(3)$, $c = 2209.6(3)$ pm, contains four molecules yielding a calculated density of 1.539 g cm^{-3}. The data were collected at 293 K on a Nicolet $P2_1$ diffractometer using graphite-monochromated Cu-K_α radiation ($\lambda = 154.18$ pm) in the θ–2θ mode, in the range $3° \leqslant 2\theta \leqslant 135°$ at a scan speed between 2.93 and 29.30° min^{-1} depending on the intensity of the reflection.

The data were corrected for Lorentz-, polarization but not for absorption effects ($\mu = 7.205$ mm^{-1}). The structure was solved by direct methods and difference-Fourier synthesis. Hydrogen atom positions were calculated from those of the directly bound atoms and refined as "riding atoms". The refinement using 7916 out of 9058 measured independent reflections ($F \geqslant 4.0\sigma(F)$) converged at $R = 0.057$ ($R_w = 0.058$). The program SHELX-76[29] and our own programs were used. Complex atom scattering factors[30] were employed.

Preparation of compound **7**

As described in the preceding experiment, a solution of 0.382 g (1.3 mmol) of **3a** in 5 cm^3 of benzene and a solution of 0.995 g (1.3 mmol) of **4** in *ca* 10 cm^3 of benzene were combined and stirred at room temperature for 1 week. The solvent was removed *in vacuo* and the remaining product dissolved in 15 cm^3 of toluene. Upon concentration of this solution *in vacuo* (1 torr), formation of a white solid occurred which was recrystallized from 6 cm^3 of a 1 : 2 mixture of dichloromethane–methylcyclohexane. Yield 0.2 g (32%); m.p. 241–244°C (dec.). Found: C, 24.6; H, 4.6; P, 11.8. Calc. for $C_{18}H_{44}Cl_2N_6O_2P_4Pt_2$ (961.57): C, 22.5; H, 4.9; P, 12.9. Mass spectrum (FD): $M^+ = 962$. ^{1}H NMR spectrum (CD_2Cl_2, 400.1 MHz): $\delta = 1.11$ (t, NCCH_3, ^3J(HH) = 7.2 Hz); 1.96 ("d", PCH_3, separation 7.2 Hz); 2.00 (m, PCH_3); 2.93 ("d", NCH_3, separation 7.0 Hz); 3.13 (m, NCH_2); 3.36 (NCH_3, separation 8.2 Hz); ^{31}P NMR spectrum ($CDCl_3$, 36.4 MHz) and ^{195}Pt NMR spectra ($CDCl_3$, 19.16 MHz): see Table 4.

Preparation of compound **9**

As described for **6** and **7**, a solution of 1.03 g (1.4 mmol) of **4** in 10 cm^3 of benzene was combined with a solution of 0.9 g (2.8 mmol) of **2** in 5 cm^3 of benzene. The solid product formed after 1 day was collected, washed with three 5 cm^3-portions of toluene and dried *in vacuo* (1 torr). Yield 68%; m.p. 143°C (dec.). Found: C; 49.1; H, 4.6; N, 6.5; P, 11.9. Calc. for $C_{46}H_{52}FN_5O_2P_4Pt$ (1044.92): C, 52.6; H, 5.0; N, 6.7; P, 11.9%. ^{31}P NMR spectrum ($CDCl_3$, 162.0 MHz): $\delta = -58.94$ (ddt, PtP*P*F, ^1J(PF) = 697.4 Hz, ^1J(PP) = 27.9 Hz, ^3J(PP) = 17.7 Hz); 49.76 (dd, *P*PtPPF, ^2J(PP) = 176.6 Hz, ^3J(PP) = 17.7 Hz, ^1J(Pt,P) = 4433 Hz); 101.42 (tdd, Pt*P*PF, ^2J(PP) = 176.6 Hz, ^1J(PP) = 27.9 Hz, ^2J(PF) = 33.9 Hz, ^1J(Pt,P) = 5417 Hz); ^{19}F NMR spectrum ($CDCl_3$, 376.5 MHz): $\delta = -26.92$ (dd, ^1J(PF) = 697.4 Hz, ^2J(PF) = 33.9 Hz).

(*Received* 4 *April* 1989; *accepted* 2 *June* 1989)

Abstract—The reaction between $SbCl_3$ and 3 equiv. of $Na[M(CO)_3(\eta\text{-}C_5H_5)]$ (M = Mo, W) affords the trimetal–antimony complexes $[Sb\{M(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**1**, M = Mo; **8**, M = W) both of which were characterized by spectroscopic and analytical methods. Mass spectra obtained on these complexes are particularly informative and are discussed. The reaction between $SbCl_3$ and 2 equiv. of $Na[M(CO)_3(\eta\text{-}C_5H_5)]$ affords the dimetal–antimony complexes $[SbCl\{M(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**5**, M = Mo; **9**, M = W). Both complexes were characterized spectroscopically and, in addition, **5** was characterized by X-ray crystallography. Compound **5** crystallizes in the monoclinic space group $P2_1/n$ with $a = 7.399(2)$, $b = 9.611(3)$, $c = 27.031(7)$ Å, $\beta = 92.70(2)^\circ$ and $Z = 4$. The structure comprises monomeric units of **5** which contain a central antimony atom in a trigonal pyramidal coordination bonded to a single chlorine and two $Mo(CO)_3(\eta\text{-}C_5H_5)$ fragments. The reaction between **1** and $SbCl_3$, which affords **5**, is also described and discussed, as are the reactions between $SbCl_3$ and 2 and 3 equiv. of $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$ which afford $[SbCl\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ (**11**) and $[Sb\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_3]$ (**13**), respectively. Both iron-containing compounds were characterized spectroscopically and analytically and, in addition, **13** was characterized by X-ray crystallography. Compound **13** crystallizes in the monoclinic space group $P2_1/n$ with $a = 16.686(5)$, $b = 16.927(4)$, $c = 16.894(5)$ Å, $\beta = 110.95(2)^\circ$ and $Z = 8$. The structure contains two monomeric molecules of **13** in the asymmetric unit, although the geometries of both are very similar in all respects. Each molecule contains a central antimony atom with trigonal pyramidal coordination bonded to three $Fe(CO)_2(\eta\text{-}C_5H_5)$ fragments.

Compounds containing organotransition metal fragments and atoms or small aggregates of the main group elements ("Inorganometallic Chemistry" as Fehlner has recently called it[1]) is an area of inorganic chemistry which continues to attract the attention of synthetic chemists. Quite apart from any inherent academic appeal that such compounds may have, this interest can be traced, at least in part, to their potential importance or relevance regarding the synthesis of "new materials" and a number of general reviews on this area have recently appeared,[2] the most comprehensive being that of Whitmire.[2c]

With particular reference to complexes containing antimony, and specifically those containing antimony–transition metal bonds, a range of types of complexes are known. Perhaps the simplest of these are the stibine (R_3Sb) complexes,[3] analogous to the more commonly encountered phosphorus congeners, and those, although fewer in number, involving distibines ($R_2Sb—SbR_2$).[4] A range of stibido (R_2Sb) complexes have also been charac-

* Authors to whom correspondence should be addressed.

terized, primarily by Malisch and co-workers, comprising both mononuclear[5] and dinuclear[5,6] examples, the latter often derived from the former by a formal dative interaction between the antimony lone pair and a 16-electron transition metal fragment.[5a,c,e,f,g,6b,c]

Compounds containing the stibinidene or stibinediyl (RSb) fragments are also known, a range of coordination modes having been observed. These include the di-metal complexes which contain a trigonal planar antimony and some degree of multiple metal–antimony bonding,[7] *viz.* $L_nM{=\!=\!=}Sb(R){=\!=\!=}ML_n$ (ML_n = 16 electron transition metal fragment), a valence isomer of this form incorporating a trigonal pyramidal antimony[8] and cluster bound examples.[7c,g,8,9] An important additional class of stibinidene-containing complexes, with regard to the present work, are those involving two 17 electron transition metal fragments, i.e. L_nM—Sb(R)—ML_n,* most examples having been prepared by Malisch and co-workers.[5c,d,g]

Coordination complexes involving the formally doubly bonded distibenes (RSb=SbR) have also been characterized, primarily by Huttner[7a,b,c,11] and Cowley,[8] and exhibit a range of bonding modes with electron pair donation to transition metal centres occurring through antimony lone pairs and the formal Sb—Sb π-bond.

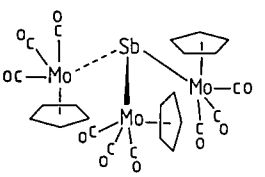
Of more relevance to the present work are those compounds incorporating antimony bonded only to transition metals. These include $[\{Cr(CO)_5\}_2\{M(CO)_5\}Sb]^-$ (M = Cr, Mo, W) containing a trigonal planar antimony,[12] $[Co_4Sb_4(CO)_{12}]$,[13] $[Rh_{12}Sb(CO)_{27}]^{3-}$ containing an interstitial antimony atom,[14] $[W_3Sb_2(CO)_{15}]$ which incorporates a di-antimony (formally Sb≡Sb) ligand acting as a six-electron donor,[11] and a number of iron carbonyl–antimony clusters.[15]

We note also that a range of four-coordinate, cationic antimony complexes have also been prepared. Cullen[16] has reported analytical and IR data on compounds of the general formula $[SbX\{Fe(CO)_2(C_5H_5)\}_3]^+$ (X = Cl, Br), $[SbX_2\{Fe(CO)_2(C_5H_5)\}_2]^+$ (X = Cl, Br, CF_3), $[Sb\{Fe(CO)_2(NO)(PPh_3)\}_4]^+$ and $[Sb\{Co(CO)_3(PPh_3)\}_4]^+$, and X-ray crystal structure determinations have been described for $[SbCl_2\{Fe(CO)_2(C_5H_5)\}_2]^+$,[17] $[SbCl\{Fe(CO)_2(C_5H_5)\}_3]^+$[18] and $[Sb\{Co(CO)_3(PPh_3)\}_4]^+$.[19]

Herein we report details of our own studies on trimetalla-stibines, $[Sb(ML_n)_3]$ (ML_n = 17 electron transition metal fragment), we are aware of only one other example in the literature,[20] and chlorodimetalla-stibines $[SbCl(ML_n)_2]$.

RESULTS AND DISCUSSION

The reaction between $SbCl_3$ and 3 equiv. of $Na[Mo(CO)_3(\eta\text{-}C_5H_5)]$ in THF solution afforded, after work-up, the trimolybdenum–antimony complex, $[Sb\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**1**), as a red–brown powder. Spectroscopic and analytical data (presented in Table 1) were consistent with the above formula, particularly the solution IR spectrum (Table 1, Fig. 1) which showed a pattern in the carbonyl stretching region very similar to that observed for the analogous bismuth complex, $[Bi\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**2**).[21] Unfortunately,



1 **2**

however, crystals suitable for an X-ray crystallographic study could not be obtained for **1** (or the related tungsten analogue, see later) and so precise structural details are not available. The electron-impact mass spectrum of **1** was particularly informative and showed signals attributable to ions with metal element ratios Mo_3Sb and Mo_2Sb_2 (full details are given in the Experimental). The former set of ions were consistent with the derived formula for **1**, while the latter indicated the presence of the dimolybdenum–diantimony complex, $[Mo_2Sb_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (**3**). Moreover, these data were interesting when compared with the corresponding results for the bismuth complex, **2**.[21] It had been observed that the mass spectrum of **2** exhibited signals attributable only to the dimolybdenum–dibismuth complex, $[Mo_2Bi_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (**4**), with no peaks corresponding to Mo_3Bi-containing ions. This was in contrast, therefore, to the antimony analogue, **1**, where both Mo_3Sb and Mo_2Sb_2 signals were observed. The fact that the former were seen (similar experimental conditions for both

* The relationship between the trigonal planar or "open" stibindene complexes and the isomeric trigonal pyramidal or "closed" complexes, both of which contain 16 electron transition metal fragments, has been addressed in refs 7(a), (b) and 8. The factors affecting which isomeric form is adopted in these and the related phosphorus compounds are discussed in ref. 10. Compounds containing two 17 electron transition metal fragments are probably better described as dimetallastibines as opposed to stibinidene complexes, although this defintion is somewhat arbitrary.

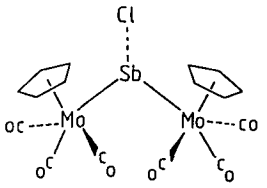
bismuth and antimony) suggests that the antimony complex is a little more robust which, in turn, indicates that the Sb—Mo bonds in **1** are somewhat stronger than the Bi—Mo bonds in **2**. Nevertheless, some rearrangement of **1** to **3** does occur which suggests that **3** is a viable target for chemical synthesis.

The dibismuth complex **4**, has been synthesized by photolysis of **2**[22] and this approach is currently under investigation as a possible route to **3**.

If the reaction between $SbCl_3$ and 2 equiv. of $Na[Mo(CO)_3(\eta\text{-}C_5H_5)]$ is carried out, purple crystals of the dimolybdenum–antimony complex, $[SbCl\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**5**), are obtained. Compound **5** was characterized by normal spectroscopic methods (Table 1) which were consistent with the anticipated structure. Specifically, the solution IR spectrum of **5** in the carbonyl stretching region (Fig. 1) was very similar to that observed for the analogous bismuth complex, $[BiCl\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**6**),[21] which had been characterized by X-ray crystallography.[21b] However, although the molecular structure of **5** had been adequately established by spectroscopic means, an X-ray crystallographic study was undertaken to precisely determine the solid-state structure. This was of interest since it had been observed for **6** that secondary



5

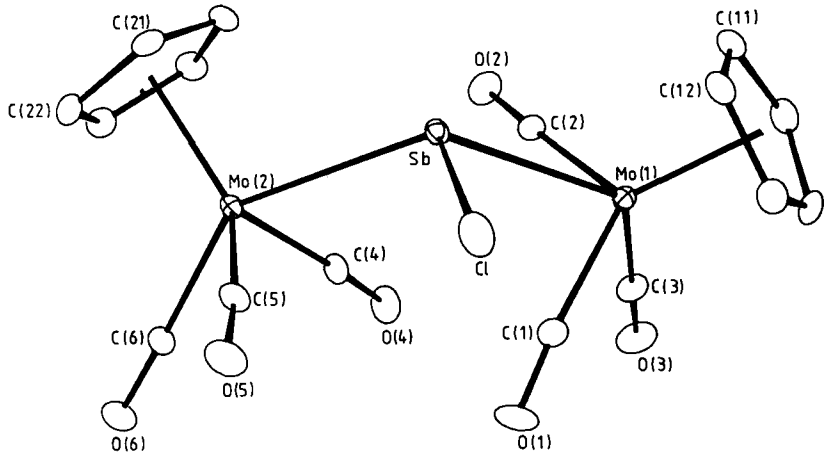


Fig. 2. Molecular structure of **5**, showing the atom numbering scheme adopted. Thermal ellipsoids are drawn at the 10% probability level.

Bi----Cl interactions between molecules existed, arising from the Lewis acidity of the bismuth centre.[21b] The results of the X-ray study on **5** are shown in Fig. 2; selected bond lengths and angles are given in Table 2. The molecule consists of a central antimony atom bonded to one chlorine (Sb—Cl, 2.449(2) Å) and two molybdenum atoms (av. Sb—Mo, 2.845 Å), the latter being each further ligated by a cyclopentadienyl and three carbonyl ligands, with an overall geometry of the familiar $CpML_4$ "piano-stool" type. The antimony atom adopts a trigonal pyramidal coordination geometry (sum of angles, 324.5°) although the pyramid is more open than that found about bismuth in **6** (sum of angles at Bi, av. 315.2°).[21b] A trend of increasing pyramidality is usually observed in three-coordinate group 15 complexes as the group is descended.[23] More interestingly, however, the crystal structure of **5** reveals no short contacts between antimony and chlorine atoms in neighbouring molecules, in contrast to those observed between bismuth and chlorine in **6** (the shortest intermolecular Sb----Cl contact is 5.903(2) Å). This suggests that the antimony centre in **5** is less Lewis acidic than the bismuth centre in **6**, but care must be exercised in making such claims. The structure of **6** reveals that dramatic differences in the lengths of intermolecular contacts can occur even within the same crystal structure and thus implies that even very small changes in structure can lead to large differences in the distances of secondary intermolecular interactions. We note, however, the overall similarity in molecular structure between **5** and **6** in that the conformations about the Sb—Mo bonds in **5** are similar to those found for the Bi—Mo bonds in **6**.[21b]

Table 2. Selected bond lengths (Å) and bond angles (°) for **5**[a]

Mo(2)—Sb—Cl	108.1(1)		

[a] Numbers in parentheses are the estimated standard deviation in the least significant digit in this and all subsequent tables.

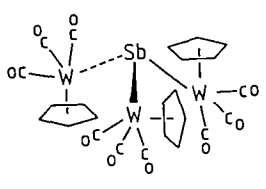
Malisch and Panster have previously reported spectroscopic and analytical data on the bromo analogue of **5**, $[SbBr\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**7a**), together with the related tungsten complex $[SbBr\{W(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**7b**),[5g] and details of the methyl-substituted derivative, $[SbMe\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**7c**), have also been presented.[5d] Complex **1** has been briefly referred to,[5g] although no details of its isolation and characterization were described.

Having established synthetic routes to the molybdenum–antimony complexes, **1** and **5**, it was of interest to see whether exchange reactions involving heterolysis of Sb—Cl and Sb—Mo bonds were apparent in solution. Accordingly, a THF solution of **1** was treated with a THF solution containing 0.5 equiv. of $SbCl_3$, whereupon an immediate reaction occurred resulting in an essentially quantitative conversion (as determined by IR spectroscopy) to **5**. These results implied a reaction in accordance with eq. (1):

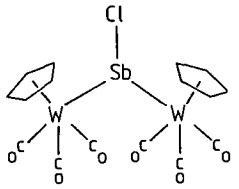
$$\underset{\textbf{(1)}}{2[Sb\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]} + SbCl_3 \rightleftharpoons 3[SbCl\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2], \quad (1)$$
$$\textbf{(5)}$$

albeit with the equilibrium lying, in the THF solution, far to the right and thus favouring the formation of **5**. Exactly analogous results have been found for the bismuth analogues, **2** and **6**.[21b]

The tri- and ditungsten compounds, $[Sb\{W(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**8**) and $[SbCl\{W(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**9**), were synthesized in a similar manner to the



8



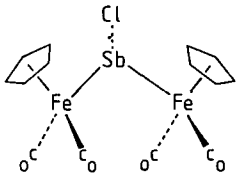
9

corresponding molybdenum derivatives (see Experimental). Spectroscopic data for **8** (Table 1) were in accord with a structure analogous to **1**, particularly the solution IR spectrum (Fig. 1) in the carbonyl region. The electron-impact mass spectrum of **8** was also similar to that observed for **1**, in as much as signals corresponding to fragment ions with metal ratios of W_3Sb and W_2Sb_2 were seen. Full details are given in the Experimental, but the former set of signals, i.e. W_3Sb were consistent with the derived structure of **8** whilst the latter, i.e. W_2Sb_2, were attributed to the rearranged product, $[W_2Sb_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (**10**).

The ditungsten–antimony complex, **9**, was isolated as a purple crystalline solid. Spectroscopic and analytical data are presented in Table 1 and establish the close similarity between **9** and **5**, particularly the solution IR spectra (Fig. 1). As mentioned previously, Malisch and Panster have described the synthesis of the bromo analogue of **9**, i.e. **7b**.[5g] In the analogous tungsten–bismuth chemistry it was originally reported[21a] that the tritungsten bismuth complex, $[Bi\{W(CO)_3(\eta\text{-}C_5H_5)\}_3]$, was not formed in the reaction between $BiCl_3$ and 3 equiv. of $Na[W(CO)_3(\eta\text{-}C_5H_5)]$. Subsequent, more detailed work, however,[21b] demonstrated that the tritungsten complex was formed, albeit with concomitant formation of $[BiCl\{W(CO)_3(\eta\text{-}C_5H_5)\}_2]$ and $[WCl(CO)_3(\eta\text{-}C_5H_5)]$. Full details of the preparative routes to the bismuth complexes are reported in ref. 21(b). We note, however, that the reaction between $SbCl_3$ and 3 equiv. of $Na[W(CO)_3(\eta\text{-}C_5H_5)]$ appears to proceed more cleanly without substantial amounts of $[SbCl\{W(CO)_3(\eta\text{-}C_5H_5)\}_2]$ and $[WCl(CO)_3(\eta\text{-}C_5H_5)]$ being formed. Nevertheless, $[Sb\{W(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**9**) is difficult to purify and fully satisfactory microanalytical data could not be obtained.

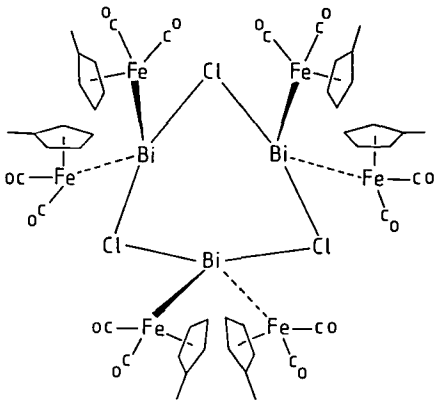
Having studied the chemistry of antimony complexes incorporating organomolybdenum and -tungsten groups, the related iron chemistry, *viz.* complexes containing the $Fe(CO)_2(\eta\text{-}C_5H_5)$ fragment was examined.

Treatment of $SbCl_3$ with 2 equiv. of $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$ afforded, after work-up, red crystals of the di-iron antimony complex $[SbCl\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ (**11**). Spectroscopic and analytical data



11

(Table 1) were in accord with an empirical structure as represented in the diagram but gave little indication as to any degree of intermolecular interactions which might exist. This factor was considered important, since in the analogous bismuth complex, a cyclotrimeric structure exists in the solid state,[24,25] *viz.* $[(BiCl\{Fe(CO)_2(\eta\text{-}C_5H_4R)\}_2)_3]$ (R = H, Me) (**12**), involving Cl—Bi—Cl bridging. The extent to which this also occurs in **11** is uncertain since an X-ray crystallographic study carried out on crystals of **11** was hampered by severe disorder problems, which prevented an informative solution from being obtained. It should be noted that the solution IR spectrum of **11** (Fig. 1) is very similar in appearance to that observed for **12**,[24]

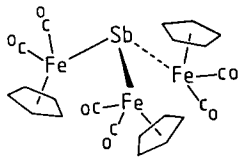


12

although this is of limited diagnostic value since the extent of association of **12** in solution is unknown. Nevertheless, the solution state structures of **11** and **12** are clearly very similar.

The bromo and methyl analogues of **11** have been reported by Malisch and Panster,[5c,d] *viz.* $[Sb(R)\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ (R = Br, Me), the bromo derivative having a solution IR spectrum essentially identical to that obtained for **11** (Table 1).

The reaction between $SbCl_3$ and 3 equiv. of $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$ was also studied and afforded dark red–brown crystals of the tri-iron antimony complex, $[Sb\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_3]$ (**13**).



13

Spectroscopic and analytical data (Table 1) were in accord with the proposed structure and this was confirmed by an X-ray crystallographic study, the results of which are shown in Fig. 3; selected bond length and angle data are given in Table 3. The structure consists of two symmetry independent molecules with no short intermolecular contacts. Both molecules are essentially identical and contain an antimony atom in a trigonal pyramidal coordination environment (sum of angles: 330.9°, molecule A and 330.9°, molecule B) each being bonded to three $Fe(CO)_2(\eta\text{-}C_5H_5)$ fragments by unsupported Sb—Fe bonds (av. Sb—Fe, 2.651 Å, molecule A; av. Sb—Fe, 2.653 Å, molecule B). Compound **13** may thus be described as a trimetallastibine and is closely related to the analogous bismuth complex $[Bi\{Fe(CO)_2(\eta\text{-}C_5H_4Me)\}_3]$ (**14**), which has also been characterized by X-ray crystallography.[24b] Both the antimony and bismuth complexes are structurally very similar, including the conformations about the element–iron bonds which give the molecule approximate C_3 symmetry. However, the bismuth atom in **14** is slightly more pyramidal (av. Fe—Bi—Fe, 109.3°) than the antimony atoms in **13** (av. Fe—Sb—Fe, 110.3°), although this structural trend is expected and has already been discussed in relation to the structures of **5** and **6**. Each iron is additionally ligated by a cyclopentadienyl ligand and two terminal carbonyls, all of normal geometry with the iron adopting a $CpML_3$ "piano-stool" configuration. The structure of **13** is the first to be reported for a trimetallastibine of which we are aware but it is closely related, however, to the cationic complexes $[SbCl_2\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]^+$[18] (av. Sb—Fe, 2.439 Å) and $[SbCl\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_3]^+$[19] (av. Sb—Fe, 2.539 Å). Other examples of antimony–iron complexes that have been structurally characterized include $[Fe_2(CO)_6\{\mu\text{-}Sb(Fe_2(CO)_8)\}_2]$[15a,b] (av. Sb—Fe, 2.529 Å), $[Fe_3(CO)_9(\mu_3\text{-}CO)\{\mu_3\text{-}Sb(Fe(CO)_4)\}]^-$[15c] (av. Sb—Fe, 2.493 Å), $[Fe_3(CO)_9\{\mu_3\text{-}Sb(Fe(CO)_4)\}_2]^{2-}$[15c] (av. Sb—Fe, 2.523 Å), the stibine complex $[Fe(CO)_2(SbPh_3)(\eta\text{-}C_5H_5)]^+$[26] (Sb—Fe, 2.477(1) Å), $[Fe(CO)(PMe_3)(\eta\text{-}C_5H_5)\{Sb(Br)_2PMe_3\}]$[5b] (Sb—Fe, 2.551(2) Å) and $[Fe(Ph)(CO)_3(SbPh_3)\{Sb(Ph)_2Fe(CO)_4\}]$[6a] (Sb—Fe, 2.515, 2.525, 2.606 Å).

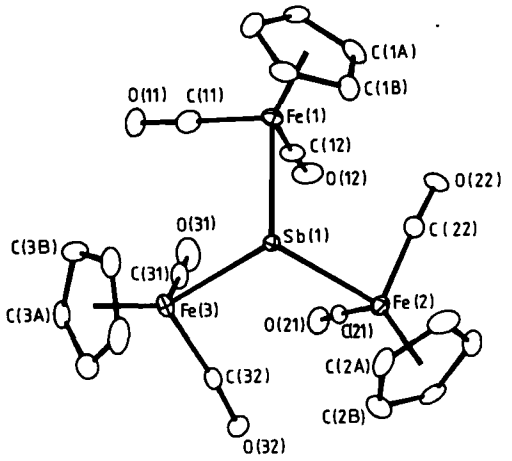


Fig. 3. Molecular structure of one of the two symmetry independent molecules of **13**, showing the atom numbering scheme adopted. Thermal ellipsoids are drawn at the 10% probability level.

Table 3. Selected bond lengths (Å) and bond angles (°) for **13**

Molecule A			
Sb(1)—Fe(1)	2.638(2)	Sb(1)—Fe(2)	2.676(2)

Fe(4)—Sb(2)—Fe(5)	110.8(1)		
Fe(4)—Sb(2)—Fe(6)	109.1(1)		
Fe(5)—Sb(2)—Fe(6)	111.0(1)		

Brief details of the synthesis of **13** have been reported by Malisch and Panster,[20] together with a study of its behaviour as a Lewis base through antimony to 16 electron transition metal fragments.

Finally we note that solution photolysis of **13** did not result in isolable products. In the case of the bismuth analogue, **14**, it had been observed that photolysis cleanly afforded the *closo*-Fe_3Bi cluster, $[Fe_3Bi(CO)_3(\eta\text{-}C_5H_4Me)_3]$ (**15**),[24b] in good yield (Schmidbaur had also reported similar results for the C_5H_5 derivatives[25]). While a reaction certainly occurred in the antimony case, as evidenced by IR spectroscopy, a mixture of products seemed to be formed from which it was not possible to isolate and characterize any pure materials.

CONCLUSIONS

Synthetic routes to a range of organomolybdenum, -tungsten and -iron antimony complexes are reported herein together with details of their spectroscopic and structural properties. These studies establish, together with previous related work,[5,20] that transition metal–antimony bonds are readily formed and suggest that a wide range of compounds are capable of being prepared. Further synthetic studies are in progress together with reactivity and electrochemical studies involving the compounds described.

EXPERIMENTAL

General procedures

All experiments were performed using standard Schlenk techniques under an atmosphere of dry oxygen-free dinitrogen. All solvents were freshly distilled over appropriate drying agents immediately prior to use. ^1H and ^{13}C NMR spectra were recorded on a Bruker WP200 spectrometer operating at 200.13 and 50.324 MHz, respectively.[27] IR spectra were recorded on a Nicolet 20SXB FTIR spectrophotometer, and mass spectra were obtained on Kratos MS9 and MS80 instruments. Microanalytical data were obtained at the University of Newcastle.

Antimony trichloride and $[Fe_2(CO)_4(\eta\text{-}C_5H_5)_2]$ were procured commercially and used without further purification. $[M_2(CO)_6(\eta\text{-}C_5H_5)_2]$ (M = Mo, W) were prepared by the method of Manning *et al.*[28] Spectroscopic and analytical data for all new complexes are presented in Table 1. Mass spectrometric data are recorded below.

Preparations

Preparation of $[Sb\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**1**). A solution of $Na[Mo(CO)_3(\eta\text{-}C_5H_5)]$ derived from a sodium amalgam reduction of $[Mo_2(CO)_6(\eta\text{-}C_5H_5)_2]$ (0.574 g, 1.17 mmol) in THF (20 cm^3) was cooled to −78°C by means of a dry-ice–ethanol bath. To this, a solution of $SbCl_3$ (0.178 g, 0.780 mmol) in THF (10 cm^3) was slowly added with continuous stirring. This resulted in a colour change from pale yellow–green to dark red. After complete addition, the reaction mixture was allowed to warm to room temperature and stirred for 1 h. The reaction mixture was then filtered through Celite to remove NaCl, resulting in a dark red solution. The solvent volume was then reduced to about 10 cm^3 and hexane (20 cm^3) was layered over the more concentrated red solution. Solvent diffusion at −26°C over a period of days resulted in the formation of a red–brown solid, subsequently characterized as **1** (0.328 g, 49% yield). Purification of the original reaction solution may also be effected by column chromatography (Florisil, THF eluant), although a simple filtration is usually sufficient.

The tungsten analogue $[Sb\{W(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**8**) was prepared in an exactly analogous manner with typical yields of about 48% being obtained.

The electron-impact mass spectrum for **1** (probe temperature 200°C), *m/z* 772, P −3CO (P = $SbMo_3(CO)_9(C_5H_5)_3$); 678, P′ (P′ = $Sb_2Mo_2(CO)_4(C_5H_5)_2$); 622, P′ −2CO; 594, P′ −3CO; 566, P′ −4CO; 436, P′ −4CO+2C_5H_5. The ratio between the peak heights for the signals at 772 and 678 was approximately 1 : 10.

The electron-impact mass spectrum for **8** (probe temperature 220°C), *m/z* 1036, P −3CO (P = $SbW_3(CO)_9(C_5H_5)_3$); 980, P −5CO; 924, P −7CO; 896, P −8CO; 868, P −9CO; 854, P′ (P′ = $Sb_2W_2(CO)_4(C_5H_5)_2$); 798, P′ −2CO; 770, P′ −3CO; 742, P′ −4CO; 612, P′ −4CO+2C_5H_5. The ratio between the peak heights for the signals at 1036 and 854 was approximately 1 : 30. In all cases the numbers given are for the observed peak of maximum intensity. Good fits were obtained between observed and calculated isotope patterns in all cases. Two of these, P −3CO and P′ for **8**, are shown in Diagram 1.

Two further points are noteworthy regarding the mass spectral results. Firstly, the observation of more fragment ions with a W_3Sb metal ratio, in the spectrum of **8** compared with the number of Mo_3Sb type ions seen for **1**, suggests that the former is more robust and this, in turn, can be taken as evidence consistent with stronger W—Sb bonds compared to those of Mo—Sb. Secondly, the observation of fairly strong signals corresponding to the ions $SbM_3(CO)_6(C_5H_5)_3$ (**1**, M = Mo; **8** M = W) suggests that the neutral molecules from which these are formally derived may be quite stable and therefore viable targets for chemical synthesis. This view is strengthened by the fact than an arsenic analogue, $[AsMo_3(CO)_6(C_5H_5)_3]$, has recently been prepared and fully characterized.[29] Attempts are in progress to synthesize these species.

Good fits between observed and calculated isotope patterns were also found in all other cases where EI mass spectra are quoted in this paper.

Preparation of $[SbCl\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**5**). A solution of $Na[Mo(CO)_3(\eta\text{-}C_5H_5)]$, derived from a sodium amalgam reduction of $[Mo_2(CO)_6(\eta\text{-}C_5H_5)_2]$ (0.514 g, 1.05 mmol), in THF (20 cm^3) was added to a solution of $SbCl_3$ (0.239 g, 1.05 mmol) in THF (10 cm^3) at 0°C, resulting in an immediate colour change to red–brown. The reaction was then

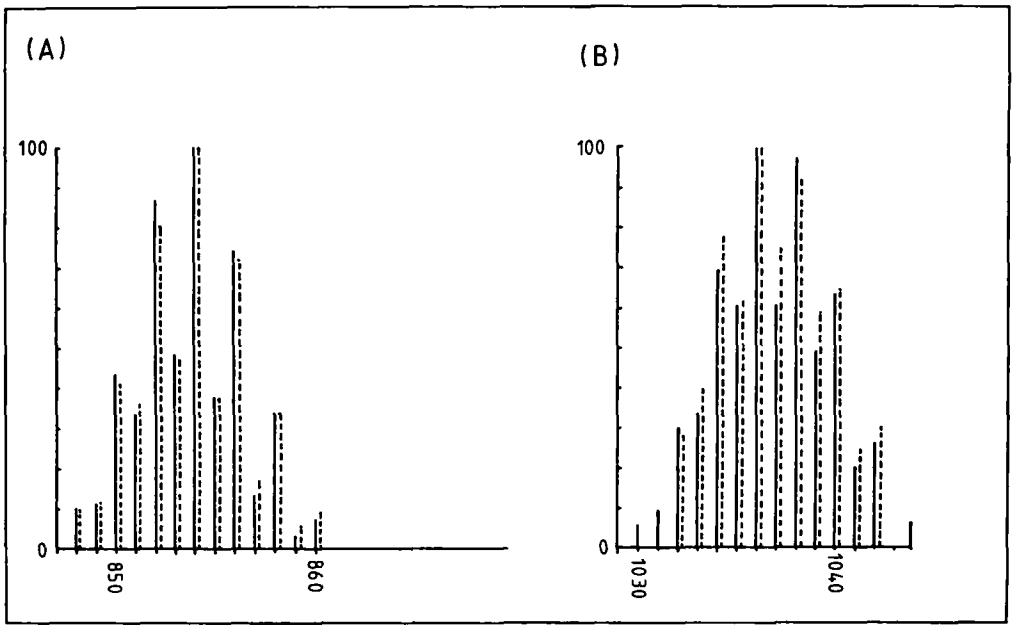

Diagram 1. Electron-impact mass spectra showing observed (----) and calculated (——) isotope patterns for the ions: (**A**), $Sb_2W_2(CO)_4(C_5H_5)_2$; (**B**) $SbW_3(CO)_6(C_5H_5)_3$.

allowed to warm to room temperature and was stirred for a further 2 h. After this time, the reaction mixture was filtered (Celite) and the solvent volume of the filtrate was reduced to ~7 cm^3 *in vacuo*. Hexane (40 cm^3) was layered over the concentrated filtrate and solvent diffusion over a period of days at −26°C afforded dark purple crystals of **5** (0.403 g, 59%).

The ditungsten complex, $[SbCl\{W(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**9**), was synthesized in an analogous manner and with similar yields.

The electron-impact mass spectrum for **5**, *m/z* 648, P (P = $SbClMo_2(CO)_6(C_5H_5)_2$); 585, P −1CO+1Cl; 480, P −6CO. In addition, signals due to **3** were also observed, *m/z* 678, P′ (P′ = $Sb_2Mo_2(CO)_4(C_5H_5)_2$); 622, P′ −2CO; 594, P′ −3CO; 566, P′ −4CO.

The electron-impact mass spectrum for **9**, *m/z* 822, P (P = $SbClW_2(CO)_6(C_5H_5)_2$). Signals due to **10** were also observed, *m/z* 854, P′ (P′ = $Sb_2W_2(CO)_4(C_5H_5)_2$); 798, P′ −2CO; 770, P′ −3CO; 742, P′ −4CO; 612, P′ −4CO+2C_5H_5.

Compound **5** can also be prepared by addition of $SbCl_3$ to **1** as follows. A solution of $SbCl_3$ (0.003 g, 0.0132 mmol) in THF (1 cm^3) was added to a stirred solution of $[Sb\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (**1**) (0.023 g, 0.0264 mmol) in THF (2 cm^3) at room temperature. Monitoring of the reaction by IR spectroscopy revealed that **5** is formed in essentially quantitative yield after about 20 min.

Preparation of $[SbCl\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ (**11**). A solution of $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$, derived from a sodium amalgam reduction of the dimer $[Fe_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (0.341 g, 0.964 mmol), in THF (20 cm^3) was added to a stirred solution of $SbCl_3$ (0.220 g, 0.964 mmol) in THF (10 cm^3) at 0°C, resulting in an immediate colour change to dark red–brown. The reaction mixture was then allowed to warm to room temperature and stirred for 90 min. After this time, the mixture was filtered (glass frit) and the solvent volume of the filtrate was reduced to ~6 cm^3 *in vacuo*. Hexane (35 cm^3) was layered over the concentrated filtrate and solvent diffusion over a period of days at −26°C afforded red crystals of **11** (34%).

The electron-impact mass spectrum for **11**, *m/z* 510, P (P = $SbClFe_2(CO)_4(C_5H_5)_2$); 454, P −2CO; 398, P −4CO.

The methylcyclopentadienyl derivative $[SbCl\{Fe(CO)_2(\eta\text{-}C_5H_4Me)\}_2]$ was also prepared by an analogous synthetic route with the hope of obtaining X-ray quality crystals, although this was not fulfilled. Pertinent data: IR ν(CO)/cm^{-1}, 2040s, 2017s, 1985s. The electron-impact mass spectrum, *m/z* 538, P (P = $SbClFe_2(CO)_4(C_5H_4Me)_2$); 510, P −1CO; 482, P −2CO; 454, P −3CO; 426, P −4CO; 503, P −1Cl.

Preparation of $[Sb\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_3]$ (**13**). A stirred solution of $Na[Fe(CO)_2(\eta\text{-}C_5H_5)]$, derived from a sodium amalgam reduction of $[Fe_2(CO)_4(\eta\text{-}C_5H_5)_2]$ (0.544 g, 1.539 mmol), in THF (25 cm^3) was cooled to −78°C by means of a dry-ice–ethanol bath. To this, a solution of $SbCl_3$ (0.234 g, 1.026 mmol) in THF (10 cm^3) was added, resulting in a

colour change to dark red. The resulting reaction mixture was then allowed to warm to room temperature and stirred for 3 h. All volatiles were then removed *in vacuo*. Extraction with Et_2O (5×20 cm^3) followed by filtration (glass frit) afforded a dark red–brown solution, from which dark red–brown crystals of **13** were obtained (0.370 g, 55%) by solvent diffusion from Et_2O (20 cm^3)–hexane (40 cm^3) at −26°C over a period of days.

The electron-impact mass spectrum for **13**, *m/z* 652, P (P = $SbFe_3(CO)_6(C_5H_5)_3$); 624, P −1CO; 596, P −2CO; 568, P −3CO; 540, P −4CO; 512, P −5CO; 484, P −6CO; 419, P −6CO+C_5H_5; 354, P −6CO+$2C_5H_5$; 475, P −$Fe(CO)_2(C_5H_5)$; 298, P −$2Fe(CO)_2(C_5H_5)$.

A slightly different synthesis of **13** is reported in ref. 20.

X-ray crystallographic studies

Structure determinations of [$SbCl\{Mo(CO)_3(\eta$-$C_5H_5)\}_2$] (**5**) and [$Sb\{Fe(CO)_2(\eta$-$C_5H_5)\}_3$] (**13**). The following structure determination method is for compound **5** unless otherwise stated. The corresponding values for **13** are in parentheses following those for **5**.

A crystal of approximate dimensions $0.25 \times 0.35 \times 0.7$ ($0.7 \times 0.4 \times 0.2$) mm was mounted in a general position on a glass fibre and coated with acrylic resin. Data were collected at ambient temperatures, using the θ–2θ scan mode, on a CAD4F automated diffractometer with graphite monochromated X-radiation ($\lambda = 0.71069$ Å). Unit cell parameters were determined by refinement of the setting angles ($\theta \geqslant 12°$) of 25 reflections. The standard reflections $\bar{2}$ 0 14, $\bar{4}$ 0 $\bar{6}$, and $\bar{2}$ $\bar{4}$ 8 (6 $\bar{7}$ 0, $\bar{4}$ 7 6) were measured every 2 h and a slight increase in intensities of *ca* 1.37% (5.6% decay) in 10,000 reflections was observed and corrected for. This increase is attributed to a reduction of secondary extinction caused by a gradual increase in the mosaicity of the crystal during data collection. Lorentz-polarization and absorption/extinction (DIFABS[30]) corrections were also applied. A total of 3650 (9045) measured reflections, θ range 2–25°, h 0 → 8, k 0 → 11, l −32 → +32, (θ range 2–26°, h 0 → 20, k 0 → 20, l −20 → +20) yielded 3369 (8738) independent data, of which 2707 (5316) having an intensity $> 3\sigma(I)$ were considered observed and used for structure solution and refinement. Systematic absences uniquely determined the centrosymmetric space group $P2_1/n$ ($P2_1/n$). The structure was solved by direct methods (MITHRIL[31]) and subsequent electron density difference syntheses. Refinement was by full-matrix least-squares minimizing the function $w(|F_o| - |F_c|)^2$ with the weighting scheme $w = [\sigma^2(F_o)]^{-1}$ used and judged satisfactory. $\sigma(F_o)$ was estimated from counting statistics. The parameter list for **13** was refined in two separate blocks due to matrix size limitations. Hydrogen atoms were included at calculated positions (C—H = 1.0 Å), with fixed contributions to the structure factors. The C_5H_5 groups for **13** were refined as rigid groups with a regular pentagonal geometry for the ring, and C—C = 1.395 Å. Refinement using a total of 235 (307) parameters converged at $R/R_w = 0.028/0.035$ (0.057/0.066), with mean and maximum Δ/σ values of 0.008 (0.005) and 0.05 (0.02), respectively, in the final cycle. A final electron density difference synthesis

(*Received* 18 *April* 1989; *accepted* 2 *June* 1989)

Abstract—Reaction of *o*-$(NH_2)_2C_6H_3$-4-NO_2 with $PtCl_2(PR_3)_2$ in liquid ammonia gives $Pt\{(NH)_2C_6H_3NO_2^{2-}\}(PR_3)_2$ (PR_3 = PEt_3, PMe_2Ph, PPh_2Me, 1/2dppe) in good yield (80% isolated). The new complexes were characterized by ^{31}P, ^1H NMR, IR, UV–vis, mass spectra, microanalyses and, in the case of PR_3 = PMe_2Ph, by X-ray crystallography.

Although there are a great number of amine complexes of platinum there are relatively few examples of species containing di-imido ligands. Formally, these ligands are isoelectronic with dithiolenes and may thus be of interest from the point of view of preparing stacking compounds. There have been previous reports of the preparation of bis complexes containing two $C_6H_4(NH)_2^{2-}$ ligands[1,2] and work is in progress (by other groups) on tris complexes of rhenium.[3] Here we report on the reactivity of *p*-nitro-*o*-phenylenediamine (**1**) with *cis*-$PtCl_2(PR_3)_2$ (**2**) in liquid ammonia. The products from this reaction (**3**)–(**7**) contain the doubly deprotonated dianion $[p\text{-}O_2NC_6H_3(NH)_2]^{2-}$ as a ligand in simple platinum(II) complexes.

EXPERIMENTAL

All solvents were dried prior to use and reactions performed under an inert atmosphere (N_2, Ar). The bis-phosphine–platinum (palladium) dichlorides were made as previously described.[4] Ammonia (BOC) and 4-nitro-*o*-phenylenediamine (Aldrich) were used as suplied. ^{31}P-{^1H} and ^1H NMR spectra were obtained using a JEOL FX90Q spectrometer operating at 36.21 and 89.55 MHz and are refered to external 85% H_3PO_4 and internal TMS, respectively. Some ^{31}P NMR spectra were also run at higher field on a Bruker WM 250 spectrometer at 101.1 MHz and referred to external 85% H_3PO_4. IR spectra were recorded as pressed KBr discs using a Perkin–Elmer 1720X instrument. UV–vis spectra were obtained on a PE Lambda 3. Mass spectra were taken on a Varian VG 2020 spectrometer in the E.I. mode. Elemental analyses were performed by the microanalytical service at Imperial College.

In a typical reaction 4-nitro-*o*-phenylenediamine (0.16 mmol) was dissolved in liquid ammonia at −78°C to generate a red solution, whereupon $PtCl_2(PR_3)_2$ (0.15 mmol) was added. The resultant slurry was stirred for 0.5 h at −78°C and the ammonia allowed to evaporate under a blanket of nitrogen as the solution warmed slowly to room temperature, leaving a black–purple solid. Purification was achieved by extraction with CH_2Cl_2 (5 cm^3), followed by filtration through a celite/glass wool plug and passage down a Biobead (SX-8) column with CH_2Cl_2 as the eluent. The product, $Pt\{(NH)_2C_6H_3NO_2\}(PR_3)_2$ (**3**)–(**7**), was obtained,

* Author to whom correspondence should be addressed.

upon removal of the solvent *in vacuo*, from the first purple band which eluted (0.12 mmol, *ca* 80%). Crystals suitable for X-ray studies were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **3**. Microanalyses, yields, ^{31}P and ^{1}H NMR are given in Table 1, mass spectra and selected IR data in Table 2.

X-ray crystallography

All X-ray measurements were made on a CAD4 diffractometer operating in the ω–2θ scan mode with graphite monochromated Mo-K_α, following procedures previously described in detail.[5] The structure was solved and refined by the heavy atom method and full-matrix least-squares in a routine manner. All non-hydrogen atoms were refined anisotropically. Phosphine phenyl rings were treated as rigid bodies with hydrogens included in idealized positions with group U_{iso} values. Methyl hydrogens and those on the phenylene-diimine were freely refined with individual U_{iso} values.

Crystal data. $C_{22}H_{27}N_3O_2P_2Pt$, $M = 622.512$, monoclinic, $a = 12.817(3)$, $b = 14.262(2)$, $c = 13.013(2)$ Å, $\beta = 96.17(1)°$, $U = 2364.9$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.75$ g cm^{-3}, μ(Mo-K_α) = 61.5 cm^{-1}, $\lambda = 0.71069$ Å.

Data collection. ($1.5\theta \leqslant 25°$), graphite monochromated Mo-K_α radiation; 4547 independent measured reflections, 2906 observed [$|F_o| > 1.5\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction.

Refinement. 281 parameters, weighting scheme $1/[F_o + 0.001431F_o]$ $R = 0.042$, $R_g = 0.0527$. Phenyl rings refined as rigid groups. All non-hydrogens anisotropic; hydrogens fixed. Computations were carried out on an VAX 11.750 computer using the SHELX76 program system. Final atomic positional and thermal parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Upon dissolving **1** in liquid ammonia, an intense red coloured solution is observed. If this solution is reacted with **2** the new complexes **3**–**7** are obtained [Eq. (1)]:

$$\underset{\textbf{(1)}}{O_2NC_6H_3(NH_2)_2} + \underset{\textbf{(2)}}{PtCl_2(PR_3)_2} \xrightarrow{\text{liq } NH_3} \underset{\textbf{(3)–(7)}}{Pt\{(NH)_2C_6H_3NO_2\}(PR_3)_2} + 2NH_4Cl. \quad (1)$$

M^+ = parent ion. Percentage abundance of the above fragmentation ions exceed 25% of the base peak. The molecular and fragment ions had the expected isotopic variation around the main peak.

The colour changes during the course of the reaction suggest that **1** is deprotonated by liquid ammonia to form an anionic species. However, we have no strong evidence for this. At best a monoanion would be formed and we presume that this forms an (unobserved) intermediate which eliminates HCl to give the desired product. Compounds **3–7** were characterized by NMR, mass spectra, IR and, in the case of $PR_3 = PMe_2Ph$, X-ray crystallography.

The ^{31}P NMR of **3–7** (Fig. 1, Table 1) consist at low field (36.21 MHz) of a central resonance with complex satellites due to coupling to ^{195}Pt. The magnitude of the $^1J\ ^{31}P–^{195}Pt$ coupling constants show an inequivalence and are typical of the pattern normally observed in AX spectra. The substituted NO_2 group of 4-nitro-1,2-diaminobenzene makes the two nitrogen donor atoms slightly different. Thus, although the chemical shift for the phosphorus atoms are essentially the same at 36.21 MHz, the ^1J coupling constants are of sufficiently different magnitude (40 Hz) to be seen. On going to higher field (101.1 MHz) the small chemical shift difference between the phosphorus atoms is enough for the individual resonances to be seen. The magnitude of the $^1J\ ^{31}P–^{195}Pt$ coupling constant of *ca* 2940 Hz is typical of square-planar *cis*-phosphine platinum(II) species with nitrogen donor ligands[6,7] ($^1J\ ^{31}P–^{195}Pt$ in $Pt(NSO)_2(PR_3)_2$ is 3100 Hz and in $Pt(S_2N_2)(PR_3)_2$ is 2800 Hz). The chemical shift variation between **3–7** is due to the variation of the phosphine group. The $^2J\ ^{31}P–^{31}P$ coupling constant of 22 Hz is as expected for *cis*-phosphine groups on platinum(II). The lower $^2J\ ^{31}P–^{31}P$ coupling constant for **6** of 12 Hz could be due to contributions of ^2J(P—Pt—P) combined with a contribution directed via a ^3J(P—CH_2—CH_2—P) pathway.

The ^1H NMR spectra of **3–7** show the phosphine protons often overlapping the aromatic protons of the $NO_2C_6H_3(NH)_2$ ring. The N—H protons are observed at *ca* 6.2 ppm as a doublet ($^3J\ ^{31}P–^1H$, *ca* 5 Hz). This indicates coupling to the *trans*-phosphorus. No $^2J\ ^{195}Pt–^1H$ coupling is observed.

The mass spectra of **3–7** show the parent ion with the expected isotopic correlation (principally due to the platinum isotopes). Fragment ions mainly consist of loss of phosphine to form $[Pt\{(NH)_2C_6H_3NO_2\}(PR_3)]^+$, loss of $(NH)_2C_6H_4NO_2$ to leave $[Pt(PR_3)_2]^+$ and loss of NO_2 to form $Pt\{(NH)_2C_6H_3\}(PR_3)_2$. In the case of the bidentate derivatives (**6**, **7**) the $M-(PR_3)$ peak is not observed, a peak due to loss of (O_2) is seen.

The IR spectra of **3–7** show the expected phosphine and $\{(NH)_2C_6H_3NO_2\}$ ligand vibrations. Two intense ν(NH) vibrations at *ca* 3405 and 3380

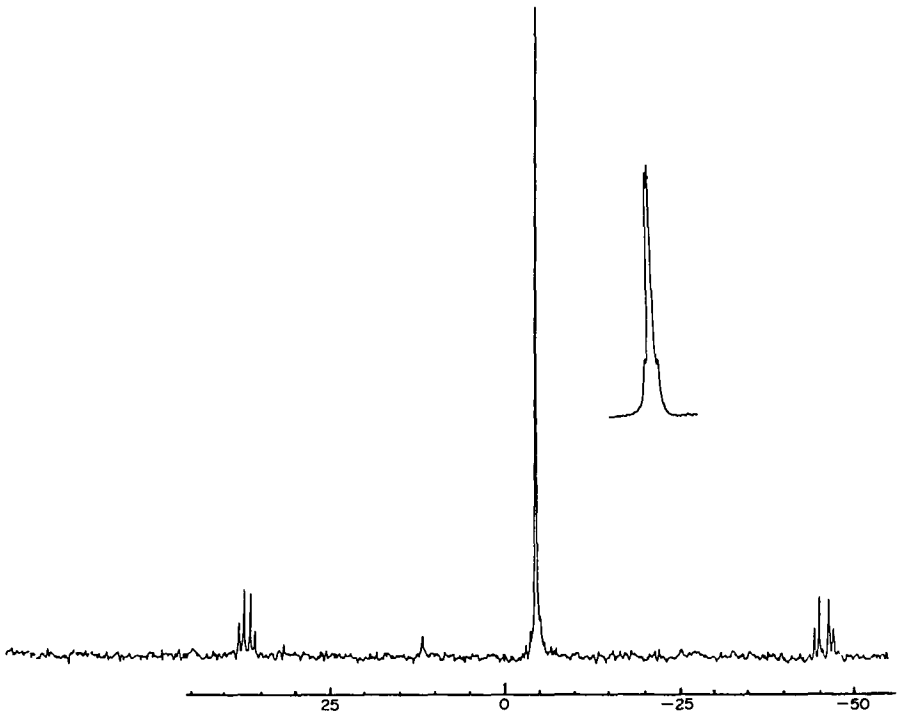

Fig. 1. ^{31}P NMR of **4** at 36.21 MHz, with the insert showing the central resonances measured at 101.1 MHz.

cm^{-1} are observed for **3–5** and one for **6**, **7** at 3395 cm^{-1}. The free ligand 4-nitro-1,2-phenylinediamine has four distinguishable ν(NH) vibrations and the loss of two vibrations is consistent with the ligand having been doubly deprotonated on complexation. The observed ν(NH) vibrations are higher than that observed in the homoleptic rhenium compounds[3] at 3264 cm^{-1} and normal aromatic ν(NH) vibrations at 3250 cm^{-1}. The most intense band in the spectrum is the $\nu(NO_2)$ stretching vibration at 1250 cm^{-1}. This is lower than its assigned value in the free ligand at 1293 cm^{-1}. An assignable ν(CN) vibration is observed at 1567 cm^{-1}, as this vibration does not exist in either starting material. Typically in the homoleptic analogues ν(CN) occurs at *ca* 1594 cm^{-1}.

The UV–vis spectra of **3–6** show four main bands at *ca* 230, 350, 385 and 547 nm. The high energy band at 230 nm is associated with aromatic ring transitions and is of higher intensity in **3**, **4** and **6** due to the aromatic groups also present on the phosphine ligand. The bands at 350 and 385 nm are due to the nitro group. Whilst the weak band at 547 nm, responsible for the purple colour in solution, is due to the complexed ligand.

The X-ray crystal structure of **3** (Table 3, Fig. 2) reveals the expected square-planar geometry at platinum. The Pt—P and Pt—N bond lengths are normal, whilst the C—N bond lengths are, as expected, consistent with formal C=N bond lengths. There are no short contacts in the crystal structure which would indicate any significant intermolecular interactions.

The compounds **3–7** are sensitive to hydrolysis and weak acids. Dichloromethane solutions of **3–7** show gradual deterioration to the free ligand and $PtCl_2(PR_3)_2$ (detected by both ^{31}P NMR and UV–vis). This is presumably due to residual HCl from the CH_2Cl_2 reacting with **3–7** [eq. (2)]:

$$Pt\{(NH)_2C_6H_3NO_2\}(PR_3)_2 + 2HCl \rightleftharpoons (NH_2)_2C_6H_3NO_2 + PtCl_2(PR_3)_2. \quad (2)$$

The complexes **3–7** show no change in the NMR spectrum on adding excess CH_3OD. Similarly, the

(*Received* 10 *April* 1989; *accepted* 17 *May* 1989)

Abstract—The reactions of dioxygen with the binuclear tricoordinate copper(I) complexes, derived from the condensation of benzene-1,3-dicarboxaldehyde and two molecules of a diamine, give phenoxy-bridged copper(II) complexes by direct hydroxylation of the benzene ring.

In our previous work[1] we attempted to design a macrocyclic ligand in which a dinuclear copper(I) centre binds dioxygen and then transfers it into an aryl C—H bond. Such a system simulates the action of copper-containing enzymes such as haemocyanin[2] which binds and transports oxygen, and also tyrosinase[3] and dopamine mono-oxygenase[4] which incorporate oxygen from dioxygen into organic systems. Studies on biomimicking chemical models can be useful in elucidating the structural and spectroscopic properties of enzyme active sites.

We have recently developed such a system. We report on the structure and properties of the dicopper(I) complex (**1a**) and the dicopper(II) complex (**2a**) which contain phenoxy- and hydroxy-bridge ligands. Karlin and co-workers[6] have prepared related complexes by direct synthesis from a diamine and 2-hydroxy-5-methylbenzene-1,3-dialdehyde and by peroxide oxidation of the related ligand incorporating 5-methylisophthalaldehyde.

The binuclear complex, **1a**, was prepared by condensation of 1 equivalent of benzene-1,3-dialdehyde and 2 equivalents of the appropriate amine with 2 equivalents of copper(I) acetonitrile perchlorate in refluxing acetonitrile methanol mixture under an inert atmosphere. A yellow crystalline solid separated in high yield. The IR spectrum of **1a** displayed a band at 1630 cm^{-1} due to the $\nu(C{=}N)$ stretching vibration of the coordinated macrocycle. A weak set of absorptions at 2310–2260 cm^{-1} is due to $\nu(C{\equiv}N)$ stretching vibrations. The IR spectrum also shows uncoordinated perchlorate. The ^1H NMR spectrum of compound **1a** was recorded in deoxygenated CD_3CN and supports the proposed structure. Each copper(I) ion is presumably three-coordinate. This compound was very sensitive to oxygen, both in solution and in the solid state. Compound **1a** in dichloromethane solution reacted rapidly with dioxygen (5 min) producing a blue crystalline compound, **2a** in 90% yield. The oxygen uptake was measured at 25°C in DMA solution. The observed stoichiometry was 0.95 molecule of dioxygen per two copper atoms. This is close to the stoichiometry found for deoxyhaemocyanin[7] and deoxytyrosinase.[8] During the oxidation an intense absorption band formed near 358 nm (ε = 11,000) and a much weaker band near 682 nm (ε = 300) which is characteristic for phenoxo- and hydroxy-bridged copper(II) complexes occurred.[5,6] The IR spectrum of compound **2a** displayed a very strong

$[Cu_2L^2(OH)(OH_2)](ClO_4)_2$ **(2a)**

band near 1560 cm^{-1} which does not exist in compound **1a**, but is typical for the ν(C=O) vibration of the phenol in the 2-hydroxyphenylimino chromophore.[8,4]

Correct analytical data were obtained for compound **2a** as a diperchlorate and 2-hydroxybenzene-1,3-dialdehyde (**3**) was obtained as a colourless, crystalline solid by hydrolysis with 2 M hydrochloric acid, and was identified by IR, elemental analysis and M^+ at m/z 150. Crystal data* for compound **2a**, $[Cu_2L^2(OH)(OH_2)](ClO_4)_2$, $Cu_2N_4Cl_8H_{32}O_{11}Cl_2$, $M = 678.2$, $a = 12.340(10)$, $b = 18.53(1)$, $c = 11.79(1)$ Å, $\beta = 107.0(1)°$, $U = 2578.8$ Å^3, $D_c = 1.75$ g cm^{-3}, $F(000) = 1392$, $Z = 4$, $\lambda = 0.71907$ Å, $\mu = 19.8$ cm^{-1}, space group *Aa*.

1660 independent reflections above background [$I > 2\sigma(I)$] were measured on a diffractometer. The structure was solved by heavy-atom methods and refined (Cu, O, N, C anisotropic, H isotropic in the cation, Cl anisotropic, O isotropic in the anions) to $R = 0.075$ ($R_w = 0.083$). Hydrogen atoms on carbon were placed in fixed positions, those bonded to oxygen were located in a difference Fourier and positions were fixed in the refinement. One perchlorate anion was disordered and two sets of oxygen atoms were refined. In both anions Cl—O and O···O distances were constrained.

The structure of **2a** (see Fig. 1) consists of two copper(II) atoms bridged by a phenolate oxygen

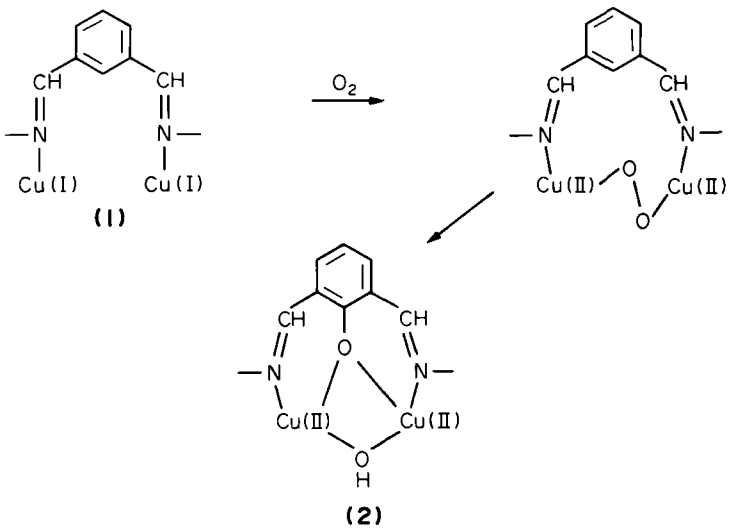

Scheme 1.

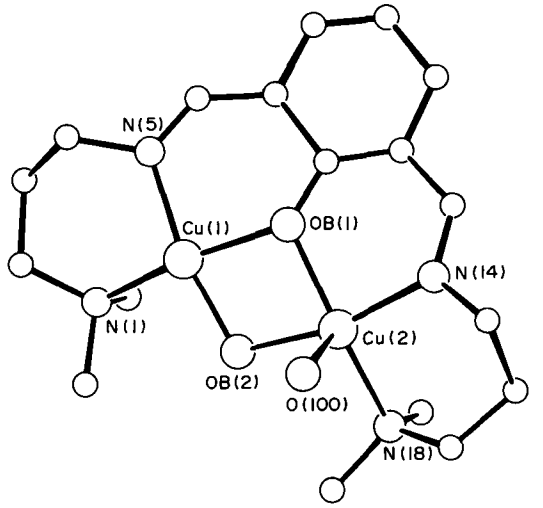

Fig. 1. The structure of the $[Cu_2L^2(OH)(OH_2)]^{2+}$ cation. Cu(1) is four-coordinate with bond lengths Cu(1)—OB(1), 1.99(1); Cu(1)—OB(2), 1.84(1); Cu(1)—N(1), 2.05(1); Cu(1)—N(5), 1.91(1) Å. There is also a close contact of 2.53(5) Å between Cu(1) and a perchlorate oxygen (not shown). Cu(2) is five-coordinate with bond lengths Cu(2)—OB(1), 1.97(1); Cu(2)—OB(2), 1.90(1); Cu(2)—N(14), 1.91(2); —N(18), 2.02(1); Cu(2)—D(100), 2.26(2) Å. The Cu(1)···Cu(2) distance is 3.015(3) Å.

and a hydroxide oxygen. The two copper atoms differ in their environments primarily in the presence of a water molecule on Cu(2); thus while Cu(1) has a distorted four-coordinate square environment, Cu(2) has a distorted four-coordinate square-pyramidal environment. Both metal geometries exhibit tetrahedral distortions of the equatorial planes—thus the angle between CuO_2 and CuN_2 planes is 18.4 and 23.2° for Cu(1) and Cu(2), respectively. This oxygenation of compound **1a** to **2a** with hydroxylation of the benzene ring, suggests that peroxo-copper intermediates are involved as shown in Scheme 1. Other examples of this reaction are the conversion of **1b** to **2b** and **1c** to **2c**.

CYCLOPALLADATION OF N,N-DIMETHYL-2(OR -3)-FURANCARBOSELENOAMIDE TO FORM A CHELATE WITH SELENIUM AND CARBON AS DONOR ATOMS

MATSUO NONOYAMA*

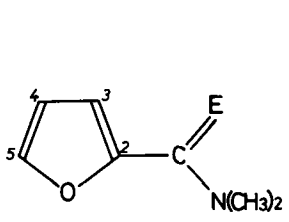
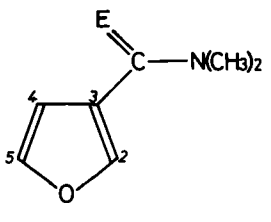
(*Received* 3 *July* 1989; *accepted* 24 *July* 1989)

Abstract—N,N-Dimethyl-2(or -3)-furancarboselenoamide was prepared by the reaction of N,N-dimethyl-2(or -3)-furancarboxamide with phenyldichlorophosphineselenide. The selenoamides were cyclopalladated with lithium tetrachloropalladate to form a five-membered palladaselenaheterocycle.

Selenium is seldom employed as a donor atom in organometallic coordination compounds, contrary to nitrogen, phosphorus and sulphur,[1] e.g. in N,N-dimethyl-2-furancarbothioamide (abbreviated as Haft).[2] The selenium atom of a similar selenoamide is expected to act in the same way to form a related palladaselenaheterocycle. N,N-Dimethyl-2-(or -3)-furancarboselenoamide [abbreviated as Hafs (or Hbfs)] has been prepared and reacted with lithium terachloropalladate. To the best of our knowledge cyclopalladation of a selenoamide is without precedent.



E=Se,Hafs; E=S,Haft



E=Se,Hbfs; E=S,Hbft

Hafs (or Hbfs) was prepared by the reaction of N,N-dimethyl-2(or -3)-furancarboxamide with phenyldichlorophosphineselenide in xylene, followed by purification on an alumina column.[3] Hafs and Hbfs are orange solids which melt at 37–38°C and 27–28°C, respectively. They gave satisfactory elemental analyses and were characterized spectroscopically. The IR and NMR spectra of the selenoamides are very similar to those of the corresponding thioamides.[2] Some important features are as follows.

The $^{13}C\{^1H\}$ NMR spectra (Table 1) show that the ^{13}C signal of the selenoamide group is coupled with a ^{77}Se nucleus: $^1J(C—Se) = 206.6$ Hz for Hafs and 206.9 Hz for Hbfs. These large values suggest a C(sp^2)—Se double bond.[4] The rotational barrier of the selenoamide C—N bond of Hafs and Hbfs is higher than that of the corresponding thioamide C—N bond: the coalescence temperature of the ^1H signal of the $N(CH_3)_2$ group of Hafs is 77°C while that of Haft is 45°C, and that of Hbfs is 111°C while that of Hbft is 80°C (in deuterated dimethylsulphoxide, DMSO-d_6, determined by 90 MHz ^1H NMR spectra).[5] Comparison of the IR spectrum of Hafs with that of Haft reveals that a band at 907 cm^{-1} is assigned to ν(Se=C) (ν(S=C) of Haft is at 927 cm^{-1}). A band at 906 cm^{-1} is likewise

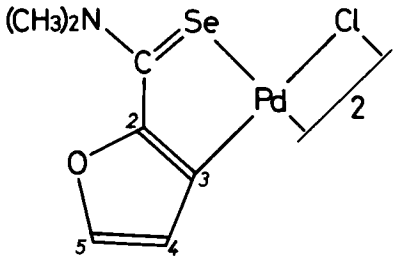
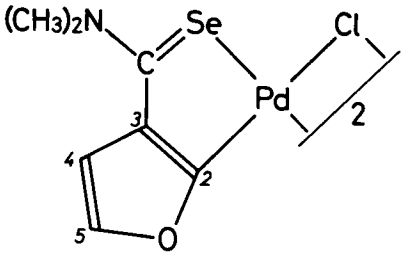
assigned to ν(Se=C) of Hbfs (ν(S=C) of Hbft is at 936 cm^{-1}).[6]

Hafs and Hbfs react with lithium tetrachloropalladate in methanol overnight at room temperature to give, respectively, PdCl(afs) and PdCl(bfs). The two gave satisfactory elemental analyses and were identified spectroscopically. They were practically insoluble in solvents except DMSO, in which they are slightly soluble. The ^1H NMR spectra (90 MHz) of DMSO-d_6 solutions show that the 3-H of the furan ring of free Hafs is removed in PdCl(afs) and the 2-H of free Hbfs in PdCl(bfs). Both the 3-C signal of PdCl(afs) and the 2-C signal of PdCl(bfs) shift, respectively, downfield compared with the corresponding signals of the free ligands (Table 1) by analogy with cyclopalladation of Haft and Hbft.[2]

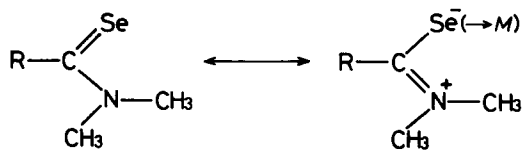
In the IR spectra, higher frequency shifts of ν(C—N) of the selenoamide group upon complexation (Table 1) are indicative of selenium coordination because this coordination increases the double bond character of the C—N bond: an increase in the contribution of the canonical structure (II). A similar shift has been confirmed for sulphur coordination of a thioamide group.[6] The coordination shift of ν(Se=C) is in reverse. Shielding of the ^{13}C signal of the selenoamide group upon complexation is similar to that observed for sulphur coordination of the thioamide group.[2] The following structures are proposed for PdCl(afs) and PdCl(bfs).



PdCl(afs)



PdCl(bfs)



I II

The coordination of chlorine is supported by strong bands at 281 and 241 cm^{-1} [PdCl(afs)] or at 304 and 288 cm^{-1} [PdCl(bfs)]. Further investigations on cyclometallation of selenoamides are in progress.

PLATINUM–IRON CARBONYL CLUSTER COMPLEXES. THE SYNTHESIS AND STRUCTURAL CHARACTERIZATIONS OF $Pt_3Fe_3(CO)_{15}$ and $Pt_5Fe_2(CO)_{12}(COD)_2$

RICHARD D. ADAMS,* GONG CHEN and JIN-GUU WANG

Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 22 *July* 1989; *accepted* 4 *August* 1989)

Abstract—The reaction of $Fe(CO)_5$ with $Pt(COD)_2$ has yielded the products $Pt_3Fe_3(CO)_{15}$ (**1**), 9%, $PtFe_2(CO)_8(COD)$ (**2**), 3% and $Pt_5Fe_2(CO)_{12}(COD)_2$ (**3**), 40%. The new compounds **1** and **3** were characterized by single-crystal X-ray diffraction analyses. Compound **1** contains a planar raft structure of six metal atoms consisting of a central triangular group of three platinum atoms with $Fe(CO)_4$ groups bridging each Pt—Pt edge of the cluster. The Pt—Pt distances are significantly shorter than those of the structurally related anions $[Pt_3Fe_3(CO)_{15}]^-$ and $[Pt_3Fe_3(CO)_{15}]^{2-}$. Compound **3** contains a tetrahedral cluster of platinum atoms. One edge of the tetrahedron is bridged by a Pt(CO) group and each of the Pt—Pt bonds to this group contains a bridging $Fe(CO)_4$ group.

Heteronuclear bimetallic cluster complexes containing platinum are of great interest because of the importance of bimetallic platinum catalysts to petroleum reforming processes.[1] Stone has shown that $Pt(COD)_2$ is an excellent reagent for the preparation of heteronuclear metal complexes containing platinum.[2] Recently, we have achieved success in the synthesis of new cluster complexes by employing the pentacarbonyl complexes of the iron subgroup as reagents.[3–5]. We are currently investigating the reactions of $Fe(CO)_5$ with $Pt(COD)_2$ and wish to report here some preliminary results of these studies.

The reaction of $Pt(COD)_2$ (100 mg, 0.24 mmol) with $Fe(CO)_5$ (1.03 g, 5.28 mmol) in hexane solution at 25°C for 10 min has yielded the following complexes, brown $Pt_3Fe_3(CO)_{15}$ (**1**, 9.0 mg, 9%) and red $PtFe_2(CO)_8(COD)$ (**2**, 5.0 mg, 3%) and dark brown $Pt_5Fe_2(CO)_{12}(COD)_2$ (**3**, 32 mg, 40%) after separation by TLC on silica gel. Compound **2** has been reported previously.[6] Compounds **1** and **3** are new and were characterized by single-crystal X-ray diffraction analyses. An ORTEP diagram of the molecular structure of compound **1** is shown in Fig. 1.† The molecule contains a crystallographically-imposed two-fold rotation axis that passes through the atoms Fe(1), Pt(1), C(11) and O(11). The molecule consists of a raft-like planar cluster of the six metal atoms.

The three platinum atoms form a central triangular cluster with $Fe(CO)_4$ groupings bridging each Pt—Pt edge of the triangle. Each platinum atom also contains one linear terminal carbonyl ligand. Compound **1** is a new uncharged member of the series of anions $[Pt_3Fe_3(CO)_{15}]^{-,2-}$ that were reported by Longoni *et al.* in 1980.[7] All three complexes are isostructural but differ in the total number of electrons. On the basis of the significant decreases of the Pt—Pt bond lengths in going from

the dianion, $\mathbf{1}^{2-}$, to the monoanion, $\mathbf{1}^{-}$ (see Table 1), Longoni concluded that the highest occupied molecular orbital was centred on the Pt_3 triangle and was antibonding in character. This conclusion is further supported by the analysis of compound **1** which shows that the formal removal of one electron from $\mathbf{1}^{-}$ to yield **1** produces yet another significant decrease, 0.066(2) Å, in the Pt—Pt bond lengths. There is also a progressive, but much smaller decrease in the Pt—Fe distances as charge is removed from the cluster.

An ORTEP drawing of the molecular structure of compound **3** is shown in Fig. 2.* The molecule consists of a tetrahedron of four platinum atoms with the fifth platinum atom, Pt(3), bridging an edge of this tetrahedron. $Fe(CO)_4$ groups bridge the Pt—Pt bonds between Pt(3) and the tetrahedral grouping. COD ligands are coordinated to platinum atoms Pt(4) and Pt(5). The Pt(4)—Pt(5) bond is bridged by a carbonyl ligand, but curiously this bond remains by far the longest in the molecule at 2.958(1) Å. The other platinum atoms each contain

Abstract—The reaction of uranyl nitrate hexahydrate with salicylaldehyde, and acyl- and aroyl-dihydrazines in a 1:4:2 molar ratio in ethanol medium results in complexes of the composition $[UO_2(H_3L_2)_2]\cdot nH_2O$ ($n = 0$, 2), where H_4L_2 refers to salicylaldehyde-oxaloyldihydrazone (H_4A_2), -malonoyldihydrazone (H_4B_2), -succinoyldihydrazone (H_4C_2), -glutaroyldihydrazone (H_4D_2), -adipoyldihydrazone (H_4E_2) and -phthaloyl-dihydrazone (H_4F_2), in high yields. The complexes have been characterized by elemental analyses, thermoanalytical data, decomposition points, molar conductance, and IR, Raman and electronic spectral data. The presence of monobasic tridentate ligands has been ascertained from the IR spectra. The ligands are coordinated through the phenolic oxygen, carbonyl oxygen and azomethine nitrogen atoms. All the complexes contain only one band due to the asymmetric stretching vibration of the uranyl group, indicating the same coordination environment around the uranium atom in all the complexes. The complexes are considered to be polymeric structures containing an eight-coordinated uranium atom with six ligand atoms forming an equatorial ring in a plane perpendicular to the linear uranyl group.

The study of novel ligands which can bind two metals in close proximity to one another has recently created much interest among chemists, because the magneto- and electrochemical properties of such complexes show promise in developing theories whereby electron transport phenomena can be further understood.[1] Acyl- and aroyl-dihydrazones are two of the few examples of ligands which can yield binuclear, heteronuclear and polynuclear complexes of transition and inner-transition metals possessing interesting magnetic and electrochemical properties,[2] and which can serve as models in bioinorganic chemistry.[3] Acyl- and aroyl-dihydrazones derived from the condensation of *o*-hydroxy aromatic aldehydes and ketones, and acyl- and aroyl-dihydrazines in which two hydrazone groups are separated from each other by methylene chains of varying length or phenyl groups, constitute a special class of molecules. This class of molecules react in the keto, keto–enol and enol forms[4–8] depending upon the mode of preparation of the complexes, the nature of the reaction medium, the pH of the reaction medium, the nature of the metal salt and the molar ratio of the metal salt, and the ligand employed, and can act as mono-, di-, tri- and tetrabasic hexadentate ligands, and give rise to polymeric complexes through both ligand-bridging due to their flexibility in three-dimensional space, and oxo-bridging through the phenolic oxygen atoms. Recently, we initiated studies on the isolation and characterization of uranyl complexes with acyl- and aroyl-dihydrazones in order to determine the form in which the ligands coordinate to the uranyl group, the possible coordination arrangement of the donor groups around the uranyl group, the relationship between the U=O stretching frequency and the increasing length of the methylene chain between the two hydrazone groups, and the effect of the presence of other ligands in the coordination sphere on the U=O stretching frequency, and also the effect of replacement of the methyl groups by phenyl groups on

complexation. The uranyl ion is the most stable species amongst the uranium compounds present in nature, and is peculiar in the sense that it retains its identity over a wide range of variation in the experimental conditions, and offers a large number of geometric structures usually hexa-to-deca-coordinate, a feature unusual in the coordination chemistry of transition elements. The present paper is a report on the synthesis, characterization and structural assessment of uranyl complexes obtained from the reaction of uranyl nitrate hexahydrate with disalicylaldehyde acyl- and aroyl-dihydrazones (I) (Fig. 1) in 1 : 2 molar ratio in alcoholic media.

EXPERIMENTAL

Materials and measurements

Uranyl nitrate hexahydrate, diethyl esters of oxalic, malonic, succinic, glutaric, adipic and phthalic acids, hydrazine hydrate and salicylaldehyde were from BDH, AR or of equivalent grade. The organic acid dihydrazides *viz.* oxalic, malonic, succinic, glutaric, adipic and phthalic acid dihydrazides were prepared by reacting the diethyl esters (1 mol) with hydrazine hydrate (2 mol). The dihydrazones were prepared by reacting warm or refluxing dilute ethanol solutions of the above acid dihydrazides (1 mol) with salicylaldehyde (2 mol). All the ligands were suction filtered, washed with water and ethanol, and dried at 70°C in an electric oven.[9]

Preparation of the complexes

The complexes were prepared by the following procedure. As all the complexes were prepared by the same method, only a representative procedure is described.

To uranylnitrate hexahydrate (0.05 mol) in ethanol (50 cm^3) was added salicylaldehyde (0.1 mol) in ethanol (100 cm^3), and the reaction mixture was refluxed for 15 min. Oxaloyldihydrazine was finely powdered in an agate mortar, and suspended in ethanol to give a slurry (0.05 mol) which was added slowly (100 cm^3) to the hot mixture of uranyl nitrate hexahydrate and salicylaldehyde, accompanied by gentle warming maintaining the molar ratio at 1 : 4 : 2. The whole mixture was refluxed for 3 h on a water bath accompanied by occasional vapourization to reduce the volume of the reaction mixture to 70–90 cm^3. In H_4A_2, the complex started to appear straight away. But in the remaining cases, the complexes precipitated only when the volume was reduced to 125–100 cm^3. The solution was cooled and the complexes removed by filtration, these were washed with hot benzene, hot ethanol and finally with ether, then dried and collected.

Elemental analyses (Table 1) and measurements

Uranium was determined by standard literature procedures. The ligands in the complexes were estimated volumetrically in 5 M H_2SO_4 with standard $KMnO_4$ using a calibration curve. Carbon, hydrogen and nitrogen were estimated by microanalytical methods. A thermogravimetric study of one sample as an example was carried out manually by heating the sample at the rate of 10°C min^{-1} on a TGA unit supplied by the Fertilizer Corporation of India (FCI), Sindri. The molar conductance of the complexes at 10^{-3} M dilution in DMSO were measured using an Elico conductivity bridge model CM-82T with a dip-type conductivity cell. IR spectra were recorded on a Perkin–Elmer 983 spectrophotometer as KBr pellets in the 4000–180 cm^{-1} region. The Raman spectrum was recorded on a Raman spectrophotometer (Ramalog 1403) as KBr pellets by employing the rotating sample technique to avoid

decomposition of the sample. The electronic spectra in the solid state, and in solution were recorded on a Carl Zeiss (GDR) VSU2-P ultraviolet and visible spectrophotometer with a reflectance attachment, using MgO as the reference, and a Pye-Unichem PU-8800 spectrophotometer, respectively.

RESULTS AND DISCUSSION

The reaction of uranyl nitrate hexahydrate with salicylaldehyde and dihydrazides in 1:4:2 molar ratio results in the formation of solid brown, dull brown, brownish orange, orange and yellow compounds. The analytical results are in accord with the formulation $[UO_2(HLLH_2)_2]\cdot 2H_2O$, in which $HLLH_2$ represents the loss of the phenolic-OH proton of one H_2L-group of the ligand H_2LLH_2. These compounds are finely divided powders all of which decompose above 300°C except for $[UO_2(HLLH_2)_2]\cdot nH_2O$ ($H_4L_2 = H_4B_2$, H_4E_2) which decomposes at 260 and 270°C. The compounds could not be crystallized since they are mostly insoluble in water and common organic solvents, but dissolve in coordinating solvents like DMF and DMSO only. The complexes, upon dissolution in DMF and DMSO, are not accompanied by a colour change, thus ruling out the possibility of the displacement of ligand molecules by solvent molecules. This fact was confirmed by recording the UV–vis spectra of the complex, $[UO_2(H_3E_2)_2]\cdot 2H_2O$, as a representative sample, in the solid state, in DMF and DMSO solutions. The solid state electronic spectrum of the complex shows absorption maxima at 280, 290, 330 and 380 nm, compared to the positions of the maximum absorption bands in the spectrum of the free ligand at 245, 290, 300 and 344 nm.[9] The spectra of the complex in DMF and DMSO solutions show maximum absorption bands at 280, 310, 335, 380 nm and 280, 295, 330, 380 nm, respectively. The essential features of the spectrum of the complex in the solid state and in solutions are entirely different when compared to that of the free ligand, which supports the coordination of the ligand to the uranyl ion in the solid state as well as in the solutions. The apical oxygen $\rightarrow f$ transition within the uranyl entity, centred at about 380 nm, is covered by a strong charge-transfer absorption from the ligand π-orbital to the $5f$ and/or $6d$ orbitals of the uranium atom. This ligand-to-metal charge-transfer band, which is strongly influenced by the chemical nature of the ligand within a given stereochemistry, is responsible for the colours of the complexes.[10] The decomposition temperature of the complexes coupled with their insolubility in common organic solvents suggests that they are associated polymeric species. The water molecules were determined by heating the compounds at 110°C for 4 h in an electric oven and estimating the loss of weight. The expulsion of two water molecules at 110°C indicates that they are part of the lattice, most probably, in the hydrogen bonded form with the ligand which permeates the lattice. The molar conductances of all the complexes fall in the range 0.8–2.3 Ω^{-1} cm^2 mol^{-1} in DMSO. Since 1:1 electrolytes in this solvent generally have molar conductivities between 35 and 70, it is apparent that in this solvent the complexes are non-electrolytes.[11]

The detailed thermogravimetric analyses of the

compound $[UO_2(HEEH_2)_2]\cdot 2H_2O$ was carried out as a representative sample up to 800°C. When heating was carried out in a thermobalance with a heating rate of 10°C min^{-1}, the mass loss corresponded to *ca* 3.56% of the total mass of the compound, corresponding to two water molecules, which indicates that they are part of the lattice or hydrogen bonded in the structural unit of the complexes. The decomposition of the complex occurs in four prominent steps, 80–120°C, 270–420°C, 420–460°C, and 520–640°C. Beyond 120°C, the complex is stable up to 270°C as the average mass loss is about 0.36% at a temperature interval of 20°C. The complex starts losing weight above 270°C by about 2.5% at the 20°C temperature interval, and continues up to 420°C. The most significant decomposition of the complex occurs between the temperature ranges 420–460°C and 520–640°C, the mass losses being about 5.0 and 5.35% at the temperature intervals of 20°C. The loss of the ligand begins at 270°C and occurs in three steps, and is complete at 680°C when the weight of the complex becomes constant; this corresponds to U_3O_8. The mass loss in the temperature range 270–680°C corresponds to two ligand molecules devoid of only one oxygen atom from each ligand molecule. Compared to the 1 : 1 (uranium–ligand) complex,[12] in which the loss of ligand occurred in the 300–420°C temperature range, beyond which the complex shows negligible mass loss and the weight becomes constant at temperatures greater than 460°C, the thermal decomposition behaviour of the present complex is entirely different, showing unsymmetrical decomposition of the ligand, which in turn, indicates the unsymmetrical bonding of the ligand to the uranyl ion.

It is difficult to unambiguously assign the bands due to the various groups and locate their respective positions in the IR spectra of the uncoordinated ligands because of the presence of a number of bands due to groups, viz. >C=O, >C=N, N—C=O, —NH, —OH, phenyl ring, C—N and C—H, which absorb in the overlapping regions, yet few significant bands have been selected to show the effect of coordination on ligand vibrations in the complexes. The assignments of the bands are based on literature reports.

Medium to strong broad bands in the 3500–3250 and 3200–3000 cm^{-1} regions, with multiplet structure, with maximum absorption in the 3423–3328 cm^{-1}, and 3195–3149 cm^{-1} regions are present in the IR spectra of the uncoordinated ligands. H_4A_2 shows additional bands at 3278 and 3232 cm^{-1}, and H_4F_2 shows only a single absorption band at 3149 cm^{-1}. These bands are attributed to ν(OH) and ν(NH) stretching vibrations of the ligands and have composite nature.

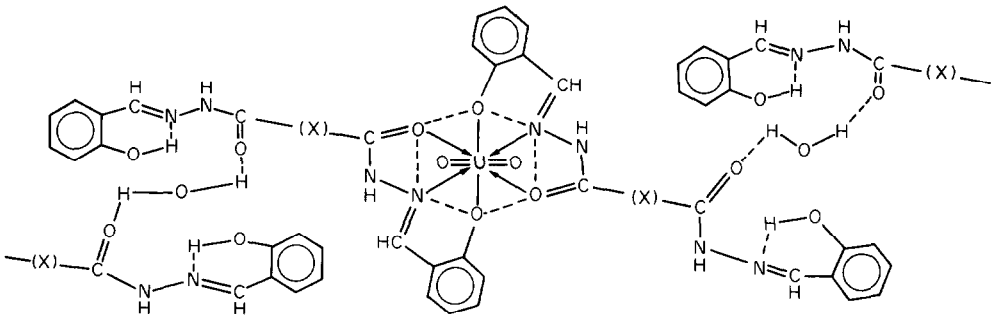
The IR spectra of the ligands in the region 3500–3100 cm^{-1} on complexation undergo splitting into three to five medium to strong bands, some of which undergo a blue shift on complexation. In the IR spectra of the uncoordinated ligands, the bands in the region 3423–3328 cm^{-1} on complexation undergo a blue shift and appear in the region 3576–3422 cm^{-1}, indicating the presence of water molecules in the complexes and the involvement of only one —OH group in coordination. In the IR spectra of the complexes, the appearance of the absorption bands in the 3579–3422 cm^{-1} region is almost similar to that observed in salicylaldehyde and *o*-hydroxyacetophenone, indicating the presence of hydrogen bonding in the molecular lattice. However, it appears that the strength of the hydrogen bonding in the complexed ligands is weakened compared to that in the uncoordinated ligands. The band observed in the 3232–3149 cm^{-1} region in the IR spectra of the uncoordinated ligands splits into two to three bands on complexation. One band suffers a blue shift of about 28–223 cm^{-1}, while the other band remains almost unchanged in its position. This behaviour of the absorption band in the region 3232–3149 cm^{-1} of the uncoordinated ligands on complexation shows that the ν(NH) vibration of one half of the ligand undergoes a blue shift due to the involvement of the >C=O group in coordination, while the other ν(NH) signal remains almost unchanged due to non-involvement of the other half of the ligand in coordination. This shows that half of the ligand is involved in coordination while the other half remains intact and hydrogen bonded, without taking part in coordination. This conclusion based on the position of the absorption bands in the 3232–3149 cm^{-1} region is further substantiated by the positions of the absorptions in the region 1674–1666 cm^{-1} which contains bands due to amide I. The complexes show a feature characteristic of ligand coordination through one carbonyl oxygen only, while the other carbonyl group remains uncoordinated. This is evident from the fact that in the complexes, one amide I band shows a negative shift by about 7–52 cm^{-1} and appears in the region 1666–1621 cm^{-1} in the IR spectra of the complexes, while the other band almost retains its original frequency or shifts to higher frequency. In some cases the intensity of the band is also reduced. The coordination of the ligands to the uranyl ion through the azomethine nitrogen is evident from the fact that the bands present in the 1624–1609 cm^{-1} region in the IR spectra of the uncoordinated ligands, attributed to the ν(C=N) stretching fre-

quency, suffer negative shifts by 10–20 cm^{-1} in the spectra of the complexes, and appear in the 1613–1604 cm^{-1} region as medium to strong bands. The IR spectra of the ligands contain bands in the 1573–1552 cm^{-1} region which are assigned to amide II + ν(C—O) (phenolic). The bands in the IR spectra of the complexes in this region split into several bands, and suffer positive as well as negative shifts, and appear in the regions 1589–1563 and 1563–1518 cm^{-1}, respectively; while some bands appear at almost the same position as in the uncoordinated ligands but reduced in intensity. This indicated the involvement of the ligands in coordination through the >C=O and —OH groups of one half, while the other half remained intact, hydrogen bonded and uncoordinated.[13]

It should be noted that when the two phenolic-OH groups of the phthaloyldihydrazone ligand are coordinated to the uranyl ion, the ν(C=N) stretching frequency shifts to higher wave number, which suggests the flow of the electron density from the salicylaldimine phenyl ring through the azine group nitrogen atoms to the uranyl ion. Consequently, this increases the carbon and nitrogen bond orders. This has been attributed to the replacement of the methylene groups by the phenyl ring between the two hydrazone groups of the phthaloyldihydrazone ligand, which exerts electron-withdrawing power over the salicylaldimine phenyl ring. However, in the present case, in bis(disalicylaldehyde phthaloyldihydrazonato)dioxouranium (VI) complex, the ν(C=N) stretching frequency shows a negative shift, a trend usually observed, in general, in acyl- and aroyl-hydrazone complexes. Hence, it may be argued that the phthaloyl phenyl ring of the phthaloyldihydrazone ligand situated between the two hydrazone groups becomes activated, and exerts electron-withdrawing power only when both the phenolic-OH groups are bonded to the uranyl ion. On the other hand, in the bis(disalicylaldehyde phthaloyldihydrazonato)dioxouranium (VI) complex, the ligand is bonded to the uranyl ion through one phenolic-OH group only, as a result of which the phthaloyl phenyl ring does not experience deficiency in its electron concentration and remains unactivated. Moreover, the drainage of the electron density from half of the coordinated phthaloyldihydrazone ligand to the uranyl ion withdraws the electrons from the phthaloyl phenyl ring which, in turn, withdraws electrons from the carbonyl oxygen of the other half of the ligand to make-up its electron deficiency. This is evident from the splitting of the amide I band, and its appearance at 1700, 1660 and 1642 cm^{-1}, respectively, corresponding to uncoordinated and coordinated carbonyl groups, in the IR spectrum of the complex.

The bands appearing in the region 1279–1261 cm^{-1} in the IR spectra of the uncoordinated ligands may be assigned to stretching vibrations of the phenolic C—O group. The bands in this region show splitting, and some of them show considerable higher frequency shifts in the complexes and appear in the 1332–1290 cm^{-1} region, while the other bands remain almost unchanged in position. Such features of the IR spectra of the complexes in this region indicate the involvement of only one C—O group of the ligand in chelation, while the other one remains hydrogen bonded.[14,15] From the above discussion, it is evident that the ligands coordinate to the uranyl ion in the keto form, they act as monobasic tridentate ligands, and coordinate through the phenolic and carbonyl oxygens and the azomethine nitrogen. The non-ligand bands occurring in the regions 605–558; 502–459 and 379–316 cm^{-1} have been assigned to ν(U—O) (phenolic),[16] ν(U—O) (carbonyl)[16] and ν(U—N)[17] vibrations, respectively.

All the uranyl complexes show a strong absorption in the *ca* 926–887 cm^{-1} region, assigned to the ν_3 vibrations of the uranyl group. In some complexes, a weak to medium band is observed in the 866–851 cm^{-1} region. This band may be assigned to the ν_1 vibration of the uranyl group. Although the ν_1 vibration of the uranyl group is normally IR forbidden, it has been reported to occur in the 900–790 cm^{-1} region. The forbidden vibrations may become allowed as a result of the particular symmetry properties of the ligand-field around the uranyl group in the complexes, rather than slight bending of this group. However, the band in the 866–851 cm^{-1} region in the IR spectra of the complexes may originate from the ligands as well, because the ligands also show weak to medium bands in the 890–834 cm^{-1} region which might be activated on complexation. The IR spectrum of the complex $[UO_2(HDDH_2)_2]\cdot 2H_2O$ shows strong bands at 926 and 906 cm^{-1} due to the ν_3 asymmetric stretching vibration. The IR spectrum of the uncoordinated H_4D_2 shows a band of medium intensity at 892 cm^{-1}. It is quite likely that this band in uncoordinated H_4D_2 is activated on complex formation, and retains its identity in the complex as a strong band. Hence, it can be assumed that of the two bands in $[UO_2(HDDH_2)_2]\cdot 2H_2O$, one band originates from the ligand. The Raman spectrum of the complex $[UO_2(HAAH_2)_2]\cdot 2H_2O$ shows a strong broad band centred at 870 cm^{-1}. The double degenerate O—U—O bending vibration is observed as a medium to strong band in the 283–244 cm^{-1} region, and masks the ligand band occurring in this region. As all the complexes show only one band



(II)

corresponding to the ν_3 vibration of the uranyl group, it suggests that the uranyl groups are in the same coordination environment in the structural units of the complexes.[7]

Considering the composition of the complexes, their insolubility behaviour in common organic solvents, decomposition/melting point, the monobasic tridentate nature of the ligand and the presence of hydrogen bonded water molecules, the dioxouranium(VI) complexes may, tentatively, be assigned as polymeric structures (**II**) involving eight-coordinated uranium. The complex (No. 6) may involve hydrogen bonding between the uncoordinated halves of the ligand in its structural unit. The six equatorial positions are occupied by four oxygen atoms (two from two phenolic-OH groups and two from two carbonyl groups of half of the two coordinated ligands) and two nitrogen atoms from the azomethine groups of the same half of the coordinated ligands, forming a ring around the linear uranyl group.

EXTRACTION OF CADMIUM(II) BY MIXTURES OF ORGANOPHOSPHORUS COMPOUNDS

I. CASAS, N. MIRALLES, A. M. SASTRE* and M. AGUILAR

Dpt. d'Enginyeria Química, E.T.S.E.I.B., Avd. Diagonal 647, 08028 Barcelona, Spain

(*Received* 24 *April* 1989; *accepted* 24 *May* 1989)

Abstract—The extraction of cadmium(II) by mixtures of di(2-ethylhexyl)phosphoric acid (HDEHP) and trioctylphosphine oxide (TOPO) dissolved in tetradecane from aqueous chloride solution has been studied at 25°C. The distribution of metal has been determined as a function of both HDEHP and TOPO concentration. Distribution data have been treated numerically using the program LETAGROP–DISTR, and the composition of the extracted species into the organic phase has been determined. The extraction constants for these species are given.

In a series of previous papers the extraction of divalent metal ions by organophosphorus extractants dissolved in commercial diluents has been studied.[1,2]

As a part of this series, the extraction of cadmium(II) with di(2-ethylhexyl)phosphoric acid (henceforth HDEHP in the text and HA in formulae) has been thoroughly studied and the system has been described in terms of species and extraction constants,[3] to establish, as in the earlier work, if the speciation in the organic phase could provide certain differences in composition which could be utilized for the design of separation methods.[4]

A step forward in the aims of this work is to study the possibility of using combinations of extractants to investigate the appearance of a synergic effect that could increase the extraction of the metal ion. The first type of synergistic system classified by Healy[5] consisting of the mixture of acidic plus neutral extractants was selected for this purpose. This particular system has shown its possibilities, for instance, in the extraction of rare earth elements.[6] Subsequent work revealed, however, that the phenomenon can be realized in a variety of extractant combinations and be effective for a number of metals.[7]

Since the extraction of cadmium by HDEHP is well known, as explained above, this organophosphorus compound was selected as the acidic extractant. For the selection of the neutral one, it was found that the recovery of cadmium(II) using this kind of extractant has been undertaken by several authors[8–10] and the compounds which are most frequently used are tri-*n*-butylphosphate (TBP) and trioctylphosphine oxide (henceforth TOPO in the text and S in formulae).

The possibilities of finding synergisms which might be used for Zn/Cd separations have also been studied with mixtures of HDEHP and either TOPO or TBP, but no effort to determine the composition of the extracted species and their equilibrium constants has been carried out. On the other hand, the addition of TBP to the system Zn–HDEHP has been found to decrease the extraction, whereas the addition of TOPO to the same system causes an increase in the distribution ratio at low concentrations and a decrease at higher concentrations of TOPO.[11]

In this context, some difficulties arise mainly because organophosphorus compounds interact in the organic phase and may affect the interpretation of the data. For this reason several studies describing the behaviour of the HDEHP–TOPO system were undertaken.[12]

This work is a detailed study of the extraction of cadmium(II) in chloride medium by mixtures of HDEHP–TOPO dissolved in tetradecane. Its objective is to define the system in terms of the composition of the extracted species and their equilibrium constants, as well as the interaction species formed between the organophosphorus extractants.

EXPERIMENTAL

Reagents

Di(2-ethylhexyl)phosphoric acid was supplied by BDH. Its purity was determined by potentiometric titration of an 80% ethanol solution of the acid with NaOH (0.1 mol dm^{-3}) using Gran plots.[13] The purity was found to be 98.2%. Trioctylphosphine oxide, supplied by Merck p.a., was used without further purification. Tetradecane, supplied by PETRESA, is a commercial hydrocarbon with the following characteristics: density at 15°C 0.768; aromatic content (ppm) 215; water content (ppm) 50 max.; boiling point at 760 mm Hg 253.7°C; distribution (%): C_{13}, 1.2; C_{14}, 98.2; C_{15}, 0.1. Tetradecane was washed with NaOH (0.1 mol dm^{-3}), distilled water, HCl (0.1 mol dm^{-3}) and finally distilled water until no chloride ions were detected in the aqueous solution. Sodium chloride, used as ionic medium, was prepared as described in ref. 14. Hydrochloric acid, Merck p.a., was used without further purification. A stock solution of acid was prepared and standardized against HgO and NaI.[15] Cadmium chloride, Merck p.a., was used without further purification. A stock solution was prepared. The cadmium concentration of the stock solution was determined by complexometric titration with EDTA using eriochrome black T as indicator.[16]

Extraction procedure

All experiments were carried out at 25°C. The phases in contact had the following composition: aqueous phase: (Na^+, H^+, Cd^{2+}) Cl^-, 0.1 mol dm^{-3}; organic phase: C mol dm^{-3} of HA and B mol dm^{-3} of S in tetradecane.

The volumes (15 cm^3) of each phase were shaken out mechanically in stoppered glass tubes over 30 min, which was enough time to reach equilibrium, and subsequently the tubes were centrifuged.

The cadmium content in the aqueous phase was determined using a 2380 Perkin–Elmer atomic absorption spectrophotometer. The metal in the organic phase was stripped from an aliquot by dilute nitric acid and determined in the same way.

RESULTS AND DISCUSSION

The distribution coefficient of cadmium(II) between the organic and aqueous phases was obtained directly as the ratio of the total cadmium concentration in both phases:

$$D = \frac{[Cd^{II}]_{org}}{[Cd^{II}]_{aq}}. \quad (1)$$

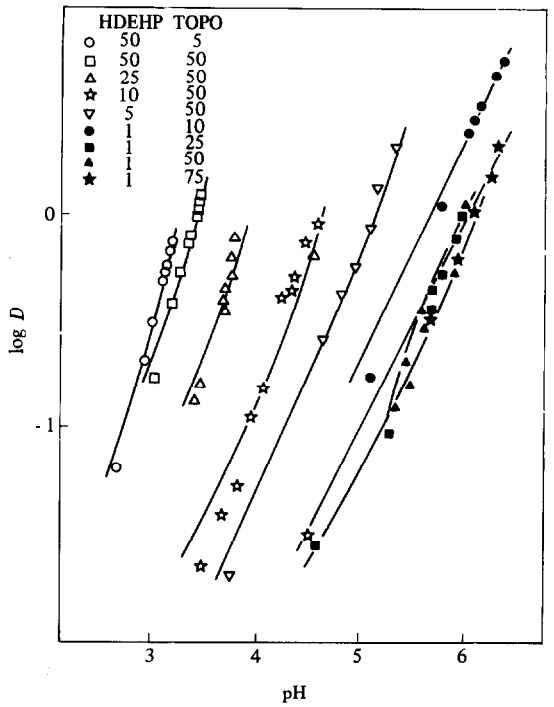

Fig. 1. log D plotted as a function of pH for different total HDEHP and TOPO concentrations in tetradecane at 0.1 mol dm^{-3} ionic strength in chloride medium. The full lines have been calculated using the constants given in Table 2.

Values of D were measured as a function of pH for different total HDEHP and TOPO concentrations, which ranged from 0.001 to 0.05 M and from 0 to 0.075 M, respectively. The experimental results are shown in Fig. 1.

The extraction of cadmium(II) with a mixture of the acid extractant, HA, and a neutral organophosphorus compound, S, can be written as:

$$Cd^{2+} + (p+q)[HA]_{org} + sS_{org} + (2-p)Cl^- = [CdA_pCl_{(2-p)}(HA)_qS_s]_{org} + pH^+. \quad (2)$$

β_{pqs} is the formation constant defined by

$$\beta_{pqs} = \frac{[CdA_pCl_{(2-p)}(HA)_qS_s]_{org}[H^+]^p}{[Cd^{2+}][HA]_{org}^{(p+q)}[S]_{org}^s[Cl^-]^{(2-p)}}. \quad (3)$$

Due to the low metal concentrations employed, the presence of polynuclear species was not considered.

From the literature,[12] the interaction between TOPO and HDEHP in these systems can be written as

$$HA + S = HA \cdot S \quad (4)$$

$$2HA + S = (HA)_2 \cdot S. \quad (5)$$

By taking into account eqs (4) and (5), the mass balance equations for HDEHP and TOPO can be

written as:

$$C_{HA} = [HA] + 2[(HA)_2] + [HA \cdot S] + 2[(HA)_2 \cdot S] + \Sigma_p \Sigma_q [CdA_p Cl_{(2-p)} (HA)_q S_s] \quad (6)$$

$$C_S = [S] + [HA \cdot S] + [(HA)_2 \cdot S] + \Sigma_s CdA_p Cl_{(2-p)} (HA)_q S_s, \quad (7)$$

respectively.

In the present case, no approximation can be made in the mass balance equations due to the strong interaction between the two extractants, and because metal complexes are not negligible in the organic phase. For this reason data have only been treated numerically.

Numerical treatment was performed using the general minimizing program LETAGROP–DISTR,[17] which is especially adapted to the treatment of distribution data. The program searches for the best set of formation constants that would minimize the error squares sum defined by:

$$U = \Sigma (\log D_{exp} - \log D_{calc})^2, \quad (8)$$

where D_{exp} is the distribution ratio of cadmium determined experimentally and D_{calc} is the calculated D value obtained by solving the mass balance equation for HDEHP, TOPO, Cd^{2+} and Cl^-. The program also calculates the standard deviation $\sigma(\log D)$ defined by

$$\sigma(\log D) = [\Sigma (\log D_{exp} - \log D_{calc})^2 / N_p]^{1/2}. \quad (9)$$

Several calculations with LETAGROP–DISTR were carried out in order to investigate the best set of complexes which would fit the experimental data. The criteria used to select the set of complexes used as input were as follows. First, a set of species including the complexes obtained in both Cd–HDEHP[3] and Cd–TOPO[9] systems, as well as the TOPO–HDEHP[12] interaction was tried. Next, because the slope of the lines log D vs pH varies between 1 and 2 (Fig. 1), the presence of mixed species in the organic phase with p [eq. (2)] ranging from 0 to 2 could give a closer description of the composition of the system. For this reason several sets of complexes including mixed species were used as input. The results obtained in these calculations, listed in Table 1, show the improvement obtained.

Furthermore, the equilibrium constants for the species formed were also determined. The results are given in Table 2. Subsequently, these values were used to calculate the full lines on Fig. 1 by means of the program HALTAFALL.[18] The good agreement obtained between both experimental and calculated values gives great confidence to the proposed model. The fit of the data is also illustrated in Fig. 2, where $\log D_{exp} - \log D_{calc}$ has been plotted against pH.

The distribution of species has been calculated as a function of HDEHP concentration for a total constant TOPO concentration at pH 4. The program HALTAFALL[18] has also been used for these calculations with the constants given in Table 2. The results obtained are shown in Figs 3 and 4.

The results so far obtained can be summarized as follows. The extraction of cadmium(II) from chloride media using mixtures of HDEHP and TOPO dissolved in tetradecane may be explained by the formation in the organic phase of the species $CdA_2(HA)_2$, $[CdA_2(HA)(TOPO)]$, $[CdACl(HA)(TOPO)]$, $[CdACl(TOPO)_3]$ and $[CdCl_2(TOPO)_2]$. Among them, the predominant species in the organic phase are $CdA_2(HA)_2$ and $[CdA_2(HA)(TOPO)]$ when the HDEHP–TOPO ratio is higher or lower than 1.5, respectively, in the experimental conditions employed (see Figs 3 and 4).

The value of the constant for the formation of the species $CdA_2(HA)_2$ is in good agreement with the value previously reported,[3] whereas $CdA_2(HA)_3$ has not been found to be predominant at the low HDEHP–Cd ratio employed in the experiments.

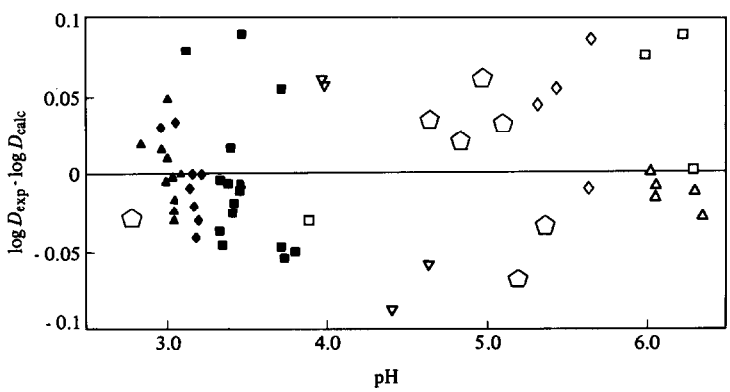

Fig. 2. Values of ($\log D_{exp} - \log D_{calc}$) calculated by the LETAGROP program plotted against pH.

Table 1. Some details of the calculations with LETAGROP–DISTR

Tetradecane	—	3.78	This work

[a] K is the formation constant defined by:

$$K = \frac{[HA \cdot TOPO]_{org}}{[(HA)_2]_{org}^{1/2}[TOPO]_{org}}.$$

[b] β_{011} is the formation constant of reaction (2) calculated from the expression $\beta_{011} = K \times K_D^{1/2}$, where K_D is the dimerization constant defined by $2HA_{org} = (HA)_{2org}$ (Ref. 21).

On the other hand, the extraction of metals has been demonstrated to be an effective method for determining the interaction between the extractants present in the organic phase. The results obtained show that interactions between the organophosphorus compounds in the organic phase are due only to one species HA · TOPO, whereas $(HA)_2TOPO$, which has previously been found by different authors, is negligible in the experimental conditions employed in the present study. As can be seen from Table 3, the interaction constant for the formation of the HA · TOPO species is in good agreement with the values previously reported.

The antisynergism observed in the extraction of cadmium by HDEHP in presence of TOPO can be explained by taking into account the interaction between the organophosphorus extractants, as can be seen in Figs 3 and 4. This effect is clearly observed in Fig. 5, where an increase in the TOPO–HDEHP ratio increases the HA · TOPO species in the organic

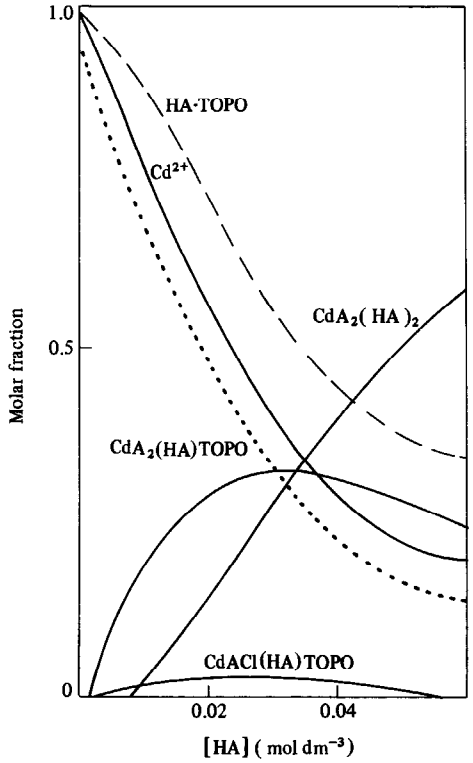

Fig. 3. Fraction of the different species present in the organic phase plotted as a function of the total HDEHP concentration for a constant total TOPO concentration of 0.025 mol dm^{-3}. The dotted line (....) shows the fraction of cadmium in the aqueous phase in the absence of TOPO (Ref. 3).

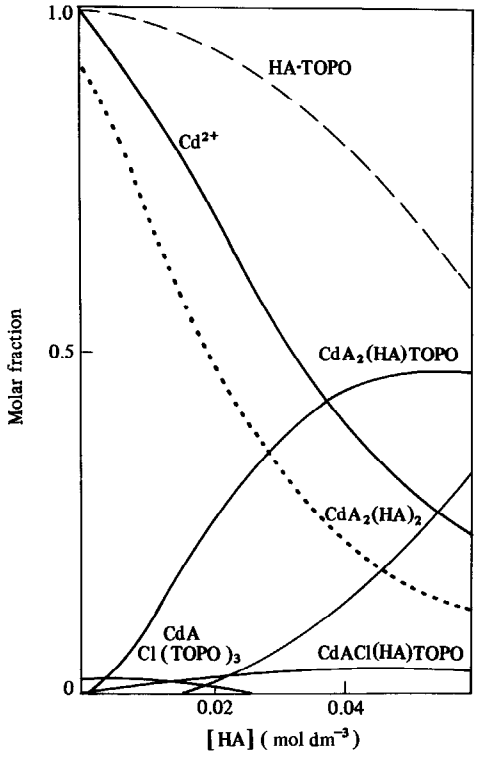

Fig. 4. Fraction of the different species present in the organic phase plotted as a function of the total HDEHP concentration for a constant total TOPO concentration of 0.050 mol dm^{-3}. The dotted line (....) shows the fraction of cadmium in the aqueous phase in absence of TOPO (Ref. 3).

THE ELECTROCHEMICAL SYNTHESIS OF NEUTRAL COPPER(II) COMPLEXES OF SCHIFF BASE LIGANDS: THE CRYSTAL STRUCTURES OF BIS-{N-[2-(3-METHYLPYRIDYL)]-5-METHOXYSALICYLIDENEIMINATO}COPPER(II) AND BIS-{N-[2-(6-METHYLPYRIDYL)]-SALICYLIDENEIMINATO}COPPER(II)

(*Received* 1 *March* 1989; *accepted* 5 *June* 1989)

Abstract—Neutral copper(II) complexes of Schiff bases derived from substituted salicylaldehydes and 2-aminopyridine methyl derivatives have been synthesized by an electrochemical procedure. The crystal and molecular structure of bis{N-[2-(3-methylpyridyl)]-5-methoxysalicylideneiminato}copper(II) and of bis{N-[2-(6-methylpyridyl)]-salicylideneiminato}copper(II) have been determined by X-ray diffraction. The former compound crystallizes in the monoclinic space group $C2/c$ with four molecules in the unit cell and cell constants $a = 16.784(2)$, $b = 16.344(2)$ and $c = 11.211(2)$ Å, and $\beta = 124.08(1)°$, while the other complex crystallizes in the monoclinic space group $P2_1/c$ with two molecules in a cell of dimensions $a = 12.456(1)$, $b = 7.812(2)$ and $c = 12.047(2)$ Å, and $\beta = 110.48(1)°$. In both structures, the metals adopt square-planar coordination geometries and the pyridyl nitrogen atoms are not coordinated. The electronic and IR spectra of the complexes are discussed and related to the structure.

Schiff bases derived from substituted salicylaldehydes and 2-aminopyridine derivatives (**1**) have previously been studied as potentially terdentate ligands. Osipov *et al.*[1] have isolated complexes of the type CuL_2 (L = anion of **1** in which X = H, 5-Cl, 5-Br, 5-NO_2 or 5,6-benzo and Y = H), and suggested a tetrahedral (or pyramidal) structure for them. Yamada and Yamanouchi[2] have also synthesized complexes of the type $ML_2 \cdot nH_2O$ (where M = Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} or Pd^{II}). On the basis of electronic spectroscopic measurements they deduced square-planar structures for the copper complexes. While steric considerations led them to suggest that the Schiff bases were bidentate ligands, with the pyridine nitrogen uncoordinated in all complexes except one nickel(II) complex in which the ligand is terdentate. Kolawole[3] studied the oxovanadium(IV) complexes of these ligands, and from IR and electronic spectroscopic data concluded that the ligands are acting bidentate through the phenolic oxygen and either the azomethine or pyridine nitrogen (depending on electronic effects of the substituents on the phenyl ring). Recently, Parashar *et al.*[4] prepared the complex CuL_2 (where X = Y = H), and from spectroscopic properties deduced that the environment at the metal was octahedral and the ligand terdentate.

The electrochemical synthesis described here constitutes a simple new route to neutral CuL_2 ($L = L^1$—L^{13}) complexes and it was therefore of interest to determine the structure of some complexes in order to establish the facultative properties of the ligand.

EXPERIMENTAL

Acetonitrile, aldehydes and amines were used as supplied. Copper (Ega Chemie) was used as plates (approx. 2×2 cm square). The ligands were prepared by reaction of equimolar amounts of the appropriate aldehyde and amine in benzene until the theoretical amount of water had been collected in a Dean–Stark trap; the solid product was washed with dry diethyl ether and its purity checked by recording its IR and ^1H NMR spectra.

Preparation of complexes

The electrochemical method used in the synthesis of the copper complexes was similar to that described by Tuck.[5] The cell was a 100 cm^3 tall-form beaker fitted with a rubber bung through which the electrical leads passed. The foil anode was suspended from a platinum wire and the cathode was also a platinum wire. The ligand was dissolved in acetonitrile and a small amount of tetramethylammonium perchlorate was added to the solution. Direct current was obtained from a purpose-built d.c. power supply. The cell can be summarized as

$$Pt_{(-)}/CH_3CN + HL/Cu_{(+)}.$$

During electrolysis hydrogen was evolved at the cathode. In some cases insoluble compounds became visible within a few minutes, but in others crystals were formed slowly after concentration of the solution at room temperature. The solids obtained were washed with acetonitrile and diethyl ether and dried at room temperature. The experimental conditions are set out in Table 1.

Physical measurements

Microanalyses were performed using a Perkin–Elmer 240B microanalyser. IR spectra were recorded in Nujol and hexachlorobutadiene mulls between CsI plates on a Perkin–Elmer 180 spectrophotometer. Proton NMR spectra were recorded on a Bruker WM at 250 MHz. Solid reflectance spectra were recorded on a Unicam 5P735 diffuse reflectance spectrophotometer.

Dark amber prismatic crystal of approximate dimensions $0.20 \times 0.09 \times 0.20$ mm, monoclinic, $P2_1/c$ (no. 14), $a = 12.456(1)$, $b = 7.812(2)$, $c = 12.047(2)$ Å, $\beta = 110.48(1)°$, $V = 1098.11$ Å^3, $Z = 2$, $D_x = 1.470$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $F(000) = 502$.

Data collection

Data for both crystals were obtained using an Enraf–Nonius CAD-4 four-circle diffractometer with graphite monochromated Mo-K_α radiation. The cell constants were determined from setting angles for 25 reflections. Reflections were measured at 296 K by the ω–θ scan technique with scan widths of $(1.10 + 0.35 \operatorname{tg}\theta)°$ and a maximum scan speed of 10° min^{-1}. The *hkl* range was $-19 < h < 19$, $k < 18$, $l < 12$ $(3 < \sigma < 24°)$ for CuL_2^6 and $-15 < h < 15$, $k < 9$, $l < 14$ $(3 < \sigma < 26°)$ for CuL_2^9. Of 4417 reflections measured for CuL_2^6 (including the systematic absences due to C-centering), 1994 were unique ($R_{int} = 0.015$). A total of 2433 reflections were collected for CuL_2^9, of which 2156 were unique ($R_{int} = 0.049$). The standard reflection varied by ±0.3% (for CuL_2^6) or ±0.1% (for CuL_2^9) of the mean intensity during data collection. Lorentz and polarization corrections and an empirical absorption correction[6] were applied; maximum and minimum transmission factors: CuL_2^6, 1.2650 and 0.8759; CuL_2^9, 1.2178 and 0.6652.

Solution and refinement of the structures

For both compounds, least-squares calculations were carried out on F, the function minimized being $\Sigma w(|F_o| - |F_c|)^2$ with $\omega^{-1} = \sigma^2(F_o)$.

[CuL_2^6]. The structure was solved by direct techniques and Fourier difference synthesis. Refinement was carried out using the 1551 reflections with $|I_o| > 3\sigma|I_o|$. In the final cycles of full-matrix least-squares refinement, all non-hydrogen atoms were treated anisotropically. A total of 222 parameters were refined. A correction for secondary extinction was applied: $F_{corr} = F_c(1 + kF_c^2/\sin 2\theta)^{0.25}$, where k refined to 2.7699×10^{-7} in the final run. At that stage, the R factors were $R = 0.030$, $R_w = 0.031$. The final difference map showed electron density maxima of 0.264 eÅ^{-3}.

[CuL_2^9]. The structure was solved by the Patterson method, which revealed the positions of all non-hydrogen atoms. Refinement was carried out using the 813 reflections with $|I_o| > 3\sigma|I_o|$. The positions of all hydrogen atoms were estimated geometrically and were not refined (C—H = 0.95 Å; $B_{iso} = 4.0$ Å^2). In the final least-squares cycles, copper, oxygen and nitrogen atoms were treated anisotropically. A total of 86 parameters were refined. At that stage, the R factors were $R = 0.058$ and $R_w = 0.066$. A final difference map showed electron density maxima of 0.413 eÅ^{-3}.

For both structures, scattering factors and corrections for anomalous dispersion were taken from *International Tables.*[7] Calculations were performed with the SHELXS-86[8] and SDP program systems[9] on a DECMicro VAXII computer. The atomic position coordinates, full list of bond lengths and angles and other crystallographic data have been deposited as Supplementary Publication No. CSD 53254. Copies can be obtained through the Fachinformations-zentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen.

RESULTS AND DISCUSSION

The analytical data reported in Table 2 show that an electrochemical procedure can be satisfactorily used for the synthesis of compounds of general formula CuL_2 ($L = L^1$–L^{13}). The electrochemical efficiency, defined as the amount of metal dissolved per Faraday of charge, was close to 1 mol F^{-1}, which is compatible with the following reaction scheme.[10]

Cathode: $HL + e^- \longrightarrow L^- + 1/2H_2$

Anode: $L^- + Cu \longrightarrow CuL + e^-$

$CuL + HL \longrightarrow CuL_2 + 1/2H_2$.

ORTEP views of the structures of CuL_2^6 and CuL_2^9 are shown in Figs 1 and 2 with the atom labelling used in the corresponding Table. The bond distances and angles, along with their associated estimated standard deviations are given in Table 3. Both complexes have similar structures, with the copper atom located at a crystallographic inversion centre and coordinated to the azomethine nitrogen and phenolic oxygen atoms of two symmetry related moieties. The pyridyl nitrogen atom is not coordinated to the copper. The configurations are exactly square-planar to within experimental accuracy. These structures differ from those proposed by Osipov *et al.*[1] and Parashar *et al.*,[4] but are very similar to that determined for bis{N-[2′-(2″-pyridyl)ethyl] -4, 6- dimethoxysalicylideneiminato} copper(II).[10]

The Cu—N distances (1.992 Å in CuL_2^6 and

frequencies. The band attributable to ν(C=N) of the azomethine group undergoes a shift to lower frequencies in all of the metal complexes. In view of the X-ray structures, this behaviour can be taken as proof of coordination through the phenolic oxygen and azomethine nitrogen.

The pyridine ring stretching bands observed between 1610 and 1440 cm^{-1} and the ring deformation bands which appear at about 400 and 600 cm^{-1} are shifted to higher frequencies in the complexes. This behaviour might be taken to be a result of coordination by the pyridine nitrogen,[16,17] and Parashar[4] has accordingly suggested an octahedral copper(II) environment for CuL_2^1. However, this inference is not supported by the X-ray data. The above results clearly establish that for ligands with an azomethine group conjugated to a pyridine ring, caution must therefore be exercised in using IR data alone as an indication of whether the pyridine is coordinated or not.

The solid state electronic spectra of the complexes show two *d–d* bands at around 13500 and 17000 cm^{-1} except in the case of CuL_2^5, CuL_2^7 and CuL_2^8, for which only one broad band, presumably the envelope of the above two bands, is observed. In all cases, the band that appears at *ca* 21000 cm^{-1} may be assigned to a charge-transfer transition. These

Abstract—The potentially pentadentate ligand, 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (L, quinquepy) forms double helical complexes with first row transition metal cations of 2:2 stoichiometry. The X-ray crystal structure of the first such double helical bis-nickel(II) complex is reported, together with the electrochemical properties.

Helicity is a widespread phenomenon in natural systems,[1] although examples of this geometry in inorganic coordination compounds are relatively rare.[2] Recently it has been demonstrated that polydentate ligands based on oligopyridines spontaneously assemble binuclear double helical complexes upon reaction with transition metal cations.[3,4] In this paper we wish to report the first example of a structurally characterized double helical complex with cations other than those in group 1B.

EXPERIMENTAL

Quinquepy (L) was prepared by the literature method.[5] Electrochemical experiments were performed with a Princeton Applied Research Model 170 electrochemistry system, or with an Amel model 553 potentiostat connected to an Amel model 567 function generator and an Amel model 560-A recorder interface; all experiments were conducted using purified acetonitrile as solvent with 0.1 M $[^nBu_4N][BF_4]$ as the supporting electrolyte. For the cyclic voltammetry experiments, platinum beads were used as working and auxiliary electrodes with an Ag/AgCl electrode as reference; in all cases, ferrocene was added at the end of the experiment as an internal reference. Bulk electrolyses were performed using a cylindrical platinum gauze as the working electrode, with a smaller co-axial platinum gauze as the auxiliary electrode; an Ag/AgCl electrode was used as reference, calibrated against internal ferrocene at the end of each experiment. Coulometric measurements were made using an Amel model 731 integrator. IR spectra were recorded using a Perkin-Elmer 1710 FT spectrometer with the compound in compressed KBr pellets. ESR spectra were recorded on a Varian E109 spectrometer as powders, or in acetonitrile glasses at 4 or 77 K. Fast atom bombardment mass spectra were measured using a Kratos MS-50 spectrometer, with 3-nitrobenzyl alcohol as the supporting matrix.

Preparation of $[Ni_2L_2(OAc)][PF_6]_3$

Quinquepy (100 mg, 0.26 mmol) was added to a solution of $Ni(OAc)_2 \cdot 4H_2O$ (0.3 mmol) in boiling methanol (20 cm^3). The solution was heated until all of the ligand had dissolved, treated with $[NH_4][PF_6]$ and cooled, when $[Ni_2L_2(OAc)][PF_6]_3$ precipitated as a pale green microcrystalline powder (80%). The product was recrystallized by the diffusion of diethyl ether vapour into an acetonitrile solution to yield the tris-acetonitrile solvate. Found: C, 44.3; H, 2.7; N, 9.9; Ni, 8.2. Calc. for $Ni_2N_{10}C_{52}H_{37}O_2P_3F_{18}$: C, 45.0; H, 2.7; N, 10.1; Ni, 8.3%.

Crystal structure determination of $[Ni_2L_2(OAc)][PF_6]_3 \cdot 3MeCN$

Suitable single crystals were obtained as pale green blocks by the slow diffusion of diethyl ether vapour into an acetonitrile solution of the complex.

Crystal data for $[Ni_2L_2(OAc)][PF_6]_3 \cdot 3MeCN$

$Ni_2N_{13}C_{58}H_{46}O_2P_3F_{18}$, green crystals, $M = 1508.4$, triclinic, $a = 11.710(8)$, $b = 13.811(11)$, $c = 20.542(19)$ Å, $\alpha = 74.6(1)$, $\beta = 94.9(1)$, $\gamma = 75.0(1)°$, $U = 3051.8$ Å^3, $F(000) = 1420$, space group $P\bar{1}$, $Z = 2$, $D_m = 1.65$, $D_c = 1.63$ g cm^{-3}, Mo-K_α radiation ($\lambda = 0.7107$ Å), μ(Mo-K_α) = 8.1 cm^{-1}.

Data collection and processing

A crystal was set up to rotate about the a axis on a Stoe Stadi2 diffractometer and data were collected via variable width ω scan. Background counts were for 20 s and a scan rate of 0.0333° s^{-1} was applied to a width of $(1.5 + \sin\mu/\tan\theta)$. 7121 independent reflections with 2θ(max) of 50° were measured on a diffractometer, of which 1911 with $I > 2\sigma(I)$ were used in subsequent calculations.

Structure analysis and refinement

The structure was determined by the heavy-atom method. In the cation, the nickel atoms were refined anisotropically and the nitrogen, carbon and oxygen atoms isotropically. Hydrogen atoms were included in calculated positions for the cation. The PF_6 anions were refined anisotropically; it was possible that these atoms were disordered as we were unable to find a suitable model. The solvent molecules were difficult to disentangle. Five acetonitrile molecules were located; one was distinct and refined with 100% occupancy, while the other four formed two sets of two. The two molecules of each set were superimposed and contained atoms in common. Each of the four molecules were given 50% occupancy though some individual atoms were refined with 100% occupancy. Calculations were performed using full-matrix least-squares methods with a weighting scheme $w = 1/[\sigma^2(|F|) + 0.003|F|^2]$. Calculations were performed using SHELX 76 on the Amdahl V7 Computer at the University of Reading.[6] The final R values were $R = 0.102$ ($R_w = 0.113$). Molecular dimensions within the coordination spheres are presented in Table 1.*

RESULTS AND DISCUSSION

2,2′:6′,2″:6″,2‴:6‴,2⁗-Quinquepyridine was prepared by the method of Kröhnke as a white powder, and the structure of the ligand was confirmed by electron impact (M^+, m/z 387) and FAB (MH^+, m/z 388) mass spectroscopy, microanalysis and ^{1}H NMR spectroscopy.

The reaction of nickel(II) acetate with quinquepy in methanol results in the formation of a pale green solution, from which a pale green crystalline solid was obtained upon the addition of $[NH_4][PF_6]$. The FAB mass spectrum of the complex exhibited peaks at m/z 1035, 1094, 1180 and 1239, which may be assigned to the species $\{Ni_2L_2(PF_6)\}^+$, $\{Ni_2L_2(OAc)(PF_6)\}^+$, $\{Ni_2L_2(PF_6)_2\}^+$ and $\{Ni_2L_2(OAc)(PF_6)_2\}^+$. A fragmentation peak is observed at m/z 504 ($\{NiL(OAc)\}^+$) which suggests that the compound should be formulated as $[Ni_2L_2(OAc)][PF_6]_3$; microanalysis is in accord with this formulation. The complex is initially obtained as a hydrate, but drying *in vacuo* yields the anhydrous compound. Recrystallization from acetonitrile by vapour diffusion of diethyl ether into the solution yields an air-stable green tris-acetonitrile solvate.

The crystal and molecular structure of $[Ni_2L_2(OAc)][PF_6]_3$ has been determined, and the molecular structure of one of the enantiomers of the cation is presented in Fig. 1. Selected bond lengths and bond angles are listed in Table 1. The structural determination confirms the binuclear formulation, and reveals that the two quinquepy ligands have adopted a double helical configuration about the two nickel atoms. The double helical

* Atomic coordinates, displacement factor coefficients, full lists of bond lengths and bond angles, and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

arrangement is emphasized in the skeletal space-filling diagram presented in Fig. 2, which shows the nitrogen atoms and the linking 2 and 6 carbon atoms of the ligands only.

The structure is very similar to that of the analogous $[Cu_2L_2(OAc)]^{3+}$ cation.[4] The two nickel atoms are both six-coordinate, but non-equivalent; Ni(1) is bonded to three consecutive nitrogen atoms from each quinquepy ligand, whilst Ni(2) is bonded to the two remaining nitrogen atoms from each quinquepy, and two oxygen atoms of a bidentate acetate. The principal differences between $[Cu_2L_2(OAc)]^{3+}$ and $[Ni_2L_2(OAc)]^{3+}$ are associated with the presence of a bidentate acetate group in the nickel compound as opposed to a monodentate ligand in $[Cu_2L_2(OAc)]^{3+}$. The IR spectrum of the complex exhibits absorptions at 1538 and 1425 cm^{-1}; the difference of 113 cm^{-1} is characteristic of a weakly bound bidentate acetate group. This is undoubtedly associated with a Jahn–Teller effect in the copper complex giving rise to two distinct Cu—O distances of 2.038(11) and 2.683(16) Å, whereas the two Ni—O distances are remarkably similar at 2.158(19) and 2.110(20) Å.

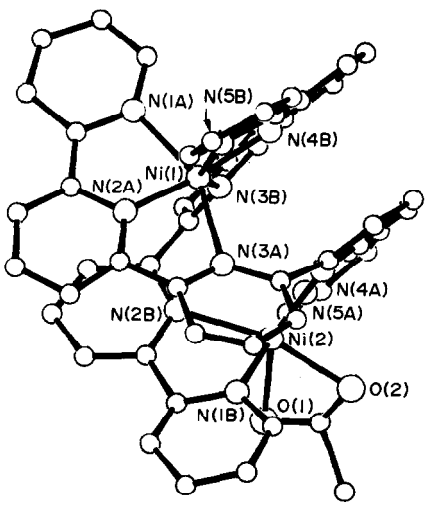

Fig. 1. The crystal and molecular structure of the $[Ni_2L_2(OAc)]^{3+}$ cation in $[Ni_2L_2(OAc)][PF_6]_3$, showing the numbering scheme adopted.

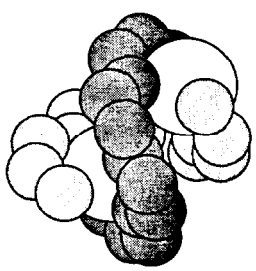

Fig. 2. A skeletal space filling depiction of the cation $[Ni_2L_2(OAc)]^{3+}$ showing only the nickel, the nitrogen and the linking carbon atoms of the ligand to emphasize the double helical geometry.

In all other respects, the metal atoms in $[Cu_2L_2(OAc)]^{3+}$ and $[Ni_2L_2(OAc)]^{3+}$ are in very similar distorted environments. The Ni(2)—N bond lengths closely resemble those observed for the five-coordinate copper atom in $[Cu_2L_2(OAc)]^{3+}$. For Ni(1) the bond lengths to the terminal pyridine rings of 2.160(20), 2.248(22), 2.288(20) and 2.233(21) Å are similar, and significantly shorter than those to the "central" rings of the terpyridine moiety of 1.857(32) and 1.879(28) Å. This reflects the helical twist of the ligand, which is most apparent at these rings, and results in considerable distortion of the "axial" interactions [∠N(3A)—Ni—N(1A) 153.1(9)°, ∠N(5B)—Ni—N(3B) 150.4(9)°]. Despite the differences in coordination number, the structure of $[Ni_2L_2(OAc)]^{3+}$ does not differ dramatically from that of $[Cu_2L_2(OAc)]^{3+}$, and serves to emphasize the structural rôle played by the stacked double helical array of ligands in dictating the geometry of the final complex.

The quinquepy ligands are principally twisted about the interannular bonds between the bidentate and terdentate portions of the molecules. The two quinquepy ligands are similar, but not identical, with all bond lengths and angles within the pyridine rings unremarkable. The interannular distances vary considerably in the range 1.445(23)–1.527(20) Å, although this is not simply related to the metal–ligand or ligand–ligand interactions. The most significant and noticeable feature is the twisting of the ligands into non-planar configurations to form the helical arrangement. The principal twist (58–60°) is about the bond between the "terpyridine" and "bipyridine" portions of each ligand, although smaller twists of 3–18° between the other rings are also observed.

It is also apparent that the double helical geometry results from a stacking interaction of aromatic rings. The stacking interaction involves a "terpyridine" fragment of one ligand with a "bipyridine" fragment of the other. The average interplanar distance in the stacked systems is 3.2 Å. In each complex the two stacked systems are approximately parallel with least squares planes calculations showing angles of intersection of 1.3–8.6°. The Ni(1)—Ni(2) distance is 4.45 Å, which is comparable to the Cu(1)—Cu(2) distance in $[Cu_2L_2(OAc)]^{3+}$ of 4.50 Å; there is no direct Ni—Ni interaction. In neither complex are there any intermolecular distances less than the sums of the van der Waals' radii.

We have previously demonstrated that the double helical geometry results from a small metal ion coordinating to a flexible, highly conjugated polydentate ligand.[4] To date, structurally characterized double helical complexes have incorporated group 1B ions, which do not exert strong preferences for any specific coordination geometry. The observation of the double helical geometry in a nickel complex indicates that the electronic preferences of the metal ion are not dominant in dictating the self-assembly of the helix.

Solutions of the complex in acetonitrile showed no oxidation waves in their cyclic voltammograms up to +1.5 V vs Fc/Fc^+, indicating that a nickel(III) state is not readily accessible. An irreversible reduction centred at −1.23 V vs Fc/Fc^+ is observed which is dependent on the scan rate ($E_c - E_a$ = 190 Mv at 20 mV s^{-1}, 240 mV at 200 mV s^{-1}) and is depicted in Fig. 3. The relative intensities of the forward and reverse waves do not alter with scan rate, and we believe the large peak splitting is due to slow electron transfer to the complex. At very slow scan rates (20 mV s^{-1} or less) the forward wave develops an asymmetry which might be indicative of two near coincident processes, but we have not succeeded in resolving the two processes. The two nickel(II) ions are in significantly different chemical environments, and it might be expected that the two reduction processes could be resolved. We believe the apparent coincidence is a result of the electron transfer kinetics. Bulk electrolysis of an acetonitrile solution (−1.4 V) resulted in a colour change to purple, followed by slow decomposition to a colourless solution containing a suspension of free quinquepy. Coulometry indicated the transfer of 1.86 ± 10% electrons to the binuclear complex, suggesting that this is a reduction to a formally Ni^INi^I

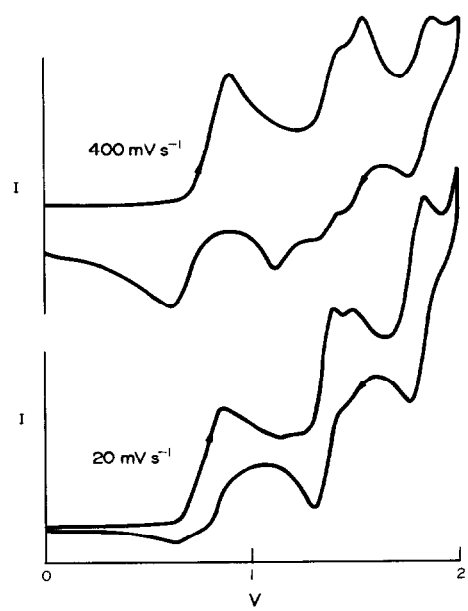

Fig. 3. Cyclic voltammograms of $[Ni_2L_2(OAc)][PF_6]_3$ in MeCN at various scan rates. Details as in Experimental.

complex (but not necessarily a single two-electron process). The EPR spectrum of a frozen acetonitrile glass of the purple complex exhibits a broad anisotropic signal (g_1, 2.72; g_2, 2.127) consistent with the formation of $[Ni^{I}Ni^{I}L_2]^{2+}$ rather than $[Ni^{II}Ni^{II}(L^{-})_2]^{2+}$ or $[Ni^{II}Ni^{I}L(L^{-})]^{2+}$. This is analogous to the reduction of the nickel(II) complex of 4′,4‴-diphenyl-2,2′ : 6′,2″ : 6″,2‴ : 6‴,2⁗-quinquepyridine, which we now know to be a double helical binuclear species, which also gives a bis-nickel(I) complex.[7] The cyclic voltammogram also exhibits two further ligand-based processes centred at −1.81 and −1.92 V vs Fc/Fc^{+}. The first of these two processes is independent of scan rate, with $E_c - E_a = 100$ mV at both 20 and 200 mV s^{-1} scan rates. The second process is scan rate dependent and becomes more noticeable at faster scan rates. At a scan rate of 200 mV s^{-1} this second reduction approaches a two-electron reversible limit ($E_c - E_a = 40$ mV). Finally, a quasi-reversible reduction is observed at −2.24 V vs Fc/Fc^{+}.
